Abstract
A low-cyclic fatigue micromechanical model proposed recently [1] for emphasizing the concept of damage induced anisotropy is used. The solution of these nonlinear constitutive relations is an important topic since it requires an important computational time. With a high nonlinearity due to damage, the identification of model parameters represents consequently an important subject. In fact, a combination of the genetic algorithm (for the global optimization) with pattern search algorithm (for the local optimization) is proposed. A comparative study is conducted under complex cyclic loadings showing the ability of the proposed approach in calibrating model parameters.

Keywords Low-cyclic fatigue, parameters identification, global minimum and local minimum optimization

1. Introduction

Despite the existence of increasingly powerful computers, the progress in the constitutive equations development is continuous and can be conducted via computational optimization process. Several types of modes like micromechanical approaches are proposed for describing mechanical complex phenomena. Non-linear responses under cyclic loading, for example, make the related resolutions very expensive in computing time and in memory capacity. Numerically, it has been recently reported that the algorithm of Burlisch–Stöer gives the best compromise between computational time and precision compared to other well-known algorithms.
For a given model, the identification of parameters is an important issue and should be as accurate as possible to describe efficiently the material behavior. In fact, the use of reliable optimization algorithms is to minimize the difference between the model prediction and experimental behavior. Different methods have been developed to resolve this type of problem. They can, in general, be divided into two major groups: the first one which converges quickly is for local optimization. However, its major disadvantage is the possibility of converging towards local minimums. The Pattern Search algorithm is part of this group. It does not require the gradient calculation of the objective function and accepts parallel computing on different computer processors. The second group is formed by the evolutionary method based on the evolution of individuals. The genetic algorithm is a part of this group which is related to the global minimum convergence. However, it is slow because it requires several evaluations of the objective function.
Therefore, this study highlights the concept of damage induced anisotropy via the used model. Numerical solutions of these nonlinear constitutive equations require normally an important computational time. Therefore, a new strategy of model parameters calibration is considered. In fact, a hybrid approach is used, in this paper, to exploit the benefits of these groups of algorithms. Hence, a combination of the genetic algorithm (GA) with pattern search algorithm (PSA) is proposed. The basic idea of this approach is to look for the global minimum with the GA, then move to the local

minimum search via the PSA to improve the obtained result. Since the identification of the model parameters is of particular interest in this paper, therefore, several applications are presented. They deal with cyclic plasticity with damage induced anisotropy behavior of polycrystals and its related phenomena under complex history of loading path conditions. To conduct the identification process, the two methods (GA&PSA) are complementary and have different applications. The GA optimizes globally the model parameters leaving the field to the local method, PSA, to determine the final values of these parameters. Then, in order to evaluate the performances of the proposed method, a comparative study is performed under complex cyclic loadings showing the ability of such strategy to identify the model parameters.

2. Employed Micromechanical Model

The used micromechanical model utilizes three operating levels which are: microscale (slip system), mesoscale (granular) and macroscale (overall). The theoretical formulation of the developed model is presented in detail in [1]. However, a short description of the main features of the model equations at the overall level is illustrated below.

$$\underline{\underline{\Sigma}} = \sum_{i=1}^{3} \sum_{i}^{*} p_i \otimes \underline{p}_i \tag{1}$$

$$\underline{\underline{Q}} = \sum_{i=1}^{3} p_i \otimes p_i \tag{2}$$

$$\underline{\underline{Q}}^{+} = \sum_{i=1}^{3} H(\Sigma_i^{*})\, p_i \otimes p_i \tag{3}$$

$$p_{ijkl}^{+} = Q_{ia}^{+} Q_{jb}^{+} Q_{ka}^{+} Q_{lb}^{+} \tag{4}$$

$$\underline{\underline{\underline{\underline{D}}}} = D^{T}\, \underline{\underline{\underline{\underline{p}}}}^{+} \tag{5}$$

$$\underline{\underline{\underline{\underline{R}}}}^{d} = \left(\underline{\underline{\underline{\underline{I}}}} - \underline{\underline{\underline{\underline{D}}}}^{T} \right) : \underline{\underline{\underline{\underline{R}}}}^{o} \tag{6}$$

$$\dot{\underline{\underline{\underline{\underline{R}}}}}^{d} = \left(\dot{D}^{T}\, \underline{\underline{\underline{\underline{p}}}}^{+} + \dot{D}^{T}\, \underline{\underline{\underline{\underline{p}}}}^{+} \right) : \underline{\underline{\underline{\underline{R}}}}^{o} \tag{7}$$

$$\dot{\underline{\underline{\Sigma}}} = \dot{\underline{\underline{\underline{\underline{R}}}}}^{d} : \underline{\underline{E}}_{e} + \underline{\underline{\underline{\underline{R}}}}^{d} : \dot{\underline{\underline{E}}}_{e} + \dot{\underline{\underline{M}}} \tag{8}$$

$$\dot{\underline{\underline{M}}} = -\frac{1}{2} \dot{D}^{T} \frac{\partial\, \underline{\underline{\underline{\underline{p}}}}^{+}}{\partial\, \underline{\underline{E}}_{e}} : \underline{\underline{\underline{\underline{R}}}}^{o} : \underline{\underline{E}}_{e} : \underline{\underline{E}}_{e} - \frac{1}{2} D^{T} \frac{\partial\, \dot{\underline{\underline{\underline{\underline{p}}}}}^{+}}{\partial\, \underline{\underline{E}}_{e}} : \underline{\underline{\underline{\underline{R}}}}^{o} : \underline{\underline{E}}_{e} : \underline{\underline{E}}_{e} - D^{T} \frac{\partial\, \underline{\underline{\underline{\underline{p}}}}^{+}}{\partial\, \underline{\underline{E}}_{e}} : \underline{\underline{\underline{\underline{R}}}}^{o} : \dot{\underline{\underline{E}}}_{e} : \underline{\underline{E}}_{e} \tag{9}$$

To determine the overall damage tensor $\underline{\underline{D}}$ (Eq. 5), the spectral decomposition concept of stress tensor is adopted (Eqs. 1-4). Σ_i^* is the i^{th} principal strain and p_i the i^{th} corresponding to the unit principal direction of eigenvalue and eigenvector of Σ^*. The symbol $\otimes$ represents the tensor product. The 4^{th} order positive spectral projection tensor $\underline{\underline{P}}^+$ given in (Eq. 4) is determined by equations (Eq. 2) and (Eq. 3). According to (Eq. 5), the damage is considered to be entirely active when all the eigenvalues are positive in the three principal directions; whereas, it becomes fully passive once the eigenvalues are negative, i.e., depending on the $\underline{\underline{P}}^+$ configuration. Hence, $\underline{\underline{P}}^+$ allows verifying naturally the complexity of the damage activation/deactivation phenomenon whatever the applied loading path. The overall rigidity tensor for a damaged material $\underline{\underline{R}}^d$ and its evolution $\dot{\underline{\underline{R}}}^d$ are defined respectively by equations (Eq. 6) and (Eq. 7), where $\underline{\underline{R}}^o$ is the classical 4^{th} order rigidity tensor for an initially isotropic material. As recently proposed [1], the overall stress tensor evolution coupled with damage activation/deactivation phenomenon is mathematically described by (Eq. 8). In (Eq. 9), the second term in the right-hand side depends explicitly on the eigenvectors variation during cyclic loading. Thus, when the loading is applied according to laboratory reference axes, the principal vectors coincide with the latter. In this case, these vectors are constant, i.e., their characteristics vary neither with respect to time, nor according to the deformation. Hence, the second and third terms in the right-hand side of (Eq. 9) vanishes. As a result, (Eq. 8) has the advantage to successfully treat a great number of loading types especially the multiaxial ones.

3. Algorithms of optimization

The identification process is to find numerically a set of model coefficients, which correlates the best possible predictions and experimental results. It is based on minimizing the difference between the recorded model response and the given experimental result. Such a difference can never be zero. However, the rule states that when the difference is smaller, the set of coefficients is better. In this work, identification (calibration) of the model parameters is to find a search space where these values should minimize the gap between experimental results and predictions. Solving this problem is realized by minimizing the following function:

$$F(P) = \sum_{n=1}^{N} F_n(P), \tag{10}$$

$$F_n(P) = \frac{1}{t_1 - t_0} \int_{t_0}^{t_1} \left(V_{\exp} - V_{sim}\right)^T D \left(V_{\exp} - V_{sim}\right) dt. \tag{11}$$

where, P: Model parameters, N: number of tests, $[t_0, t_1]$: time interval of the test n, V_{exp}-V_{sim}: difference between observed experiments and their simulations for the test n, D: weighting matrix of the test n.

The complexities of search space are the minimum function using radically different methods of resolutions. As a first approximation, the deterministic method is suitable for search in small

state-space; whereas for complex and large search state-space, this requires rather a method of stochastic search (genetic algorithm, pattern search ...).
The difficulties of these problems via conventional optimization methods give rapidly this family of algorithms able to handle large combinatorial problems with mixed variable. It is more interested for solving practical problems by a general classification of optimization problems and solved methods [2,3]. Briefly, genetic algorithms are adaptive heuristic search algorithm based on the evolutionary idea of natural selection and genetic. Moreover, they are a part of evolutionary computing, a rapidly growing area of artificial intelligence.
The strategy proposed in this work is to utilize a combination of the GA with the PSA. We will briefly describe these two algorithms.

3.1 Genetic Algorithm

This algorithm starts with the creation of the initial population of individuals and terminates with the convergence towards the best individuals of population giving therefore the optimized solution. The transition from one generation to another is accomplished by applying the following process: (i) mechanism of evaluation, (ii) selection and (iii) modification, up to obtaining a stopping criterion. The structure of this algorithm is given by the flowchart [4] (figure 1).

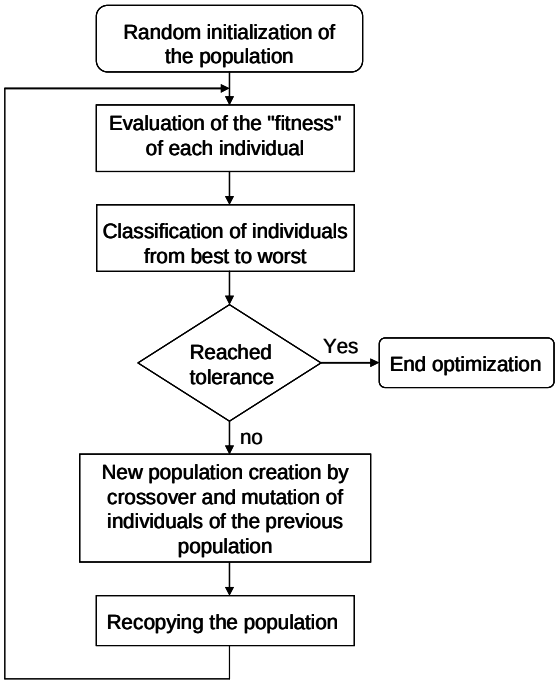

Figure 1 Structure of the genetic algorithm

Each individual of a given population is defined by a chain of genes that correspond to the different parameters to be identified. To avoid the difficulties that may arise in the binary coding and decoding of individual, a real coding GA is used [4]. The values of each parameter are bounded by

an interval [x_{min}, x_{max}] normally determined in this type of modeling according to mechanical bases. The main reason to establish these limits is to make the search process more efficient by reducing its space.

The initial population is produced by:

- Initial solutions (individuals) proposed based on the expert opinion and on experimental observations;
- Solutions chosen randomly in the search space.

This allows, in fact, to start the search from various solutions of the search space incorporating expert opinion.

Different numerical tests should be conducted and led to choice of stochastic operators as follows:

- Selection type elitism, which allows to highlight the best individuals in the population. These are the most developed individuals which will participate in the improvement. Such a technique has the advantage of faster convergence to the best individuals to the detriment of individuals which seem less appropriate and could provide elements for the creation of new individuals.
- Crossover scattered, which is cut individuals into several portions (2 or 3 portions) to obtain new individuals
- Adapt feasible mutation which randomly generates directions that are adaptive compared to the last generation successful or not. The feasible region is limited by the constraints. A pitch length is selected along each direction in such a manner that the bounds constraints are satisfied.

3.2. Pattern Search Algorithm

Pattern search is a direct search method. This method is employed for solving optimization problems that does not require any information about the gradient of the objective function. The pattern search begins at the initial point x_o. At the first iteration the mesh size is 1 and the GPS (Generalized Pattern Search) algorithm adds the pattern vectors to the initial point x_o to compute the following mesh points. The algorithm computes the objective function at the mesh points using the following approach:

$$xm_i = x_n + v_i \Delta_n \tag{12}$$

$$x_{n+1} = xm_j \,/\, f(xmj) = \min_i(f(xm_i)) \tag{13}$$

Where xm_i: the mesh points, x_n: the current point, v_i: the pattern vector and Δ_n: the current mesh size.

A pattern is a set of vectors $\{v_i\}$ that the PSA utilizes to define which points to search at each iteration. The set $\{v_i\}$ is determined by the number of independent variables in the objective function. For example, if there are three independent variables in the optimization problem, the default for a 2N positive basis consists of the following pattern vectors:

$$\begin{cases} v_1 = [1 \quad 0 \quad 0] \\ v_2 = [0 \quad 1 \quad 0] \\ v_3 = [0 \quad 0 \quad 1] \\ v_4 = [-1 \quad 0 \quad 0] \\ v_5 = [0 \quad -1 \quad 0] \\ v_6 = [0 \quad 0 \quad -1] \end{cases} \tag{14}$$

For a more description of this, see Kolda, Lewis, and Torczon [5].

To accelerate the convergence, we stop the iteration as soon as it finds a mesh point whose fitness value is smaller than that of the current point.
After a successful poll, the algorithm multiplies the current mesh size by 2. If none of the mesh points has a smaller objective function value at current point, so the poll is unsuccessful, the algorithm does not change the current point at the next iteration and multiplies the current mesh size by 0.5.
In our application the criteria for stopping the pattern search are the number of objective function evaluations.

4. Numerical applications

The evaluation of the proposed new strategy for identification is carried out through the description of the elastic-inelastic cyclic behavior of a polycrystal under uniaxial tension-compression (TC), biaxial tension-torsion with 90° out-of-phase angle (TT90). Our polycrystal is a random orientation distribution of 40 grains of a single-phase FCC. Initially, a database for both cyclic loading (TC and TT90) is numerically made up to final damaging of this grains distribution using the coefficients summed up in (Table 1)

Table 1 Coefficients used to create the database

Elastic-Inelastic parameters												
Model parameters	E (MPa)	ν	α	z	K	b^s	K_o (MPa)	Q^s (MPa)	$h_1=h_2=\ldots=h_5$	h_6	C^g (MPa)	a^g
coefficients	215000	0.32	1	20	50	13	240	256	1	2.29	95100	10

Damage parameters						
Model parameters	S^s	s_o	w^s	d_1	d_2	γ_0
coefficients	2	0.95	1	1	1.4	1.25

Such a database is considered as an experimental one. Thereafter, the identification process of model parameters is started by setting the damage parameters changing six key parameters related to the inelastic behavior (b^s, k_o, Q^s, h_6, C^g and a^g). Therefore, the identification process by the global minimum optimization concept is made through the genetic algorithm. After several tests on the population size, a population of 600 individuals is employed to optimize 6 coefficients of the model. Several iterations are made obtaining several families of model parameters followed by a local identification using the pattern search algorithm. The optimized model parameters are summed up

in (Table 2).

Table 2 Initial and optimized coefficients

Elastic-inelastic parameters												
Model parameters	E (MPa)	ν	α	z	K	b^s	k_o (MPa)	Q^s (MPa)	$h_1=h_2=\ldots=h_5$	h_6	C^g (MPa)	a^g
Initial	215000	0.32	1	20	50	24.5	340	100	1	1.7	75100	6
Optimized	215000	0.32	1	20	50	14.5	267.5	397.6	1	6.3	33830	8.71

Damage parameters						
Model parameters	S^s	s_o	w^s	d_1	d_2	γ_0
Initial	2	0.95	1	1	1.4	1.25
optimized	2	0.95	1	1	1.4	1.25

One of the main reasons which promotes this association is that both algorithms are parallelizable as shown in [2,3]. This allows gaining in computation time by exploiting computer multiprocessor. The experimental recorded fatigue lives are 38, and 14 cycles for TC and TT90, respectively. The model predicts these lives faithfully giving therefore 38, and 12 cycles in TC and TT90, respectively.

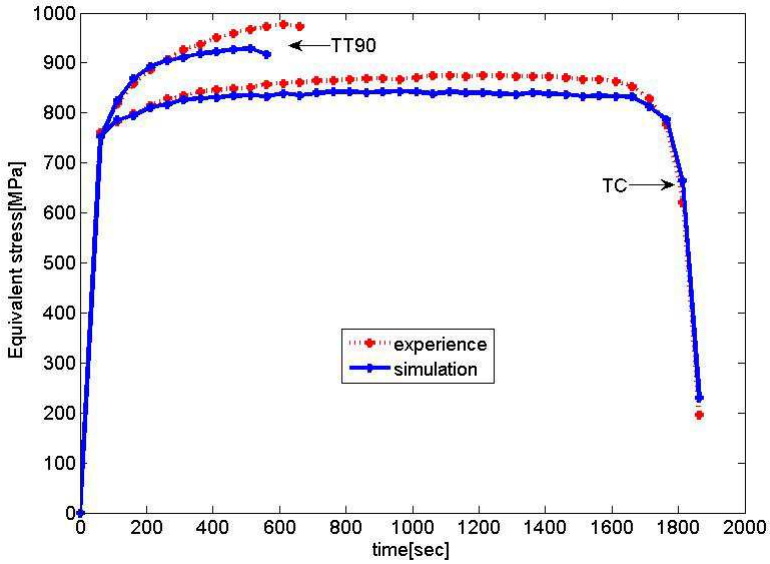

Figure 2 Evolution of the overall stress during TC and TT90 up to the final fracture

Figure 2 represents the typical evolutions of the maximum overall stress (pick stress value for each cycle) versus cyclic time using the same maximum von-Mises equivalent macro-strain for the two cyclic loading paths (TC and TT90). The predicted responses describe properly the experimental

results. Note that these predicted results are computed with the optimized model parameters summarized in table 2.

5. Conclusion

The objective of this work is to propose a new strategy to optimize the identification parameters of a micromechanical model coupled with damage [1]. Hence, a combination of genetic algorithm with pattern search algorithm is developed. The genetic algorithm optimizes globally the model parameters; whereas the pattern search algorithm, considered as a local method, has a role to determine the final values of these model coefficients. This model is tested under different cyclic loading complexities. It is recognized that this combination shows its ability to optimize the identification process. Consequently, the predicted responses describe faithfully the experimental results.

Abstract Reactor pressure vessels (RPV) are manufactured from medium strength low allow ferritic steel specifically selected of its high toughness and weldability. The ability of the RPV to withstand crack propagation is crucial to maintaining the operational safety of the reactor plant. Current generations of RPV steels operate at sufficiently high temperatures to ensure that the material remains ductile during its service life. Furthermore, new materials are engineered to exhibit greater ductility and fracture toughness throughout their operating life. Therefore understanding and being able to predict the ductile fracture behaviour is critical for assuring the safety of RPV steels during operating conditions.

This paper presents the results of an experimental programme aimed at using 3D X-ray tomography to quantify the volume fraction of ductile voids in tested pre-cracked specimens manufactured from A508 Class 3 RPV steel.

The results indicate a high concentration of voids very close to the fracture surface and voids extending 3.6mm below the crack. The data and experimental methodology could be used to calibrate predictive mechanistically based models such as the Gurson-Tvergaard-Needlman (GTN).

Keywords Ductile, Tearing, Steel, X-ray, Tomography

1. Introduction

The mechanism of ductile fracture is characterised by the nucleation, growth and coalescence of voids at initiating particles. These particles are categorised as inclusions and second phase particles, and in ferritic steel are most often manganese sulphide (MnS) inclusions and metallic carbide particles (M_nC). The voids form at these particles within the volume of high plastic strain and triaxial stresses ahead of a crack-tip or stress concentrator.

Two nucleating processes have been observed [1]: voids formation by either decohesion of the interface between the matrix and the inclusion/particle, or by cracking of the inclusion/particle itself. Voids then grow under the influence of increasing plastic strain and high hydrostatic stress within the material. A crack will propagate once neighbouring voids coalesce and/or reach a critical size producing a macroscopic flaw. The coalescence of the voids can be considered as the final stage in the crack growth mechanism.

The larger particles nucleate voids at lower stresses and strains [2] . Smaller particles will start contributing to void nucleation when the material is subjected to greater plastic deformation. The nucleation of these smaller voids at proximity to smaller particles, often between larger voids or

microcracks where intense shear bands are present, may result in a void sheeting effect further contributing to void coalescence [3, 4].

The metallurgical characteristics of the microstructure, including the size and distribution of the initiating particles which can often concentrate close to or on the grain boundaries will contribute to the nucleation and coalescence process. The distribution of these particles may also be uneven within the material with banding regions of greater concentration of particles or varying grain sizes [5].

There exists a range of mechanistically based models that have been developed to describe the ductile fracture process. One of these is the Gurson-Tvergaard-Needleman (GTN) model [6] which characterises failure by defining a material yield function which depends greatly on the stress states and on material specific characteristics. These characteristics need to be calibrated to enable a simulation of ductile crack growth.

1.1 The Gurson Tvergaard Needleman

The GTN model assumes the material is homogeneous and behaves as a continuum with an idealised void volume fraction distribution. Crucially, the model takes into consideration both the strain softening effects of void nucleation, growth and coalescence as well as the competing effect of the matrix hardening behaviour to define a material yielding function Φ, defined as (Eq.1):

$$\Phi\left(\sigma_e,\sigma_m,\bar{\sigma},f^*\right)=\left(\frac{\sigma_e}{\bar{\sigma}}\right)^2+2q_1f^*\cosh\left(\frac{3q_2\sigma_m}{2\bar{\sigma}}\right)-\left(1+q_3f^{*2}\right)=0 \quad (1)$$

Where:
σ_e = macroscopic Von Mises Stress
σ_m = macroscopic mean stress
$\bar{\sigma}$ = flow stress for the matrix material
f^* = current void fraction

The values for q_1, q_2 and q_3 were introduced by Tvergaard and Needleman to better simulate the experimental observations. These are often taken as $q_1 = 1.5$, $q_2 = 1.0$ and $q_3 = q_1^2$. The rate of void growth is related to the plastic part of the strain rate tensor $\dot{\varepsilon}^p_{kk}$ and the void nucleation rate is related to the equivalent plastic strain rate, $\dot{\varepsilon}^p_{eq}$ in (Eq. 2):

$$f^*=f_{growth}+f_{nucleation}=(1-f)\dot{\varepsilon}^p_{kk}+\Lambda\dot{\varepsilon}^p_{eq} \quad (2)$$

The first term expresses the growth rate of existing voids assuming the matrix material is incompressible and the second term defines the quantity of new voids that have nucleated as a result of the increasing plastic strain.

The scaling coefficient, Λ is characterised by (Eq. 3):

$$\Lambda = \frac{f_N}{s_N\sqrt{2\pi}} \exp\left[-\frac{1}{2}\left(\frac{\varepsilon_{eq}^{p} - \varepsilon_N}{S_N}\right)^2\right] \quad (3)$$

Where:
f_N= volume fraction of void nucleating particles
s_N = standard deviation
ε_N = mean value
ε_{eq}^{P} = equivalent plastic strain.

An additional feature of the GTN model, introduced by Tvergaard and Needleman, was to take into consideration the initial void fraction f_0, a critical void volume fraction for coalescence f_c, and a critical void fraction that corresponds to the failure of the matrix, f_F.

$$f^* = \begin{cases} f & \text{for } f \le f_c \\ f_c - \dfrac{f_u^* - f_c}{f_F - f_c}(f - f_c) & \text{for } f > f_c \end{cases} \quad (4)$$

Where:
f_c = critical void volume fraction (typically $f_c = 0.15$ for carbon steel)
f_F = actual void volume fraction at final fracture
f_u^* = modified void volume fraction (typically $f_u^* = 1/q_1$)

The distribution of the initiating particles as well as their void volume fraction are key microstructural features that are needed to accurately calibrate the GTN model. These material specific parameters are usually calibrated using metallographic observations of the non-fractured material and the material volume around fractured test specimens from carefully controlled experiments. The fracture tests can be performed using a range of specimens introducing different levels of constraint and stress states. The highly constrained pre-cracked compact test (CT) specimen is frequently used to measure fracture toughness and will be used and discussed throughout this paper.

Previous experiments have shown that void volume fractions (VVF) may vary by material but also by specimen types. Work by Kerry et al [7] on a high strength and low toughness aluminium alloy AL2024-T351 have shown that there is a difference in the distribution of the void volume fraction below the fracture surface for notched tensile specimens when compared with CT specimens. Using 3D X-ray tomography Taylor et al demonstrated that the CT specimens exhibited a higher concentration of voids close to the fracture surface when compared with that measured close to the fracture surface in notched tensile specimens. On the other hand, the voids extended further below the fracture surface in notched tensile specimens than was observed in CT specimens.

Further work has recently been performed by Daly et al [8] with respect to an A508 Class 3 RPV ferritic steel to quantify the void volume fraction using 2D optical micrographs. Similar

observations showed a higher concentration of voids for pre-cracked specimens than for notched tensile specimens. Additionally, a greater analysis of the area below the fracture surface has shown that the void volume fraction can extend to a few millimetres below the fracture surface with large clusters of voids extending up to 3.5mm below the fracture surface.

The aim of this paper is to extend the observations made in this previous work by using 3D X-ray tomography to further quantify the void volume fraction below the fracture surface in pre-cracked CT specimens of A508 Class 3 RPV ferritic steel. The methodology and observations will be discussed as well as its implications for the calibration and application of the GTN model.

2. Experimental

2.1 Material

The material used throughout this experiment was an A508 Class 3 ferritic steel. The specimens were extracted from the outer ring of an upright wedge-shaped block originating from a larger ring forging. All the specimens were extracted from the same location and in the same orientation. The chemical composition (wt%) of the ferritic steel was evaluated using spectographic analysis and the results are indicated in Table 1.

Table 1: Chemical composition in wt% of A508 Class 3 steel.

C	Si	Mn	P	S	Cr	Mo	Ni	Al	Co	Cu	Sn	Ti	V
0.18	0.23	1.3	<0.005	<0.005	0.25	0.55	0.81	0.02	0.01	0.04	0.005	<0.01	0.01

2.2 Mechanical testing

The tensile properties of the material were determined using standard round-bar test specimens oriented in the hoop direction. Three tensile specimens were tested on a Zwick 1464 at room temperature using a strain rate of 0.025% s^{-1} according to BS EN ISO 6892 procedure [9].

Ten fracture toughness tests were performed according to the ESIS P2-92 [10] standard using CT specimens with standard dimensions of thickness, B = 25mm, width, W = 50mm and a crack length to specimen width ratio, a/W = 0.53. Specimens were 20% side-grooved following fatigue pre-cracking. Tests were performed using both the unloading compliance and the multi specimen methods. Out of the ten tested CT specimens, two were left intact in order to preserve the crack tip for analysis.

2.3 Metallographic analysis

The cracked and parent material was imaged using optical and scanning electron microscopes. The parent material was imaged to characterise the general microstructure of the ferritic steel with a specific interest on grain size and inclusion/particle type and distribution. The cracked specimens were analysed to characterise the ductile fracture mechanism and distribution of voids below the

fracture surface.

For the parent material, metallographic sections were taken to view the material in the axial-radial plane. The fractured sections were machined through the tested specimen halves in the region where plain strain fracture was expected to take place. The metallographic sections were progressively ground and polished to a mirror finish of 0.25 μm using diamond paste and etched using colloidal silica and 2% Nital.

2.4 X-ray Tomography Analysis

The test samples for X-ray tomography imaging were machined below the fracture surface of three CT specimens using electrical discharge machining (EDM). The samples were approximately 0.5mm in diameter and 12mm in length and were extracted at regular intervals starting at the pre-cracked region but before the initiation of ductile tearing. The remaining specimens were extracted from below the ductile crack path and beyond the crack arrest point. The sections were extracted as close as possible to the region where plane strain was expected to take place with the greatest amount of ductile tearing damage. The surfaces of these small cylinders were lightly polished to remove any rust or scaling resulting from the EDM.

The top 4mm very close to the fracture surface of these specimens were scanned at the Henry Moseley X-ray Imaging Facility at The University of Manchester using the Nikon Metrology 225/320 kV Custom Bay system equipped with a 225 kV static multi-metal anode source and a PerkinElmer 2000 × 2000 pixels 16-bit amorphous silicon flat panel detector.

The scanning was performed with a molybdenum target using a voltage of 80 kV and a current of 130 μA. The data acquisition was carried out with an exposure time of 1000 ms with no filtration. The number of projections was set to 3,142 and the number of frames per projection was 1. The entire volume was reconstructed at full resolution with a voxel size of 2.0 μm along the x, y, and z directions.

The data processing was performed with Avizo® Fire 7.0 software. An edge preserving smoothing filter was applied to the raw data to reduce image noise in each data set. Standard data processing was used to determine the void size distribution whereas a methodology similar to [11] was employed to determine the void to fracture surface distance and evolution of void volume fraction.

2.5 Quantification of ductile tearing damage

Using the Avizo Fire data, the void volume fraction was estimated by measuring the voxel counts of metallic voxels against the count of porous voxels below the fracture surface. The VVF was calculated for each Regions Of Interest (ROI). A ROI of 100μm in height was utilised to divide the specimens into smaller cylinder regions which were comparable to the units used in Daly et al [8]. The VVF was calculated for the specimens originating below the pre-cracked surface as well as the region below the ductile tearing surface and beyond the crack arrest.

3. Results

The results from the three tensile tests at room temperature are summarised in Table 2. The average yield stress was 446 MPa and the ultimate tensile stress was 594 MPa.

The fracture toughness properties of the A508 Class 3 steel are illustrated as a J R-curve in Figure 1 which includes data from both the unloading compliance tests and monotonically loaded tests presented together. The data from both test types are in agreement and the initiation toughness, measured by the intersection of the blunting line including 0.2 mm tearing and the power-law curve fit to the data is ~ 475 kJ/m^2. The specimens for tomography analysis were extracted from test samples B, G and C as these specimens were subjected to the most ductile tearing.

Table 2: Tensile Test results

Specimen No.	1	2	3	Average
Modulus (GPa):	211	210	208	210
0.2 % Stress (MPa):	445	457	436	446
UTS (MPa):	595	602	586	594
Elongation (%)	29	27	27	28
Reduction of Area (%)	75	75	74	75

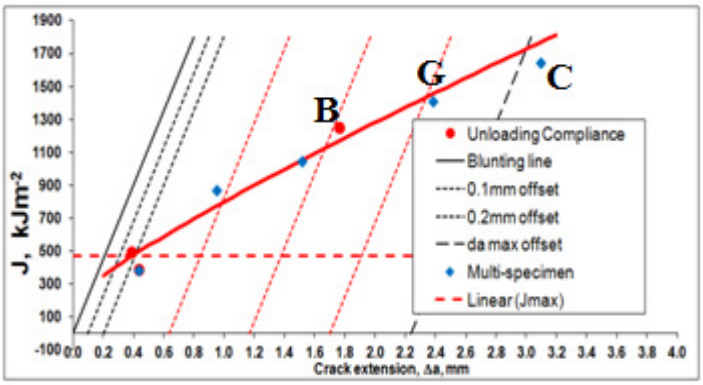

Figure 1: J R-curve for A508 Class 3 material tested in the hoop-radial direction at 23°C.

Figure 2 illustrates the general upper bainitic microstructure of the ferritic steel under the optical microscope and SEM respectively. The average grain size was estimated at 11µm. But the microstructure is interspersed with clusters of very small grains and regions where very large grains are present.

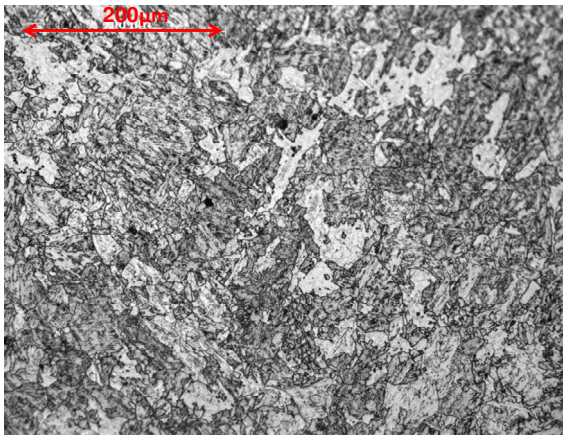

Figure 2: General microstructure of the bainitic steel under optical microscope.

Figure 3Figure 4 illustrate selected microstructural observations of voids in the material. Microvoids

were observed to initiate and grow by the decohesion of carbides from the matrix. Larger voids, in some cases, were shown to nucleate at large particles. These larger voids were observed to be present well below the fracture surface and ahead of the crack tip.

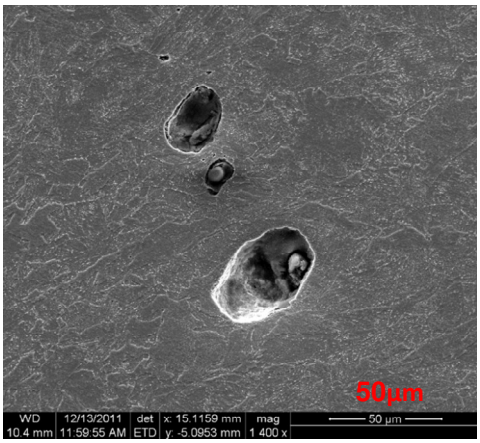

Figure 3: Large macroscopic voids with an inclusion

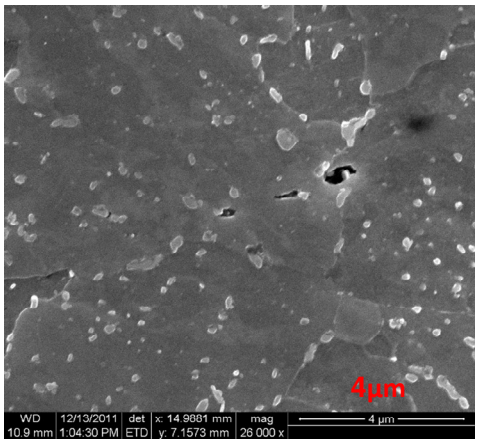

Figure 4: Microvoids nucleating at proximity of carbides

3.1 X-ray Tomography

The X-ray tomography images of Figure 5 shows the typical distribution of voids below the fracture surface for a specimen extracted from the fracture surface. Voids as small as 10µm in diameter could be resolved with a high degree of confidence. Figure 6 shows a render of the range of shapes and sizes of voids observed. Some voids have dumbbells morphologies possibly indicating coalescence. The ability to use the X-ray tomography technique enabled the imaging of voids in their entirety. Furthermore, this technique demonstrated the ability to visualise and quantify voids and in some cases, clusters of voids up to 3.6mm below the fracture surface.

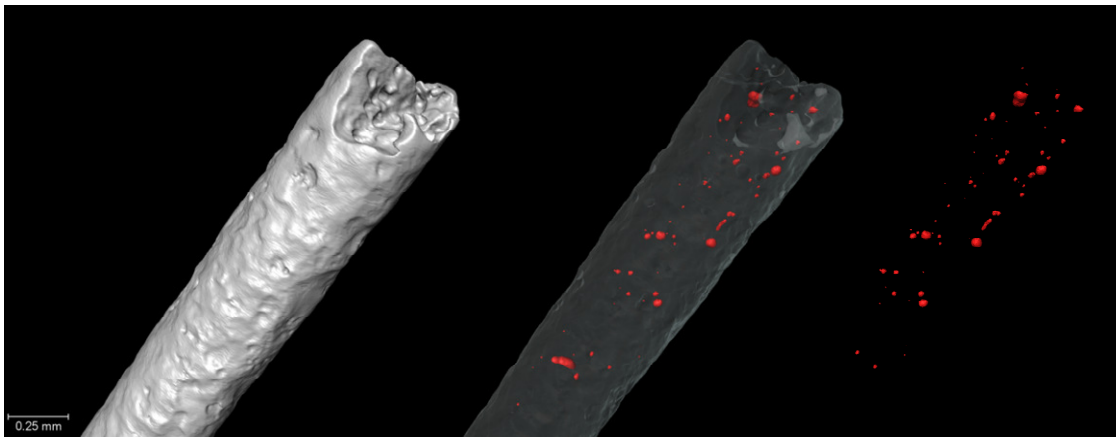

Figure 5: 3D tomographic image of the ferritic steel samples and the void distribution below the fracture surface.

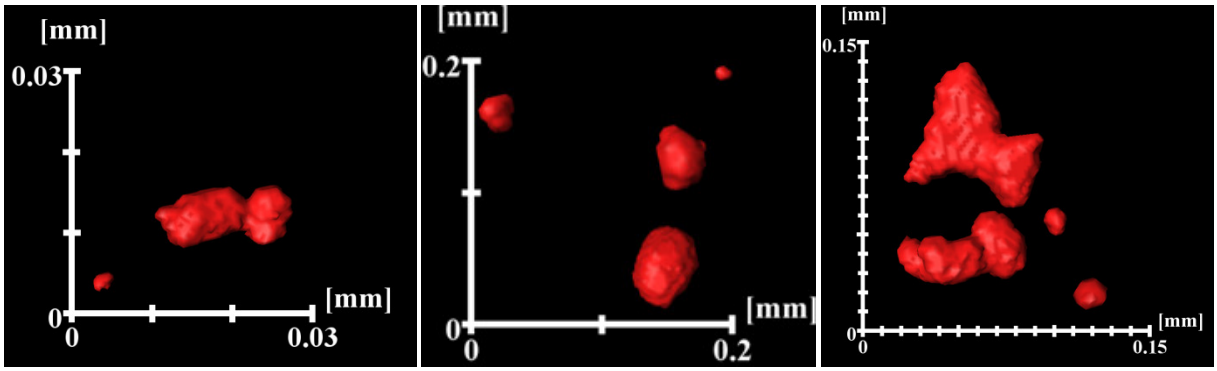

Figure 6: Magnified 3D tomographic images showing the range of sizes and shapes of voids quantified below the fracture surface.

3.2 Quantification results

The variation of the void volume fraction as a function of distance below the fracture surface in the CT specimens is illustrated in Figure **7**. The data were calculated by quantifying the average VVF for cylindrical cells of 100µm in height and starting from the fracture surface. The VVF for each specimen location (0mm, 0.5mm…) was averaged over all three specimens (B, C and G) to obtain an average VVF for the first 100µm below the fracture surface and every 100µm down to 3.6mm.

The presence of voids ahead of the final crack tip was also taking into consideration. Samples B and G had crack extensions of approximately 2mm, the extractions beyond the crack front were averaged separately and labeled as “beyond crack tip” on the plot.

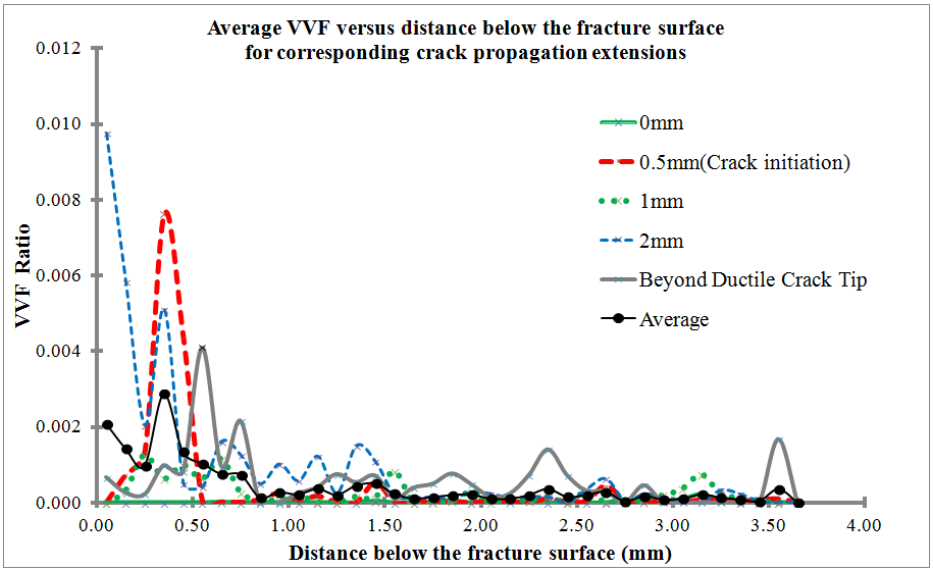

Figure 7: VVF as a function of distance below the fracture surface

The following observations can be made:

- The void volume fraction is highest close to the fracture surface and reduces to zero as a function of distance below the crack. A maximum VVF of 9.75×10^{-3} is measured

for the 2mm specimens. The VVF remains relatively high up to 800μm below the fracture surface.

- Secondary peaks are observed well below the fracture surface especially for the specimens extracted below extensive ductile tearing. The peaks are often representative of clusters of voids or very large voids at depths ranging from 1mm to 3.6mm.
- Pre-cracking of the fracture toughness specimens produces very little observable ductile tearing damage.
- At 2mm of ductile tearing, the ductile damage is immediately quantifiable very close to the fracture surface. For the other specimens, voids only become visible after 250μm below the fracture surface and peaks at a ratio of 7.60×10^{-3}.
- The data captured within the volume of material at proximity to the crack initiation and blunting (0.5mm) produce some of the highest VVF values with a maximum of 7.60×10^{-3} at 350μm below the crack surface.
- Voids have been imaged and quantified beyond the crack tips indicating ductile tearing damage ahead of the crack path.

4. Discussion

Taylor et al [7] quantified the void volume fraction below the fracture surface in failed CT specimens of AL2024-T351 aluminium alloy using optical and X-ray tomography. A critical void volume fraction f_f of approximately 1.0×10^{-2} was calculated for the aluminium alloy which compares favourably with the results obtained for the RPV ferritic steel of $f_f = 9.75\times10^{-3}$.

It is worth noting that the peaks within the void volume fraction data may disproportionately increase the average volume fraction well below the fracture surface for the three test specimens. But as the material should be considered as a continuum with an even distribution of initial voids and initiating particles, the average void volume fraction over a large number of tests should be representative of the material's bulk and fracture characteristics.

On the other hand, the ductile damage extends further beyond the crack surface in the ferritic steel than in the aluminium alloy. The aluminium alloy exhibits a sharp reduction in the VVF which reaches $f = 0$ at 300μm below the fracture surface. The ferritic steel exhibits ductile tearing damage up to 3.6 mm below the fracture surface identified by large voids and clusters of voids. The extent of the ductile damage was equally observed by previous work from Daly et al [8] using optical imaging analysis.

The substantial extent of the ductile damage was further observed in an equivalent HY100 ferritic steel. The work from Everett et al [2] identified voids below the fracture surface of fractured notched tensile specimens using a synchrotron source with equivalent resolutions. The distribution of voids deep below the fracture surface was attributed to microstructural banding and larger MnS inclusions. These larger MnS inclusions preferentially promoted the nucleation of voids at relatively low strains.

The effect of the plastic strain field produced from the propagating crack may provide sufficient strains at inclusions and particles to nucleate and grow relatively large voids deep below the fracture surface. A correlation of the experimental work with a finite element analysis is required to attain an estimate of the gradient of strains ahead and below the crack during propagation.

Finally, the tomographic images suffered from a blurring effect as a result of the X-ray beam hardening and X-ray spot being too large in comparison with the void sizes that were being imaged. Consequently, a substantial number of voids were only partially resolved and quantified since the pixel colours of these voids matched other metallic areas of the specimens and needed to be culled to obtain a reproducible and systematic quantifying tool. Further work will aim to use a synchrotron facility that will reduce such imaging artefacts and will ultimately increase the overall void volume fraction within the specimens.

5. Conclusions

This paper has described preliminary work undertaken to characterise the ductile fracture properties and fracture mechanism in A508 Class 3 steel using X-ray tomography analysis. The main conclusions from the work are as follows:

- The mechanical and fracture toughness properties have been quantified in the hoop direction. The average yield stress is 446 MPa and the initiation toughness defined by the 0.2 mm blunting line is ~ 475 kJ/m^2.
- The ductile fracture mechanism was identified to occur by the decohesion of the matrix from inclusions and second phase particles.
- The ductile damage was successfully imaged and quantified in 3D using X-ray laboratory sources to image voids of approximately 10µm in diameter and larger below the crack surface of compact test specimens.
- A relatively high VVF was quantified for specimens extracted at a 2mm crack extension but high concentrations of voids were also observed at 350µm and intermittently until 3600µm for specimens extracted along the length of the crack path. The results differ from experiments carried out with aluminium alloys where the VVF reached the background level at 300µm below the fracture surface.
- As a result of the limitations of the X-ray machine and software, a proportion of the voids were not quantified which has produced a VVF lower than is actually present in the material.
- The distribution of the voids deep below the fracture surface is attributed to microstructural banding and larger inclusions requiring lower strains.

Abstract
The mechanical performance of automotive structures made of advanced high strength steels (AHSS) is often seen reduced by the presence of cut-edges. Here an attempt is made to gain insight into the initial damage state and the damage evolution during loading of a cut-edge. This is assessed in 3D and in-situ by synchrotron laminography observation during simultaneous tensile and bending loading of a cut-edge produced by stamping. Laminography is a technique that allows to observe regions of interest in thin sheet-like objects. It is found for the DP600 laboratory steel grade that the fracture zone is very rough and that needle voids from the surface and in the material bulk follow ferrite-martensite flow lines. During loading the needle voids grow from the fracture zone surface and coalesce with voids in the bulk. The needle cracks coalesce with the burnish zone though narrow zones, called void sheets. The formed cracks are inclined by 45° compared to the load direction.

Keywords: Dual phase steels, cutting edges, X-ray laminography, damage

1. Introduction

Advanced High Strength Steels (AHSS) grades remain the most widely used and developed materials in the automotive industry in order to reduce the "weight" of structural parts. Among these AHSS grades, dual phase (DP) steels with their ferrite-martensite composite microstructure present a good compromise between strength and formability. DP steels consist of a ferritic matrix containing a hard martensitic second phase in the form of islands. They are produced by controlled cooling from the austenite phase (in hot-rolled products) or from the two-phase ferrite plus austenite phase (for continuously annealed cold-rolled and hot-dip coated products) to transform some austenite to ferrite before a rapid cooling transforms the remaining austenite to martensite. However, the forming processes could affect the mechanical behavior of these grades. Some observations have shown that the cutting step tended to alter the good mechanical properties of this grade [1,2]. These studies have shown that the cutting process of DP sheets affects the adjacent material that extends into the bulk region of the sheet. This affected zone is characterized by a hardening and microstructural deformation which leads to local decohesion of ferritic and martensitic phases [1,11]. This drop in mechanical performance can significantly reduce the properties and then the use of AHSS.

While ductile fracture mechanisms of this steel and its base materials (i.e. ferrite and austenite separately) have been discussed in the past [5,6,7,8], the damage mechanisms of DP cut-edges are not well known. This study aims at offering knowledge of the microstructural initial state of a cut-edge and the evolution of damage from using three dimensions in-situ X-ray synchrotron laminography adapted to 3D observation of regions of interest sheet-like specimen and to identify the damage mechanisms leading to the crack formation initiating from the cut-edge.

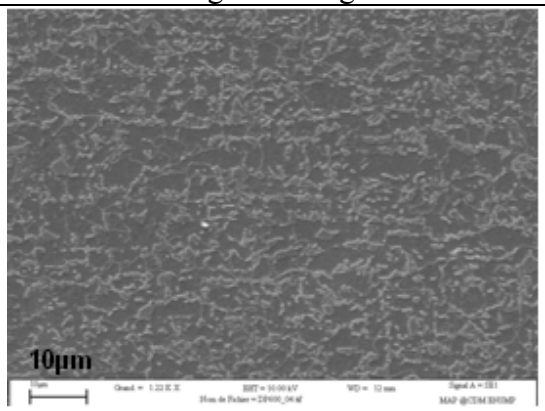
X-ray synchrotron laminography has been used in the present study to visualize for the first time

damage evolution from a cut-edge during in-situ tensile bending test. The method, in contrast to computed tomography which is for axisymetric objects, allows to image in three dimensions a region of interest (for instance the crack tip) inside a sheet-like sample without cutting it. The laminography set-up used here is located at the ID19 beam line at the European Synchrotron Radiation Facility (ESRF) in Grenoble (France). The acquisition was performed with a voxel size of 0.778 μm^3. Applications in the study of damage of an aluminum grade can be found in the literature [12]. More details about the laminography technique are also given elsewhere [12,13].

2. Material and experiment

2.1. Studied material

The material used in this study is a laboratory dual phase steel with a ultimate tensile strength of approximately 600 MPa and a fracture strain of around 17 % at the as-received condition. The material was supplied as a 0.8mm thick cold rolled sheet. The chemical composition and microstructure are given in figure1.



(a)

C	Mn	Si	Cr
0.08	0.8	0.23	0.68

(b)

Figure 1: (a) DP microstructure visualized by scanning electron microscopy (after nital 0.2% etching). (b) Chemical composition of DP600 steel (weight %)

The martensite islands appear to be aligned along the rolling direction. In the following the rolling direction will be referred to as L, the long transverse direction as T and the short transverse direction as S.

2.2. The cut-edge profile

The shearing, which is a cutting in a straight line over the entire width of the sheet by the action of a moving blade perpendicular to the plane of the sheet, is the most widely used and least expensive process for separating metal panels. In this study, we assume that the shearing and punching have the same effects on the cut edge as the 2D descriptions of these processes are identical. Figure 2 shows an optical micrograph of the polished surface of a sample after the cutting process. The sheared surface profile is characterized by the existence of 4 characteristic zones: rollover, fracture, burnish and burr (figure2). This observation is consistent with the results found in the literature [1,3].

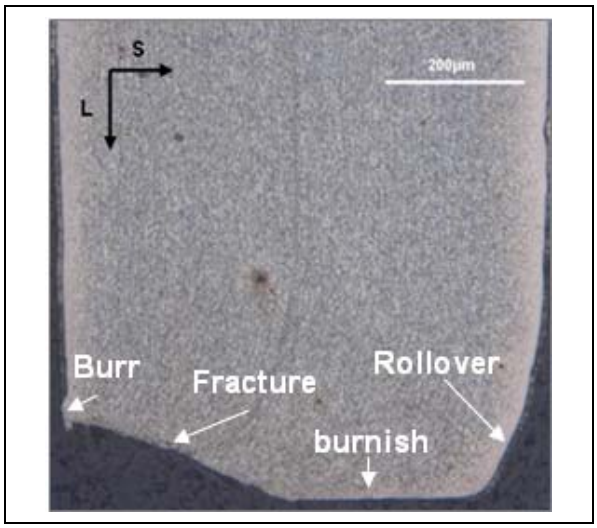


Figure 2: optical micrograph of a DP600 cut-edge profile (after 0.2% nital etching)

The proportion of these 4 characteristic zones are heavily dependent on cutting parameters such as the material nature, clearance, cutting edge radius and cutting speed [3,4,9]. The fracture zone displays the highest damage and presents a high roughness. Some zones of decohesion at the ferrite-martensite interfaces can be observed in the fracture zone and are aligned along the flow lines [1].

2.3. Experiment

The experimental technique used in this study was synchrotron radiation computed laminography (SRCL). It is a non-destructive technique similar to synchrotron radiation computed tomography (SRCT), for three dimensions imaging of objects that are extended in two dimensions. It provides a unique opportunity to observe internal damage mechanisms in three dimensions during extended crack propagation in sheet materials [12]. Unlike SRCT which is especially adapted to compact or one-dimensionally elongated objects which stay in the field of view of the detector system under rotation, SRCL is optimized to image regions of interest (ROIs) out of flat, sheet-like specimens. For this, the specimen rotation axis is inclined at an angle of $\theta < 90°$ with respect to the beam direction ($\theta = 90°$ corresponds to the case of CT). For sheet-like specimens, this enables a relatively constant average X-ray transmission over the entire scanning range of 360°, which allows reliable projection data to be acquired [12]. Although the 3D Fourier domain of the specimen is not sampled completely [13], which leads to imaging artefacts, these artefacts are often less disruptive than the ones produced by (limited-angle) CT [13].

The sample geometry shown in figure3 (a) was used. A hole with a radius of 5 mm was punched out from a sheet of DP steel and an elongated crack was machined up to one edge. The loading was achieved perpendicular to the crack, via a two-screw displacement-controlled wedging device that controls the specimen notch crack mouth opening displacement (CMOD) similar to the one used in Ref. [13,14].

To avoid the sample buckling and out-of-plane motion, an anti-buckling device was used. The entire rig was mounted in a dedicated plate that was removed from the SRCL rotation stage between loading steps. The loading was applied via stepwise increases in the CMOD, one turn of the screw corresponding to 1 mm of CMOD. 3 scans were performed before any loading in order to map and image the initial state of the cut-edge. After each loading step, a scan of the ROI containing the crack tip was carried out.

Observation was performed on the laminography instrument installed at ID19 at the European Synchrotron Radiation Facility (ESRF) in Grenoble (France). The axis inclination angle used was around 30° and a white beam was set up, centered around a 60 keV X-ray energy. The scanned region of interest (ROI) was about 1 mm^3.

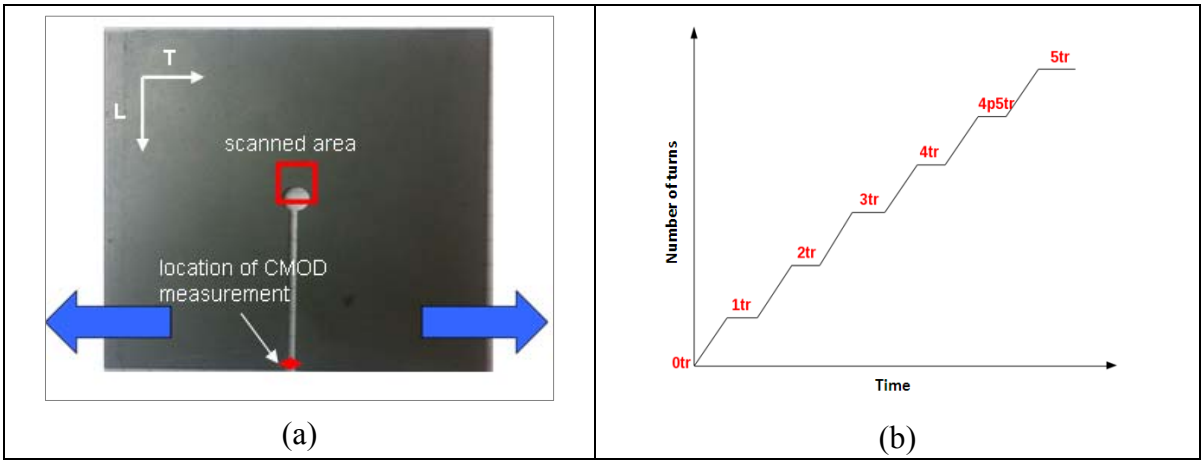

Figure 3: (a) the sample used in in-situ laminography observation and loading direction. (b) Schematic demonstration of stepwise loading applied during the in-situ observation.

3. 2D in-situ visualization of damage evolution from a cut-edge

The figure 4a-f shows the reconstructed 2D laminography sections at different loading stages. Ferrite and martensite phases have the same grayscale due to the fact that the phases have similar attenuation coefficients. They are shown in gray and the initial internal voids can be seen in black in the matrix (ferrite+martensite). Figure 4a shows the material at delivery state after punching in the L-T plane. The 2D sections (figures 4a-f) were taken from the burnish zone. The circular punched hole can be seen at the bottom of the sample. Some artifacts can be observed (cf [12]) that do not influence the segmentation of the voids (figure 5). The 2D sections (figure 4a-f) were taken from the burnish zone. A geometrical defect can be seen in the cut-edge.

Figure 4c, taken from at loading step corresponding to a CMOD equal to 2 mm, shows that a microcrack initiates on the cut-edge close to the geometrical defect. These observations of ductile crack propagation from a cut-edge and coalescence with internal porosities have never been seen before using SRCL with such a high level of details. The coalescence sheets are inclined by 45° compared to the L-direction. Other microcracks initiate from cut-edge but the crack located close to the geometrical defect grows faster. This is consistent with the increased level of stress triaxiality caused by the geometrical defect.

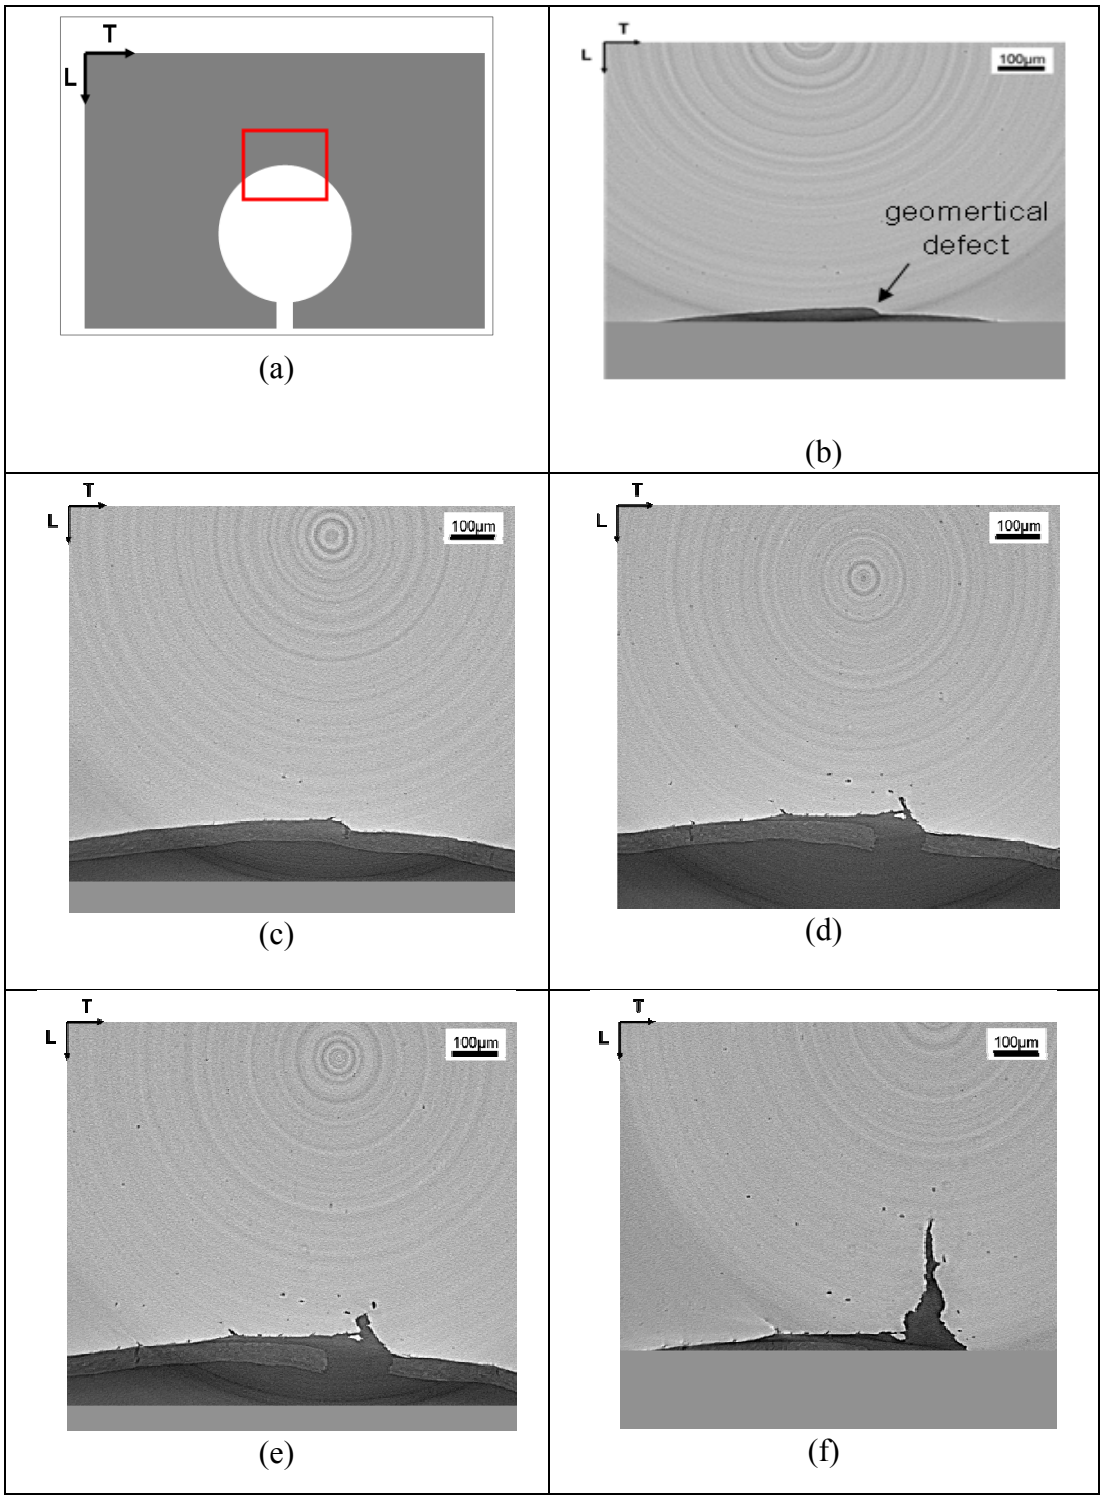

Figure 4: 2D sections at the burnish zone of the steel sheet plane of reconstructed laminography data of damage evolution from a cut-edge at CMODs. (a) The scanned zone (b) material at delivery state; (c) CMOD = 2 mm; (d) CMOD = 3 mm; (e) CMOD = 4 mm; (f) CMOD = 4.5 mm.

4. 3D in-situ observation of damage evolution from a cut-edge

Thanks to SRCL it is possible to visualize the voids in three dimensions, as shown in figure 5a-f, where voids are shown in volumes taken around the mid-thickness at different CMODs. Figure 4a shows the as-received material after punching. The fracture and burnish characteristic zones

surfaces and the geometrical defect located in the fracture-to-burnish transition zone can be seen. The initial porosities can be seen in the bulk of the specimen in black. These voids are aligned along the martensite alignments (interfaces ferrite-martensite) [1]. Coalescence sheets can be seen in figure 5e-f where needle voids growing from the cut-edge, i.e. fracture zone surface, coalesce with the internal needle voids corresponding to the decohesion of ferrite-martensite interfaces. These needle voids then coalesce with the burnish zone though narrow areas known as void sheets.

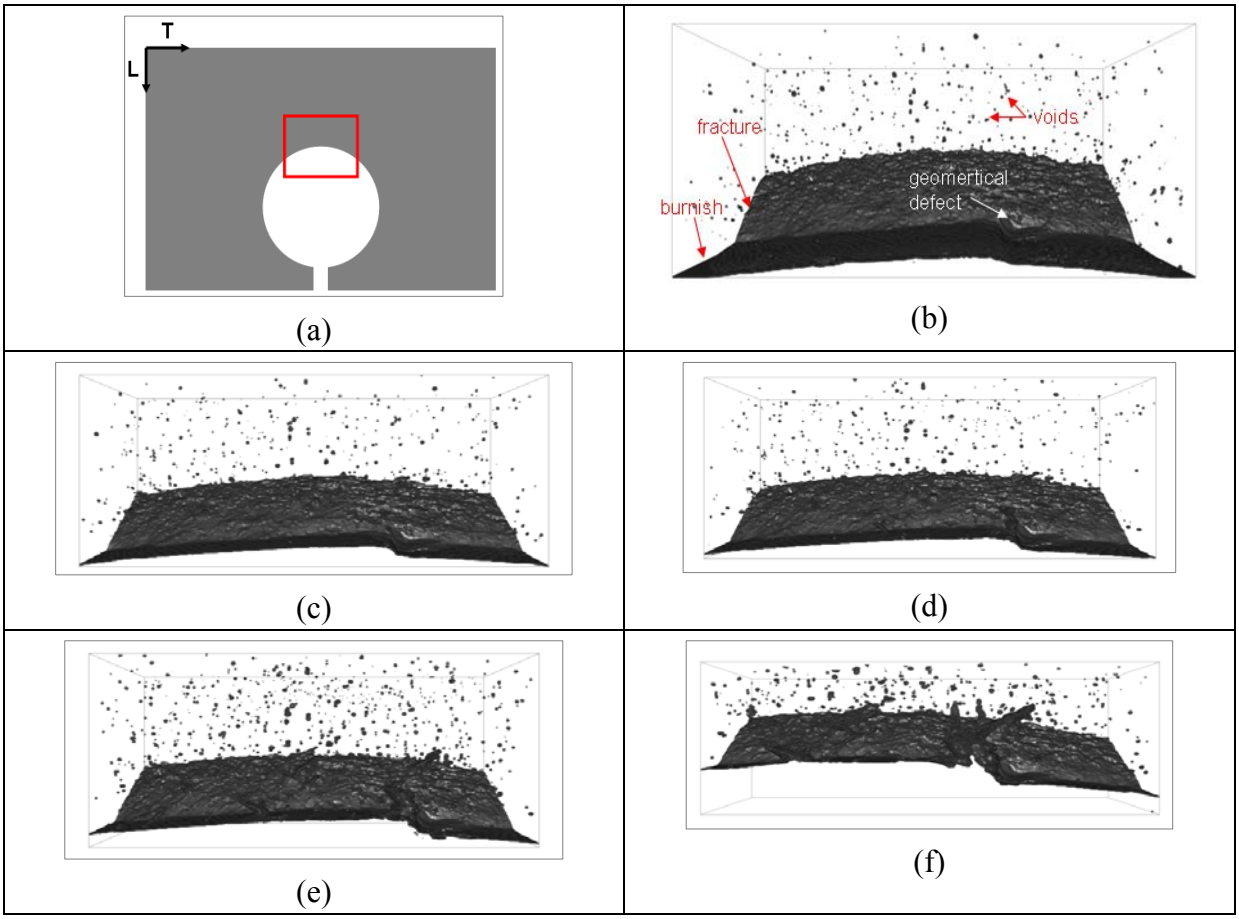

Figure 5: L-T views of 3D volumes of the steel sheet plane of reconstructed laminography data of damage evolution from a cut-edge at CMODs. (a) The scanned zone (b) material at delivery state (700x350x504 μm^3); (c) CMOD = 1 mm, (700x350x294 μm^3); (d) CMOD = 2 mm, (700x350x294 μm^3); (e) CMOD = 3 mm, (700x350x294 μm^3); (f) CMOD = 4 mm, (700x300x260 μm^3).

Figure 6 shows the shape of needle voids grown from the fracture zone surface and in the bulk. These needle voids consist with the decohesion of ferrite-martensite interfaces (i.e. the flow lines) characterized in Ref [1].

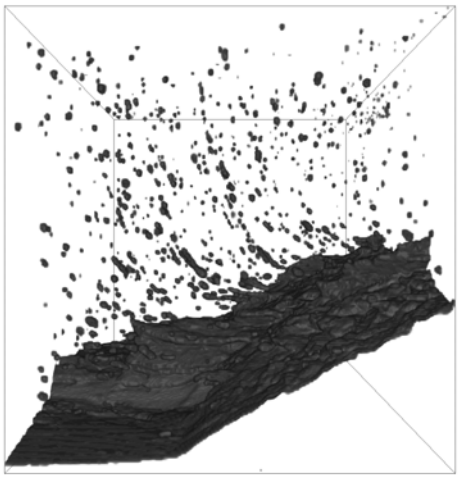

Figure 6: L-S 3D view of reconstructed laminography data of a DP600 cut-edge at CMOD = 3 mm (260x350x700 μm^3)

Figure 7 shows L-S views of reconstructed laminography data of DP600 cut-edge. Figure 7a illustrates the cut-edge profile with the 4 characteristic zones. Microcracks, needle voids from the fracture zone surface and needle voids in the bulk can be seen in figure 7a. Figure 7b shows the coalescence sheet of needle voids growing from the fracture zone and the burnish zone.

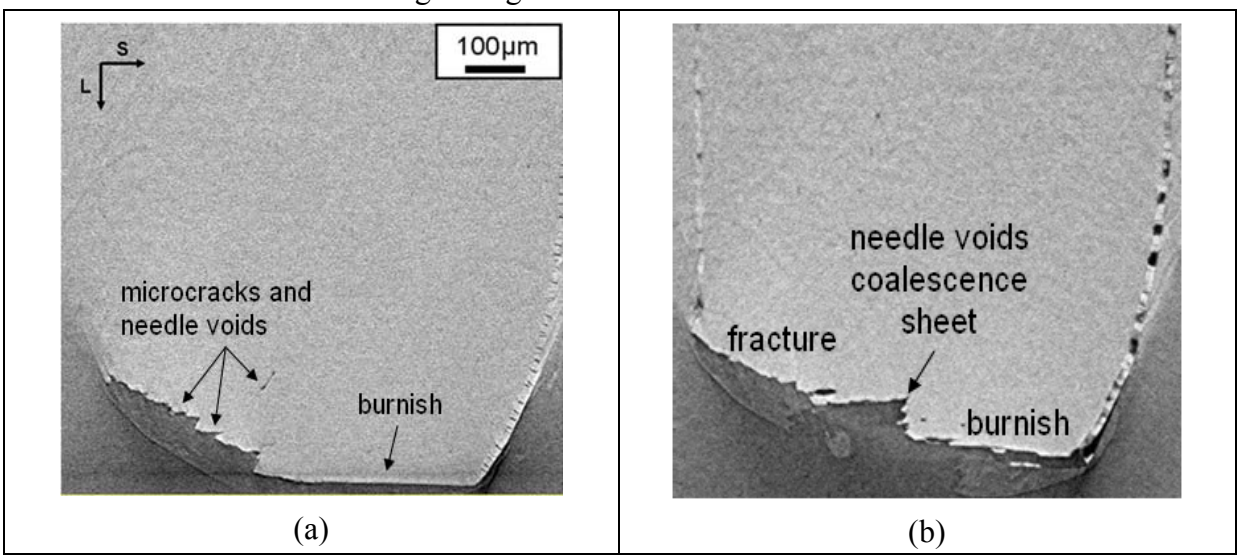

Figure 7: L-S 2D sections of reconstructed laminography data. (a) cut-edge profile at initial state. (b) Coalescence sheet at CMOD = 3 mm.

5. Conclusion

The experimental study presented in this paper aims at gaining insight into the initial damage state and subsequent damage evolution during mechanical loading from DP600 steel grade cut-edges. 3D imaging using synchrotron radiation computed laminography has allowed us to identify different defects that a cut-edge at initial state contains. These include roughness in the fracture zone, needle voids in the bulk from fracture zone and alignment of needle voids along the flow lines i.e. martensite alignments. These results are consistent with the ones found in Ref. [1,3].

The 3D in-situ laminography observation, particularly adapted to the observation of sheet-like objects, carried out on a sample with a circular punched hole has allowed us to characterize, for the first time, the damage evolution from a cut-edge in-situ and in 3D during mechanical tension and bending loading. The growth of needle voids was especially along flow lines from fracture zone surface but also in the bulk along the martensite alignments. The initial void growth direction is parallel to the burnish plan and normal to the loading direction. We observe that the coalescence of needle voids from the fracture zone with the burnish zone occurs via narrow coalescence zones. These cracks are inclined by 45° compared to the L-direction. Several cracks are formed, especially in the fracture zone, but the one located close to the geometrical defect grows faster. This is consistent with the increased level of stress triaxiality that is known to favor ductile damage growth.

Numerical Simulation Method of radiation damage effects in plate-type dispersion nuclear fuel elements

Yunmei Zhao, Shurong Ding*, Xin Gong, Yongzhong Huo

* Corresponding author: dsr1971@163.com

Abstract A metal-matrix dispersion nuclear fuel plate is composed of dispersion nuclear fuel meat and metal cladding. The fuel meat is similar to a kind of particle composite with the fuel particles embedded in the metal matrix. The extremely harsh irradiation environment results in the complex thermo-mechanical coupling behaviors occurring in the dispersion fuel plate. Especially, this complexity stems more from the irradiation damage effects, such as irradiation hardening and creep in the metal materials induced by the high-energy fission fragments and neutrons, and the thermal conductivity degradation of fuel particles as well. In this study, for heterogeneous irradiation conditions, the three-dimensional large deformation constitutive relations and stress update algorithms are built and validated for the homogenized fuel meat and cladding in the co-rotational coordinate system through forming subroutines in ABAQUS. The obtained results for the whole fuel plate indicate that when the non-homogeneous irradiation condition introduced: (1) both the mechanical and temperature fields show remarkable non-uniform characters along the length direction; (2) the deformation of the plate surface tends to be an arch, which could affect the normal flow of coolant with increasing burnup. The developed numerical simulation method provides a convenient way to simulate the heterogeneous irradiation damage. This study can lay a basis for establishing failure criteria for metal materials in the irradiation environment.

Keywords radiation damage, stress update algorithm, non-homogeneous irradiation condition, thermo-mechanical coupling

1. Introduction

Dispersion nuclear fuel elements are composed of metal cladding and fuel meat [1] with a certain volume fraction of fuel particles embedded in the matrix. Compared to the presently used nuclear fuel elements in nuclear plants, they have much better thermal conductivity and thus can reach higher burnup. They have a promising usage in the advanced nuclear reactors and disposal of nuclear wastes. The thermo-mechanical behaviors evolution of nuclear fuel elements and assembly is one of the mostly concerned issues for their in-pile safety, and it is a critical issue in their optimal design as well. Recent researches on thermo-mechanical behaviors in dispersion fuel elements with the finite element method (FEM) have been becoming a development trend, and the numerical simulation method is expected to be an important way for their optimal design. Some finite element method codes, such as FASTDART [2-3], PLATE [4-5], MAIA [6-7] and DART-TM [8], were developed with the attempt to study their thermal and thermal-mechanical behaviors. Van Duyn's study [9] treated the rod-like dispersion fuel pellet as a composite and established a three-dimensional model with the mutual interaction between the particles and matrix considered. Shurong Ding [10-11]studied the thermal and mechanical behaviors and Qiming Wang [12] studied the interfacial behaviors of the plate-type dispersion nuclear fuel elements based on the Representative Volume Element (RVE) method. In the demanding environment of nuclear reactors,

irradiation swelling occurs in nuclear fuels, and their thermal conductivity is degraded due to nuclear fissions; the metal materials within fuel elements experience irradiation damage effects, such as irradiation hardening and creep [13]. Besides, for the dispersion nuclear fuel plate, the research of nuclear reactor physics indicates that the irradiation damage along the length direction is heterogeneous owing to the non-homogeneous distribution of fast neutrons. All the above researches haven't well taken the irradiation damage effects into account, and a good simulation method for un-uniform irradiation conditions is waiting to be developed.

In order to study the thermo-mechanical behaviors of a whole fuel plate under non-homogeneous irradiation conditions, in this study, based on micromechanics, an equivalent fuel meat is obtained with the homogenized thermo-mechanical material properties related to the ones of fuel particles and metal matrix. With the thermo-elastic and irradiation swelling effects in the equivalent fuel meat, and with the thermo-elasto-plastic and irradiation hardening behaviors involved in the metal cladding, the respective three-dimensional thermo-mechanical constitutive relations and stress update methods are constructed. Assuming that the heat generation rates and neutron flux along the plate length direction are linear with the maximums appearing in the middle location, the numerical simulation methods are realized through several subroutines in ABAQUS. The material points have been given different constitutive relations according to time and their locations, thus the time and location-dependent constitutive relation can be carried out. The proposed numerical method is validated and the un-uniform thermo-mechanical fields are obtained and analyzed.

2. The constitutive relations and numerical simulation methods

The whole fuel plate is regarded as the research object in this study and its thermo-mechanical behaviors evolution is focused on under the heterogeneous irradiation conditions. In the fuel meat, there contain a large number of fuel particles. It is impossible to consider the mutual interactions between the fuel particles and the matrix in the finite element model and it is necessary to deal with it as an equivalent homogenous material. As follows, the equivalent thermo-mechanical parameters are obtained on the base of homogenization theory. Owing to the temperature-dependent and time-dependent performances of the component materials together with the resultant location-dependent ones due to the heterogeneous irradiation conditions, the equivalent meat also has the above special properties. For the fuel cladding, the irradiation hardening effect is included in the large-deformation thermo-elasto-plastic behaviors.

For the fuel meat and cladding, the thermal constitutive relations are comparably simple, which can be implemented with the subroutine UMATHT. According to the temperature, location and real time of the incremental step, the integration points can be applied with different thermal constitutive relations. In the following, the mechanical constitutive relations are mainly built and the relative numerical simulation methods are given.

2.1. Constitutive models of the equivalent fuel meat

2.1.1. Parameters of the equivalent meat

Homogenization theory [14-15] has been introduced to a dispersion nuclear fuel meat, and the

material properties including both the mechanical and thermal properties are obtained as follows.

According to the mean field model by MAXWELL [16], the conductivity of the equivalent meat $\mathrm{K(T,t,X)}$ can be described as:

$$\mathrm{K(T,t,X)} = \frac{K_m(2K_m+K_p-2V_f(K_m+K_p))}{2K_m+K_p+V_f(K_m-K_p)}, \tag{1}$$

Where K_m and K_p separately represent the conductivity of the matrix and the inclusion phase of fuel particles.

This analysis adopts Mori-Tanaka Method [17] to calculate the equivalent Young's modulus and Poisson's ratio. That's:

$$\mathrm{E(T,t,X)} = E_m(1+\frac{V_f(\frac{E_p}{E_m}-1)}{1+(1-V_f(E_p/E_m-1)}; \upsilon = \upsilon_m(1+\frac{V_f(\frac{\upsilon_p}{\upsilon_m}-1)}{1+(1-V_f(\upsilon_p/\upsilon_m-1)}, \tag{2}$$

where E is equivalent Young's modulus (MPa) and υ is the equivalent Poisson's ratio, they are related to the Young's Modula and Poisson's ratios of fuel particles and matrix.

Only the fuel particles in the dispersion fuel meat can generate heat, and the heat generation rate of the particles corresponds to their fission rate. The heat generation rate of the fuel particles $\dot{q_p}$ can be expressed as

$$\dot{q_p}(X) = c \cdot \dot{f}, \tag{3}$$

with the unit is W/mm^3. Where $\mathrm{c} = 3.204 \times 10^{-11}$J/fission is the generated heat energy every fission event and $\dot{f}$ is the fission rate of fuel particles, while in this analysis the value of $\dot{f}$ is linearly distributed along the length direction like the fast neutrons, which has the largest one $0.6408\ \mathrm{W}/mm^3$ in the middle location as twice as the lowest one at the margin of the fuel meat.

The corresponding heat generation rate of the equivalent meat can be obtained as:

$$\dot{q(X)} = V_f \cdot \dot{q_p} \tag{4}$$

The swelling rate of the equivalent meat is obtained similarly as

$$\mathrm{SW(T,t,X)} = \frac{\Delta \mathrm{V}}{\mathrm{V_0}} = V_f \cdot \mathrm{SW}_p, \tag{5}$$

where $\dot{q_p}$ and SW_p separately denote the heat generation rate and swelling rate of fuel particles, they are both location-dependent and SW_p increases with burnup [3].

The thermal expansion of the equivalent meat α_c can be expressed as

$$\alpha_c(T) = 5.84 \times 10^{-6} + 1.9 \times 10^{-7} \times \frac{V_f-0.1}{0.05} + 2 \times 10^{-7} \times \frac{T-350}{450}, \tag{6}$$

where T is temperature in Kelvin with the application range from 350K to 730K.

In the above equations, the subscript p represents the material parameters of the fuel particles and subscript m represents the ones of matrix, and V_f denotes the volume fraction of fuel particles in the fuel meat. In this study, the considered volume fraction is 10%. Under heterogeneous irradiation conditions, the above obtained equivalent parameters vary with location, temperature and time.

2.1.2. Constitutive relationship of the equivalent meat

The large-deformation elastic constitutive relationship for the equivalent meat in a co-rotational coordinate system can be expressed as the following relation between Cauchy stress and elastic logarithmic strain:

$$\sigma_{ij} = \lambda(T,t,X)\delta_{ij}{\varepsilon_{kk}}^{el} + 2\mu(T,t,X){\varepsilon_{ij}}^{el}, \tag{7}$$

where $\lambda(T,t,X)$ and $\mu(T,t,X)$ is the Lame constants, they are related to the Young's Modulus and Poisson's ratio in Eq. (2).

The incremental form for a time step from t to $t+\Delta t$ with the temperature change from T to T+ΔT in a corotational framework can be obtained as

$$\Delta\sigma_{ij} = \lambda(T+\Delta T, t+\Delta t, X)\Delta\varepsilon_{kk}^{el}\delta_{ij} + 2\mu(T+\Delta T, t+\Delta t, X)\Delta\varepsilon_{ij}^{el} + \Delta\lambda\varepsilon_{kk}^{el(t)}\delta_{ij} + 2\Delta\mu\varepsilon_{ij}^{el(t)} \quad (8)$$

$$\Delta\varepsilon_{ij}^{el} = \Delta\varepsilon_{ij} - \Delta\varepsilon_{ij}^{th} - \Delta\varepsilon_{ij}^{sw} \quad (9)$$

$$\Delta\lambda = \lambda(T+\Delta T, t+\Delta t, X) - \lambda(T, t, X),\ \Delta\mu = \mu(T+\Delta T, t+\Delta t, X) - \mu(T, t, X) \quad (10)$$

where $\Delta\varepsilon_{ij}$ represents the total strain increment and $\Delta\varepsilon_{ij}^{el}$ represents the elastic one, $\varepsilon_{ij}^{el(t)}$ depicts the elastic strain at time *t*; $\Delta\varepsilon_{ij}^{th}$ and $\Delta\varepsilon_{ij}^{sw}$ mean the thermal strain increment and swelling one as the following

$$\Delta\varepsilon_{ij}^{th} = (\ln(1+\alpha_{c(T+\Delta T)}(T+\Delta T-T_0) - \ln(1+\alpha_{c(T)}(T-T_0))\delta_{ij} \quad (11)$$

$$\Delta\varepsilon_{ij}^{sw} = \frac{1}{3}\delta_{ij}(\ln(1+\mathrm{SW}(\mathrm{T}+\Delta\mathrm{T}, \mathrm{t}+\Delta\mathrm{t}, \mathrm{X})) - \ln(1+\mathrm{SW}(\mathrm{T}, \mathrm{t}, \mathrm{X}))) \quad (12)$$

Where T_0 is the reference temperature which is set as 350K.

2.2. Constitutive relationship of the cladding

2.2.1. Irradiation hardening model for the cladding material

The strain-hardening curve of unirradiated Zircaloy is described as [18]

$$\sigma = \mathrm{K}\varepsilon^n \cdot (\frac{\dot{\varepsilon}}{10^{-3}})^m \quad (13)$$

where σ is the true stress(Pa), ε is the true strain, n is the strain-hardening exponent, *K* is the strength coefficient and *m* is the strain rate sensitivity exponent. $\dot{\varepsilon}$ is the true strain rate. If $\dot{\varepsilon} < 10^{-5}/s$, set $\dot{\varepsilon} = 10^{-5}/s$.

$$\mathrm{K} = 1.17628\times10^9 + T(4.54859\times10^5 + T(-3.28185\times10^3 + 1.72752T)) \quad (14)$$

$$\mathrm{n} = -9.49\times10^{-2} + T(1.165\times10^{-3} + T(-1.992\times10^{-6} + 9.588\times10^{-10}T)) \quad (15)$$

$$\mathrm{m} = 0.02 \quad (16)$$

where *T* is the temperature in Kelvin ranged from 300 K to 730K.

Due to the irradiation hardening effect, the strain hardening exponent [18] is described by further multiplying the coefficient given in Eq. (17)

$$k_2 = 1.369 + 0.032\times10^{-25}\cdot(\phi\cdot t) \quad (17)$$

The strength coefficient under irradiation [18] is given by adding the value given in Eq. (14) to Eq.(18)

$$k_3 = 5.54\times10^{-18}\cdot(\phi\cdot t) \quad (18)$$

The factors in Eqs. (17-18) are both dimensionless, and $\phi\cdot t$ denotes the fast neutron fluence (n/m^2); $\phi$is the fast neutron flux, which is location-dependent due to the heterogeneous irradiation conditions.

2.2.2. Three-dimensional constitutive relation for the cladding

The incremental constitutive relation for the cladding is similar to Eq. (8) as

$$\Delta\sigma_{ij} = \lambda(T+\Delta T, t+\Delta t, X)\Delta\varepsilon_{kk}^{el}\delta_{ij} + 2\mu(T+\Delta T, t+\Delta t, X)\Delta\varepsilon_{ij}^{el} + \Delta\lambda\varepsilon_{kk}^{el(t)}\delta_{ij} + 2\Delta\mu\varepsilon_{ij}^{el(t)}$$

Since the large-deformation thermo-elasto-plastic behaviors are considered, the elastic strain increment can be expressed as:

$$\Delta\varepsilon_{kk}^{el} = \Delta\varepsilon_{ij} - \Delta\varepsilon_{ij}^{th} - \Delta\varepsilon_{ij}^{p}, \quad (19)$$

Where $\Delta\varepsilon_{ij}^{p}$ can be obtained according to the backward Euler Integration and plastic constitutive

theory [19] as

$$\Delta\varepsilon_{ij}^{p} = \frac{3S_{ij}^{t+\Delta t}}{2\bar{\sigma}^{t+\Delta t}}\Delta\bar{\varepsilon}^{p}; \tag{20}$$

$$\sigma_{ij}^{t+\Delta t} = \sigma_{ij}^{t} + \Delta\sigma_{ij} \tag{21}$$

Where $S_{ij}^{t+\Delta t}$ are the components of the deviatoric tensor of the Cauchy stress at $t+\Delta t$; $\bar{\sigma}^{t+\Delta t}$ is the Mises stress at $t+\Delta t$, which is dependent on the equivalent plastic strain increment $\Delta\bar{\varepsilon_p}$. After some manipulations, a closed form expression for $\Delta\bar{\varepsilon}^{p}$ can be obtained:

$$\bar{\sigma}^{t+\Delta t} + 3G\Delta\bar{\varepsilon_p} - \bar{\sigma}^{pr(t+\Delta t)} = 0, \tag{22}$$

Where the Mises stress and equivalent plastic strain at $t+\Delta t$ should obey the irradiated strain-hardening curve in Section 2.2.1; $\bar{\sigma}^{pr(t+\Delta t)}$ is the trial Mises stress with the assumption of no plastic strain increments in Eq. (19). Eq. (22) is a nonlinear equation of $\Delta\bar{\varepsilon_p}$. Newton Iteration is applied to solve this nonlinear equation. When the converged equivalent plastic strain increment is obtained, the stress and strain can be updated.

Based on the developed constitutive relations and stress update methods for the fuel meat and cladding, the subroutines UMAT are written to simulate the non-homogeneous irradiation-induced mechanical behaviors.

3. Finite element model

3.1. Finite element geometric model

A dispersion nuclear fuel plate is taken as the research object, whose length and width is much larger than its thickness. The bonding between the fuel meat and the cladding is assumed perfect. As mentioned above, the thermo-mechanical behaviors evolution for un-uniform irradiation conditions is to be simulated. According to the symmetry in geometry and loading, a 1/8 part of the whole fuel plate is set as the finite element geometric model including the corresponding parts of fuel meat and cladding, as illustrated in Fig.1. Using the reduced Integration element C3D8RT, the FE model in Fig.1 is meshed with 49950 elements and 56848 nodes.

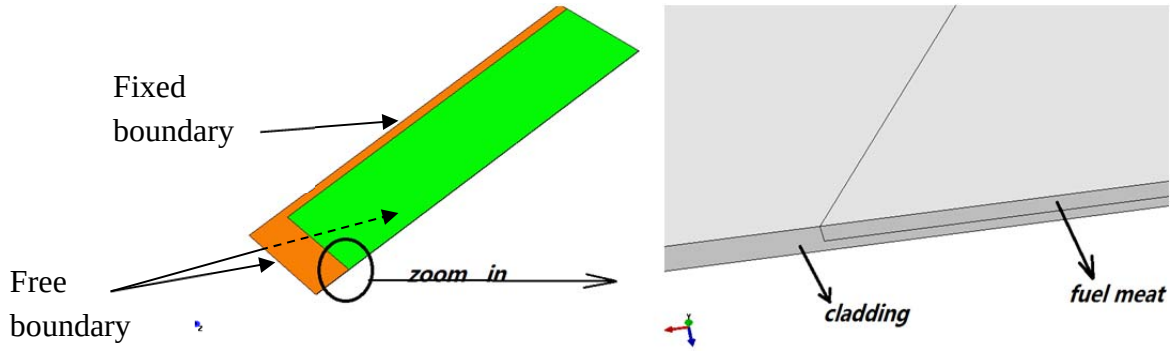

Figure.1 FEM Model

3.2 .boundary conditions

The boundary conditions to determine the temperature field are given as

(1) The surface to contact with the coolant water satisfies the convection boundary condition $-\mathrm{K}\frac{\partial T}{\partial n} = h(T - T_f)$, where the temperature of periphery fluid T_f is 573K. And the used heat transfer coefficient is $2\times10^{-2}\ W/mm^2K$.

(2) Other surfaces satisfy: $-\mathrm{K}\frac{\partial T}{\partial n} = 0$.

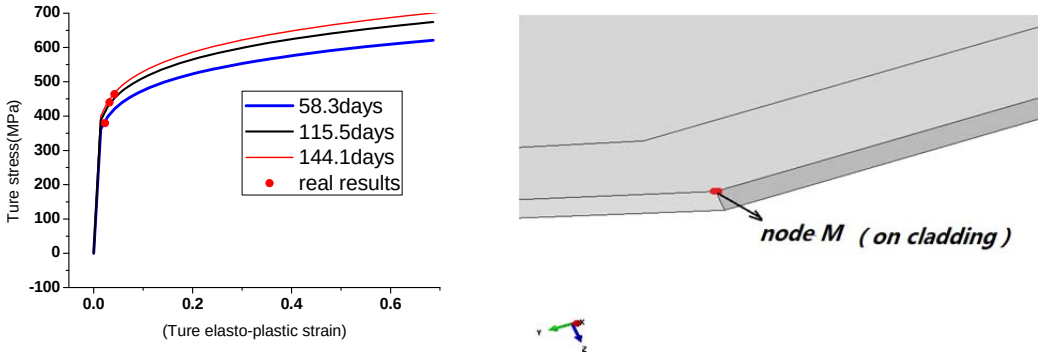
The used boundary conditions to determine the mechanical field are as follows
(1) Fixed boundary condition is applied to the side surface, shown as Fig.1
(2) The unseen lower surface and the front surface are set as free boundaries.
(3) Other surfaces are applied with symmetric boundary conditions.

4. Results and discussion

In this section, the effectiveness of the irradiation hardening simulation is validated, and the obtained temperature field and mechanical ones are to be shown and discussed.

4.1. Validation of irradiation hardening simulation

In order to make the correctness of irradiation hardening simulation confirmed, node M in the cladding is selected and the calculated Mises stresses and equivalent elasto-plastic strains at different time have been output. Taking them as the longitudinal and transverse ordinates respectively, three points can be produced in Fig.3. Meanwhile the irradiation hardening curves of the cladding material at the corresponding irradiation damage and temperature are plotted in Fig.3. It can be seen that the obtained computation results obey the irradiation hardening curves, which denotes that the irradiation hardening effect is correctly simulated.



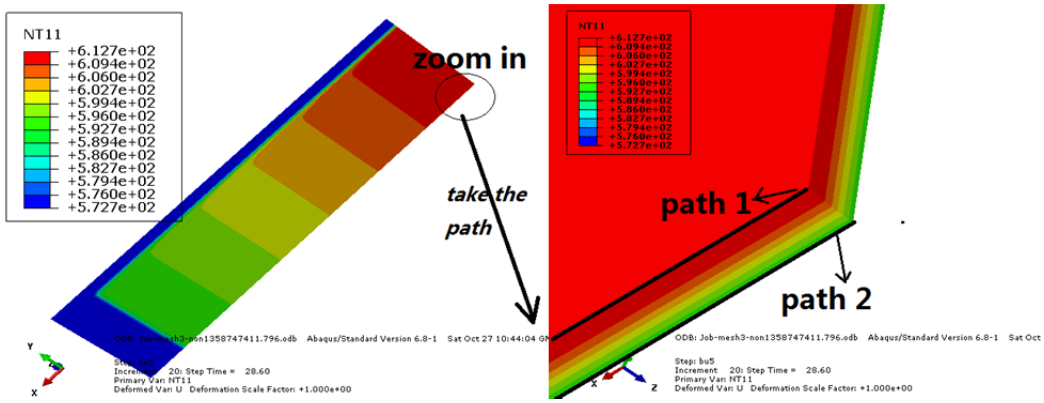
(a) (b)

Figure.2 (a) The stress-strain curves and the numerical results of (b) node M in the cladding

4.2. The temperature results

The calculated temperature field under heterogeneous irradiation condition is depicted in Fig.3 (a). It can be observed that the highest temperature with the red color locates in the fuel meat, precisely speaking, in the middle location along both the length and thickness directions. These phenomena result from the higher heat generation rate there. Thus, two paths in Fig.3 (b) are chosen to output the calculated temperatures at different time. The results under the uniform irradiation condition in Fig.4 are unchanged along the length direction of fuel plate. However, the temperature distribution under non-homogeneous conditions is approximately linear along the two paths, which is closely related to the heat generation rate of fuel meat. From 1.1 days to 144.1 days, the temperature

changes only 0.5 K, it is obvious that the temperature variation with burnup is very slight with a constant irradiation condition. Meanwhile, from comparison of the results along Path 1 and Path 2, it can be found that the maximum temperature in Path 1 is about 9K higher than the one in Path 2, which is for the reason that Path 2 is closer to the coolant water.



(a) (b)

Figure.3 (a) Temperature distribution at 144.1days and (b) the paths to output the results

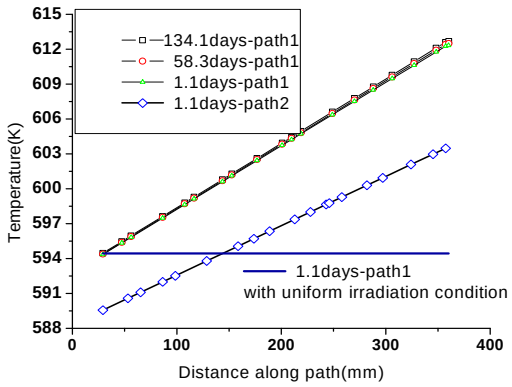


Figure. 4 Temperature distribution in the fuel meat

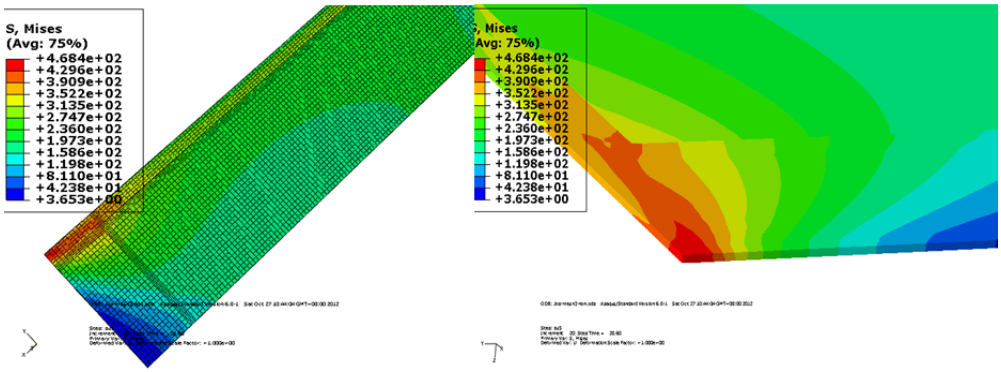
4.3. Mechanical behaviors in the cladding

The cladding is the first barrier to keep the radioactive substance from leakage. It's of huge importance to maintain its integrity. For the metal material, the Mises stress is firstly concerned. The contour plot at 144.1days is given in Fig.5. One can see that a stress concentration zone exists in the corner of cladding with the largest Mises stress reaching 468.4MPa, which is caused by the fixed boundary condition. To investigate the Mises stress distribution in the zone, two paths were taken in Fig.6. Through comparison of the results on path1 and path2, it can be discovered that path1 has slightly higher Mises stress than path2, as is shown in Fig. 6(a). Also, one can find that with increasing time the Mises stress demonstrate the same variation law on path1 as that the maximum numerical result always appears at the tip of the stress concentration zone. Meanwhile, from 29.7days to 144.1days, the maximum Mises stress on path1 increases from 341.52MPa to 465.4MPa. Observation of Mises stress distribution in the cladding part with the fuel meat

underneath shows that there exist the largest results in the middle location of fuel plate, that is, they locates at the right zone of the finite element model. It is induced by the fact that there exists the largest neutron flux which leads to the highest heat generation and irradiation swelling of fuel meat together with strengthened irradiation hardening in the cladding. This is the result of un-uniform irradiation conditions. In a word, it is necessary to optimize the constraint and irradiation conditions for fuel elements in order to assure their safety.



(a) (b)

Figure.5 (a) The Mises stress contours and (b) the stress concentration zone in cladding at 144.1days

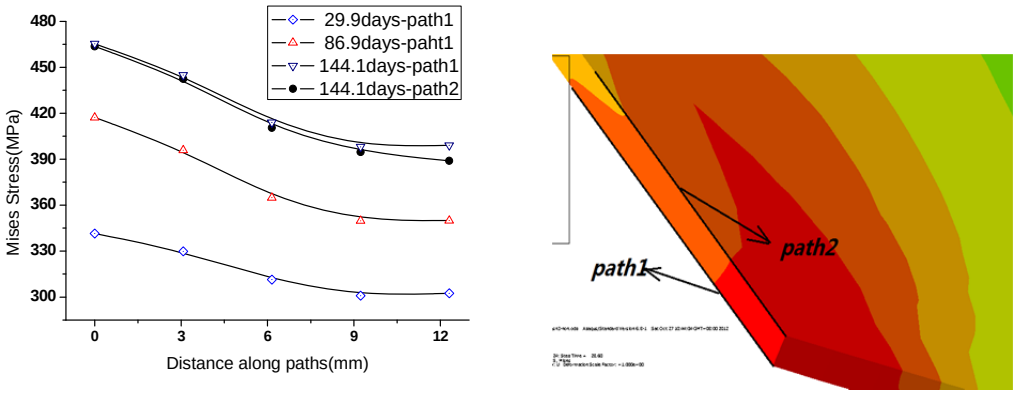


Figure.6 (a) The Mises Stress in different time along (b) the two paths in cladding

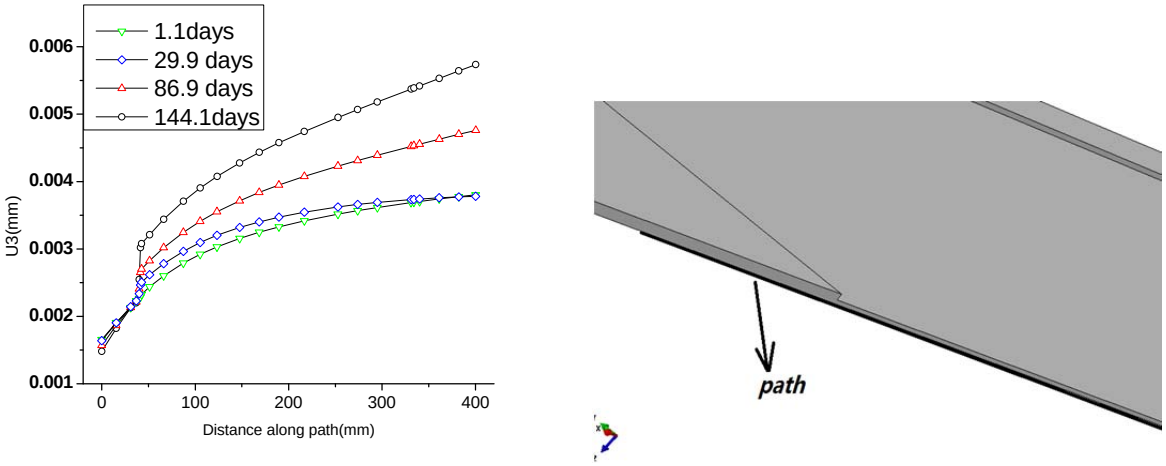
4.4. Deformation in the thickness direction

It is well known that the exceeding deformation along the plate thickness direction will narrow the coolant water channel, which will further lead to degradation of the heat transfer coefficient between the fuel plate and the coolant water. This could even result in accident with rapid temperature rise. Thus, the deformation in the thickness direction of fuel plate under nonhomogeneous neutron flux is mainly investigated. Fig.7 (a) reveals the displacements in the thickness direction of fuel plate along the surface path depicted in Fig. 7 (b). It can be observed that (1) the displacements is very small at the part with no fuel meat underneath and they change little with time; (2) the large displacements mainly exist in the part with the fuel meat underneath, and they increase with time distantly; (3) as expected, the maximum deformation arises in the middle part along the plate length direction, and its increasing rate with time is highest. The fuel plate tends to be an arch. As can be easily understood, the main contribution of the above deformation is from

the irradiation swelling of fuel meat, and the swelling is largest in the middle together with the highest temperature there. For the sake of in-pile safety, the initial gap between the fuel elements in the fuel assembly should be properly designed.



(a) (b)

Figure.7 (a) The displacements in the thickness direction along (b) the plate surface path

5. Conclusions

The stress update algorithms and UMAT subroutines for the dispersion nuclear elements are effective to simulate the thermal-mechanical behaviors under the assumed linearly distributed irradiation condition. Several conclusions can be obtained as the following

(1) The temperature distribution in the equivalent meat is corresponding to the heat generation setting and the middle position holds the highest temperature.

(2) The fixed long side of the cladding causes a stress concentration zone in the fuel plate corner, and the high neutron flux in the middle location leads to existence of the relatively large stress with the fuel meat underneath.

(3) Deformation of the thickness is un-uniformly distributed along the plate length direction and the largest one is at the middle position with the highest neutron flux.

In the future, other irradiation damage effects will be further included in our constitutive relation and numerical simulation, and different constraint conditions and more practical heterogeneous irradiation conditions for dispersion fuel plates will be studied.

Abstract Multiple surface cracking has significant effect on the failure of thermal barrier coating system (TBCs). The surface cracking is influenced by interface defects. It is of significance to study the relationship between the interface defect and the surface crack. In present work, the effect of interface defect on the surface crack behavior of TBCs has been investigated by using finite element method. The strain energy release rate (SERR) of the surface vertical crack is obtained as functions of the interfacial defect length and location. The results show that both the defect location and the defect length have a significant influence on the driving force of surface crack. It is concluded that the interface defect under the surface crack may induce a more intense facilitation on the surface cracking behavior than the remote defect. Moreover, a large scale interface defect may also induce a larger SERR of the surface crack which may promote its propagation.

Keywords Thermal barrier coating, Surface crack, Interfacial delamination, Strain energy release rate

1. Introduction

Thermal barrier coating systems (TBCs) are widely used in gas turbines or diesel engines due to their excellent heat-insulating property, which can efficiently prolong the life of the turbines blades[1, 2]. The major role contributing to the heat-insulating is the top layer of the TBCs, a ceramic coat with low thermal conductivity, which provides a temperature reduction of the metallic substrate[3, 4]. In order to protect the substrate from oxidation and make a better bond strength of the top coat to the substrate, a metallic bond coat is deposited between the top coat and the substrate. The top ceramic coat, metallic bond coat and substrate build up the typical TBCs.

Due to the mismatch of the geometric dimensions and the material properties, some fracture phenomena are inevitable in the TBCs[5, 6]. The common fracture behaviors observed during the service are the multiple surface cracks and the interface cracks[7, 8]. Considerable work was focused on the surface cracking behavior in the film/substrate system. Schulze and Erdogan[9] analyzed the periodic cracking of an elastic coating bonded to a homogeneous substrate. Vlassak[10] studied the channel cracking in thin films on substrates of finite thickness in order to simulate the segmentation of the ceramic layer of TBCs. Recently, by using finite element method, Fan *et al*.[11, 12] and Zhang *et al*.[13] built a three-layer model to investigate the effects of several important characteristic parameters, e.g. the interface roughness, thermally grown oxide (TGO), etc., on the periodic surface crack behavior. However, it is assumed in most of the aforementioned investigations that the ceramic/bond coat interface of TBCs is perfect, which ignores the fact that interface cracks may be initiated due to stress concentration.

The interface cracks have been frequently observed during the service, which lead to the spalling of ceramic coating and eventual failure of TBCs. The analyses and explanations for the appearances of interface cracks were presented by many researchers. Rice[14] developed the elastic fracture mechanics concepts for interfacial cracks between dissimilar solids, which made a great contribution to the interface cracks analysis in TBCs. Mumm and Evans[15] focused on the interface crack induced by the TGO growth. In their study, the morphological imperfections in the TGO played a great role in the failure of TBCs. Another significant reason for the initiation of interface cracks is the natural restrictions of depositing process especially the air plasma spraying. Currently, it is generally accepted that the ceramic coating of air plasma spraying TBCs exhibits laminar structural characteristic. Pores and micro-cracks are inevitable due to the internal thermal

stress in the process of thermal spraying[16-18]. The defects near the interface may coalesce during the service, leading to the interface cracks[19, 20].

The original motivate of present work is the author's experiment observations to TBCs that the surface cracks intensively appears in some areas of the ceramic coating of TBCs. Generally, one reason for the phenomenon is that, after air plasma spraying, as previous mentions, the ceramic/bond coat interface usually contains numbers of small scale delamination, which may promote the surface crack emerging above it. Another one is that the facilitation of the interfacial delamination induced by TGO growth or material property mismatch to the surface cracks. In general, the interaction between the interface defect and surface rupture make a great contribution to the experiment observations. In order to understand the fracture mechanisms of the TBCs clearly, the analyses of the mutual effects between the interface defect and surface rupture should be extremely necessary. More recently, investigations focus on the interaction of interfacial delamination and surface cracks[21, 22]. Among these studies, much attention has been paid on the effect of the surface cracks on the interfacial delamination, the basic assumption of which is that the interfacial delamination initiated from roots of surface channel cracks. However, for most cases, the interface cracks exist before the top ceramic coating starts to failure. Therefore, it is important to investigate the effect of the pre-existing interfacial defect on the ceramic failure especially on the initiation and propagation of the surface vertical crack. Zhou and Kokini[21] investigated the effect of pre-existing surface crack morphology on the interfacial thermal fracture and demonstrated that the large density of the period surface cracks can postpone the interfacial delamination, Fan *et al*. [22] used FEM to obtain the critical spacing of the periodic surface cracking below which the surface channel cracks have a dramatic effect on the interfacial delamination. However, much less attention has been paid directly to the effect of interface defect on the coating rupturing. In practice, actual spalling failure of TBC is followed by multiple surface cracks that propagate through the top coat and coalesce with interfacial crack between the top coat and the bond coat[22]. Therefore, to design excellent TBCs with high durability, it is necessary to study the effect of the interface cracks on the surface cracks which determines the coalescent of the surface cracks and interface cracks. In this paper, we build a multiple-layers TBCs model which contains pre-existing interfacial defect to investigate the effect of pre-existing interfacial defect on surface cracking. In Section 2, we firstly descript the numerical model for the problem of surface cracks and interfacial defect in TBCs. In Section 3, the crack driving forces for surface cracks are calculated, and moreover the effect of interfacial defect on surface cracks is discussed in detail. Section 4 summarizes the concluding remarks and emphasizes the effect of interfacial cracks on the durability of TBC system.

2. Statement of the problem

Due to the pre-existing interfacial defect after air plasma spraying or the interface cracks induced by thermal stress, the interfacial delamination probably emerges in some small areas, which effects the inevitable following surface cracks and the subsequent coalescent of the surface cracks and interface cracks. A steady state concept for cracks in multilayer structure is essential for many situations, where the crack driving force of surface crack is independent of the tunnel length if the length is enough long. Once the steady state is reached, the crack driving force can be calculated by using a two-dimensional (2D) plane strain model[23]. As a result, a three-dimensional TBCs model with surface cracks and interface defects is reduced to a 2D plane stain model. Fig. 1 shows the 2D plane strain model of steady state multiple surface cracks accompanied with interfacial cracks, in which h, a and W are the ceramic coating thickness, the surface crack length, and the cell model width, respectively. Based on our experimental observation[22], when the distance between adjacent surface cracks is large enough (about ten to twenty times the film thickness), the interaction between neighboring surface cracks can be ignored. Therefore, a unit cell model with single surface crack and interfacial defect can be constructed to simulate the actual TBCs with multiple cracks by setting the W equal twenty times the ceramic coating thickness.

The coordinate system (x, y) is set at the top surface of the film with surface crack, whose length a is along to y-axis. An interface defect with length l is presetting at the top/bond coating interface, the center of which offsets from the y-direction by c.

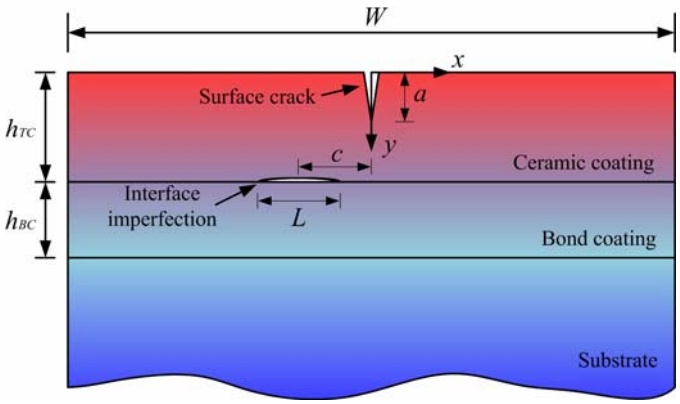

Figure 1. The TBCs model with surface crack in the TC and interfacial crack at TC/BC interface.

Assume a uniform strain is remotely applied to the TBCs system in the x-direction, the remote stress in the top coating is given by

$$\sigma_0 = \frac{\varepsilon_0 E_1}{1-\upsilon_1^2} \tag{1}$$

where E_1, υ_1 are the Young's modulus and Poisson's ratio of top coating. Therefore, the mixed boundary conditions on the surface crack faces can be expressed as

$$\begin{cases} \sigma_{ij}(0,y) = 0, & 0 < y < a \\ u_i(0+0,y) = u_i(0-0,y), & a < y < h \end{cases} \tag{2}$$

where σ_{ij} $(i,j=x,y)$ is the stress component and u_i $(i,j=x,y)$ is the displacement in x-direction or y-direction, respectively.

Moreover, the stress on the interface crack face at interfacial delamination area should be zero and in other area at the interface the displacement should be continuous. The mixed boundary conditions at the interface are shown as

$$\begin{cases} \sigma_{ij}(x,h) = 0, & -c-\dfrac{l}{2} < x < -c+\dfrac{l}{2} \\ u_i(x,h-0) = u_i(x,h+0), & x < -c-\dfrac{l}{2} \text{ and } x > -c+\dfrac{l}{2} \end{cases} \tag{3}$$

The problem can be solved by the superposition technique. The film/substrate system without any cracks is solved first and then added the stresses to the crack faces to represent the applied external loads σ_0. Then the numerical solution for mode I stress intensity factor (SIF) of the surface crack in a film/substrate system without any interfacial defect has been given by Beuth[24]

$$K/\sigma_0\sqrt{h} = 1.1215\sqrt{\pi}\left(a/h\right)^{1/2}\left(1-a/h\right)^{1/2-s}\left(1+\lambda a/h\right) \tag{4}$$

where the λ is a curve fitting parameter which is dependent of a/h, The value of λ also been given by Beuth[24]. The s is the singularity exponent which depends on elastic mismatch, and is the root to

$$\cos(s\pi) - 2\frac{\alpha-\beta}{1-\beta}(1-s)^2 + \frac{\alpha-\beta^2}{1-\beta^2} = 0 \tag{5}$$

where α, β are two non-dimensional Dundurs' parameters representing the material mismatch between adjacent layers[25]. For the plane strain problem, the Dundurs' parameters α, β can be

expressed as

$$\alpha = \frac{\bar{E}_1 - \bar{E}_2}{\bar{E}_1 + \bar{E}_2} \tag{6}$$

$$\beta = \frac{1}{2}\frac{\mu_1(1-2\upsilon_2) - \mu_2(1-2\upsilon_1)}{\mu_1(1-\upsilon_2) - \mu_2(1-\upsilon_1)} \tag{7}$$

where $\bar{E}_i = E_i / \left(1 - v_i^2\right)$, E_i, υ_1 and μ_1 are the plane strain modulus, Young's modulus, Poisson's ratio, and shear modulus of film/substrate systems' components, respectively. For homogeneous materials, the Dundurs' parameters are written as $\alpha = \beta = 0$.

Strain energy release rate (SERR) is another basic concept to study the driving force of an crack. A larger SERR value of the surface crack tip presents the more probability of surface rupturing. The SERR can be calculated by SIF and the Young's modulus of the top coating

$$G = \frac{K^2}{\bar{E}} \tag{8}$$

In present work, the multiple layers TBCs model with pre-existing interface crack has tiny differences with the typical film/substrate system. In detail, the interfacial defect existence may make it difficult to investigate the fracture mechanism in TBCs by using classical fracture mechanism. Fortunately, the finite element method can calculate the value of SIF and SERR accurately. Therefore, the commercial soft ABAQUS is adopted in present work to obtain the effect of the interfacial defect on the surface crack driving force (e.g. SERR). In the preliminary calculation, we found that a relatively small interfacial defect has little influence on the crack mode. In general, the mode II SIF is less than one-tenth of the mode I SIF, which means that the mode I crack dominates the fracture behavior and mode II crack can be ignored in the following analyses. Therefore, the SERR for the surface crack can be written in a similar form with Eq. (4)

$$K / \sigma\sqrt{h} = w(\alpha, \beta, \bar{a}, \bar{L}, \bar{c}) = \eta(\alpha, \beta, \bar{a}, \bar{L}, \bar{c})\bar{w}(\alpha, \beta, \bar{a}) \tag{9}$$

where the function w is the value of normalized SIF of surface crack obtained by FEM, and $\bar{w}$ represents the right expression of Eq. (4), which is determined by the Dundurs' parameters α, β and surface crack length $\bar{a} = a / h$. The revised function η is regarded as the function of the interface crack geometric characteristic, the crack length $\bar{L} = L / W$ and the crack location $\bar{c} = c / W$. Similarly, the SERR can also be written as follow by using the Eq. (8) and Eq. (9)

$$\frac{G\bar{E}}{\sigma^2 h} = Z(\alpha, \beta, \bar{a}, \bar{L}, \bar{c}) = \kappa(\alpha, \beta, \bar{a}, \bar{L}, \bar{c})\bar{Z}(\alpha, \beta, \bar{a}) \tag{10}$$

where the function Z, κ and $\bar{Z}$ represent the SERR value function, the revised function of the interfacial defect and the original SERR function without interfacial defect, respectively.

Since it is intractable to calculate SIF and SERR for an crack in TBCs, the more convenient calculation of SERR is applied in this paper. In the linear elastic fracture mechanics, the SIF and the SERR can be represented by the value of J-integral. Therefore, SERR associated with crack length can be calculated by J-integral method. For a virtual crack advance $\lambda(s)$, the value of J-integral can be calculated by [26]

$$\bar{J} = \int_A \lambda(s)\mathbf{n} \cdot \mathbf{H} \cdot \mathbf{q} dA \tag{11}$$

where dA is the total areas of a layer of elements enclosing the crack tip, $\mathbf{n}$ is the outward normal vector to the corresponding integral contour, and $\mathbf{q}$ is the direction of virtual crack extension, $\mathbf{H}$ is given by

$$\mathbf{H} = \left(W\mathbf{I} - \boldsymbol{\sigma} \cdot \frac{\partial \mathbf{u}}{\partial \mathbf{x}} \right) \tag{12}$$

where W is strain energy.

The finite element code ABAQUS is employed for numerical calculations. A fine mesh near

the crack tip is necessary for the regular finite element method in the typical TBCs model. Eight-node bilinear plane strain quadrilateral reduced integration elements are selected for all three layers except the crack tip region, where very fine mesh of singular elements are constructed. In addition, The J contour integral values are independent to the mesh configuration if the mesh configuration is fine enough around the crack tip. Herein, each layer in TBC is taken to be homogeneous, isotropic and linear elastic materials whose geometry and material properties are $h = h_{TC} = 0.2$ mm , $h_{BC} = 0.1$ mm , $h_S = 30$ mm , $E_{TC} = 60$ GPa , $E_{BC} = 200$ GPa , $E_S = 211$ GPa , $\nu_S = \nu_{BC} = \nu_{TC} = 0.3$ and $W / h = 20$, where the subscripts TC, BC and S represent top coat, bond coat and substrate, respectively.

3. Result and Discussion

In fracture mechanics, SERR at the crack tip can regarded as the driving force of the crack. Therefore, obtaining the SERR value of the surface crack for different lengths can detailedly describe the initiation and propagation of it. Fig.2 shows reduced revised function $\kappa(\bar{a},\bar{L},\bar{c})$ as a function of interfacial defect location for different surface crack length. Noted that the length of presetting interface crack is fixed as a uniform value $\bar{L} = 0.15$ in order to investigate the separate effect of interface crack location on the driving force of surface crack. As discussed earlier, the SERR for the surface crack in the TBCs with interface defect can be written as Eq. (10) which consist two functions, the revised function and the original SERR function without interface defect, respectively. In Fig.2, the value of $Z(\alpha,\beta,\bar{a},\bar{L},\bar{c}) / \bar{Z}(\alpha,\beta,\bar{a})$ in Eq. (10) for a constant $\bar{L} = 0.15$ equals to the normalized SERR $G / \bar{G}$. Therefore, the reduced revised function $\kappa(\bar{a},\bar{L},\bar{c})$ (α,β is constant since the material parameter is uniform) for $\bar{L} = 0.15$ can be obtained from the normalized SERR. The $\kappa(\bar{a},\bar{L},\bar{c})$ for $\bar{L} = 0.15$ is always larger than 1 for all surface crack length, a / h , which means the interface defect always promotes the initiation and propagation. This promotion is the result of the constrain reducing for the top coating caused by the interface defect. The close analyses have also been made by Tsui *et al.*[27] and Thouless *et al.*[28].

Noted that the $\kappa(\bar{a},\bar{L},\bar{c})$ curve for small a / h slightly deviates from the dash line standing for the SERR function without interface defect $\bar{Z}(\alpha,\beta,\bar{a})$ while the $\kappa(\bar{a},\bar{L},\bar{c})$ for relatively large a / h is much bigger ,which means that the interface defect effects the propagation of the surface crack more dramatically than the initiation. That's to say, the initiation of the surface crack appears to be impendent on the interface defect offset while the propagation intensively depend on the interface defect location. In addition, when the surface crack approach to the interface, the $\kappa(\bar{a},\bar{L},\bar{c})$ seems to decrease slightly (i.e. the curves for a / h =0.8 or 0.9 is in a low degree compared to that for a / h =0.6 or 0.7).

As shown in Fig.2, the interface defect offset $\bar{c}$ is a significant factor to affect the propagation of the surface crack. For the large offset $\bar{c}$, the $\kappa(\bar{a},\bar{L},\bar{c})$ is approach to 1, indicating the variation of SERR is exactly similar to the solution for perfect interface. Therefore, in this case, the remote interface defect appears to have relatively little influence on the surface cracking behavior. Conversely, when the offset is equal to zero, the $\kappa(\bar{a},\bar{L},\bar{c})$ seems to largely deviate from the dash line(i.e. the solution for perfect interface). In other words, the interface defect under the surface crack may promote the surface crack propagation more vigorously than the remote one. As a result, the surface cracks centralizing in some areas under of which there exists potential interface cracks may propagate much faster. Then they easily penetrate into the interface and coalesce with the interface cracks, which lead the eventual spalling of the ceramic coating. Therefore, we consider the interface defect as a significant reason for the premature failure of TBCs during service.

As the absolute value of $\bar{c}$ enlarges to a critical value, the $\kappa(\bar{a},\bar{L},\bar{c})$ for $\bar{L} = 0.15$ becomes

asymptotic to 1. Therefore, $Z(\alpha,\beta,\bar{a},\bar{L},\bar{c})$ seems to approach to $\bar{Z}(\alpha,\beta,\bar{a})$ which indicates the influence of interface can be ignored. In present model, the critical offset value is about 0.15 above which the interaction between surface crack and interface defect can be ignored. Moreover, a interesting finding in Fig.2 is that the $\kappa(\bar{a},\bar{L},\bar{c})$ for $a/h=$ 0.8 and 0.9 exhibits an irregular convex at $\bar{c}=\pm 0.05$. This irregular effect on surface cracking behavior is related to the extra deviating driving force induced by an asymmetric loading and restraint which are a result of the offsetting interface defect. Next part we will discuss this irregular behavior.

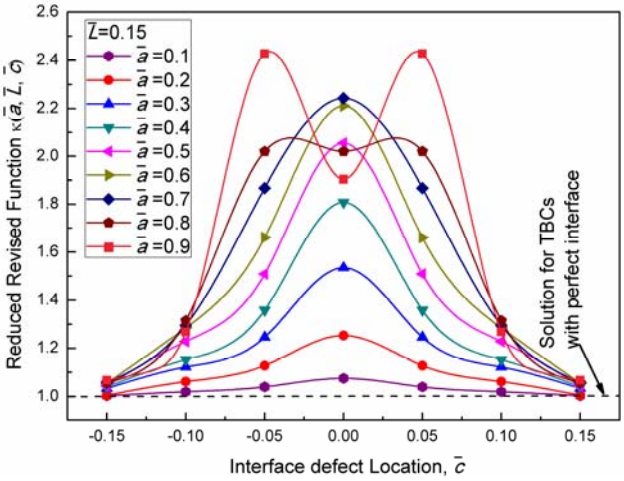

Figure 2. The reduced revised function $\kappa(\bar{a},\bar{L},\bar{c})$ as a function of interface defect location for different surface crack length.

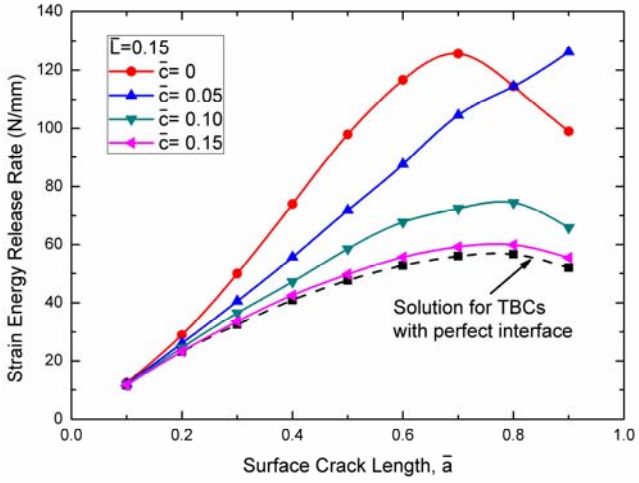

Figure 3. The SERR as a function of surface crack length for different interface defect offset.

Figure 3 shows the variations of SERR with normalized crack length a/h for the different offset of the interfacial defect. Moreover, SERR for the TBCs model with perfect interface is also plotted in Figure 3 for comparing. It is seen that the SERR for perfect interface rises to the maximum value as surface crack propagates and then drops as the crack approaches to interface, which coincides with the results obtained by Beuth[24]. Moreover, it is interesting to find that the overall trend of SERR curve in Figure 3 would change as the offset decrease. For the remote defect (e.g. $\bar{c}=0.15$), the curve of is much similar to the solution for perfect interface which, as previous described, rises to the maximum value as surface crack propagates and then drops as the crack approaches to interface. However, when the defect offset diminishes to 0.05, the SERR curve turns to monotonously ascend (e.g. $\bar{c}=0.05$). Then, Continue to decrease the offset of the defect, the

oscillation of SERR curve appears again (e.g. $\bar{c} = 0$) and the SERR reduces to a relatively low value. This behavior seems to be a result of the asymmetric loading and restraint causing by the offset of interface defect. An asymmetric loading and restraint may induce the extra deviating force for the surface crack. Therefore, the driving force would continue to increase instead of dropping as the crack approaches to interface, which may facilitate the deviation of the surface crack when it approaches to interface. Obviously, it can explain why the SERR curve for $a/h =$ 0.8 and 0.9 exhibit irregular convex at $\bar{c} = \pm 0.05$.Interestingly, this deviation has been observed by present researchers in their experiments[6]. If the defect is remote from the surface crack, its influence on surface crack is much small so that the deviating force is inconspicuous. Therefore, for the remote defect (e.g. $\bar{c} = 0.15$), the curve of SERR do not appear monotonous increasing.

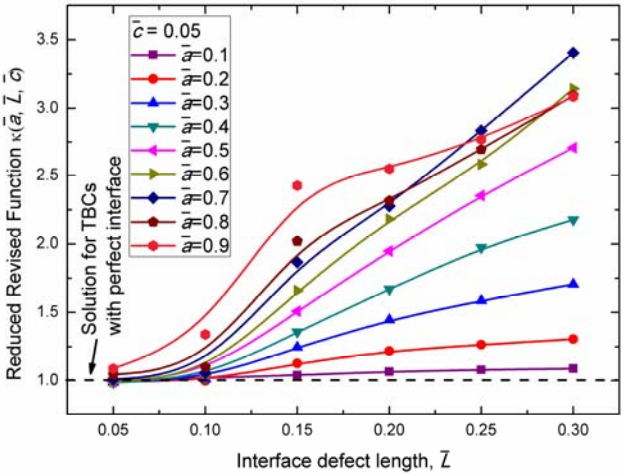

Figure 4. The reduced revised function $\kappa(\bar{a}, \bar{L}, \bar{c})$ as a function of interface defect length for different surface crack length.

The reduced revised function $\kappa(\bar{a}, \bar{L}, \bar{c})$ as a function of normalized surface crack length for different interfacial defect length is plotted in Fig. 4. In present figure, the interface defect offset $\bar{c}$ has been fixed as 0.05 and the surface crack length has been enlarged in order to simulate the spread of interface defect during the service of TBCs. Since the interface defect location has been fixed, the altering of $\kappa(\bar{a}, \bar{L}, \bar{c})$, which is obtained, as mentioned earlier, by the normalized SERR, can separately demonstrate the effect of defect length. In Fig. 4, it is seen that interfacial defect length is also a significant factor that affects the surface crack driving force.

For a small interface defect, the interface defect seems to have little influence to the surface crack. Noted that when the $\bar{L}$ is about 0.05, the value of SERR is close to the solution for perfect interface (the dash line in Fig. 4), which indicates that there may be an asymptotic curve for very low values of interface defect length. In other words, in present model, when the normalized length of interface defect with offset $\bar{c} = 0.05$ is smaller than 0.05, the interface can be regarded as a perfect one. For a relatively large interface defect, the value of $\kappa(\bar{a}, \bar{L}, \bar{c})$ rises to a high degree. For example, when the surface crack propagates about seventy percent of the ceramic coating, the $\kappa(\bar{a}, \bar{L}, \bar{c})$ for the $\bar{L} = 0.3$ is about 3.3, which indicate an interface defect with a length $\bar{L} = 0.3$ would make the driving force of surface crack more than three times larger since the substrate restrain is greatly reduced due to the interface defect. Obviously, the facilitation of the large scale interface defect may induce the premature coalescent of the surface crack and the interface crack, which contributes to the spalling of the ceramic coating. Therefore, a well bonded interface should be ensured in order to enhance the durability of the TBCs.

Compared to the Fig. 2, it seems that the effect of lengthening the interface defect length on the surface crack driving force is very similar to the effect of diminishing the offset of the interface

defect. They both promote the propagation of surface crack dramatically. Interestingly, as the interface defect length enlarges, the transformation of the SERR curves from oscillation (e.g. $\overline{L}=0.05$) to monotone (e.g. $\overline{L}=0.15$) and then back to oscillation (e.g. $\overline{L}=0.25$), which, as previous discussed, is induced by the extra deviating force, can also been found in Fig. 4.

As discussed above, it is concluded that the interface defect would promote the surface cracking behavior by increasing the SERR around the crack tip. Herein, it is generally accepted that the maximum increment of SERR induced by the interface defect is critical to estimate emanation of surface crack. Fig. 5 shows the maximum normalized SERR increment as a function of interfacial defect length and location. Two most important characteristics of interface defect, the length and the location, have been taken into consideration to investigate the their combined effect on surface crack. As shown in Fig. 5, the maximum normalized SERR increment for a remote interface defect ($\overline{c}=0.15$) is near to zero for a relatively small critical defect length (e.g. when $\overline{L}$ is less than 0.15), which means the remote and small defect has less potential to affect the surface cracking behavior. However, when interface defect is closer to the surface crack(e.g. $\overline{c}=0.05$), the critical defect length below which the defect can be ignored correspondingly decreases (e.g. $\overline{L}$ is less than 0.05). The most extreme situation is that the interface defect locates under the surface crack, in which the small defect cannot be ignored (as the black line in Fig. 5). In general, the maximum normalized SERR increment for a central interface defect is higher than the counterpart for the offsetting defect excepted the appearance of the extra deviating force for the surface crack, as discussed earlier, induced by asymmetric loading and restraint. The oscillation of the maximum normalized SERR increment curve stands for the extra deviating force.

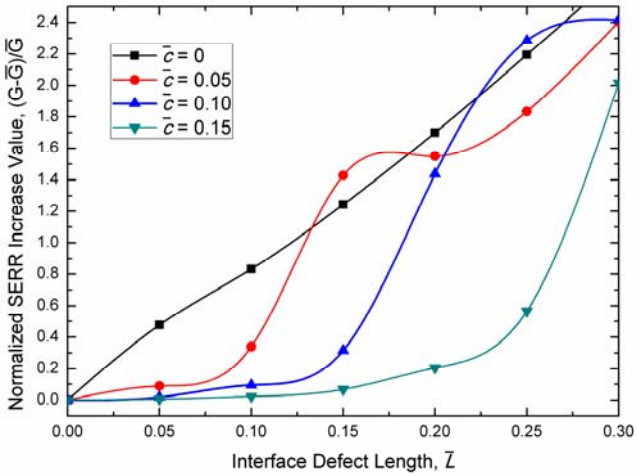

Figure 5. The maximum normalized SERR increment as a function of interfacial defect length and location.

4. Conclusions

The effects of interface defect on the surface fracture behavior of thermal barrier coating system (TBCs) are investigated in this work. The results show that the two important characteristic parameters, defect location and defect length, both have a significant influence on the driving force of surface crack. It is concluded a surface crack initiated above an interface defect propagates more easily since the enhancement of surface crack driving force is largest for the defect directly beneath the surface crack. Similarly, the surface crack propagates easier as the defect length increases. In present work, the critical value of the defect offset (below which the effect of an interface defect can be ignored) has been obtained and so does the critical value of defect length. By understanding the effect of the interface detect on the surface crack and using the critical value of the defect offset and defect length, the surface cracking behavior can be partially controlled. It is beneficial for

improving the durability of TBCs no matter by increasing the surface crack density to enlarge the strain tolerance of ceramic coating or reducing the surface crack to prolong the spalling of the ceramic coating.

Abstract There is a long list of empirical slow crack growth (SCG) equations that present the crack propagation rate as a function of stress intensity factor (SIF) or energy release rate (ERR). Experiments with crack growth through a heterogeneous stress field reveal the limitations of such type of equations resulting from existence of a process zone (PZ) surrounding the crack. PZ is a material "defense" against stress concentration caused by the crack and is commonly observed in most of engineering materials. It plays an important role in determination of the direction and rate of fracture propagation. Therefore, the PZ and crack are treated as two coupled elements of one Crack Layer (CL) system and CL propagation is represented by two coupled possesses: (i) the PZ evolution by transformation of the original material into a "damaged" and often anisotropic PZ material and (ii) crack growth into PZ. The CL driving forces are introduced as the negative derivative of Gibbs free energy with respect to CL geometrical parameters. The constitutive equations of CL propagation are formulated in form of simple relations between the crack and PZ growth rates and corresponding thermodynamic forces. Qualitative analysis of these equations suggests two distinctly different patterns of CL propagation: continuous and discontinuous, stepwise growth. A special experimental setup and test material have been selected to simplify and examine the proposed constitutive equations of CL growth. CL model provides a very good agreement with a large set of experimental data at various load levels, temperatures and specimen geometries.

Keywords Crack layer model, slow crack growth, process zone, constitutive equations

1. Introduction

Crack in engineering materials formed under fatigue and creep conditions usually appears as a narrow cut with small amplitude random deviations from a straight or slightly curved trajectory. A close observation of such crack reveals a presence of a process zone (PZ) (also called damage zone, plastic deformation zone, etc.) that precedes and surrounds the crack. Depending on material chemical composition and morphology, temperature, loading rate, specimen geometry, etc. various types of micro defects such as crazes, shear bands, microcracks, micro-voids constitute PZ. In general, micro-defects are strain localizations on micro scale and based on their orientation one can distinguish brittle, such as crazes and micro-cracks, and ductile like shear bands and micro-voids, types of damage. The micro-defects are commonly formed in response to stress concentration, and shield the vicinity of the crack front from high elastic stresses by increase of an effective (inelastic) material compliance. The crack growth is closely coupled with formation and evolution of the micro-defects population within PZ. A system of coupled crack and PZ is referred to as Crack Layer (CL).

There is a strong interaction between micro-defects in a vicinity of the crack front and the crack [1–4]. It results in significant modification of the crack tip fields. Apparently, it also affects the stress intensity factor (SIF) K. Figure 1 illustrates the effect of micro-cracking (displacement discontinuities) on SIF. An individual micro-crack is modeled as a displacement discontinuity across an elementary segment (area in 3D) with orientation $\underline{n}$ and displacement jump $\underline{b}$. In the specific example shown in Figure 1 all micro-cracks are considered to be parallel to the crack and have opening in the normal direction. The arrays of curves emanating from the crack tip forward and backward present contours of equal level of the mode I SIF Green's function $G_1^{SIF}(\underline{\xi})$ due to unit normal displacement dipole with $\underline{n}(0,1)$ and $\underline{b}(0,1)$ at the point $\underline{\xi}$ [3–5]. The continuous lines indicate SIF amplification effect due to the discontinuities located on the lines in front of the crack; whereas the two "butterfly wings" of dotted lines show the reduction of SIF, i.e., shielding effect of the discontinuities located on the lines

on both sides of the crack. The numbers above the lines indicate the magnitude of amplification and reduction of SIF. The external solid line indicates schematically the boundary of the process zone and therefore CL.

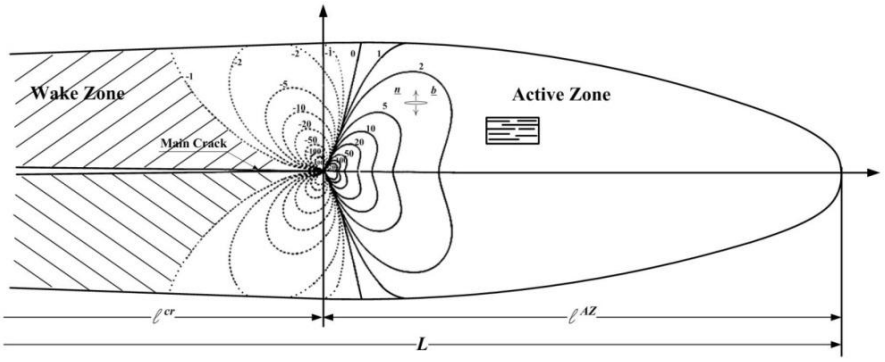

Figure 1. Dimensionless Mode-I SIF Green's Function due to a unit normal displacement dipole with orientation (θ = 0°) with respect to the x-axis.

By distributing the individual micro-cracks and passing to a continuum damage, we introduce damage density as a bivector $\rho(\underline{\xi})$ that represents the total micro-cracks area per unit volume (with dimensions $[\rho] = mm^2/mm^3$). There is a domain of PZ, where the defects constituting PZ strongly interact with crack by shielding and/or amplifying the crack tip fields. The crack in turn causes the new defects formation and growth, i.e., $\dot{\rho} \geq 0$ in that domain. Such domain is referred to as active zone (AZ) of CL. It leads to material degradation in the immediate vicinity of crack front and crack movement into PZ. As the crack advances through AZ, the latter "moves" away from the crack by forming new defects and leaves behind a wake zone (WZ) constituted by the defects that remain after unloading of AZ. Thus, CL propagation occurs as AZ "movement" in material frame of reference and crack advancement into AZ.

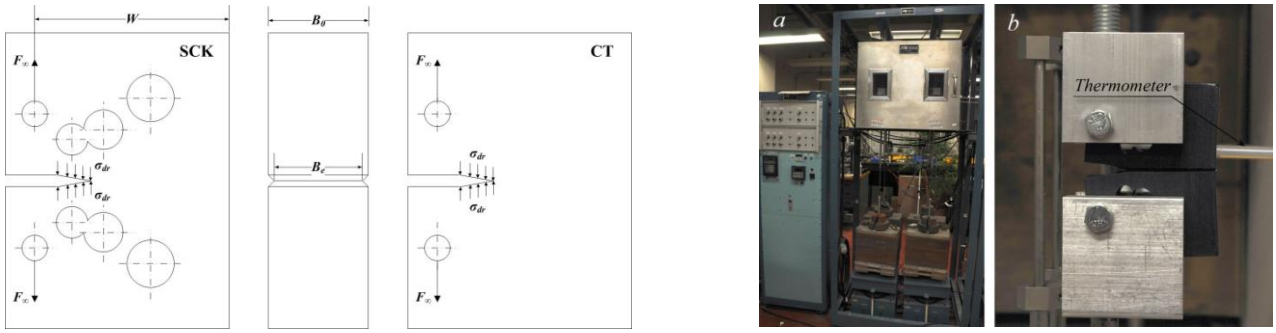
The total SIF is the sum of SIF K_I^0 due to remote load and the increment of SIF due to distributed micro-cracks with opening $\underline{b}$ dependent on the main crack – micro-cracks array interaction [3–5]:

$$K_I^{tot} = K_I^0 + \int_V G_I^{SIF}(\xi_i) \cdot b(\xi_i) \wedge \rho(\xi_i) dV \,. \tag{1}$$

The calculations suggest that the shielding effect (a negative SIF increment) is stronger than the amplification and the total SIF in some cases is vanishing [4]. In such cases the "beak" type crack tip opening displacement profile is observed [1].

2. Experimental and Results

To observe the details of CL evolution a set of creep tests was conducted at various loads and temperatures. The creep testing machine equipped with high temperature chamber with four creep stations and two observation windows, pneumatic system of graduate load application and continuous displacement monitoring device is used for tests (see Figure 3 (a)).



(b) (a)

Figure 3. (b) The geometry and loading of SCK and CT specimens; (a) Slow crack growth test setup.

Various specimen geometries have been used in the tests. One is the standard compact tension (CT) specimen. Another is a specially design stiff constant-*K* (SCK) specimen. SCK specimen poses the highest stiffness among comparable specimen geometries and provides a constant *K* within the crack size range $0.15 < a/W < 0.4$. The diameters and locations of holes are designed to maintain the constancy of SIF while crack is propagating. The side grooves are introduced to reduce the plane stress effect within the surface layers and guide the crack growth along the plane of symmetry. The CT specimen has the same shape and dimension as that in SCK, but does not have holes, as shown in Figure 3 (b). Both types CT and SCK specimens were machined from a commercial large diameter HDPE pipe with $3''$ wall thickness. The SIF is continuously increasing with crack growth in CT specimen. We selected HDPE material for this study since it displays the simplest, but not trivial PZ geometry observable in fracture experiments: a narrow wage shape domain of cold drawn fibers and membranes with sharp boundaries separating PZ and original bulk material.

Figure 4 shows the records of the load-point displacement vs. time monitored in the creep tests at various loads (SIFs) and temperatures. Curve *a* in Figure 4 (initial SIF: $K_0 = 10MPa \cdot \sqrt{mm}$ and $T = 80^{o}\mathrm{C}$) clearly shows a transition from continuous to stepwise growth. The same but subtler transition is also observed in Curve *b* (initial SIF $K_0 = 12MPa \cdot \sqrt{mm}$ and the same temperature compared to Curve *a*). At the same temperature, if the SIF is increased to $K_0 = 18MPa \cdot \sqrt{mm}$ (initial SIF), a pure stepwise growth is observed as displayed by Curve *c*. The length of individual step in CT specimen is continuously increasing due to the increasing SIF in contrast with that in SCK specimen (reported in [6]). However, there are no visible steps in load-point displacement record (Curve *d*), even for a significantly higher load ($K_0 = 48MPa \cdot \sqrt{mm}$ initial SIF), if the temperature is reduced to room temperature ($T = 23^{o}\mathrm{C}$),.

The continuous, discontinuous as well as transitional mechanisms of SCG are revealed even more explicitly by CL side view and fracture surfaces. For example, a homogeneous and continuous CL growth occurs at an elevated temperature with a much lower initial SIF ($K_0 = 10MPa \cdot \sqrt{mm}$) (see Figure 5 (a)). The upper picture in Figure 5 (a) presents a general view of CL developed during 290 hours of creep with initial SIF $K_0 = 10MPa \cdot \sqrt{mm}$ at 80°C. There are no steps as well, rather monotonically decreasing width of the triangular CL and crack opening toward a very weakly visible PZ tip. The bottom picture shows a homogeneous surface without any striations. At the very end, we can see a smooth strip that corresponds to the last process zone broken in liquid nitrogen.

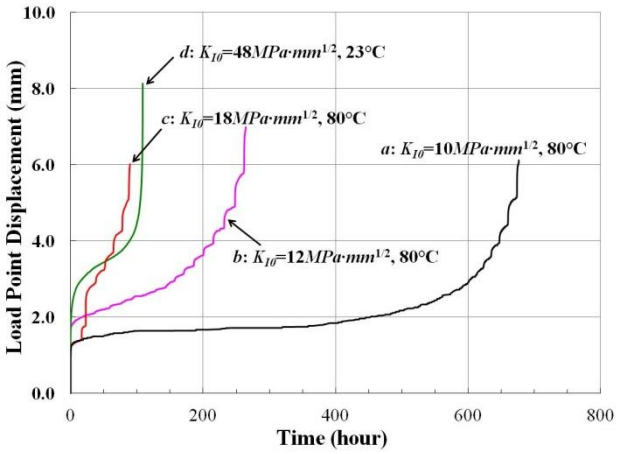


Figure 4. Load-point displacement vs. time recorded in creep test conducted at *a*) $K_0 = 10MPa \cdot \sqrt{mm}$, $T = 80^{\circ}\mathrm{C}$; *b*) $K_0 = 12MPa \cdot \sqrt{mm}$, $T = 80^{\circ}\mathrm{C}$; *c*) $K_0 = 18MPa \cdot \sqrt{mm}$, $T = 80^{\circ}\mathrm{C}$; *d*) $K_0 = 48MPa \cdot \sqrt{mm}$, $T = 23^{\circ}\mathrm{C}$.

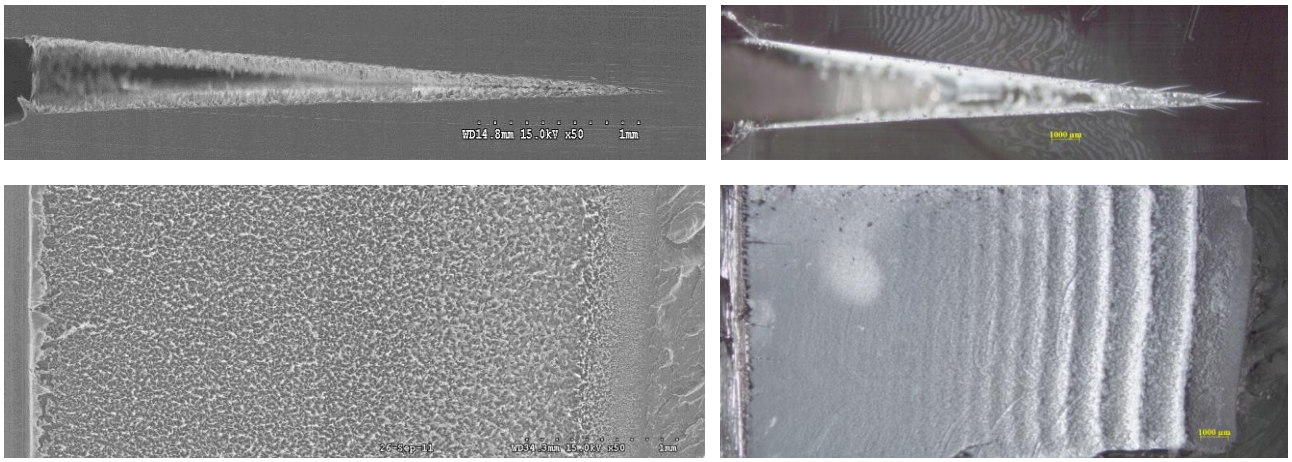

(a) (b)

Figure 5. CT specimens tested at 80°C with initial $K_0 = 10MPa \cdot \sqrt{mm}$: (a) tested for 290 hours, Upper: side view; Lower: fracture surface. (b) tested for 680 hours, Upper: side view; Lower: fracture surface.

The striking observation is that, given the same testing conditions ($K_0 = 10MPa \cdot \sqrt{mm}$, 80°C), if the test is conducted longer (680 hours), a transition from continuous to stepwise growth occurs. The upper picture in Figure 5 (b) depicts a monotonically decreasing opening of crack toward the tip, and pairs of symmetrical "flankers" emanating from two sides of the boundary in the region close to the crack tip. The positions of flankers correspond to white shining striations observed in the lower image, and are signs of discontinuous growth. This evolution from continuous to stepwise growth is manifested in the lower image in such a way that fracture surface first shows homogeneity then striations gradually appear with a wider and wider spacing due to increasing SIFs.

When the initial SIF is increased to certain level, the discontinuous fracture propagation takes place from the beginning. It is illustrated in Figure 6 that shows CL in a CT specimen tested at 80°C with initial SIF $K_0 = 18MPa \cdot \sqrt{mm}$ (Note: the sample was step loaded from $K = 12MPa \cdot \sqrt{mm}$ to $K = 18MPa \cdot \sqrt{mm}$ during a short period, and the latter is considered as the initial SIF.). A wedge-type pulsating domain indicates a discontinuously CL grown with six well defined steps in upper image

(the very first step is neglected for reason addressed above). Five steps are filled with drawn and broken fibers. The sixth one, a weakly visible and elongated wedge type domain, is the process zone with freshly drawn intact fibers. The fibrillated process zone is separated by a sharp boundary from a uniform grey domain of the original HDPE. It is also obvious that five completed steps exhibit an increasing size of PZ, in contrast with an equal size PZ in SCK specimen [6].

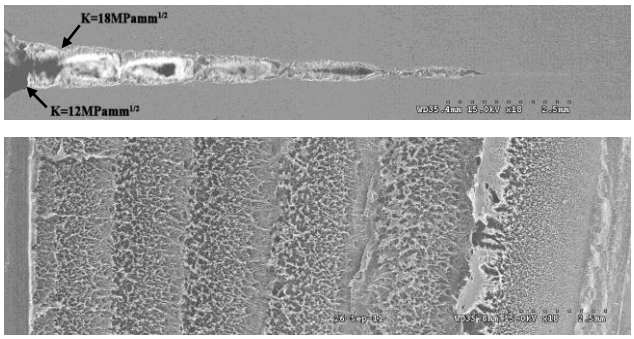

Figure 6. CL in CT specimen tested at 80°C with an initial SIF $K_0 = 18MPa \cdot \sqrt{mm}$ for 90 hours, Upper: side view; Lower: fracture surface (18×).

The data presented above clearly indicate that there are two different mechanisms of SCG: continuous and discontinuous ones. The transition from continuous to discontinuous SCG strongly depends on stress and temperature. A SCG mechanisms map has been proposed and discussed in [6, 7]. The equilibrium process-zone sizes are recorded using micrographs similar to that shown in Fig.6 and used for evaluation of CL parameters. Details of such work are presented in the accompanying paper [8].

3. Constitutive Equations of CL Model

As stated above, CL in PE poses the simplest PZ that displays the characteristic features of PZ evolution. Therefore, we use it as a showcase for formulation of CL constitutive equations.

3.1. Crack Layer Thermodynamic Forces

The active zone of CL in PE has narrow wedge shape geometry with a sharp boundary separating PZ from the surrounding original material (see upper Fig.5a). It consists of cold drawn fibers connected with original material. The crack propagation is the process of breaking fibers under creep condition and forming a fracture "surfaces" (see lower Fig 5a). The width of CL is very small in comparison to the CL length. Therefore we employ the conventional Fracture Mechanics formalism in modeling the external with respect to CL domain. However, addressing the fracture propagation through AZ we use an effective continuum with properties reflecting discrete fibrillated and oriented AZ material. In energy balance, we also consider the energy of transformation of the original material into cold drawn, highly oriented structure of PZ. For such analysis, it is convenient to decompose the specimen with CL into a specimen with CL cutoff and a thin wedge shape CL domain with variable width ω_0 of original material that undergoes cold drawing in process of PZ formation (see Figure 8). The stress analysis problem shown in Figure 8 (a) is presented as superposition of the same specimen geometry and external load with a cut of CL. The mechanical interaction between AZ of CL and the specimen is taken into consideration by application of the drawing stress σ_{dr} along the boundaryof AZ since there is a mechanical equilibrium between the drawn and original materials along that boundary (see Figure 8,b). The second part of the superposition is CL cutoff with stress σ_{dr} acting on the AZ from the specimen side (Figure 8,c). The width of AZ in the reference configuration ω_0 is a function of

location x, $0 \le x \le \ell^{AZ}$ within AZ and time t, since AZ evolves in time: $\omega_0 = \omega_0(x,t)$. Fig 8a should be AZ instead of PZ

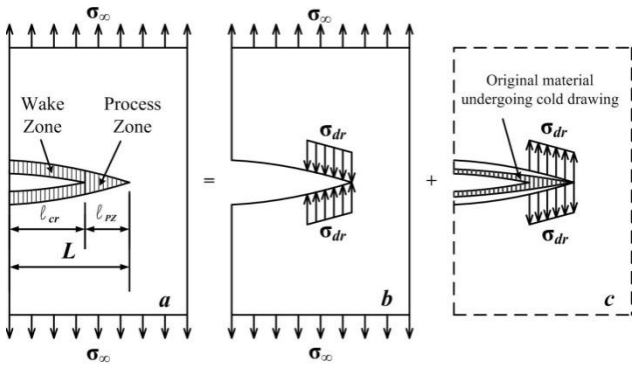

Figure 8. Decomposition of the stress analysis problem of CL

The width of AZ in actual configuration (after drawing) is $\omega = \lambda \cdot \omega_0$ (λ is the natural draw ratio). Thus, the displacement discontinuity in normal to the crack direction due to cold drawing is $(\lambda - 1)\omega_0$. To determine the amount of material that undergoes cold drawing and builds up AZ, i.e., the width ω_0, we consider crack opening displacement (COD) as an approximation of the opening of a slit in the specimen with CL cutoff. The approximation is quite accurate due to presence of a small parameter: the ratio of the width over the length of the slit. Then, we make use of conventional Fracture Mechanics formalism and compute COD for the boundary value problem depicted in the Figure 8b. Thus, ω_0 is found from the continuity conditions of the original problem: the COD $\delta(x, t)$ in the specimen with PZ cutoff and the traction σ_{dr} along AZ boundary should be equal to the displacement discontinuity in drawing process within AZ:

$$\omega_o(x,t) = (\lambda - 1)^{-1} \cdot \delta(x,t)\,. \tag{2}$$

The Eq. (2) establishes the functional relation between the width ω_0 and COD in the specimen and loading shown in the Figure 8b. The COD depends on applied load σ_∞, σ_{dr} and the specimen dimensions W, crack length ℓ^{cr}, AZ length ℓ^{AZ} and CL lengths L ($L = \ell^{cr} + \ell^{AZ}$). Thus, in this case, we have only two independent geometrical parameters of CL (ℓ^{cr} and ℓ^{AZ}), since ω_0 is not an independent one. That is the reason for simplification of CL in PE: it is reduced to two-parameter model. The stationary state of a solid with two-parameter CL is determined by the minimum of the total Gibbs potential G_{tot} for the problem of Fig 8a. Based on the decomposition of Fig. 8, the total Gibbs potential is the sum of the Gibbs potentials of the specimen with CL cutoff G_0 and the PZ potential G_{PZ} illustrated in Figure 8:

$$G_{tot} = G_0(\sigma_\infty, T, \sigma_{dr}; L, \ell^{AZ}, W) + G_{PZ}(\sigma_{dr}; \ell^{cr}, \ell^{AZ}, T)\,. \tag{3}$$

The Gibbs potential of PZ in turn consists of the wake zone G_{WZ} and active zone G_{AZ} potentials (see the definitions on WZ in Figure 1). AZ consists of homogeneous drawn material with properties different from that of the surrounding original material. It is also separated from the original by distinct boundary with drawing stress acting along it. As a result, the AZ Gibbs potential can be presented as:

$$G_{AZ} = \gamma^{tr} \cdot V_{AZ}\,. \tag{4}$$

The multiplier γ^{tr} in Eq. (4) stands for the specific energy of transformation of a unit mass of original material into the oriented drawn state under drawing stress σ_{dr}: $\gamma^{tr} = g^{tr}(T) - g^0(T)$, where the Gibb potential density is defined as $g(\sigma,T) = f(\varepsilon,T) - w$, where $f(\varepsilon,T)$ is the strain energy density and w stands for work density [9].

The potential of WZ is different in two ways: 1) it does not contain the strain energy of the stretched

fibers, since the crack is traction free; and 2) it contains the surface energy term of the crack faces:

$$G_{WZ} = \gamma_0^{tr} \cdot V_{PZ} + \gamma \cdot \ell^{cr} . \tag{5}$$

Finally, the total Gibbs potential can be expressed as follows:

$$G_{tot} = G_0(\sigma_\infty, \sigma_{dr}; L, \ell^{AZ}, W) + \gamma^{tr} \cdot V_{AZ}(\sigma_{dr}; \ell^{cr}, \ell^{AZ}) + \gamma_0^{tr} \cdot V_{WZ}(\ell^{cr}, L) + \gamma \cdot \ell^{cr} . \tag{6}$$

We compute the volume V^{AZ} of AZ material in the reference state by integrating the AZ width, which is expressed in terms of total COD in the specimen with PZ cutoff (Eq. (2)):

$$V^{AZ} = B_{eff} \int_{\ell^{cr}}^{L} \omega_o(x) dx = \frac{B_{eff}}{\lambda - 1} \int_{\ell^{cr}}^{L} \delta_{tot}\left(x; \ell^{cr}, \ell^{AZ}, W; \sigma_\infty, \sigma_{dr}\right) dx . \tag{7}$$

The total COD δ_{tot} in Eq. (7) is obtained as the superposition of COD $\delta_\infty = \delta_\infty(\sigma_\infty, L)$ due to remote load σ_∞ and crack "closure" $\delta_{dr} = \delta_{dr}(\sigma_{dr}; \ell^{cr}, \ell^{AZ})$ by the traction σ_{dr} acting along AZ boundary as shown in Figure 8.

The thermodynamic forces X^{AZ} and X^{CR} responsible for AZ (ℓ^{AZ}) and crack (ℓ^{cr}) growth are expressed as the partial derivative of total Gibbs potential G_{tot} with respect to corresponding parameters ℓ^{cr} and ℓ^{AZ}, since they are the only independent geometrical characteristics of CL:

$$X^{CR} = -\frac{\partial G_{tot}}{B_{eff} \partial \ell^{cr}}; \qquad X^{AZ} = -\frac{\partial G_{tot}}{B_{eff} \partial \ell^{AZ}} . \tag{8}$$

The derivative with respect to crack length ℓ^{cr} of the first term of G_{tot} decomposition Eq. (6) is zero, when CL length L is fixed. The derivative of the second and third terms of Eq. (6) is the energy release rate (ERR) J_1^{cr} due to crack extension into PZ, when PZ is stationary (L is constant); and the derivative of the fourth term is simply 2γ. Thus, the thermodynamic force reciprocal to crack length is:

$$X^{CR} = J_1^{cr} - 2\gamma . \tag{9}$$

We compute the thermodynamic force reciprocal to AZ in a similar manner considering the specimen with PZ cutoff as a linear elastic solid. The derivative of the first term of decomposition Eq. (6) gives the energy release rate in the specimen with crack of length L loaded by remote load σ_∞ and traction σ_{dr} applied on ℓ^{AZ} part of L:

$$-\frac{\partial G_0}{B_{eff} \partial \ell^{AZ}} = G_1 = \frac{K_{tot}^2}{E'} , \tag{10}$$

where E' is the plain strain Young's modulus and K_{tot} is the sum of SIFs due to remote load and traction along the AZ boundary:

$$K_{tot} = K_\infty(\sigma_\infty, L, W) - K_{dr}(\sigma_{dr}, W, L, \ell^{AZ}) , \tag{11}$$

The derivative of the V^{AZ} (Eq. (7)) with respect to ℓ^{AZ} is expressed as the following integral:

$$\frac{\partial V^{AZ}}{B_{eff} \partial \ell^{AZ}} = \frac{1}{\lambda - 1} \int_{\ell^{cr}}^{L} \frac{\partial \delta_{tot}}{\partial \ell^{AZ}}\left(x; \ell^{cr}, \ell^{AZ}, W; F_\infty, \sigma_{dr}\right) dx . \tag{12}$$

It is evaluated numerically and found to be approximately equal to COD at the root of PZ with a reasonable accuracy (any estimation of accuracy?):

$$\frac{\partial V^{AZ}}{B_{eff}\partial \ell^{AZ}} \cong \left.\frac{\delta_{tot}\left(x;\ell^{cr},\ell^{AZ},L,W;F_{\infty},\sigma_{dr}\right)}{\lambda-1}\right|_{x=\ell^{cr}}. \tag{13}$$

Since the WZ does not change if ℓ^{cr} is fixed, the derivative of the third term in Eq. (6) with respect to ℓ^{AZ} is zero. Finally, putting together Eq. (6), Eq. (8), Eq. (10) and Eq. (13) we obtain the expression for X^{AZ}:

$$X^{AZ} = \frac{K_{tot}^2}{E'} - \left.\frac{\gamma^{tr}}{\lambda-1}\cdot\delta_{tot}(x)\right|_{x=\ell^{cr}}. \tag{14}$$

The AZ reaches equilibrium when the thermodynamic force is vanishing. Therefore, the equilibrium AZ length ℓ_{eq}^{AZ} is determined by the following equation:

$$\frac{K_{tot}^2}{E'} - \left.\frac{\gamma^{tr}}{\lambda-1}\cdot\delta_{tot}(x)\right|_{x=\ell^{cr}} = 0. \tag{15}$$

For a given external load, and crack length, the equilibrium AZ size depends on γ^{tr} and drawing stress σ_{dr}. The cold drawing phenomenon in PE is long studied using macroscopical specimens. It is well established that the drawing stress σ_{dr} increases with the loading rate [7]. Unfortunately, it is difficult to evaluate σ_{dr} on microfibers. Therefore, we use the linear relations between σ_{dr} and log strain rate obtained in macroscopical tests. Since the loading rate of the AZ material changes with CL growth, the σ_{dr} acting along AZ boundary is also varies with CL growth and can be estimated on the basis of either a combination of COD rate and macroscopical $\sigma_{dr}\sim\ln\dot{\varepsilon}$ relations or indirectly on duration of AZ stationary state. Regarding γ^{tr}, the transformation of the original continuum media into highly oriented fibrillated structure within PZ is a complex process. It starts with cavitation ahead of the crack front as a precursor of drawing. The cavitation makes it possible to draw thin membranes between the cavities. Further drawing leads to splitting some of the membranes into thin fibers. For such micron scale of processes, a surface energy of microfibers and membrane becomes comparable to the bulk material energy. It complicates a theoretical evaluation of γ^{tr}. A comparison of the value of AZ size ℓ_{eq}^{AZ} resulting from solution of the Eq. (16) with actual ℓ_{eq}^{AZ} observed in the experiment allows evaluating of an effective (phenomenological) value of γ^{tr}. This estimation has been performed and reported in a separate paper accompanying this one.

3.2. Kinetic Equations of Crack Layer Growth in PE

A stationary CL configuration takes place, when the CL thermodynamic forces are not positive, i.e., $X^{AZ}\le 0$ and $X^{CR}\le 0$. The equilibrium is achieved, when the forces equal 0 (for example Eq. (15) for AZ equilibrium). At a small deviation from equilibrium, a thermodynamic system has a tendency to return to the equilibrium state. However, fracture is an essentially irreversible process: there is no return, when the crack is moving into AZ by breaking fibers, or AZ advances into the original material via cavitation followed by cold drawing of the material between the cavities and formation of membranes and fibers. Thus, when CL departs from equilibrium stationary state, it evolves to the next stationary configuration.

Close observation of the micromechanisms of CL growth reveals that there is always formation of AZ first in a vicinity of a a micro defect or specially made notch. After some time of growth, AZ reaches a stationary state, at which its length does not visibly change. It implies that the thermodynamic force reciprocal to AZ length has vanished. During that time, however, we observe an increasing load point displacement. It can be noticed from the load point displacement records of discontinuous (stepwise) SCG (Figure 4). The increase of load point displacement during a stationary AZ size stems from the macroscopical creep of the bulk material accompanied by an increasing width of AZ. The later may result from either drawing of an additional material across AZ boundary or creep of the drawn material of AZ or both.

The absence of a crack growth from a macroscopical view point means that the crack driving force $X^{CR} \leq 0$, i.e., $J_1^{CR} \leq 2\gamma$. This inequality may change the sign after a certain time of creep and degradation of fibers within AZ, since the specific fracture energy γ decays due to degradation of microfibers. Then, the crack moves into AZ for the distance controlled by an interplay between J_1^{CR} and $2\gamma(x,t)$. The advancement of the crack into AZ reduces AZ length and thus violates the AZ equilibrium condition, giving rise to an increase of AZ force that result in the AZ growth.

Thus, the role of AZ is in moderating high stress concentration caused by a crack. It is achieved by strain localization (displacement discontinuity) in form of cavitation and cold drawing. However, AZ can only delay the fracture propagation process: the creep and/or other types of degradation of the AZ material reduce its toughness with time and ultimately allow crack penetration into AZ. Such process of CL propagation continues by crack and AZ assisting mutual growth. The described scenarios of CL growth is formalized in the following system of coupled ordinary differential equations with respect to ℓ^{cr} and ℓ^{AZ}:

$$\begin{cases} \dot{\ell}^{cr} = k_1 X^{CR}, & if\ X^{CR} \geq 0,\ and\ \dot{\ell}^{cr} = 0,\ if\ X^{CR} < 0 \\ \dot{\ell}^{AZ} = k_2 X^{AZ}, & if\ X^{AZ} \geq 0,\ and\ \dot{\ell}^{AZ} = 0,\ if\ X^{AZ} < 0 \end{cases}. \tag{16}$$

The kinetic coefficients k_1 and k_2 in Eq. (16) as well as the parameters entering the CL driving forces X^{AZ} and X^{CR} are evaluated by matching the model predictions with observed CL evolution reflected by load point displacement vs. time plot like shown in Figure 4, side views and fracture surface micrographs similar to that shown in Figures 5, 6, and 7.

The crack and AZ thermodynamic forces are non-linear functions of crack and AZ lengths. Thus, the system of Eq. (17) despite of its simple appearance is a nonlinear system of ODE, solution of which calls for numerical methods. An illustration of numerical simulation of CL growth in a CT specimen is presented in the accompanying paper [8].

4. Conclusion

The focus of the paper is brittle fracture resulting from SCG. The limitation of the conventional approach of lifetime assessment in brittle fracture originates from complexity of SCG process. Specifically, relatively new data on continuous vs. discontinuous modes of SCG is presented in details. Only continuous CL growth takes place for low enough load. Above that value, both continuous and discontinuous modes of SCG are possible at different temperature.

The active zone of CL constituted by cold drawn microfibers and the energy dissipation associated with AZ formation play a major role in fracture process. A brittle fracture of microfibers in process

of drawing or soon after completion of drawing results in a continuous CL growth. In contrast with that, a ductile behavior (creep) of drawn microfibers within AZ is the underlying cause of the discontinuous CL growth.

A transition in the mechanism and kinetics of SCG takes place at certain combination of temperature and SIF. It suggests that commonly used extrapolation of data obtained at elevated temperature into service condition is limited by the requirement of similarity in the mechanisms and kinetics of fracture process. Therefore, the commonly used acceleration technique based on extrapolation of 1-1.5 years elevated temperature test data into 50 and 100-year life in service condition is a suspect. In addition, there is a hidden assumption that after decades of services the material retains the same properties as the one tested for a year or two. The material aging process (chemical degradation and/or physical aging) commonly takes place over time. It should be taken into consideration. An alternative approach to the lifetime assessment problem is a formulation of a sound physical model of initiation and SCG processes and numerical simulation of brittle fracture.

Investigation of Void Linkage in Magnesium Using SEM and Micro Computed X-ray Tomography

Abstract Ductile fracture in metallic materials occurs by the nucleation, growth, and linkage of microvoids within the bulk of the material. As a result, two dimensional techniques must be complimented with three dimensional techniques in order to completely characterize the fracture process. In the present study, tensile testing coupled with: scanning electron microscope (SEM) imaging, electron backscattered diffraction (EBSD) patterning, and micro computed x-ray tomography (XCT), have been used to analyze void linkage in magnesium, which exhibits poor formability at room temperature. SEM imaging and EBSD patterning have been used to characterize the mechanisms responsible for void linkage and to determine the effects of void fraction and void orientation on the failure strain. Micro XCT has been used to examine the evolution of internal voids. It has been established that void fraction and void orientation have a weak influence on the failure strain due to the premature linkage of voids. EBSD analysis has shown that this premature void linkage is associated with the failure of twin and grain boundaries. The results suggest that (in contrast with more ductile fcc metals) the local microstructure has a significant impact on void linkage.

Keywords Magnesium, Void Linkage, Micro computed tomography

1. Introduction

Magnesium exhibits limited ductility when deformed at room temperature. The HCP crystal structure of the material does not provide an adequate amount of slip systems to satisfy the von Mises criterion. As a result, mechanical twins are activated to accommodate stress concentrations [1]. Void nucleation typically occurs within the bulk of the material. As a result, characterization techniques which can detect internal flaws are required to fully understand fracture. In the past, model materials were fabricated to better understand void growth and coalescence [2]. The 2D model materials consisted of thin sheets containing laser drilled holes through the thickness which simulated voids [3]. These model materials were pulled in tension within the SEM such that the growth and linkage of the holes could be analyzed in increments of deformation. FCC materials (aluminum and copper) were studied which are more isotropic than HCP materials. The results showed that void growth was uniform. Linkage of the voids occurred by the internal necking mechanism observed by Puttick [4]. Furthermore, experiments were carried out to determine the effects of the void fraction and void orientation on the failure strain. It was concluded that both parameters had a strong correlation with the failure strain.

The experiments were then extended to 3D to determine if the 2D experiments were representative of what occurs in the bulk [5]. 3D model materials were fabricated by diffusion bonding multiple sheets containing laser drilled holes between hole free sheets. These were used to simulate a 3D distribution of internal voids. The 3D model materials were tested in situ. The voids in the material are resolved using x-ray tomography from a synchrotron source based on the difference in the attenuation coefficient between the metal and the void. The use of tomography in materials science has significantly increased in the past few years [6]. In the present work, tomography is coupled with EBSD and SEM to understand the fracture of magnesium materials which display mechanical anisotropy.

2. Experiments

Commercially pure magnesium was hot rolled to a thickness of 125 µm. Tensile specimens were machined using electrical-discharge wire cutting. The tensile specimens had a reduced gage section with a length of 2 mm and a width of 1 mm. The samples were polished with 0.05 µm colloidal silica to ensure a smooth surface for laser machining. Holes with a diameter of approximately 13 µm, were laser drilled into the gage section of the tensile samples using a Ti:sapphire laser system. For one set of experiments, samples with a single row of holes perpendicular to the tensile axis were tested with different center to center hole distances to examine the effects of void fraction on the failure strain. The distances used were 40, 55 and 70 µm. In another set of experiments, samples with a single row of holes oriented at various angles with respect to the tensile direction were tested to analyze the effects of void orientation on failure strain. The angles were 45, 60 and 75˚. After laser drilling, the samples were annealed in a tube furnace purged with argon, at 450 ˚C for 1 hour, to remove the heat affected zone in the vicinity of the holes. The average grain size was approximately 50 µm with a standard deviation of 25 µm, after the final annealing process.

EBSD patterns were obtained to determine the initial texture in the vicinity of the holes. Tensile tests coupled with electron microscopy have been used to visualize void growth and linkage in-situ. Samples were pulled in uniaxial tension at room temperature under the SEM. The tensile stage utilizes a 220 N load cell and experiments were carried out at a constant test speed of 10 µm/s. Images were obtained in increments during deformation. Tests were stopped when microstructural features or damage was observed. EBSD was carried out on the deformed samples and micro computed tomography scans were employed to observe the bulk of the deformed samples. The Skyscan 1172 micro computed tomography unit was used in the analysis.

3. Results

The EBSD patterns obtained on the deformed samples allowed for characterization of the microstructural features which led to failure. Figure 1 shows the SEM image series of a row of holes perpendicular to the tensile axis with a center to center hole distance of 40 µm. The EBSD patterns have been overlaid on the SEM images where necessary.

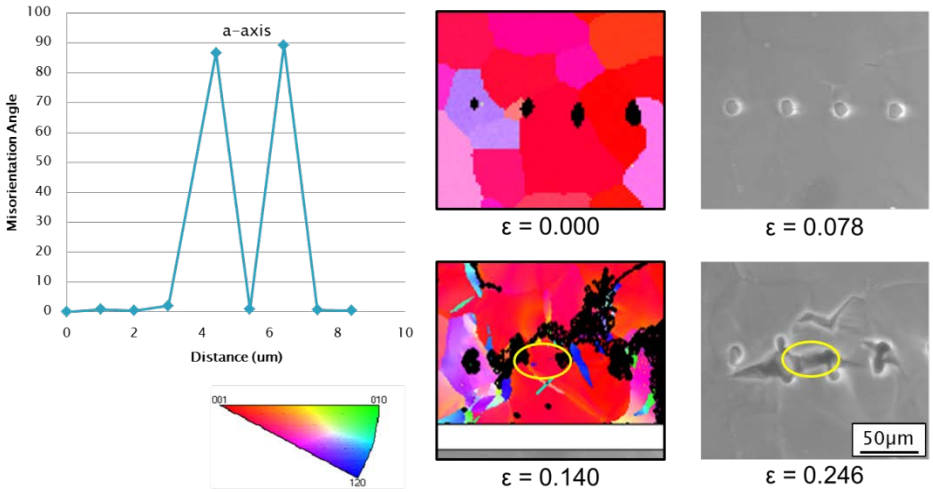

Figure 1: SEM image series at various far field strains and misorientation profile across the twin circled.

At a far field strain of 0.14, a twin was resolved which is circled in Figure 1. The twin was identified as an extension twin, which forms along the $\{10\bar{1}2\}$ plane in magnesium. The misorientation profile in Figure 1 displays a rotation of approximately 86˚ about the $<11\bar{2}0>$ direction (a-axis) with respect to the parent grain. This geometrical relationship is characteristic of the extension twin. The twin became a site for crack propagation at a far field strain of 0.246. It has been established that extension twins form at lower stresses to accommodate extension along the <0001> direction (c-axis). However, once nucleated the twins become stress concentrators and eventually become failure sites.

Figure 2 shows the SEM image series of a row of holes perpendicular to the tensile axis with a center to center hole distance of 70 μm. EBSD patterns were overlaid in the increments where they were obtained.

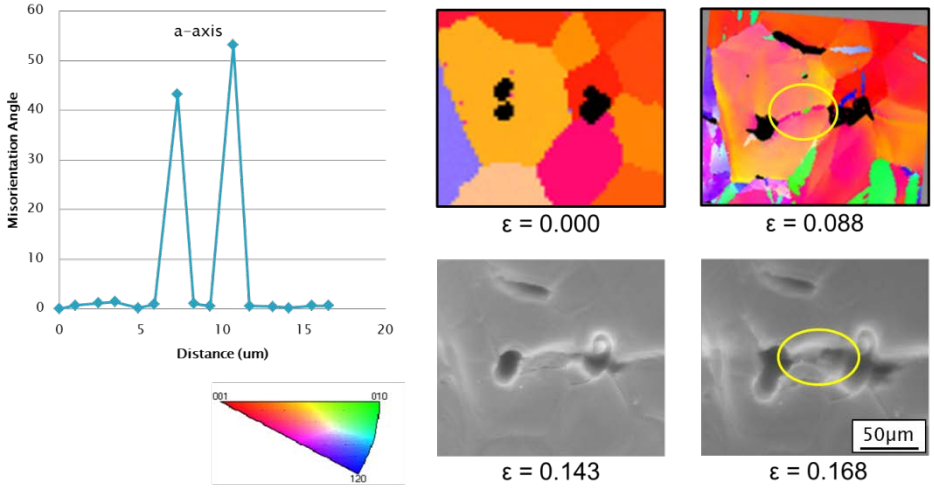

Figure 2: SEM image series at various far field strains and misorientation profile across the twin circled.

A twin was resolved by EBSD at a far field strain of 0.088 which is circled in Figure 2. The twin was characterized as a compression twin, which forms along the $\{10\bar{1}1\}$ plane in magnesium. The misorientation profile in Figure 2 reveals a rotation which is approximately 56˚ about the a-axis with respect to the parent grain. This is characteristic of the compression twin which accommodates compression along the c-axis. The twin boundary failed at a far field strain of 0.168. It has been established that this twin type requires high stresses to activate. The twin nucleated at a relatively low far field strain. This suggests that a complex stress state occurs within the material. Some grains experience much higher stresses than others due to the mechanical anisotropy of the material. Figures 1 and 2 both show failure at grain boundaries. Grain boundary failure is another dominant fracture mechanism.

The effects of void fraction on failure were observed by performing tests on void rows with different center to center holes distances. The center to center hole distance can be related to the void fraction f by

$$f = \frac{2r}{\lambda} \qquad (1)$$

where r is the radius of the hole and λ is the center to center spacing. The normalized length of the

voids which contributed to the first crack was plotted as a function of the void fraction. The normalized length in the tensile direction represents the local displacement field within the vicinity of a void. The results are shown in Figure 3.

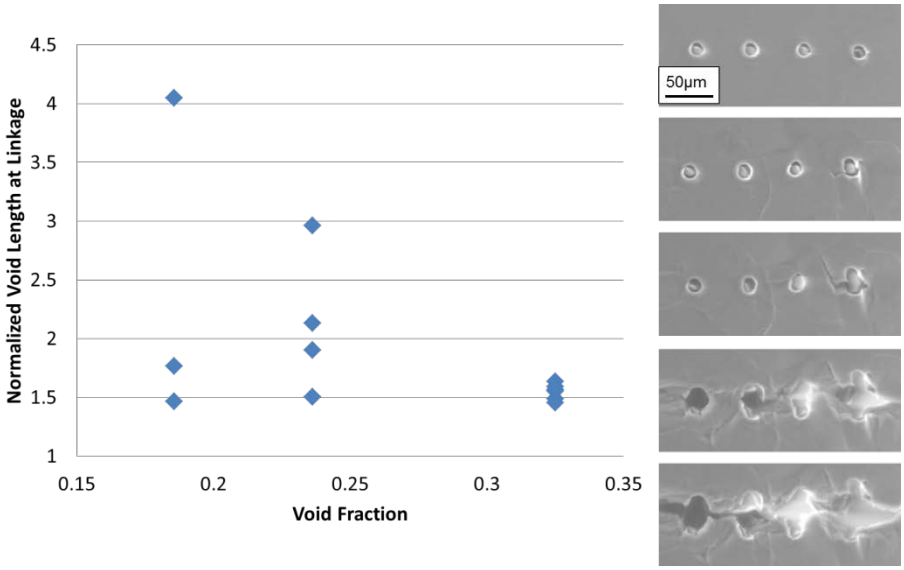

Figure 3: Normalized void length vs. void fraction.

The data does not show a strong correlation between the void lengths at failure and void fraction. This is different from what has been observed in isotropic materials. The variability of the data for a given void fraction suggests that the voids do not grow uniformly.

The effects of void orientation on failure were examined by testing samples with the holes oriented at various angles from the tensile axis. The center to center spacing of the holes was held constant in these experiments at 40 μm. The results are shown in Figure 4.

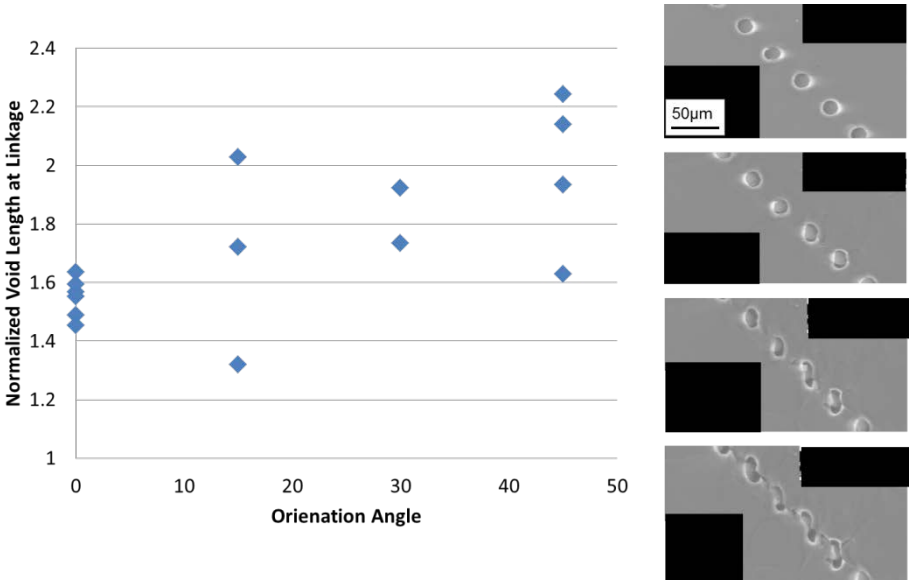

Figure 4: Normalized void length vs. void orientation.

The correlation between the void lengths at failure and void orientation is not strong. This is different from what was predicted in the work of Hosokawa et al [5]. However, in the previous work isotropic materials were tested where void growth was uniform and linkage occurred by internal necking of the voids. In the magnesium materials tested premature linkage occurs by grain and twin boundary failure. Therefore, the weak relationship between the void fraction and void orientation can be attributed to the fact that the linkage of the holes is not driven solely by plasticity in the magnesium materials tested.

Micro XCT has been used to investigate the bulk of the deformed samples. Figure 5 shows a deformed sample with a row of voids perpendicular to the tensile axis with a center to center hole distance of 70 µm. A grain boundary crack was detected by SEM shown in Figure 5a). The reconstructed 3D volume is shown in Figure 5b).

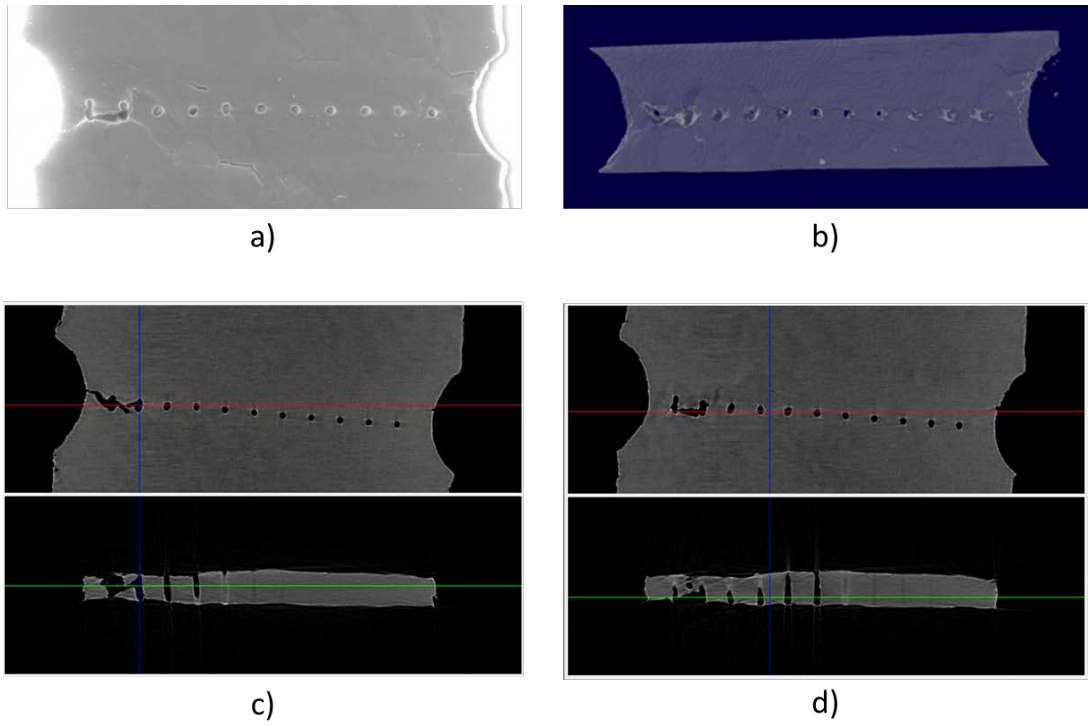

Figure 5: a) SEM image b) Reconstructed 3D volume c) Data slice at the back of the sample d) Data slice at the front of the sample.

The volume was examined using the Data Viewer software developed by SkyScan which allows the user to view the reconstruction slice by slice. Figure 5c) reveals that a crack has already developed on the side of the sample which cannot be detected by SEM. Figure 5d) shows the depth of the crack that is shown in the SEM image. The results suggest that the failure of the materials tested is very complex and the 3D structure must be accounted for to accurately predict the failure of these materials.

4. Discussion

Void linkage occurs prematurely in the magnesium materials tested. The premature linkage is associated with the failure of grain and twin boundaries. Both extension and compression twins have been characterized and contribute to the final failure. The weak correlation between the void fraction and void orientation on failure is a direct consequence of the fact that void linkage is not entirely driven by plasticity. Tomography tests have shown that the failure of the materials is quite complex and 3D techniques must be used to determine where the first failure site occurs.

A new macroscopic model based on non-local interactions to predict damage and failure in quasibrittle materials

Abstract The purpose of this paper is to propose a new macroscopic approach to describe the evolving non-local interactions during damage and failure in quasi-brittle materials. A new integral-type non-local model is proposed where the weight function is directly built from these interactions. The structure is considered as an assembly of inclusions, which are successively elastically dilated in order to characterize the transfer of information inside the material. By this way, the new macroscale weight function takes into account intrinsically the interactions evolution during the material failure similarly as a mesoscale model does. This new model is first validated on simple 1D cases and its performances are compared with the performances of other models proposed in the literature. It is shown that the new model is able to describe the continuous/discrete transition during the dynamic failure of a rod. It is also shown that the new model is able to describe boundary effect during a spalling test. Finally, the model is used to predict damage and failure during 3 points bending fracture tests on notched and unnotched concrete beams.

Keywords Non-local model, interactions, damage, quasi-brittle materials

1. Introduction

Classical failure constitutive models involve strain softening due to progressive cracking and a regularization technique for avoiding spurious strain and damage localization. Different approaches have been promoted in the literature such as integral-type non-local models (e.g. [1]), gradient damage formulations (e.g. [2]), cohesive cracks models (e.g. [3] with classical finite elements and e.g. [4] with extended finite elements), or strong discontinuity approaches (e.g. [5]). Such macroscale failure models have been applied on a wide range of problems, including the description of damage and failure in strain softening quasi-brittle materials [1], softening plasticity [6–8], creep [9] or composite degradation [10]. They may exhibit, however, some inconsistencies such as (*i*) incorrect crack initiation, ahead of the crack tip; (*ii*) propagating damage fronts after failure due to non-local averaging, (*iii*) incorrect shielding effect with non-zero non-local interactions across a crack surface; (*iv*) deficiencies at capturing spalling properly in dynamics, with spalls of zero thickness when the expected spall size is below the internal length of the model (see e.g. [11–14]). Moreover changing geometry, e.g. from tensile to bending loads or from unnotched to notched specimens, results generally in the loss of predictive capabilities of the macro-scale non-local models [15, 16]. On the contrary, it has been shown recently [15, 17] that meso-scale models gave good prospect in the prediction of failure and size effect for notched and unnotched concrete beams. Indeed meso-scale results have been compared to a new experimental database [16] consisting in 3 point bending failure tests for similar notched and unnotched concrete specimens of four different sizes but made from the same formulation. Not only the different peak loads for all geometries are recovered but also the failure softening phase is well predicted which is a more challenging issue. It means that the meso-scale models intrinsically contain relevant information leading to a good description of the size effect, the boundary effect and the whole failure process.
At the macro-scale, the prediction of failure in quasi-brittle materials needs enhancement of existing non-local damage models and the way the non-locality is taken into account in the macro-scale models has to be redefined. Non-locality finds its origin in the interaction between material points

undergoing damage in the course of failure [18, 19]. There are several mechanisms, which should be considered when looking at the non-locality due to the interaction between damaged points: (*i*) an interaction exists if there is damage, which produces this interaction. Assuming that damage corresponds to the growth of micro-cracks, this interaction grows with the size of the defect; (*ii*) shielding effects are also expected: the interaction between two points located apart from a crack should not exist; (*iii*) on free existing or evolving boundaries, and along the normal to these boundaries, non-local interactions should vanish as demonstrated in [20]. The internal length in the non-local model is the parameter inside the weight function that encompasses the non-locality and there is a consensus that this quantity may not be constant, but should depend on the geometry of the specimen or on the state of damage. Therefore enhanced non-local models accounting for a variation of the internal length have been proposed recently [13, 20, 21]. Proposals discussed in [13, 20] are considered on academic one-dimensional problems. Their implementation and extension to 2D or 3D problems are really not trivial as they involve the computation of path integrals, which are tedious in a finite element setting. The stress-based model in [21] is more tractable in 2D/3D computations but the evolution of non-locality is rather empirical.
The purpose of this paper is to discuss a new approach to non-local interactions during failure in quasi-brittle materials and to upscale the relevant information present from the meso-scale to the macro-scale. Therefore, the paper focuses on the estimation of the non-local weight function directly from interactions. The material is modeled as an assembly of inclusions and the elastic interactions upon dilation of each inclusion are computed in a similar ways to a classical Eshelby's problem [22]. A new interaction-based weight function is then built from these interactions. This new interaction-based non-local model is validated on simple 1D problems and its performances are compared with the classical integral-type nonlocal model.

2. A new interaction-based non-local model

2.1. Non-locality in integral-type macro-scale models

In classical non-local models, such as the integral-type [1], the internal length is the parameter inside the weight function that encompasses the non-locality. Associated with a classical Gaussian weight function, it set how and how far the interactions produce inside the materials. However, the main drawback of the formulation is that this parameter is constant whatever the geometry and the failure process. For instance, close to a boundary, the part of the nonlocal averaging domain that protrudes outside the boundary is classically chopped off [1]. Improved models can be found in the literature, with a different averaging process close to the boundary of the solid [12,23] or with a varying internal length in the course of damage [13, 20, 21]. However, even if the internal length variations are based on micro-mechanical concepts, such as the crack growth interaction effect or the transfer of information through a damaged area, the final choice of the weigh function and thus the evolution of non-locality are rather empirical.

2.2. Non-locality in meso-scale models

In meso-scale models, the non-locality is intrinsically included by representing the meso-structure of the materials (e.g. granular, matrix and interfaces in concrete). Therefore, the non-locality does not behave the same close to a boundary, close to a damaged area, at initiation or during the failure process. It has been shown recently that such models are able to capture challenging issues of quasi-brittle materials failure such as predicting the peak loads and even the whole softening load-displacement responses of notched and unnotched beams in three-point bending [15, 17]. In the following, we aim at building a new interaction-based non-local weight function, which will evolve intrinsically when damage occurs inside the materials.

2.3. A new interaction-based non-local weight function

The purpose of the paper is to discuss a new approach to non-local interactions during failure in quasi-brittle materials and to upscale the relevant information present from the meso-scale to the macro-scale. Therefore, we aim at estimating the non-local weight function directly from interactions.

Before we get to the weight function to be inserted in a non-local integral model, let us first consider elastic interactions. In order to compute the effect of point ξ on point x, we look at the strain induced at point x due to the dilation of ε^* of a circular inclusion of radius a centered at point ξ (see Fig. 1).

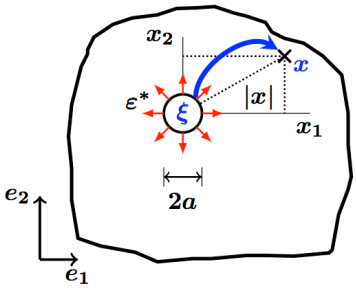

Figure 1. Non-local contribution seen by a point x when a perturbation is produced in ξ.

Assuming now that the induced strain at point x has been computed, numerically for instance. The growth of damage is often defined from energy considerations and we shall look at a norm of this strain, denoted as A, instead of the strain tensor itself:

$$A(x,\xi,\varepsilon^*,a)=\sqrt{\sum_{i=1}^{3}\left|\varepsilon_i(x)\right|^2} \tag{1}$$

where $\varepsilon_i(x)$ is the ith principal strain. Note that we could have chosen the true elastic energy instead of a norm of the strain tensor. It would not have changed much the following development. Then, the interaction is represented by this norm transmitted from the dilation in the inclusion centered at ξ to x. It depends on the geometry of the solid, on the inclusion size a, and on the material elastic properties inside and outside the inclusion. Formally, the norm A transmitted to x by the dilation ε^* writes also:

$$A(x,\xi,\varepsilon^*,a)=\left\|\varepsilon^*\right\|A^*(x,\xi,a) \tag{2}$$

where A^* represents the interaction produced at x due to ξ for a unit dilation.

2.4. Final formulation

2.4.1. Non-local averaging

We assume now that it is this interaction A^*, which governs the weight function involved in non-local averaging. This non-local averaging writes:

$$\bar{\varepsilon}_{eq}(x)=\frac{1}{\Omega_r}\int_\Omega \psi(x,\xi)\varepsilon_{eq}(\xi)\,d\xi \quad \text{with} \quad \Omega_r=\int_\Omega \psi(x,\xi)\,d\xi \tag{3}$$

where $\bar{\varepsilon}_{eq}$ is the non-local strain and ε_{eq} is the effective strain defined by Mazars [24] as:

$$\varepsilon_{eq}=\sqrt{\sum_{i=1}^{3}\left\langle\varepsilon_i\right\rangle_+^2} \tag{4}$$

where $\langle \bullet \rangle_+$ is the positive part function, Ω is the volume of the structure, Ω_r is a characteristic volume introduced in such a way that the non-local operator does not affect an uniform distribution of equivalent strain far away from the boundary when no damage occurs in the structure. The analogy between the interactions defined above and the weight function ψ suggests:

$$\psi(x,\xi) \equiv A^*(x,\xi,a) = \frac{A(x,\xi,\varepsilon^*,a)}{\|\varepsilon^*\|} \equiv \frac{\sqrt{\sum_{i=1}^{3} |\varepsilon_i(x)|^2}}{\|\varepsilon^*\|} \quad \text{with} \quad \Omega_r = \int_\Omega A_0^*(x,\xi,a)\,d\xi \tag{5}$$

where $A_0^*(x,\xi,a)$ is the interaction function reconstructed when no damage occurs in the structure (typically at the beginning of the computation).

Practically, the computation of the interactions (function A∗) is performed using a finite element setup, which is identical to that of the mechanical problem to be solved, with the same mesh. The finite elements which belong to each inclusion centered on a given integration point are subjected to a thermal expansion ($\varepsilon^* = \alpha \Delta T I$) where α is the thermal expansion coefficient, I is the identity tensor, and T is the temperature. If the structure has n inclusions (integration points), n elastic computations are performed to build the weight function at each loading step. Since the construction process of the interaction-based weight function is cinematically driven by the successive thermal expansions, all boundary conditions are clamped during the reconstruction process in order to avoid the perturbation of the kinematics on the boundary.

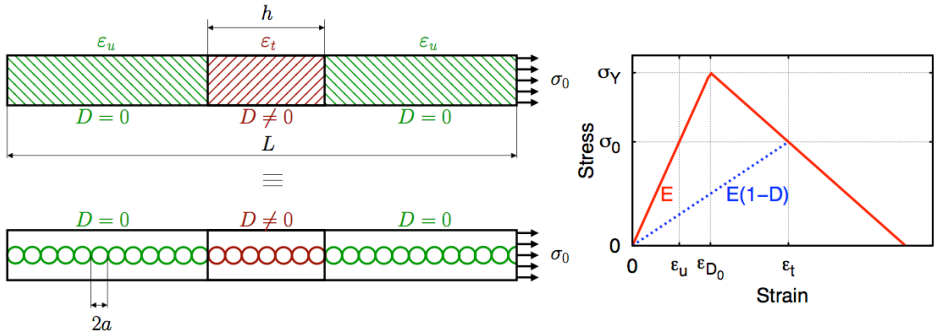
The single model parameter which remains to be determined is the inclusion size a. This inclusion size is the internal length involved in the formulation. It ought to be related to the average size of the heterogeneities in the underlying heterogeneous material to be modeled.

2.4.2. Constitutive model

Damage is considered to be isotropic. Temperature and time-dependent effects are neglected. Damage is a function of the amount of extension in the material, defined locally by the equivalent strain (see Eq. 4). The evolution of damage is a function of the non-local equivalent strain and it is governed by the Kuhn-Tucker loading-unloading condition (see [15] or [16] for details).

3. Validation and performances

3.1. Clamped bar in tension



(L =10 cm, σ_Y =3 MPa, E =30 GPa, ε_{D0} =10^{-4}, σ_0 =1.8 MPa, D =70 %)

Figure 2. Simple problem of a clamped bar in tension.

We are going to illustrate the influence of the inclusion size a on the weight function and we shall look at the evolution of the non-local contributions nearby the boundary of a damaged zone. For this purpose, we look at a one-dimensional problem of a clamped bar subjected to tension. The bar has a damaged zone in the middle, the rest being undamaged. The distribution of damage is fixed a priori. The strain distribution inside the bar corresponds to the onset of evolution of damage from this initial state. The strains ε_u and ε_t are obtained from a bilinear softening constitutive law (see Fig. 2).

Although the bar is one-dimensional, the interactions are computed following a 2D, plane stress description. The weight functions are computed from a discrete set of circular inclusions located on the neutral axis of the bar (see Fig. 2). Their size is much smaller than the bar depth in order to avoid interactions with upper and lower boundaries. The finite element meshes consist in triangular elements with 1 integration point and the meshes are built in such a way that there are always 4 elements in the inclusion diameter. Each inclusion is dilated successively in order to reconstruct the weight functions. The weight functions are normalized afterwards so that their integral over the bar is equal to 1 (through the functional Ω_r in Eq. 5).

Fig. 3 presents the influence of the size of the inclusion on the weight function in the case where damage is equal to zero.

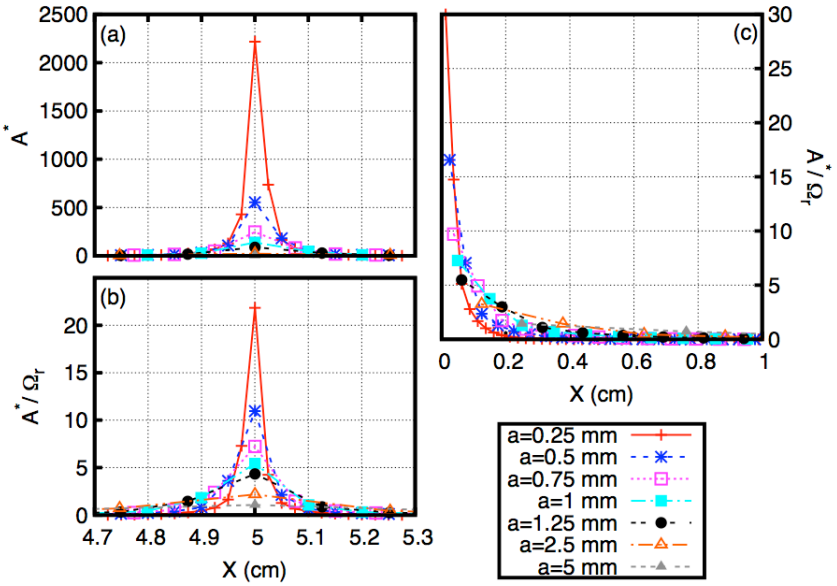


Figure 3. Influence of the inclusion size on the weight function (Reproduced from [25]):
(a) computed far from the boundaries; (b) normalized and computed far from the boundaries;
(c) normalized and computed near the boundary.

Far away from the center of the inclusion (Fig. 3.a), the weight function does not depend on the inclusion size and decreases as $1/X^2$ following the Eshelby's theory (see e.g. [22]). Fig. 3.b presents the same influence of the size of the inclusion but on the normalized weight function. If the inclusion size tends to zero, the computation of the interactions reduces to the construction of Green functions in which it is well known that no internal length is involved. One can demonstrate from the construction of the normalized weight function that it becomes a Dirac delta function and the constitutive model becomes local. Fig. 3.c shows the same calculation nearby the boundary of the solid. The weight function is centered in the inclusion, which sits right next to the boundary. Again, upon decreasing of the radius of the inclusions, the weight function converges toward a Dirac Delta function. According to the results due to [12], [20] and [23], it is expected that at the boundary of

the solid the response becomes local. In mesoscale models, there is a wall effect on the boundaries and large inclusions may not be fitted in a boundary layer smaller than their radius. Nearby a boundary, the inclusion size is constrained by the distance to the free surface, as it cannot protrude outside the solid. This feature can be easily introduced in the present model: at points located close to the boundary, the inclusion size is decreased so that it cannot protrude outside the solid. In a boundary layer of thickness l, inclusions of diameter l shall be considered only when $l < a$. Thus interactions tend to vanish as we consider points closer and closer to the boundary of the solid.

Fig. 4.b presents the normalized non-local contributions when the non local strain is computed at the center of the inclusion located close to the damage band in the region which unloads on the left side. The damage band contains 7 inclusions ($a = 1.25mm$, $h = 8.75mm$). A comparison with the gauss-type weight function used in the classical non-local damage model is also provided (Fig. 4.a). With the Gauss weight function and because the strain inside the damage band is larger than outside the damage band, the non-local contribution from points lying inside the band is much larger than those of points lying outside the band. This will trigger the propagation of the damage band, which should expand in the course of the calculation eventually. Fig. 4.b shows that a shielding effect is observed with the new formulation. The non-local weights outside the damage band are the most important. As a matter of fact, the weight at points lying inside the band is decreasing with increasing damage. There is a shielding effect due to damage, which derives directly from the method used for the calculation of interactions. In the extreme case of a fully damaged band, the dilation of an inclusion sitting inside the band will not be transmitted to the stiffer zone outside the band.

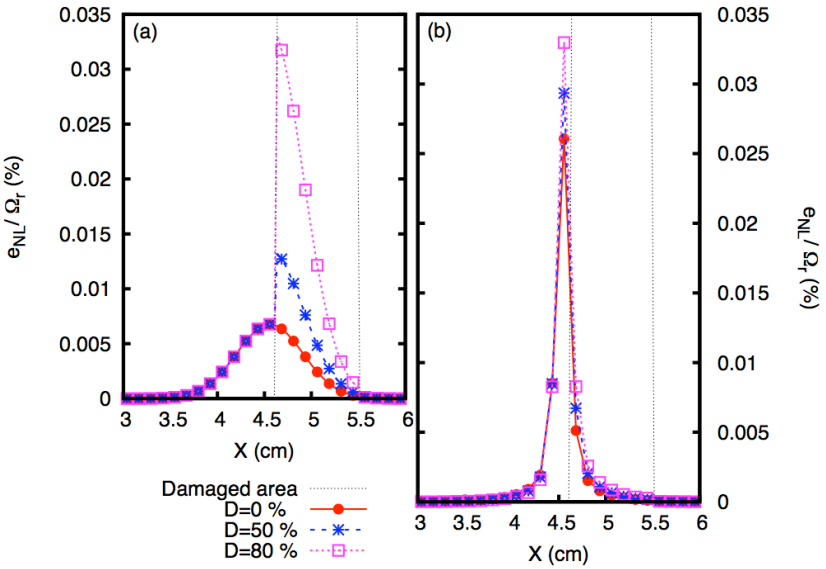

Figure 4. Response close to a damaged area (Reproduced from [25]):
(a) original formulation; (b) interaction-based formulation.

There is, however, a limitation to the shielding effect when the radius of the inclusions is larger than the width of the damage band. In this case, the interaction induced by the dilation of the inclusion will extend across the band. It is expected then that a point lying on one side of the band will feel the interaction from points lying on the other side. We recover here the case of an inclusion located near a boundary, a fully formed crack being two free boundaries facing each other. In order to avoid this problem, we impose that the radius of the circular inclusion reduces as damage grows and we adopt the following rule, which encompasses the situation where an inclusion is centered at a point nearby a damage zone or near a boundary of the solid:

$$a(x) = \min(a_0\sqrt{1-D(x)}, d(x)) \tag{6}$$

where *a(x)* represents the radius of the sphere containing the integration points where the thermal expansion is imposed to reconstruct the interaction-based weigh function, a_0 is a model parameter related to the maximum aggregate size, D is the local damage, d is the minimal distance from any boundary of the structure.

3.2. Dynamic failure of a rod

This example is used to test the relevance of the proposed model and its capabilities to describe progressive failure and complete failure. A bar is submitted at both extremities to constant strain waves, which propagate toward the center in the linear elastic regime (see Fig. 5 and Table 1). When the two waves meet at the center, the strain amplitude is doubled, the material enters the softening regime suddenly, and failure occurs. In all computations, the time step is chosen to be equal to the critical time step.

Table 1. Characteristics of the rod dynamic failure test

Parameter	L	v	E	ρ	l_c/a_0	ε_{D0}	α_t	A_t	B_t	α_c
Unit	cm	cms^{-1}	MPa	kgm^{-3}	cm					
Value	30	0.7	1	1	4	1	1	1	2	0

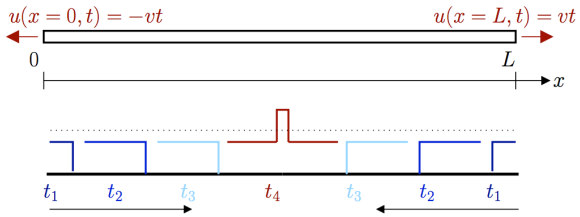

Figure 5. Dynamic failure of a rod: test description and time evolution of the strain amplitude repartition along the rod.

In the course of damage, the crack opening displacement (COD) can be estimated using the method proposed by [26] and compared to an ideal crack opening profile obtained from a strong discontinuity analysis (single crack). The comparison, e.g., the distance between the two profiles, indicates how close the strain and damage distributions are from those corresponding to a single crack surrounded by a fracture process zone. Details may be found in [13] based on [26].

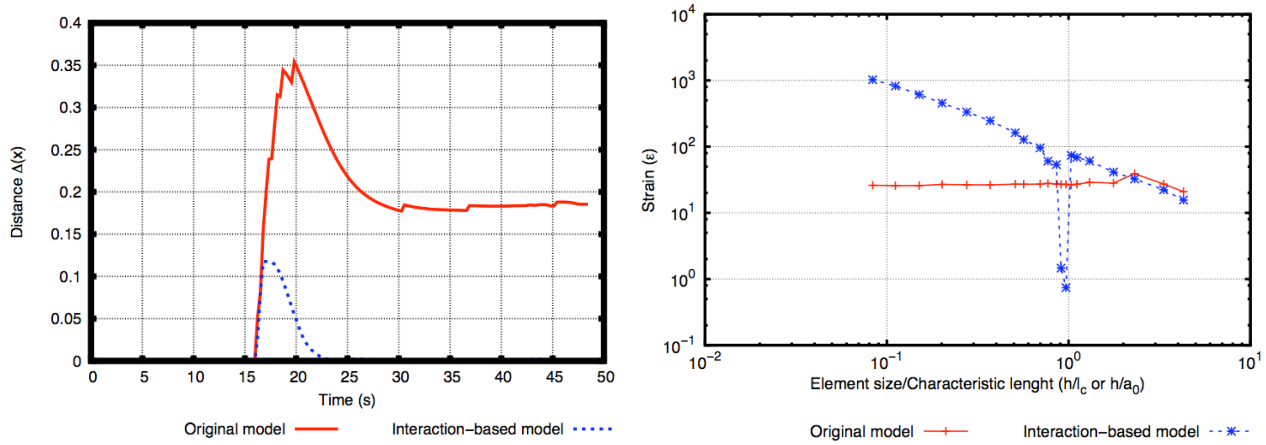

Figure 6. Dynamic failure of a rod (Reproduced from [25]): (left) distance between the computed COD and an ideal opening profile obtained for a strong discontinuity versus time; (right) strain in the cracked element versus adimensional element size at complete failure.

Figure 6 shows that the failure process is better described with the interaction-based model since the distance between its crack opening profile and the one corresponding to a strong discontinuity COD tends rapidly to zero. At complete failure, the crack opening computed according to the same technique should be independent of the element size. In a simple 1D setting, for instance, and assuming that the crack opening is smeared over the finite element that contains the discontinuous displacement at complete failure, the crack opening is equal to the strain distribution times the element size. Therefore, after complete failure, the strain in the cracked element should evolve in inverse proportion of the element size (for constant strain element). Figure 6 shows that the complete failure is better described with the interaction-based model since the strain versus adimensional element size curve follows a linear trend in a logarithmic plot. Moreover the slope is coherent with the CMOD estimated at complete failure. Note that in the original model, the element size is dimensioned by the internal length l_c whereas in the new model, it is dimensioned by the characteristic length a_0 . For the integration-based model, a peak discontinuity is observed when the element size is approximately equal to the characteristics length a_0. It means that several elements are needed inside the inclusion where the perturbation is produced to well reconstruct the interaction-based weight function.

3.3. Spalling test

A second 1D example is used to test the response of the new model close to a boundary. This 1D example consists of a spalling test presented by [12] based on a split Hopkinson pressure bar test primarily developed by [27] for material dynamic behavior characterization, but often adapted for dynamic fracture testing [28, 29]. A striker bar generates a square compressive wave that then propagates along the bar in the linear elastic regime. When this compressive wave reaches the free extremity of the bar, it is converted into a tensile wave and added to the incoming compressive wave (see Fig. 7 and Table 2). The resulting wave stays equal to zero until the tensile one reaches a distance from the boundary equal to half the initial signal length. Failure is initiated at this point if the amplitude is greater than the tensile strength, generating a spall at a controlled distance from the boundary that depends on the initial compressive signal duration. For all numerical studies, the time step is chosen to be equal to the critical time step of the corresponding element size.

Figure 7 shows that the spalling failure is better described with the interaction-based model since the spall location is predicted inside the bar whereas the damage is maximum on the boundary with the original model.

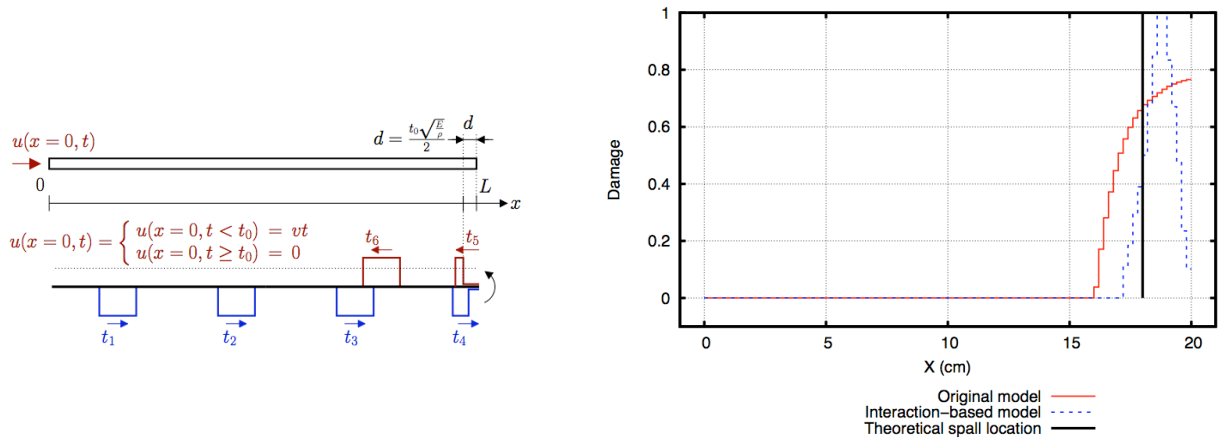

Figure 7. Spalling test: test description, time evolution of the strain amplitude repartition along the rod (left) and damage repartition along the bar after failure (right).

Table 2. Characteristics of the spalling test

Parameter	L	t_0	v	E	ρ	l_c/a_0	ε_{D0}	α_t	A_t	B_t	α_c
Unit	cm	s	cms^{-1}	MPa	kgm^{-3}	cm					
Value	20	4	1,5	1	1	4	1	1	1	2	0

4. Concluding remarks

A new interaction-based non-local formulation has been proposed. In this formulation, the material is modeled as an assembly of inclusions and the elastic interactions upon dilation of each inclusion are computed in a similar ways to a classical Eshelby's problem. A new interaction-based weight function is then built from these interactions. This new interaction-based non-local model has been first validated on simple 1D problems and its performances have been compared with the classical integral-type non-local model.

Different results have been presented in the paper:
(i) In the course of damage, the crack opening displacement has been estimated and the comparisons show that the failure process is better described with the new formulation. Indeed the crack opening profile is very close to an ideal opening profile obtained for a strong discontinuity.
(ii) At complete failure, the crack opening should be independent of the element size. Therefore, after complete failure, the strain in the cracked element should evolve in inverse proportion of the element size, assuming that the crack opening is smeared over the finite element that contains the discontinuous displacement. It has been shown that for the new formulation, the strain versus element size curve follows a linear trend in a logarithmic plot. Moreover the slope is coherent with the CMOD estimated at complete failure.
(iii) Close to a boundary, it has been shown that the spalling failure is better described with the interaction-based model since the spall location is predicted inside the bar whereas the damage is maximum on the boundary with the original model.

Finally, it has been shown that this new interaction-based formulation fulfill several deficiencies of the classical integral-type non-local model and the formulation has to be implemented in 2D in order to test its performance on more challenging issues of quasi-brittle materials failure such as reproducing the peak loads and even the whole softening load-displacement responses of notched and un-notched beams in three-point experimental bending tests [16].

Abstract **Abstract** Thermal barrier coatings (TBCs) are used in hot parts of gas-turbine engines in order to increase gas temperatures and improve thermal efficiency. A TBC consists of a metallic bond coat (BC) and a ceramic top coat (TC).
During high-temperature service, thermally grown oxide will form in the BC/TC interface. This together with the general difference in mechanical and thermal expansion properties leads to a tendency of spalling damage, by which areas of the coating will flake off during thermomechanical cycling.
The modelling of this damage process is rather difficult, but the authors have managed to set up a fracture-mechanically based model, which takes thermal cycling, mechanical cycling and oxide growth into account. The model has been tested and verified under controlled laboratory conditions, using thermal cycling furnaces and continuous inspection of damage development. It has also been used in an FEM computation environment for prediction of TBC spalling in real gas-turbine components.
In this article, the model is described, computations are shown of the development of a typical delamination crack in the BC/TC interface, and the computed results are compared with actual delamination crack behaviour seen in the corresponding testing.

Keywords TBC, fracture-mechanical model, experimental, FEM, interface crack

1. Introduction

A thermal barrier coating (TBC) is a ceramic coating applied for thermal insulation purposes on a metallic substrate.

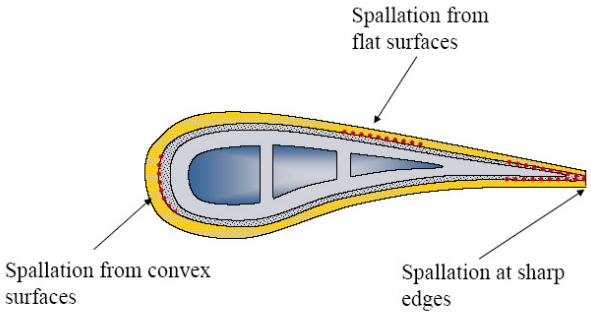

Figure 1. Schematic figure of a TBC-coated gas-turbine blade. Typical spalling mechanisms marked are explained below

Fig. 1 shows a schematic example of a TBC-coated gas-turbine blade. The TBC consists of a substrate (light grey in Fig. 1) on which a metallic bond coat (darker grey in Fig. 1) is applied. On top of the bond coat, finally, the top coat ceramic (yellow in Fig. 1) is applied. The substrate is usually a nickel-based superalloy, the bond coat is an alloy, rich in Al, and the top coat ceramic is usually

ZrO2 with an addition of 6 à 8% Y2O3. . The purpose of the bond coat is to improve the adhesion and to prevent the oxidation by itself forming a dense oxide with as good mechanical properties as possible..

In the typical gas-turbine application, such components will be loaded by the thermomechanical start/stop cycle, *i.e.*, a start, followed by a full-load high-temperature period of from a couple of hours up to several days, finally followed by a shut-down. The design life requirements between inspections for a land-based gas turbine can typically be 3 000 cycles and 30 000 full-load high-temperature hours, after which the TBC must still be functional.

This document deals with air-plasma-sprayed (APS) TBC, which is the type most commonly used in stationary gas turbines.

2. TBC fatigue life

Thermomechanical fatigue (TMF) aspects. Experience shows that with time (and, consequently, accumulated load cycles) TBCs are prone to failing by spalling (flaking). The most dangerous spalling mechanisms have been shown to appear at the end of the shutdown after a long high-temperature full-load period. At the end of the high-temperature full-load period, the stress state in the interface-near region will be low due to high-temperature creep, and as the top coat (ceramic) has a much lower thermal expansion than the metallic layers below, the top coat will be in strong compression at the end of the shut-down (at 'room temperature'). This leads to the three main spalling mechanisms illustrated in Fig. 1.

Of the spalling mechanisms shown in the figure, most research has been concentrated on the explanation and analysis of the spalling from flat surfaces.

TBC life models: history and present status. Early research (see, for instance, [1]) showed that the geometry of the interface (which has a pattern of repeated ridges and valleys caused by the plasma-spray process) leads to tensile stress normal to the interface during the stop cycle of the gas turbine, so that the initiation and growth of cracks in the interface is made possible. Similar analyses on an improved 3-D FE model in [2] confirmed this mechanism. This insight led us to the set-up of a fracture-mechanicallly based life model

3. Fracture-mechanical model of a TBC

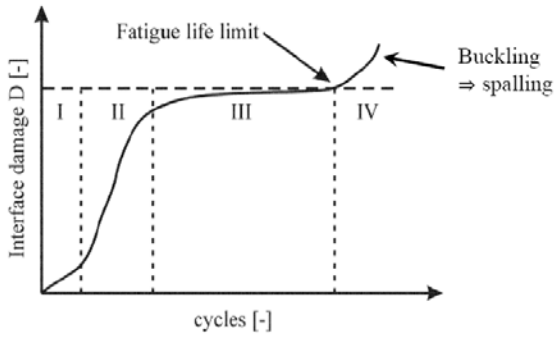

Figure 2. Measured damage evolution in APS TBC

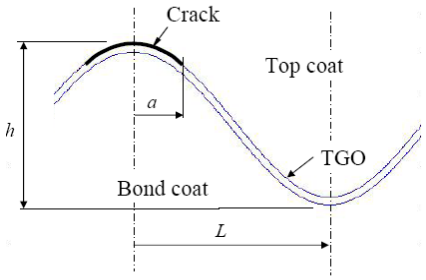

Figure 3. Idealised interface/crack geometry for the FM model

For the fracture-mechanical computations, a least representative cell has been defined, consisting of a substrate+bond coat+TGO+top coat cell, having the width L (= half the period of the idealised cosine wave of Fig. 3). This cell has been given boundary conditions corresponding to symmetry along the left-hand vertical boundary.

The model bases on an idealised (sinusoidal) bond coat (BC)/top coat (TC) interface profile, in which the thermally grown oxide (TGO) is assumed to grow. See Fig. 3. Equal cracks grow symmetrically from all profile tops, *i.e.*, when $D = a/L = 1.0$, cracks extend along the whole interface, leading to complete failure. Further essential model assumptions:

- Plane strain
- Stress-free TBC system at the end of the high-temperature part of the cycle
- The maximum damage-driving energy release rate G and stress intensity factors K_I and K_{II} appear after cooling down from the maximum temperature (low thermal expansion of the TC)
- The material behaviour of all components of the TBC aggregate during the cooling down from maximum temperature is assumed to be linearly elastic

G, K_I and K_{II} are computed by a virtual crack extension method and by interface crack theory (see [3] and appendix)

Fig 4 shows examples of the FE geometry and of the stress pattern in the interface region for 4 typical h/L cases

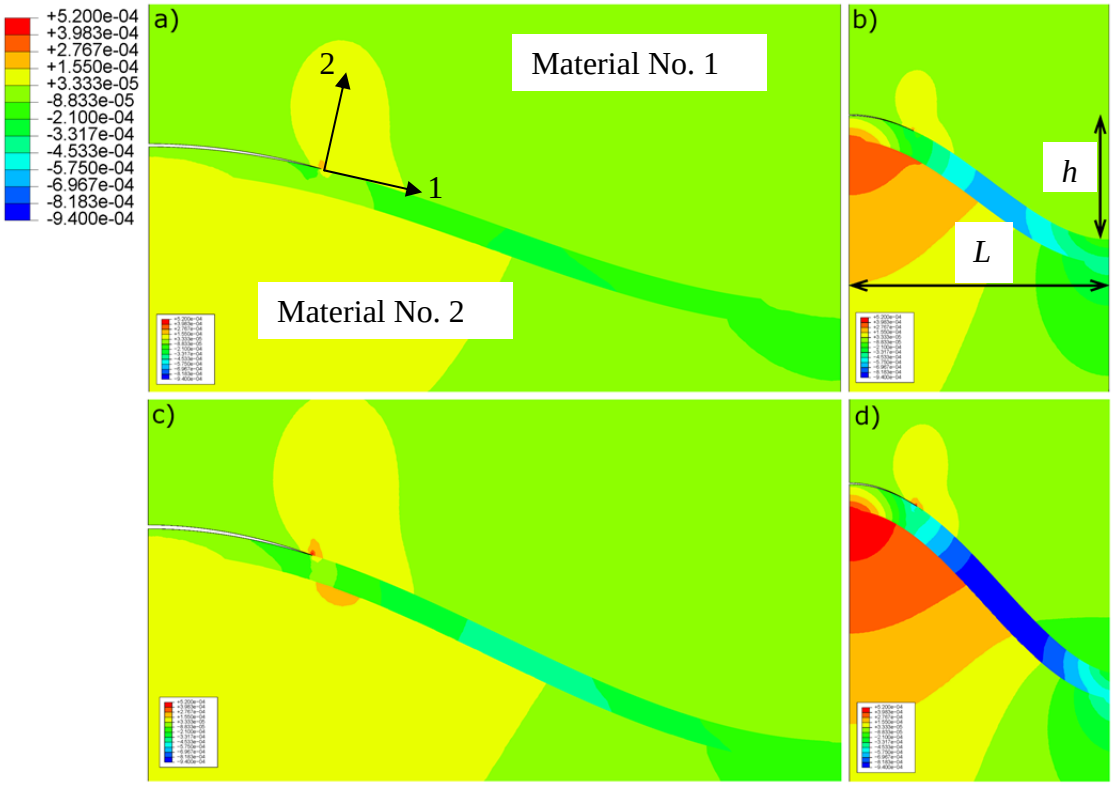

Figure 4. Examples of the FE geometry and of the stress pattern in the interface region for 4 typical *h/L* cases.

Most of the FE computations so far have been done in an in-house code. We have, however, moved over to the commercial code Abaqus for a planned continuation, which will, among other things, in-

volve creep modelling of the bond coat.

G, K_I and K_{II} have been computed for different h/L, different δ_{TGO} and continuously increasing crack lengths corresponding to damage $D_m = a/L$ in the interval $0.0 < D_m < 1.0$. See examples in Fig.5.

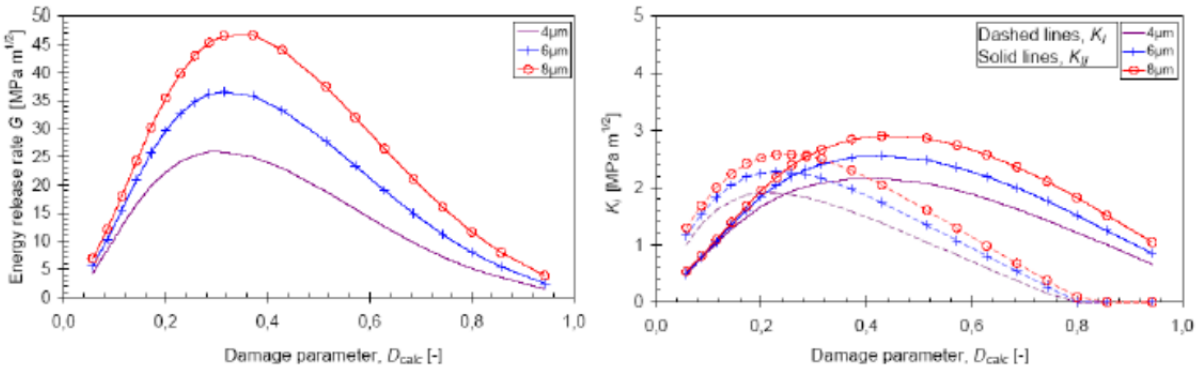

Figure 5. Energy release rate G and stress intensity factors K_I and K_{II} computed for the TCF test.

4. Experimental details

An experimental study has been conducted with the aim at giving quantitative data on crack propagation at a ceramic / metal interface. Evaluations are done on thermally cycled material and material exposed to engine conditions. The coatings evaluated are thin thermal barrier NiCoCrAlY coatings, with nominal thicknesses of top coat equal to 300µm and bond coat thickness of 150µm.

Thermal cycling is performed in air with furnace heating and cooling by forced air. The furnace cycling consists of a standard cycle type where small coupons 30x50x5 mm are exposed to a thermal cycle with 60 minutes dwell time in the furnace at constant temperature. Heating and cooling parts of the cycle are 10 minutes respectively. Data have been retrieved for interrupted tests where the cycling has been stopped after approximately 30% of the expected fatigue. Ex-serviced material has been included with corresponding conditions, i.e. 30-40% of the expected service life.

Coating infiltration by epoxy ensures that the exposed microstructure is retained and that the structure studied is not an artifact after sample preparation. After the epoxy infiltration, the material is cut and mounted for grinding and final polishing. All evaluations are done on as polished cross sections.

Cracks at the top coat / bond coat interface are identified and measured. Measurements are registered for the general microstructure geometry in regions where isolated defects are detected, see Figure 6. In Figure 6 the typical microstructure TBC is shown (a). The interface is undulating and a least representative cell is not easily detected. Instead the morphology of individual undulations needs to be considered (b). The structure is necessarily not similar to the structure observed in the modeling approach (c). In general, the microstructure is assumed to be described with the height over width ratio as defined for modeling purposes.

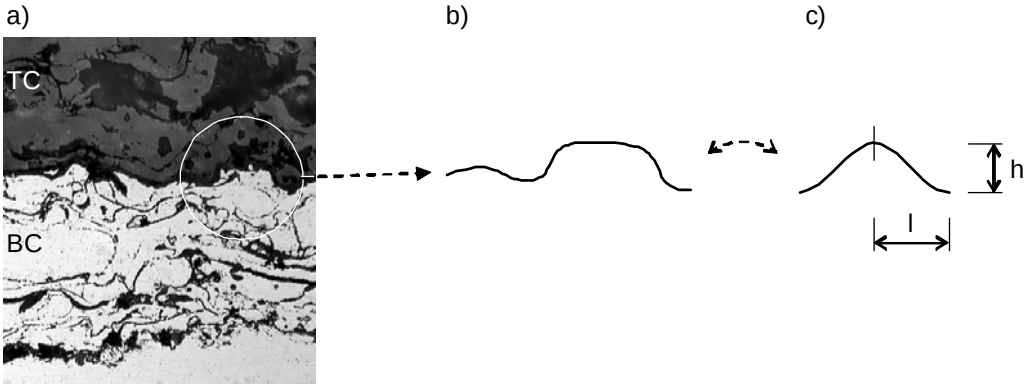

Figure 6. Comparison of interface microstructure / morphology in actual thermal barrier coatings.

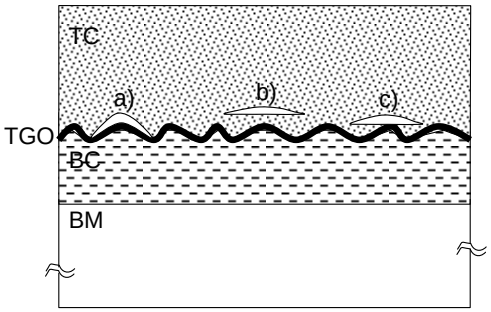

Figure 7. Crack patterns observed in thermal barrier coatings. (a) black interface crack, (b)ceramic white crack and (c) mixed black/white crack with the crack partly at the interface, partly in the top coat.

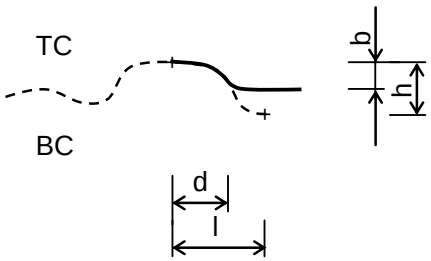

Figure 8. Definition of measurement on deflected kink crack.

Different crack types can theoretically be observed in the ceramic / metal material system. The three typical crack patterns are shown in **Error! Reference source not found.**. The different crack patterns (a), (b) and (c) are identified as black TC/BC interface cracks, white ceramic TC cracks and mixed kink cracks with portions of the crack both at the TC / BC interface as well as portions in the ceramic TC respectively. Cracks of type (c) are contained inside the TGO layer especially if the oxide is formed on an alloy with relatively low Al concentration. In such cases, the oxide is often observed to contain many defects and can be described as layered. During thermal fatigue exposure of the coatings, damages of type (a) are common. Also damage of type (c) is frequently observed after furnace testing and engine exposure. Damage of type (b) is not frequently occurring. This damage pattern is more related to high heat flux situations in burner test rigs and corresponding engine situations with high thermal loads

A schematic picture of the measurements taken is shown in **Error! Reference source not found.**. The measure *d* is defined as the distance from a ridge to the location where a crack deflects away from the interface into the top coat projected on a plane parallel to the interface (and the TBC outer surface). Also the distance vertically (perpendicular) from the ridge to the location of crack deflection is measured, in **Error! Reference source not found.** defined as *b*.

At the location of crack deflection from interface to TC crack the curve shape tangent *dy/dx*, or curve shape first derivative, is measured (a). On the corresponding model, the curvature has been described by a tangent as shown in (b) and (c). The tangent (b) is the slope at the inflexion point

with the highest value of *dy/dx*. This is to be compared to the average *dy/dx* value measured as the measure peak–to–valley over half wavelength, i.e. *h/l.*

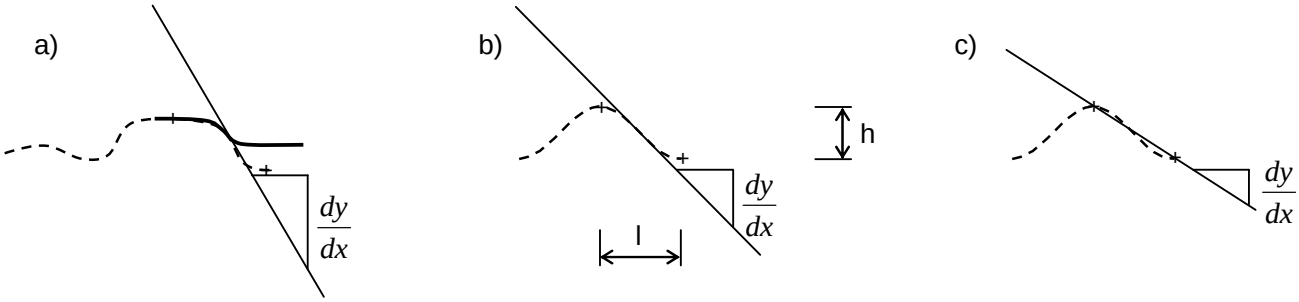

Figure 9. Definition of measurements for determination of angle for crack deflection. Figure (a) represents a real interface, (b) measurement of maximum slope for theoretical sinusoidal interface and (c) measurement of average slope for theoretical sinusoidal interface.

5. Comparison of fracture-mechanical model results and microstructural damage evolution

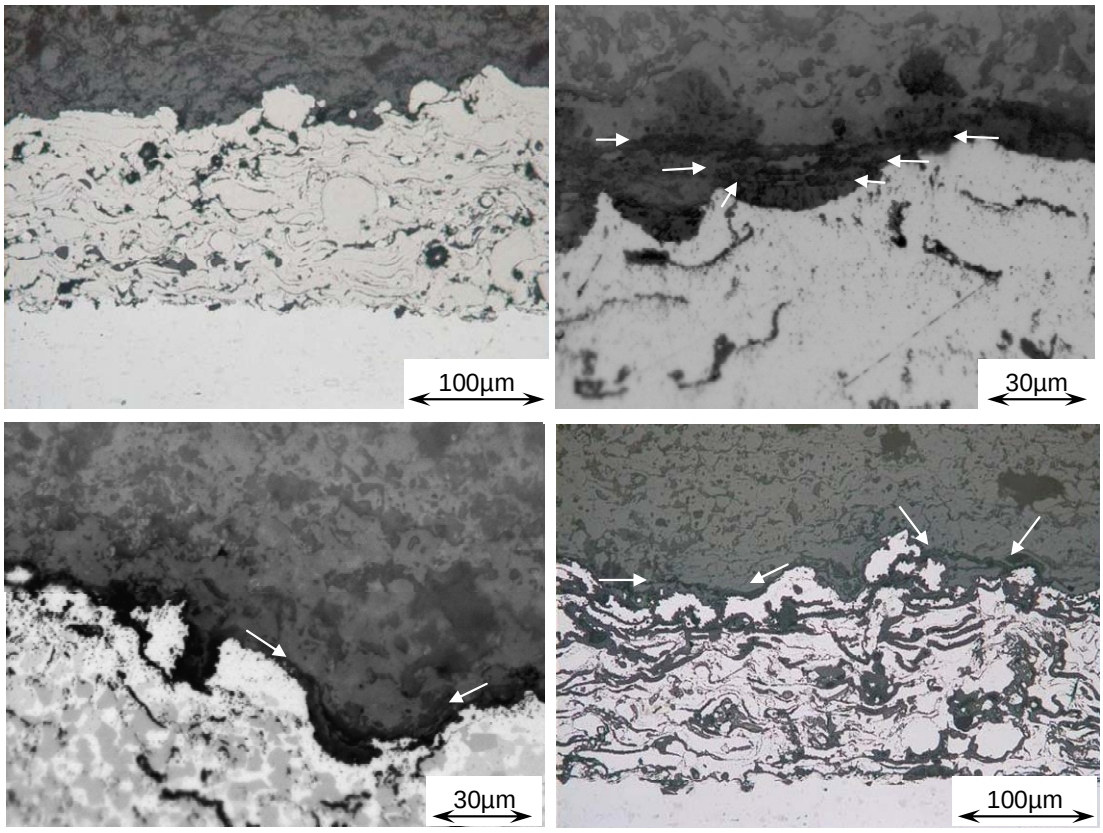

Figure 10. Typical microstructures of virgin (a) and ex-serviced materials (b) – (d). Multiple kink cracks (b) interface crack (c) and kink/white cracks after furnace testing (d).

Examinations of thermally cycled material (furnace and engine exposed) reveal that the material damage is similar. To a large extent the material damage is of interface type (black) but mixed cracking (black/white kink cracks) is frequently detected. Typical microstructures are shown in Figure 10. Image (a) is as manufactured, (b) and (d) indicate mixed (kink) deflected cracks from

furnace-cycled and engine-exposed, respectively. An interface crack formed during furnace cycling is shown in image (c).

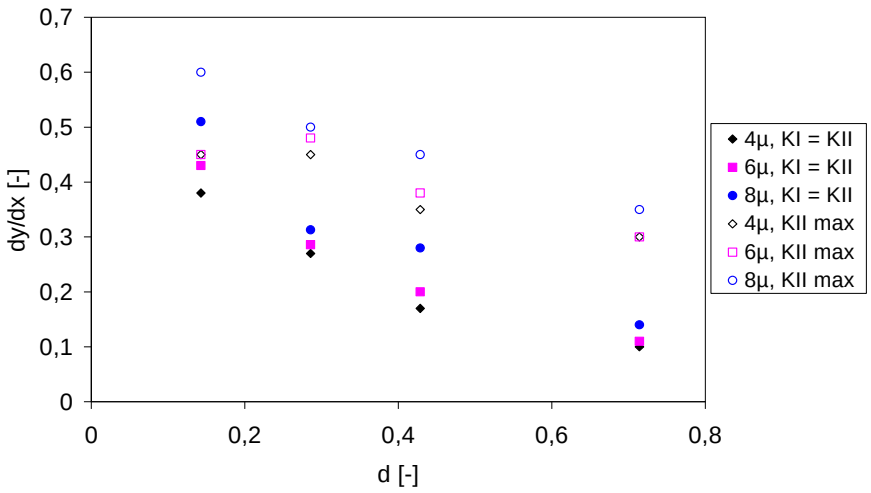

Figure 11. Correlation $dy/dx = f(\mathrm{D}, K_I = K_{II})$ and $D = f(K_{II\ max})$.

From the data in Figure 5 the damage level D for $K_I = K_{II}$ and maximum K_{II} are determined. These data are presented in Figure 11. Data in Figure 11 are for interface roughness 10/70, 20/70, 30/70 and 50/70 µm/µm. Series are included for a range of oxide thickness values.

For individual kink cracks data are collected for peak-to-valley h, half-wavelength l, distance b and d for crack deflection and interface slope dy/dx at location for crack deflection.

Data indicate that the actual location for crack deflection from an interface crack to a deflected kink crack best can be described by a correlation of peak to location for deflection b along the surface normal rather than the projection on a plane parallel to the interface. It is also obvious that the condition for crack deflection best is described by a correlation to the maximum slope of the generalised model interface.

Results according to Figure 13 should be interpreted with the stress state at the interface in mind. For short cracks, the stress state is K_I dominated. As the crack progresses, the stress state will be increased dominated by shear stresses. Considering crack growth in an isotropic material, the general assumption is that a crack growing in a mixed mode stress field will try to grow in the direction that enables growth under a K_I modus. In the case of crack growth at a biomaterial interface, this is not necessarily true. A crack can continue to grow at the interface, if, for instance, the interface acts a weak link. An example of this is the TBC system with a thick thermally grown oxide that acts as a prescribed crack path. In cases where the thermally grown oxide is dense and adherent to the underlying metallic material, the crack should, in principle, be able to deflect away from the interface and into the top coat where crack growth can take place under a K_I dominated stress field. Figure 14 visualises the criterion that can be used to determine when the crack should have possibility to deflect into the top coat. For short cracks and low stress intensities, the crack is confined to the interface. As the crack grows longer and the interface oxidizes, the shear stress increases and the conditions for crack deflection can be fulfilled at $D=D_m$. It is important to notice that not all cracks will deflect. One important factor can be local TGO growth. It is well-known that the oxide thickness is not constant throughout a thermally exposed TBC coating even if the temperature is known and constant over the coating at T_{max}.

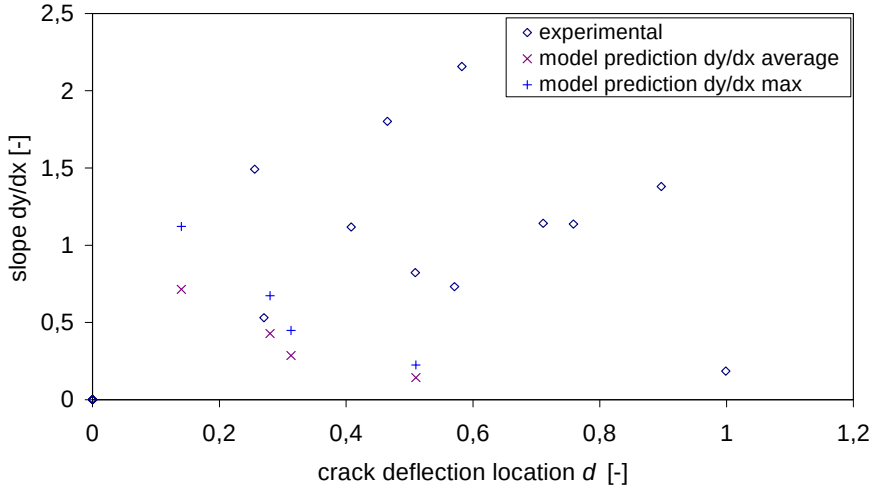

Figure 12. a) Correlation $dy/dx = f(d)$ and $dy/dx_{average} = d(K_I = K_{II})$ for experimental data and model results. b) Correlation $dy/dx = f(d)$ and $dy/dx_{max} = d(K_I = K_{II})$ for experimental data and model results.

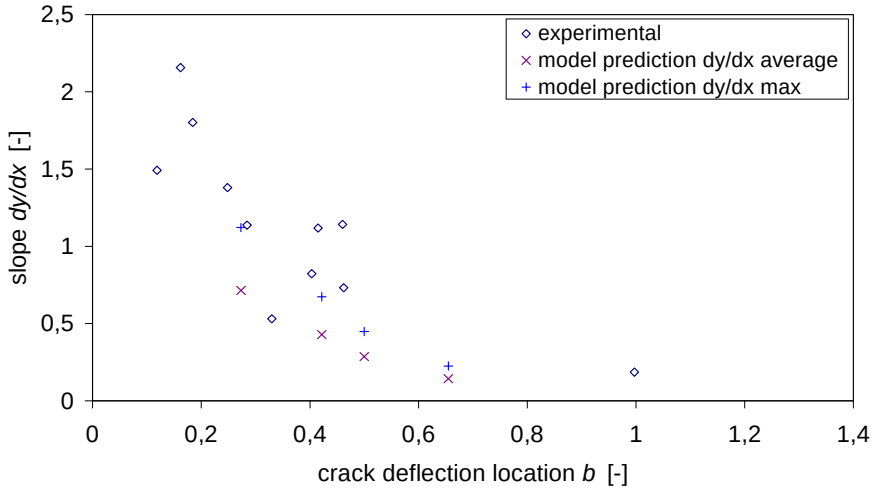

Figure 13. Correlation $dy/dx = f(b)$ and $dy/dx_{average} = b(K_I = K_{II})$ for experimental data and model results. b) Correlation $dy/dx = f(b)$ and $dy/dx_{max} = b(K_I = K_{II})$ for experimental data and model results.

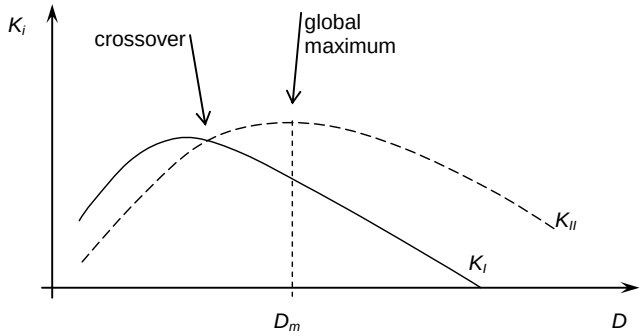

Figure 14. Possible criteria for change from interface crack to kink crack.

To some extent, the model tends to underestimate the slope required for transfer form mixed mode crack growth over to crack growth under a K_I dominated stress state. Hence, it can be argued that the stress state is overestimated at the interface. From these facts the conclusion could be that the

stress state determined by an FE-model is in the correct order of magnitude, and that the location for crack deflection can be described by $K_{II\,MAX}$ correlated to interface slope. However, it is likely that the stress level should be subject to further investigation. If $K_{II\,MAX}$ can be used as a criterion for crack deflection and the model prescribes this phenomenon to occur prematurely, the material response causes stresses to be exaggerated. Factors that can play a role in the mathematical modelling can be top coat stiffness, interface geometry, BC constitutive model, oxidation behaviour and thermal/mechanical load.

6. Conclusions

The current paper compares experimental findings and modelling results coupled to conditions for when a TBC delamination will change from an interface crack to a kink crack contained partly at the interface, partly in the ceramic top coat. It is shown that the condition for change from interface to kink crack can be fulfilled by comparison of interface slope and interface geometry in terms of asperity height. Comparisons indicate that the interface slope plays an important role ad that experimental and modelling results correlate if the distance from peak to deflection point is taken into consideration. In the comparison, modelling results give the best agreement if the location for KII max is chosen as a criterion for when deflection is to be expected.

Appendix: Mechanics of the interface crack

For a description of the theory of an interface crack see, for instance, [3].

From the FE solution, the energy release rate G and the crack flank displacements $u_1^{(u)}$, $u_1^{(l)}$, $u_2^{(u)}$ and $u_2^{(l)}$ at a number of nodes along the crack flank are used. (For definition of materials Nos. 1 and 2 and coordinate directions 1 and 2, see Fig. 4.)
The relation between G, K_I and K_{II} is given by

$$G = \left(\frac{1}{E_1^*} + \frac{1}{E_2^*}\right) \cdot \frac{1}{2\cosh^2(\pi\epsilon)} (K_I^2 + K_{II}^2) \tag{1}$$

in which

$$\epsilon = \frac{1}{2\pi} \ln \frac{\frac{1+\nu_2}{E_2} + \kappa_1 \frac{1+\nu_1}{E_1}}{\kappa_2 \frac{1+\nu_2}{E_2} + \frac{1+\nu_1}{E_1}} \tag{2}$$

$$\kappa_i = \begin{cases} 3 - 4\nu_i \text{ ; plane strain} \\ \dfrac{3-\nu_i}{1+\nu_i} \text{ ; plane stress} \end{cases} ; i = 1,2 \tag{3}$$

$$E_i^* = \begin{cases} \dfrac{E_i}{1-\nu_i^2} \text{ ; plane strain} \\ E_i \text{ ; plane stress} \end{cases} ; i = 1,2 \tag{4}$$

Using the general fracture-mechanical solution for an interface crack, $\delta_1 = u_1^{(u)} - u_1^{(l)}$ and $\delta_2 = u_2^{(u)} - u_2^{(l)}$ (where superscripts *(u)* and *(l)* stand for upper and lower crack flanks, respectively) are then given by

$$\begin{bmatrix}\delta_1 \\ \delta_2\end{bmatrix} = \Psi \cdot \begin{bmatrix}\sin(\epsilon \ln r) - 2\epsilon\cos(\epsilon \ln r) & 2\epsilon \sin(\epsilon \ln r) + \cos(\epsilon \ln r) \\ 2\epsilon \sin(\epsilon \ln r) + \cos(\epsilon \ln r) & -\sin(\epsilon \ln r) + 2\epsilon\cos(\epsilon \ln r)\end{bmatrix}\begin{bmatrix}K_I \\ K_{II}\end{bmatrix} \tag{5}$$

where

$$\Psi = \frac{1}{2}\left(\frac{1}{E_1^*} + \frac{1}{E_2^*}\right) \cdot \frac{8}{(1+4\epsilon^2)\cosh(\pi\epsilon)} \cdot \left(\frac{r}{2\pi}\right)^{\frac{1}{2}} \tag{6}$$

Eq. (6) is only used for establishing an expression for $\beta = K_I/K_{II}$:

$$\beta = \frac{K_I}{K_{II}} = \frac{-[\sin(\epsilon \ln r) - 2\epsilon\cos(\epsilon \ln r)] \cdot \delta_1 - [2\epsilon \sin(\epsilon \ln r) + \cos(\epsilon \ln r)] \cdot \delta_2}{-[2\epsilon \sin(\epsilon \ln r) + \cos(\epsilon \ln r)] \cdot \delta_1 + [\sin(\epsilon \ln r) - 2\epsilon\cos(\epsilon \ln r)] \cdot \delta_2} \tag{7}$$

In order to improve numerical performance, this computation of β is done for a number of positions along the crack, and the average of these is used together with Eq. (1) for the final computation of K_I and K_{II}:

$$\begin{cases} K_I = \sqrt{\dfrac{GH}{1+\dfrac{1}{\beta^2}}} \\ K_{II} = \sqrt{\dfrac{GH}{1+\beta^2}} \end{cases} \tag{8}$$

General laws of multiple fracture at static, cyclic and dynamic loading

Luidmila R. Botvina

Department of SSA, A.A.Baikov Institute of Metallurgy and Materials Science, Russian Academy of Sciences, 119991 Moscow, Russia, botvina@imet.ac.ru

Abstract Multiple fracture patterns of specimens from low - and medium carbon steel tested in conditions of static, dynamic and cyclic loading were studied. Cumulative distributions of microcracks by length under static and cyclic loading, distributions of the number of fragments by their mass under dynamic loading and amplitude distributions of acoustic emission signals were plotted. The parameters of these distributions at different stages of loading were estimated. It was studied the influence of specimen thickness, the distance to the fracture surface, the grain size and the failure mechanism on these parameters. The general laws characterizing multiple fractures at different loading conditions were found. They include, in particular, a change in function describing the distributions and a reduction of the exponents of these functions before fracture. The physical meaning of the estimated distribution parameters, the possibility of their use for the fracture prediction and material selection are discussed.

Keywords Multiple fracture, Damage evolution, General fracture laws

1. Introduction

The fundamental problem of materials science is associated with the need to relate macro characteristics of mechanical behavior of material with parameters of structure and its response to the loading conditions. This response is expressed in the formation of the localized plastic zone with a certain geometry and accumulation of internal damage, characterized by the size and density of microcracks. The evaluation of these parameters by the method of replicas removed from the surface of the polished specimens tested under different types of loading showed that there are some general regularities of the damage accumulation or the multiple fracture at the stage of macrocrack initiation, which will be discussed below.

2. Results of the study

2.1 Two stage of defect growth

Multiple fracture under conditions of irradiation and thermal fatigue [1], was studied using the histograms of the number - size distribution of voids in the aluminum irradiated using different neutron doses [2] and histograms of the distribution of thermal fatigue microcracks in the 06Cr18Ni11steel tested at different number of cycles [3].

Analysis of the cumulative number - size distributions of radiation defects with size of several angstroms in the aluminum [1] showed that these curves corresponding to different neutron doses can be reduced to a single distribution curve by normalization. This demonstrates the self-similarity of the process of accumulation defects at this early stage of their growth [4].

The thermal fatigue microcracks are longer than the radiation voids by several orders of magnitude. Figure 1 shows that the first self-similar stage of defect accumulation is described by an exponential law (the curves 1 – 3, Fig.1, a, b) and the second stage, by a power law (the curves 4 - 5). The exponents in the exponential laws decrease with the number of cycles and are 0.38, 0.17, 0.09 (R^2>0.92), respectively. The distribution curves 4 - 5 corresponding to stage of coalescence of voids are well described by a power law with the exponent 0.91 (R^2=0.98) (Fig.1, b, solid lines).

Thus, there are two stages of accumulation of defects: the first stage of growth of isolated voids

characterized by exponential distribution curves and the stage of accelerated growth due to void coalescence which is described by the power - law function.

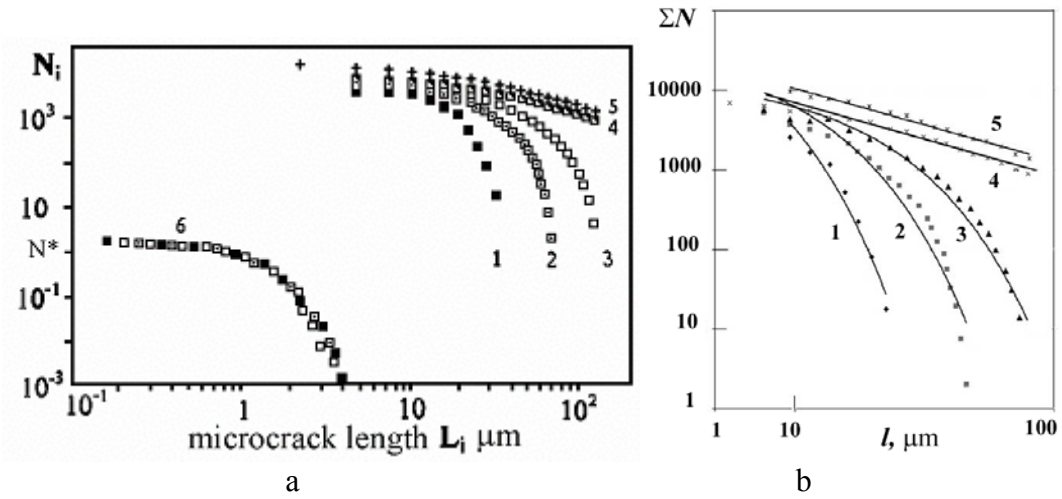

Figure 1. The cumulative number - size distributions of thermal fatigue microcracks in steel X6CrNi181 plotted using initial data [3] on microcrack growth at various numbers of cycles *N*: 2500 (curve 1), 4500 (2), 6500 (3), 11000 (4), 15000 (5). The curve 6 was obtained by normalizing the curves 1 - 3 with respect to the coordinates of their knee points. Solids lines in (b) correspond to the exponential (1-3) and power law (4, 5) relations

We assume that both the initial stages may obey the hypothesis of self-similarity, even though the characters of the laws describing these two stages of damage accumulation are different. It is important to note that the exponents in the exponential functions characterizing the first stage decrease with increasing a number of cycles.

2.2. Distributions of microcracks by their length at static loading

Similar results were obtained by means of analyzing the multiple fracture patterns in plastic zone of notched specimens from low carbon steel [5, 6]. The cumulative length - frequency distributions of microcracks in the plastic zones are shown in Fig. 2, which allows us to observe evolution of the distribution curves over different loading stages. It shows that as the tensile load increases, the change in these curves is similar to the change observed in thermal fatigue.

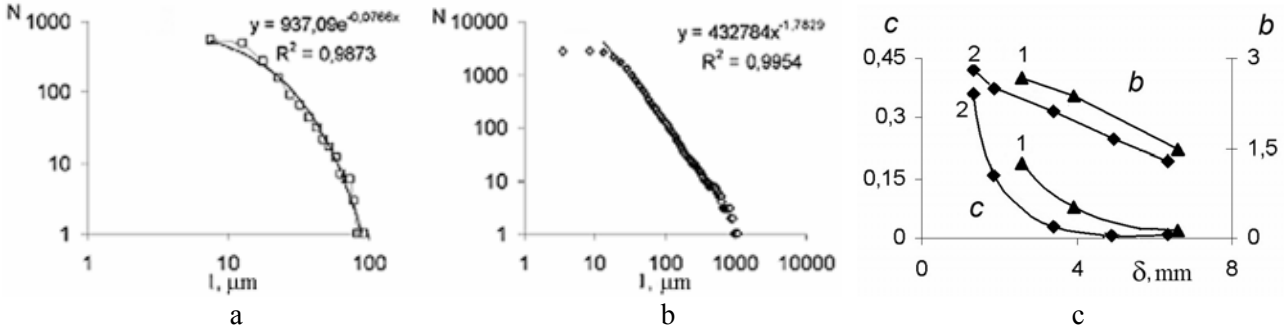

Figure 2. The cumulative distributions of microcracks in notched specimens from low carbon steel at different tension stages (a, b) (the specimen thickness is 6 mm): (a) – δ =2.8, P/P_{gy}=1,7; (b) –δ = 5.2, P/P_{gy} = 2.1, and dependencies (c) of the b - and c - values in the power-law and exponential cumulative number-length distributions of microcracks on the displacement of specimens (1) 16 and (2) 4 mm thick [4]

At the stage of the main crack formation, the exponential law

$$N \sim A \exp(-cl) \quad (1),$$

which describes multiple fracture patterns at the initial loading stage (Figure 2 a) is replaced by the power law

$$N \sim B\, l^{-b} \quad (2)$$

(Fig. 2 b). Both laws are characterized by the respective c and b exponents, whose absolute values decrease with load (Figure 2 c) and the specimen thickness.
An analysis of the amplitude distributions of the acoustic emission signals evaluated during tension has revealed the regularities similar to those, which were observed during tension; these are the change of the type of cumulative functions describing the number-amplitude distributions of signals and the reduction in the exponents of these functions before fracture.

2.3. Distributions of microcracks by their length at cyclic loading

The analysis of the distribution curves of fatigue microcracks in mild steel leads to the conclusion that the change of function describing these curves occurs with increasing a number of cycles (Fig. 3 a) and decreasing a distance from the specimen fracture surface (Fig. 3 b). As in the case of thermal fatigue, the change is accompanied by a reduction of the exponents of these functions.

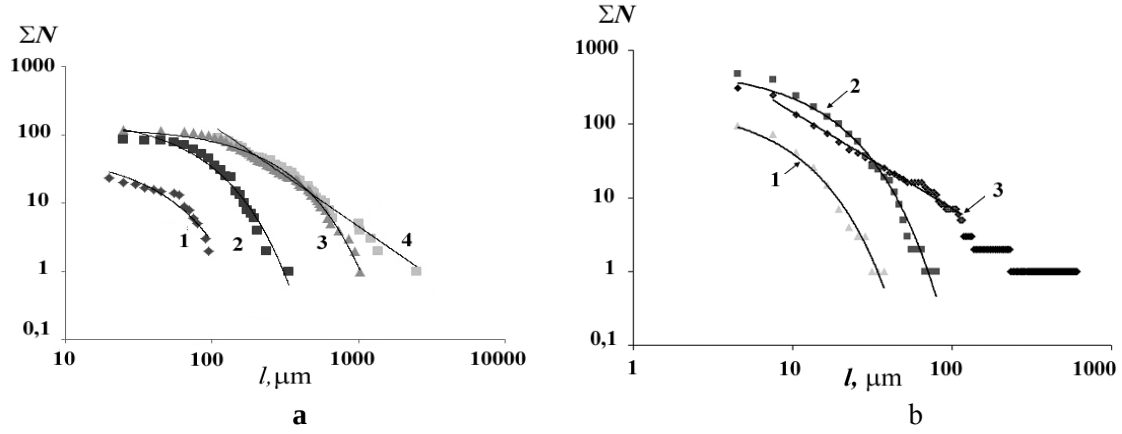

Figure 3. The cumulative distributions of fatigue microcracks in mild steel plotted on the data of Suh et al [7] at different relative number of cycles (a): n/n_f= 0,17 (1), 0,43 (2), 0,87 (3), 0,95 (4) and on data [5, 6] for microcracks located at a distance of 5.39 (1) 2.31 (2) and 0.79 mm from the fracture surface (b). Solid lines obey the exponential (a-curves 1-3, and b -1, 2) and power- law functions (a- curve 4, b- curve 3)

2.4. Distributions of fragments by their mass at dynamic loading

The similar conclusion was also made in studying the dynamic fracture [8, 9] (Fig. 4). The data presented in the Figure 4 show, firstly, that the number - mass distributions of fragments of shells made of brittle and ductile steels may be described by a simple exponential function:

$$\sum N \sim N_O \exp(-m/m_o) \quad (3),$$

and, as is seen from Fig. 4 b, the fragment distributions for the ductile material approach the power law N - m dependence. Secondly, the exponents of these distributions ($1/m_o$) are determined by the

mechanical properties of the fragment material and, in particular, by impact toughness of material in initial state (Fig. 4 c).

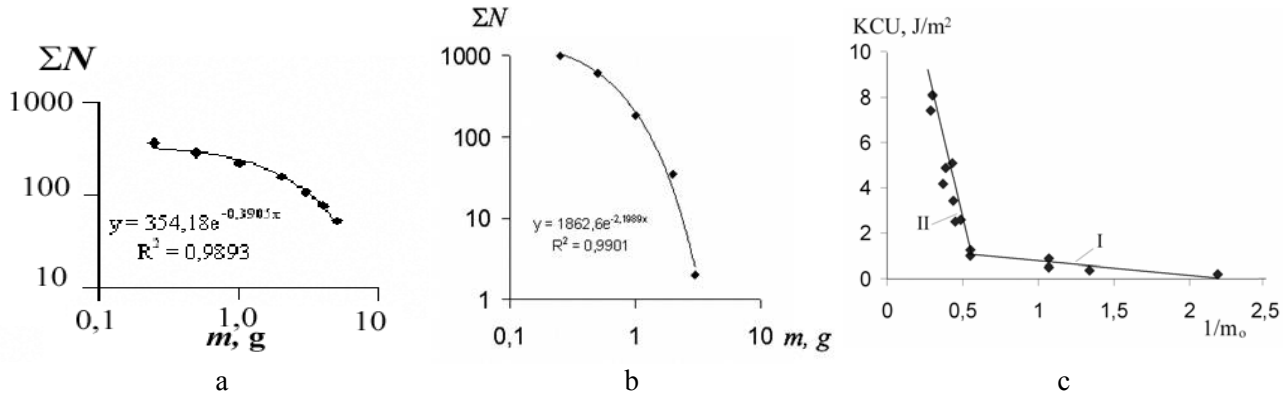

Figure 4. Cumulative number-mass distributions of shell fragments from brittle (a) and ductile (b) carbon steels, and dependence of impact toughness of the brittle (I) and ductile (II) steels on the exponents in the exponential relations describing distributions of fragments (c)

2.5. Concentration criterion of defects

At different stages of tension and fatigue, the average length of the microcracks L_{av}, their density n, fraction of the damages ω, and the values of concentration criterion k suggested in [10] and estimated by the relation

$$k = n^{-1/2} / L_{av} \tag{4}$$

were evaluated. It allowed to find that the transition from the exponential to the power - law relation with development of damage accumulation process is accompanied by reduction of the concentration criterion related to the coalescence of microcracks in the plastic deformation zone.

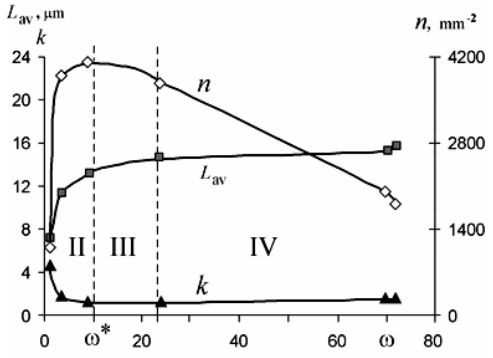

Fig. 5. Dependences of the average length (L_{av}), density of microcracks (n) and the concentration criterion (k) on the relative fraction of damages (ω) at the different loading stages of damage development (II, III, IV) (at the stage I plastic zone forms)

Four stages of the damage accumulation were found. At the first (I) stage, in the notch tip of specimen, slip bands appear and plastic zone is formed (before approaching the yield strength); at the second stage (II), the formation and the accumulation of the microcracks occur. Interaction of microcracks at the third stage (III) leads to their coalescence and initiation of macrocrack. At the fourth stage (IV), the main crack appears in a secondary plastic zone in its tip; the area of the

damaged surface grows as a result of the opening of microcracks. The development of the main crack leads to the complete fracture. Changes of the damage parameters at the observed stages of multiple fracture are shown in Fig. 5. It follows from the graphs that the critical situation appears at reaching the area of damages (ω*) close to 10%, when the microcrack opening increases, density of defects decreases as a result of their coalescence, and concentration criterion falls to the constant value (k~1.5). The value of ω*=10% is close to the threshold of percolation for many systems; therefore, changes at the third stage precede the critical event (specimen fracture). With reaching ω*, the exponential relation, which describes the cumulative distributions of microcracks and acoustic emission signals, becomes close to the power relation, and exponents in these relations reduce.

2.6. Activation energy of fracture process

An analysis of the established regularities of changes in exponents of the functions describing the statistical distributions allows us to connect them with a change in another important parameter of kinetic process, namely, in the activation energy of fracture.

According to Arrhenius – Zhurkov equation of [11], the lifetime (t) of solids is the function of the activation energy of fracture process $U(\sigma)$, the absolute temperature T, the energy of a thermal motion R and obeys the exponential relation:

$$t = t_0 \exp\left[\frac{U_0 - U(\sigma)}{RT}\right] \tag{5}$$

This relation may be obtained from a correlation $\lg t = \lg t_0 + b(\sigma)/T$, where $b(\sigma)$ is the slope of dependence $\lg t - 1/T$, $b(\sigma) = b = \Delta(\lg t)/\Delta(1/T)$,

or $t = t_0 \exp(\beta/T)$, where $\beta = 2.3b$.

Multiplying the numerator and denominator of the exponential function index by the Boltzmann constant and denoting $k\beta = U$ leads to (Eq. 5).

Thus, the activation energy is evaluated on the slope coefficient b of creep curves plotted in semi logarithmic coordinates [12]. The stress dependence of the activation energy of fracture of polymethylmethacrylate, which was plotted using these data [13], showed that the activation energy decreases with increasing the stress and the stress dependence of activation energy corresponds to the exponential relation with the exponent equal to 0.02 and R^2=0.98. Similar decrease of the slope coefficient with increasing the load or specimen displacement is presented in Fig. 2 c.

The activation energy of solids is traditionally related (by the analogy with that of chemical reactions) to the energy given for the overcoming of inter-atomic interaction by thermal fluctuations. Although the fracture process in the whole is determined by the strength of atomic bonds in the region of fracture localization, this approval calls for the special confirmation. Indeed, the slope coefficient of strength dependencies obtained for laboratory specimens is the macroscopic parameter revealing the kinetics of initiation and accumulation of microcracks and growth of a macrocrack. These processes are connected to changes in the fracture process zone size and damage accumulation in this zone. Therefore, the decrease in the activation energy with increasing stress may be a consequence of considered above regularities of damage accumulation in the fracture process zone that are due to the interaction of defects resulting in a decrease in the slope coefficients of statistical distributions. This assumption is confirmed by an analysis performed in [6, 13], which showed an interrelationship between the activation energy and exponents in power law equations characterizing the fracture development, namely, in both the Paris relation and the equation based on the phase transition theory.

3. Summary

The patterns of multiple fractures in carbon steel specimens at different stages of tension, cyclic and dynamic loading were studied; characteristics of damage accumulation were estimated and the cumulative distributions of microcracks and shell fragments were plotted. Analysis of damage accumulation process with the use of mechanical and physical methods allows us to establish some general laws characterizing this process on different stages. They include, in particular, the following.

- Distributions of microcracks under static and cyclic loading and amplitude distributions of acoustic emission signals measured during static loading are described by an exponential function at the initial stage of fracture and a power –law one at the final stage of fracture.
- Cumulative number-mass distributions of the shell fragments obey the exponential relations with the slope coefficients, which decrease for the brittle materials.
- There is a quantitative relationships of the exponents of functions approximating the distributions with material properties and loading parameters.
- Parameters of the cumulative distributions of microcracks and amplitude distributions of acoustic emission signals, as well as the concentration criterion are reduced at the stage of pre-fracture and can serve as diagnostic signs of the approaching fracture.

Abstract Cast irons' position as an important engineering material is un-disputed. They are widely used in many important industrial applications such as the automotives and workshop machinery. Nevertheless, fracture mechanisms in cast irons are not fully understood. In this study the fracture path and non-linear elastic behaviour of a fully pearlitic flake cast iron under uniaxial tensile loading have been investigated in a Scanning Electron Microscope (SEM) equipped with an Electron Backscattering Diffraction (EBSD) detector. The tensile load was applied via a specially made sample stage. Under uniaxial tensile loading the graphite flakes act as notches or cracks and therefore the fracture process starts at one or many graphite tips. The crack can propagate in many different ways, at the graphite and matrix interface, through the graphite, at the interface between cementite and ferrite or through the pearlitic grains. At the point where the stress strain curve deviates from its linear path plastic deformation at graphite tips can be noticed. Interface cracking between graphite and the matrix also starts at this point.

Keywords in-situ SEM, deformation, fracture, flake cast iron, EBSD

1. Introduction

Flake cast iron exhibits brittle failure under tension loading. Due to its many graphite tips acting as notches or small cracks they are considered to be initiation points for cracks in the material. The common knowledge on how cracks propagates in flake cast irons is that the crack initiation point is one or several of the many graphite tips, from the tips the crack propagates along the graphite flakes in the graphite-matrix interface. At strains just before break down, the crack propagates through the matrix and connecting graphite tips.

In a work done by Diószegi at al [1] the crack path was found to be through eutectic cells and along the graphite flakes. Depending on cooling condition the main crack path varied so to propagate along dendrites.

The mechanisms explaining the non-linear stress-strain curve founded for flake cast irons involves a small plastic zone at graphite tips [2]. A typical stress-strain curve for a flake cast iron with σ_{UTS} of 290 MPa can be seen in Figure 3. As can be seen there is a small portion when the curve is straight linear; according to literature the explanation for this linear part is the atomic bonds and the interface forces between the graphite and the matrix [3, 4]. Plastic deformation at graphite tips and separation between graphite and matrix seems to be an excepted description what happens in the material when the stress-strain curve starts to deviate from its linear path during tensile loading [4].

An electron backscatter detector (EBSD) uses kikuchi patterns and a database to identify crystal structure and crystallographic orientation. Especially grain lattice orientation and grain size is commonly determined with this technique [5-10]. Texture analysis of metallic material using EBSD is a commonly usages of this technique [8, 10-11]. Strain variations in each grain near the machined surface give vital information on damages from machining processes [12]. From distribution and amount of low angle grain boundaries (LAGB) in the material, strain variations from external forces as well as from the solidification process can gathered. In a work done by Bjerkaas at al. on an AlMgSi alloy the benefits of this technique (EBSD) shows that grain lattice orientation during

tensile testing depends much on originally un-tested grain orientation, so different slip systems becomes active depending on grain orientation [6].

Several different research groups have performed tensile in-situ scanning electron microscope (SEM) investigations, studying microstructural changes and deformation and/or fracture mechanisms on different materials [6, 10, 13-15]. From their experiments one can conclude that in-situ SEM investigations can give very accurate information about microstructural changes due to external forces. Some of the recent works in this field have also performed EBSD to analyse the microstructural changes, e.g. grain orientation and grain reorientation, due to loading.

In this study the crack initiation point(s) and crack propagation in a grey cast iron where studied during axial loading in a SEM. Thanks to a specially designed stage mounted to the SEM, in-situ analysis of the crack initiation and its propagation as well as crystallographic changes were detected with EBSD and analysed. The microstructural features associated with different proportions of the stress-strain curve were investigated and explained.

2. Experimental details

The flake cast iron had a fully pearlitic matrix and the composition of the material used is listed in Table 1 below.

Table 1. Nominal composition of flake cast iron used

Element	C	Si	Mn	P	S	Cu	Cr	Mo	Fe
Wt %	3.1	1.8	0.65	<0.08	0.12	0.90	0.14	0.25	Bal.

The samples were cut out to a thickness of 1.0 mm from an as-cast cylinder head, using an electronic discharge wire to minimize the effects of surface hardening and residual stresses. On one side of the sample a notch was cut out with a total depth of 1.0 mm and a notch root radius of 0.25 mm. Both sides of the samples were carefully grinded and one side future prepared for EBSD analysis. On the rougher side of the sample a strain gauge were attached to enhance the accuracy of the actual loading when inside the SEM. Due to the brittleness of flake cast iron and the small elongation before rapture, some points on the stress strain curve in vacuum could then be conducted. Strain gauge signals were transmitted through pins on the stage specially designed for signal transmission from the vacuum chamber.

The samples were investigated at loadings of approximately 0 MPa, 50 MPa, 90 MPa, 140 MPa, 200 MPa and 250 MPa. EBSD mapping with a step size of 0.3 µm and SE images on each loading were performed in a Hitachi SU-70 FEG-SEM equipped with an OXFORD Electron Backscatter Diffraction system with HKL software. Due to contamination of the surface (carbon diffusion from the material when the electron beam hits the sample) from the EBSD analysis two different locations were used.

In all the figures the loading axis is in the horizontal plane, excluding Figure 3 and Figure 7.

3. Results

The un-tested material shows a great amount of LAGB, Figure 1c display the frequency distribution of LAGB and grain boundaries (GB). Revealing that LAGB of 2-3° is most common and that GB most commonly have angels around 30° and 60°. Figure 1b also reveals where the LAGB and GB are located; the most common LAGB is represented as red line and is randomly distributed in the microstructure. This resulted in two different LAGB intervals in this analysis to increase the detectability of LAGB changes. They are denoted as type I (2-6 °, red lines) and type II (6-12 °, green lines) LAGB respectively.

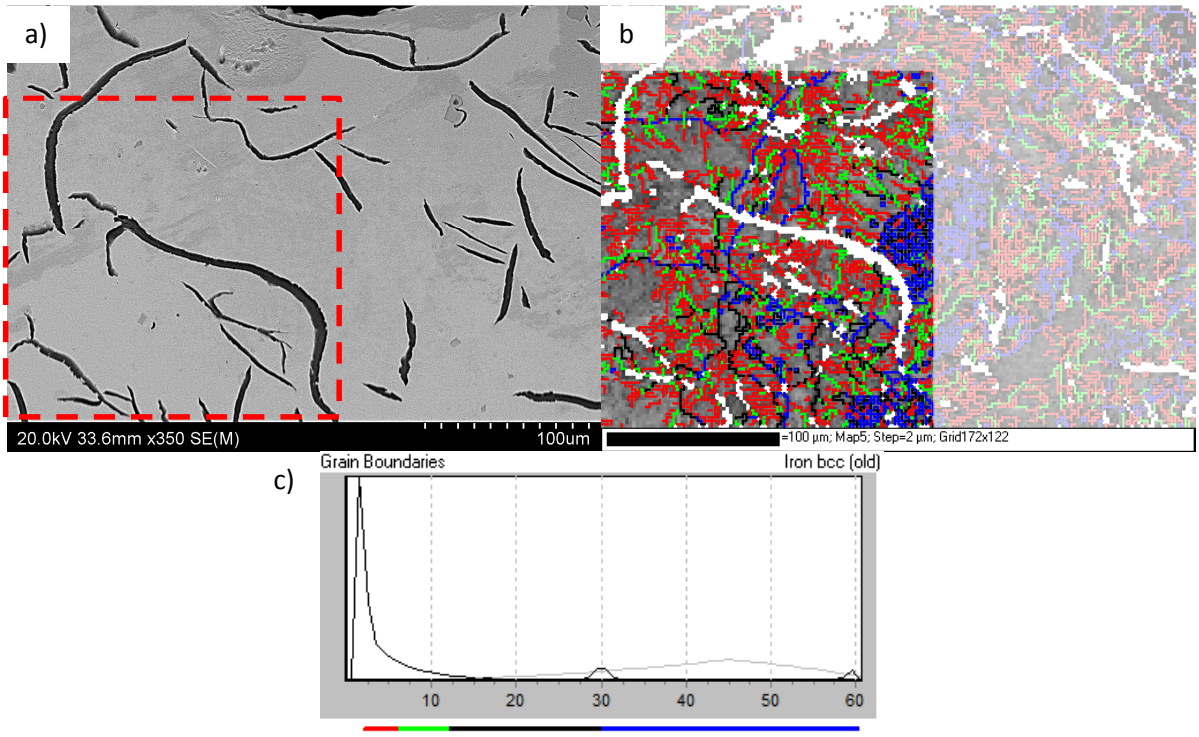

Figure 1. Display a) SE-picture with red marked EBSD-analysis area, b) EBSD-map showing band slope and the distribution of LAGB and grain boundaries (GB) and c) the grain boundary legend shows the colour of corresponding angle [°] and the frequency distribution of LAGB and GB. Zero solution is marked white.

In Figure 2 the LAGB distribution can be seen when a force corresponding to 200 MPa is applied. In Figure 2a graphite flakes have become larger due to internal cracking and matrix-graphite interface delamination, despite this the LAGB:s is unchanged.

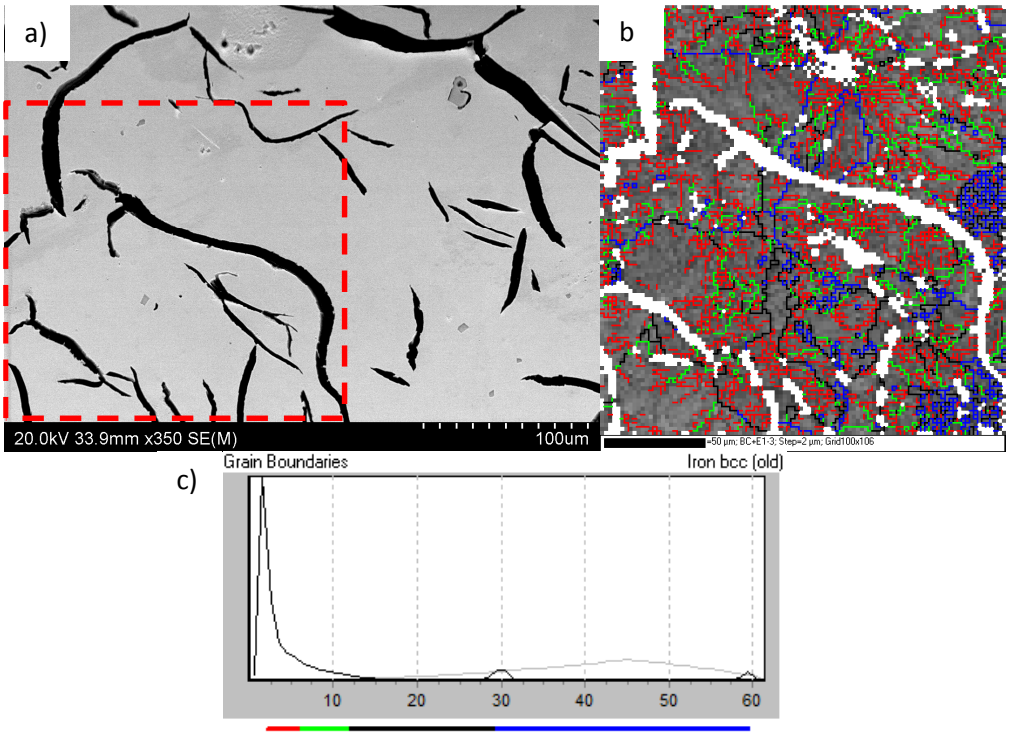

Figure 2. Display a) SE-picture with red dots marking the area of EBSD-analysis, b) EBSD-map showing band slope and the distribution of LAGB and grain boundaries (GB) and c) the grain boundary legend shows the colour of corresponding angle [°] and the frequency distribution of LAGB and GB. Zero solution is marked white.

The pure linear elastic part of a typical stress-strain curve for a flake graphite iron can related to the small tensile load that the graphite can withstand without microscopic yielding [16, 17] and the atomic forces. In this region the SE images did not revile any changes in the microstructure in neither the matrix nor the graphite. Also the EBSD mapping looks the same as in the un-stressed case, no statistical significant changes were found.

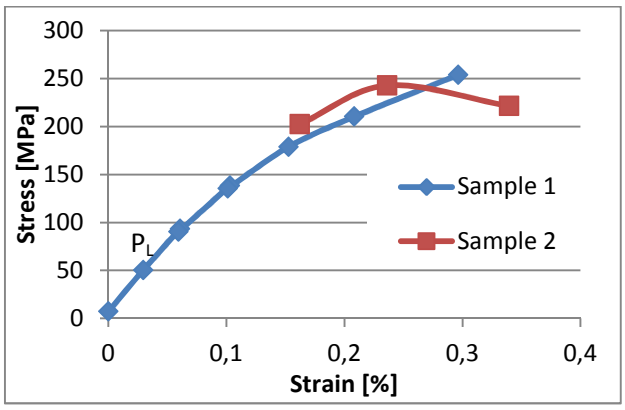

Figure 3. Obtained stress-strain curve from the experiment.

What then can be seen in SE-images, see Figure 2, when the applied load is slightly more than the critical value $P_{L;}$ (were the stress-strain curve starts to deviate from its linear path) the flaky graphite tends to open in the middle and a void appears inside. This phenomenon can be seen and detected in graphite orientated both perpendicular and parallel to the loading axis at loading levels above P_L ,

see Figure 3. At this stage the changes in the matrix is still too small to be detected with the set-up used.

When increasing the load, ($P>P_L$) the interface between the flaky graphite and the matrix starts to separate at several places in the material, mostly graphite flakes oriented perpendicular to the load shows this phenomenon. Still the cracks/voids earlier founded inside the flaky graphite opens more independent of the graphite's orientation, but the degree of opening is more evidence in graphite perpendicular to the load axis. The pearlitic matrix also starts to undergo microplasticity at several graphite tips, the matrix undergo local plastically deformation which can be seen in Figure 4 and Figure 5.

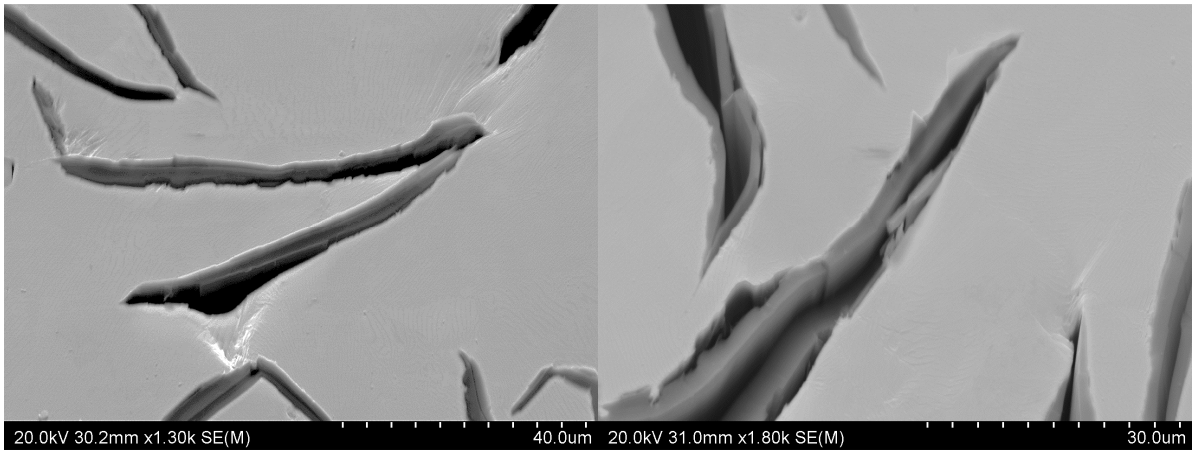

Figure 4. Plastic deformation at graphite tips and a bulge is evidence in the left picture. To the right multiple cracking with crack path both inside the graphite and at the graphite-matrix interface can be seen.

The delamination of the graphite-matrix interface is easy to identify and when increasing the load even more, above 200 MPa, small bulges in the separated graphite-matrix interface is evidence of the weakest pearlite, see Figure 4. Here at these bulges the matrix limited plasticity results in a crack path when the load is increased even more, local necking in the matrix.

At loads above $\sigma_{ys0.2\%}$ the crack also finds its way through the matrix in the ferrite-cementite interface as can be seen in Figure 5 below.

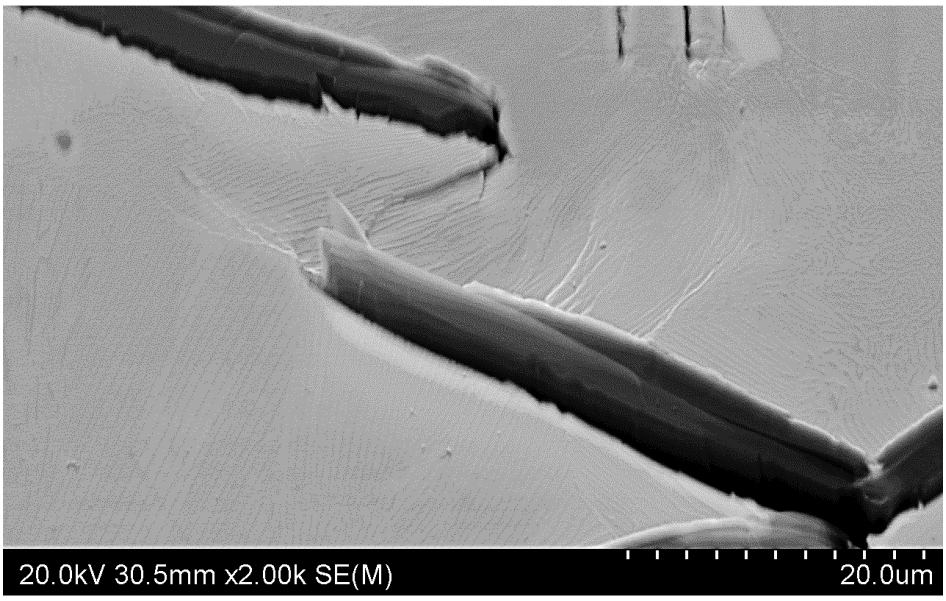

Figure 5. Cracking in the ferrite-cementite interface between two graphite tips.

At stresses above $\sigma_{ys0.2\%}$ the phenomenon of multiple cracking is also evident in the material, showing the complexity of the fracture behaviour of the material. In Figure 6 below this phenomenon can easily be seen in the left picture. The right picture is zoomed out from the left showing obviously multiple cracking.

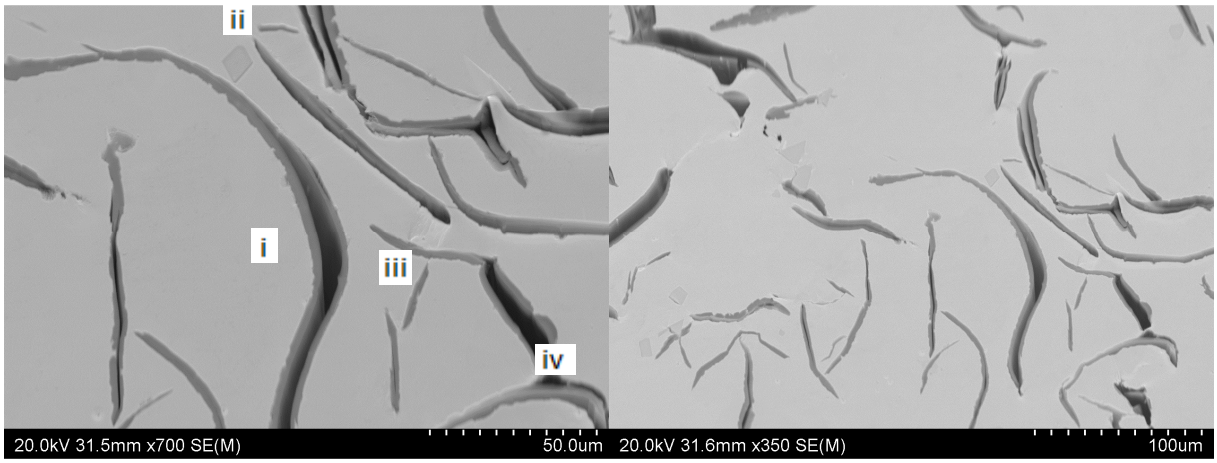

Figure 6. Showing voids inside graphite flakes (i), delamination of the graphite-matrix interface (ii), plastic deformation at graphite tips (iii) and a bulge (iv).

Fractorgraphy revealed that both ductile-like and cleavage-like fracture is present in flake cast iron. Near the notch almost all pearlite grains showed evidence of ductile crack surface, whereas the opposite side of the sample showed mainly river-pattern in the cracked pearlite associated with cleavage fracture. In Figure 7 below both these features can be seen along with a part of a graphite flake.

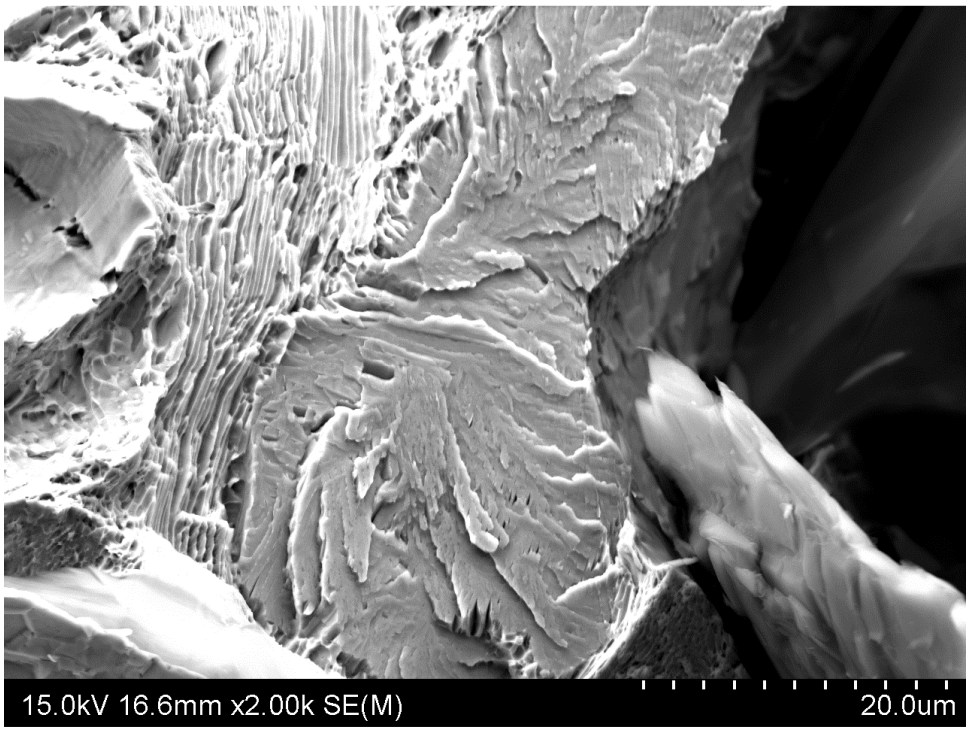

Figure 7. Fracture surface showing features associated with both ductile and brittle fracture in the pearlite matrix. On the right side a part of a graphite flake is seen.

4. Discussion

Even though pearlitic flake cast iron is widely used and is an important engineering material the knowledge on its fracture behaviour and the deformation due to axial loading is still very limited. One of the main goals with this research was to gain deeper knowledge on the deformation and fracture behaviour of a pearlitic flake cast iron. The use of the special designed stage in the SEM together with EBSD analysis can give a unique insight in the deformation and fracture behaviour of the material studied. In this study the amount of pre-existing LAGB's made the analysis of their changes due to loading very difficult and no clear effects where shown. The great amount of LAGB's detected is an effect of the solidification process and the material used had not been stress-relived. The heat treatment should decrease the amount of LAGB's once the internal thermal residual stresses from the solidification process minimizes. One aim with this study was to investigate the LAGB changes and the grain orientation due to axial loading and from these results no changes were detected.

The deformation of a flake cast iron under axial loading can be divided into several different main events. First deformation detected in the material was the development of voids inside graphite flakes. This material deformation was detected at loads as low as 50 MPa and the strength of the weakest slip plane in the graphite is approximately 40 Mpa which then makes the fact that it separates at 50 Mpa very understandable. With compressive residual stresses presence at the surface this deformation would not be seen at this load-level and thanks to careful polishing this effect could be discovered. Interesting to see is that when increasing the load these voids can be found in graphite flakes independent of its orientation to the load axis. Delamination of the graphite-matrix interface was the second kind of deformation detected in the material. This deformation requires slightly more applied load and a suggested explanation for this is that the interface forces between the two phases is just greater than the weakest slip plane in the graphite. By looking at the stress strain curve seen in Figure 3 one can see that curve deviates from its linear path at stresses between 50 and 90 Mpa and it is proposed by the authors that this is an effect of both the delamination of the graphite-matrix interface and the presence of voids inside the graphite flakes. These effects are also responsible in the change of Young´s modulus as seen in for flake cast iron subjected to cyclic loading, less elastic deformation is possible for this multi-phased material. Plastic deformation at graphite tips was the third permanent deformation detected in the material. Loads generating stresses in the magnitude of 140 Mpa and more results in plastic deformation at graphite tips. With increasing load the size of the plastic zone is increased and also amount of plastic deformation around graphite tips increases with increasing load. This is expected to be seen but not that the sizes of voids inside graphite flakes to decrease for those voids lying a bit away from the real crack path. Obviously some kind of stress relaxation occurs in the material when the pearlite starts to hardens due to the plastic deformation at the graphite tips. The last type of deformation detected was the development of bulges just before rapture, as a consequence of stress concentrations at the graphite. When study the final fracture it was then evident that the crack path had been via these bulges. The plastic deformation at these bulges is severe and a phenomenon of local necking is present.

Fracture behaviour becomes more and more complex as the applied load increases and several distinct features acting simultaneously resulting in final failure. The graphite tips acts as notches and clearly the plastic deformation at the tips indicates where the crack later will propagate. Due to multiple cracking not every graphite flake with local plastic deformation at the tip will be a part of the final cracking. Fractography reviled a ductile fracture where the bulges earlier had been detected leading to the conclusion that severe plastic deformation at the tips results in the ductile-like fracture found in the material.

Not every graphite flake that opens inside contributes to the final crack but once they have opened it affects the mechanical properties of the cast iron. It has been identified in this investigation that the first fracture observed in the material actually occurs inside the graphite flakes followed by delamination of the graphite-matrix interface. The non-linear elastic behaviour and the decrease in Young´s modulus observed in flake cast iron is proposed by the authors to a result of these two permanent deformation phenomenon´s in the material.

5. Conclusions

The fracture behaviour of flake cast iron can be summarized in a few steps of main events. The first noticeable microstructural feature due to the axial loading is the opening of graphite. Graphite flakes opens inside the flakes and this feature can be found in graphite flakes independent of its orientation to the applied load. As a second important and noticeable event is the delamination of the graphite-matrix interface. Parallel to this event one can see that the graphite that had opened inside opens even more. The third crack feature is the local plasticity at graphite tips laying perpendicular to the loading. Fourth and last important feature is the bulge of the matrix at the delaminated interface, where the crack later will propagate. Some of the graphite with an opening inside had also generated a delamination of the graphite-matrix interface. Development of bulges start once the plastic deformation at graphite tips is evidence but stresses close to and above $\sigma_{ys0.2\%}$ is needed to clarifying that a bulge is developed and not just local plastic deformation. At applied loadings just before rapture the fracture behaviour of flake cast iron results in multiple cracking, which makes it possible for the main crack to “jump” relatively large distances due to the network of flaky graphite. The weakest points in the sample will then link together which results in a rough topography of the fracture surface. As a final occurrence of fracture behaviour in flake cast iron subjected to axial loading the crack propagates in one of the following alternatives:

- Through the opening inside the graphite.
- Through the delaminated interface.
- Via the closest distance between graphite tips where the local plastic deformation results in a ductile-like fracture appearance.
- At the pearlitic grain boundaries leaving a ductile-like fracture.
- Straightforward through the matrix resulting in a cleavage fracture.
- Along the ferrite-cementite interface giving cleavage fracture.

Grain orientation and changes of LAGB’s in flake cast iron due to axial loading is very small, if existing, the relative fine step-size used could not show any differences. Fractography give instant insight why the crack propagated to the right in Figure 1 and not on the left side as large graphite flakes where located just below the surface to the right and not to the left. Analyse of the fractured surface revealed both ductile and cleavage fracture and an increase in fracture topology where multiple cracks was easily detected.

Abstract

A multi-scale damage percolation model has been developed to predict fracture in advanced materials with heterogeneous particle distributions. The percolation model was implemented into a commercial finite-element code using so-called "percolation elements" to capture the complex stress- and strain-gradients that develop within the microstructure during deformation. In this approach, fracture is predicted as a direct consequence of the stress state, material properties and local conditions within the microstructure. Void nucleation, growth and coalescence models are applied for ellipsoidal voids subjected to general loading conditions. A novel void nucleation rule is employed for particle cracking based upon the particle morphology and stress state. A particle field generator has been implemented into the percolation software to generate representative particle fields based upon the field statistics obtained using x-ray micro-tomography. The percolation model was validated numerically and experimentally for an automotive-grade aluminum alloy in a notched tensile test used for material characterization.

Keywords: Void, Particle, Nucleation, Coalescence, Multi-scale

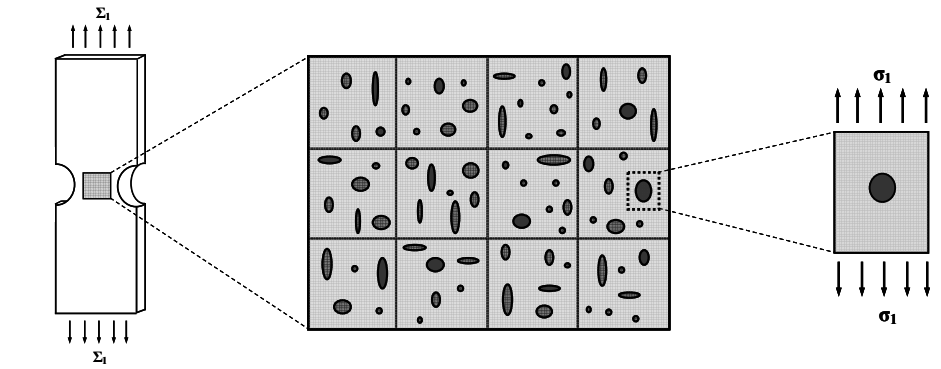
1. Introduction

The traditional approach to modeling ductile fracture involves homogenizing the microstructure of a material into a simple, equivalent geometry from which the relevant constitutive laws can be derived [1]. While attractive from a modeling perspective, critical details of the microstructure are lost in this homogenization process such as the particle size, shape, orientation, distribution and degree of clustering. Since void initiation and evolution is a highly localized phenomenon originating within heterogeneous particle clusters, these models fail to reliably predict fracture without requiring many calibration parameters. These limitations can be overcome using a damage percolation model that relies upon measured particle distributions obtained using digital imaging or x-ray micro-tomography. Micromechanical models can then be applied to each void and particle within the material to forge a direct link between local changes in the microstructure and the overall material behaviour. An advanced damage percolation model has been developed by Butcher [2] that was directly integrated into a commercial finite-element code as illustrated in Figure 1. The performance of this percolation model is evaluated by applying it to a notched tensile test specimen of AA5182 sheet. The predicted fracture strains, porosity and nucleation trends are compared and validated with the experiment data and the porosity data available in the literature.

1.1 Basics of the percolation model

The basics of the damage percolation model were established by Worswick et al. [3-4] and Chen [5] where particle fields are obtained via digital imaging techniques or micro-tomography. The particle field is then tessellated to extract the size, shape, location, and nearest neighbours of each particle and void within the field. This information is then used to re-create the particle field so that micromechanical models can be applied to each particle and void and thus predict fracture within heterogeneous particle distributions. The particles, voids and cracks are all assumed to be ellipsoidal where cracks are first formed by the coalescence of voids. The cracks are formed via a bounding box method and are subject to the same evolution laws as the voids. In the coupled

FE-percolation model of Butcher [2], the particle field is decomposed into "percolation elements" based upon the resolution of the finite-element mesh to better capture local stress and strain gradients within the microstructure. Void nucleation and coalescence occur within each percolation element with a global search for void coalescence occurring between elements at the end of each time step. The general percolation modeling strategy is outlined in Figure 2 and discussed in the subsequent sections. The interested reader is referred to [2] for additional details.



Finite-element model of a notched tensile test

Finite-elements are mapped onto a measured particle field

Micromechanical models are applied to each particle to characterize local void initiation and evolution leading to fracture

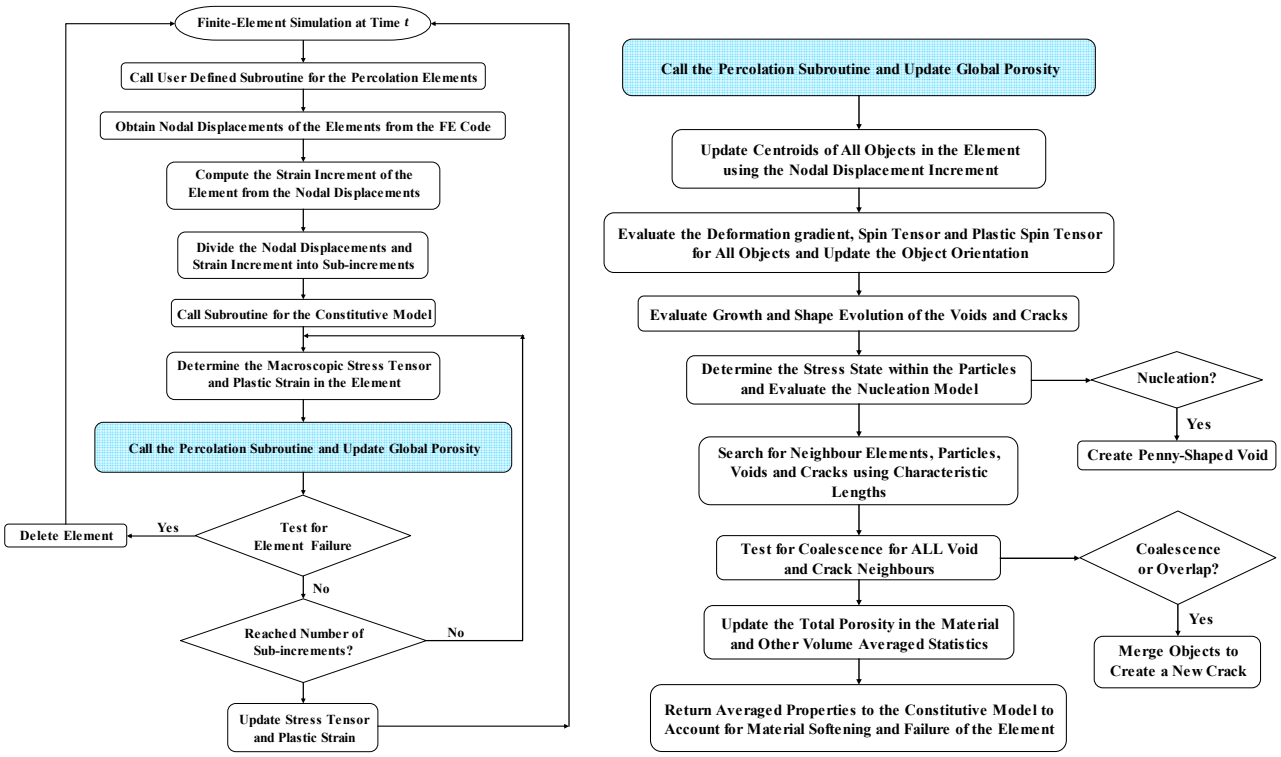

Figure 2: Flow-chart of the percolation modeling process

2. Constitutive model

The percolation material model was written as a user-defined subroutine for LS-DYNA [6] to integrate the stress state, analyze the microstructure for void evolution and return the stress tensor

and plastic strain to the finite-element program. The macroscopic stress and strain rate tensors are denoted as, Σ_{ij}, and D_{ij}, respectively. The porosity (void volume fraction), spheroidal aspect ratio and void spacing ratio are denoted as f, W, and χ, respectively. A Gurson-based yield criterion [1,7] using the modification of Ragab [8] for the q_i parameters is employed to account for material softening within the percolation element and is expressed as

$$\Phi = \left(\frac{\Sigma_{\text{eq}}}{\bar{\sigma}}\right)^2 + 2\bar{f}_d q_1(\Sigma_{\text{hyd}}, \Sigma_{\text{eq}}, n)\cosh\left(\bar{q}_2 \frac{3}{2}\frac{\Sigma_{\text{hyd}}}{\bar{\sigma}}\right) - q_1^2(\Sigma_{\text{hyd}}, \Sigma_{\text{eq}}, n)\bar{f}_d^2 - 1 = 0 \tag{1}$$

where the global porosity and average q_2 value of the voids and cracks are defined as

$$\bar{f}_d = \sum_{i=1}^{n_v} f_i^v + \sum_{i=1}^{n_c} f_i^c \qquad \bar{q}_2 = \frac{1}{\bar{f}_v}\sum_{i=1}^{n_v} f_i^v q_{2i}^v + \frac{1}{\bar{f}_c}\sum_{j=1}^{n_c} f_j^c q_{2j}^c \tag{2, 3}$$

with the subscripts v and c denote quantities for the voids and cracks, respectively, and an overbar symbol denotes a global quantity. The q_1 parameter does not require an averaging procedure since it is a function of the stress triaxiality and hardening exponent and these quantities are assumed to be homogeneous in the element. Alternatively, the q_2 parameter is a function of the void shape and stress state and will typically be different for each void and crack. The relations for the q_i parameters and the triaxiality, T, are

$$q_1 = A_0 + A_1 T + A_2 T^2 + A_3 T^3 \qquad q_2 = W^{\eta(T,n)} \qquad T = \Sigma_{\text{hyd}}/\Sigma_{\text{eq}} \tag{4-6}$$

where A_i, and η are coefficients found in Ragab [8]. The associated flow rule of the GT model yields the void growth relation that is applied for each void and crack as

$$\dot{f}_{\text{growth}} = \frac{3f(1-f)q_1 q_2 \sinh\left(q_2 \frac{3}{2}\frac{\Sigma_{\text{hyd}}}{\bar{\sigma}}\right)}{3\left(\frac{\Sigma_1 - \Sigma_{\text{hyd}}}{\bar{\sigma}}\right) + fq_1 q_2 \sinh\left(q_2 \frac{3}{2}\frac{\Sigma_{\text{hyd}}}{\bar{\sigma}}\right)} D_1^{\text{p}} \tag{7}$$

where Σ_1 and D_1^{p} are the stress and plastic strain rate in the principal loading direction.

Void coalescence is modeled using the criterion of Pardoen and Hutchinson [9] for internal necking coalescence. The onset of coalescence occurs when the following constraint is satisfied:

$$\frac{\Sigma_1}{\bar{\sigma}\left(1-\kappa_{uc}\chi^2\right)} \geq \left(\left(0.1 + 0.22n + 4.8n^2\right)\left(\frac{1-\chi}{W\chi}\right)^2 + \frac{1.24}{\sqrt{\chi}}\right) \tag{8}$$

where $\kappa_{uc} = \pi/4$ for a cubic cell. The void spacing ratio and the cell aspect ratio, λ, are defined as

$$\chi = \left(\frac{f}{\gamma}\frac{\lambda}{W}\right)^{\frac{1}{3}} \qquad \lambda = \frac{L_y}{\sqrt{L_x L_z}} \tag{9a,b}$$

where $\gamma = \pi/6$ for a cubic unit cell and L_i are its side-lengths that evolve with the applied strain. The criterion in Eq. (8) is also used to identify the onset of profuse void coalescence and failure of the percolation element. In this case, the global void aspect ratio and spacing ratios are:

$$\bar{W} = \frac{1}{\bar{f}_v}\sum_{i=1}^{n_v} f_i^v W_i^v + \frac{1}{\bar{f}_c}\sum_{j=1}^{n_c} f_j^c W_j^c \qquad \bar{\chi} = \left(\frac{\bar{f}_d \lambda_e}{\gamma \bar{W}}\right)^{\frac{1}{3}} \qquad (10,11)$$

where λ_e is the aspect ratio of the finite-element with respect to the principal loading direction.

2.1 Calibration of the void evolution and coalescence models

To ensure that the extended GT constitutive model described in the previous section is accurate for a single void, an extensive study of axisymmetric unit cells containing a dilute concentration of voids was performed with initial void aspect ratios ranging from 0.001 to 6. Each unit cell was subjected to constant triaxial loadings ranging from, T = 1/3 - 3, for a material with a hardening exponent of 0.1. Following the method of Ragab [8], the q_2 coefficient in Eq. (7) was calibrated for each void shape to ensure accurate predictions of the porosity. Second-order polynomials were used to describe the evolution of the void aspect ratios to high accuracy. See Butcher [2] for the complete results of this numerical study along with the calibrated coefficients for void evolution. When void growth and shape evolution are properly modeled, the coalescence strains predicted using Eq. (8) were in very good agreement with the numerical results. An example of the accuracy of the calibrated porosity trends for penny-shaped voids is shown in Figure 3a when the unit cell data is used to evaluate Eq. (7). Similarly, the predicted porosity and coalescence strains are shown in Figure 3b when the GT model in Eq. (1) is used to integrate the stress state. The good agreement of the calibrated GT model in Fig. 3b demonstrates that the predictions for void evolution and coalescence within the particle field are well represented for isolated voids.

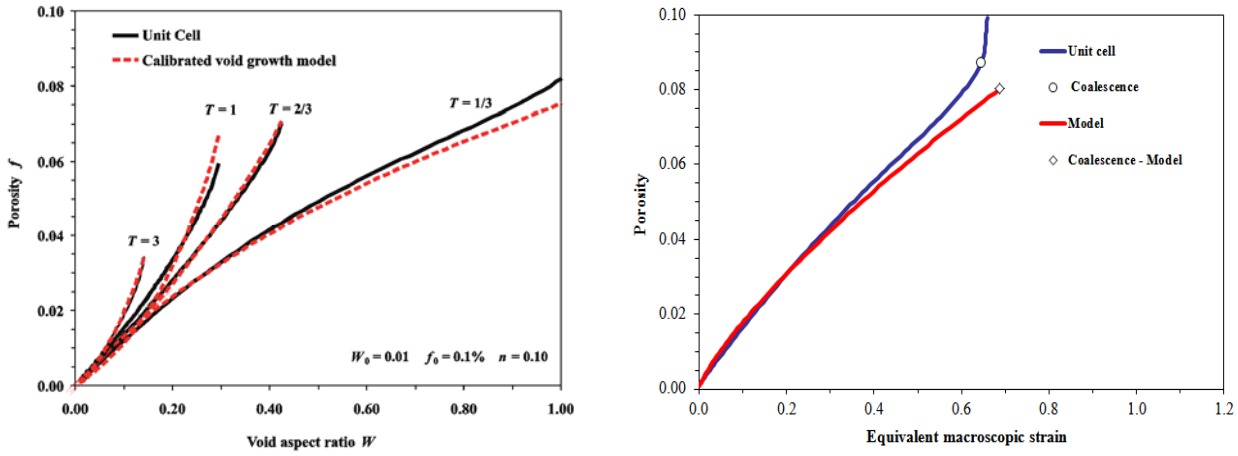

Figure 3: (a) Comparison of the porosity evolution in the unit cell and with Eq. (7) when it is evaluated using the stress state from the unit cell. (b) Comparison of the predicted void evolution and coalescence when using the GT yield criterion in Eq. (1) to integrate the stress state for a penny-shaped void in uniaxial tension.

2.2 Void nucleation

The secant-based particle homogenization scheme of Tandon and Weng [10] was implemented using the procedure of Butcher et al. [11]. Using this method, the stress state within the particles can be estimated based upon the global stress state, particle shape, volume fraction and its mechanical properties. For AA5182, the iron-rich intermetallic particles are assumed to remain elastic during deformation and nucleate voids via a penny-shaped crack in a brittle-type fracture.

Butcher et al. [11] adapted the volume-based criterion of Moulin et al. [12] for the break-up of irregularly shaped particles during rolling to ellipsoidal particles for void nucleation as:

$$\sigma_N = \frac{1}{\sqrt{\pi}} \frac{K_{1c}^*}{\sqrt[6]{V_p}} \qquad K_{1c}^* = K_{1c}\sqrt{\alpha} \qquad \alpha \approx 1 \tag{12}$$

where K_{1C}^* is the effective critical toughness of the particle material, V_p is the average particle volume and α is a geometry parameter in the Griffith mode I crack criterion to account for various effects such as crack blunting. This criterion contains only one physically-based parameter, K_{1c}, and captures the particle size-effect where small particles nucleate at high strains while large particles nucleate at low stresses [13]. The nucleation model also predicts that brittle phases are more likely to crack than more ductile phases.

3. Generation of representative particle fields

A particle field generator was developed and implemented into LS-DYNA [6] as a pre-processor for the percolation model. The measured probability distributions from micro-tomography studies were then re-created using rejection-sampling techniques. In this work, the distributions obtained by Orlov [14] were adopted for the semi-axes, orientations, volume fractions, and spacings of the voids and particles found in AA5182. The coupling of the percolation model with a particle field generator can enable stochastic predictions of fracture by performing multiple percolation model simulations. A typical particle field with a volume of 200 µm x 200 µm x 200 µm is shown in Figure 4 where the clustering of the voids and particles is evident along with their preferential orientation along the rolling direction. The respective number of voids, Mg_2Si and Fe-rich particles in this volume are 447, 616, 5273, corresponding to volume fractions of 0.053%, 0.049% and 0.483%.

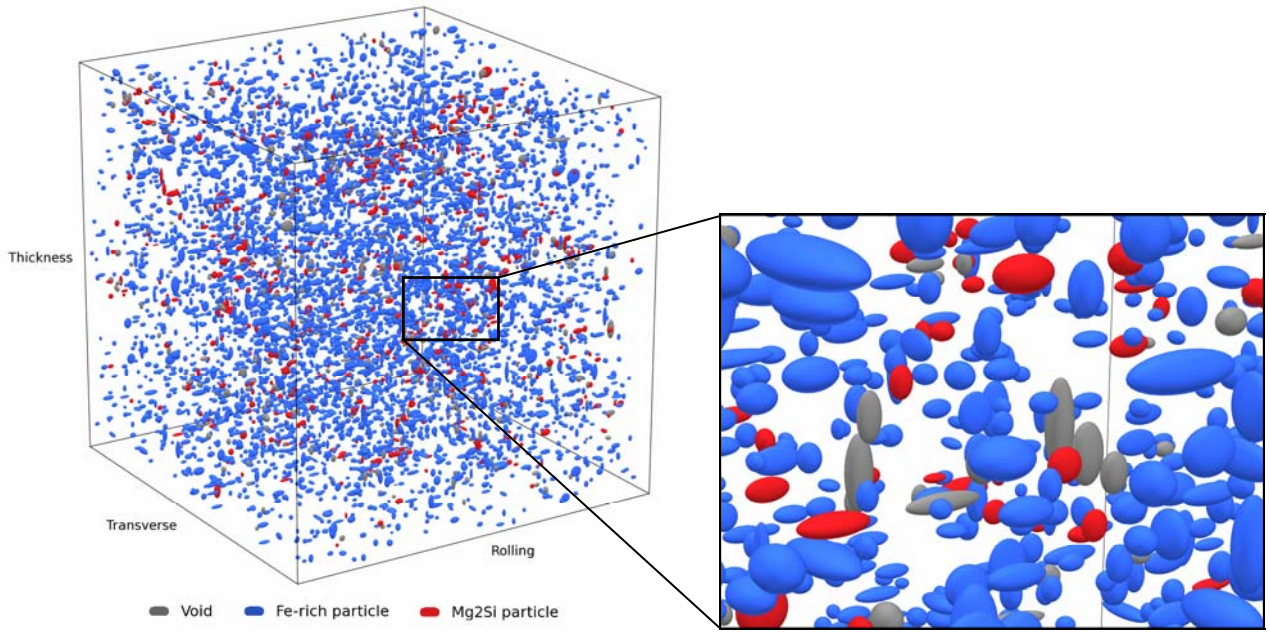

Figure 4: Generated particle field of AA5182 with a volume of 200 µm x 200 µm x 200 µm.

4. Application to a notched tensile test

Six notched tensile specimens of 1.5 mm thick AA5182 sheet with a notch radius, *R*, of 3 mm, gage length, *L*, of 12.5 mm, width, *w*, of 18 mm, and total sample length of 80 mm were tested to failure under quasi-static conditions. The notch ligament length is characterized using the notch ratio defined as $\rho = 2R/w = 0.25$ in this study. Fracture is characterized using both the ligament strain and axial or elongation strains. The ligament strain is representative of deformation in the region where fracture originates whereas the axial strain provides a metric for fracture based upon the bulk elongation of the material. The axial and ligament strains at fracture are defined as

$$\varepsilon_{a_f} = \ln\left(\frac{L_f}{L_o}\right) \qquad \varepsilon_{lig_f} = \ln\left(\frac{lig_f}{lig_o}\right) \tag{13,14}$$

where the initial ligament length is: $lig_o = w_o - 2R = 12$ mm. The axial strain at failure is recorded at the appearance of a macro-crack at the notch root and not final failure since the objective of the finite-element models is to predict the formation of a macro-crack and not the subsequent tearing process. Tensile specimens with notch ratios smaller than 1/3 exhibit visible cracking at the notch root prior to fracture and the appearance of a macro crack corresponds to a sharp drop in the experimental load displacement curve [15].

4.1 Material characterization

Three tensile specimens were evaluated to characterize a Voce hardening law for AA5182 as:

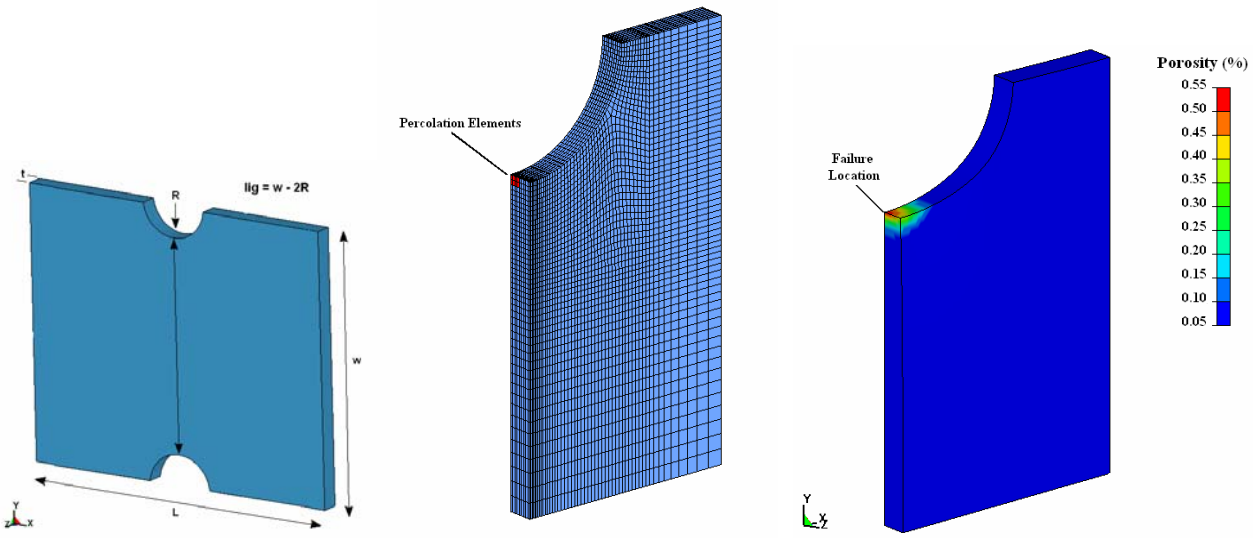
$$\bar{\sigma}(\text{MPa}) = 398.1 - 275.4\exp\left[-7.631\left(\bar{\varepsilon}^{p}\right)^{0.905}\right] \qquad n = \frac{\bar{\varepsilon}^{p}}{\bar{\sigma}}\frac{d\bar{\sigma}}{d\bar{\varepsilon}^{p}} \tag{15a, b}$$

with a yield stress of 122.7 MPa, and elastic moduli, $E = 65.33$ GPa and $\nu = 0.33$. Void nucleation in the AA5182 alloy is attributed to the iron-rich intermetallics and not the Mg_2Si particles based upon the micro-tomography study by Orlov [14]. The elastic constants of the Fe-rich particles are taken as those of steel with an elastic modulus of 200 GPa and a Poisson ratio of 0.28. It is assumed that the Fe-rich particles nucleate penny-shaped voids with an aspect ratio of 0.01 via particle cracking. The fracture toughness of the Fe-rich particles in Eq. (12) is taken as 2.15 MPa-$m^{1/2}$ based upon the measurements of Rathod and Katsuna [16].

4.2 Finite-element model

A one-eighth finite-element model of the notched specimen containing 24000 constant stress brick elements is shown in Figure 5a. For computational efficiency, only percolation elements are placed at the notch root (Figure 5b) to capture the initiation of the macro-crack while the remaining elements obey J_2 plasticity using the hardening rule in Eq. (15). The percolation model is computationally expensive and the size of the global particle field in this specific model is limited to a size of 4000 particles split into four elements. The placement of only several percolation elements at the notch root is acceptable for this specific notch geometry because deformation is

highly localized at the notch root. A previous study by Butcher and Chen [15] using a Gurson-based constitutive model has shown that the only appreciable damage occurs within this region (Figure 5c). The resulting ligament and axial strains are extracted from the FE model upon the onset of element deletion. The simulations are repeated five times for particle fields denoted P1-P5 that were generated from the tomography data of Orlov [14].



(a) (b) (c)

Figure 5: (a) Typical notch geometry. (b) 1/8th FE mesh showing percolation elements and (c) Porosity distribution obtained by Butcher and Chen (2011) using a traditional GT damage model.

5. Results and discussion

The predictions of the percolation model for the axial and ligament strain with the experimental values are shown in Figures 6a and 6b. The fracture strains are presented as 95% confidence intervals due to the stochastic nature of the percolation model. Although only five particle fields were considered, the variation in the axial strain predicted by the percolation model is comparable to the experimental variation.

The predicted porosity distributions of the five particle fields considered are shown in Figure 7a. All of the particle fields are in excellent agreement with the experimental porosity data of [14] at a plastic strain up to 0.10 and show generally good agreement at the higher strain levels. All of the particle fields considered, P1-P5, exhibit the same behaviour where deformation is relatively homogenous until the commencement of void nucleation at higher strains. The start of nucleation is followed by localized coalescence which promptly sweeps throughout the particle field causing failure. The fracture porosities are also in good agreement with the metallographic observations of Smerd et al. [17] who reported failure porosities on the order of 0.3%.

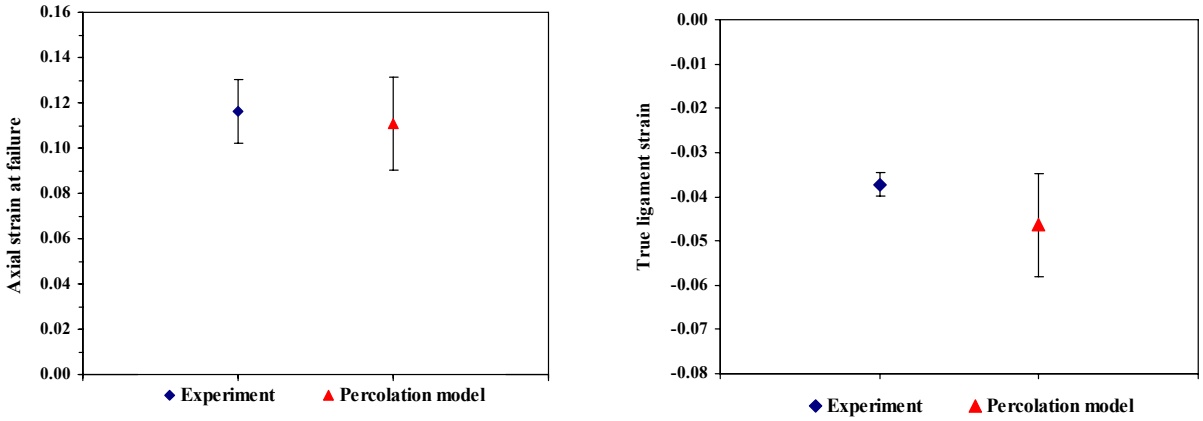


Figure 6: (a) Comparison of the experimental and predicted 95% confidence intervals for the true axial strain at failure and (b) true ligament strain.

The number of voids in the particle field is representative of void nucleation and the experimental and numerical predicted values are presented in Figure 7b. The predicted number of voids in each of the particle fields are in are in very good agreement with the experimental measurements of Orlov [17]. The convergence of the nucleation predictions demonstrates that only several particle fields are required to obtain the general trends. The porosity and fracture strains in the previous figures are expected to exhibit the most variation because they are related to coalescence which is strongly dependent upon the local microstructure. This agreement with the experimental nucleation trends is very encouraging for the physical foundation of both the percolation and the nucleation models.

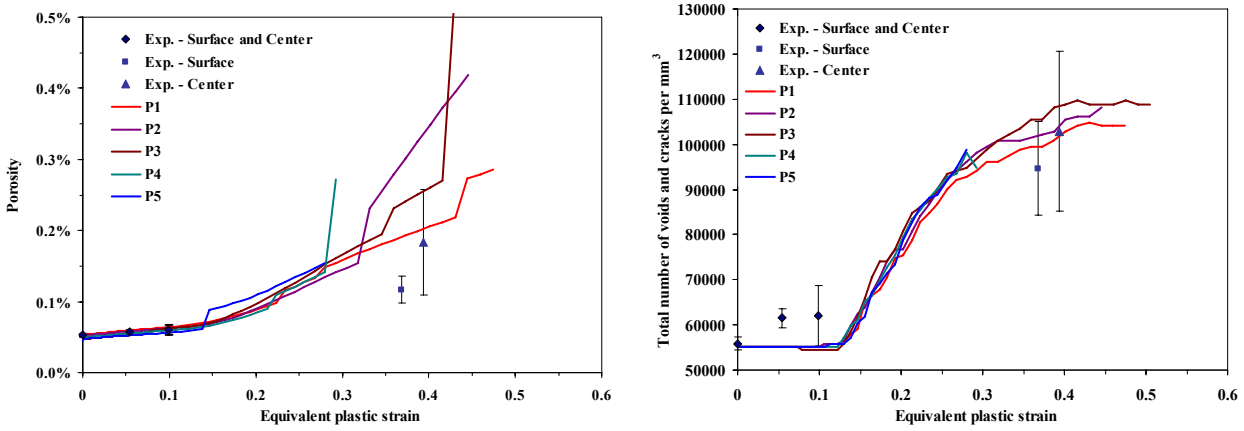

Figure 7: (a) Comparison of the predicted porosity and (b) total number of voids and cracks in the center of the notch root. The experimental tomography data is from [17] using a standard tensile specimen.

The average principal stress in the particles upon cracking (void nucleation) is shown in Figure 8a. Large particles crack at low stresses early in the deformation process while the smaller particles do not nucleate until the later in the deformation process. From this result, the stress required to fracture an Fe-rich particle is about 950 MPa. A strain-based nucleation criterion can also be developed by comparing the average volume of a broken particle to the global plastic strain

at which it nucleated as shown in Figure 8b. All of the particle fields display the well-known behaviour that small voids will nucleate only at high strains while larger particles display a negligible size effect and have a near constant nucleation stress or strain. Orlov [14] experimentally observed that no particles that had a volume smaller than 17.8 μm^3 nucleated a void and this is in accordance with the predictions of the model.

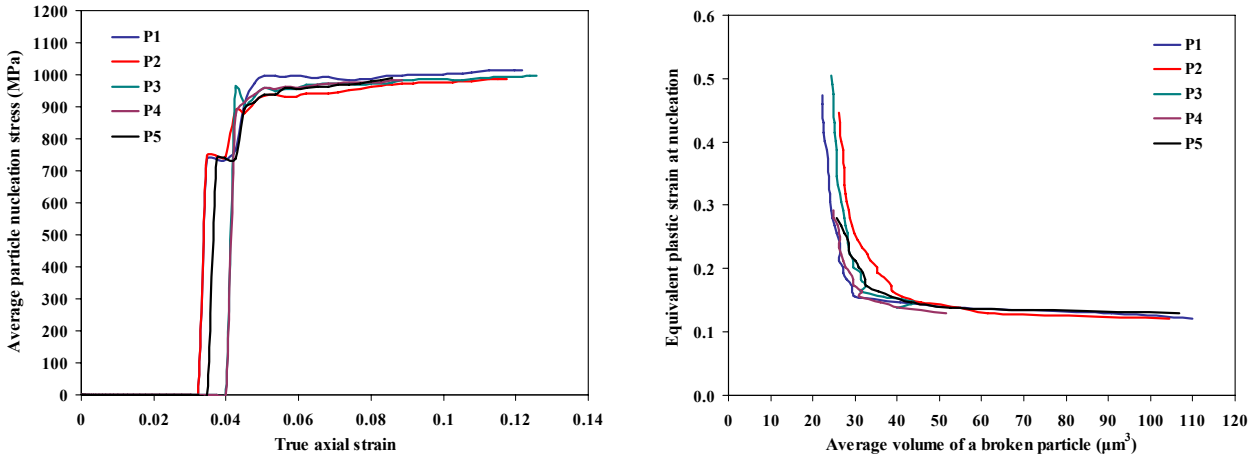

Figure 8: (a) Comparison of the average maximum principal stress in the particles at nucleation and (b) equivalent plastic strain in the matrix upon nucleation.

6. Summary

The complete damage percolation model was used to predict fracture and damage evolution in a notched tensile sheet specimen of AA5182 sheet. Representative particle distributions were created and mapped to the percolation elements located at the notch root where fracture initiates in the sample. The fracture strain, porosity, and nucleation predictions of the model are in very good agreement with the experiment data of Orlov [14]. No calibration or adjustable parameters were employed in the model and its good predictions of the experiment data attest to the strong physical foundation of the model. Fracture is a sole consequence of the stress state, material composition and the particle distribution. The main advantages of the present percolation model are that it is directly coupled into a finite-element code, contains a particle field generator as a preprocessor, and rests upon a minimum of assumptions regarding void evolution. At present, the main limitation of the model is its significant computational cost. The next phase of development of the percolation model will address this limitation and involve a large-scale application to a practical metal forming operation.

Abstract In the present study, we investigate the strength properties of ductile porous materials reinforced by rigid particles. The microporous medium is constituted of a Drucker-Prager solid phase containing spherical voids; its behaviour is described by means of an elliptic criterion (issued from a modified secant moduli approach) whose corresponding support function is determined. The later is then implemented in a limit analysis approach in which a careful attention is paid for the contribution of the inclusion matrix-interface. This delivers parametric equations of the effective strength properties of the porous material reinforced by rigid particles. The predictions are compared to available results obtained by means of variationnal homogenization methods successively applied for micro-to-meso and then for meso-to-macro scales transitions. Moreover, we discuss in detail the predictions of the material strength under isotropic mechanical loadings. To this end, additional static solutions are derived and compared to the kinematics limit analysis ones. Finally, we derive an approximate closed-form expression of the macroscopic strength which proves to be very accurate.

Keywords Porous; Strength; Drucker-Prager; inclusion-matrix, interfaces.

1. Introduction

Being hard clayey rocks, COx Argillite is a porous clay matrix in which quartz or silica inclusions are embedded. In the present study, we mainly aim to derive new closed-form results for the strength of the COx argillite, under the assumption that the solid phase of the clay is a Drucker-Prager perfectly plastic material. Therefore, the behaviour of the microporous clay is described by means of an elliptic criterion [2] whose corresponding support function is determined in this paper. Then by using this support function, we explore an alternative approach which can be viewed as an extension of the original Gurson model. Instead of a spherical cavity surrounded by a matrix, the proposed 'rigid core sphere model' consists of a rigid spherical core surrounded by the homogeneous porous material. The failure criterion of this 'rigid core sphere model' is derived in the framework of the cinematic approach of limit analysis (LA). It is worth noting that from the LA point of view the failure mechanism can include a strain concentration at the core-matrix interface which can be described mathematically. ([1-3],[6],[9],[11],[12]). **Notations:** $\mathbf{1}$ and $\mathbb{I}$ are the second and fourth order identity tensors. $\mathbb{J}=(1/3)\mathbf{1}\otimes\mathbf{1}, \mathbb{K}=\mathbb{I}-\mathbb{J}$ are respectively the spherical and deviatoric projectors of isotropic fourth order symmetric tensor.

2. The micro-to-meso transition: support function of porous matrix

The first homogenization step approach starts at the microscopic scale. At this scale, the porous clay matrix is described as a heterogeneous material being made up of a Drucker-Prager perfectly plastic solid in which pores are embedded. Let $\tilde{\boldsymbol{\sigma}}_d=\tilde{\boldsymbol{\sigma}}-\tilde{\sigma}_m\mathbf{1}$ denote the deviatoric part of the stress tensor $\tilde{\boldsymbol{\sigma}}$ at the microscopic scale. The scalar deviatoric stresses $\tilde{\sigma}_m$ are defined as $\tilde{\sigma}_d=\sqrt{\tilde{\boldsymbol{\sigma}}:\mathbb{K}:\tilde{\boldsymbol{\sigma}}}$ and $\tilde{\sigma}_m=(\mathbf{1}:\mathbb{J}:\tilde{\boldsymbol{\sigma}})/3$ and the Drucker-Prager criterion reads:

$$\tilde{\sigma}_d + T(\tilde{\sigma}_m - h) \le 0\,. \tag{1}$$

The parameters T and h respectively characterize the friction coefficient and the tensile strength of the solid phase of the clay matrix.

The result of the first homogenization step is the derivation of the strength properties of the porous clay matrix at the mesoscopic scale where it is described as a homogeneous material. These properties were estimated successfully in [6] by means of the modified secant method. Now $\boldsymbol{\sigma}_d = \boldsymbol{\sigma} - \sigma_m \mathbf{1}$ denotes the deviatoric part of the stress tensor $\boldsymbol{\sigma}$ at the mesoscopic scale and we introduce $\sigma_d = \sqrt{\boldsymbol{\sigma} : \mathbb{K} : \boldsymbol{\sigma}}$ and $\sigma_m = (\mathbf{1} : \mathbb{J} : \boldsymbol{\sigma})/3$. In the situation of associated plasticity, the domain of admissible stress states is an ellipse in the (σ_m, σ_d)-plane:

$$F^{meso}(\boldsymbol{\sigma}, f, T) = \frac{1+2f/3}{T^2}\sigma_d^2 + (\frac{3f}{2T^2} - 1)\sigma_m^2 + 2(1-f)h\sigma_m - (1-f)^2 h^2 \le 0\,. \tag{2}$$

Note that $0 < T \le \sqrt{3f/2}$ (see [6]), f is the porosity. At the mesoscopic scale, the clay matrix is described by the elliptic criterion (2). In the framework of limit analysis theory (see e.g. [10]), a dual characterization of the strength criterion $F(\sigma) \le 0$ is the support function $\pi_{_F}(\mathbf{d}) = \sup(\sigma : \mathbf{d}, F(\sigma) \le 0\}$ of the convex set of admissible stress states. The support function $\pi(\mathbf{d})$ associated with (2) of the porous matrix finally takes the form

$$\pi_{_F}(\mathbf{d}) = \sigma_0 d_{_{EQ}} - \lambda d_v \qquad \text{with} \quad d_{_{EQ}} = \sqrt{\frac{2}{3}\mathbf{d} : H : \mathbf{d}}\,. \tag{3}$$

$$\sigma_0 = (1-f)h\sqrt{\frac{3}{2}}\sqrt{\frac{3f}{3f-2T^2}\frac{T^2}{1+2f/3}} \quad ; \quad \lambda = (1-f)h\frac{2T^2}{3f-2T^2}\,. \tag{4}$$

where $\mathbb{H} = \frac{1}{\alpha}\mathbb{J} + \mathbb{K}$ is a fourth order tensor, with

$$\alpha = \frac{3f/2 - T^2}{3+2f}\,. \tag{5}$$

3. Overall dissipation at the mesoscopic scale

We now focus on the transition from the mesoscopic scale to the macroscopic scale which constitutes the second homogenization step and is the main subject of the present paper. We seek the macroscopic criterion by means of a Gurson-type approach. As already stated, the microstructure at the mesoscopic scale is described by a composite sphere Ω with a rigid core surrounded by the homogenized clay resulting from the micro-to-meso transition. The external (resp. internal) radius is denoted by r_e (resp. r_i). The shell Ω_m ($r_i \le r \le r_e$) around the core represents the clay. The volume fraction $\rho = (r_i / r_e)^3$ of the core in the composite sphere is equal to the volume fraction of the rigid inclusions in a representative volume element of argillite.

3.1 Velocity field at the mesoscopic scale

For geomaterials, we define here a family of cinematically admissible (k.a.) velocity fields with $\mathbf{D}$, depending on one compressible parameter A:

$$r \ge r_i : \quad \underline{v}_A = A\underline{x} + (D_m - A)\frac{r_e^3}{r^2}\underline{e}_r + \mathbf{D}_d \cdot \underline{x}\,. \tag{6}$$

The strain rate in the clay ($r_i \le r \le r_e$) can be determined from (6):

$$\mathbf{d}_A = A\mathrm{l} + \mathbf{D}_d + (D_m - A)\frac{r_e^3}{r^3}\left(1 - 3\underline{e}_r \otimes \underline{e}_r\right). \tag{7}$$

From (7), with $D_d^2 = \mathbf{D_d} : \mathbf{D_d}$, the expression of d_{EQ} in (3) can be written as

$$d_{EQ}{}^2 = \frac{2A^2}{\alpha} + 4(D_m - A)^2 \frac{r_e^6}{r^6} + \frac{2D_d^2}{3} + \frac{4(D_m - A)}{3}\frac{r_e^3}{r^3}\mathbf{D}_d : \left(1 - 3\underline{e}_r \otimes \underline{e}_r\right). \tag{8}$$

The velocity is $\underline{v}_O = 0$ in the rigid core. Note that the condition $\underline{v}_A = 0$ on the boundary $r = r_i$ cannot be fulfilled by the velocity field defined in (6). This implies that the dissipation associated with a discontinuity of velocity must be considered at the boundary I ($r = r_i$) (section 3.4).

3.2 Macroscopic support function

Defining the macroscopic strength domain G^{hom} as the set of admissible macroscopic stress states Σ, the macroscopic support function reads $\Pi^{hom}(\mathbf{D}) = \sup(\Sigma : \mathbf{D}, \Sigma \in G^{hom})$. Considering the set K of k.a. velocity fields with $\mathbf{D}$, $\Pi^{hom}(\mathbf{D})$ is characterized as [5]:

$$\Pi^{hom}(\mathbf{D}) = \frac{1}{|\Omega|}\inf_{\mathrm{v}\in K}\left(\int_{\Omega_m} \pi_F(\mathbf{d}_A)\, dV + \int_I \pi(\underline{v}_A)\, dS\right). \tag{9}$$

where $|\Omega| = 4\pi r_e^3/3$. In the surface integral, $\underline{v}$ denotes the velocity discontinuity at the core boundary I and $\pi(\underline{v})$ represents the associated surface density of dissipation. In the line of reasoning of Gurson approach, $\Pi^{hom}(\mathbf{D})$ is approximated by the minimal dissipation obtained among the velocity fields $\underline{v}_A$ defined in (6):

$$\Pi^{hom}(\mathbf{D}) = \frac{1}{|\Omega|}\inf_{A\in R}\left(\int_{\Omega_m} \pi_F(\mathbf{d}_A)\, dV + \int_I \pi(\underline{v}_A)\, dS\right). \tag{10}$$

For further use, let us introduce the following notation:

$$\frac{1}{|\Omega|}\int_{\Omega_m} \pi_F(\mathbf{d}_A)\, dV = \tilde{\Pi}^m(\mathbf{D}, A) \quad ; \quad \frac{1}{|\Omega|}\int_I \pi(\underline{v}_A)\, dS = \tilde{\Pi}^I(\mathbf{D}, A). \tag{11}$$

Accordingly:

$$\Pi^{hom}(\mathbf{D}) = \inf_{A\in R} \tilde{\Pi}(\mathbf{D}, A). \tag{12}$$

$$\tilde{\Pi}(\mathbf{D}, A) = \tilde{\Pi}^m(\mathbf{D}, A) + \tilde{\Pi}^I(\mathbf{D}, A). \tag{13}$$

Once $\Pi^{hom}(\mathbf{D})$ is determined, the macroscopic admissible stress states on the boundary ∂G^{hom} are derived according to:

$$\Sigma = \frac{\partial \Pi^{hom}}{\partial \mathbf{D}}(\mathbf{D}). \tag{14}$$

The stress state of (14) lies on the boundary of G^{hom} at the location where the normal is parallel to $\mathbf{D}$. The overall dissipation of (12) proves to read in the following form:

$$\tilde{\Pi}(\mathbf{D},A)=\sigma_0\left[\,Narcsinh\left(\frac{uN}{M}\right)-\frac{\sqrt{M^2+u^2N^2}}{u}\right]_1^{\frac{1}{\rho}}+\sigma_0\sqrt{\frac{2}{3}}Y-3\lambda D_m\,. \tag{15}$$

with the notations introduced in (19), (27) and (28). For the sake of completeness, sections 3.3 and 3.4 respectively determine the contribution (18) of the shell Ω_m (volume integral in (10)) and the contribution (26) of the interface *I* (surface integral in (10)) which has led to (15). Section 4 will consider the minimization w.r.t. parameter *A*.

3.3 Contribution of the shell to dissipation

For a given value of parameter *A*, the contribution of the matrix to the macroscopic dissipation reads

$$\tilde{\Pi}^m(\mathbf{D},A)=\frac{1}{|\Omega|}\int_{\Omega_m}\left(\sigma_0 d_{EQ}-\lambda d_v\right)dV\,. \tag{16}$$

In order to obtain an analytical expression of $\tilde{\Pi}^m(\mathbf{D},A)$, the approximation introduced in [4] is applied. Let $S(r)$ denote the sphere of radius *r*. As a consequence of the Cauchy-Schwarz inequality, it is readily seen that

$$\int_{S(r)} d_{EQ}\,dS\le\sqrt{4\pi r^2}\sqrt{\int_{S(r)} d_{EQ}^2\,dS}\,. \tag{17}$$

We observe that the average $\left\langle \mathbf{1}-3\underline{e}_r\otimes\underline{e}_r\right\rangle_{S(r)}$ of $\mathbf{1}-3\underline{e}_r\otimes\underline{e}_r$ over the orientations of $\underline{e}_r$ on the sphere $S(r)$ is equal to 0. Then, using (8) and (17) in (16), $\tilde{\Pi}^m(\mathbf{D},A)$ reads

$$\begin{aligned}\tilde{\Pi}^m(\mathbf{D},A)&=\frac{4\pi\sigma_0}{\Omega}\int_{r_i}^{r_e} r^2\sqrt{\frac{2A^2}{\alpha}+4(D_m-A)^2\frac{r_e^6}{r^6}+\frac{2D_d^2}{3}}dr-\frac{\lambda}{\Omega}\int_{\Omega^m} d_v dV\\&=\sigma_0\left[\,Narcsinh\left(\frac{uN}{M}\right)-\frac{\sqrt{M^2+u^2N^2}}{u}\right]_1^{\frac{1}{\rho}}-3(1-\rho)\lambda A\end{aligned}\,. \tag{18}$$

with

$$M^2=\frac{2A^2}{\alpha}+\frac{2D_d^2}{3},\quad N^2=4(D_m-A)^2\,. \tag{19}$$

3.4. Inclusion-matrix interface

Unlike the classical Gurson's 'hollow sphere model', the model proposed in this paper substitutes a rigid core for the void in the center of the thick-walled sphere. Therefore, owing to null velocity ($\underline{v}_O=0$) in the rigid core, a velocity discontinuity tales place at the core boundary: $\underline{v}_A=\underline{v}_A(r_a\underline{e}_r)-\underline{v}_O=\underline{v}_A(r_a\underline{e}_r)$.

3.4.1. Surface density of dissipation

The velocity field $\underline{v}_A$ being discontinuous across the surface *I* (rigid core boundary), its gradient and the associated strain rate are to be defined in the sense of the distribution theory:

$$\mathbf{d} = \{\mathbf{d}\} + \frac{1}{2}\left(\underline{n} \otimes \underline{v}_A + \underline{v}_A \otimes \underline{n}\right)\delta_I \,. \tag{20}$$

where $\{\mathbf{d}\}$ is the standard expression of the strain rate corresponding to its smooth part, δ_I is the Dirac distribution which support is the surface of discontinuity I and $\underline{n} = \underline{e}_r$ is the unit normal to this surface. The surface density of dissipation $\pi(\underline{v}_A)$ contributed by the velocity jump $\underline{v}_A$ is therefore related to the support function $\pi_{_F}$ according to (see e.g. [10]):

$$\pi(\underline{v}_A) = \pi_{_F}(\mathbf{d}^I) \,. \tag{21}$$

where $\mathbf{d}^I$ is defined as

$$\mathbf{d}^I = \frac{1}{2}\left(\underline{n} \otimes \underline{v}_A + \underline{v}_A \otimes \underline{n}\right). \tag{22}$$

Recalling (6) and (22), the strain rate $\mathbf{d}^I$ associated with the velocity jump can be obtained and written as

$$\mathbf{d}^I = r_i\left(\left(\frac{1}{\rho}D_m + (1-\frac{1}{\rho})A\right)\underline{e}_r \otimes \underline{e}_r + \frac{1}{2}\left((\mathbf{D}_d \cdot \underline{e}_r) \otimes \underline{e}_r + \underline{e}_r \otimes (\mathbf{D}_d \cdot \underline{e}_r)\right)\right). \tag{23}$$

Eventually, the surface density of dissipation is derived from the combination of (21) and (3)

$$\pi(\underline{v}_A) = \sigma_0 d^I_{_{EQ}} - \lambda d^I_v \qquad \text{with} \quad d^I_{_{EQ}} = \sqrt{\frac{2}{3}\mathbf{d}^I : H : \mathbf{d}^I} \quad ; \quad d^I_v = \operatorname{tr}\mathbf{d}^I \,. \tag{24}$$

3.4.2. Contribution of the interface to dissipation

Recalling (16), the macroscopic dissipation related to the part of inclusion-matrix interface depending also on the scalar *A* can be written as

$$\tilde{\Pi}^I(\mathbf{D}, A) = \frac{1}{\Omega}\int_{r=r_i}\left(\sigma_0 d^I_{_{EQ}} - \lambda d^I_v\right)dS \,. \tag{25}$$

Again, the integration of d^I_{eq} is approximated by the upper bound (17) which yields

$$\tilde{\Pi}^I(\mathbf{D}, A) = \sigma_0\sqrt{\frac{2}{3}}Y - \lambda X \quad ; \quad Y = \frac{\sqrt{4\pi r_i^2}}{\Omega}\sqrt{\int_{r=r_i}\mathbf{d}^I : H : \mathbf{d}^I dS} \,. \tag{26}$$

Using (23), *Y* takes the form

$$Y = \sqrt{\frac{P^2 + Q^2}{15\alpha}} \,. \tag{27}$$

with

$$Q^2 = \left(\frac{51}{2}\alpha + 6\right)\rho^2 D_d^2, \quad P^2 = 45(1+2\alpha)\left[D_m - A(1-\rho)\right]^2 . \tag{28}$$

In turn, observing that the average $\left\langle \underline{e}_r \cdot \mathbf{D}_d \cdot \underline{e}_r \right\rangle_{r=r_i}$ of $\left\langle \underline{e}_r \cdot \mathbf{D}_d \cdot \underline{e}_r \right\rangle_{r=r_i}$ over the orientations of $\underline{e}_r$ on the sphere *I* is equal to 0, it is readily seen that

$$X = \frac{1}{\Omega}\int_{S(r_a)} d^I_v dS = 3\left(D_m - A(1-\rho)\right). \tag{29}$$

4. Macroscopic criterion

The macroscopic support function can be determined by minimizing the sum $\tilde{\Pi}(\mathbf{D},A)=\tilde{\Pi}^{m}(\mathbf{D},A)+\tilde{\Pi}^{I}(\mathbf{D},A)$ with respect to the parameter A. Accordingly, the boundary of G^{hom} is determined according to (14)[7]:

$$\Sigma=\frac{\partial\tilde{\Pi}(\mathbf{D},A)}{\partial\mathbf{D}},\qquad\text{with}\qquad\frac{\partial\tilde{\Pi}(\mathbf{D},A)}{\partial A}=0\,. \tag{30}$$

5. Comparison with the result obtained by a variational approach

Predictions according to (30) of the macroscopic criterion derived in the framework of the cinematic approach of limit analysis are now compared with the result obtained by the variational approach [11]. For the derivation of their criterion, these authors consider a variational approach in the two homogenization steps. Their criterion reads:

$$F^{\hom}(\Sigma,f,T)=\Theta\Sigma_d^2+\left(\frac{3f}{2T^2}-1\right)\Sigma_m^2+2(1-f)h\Sigma_m-\frac{3+2f+3f\rho}{3+2f}(1-f)^2h^2=0\,. \tag{31}$$

with

$$\Theta=\frac{\frac{1+2f/3}{T^2}+\frac{2}{3}\rho\left(\frac{3f}{2T^2}-1\right)}{\frac{4T^2-12f-9}{6T^2-13f-6}\rho+1}\,. \tag{32}$$

Applying the parameters f=0.25 and T=0.525, the comparison between the results predicted by the two different methods is shown in Fig.1 As it can be seen in Fig.1, the analytical estimate (31) obtained by the variational approach and the prediction from (30) based on the 'rigid core sphere model' show a very good agreement for purely isotropic stress states, both in traction and compression. It is noteworthy that the strength under purely isotropic stress seems surprisingly almost unaffected by the volume fraction ρ of the rigid core. Although the shapes of the yield surfaces predicted by the two methods are similar, the strength predicted by limit analysis always overestimates that predicted by the variational method. In particular, as far as the strength under pure shear loading is concerned, the difference becomes very important when the volume fraction of the rigid core ρ is larger. In order to gain a deeper understanding of the effect of the parameter ρ, the isotropic strength will now be compared with the exact solution predicted by the so-called static approach (sections 6). On the other hand, we note that the strength predicted by limit analysis (upper bounds) overestimates that predicted by the variational method under shear loading.(*We focus on the strength proprieties under isotropic loading. The strength under shear loading has not been discussed in the present paper.)*

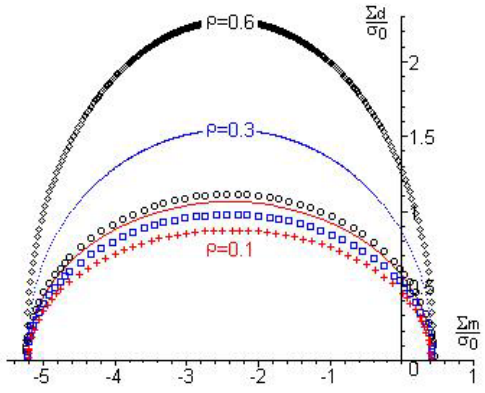

Figure 1. Comparison between the results predicted by limit analysis and the variational approach for different volume fractions of the rigid inclusion
-'line': limit analysis with ρ=0.1, -'cross': variational approach with ρ=0.1,
-'point': limit analysis with ρ=0.3, -'box': variational approach with ρ=0.3,
-'diamond': limit analysis with ρ=0.6, -'circle': variational approach with ρ=0.6

6. Strength under isotropic loading

6.1. Static approach of the limit analysis problem

The theory of limit analysis teaches that a cinematic approach like the Gurson one provides an upper bound of the true strength. In order to check the accuracy of a cinematic estimate, it is therefore highly desirable to derive a static approach which in turn will deliver a lower bound of the true strength. We therefore seek the stress field solution to an isotropic loading (traction or compression) in the framework of the 'rigid core sphere model'. The macroscopic stress state is of the form $\Sigma_m 1$. Accordingly the external boundary ($r = r_e$) is subjected to a radial surface force $\sigma \cdot \underline{n} = \Sigma_m \underline{n}$. We implement the so-called static approach of limit analysis. It consists in deriving a mesoscopic stress field σ which must be statically admissible with these boundary conditions and meet the criterion $F^{meso}(\sigma) = 0$ (see (2)). Owing to the spherical symmetry, this statically admissible stress field can be sought in the form (spherical coordinates):

$$\sigma = \sigma_{rr}(r)\underline{e}_r \otimes \underline{e}_r + \sigma_{\theta\theta}(r)\left(\underline{e}_\theta \otimes \underline{e}_\theta + \underline{e}_\varphi \otimes \underline{e}_\varphi\right). \tag{33}$$

The boundary condition on the surface $r = r_e$ reads

$$\sigma_{rr}(r_e) = \Sigma_m . \tag{34}$$

The momentum balance equation $div\sigma = 0$ reduces to

$$\frac{d\sigma_{rr}}{dr} = 2\frac{\sigma_{\theta\theta} - \sigma_{rr}}{r} . \tag{35}$$

With the notation $X = \sigma_{\theta\theta} - \sigma_{rr}$ (note that $X^2 = \frac{3}{2}\sigma_d^2$), it is found that $\sigma_m = \sigma_{rr} - \frac{2}{3}X$, so that the criterion (2) yields

$$\frac{2}{3}\frac{\left(1+\frac{2}{3}f\right)X^2}{T^2} + \frac{3f-2T^2}{2T^2}\left(\sigma_{rr} + \frac{2}{3}X\right)^2 + 2(1-f)h\left(\sigma_{rr} + \frac{2}{3}X\right) - (1-f)^2h^2 = 0 . \tag{36}$$

The values of *X* solutions of (36) read:

$$X = \frac{3}{2}\frac{(3f-2T^2)\sigma_{rr} - 2hT^2(f-1) \pm \sqrt{\Delta}}{2T^2 - 5f - 3}, \quad \text{with} . \tag{37}$$

$$\Delta = (2f+3)(2T^2-3f)\sigma_{rr}^2 + 4hT^2(2f+3)(f-1)\sigma_{rr} + 2h^2T^2(5f+3)(f-1)^2 . \tag{38}$$

Recalling (35), an ordinary differential equation with respect to σ_{rr} is obtained in the form:

$$X(\sigma_{rr}) = \frac{r}{2}\frac{d\sigma_{rr}}{dr} . \tag{39}$$

Introducing (37) into (39) and integrating over the interval $\left[r_i, r_e\right]$, one obtains

$$\frac{1}{3}\ln(\rho)=\int_{c}^{\Sigma_m}\frac{1}{3}\frac{2T^2-5f-3}{(2T^2-3f)\sigma_{rr}+2hT^2(f-1)+\varepsilon\sqrt{\Delta}}d\sigma_{rr}\,. \tag{40}$$

where the notation $c=\sigma_{rr}(r_a)$ and the boundary condition (34) at $r=r_e$ have been used. Note that no boundary condition is available at $r=r_i$. The physical meaning of (40) is the following: Whenever there exists a constant *c* such that (40) is fulfilled (with $\varepsilon=+1$ or -1), then Σ_m is an admissible loading for the value of ρ at stake. We seek the highest possible value $\Sigma_m^+>0$ of Σ_m (isotropic strength in traction) and the lowest one, denoted by $\Sigma_m^-<0$ (isotropic strength on compression). For the simplification of the following discussion, the denominator in the integral of (40) is denoted by D_ε:

$$D_\varepsilon=(2T^2-3f)\sigma_{rr}+2hT^2(f-1)+\varepsilon\sqrt{\Delta}\,. \tag{41}$$

In order for this integral to be defined, two mathematical conditions are to be met, namely $\Delta\geq 0$ and $D_\varepsilon\neq 0$. This remark leads to introduce the solutions to the equations of $\Delta=0$ and of $D_\varepsilon=0$.

First, let $\Sigma_{1m}^{\pm}$ denote the solutions to $\Delta=0$, which read:

$$\Sigma_{1m}^{+}=\frac{\left[2T(3+2f)-\sqrt{6f(3+2f)(5f-2T^2+3)}\right](1-f)hT}{(3+2f)(2T^2-3f)}$$
$$\Sigma_{1m}^{-}=\frac{\left[2T(3+2f)+\sqrt{6f(3+2f)(5f-2T^2+3)}\right](1-f)hT}{(3+2f)(2T^2-3f)} \tag{42}$$

Secondly, let Σ_{2m}^{+} (resp. Σ_{2m}^{-}) denote the solution to $D_+=0$ (resp. $D_-=0$):

$$\Sigma_{2m}^{-}=\frac{\left(2T+\sqrt{6}\sqrt{f}\right)(f-1)Th}{3f-2T^2}\,. \tag{43}$$

$$\Sigma_{2m}^{+}=\frac{\left(2T-\sqrt{6}\sqrt{f}\right)(f-1)Th}{3f-2T^2}\,. \tag{44}$$

After some reasoning, the static solution can be finally determined by numerical integration. Then the static solution is compared to the cinematic solution in the following subsection.

6.2. Comparison between static and cinematic solutions

The comparison between the static solution and the cinematic solution as functions of the rigid core volume fraction ρ (f=0.25 and T=0.525) has been performed. It is found that the two solutions can hardly be differentiated. it can be concluded that they can be regarded as the exact strength of the composite material, within the rigid core model. .

6.3. Analytical expressions of the strength under isotropic loading

Due to the complexity of the integrals in (40), these equations can hardly be solved analytically.

However, we observe that $\Sigma_m^{\pm}$ remain in the neighborhood of $\Sigma_{2m}^{\pm}$. We therefore propose to approximate the functions D_+ and D_- by series expansions in the neighborhood of Σ_{2m}^{+} and Σ_{2m}^{-}. In the case of of series expansion to the second order, The analytical solutions at order 2 read:

$$\Sigma_m^{\pm} = \eta + \rho \frac{c-\eta}{\kappa(c-\eta)(1-\rho)+1}. \tag{45}$$

with the following parameters for isotropic compression or traction:

$$\begin{cases} \eta = \Sigma_{2m}^{-} \\ \kappa = \dfrac{1}{2\sqrt{6}} \dfrac{3+2f}{(f-1)\sqrt{f}\,hT} \\ c = \Sigma_{1m}^{-} \end{cases} \quad \text{or} \quad \begin{cases} \eta = \Sigma_{2m}^{+} \\ \kappa = \dfrac{1}{2\sqrt{6}} \dfrac{3+2f}{(1-f)\sqrt{f}\,hT} \\ c = \Sigma_{1m}^{+} \end{cases}. \tag{46}$$

7. An approximate analytical macroscopic criterion

We seek an approximation of the criterion by an ellipse in the (Σ_m, Σ_d) plane. The ellipse intersects the Σ_m-axis at the points $(\Sigma_m^{-}, 0)$ and $(\Sigma_m^{+}, 0)$. The center of the ellipse is located at the middle of these points. We still have to determine the ordinate of the center of the ellipse which corresponds to the strength under pure shear ($D_m = 0$).

With the condition $D_m = 0$, it is readily seen that the value of the parameter A which minimizes $\tilde{\Pi}(\mathbf{D}, A)$ is A=0. With D_m=0 and A=0, closed-form expressions of the mean stress and the maximum shear stress can be obtained from (30):

$$\Sigma_{m,c} = -\lambda \quad ; \quad \Sigma_{d,c} = \sigma_0 \left[\sqrt{\frac{2}{3}}(1-\rho) + \sqrt{\frac{17\alpha+4}{15\alpha}}\rho \right]. \tag{47}$$

where $\lambda, \sigma_0, \alpha$ have been defined in (4) and (5). The subscript c recalls that this point is the center of the ellipse.

Now let us try to approximate the criterion given in parametric form (obtained by means of cinematic approach) found in section 4 by an analytical elliptic criterion. Analytical expressions of the strength have been established at particular stress states, namely under isotropic loading and under pure shear loading (with $\Sigma_m = -\lambda$). Recalling (45) (46) for the expressions of $\Sigma_m^{+}, \Sigma_m^{-}$ in the case of a second order expansion, together with (47) for the expression of $\Sigma_{d,c}$, the macroscopic criterion can be approached by the following analytical elliptic function:

$$\left(\frac{\Sigma_m - \lambda}{\Sigma_L / 2} \right)^2 + \left(\frac{\Sigma_d}{\Sigma_{d,c}} \right)^2 = 1. \tag{48}$$

with $\Sigma_L = \Sigma_m^{+} - \Sigma_m^{-}$ and $\lambda = (\Sigma_m^{+} + \Sigma_m^{-})/2$. Recall that $\Sigma_m^{+}, \Sigma_m^{-}, \Sigma_{d,c}$ are quantified in (45),(47) by (42),(43),(44); and $\lambda, \sigma_0, \alpha$ are given in (4),(5).

According to the comparison between the predictions of the analytical macroscopic criterion, (48), and the parametric criterion predicted by (30). We found that the comparison shows an excellent accuracy of (48).

8. Conclusion

On the basis of a limit analysis approach, we have proposed an extension of available models (devoted to the macroscopic strength of porous media). This extension concerns porous materials with a Drucker- Prager solid phase, reinforced by rigid particles. The proposed model concerns in particular, the Callovo Oxfordian clay as a composite material made up of rigid inclusions embedded in a porous clay matrix. The obtained results has been compared to the estimate of the strength recently derived by [4] on the basis of a variational non linear homogenization approach. A good accuracy of the estimate of the strength under isotropic loadings has been shown by a comparison with the results of a static (stress based) approach of the limit analysis problem. An interesting observation is that the estimates of the isotropic strength in traction or in compression do not depend on the homogenization method (limit analysis, variational method). Furthermore, the isotropic strength proves to be only slightly affected by the rigid core volume fraction. The practical implication is that the isotropic strength properties of the clay matrix and of the Callovo Oxfordian argillite are very close, irrespective of the quartz/calcite content. In contrast, a significant discrepancy between the failure envelopes is observed on the shear strength for large values of the rigid inclusions concentration.

Abstract The paper presents a theoretical treatment of the dynamic behavior of fibre reinforced composites containing matrix cracks and reinforcing inhomogeneities. A pseudo-incident wave method is used to treat the dynamic interaction between cracks and inhomogeneities. Using this method, the original interaction problem is reduced to the solution of coupled single crack/inhomogeneity subproblems, for which analytical solutions could be derived. The interaction effects are introduced via the superposition of the different subproblems. The steady state solution of the interacting crack problem is obtained using integral transform method and the solution of the inhomogeneity problem is determined using Fourier expansion. The dynamic stress intensity factors (SIFs) at the matrix crack are obtained and numerical examples are provided to show the effect of the frequency, geometry of microdefects and material properties upon the dynamic SIFs.

Keywords Dynamic interaction, Crack, Inhomogeneity, Composite

1. Introduction

A major issue in modeling the micromechanical behaviour of advanced composites is how to deal with the interaction between cracks and inhomogeneities, which governs the overall failure mechanism of the materials [1-4]. The quasi-static interaction problem in composite materials has received considerable attention but the dynamic interaction between cracks and inhomogeneities is still limited [5-9]. Compared with quasistatic problems, the formulation of dynamic problems is much more complicated and difficult to deal with and the experimental data are difficult to obtain. It should be mentioned that most advanced composite materials are currently being used or considered for use in situations involving dynamic loading. Numerical methods, such as finite element analysis or boundary element method, can be used for this type of dynamic analyses under certain conditions but has their own limitations when multiple defects are involved. Analytical study of interacting cracks under dynamic loads is still attracting researchers [10-12] because of its high reliability and accuracy in simulating the dynamic response of multiple defects in composite materials.

It is the objective of the present paper to review and present the usage of the pseudo-incident wave method for the analysis of steady state dynamic interaction problems. Based on this method, the original interaction problem is reduced into single crack and single inhomogeneity subproblems, which are coupled through the scattered waves. The single crack and single inhomogeneity problems are solved analytically using integral transform method and Fourier expansion, respectively. Following this introduction, the paper is divided into three more sections: the formulations, results and discussions and conclusions.

2. Formulation of the Problem

Consider now the dynamic interaction between arbitrary defects, which could be in forms of cracks or inhomogeneities, in an infinite elastic isotropic solid under steady state dynamic antiplane loading, as shown in Fig.1. The displacement field corresponding to a steady state dynamic loading can be generally expressed in terms of the frequency ω as

$$w^*(x,y,t) = w(x,y)e^{i\omega t} \tag{1}$$

For the sake of convenience, the time factor $e^{i\omega t}$ will be suppressed and only the magnitude $w(x,y)$ will be considered. The harmonic displacement field must satisfy the Helmholtz equation [13],

$$\frac{\partial^2 w}{\partial x^2}+\frac{\partial^2 w}{\partial y^2}+\frac{\omega^2}{c_T^2}w=0 \tag{2}$$

where $c_T=(\mu/\rho)^{1/2}$ is the shear wave speed of the medium. The non-vanishing shear stress components are

$$\tau_{yz}=\mu\frac{\partial w}{\partial y} \quad , \quad \tau_{xz}=\mu\frac{\partial w}{\partial x} \tag{3}$$

where μ is the shear modulus of the material.

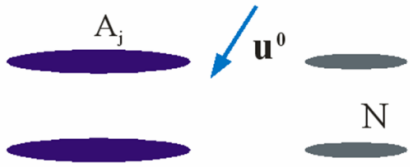

Figure 1. Interacting defects subjected to an incident wave

Instead of solving the original interaction problem, single defect problems will be considered. For any individual defect the interaction with other ones will be treated as an unknown wave, pseudo-incident wave. This wave represents the scattered waves from all other defects and will be determined by considering the consistency condition between defects.

2.1 Single crack problem

Consider the single defect problem first. For a single crack subjected to a dynamic antiplane loading, the boundary conditions along the crack surfaces are,

$$w(x,0)=0 \quad |x|\geq c \quad , \quad \tau_{yz}(x,0)=-\tau_1(x) \quad |x|<c \qquad sgn(y)=\begin{cases}1 & y>0\\ -1 & y<0\end{cases} \tag{4}$$

with τ_1 being the shear stress caused by the incident wave. x is the axis along the crack surface and c is the half length of the crack.

By making use of Fourier transform, the general solution of the displacement and stress fields in the transformation domain can be expressed as

$$w^*(s,y)=-\frac{sgn(y)}{2\pi i}\int_{-c}^{c} f(u)\frac{1}{s}e^{isu-\alpha|y|}du \tag{5}$$

where y is an axis starts from the centre of the crack and is perpendicular to the crack surfaces, s is the Fourier transform parameter of x, $f(x)$ represents the deformation of the crack surfaces, defined by

$$f(x)=\frac{\partial w(x,0)}{\partial x} \tag{6}$$

and

$$\alpha=\sqrt{s^2-\frac{\omega^2}{c_T^2}} \quad with \quad Re(\alpha)\geq 0$$

The solution of the problem can be obtained by using Chebyshev polynomial expansion of $f(x)$ as,

$$f(x)=\sum_{j=0}^{\infty}\frac{c_j}{\sqrt{1-\frac{x^2}{c^2}}}T_j(\frac{x}{c}) \tag{7}$$

where T_j are Chebyshev polynomials of the first kind and c_j are unknown constants. By satisfying the boundary condition at selected collocation points along the crack surfaces, the parameters c_j can be determined in terms of the boundary stress as,

$$[S]\{A\} = \{f\} \tag{8}$$

where $[S]$ is a known matrix, $\{A\}=\{c_1, c_2, \dots\}^T$ and $\{f\}$ is a matrix containing the boundary stresses at the collocation points along the crack surfaces. From this solution, the stress and displacement field caused by this crack can be calculated in terms of $\{A\}$.

2.2 Interaction problem

The solution of other single defect problems can also be determined and the solution can be expressed in the similar format as shown in Eq. (8). When multiple defects are involved, for defect A_j, as shown in Fig.2(a), all scattered waves from other defects will become an incident wave, i.e. the pseudo-incidenr wave (u_j^p). Therefore, defect A_j is subjected to both the original incident wave and the pseudo-incident wave and results in a scattered wave, as shown by Fig.2(b).

(a) (b)

Figure 2 Illustration of pseudo-incident waves
(a) scattering from other defects, (b) total incident wave for a defect

Based on the relation between defects discussed above, for defect A_j the solution can be expressed as

$$[S_j]\{A_j\} = \{f_j\} + \{f_j^p\} \tag{9}$$

where $[S_j]$ is the matrix given by (8) for A_j, and the two terms on the right hand side represent the original incident wave and the pseudo-incident wave.

If Eq. (9) is applied to all the defects and the pseudo-incident waves are represented in terms of the scattered waves, the governing equation for the interaction problem can be determined,

$$\left\{\begin{bmatrix}[S_1] & \cdots & 0\\ \vdots & \ddots & \vdots\\ 0 & \cdots & [S_n]\end{bmatrix} + \begin{bmatrix}[Q_1]\\ \cdots\\ [Q_n]\end{bmatrix}\right\}\begin{Bmatrix}\{A_1\}\\ \cdots\\ \{A_n\}\end{Bmatrix} = \begin{Bmatrix}\{f_1\}\\ \cdots\\ \{f_n\}\end{Bmatrix} \tag{10}$$

where $[Q_j]$ are determined by the scattered waves of the defects, $\{f_j\}$ are the original incident wave at different defects. It should be mentioned that both $[S]$ and $[Q]$ matrices are obtained from the analytical solution of single defects. By solving this linear equation, the solution of the interaction problem can be determined.

3. Results and Discussion

The solution presented in the previous section can provide reliable and accurate prediction of the stress field caused by the dynamic interaction. The method can be used to treat interaction between different defects [8,10,11]. Although only the single crack solution is presented in the previous section, solutions of other single defects can be similarly and easily assembled into Eq. (10). In this section, typical examples are presented to illustrate the dynamic interaction between different defects. The numerical simulation is conducted by solving Eq. (10) and the convergence of the solution has been carefully evaluated. Specifically, numerical results are presented to illustrate the dynamic interaction between a main crack and a second crack or an inhomogeneity. The incident antiplane wave is perpendicular to the crack surface.

To evaluate the accuracy of the current method, Fig. 3 shows the static interaction between a circular inhomogeneity and a collinear crack subjected to an initial stress intensity factor (K_0). Comparing with the closed form solution (lines) [14] excellent agreement is observed.

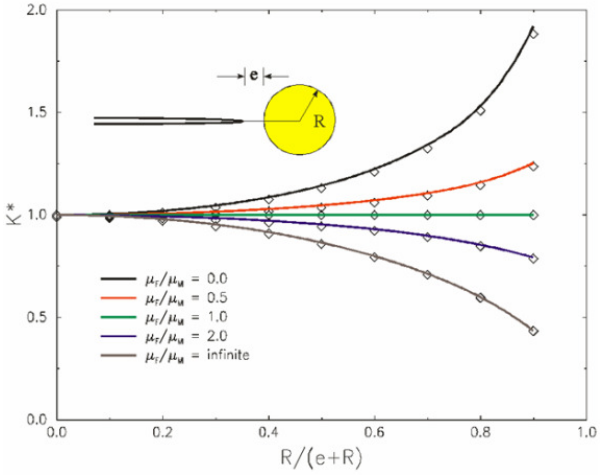

Figure 3. Static interaction

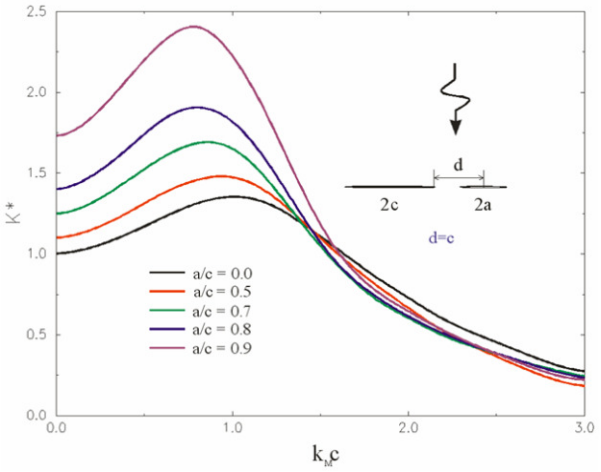

Figure 4. Interacting cracks

Fig.4 shows the effect of a collinear crack of length *2a* on the normalized stress intensity factor crack of a main crack of length *2c*. *a/c=0* corresponds to the case of a single crack. Comparing these curves indicates that significant interaction between cracks exists for low frequencies. But the interaction effect is significantly reduced at higher frequencies.

Fig.5 shows the result of interaction between a crack and an inhomogeneity. The variation of the normalized stress intensity factor for different crack-inhomogeneity configurations is presented. Unlike the collinear crack case where only amplification effects are observed, when the inhomogeneity, with a higher stiffness, is ahead of crack, the stress field is shielded. i.e. the dynamic stress intensity factor at the main crack attains a value lower than the dynamic single crack solution. Fig.6 presents the result of a similar inhomogeneity with a partially debonded interface near the crack tip, as shown. With the increase of the size of the debonded interface, the stress intensity factor at the crack tip increases and indicates an amplification effect. For high loading frequencies, the interaction effect becomes insignificant because the distance between the crack and the inhomogeneity is much larger than the wave length.

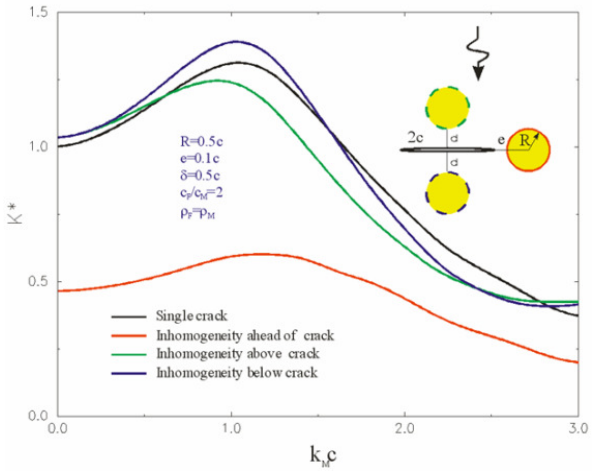

Figure 5. Crack and inhomogeneity

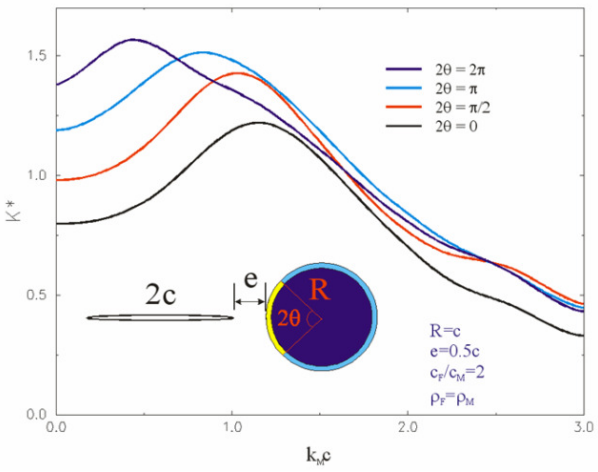

Figure 6. Crack and debonded inhomogenity

4. Conclusions

A pseudo-incident wave method is developed to predict the dynamic interaction effects between cracks and inhomogeneities. This approach enabled us to reduce the original interaction problem into the solution of coupled single crack/inhomogeneity subproblems, for which analytical solutions could be easily obtained which are coupled through the scattered waves. The steady state solution of the crack problem is obtained using integral transform method and the solution of the inhomogeneity problem is determined using Fourier expansion. The dynamic stress intensity factors (SIFs) at the matrix crack are obtained and numerical examples are provided to show the effect of the frequency, geometry of microdefects and material properties upon the dynamic SIFs. Both shielding and amplification effects are experienced and discussed.

Abstract Timber elements placed in outdoor conditions are solicited by mechanical loadings and climatic variations. Joints or notched beams are subjected to stress concentrations which can cause a crack growth process due to drying phases. This paper deals with the experimental and analytical approaches about the fracture process in timber element subjected to different moisture content conditions. Two lots of SEN specimens are conditioned in different air conditions and tested in opening mode. A quasi-brittle fracture behavior is studied using a thermodynamic approach taking into account the dissipation based on the crack surface separation and the development of a process zone around the crack tip. The model includes the fracture and damage energy release rate concepts. Based on fracture and damage approaches, the dissipation separation is realized using the coupling of a finite element approach and image analysis tracking the visible crack tip during the experimental test. Experimental results and numerical treatments allow highlighting the moisture content effect on damage and crack growth with an increase of the ductility for high moisture content levels caused by the increase of the process zone size. This work allows envisaging the comprehension of the crack growth process under climatic variations introducing mechano-sorptive aspects.

Keywords Fracture mechanic, Viscoelastic behavior, Mechano-sorptive effects

1. Introduction

Timber elements placed in outdoor conditions are solicited by mechanical loadings and climatic variations. Around knots and joints, stress concentrations can induce crack growth initiation until fracture. Around these singularities, moisture content can be concentrated accentuated with climatic variations, .This coupling is usually treated by a mechano-sorptive approach coupling mechanical fields and moisture content gradients. In the past, a lot of works has been developed in order to understand this interaction at a material scale and for bending behavior. If we take the example of timber joints, the toughness can be accelerate by moisture content variations by provoking a crack initiation and the crack propagation until a partial collapse [1]. The one difficulty meet by the scientist community is the illustration of the mechano-sorptive effects in the fracture mechanic kinetic. Several scientific explorations have shown that coupling between moisture content variations and mechanical loading is subject to shrinkage-swelling effects and a modification of elastic or viscoelastic properties. In terms of thermodynamic visions, the last phenomenon is traduced, for constant mechanical loadings, by an increase of compliance properties during moistening phases and a blocking of strains during drying process corresponding to a partial storage of the free energy. These last observations request to put in evidence the local fracture behavior in moistening and drying phases. However, before to highlight the mechano-sorptive effects during wetting and drying phases, it is necessary to characterize the mechanical properties for dry and wet conditions.

The first section deals with the experimental setup based on a double cantilever beam specimen in Douglas fire using a electromechanical testing machine associated with a regulated environment chamber. These tests allow the determination of the specimen compliance and the critical energy release rate versus the crack tip position for dry and wet conditions.

Moisture content variations are stud in the second session. This part allows showing effects of a drying phase on the crack growth initiation under a creep loading.

2. Experimental setup

2.1. Material and methods

Experimental tests are based on the use of a double cantilever beam in Douglas fire submitted at a displacement control loading. Two sample groups are conditioned in dry and wet environments, respectively. In the other hand, for initial moistened specimens, a ramp of drying is imposed. All tests are filmed by CCD camera in order to record the crack tip advance. The Douglas fire specimen is a Double Cantilever Beam. Dimensions are fixed in Figure 1. The initial crack is oriented in the longitudinal axis with an initial length of 50mm. Its thickness is 20mm. The loading axes have a diameter of 10mm. The crack propagation is assumed to be in the Radial Longitudinal plane.

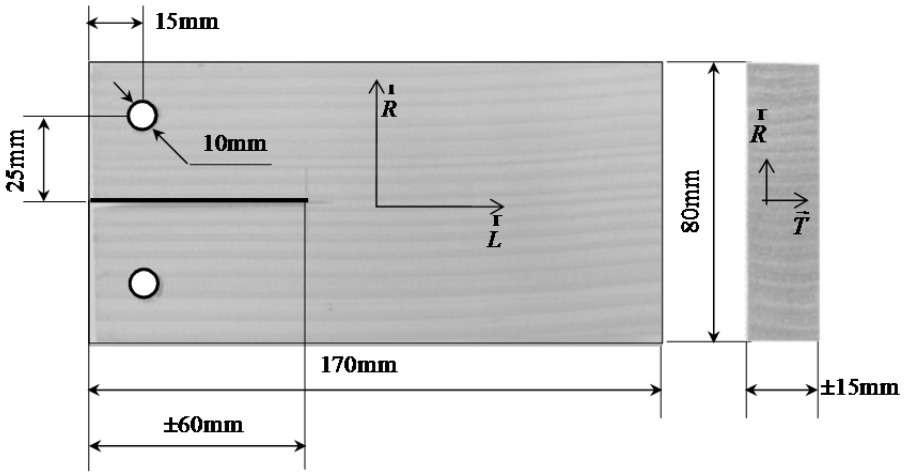

Figure 1. Double Cantilever Beam geometry

Two families of four specimens are placed in a dry (20°C, 40%HR) and wet (20°C, 85%HR) climate corresponding to moisture contents of approximately 9% and 19%, respectively. These specimens are acclimated during several weeks in order to obtain a moisture content homogeneity. The testing machine is a Zwick electromechanic incorporating an environmental chamber allowing the time synchronization between force-displacement and temperature/humidity histories, Figure 2.

Figure 2. Zwick electromechanic machine and CCD camera

The experimental device is completed by the crack tip advance monitoring using a CCD camera. The synchronization between images and mechanical data (force and displacement of the machine crossbar) is permitted by using a tracking marker technique of the point of force application, Figure 3.

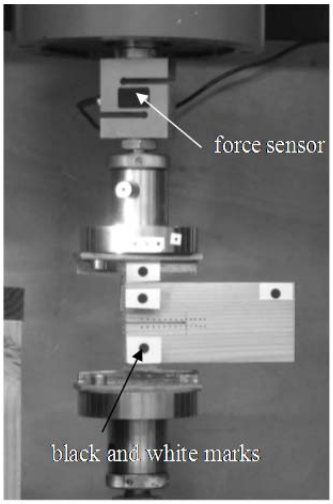

Figure 3. Synchronization with marker tracking method

During tests, the environment chamber is regulated in order to impose the equivalent moisture content conditioning. In order to limit creep effects, we impose a high constant displacement speed of 0,5mm/min until the total specimen collapse. In these conditions, the total test time does not exceed 4 minutes. Viscoelastic effects can be neglected in the following of this study.

2.2. Experimental results

Experimental results are composed of the force evolutions and the crack tip advance versus displacements. The force displacement curves are posted in Figure 4. First results highlight a decrease of the initial sample stiffness and the strength with eth moisture content increasing. In the other hand, wet samples seem to be characterized by a higher ductility.

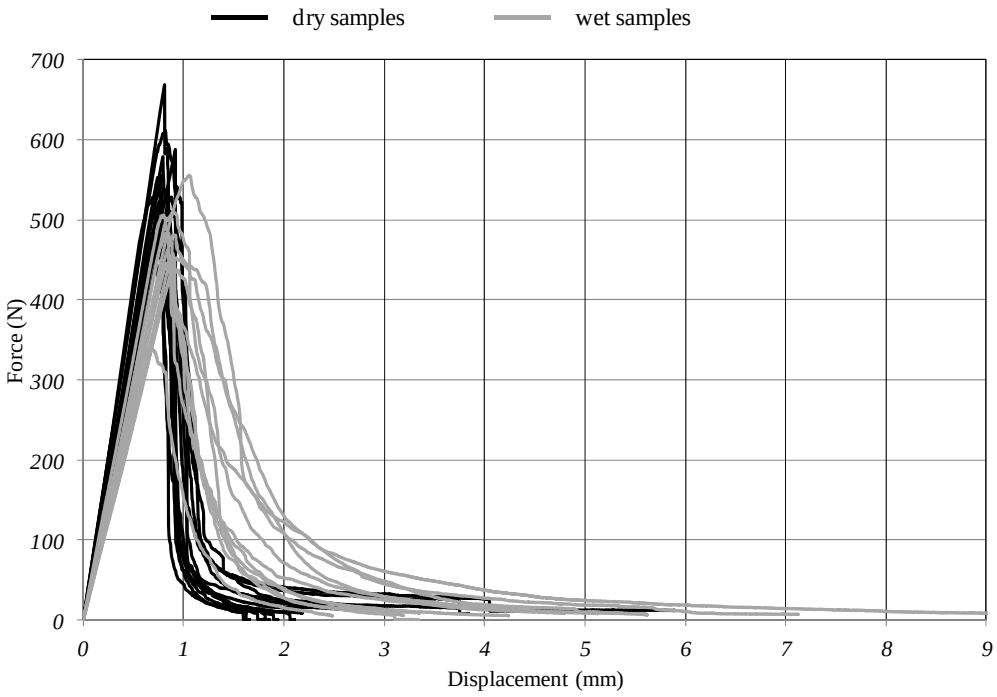

Figure 4. Force displacement curves under dry and wet conditions

All tests being filmed, the visible crack tip position can be noted versus displacements. In Figure 5, they are plotted crack length versus critical displacement corresponding to the crack tip advance. The graph highlights moisture content effect with an increase of sample compliance at a given crack length at high moisture content level (grey marks).

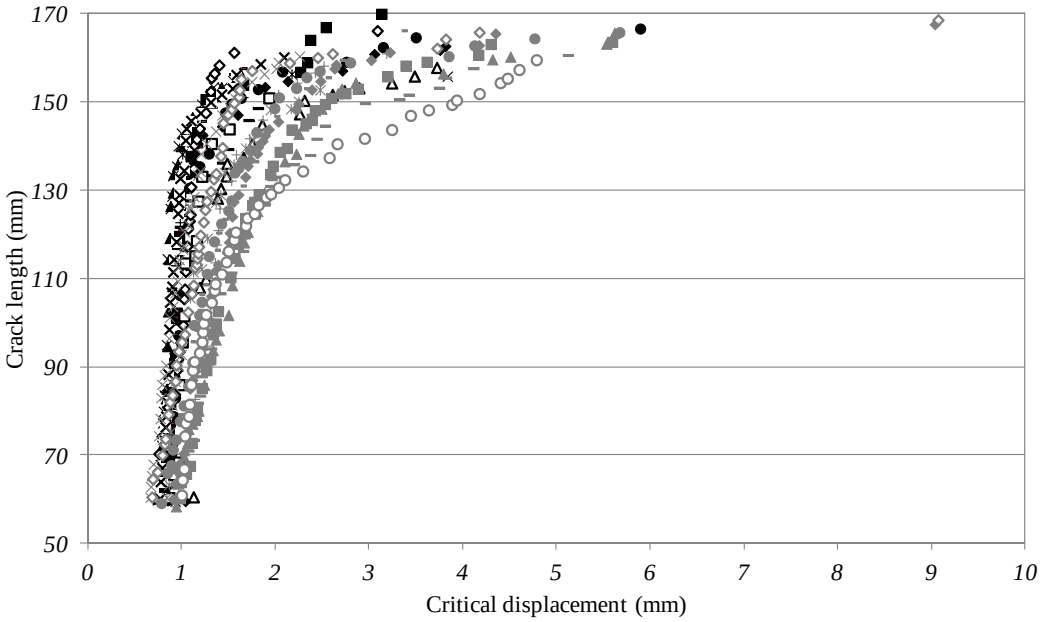

Figure 5. Visible crack length vs critical displacement

These observations prompt us to understand the cracking process by an energy approach. This one will clearly identify the effects of moisture content on the crack growth process by identifying energetic dissipation in terms of crack surface formations and process zone development.

3. Global thermodynamic approach

3.1. Thermodynamic formalism

Experimental results, shown in Figure 4 and 5, enables us to describe, at a global scale, energetic balance by introducing the global Helmholtz free energy $\psi[J]$ defined by observable variables represented by the total displacement d and an internal variable inducing softening of the sample stiffness [2]. By analogy with a damage theory, we introduce a virtual damage variable D and the effective stiffness $\tilde{k}(D)$. D represents the effects of the crack growth surface and the damage evolution in the process zone. Its form can be calculated from the non damage stiffness k such as :

$$D = 1 - \frac{\tilde{k}}{k} \quad \text{or} \quad \tilde{k} = (1 - D) \cdot k \tag{1}$$

Considering $F[N]$ as the reaction force, the global sample behavior can be defined as the relationship between this force and the global displacement u such as:

$$F = \tilde{k}(D) \cdot u \tag{2}$$

According to the thermodynamic approaches introduced by Lemaître, let us introduce the global thermodynamic potential in the form of the Helmholtz free energy variation is defined as:

$$\dot{\psi} = \frac{\partial \psi}{\partial u} \cdot \dot{u} + \frac{\partial \psi}{\partial D} \cdot \dot{D} \tag{3}$$

By assuming a total crack closure after unloading, the global elastic behavior (2) provides the first state equation:

$$F = \frac{\partial \psi}{\partial u} \tag{4}$$

Crossing expressions (2) and (4), the Helmholtz free energy can take the following form:

$$\psi = \frac{1}{2}\tilde{k}(D)\cdot u^2 \tag{5}$$

The energy release rate Y_D (associated to damage variable) can be defined as follow:

$$Y_D = \frac{\partial \psi}{\partial D} \tag{6}$$

Introducing equation (5) in (6), its definition becomes:

$$Y_D = \frac{u^2}{2}\cdot\frac{\partial \tilde{k}}{\partial D} \tag{7}$$

Considering the damage definition in expression (1), the energy release rate (7) can be rewritten by:

$$Y_D = -\frac{1}{2}\cdot k \cdot u^2 \tag{8}$$

By considering the Clausius-Duhem relationship, the dissipation, induced by the crack growth process φ can be defined by, Figure 6:

$$\dot{\varphi} = -Y_D \cdot \dot{D} \tag{9}$$

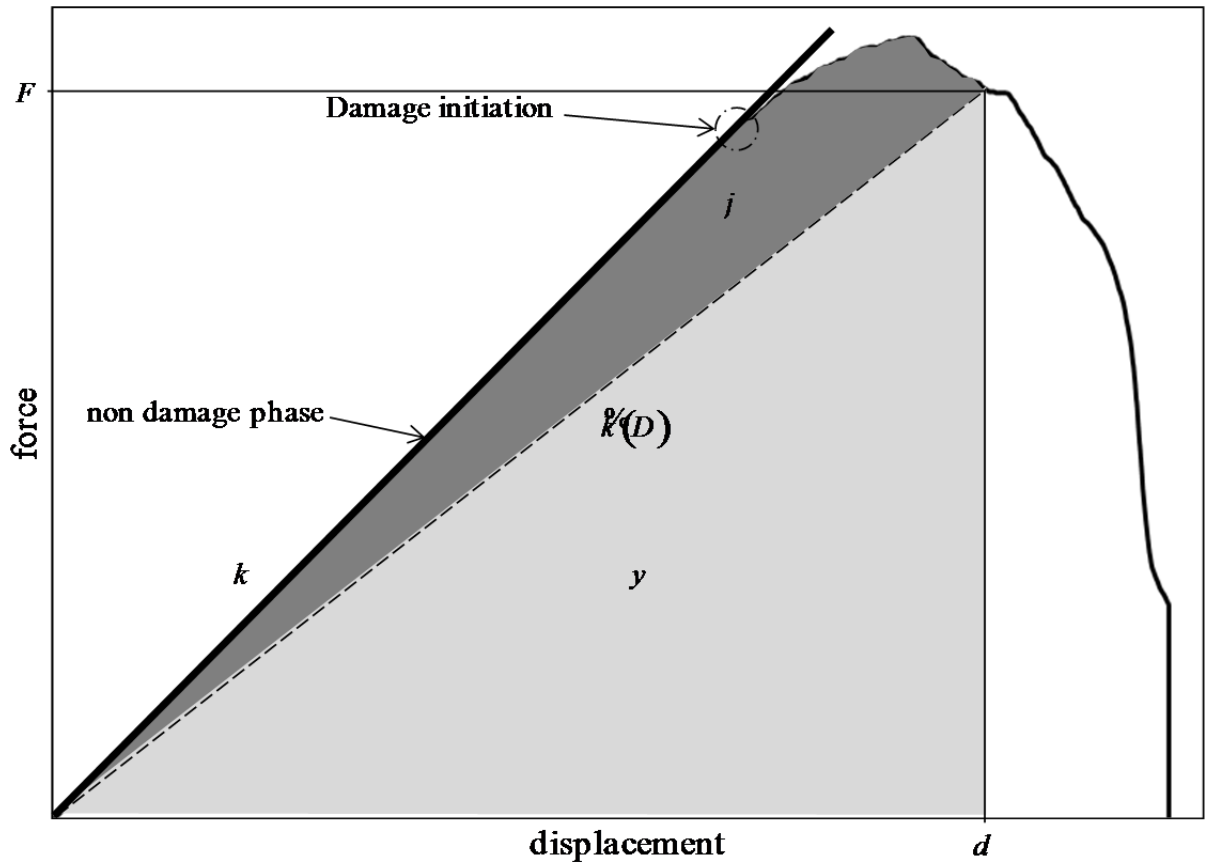

Figure 6. Experimental force-displacement he curve and thermodynamic description

3.2. Thermodynamic formalism

In the thermodynamic approach, an additional behavior law consists on the relationship between energy release rate and the global damage variable. Experimentally crossing expressions (1) and (8), we can easily plot the energy release rate – damage curve as shown in Figure 1. We can clearly note a behavior difference between dry and wet samples with a higher ductility at high moisture content levels. The behavior law can be separated into two regions. The first concerns the damage growth initiation which can be described by the following criterion:

$$D = 0 \quad \text{and} \quad \dot{D} = 0 \quad \text{if} \quad |Y_D| < Y_c \tag{10}$$

Where Y_c is a critical energy release rate value corresponding to a damage growth initiation. The second is the damage evolution function versus energy release rate. According to the global form, we propose an evolution under a Prony's serie form such as:

$$D = \chi_1 \cdot \left(1 - \exp\left(\frac{Y_D + Y_c}{Y_1}\right)\right) + \chi_2 \cdot \left(1 - \exp\left(\frac{Y_D + Y_c}{Y_2}\right)\right) \tag{11}$$

For dry and wet samples, **Error! Reference source not found.** and **Error! Reference source not found.** fixe thermodynamic parameters, respectively.

Table 1. Thermodynamic parameters for dry samples

	$Y_c\ (mJ)$	$Y_1\ (mJ)$	$Y_2\ (mJ)$	χ_1	χ_2	$k\ (N/mm)$
Average	207	88	794	0.94	0.06	709
Standard Variation	57	28	26	0.05	0.05	79

Table 2. Thermodynamic parameters for wet samples

	$Y_c\ (mJ)$	$Y_1\ (mJ)$	$Y_2\ (mJ)$	χ_1	χ_2	$k\ (N/mm)$
Average	169	183	787	0.81	0.19	571
Standard Variation	41	67	19	0.15	0.15	50

3.3. Average global behavior

The average behavior for dry and wet samples can be built by the following algorithm. Firstly, a global displacement history $u(t)$ is fixed. The energy release rate Y_D is calculated according to expression (8). The equation (11) allows defining the damage evolution. In a last time, the global sample behavior (2) after updating the effective stiffness (1). Results can be shown in Figures 7 and 8. The model can represent the differences in terms of ductility behavior between average dry and wet tests. The main criticism that we could do on this approach and the non decoupling process of crack propagation and the process zone. If our approach allows reproducing experimental test, it cannot be generalized for other geometry and doesn't take into account a scale effect induced by the

process zone existence.

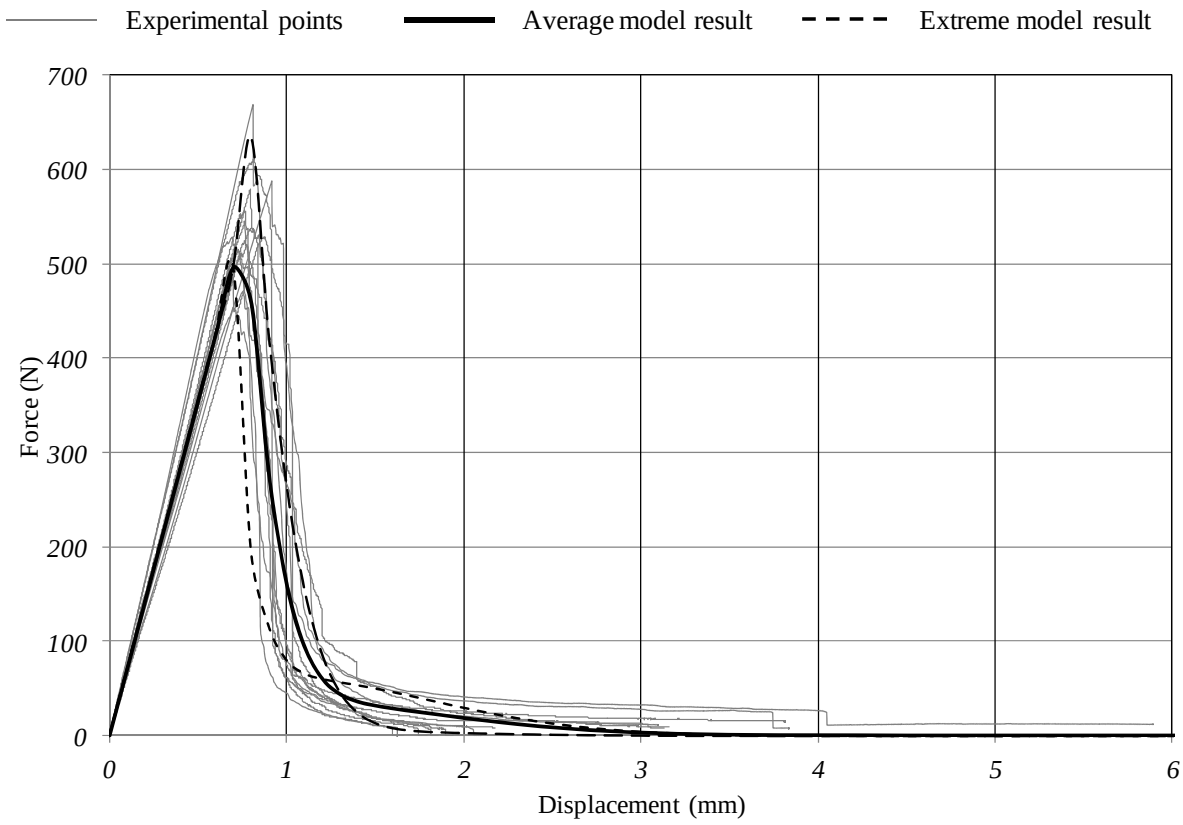

Figure 7. Modeling of fracture process for dry samples

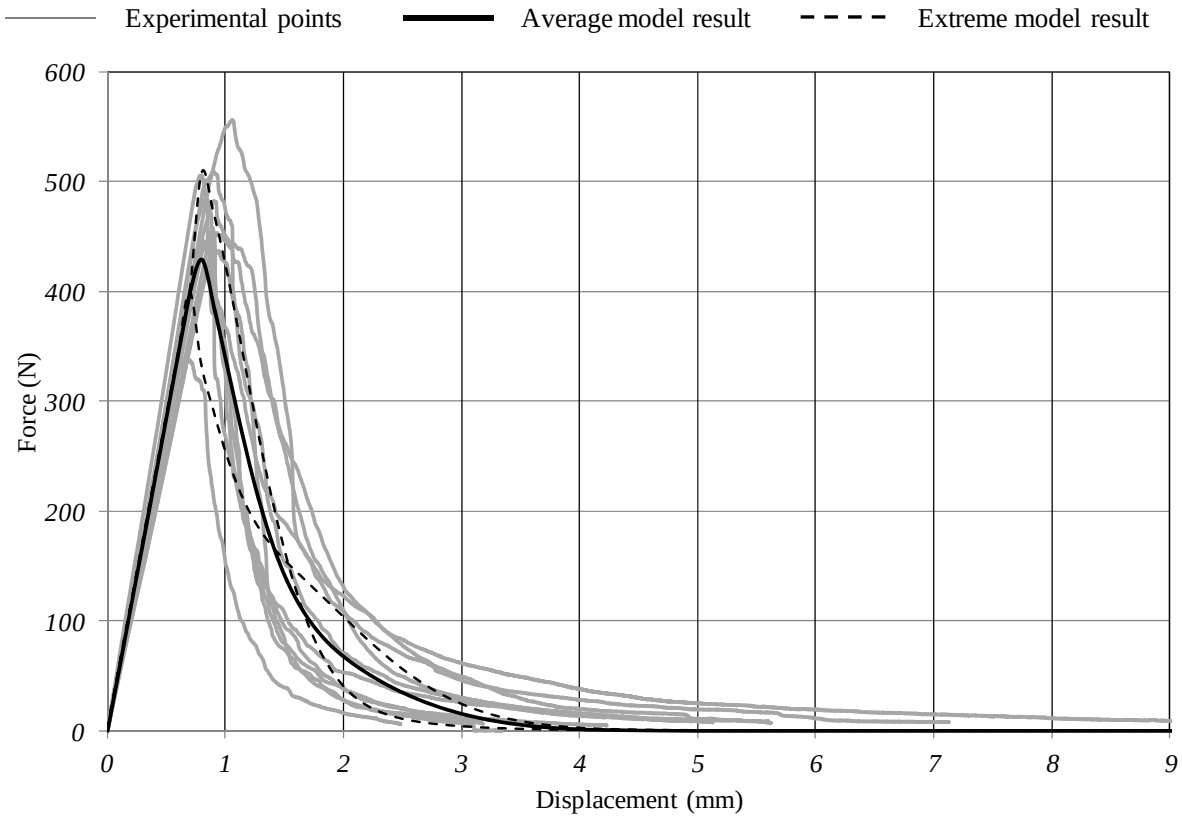

Figure 8. Modeling of fracture process for wet samples

4. Mechanical tests under variable climate

The mechanical test under variable climate conditions is based on a creep loading accompanied by relative humidity changes. This test allows the introduction, in the fracture behavior, effects of the viscoelasticity, the shrinkage or swelling and mechano-sorptive process. In this paper, we focus our investigation of drying process.

4.1. Loading history

The association of the mechanical loading with the decrease of the relative humidity requests to introduce the time as synchronization variable. In your case, we choose to load the specimen conditioned in a wet environment (20°C, 85%HR). The loading value is chosen according to a static displacement of 1mm with a displacement speed of 0,5mm/min. At this time, the force is fixed as constant during 10 minutes in order to observe creep response in constant wet climate. The next step is characterized by a drying phase by changing climate conditions at a dry state (20°C, 30%HR). The experimenters expect now the complete collapse of the sample. The Figure 8 summarizes the hygro-mechanical loading.

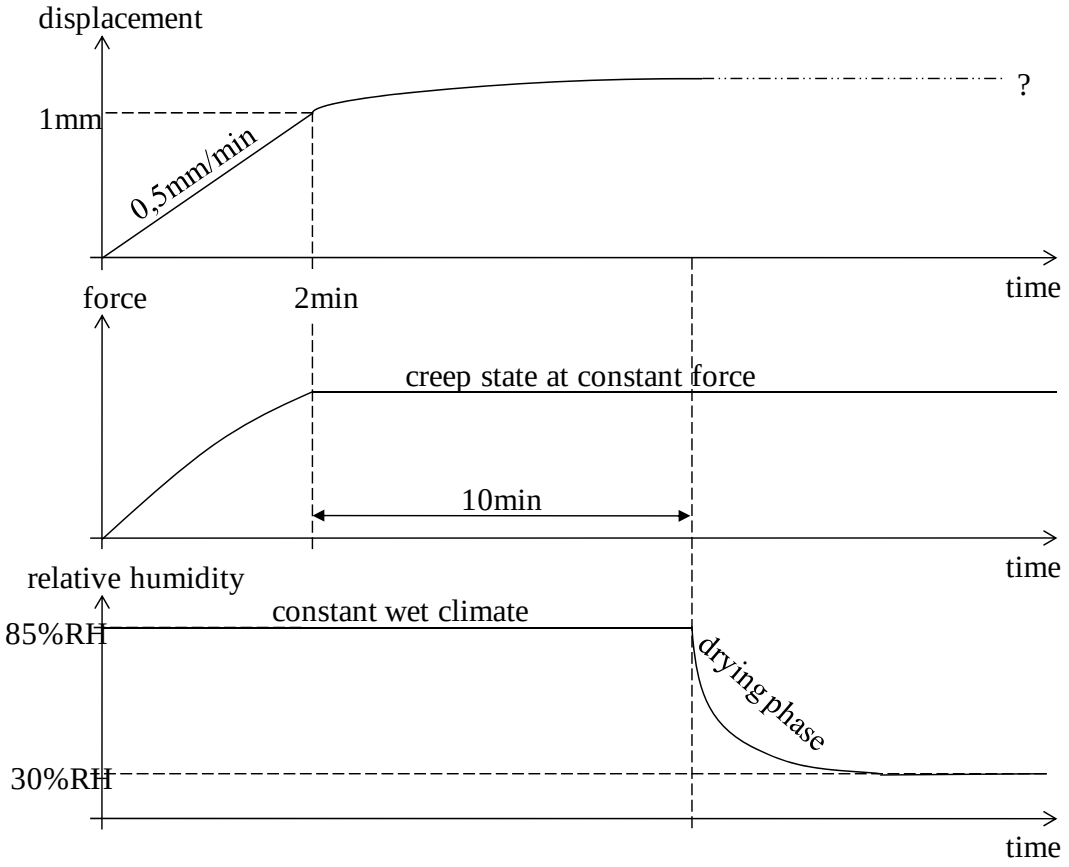

Figure 9. Hygro-mechanic loading history

4.2. Experimental results

The force-displacement curve vs time is posted in Figure 10. The graph can be separated in four

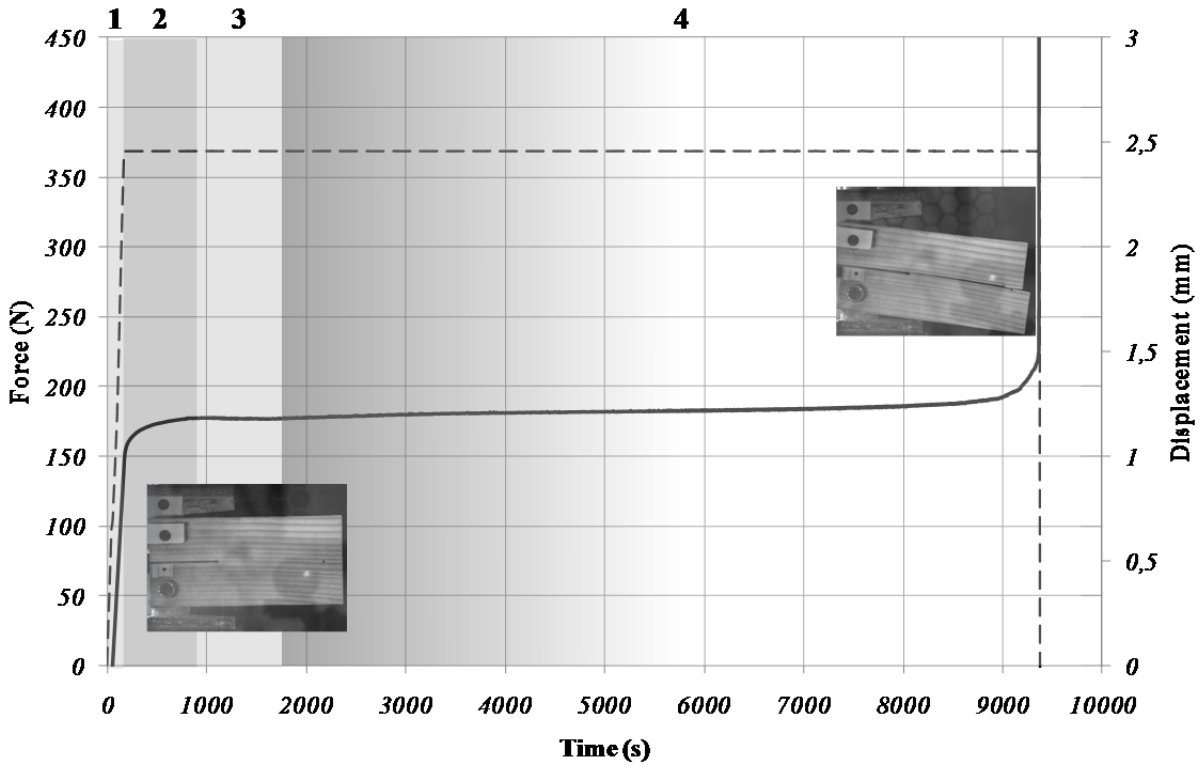
specific zones.

1- This zone corresponds to the loading of the wet sample with a displacement speed of 0,5mm/min. The overall stiffness is equal to 260N/mm. According to a finale displacement of 1mm, the corresponding force is 355N.

2- During ten minutes, the force is kept constant. The sample mechanical state is in a creep configuration. We can observe the displacement evolution versus time. At this state, the relative humidity is maintained at 85%.

3- At this time, the phase of drying starts. According to diffusion process, the specimen begins to dry from the outside surface. The creep response results on the combination of mechano-sorptive and shrinkage effects. We can observe a displacement blocking characterizing of mechano-sorptive effects and, more particularly, its hygro-lock properties [3], [4], [5].

4- The last phenomenon is characterized by a continuum increase of displacements. According to a non linear behavior, this phase can be assimilated at a secondary creep state accentuated by the 3D diffusion process. The total collapse can be observed after a total time of 2h40.



he th

Figure 10. Experimental results

5. Conclusion and outlook

This present thermodynamic approach allows studding the crack growth process by taking into account the global dissipation process induced by the new crack surfaces formations and a process zone development. The generalization of this approach for climatic variations request introducing mechano-sorptive behavior in the energetic balance. In the same time, the global behavior needs the uncoupling of shrinkage-swelling effect. In this last case, a finite element modeling allows the prediction of the free displacement induced by moisture content level taking into account orthotropic properties in the specimen thickness and diffusion process in the transverse section.

Abstract Cu–Zn–Al shape memory alloys exhibit shape memory behavior within a certain range of composition. They are characterized by a stable high temperature disordered bcc structure named β-phase, followed by a transition to a B2 structure after appropriate cooling and from secondary B2 to DO3 ordering under other cooling procedures. It is also know that martensite stabilization can be reduced by a step-quenched treatment. Shape memory properties are often absolutely interesting and many grades of shape memory alloys are extensively used in the technological world, e. g. in surgery and dentistry. Copper-based shape memory alloys are preferred for their good memory properties and low cost of production.

In this work, the main crack initiation and its propagation in an tensile test is analyzed in order to evaluate crack path and its behavior corresponding to low and to high deformation values. Furthermore, results are associated to X-Ray diffraction in order to correlate structural transition involved in an Cu-Zn-Al alloy characterized by a PE behavior.

Keywords Shape Memory Alloy; Pseudo-Elastic Behaviour; Fracture; CuZnAl alloy.

1. Introduction

Shape memory alloys (SMA) and pseudo-elastic alloys (PEA) are able to recover their original shape after high mechanical deformations: the first ones by heating up to characteristic temperature (Shape Memory Effect, SME), and the second ones simply by removing the mechanical load (Pseudo-elastic Effect, PE). Different shape memory alloys have been optimized in the last decades, such as the copper-zinc-aluminum (ZnCuAl), copper-aluminum-nickel (CuAlNi), nickel-manganese-gallium (NiMnGa), nickel-titanium (NiTi), and other SMAs obtained alloying zinc, copper, gold, iron, etc.. However, the near equiatomic NiTi binary system shows the most interesting properties and it is currently used in an increasing number of applications in many fields of engineering, for the realization of smart sensors and actuators, joining devices, hydraulic and pneumatic valves, release/separation systems, consumer applications and commercial gadgets [1, 2]. Due to their good biocompatibility, another important field of SMA application is medicine, where the pseudo-elasticity is mainly exploited for the realization of several components such as cardiovascular stent, embolic protection filters, orthopedic components, orthodontic wires, micro surgical and endoscopic devices [3].

From the microstructural point of view, shape memory and pseudo-elastic effects are due to a reversible solid state microstructural transition from austenite to martensite, which can be activated by mechanical and/or thermal loads [4].

Copper-based shape-memory alloys are very sensitive to thermal effects, and it is possible that in

thermal cycles its properties change (e.g., shape-recovery ratio, transformation temperatures, crystal structures, hysteresis and mechanical behavior).
Cu–Zn–Al shape memory alloys exhibit shape memory behavior within a certain range of composition. It is characterized by a stable high temperature disordered bcc structure named β-phase. After a customized cooling process, a B2 structure is obtained followed a DO3 ordering. It is also know that martensite stabilization can be reduced by a step-quenched treatment.
Cu ZnAl alloys mechanical properties are influenced by [5]:

- martensite stabilization;
- grain size;
- processes procedure (e.g., temperature, heat treatment cycles number).

Other investigations carried out on CuZnAl alloys, showed a strain influence on the macroscopic behavior and on martensite morphology. Martensitic transformation occurs initially in deformed material and the manufact shape follows the transformation [6]. Larger grains dimensions allow an easier transformation process, allowing the growth of 18R martensite [7].
In this work, damaging micromechanism during a tensile test in a CuZnAl alloy has been investigated, focusing the crack inititiation and its stable growth. Deformation influence on alloy microstructure has been investigated during the tensile test by means of X-Ray diffraction .

2. Material and methods

In this work a CuZnAl pseudo-elastic alloy, made in laboratory by using controlled atmosphere furnace and characterized by chemical composition shown in Table 1, has been used to investigate mechanical behavior in tensile conditions.

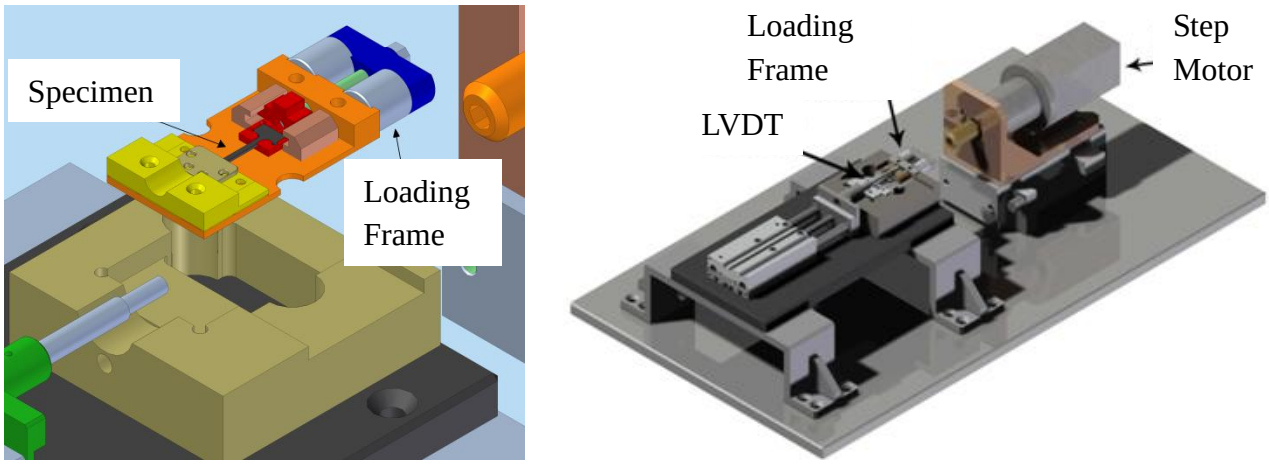
Table 1. Chemical composition of CuZnAl investigated alloy

Cu	Zn	Al	Other
73.00	21.80	5.04	0.16

The evolution of the microstructure during uniaxial deformation was analyzed by a miniature testing machine (Fig. 1) which allows in-situ scanning electron microscopic (SEM) observations as well as X-Ray micro-diffraction analyses.
In particular, the testing machine is equipped with a simple and removable loading frame, which allows SEM and X-Ray analyses at fixed values of applied load and/or deformations. The machine is powered by a stepping motor, which applies the mechanical deformation to the specimen through a calibrated screw, with pitch of 0.8mm, and a control electronic allows simultaneous measurement and/or control of applied load and stroke of the specimen head. The stroke is measured by a Linear Variable Differential Transformer (LVDT) while the load is measured by two miniaturized load cells with maximum capacity of 10 kN. Miniature dog bone shaped specimens were machined from alloy samples obtained by cold cutting of mini sheets from as cast ingots, by wire electro discharge machining.
Step by step isothermal tensile tests were carried out, at room temperature, at increasing values of

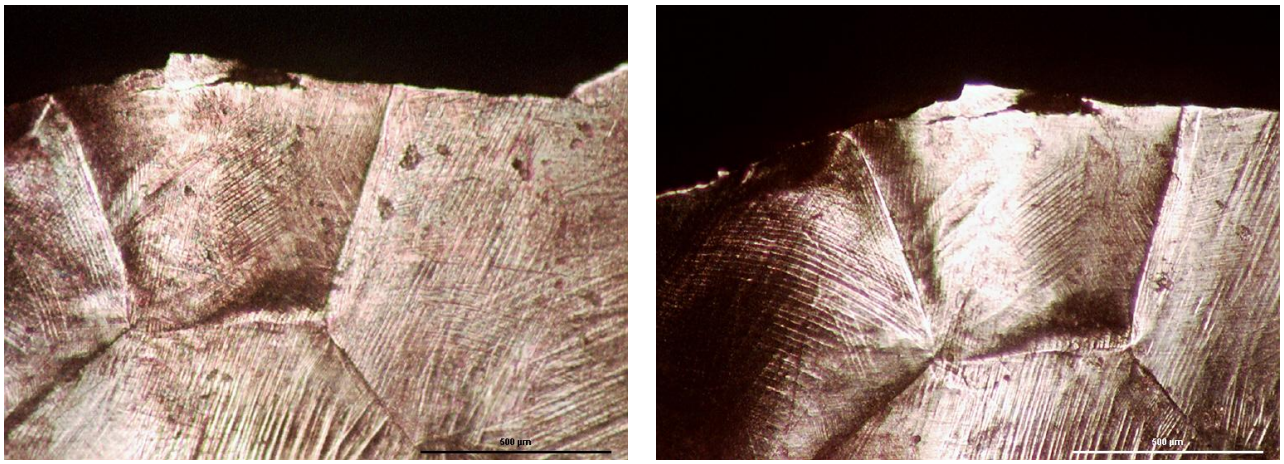
the specimens elongation. For each loading step, the loading frame containing the specimen was removed from the testing machine, at fixed values of deformation. The specimens, under load condition, was analyzed by means of:

1) a light optical microscope, characterized by a wide observation field; all the investigated specimen length was observed in order to identify the crack initiation site. The investigated steps are ε_{eng} = 0%, 5%, 10%, and 14% (failure);
2) a diffractometer in order to evaluate XRD spectra. XRD measurements were made with a Philips X-PERT diffractometer equipped with a vertical Bragg–Brentano powder goniometer. A step–scan mode was used in the 2θ range from 40° to 90° with a step width of 0.02° and a counting time of 2 s per step. The employed radiation was monochromated CuKα (40 kV – 40 mA). The calculation of theoretical diffractograms and the generation of structure models were performed using the PowderCell software [8]. The investigated steps are at ε_{eng} = 0% and 5%.



a) b)

Figure 1. Tensile equipment: a) loading frame, b) tensile machine.



a) b)

Figure 2. Etched surface: a) etched-deformed and observed, b) deformed, cleaned and re-etched.

Finally, SEM observations on fracture surface have been performed in order to evaluate the main fracture micromechanisms.
In order to check the correctness of the LOM observation procedure, a preliminary test has been performed. An unloaded and metallographically prepared specimen has been deformed up to ε_{eng}=0% and then LOM observed (Fig. 2a). Subsequently the same specimen (loaded) has been metallographically prepared and LOM observed (Fig. 2b). It is evident the possibility to follow the grains modifications in the investigated SMA only performing the first metallographic preparation.

3. Results

Engineering stress strain curve of investigated alloy is shown in Fig. 3, where a plateau has not been observed. The investigated deformation conditions correspond to:

1. ε_{eng} = 0% - starting test conditions;
2. ε_{eng} = 5% - near yield point;
3. ε_{eng} = 10% - plastic zone;
4. ε_{eng} = 14% - specimen failure.

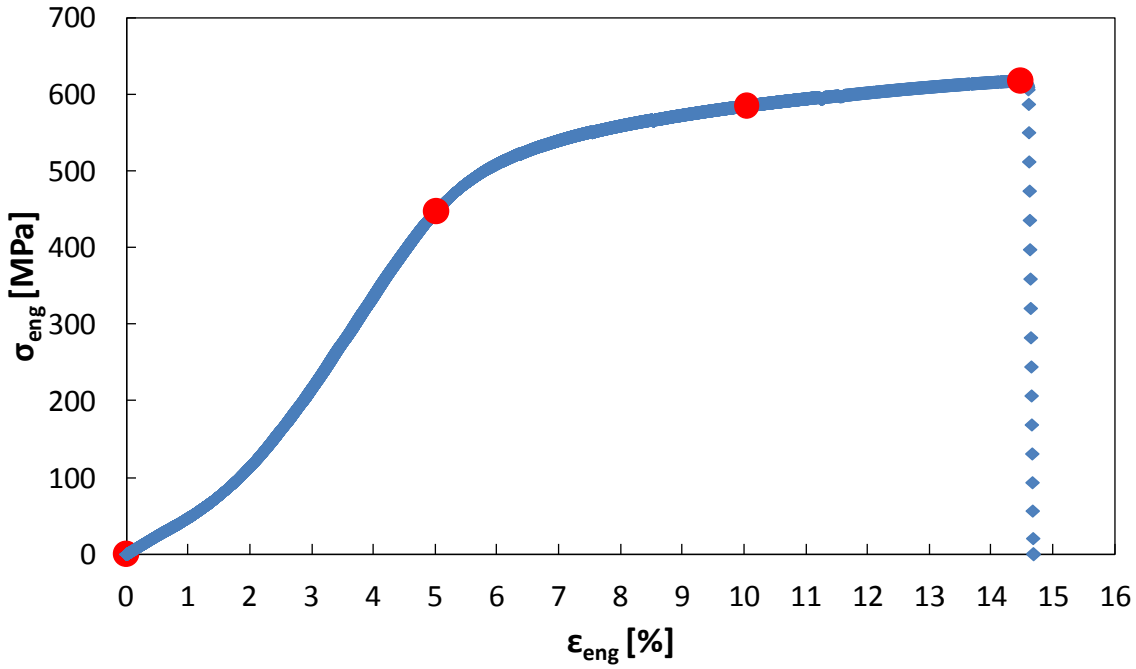


Figure 3. Engineering Stress-Strain curve (red points correspond to the investigated conditions).

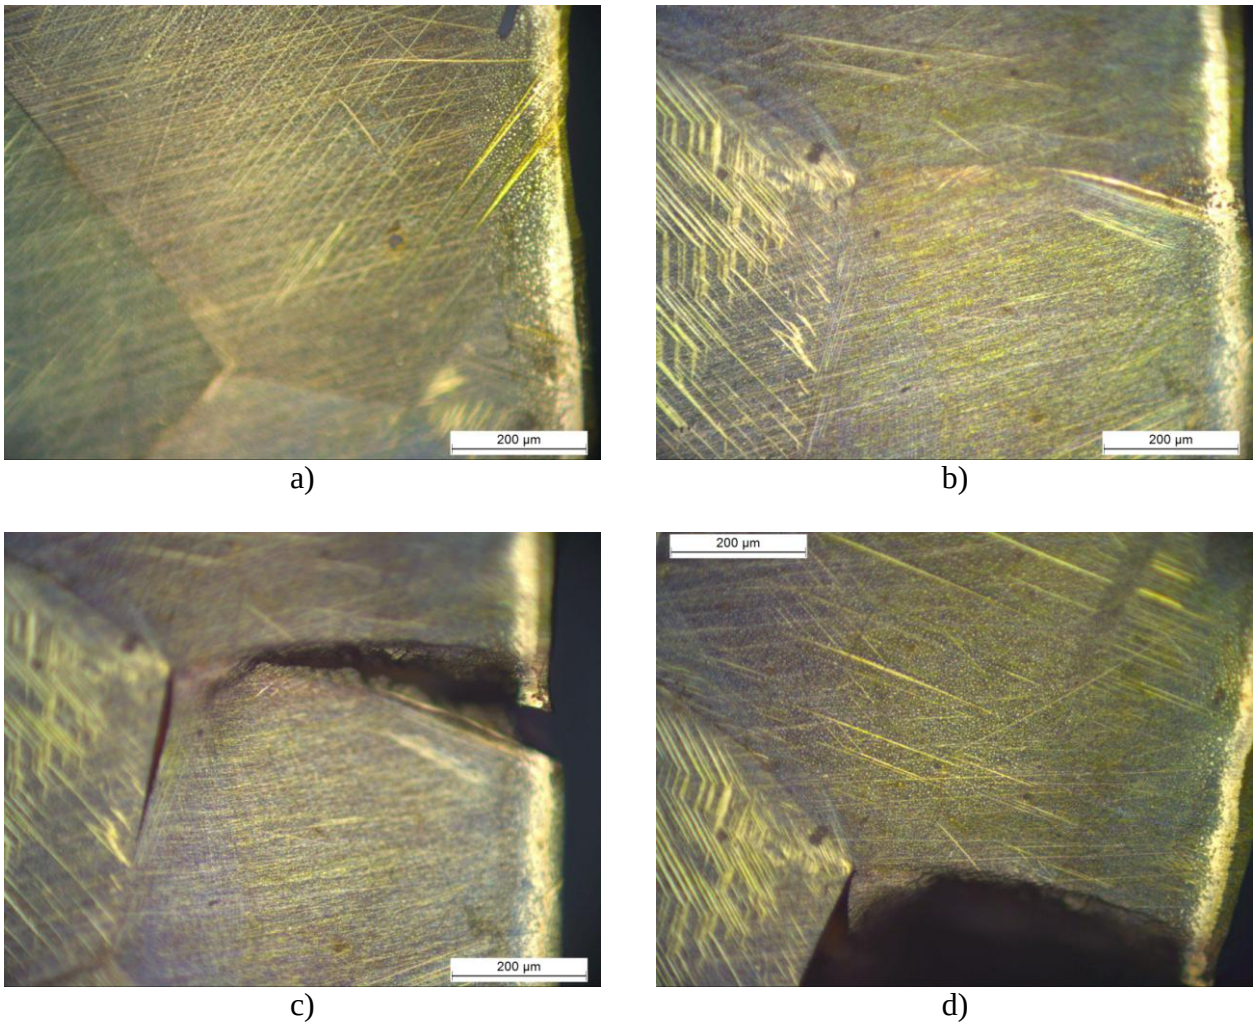
The failure initiation site (Fig. 4), for ε_{eng} = 0%, is characterized by the presence of three grains (Fig. 4a). For ε_{eng} = 5% (Fig. 4b) the three grains show an unchanged orientation, no sub-grains nucleation and a grain boundary deformation from linear to curved shape, probably due to phase transition. This is more evident in the grain on the left, where a surface modification is observed (sort of zig-zag lines on the surface). For ε_{eng} = 10% (Fig. 4c), an intergranular crack initiate from the lateral specimen surface, with a secondary intergranular crack, that is more or less parallel to the applied load. This secondary crack is probably due to the phases transition in grains with different orientations, with a consequent τ stress increase at the grain boundary [7]. The increase of the macroscopical deformation implies an increase of the localized damage level, with the coalescence

of main and secondary cracks (Fig. 4d). Final failure is obtained by means of a crack propagation from one side to the opposite side of the specimen ("fracture ending zone").
In Fig. 5, the "fracture ending zone" is shown. For ε_{eng} = 0, 5 and 10%, corresponding respectively to Fig. 5a, b and c, no transformations are evident: surface modifications due to phase transformations are not observed in this zone. For ε_{eng} = 14% (Fig. 5d), it is possible to observe a localized ductile deformation.



a) b)

c) d)

Figure 4. Fracture initiation zone: a) ε_{eng} = 0%, b) ε_{eng} = 5%, c) ε_{eng} = 10%, d) ε_{eng} = 14% (failure).

Evidence of structure transitions are in Fig. 6, where two diffractograms show respectively the undeformed and the deformed at ε_{eng} = 5% specimen. The undeformed specimen spectrum shows four peaks corresponding to 42.35°, 43.71°, 70.39°, 80.23°. The ε_{eng} = 5% deformed specimen shows also four peaks but corresponding to different diffraction angles (42.27°, 43.43°, 43.85° and 85.71°). Peaks modifications (considering both angles and intensity) show the mechanical deformation influence on the microstructure modifications.
Fracture surfaces are characterized by a brittle morphology, as the intergranular cleavage shown in Fig.7a, which confirms the path observed on the lateral surface (Fig. 4c, d). According to the LOM damaging micromechanisms analysis and to SEM fracture surface analysis, grains decohesion seems to be main damaging micromechamisms.
Inclusions presence implies the initiation of secondary microcracks (Fig. 7b), probably due to the same mechanism which characterizes the grains decohesion.

c) d)

Figure 5. Fracture ending zone: a) ε_{eng} = 0%, b) ε_{eng} = 5%, c) ε_{eng} = 10%, d) ε_{eng} = 14% (failure).

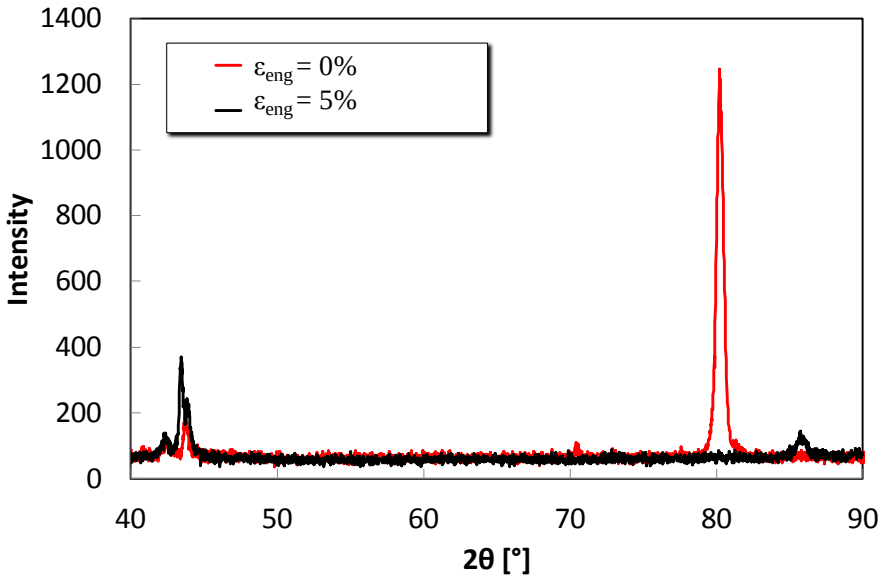

Figure 6. Diffraction spectra.

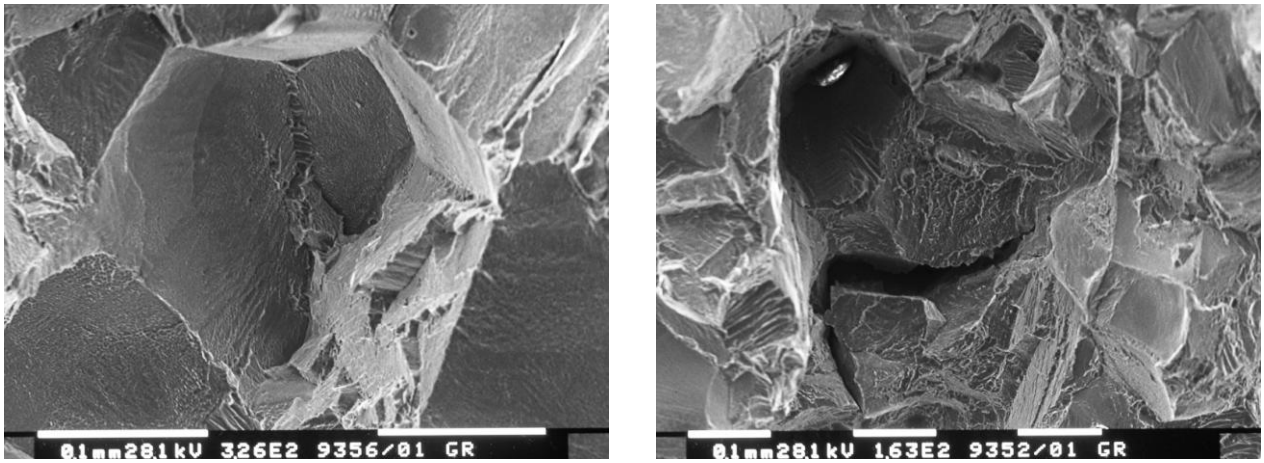
In the "ending fracture zone", corresponding to the highest deformation values (Fig. 5d), ductile fracture micromechanisms are shown (Fig 8). Two ductile morphologies are observed in Fig. 8 (respectively indicated by arrows with letters A and B). Morphology in A is characterized by an oriented plastic deformation, while morphology in B is characterized by an unoriented deformation.



a) b)

Figure 7. Fracture surface: a) intergranular cleavage, b) secondary crack in presence of inclusion.

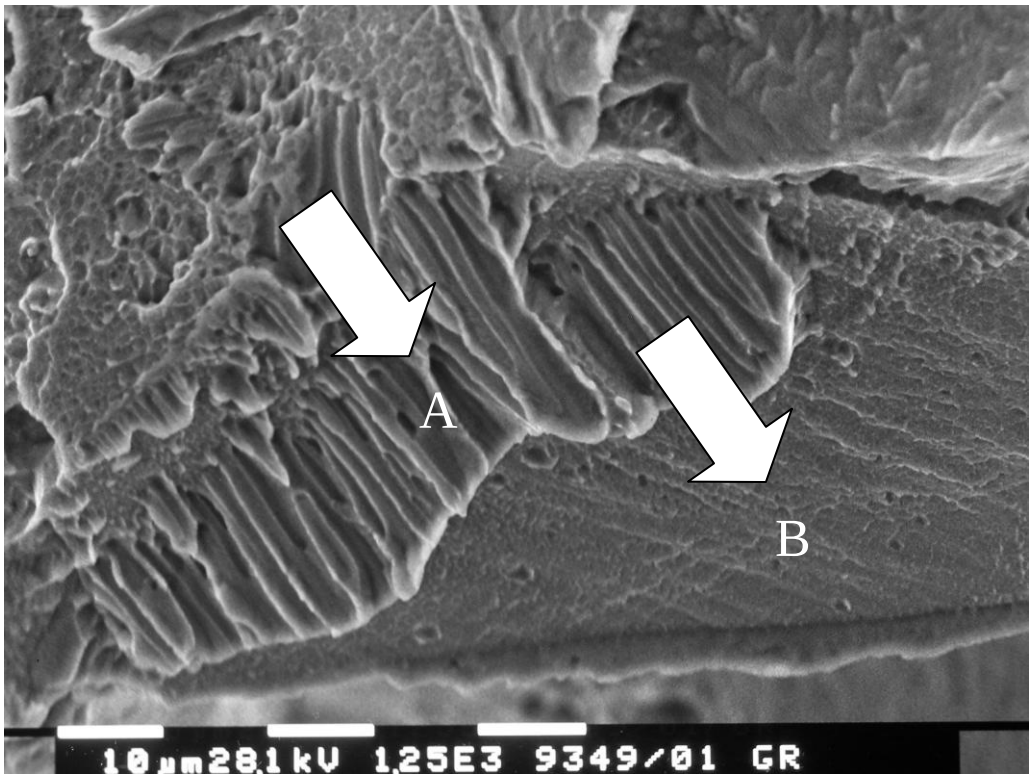


Figure 8. Fracture surface in the ending zone (as Fig. 5d)

Higher magnifications SEM observations (Fig. 9a and b) allow to confirm the ductile morphology of the fracture surface shown in Fig. 8.

4. Conclusions

In this work, the main crack initiation and propagation micromechanisms during tensile tests performed on a CuZnAl SMA has been analyzed. According to the experimental results, the following conclusions can be summarized:

- Cracks initiate at grains boundaries due both to high deformation values and to phases transitions;
- Memory effect is not only due to phases transitions, but also to the unchanging of numbers of grins boundary;
- The main fracture surface morphology is brittle and is characterized by intergranular cleavage;
- Corresponding to the highest deformation values (“ending fracture zone”) the main damaging micromechanism is ductile.

Abstract In this article was investigated the mechanisms of delamination phenomena occurs in the X70 steel during fracture process from the Charpy impact testing. Microtexture and Taylor factor map analysis were performed by electron backscatter diffraction (EBSD) technique in two fractured surface regions, namely, in the perpendicular and parallel regions to the propagation fracture direction where delamination occurred. As result, was observed two types of delaminations during fracture process, the crack arrester-type delamination and crack divider-type delamination. The main microtexture components obtained in the perpendicular and parallel regions to the direction of fracture propagation from orientation distribution function (ODF) were (221) [1-10] (223) [1-10] (112) [1-3 -2] (332) [023] and (223) [0-32] and (332) [1-10] orientations, respectively. It was also observed the presence of the (100) planes and Taylor factor value close to 2.7 in the respective regions investigated, consequently, a smaller stored energy was observed.

Keywords Delamination, Charpy impact test, crystallography orientation

1. Introduction

The transport of oil and gas through pipelines requires steels that are characterized by a combination of high strength and toughness, these steels are specified by the API 5L standard. However, during the fracture process by Charpy impact test, these steels exhibit the phenomenon known as delamination. This delamination can be attributed to crystallographic texture, intergranular fracture along grain boundaries of retained austenite, segregation of elements such as phosphorus and sulfur, microstructural anisotropy, banding, inclusions and aligned particles [1]. In this context many studies have been conducted to determine the relationship between microstructure and mechanical properties, where the technique by electron backscatter diffraction (EBSD) has been gained the ability to relate the spatial distribution of plastic deformation with the microstructural characteristics. Besides it allows a better understanding of the mechanisms responsible for the nucleation and propagation of cracks from delamination, which is a major problem in HSLA steels [2,3].The aim of present work is to investigate the mechanisms of delamination phenomena takes place in the API 5L X70 steel during fracture process from the Charpy impact testing in specimens with L-T and T-L orientations. Evaluation of microtexture and Taylor factor mapping were performed from the EBSD technique in two regions, namely, in the perpendicular and parallel regions to the propagation fracture direction where delamination occurred.

2. Experimental procedures

2.1 Material

The material used in this investigation was microalloyed steel specified by API 5L Grade X70 standards. The same was obtained by thermomechanical treatment by controlled rolling. The chemical composition obtained by optical spectrometry technique is shown in Table 1:

Table 1. Chemical composition of API X 70 steel

C	Si	Mn	P	Al	Cu	S
0.14	0.27	1.45	0.01	0.05	0.03	0.00076
Nb	V	Ti	Cr	Ni	Mo	
0.051	0.041	0.018	0.0005	0.001	0.0045	

2.2 Procedures

2.2.1 Charpy impact testing

Charpy impact testing specimens were removed from the orientation and dimensions according to ASTM E-23 [4], as can be seen in Fig. 1.

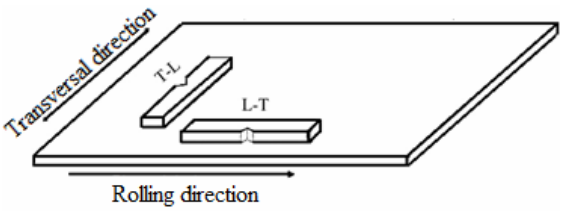

Figure 1. Schematic drawing of the orientation notch specimens

The tests were carried out in a range of temperature variation at 27°C up to -196°C, the specimens were immersed in a cryogenic bath of nitrogen and anhydrous alcohol liquids for 10 minutes, after that the same were withdrawn of the mixture and positioned on the machine. To increase the accuracy of this procedure the hammer would only be released whether all process occurred within 8 seconds.

2.2.2 Microtexture

Microtexture analyses were performed by EBSD technique. To carry out these measurements were used two samples from the fractured specimens in the L-T orientation by impact testing at -25 °C and 226J of absorbed energy in the ductile brittle transition temperature region. The surface specimens analyzed were carried out in the perpendicular region to the direction of fracture propagation and near the edges of the crack generated by crack divider-type delamination, as shown in Fig. 2a), another analysis was performed parallel to the direction of fracture propagation and near the edge separation caused by delamination, as shown in Fig. 2b). Samples were polished in the

solution of OP-S (colloidal silica), and then etched with Nital 2%. For EBSD data collection was used software TSL 5 IOM Data collection and for data processing was used software OIM Analysis 5. The scanning electron microscope used for performing of such measures was the EDAX TSL EVO MA 10.

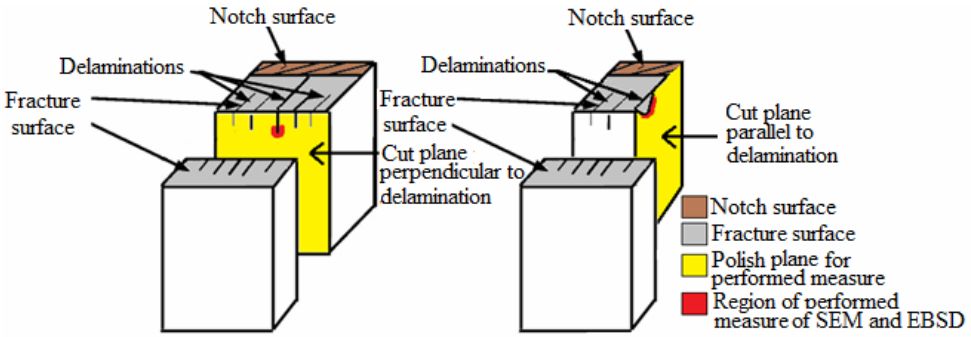

Figure 2. Schematic representation of removed samples for performing EBSD. a) Cut plane of the perpendicular direction of fracture propagation, b) Cut plane in the parallel region to the direction of fracture propagation.

3. Results and Discussion

3.2 Charpy impact testing

Fig. 3a) shows the curve of absorbed energy versus temperature for L-T and T-L orientations. It is possible to notice that there was a greater dispersion of energy values for the samples of L-T orientation when compared to the T-L orientation. At the lower upper shelf energy where the cleavage fracture occurs, both directions have obtained the same amount of energy, 5J. The L-T orientation has a higher upper shelf energy regarding T-L orientation, consequently this direction has higher absorbed energy for all temperatures. Concerning the ductile-brittle transition temperature, the L-T orientation has also obtained the highest absorbed energy values as a function of orientation, as can be seen in Fig. 3b).

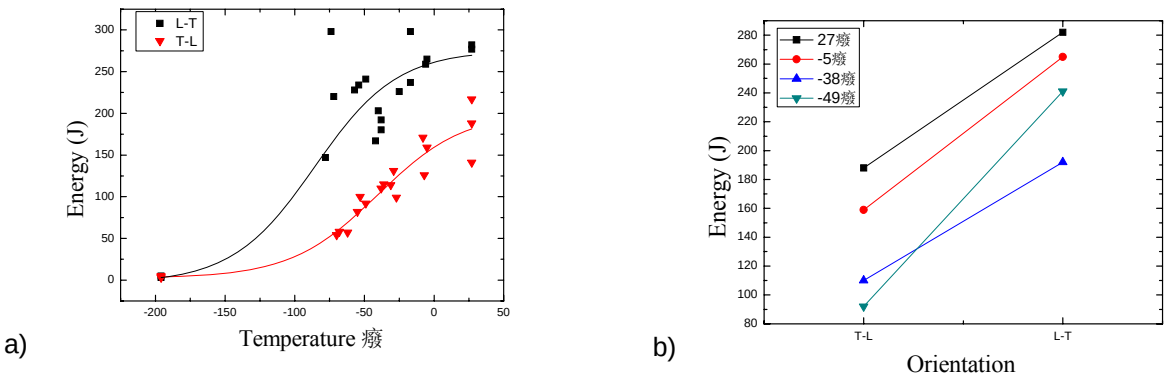

Figure 3. Charpy impact testing a) as a function of temperature, b) as a function of the orientation (for some temperatures)

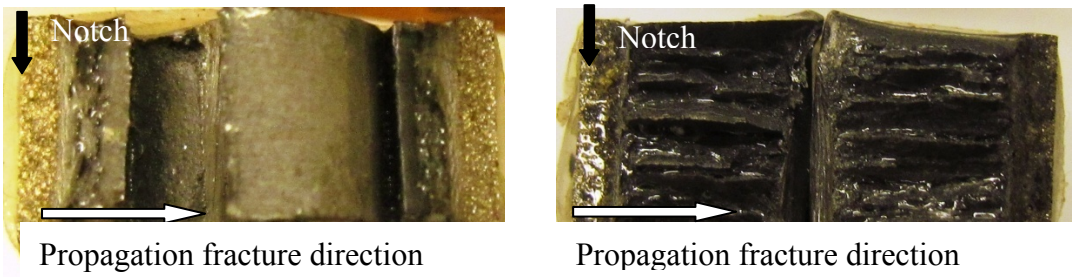
The ductile-brittle transition temperature was estimated by comparing the percentage of ductile fracture area following the specifications of ASTM E-23[4]. Specimens with L-T orientation showed range lower values of transitions temperature between -38°C to -57°C, while the specimens with T-L orientation exhibited a greater range of the transition temperature values between -8 ° C up to -38 ° C.

3.3. Aspects of delamination phenomenon

Fig. 5) shows fractured surface samples with delaminations from the Charpy impact test. In Fig. 5a) is possible to observe crack arrester-type delamination from the specimen tested at -5°C and 265J of absorbed energy. Fig. 5b) also shows a set of crack divider- type delamination from the specimen tested at -36°C and 100J of absorbed energy.



a) b)

Figure 4. Fractured surface by impact test showing the phenomenon of delamination. a) Crack arrester-type delamination, b) Crack divider-type delamination

It can be seen in Fig. 4a) the crack arrester-type delamination is formed perpendicular to the propagation fracture direction and parallel to the notch, while the crack divider-type delamination (Fig. 4b)) occurs parallel to the propagation fracture direction and perpendicular at notch. Cracks arrester-type delaminations are known by their beneficial effect to increase upper shelf energy [5], this suggests a higher tendency of the L-T orientation specimens present crack arrester-type delamination, which may contribute to increase of energy values for L-T orientation independent on the temperature used, as can be seen in Fig 3a).

3.4. Microtexture

Fig. 5 shows an image obtained by scanning electron microscopy in the regions in front of propagated crack by crack divider-type delamination, the distribution map of orientations, the inverse pole figure, the orientation distribution function (ODF) for Bunge angle $\Phi_2 = 45°$, and the pole figures of the (100) and (110) planes. Quantification of microtexture was made by EBSD technique, with the following parameters: Fig. 5b) was used step size of 1 micron and 1000 X magnification and Fig. 5c) was used step size of 3 microns and a magnification of 3000X.
From Fig. 5b) is possible to notice the presence of dark regions, where shows a crack produced by the formation of delamination. The remaining points may be regions of perlite, which have very

thin lamella (about 200nm). As the distance between layers is smaller than the step size used, the occurrence to indexation of crystallographic planes to these regions was not possible, resulting in dark regions. Another plausible explanation is associated to the material deformation, which can contribute to the accumulation of dislocations at grain boundaries, resulting in the non-indexed regions. In Fig. 5b) there is a grain size distributions quite heterogeneous and the absence of (100) plans. While in Fig.5c) shows the propagated crack region by delamination, the same propagates in the grain boundary, featuring an intergranular fracture mechanism. It is confirmed by separation of grains with [111]||ND and [101]||ND texture components indicated by 1 up to 5 grains, respectively.

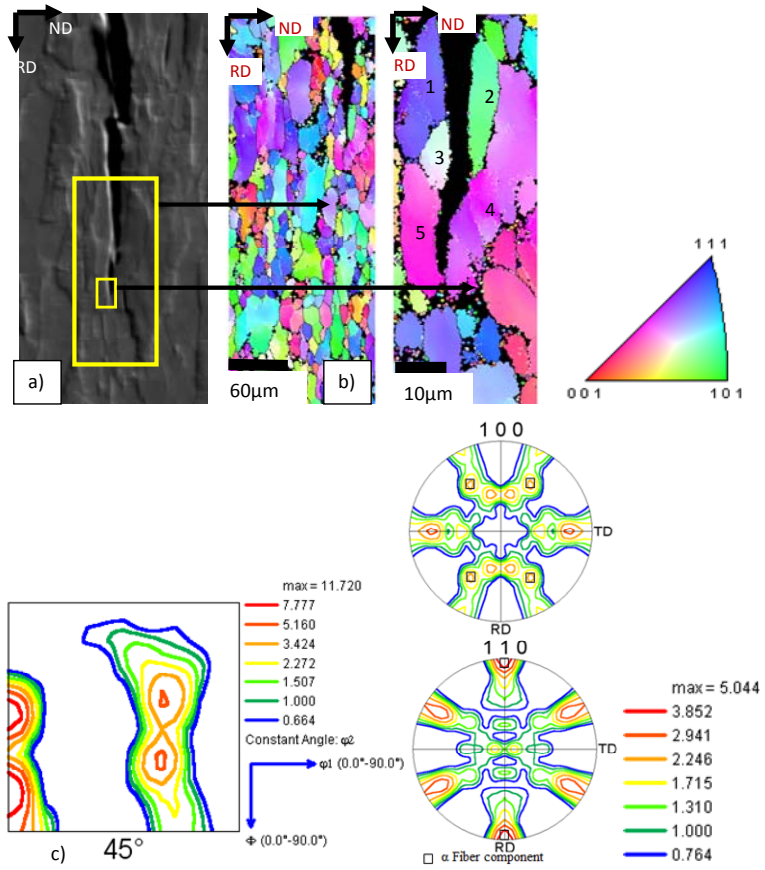


Figure 5. Microtexture in the region near the crack delaminated. a) SEM from the scanned region, b) distribution maps of orientation and inverse pole figure c) orientation distribution function (ODF) and pole figures.

It is well known that intergranular propagation occurs through high angle boundaries. In this context the Fig. 6 shows the misorientation obtained by EBSD technique from the scanned region (Fig 5b)). For generation of statistical data points only disorientation greater than 2° was considered. It is possible to see at Fig. 6 that approximately 42% of the misorientation angles between adjacent grains are smaller than 10° (low angle boundaries) while the other 58% are distributed randomly between 10° and 110°, indicating a high grain boundary angle.

For the generation of pole figures and ODF shown in Fig 5c) was used an orientation map from Fig. 5 b) which provides a better precision in the information due to its higher scanned area. The ODF shown in Fig. 5c) reveals that the orientations have α fiber components. The main components

obtained from ODF are (221) [1-10] (223) [1-10] (112) [1-3 -2] and (332) [023] orientations. Pole figures shown in Fig. 5c) confirm the presence of the α fiber components identified by the ODF.

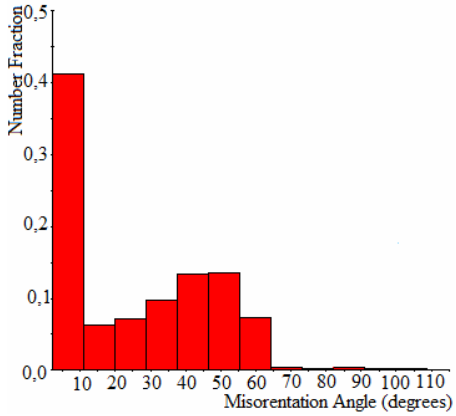

Figure 6. Misorientation angles between adjacent grains near to edges of delamination

Furthermore, materials with crystallographic plane with (100) orientation aligned in the rolling direction show a strong tendency to occur cleavage fracture during impact [1,2,6,7,8,9,10]. To identify whether in this case occurred the separation of the (100) planes were measured microtexture on the edge of the fractured surface where was generated the delamination. This sample was the same used in the analysis of Fig. 6b), but using step size of 1 micron and 1000X magnification, and the results obtained are displayed in Fig. 7. It can be observed in Fig. 7a) the difference of depth between the ferrite and pearlite. While in Fig. 7b) shows the distribution orientations map, there is a heterogeneous distribution of grain sizes and a few areas where there were not indexing of the plans, there is also the presence of (100) plans. The ODF to Bunge angle $\Phi_2 = 45°$ is shown in Fig 7c) and its indexing shows the main texture components was (223) [0-32] and (332) [1-10]. The pole figures are shown in Fig. 7d) where it is possible to notice that higher centering occurred in the (111) plane, however, it also notice that occurred to the (100) plane and indexing of some components reveals the presence of {100} planes families and the <011> families directions. As seen in Fig.5c) the crack nucleated by delamination separated grains with (111)||ND and (101)||ND texture components. It is evident that in this case should be noticed, the presence of the (111)||ND components close to the delamination, confirming the separation of ferrite plans. However the presence of the (100) planes was also confirmed. Whereas when if analyzes the microtexture, it cannot confirm whether this is a general rule for the nucleation of delamination in the material under study.

Experimentally, it is known that the stored energy during deformation changes with the crystallographic orientation of the grains. The Taylor factor is a parameter that correlates to macroscopic deformation behavior with microstructural characteristics of the material [11]. According to the theory of plasticity, the stored energy increases with the Taylor factor which in turn, depends on the crystallographic orientation of the grain in relation to the direction of applied stress [12]. The Taylor factor is defined as:

$$M = \sum \delta\gamma_i / \delta\varepsilon \tag{1}$$

Where $\delta\gamma_i$ represent shear portions in each of activated sliding systems in determinate grain while the sample receives a macroscopic deformation $\delta\varepsilon$ [13].

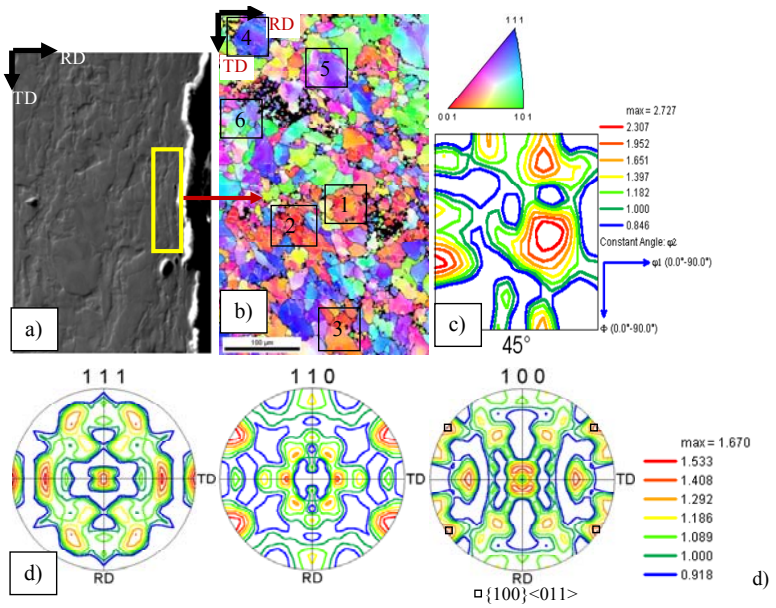

Figure 7. Microtexture analysis by EBSD. a) SEM scanning region, b) Distribution maps of orientation, magnification of 1000X, c) Inverse pole figure and ODF, d) pole figures

Fig. 8 shows the mapping of Taylor factor in front of the crack region for sample shown in Fig. 5b). It is possible to note in Fig. 8a) that mapping shows the separating generated by propagation crack occurs with grains with different Taylor factor values, indicating that the crack delamination intergranular propagate mode. The first and second grains were separated with factor Taylor value around 4.8 and 3.5, respectively. The same situation took place for 5 and 7 grains. Already the 3 and 4 grains also show Taylor factor values in the range of 3.0 and 3.6 respectively, the same has occurred with 5 and 6 grains. It notes that approximately 14% of the grains have Taylor factor values between 4.7 and 4.8 and close to 57% of the grains have Taylor factor values between 2.9 and 3.6.

Figure 8. Mapping of Taylor Factor. a) Scanned region, b) Histogram of number fractions

Besides, in the Fig. 9 shows the mapping of Taylor factor from the sample region shown in Fig. 7b). In the Fig. 9 is possible to observe that approximately 55.34% of the grains have Taylor factor between 2.7 and 3.4.

The stored energy in low carbon steels can be different conform to the sequence: $E_{(110)} > E_{(111)} > E_{(211)} > E_{(100)}$ where hkl plans are related to rolling plans in each grain (12). Thus a comparison can be made from the 1, 2 and 3 numbered regions of the following Figs. 7b) and 9a), where is observed the presence of the (100) planes and Taylor factor value close to 2.7 in the respective regions, consequently, a smaller stored energy was absorbed. Whereas, the 4, 5 and 6 numbered regions of the same figures show a predominance of the (111) planes and Taylor factor value close to 4.5, but the number fraction of grains with this Taylor factor value is low (about 1.53).

Figure 9. Mapping of Taylor Factor a) Scanned region, b) Histogram of number fractions

4. Conclusions

Charpy impact testing showed that specimens with L-T orientation absorbed more energy than specimens with T-L orientation. It was observed two types of delaminations during fracture process, the crack arrester-type delamination and crack divider-type delamination. The first type propagates parallel to the notch, while the second propagates perpendicular to notch. Crack arrester-type delamination tends to increase upper shelf energy during Charpy impact testing, and both types of delaminations tend to disappear with decreasing temperature.

The results obtained by EBSD technique shows the propagation mode of a crack generated by a divider-type delamination was intergranular. The main microtexture components obtained in the perpendicular region to the direction of fracture propagation from ODF were (221) [1-10] (223) [1-10] (112) [1-3 -2] and (332) [023] orientations. While in the parallel region to the direction of fracture propagation the (223) [0-32] and (332) [1-10] orientations were the main microtexture components.

The Taylor factor analysis display the difference in the Taylor factor values with crystallographic orientation, as expected. It was also observed the presence of the (100) planes and Taylor factor value close to 2.7 in the respective regions investigated, consequently, a smaller stored energy was observed. This confirms the fracture mechanisms from the delaminations are given by little plastic deformation, namely, brittle fracture.

Abstract: Large–diameter, high-pressure gas transmission pipelines have been used more and more widely all over the world. With the development of the pipeline network, safety and maintenance become an important task. Controlled thermo-mechanical processing is considered as the primary route for the development of API grade linepipe steels because it provides desirable and fine grained microstructure. It is known that crystallographic orientation can generate anisotropy of mechanical properties. Furthermore, studies on pipeline steels, such as X60, X70 and X80, suggest that delamination phenomenon the fracture surface in fracture toughness test specimens affects the measured fracture toughness and therefore safety evaluation of pipeline steels. Microtexture analysis by electron backscattering diffractions (EBSD) was carried out to obtain crystallographic orientation from the fracture process in which occurs the delamination phenomenon. Experimental results obtained by EBSD technique have shown that delamination phenomenon occurs in the {100}<011>crystallographic orientation. The α fiber texture such as :{113}<110>, {112}<110> and {223}<110>, have produced anisotropic mechanical properties that during fracture process act to reduce the plastic constraint and contributing to increase the stress plane

Keywords Delamination, fracture toughness test , crystallographic orientation, API X70 steel

1. Introduction

One of the most widely used classes of steel pipes is based on the standard API (American Petroleum Institute), which are classified according to chemical composition and mechanical properties [1]. These steels generally undergo thermomechanical processing, associated with addition of alloying elements such as Nb and Ti to obtain a material with high toughness and ductility, as well as good weldability, well known as HSLA steels (high strength low alloy) [2]. The thermomechanical processing imposed on HSLA leads to generation of preferential orientation (texture), resulting in anisotropy mechanical properties [3-6]. The occurrence of texture is most evident during the controlled rolling process which can produce recrystallization, transformation and deformation texture [3].

Special attention should be given the {100} <110> texture component which is parallel to the rolling plate direction. During the monotonic and dynamic test this component contributes to the occurrence of cleavage planes [3, 7 ,8 ,9, 10]. This cleavage planes also contribute to appearance of the delamination (split), as can be seen in Fig. 1. Other factors leading to the occurrence of delaminations are the formation of precipitates at grain boundaries [11, 12], inclusions [13, 14], elongated grains [11, 15], decohesion of grain boundaries [13, 14].

The aim of present work was to investigate the microtexture from the delamination region takes

place in the API 5L X70 steel during fracture process from the fracture toughness testing. Evaluation of microtexture and Taylor factor mapping were performed from the EBSD technique in the perpendicular region to the propagation fracture direction where delamination occurred.

2. Experimental Procedure

The material used in the investigation was obtained from an API X60 steel plate grade of 5/8 inch thickness. Table 1 shows the chemical composition of API X60 steel and the requirement of the API standard.

Table 1. Chemical Composition obtained for API X60 steel and maximum specification through API standard (in wt. %) [1].

Element	C	Mn	P	S	Ni +V+T	Cr	Cu	Co	Si
Composition	0,15	1,45	0,014	0,005	0,011	0,032	0,037	0,02	0,3
API Specification	0,26	1,40	0,030	0,030	0,015				

To obtain the tensile properties, three specimens from the rolling direction (RD) and transverse direction (TD) were extracted in each direction. The specimens were tested in tensile testing SHIMADZU machine at room temperature according to ASTM E8M [16].

The single edge tension SE(T) specimens were used to obtain *J-R* curves. All specimens crack planes were oriented in the LT orientation according to ASTM E1820 [17]. The SE(T) specimen has following dimensions: length of reduction section of 156 mm, radius of fillet of 10 mm, overall length of 276 mm, width, W, of 32 mm and thickness of 12.5 mm. This specimen was loaded with a centered pin at center distance of 214 mm. Crack length to width ratios of 0.21 and 0.52 were investigated, corresponding shallow and deep cracks respectively. The specimens were loaded in three-point bending with a span of 128 mm, after precracking by fatigue according to the procedure in ASTM E1820. The specimens were side grooved using a Charpy cutter to a total thickness reduction of 20%, in an attempt to develop plane strains conditions along crack front. The fracture toughness tests were performed in MTS Flex Test GT servo hydraulic machine according to ASTM E1820 [17]. All specimens were tested at room temperature. The J-R curves were obtained from unloading compliance technique using clip gage to measure the crack mouth opening displacement (CMOD). Procedure to calculate the J-R resistance such as, k, η, γ factors were obtained from the results of Cravero [18].

Microstructure analysis were performed from the rolling direction (RD), transverse (TD) and normal direction (ND) which were grinding, polished and chemically etched with Nital 2%.

The microtexture was carried out by EBSD technique. The sample was obtained from perpendicular fracture surface in the delamination region, as can be seen in Figs. 1.a e 1.b. Samples were polished in the solution of OP-S (colloidal silica), and then etched with Nital 2%. For EBSD data collection was used software TSL 5 IOM Data collection and for data processing was used software OIM Analysis 5. The scanning electron microscope used for performing of such measures was the EDAX TSL EVO MA 10.

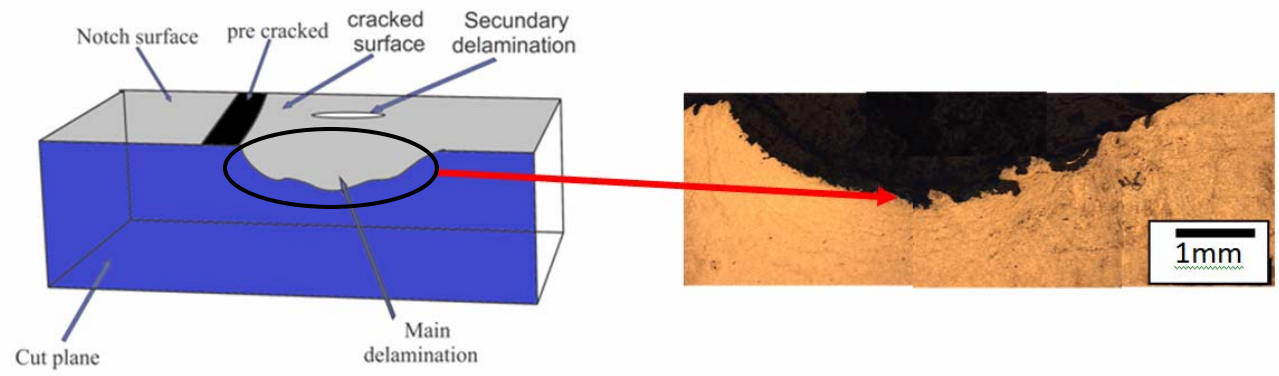

Figure 1 a) Schematic drawing shows the specimen section where was made cut perpendicular to the fracture surface b) fractured surface from the delamination region.

The scan was performed with step size of 1μm and magnification of 1000 times. Pole figures were obtained from the (100), (110) and (111) centered planes. While orientation distribution functions (ODF) was performed from the Euler space and the Bunge notation. Whereas, Taylor factor maps and misorientation angles distribution were generated in software for further analysis.

3. Results and Discussion

The chemical composition is according to the API standard [1], as shown the Table 1. The tensile properties obtained for the API X70 steel are shown in Table 2. The yield strength (YS), ultimate tensile strength (UTS) and elongation values are according to API standard [1].

Table 2. The tensile properties obtained from the tensile test for API X70 steel.

YS (MPa)	UTS (MPa)	Elongation (%)	Hardening exponent (%)	Modulus Elastic (GPa)
515	586	23	15	207

Fig. 2.a shows the three dimensional view of the API X70 microstructure steel. It can be observed a microstructure consisting of alternated layer of ferrite and pearlite in the RD and TD directions as also random distribution of ferrite and pearlite in the DN direction. Fig. 2.b shows the delamination region which can be noticed the banded microstructure caused by delamination.

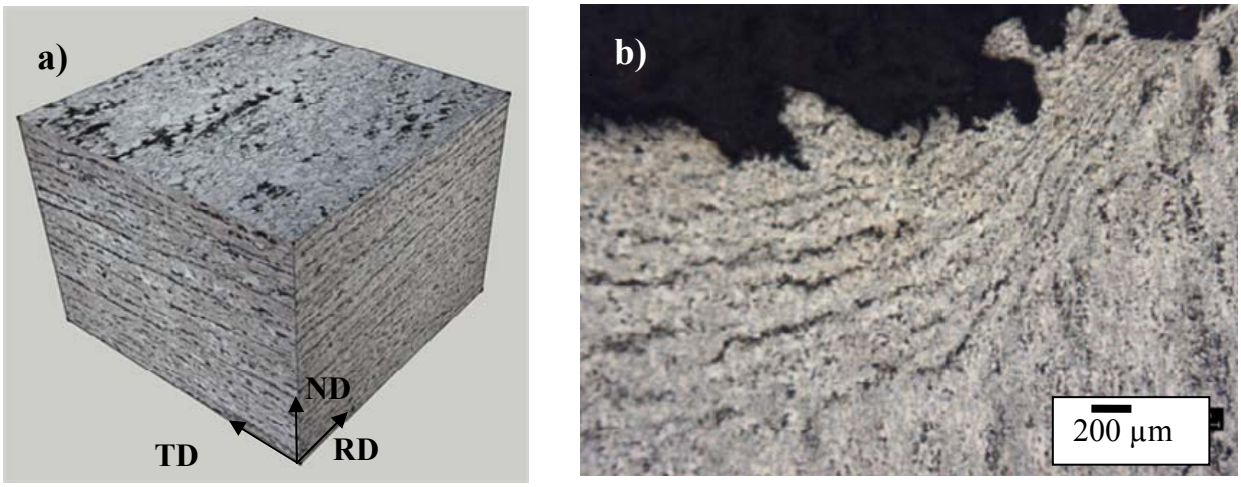

Figure 2. Microstructure of API X70 steel: a) three-dimensional view of the API X70 steel microstructure b) banded microstructure in the delamination region.

Fig. 3.a shows the fractured surface from tested specimen where it can be seen the notch, pre-fatigue crack, ductile crack extension. As the out-of-plane constraint is highest at the centre of the specimen, accordingly the delamination is most severe. Secondary delaminations are concentrated at the 1/4 thickness points from the free surfaces and similar to the main delamination [19, 20]. Fig. 3.b shows the P x CMOD curve from the unloading compliance method indicating the occurrence of delamination on the curve. It is possible to notice load-displacement curve a degree or register sequence failure. This feature is associated to the occurrence delamination phenomenon.

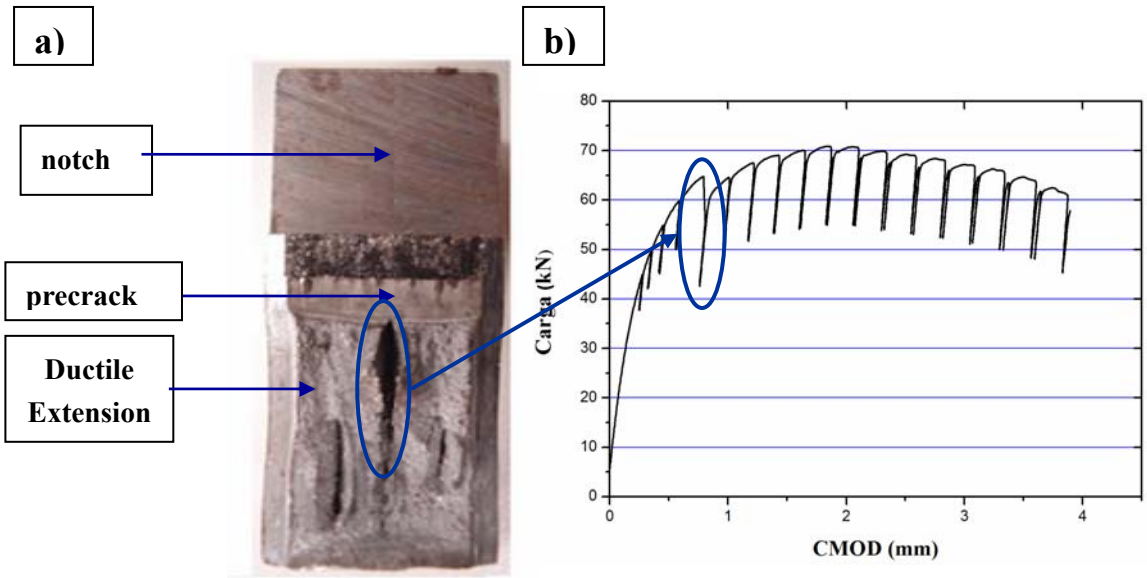

Figure 3. a) Fractured surface of sample from the fracture toughness test showing the notch, pre-fatigue and ductile extension, b) PxCMOD curve from the unloading compliance method indicating the occurrence of delamination on the curve.

Fig. 4.a shows the delamination region that was investigated by EBSD technique to obtaining of the microtexture. Fig. 4.b displays the orientation map, as well orientation triangle, where it can be observed a random grain sizes distribution from the rolling process occurred in the (α + γ) range, as also the higher predominance of <111> and <100> orientations. Also in Fig. 4.b displays the remaining points may be perlite regions, which have very fine lamella (about 200nm). As the distance between lamellas is smaller than the step size used, the occurrence to indexation of crystallographic planes to these regions was not possible, resulting in dark regions. Another plausible explanation is associated to the material deformation, which can contribute to the accumulation of dislocations at grain boundaries, resulting in non-indexed regions.

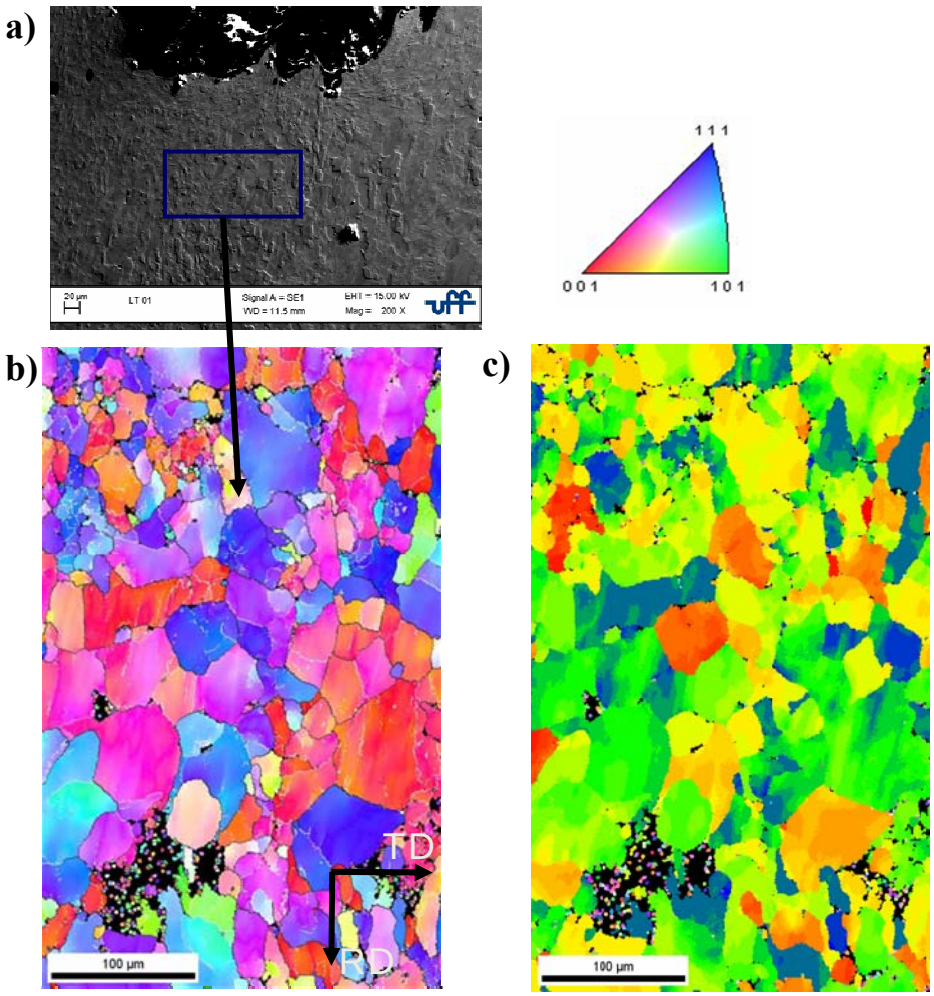

Figure 4. a) Delamination region used for microtexture analysis by EBSD technique b) orientation map of the selected region in the figure 3.a c) The Taylor factor Map of the same region.

Fig. 5 shows the Taylor factor distribution from the delamination region. It is possible to note the higher predominance of Taylor factor value between 2.5 to 3.5 corresponding 68% of grains. Moreover, 41% of grains have Taylor factor value lower 3 indicating lower absorbed energy. This indicates that the delamination phenomenon occur in the lower Taylor factor values. While the higher Taylor factor value (4) corresponded only 6% of grains.

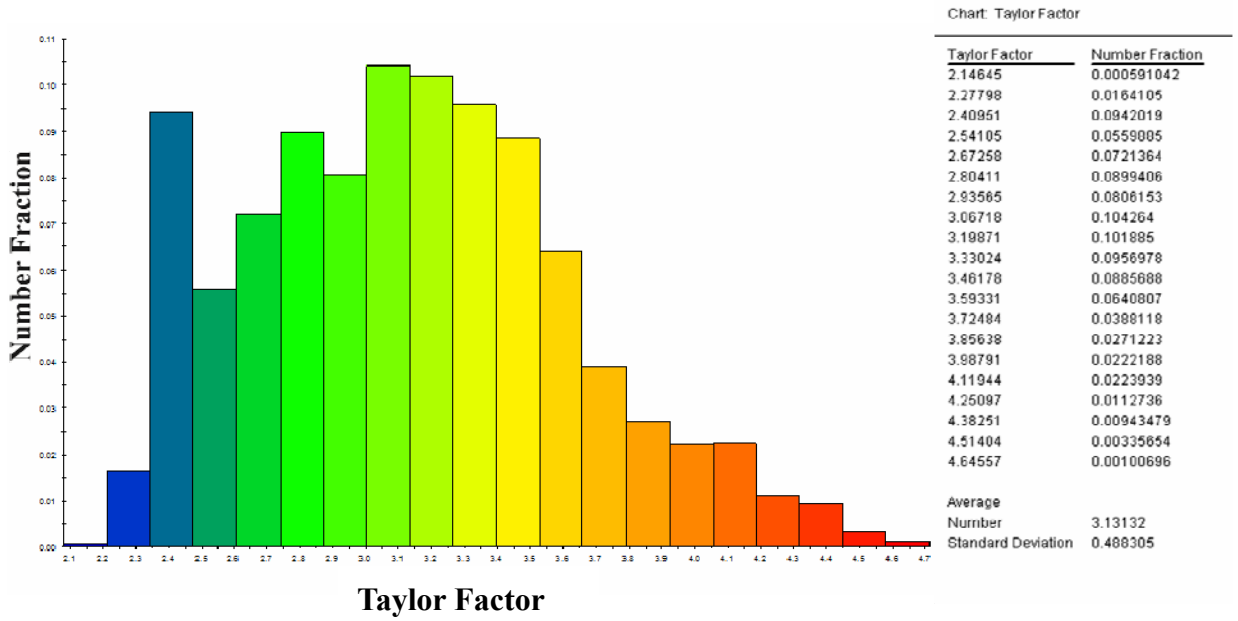

Figure 5. Histogram the Taylor factor distribution from Fig. 4.c.

Fig. 6.a shows the pole figures from the (111), (110) and (100) centered plans in the delamination region. Fig. 6.b shows the orientation distribution function (ODF) obtained for the section $\varphi_2 = 45$ °, which is the most important section on steels analysis, φ_1 is Euler angle aligned with RD while Φ is aligned to TD. The main components were obtained from ODF's because pole figures provide incomplete information [21]. It can be seen in Figs. 6.a and 6.b the formation of fiber texture: α fiber or fiber DL, γ fiber or fiber DN and cube textures. The presence these components are common in low carbon steel from the controlled rolling process. It can suffer change in the intensity value according to different processing and composition chemical of the steel [3].

The α fiber components more intense were: {113} <110>, {112} <110> and {223} <110>, which it can cause anisotropy mechanical properties [3, 5, 6]. This manner, the {113} <110> fiber component is generated from the deformed austenite recrystallization {112} <111> component. While the {112} <110> and {223} <110> fiber components both are produced by deformation from the {113}<110> rotation component. The same components can be contributing to ductile crack propagation during the test.

The cube fiber components were: {100} <120> and {100} <230>. These components usually are the lower intensity than γ and α fiber texture, this feature is attributed to recrystallization process [3]. The {100} <110> texture component was also found, the same is parallel to the rolling direction and contribute to both occurrence the cleavage plane and delamination phenomenon [3, 7, 8, 9, 10].

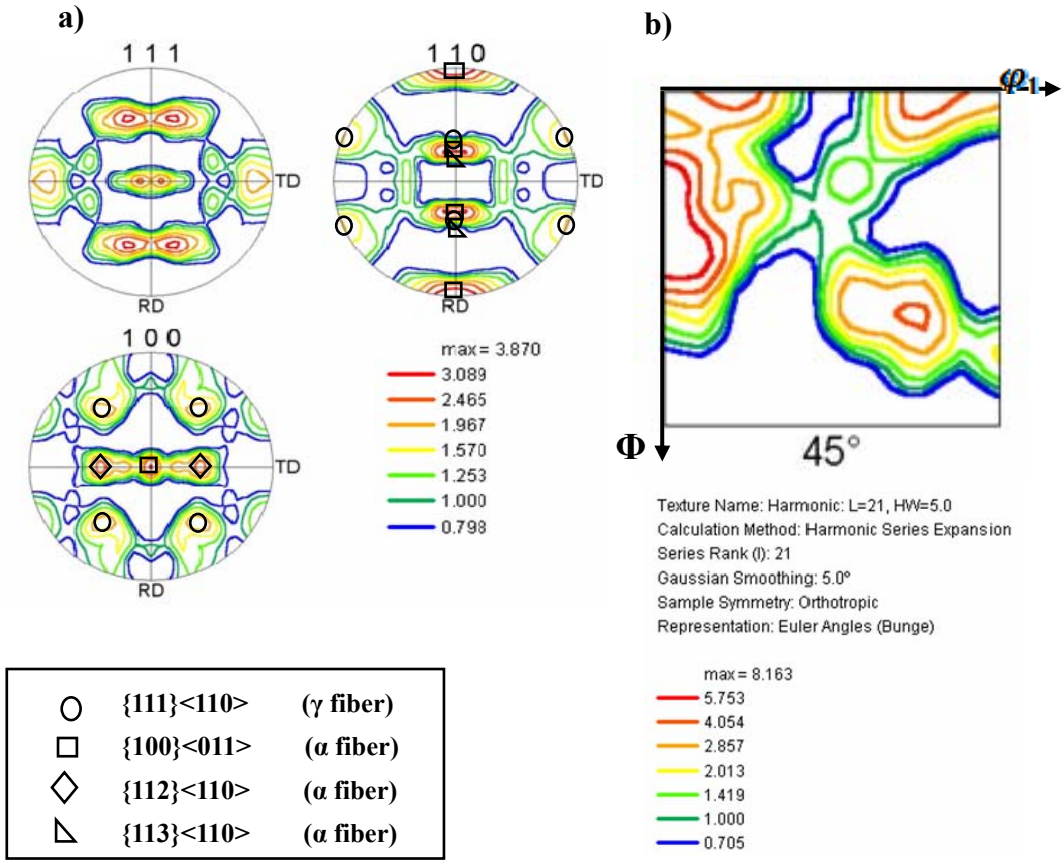

Figure 6. a) Pole figures from the (111), (110) and (100) centered planes obtained in the delamination region. b) orientation function o distribution for the section $\varphi_2 = 45°$.

5. Conclusions

The orientation maps close to the delamination region have displayed a heterogeneous grain size distribution. The Taylor factor values were the lower absorbed energy with <100> type orientation. While the <111> type orientation has shown higher absorbed energy, consequently, a higher Taylor factor value. The orientation distribution function and pole figure have shown the presence of the α fiber texture such as :{113}<110>, {112}<110> e {223}<110>, these components produce anisotropic mechanical properties that during fracture process act to reduce the plastic constraint and contributing to increase the stress plane. The {100}<110> cube fiber component has been found in the delamination region, it is main responsible to the occurrence of phenomenon in HSLA.

Abstract By introducing a conformal mapping and using the complex variable function method, the fracture behavior of a lip-shape crack in one-dimensional hexagonal quasi-crystals materials is investigated under anti-plane loading at infinity. The expressions for stress, strains, displacements and field intensity factors of the phonon and the phason fields in the vicinity of the crack tip are obtained. When the height of the lip-shape crack approaches to zero, the present results can be reduced to the solutions of the Griffith crack

Keywords one-dimensional hexagonal quasi-crystals; lip-shape crack; complex variable function method; stress intensity factor

1. Introduction

The discovery of quasi-crystals (QCs) in 1984 is a significant breakthrough for condensed matter physics, which won the Nobel's award in 2011 [1]. A theoretical description of the deformed state of QCs requires a combined consideration of interrelated phonon and phason fields. The phonon field describes the motion of lattices in physical space, while the phason field describes quasiperiodic arrangement of atoms in the complementary orthogonal space, which interact with one another. Since the discovery of QCs, they have attracted the extensive attention of researchers engaged in experimental and theoretical work. A quantity of significant achievements of QCs have been done [2-11] recent years. Experiments have shown that quasi-crystals are quite brittle and the defects of quasicrystalline materials have been observed [12,13]. When quasicrystalline materials are subjected to mechanical stresses in service, the propagation of flaws or defects produced during their manufacturing process may result in premature failure of these materials. Therefore, the study of crack problem of quasicrystalline materials is meaningful both in theoretical and practical applications.

At present, the study on the fracture problems of quasicrystalline materials is mainly confined to relatively simple defects. Thus, the elastic problem of one-dimensional (1D) hexagonal quasicrystal materials becomes the primary object and made many of significant achievements. A moving screw dislocation in 1D hexagonal QCs was investigated [14]. The exact solutions of a semi-infinite crack and two semi-infinite collinear cracks in a strip of 1D hexagonal QCs were obtained [15,16]. The interaction of between dislocations and cracks in 1D hexagonal QCs were considered by the complex variable function method. Very recently, the analytical solutions of several complicated defects such as cracks originating from holes in 1D hexagonal QCs were obtained [17-19].

In this paper, by using the Stroh-type formulism for anti-plane deformation in 1D hexagonal QCs, the fracture mechanic of a lip-shape crack in a 1D hexagonal QC is investigated under uniform remote anti-plane shear loadings of the phonon field and the phason field. By introducing a conformal mapping and using the complex variable function method, which is further solved analytically. The expressions for stress, strains, displacements and field intensity factors of the

phonon and the phason fields in the vicinity of the crack tip are obtained. The exact solutions of the stress intensity factors for the phonon field and the phason field are obtained respectively, which are very useful in practice.

2. Basic equations

When defects parallel to the quasi-periodic axis of 1D hexagonal QCs exist, the geometrical properties of the materials will be invariable along the quasi-periodic direction. In this case, the corresponding elasticity problem can be decomposed into two independent problems, i.e., a plane elasticity of conventional hexagonal crystal which can be solved by the route of the linear elastic theory [19] and an anti-plane phonon-phason field coupling elasticity problem [4]. Thus, we only need consider the latter one. The physical problem considered in this paper is shown in Fig. 1.

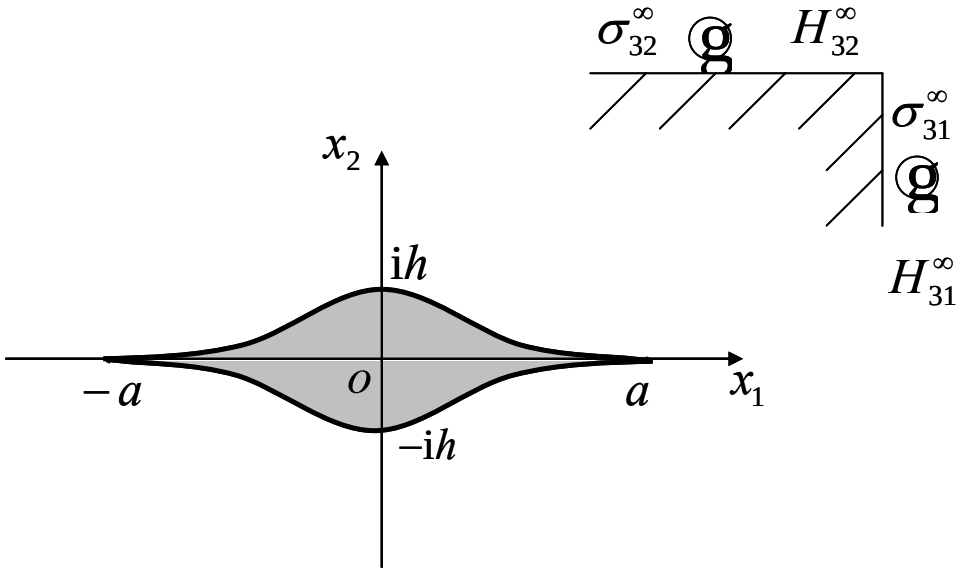

Figure 1. A lip-shape crack in 1D hexagonal QCs.

It is assumed that the quasi-periodic direction of 1D hexagonal QCs is along the positive direction of x_3 axis. In this case, all field variables are independent of x_3 and we have the following deformation geometrical equations [4]

$$\varepsilon_{3j} = \varepsilon_{j3} = u_{3,j}/2, \qquad w_{3j} = v_{3,j}, \tag{1}$$

the equilibrium equations

$$\sigma_{3j,j} = 0, \qquad H_{3j,j} = 0, \tag{2}$$

and the generalized Hooke's law

$$\sigma_{3j} = C_{44}u_{3,j} + R_3 v_{3,j}, \qquad H_{3j} = R_3 u_{3,j} + K_2 v_{3,j}, \tag{3}$$

where $j = 1, 2$; the repeated indices denote summation; a comma in the subscripts stands for a

partial differentiation; σ_{ij}, ε_{3j}, u_3 are the stress, strain and displacement of the phonon field, respectively; H_{ij}, w_{3j}, v_3 are the stress, strain and displacement of the phason field; C_{44} and K_2 are the elastic constants of the phonon field and the phason field, respectively; R_3 is the phonon-phason coupling elastic constant.

Substituting Eq. (3) into Eq. (2) ,then we can obtain the following result

$$\mathbf{B}_0 ? \nabla^2 \mathbf{u} \quad \mathbf{0}, \tag{4}$$

where ∇^2 indicates the two-dimensional Laplace operator, and

$$\mathbf{u} = [u_3, v_3]^T, \ \mathbf{B}_0 = \begin{matrix} 矩 \\ 阵 \end{matrix} \begin{matrix} C_{44} & R_3 \\ R_3 & K_2 \end{matrix}, \tag{5}$$

where the superscript T represents the transpose.

Because $C_{44}K_2 - R_3^2 \neq 0$, $\mathbf{B}_0^{-1}$ exists and thus Eq. (4) is equivalent to

$$? \nabla^2 \mathbf{u} \quad \mathbf{0}. \tag{6}$$

The general solution to Eq. (6) is

$$\mathbf{u} = \mathbf{f}(z) + \overline{\mathbf{f}(z)}, \qquad z = x_1 + \mathrm{i}x_2, \tag{7}$$

where $\mathbf{f}(z)$ is an unknown complex vector; and $\overline{\mathbf{f}(z)}$ stands for the conjugate of $\mathbf{f}(z)$.

To introduction Stroh-type formalism for anti-plane deformation, we take a generalized stress function vector $\sum$, such that [21,22]

$$[s_{31}, H_{31}]^T = - \boldsymbol{\sigma}_{,2} \ [s_{32}, H_{32}]^T = \boldsymbol{\sigma}_{,1} \tag{8}$$

Inserting Eq. (3) into Eq. (8) results in

$$- \boldsymbol{\sigma}_{,2} = \mathbf{B}_0 \frac{\partial \mathbf{f}}{\partial x_1} + \mathbf{B}_0 \frac{\bar{\mathbf{f}}}{x_1} \tag{9}$$

$$\boldsymbol{\sigma}_{,1} = \mathbf{B}_0 \frac{\partial \mathbf{f}}{\partial x_2} + \mathbf{B}_0 \frac{\bar{\mathbf{f}}}{x_2} \tag{10}$$

Eq. (9) or Eq. (10) gives

$$\boldsymbol{\sigma} = \mathrm{i}\mathbf{B}_0 \mathbf{f}(z) - \mathrm{i}\mathbf{B}_0 \overline{\mathrm{f}(z)} \tag{11}$$

Eqs. (7) and (11) can be rewritten as

$$\mathbf{u} = \mathbf{A}\mathbf{f}(z) + \overline{\mathbf{A}\mathbf{f}(z)}, \tag{12}$$

$$\boldsymbol{\sigma} = \mathbf{B}\mathbf{f}(z) + \overline{\mathbf{B}\mathbf{f}(z)}, \tag{13}$$

where

$$\mathbf{A} = \mathbf{I}, \qquad \mathbf{B} = \mathrm{i}\mathbf{B}_0 \tag{14}$$

where $\mathbf{I}$ is a 2×2 unit matrix.

Eqs. (12) and (13) are the general solutions of anti-plane deformations. It is seen that the stresses and stains of the phonon field and the phason field can be obtained from Eqs. (7) and (8) if the complex potential vector $\mathbf{f}(z)$ is available.

3. Stress fields and stress intensity factors

We consider a lip-shape crack in a 1D hexagonal quasicrystal solid infinitely large. It is assumed that the quasi-periodic direction of 1D hexagonal QCs is along the positive direction of x_3 axis. The solid is subjected to uniform remote anti-plane shear loadings of the phonon field and the phason field, as shown in Fig. 1 $2a$ is the crack length and $2h$ is the crack height. For the current case, we will study the complex potentials and the stress intensity factors under anti-plane shear loadings of the phonon field and the phason field at infinity. In this case, the complex function $\mathbf{f}(z)$ has the following form [21]

$$\mathbf{f}(z) = \mathbf{c}^{\text{¥}}\, z + \mathbf{f}_0(z), \tag{15}$$

c^{∞} is a complex constant related to the remote loading conditions, and $\mathbf{f}_0(z)$ is an unknown complex function vector, which vanishes at infinity, i.e., $\mathbf{f}_0(?\ )\quad 0$.

Differentiating Eqs. (12) and (13) with respect to x_1, we have

$$\mathbf{u}_{,1} = \mathbf{A}\mathbf{F}(z) + \overline{\mathbf{A}\mathbf{F}(z)}, \tag{16}$$

$$\sum_{,1} = \mathbf{B}\mathbf{F}(z) + \overline{\mathbf{B}\mathbf{F}(z)}, \tag{17}$$

where $\mathbf{F}(z) = d\mathbf{f}(z)/dz$. Substituting Eq. (15) into Eqs. (16) and (17), and then taking $z \to \infty$, results in

$$\mathbf{u}_{,1}^{\infty} = \mathbf{A}\mathbf{c}^{\infty} + \overline{\mathbf{A}}\,\overline{\mathbf{c}^{\infty}}, \tag{18}$$

$$\sum_{,1}^{\infty} = \mathbf{B}\mathbf{c}^{\infty} + \overline{\mathbf{B}}\,\overline{\mathbf{c}^{\infty}}, \tag{19}$$

$$\sum_{,1}^{\infty} = \left[\sigma_{32}^{\infty}, H_{32}^{\infty}\right]^T, \qquad \mathbf{u}_{,1}^{\infty} = \left[\varepsilon_{31}^{\infty}, w_{32}^{\infty}\right]^T. \tag{20}$$

The boundary along the surfaces of cracks is

$$\mathbf{B}\mathbf{f}(z) + \overline{\mathbf{B}\mathbf{f}(z)} = \int_s t_s\, ds, \qquad t_s = \left[t_3, h_3\right]^T, \tag{21}$$

where t_3 and h_3 represent the anti-plane shear traction of the phonon field and the phason field along the boundaries of cracks. In the current case, the surfaces of the cracks are free of external loadings, thus, Eq. (21) becomes

$$\mathbf{Bf}\left(z\right)+\overline{\mathbf{Bf}\left(z\right)}=0. \tag{22}$$

Inserting Eq. (15) into Eq. (22) gives

$$\mathbf{Bf}_0\left(z\right)+\overline{\mathbf{Bf}_0\left(z\right)}=-\left(\mathbf{Bc}^{\infty}z+\overline{\mathbf{Bc}}^{\infty}\bar{z}\right). \tag{23}$$

In order to obtain the complex function $\mathbf{f}_0\left(z\right)$ from Eq. (23), we introduce the following mapping function [23]

$$z=\omega\left(\zeta\right)=\frac{a}{2}\rho\mathrm{i}\left[m\zeta+\frac{1}{\zeta}-\frac{\zeta}{\rho^2\left(1+m\zeta^2\right)}\right], \tag{24}$$

in which

$$\rho=\frac{1}{1-m},\qquad \beta=\frac{h}{a}=\frac{1}{2}\frac{1+m}{1-m}\left[1-\frac{\left(1-m\right)^2}{\left(1+m\right)^2}\right]^2 \tag{25}$$

$\beta<1$,the approximate representations are

$$\rho\approx1+\frac{\beta}{2}+\frac{\beta^2}{4},\qquad m\approx\frac{\beta}{2}-\frac{\beta^2}{8} \tag{26}$$

It can be shown that Eq. (24) maps the exterior region of a lip-shape crack in the z plane into the interior of a unit circle in the ζ plane, and the boundary of the lip-shape crack is transformed the unit circle τ, where we take $\omega^{-1}\left(a\right)\to$ –i, $\omega^{-1}\left(-a\right)\to$ i, as shown in Fig. 2.

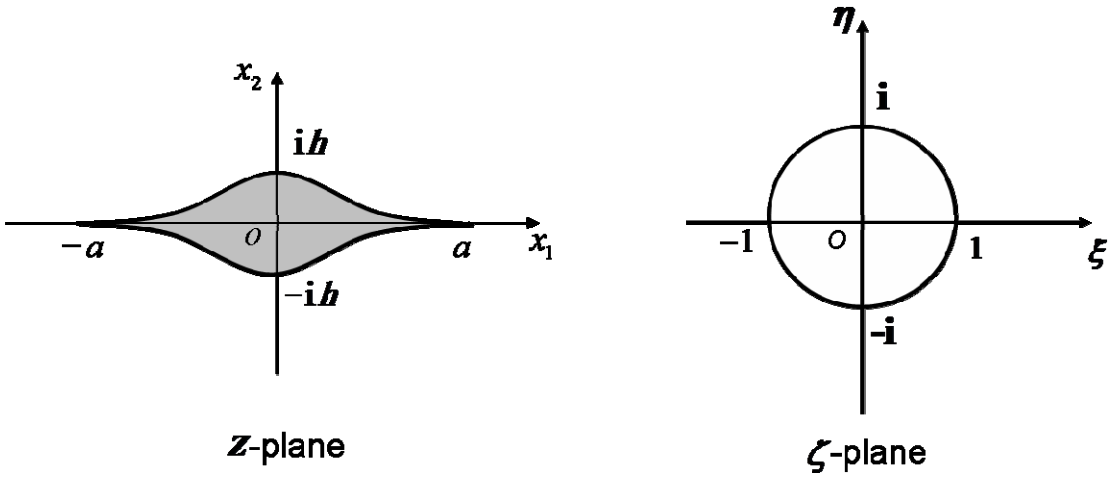

Figure 2. Mapping function of lip-shape crack into a unit circle.

Inserting Eq. (24) into Eq. (22),and then taking $\zeta = \sigma$, results in

$$\mathbf{B}\mathbf{f}_0(\sigma) + \overline{\mathbf{B}}\overline{\mathbf{f}_0(\sigma)} = -\left[\mathbf{B}\mathbf{c}^{\infty}\omega(\sigma) + \overline{\mathbf{B}}\overline{\mathbf{c}^{\infty}}\overline{\omega(\sigma)}\right], \tag{27}$$

where σ is the point on the unit circle, and $\mathbf{f}_0(\sigma) = \mathbf{f}_0(\omega(\sigma))$ is defined.

Multiplying Eq. (27) by $d\sigma/\left[2\pi\mathrm{i}(\sigma-\zeta)\right]$, where ζ is an arbitrary point inside the unit circle, and performing the Cauchy integral along the unit circle τ in the anticlockwise direction, we have

$$\mathbf{B}\mathbf{f}_0(\zeta) = -\mathbf{B}\mathbf{c}^{\infty}\frac{1}{2\pi\mathrm{i}}\int\frac{\omega(\sigma)}{\sigma-\zeta}d\sigma - \overline{\mathbf{B}}\overline{\mathbf{c}^{\infty}}\frac{1}{2\pi\mathrm{i}}\int_{\tau}\frac{\overline{\omega(\sigma)}}{\sigma-\zeta}d\sigma \tag{28}$$

$\omega(\zeta)$ is analytic inside the unit circle, except for a simple pole at $\zeta = 0$. Since $\overline{\omega(\zeta)}$ is analytic inside the unit circle, except for the simple poles at $\zeta = 0$, $\zeta = \sqrt{m}\mathrm{i}$, $\zeta = -\sqrt{m}\mathrm{i}$. By the residue theorem in complex variable function, one has

$$\frac{1}{2\pi\mathrm{i}}\int\frac{\omega(\sigma)}{\sigma-\zeta}d\sigma = \omega(\zeta) - \frac{a}{2}\rho\mathrm{i}\frac{1}{\zeta}, \tag{29}$$

$$\frac{1}{2\pi\mathrm{i}}\int_{\tau}\frac{\overline{\omega(\sigma)}}{\sigma-\zeta}d\sigma = \overline{\omega(\zeta)} + \frac{a}{2}m\rho\mathrm{i}\frac{1}{\zeta} - \frac{a}{2}\mathrm{i}\frac{\zeta}{\rho\left(m+\zeta^2\right)}. \tag{30}$$

The following result can be obtained by Eq.(18),Eq.(19),Eq.(20)

$$\mathbf{B}\mathbf{c}^{\infty} = \frac{1}{2}\left\{\left[\sigma_{32}^{\infty}, H_{32}^{\infty}\right]^T + \mathrm{i}\left[\sigma_{31}^{\infty}, H_{31}^{\infty}\right]^T\right\}, \tag{31}$$

$$\overline{\mathbf{B}}\overline{\mathbf{c}^{\infty}} = \frac{1}{2}\left\{\left[\sigma_{32}^{\infty}, H_{32}^{\infty}\right]^T - \mathrm{i}\left[\sigma_{31}^{\infty}, H_{31}^{\infty}\right]^T\right\}, \tag{32}$$

Substituting Eqs. (31) and (32) into Eq. (28), then differentiating the obtained results with respect to ζ leads to

$$\mathbf{B}\mathbf{F}_0(\zeta) = \frac{a\rho}{4}\left[m+1-\frac{1-m\zeta^2}{\rho^2\left(1+m\zeta^2\right)^2}\right]\begin{bmatrix}\sigma_{31}^{\infty}\\ H_{31}^{\infty}\end{bmatrix} - \frac{a\rho}{4}\left[m-1-\frac{1-m\zeta^2}{\rho^2\left(1+m\zeta^2\right)^2}\right]\begin{bmatrix}\sigma_{32}^{\infty}\\ H_{32}^{\infty}\end{bmatrix} \tag{33}$$

$\mathbf{F}_0(\zeta) = d\mathbf{f}_0(\zeta)/d\zeta$.

$\omega'(\zeta)$ and $\left[\overline{\omega(\zeta)}\right]'$ can be given by Eq. (24) as follows

$$\omega'(\zeta) = \frac{a}{2}\rho\mathrm{i}\left[m - \frac{1}{\zeta^2} - \frac{1-m\zeta^2}{\rho^2\left(1+m\zeta^2\right)^2}\right], \tag{34}$$

$$\left[\overline{\omega(\zeta)}\right]' = -\frac{a}{2}\rho\mathrm{i}\left[1-\frac{m}{\zeta^2}-\frac{m-\zeta^2}{\rho^2\left(m+\zeta^2\right)^2}\right], \tag{35}$$

It is found from Eq. (33) that the stress fields can be obtained from the relations between the stress and stress function.

The stress intensity factor at the crack tip is a very important physical quantity in fracture mechanics, which can reflect the stress intensity around the crack tip. The vector of the stress intensity factors can be defined as

$$\boldsymbol{k} = \left[K_{III}^{h}, K_{III}^{\perp}\right]^T = \lim_{z\to z_1}\sqrt{2\pi\left(z-z_1\right)}\sum\nolimits_{,1}, \tag{36}$$

where K_{III}^{h} and $K_{III}^{\perp}$ denote the stress intensity factors of the phonon field and the phason field, respectively.

Substituting Eq. (17) into Eq. (36) gives

$$\boldsymbol{k} = \left[K_{III}^{h}, K_{III}^{\perp}\right]^T = 2\lim_{z\to z_1}\sqrt{2\pi\left(z-z_1\right)}\mathbf{B}\mathbf{F}_0\left(z\right) \tag{37}$$

in which the condition that $\mathbf{B}\mathbf{F}_0\left(z\right)$ is imaginary along the x_2 axis is used.

In the ζ plane, Eq. (37) becomes

$$\boldsymbol{k} = 2\sqrt{2\pi}\lim_{\zeta\to-\mathrm{i}}\sqrt{\omega(\zeta)-\omega(-\mathrm{i})}\frac{\mathbf{B}\mathbf{F}_0\left(\zeta\right)}{\omega'\left(\zeta\right)}, \tag{38}$$

where $\zeta = -\mathrm{i}$ is the corresponding point of the crack tip $z = a$.

It is obvious from Eqs. (33) and (34) that one finds $\lim_{\zeta\to-\mathrm{i}}\omega'\left(\zeta\right)$ exists and $\lim_{\zeta\to-\mathrm{i}}\mathbf{B}\mathbf{F}_0\left(\zeta\right)\neq 0$. Thus, by the L'Hospital rule, Eq.(38) results in

$$\boldsymbol{k} = 2\sqrt{2\pi}\lim_{\zeta\to-\mathrm{i}}\frac{\mathbf{B}\mathbf{F}_0\left(\zeta\right)}{\sqrt{\omega''\left(\zeta\right)}}, \tag{39}$$

$\omega''(\zeta)$ can be obtained by Eq.(34)

$$\omega''(\zeta) = \frac{a}{2}\rho\mathrm{i}\left[\frac{2}{\zeta^3}-\frac{2m^2\zeta^3-6m\zeta}{\rho^2\left(1+m\zeta^2\right)^3}\right], \tag{40}$$

Inserting Eqs. (33) and (40) into Eq. (39), the analytic expressions of the stress intensity factors at the crack tip $\left(a,0,0\right)$ for the anti-plane shear problem are derived as follows

$$\boldsymbol{k} = \begin{bmatrix}\sigma_{32}^{\infty}\\ H_{32}^{\infty}\end{bmatrix}\sqrt{\pi a}K, \tag{41}$$

where

$$K=\sqrt{\frac{\rho}{1+3m\rho+m^2\rho}}. \tag{42}$$

If the crack height h tends to zero, one has $m=0,\ \rho=1$ and then Eq. (41) reduces to

$$K=\sqrt{\frac{\rho}{1+3m\rho+m^2\rho}}=1. \tag{43}$$

which is the solution of Griffith cracks in a 1D hexagonal QC [15].

4. Numerical examples

We consider the variation of K with $\beta=\frac{h}{a}$. It can be shown from Fig. 3 that if $\beta<1$, the dimensionless field intensity factor K decreases with the value of β becomes large. It indicates that an increase of the height of the tip-shape crack will retard the crack propagation. In particular, when the height of the lip-shape crack approaches to zero, the current case can be reduced to the Griffith crack, i.e., $K=1$, which is easier to propagate.

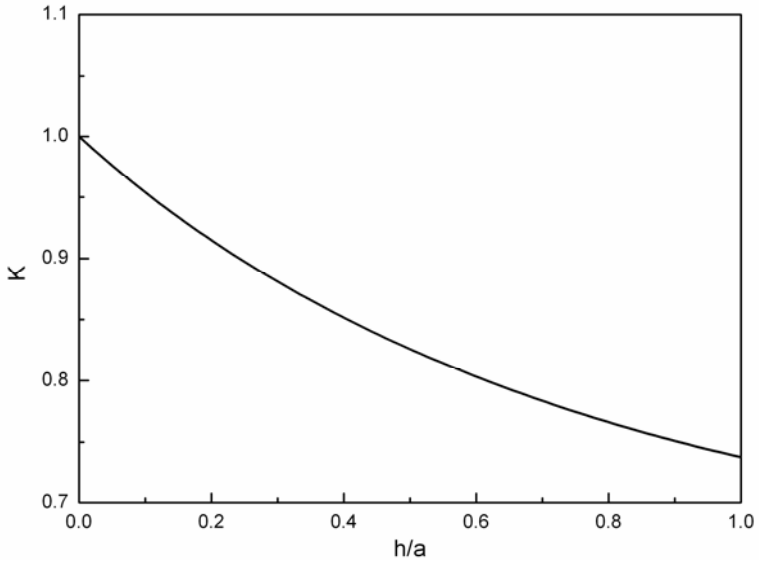

Figure 3. Variation of K with $\beta=\frac{h}{a}$

Abstract

Fretting is a small amplitude oscillatory movement appearing between two contacting surfaces subjected to vibrations. This phenomenon may generate crack growth propagation. The aim of the present work is to estimate the ΔK_{Ith} (Crack arrest stress intensity factor) related to the crack arrest condition of a material subjected to partial slip fretting loadings by coupling experimental results and numerical simulations. The study is limited to cylinder/plane models TA6V/Al-alloys. In this approach, fretting tests are first performed for each configuration to obtain the crack length as a function of fretting cycles in order to establish the length of the arrested crack. Then an automatic program based on FEM simulations of the experimental test is developed to estimate the stress intensity factor corresponding to the crack arrest. Using a reverse analysis, the ΔK_{th} corresponding to the crack arrest condition is identified and different materials are compared.

Keywords Fretting tests, Fatigue crack arrest, Crack closing, Stress intensity factor

1. Introduction

Araujo et al. [1] demonstrated that the fretting fatigue endurance can be formalized using a short crack arrest methodology. This approach has been adopted in [2] to estimate the crack arrest boundary in the fretting fatigue map approach. Such analysis consists in computing the evolution of the stress intensity factor as a function of the crack length and to evaluate if this K-factor loading path intercepts or not the short crack arrest boundary. If the ΔK loading path overpasses this boundary, then a fretting fatigue failure is expected. Note that the short crack arrest boundary is approximated using either KT or El Haddad formalism.

Such a methodology usually considers a crack localized at the contact border and perpendicular to the contact surface. However, experimental results show that the crack path below the interface is more complex and usually displays an oblique angle oriented toward the inner part of the contact. A major question is to know if the normal crack approximation is relevant to describe the real crack path evolution.

A second aspect concerns the short crack methodology which is usually applied to approximate the crack arrest condition. In this research work, we consider an original reverse approach which consists in estimating the ΔK_{Ith} related to the studied material by applying a reverse identification method of our experimental results.

2. Materials and experimental procedure

2.1. Materials

A 2000 series al alloy (2196) aluminum alloy was investigated with the chemical composition detailed in Table 1.

Table 1. Chemical composition of the 2196 aluminum

% Cu	% Li	% Mg	% Mn	% Ag	% Zr	% Zn	% Si	% Fe
2.5-3.3	1.4-2.1	0.25-0.8	< 0.35	0.25-0.6	0.04-0.18	< 0.35	< 1.2	< 0.15

Two different heat treatments were applied: the industrial peak aged on one side called T8, and the experimental treatment at low temperature (120°C during 96 hours) on the other, called UA (Under-Aged). These two ageing treatments involve equivalent elastic properties with an elastic modulus E about 79000 MPa and the Poisson's coefficient about 0.305, but different monotonic and fatigue properties like the ultimate stress R_m, the yield stress $R_{0.2}$ and the elongation's rate A% (Table 2), which imply different ΔK_{th} values. Note that for confidential reasons, all data regarding fatigue properties are not available.

Table 2. Mechanical properties of the 2196 aluminum, depending on the heat treatment

State	$R_{0.2}$ (MPa)	R_m (MPa)	A%
T8	559	594	5.9
UA	428	520	11.1

For each alloy, small cubic specimen were machined and polished to achieve a 0.2 µm R_a roughness. Samples were adjusted so that the fretting loading was applied along the rolling direction of the alloy (Fig. 1).

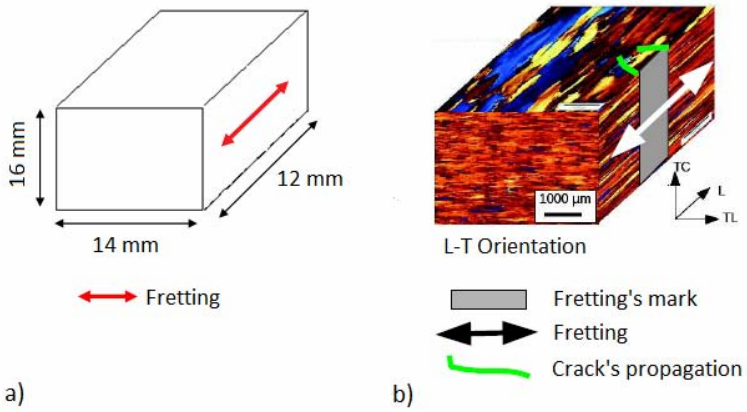

Figure 1. a) Sample's geometry - b) Microstructure [3]

2.2. Plain Fretting Experiment

Plain partial slip fretting tests were performed on a hydraulic set up at the LTDS previously described by Heredia [2]. The normal force (P) is kept constant, while the tangential force (Q) and displacement (δ) amplitudes are recorded. The fretting loop can be plotted and the corresponding amplitude values (respectively Q* and δ*) defined (Fig. 2).

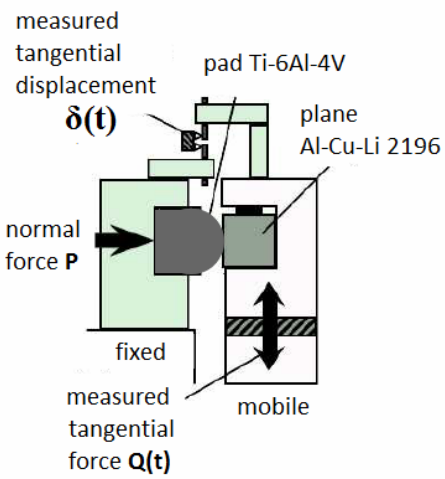

Figure 2. Experimental set up [2&3]

In the present fretting cracking investigation the displacement amplitude was monitored in order to maintain partial slip conditions, keeping constant the tangential force amplitude during the whole test duration. A cylinder/plane configuration was applied. The fretting pad consists of a Ti-6Al-4V alloy which displays the following elastic properties: 119500 MPa for the elastic modulus and 0.287 for the Poisson's coefficient. The cylinder's radius was fixed at 80 mm and the applied normal force at P=436.5 N/mm which induces a maximum hertzian constant pressure p_0=300 MPa and a hertzian constant radius a_H=0.92 mm. The lateral width of the cylinder pad was about 8 mm which corresponds to plain strain conditions along the median axis of the fretting scar. Previous tests were done to determine the friction coefficient at the sliding transition μ_t=0.85. [4]

3. Experimental results

Our objective was to identify the evolution of the crack length as a function of the fretting cycle to establish the "plateau" value related to the crack arrest condition. The tangential force was kept constant for all the experiment with Q*=200 N/mm. This tangential loading was previously adjusted to guarantee significant fretting cracking for elastic configurations (i.e. the stress is inferior to the yield stress $R_{0.2}$).

Figure 3 shows a typical crack path observed for the studied configuration after 2.10^6 cycles. As usually observed the incipient crack propagation a near 45° orientation compared to the normal of the surface until about 30 µm in depth. Below 200 µm, the crack propagation direction is normal to the plan. Between 30 and 200 µm, the crack path is considered to be linear with a 10° angle with respect to the normal of the surface. A schematic description of the crack path is given in Figure 3. The major part of the crack expertise leads to similar evolutions, so that the overall crack path description can be provided by linear segments (Fig. 3), and by making the average, we kept the first angle at 47.5°, the second at 15.5 and the last at 0° for the numerical model exposed hereafter.

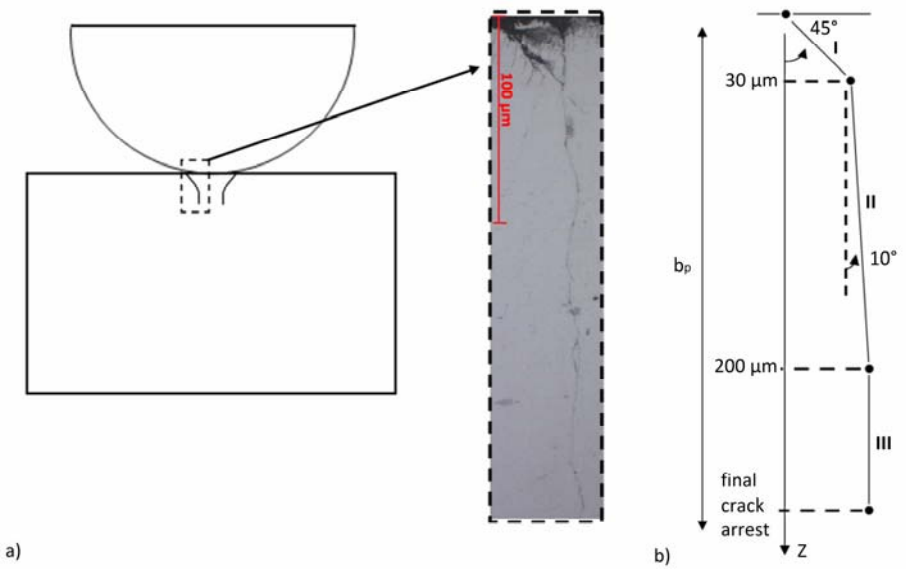

Figure 3. Crack path description a) Schematic and photo of the 2196-UA at N=2.10^6 - b) Discretization of the real crack path

This typical crack path evolution will be considered later for the crack modelling. To simplify the crack length analysis only the projected crack length (b_p parameter on Fig. 3) was considered. Figure 4 compares the evolution of the maximum projected crack length which was represented as a function of the fretting cycle.

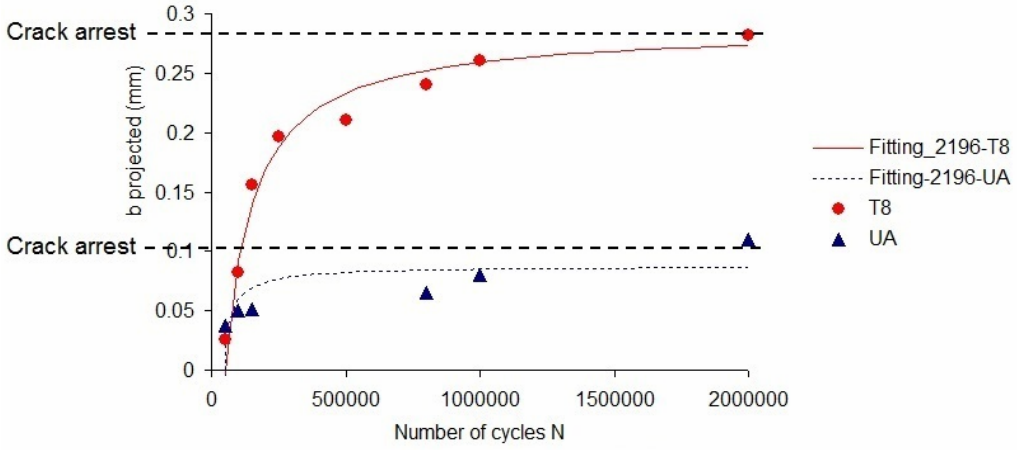

Figure 4. Propagation's curves

For the two materials, asymptotic evolutions can be observed. This analysis shows that the maximum crack length stabilized after 10^6 cycles. This allows us to estimate the crack length related to the crack arrest condition for the studied (P=436.5 N/mm; Q*=200 N/mm) plain fretting condition. We found respectively for the T8 and UA ageing treatments the following b_{pth}(T8)=280 µm and b_{pth}(UA)=100 µm crack length values. Because the maximum crack length achieved for the T8-ageing is longer than the one observed for the UA-ageing, it can be intuited that the threshold Stress Intensity Factor (SIF) related to the T8-treatment is significantly smaller than the one expected for the UA-ageing. The following analysis will consist in quantifying this aspect.

4. FEM computation of the Stress Intensity Factor's (SIF) evolution below the fretting contact

4.1. Contact modeling

A 2D-plain strain FEM modeling of the studied plain fretting test was developed. All the elastic and friction properties previously defined during experiment tests were implemented in the FEM-model. The fretting model is composed of a fixed plane and a moving cylindrical pad (Fig. 5). The mesh is composed of triangular (CPE3) and quadratic (CPE4R) linear elements. Quadratic elements were used to define the crack tip zone in a round domain of a radius of 5µm. Outside the crack tip zone, triangular elements were considered in order to reduce time costs. The mesh size in the contact zone was refined down to 20 µm in order to provide a more accurate estimation of the contact stress fields. The contact and the crack were described by a master-slave algorithm, and the tangential loading was determined by Lagrange multipliers through a constant friction coefficient (μ_t=0.85). During a computation, a fretting cycle were reproduced through the introduction of a normal load P=436.5 N/mm and through the application of a cyclic tangential cycle with a Q*=200 N/mm.

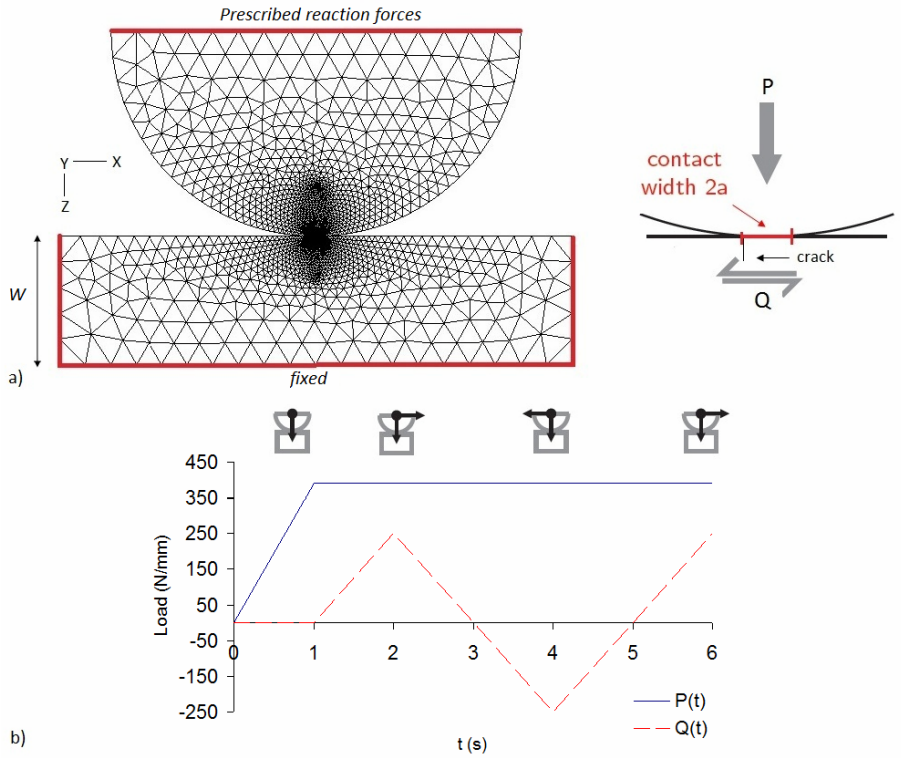

Figure 5. FEM description of the plain fretting cracking experiments a) FEM model - b) Loads applied

As elastic loads were imposed, the cracking computation was restricted to a single loading cycle. Results and interpretations were made for a single crack located at the trailing contact border ($x=-a_H$) at the loading stage (Q=Q*) which infers an open crack condition (Fig. 5).

4.2. Computation of the SIF parameter, crack meshing

An automatic Matlab code was developed to generate Abaqus input scripts, which remesh the cracks in a fretting cylinder/plane interface during the propagation's stage. This model with its mesh was inspired by the work of H. Proudhon [5]. The crack patch can be located anywhere in the plane's interface and can be described using sequential segments to reproduce as close as possible the real crack path. In the present investigation, crack nucleation is located at the contact border which is confirmed by experimental observations and multiaxial fatigue Modelling [1, 2, 6]. Two different crack path descriptions will be considered in the present analysis:

a) **The crack is normal to the surface**. Indeed, as indicated in the introduction, in numerous works published in the literature [1, 2] the crack is assumed to propagate in the normal direction of the surface in a fretting configuration. For such conditions only, one segment is required for the FEM simulation.

b) **The crack is kinked**. The path is described thanks to three segments provided in Figure 6.b. to approximate the real evolution of the crack propagation. This involves an angle of nearly 47.5° on the surface down to 0° deeper below the interface. This description is more complex to implement but it is also more relevant considering the real crack path evolution.

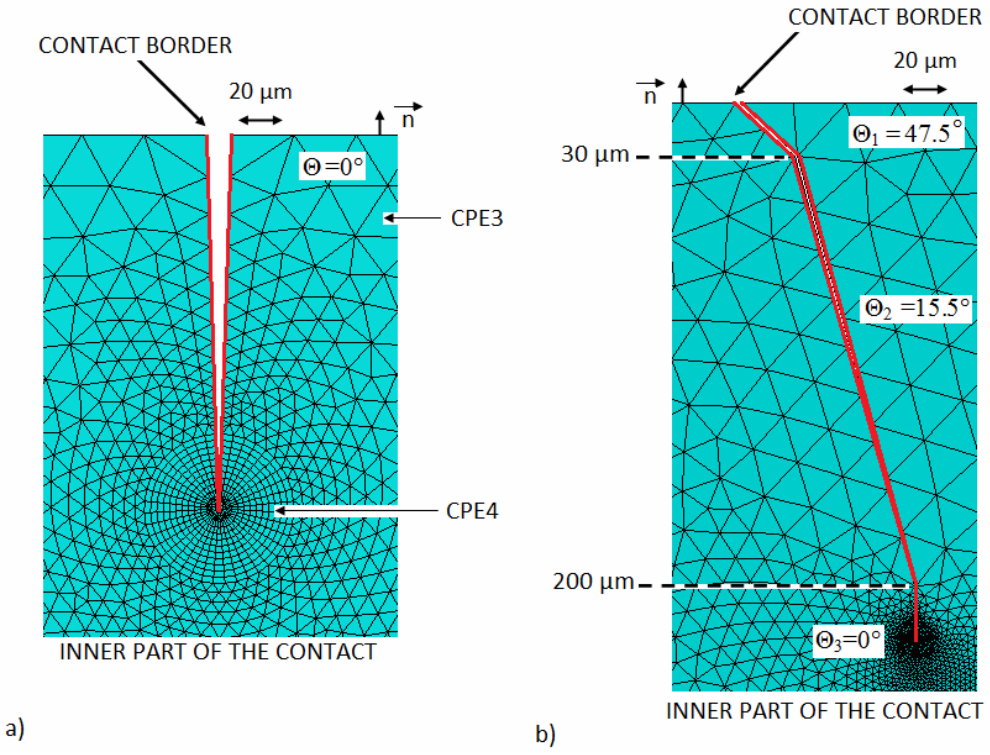

Figure 6. Illustration of the two crack mesh developed in the present investigation a) Plain normal crack hypothesis - b) Kinked crack's description

The Contour Integral's method (CI) is used by Abaqus 6.9 to estimate Stress Intensity Factors (SIF) at the crack tip. First, the Rice's integral (J-integral) is calculated, to then be related to K_I and K_{II} [7]. CPE3 triangular elements are used everywhere in the model except for the crack tip, where CPE4 quadrilateral elements are used for the CI. In the present analysis, only the mode I component (K_I) will be considered as it is applied in many fretting fatigue modelling description [1]. Although the

model allows us to consider the friction coefficient within the crack lips, in this first analysis, this friction's value (which highly influences the value of the SIF in second mode) is presently assumed to be equal to zero. The stress state below the interface is very complex, to quantify the crack propagation. An effective SIF value based on the ELBER formalism is addressed:

$$\Delta K_{Ieff} = K_{Imax} - 4 \quad \text{for } R>0$$

$$\Delta K_{Ieff} = K_{Imax} - (4.R + 4) \quad \text{for } -1<R<0 \qquad \text{with} \quad R = \frac{K_{Imin}}{K_{Imax}}$$

$$\Delta K_{Ieff} = K_{Imax} \quad \text{for } R<-1 \qquad (1)$$

An important aspect of this coupled FEM simulation is the fact that the fretting contact description includes the crack's presence in the contact stress analysis. Indeed, the crack can induce a local pressure's and shear's discontinuity at the contact border which will successively modify the contact loading and finally the crack's propagation process (Fig. 7). Note that such coupled interaction between crack and contact stressing is not considered in usual decoupled approaches involving dislocation methods or weight functions [8].

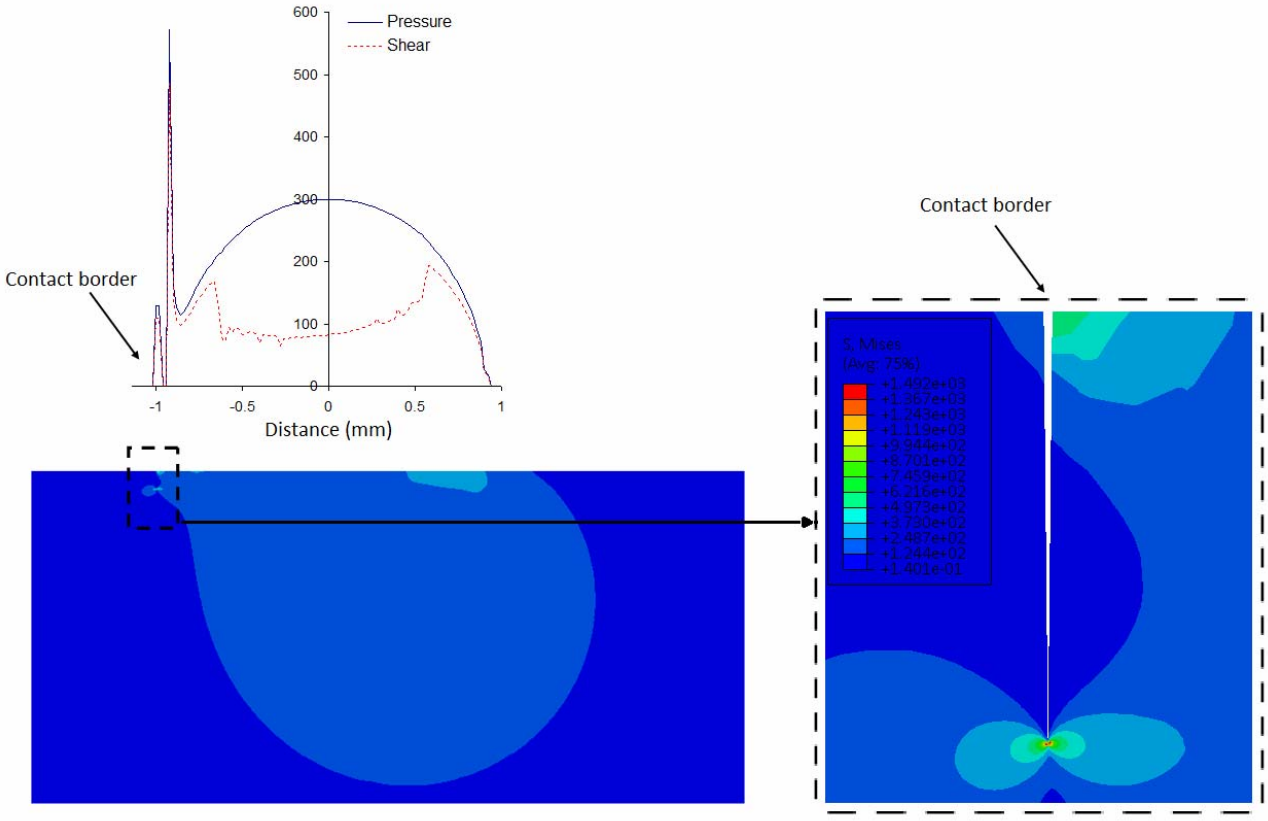

Figure 7. Illustration of the interaction between the contact stress and the crack's presence in the interface (Q=Q*, case of a normal crack with b_p=100 µm)

4.3. Results: comparisons between normal and kinked cracks

Figure 8 compares the evolution of the K_{Imax} as a function of the projected crack length obtained for the two crack descriptions.

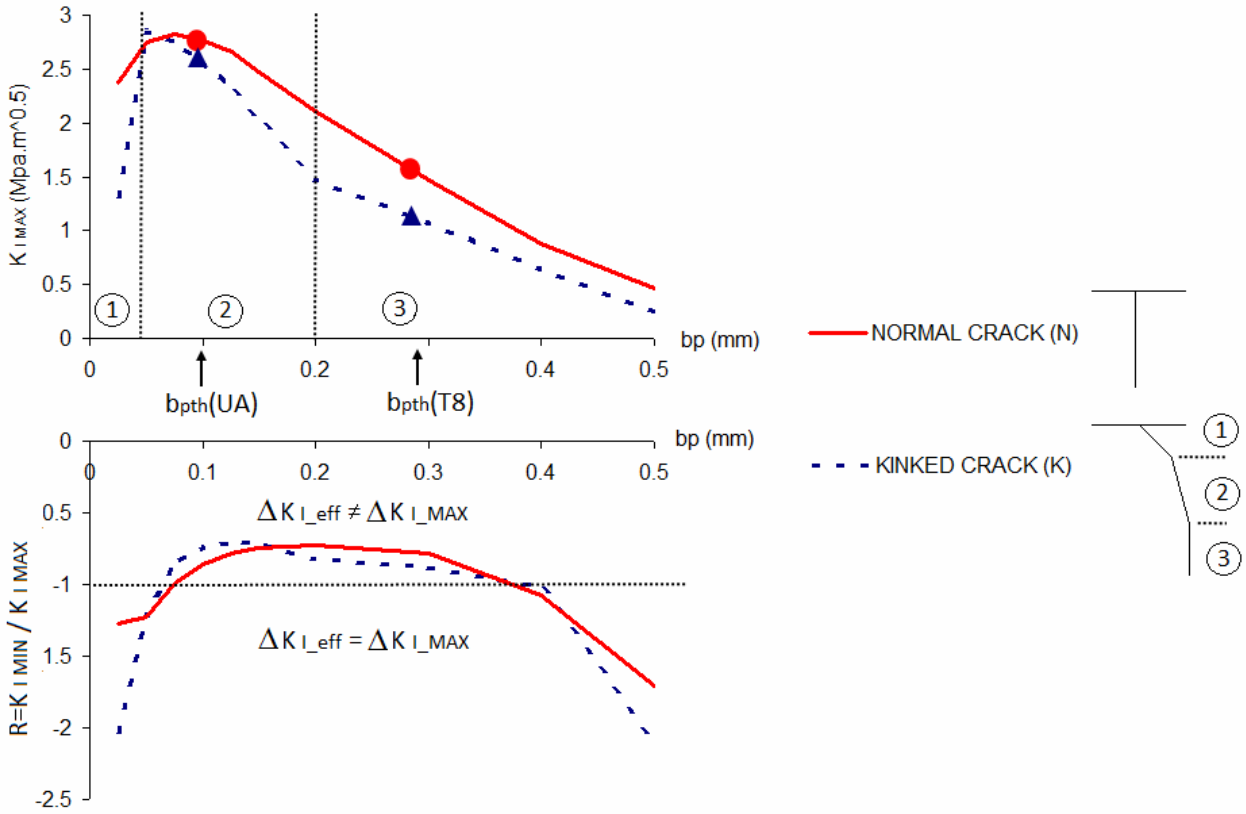

Figure 8. Evolution of the K_{Imax} and R ratio as a function of the projected crack length (P=436.5 N/mm; Q=200 N/mm) computed for the two normal and kinked crack descriptions

Both normal and kinked descriptions lead to similar non monotonic evolutions of the K_{Imax} values. As previously depicted in [9], the K_{Imax} value first increases with the crack length but then decreases when the tip of the crack is more and more remote from the surface due to the very sharp stress decrease induced by the severe contact stress gradients. Focusing on the comparison between kinked and the normal crack path descriptions, it can be said that in the zone 1, next to the surface, the crack angle ($\Theta_1 = 47°$) which is considered in the kinked description tends to reduce the mode I SIF value compared the normal crack description (Fig. 8. zone 1). Then, in the deeper zone 2, the angle decreases ($\Theta_2 = 15.5°$) so that the K_{Imax} value extrapolated from the kinked description is becoming closer to one defined from the normal crack approximation. Finally, in the very deep region 3, the crack orientation turns to the normal direction ($\Theta_3 = 0°$), however the K_{Imax} value provided by the kinked description is still smaller than the value extrapolated using the normal crack description. This difference can be explained by the fact that the lateral position of the crack tip is not the same. Indeed, if the crack tip is still at the vertical of the contact border for the normal crack description, it is now located in the inner compressive part of the contact for the kinked description. A major conclusion of this comparison is the fact that the two approximations of the crack path are in fact rather close. Note that the gap between the K_{Imax} values tends to decrease in

depth. Beside the normal approximation leads systematically higher K_{Imax} values providing conservative descriptions of the crack propagation's risk. Confirming former analytical analyses [9], it can be concluded that the usual "normal" crack path description provides relevant and conservative estimations of the fretting K_{Imax} evolutions. This result is important because it supports numerous plain fretting and fretting fatigue crack propagation's descriptions given in the literature.

4.4. Identification of the ΔK_{th} crack arrest value

By reporting the maximum projected crack length b_{pth}(T8) and b_{pth}(UA) on the previous graph, it is possible to extrapolate the related ΔK_{Ith} crack arrest value. Hence assuming the "Normal" crack's description we found:

$\Delta K_{Ith\_N}(T8) = 1.6MPa.\sqrt{m}$ (R=-0.9) and $\Delta K_{Ith\_N}(UA) = 2.7MPa.\sqrt{m}$ (R=-0.9)

Whereas using the "kinked" crack description we obtain:

$\Delta K_{Ith\_K}(T8) = 1.2MPa.\sqrt{m}$ (R=-0.9) and $\Delta K_{Ith\_K}(UA) = 2.6MPa.\sqrt{m}$ (R=-0.75)

The extrapolated values are rather small but quite representative of values for such aluminium alloys. Note that such values come from very low stress ratios (R) conditions, which is quite uncommon in conventional fatigue investigations. Considering the "Normal" crack description, which is usually the case in the literature for fretting fatigue cracking's characterizations, we can compare the obtained values with the ultimate stress values (Fig. 9.).

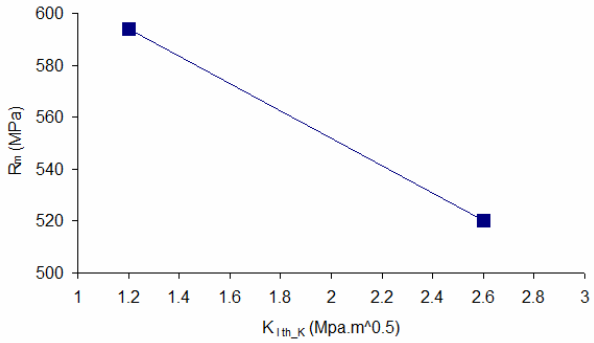

Figure 9. The ultimate stress as a function of ΔK_{th}

We confirm that for a given alloy, a heat treatment inducing an increase of the ultimate stress, leads to a decrease of the ΔK_{Ith}. Further developments will consist in comparing the ΔK_{Ith} identified from this inverse fretting identification's approach with conventional crack propagation fatigue analysis, thus to evaluate the pertinence of this approach and to estimate how very low stress R ratios can be considered regarding the crack arrest process. Besides, mixed mode descriptions including the mode II contribution and the friction coefficient in the crack lips will be addressed.

5. Conclusion

Using this reverse analysis, the ΔK_{Ith} values related to two different microstructures of a similar

Al-alloy were extrapolated. We confirmed that a heat-treatment inducing higher ultimate stresses leads to lower crack arrest stress intensity factors. This investigation underlines that despite its simplicity, a normal description of the fretting crack propagation path provides relevant and above all conservative estimations of the maximum Stress Intensity Factor (K_{Imax}). In the present work, plain fretting conditions involving very low R ratios (close to -1 or inferior) and a basic mode I description were considered. Besides the effect of the microstructure relate to the multi-crack process is not considered [10]. Future developments will consist in investigating fretting fatigue and fretting on pre-stressed specimen to consider higher R ratio and by implementing a mixed-mode [11] description of the SIF taking into account the coefficient of friction which is operating between the crack edges during the unloading compressive stage.

Abstract: Based on fracture mechanics and fuzzy theory, a model of fatigue life is developed to predict the fatigue life of structure. The dangerous point and stress amplitude can be gotten by finite element analysis method. According to fracture mechanics theory, considering fuzziness of fatigue life factors, the Paris' formula is combined with fuzzy theory and the model of fatigue life based on fuzzy theory is developed. The fuzziness of fatigue life factors is considered in the model so the results are more close to real situation. The model offers reference for fatigue life analysis.

Keywords : fracture mechanics, fuzzy, fatigue

1. Introduction

In vessels, pipelines, bridges, ships, offshore structures and many other engineering structures, there were a lot of disastrous accidents because of fatigue cracks. A report from American National Standards Institute indicates that cracks cause America a loss of 119 billion dollars every year. It is about 4 percents of American cross national products in 1982. According to a survey result of Committee of the Fatigue and Fracture, a sub-committee of ASCE, about 80-90% destruction of steel structures relates to fatigue cracks. From 1978 to 1981, America did a research against 20 states and Ontario Province in Canada. They collected the data of 142 bridges which had cracks. Among them, they found that the cracks on 115 bridges resulted from fatigue fracture[1]. How to analyze and estimate the fatigue life of member in construction correctly has become an important issue. This paper proposes a analysis modal which is based on fuzzy theory and combined with fracture mechanics.

2. Fuzzy phenomenon in analysis of fatigue life

The fuzziness of objects means the boundary is not clear, we cannot distinguish the difference between the right and wrong in its implication correctly, and we cannot divide its boundaries in our discussion range. The fuzziness is a natural characteristic of objects, it is a transient process between difference of objects.[2,3]

Broadly speaking, strength includes fatigue life, fracture toughness, residual strength and so on. In order to judge a structure is invalid or reliable, we must know the strength of material and structure. But because we get the data of strength from experiment, so it's inevitable to bring fuzziness.[4,5] It's feasible to apply the method of S-N curve and fracture mechanics. This paper is based on fuzzy theory, applys the method of fracture mrchanics to predict the fatigue life of structure.

Paris formula[9] is a always used to calculate the fatigue life in fracture mechanics, namely

$$\frac{da}{dN} = C\left(\Delta K\right)^m \quad , \tag{1}$$

Among it, a-crack size; N-number of load cycles; C, m-material constants; ΔK - stress strength

amplitude
Based on theory of fracture mechanics,

$$\Delta K = Y\Delta\sigma\sqrt{a\pi} \quad , \tag{2}$$

Y-coefficient of crack shape (generally it is 1),
$\Delta\sigma$ -alternative stress amplitude
We make (2) type substitute (1) type, we can get

$$N = \frac{1}{C}\int_{a_0}^{a_c}\frac{da}{(\Delta K)^m} = \frac{1}{C}\int_{a_0}^{a_c}\frac{da}{\left(\Delta\sigma\sqrt{a\pi}\right)^m} \quad , \tag{2-1}$$

Integrating, we can get

$$N = \begin{cases} \dfrac{a_c^{1-m/2} - a_0^{1-m/2}}{C\pi^{m/2}(1-m/2)(\Delta\sigma)^m} & m \neq 2 \\ \dfrac{\ln a_c - \ln a_0}{C\pi(\Delta\sigma)^2} & m = 2 \end{cases} , \tag{1}$$

Implied by some statistical data, initial crack length a_0 of welded structure is about 0.1~1.0mm. On average, we can think that a_0 is equal to 0.5mm[6]. Critical crack size a_c depends on the fracture toughness and stress level of material. According to the theory of fracture, we can get:

$$a_c = \frac{1}{\pi}\left(\frac{K_c}{\sigma}\right)^2 \quad , \tag{2}$$

Among it, K_c -the fracture toughness of material, we can get it from material data;
σ -structure stress
Because of some uncertain factors, such as fabrication technology, material properties and environment for use, we cannot get a most realistic number of C, so there are different numbers of C in different documents. For this reason that C is a variable quantity with fuzzifrfication, we can select some point among C's feasible region and on its edge. Then we put them into formula (3) and get their fatigue life respectively. Finally, based on the method of fuzzy comprehensive evaluation, we can make a forecast of its fatigue life.

3. Model of fuzzy comprehensive evaluation

3.1 Degree of membership

Assuming $C = (c_1, c_2, \mathrm{L}\ , c_m)$ which is the factor set that affect structure's fatigue life, $V = (v_1, v_2, \mathrm{L}\ , v_n)$ which is the set of evolution level. Among them, $c_i (i = 1, 2, \mathrm{L}\ , m)$ means number i influencing factors, $v_j (j = 1, 2, \mathrm{L}\ , n)$ means evolution level. So the array of degree of membership of set V is:

$$R=\begin{bmatrix} r_{11} & r_{12} & \mathrm{L} & r_{1n} \\ r_{21} & r_{22} & \mathrm{L} & r_{2n} \\ \mathrm{L} & \mathrm{L} & \mathrm{L} & \mathrm{L} \\ r_{m1} & r_{m2} & \mathrm{L} & r_{mn} \end{bmatrix}=\left(r_{ij}\right)_{m\times n} \quad , \tag{5}$$

among it, $i=1,2,\mathrm{L}\ m$, $j=1,2,\mathrm{L}\ n$ 。

In the factor set, for reflecting the different importance of each factor, we give each factor c_i a corresponding weight. The degree of membership of proposal j[7]:

$$u_j=\frac{1}{1+\left(\dfrac{\sum_{i=1}^{m}\left[w_i\left(r_{ij}-1\right)\right]}{\sum_{i=1}^{m}\left(w_i r_{ij}\right)}\right)^2} \tag{6}$$

We can get the fatigue life through the weighting factor method:

$$\bar{N}=\sum_{j=1}^{n}u_j N_j \tag{3}$$

Among it, N_j is the fatigue life of structure when evolution level is j.

2.2 Weight vector

For decreasing the affection of human factors, the method of getting the weight w_i is based on its relative degree of fuzziness membership. Generally speaking, the higher degree of membership of target, the bigger attention will be pay. In other words, the bigger weight will be given. According to the fuzzy set, we can regard the degree of membership as the weight. So we transpose the array R, and get the array of relative degree of membership which is target to the “importance”, namely

$$W=\begin{bmatrix} w_{11} & w_{12} & \mathrm{L} & w_{1m} \\ w_{21} & w_{22} & \mathrm{L} & w_{2m} \\ \mathrm{L} & \mathrm{L} & \mathrm{L} & \mathrm{L} \\ w_{n1} & w_{n2} & \mathrm{L} & w_{nm} \end{bmatrix}=(w_{ji})_{n\times m}=R^T \tag{7-1}$$

From array W, we can know the vector $\mathrm{r}_{w_{(i)}}=(w_{1i},w_{2i},\mathrm{L}\ ,w_{ni})^T$ of relative degree of membership. It is a vector of n proposals that are about factors c_i to the “importance”. Because each proposal in set V completes fairly, so n proposals have the same weight to the importance of factor c_i. So weight vector is[7]:

$$w_{(i)}=(1+d_{yi}^2\cdot d_{zi}^{-2})^{-1} \tag{4}$$

Among it： $d_{yi}=\left\{\sum_{j=1}^{n}(1-w_{ji})^p\right\}^{1/p}$, $d_{zi}=\left\{\sum_{j=1}^{n}w_{ji}^p\right\}^{1/p}$

p is the index of distance, when p is one， it is Hamming distance; when p is two, it is Euclidean distance

4. Calculation example

The stiffening girder of steel truss on one over-sea bridge is composed by main truss, main beam and upper and lower bracing. Main truss is connected by integral joint plate, and all the members' sections are closed box. Main truss is composed by top chord members, lower chord members, vertical web members and inclined web members. Main truss is 10m tall, and each standard segment is 10m long. The structure of integral joint on top chord member is shown in figure1. It is made of Q345steel. This joint is under multi-direction stress, it has a complicated stress field. It is connected by large numbers of variable welding lines, so vehicle load could cause fatigue problem easily.

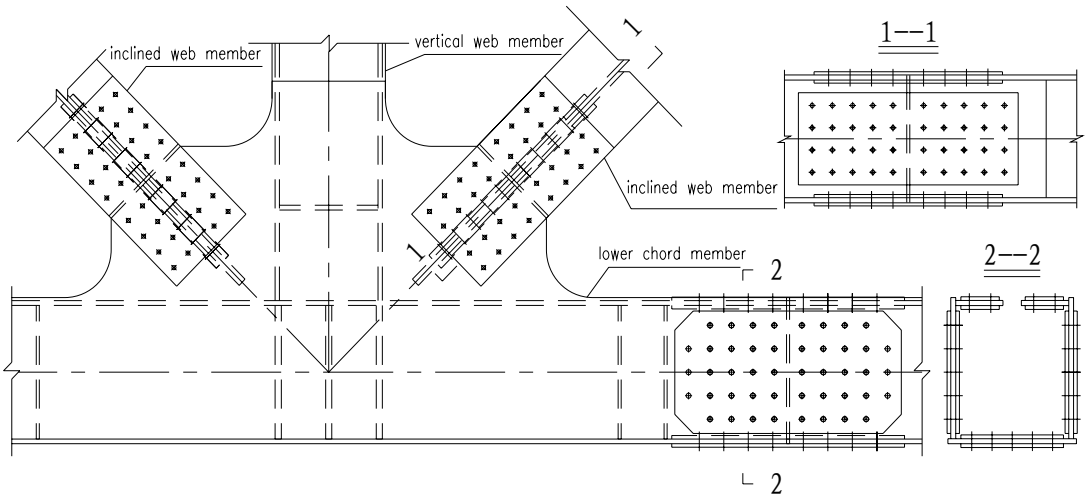

Fig.1 Schematic diagram of integral joint

4.1 Analysis based on crack mechanics

Through finite element analysis, we know that there is obvious stress concentration at the intersection of integral joint plant and inclined web member. As shown in figure2, the biggest stress amplitude $\Delta\sigma = 84.4Mpa$.

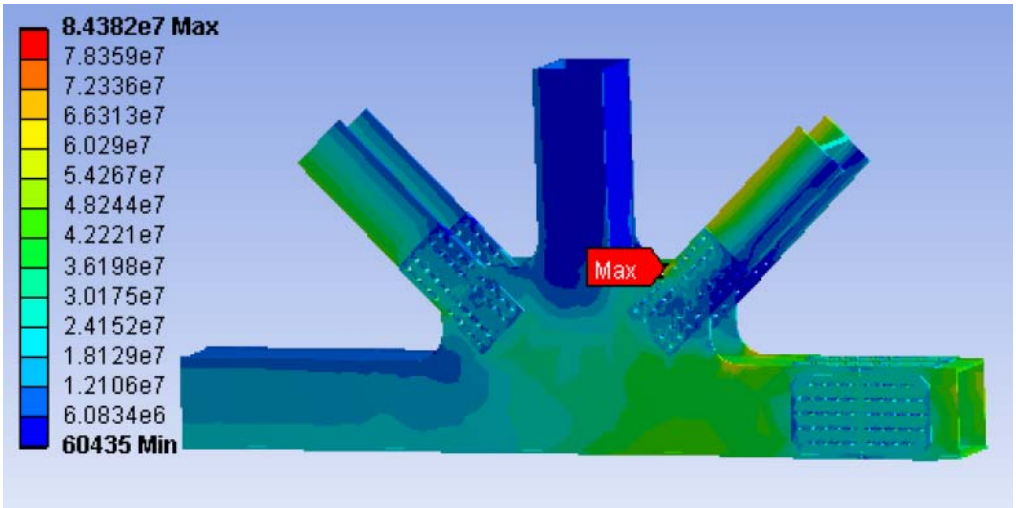

Fig.2 Equivalent stress nephogram of integral joint

The crack toughness of Q345steel is: $K_c = 207.91 Mpa \bullet mm^{\frac{1}{2}}$. According to formula (4), we can get the critical crack size:

$$a_c = \frac{1}{\pi}\left(\frac{K_c}{\sigma}\right)^2 = \frac{1}{\pi}\left(\frac{207.91}{84.4}\right)^2 = 1.93mm$$

Initial crack size: $a_0 = 0.5mm$, material constant $m = 3.0$, material constant C, average $\mu_c = 2.12 \times 10^{-13}$, coefficient of variation $C_v = 0.15$ [8].
According to formula (3), we can get the fatigue life is 2310340 times, 2123015 times, 1963789 times, 1826781 times and 1707643 times under different levels.

4.2 Create the factor set

Considering the specific condition of truss structure, the influencing factors of fatigue life of integral joint plate are as follows:
$C = (c_1, c_2, c_3)$

Among it, c_1 means fabrication technology, c_2 means material properties, c_3 means environment for use.

4.3 Create the evolution set

According to the trends consistency principle, five evolution indexes should be created which are shown in table1.

Tab.1 Grade of each evaluation factors

	v_1	v_2	v_3	v_4	v_5
c_1	excellent	good	average	bad	worse
c_2	excellent	good	average	bad	worse
c_3	excellent	good	average	bad	worse

4.4 Create the array of degree of membership

By the evolution of experts and technical staffs, array of degree of membership should be created as follows:

$$R=\begin{pmatrix} 0.10 & 0.45 & 0.30 & 0.10 & 0.05 \\ 0.05 & 0.50 & 0.35 & 0.05 & 0.05 \\ 0.05 & 0.10 & 0.25 & 0.45 & 0.15 \end{pmatrix}$$

According to (6) and (8) formula, we can get:

$u=(0.010,0.511,0.322,0.139,0.018)$.

So the fatigue life is:

$$\bar{N}=\sum_{j=1}^{5}u_j N_j = 2024965 \text{ times.}$$

5. Conclusion

In this paper, we propose an analysis model of fatigue life which is based on fuzzy theory. If we can combine it with actual construction situation, combine the fuzzy theory with crack mechanics, and we consider the fuzziness of factors which affect fatigue life, we can get a more accurate calculation result, and offer reference for fatigue life analysis.

Abstract Load-controlled fatigue and dwell-fatigue tests were conducted at elevated temperature to describe the high temperature behavior of nano-silver sintered lap-shear joints. The results show that the shear strength of nano-silver sintered lap-shear joints are strongly temperature dependent, and almost halved at the temperature of 325℃. To describe the temperature effect on fatigue life under fully-reversed loading, Basquin's equation is developed by introducing temperature factor, and shows a good agreement with experiment results. In dwell-fatigue tests, creep is found the main factor resulted in failure acceleration and cyclic life reduction.

Keywords lap-shear, fatigue, dwell-fatigue, Basquin' equation, temperature dependent

1. Introduction

Nowadays, the use of tin-lead solder in certain application has been banned for its damage on healthy. However, there still are some fields such as power electronics packaging using high lead solder as interconnected material [1], which can be mainly attributed to the absence of appropriate substitution. Therefore, the introducing of environmental friendly die-attaching material becomes more and more important due to increasing stringent requirements of weight reduction, size miniaturization, high thermal dissipation, etc. [2].

In the 1970s, the view of diffusion welding silver film had been introduced by O'brien et al.[3], and thus a new die-attaching technology named low-temperature joining technology was remarkably promoted. With the assistance of mechanical pressure of about 40MPa, micro-sized silver powder could be sintered at temperature below 300℃ [4]. From then on, silver is used widely in microelectronic packages as a promising interconnection material between substrates and chips because of its superior electrical/thermal conductivity, high melting temperature (1,233 K), and good reliability. Though, for brittle silicon chips and ceramic substrates, the aided pressure might be destructive even slightest irregularities [5]. To raise the sintering driving force of this interconnection material, the paste formed by nano-sized silver powder, which gained the close attention of both scientists and power electronics engineers, was introduced by Lu et al [6].

Before the sintering technology coming into practical application, the processing profile and the property of nano-silver paste had been studied. In recent years, A low-temperature sintering profile with sintering temperature of 285℃, heating rate of 10℃/min, and holding time of 60 min was introduced by Wang et al [7]. Yu et al. studied the tensile behaviors of low-temperature sintered nano-silver films and proved that accumulation of plastic strain took place in silver-bonding layer during thermal cycling, which might lead to the final failure of the chip-attachment [8]. Chen et al. stated that the process of damage evolution of the nano-silver films was temperature independent by

mass of creep test data at elevated temperatures [9]. However, these studies only revealed the properties of sintered silver film, which in turn imposed a limitation to consider the thermally induced strain due to thermal expansion coefficient mismatch between substrate and chip in actual applications. Li et al. [10, 11] constructed a lap-shear structure to study the mechanical property of sintered nano-silver as a joint. Following this lap-shear structure, further research on fatigue and dwell-fatigue property of sintered nano-silver joint was conducted in this study.

Not only tensile and fatigue tests but also creep-fatigue tests were conducted in this article in order to understand the failure mechanism of nano-silver sintered lap shear joint at elevated temperature, study any possible relation between creep and fatigue in the low-cycle regime and learn the probabilistic observed mechanisms The creep-fatigue tests were conducted at the temperature of 325℃, at which both dwell time and fatigue process interacted and failure occurred in the low-cycle regime.

2. Sample preparation and experiment procedure

Details about lap-shear joint preparing have been presented elsewhere [11]. The well prepared sintered nano-silver structure with 2mm×1mm×50μm joint used in this study is showed in Fig. 1. All the tests were conducted on Micro Uniaxial Fatigue Testing System (MUT-1020) provided by CARE Measure & Control Co., Ltd. as shown in Fig. 2.

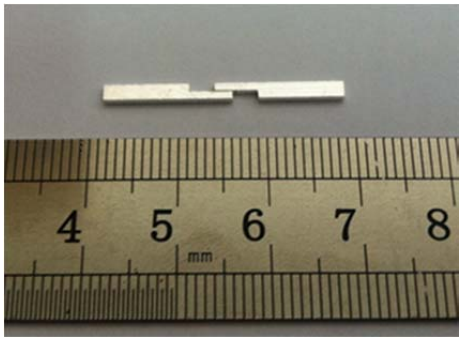

Fig. 1 Prepared sintered nano-silver lap-shear structure

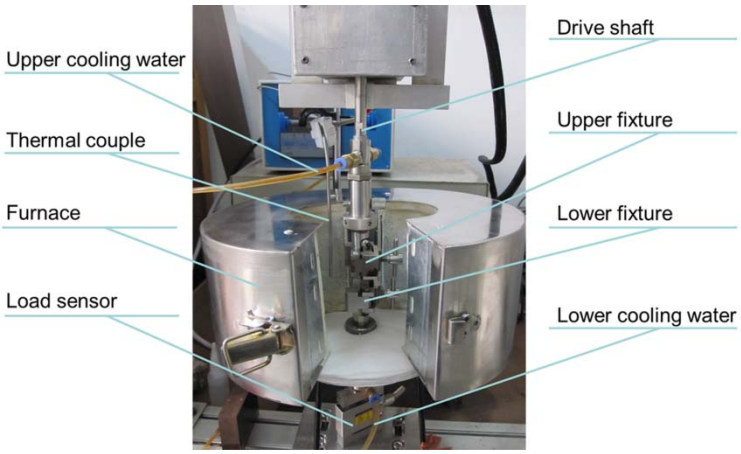

Fig.2 The testing apparatus

In order to obtain the shear stress-strain relations of sintered lap shear joints as the base for cyclic tests, a series of shear tests were conducted at four different ambient temperatures of 25℃, 225℃, 275℃ and 325℃. For fatigue and dwell-fatigue tests, the loading conditions are listed in Table 1. 3 samples were conducted for each loading condition. All the shear and cyclic tests were conducted under stress-controlled mode with loading rate of 2MPa/s.

3. Results and discussion

3.1 Shear behavior at elevated temperatures

As shown in Fig.3, the effect of temperature on strain level of nano-silver joints can be concluded. At room temperature of 25℃, the failure strain is less than 1.5%, which contains a small part of plastic strain and thus a brittle failure. With the temperature increasing, the shear modulus is decreased and the plastic flow of the joint was more obvious. The average shear strength under 4 ambient temperatures is given in Fig. 4. When the temperature is higher than 225 ℃, the shear strength drops dramatically, and almost halve at the temperature of 325℃ (14MPa).

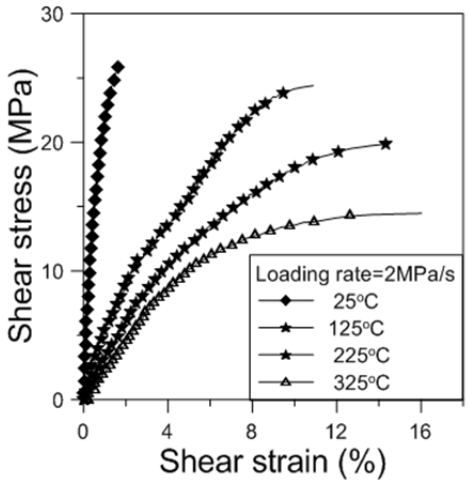

Fig.3 Shear stress-strain relationship of sintered nano-silver joint

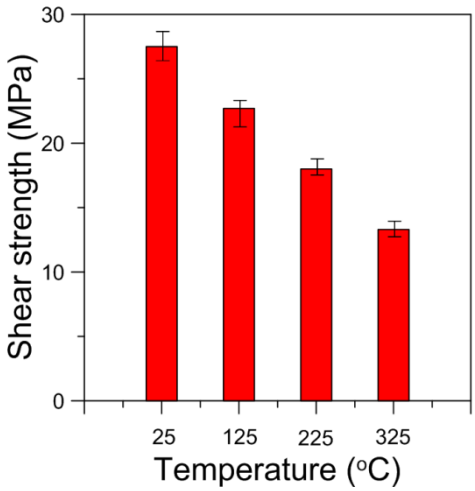

Fig.4 Shear strength of sintered nano-silver joint

3.2 Fatigue tests of fully reversed at elevated temperature

3.2.1 Fatigue behavior

Figure 5 shows shear stress-strain hysteresis loop under different loading amplitudes. From Fig. 5 we can find that the shear strain amplitude increases with the loading amplitude increasing under fully reversed loading situation. The increasing of hysteresis loops with loading amplitudes demonstrates the larger energy dissipating per unit volume during a cycle, which results in fewer cycles.

The plot of shear strain range versus number of cycles as shown in Fig.6 illustrates that the initial shear strain range increases as the increasing of the loading amplitudes. The evolution of shear strain range can be divided into three stages. The first stage has the longest duration of about 60-80 percent of the fatigue life and takes almost constant shear strain amplitude. When the fatigue test steps into the second stage of 80-90 percent of fatigue life, the shear strain slowly increases, which can be considered as the crack initiation. The final 10 percent of fatigue life is involving the third stage, during which the fatigue damage accumulation accelerates and results in ultimate failure.

The true strain-stress hysteresis loops of the nano-silver joint at load amplitude of 6MPa and 8MPa are displayed at Fig. 7. The enclosed area of the hysteresis loop represents the cyclic plastic energy consumed in each cycle. At certain loading amplitude, with the increasing of the cycles, the enclosing area increases gradually. The enclosed area of hysteresis loop experiences a rapid increase before the nano-silver joint comes to the final failure.

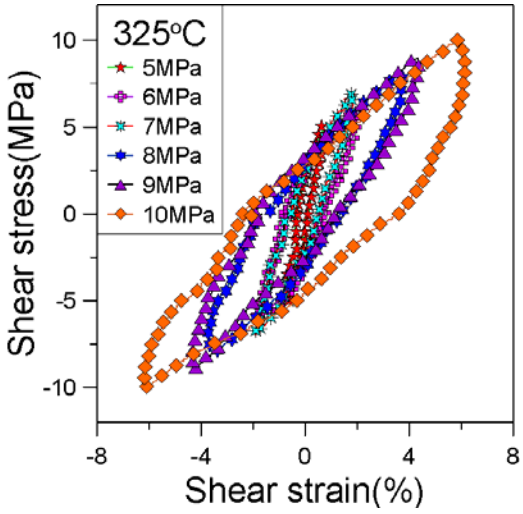

Fig. 5 Comparison of hysteresis loop under different loading amplitudes

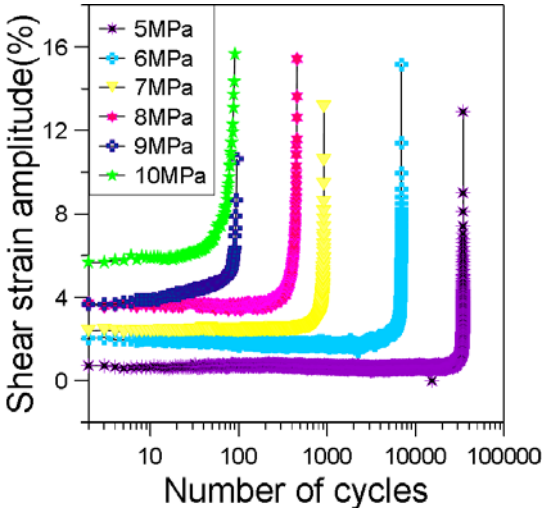

Fig. 6 Comparison of strain amplitude under different loading amplitudes at the temperature of 325℃

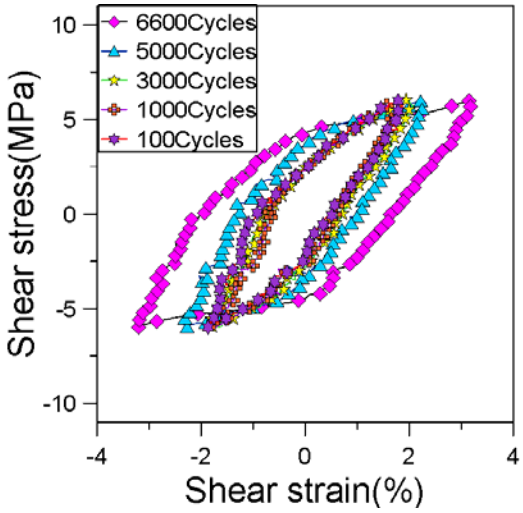
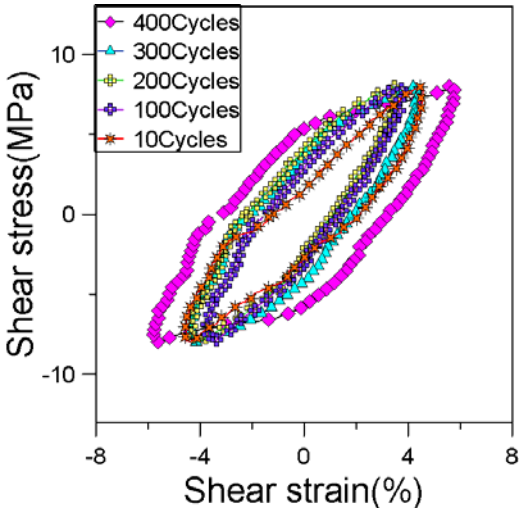


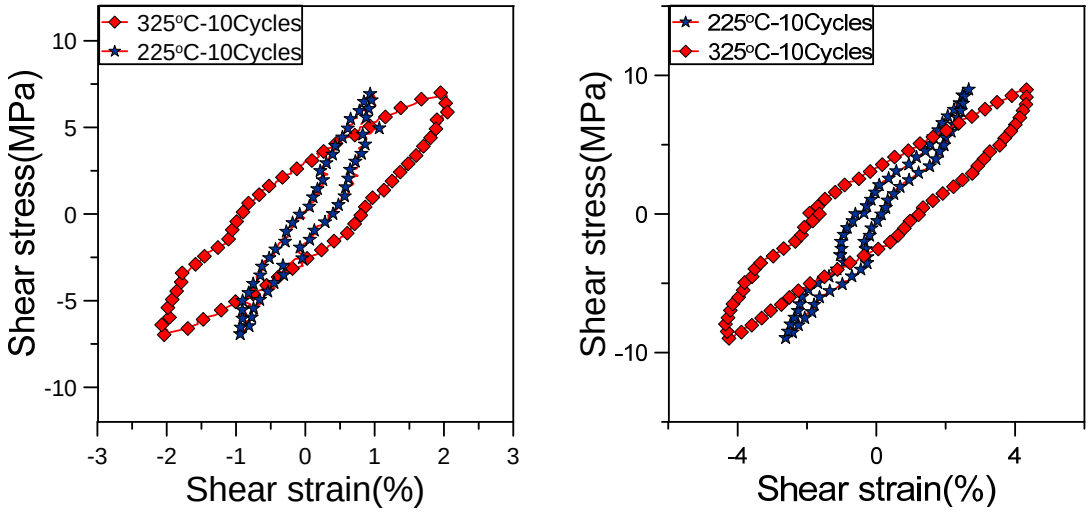
(a) At the loading amplitude of 6 MPa



(b) At the loading amplitude of 8MPa

Fig. 7 Comparisons of hysteresis loops under different cycles

The temperature effects on hysteresis loops under 7MPa and 9MPa loading amplitude are shown in Fig. 8. It can be found that at higher temperature of 325℃, more plastic strain is present and the loops are wider, which causes the cyclic plastic deformation in the joint to be more severe. As a result, the fatigue life at the temperature of 325℃ is shorter than that at the temperature of 225 ℃. It should not be ignored that higher temperature could mobilize the dislocation of the nano-silver joints, which leads to a significant reduction of fatigue life.



(a) At the loading amplitude of 7MPa (b) At the loading amplitude of 9MPa

Fig. 8 Comparison of the hysteresis loops at the temperature of 325℃ and 225℃

3.2.2 Fatigue life prediction

The stress-life (S-N) data can be plotted linearly in a log-log scale which is firstly observed by Basquin [12]. Here the formula can be expressed as

$$\Delta\tau/2 = \sigma'_{ft}(2N_f)^b \quad \text{(Eq. 1)}$$

The relationship between the shear stress amplitude and the fatigue life for sintered nano-silver lap shear joint at 325℃ and 225℃ are linearly fitted as Basquin's equation in the logarithm coordinate system as shown in Fig. 9. The fatigue strength exponent b and fatigue strength coefficient σ'_{ft} for sintered lap shear joint are given in Table 2. It can be obviously observed that the fatigue strength coefficient increased with decreasing temperature. The fatigue strength exponent has little change at different temperature as is shown in Fig. 9. The fatigue life of the nano-silver sintered lap-shear joints at the temperature of 325℃ and 225 ℃ are fitted well.

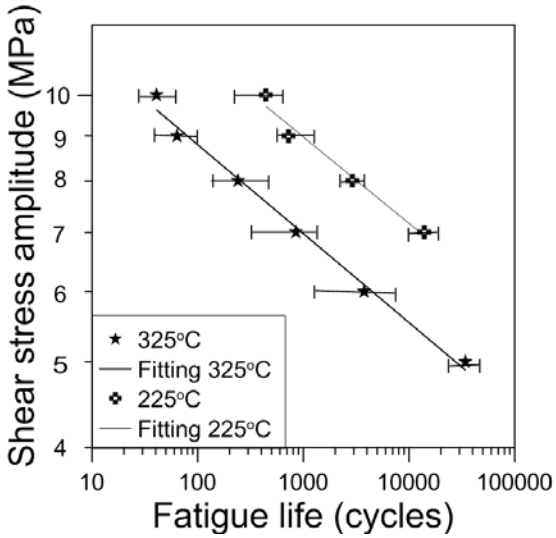


Fig. 9 S-N curve for nano-silver sintered lap-shear joints

Table 2. Comparison of fatigue properties between experimental value and empirical value

Temperature (℃)	σ'_{ft}	B
225	19.2	-0.1056
325	15.3	-0.1061

3.3 The dwell-fatigue behavior of nano-silver sintered lap-shear joints

As listed in Table 2, a series of dwell-fatigue tests (A7-A11) are conducted at the loading amplitude of 6MPa and the temperature of 325℃. From the results show in Table 3 we can find that with the increasing of dwell time, the fatigue life in cycle decreases at a rapid rate. But the total creep time (dwell time summation) holds between 2000-4000s, which indicates that the creep take a more important part in the failure process and might lead to the final failure. A point should be put forward that dwell sensitivity accelerates the fatigue failure while the cyclic loading prolong the creep life, since the creep life of the joints under the same loading amplitude is only 415s.

Table 3. The dwell-fatigue tests data under different dwell time.

Spec. ID	Temperature /℃	Dwell time (s)	Fatigue Life (cycles)	Total creep Time (s)
A6	325	0	6925	0
A7	325	1	2538	2538
A8	325	3	1226	3678
A9	325	5	438	2180
A10	325	7	536	3752
A11	325	9	239	2151
B4	225	0	9800	0
B5	225	1	4590	4590
B6	225	7	919	6433
B7	225	9	409	3681

Fig.10 indicates that the number of cycles verses dwell time is a straight line on the semi-log plot. The life in cycles reduces with the increasing of dwell time. It should be pointed out that the effect of dwell time at the temperature of 325℃ is more significant than that of 225℃. In other words, as the creep behavior of nano-silver sintered lap-shear joints is significantly influenced by temperature, so creep plays a more important part to the final failure of specimens at the temperature of 325℃ than 225℃. However, a series of creep-fatigue tests need to be conducted for further study of the effect of creep on creep-fatigue tests.

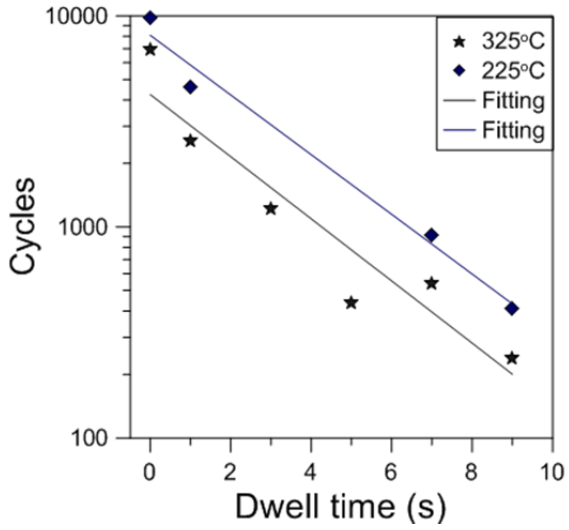

Fig.10 The fatigue data with different dwelling time

4. Conclusions

Firstly, the shear tests of nano-silver sintered lap-shear joints at elevated temperatures were conducted to study the effect of temperature on shear behavior. Secondly, a series of fatigue tests under fully reversed loading indicated how temperature affected the Basquin equation. Finally, the effect of creep on fatigue was studied at high temperature of 325 ℃. The following conclusions are obtained.

(1) Shear behaviors are temperature dependent. The shear strength decreases with the increased of temperature. The shear strength at room temperature is as high as 28MPa, which halve at the temperature of 325℃.

(2) Basquin's equation is presented to predict the fatigue life of the nano-sintered lap-shear joints at different temperatures, where the fatigue strength exponent b is a constant and the fatigue strength coefficient σ_{ft}' is a value dependent on temperature, which decreases with the elevated temperature

(3) With the increasing of the dwell time, the effect of creep becomes more and more significant. It can be concluded from the dwell-fatigue tests at the temperature of 325℃ that creep is the main factor that lead to the final failure of the specimen.

Abstract Fretting fatigue, which is a composite phenomenon of metal fatigue and friction, is one of the major factors in the design of mechanical components as it significantly reduces fatigue strength. Since hydrogen can influence both fatigue and friction, fretting fatigue is one of the important concerns in designing hydrogen equipment. The authors carried out the fretting fatigue tests on austenitic stainless steels in order to characterize the effect of hydrogen and to explain the mechanism responsible for hydrogen embrittlement. In this study, the significant reduction in fretting fatigue strength due to hydrogen is shown including other factors influencing the fretting fatigue strength such as surface roughness, hydrogen content and the addition of oxygen. The cause of the reduction in the fretting fatigue strength in hydrogen is local adhesion between the contacting surfaces and subsequent formation of many small cracks. Furthermore, hydrogen enhances crack initiation under fretting fatigue conditions. Transformation of the microstructure from austenite to martensite is another possible reason. A hydrogen charge also reduces the fretting fatigue strength. The cause is the reduction in the crack growth threshold, ΔK_{th}, due to hydrogen.

Keywords Hydrogen, Fretting, Fatigue, Austenitic stainless steels, Adhesion

1. Introduction

Hydrogen embrittlement is a classic problem, but recent studies on hydrogen embrittlement have clarified that there are many technical challenges to achieving a balance between reducing the cost of hydrogen equipment and ensuring their safety. In this study, fretting fatigue in hydrogen is the focus, since fretting fatigue is one of the major factors in the design of mechanical components due to the significant reduction in fatigue strength. It has been reported that fretting can cause a reduction in fatigue strength by half to one-thirtieth of that of a smooth specimen [1]. Fretting fatigue occurs at the position where metal fatigue and fretting occur simultaneously. Fretting is the cyclic relative slip motion involving wear between the contacting surfaces of components mechanically fastened. In hydrogen equipment, fretting fatigue is definitely an important issue, since hydrogen can have an influence on both fatigue and friction phenomena. A significant reduction in the fretting fatigue strength due to hydrogen and the mechanisms causing the reduction are described. Several factors influencing the fretting fatigue properties in hydrogen are also investigated.

2. Procedures

2.1 Fretting fatigue test method

Figure 1 shows the fretting fatigue test method under tension and compression loading. In addition, a bending fretting fatigue test was also carried out. Detailed configurations of the specimen and contact pad are shown in refs. [2, 3]. In either case, two contact pads were pressed onto the front and back side surfaces of the fatigue test specimen. When a fatigue load is applied to the specimen, fretting is induced between the contacting surfaces due to the difference in the

deformation between the specimen and contact pad. The shape of the contact pad is the so-called bridge type in which there are two contact parts. As shown in Fig. 1, a strain gage was cemented at the midpoint of the contact parts to measure the friction force.

The nominal contact pressure was 100MPa. The tangential force coefficient, ϕ, was defined as the ratio of the friction force and the contact force. The fretting fatigue test was carried out with a stress ratio, *R*, of -1 at a loading frequency, *f*, of 20Hz. The test environment was hydrogen and laboratory air. The hydrogen pressure was 0.2MPa. The test temperature was room temperature. The fretting fatigue test in this study was terminated at 10^7 cycles if no specimen failure occurred.

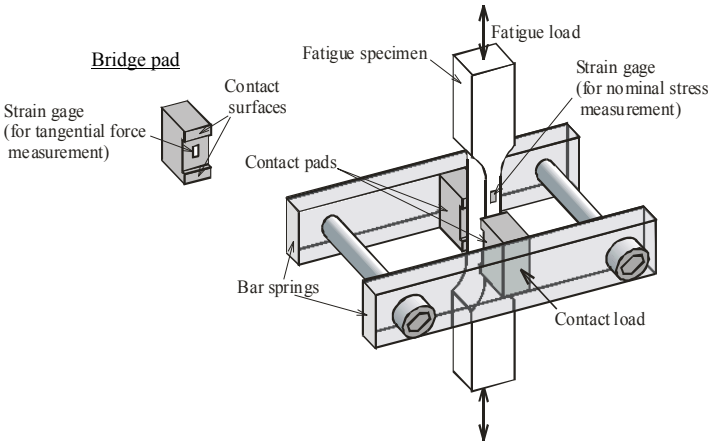

Figure 1. Fretting fatigue test method

2.2. Material

The test materials were three kinds of austenitic stainless steels, JIS SUS304, SUS316 and SUS316L. The chemical compositions of the materials are listed in Table 1. A solution heat treatment was done to the materials by quenching following heating at 1303K for 3.9ks.

Since fretting is a surface phenomenon, hydrogen diffusion into the material is one of the important issues. Therefore, hydrogen pre-charged materials were used in a part of the fretting fatigue test. The method of hydrogen pre-charging was thermal hydrogen charging.

Table 1. Chemical composition

Material	C	Si	Mn	P	S	Ni	Cr	Mo	Fe
SUS 304	0.06	0.51	0.92	0.033	0.004	8.08	18.8	-	Bal.
SUS 316	0.05	0.49	1.31	0.030	0.027	10.22	17.0	2.04	Bal.
SUS 316L	0.012	0.19	1.64	0.031	0.012	12.19	16.6	2.22	Bal.

3. Effect of hydrogen on fretting fatigue strength

3.1. *S-N* curves

Figure 2 shows the fretting fatigue *S-N* diagrams. For the SUS304, the fretting fatigue strength of the uncharged material was significantly lower in the hydrogen than in air (□ and ○). The effect of hydrogen pre-charging is also shown in Fig. 2. The details of the hydrogen pre-charging are found in ref. [1]. In air, the fretting fatigue strength was significantly reduced by the hydrogen pre-charging (● and ○). The fretting fatigue strength of SUS304 is reduced by not only gaseous hydrogen, but also internal hydrogen. When the fretting fatigue test of the hydrogen-charged material was done in hydrogen, the reduction in the fretting fatigue strength was very significant (■). The gaseous hydrogen and internal hydrogen synergistically works in decreasing the fretting fatigue strength. The mechanisms will be discussed in the latter part of this paper.

Figure 2 also shows the fretting fatigue strength of SUS316L. A failure of the hydrogen-charged specimen occurred at the fretting fatigue limit of the uncharged material. There was a trend that the finite life of the hydrogen-charged material was shorter than that of the uncharged material. Although the amount of the reduction in the fretting fatigue was small compared to SUS304, hydrogen reduced the fretting fatigue strength of the SUS316L. Since this material is recognized as a hydrogen compatible material [4, 5], the result which shows the reduction in fatigue strength is important for the design of hydrogen equipment. The hydrogen embrittlement during the fatigue of SUS316L was also reported by Murakami et al [6].

Figure 2. Effect of hydrogen on fretting fatigue strength

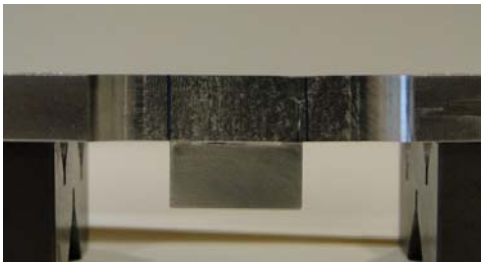
3.2. Mechanism that causes the reduction in fretting fatigue strength due to hydrogen

3.2.1. Local adhesion between contacting surfaces

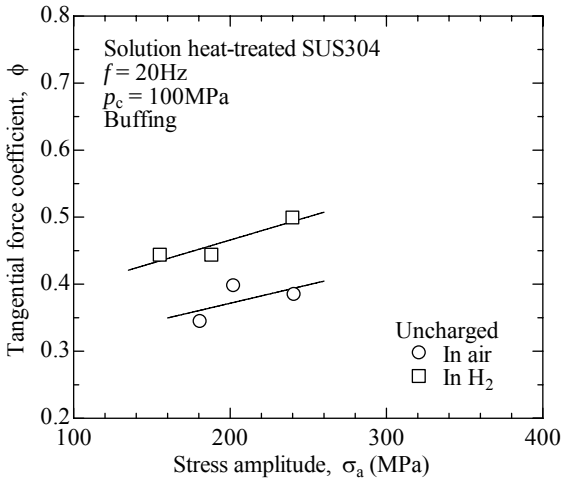
Figure 3 shows the characteristic phenomenon that occurs during fretting fatigue in hydrogen. The specimen and contact pad adhered to each other during the fretting fatigue in hydrogen. During the fretting in air, oxidized fretting wear particles separate the specimen and pad. In air, the fretting damage is produced by an oxidation dominant process. On the other hand, during the fretting in non-oxidative environments, such as a vacuum [7] or nitrogen [8], the fretting damage mechanism changes to an adhesion dominant process. In hydrogen, a similar mechanism may occur.

Figure 3 also shows the tangential force coefficient in each environment. An increase in the tangential force in hydrogen is clearly shown. The adhesion between the contacting surfaces is the cause of the increased tangential force in hydrogen. The stress conditions on the fretted surface are determined by the fatigue stress, contact stress and tangential stress due to friction [9]. The tangential force is a dominant factor of the fretting fatigue strength [10]. The increase in the tangential force in hydrogen causes an increase in the mechanical stresses on the contact surface. Consequently, the increase in the tangential force due to adhesion is one of the possible reasons for the reduced fretting fatigue strength in hydrogen.

Figure 4 shows the section along the specimen axis of the adhered specimen and contact pad during the fretting fatigue test in hydrogen. There were many small cracks at the interface between the specimen and pad. The small cracks propagated in two directions at which the small cracks made angles of approximately 45 or 135 degrees to the contact surface. During the fretting fatigue in air, small oblique cracks and multiple small cracks are the typical characteristics [11]. However, the angle of the oblique small cracks is constant [12]. Furthermore, the small cracks observed in this experiment propagated into both the specimen and the contact pad. Fretting fatigue cracks are



(a) Adhered specimen and contact pad (SUS316L, uncharged, σ_a = 200MPa, $N_f = 5.4\times10^5$)



(b) Increase in tangential force coefficient

Figure 3. Adhesion between contacting surfaces during fretting fatigue test in hydrogen

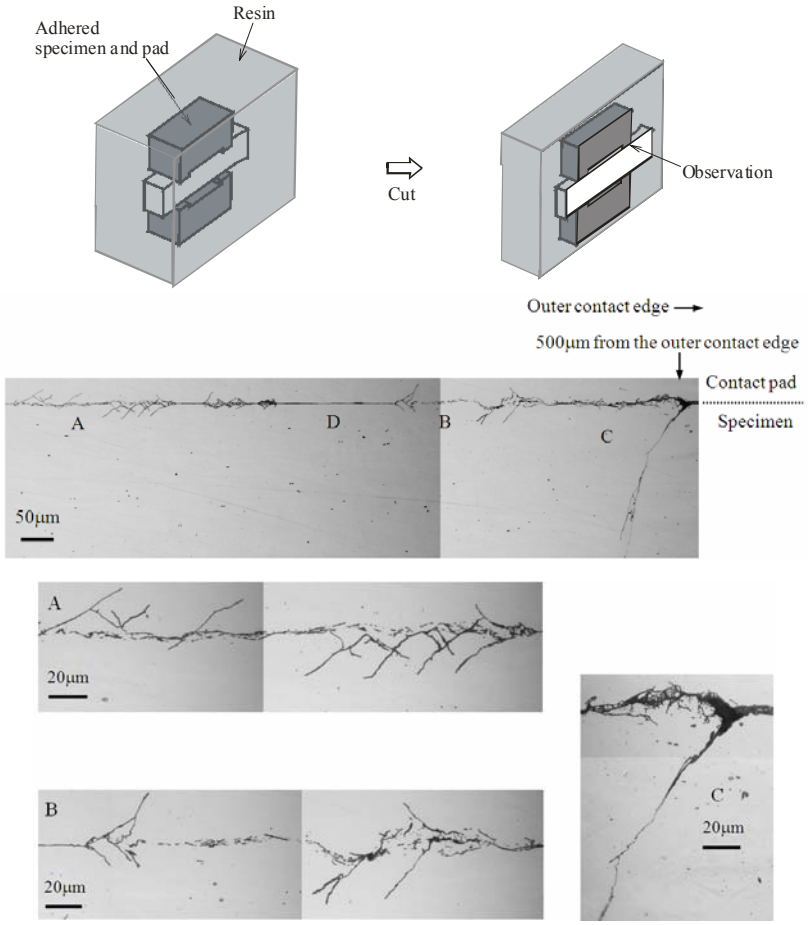


Figure 4. Observation of adhered part at the longitudinal section of the adhered specimen and pad (SUS304, σ_a = 180MPa, $N = 1.0\times10^6$).

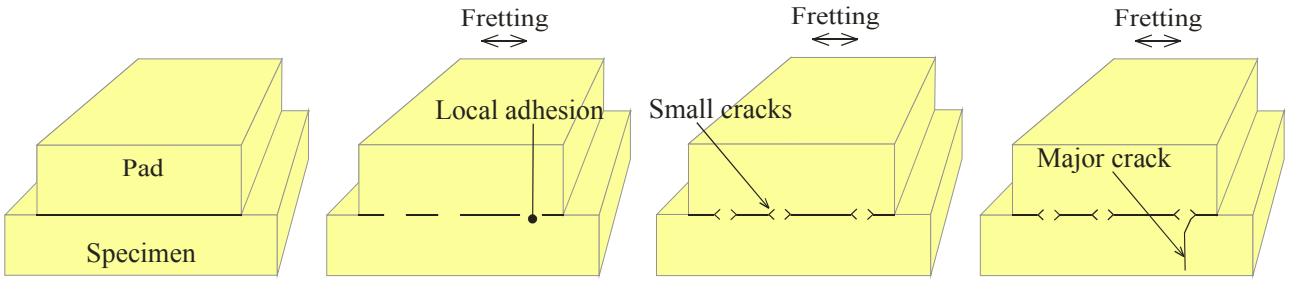
typically found in a specimen because no fatigue stress is applied to the contact pad. The morphology of the small fretting fatigue cracks in hydrogen was unique compared to that observed in air.

If a contact pad is simply placed on the specimen without fretting, the boundary of the specimen and pad should be a straight line. However, at positions A, B and C, the interface was not

continuous and winding. These are microscopic evidence of adhesion. At position D where a straight line was observed, there was no fretting fatigue cracks. Therefore, the formation of the small cracks is related to the local adhesion.

There was a major crack leading to specimen failure at position C. The major crack started to grow from one of the small cracks that emanated from the adhered spot. Therefore, the adhesion and the subsequent formation of many small cracks are one of the root causes of the reduced fretting fatigue strength in hydrogen. Based on this observation, a model to describe the fretting fatigue failure in hydrogen is shown in Fig. 5.



(a) Before test (b) Local adhesion (c) Crack initiation (d) Specimen failure

Figure 5. Model to cause fretting fatigue failure in hydrogen

3.2.2. Effect of hydrogen on fretting fatigue crack initiation

Figure 6 shows the test method used to investigate the effect of hydrogen on the initiation of a fretting fatigue crack. The specimen and contact pads were welded using a spot welding machine to mimic adhesion during fretting fatigue in hydrogen. A compressive load, which corresponds to the contact load in the fretting fatigue test, was applied. The fatigue test was interrupted at 10^5 cycles and identification of a small crack was then carried out. The details of the experiment are described in ref. [13].

Figure 7 shows an example of the fatigue crack in the adhesion mimic test. About 100 μm-deep cracks were found. The morphology of the cracks is similar to that observed in the fretting fatigue test in hydrogen as shown in the figure.

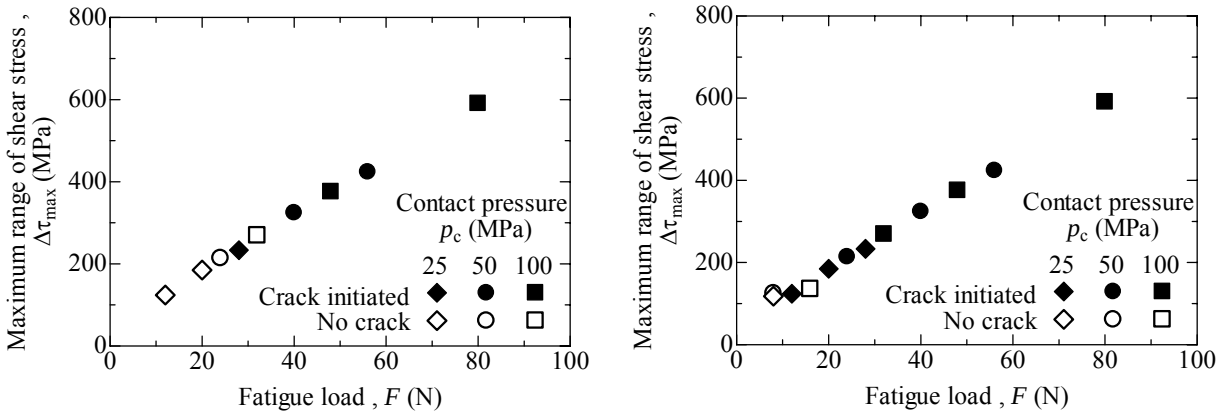
(a) Small crack in adhesion mimic test (b) Morphology of small crack

Figure 7. Observation of small cracks



(a) In air (b) In hydrogen

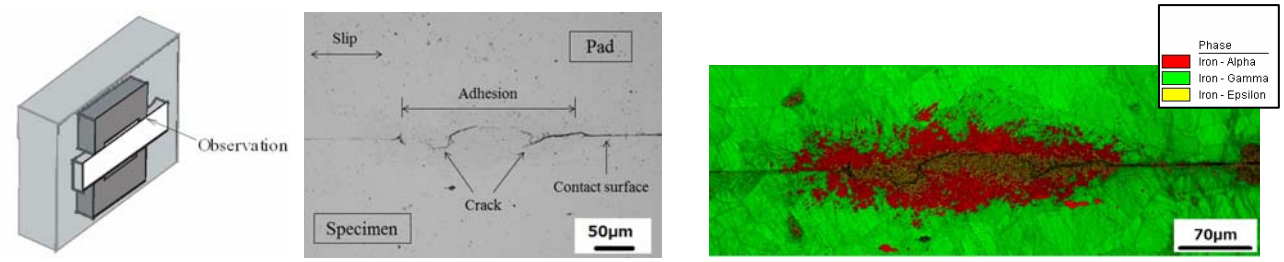
Figure 8. Effect of hydrogen on crack initiation under adhesion condition

The result of the local adhesion mimic fatigue test is shown in Fig. 8. The maximum range of shear stress was obtained by an elastic-plastic finite element (FE) analysis [13]. The crack initiation occurred in a significantly lower maximum shear stress range in hydrogen than in air. It was confirmed that hydrogen assisted the crack initiation in this experiment. This is one of the mechanisms other than stress concentration due to local adhesion that causes a reduction in the fretting fatigue strength in hydrogen.

The maximum shear stress range was greater than the proof strength of the material. Since the regions with a higher strain attract more hydrogen [14] and mobile dislocations transport hydrogen [15], it is presumed that the local adhesion activates the hydrogen embrittlement. As further evidence, the authors confirmed the facilitating of crack initiation due to hydrogen in a low-cycle fatigue of austenitic stainless steel [16]. Furthermore, fretting wear removes the oxidized surface which may prevent the diffusion of hydrogen into the material. There is a possibility that such a higher stress causes a microstructure change from austenite to martensite. The microstructure change during the fretting fatigue will be described in the next section.

3.2.3. Microstructure change

Figure 9 shows the result of the electron backscatter diffraction (EBSD) observations of the adhered part. Alpha-prime, which is considered to be strain-induced martensite, was detected at the adhered part. Martensite is vulnerable to hydrogen. Besides this, the diffusivity of hydrogen is significantly greater in the martensitic phase than in the austenitic phase [17]. As a result, the transformed martensite in the austenitic stainless steel can act as a low resistance diffusion pathway for hydrogen diffusion [18]. The transformation of the microstructure is one of the important mechanisms that cause a reduction in the fretting fatigue strength in hydrogen.

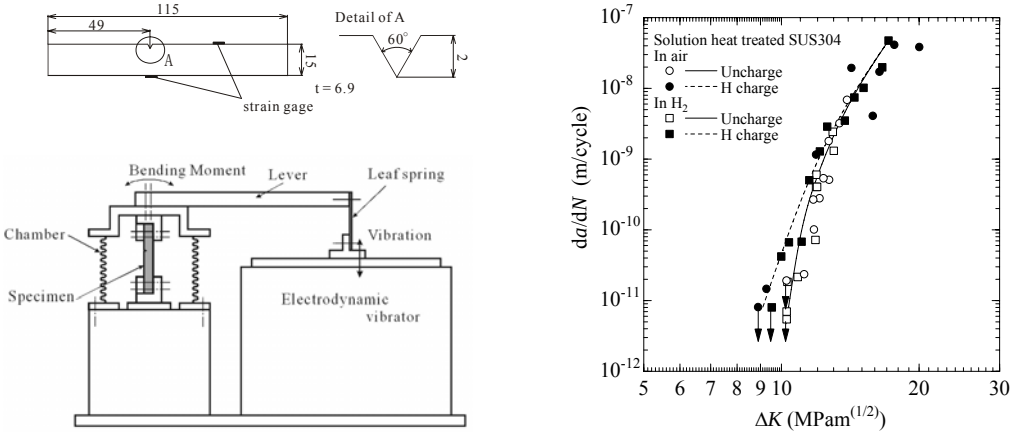


(a) SEM image (b) Phase map obtained by EBSD

Figure 9. Microstructure change due to local adhesion between fretting surfaces
(SUS316, σ_a = 182MPa, $N_f = 10^6$)

3.2.4. Reduction in fatigue threshold by absorbed hydrogen

Figure 10 shows the result of the crack growth test. The details of the test method are found in ref. [19]. In the hydrogen-charged specimen, the reduction in the threshold stress intensity factor, ΔK_{th}, is clearly shown. The reduction in ΔK_{th} is one of the causes of the reduced fretting fatigue strength by a hydrogen charge. The fretting fatigue limit of both the hydrogen-charged and uncharged materials can be quantitatively evaluated by the model based on the ΔK_{th} [19].



(a) Specimen and test method (b) Crack growth curves

Figure 10. Effect of hydrogen on crack growth threshold of SUS304

4. Effect of work-hardening

Work-hardening is a fundamental method of increasing the strength of austenitic stainless steels. Strengthened austenitic stainless steels are frequently used for high-pressure components. A 40% plastic strain was applied to the solution heat-treated materials by the tensile test at room temperature. The mechanical properties of the work-hardened austenitic stainless steels are shown in Table 2.

Figure 11 shows the result of the fretting fatigue test of the work-hardened SUS304. When the fretting fatigue strength of the uncharged material in air was compared between the solution heat-treated material (Fig. 2) and work-hardened material, it was found that the work-hardening improved the fretting fatigue strength (○ in each graph). However, the reduced fretting fatigue strength due to hydrogen was almost equivalent between the solution heat-treated material and the work-hardened material. The effect of the work-hardening was suppressed by the hydrogen. This indicates that special consideration is required in the design of hydrogen equipment made of work-hardened austenitic stainless steels.

5. Effect of surface roughness

For mechanical components requiring a gas tightness, surface roughness is one of the design factors. Figure 12 shows the fretting fatigue *S-N* curves of SUS316 in which the specimens have two

Table 2. Mechanical properties and Vickers hardness

Material	Conditions	Proof strength $\sigma_{0.2}$ (MPa)	UTS σ_B (MPa)	Elongation δ (%)	Vickers hardness HV
SUS304	Solution heat-treated	294	667	60	242
	40% pre-strained	955	1027	26	358

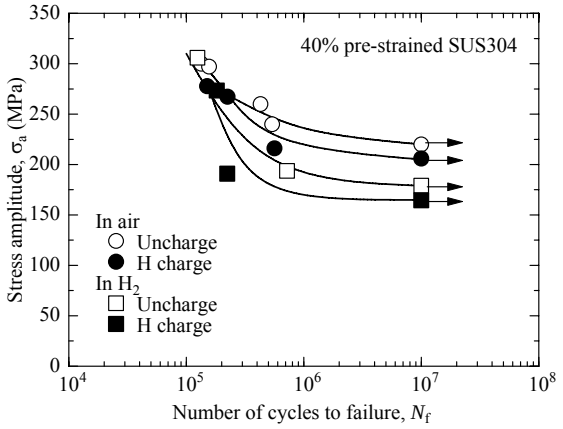


Figure 11. Effects of work-hardening and hydrogen on fretting fatigue strength of SUS304.

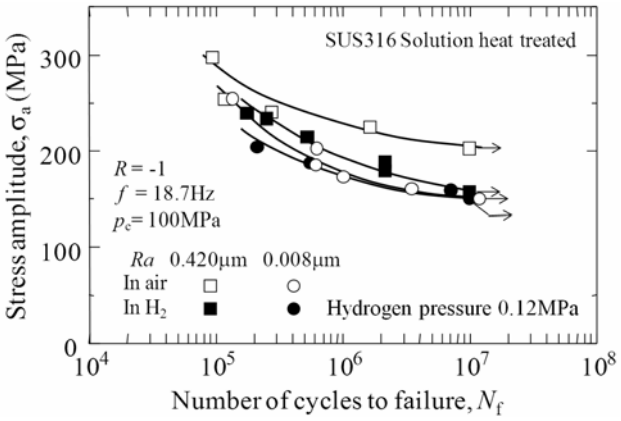

Figure 12. Effects of surface roughness and hydrogen on fretting fatigue strength of SUS316.

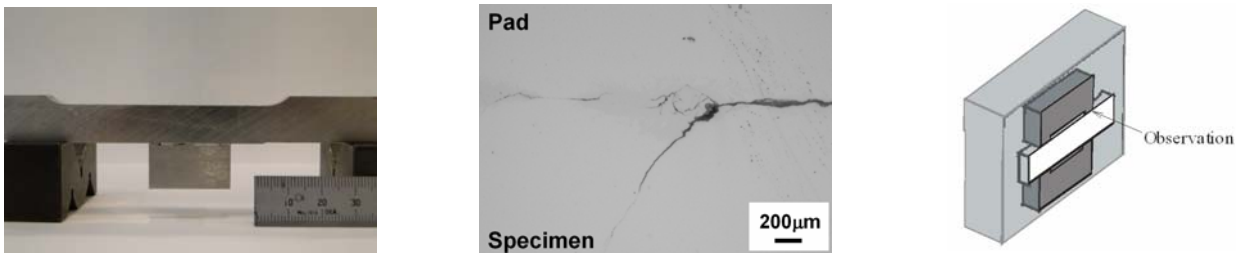
different contact surface roughnesses. The smoother surface specimen showed a considerably lower fretting fatigue strength than the rougher surface one (○ and □). The effect of hydrogen was significant in the rougher surface specimen (□ and ■), but not so in the smoother surface specimen (○ and ●).

These results can be interpreted by the crack nucleation mechanism. Figure 13 shows the major crack in the smoother surface specimen used for the fretting fatigue test in air. The major crack started to grow from the locally adhered spot similar to that observed in hydrogen. That is, when the contact surface has an extremely low surface roughness, adhesion occurred even in air and the adhesion played a dominant role in causing the fretting fatigue failure.



(a) Adhered specimen and pad (b) Major crack emanated from adhered spot

Figure 13. Fretting fatigue test of smooth contact surface specimen in air

6. Effect of hydrogen content

Figure 14 shows the fretting fatigue strength of the SUS316 for specimens having different hydrogen contents. The hydrogen content in the material was increased by the thermal hydrogen charging at 573K for 200h. The fretting fatigue strength of the SUS316 decreased with an increase in the hydrogen content.

7. Effect of hydrogen-containing oxygen as minor impurity

The purity of hydrogen used in hydrogen equipment is one of the most important concerns in terms of the performance of hydrogen equipment and the cost of hydrogen. Figure 15 shows the effect of oxygen addition on the fretting fatigue strength of the SUS304 in hydrogen. The oxygen content was 100vol ppm. The fretting fatigue strength in the oxygen-hydrogen mixture was between that in the pure hydrogen and in air.

One of the causes of the increase in the fretting fatigue strength in the oxygen-hydrogen mixture is the reduction of the tangential force between the contacting surfaces due to generation of oxidized fretting wear particles. Another cause is the increase in the crack initiation limit. Based on the adhesion mimic test (section 3.2.2), the critical maximum shear stress range to crack initiation in the hydrogen-oxygen mixture was between that in hydrogen and air [20].

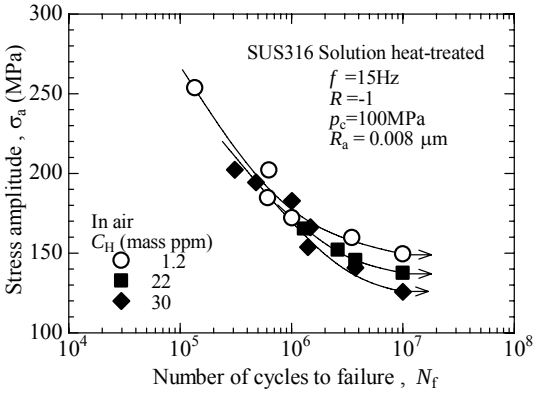


Figure 14. Effect of hydrogen content on fretting fatigue strength of SUS316

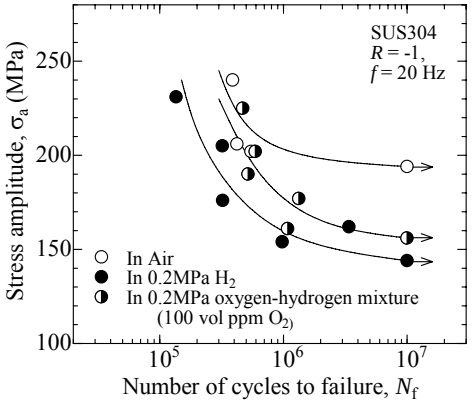

Figure 15. Effect of addition of oxygen on fretting fatigue strength of SUS304 in hydrogen

8. Conclusions

Fretting fatigue is one of the major concerns in various engineering fields such as railway, energy, aviation, automobile, etc., because fretting fatigue strength is significantly lower than the fatigue strength of a smooth specimen. This study showed the additional reduction in fretting fatigue strength due to hydrogen. The major results can be summarized as:

- ***S-N* curves:** the fretting fatigue strength of SUS304 and SUS316L is reduced by gaseous hydrogen. When the fretting fatigue test of the hydrogen-charged material, such as SUS304 was done in hydrogen, the reduction in the fretting fatigue strength was more affected due to the synergistic effect of gaseous hydrogen and internal hydrogen;
- **Mechanisms that cause the reduction in fretting fatigue strength in gaseous hydrogen:** The first mechanism is explained by the action of hydrogen as the cause for local adhesion between contacting surfaces in fretting-fatigue samples of both SUS304 and SUS316L. The second one is the microstructure change to martensite in the local adhesion part. Both mechanisms will act together in lowering the fretting fatigue strength of these stainless steels in contact with gaseous hydrogen;
- **Reduction in fatigue threshold by absorbed hydrogen:** The reduction in ΔK_{th} is one of the causes of the reduced fretting fatigue strength by a hydrogen;
- **Effect of surface roughness:** The effect of hydrogen was significant in the rougher surface specimen, but not so in the smoother surface specimen. Rough surfaces present more stress concentrators to attract hydrogen;
- **Effect of hydrogen content:** The fretting fatigue strength of the SUS316 decreased with an increase in the hydrogen content;
- **Effect of hydrogen-containing oxygen as minor impurity:** The oxygen content of 100vol ppm in gaseous hydrogen had a beneficial effect by improving fretting fatigue strength of SUS304. Even at this low impurity level, oxygen causes the reduction of the tangential force between the contacting surfaces due to generation of oxidized fretting wear particles, and the increase in the crack initiation limit.

Despite all these findings, additional work is needed to better explore the mitigating effects of oxidizing impurities in hydrogen environments.

Hydrogen Effect on Fatigue Crack Initiation Behavior of Structural Materials

Ryuichiro Ebara*
Institute of Materials Science and Technology, Fukuoka University, Fukuoka-city, 814-0180,Japan
* ebara@gold.megaegg.ne.jp

Abstract Hydrogen effect on fatigue crack initiation behavior of structural materials related to the internal hydrogen embrittlement and hydrogen environment embrittlement is reviewed. Mechanisms of hydrogen effect on fatigue crack initiation behavior of structural materials are briefly summarized. The emphasis is focused upon the hydrogen related corrosion fatigue crack initiation behavior of structural materials in aggressive gas and sour crude oil environments. Finally recommended researches in hydrogen effect on fatigue crack initiation of structural materials are touched on briefly.

Keywords Hydrogen, Fatigue, Corrosion fatigue, Corrosion pit, Crack initiation

1. Introduction

Hydrogen effect has been investigated on structural materials used for important machinery components in oil and energy related industries so far. It is well recognized that hydrogen drastically accelerate crack propagation rate of structural materials [1]. However hydrogen effect on crack initiation behavior of structural materials is not well understood. Prevention of hydrogen related fatigue crack initiation of structural materials is indispensable for safety use of fuel cell vehicle and hydrogen fueled internal combustion engine yet to come[2,3]. In this paper hydrogen related fatigue crack initiation behavior of structural materials is reviewed mainly on the basis of the author's experimental results. First the proposed mechanisms of hydrogen effect on fatigue crack initiation and propagation behavior of structural materials are briefly summarized. Then the corrosion related fatigue crack initiation behavior of structural materials in steam, humid air and aqueous solution including industrial gas such as H_2S, SO_2 and CO_2 are summarized. Hydrogen related corrosion fatigue crack initiation behavior of ship hull structural steels in sour crude oil environment is also emphasized. Finally recommended studies in hydrogen effect on fatigue crack initiation behavior of structural materials are touched on briefly.

2. Mechanism of hydrogen effect on fatigue crack initiation behavior of structural materials

It has been well recognized that fatigue strength of structural materials is affected by oxygen and humidity in air. Therefore oxygen effect on fatigue crack initiation of structural materials has been well investigated. The mechanisms for oxygen effect on fatigue crack initiation such as the oxygen intake mechanism with dislocation motion [4] were proposed so far. However the decisive mechanism for hydrogen effect on fatigue crack initiation has not yet proposed so far. Hydrogen effect on fatigue strength of mild steel with round notched plate specimen was not significant as compared with effect of oxygen and humidity [5]. Suzuki et al. conducted low cycle fatigue tests for normalized S45C round bar specimens with different purity with P,S,N,O and Al in order to investigate the pre-charged hydrogen effect [6]. The pre-charged hydrogen effect on low cycle fatigue life was not significant for high purity S45C steel. On the contrary low cycle fatigue life of low purity S45C steel was 50 to 90 % lower than that of conventional normalized S45C steel. They concluded that cyclic softening reduce the dislocation density in S45C steel with high purity and make the steel insensitive to hydrogen. Low cycle fatigue tests were also conducted for 21/4 Cr-1Mo steel in high temperature and

high pressure hydrogen environment (P_{H_2}:24.5MPa,733K) [7].The low cycle fatigue life was50% lower than that in nitrogen environment. The low cycle fatigue life in hydrogen environment was dependent on loading frequency and the hydrogen effect on crack initiation was observed. In order to ensure the safety of pipe and vessel used in high pressure hydrogen gaseous environment Nakamura et al. conducted cyclic pressurization fatigue tests for plane and pre-cracked austenitic stainless steels such as SUS304 steel, SUS316 steel, 32% cold worked SUS316 steel, precipitation hardening A286 steel and SCM435 low alloy steel with different tensile strength in hydrogen environment (P_{H_2}:35MPa) [8]. The stable austenitic stainless steel SUS316 showed no reduction of fatigue life in high pressure hydrogen gaseous environment. In contrast significant reduction of fatigue life was observed on metastable SUS304 steel, precipitation hardening A-286 steel and SCM 435 steels. They concluded that hydrogen condensation at austenitic phase for metastable 304 steel and hydrogen trapping at cementite for A286 steel is the cause of fatigue life reduction in high pressure hydrogen embrittlement.

Fatigue crack propagation process in structural materials is significantly affected by hydrogen. It has been reported that fatigue crack propagation rate was significantly accelerated by hydrogen for various kinds of structural materials such as Nickel base alloy, Inconel 718 and Waspaloy for space shuttle engine[9], 21/4Cr-1Mo steel[10],mild steel,HT790 steel[11],low alloy steel, super dual phase stainless steel,super ferritic stainless steel[12,13] and BS4360 steel[14]. R.P.Wei proposed hydrogen embrittlement mechanism at local stressed area ahead of crack tip [15]. Hydrogen by transportation process diffused into the local processed area (fracture zone) where embrittlement reaction occurs. Quantitative relation of plastic zone size during fatigue crack propagation and hydrogen embrittlement fracture zone size is recommended to evaluate. The potential hydrogen trap site might be martensite laths, carbides, sulfides or oxy sulfides[16].Certain gaseous activities to a hydrogen atmosphere can stop a running crack in 4340 steel[17].The hydrogen-metal interactions was prevented by the addition of gaseous specie such as O_2,CO_2 and N_2O[18]. In the results of accelerated fatigue crack propagation rate by hydrogen fracture surfaces such as intergranular, cleavage and quasi cleavage are predominantly observed [18,19 and 20].

Hydrogen effect on fatigue crack initiation in structural materials seems not to be prominent as compared with that on fatigue crack propagation. Nagumo explained that hydrogen embrittlement fracture surface is characterized by hydrogen assisted nano scale failure such as vacancy defect and dislocation interaction in ductile fracture process [21]. Hydrogen embrittlement is deeply related to plastic slip [22, 23]. The microscopic mechanism related to dislocation motion is recommended to investigate in order to understand hydrogen effect on fatigue crack initiation of structural materials more in detail.

3. Hydrogen related corrosion fatigue crack initiation behavior of structural materials

In order to determine the design stress of machinery components in oil and energy related industries it is indispensable to consider the effect of gaseous environment such as H_2, H_2S, SO_2 and CO_2, and sour crude oil on fatigue strength of structural materials. However, these environments are aggressive and injurious to human health. Therefor corrosion fatigue data under such aggressive environments are very few to find because of difficulty to conduct corrosion fatigue testing.

3.1 Effect of aggressive gas in steam and humid air

Fig. 1 shows S-N diagrams of plain bar specimens for 12Cr stainless steel and Ti-6Al-4V alloy in steam containing industrial gases such as H_2S and CO_2[24]. Reduction of corrosion fatigue strength in 12 Cr stainless steel is 87.5% in steam containing 20ppm H_2S gas, while the reduction of corrosion fatigue strength in Ti-6Al-4V alloy is only 4%. The SO_2 gas effect in humid air was as same as that of H_2S gas in humid air. The CO_2 gas effect in steam was not remarkable as compared with that of H_2S gas in steam. In the results of fatigue crack propagation tests with frequency of 30 Hz for 12 Cr plate specimen the effect of 20ppm H_2S gas containing in humid air on corrosion fatigue crack propagation rate of 12 Cr stainless steel was scarcely noticeable. Therefore it can be concluded that the major cause of the reduction in corrosion fatigue strength of 12Cr stainless steel is acceleration of corrosion fatigue crack initiation by H_2S gas in steam and humid air. In fact fracture surface observations revealed that crack initiated at a corrosion pit with about 10 μm depth and propagated in association with intergranular fracture as shown in Fig.2.

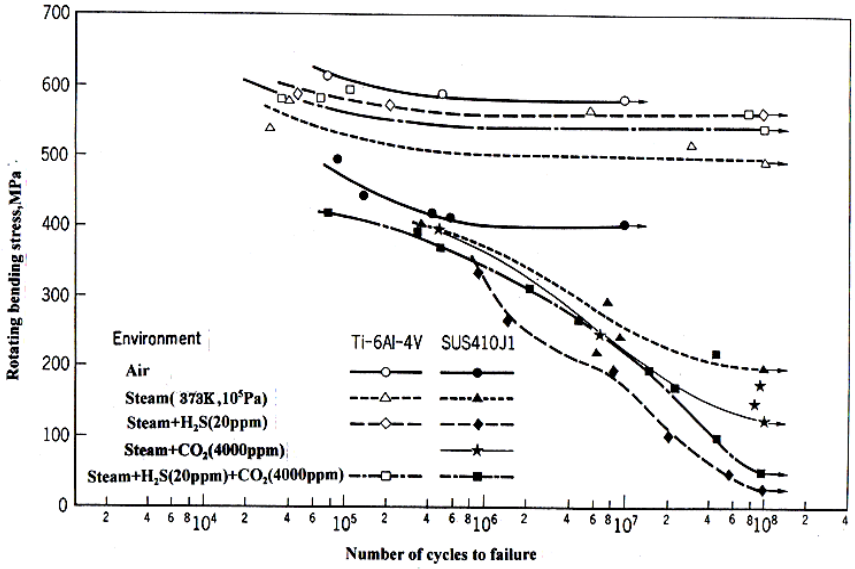

Figure1. Influence of industrial gas in steam on fatigue strength of SUS410J1and Ti-6Al-4V[Ebara[24]].

a) Corrosion pit at initiation area
b) 2mm from initiation

The corrosion pit initiated in the result of reaction between 12Cr stainless steel and H_2S gas in humid air. Intergranular fracture surface was induced by hydrogen occurred in the corrosion reaction.Fig.3 also shows plane bending corrosion fatigue testing results for T type welded joints of high 17-4PH stainless steel 5000ppm H_2S and 99.9% CO_2 gas in a humid air[25]. The remarkable reduction of corrosion fatigue strength of T type welded joints can be observed. The similar results were obtained on AISI410 and AISI4330 steel [26]. The higher the ultimate tensile strength of the steel, the larger the influence of H_2S gas environment was. In 5000ppm H_2S and 99.9% CO_2 environment corrosion fatigue crack initiated from corrosion pit at welded toe. Striation was predominant at crack propagation area. Typical fracture surface of 17-4 PH steel in humid H_2S gas environment is shown in Fig. 4. The following reaction can be considered.

294.3MPa,1.4x10 ^{7}cycles
a) corrosion pit at crack initiation area
b)3mm from initiation area,
Arrow shows crack propagation direction

In humid H_2S gas environment

$$Fe + H_2S \rightarrow FeS + H_2 \quad (1)$$

$$Fe + H_2S + H_2O + 3/2O_2 \rightarrow FeSO_4 + 2H_2 \quad (2)$$

In humid CO_2 gas environment

$$CO_2 + H_2O \rightarrow H_2CO_3 \quad (3)$$

$$Fe + H_2CO_3 \rightarrow FeCO_3 + H_2 \quad (4)$$

In the results of reaction between these steels' welded joints and aggressive gas such as H_2S and CO_2 corrosion products such as $FeSO_4$ and $FeCO_3$ were formed and corrosion pit initiated at corrosion fatigue crack initiation area. H_2 also evolved in the result of reaction. However the role of hydrogen in fatigue crack initiation is not understood well. Corrosion fatigue behavior of structural steels in geothermal steam environment at Onikobe and Katayama have been reported on power plant steels such as 13CrMo,12CrMoV,3.7NiCrMo and CrMoV. Reduction rate of corrosion fatigue strength of these steels was dependent on Cr content in steel. It was concluded that the major cause of corrosion fatigue strength reduction was stress concentration at corrosion pit formed at corrosion fatigue crack initiation area [27]. Corrosion fatigue strength reduction was also reported on AISI 403, AISI422 steel at Geysers geothermal steam [28] and 13Cr, 2.5NiCrMoV steel at Otake geothermal steam [28]. Fatigue life decrease of a medium carbon steel for compressor valve springs and sucker rods was observed in hydrogen sulfide environment[29].Quasi cleavage fracture and FeS reaction product was observed on fracture surface[30]. Thus it is apparent that major cause of reduction of corrosion fatigue strength of structural steels and welded joints in humid aggressive gas such as H_2S and CO_2 can be attributed to corrosion pit formed at corrosion fatigue crack initiation area. Mechanism of hydrogen effect on corrosion fatigue crack initiation in structural materials is still veiled in aggressive gas in steam and humid air.

3.2 Effect of aggressive gas in aqueous solution

Corrosion fatigue strength decrease of plain carbon steel used for machinery of oil and gas production in brine with H_2S was due to hydrogen effect [31]. The similar findings were obtained by plane bending and axial corrosion fatigue testing on oil well sucker rods [32,33]. Tsukada et al. conducted corrosion fatigue life tests for a SAE4135 steel and a modified SAE 4135 steel in a 0.5% percent acetic acid solution in saturated with H_2S gas [34]. The modification of SAE4135 steel consists of an increase in molybdenum content of 0.20 to 0.75 percent and addition of 0.036 percent columbium. Corrosion pits and sub cracks were severely observed at the corrosion fatigue crack initiation area of these steels in H_2S gas environment. High cycle corrosion fatigue strength for the modified steel was 66 percent higher than that of the standard steel. They concluded that the improvement was attributed to an increase in resistance of hydrogen embrittlement brought about by a higher tempering temperature which reduces the amount of phosphorus on grain boundaries, as well as the beneficial scavenging effects associated with the increase in molybdenum content and the presence of columbium. They also conducted crack propagation tests for both steels. However crack propagation behavior of these steels were similar and hydrogen effect was significant at lower ΔK region. Fatigue life decrease of weathering steel in artificial sea water saturated with H_2S [35] and work hardened nickel in hydrogen sulfide saturated water [36] were also observed.

3.3 Effect of aggressive gas in crude oil

Fig.5 shows S-N diagrams of high strength steel (HT50,TMCP) notched round bar specimen with stress concentration factor of 4.02 in air and in sour crude oil with 400ppm H_2S[37]. The

effect of sour crude oil on the fatigue life of round notched specimen is pronounced in high stress region and tends to decrease as decreasing the stress. At nominal stress of about 470MPa the fatigue life in the sour crude oil decreased to about 10 % of the fatigue life in air. Decreasing the stress the effect of sour crude oil on fatigue life decreased. At nominal stress of about 200MPa specimen did not fail after $2x10^6$ cycles. Fatigue life testing results on boxing fillet welded specimens in air and in sour crude oil are also shown in Fig 5. At axial stress of 150MPa specimen in sour crude oil did not fail even after 10 times of the number of cycles to fail in air. Macroscopic fracture surface observation for round notched bar specimen revealed that fatigue crack initiated at notched root as shown in Fig.6 a). It is apparent from SEM observation that corrosion pit was not observed at crack initiation area[Fig. 6 b)]. Brittle striation was predominant at crack propagation area [Fig.6 c)]. It is well understood that crack propagation rate of ship structural steels and line pipe steels is accelerated in sour crude oil environment[37,38 and 39]. Hydrogen effect on crack propagation rate of these steels and welded joints was drastically observed at high ΔK region. Cleavage fracture surface and brittle striation were predominant at crack propagation area. At axial stress of 196MPa a couple of small fatigue cracks initiated at notched root as shown in Fig.7 a).Figure 7.b) is one of the forced fracture surface from these cracks. The depth of the corrosion fatigue crack was 0.2mm and notched area was brown in color. But corrosion pit was not observed at fatigue crack initiation area [Fig.7 b)]. Ductile striation was predominant at crack propagation area [Fig.7c)]. This means that crack propagation rate was not affected by hydrogen in low stress region. After corrosion fatigue life test for 2393hrs crude oil exhibited less H_2O content (340 to 210ppm), lower pH value(7.3 to 4.3) and more total S content than those before test. All these facts suggest that hydrogen (H_2) was produced through the reaction of H_2O and H_2S in sour crude oil with steel. Thus, in high stress region it can be considered that atomic hydrogen (H) accumulated in the plastic zone at fatigue crack tip accelerate crack propagation rate and reduce the fatigue life of the specimen. In the low stress region, plastic zone size is small and hydrogen does not accelerate fatigue crack propagation rate. It is assumed that wedge effect [40] of crude oil retarded corrosion fatigue crack propagation rate of notched bar specimen and boxing fillet welded specimen. Corrosion fatigue mechanism in sour crude oil is schematically illustrated in Fig, 8. Corrosion fatigue behavior is a time dependent phenomenon. If corrosion pit formed at initiation area in

lower stress level drastic reduction of corrosion fatigue strength may be anticipated. The long term corrosion fatigue test is expected to conduct in lower stress level.

4. Concluding remark

This paper has briefly summarized hydrogen effect on fatigue crack initiation behavior of structural materials. In aggressive gas such as H_2S, CO_2 and SO_2 in steam, humid air and aqueous solution corrosion fatigue crack initiation from corrosion pit reduce corrosion fatigue strength of structural materials. Under these environments it is stressed that corrosion pit initiated at fatigue crack initiation area drastically reduced fatigue strength of structural steels. On the contrary, in sour crude oil environment hydrogen from reaction of steel with H_2S accelerated corrosion fatigue crack propagation rate of steels. It can be concluded that hydrogen effect on corrosion fatigue crack initiation in sour crude oil is still veiled. For safety use of structural materials in hydrogen environment prevention of fatigue crack initiation is indispensable. Definite fatigue crack initiation mechanism in hydrogen environment is expected to propose. In order to evaluate the hydrogen related fatigue life of the structural components more precisely the following studies are recommended to investigate.

1) Microscopic crack initiation mechanism with dislocation motion
2) Quantitative evaluation of the relation between the plastic zone and hydrogen embrittlement zone size at the fatigue crack tip
3) Hydrogen effect on ΔK_{th} and near ΔK_{th} region in da/dN
4) Hydrogen resistant materials to prevent fatigue crack initiation

* Corresponding author : pluvinage@cegetel.net

Fracture toughness and fatigue résistance of two pipe steels (X52and X70) has been determined using curved specimens (roman tiles) directly extracted from pipes. In both case, hydrogen embrittlement is done by electrolytic method.
The comparative assessment of local fracture initiation at notches have been done for conditions of electrochemical hydrogenating. The factor of hydrogen concentration in metal was taken into account. The relationship between hydrogen concentration in metal and work for initiation of the local fracture emanating from the notch has been derived. The existence of some critical hydrogen concentration, which causes the significant loss of local fracture resistance of material, was also shown and discussed.
The concept of ΔK_ρ has been extended to fatigue initiation emanating from notch and under hydrogen embrittlement. Here, fatigue initiation is detected by acoustic emission. It has been found that the fatigue initiation decreases after hydrogen absorption. This can be explained by interaction of hydrogen and plasticity as can be seen for tensile and fracture behaviour steel after introduction of hydrogen.

Keywords : pipe steel, hydrogen embrittlement, local fracture energy, fatigue initiation

1.INTRODUCTION

General reason, which increases of attention to the problem hydrogen degradation of pipeline steels, is fact that hydrogen will play a decisive role in a future energy system, when fossil fuels have become scarce and thus expensive and/or unsuitable from ecological reasons. The number of aspects related to the technical feasibility and economics of developing a hydrogen energy infrastructure are presented and discussed in literature during last decades [1, 2]. The possible use of existing pipeline networks for mixtures of natural gas and hydrogen offers a unique and cost-effective opportunity to initiate the progressive introduction of hydrogen as part of the development of a full hydrogen energy system [3].
From this reason, the safety, durability and integrity issues related to hydrogen/natural gas mixtures in the existing natural gas system become actual and important. First of all, there is a potential problem of so-called “hydrogen embrittlement” of pipeline material - the effects of transported hydrogen on material mechanical properties [4].
Moreover, the specific long-term exploitation of pipelines promotes the hydrogenating of steel. The external environmental conditions cause free corroding processes, where hydrogen can evaluate on metal surface as result of cathodic counterpart of the anodic dissolution reaction. This fact has been proved by several studies [5-7].
External interference incidents are characterised by potentially severe consequences: leaks and ruptures. In majority, these types of incidents are caused by initial damaging of the pipe external surface as result of third party interference e.g. by scratches and gouges and also pitting corrosion.

Such defects can be considered as typical stress concentrators and consequently the privileged sites where the further damaging and failure processes occur.

In this paper, evidence on a critical hydrogen concentration for the ductile brittle transition of two pipe steels X52and X70 is presented. The strong influence of hydrogen embrittlement on fatigue crack initiationis the second point which focuses our attention.

2. OBJECT OF STUDY AND EXPERIMENTAL PROCEDURE

The objects of study were two API grade pipeline steels, namely: X52 and X70. Nowadays, the steel X52 is the most usable in existed gas pipelines.

The specimens for tests were machined from real pipes (Table 1). The chemical composition of steels and their mechanical properties in air are given in Table 2 and 3 respectively.

Table 1 Size of pipes

Steel grade	Outer diameter D, mm	Wall thickness t, mm
X52	610	11.0
X70	710	12.7

Table 2 Chemical compositions of steels (wt %)

Steel grade	σ_U, *MPa*	σ_Y, *MPa*	*Elongation. %*
X52	528	410	30.2
X70	712	590	18.3

For tests (fatigue and fracture), the special “Roman tile” [8] specimens were used. The specimens were notched for modelling of the longitudinal external defects under operating internal pressure. The specimen view and notch geometry are given in Fig. 1. The study was conducted in special soil solution NS4 with *pH=6.7* [9]

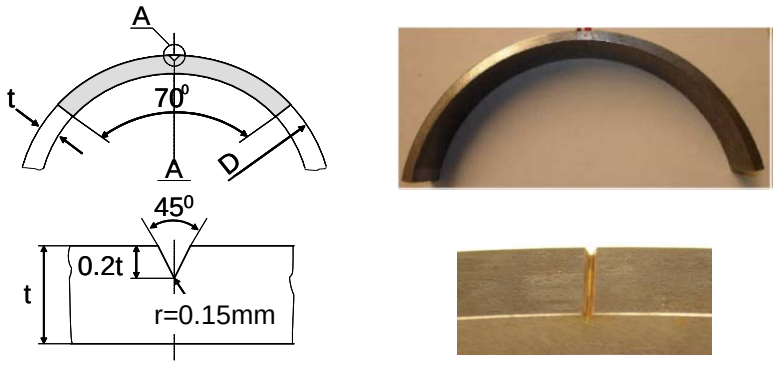

Fig. 1 “Roman tile” specimen and geometry of notch

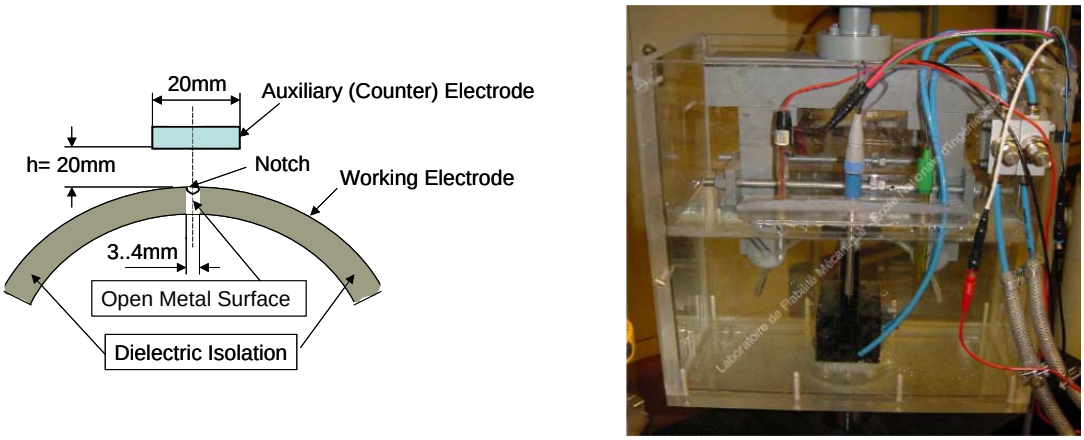

a) b)

Fig. 2 Mutual location of working electrode (specimen) and auxiliary (counter) electrode (a) and general view of corrosion cell (b)

The specimens were coated by special dielectric isolation, excepting the small area at the notch (Fig. 3). The size of auxiliary (counter) electrode was 20x40 mm. In this case its square is significantly larger than the working electrode area, which to be polarised. During testing the specimens were immersed into the cell with NS4 solution (Fig. 2) and exposed under constant potential of cathodic polarisation $E_{cath} = const$. For this experimental procedure the Potentiostat VMP has been used. During all test the level of pH was controlled and regulated between 6.6 and 6.7 by bubbling of CO_2 gas.

In given tests, the specimens were hydrogen charged at some constant potential of polarisation, which is slightly negative than free corrosion potential for the given steels. Taking into account that for studying steels the free corrosion potential is about $E_{corr} = -800mV(SCE)$, it has been chosen. Moreover, for simulating of the service conditions, the specimens were loaded during the hydrogen-charging process. The level of load was defined as the gross hoop stress σ_{gross} =194 and 195.7 MPa respectively which corresponds of the internal pressure in pipe under exploitation $p_{\exp} = 70\,bar$

The hydrogen-charging process was controlled by registration of the cathodic polarisation current $I_{cath}(\tau)$. The total quantity of evaluated hydrogen on metal surface during time of exposition τ_{exp} can be found as:

$$Q_H^{ev} = \int_0^{\tau_{\exp}} I_{cath}(\tau)d\tau \quad under\ E_{cath} = const. \tag{1}$$

Hydrogen concentration in metal has been determined on the base of hydrogen discharging process under anodic polarisation with using of hydrogen electrochemical oxidation method proposed in work [10]. For this aim, the standard three-electrode electrochemical cell has been used. The hydrogen discharging of specimen was carried out in *0.2 M NaOH* (*pH=12.4*) solution under anodic polarisation $E_{anodic} = +168\,mV(SCE)$ during some defined time τ_{dis} The total quantity of absorbed hydrogen by metal can be defined as:

$$Q_H^{abs} = \int_0^{\tau_{dis}} \left[I_H(\tau) - I_{ref}(\tau)\right]d\tau \quad under\ E_{anodic} = const. \tag{2}$$

Here $I_H(\tau)$ is anodic polarisation current for hydrogen charged specimen and $I_{ref}(\tau)$ is anodic polarisation current for specimen without hydrogen (reference curve). Calculation of hydrogen concentration was done according to formula:

$$C_H = \frac{Q_H^{abs}}{zFv}. \tag{3}$$

Where z is the number of electrons take in reaction; F is the Faraday constant; v is the effective volume of specimen: $C_H \left[mol/cm^3\right]; Q_H^{abs} \left[A \cdot s\right]; \; z = 1; \; F = 9{,}65 \cdot 10^4 \; C/mol$.

After assigned exposition under hydrogenating conditions, all specimens were tested to failure under increasing static loading or fatigue according to 3-point bending scheme. The "load – displacement" diagram and acoustic emission (AE) signals were simultaneously registered by PC during the tests. The start of fracture process has been defined by acoustic emission method.

3. RESULTS AND DISCUSSION

Process of hydrogen charging of pipeline steels at the given conditions of cathodic polarisation was characterised by following parameters: averaged meaning of cathodic current density i_c; total quantity of evaluated Q_{ev} and absorbed Q_{abs} hydrogen; coefficient of efficiency of hydrogen permeation in metal $k = Q_{abs}/Q_{ev}$ and hydrogen concentration in metal C_H. It can be seen that for assigned testing conditions, i.e. in deoxygenated, near-neutral pH NS4 solution and under loading by tensile stress, which simulates of operating conditions, the resistance to hydrogen absorption decreases with decreasing of steel strength.

Based on received experimental results, the hydrogen concentration in given steels versus time of exposition of specimens in the hydrogenating conditions can be described by power relation:

$$C_H = A \cdot 10^{-6} \cdot \tau^m. \quad \left[mol/cm^3\right]. \tag{4}$$

Where A and m are constants (see Table 4).

Table 4 Meanings of constants in formula (4)

Steel	A	m
API X52	0.30	0.57
API X70	0.40	0.42

3.1Local strength

The study of local strength of notched specimens in presence of hydrogen was resulted in the dependencies of total work U_i for initiation of the local fracture emanating from the notch. The scheme of determination of parameter U_i is presented in Fig. 3

$$U_i = \int_0^{\Delta_i} P(\Delta) \cdot d\Delta. \tag{5}$$

Here the hydrogen concentration C_H in metal was calculated by using of the analytical relation (4). The main observation based on these results is the existence of some critical time of exposition and as a consequence – some critical hydrogen concentration C_H^*, when the essential

decreasing of fracture toughness value is occurred (Fig. 3). The values of C_H^* for studied steels are given in Table 5.

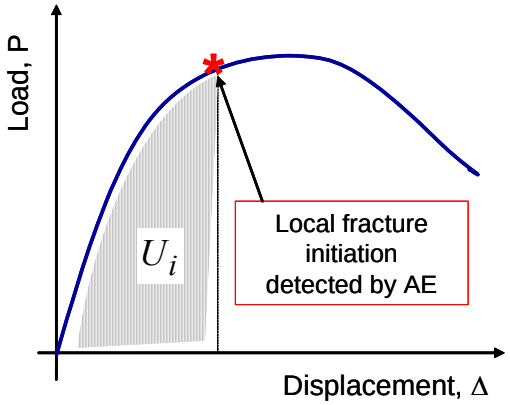

Fig 3. Scheme of determining of work for local fracture initiation

Table 5 Critical hydrogen concentrations C_H^* for API grade pipeline steels

Steel	$C_H^*, 10^6\ mol/cm^3$
X52	4.3
X70	2.3

The steel X70 demonstrates very high sensitivity to notch effect even in air and the presence of hydrogen strengthens this tendency. The hydrogen concentration about $C_H^* \approx 2.3 \cdot 10^{-6}\ mol/cm^3$ can be considered as critical, because at this conditions the given steel losses in 2.5 times its local strength with comparison of test in air. Therefore, for assigned testing conditions, steel X52 is preferable than steel X70 from the point of view of local strength at notches under hydrogen embrittlement.

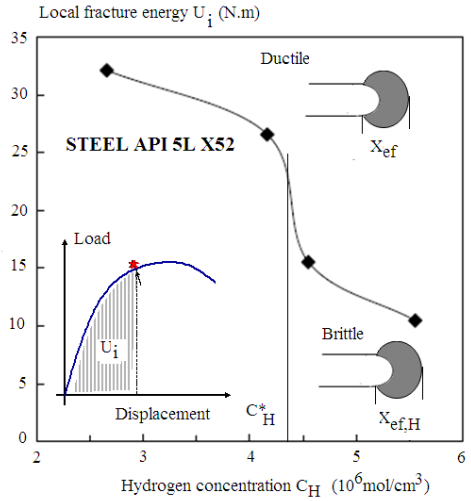

Fig .4 Ductile-brittle transition with hydrogen concentration in API5L X52 steel.

This critical hydrogen concentration at ductile brittle transition can be explained by a competition to the fracture process volume and the hydrogen affected fracture process volume. In an area approach, the effective distance X_{ef} represents the diameter of the fatigue process zone assumed as

cylindrical. Its determination is based on a procedure involving the relative stress gradient to determine an inflexion point on the notch tip opening stress distribution [8]. If X_{ef} is smaller than $X_{ef,\,H}$, the corresponding value after hydrogen embrittlement, the effective stress in the fracture process volume is greater and then the work done for fracture is higher.

There is the tendency of monotonic decreasing of C_H^* values with increasing of yield stress σ_Y or ultimate stress σ_U steel (Fig. 10). This dependency can be described by power function, like to:

$$C_H^* = B_1 \cdot (\sigma_Y)^{n_1} \text{ or } C_H^* = B_2 \cdot (\sigma_U)^{n_2}, \tag{6}$$

where B_1, B_2, n_1, n_2 are the some constants of material's properties and testing conditions. Here, the standard deviation R^2 = 0.98-0.99 that is fully acceptable. As first approximation, it can be concluded that

$$C_H^* \sim \frac{1}{\sigma_U^2}. \tag{7}$$

3.2 fatigue initiation

The fatigue resistance to initiation of the API 5L X52 and X70 steels has been measured in radial direction at room temperature using non-standard curved notched specimens, namely, "Roman tile" specimens because the pipe dimensions do not permit to measure through thickness mechanical characteristics.

The applied load, frequency and the fatigue cycle (sinusoidal) were monitored on the control panel. Hydrogen charging was made using the same cell filled with NS4 solution. Tests conditions are given in Table 6.

Table 6 : Fatigue test conditions

Shape of the cycle used	Sinus:
Frequency :	0.05 Hz
Load ratio	0.5
Working potential	- 1 V_{sce}
Electrolytic solution	New Solution 4 (NS4)
Solution pH	between 6.66 and 6.74

Wöhler curves were drawn at both initiation and failure. Results are presented in a bi logarithmic graph of stress amplitude versus number of cycles to failure. The classical power fit of the stress range versus the number of cycles to failure is in accordance with Basquin's law:

$$\Delta\sigma = \sigma'_f (N_R)^b \tag{8}$$

where σ'_f is the fatigue resistance and b the Basquin's exponent. Results are presented in Table 7.

Table 7: Fatigue resistance parameters with and without hydrogen charging for X 52and X70 steels

Steel, environment	σ'_f fatigue resistance (MPa)	exponentβ	R^2
X70 air	436	-0.023	0.94
X70 Hydrogen	395	-0.015	0.94
X52 air	343	-0.022	0.89
X52 Hydrogen	301	-0.012	0.95

Fatigue phenomenon consists of two parts, fatigue initiation and crack propagation until failure. When using optical devices, definition of initiation depends on optical resolution of the equipment. In our tests, we detect fatigue initiation by acoustic emission which is more sensitive than optical method. Acoustic emission is registered during test by two sensors. Fatigue initiation is easily detected by an energy burst. This method is also reliable and gives supplementary information on fatigue mechanism. Stress range versus number of cycles to initiation is fitted by a power law similar to Basquin's one.

$$\Delta\sigma = \sigma_i^{'}\left(N_i\right)^{\beta} \tag{9}$$

where σ'_i is fatigue initiation resistance and β an exponent. $\Delta\sigma$ is the gross stress range.

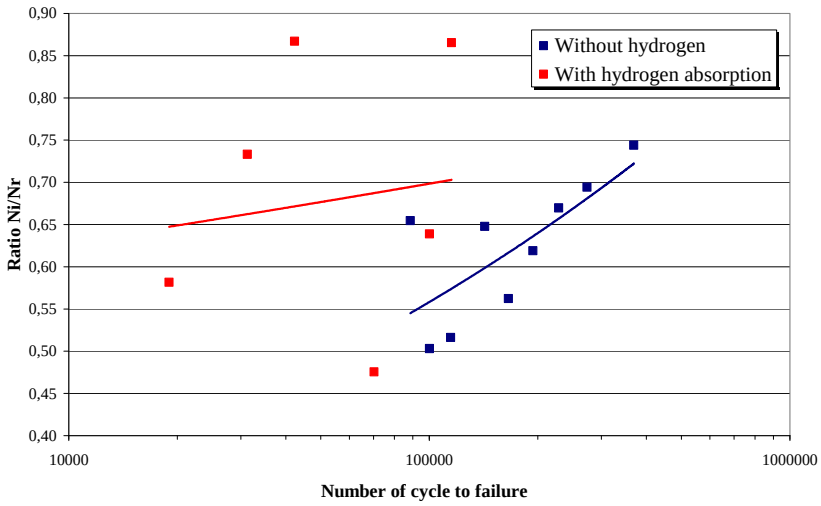

Figure 5: Evolution of ratio N_i/N_r versus number of cycles to failure for X52 steel.

Table 8: Fatigue initiation resistance parameters with and without hydrogen charging for X 52and X70 steels

Steel, environment	σ'_i fatigue initiation resistance (MPa)	Exponent β	R^2
X70 air	395	-0.016	0.96
X70 Hydrogen	368	-0.010	0.97
X52 air	325	-0.018	0.90
X52 Hydrogen	296	-0.011	0.95

Evolution of ratio N_i/N_r versus number of cycles to failure is plotted in Figure 6. We note that fatigue crack propagation is faster in presence of hydrogen because the difference N_r-N_i is strongly reduced.

Barsom and McNicol [11], Jack and Price [12], Clark [13] and Truchon [14] have used the parameter $\Delta K/\sqrt{\rho}$ to express fatigue resistance on notched specimens. Boukharouba et Al [15] have compare fatigue initiation criteria with a criterion based on the elasto plastic notch stress intensity factor K_ρ on welded specimen made in low strength steel. The same parameter has been used to plot a fatigue initiation curve K_ρ (= $f(N_i)$. One notes that this curve are not sensitive to pipe steels but sensitive to environment.

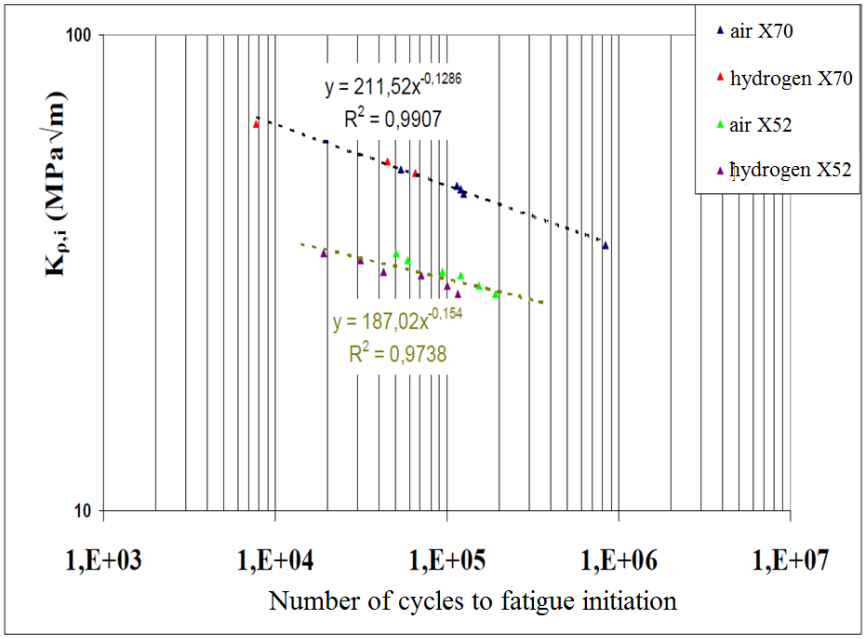

Figure 6 : Fatigue initiation curves for both steels with and without hydrogen embrittlement.

The hydrogen concentration increases as a power function of time (see equation 4) and then depends on number of cycles to initiation N_i and test frequency f. The local hydrogen concentration depends on hydrostatic stress σ_h. The average hydrogen concentration is the local one computed over the effective distance V_{ef} :

$$\overline{C}_H = \frac{1}{X_{ef}} \int_0^{X_{ef}} A\left(N_i \times \frac{1}{f}\right)^m \cdot \exp\left[-\frac{V_H \cdot \sigma_h(r)}{R \cdot (T - T_0)}\right] dr \qquad (10)$$

Where A and m are constants of equation 4, R Perfect gas constant, V_H molar hydrogen volume.

Notch Stress Intensity Factor is given according to [8] :

$$K_{\rho,air} = \sigma_{\text{ef}} \cdot \sqrt{2\pi \cdot X_{ef}} \qquad (11)$$

In hydrogen, NSIF takes the following form because maximum hydrogen concentration is localised at peak stress

$$K_{\rho,H} = \sigma_{\text{max,H}} \cdot \sqrt{2\pi \cdot X_{ef,H}} \qquad (12)$$

Effective stress σ_{ef}, peak stress $\sigma_{max,\,H}$, effective distance X_{ef} and effective distance under hydrogen concentration $X_{ef\,,H}$ are obtained by computing notch tip stress distribution by finite element and using stress strain behavior with and without hydrogen embrittlement respectively.

A plot of the following ratios $\left(\frac{\sigma_{\text{max,H}}}{\sigma_{\text{ef}}}\right)$ and $\left(\frac{X_{ef,H}}{X_{ef}}\right)$ indicates an exponential dependence with average hydrogen concentration.

$$\sigma_{\max,H} = \sigma_{ef} \cdot \exp\left(A_1 \cdot \overline{C}_H + B_1\right) ;\ X_{ef,H} = X_{ef} \cdot \exp\left(A_2 \cdot \overline{C}_H + B_2\right) \quad (13)$$

$$\begin{cases} A_1 = -9 \cdot 10^{-5} & B_1 = 0{,}1182 \\ A_2 = -5 \cdot 10^{-4} & B_2 = -0{,}0442 \end{cases}$$

So the Notch Stress Intensity factor under hydrogen can be expressed as a function of Kρ, air

$$K_{\rho,H} = K_{\rho,air} \cdot f\left(\overline{C}_H, \alpha\right) \quad (14)$$

With $f\left(\overline{C}_H\right) = \exp\left[\left(A_1 + \frac{1}{2}A_2\right) \cdot \overline{C}_H + \alpha \cdot \left(B_1 + \frac{1}{2} \cdot B_2\right)\right]$

The prameter a is introduced in order to get $K_{\rho,H} \rightarrow K_{\rho,air}$ when $\overline{C}_H \rightarrow 0$

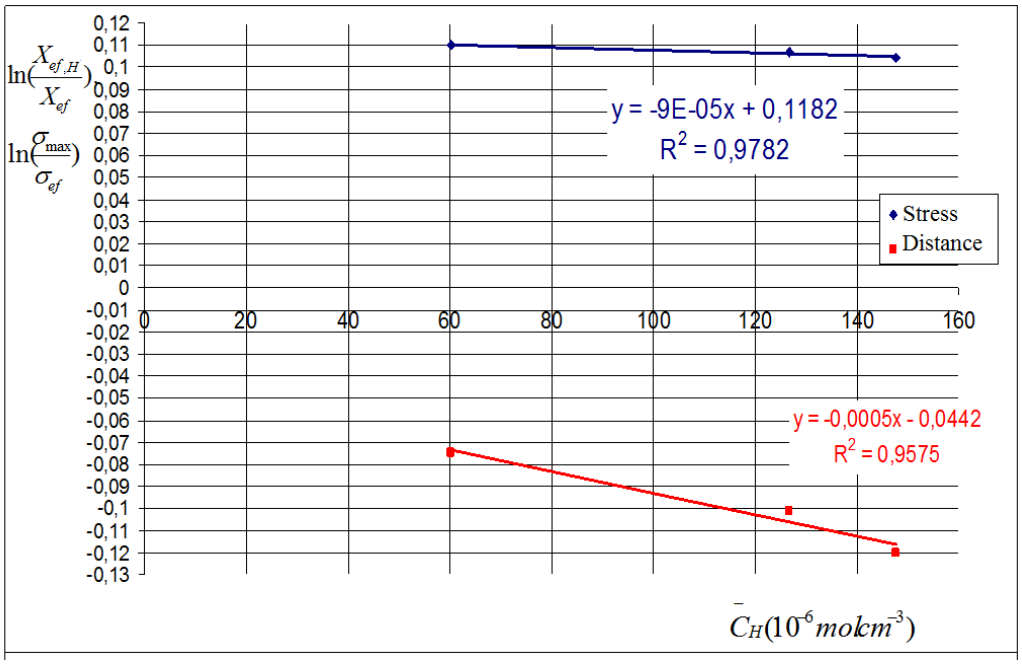

Figure 7 : Evolution of ratios $\left(\frac{\sigma_{\max,H}}{\sigma_{ef}}\right)$ and $\left(\frac{X_{ef,H}}{X_{ef}}\right)$ with average hydrogen concentration.

4. CONCLUSION

It is important to note that hydrogen concentration provides a fracture resistance transition .similarly to temperature, loading rate and notch acuity in pipe steels X52 and X. This phenomenon is describes for the first time (according to our knowledge) in this paper.

Some critical hydrogen concentration C_H^* exists for tested steels, which causes the significant loss of local fracture resistance of material at notches. The tendency of monotonic decreasing of C_H^* values with increasing of yield stress σ_Y or ultimate stress σ_U of steels has been derived.

Critical hydrogen concentration C_H^* may be considered as an important engineering parameter for forecasting of strength and reliability of exploited pipelines and under designing of new pipelines for hydrogen transportation as well.

Hydrogen embrittlement reduces fatigue life by increasing fatigue crack propagation and reducing number of cycles to initiation. Fatigue initiation can be described by the Notch Stress Intensity Factor which is sensitive to average hydrogen concentration.

Abstract The tensile properties of NiCrMo1 steel were investigated using the linearly increasing stress test (LIST) in air and with hydrogen charging. Hydrogen charging was carried out by applying an increasingly negative applied potential to -1550 $mV_{Ag/AgCl}$ in acidified 0.1 M Na_2SO_4, pH 2 solution. The LIST results showed that the yield stress of the steel was similar in air or with hydrogen charging. SEM examination showed that the specimens tested in air had no surface cracks, and the fracture surfaces comprised dimples. The failure in air was due to ductile overload. The specimens tested with hydrogen charging had obvious surface cracks in the necked region, and their length increased to about 550 μm with a more negative potential. However, the fracture surfaces were nevertheless dominated by ductile feature. These results imply that the influence of hydrogen was only associated with the final ductile fracture after the onset of necking.

Keywords: Steel 1, LIST 2, hydrogen embrittlement 3, SEM 4.

1. Introduction

Operation of metallic components is required in hydrogen (H) in the H economy being developed in response for the need for clean energy. The H economy requires pressure vessels resistant to hydrogen embrittlement (HE) for the production, distribution, storage and use of gaseous H_2. Though laboratory scale vessels can be made from expensive exotic materials, there are significant cost imperatives to use less expensive materials like steels in a commercial H economy. Some steels are susceptible to hydrogen, particularly high strength steels [1-11]. Some medium strength steels are resistant to hydrogen even under severe hydrogen charging conditions [12-15]. Using the linearly increasing stress test (LIST) [16], our previous investigation of 3.5NiCrMoV steel [15] showed that there was negligible influence of hydrogen on the yield stress and fracture stress, though the ductility was decreased for some tests. Detailed examination of the surface appearance and the fracture surfaces indicated that (i) there was no influence of hydrogen up to the yield stress of the steel; and (ii) hydrogen caused some small brittle fracture events in small localised areas associated with the final ductile fracture after the onset of necking. The LIST [16] is a stress-controlled version of the constant extension rate test (CERT) [17]. A LIST is identical to a CERT up to the onset of yielding, or the onset on subcritical crack growth. It is expect that the same apparent threshold stress would be measured using CERT as measured using LIST, an apparent threshold that related to the onset of plastic deformation.

The aim of this research was to evaluate using LIST the behavior of medium strength NiCrMo1 steel under hydrogen conditions. The results could be considered as a reference to the suitability of this steel for the H economy.

2. Experimental procedure

The material was the nickel chromium molybdenum steel, NiCrMo1. It is a quenched and tempered martensitic steel; the microstructure is tempered martensite as shown in Fig. 1. Table 1 presents the chemical composition. The steel was machined into specimens with 10 mm gauge length, 3 mm diameter and an overall length of 110 mm. The specimen was evaluated by LIST. The threshold stresses were measured with the potential drop (PD) measurement. LISTs were carried out in air, and in solution, (i) at the free corrosion potential (E_{corr}) and (ii) under hydrogen charging conditions.

The solution was acidified 0.1 M Na_2SO_4 pH 2 solution. Details about hydrogen charging, LIST and SEM sample preparation are as in [15]. After each LIST, the fracture surface was examined by SEM.

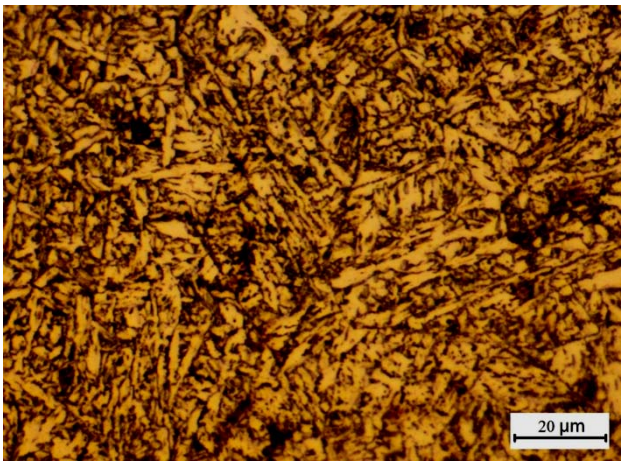

Figure 1. The microstructure of the NiCrMo1 steel.

Table 1. Chemical composition of NiCrMo1 (wt%) as determines by two independent measurements.

Steel	Composition, wt%									
	C	Ni	Cr	Mo	V	Mn	Si	S	P	Cu
NiCrMo1	0.09	1.04	0.52	0.60	0.01	0.88	0.31	0.01	0.01	0.06
	0.08	0.98	0.48	0.60	0.01	0.91	0.31	0.01	0.01	0.06

The stress rate was mostly the moderate stress rate: 0.02 MPa s^{-1}. The yield stress in air, σ_y, or the threshold stress, σ_{th}, was determined by the PD measurement. The precision for σ_y or σ_{th} was ± 5 MPa. The precision of the fracture stress was ± 2 MPa. The reduction of area, R_A, of each specimen was evaluated from the original specimen gauge diameter and the measured minimum diameter after each test. For the evaluation of σ_{th} or σ_f, in most cases the area used was the original specimen cross-section area. For tests in solution at E_{corr}, corrosion reduced the cross section area of the specimen during the LIST. In those cases, the area used was the cross section area that had undergone uniform plastic deformation.

The specimen designation can be explained by the following example: S1200.02a, where the letter ‘‘S’’ identified a specimen tested in solution (alternatively ‘‘A’’ identified a specimen tested in air), ‘‘1200’’ identified the applied potential (alternatively “ocp” identified a specimen tested in solution at the free corrosion potential), ‘‘.02’’ identified the applied stress rate, and the subsequent letter identified specimens tested under the same conditions.

3. Experimental procedure

3.1. Tensile properties

Fig. 2 shows a typical PD record for NiCrMo1 tested at 0.02 MPa s^{-1} in acidified 0.1 M Na_2SO_4 pH 2 solution at three negative potentials. Similar plots were obtained from the other experiments. Table 2 presents the measured data for σ_y, σ_{th} at which subcritical cracking appeared to initiate in solution, σ_f and R_A. The E_{corr} was about -500 $mV_{Ag/AgCl}$.

The σ_y or σ_{th} in air or at negative applied potentials were in the range of 600 to 660 MPa, while the σ_f was varied from 690 to 760 MPa. The values of R_A were about 70 ~76 %.

LIST for specimens in solution at E_{corr} produced values of the σ_{th} varying from 625 to 690 MPa, values of the σ_f varying from 710 to 800 MPa, and values of the R_A varying from 69% to 79%.

These values were comparable, or somewhat higher than, the values in air.

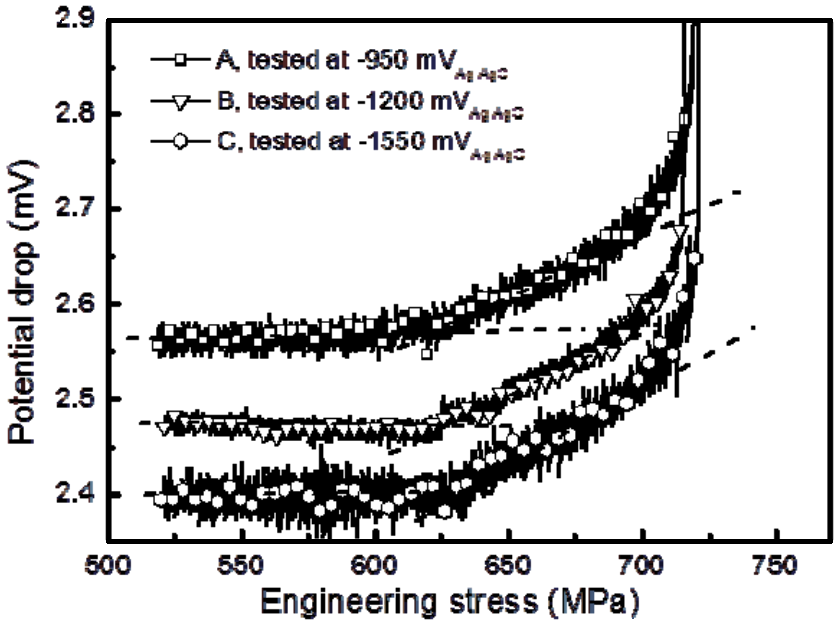

Figure 2. A typical plot of potential drop (mV) vs. engineering stress (MPa) for NiCrMo1 tested at 0.02 MPa s^{-1} in acidified 0.1 M Na_2SO_4, pH 2 solution at three potentials.

Table 2 Yield stress in air (as an engineering stress), σ_y, the apparent threshold stress at which subcritical cracking appeared to initiate in solution (as an engineering stress), σ_{th}, the fracture stress (as an engineering stress), σ_f, the reduction of area, R_A. 3.2. Surface appearance in the necked region

Visual examination of the surface appearance of each specimen showed that there was obvious necking for all the specimens. Black corrosion products, which were easily removed by EDTA, were produced on the specimens during tests at E_{corr}. For specimens tested at negative potentials, there were cracks on the specimen surface concentrated at the fracture site.

For specimens tested in air at a rate of 0.02 MPa s^{-1}, SEM observation showed necking and shallow cracks at about 45 ° to the stress direction, and linear features parallel to the stress direction in the necked region. Specimens tested at E_{corr} showed similar surface appearance except that the surface was more rough due to corrosion.

Fig. 3 presents the surface appearances of specimens tested under hydrogen charging at 0.02 MPa

s^{-1}. Specimens tested at negative potentials showed necking, and surface cracks perpendicular to the stress direction, and cracks oriented at 45 ° to the stress direction (Fig. 3(c)). The surface cracks were concentrated at the fracture site, and the number density of cracks decreased as a function of distance from the fracture surface. The surfaces of specimens tested at negative potentials were essentially similar. Fig. 3 shows that the surface cracks increased in size with increasingly negative potential.

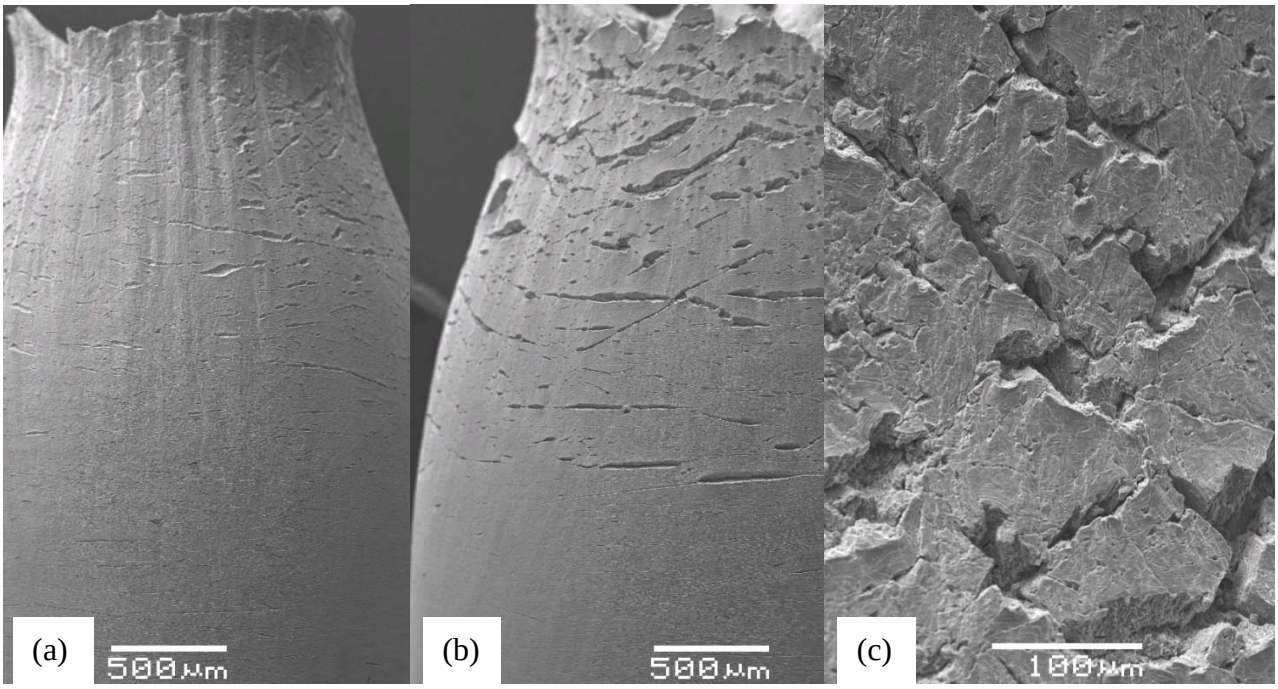

Figure 3. The surface appearances of specimens tested at negative potentials at 0.02 MPa s^{-1}. (a) -950 $mV_{Ag/AgCl}$; (b) -1550 $mV_{Ag/AgCl}$; (c) magnified view of (b) in the necked region. Tensile direction is vertical

3.3. Cross sections through fracture surface (specimen S1550.02)

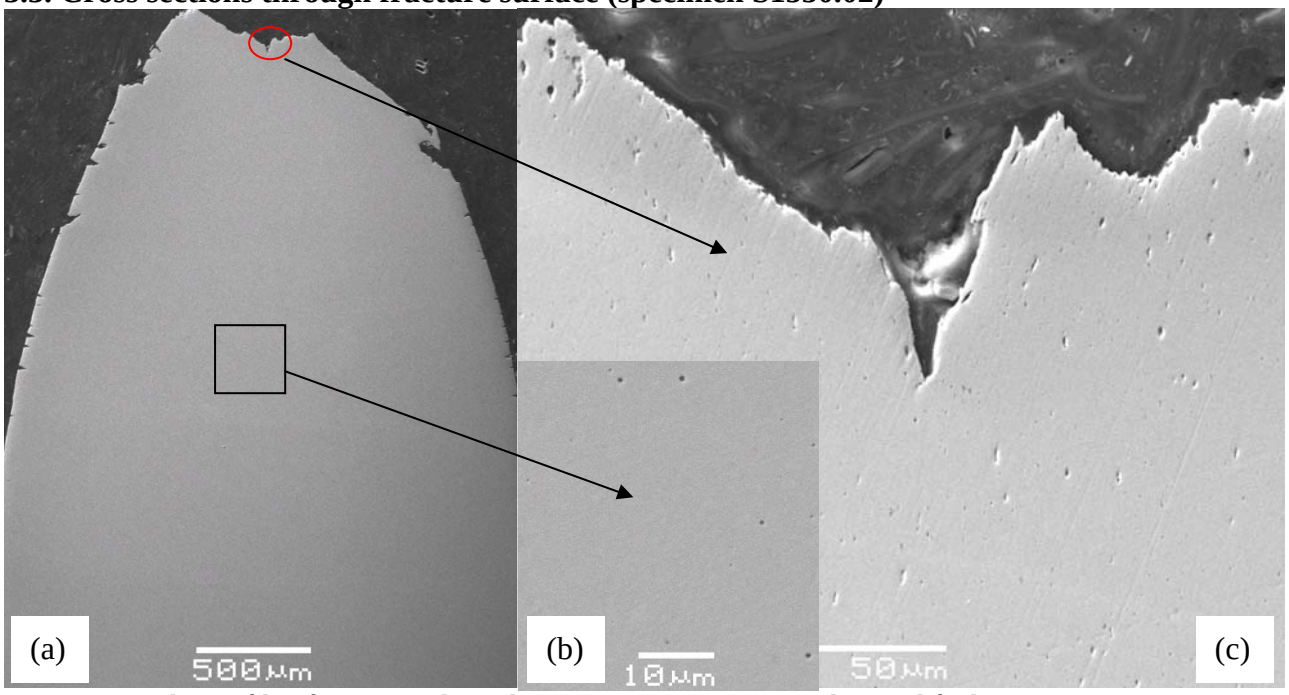

Figure 4. The profile of a section through specimen S1550.02 tested in acidified 0.1 M Na_2SO_4, pH 2 at -1550 $mV_{Ag/AgCl}$ at an applied stress rate of 0.02 MPa s^{-1}. (a) overview; (b) detailed view in the center; (c) detailed view near fracture surface. The tensile loading was in the vertical direction.

The longitudinal cross-section of specimen S1550.02 is shown in Fig. 4. Cracks initiated from the surface and extended into the specimen interior. The density of the surface cracks decreased as a function of distance from the fracture surface. Fig. 4(b) shows the detailed view in the interior of the specimen. There were small round voids, but no cracks. A magnified view of the region near the fracture surface (Fig. 4(c)) indicates that there were small holes near the fracture surface. As these sections were taken at random, it is concluded that there were no cracks in the interior of the specimens, apart from the small round voids.

3.4. SEM fractography

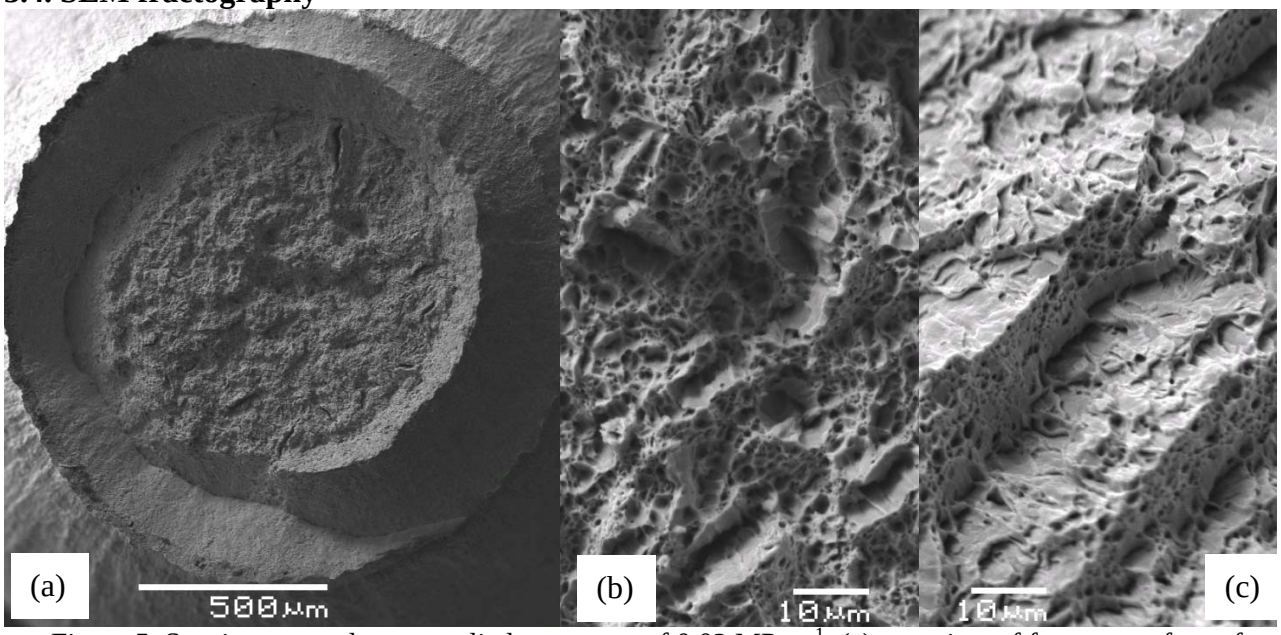

Figure 5. Specimen tested at an applied stress rate of 0.02 MPa s^{-1}: (a) overview of fracture surface of specimen A.02c, (b) a magnified view of cone part of specimen A.02c; and (c) brittle facets steps on the fracture surface of Socp.02c.

The fracture surface of specimen A.02c tested in air (Fig. 5) presented a cup and cone fracture with secondary cracks up to 140 μm in size, and showed significant ductility. These secondary cracks were surrounded by dimples, and had a small number of orientations. A magnified view of the fracture surface shown in Fig. 5 (b) indicates that the fracture surface comprised dimples, due to ductile microvoid coalescence (MVC) and secondary ductile cracks. All the secondary cracks were ductile and were surrounded by dimples. The fracture surfaces of other specimens tested in air were similar to specimen A.02c.

Similar to that obtained in air, the fracture surface of specimens Socp.02a and Socp.02b tested at E_{corr} showed a cup and cone fracture with a big secondary crack about 270 μm in size, and small secondary cracks less than 100 μm in size. However, one specimen Socp.02c tested at E_{corr} showed dimples and secondary cracks as well as some brittle facets, as shown in Fig. 5(c). Those brittle facets built up horizontal steps; dimples were like a linker between those steps. These brittle facets covered a substantial area in the middle of the fracture surface. Nevertheless, they were entirely surrounded by microvoid coalescence.

The fracture surface of specimen S950.02 tested at -950 $mV_{Ag/AgCl}$ at a rate of 0.02 MPa s^{-1} showed a cup and cone fracture as illustrated in Fig. 6. Fig. 6(b) presents a magnified view of region A, which comprised dimples and some secondary cracks. Region B at the edge, shown in Fig. 6(c), comprised brittle facets at the edge and shear dimples, i.e. dimples which had formed in the shear lips of the

cup and cone fracture at ~45° to the tensile axis, and were heavily sheared.

The fracture surfaces of specimens tested at -1200 $mV_{Ag/AgCl}$ and -1400 $mV_{Ag/AgCl}$ also showed obvious ductility, presenting a cup and cone fracture with a large secondary crack about 170 µm in size and small secondary cracks less than 150 µm in size completely surrounded by dimples.

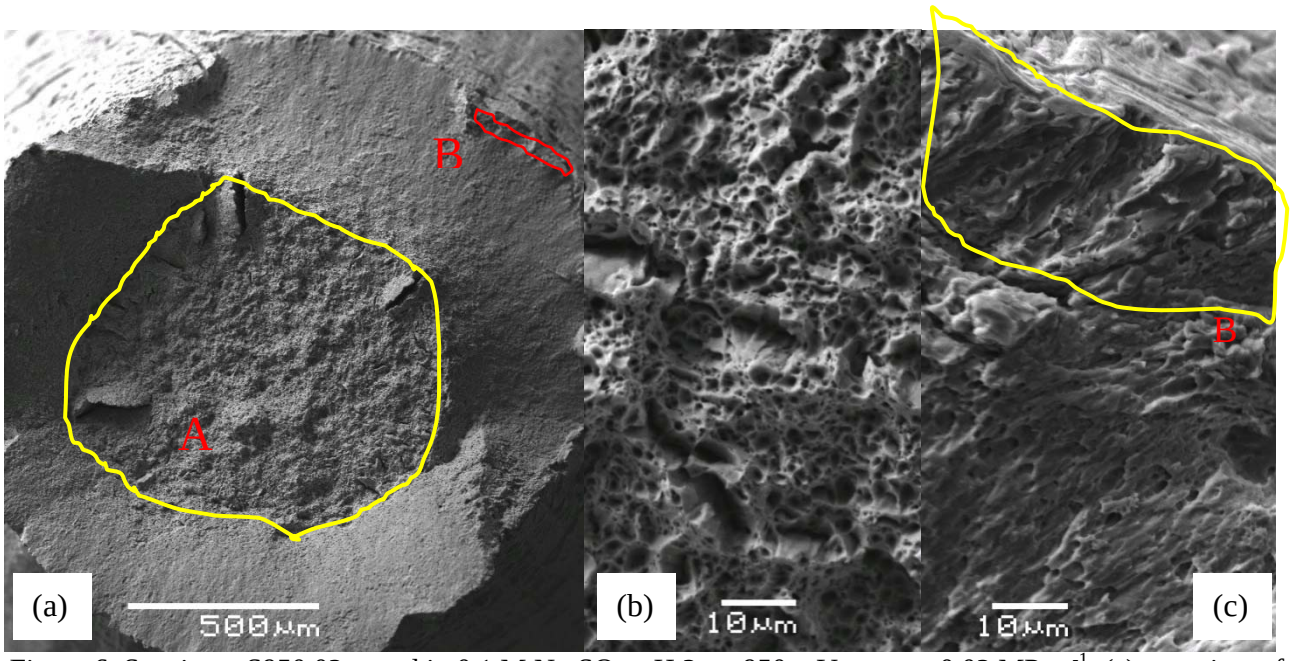

Figure 6. Specimen S950.02 tested in 0.1 M Na_2SO_4, pH 2 at -950 $mV_{Ag/AgCl}$ at 0.02 MPa s^{-1}: (a) overview of the fracture surface, (b) a magnified view of region A, and (c) a magnification of region B.

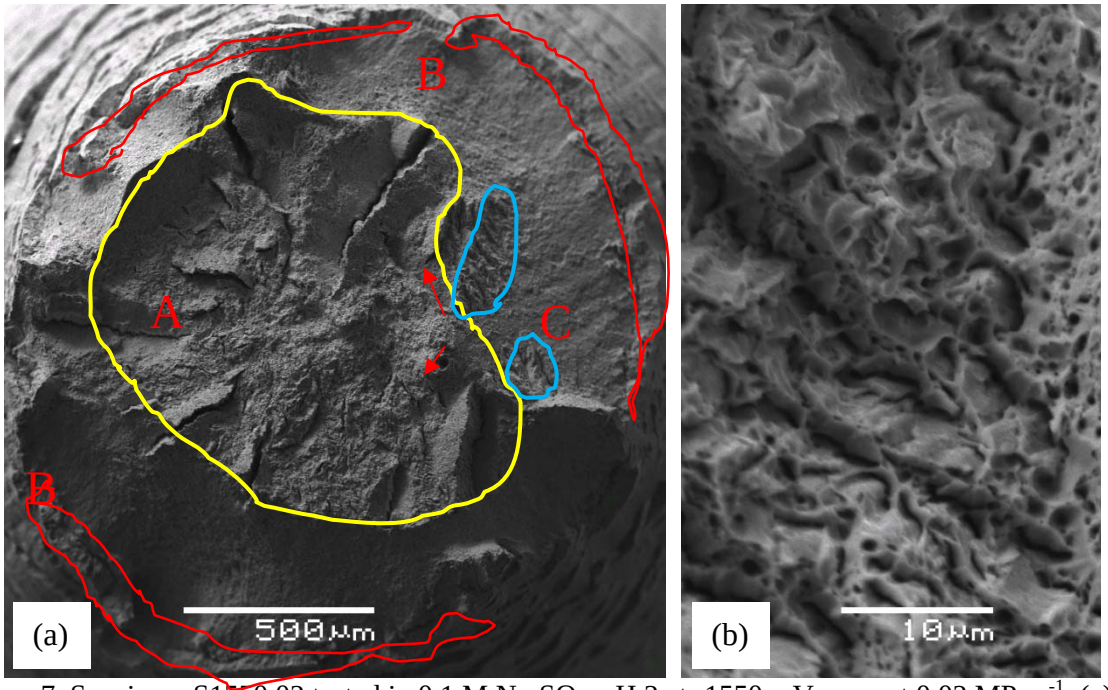

Figure 7. Specimen S1550.02 tested in 0.1 M Na_2SO_4, pH 2 at -1550 $mV_{Ag/AgCl}$ at 0.02 MPa s^{-1}: (a) an overview of the fracture surface, and (b) a detailed view in region C.

Fig. 7(a) presents the fracture surface of specimen S1550.02 tested at -1550 $mV_{Ag/AgCl}$ at a rate of 0.02 MPa s^{-1}. Region A of the fracture surface, similar to that shown in Fig. 6(b), was mainly MVC with some secondary cracks up to 550 µm. These secondary cracks surrounded by dimples were

oriented radially to the centre of the specimen. Region B was similar to that shown in Fig. 6(c). Fig. 7(b) presents a detailed view in regions C, showing small brittle facets.

4. Discussion

4.1. Tensile properties

All the specimens showed significant ductility, as demonstrated by obvious necking and high values of R_A. At the applied potentials, hydrogen was produced during each experiment at the specimen surface. The increasingly negative potentials increased the amount of H (and the H fugacity) at the specimen surface [18], and concomitantly the hydrogen concentration in the specimen. However, Table 2 indicates that decreasing applied potential did not cause any significant changes in the values of σ_{th}, σ_f and R_A. The influence of hydrogen on the tensile parameters of the NiCrMo1 steel was negligible.

4.2. Surface appearance

There were cracks at about 45° to the tensile direction on the necked surface of specimens tested in air and in solution at E_{corr}. These shallow surface cracks are attributed to the surface intersection of localised bands and stress, as the shear stress is maximum at 45 ° to the tensile direction.

For each of the specimens tested at negative potentials from -950 $mV_{Ag/AgCl}$ to -1550 $mV_{Ag/AgCl}$, there were no cracks on the surface that had undergone uniform plastic deformation, while the surface of the necked region contained cracks perpendicular to the tensile direction, and cracks about 45° to the tensile direction. The number of these cracks decreased as a function of the distance from the fracture surface. These cracks became longer with increasingly negative potential, which was attributed to high H fugacity at the specimen surface [18]. These cracks were due to the influence of hydrogen on the localized plastic deformation at the surface in the necked region of the specimen.

It can be concluded that (i) there was no hydrogen influence for stresses up to the yield stress of the material; and (ii) the influence of hydrogen was associated with localised plastic deformation and fracture. These conclusions were similar to those for the 3.5NiCrMoV steel in our previous research [15].

4.3. Cross Section

The examination of cross section of specimen S1550.02 indicated that hydrogen only had an effect (i) on the edge and places near the edge of the necked region and (ii) locations close to the fracture surface in the heavily deformed region. These facts indicate the occurrence of cracks was associated with high levels of localised plastic deformation during the process of necking during final ductile fracture. This is consistent with the results obtained from the surface appearance.

However, it is possible that the duration was not long enough for hydrogen to reach a stable concentration though the specimen, therefore, the influence of hydrogen in the centre of specimen was weaker than that of on the surface. This might provide an alternative explanation for hydrogen influence only obvious on the surface of the necked region. Nevertheless, the fact that the secondary cracks extended to the centre of the specimen tested at -1550 $mV_{Ag/AgCl}$ in Fig. 7 implies that there was sufficient hydrogen throughout the specimen under this test condition to cause hydrogen related fracture events throughout the cross section. The absence of hydrogen damage inside the specimen was not due to insufficient hydrogen inside the specimen.

4.4 Fracture surfaces

The fracture surfaces obtained in air and at E_{corr} were dominated by dimples, due to ductile

microvoid coalescence, interspersed with some secondary cracks. The difference between various specimens seems to be a slightly different amount and size of secondary cracks. These results indicated that the specimen tested in air and at E_{corr} failed due to ductile overload.

The specimens tested under negative potentials showed a significant amount of ductile features on the fracture surface, similar to those in air. Most of the substantial cracks on the fracture surfaces were oriented radially. With increasingly applied negative potential, cracks on the fracture surfaces grew longer, up to about 550 μm at -1550 $mV_{Ag/AgCl}$. However, it is hard to say that these cracks were due to hydrogen, since there were similar cracks on the fracture surfaces for specimens tested in air. The initiation of these cracks may be due to inclusions [19]. Yet the presence of hydrogen did accelerate the growth rate of these cracks.

Brittle features at the edge associated with surface cracks in the neck region were deeper at a more negative potential indicating that hydrogen had a greater influence.

There were brittle features in small localised areas in the presence of hydrogen, associated with final ductile fracture. However, these brittle features were all surrounded by regions of ductile fracture. Even at the most negative potential, the fracture surface was predominately ductile, indicating that the specimens tested under hydrogen charging also failed due to ductile overload. The influence of hydrogen was not significant.

4.5 Mechanistic interpretation

Due to (i) no measureable influence of hydrogen on the yield stress; (ii) no surface cracks in the uniformly deformed part of the specimen gauge section for any specimen, the PD technique measured the onset of plastic deformation rather than the onset of subcritical crack growth.

The influence of hydrogen was on the final fracture process after the onset of necking via two ways: (i) causing localized brittle fracture events, and (ii) accelerating crack growth rate on the fracture surface. The brittle hydrogen associated fracture events in the present study occurred simultaneously with a ductile fracture process throughout the necked region of a fracturing specimen. However, the hydrogen fracture mechanism was not comparable to the other ductile fracture mechanism attributable to the stress reaching the fracture stress, and to mechanically unstable of the specimen. The dominant fracture mechanism was ductile microvoid rupture.

There were secondary cracks on the fracture surfaces not only for the specimens tested in solution, but also from the specimens tested in air. This implies that even though these secondary cracks were accelerated by hydrogen, inclusions [19] instead of hydrogen might be responsible for the initiation of these cracks.

4.6 Implications for service

Considering the results discussed above, (i) the properties of the NiCrMo1 might be improved by reducing the inclusion density; and (ii) if the material will be used at a stress under the yield stress, the influence of hydrogen can be negligible, indicating that it is safe to use this material under the yield stress in an environment containing hydrogen for the H economy.

5. Conclusions

The tensile and fracture properties of NiCrMo1 steel under conditions of hydrogen charging were investigated by LIST and SEM. The results showed that:

1. The influence of hydrogen on the tensile parameters (σ_y, σ_{th} and R_A) was negligible;
2. There were no surface cracks in the region that had undergone uniform plastic deformation,

implying that there was no influence of hydrogen up to the yield stress of the steel;
3. There were surface cracks in the necked region on the specimens tested under hydrogen charging, implying that the influence of hydrogen was associated with the final ductile fracture process after the onset of necking.

Recovery of ductility observed in liquid gallium induced embrittlement of polycrystalline silver

Kodai Yamamoto, Kohei Arakawa, Hirokazu Koizumi*

Abstract Polycrystalline silver is embrittled by liquid gallium immediately after intimate contact between the solid and the liquid metals is made. When the tensile test is performed at room temperature, recovery of ductility has been observed if the contact time is long enough. This recovery is induced by formation of an intermetallic compound between silver and gallium. When the specimen is stressed above 420 K, embrittlement is not observed even if the contact time between the solid and liquid metals is short. This is the ductility trough reported in various solid and liquid metal couples that cause the liquid metal embrittlement. Although loss of embrittlement occurs as a function of contact time and as a function of test temperature, it may be difficult to connect the ductility trough with contact time dependent recovery from embrittlement, and there seems two independent recovery processes.

Keywords liquid metal embrittlement, ductility trough, sliver, gallium

1. Introduction

Liquid metal embrittlement (LME) is a phenomenon that normally ductile metals become brittle when they are stressed in close contact with certain kinds of liquid metals. Embrittlement appears as a decrease in maximum stress and fracture strain in a tensile test. Characteristic features of LME are [1]:
(1) LME occurs only in some solid and liquid metal couples. This is called "selectivity" and solid and liquid metal couples that cause LME are listed in ref. [2]. Solid and liquid metal couples such as polycrystalline aluminum and liquid gallium show a significant reduction of the maximum stress and fracture strain, while in case of a steel and liquid lead the maximum stress decreases to only a half of the original maximum stress [3]. The factors that determine the selectivity are not known.
(2) The embrittlement takes place immediately after intimate contact between solid and liquid metal is made. For polycrystalline aluminum-liquid gallium and polycrystalline silver-liquid mercury couples, embrittlement occurs even after the surface liquid metal is removed before stressing, if the contact time of the solid and liquid metals is long enough. In these cases, the degree of embrittlement increases with the contact time after a certain incubation time [4].
(3) The degree of embrittlement is severe near the melting temperature of the liquid metal, and the embrittlement disappears at a higher temperature. This temperature range is called "ductility trough", and is often explained as a result of temperature dependence of the yield stress [3] or stress relaxation at potential crack initiation site [5].

We have reported that liquid gallium induced embrittlement of polycrystalline silver is transitory [6, 7]. The silver tensile specimens with a small amount of gallium on the surface were kept in a furnace at the temperature T_h for a period of time t_h. The tensile test was performed to the specimens at 308 K. When t_h is small, the specimens undergo severe reduction of maximum stress and fracture strain, while for large t_h, the specimens show ductile behavior. The duration of brittleness is short when the quantity of gallium is small and the temperature of the furnace is high. For silver-gallium couple ductility trough exists as a function of the contact time.

The objective of the present investigation is to show that the ductility trough exits as a function of temperature as many other embrittlement couples, and to discuss differences between the ductility

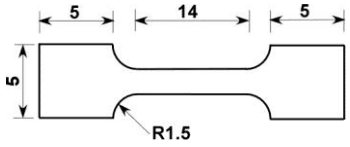

Fig. 1 Tensile specimen. The thickness is 2 mm.

trough as a function of temperature and that as a function of time.

2. Experimental

The tensile specimens used in this investigation is shown in Fig. 1. They were cut out from a silver plate of 99.98 % purity by electrodischarge machining. After mechanical polishing, the specimens were annealed at 1073 K for 2 hours. The average grain size of the specimens was 0.3 mm. A small amount of liquid gallium, 10 mg in weight and saturated with silver at 308 K, was deposited on the specimen, so that one of the four faces of the gauge section was completely covered with the gallium. To ensure the contact between the solid specimen and the liquid, the surface covered with liquid gallium was scratched with a needle. After immersing the specimen in liquid nitrogen to freeze the gallium, the specimen was placed in the tensile machine. The tensile test was performed on the specimen in a hot silicone oil bath in the temperature between 300 K and 465 K and in water between 274 K and 300 K. The strain rate was 1.2×10^{-2} s^{-1}.

The fracture surface was observed by the scanning electron micrograph (SEM).

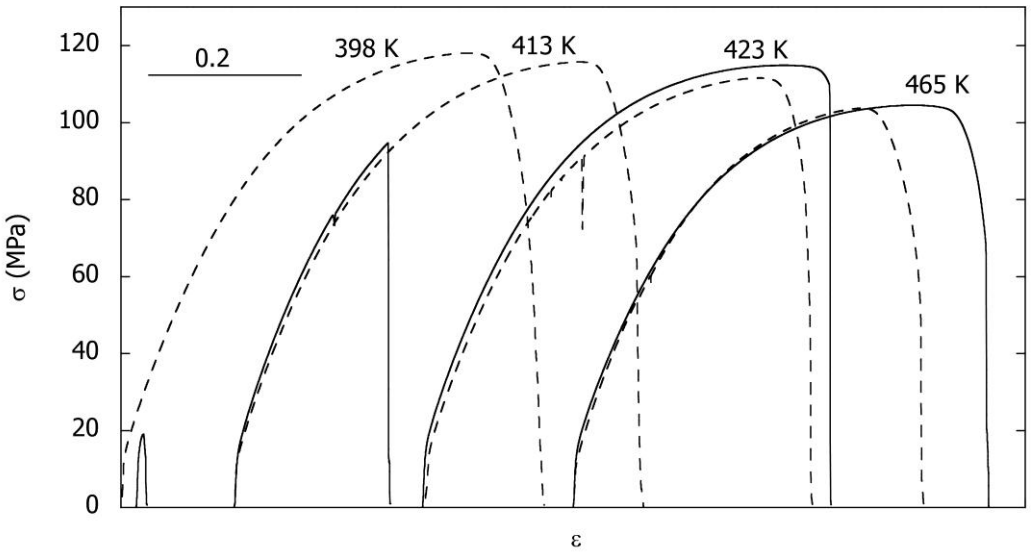

Figure 2. Stress-strain curves of silver specimen with gallium (solid lines) and without gallium (dashed lines). The test temperature is shown in the figure.

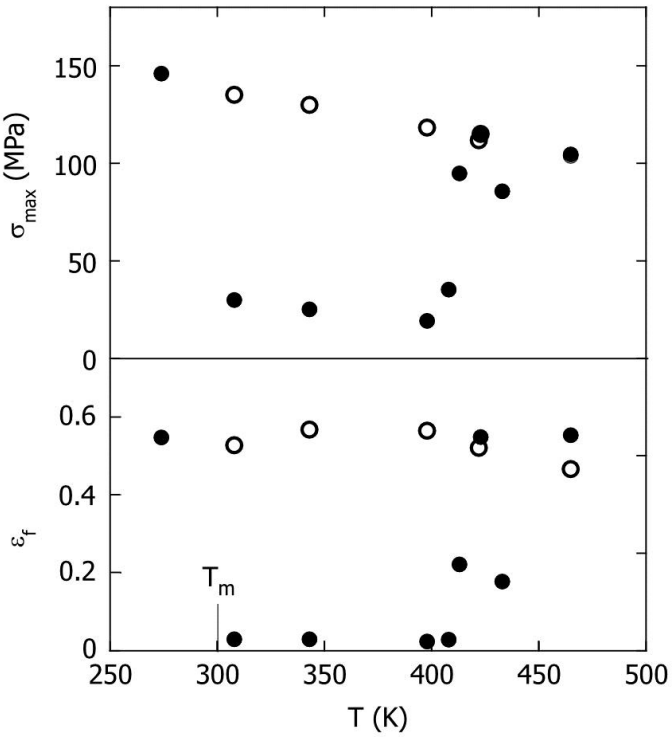

Figure 3. Temperature dependence of maximum stress σ_{max} and frcture strain ε_f of silver specimens tested with liquid gallium (solid circles) and without gallium (open circles). T_m indicates the melting point of gallium.

3. Results

Figure 2 shows some typical stress-strain curves of the specimens without and with liquid gallium on the surface. The test temperature is shown in the figure. Below 400 K, liquid gallium induces a significant reduction of the maximum stress σ_{max} and the fracture strain ε_f, while at 465 K liquid gallium has no effect on σ_{max} and no reduction of ε_f is observed. Around the transition temperature (413 K and 423 K in the figure), in the specimens with gallium the stress drops abruptly after the stress-strain curve reaches the maximum, while the decrease of the stress is gradual in the specimens without gallium at all temperatures measured and in the specimen with gallium at 465 K.

In Fig. 3 the maximum stress σ_{max} and the fracture strain ε_f are shown as a function of test temperature T. When the specimen is pulled without gallium, the maximum stress decreases with temperature, while the fracture strain is almost constant. Since the specimen was immersed in liquid nitrogen before the test to prevent supercooling of gallium, embrittlement is not observed below the melting temperature T_m of gallium (303 K). Above T_m the maximum stress and the fracture strain are reduced significantly by liquid gallium. The brittleness disappears above 420 K. This means that ductility trough starts at the melting temperature of gallium and ends around 420 K.

Figure 4 shows the SEM images of the fracture surfaces and the optical micrographs of the tensile specimens. When the test temperature is below 413 K, the fracture surface is apparently intergranular, although the surface is partially covered with liquid gallium, and the optical micrograph shows that the fracture surface is nearly perpendicular to the tensile axis. At 465 K, necking is observed in the specimen. The fracture surface is covered with liquid gallium. This

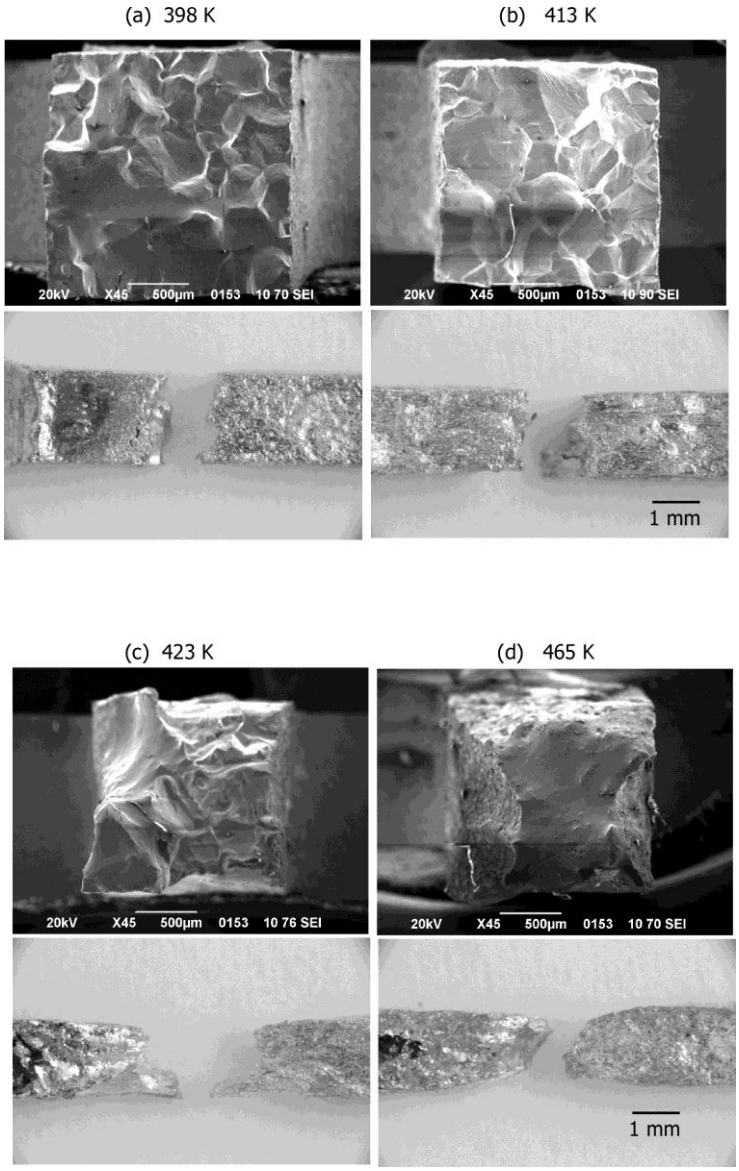

Figure 4. Scanning micrograph of the fracture surface (upper) and optical micrograph of the specimen (lower) tested at (a) 398 K, (b) 413 K, (c) 423K and (d) 465 K.

indicates that gallium is in liquid phase when the specimen fails. At 423 K, in spite of large maximum stress and fracture strain, the optical micrograph shows that reduction of cross-sectional area does not localize and the fracture surface is rough, which is different from the typical ductile fracture surface.

4. Discussion

In Fig. 3 we showed that the ductility trough exists as a function of temperature in polycrystalline silver-liquid gallium couple.

We have reported in [7] that for this couple the recovery from LME is observed if the contact time between the solid and liquid metals is long. In [7] the tensile test was performed at 308 K on the specimens with 10 mg of gallium after they were kept in a furnace at the temperature T_h for certain holding times t_h. Stress-strain curves are shown in Fig. 5(a) for the specimens of T_h =373 K. In Fig.

5(b) the maximum stress is shown as a function of the holding time t_h. Ductility recovers around 80 ks. Figure 5(c) shows the recovery time t_R as a function of the furnace temperature T_h. The recovery observed in the time dependence is considered due to formation of ζ'-phase or Ag_7Ga_3 by the X-ray diffraction analysis.

From Fig. 5(c), the recovery time of the specimen held at 465 K is estimated more than 10 ks, when it is stressed at 308 K. In the present experiment, however, the specimens stressed at 465 K is not embrittled, although the test was performed immediately after the specimen temperature became the test temperature, and the test ended in less than a few minutes. The specimen that is ductile at 465 K becomes brittle at 308 K. As shown in Fig. 4(d), the fracture surface of the specimen pulled at 465 K is covered with gallium flowing from the specimen surface. At this temperature the specimen

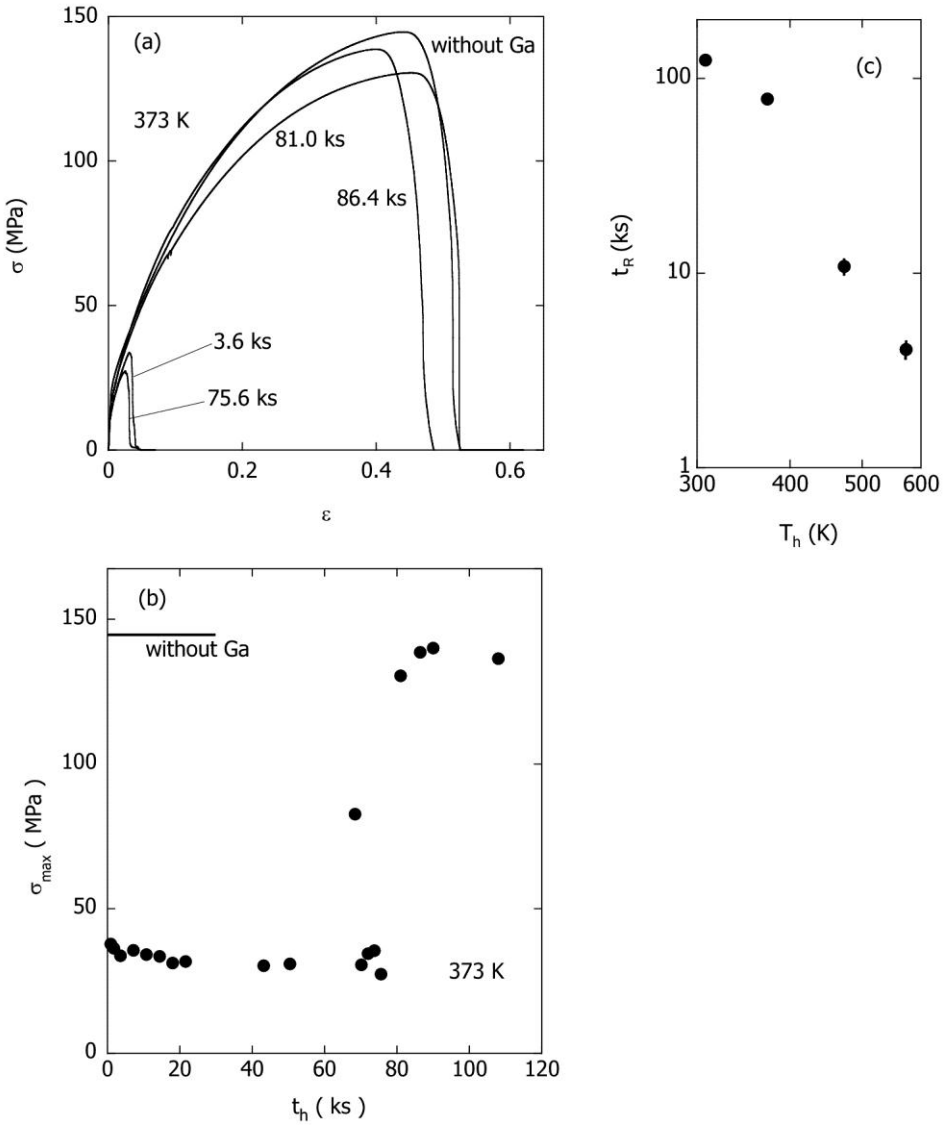

Figure 5. (a) The stress-strain curves. After the specimens were kept in contact with a small amount of gallium at 373 K for the time indicated in the figure, the tensile testing was performed at 308 K with a strain rate of 1.2×10^{-2} s^{-1}. (b) The maximum stress σ_{max} as a function of holding time t_h. (c) The time to recover ductility t_R as a function of the temperature of the furnace T_h [7].

is ductile despite gallium in liquid phase on the surface, and, therefore, the recovery of ductility at 465 K is not considered to be induced by formation of the intermetallic compound.

Various mechanisms of LME have been proposed, and it is still controversial whether crack initiation or crack propagation is a controlling process [1]. The specimen pulled at 423 K did not indicate clear necking (Fig. 4(c)), and the stress-strain curve shows abrupt drop after it reaches the maximum (Fig. 2). These indicate that a crack propagates very fast once a crack starts to move, and, therefore, a micro crack nucleation or start of crack motion seems to be especially blocked at this temperature.

5. Conclusion

Polycrystalline silver is embrittled by liquid gallium. Recovery from the embrittlement occurs if the contact time with liquid metal is long. This is considered induced by the formation of an intermetallic compound. Ductility trough is also observed as a function of test temperature in this solid and liquid metal couple. However, this ductility trough is not connected to forming the intermetallic compound.

Abstract The effect hydrogen on short-term strength, low-cycle durability and plane-stress fracture toughness of 04Cr16Ni56 and 05Cr19Ni55 alloys at pressure up to 35 MPa and temperature 293…1073 K was investigated. The modes of hydrogen action for which the mechanical properties of alloys are minimum were established: hydrogen pressure above 10 MPa (non-hydrogenated specimens of 04Cr16Ni56 alloy) and above 35 MPa (hydrogenated specimens of 05Cr19Ni55 alloy, hydrogen concentration C_H = 19 wppm). The plane-strain state conditions and, correspondingly, the conditions of the evaluation of plane-strain fracture toughness (K_{Ic}) were fulfilled on compact tension specimens of 04Cr16Ni56 with a thickness of 20 mm at hydrogen pressure above 10 MPa in the temperature range 293…473 K. Plane-stress fracture toughness K_c of 05Cr19Ni55 alloys was decreased at 293 K from 116 MPa·m$^{1/2}$ in helium to 78 MPa·m$^{1/2}$ in hydrogen under the pressure 30 MPa and to 68 MPa·m$^{1/2}$ in hydrogen under the pressure 30 MPa after preliminary high-temperature hydrogenation (with hydrogen concentration C_H = 19 wppm).

Keywords Hydrogen embrittlement, Fracture toughness, Alloy

1. Introduction

The production of turbine equipment requires a wide usage of dispersive hardened heat-resistant Fe-Ni alloys. In these products heat-resistant alloys are exploited at high temperatures in the contact with high-pressure hydrogen containing gas mixtures. Therefore one of the most important requirements for such alloys is their resistance to hydrogen degradation. In other words their ability to keep high level of mechanical properties under the action of hydrogen in wide range of exploitation parameters. At the same time, age-hardening alloys are known to be rather sensitive to hydrogen embrittlement [1-3].

The serviceability of structures in hydrogen is, as a rule, estimated according to the results of testing at room temperature [4-7]. This is explained by maximum sensitivity of steels and alloys to hydrogen degradation and complexity of experiments at elevated temperatures. However, the operating conditions of the equipment for hydrogen power engineering include static and cyclic loading of the products in hydrogen in fairly broad temperature ranges [7, 8], whereas the available literature data on the temperature dependences of mechanical properties in hydrogen are quite poor and ambiguous. In most cases, the influence of gaseous hydrogen on mechanical properties weakens as temperature increases and, according to the data presented in [6], the upper temperature of embrittlement under the analyzed conditions was equal to 573 K. At the same time, we reveal a significant decrease in the plasticity of heat-resistant nickel alloys in hydrogen under a pressure of 35 MPa at temperature1073 K [3, 7, 9].

In what follows, we study the influence of high-pressure gaseous hydrogen on short-term strength, low-cycle durability, and static crack resistance of nickel based alloys in the temperature range 293-1073 K.

2. Materials and Experimental Procedure

Two types of dispersion-hardened alloys were investigated: 04Cr16Ni56 and 05Cr19Ni55. Alloying

with niobium, vanadium, titanium, aluminum and boron leads to the formation of carbide TiC, borides Me_3B_2, and intermetallics $Ni_3(Al,Ti,Nb)$ in the amounts of to 8 % for 05Cr19Ni55 alloy and up to 15…17 % for 04Cr16Ni56 alloy, which substantially increases their high-temperature strength [8] and significantly influences the sensitivity to the action of hydrogen [3, 9]. Heat treatment regimes and the mechanical properties of alloys (Table 1) in helium and in hydrogen under a pressure of 35 MPa after preliminary hydrogenation to hydrogen content of 19 wppm (05Cr19Ni55 alloy) and 20 wppm (04Cr16Ni56 alloy). After heat treatment, the grain size was 40…60 μ, and the particle size of the intermetallic γ′-phase was 320…500 Å.

Table 1. Chemical Composition, Modes of Thermal Treatment and Mechanical Properties of Alloys in Helium/Hydrogen (35 MPa) at Room Temperature

Alloy	Thermal Treatment		Mechanical Properties					
	Solution treat-ment	Mode of aging	σ_u, MPa	σ_y MPa	δ %	ψ %	Number of cycles to frac-ture, ben-ding strain 1.6 %	K_c MPa·$m^{1/2}$
04Cr16Ni56 (C-0.04; Si-0.12; Cr-16.4; Mo-5.24; V-0.35; Nb-5.19; Ti-0.58; Al-1.0; Fe-15.14; Cu-0.49; Ni-bal)	1373K, 1 h	1023 K, 16 h + 923 K, 10 h	1320 880	840 750	34 4	48 12	3205 54	134 52
05Cr19Ni55 (C-0.05; Si-0.23; Cr-19.0; Mo-8.87; Nb-1.73; l-1.49; Fe-12.0; Cu-0.02; Ni-bal)	1323K, 1 h	1000 K, 15 h + 923 K, 10 h	1080 970	650 660	35 7	38 21	2560 199	116 68

Static tensile tests with recorded “stress-strain” curves were carried out on standard five-fold cylindrical specimens using displacement rate V = 0.1 mm/min. During the test the specimens were positioned into the chamber specially designed for high-temperature tests at 293...1093 K temperature range under 0.1...30 MPa hydrogen pressure. Specimens were tested in temperature range 293...1073 K under 30 MPa of hydrogen pressure and, as a comparison, in helium. The low-cycle durability for pure strain-controlled sign-preserving bending was investigated under pressures of 30 MPa for the strain amplitudes ε = 1.6% and loading frequency of 0.5 Hz on polished plane specimens with a working part size 3 x 6 x 20 mm. Stress intensity factor under static loading K_c was computed either for the maximum force F_c in the "F-V" linear diagram or for the force F_Q determined by using the 5% secant for nonlinear diagrams. Rectangular compact specimens 50 × 60 × 20 mm in size were tested for eccentric tension in a high-pressure chamber under pressures of 0.4-30 MPa at strain rate of 0.1 mm/min. The values of K_c can be calculated from the Srawley-Gross formula [10].

To determine the indicated mechanical characteristics in hydrogen, the working chambers were preliminarily evacuated, blown-out with hydrogen, again evacuated, and filled up with hydrogen to a given pressure. At high temperatures, the specimens were held under the testing conditions for 30 min until the attainment of thermal equilibrium.

Earlier we established that, at some region of hydrogen pressure and strain rate exists a maximum

influence of hydrogen on the plasticity, low-cycle fatigue life, and static and cyclic crack resistance of martensitic steels and high nickel alloys [3, 7, 9]. In short-term tension, austenitic dispersion-hardened steels are substantially embrittled by hydrogen only after preliminary hydrogenation at elevated temperatures when its content becomes greater than 12 wppm [3, 7]. This is why we held a part of the specimens for 10 h in a hydrogen atmosphere under 623 K and 35 MPa. These regimes provide the hydrogenation of specimens to hydrogen contents of 19 wppm (05Cr19Ni55 alloy) and 20 wppm (04Cr16Ni56 alloy). Hydrogenated and non-hydrogenated specimens were tested in helium and hydrogen under different pressures.
Hydrogen concentration (C_H) was determined with a LECO TCH 600 instrument [11] with precise 0.1 ppm (3 samples for point).

2. Hydrogen Pressure Influence on the Mechanical Properties.

It is known from the literature for almost materials and testing methods the influence of hydrogen increases proportionally to the square root of pressure [1, 4, 6, 12]. The pressure range for which this dependence is valid is studied insufficiently. In the process of short-term static tension, the properties of carbon steels deteriorate only in the range 0-10 MPa. Embrittlement of specimens made of Inconel-718 alloy begins only when the pressure reaches 10 MPa and increases up to 70 MPa [12]. Hydrogen influence on plasticity of steels and many other materials increases in the entire pressure range (0-70 MPa) [1, 3, 6, 12].
In the case of 04Cr16Ni56 alloy the dependence of low-cycle durability (N), the plasticity parameters (δ and ψ) (Fig.1a) and plane-stress fracture toughness (K_c) (Fig.2, curves 3, 4) on the hydrogen pressure consists of two regions. In the first region (low pressures), parameters N, δ, ψ and K_c drops abruptly, and in the second, the negative influence of hydrogen is practically independent of pressure (figs. 1, 2). This means that there exists a pressure which cause the limiting degradation of materials properties. An additional effect of preliminary dissolved hydrogen (C_H = 20 wppm) on the properties of 04Cr16Ni56 alloy was manifested at hydrogen environment pressure less than 10 MPa. The parameters of loading and the modes of hydrogen action for which the mechanical characteristics of the investigated alloys are minimum at 293 K can be formulated as follows: –the strain rate V_{def} = 0,1 mm/min ($6.7 \cdot 10^{-5}$ s^{-1}) at short-term static tension and static crack propagation; – the frequency and amplitude of bending under the conditions of low-cycle fatigue are ν = 0, 5 Hz and ε = 1.6% respectively, and the pressure of hydrogen must be higher than 10 MPa.

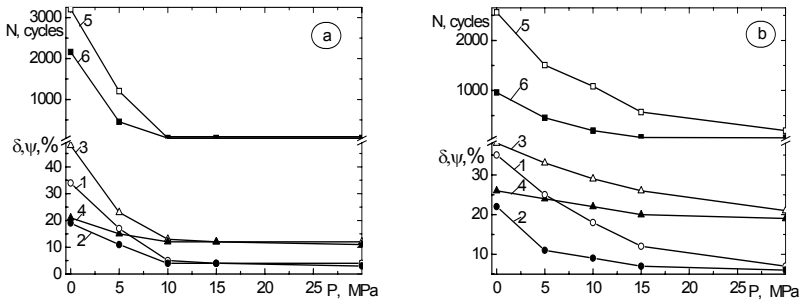

Figure 1. The relative elongation δ (1, 2), reduction of area ψ (3, 4) (V = 0,1 mm/min.) and number cycles to failure N (5, 6) (ε = 1,6%) specimens of 04Cr16Ni56 (a) and 05Cr19Ni55 (b) alloys versus hydrogen pressure P at 293 K: 1, 3, 5 – non-hydrogenated specimens; 2, 4, 6 – hydrogenated specimens.

In the case of 05Cr19Ni55 alloy the low-cycle durability N, plasticity parameters δ and ψ (Fig.2b, curves 1, 3, 5) and plane-stress fracture toughness K_c (Fig.3, curve 1) decrease in whole hydrogen pressure range. Preliminary dissolved hydrogen (C_H = 19 wppm) leads to a considerable additional decrease in the properties of this alloy (Fig.2b, curves 2, 4, 6; Fig.3, curve 2). Maximum hydrogen effect achieved on hydrogenated specimens at hydrogen pressure above 10 MPa.

Thus, to estimate the serviceability of alloy 04Cr16Ni56 it is suffices to test the specimens in gaseous hydrogen, while for alloy 05Cr19Ni55 there is a need for preliminarily hydrogenation.

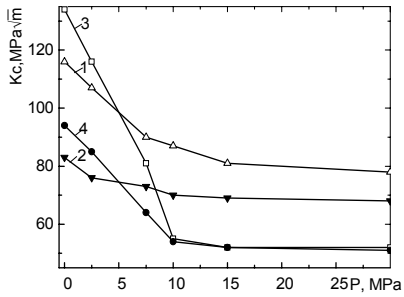

Figure 2. Fracture toughness K_c of 05Cr19Ni55 (1, 2) and 04Cr16Ni56 (3, 4) alloys versus hydrogen pressure P at 293 K: 1, 3 – non-hydrogenated specimens; 2, 4 – hydrogenated specimens.

Hydrogen decreases the stress intensity factor K_c and affects the fracture morphology. Under the conditions of maximum hydrogen embrittlement, the load-displacement diagrams become linear with sharp maxima (as functions of the load) (Fig.3a) and correspond to type I [10]. The fracture surfaces of the specimens are intergranular with cleavage facets typical of brittle fracture (Fig.4b), when in helium the honeycomb relief with ductile intergranular fracture portions is prevailed (Fig.4a). The values of K_c can be regarded as equal to K_{1c}, i.e., they satisfy the condition $l,b > 2.5(K_c^H/\sigma_{0,2}^H)^2$, where l is the crack length and b is the thickness of the specimen [10]. The indicated condition is satisfied at room temperature for alloy 04Cr16Ni56 under pressures of hydrogen higher than 10 MPa for which K_{1c} is equal to 52 MPa·m$^{1/2}$. The plane-strain state conditions were not fulfilled for the specimens made of alloy 05Cr19Ni55.

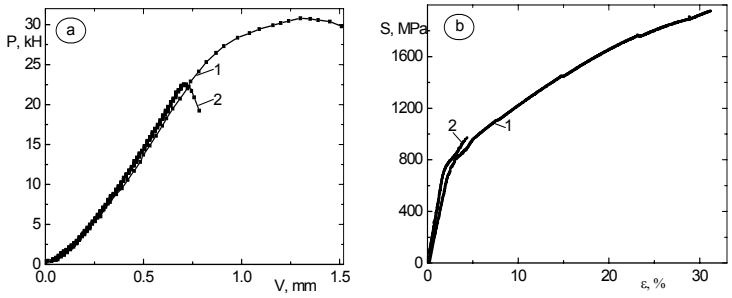

Figure 3. Diagrams "loading – crack opening displacement" (a) and true "stress-strain" diagram (b) of 04Cr16Ni56 alloys in helium (1) and hydrogen (2) under pressure 30 MPa at 293 K.

Hydrogen produced changes in true stress diagrams of both alloys in wide pressure and temperature range: essentially decrease failure stress and deformation of specimens (Fig.3b).

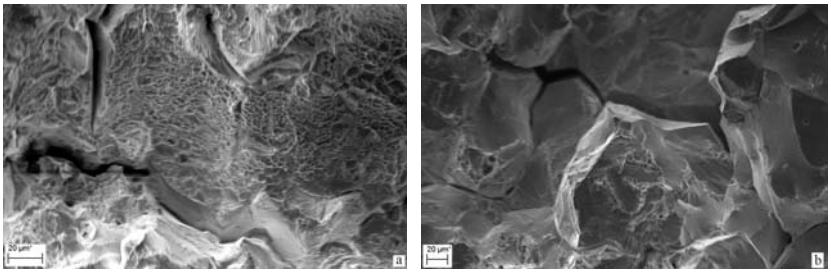

Figure 4. Fracture surface of 04Cr16Ni56 alloys under static loading of compact specimens in helium (a) and hydrogen (b) under pressure 30 MPa at 293 K.

3. Influence of Temperature on Hydrogen Embrittlement of the Alloys.

The strength of the alloy 05Cr19Ni55 significantly decreases in helium at temperatures higher than 873 K. This process is accompanied by a decrease in plasticity parameters for the alloy 05Cr19Ni55 at temperature 873 K and a significant increase in the relative elongation and reduction of area for specimens made of this alloy at temperatures 973…1073 K (Fig.5, curves 5, 6). At temperatures range 973…1073 K we observed a decrease in plasticity parameters for the alloy 04Cr16Ni56 (Fig.5, curves 7, 8).

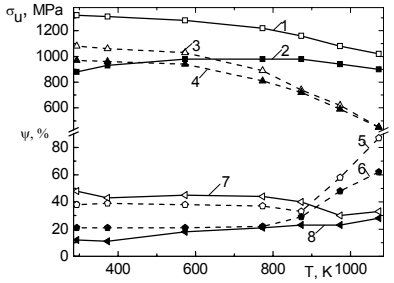

Figure 5. Temperature dependences of ultimate strength σ_u (1-4) and reduction of area ψ (5-8) of 04Cr16Ni56 (1, 2, 7, 8) and 05Cr19Ni55 (3, 4, 5, 6) alloys at helium (1, 3, 5, 7) and hydrogen (2, 4, 6, 8) under the pressure 30 MPa.

The drop of plasticity of the dispersion-hardening materials within the temperature range of intense phase transformations is caused by the localization of strains on the grain boundaries due to the intense redistribution of Ni, Ti, and Al in the boundary regions. Moreover, the increase in plasticity observed at higher temperatures is caused both by partial coagulation of hardening phases and possible dissolution of small amounts of finely divided precipitations [8]. In alloy 04Cr16Ni56 that contain higher amount of refractory elements (Table 1), the diffusion processes are decelerated and, therefore, the drop of strength is small and the temperature of plasticization is probably higher than 1073 K (Fig. 5, curves 1, 7).

The ultimate strength of alloy 04Cr16Ni56 is sensitive to hydrogen action (Fig. 5, curves 1, 2). At the same time σ_u of specimens made of alloy 05Cr19Ni55 decreases in hydrogen insignifically (Fig. 5, curves 3, 4). The hydrogen effect on plasticity parameters δ and ψ (Fig. 6), low-cycle durability N (Fig. 6) and plane-stress fracture toughness K_c (Fig. 7) of both alloys is essential in the temperature range 293…773 K and appreciable at all other temperatures. As temperature increases from 773 to 873 K the hydrogen effect on reduction of area of the alloy 05Cr19Ni55 specimens initially decrease and again increase at 973 and 1073 K (Fig. 5, curves 5, 6). That suggests that at 1073 K the hydrogen-induced processes of localization of strains and fracture (mainly intergranular) occur in this alloy so intensely that the coagulation of hardening phases is insufficient for the high-temperature plasticization observed in helium. This phenomenon we established earlier on dispersion-hardening austenitic steels [13].

The additional effect of preliminary hydrogenation on parameter of static growth resistance K_c for the alloy 05Cr19Ni55 is appreciable only at room temperature (Fig. 6, curves 3, 4, 6, 7). At 373 K the value of K_c for hydrogenated and non-hydrogenated specimens are almost equal, i.e., this temperature is sufficient for hydrogenation of dispersion-hardening nickel base alloys from the hydrogen atmosphere. For all loading modes, the degree and temperature interval of hydrogen degradation for alloy 04Cr16Ni56 is much larger than for alloy 05Cr19Ni55 (figs. 5-7).

The plane-strain condition required for the evaluation of K_{Ic} were fulfilled on compact tension specimens made of alloy 04Cr16Ni56 with a thickness of 20 mm at hydrogen pressure above 10 MPa in the temperature range 293…473 K. Fracture toughness K_c for alloy 05Cr19Ni55 was decreased at 293 K from 116 MPa·$m^{1/2}$ in helium to 78 MPa·$m^{1/2}$ in hydrogen under the pressure

30 MPa and to 68 MPa·m$^{1/2}$ in hydrogen under the pressure 30 MPa after preliminary high-temperature hydrogenation (with hydrogen concentration 19 ppm). The plane-strain conditions were not fulfilled at these two cases.

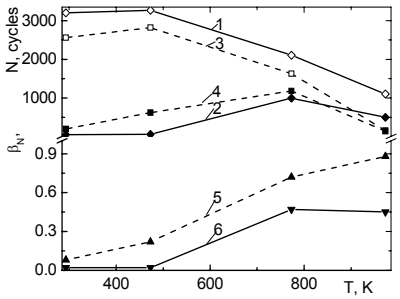

Figure 6. Temperature dependences of number cycles to failure N (1-4) (ε = 1,6%) and coefficients of hydrogen influence $\beta_N = N_H/N_{He}$ (5, 6) on 04Cr16Ni56 (1, 2, 6) and 05Cr19Ni55 (3, 4, 5) alloys: 1, 3 – helium, 2, 4 – hydrogen under the pressure 30 MPa.

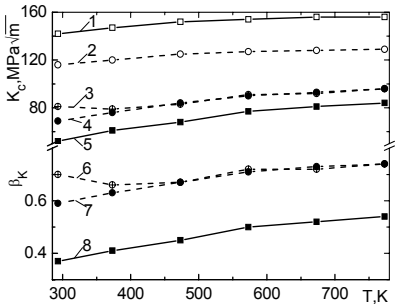

Figure 7. Temperature dependences of plane-stress fracture toughness K_c (1-5) and coefficients of hydrogen influence $\beta_K = K_c^H/K_c^{He}$ (6-8) on 04Cr16Ni56Nb5Mo5TiAl (1, 5, 8) and 05Cr19Ni55Nb2Mo9Al (2-4, 6, 7) alloys: 1, 2 – helium, 2, 3, 6 – hydrogen under the pressure 30 MPa, 4, 7 – hydrogen under the pressure 30 MPa after preliminary hydrogenation (623 K, 35 MPa H_2, 10 h).

Conclusions.

The parameters of loading and the modes of hydrogen action for which the mechanical characteristics of the investigated alloys are minimum at room temperature can be formulated as follows:

– strain rate $V_{def} \leq 6.7 \cdot 10^{-5}$ s^{-1} for tensile test and the strain amplitude ε = 1.6 % under the conditions of low-cycle fatigue at hydrogen pressures above 10 MPa for the alloy 04Cr16Ni56 and hydrogen pressures above 15 MPa at concentration of preabsorbed hydrogen 19 wppm for the alloy 05Cr19Ni55;

– for static crack propagation at hydrogen pressure above 10 MPa for the alloy 04Cr16Ni56 and hydrogen pressure above 15 MPa at concentration of absorbed hydrogen 19 wppm for the alloy 05Cr19Ni55.

The plane-strain conditions required for the evaluation of K_{Ic} were fulfilled on compact tension specimens made of alloy 04Cr16Ni56 with thickness of 20 mm at hydrogen pressure above 10 MPa in the temperature range 293…473 K.

For all loading modes, the degree and temperature interval of hydrogen degradation for 04Cr16Ni56 alloy is much larger than for 05Cr19Ni55 alloy.

Abstract Hydrogen-assisted fracture (HAF) of metals is the problem of major concern in structural integrity. HAF is rate limited by hydrogen accumulation in fracture sites in metals. Diffusion is a relevant stage of transport that supplies hydrogen to fracture process zones. Addressing the purposes of HAF analysis, modelling of hydrogen diffusion with account for physical-mechanical fields and factors of material microstructure (hydrogen trapping) is revisited. Generalised system of equations of trapping-affected hydrogen diffusion is derived from the kinetics principles. For circumstances, which are relevant to plenty of engineering HAF cases, specialised models of "microstructure informed" stress-strain-assisted hydrogen diffusion in metals are retrieved and collated under the prism of their suitability for HAF analyses.

Keywords Hydrogen assisted fracture, Hydrogen diffusion, Modelling

1. Introduction

Hydrogen is often the key factor in environmentally assisted fracture of metals, as far as it may be present *per se* in the environment or discharge in cracks due to favourable local electrochemistry [1]. Harmful effects of hydrogen on metals ("hydrogen embrittlement") form the long-standing problem of the mechanics of materials. Hydrogen transport to damage sites is ubiquitous component of every hydrogen assisted fracture (HAF) process, which is rate-limited by hydrogen delivery to meet requirements of operating fracture mechanism. A series of kinetic processes involved in HAF have been identified, among which hydrogen diffusion has been substantiated as the governing mode of hydrogen supply to fracture nuclei [1-3]. Continuum modelling of hydrogen diffusion has been focused as the key issue of HAF studies and their engineering applications [1,3-6].

Concerning hydrogen behaviour in metals, important disconformities [2,7,8] were witnessed between experience and the Fick's diffusion laws. Various issues have been pointed out as potential causes of these inconsistencies, and several analyses have been performed culminating in continuum equations of diffusion built up from microscopic or phenomenological considerations [1,4-11]. However, comprehensive accounting for a variety of potentially influencing factors is complicated undertaking, and numerous specialised diffusion models, which attended to different microstrictural features, have been raised [8]. An outlook of hydrogen diffusion modelling for the purposes of HAF analysis is here presented.

2. Background Theory of HAF [1,5]

HAF is considered a result of synergic action of stress, strain and hydrogen amount in material. Fracture event takes place in a locus identified by position vector **x,** when hydrogen concentration C accumulated there over time t reaches the critical level C_{cr} dependent on stress-strain state:

$$C(\mathbf{x},t) = C_{cr}\left(\boldsymbol{\sigma}(\mathbf{x},t), \boldsymbol{\varepsilon}_p(\mathbf{x},t)\right), \tag{1}$$

where $\boldsymbol{\sigma}$ y $\boldsymbol{\varepsilon}_p$ are, respectively, the tensors of stress and plastic strain. Condition of contact between the concentration and the criterial surfaces, $C(\mathbf{x},t)$ and $C_{cr}(\mathbf{x},t)$, respectively, which reads

$$\partial C(\mathbf{x},t)/\partial \mathbf{x} = C_{cr}\left(\boldsymbol{\sigma}(\mathbf{x},t),\boldsymbol{\varepsilon}_p(\mathbf{x},t)\right)/\partial \mathbf{x}, \tag{2}$$

accompanies the fracture criterion (1) to form the system of equations to define the location $\mathbf{x}_{cr}$ and time t_{cr} of HAF event [12]. Hydrogen transport towards fracture sites is dominated by diffusion, which defines the left-hand parts of Eqs. (1) and (2).

It is known that material damage is associated with crystal imperfections, and that they act as hydrogen traps (T-sites) for H atoms where their free energies G_T are less than that for ordinary lattice (L-)sites G_L (Fig. 1a). The ratio at.H/at.Me can there substantially exceed that in L-sites [2,3,4,6], as follows from the equilibrium partition of hydrogen between T- and L-sites [2,4,6,13]

$$\frac{\theta_T}{1-\theta_T} = \frac{\theta_L}{1-\theta_L} K \quad \left(K = e^{\beta E_b}\right), \tag{3}$$

where $\theta_X = C_X/N_X$ is hydrogen saturation of X-type sites (X = L or T) defined by volume concentrations of these sites in metal, N_X, and of hydrogen allocated to them, C_X, so that the total concentration $C = \Sigma C_X$, $E_b = G_L - G_T$ is the binding energy of hydrogen to trap, and $\beta = (RT)^{-1}$ is the Boltzmann's factor in terms of the gas constant R and temperature T. Then, e.g., for steels at usual HAF occurrence conditions $T \approx 300$ K and $\theta_L \sim 10^{-6}$ at utmost [3,6], reported values of E_b, being approximately in the range from 0.25 to 1.5 eV [2,14,15] yield $K \geq \sim 10^4$ and $\theta_T/\theta_L \geq \sim 10^4$.

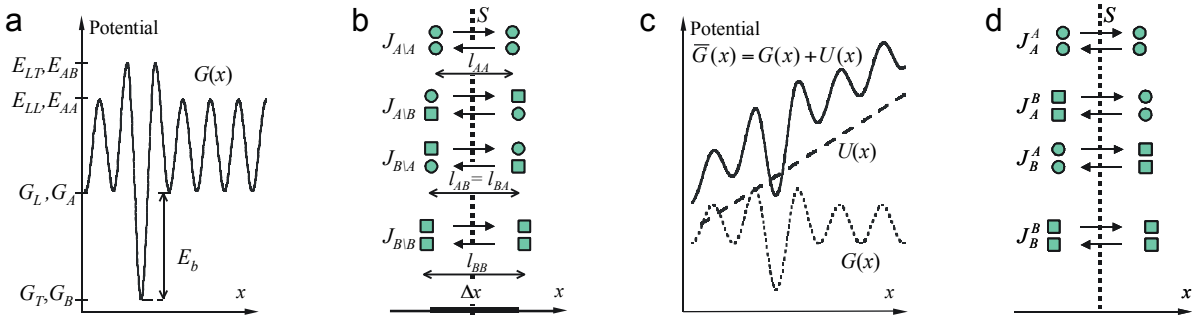

Figure 1. Schematics of (a) potential-position trace $G(x)$ for H in a lattice with different type sites L and T (or A and B); (b) combination of diffusion jumps between sites of different kinds (A – circles, B – quads) to evaluate partial fluxes; (c) distortion of lattice potential $G(x)$ by superposed field U; (d) combination of hops to establish partial balances.

To this end, whenever L/T-partition of hydrogen in volume element $d^3\mathbf{x}$ around a point $\mathbf{x}$ is in equilibrium, all partial concentrations $C_i(\mathbf{x},t)$ (i = 1,2,…) are related one to another via Eq. (3), so that all them, including the one corresponding to crystal imperfections responsible for HAF micro-mechanism, are biunivocally related to the total one $C(\mathbf{x},t)$. In this case, continuum description of local HAF event by Eqs. (1)-(2) holds, as well as it may be rewritten explicitly in terms of the responsible partial concentration C_X merely by changing there the variable according to Eq. (3). Otherwise, HAF should be described taking in Eqs. (1)-(2) responsible concentration C_X instead of C, and accounting for L/T-exchange kinetics in analysis of hydrogen transportation.

At any rate, hydrogen delivery to fracture sites proceeds by thermally activated hopping of H atoms between available sites in metal, i.e., by diffusion that turns out to be affected by trapping [2,4,6,7,10,13]. In this context, diffusion modelling is crucial for HAF analysis, prediction and control, as far as, combining with HAF experiments able to reveal fracture initiation time t_{cr} and location $\mathbf{x}_{cr}$, this allows to specify the critical concentration $C_{cr}(\boldsymbol{\sigma},\boldsymbol{\varepsilon}_p)$, i.e., the fracture criterion (1), and to employ this criterion for assessment of fracture time of structures [12,16].

3. Modelling of Hydrogen Diffusion with Trapping: Backgrounds Revisited

Both atomistic and thermodynamic arguments have been used to derive diffusion equations [1,4-11,13,15]. These approaches are not contradictory, but complementary [11] and capable to converge into the same field equations with certain insights about specific factors. Concerning traps, they were incorporated into resulting field equations in some cases via plausible postulating [4,6,7,17], but not from background principles (excepting few attempts with limited offspring [10,18,19] for HAF). In this section, diffusion equations grounding upon diffuser jumps probabilities is revisited.

3.1. Flux Equations

Isothermal diffusion by particles hopping among sites of kinds A and B is considered adopting the techniques used elsewhere [11,13,15,18-20]. Concerning the flux of the species through unit surface S normal to x-axis and situated there at position x, eight possible elementary steps can be grouped in pairs as shown in Fig. 1b, where l_{IJ} (I,J = A or B) are jump distances between specified sites, so that each couple renders the net flux $J_{A\backslash B}$ by forth and back hops between transboundary A and B sites, which are here diffuser releasers and receptors, respectively. The transition frequency Γ_{AB} from A-sites located at x' to B-ones at x'' per unit time depends on attempt frequency Ω_{AB} controlled by particle vibration frequency at given site ω_{0A} and by potential barrier $\Delta E_{AB} = E_{AB} - G_A$, where E_{AB} is the free energy at saddle point of lattice potential $G(x)$ between A and B (Fig. 1a). The frequency of successful hops depends on combined probability Y_B, which merges the probabilities γ_B that encountered receptor sites are the B-type ones and Θ_B that they are empty, that is

$$\Gamma_{AB} = \left[\Omega_{AB}\right]_{x'}\left[Y_B\right]_{x''} \text{ at } \Omega_{AB} = \omega_{0A}^{x}\exp\left(-\beta\Delta E_{AB}\right),\ Y_B = \gamma_B\Theta_B,\ \gamma_B = N_B/N\ ,\ \Theta_B = 1 - \theta_B, \qquad (4)$$

where $\omega_{0A}^{x} = \omega_{0A}f_A^{x}$ to reckon up the fraction f_A^{x} of hops that contribute to the flux through S having directions towards it, and $N = \Sigma N_i$ is the volume concentration of all available sites. (Note, that process parameters f_A, l_{AB} and ΔE_{AB}, according to the crystal symmetry, can depend on the x-axis orientation with respect to the lattice, causing this way diffusion anisotropy. They are isotropic, e.g., for interstitial sites in cubic lattice, and can be for "spherical" point-wise defects there, yielding $f_A = f = 1/6$ irrespectively of orientation.) Jump probability to any site is assumed to be not conditioned by that to another.

When some imposed potential field $U(x)$ distorts the lattice relief $G(x)$, Fig. 1c, ΔE_{AB} depends on jump sense, which biases the hopping probabilities. This implies modification of hopping frequency (4) with the factor $\exp(\pm\frac{1}{2}\beta\Delta x\nabla_x U)$, where the lower/upper sign corresponds to jumps pro-/counter-wise the x-direction, $\Delta x = x' - x''$, and ∇_x is the x-component of a gradient.

Reckoning up the hops of particles from A to B sites through control surface S at position x, using Taylor series expansions of involved variables about x with respect to Δx and truncating them at the second term, the net partial transfer by forth and back A→B jumps can be obtained

$$\mathbf{J}_{A\backslash B} = -d_{AB}\left\{Y_B \nabla C_A - C_A\left(\nabla Y_B - \beta Y_B \nabla U\right)\right\}, \tag{5}$$

where the diffusivity $d_{AB} = \Omega_{AB} l_{AB}^2$ when $\Delta x = l_{AB}$ is taken. The total diffuser flux vector $\mathbf{J}$ is the sum of the net partial ones $\mathbf{J}_{A\backslash B}$ over all pairs of site kinds A and B, which reads:

$$\mathbf{J} = \sum_{A,B} \mathbf{J}_{A\backslash B} = -\sum_{A,B} d_{AB} Y_B C_A \nabla \ln\left(e^{\beta U} C_A / Y_B\right). \tag{6}$$

This holds for arbitrary number m of site types, e.g., the L-sites and (m – 1) kinds of traps T_i (i=1,…,m – 1). Presented flux equations advance those derived elsewhere [18] in that arbitrary occupation degrees θ_i (i = 1,…,m) towards saturation are here admitted for all kinds of sites, and that alteration of lattice potential relief by some superposed field $U(x)$ is taken into account.

Description of diffusion in terms of specified partial fluxes can be supplemented with mass-balance relation being now the usual continuity equation:

$$\frac{C(\mathbf{x},t)}{\partial t} = -\nabla \cdot \mathbf{J}\left(= \nabla \cdot \sum_{A,B} d_{AB} Y_B \left[\nabla C_A - C_A \nabla \ln\left(e^{-\beta U} Y_B\right)\right]\right). \tag{7}$$

3.2. Mass Balance

In contrast to the one-level system (single kind of sites), Eq. (7) does not accomplish description of diffusion in terms of concentrations C_i (i = 1,…,m) for the m-level case (m > 1) where a system of m balance equations must be built up. This requires to combine the same diffusion steps as shown in Fig. 2d to gather all forth and back jumps across S that fill/vacate the sites of the sort A in a region Δx around a point x by surmounting saddle points at $x \pm \Delta x/2$. Desired equations are derived here following the random walk theory and its continuum implementation [19,20].

Considering two-level system and addressing the net species supply into A-sites in a domain $\Delta x \ni x$ by overcoming saddle point at $x - \Delta x/2$ from all outer A- and B-sites, involved diffusion steps include the net income flux $J_{A\backslash A}$, and the resulting B⇆A-exchange flux, which is as follows:

$$J_A^B = \left\{e^{-\frac{1}{2}\beta \Delta x \nabla_x U}\left[C_B l_{AB} \Omega_{BA}\right]_{x-\Delta x}\left[Y_A\right]_x - e^{\frac{1}{2}\beta \Delta x \nabla_x U}\left[C_A l_{AB} \Omega_{AB}\right]_x \left[Y_B\right]_{x-\Delta x}\right\}. \tag{8}$$

The net exit from A-sites in a domain Δx towards all sites beyond $x + \Delta x/2$ is defined similarly. Then, balancing transitions at both extremes of Δx, using power series expansions and disregarding higher order terms with Δx, mass balance for the species dwelling in A-sites can be derived. However, calculations in general terms are overly long and tedious, so that now we content ourselves with particular case when the sites characteristics are isotropic and uniform, i.e., jump frequencies $\Omega_{...}$ and lengths $l_{...}$ are constant, for which the following is deduced:

$$\frac{\partial C_A}{\partial t} = d_{AA}\nabla\cdot\left[Y_A C_A \nabla \ln\left(e^{\beta U} C_A / Y_A\right)\right] + d_{BA} Y_A \nabla\cdot\left[C_B \nabla \ln\left(e^{\beta U} C_B\right)\right] - d_{AB} C_A \left(\nabla^2 Y_B - \beta \nabla Y_B \cdot \nabla U\right) + \\ + \left[k_{BA} C_B \left(N_A - C_A\right) - k_{AB} C_A \left(N_B - C_B\right)\right], \quad (9)$$

where $k_{AB} = f^{-1}\Omega_{AB} / N = d_{AB} / (fNl_{AB}^2)$. Similarly, balance for a diffuser dwelling in B-sites can be derived rendering the result that differs from Eq. (9) by permutation of the site labels A and B. This description is extensible for arbitrary number m of site types by taking in the right-hand part of Eq. (9) the sum over all site kinds from a set {B;B≠A}. The last term in brackets in Eq. (9) represents transitions between the nearest neighbour sites of different types in a volume $d^3\mathbf{x}$ around a point $\mathbf{x}$.

This way, the system of nonlinear differential equations (9) is derived for partial concentrations C_i (i=A,B,… or 1,…,m). Balance in terms of total concentration $C = \Sigma C_i$ can be obtained summing up the equations of the system (9) over site kinds totality {A}. After all, the result coincides with Eq. (7). One may notice here the similarity with equations built up by Leblond-Dubois [10] following distinct approach based on construction of Boltzmann type transport equations. Present derivation advances the previous one [19] with respect to the sites saturability, their concentrations non-uniformity, and the contribution of a field U.

3.3. Equilibrium

The chemical potential μ_A of hydrogen residing in metal in sites of whichever type A is [13,15]

$$\mu_A(\theta_A) = \overline{G}_A + RT \ln\left(\theta_A / (1-\theta_A)\right), \quad (10)$$

where $\overline{G}_A$ is the free energy at the site with account for imposed potential U, $\overline{G}_A = G_A + U$ (Fig, 1c). At equilibrium, μ_A must be the same throughout a solid and in equilibrium with the input fugacity of hydrogen imposed by an environment, e.g., H_2 gas at pressure p that has chemical potential of hydrogen μ_p = const. Then, for all sites at equilibrium $\mu_A = \mu_p$, which yields

$$\left[\frac{\theta_A}{1-\theta_A}\right]_{eq} = e^{\beta\left(\mu_p - \overline{G}_A\right)} = e^{\beta\left[\mu_p - (G_A + U)\right]} \text{ or } \left[\frac{C_A}{\left(N_A - C_A\right)S_A}\right]_{eq} = \frac{1}{NS_A}\left[\frac{C_A}{Y_A}\right]_{eq} = e^{\beta\mu_p}, \quad (11)$$

where $S_A = \exp\left(-\beta \overline{G}_A\right)$ is the solubility factor. From the kinetics point of view, the numbers of forward and backward jumps between the nearest neighbour sites of distinct types in equilibrium are equal to each other in a volume $d^3\mathbf{x}$ around a point $\mathbf{x}$. This is expressed by detailed balance relation [20] being nothing else than equilibrium partition Eq. (3), which gets now more forms:

$$C_A \Omega_{AB} Y_B = C_B \Omega_{BA} Y_A \text{ or } C_A d_{AB} Y_B = C_B d_{BA} Y_A \text{ or } \theta_B\left(1-\theta_A\right) = \theta_A\left(1-\theta_B\right)\exp\left[\beta\left(G_A - G_B\right)\right]. \quad (12)$$

One can verify that fluxes $J_{I\backslash I}$ (I = A,B,…) are nil at equilibrium by virtue of Eq. (11), and that the sum $J_{A\backslash B} + J_{B\backslash A}$, A ≠ B, does the same with the aid of detailed balance (12). So, the total flux (6) is nil at equilibrium. As well, Eq. (9) at equilibrium yields $\partial C_A/\partial t = 0$ for all A-s by virtue of Eqs. (11) and (12), being the last term in brackets in Eq. (9) a paraphrase of the detailed balance (12).

4. Special Field Equations and Retrieval of the Known Models

4.1. One-level System

In the case of diffusion over identical sites, say L-sites, Eqs. (5), (6), and (9) in the absence of any potential field $U(\mathbf{x})$ render Fick's laws for isothermal diffusion with lattice diffusivity $D_L = d_{LL} = \Omega_{LL} l_{LL}^2$ [11,13,15]. As well, they lead to the equations of uphill diffusion under imposed potential U, e.g., due to lattice dilatation under hydrostatic stress σ, when $U = -V_H \beta\sigma$, V_H is the partial molar volume of H in metal, as they are known both for dilute solutions at $\theta << 1$ [1,2,11,21] (hereafter the site type labelling is skipped wherever convenient) and for arbitrary degree of saturation $\theta = C/N$ [22]. For the latter more general case, corresponding reduction of Eq. (5) reads:

$$\mathbf{J} = -D_L\left[\nabla C + \beta C(1-\theta)\nabla U\right]. \tag{13}$$

The balance equation is established then by common continuity relation, cf. Eq. (7).

4.2. Multi-level System, Implicit Description of Trapping: The Variable Solubility Model

Since the origin of potential $U(\mathbf{x})$ was not relevant in derivations, it can incorporate the intrinsic own lattice potential relief with variable depths of wells at interstitial sites, which yields variable solubility S($\mathbf{x}$) according to the well bottom $\overline{G}(\mathbf{x})$at location $\mathbf{x}$. This can be complemented with variable saddle point energy $E(\mathbf{x})$. Then, skipping site labels that become irrelevant, both Eqs. (5) and (6) can be rewritten in terms of the non-uniform both solubility and diffusivity as follows:

$$\mathbf{J} = -D(1-\theta)C\nabla \ln\left(\frac{C}{(1-\theta)S}\right) = -D(1-\theta)^2 S\nabla\left(\frac{C}{(1-\theta)S}\right), \tag{14}$$

where (cf. expressions (4), (5) and (11))

$$D(\mathbf{x}) = \omega_0(\mathbf{x})\exp\left[-\beta\left(E(\mathbf{x}) - \overline{G}(\mathbf{x})\right)\right]/2 \quad \text{and} \quad S(\mathbf{x}) = \exp\left(-\beta\overline{G}(\mathbf{x})\right). \tag{15}$$

With these flux equations, the mass balance is established by usual continuity relation, cf. Eq. (7).

This mode to describe diffusion, named [10] the non-uniform solubility model, deals with a system where neither interstitial positions nor saddle points are all identical, and so, it treats in effect a multilevel system. Though, specific sites are here indiscernible within each elementary volume $d^3\mathbf{x}$ around a point $\mathbf{x}$, where the values $\overline{G}(\mathbf{x})$ and $E(\mathbf{x})$ can be interpreted as effective averages over different sites with account for their amounts in regions, which are small in macroscopic sense, but large enough in microscopic one. Such averaging counts implicitly on equilibrium partition of a diffuser between sites of different kinds in $d^3\mathbf{x}$ disregarding traps filling/emptying kinetics.

Anyhow, excepting the term $(1 - \theta)$ that accounts for sites saturability, these equations render fairly the same as established for dilute solutions ($\theta << 1$) elsewhere booth within the frameworks of microscopic kinetics [10] and macroscopic thermodynamics [1,5,9]. To this end, built up upon

phenomenological account of measurable variables, but not relying on specification of atomic mechanisms, the latter approach extends the suitability of hydrogen diffusion description by means of Eq. (14) over much wider range of circumstances, such as non-uniformity of alloy composition, transient external fields (e.g., mechanical stresses), simultaneous (e.g., strain induced) phase transformations, cold working, non-isothermal diffusion (Soret effect), etc. [1,5,9,11]. Till now, these factors could not be incorporated satisfactorily in diffusion models via kinetics considerations. From another side, diffusion modelling accounting for the kinetics of H transitions between different microstructural entities ("sites") is not feasible on the way of thermodynamics.

4.3. Multi-level System, Explicit Description of Trapping

When conditions of system equilibrium are not fulfilled, it evolves to equilibrium. Various transitions can be discerned there. One of them is rather long-distance transfer that drives to global equilibrium via fluxes represented by respective equations of the previous section. Besides, localised processes of H exchange between the nearest sites of different kinds are there involved, too, which tend to local equilibrium expressed by the detailed balance (12). Corresponding process rates, which may depend on both intrinsic (e.g., vibration frequency and jump length) and extrinsic (such as diffusion distance) factors, may be so distinct, that in the time scale of interest (e.g., for membrane permeation or for hydrogen delivery to fracture locations) some processes may have attained equilibrium while others have not yet.

4.3.1. Diffusion under Traps-Lattice Equilibrium

One possibility of the mentioned partial equilibrium is when detailed balance is quickly reached and maintained during diffusion, e.g., when relatively long diffusion distances x_{cr} with corresponding times $t \sim x_{cr}^2/(4D)$ [23] are of interest. Suggested by Oriani [17] to be kept during diffusion, the hypothesis of local equilibrium assumes that detailed balance (12) holds for all nearest neighbour A and B sites, so that partial balance (9) in the case of multiple B-sites yields the following:

$$\frac{\partial C_A}{\partial t} = d_{AA}\nabla\cdot\left[Y_A C_A \nabla \ln\left(\left(e^{\beta U} C_A / Y_A\right)\right)\right] + \sum_B d_{AB}\frac{C_A}{C_B}\nabla\cdot\left[Y_B C_B \nabla \ln\left(\left(e^{\beta U} C_B / Y_B\right)\right)\right]. \qquad (16)$$

The global balance (7) for two-level system (for multi-level one the sum is to be taken over all site types) under local equilibrium is reduced to the next:

$$\frac{\partial C}{\partial t} \equiv \frac{\partial\left(C_A + C_B\right)}{\partial t} = \nabla\cdot\left[\left(d_{AA}Y_A C_A + 2d_{AB}Y_B C_A + d_{BB}Y_B C_B\right)\nabla \ln\left(\frac{C_A}{S_A Y_A}\right)\right]. \qquad (17)$$

Accompanying Eq. (17) with the detailed balance (12), which may be solved with respect to C_B,

$$C_B = \frac{N_B C_A K / N_A}{1 + C_A\left(K-1\right)/N_A} \quad \left(K = e^{\beta E_b},\ E_b = G_A - G_B\right), \qquad (18)$$

the system of partial-differential equations of diffusion with trapping converts into the system of

one partial-differential and a series of algebraic equations (17) and (18) with respect to partial concentrations C_I (I = A,B,…). This system transforms into the sole differential equation (17) with respect to C_A by substitution there C_B according to Eq. (18).

It can be verified that, labelling A ≡ L to be lattice sites and B ≡ T traps, at $\theta_L << 1$ and $\gamma_T << \gamma_L \approx 1$, and so, $Y_T << 1$, which are usually met in HAF of engineering alloys [6], and $d_{BX}/d_{AX} \sim \exp(-\beta E_b) < \sim 10^{-4}$ at $E_b > 0.2$ eV [2,14,15] for X = L or T, Eqs. (17)-(18) convert into the equation of trap-assisted diffusion [4] as implementation of Oriani's [17] equilibrium hypothesis:

$$\left(1+\frac{\partial C_T}{\partial C_L}\right)\frac{\partial C_L}{\partial t} = \nabla\cdot\left[D_L\left(\nabla C_L - C_L\nabla\ln S_L\right)\right] \text{ at } C_T = C_L K N_T/\left(N_L + K C_L\right). \tag{19}$$

4.3.2. Diffusion with Account for Lattice/Trap Exchange Kinetics

The system of equations (9), which describes hydrogen diffusion affected by traps in rather general terms, is tough to solve. Taking advantage of circumstances usually met in HAF, it can be reduced to more suitable forms. Namely, $\theta_L << 1$, $\gamma_T << \gamma_L \approx 1$, and thus $Y_T << Y_L \approx 1$, as well as $d_{TX}/d_{LX} << 1$ (X = T and L) usually hold in HAF, but the matter of local L/T-equilibrium is not ensured *a priori*. Then, taken for granted that T→T jumps are fairly improbable, the total flux **J**, Eq. (6), and the partial balance for C_T, Eq. (9), can be assessed as follows:

$$\mathbf{J} = \mathbf{J}_{L\backslash L}\left\{1+\frac{d_{TT}}{d_{LL}}\left[Y_T O\left(\frac{|\nabla C_T|}{|\nabla C_L|}\right)+O\left(\frac{C_T}{C_L}\right)\right]+\frac{d_{LT}}{d_{LL}}\left[Y_T O(1)+o(C_L)\right]+\frac{d_{TL}}{d_{LL}}O\left(\frac{|\nabla C_T|}{|\nabla C_L|}\right)\right\}, \tag{20}$$

$$\frac{\partial C_T}{\partial t} = \frac{d_{LT}}{d_{LL}}Y_T\nabla\cdot\mathbf{J}_{L\backslash L}+\frac{1}{fl^2}\left(d_{LT}Y_T C_L - d_{TL}C_T\right). \tag{21}$$

Accordingly, if neither ratios of partial concentrations C_T to C_L and their gradients nor the divergence of lattice-hopping flux $\mathbf{J}_{L\backslash L}$ are too large to forbid the disregard of terms with $d_{TX}/d_{LX} << 1$ and $Y_T << 1$ in Eqs. (20) and (21), then Eqs. (17)-(18) convert into the system of partial- and ordinary-differential equations postulated by McNabb-Foster [7], which is now extended for variable solubility S_L:

$$\frac{\partial}{\partial t}\left(C_L + C_T\right) = \nabla\cdot\left[D_L\left(\nabla C_L - C_L\nabla\ln S_L\right)\right];\ \frac{dC_T}{dt} = \left(k_{LT}/N\right)\left(N_T - C_T\right)C_L - k_{TL}C_T. \tag{22}$$

Obviously, these specialised equations of trap-affected diffusion are additively extensible for the case of multiple trap kinds T_i (i = 1,…) as the antecedent general Eqs. (7) and (9) do.

The system of equations (22) with respect to a number of concentrations C_i (i = 1,…,m) may complicate numerical simulations of diffusion making corresponding discrete approximations of the boundary-value problems oversized. However, the second of Eqs. (22) has the closed-form solution

$$C_T = \exp\left(-\int_0^t P_T(\xi)d\xi\right)\left[\int_0^t\left(\exp\left(\int_0^\xi P_T(\xi)d\xi\right)Q(\xi)\right)d\xi + C_T^0\right], \tag{23}$$

where $P_T(t) = k_{TL} + k_{LT}C_L(t)/N$, $Q(t) = k_{LT}N_TC_L(t)/N$, and $C_T^0 = C_T\big|_{t=0}$ is the initial condition. Substitution of the expression (23) into the first of Eqs. (22) reduces the problem to the sole integro-differential-equation with respect to C_L. Its computational implementation, e.g., via available finite element routines [4-6], requires modification only of calculation of concentration capacity matrices.

5. Summation: Suitability of Models for HAF Analysis

The system of equations of diffusion with trapping, which is derived here from kinetics principles, provides generalisation of pertinent previously suggested models, as well as it retrieves special ones typically either raised on the thermodynamics bases or postulated partially from microscopic arguments. This way, simpler equations of specialised models gain clarification of involved approximations and, respectively, of the requisites of their applicability. This allows reasoned pondering of their advantages and limitations to select optimal models for HAF-case analyses.

Demonstrated relation of general kinetics-based equations of trapping-affected diffusion with thermodynamics-grounded variable-solubility model visualises the incorporation of traps in this latter. However, its solid thermodynamics foundation makes it capable of accounting of wider variety of factors that influence hydrogen diffusion in metals, but are not amenable to incorporation in kinetics analysis. These are phase transformations under loading (e.g., $\gamma\rightarrow\alpha$ transition in steels), variable alloy composition, thermodiffusion, and all microstructural features, such as inclusions, grain boundaries or dislocations, which, strictly speaking, can hardly be treated as point-wise lattice irregularities that the majority of kinetics-based models deal with. With variable solubility model, numerous factors of H behaviour in metals can be incorporated in HAF analyses and simulations through macro-level determined, i.e., apparent or measurable, diffusivities and solubilities dependent on microstructure, cold working, etc. It is the advantage of this model in addition to its linearity, which substantially streamlines computations. However, the prominent deficiency of this model is inability to describe dissymmetry between hydrogenation and dehydrogenation kinetics. Meanwhile, the significance of this fault for HAF analysis seems to be case-dependent, e.g., it may be irrelevant whenever only monotonic hydrogenation occurs, but can be substantial under load or hydrogenation cycling. As well, this model discounts the lattice/trap exchange kinetics, which may be desired in particular HAF analyses. The importance of these deficiencies is also case-dependent, as far as HAF involves definite diffusion distances towards fracture sites x_{cr}, and corresponding diffusion times $t_{dif} \sim x_{cr}^2/(4D)$, which may be short or long compared with the characteristic time of approaching trap-lattice equilibrium $t_{T\text{-}L}^{-1} \sim k_{TL} + k_{LT}C_L/N$ according to the solution (23). E.g., the role of trap-filling kinetics may be noticeable for hydrogen assisted crack growth in high-strength or brittle materials, where sub-micrometer diffusion distances of the order of crack-tip opening displacement are involved [1,5], and it can be irrelevant otherwise.

Concerning diffusion models that account for trapping explicitly, they lack of the majority of attractions of the preceding one, as far as they cannot account for a series of cited diffusion-influencing factors. In return, they describe hydrogenation-degassing dissymmetry and a series of other trap-related abnormalities of diffusion. However, this improvement raises computational expenses of managing non-linear partial-differential or integro-differential equations. These models

count on micro-level determined mobility, binding and kinetics rates characteristics, which complicates their implementation in engineering. Regarding suitability for HAF description of explicit models of trapping-affected diffusion with or without lattice-trap equilibrium, this is basically the matter of transportation distances and corresponding times relevant to HAF process, so that whenever they are short, account for lattice-trap exchange kinetics may be advisable. However, one ought to be aware that large concentration gradients that can be met, e.g., in the proximity of hydrogen entry surface at short diffusion times can invalidate the requisites of smallness of the ratios of partial concentrations and their gradients, which justify the reduction of general system of diffusion equations (9) to the special case (22) of McNabb-Foster.

At any rate, recognising that trap populations may be affected by plastic deformation ε_p, $N_T = N_T(\varepsilon_p)$, and that the most relevant field for HAF is the stress field, $U \propto \sigma$, all considered equations describe the process of stress-strain assisted diffusion [1,4-6,16]. This way, present study gives an outlook of "microstructure informed" models of stress-strain affected hydrogen diffusion able to account for various physical variables relevant to HAF.

Abstract Hydrogen diffusion within a metal or alloy is conditioned by the stress-strain state therein. For that reason it is feasible to consider that hydrogen diffuses in the material obeying a Fick type diffusion law including an additional term to account for the effect of the stress state represented by the hydrostatic stress. According to this law hydrogen diffuses not only to the points of minimum concentration (driven by its gradient), but also to those of maximum hydrostatic stress (driven by its gradient), the diffusion itself being also conditioned by the gradient of plastic strain. In this paper the hydrogen transport by diffusion in metals is modelled in notched specimens where loading generates a triaxiality stress state. To this end, two different approaches of stress-assisted hydrogen diffusion, one-dimensional (1D) and two-dimensional (2D), were compared in the vicinity of the notch tip in four notched specimens with very distinct triaxiality level at two different loading rates. The 2D approach predicts lower values of hydrogen concentration than the 1D approach, so that a *loss of directionality* of hydrogen diffusion towards the location of highest hydrostatic stress appears in the 2D case. This loss of directionality of hydrogen diffusion depends on both notch geometry parameters (radius and depth) and loading rate (or straining rate).

Keywords Hydrogen diffusion, Numerical models, Notched samples, Directionality of diffusion.

1. Introduction

Catastrophic fracture of structural materials in harsh environments for lower loading level than in air is caused many times by hydrogen diffusion towards material lattice and accumulation in certain places where damage at microstructural level is produced [1-4]. This phenomenon, known as *hydrogen embrittlement* (HE) or *hydrogen-assisted fracture* (HAF), has a key role in prestressed concrete structures due to the high susceptibility of the prestressing steel to this type of fracture [5-7]. At the critical fracture instant, the hydrogen concentration C reaches a critical value C_{cr} in a certain material locus $\vec{x}_{cr}$. The critical value of hydrogen concentration depends on the stress-strain state at the critical instant in the critical place or prospective location for fracture initiation [8]. Thus, the fracture criterion can be expressed as follows:

$$C_{cr} = C_{cr}(\sigma_i, \varepsilon_i) \quad \text{in} \quad \vec{x} = \vec{x}_{cr}, \tag{1}$$

where $\vec{x}$ is the spatial vector coordinates. In this equation the influence of the stress-strain state on the critical value of hydrogen concentration is included by means of both tensor invariants represented by the principal stresses, σ_i, and principal plastic strains ε_i (i = 1, 2, 3).

To study this phenomenon, constant-extension-rate tensile (CERT) tests in a hydrogenating environment are commonly used. The mechanical load applied during the test generates a certain stress-strain state in the material according to the geometry of the tested specimen. Although specimens for this type of test could exhibit different shapes, diverse studies [9,10] consider round notched bars as the best suited to the evaluation of these fracture phenomena. Obviously, under CERT test load conditions the stress and strain state varies with time and, consequently, a transient analysis of the hydrogen diffusion must be carried out.

The analysis of the HAF process presents a serious difficulty: the experimental determination of the value of hydrogen concentration $C(\vec{x},t)$ at certain point, $\vec{x}$, for a given time t. This difficulty becomes particularly important in the analysis of HAF process for critical conditions, $C_{cr} = C(\vec{x}_{cr},t_{cr})$. To solve this objection is essential (i) to find the HAF focus by means of metallographic techniques of the fractured specimens analysis [9,11,12], and (ii) to determine the local values of the variables governing the diffusion process, i.e., hydrogen concentration C, the hydrostatic stresses σ_i and equivalent plastic strains ε_i^P (i = 1,2,3).

The mechanical variables representing the stress-strain state in the hydrogen diffusion model can be obtained by numerical simulation revealing the evolution of stress-strain state in the notched specimen during CERT test. Unfortunately, nowadays an advanced numerical simulation code of general use that solves the problem stated in this paper is not available: the analysis of transient hydrogen diffusion assisted by stresses considering a 2D approach. To overcome this difficulty, the hydrogen concentration at any place and time of the transient diffusion assisted by stress state can be obtained by means of an *ad hoc* numerical code based on the finite element method (FEM) developed by the authors [13]. With the help of this tool the analysis of the time evolution of hydrogen concentration can be developed in the notched samples considered in this study during the CERT tests performed under different extension rates. The numerical simulations were carried out taking into account both approaches of the hydrogen diffusion assisted by stress state: *one-dimensional* (1D) and *two-dimensional* (2D). The differences between both simulations reveal a loss of directionality of hydrogen diffusion into metal.

2. Problem Statement

The numerical modelling of this problem raises a huge complexity due to the following fact: the hydrogen diffusion equation must consider the stress field generated by the remote load applied during CERT test. In general terms hydrogen diffusion in metals obeys a Fick type diffusion law including an additional term to account the effect of the stress state, which is time dependent, i.e. transient for the analyzed cases. Thereby, the stress-assisted diffusion flux of hydrogen is:

$$\boldsymbol{J} = D\nabla C + D\frac{V_H}{RT}C\nabla\sigma, \tag{2}$$

where D is the diffusion coefficient, V_H the molar partial volume of hydrogen in metal, R the ideal gases constant and T the absolute temperature.

The role of stress in hydrogen diffusion is commonly associated with one of the stress tensor invariants: the hydrostatic stress (or mean normal stress) σ. The relevance of stress in hydrogen transport by diffusion and HAF is well known from previous references [14-16], and, according to Eq. (2) is established that hydrogen diffuses not only to the points of minimum hydrogen concentration C (driven by the gradient of concentration), but also to the sites of maximum hydrostatic stress σ (driven by the gradient of stresses) [17]. So, the hydrogen diffusion process assisted by stress in non-homogeneous stress fields can be expressed as follows [8]:

$$\frac{\partial C}{\partial t} = D\left(\nabla^2 C - \frac{V_H}{RT}\nabla C\nabla\sigma - \frac{V_H}{RT}C\nabla^2\sigma\right). \tag{3}$$

i.e., a parabolic-type partial differential equation given in terms of hydrogen concentration C and hydrostatic stress s as the relevant variables of the process od hydrogen transport.

Free of hydrogen specimens before the test were considered and, consequently, the initial condition of null hydrogen concentration at the initial time ($C(\vec{x},t)|_{t=0} = 0$) was applied in simulations. The material considered in this study is a hot rolled bar of eutectoid pearlitic steel (C 0.75%, Mn 0.67%, Si 0.200%, P 0.009%, S 0.009%, Cr 0.187%, V 0.053%), whose mechanical properties are: Young´s modulus 195 GPa, Yield Strength 720 MPa and ultimate tensile strength (UTS) 1270 MPa.

Finally the values of relevant parameters of metal-hydrogen interaction were obtained from previous works [18,19] as $D = 6.6\ 10^{-11}$ m^2/s y $V_H = 2\ 10^{-6}$ m^3/mol. The geometry of a round notched specimen can be defined by two parameters (Table 1): the notch tip radius ρ and notch depth a. To have results independent of sample dimensions these parameters were normalized with the specimen diameter d (where $d = 12$ mm for all the notched geometries analyzed in this study).

Table 1. Notch parameters of the analyzed notched specimens

Parameter	A	B	C	D
ρ/d	0.03	0.05	0.40	0.40
a/d	0.10	0.30	0.10	0.30

Fig. 1 shows a scheme of the four analyzed notched specimens, including the corresponding notation used to identify each one. To analyze the effect on hydrogen diffusion of the extension rate during the CERT tests, two different values were considered: fast extension rate, 0.1 mm/min, and slow extension rate, 0.001 mm/min.

Two numerical approaches of hydrogen diffusion model, based in previous research [13,20], are used in present work: the *one-dimensional approach* (1D) and the quite more realistic (although time-consuming) *two-dimensional approach* (2D). Transient stress state generated in the specimen by remote loading during CERT test is included as input data in the FEM code developed *ad hoc* for both simulations of diffusion process. The specimen stress state is obtained from a previous mechanical simulation of the CERT test with a commercial FEM code considering small-strain. The same stress field was considered in the two approaches (1D and 2D) used in this paper.

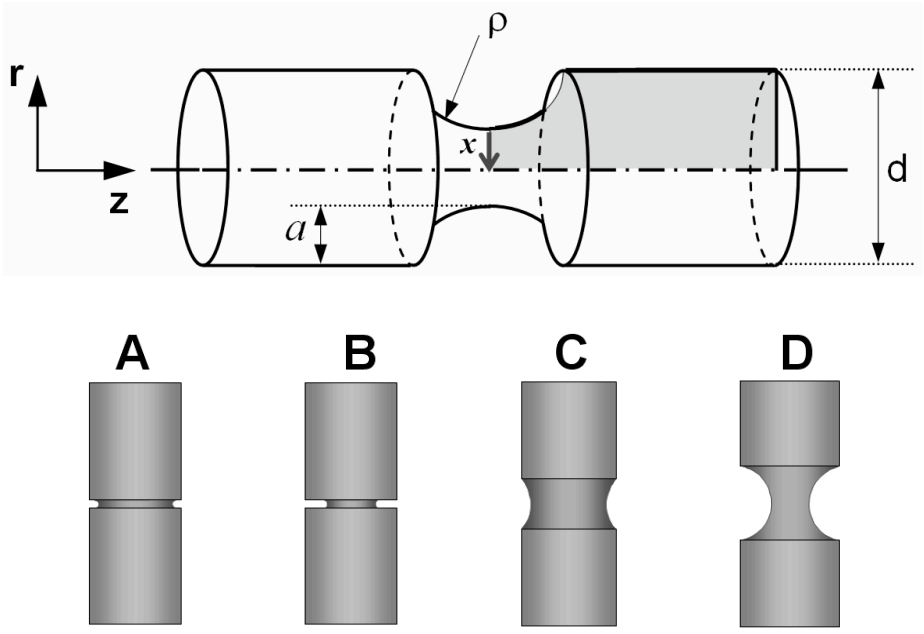

Fig. 1. Scheme of the notched specimens and parameters used for describing the notch

The 1D approach considers hydrogen diffusion is exclusively developed in radial direction (r), i.e., through the wire radius placed at notch symmetry plane. However, in 2D approach the hydrogen diffusion proceeds in both radial (r) and axial direction (z). Therefore, differences in the hydrogen concentration given by the two considered approaches can be associated to a *geometric factor*. The FEM simulation of the hydrogen diffusion assisted by stresses was performed with linear elements for both approaches (1D and 2D).

In these simulations the exposure time to harsh environment was chosen equal to the fracture time (t_f) obtained in the study [21], where similar specimens –material and notched geometries– were tested in an inert environment (air). This way, data related to fracture time due to HAF (t_{HAF}) are included in the results of the simulation performed since $t_{HAF} < t_f$ [12].

The results of the displacement at fracture instant, u_f(A) = 0.4 mm, u_f(B) = 0.13 mm, u_f(C) = 1.2 mm and u_f(D) = 0.42 mm, obtained in [21] with an extensometer of 25 mm gage length, were used to determine the time of fracture in air (t_f) according to the following relation $t_f = u_f / \dot{u}$ for each one of the two considered extension rates $\dot{u}$ (0.1 and 0.001 mm/min).

3. Numerical Results

The hydrogen accumulation in the material is represented by the relative hydrogen concentration C_r ($C_r = C/C_0$), which can be defined as the hydrogen concentration normalized with the equilibrium hydrogen concentration in a virgin material C_0, i.e., free of stress and strains. Fig. 2 shows the distribution of the relative hydrogen concentration (C/C_0) through the considered notch symmetry plane for a diffusion time lower than the fracture time in air (t_f) obtained for each one of the two extension rates considered, 0.1 mm/min and 0.001 mm/min.

As can be shown in Fig. 2 two different trends were obtained according to the extension rate: on one hand, for the highest extension rate of 0.1 mm/min (Fig. 2 left) slightly differences appear in hydrogen concentration obtained by 1D and 2D approaches of diffusion model. On the other hand, when the lowest extension rate of 0.001 mm/min is applied (Fig. 2 right) a clear influence of the geometric factor on hydrogen diffusion is revealed, especially, in the notched geometry type A where high differences in relative hydrogen concentration are obtained considering 1D and 2D approaches. Therefore the use of 1D approach (less realistic than 2D approach) leads to a loss of accuracy in the determination of relative hydrogen concentration, it being more accused for low extension rate tests and sharp notches.

According to these results hydrogen diffuses not only through the notch symmetry plane but also towards other directions. However, most of hydrogen is preferentially accumulated in the radial notch symmetry plane direction, as could be expected since H diffuses towards the location where the highest hydrostatic stress appears (situated in the notch symmetry plane [13]). So, according to Fig. 2, the lower the extension rate the more accused the effect of the *geometric factor* on hydrogen diffusion, it becoming inappreciable for high extension rate test where the hydrogen diffusion is performed practically through the notch symmetry plane with a negligible *loss of directionality*.

The influence of geometric factor on hydrogen diffusion is dependent of notch geometry parameters (radius and depth). So, the influence of this factor is lower for blunt notched samples with a high notch radius (notches C and D) than for sharply notched geometries (notches A and B) with a low notch radius (Fig. 2). According to that, a stronger influence of the geometric factor on hydrogen diffusion appears for high values of the depth (distance) from the notch tip (x).

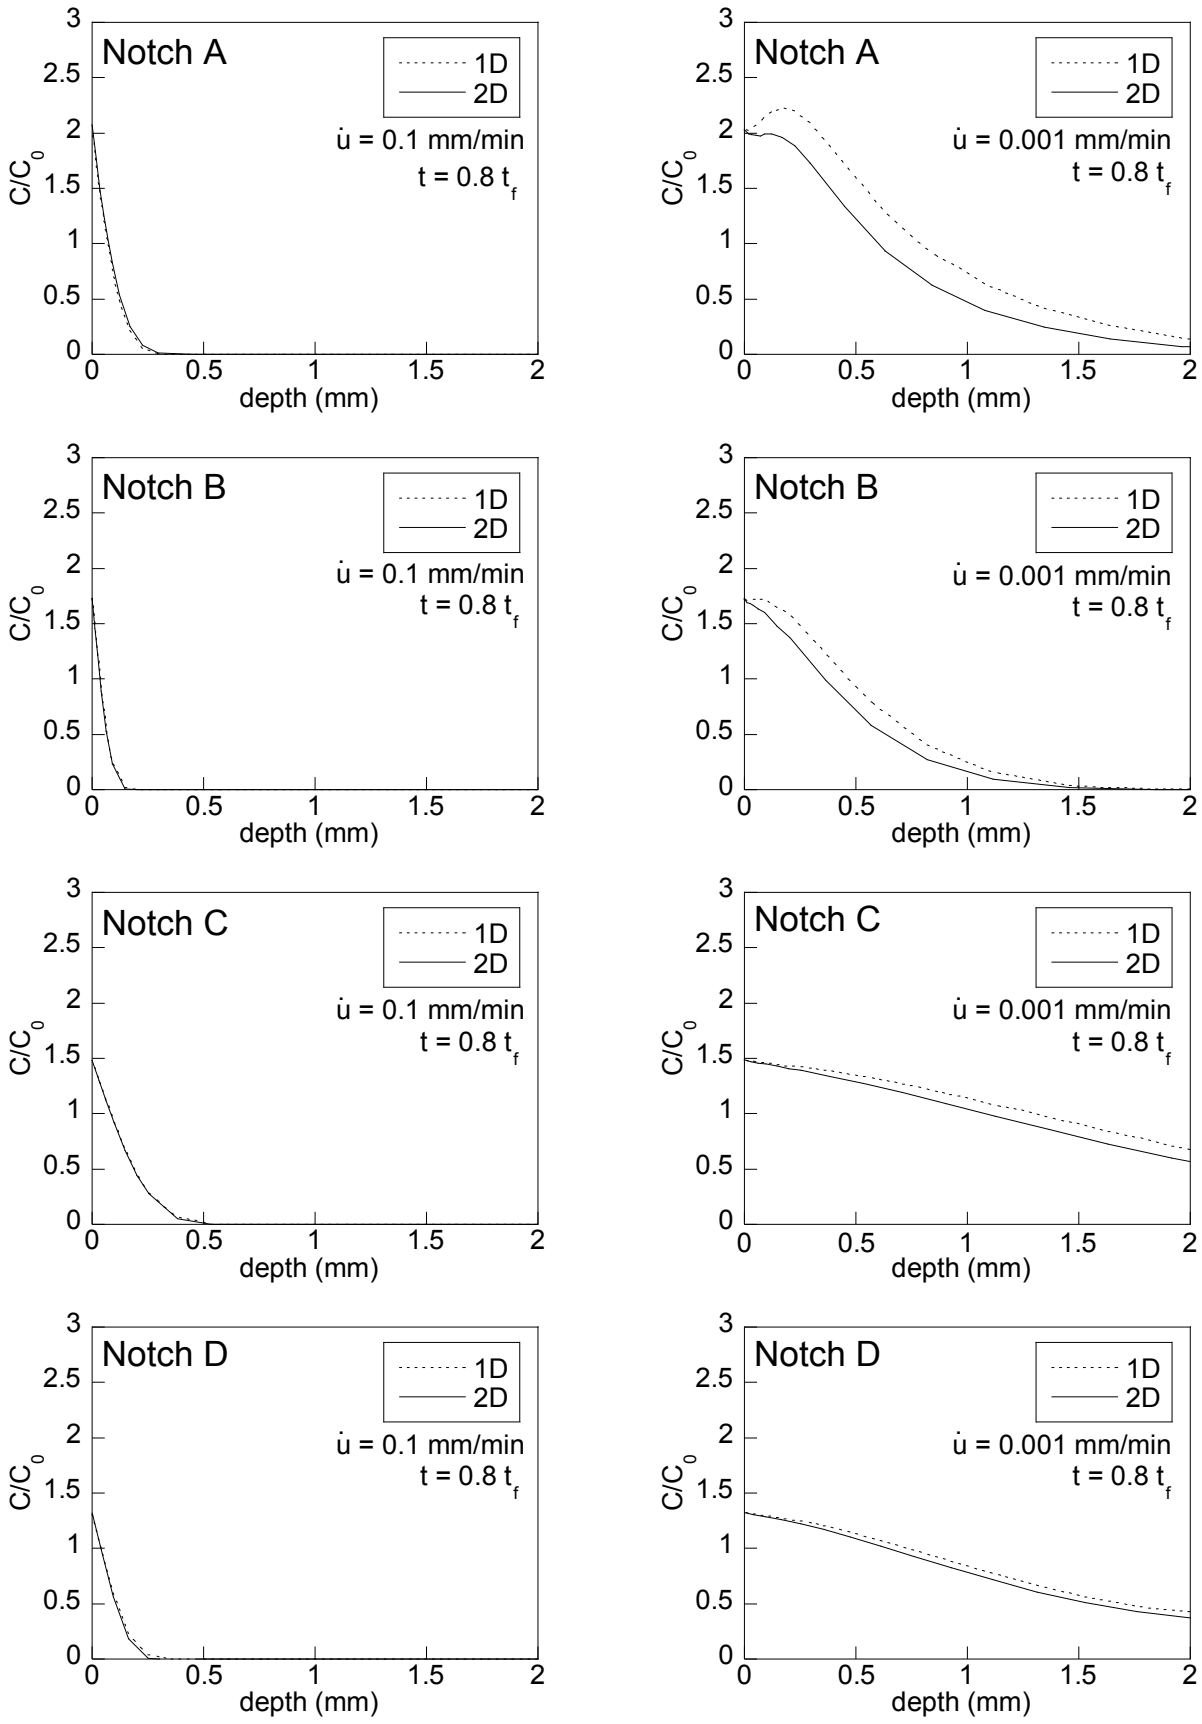

Figure 2. Distribution of hydrogen concentration through the notch symmetry plane for the geometries analyzed and an extension rate of 0.1 mm/min (left) and 0.001 mm/min (right) at exposure time $t = 0.8t_f$

The loss of accuracy of 1D approach with regard to the more realistic 2D approach can be quantitatively estimated by a new parameter λ defined as the amount of diffused hydrogen out of the notch geometry plane, thus, λ represents the *loss of hydrogen diffusion directionality:*

$$\lambda = \frac{C_r(1D) - C_r(2D)}{C_r(1D)}. \quad (4)$$

As a sketch, the 1D approach could be considered as a hollow cylindrical tube through hydrogen diffuses and the 2D approach could be considered as a hollow cylindrical tube with small holes placed in the cylinder walls. So, in first case (1D approach) a fluid that flows inside the cylinder is trapped inside it and is not able to pass through the cylinder walls whilst in second case (2D approach) the fluid can escape out of the cylinder through the holes causing a loss of fluid flux in relation to the first case.

To get a clear view of the influence of the parameters defining the different notched geometries on the loss of directionality, in Fig. 3 the distribution of the parameter through the notch symmetry plane is represented for each one of the four notched geometries simulated under the lowest loading rate, 0.001 mm/min, for a exposure time to harsh environment of 80% of the time to fracture in air, $t = 0.8\ t_f$. Fig. 3 shows a common trend for notched wires with the same notch tip radius, ρ. For blunt geometries with a higher notch radius (notches C and D) a low loss of directionality is obtained, i.e., the loss of accuracy of the 1D approach is low, cf. Fig. 2, whereas for sharp notches with a low notch radius (notches A and B) the 2D approach is required to obtain an adequate simulation.

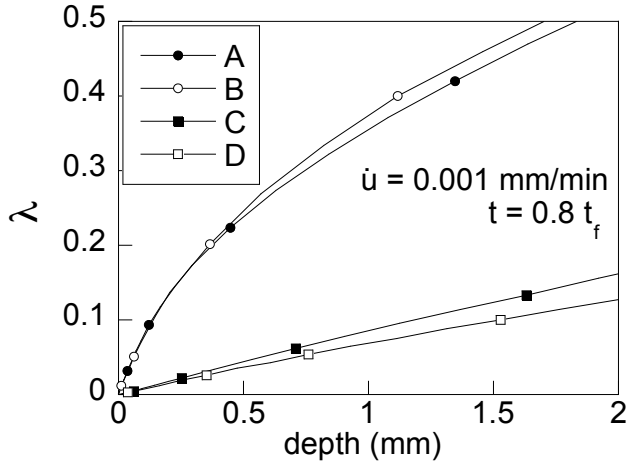

Figure 3. Distribution of loss of hydrogen diffusion directionality, through notch symmetry plane for the four notched geometries simulated under an extension rate of 0.001 mm/min at diffusion time $t = 0.8t_f$

According to these results, the notch tip radius (ρ) is the parameter governing the amount of hydrogen available for diffusing toward points out of notch symmetry plane in axial direction, with a second order effect of the notch depth (a). Fig. 4 shows a scheme of the diffusion path followed by hydrogen inside the material as a function of the dimensional approach (1D or 2D) to the process of hydrogen diffusion in the solid.

The reason why hydrogen diffuses toward the axial direction out of the notch symmetry plane can be attributed to the key role that stress state plays in the hydrogen diffusion assisted by stress model (Eq. 3). According to this model, hydrogen diffuses to the places where the maximum hydrostatic stress appears [17]. In the case of 1D approach these points are placed inside the notch symmetry

plane, which means that hydrogen diffuses exclusively inside that plane. However, in the case of 2D approach, the maximum hydrostatic stress σ appears over a *zone* [13] allowing hydrogen to move towards diverse places. Fig. 3 shows a null loss of hydrogen diffusion directionality in points near the notch tip. The same figure indicates that the deeper is the considered point the higher is the loss of directionality, which is represented in the scheme shown in Fig. 4.

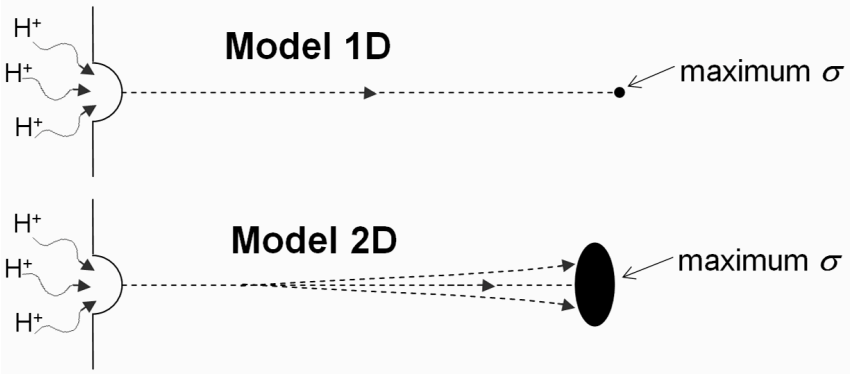

Figure 4. Scheme of hydrogen diffusion path inside a material taking into account the diffusion model approaches considered in numerical simulations.

4. Conclusions

- For high loading rates the hydrogen concentration predicted by the 1D approach to hydrogen diffusion in the material is practically equal to that predicted by the 2D approach, and therefore the influence of the *geometric factor* is not significant.
- For low loading rates during the constant extension rate tensile (CERT) tests the loss of accuracy of results obtained with the 1D approach to hydrogen diffusion in the material becomes more significant due to the loss of directionality in diffusion path.
- During the CERT tests, certain amount of hydrogen diffuses towards points placed out of the notch symmetry plane. This supposes a *loss of hydrogen diffusion directionality* in relation to the radial path obtained in 1D approach.
- The loss of directionality of hydrogen diffusion is more accused for low extension rates during the CERT tests and points placed far away from the notch tip, it becoming more significant in sharp notches with low notch radius.
- Obtained results reveal that the notch tip radius (sharp or blunt notched geometries) is the most relevant geometric parameter governing the loss of directionality of hydrogen diffusion, the notch depth exhibiting minor importance.
- Hydrogen diffusion toward points placed out of the notch symmetry plane is strongly dependent on the distribution of hydrostatic stress inside the material. In the 1D approach the maximum hydrostatic stress location is a single point, whereas in the 2D approach it is a zone.

Abstract Maraging steels are known to have not only ultrahigh strength but also large toughness so that they are promised to be as used as components or parts with structural integrity. It is also known that maraging steels are conventionally aged in two steps to obtain such good mechanical properties. Some of the present authors showed that one-step-aged maraging steels exhibited the increase in fatigue strength at intermediately high temperatures of 473 K and 673 K, compared with the strength obtained at room temperature. In addition, when low-temperature aging at 473 K and 673 K was given to one-step-aged maraging steels by varying the aging time, this second-step-aging increased the hardness of the steel. It also increased fatigue strength in an environmental situation where high humidity markedly reduced the fatigue life of one-step-aged steels. These results strongly suggest that the second-step-aging at low temperatures produces some additional microstructures which impede plastic deformation and increases resistance to fatigue cracking, even in the environmental conditions which accelerate the deformation and fracture. In the present report, a microstructural model will be proposed to interpret the effect of second-step-aging on the mechanical properties of maraging steel, which will explain the improvement of fatigue strength at intermediately high temperature and in high humidity condition.

Keywords Maraging steel, Fatigue, Two-step-aging, Microstructure, Environmental effect

1. Introduction

The high strength of maraging steels is principally based on the strengthening due to the martensitic transformation of Fe-18mass%Ni alloy, which also accompanies the introduction of dislocations with high density [1, 2]. According to a recent study of Nakashima *et al*. [3], the dislocation density introduced by martensitic transformation becomes 7×10^{15} /m^2 in ultra-low carbon Fe-18mass%Ni (0.002mass%C), leading to the yield strength of 0.66 GPa. The addition of alloying element such as Mo, Ti and Co increases the strength of maraging steels substantially by the precipitation hardening obtained by aging [1, 2]. As a result, the maraging steels exhibit the ultrahigh strength up to more than 2 GPa, without losing ductility and fracture toughness significantly. These mechanical properties are beneficial from the viewpoints of the structural integrity and the reduction in weight in practical applications.

The high strength and large ductility generally improve the fatigue strength. However it is well known that the fatigue properties of steels are very sensitive to environment [4]. Exposure to humid air or to aqueous solutions leads to the prominent deterioration of fatigue strength in high strength steels like maraging steel. Our previous studies [5−7] showed that the fatigue strength of 18Ni maraging steels aged at 753 K was lowered markedly by exposing the steel to humid air with a relative humidity (RH) of 85%. The susceptibility of fatigue strength to humidity increases with aging time in one-step-aged maraging steel, which leads to the lowest fatigue strength at peak-aging [6, 7]. The application of the second-step-aging at 673 K to the one-step-aged steel, however,

recovered the susceptibility comparable to the under-aged states. In another previous study [8], the fatigue strength of a 300G maraging steel under-aged at 753 K was shown to increase at test temperatures of 473 K and 673 K. It was also demonstrated that the hardness increases with the number of cycles at these temperatures. The second-stage-aging of this type is, hence, very effective to improve the fatigue properties at moderately elevated temperatures.
The results in the previous studies mentioned above suggest that microstructural change is induced by the static second-step-aging to improve the fatigue strength in humid air, and that dynamical aging is also caused during deformation at moderately elevated temperatures. In addition, these effects appear prominently in fatigue properties. In the present study, we try to understand the effects of the second-step-aging on the fatigue properties of maraging steels from the microstructural aspect. For this purpose, we reassess the results of previous studies. In particular, we investigate the dependence of hardness change on aging time and temperature in detail, taking into account the microstructural analyses by means of transmission electron microscopy (TEM). Based on these reassessment and analyses, the strengthening mechanism due to the second-step-aging and its role in suppressing the deterioration of fatigue properties will be discussed.

2. Experimental procedures

Chemical compositions of 300G and 350G maraging steels used are shown in Table 1. Both steels were supplied as rods of 13 mm diameter, and experienced the solution treatment conducted at 1123 K for 5.4 ks. The 300G steel was aged at 753 K for 48 ks, which led to an under-aging state. For the 350G steel, two under-aging conditions were obtained at 753 K by using the aging times of 11 ks and 100 ks, while the peak-aging was attained by heating the specimen at 753 K for 150 ks. The 300G steel specimens were subjected to rotating bend test with a frequency of 50 Hz at room temperature, 473 K and 673 K, to examine the effect of test temperature on the fatigue properties. For the 350G steel, the peak-aged specimens were subjected to second-step-aging at 473 K and 673 K by changing the keeping time, prior to tensile and rotating bend tests at room temperature. The fatigue tests of the 350G steel specimens were carried out in air with the RH of 25% and 85% to examine the influence of humidity on the fatigue properties. The details of experimental procedures used for the above fatigue tests had been reported in the previous papers [5–8]. Hereafter we assign S and D to the one-step-aging and two-step-aging, and U, P and O to the under-, peak- and over-aging, respectively, as will be shown in Table 2.
The second-stage-aging at 473 K and 673 for various time up to 800 ks was applied to the under-aged 300G steel and the peak-aged 350G steel. The Vickers hardness of the polished surfaces of these specimens was measured by using a load of 9.8 N to examine the change in hardness during the second-step-aging. The microstructures of one-step-aged and two-step-aged 350G specimens were also observed by TEM. In addition, an electrolyte extraction technique was used to identify the precipitates and evaluate their contents.

Table 1. Chemical compositions of maraging steels (mass%).

Grade	Ni	Mo	Co	Ti	Al	Mn	Si	S	C	Fe
300G	18.4	5.14	9.09	0.89	0.11	0.01	0.05	0.002	0.005	bal.
350G	17.89	4.27	12.36	1.3	0.08	0.01	0.01		0.001	bal.

3. Results

3.1 Relation between the tensile properties and hardness

Table 2 shows the yield strength (σ_y) given by 0.2% proof stress, the tensile strength (σ_{max}), the

reduction of area and the Vickers hardness (H_V) obtained for age-hardened 300G and 350G maraging steels. The aging conditions are also listed in this table. One can see from this table that under-aged 300G steel (SA-U0) has the lowest strength and hardness. It also exhibits the smallest reduction of area which represents the ductility. The increase of keeping time in one-step-aging heightens the static strength of 350G steel to the peak strength obtained at 150 ks. However, when the aging-time is longer than this, softening appears. This result suggests that over-aging is induced by the coarsening of precipitates. Fig. 2 shows the relation of the yield strength and tensile strength with the Vickers hardness. It is well known that the strength measured by tensile tests has a linear relationship with the Vickers hardness, *i.e.*, $\sigma = CH_V$, where C is a numerical constant and generally about 1/3 [9, 10]. As can be seen from solid lines depicted in Fig. 2, this relation is satisfied in the one-step-aged specimens and the value of C becomes 0.334 for yield strength and 0.346 for tensile strength. However the two-step-aged specimens do not exhibit such linear relations in both of the yield and tensile strengths. It has not been clarified why this phenomenon occurs, but the change in hardness seems to be more sensitive to microstructural change than the macroscopic properties obtained by tensile tests.

Table 2 shows the tensile properties and Vickers hardness of 300- and 350G steels

Grade	Aging condition (specification)	Yield strength, σ_y (GPa)	Tensile strength, σ_{max} (GPa)	Reduction of area (%)	Vickers hardness, H_V (GPa)
300	753 K, 48 ks (SA-U0)	2.07	2.16	47	6.21
350	753 K, 11 ks (SA-U1)	2.19	2.23	54	6.52
	753 K, 100 ks (SA-U2)	2.27	2.31	54	6.76
	753 K, 150 ks (SA-P)	2.30	2.44	54	6.91
	SA-P + 673 K, 72 ks (DA-U)	2.33	2.42	52	7.35
	SA-P + 673 K, 400 ks (DA-P)	2.42	2.55	51	7.69
	SA-P + 673 K, 673 ks (DA-O)	2.34	2.44	55	7.35

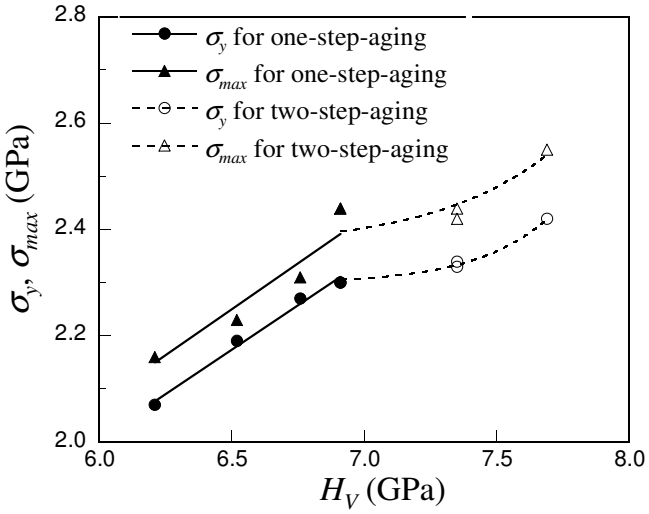

Fig. 2. The relation of yield and tensile strengths with hardness.

3.2 Change in hardness during second-step-aging

Fig. 3 shows the change in hardness with the time of second-step-aging at 473 K and 673 K, which is obtained for SA-P and SA-U0 specimens. The hardness increases very slowly at short time and then rapidly at longer time. SA-P specimen aged at 673 K, however, shows the saturation of hardness increase at 400 ks and the softening due to over-aging at longer time. Instead, the increase

in hardness due to the second-step-aging is retarded in SA-P specimen aged at 473 K, and the saturation of hardness does not appear during the time investigated. The same trend can be seen in SA-U0 specimens aged at 473 K and 673 K, while the increase in hardness occurs earlier than SA-P specimens.

The increase in hardness, ΔH_V, during the second-step-aging is considered to arise from the formation of atmosphere of solute atoms or precipitates due to this aging, as will be mentioned later. It is well known that the evolution of precipitates frequently obeys the Johnson-Mehl-Avrami equation in which the volume fraction of precipitates can be written as [11]

$$f = f_o \{1 - \exp(-kt^n)\}, \quad (1)$$

where f_o is the saturation value of volume fraction, t is time, and k and n are constants. It is believed that the hardening during the second-step-aging till the peak-hardening is caused by the shear-cutting of the newly formed precipitates by mobile dislocations. Thus the increase in hardness may be given by $\Delta H_V = Ar^{1/2}f^{1/2}$, where A is a constant and r is the radius of particles, according to the theory of precipitation hardening [12]. As will be discussed later, the coefficients of lattice diffusion of substitutional solute atoms are too small to contribute to the precipitation at 473 K. Instead their diffusion along dislocations (pipe diffusion) is considered to play a major role in the precipitation at such low temperatures. In this case the particle size is given by [13]

$$r = B\{D_d/(RT)\}^{1/5}t^{1/5}, \quad (2)$$

where B is a constant, D_d is the coefficient of pipe diffusion, R is the gas constant and T is the absolute temperature. Taking into account the incubation time t_i, which appears as the retardation of the hardness increase at 473K, we can obtain the following formula for the increase in hardness.

$$\Delta H_V = \beta(t - t_i)^{1/10}\{1 - \exp[-k(t - t_i)^n]\}^{1/2}, \quad (3)$$

where $\beta = ABf_o\{D_d/(RT)\}^{1/10}$. This equation reproduces the measured values of ΔH_V fairly well in each specimen and for each second-step-aging condition, as is shown by solid curves in Fig. 3.

Table 3 shows the values of parameters in Eq. (3). The values of β and n at 473 K are nearly equal in SA-U0 and SA-P specimens, which suggests that the precipitation proceeds with the same

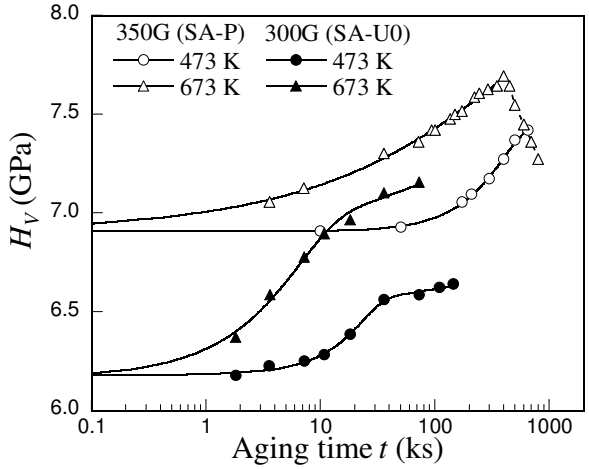

Fig. 3. Change of hardness with time during second-step-aging.

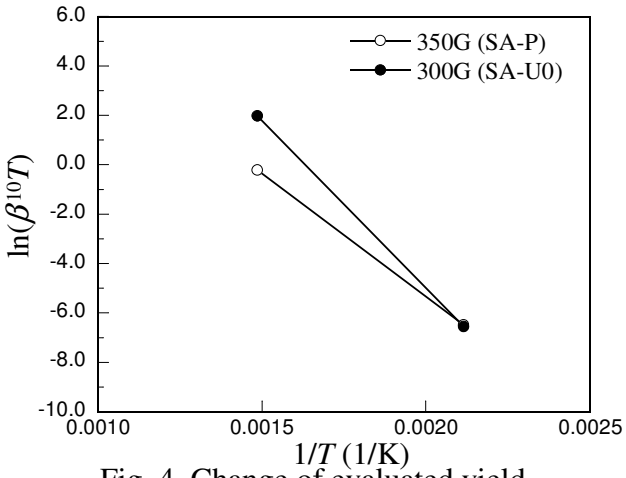

Fig. 4. Change of evaluated yield strength with aging time.

Table 3. The values of parameters in equation (4) and the activation energy of diffusion.

Specimen	T (K)	β (GPa/ks$^{1/10}$)	n	k (/ks^n)	t_i (ks)	Q_d (kJ/mol)
300G (SA-U0)	473	0.281	2.35	4.63 x 10^{-4}	~0	113
	673	0.636	1.44	0.0531	0.02	
350G (SA-P)	473	0.283	2.34	4.37 x 10^{-7}	6.47	82.9
	673	0.511	0.54	0.0377	0.01	

mechanism in both specimens. This trend can be seen at 673 K. However, since the value of n indicates the morphology of precipitates or the precipitation process [11], the smaller values of n at 673 K suggest that the nature of precipitates at this temperature may differ from that of 473 K. It should be also noted that the evaluated incubation time is very small except SA-P specimen aged at 673 K, suggesting that the precipitation starts very quickly. The assumed activation energy of pipe diffusion, Q_d, can be evaluated from the values of $\beta^{10}T$. Fig. 4 shows the Arrhenius plots of $\beta^{10}T$ evaluated for SA-P and SA-U0 specimens. The slopes of straight lines in this figure yield 82.9 kJ/mol and 113 kJ/mol for the value of Q_d in SA-P and SP-U specimens, respectively (Table 3).
These values of Q_d are nearly one third or half of the activation energy of lattice diffusion, Q_l (for instance, Q_l = 244 kJ/mol for Ni in pure Fe), and close to the activation energy of dynamic strain aging in Fe-Ni alloys (~110 kJ/mol) and Fe-Si alloy (125 kJ/mol) measured by Cuddy and Leslie [14]. Cuddy and Leslie suggest that the pipe diffusion of substitutional solute atoms which have large solution-hardening effects contributes to the occurrence of dynamic strain aging, since C atoms in the alloys they used are believed to be removed by the addition of Ti. The contribution of C atoms is also believed to be negligibly small in the maraging steels investigated here, because the content of C atoms is too small to yield the observed increase of hardness and the diffusion coefficients of C atoms at 473 K and 673 K are too large to explain the very slow increase of hardness at these temperatures.

3.3 Dynamic aging during fatigue tests

Fig. 5 shows the *SN* curves of SA-U0 specimen tested at room temperature, 473 K and 673 K. The increase in test temperature markedly increases the fatigue strength in high cycle fatigue region, and the increase of fatigue strength at the number of cycles larger than about 5 x 10^5 seems to be larger at 673 K than at 473 K. These results are in contrary with the fact that the yield strength decreases as the test temperature is increased [5]. In order to reassess the previous data, we use the following formula for the relation of stress amplitude (σ_a) with the number of cycles (N_f).

$$\sigma_a = \sigma_{ao} + k\{(N_f/N_{fo})^{-a} - 1\}^b. \quad (4)$$

Here N_{fo} is a reference number of cycles to failure, σ_a is the fatigue strength at the reference number, k is the strength factor, and a and b are numerical constants. Since the fatigue fracture does not take place at cycles larger than 10^7, as is shown by arrows in Fig. 5, the value of N_{fo} is set to be 10^7. The fatigue limit defined by σ_{ao} is evaluated to be 597 MPa, 745 MPa and 796 MPa at roomtemperature, 473 K and 673 K, respectively. In Fig. 6, the abscissa of Fig. 5 is converted into the time to failure t_f and the extrapolation to low cycle fatigue region is conducted by using Eq. (4). The σ_a-t_f curves of

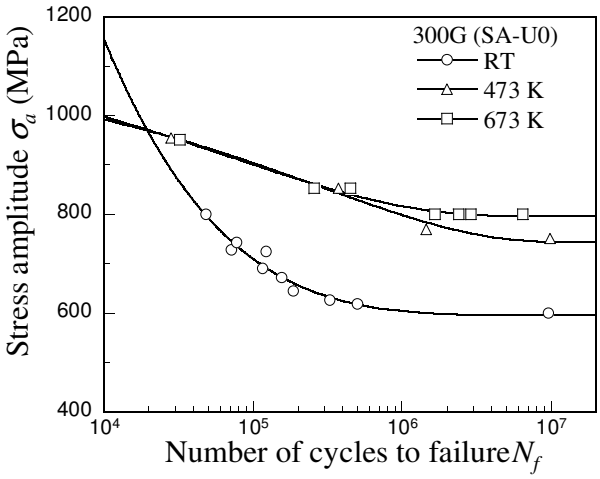

Fig. 5. SN curves of 300G steel tested at room temperature, 473 K and 673 K.

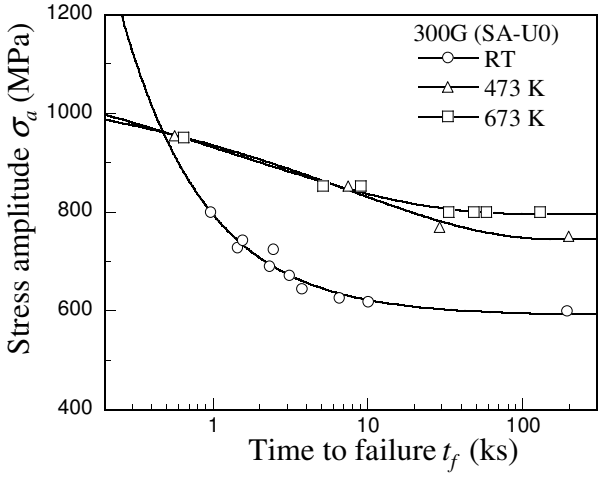

Fig. 6. Relation of stress amplitude with time to failure in 300G steel.

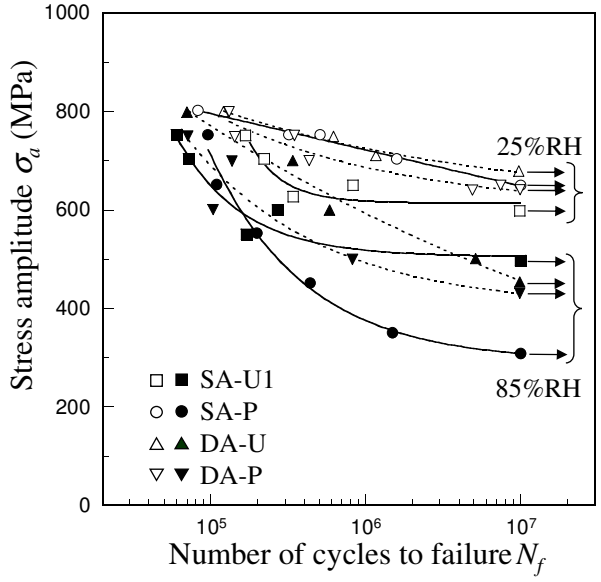

Fig. 7. SN curves of 350G maraging steels in dry and humid airs.

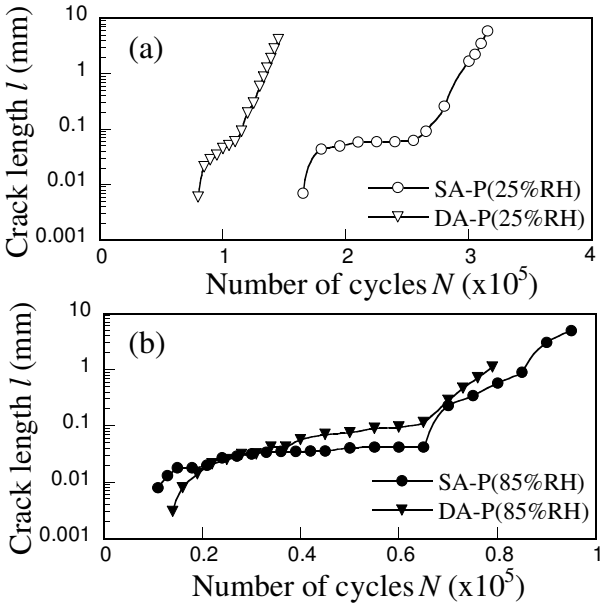

Fig. 8. Crack growth (a) in dry air and (b) in humid air.

473 K and 673 K intersect with that of room temperature at 0.4 ks ($N_f \approx 2$ x 10^4), and the dynamic aging becomes prominent at longer time than this. It also predicts that low cycle fatigue region at shorter time than 0.4 ks shows normal temperature-dependence in which the fatigue strength is lowered by increasing temperature. One can see from Fig. 3 that static aging at 673 K already appears at shorter time than 0.4 ks. However there is no increase in hardness within 2 ks when the second-step-aging is conducted at 473 K, while dynamic aging resulting in the same increase of fatigue strength as that of 673 K starts in much shorter time. These results suggest that the microstructural change at 473 K and 673 K is enhanced with the motion of dislocations during fatigue tests. From the analysis of static aging described in the previous section, it is believed that solute atoms segregate at dislocations and impede their motion. Almost the same increase of stress amplitude at 473 K and 673 K suggests that the atmosphere of solute atoms around dislocations is saturated so quickly as to have the same suppression effect on the motion of dislocations. However, the enrichment of solute atoms may lead to the formation of dense or large precipitates at 673 K for longer duration, which results in larger fatigue limit than that of 473 K as the stress level is lowered.

3.4 Effect of two-step-aging on environmentally assisted fatigue cracking

Fig. 7 shows the *SN* curves of one-step-aged and two-step-aged 350G maraging steel specimens which were tested in the air of 25% RH (dry) and 85% RH (humid) at room temperature [7]. In the dry air, the one-step-aged specimens show larger fracture strength in peak-aging than in under-aging, while fatigue strength is not affected by two-step-aging. Fatigue tests in the humid air, however, result in a marked decrease in fatigue strength, especially at high cycle fatigue region. The one-step-aged specimens exhibit the increase in the susceptibility to the humid air as the aging time increases from under-aging (SA-U1) to peak-aging (SA-P). As a result, the peak-aged specimens showed the lowest fatigue strength. The addition of second-step-aging at 673 K to the SA-P specimens increases the fatigue strength significantly compared to the original value of SA-P specimens.

Cracks are initiated at very small number of cycles in the humid air compared to in the dry air, as demonstrated by Fig. 8. After the initiation stage, cracks grow steadily in both conditions, but the crack growth is accelerated in the humid air. In particular, abrupt crack propagation seems to occur

in SA-P specimen tested in the humid air (Fig. 8(b)), while such abrupt growth does not appear in DA-P specimen. This result suggests that the second-step-aging suppresses the occurrence of abrupt crack growth in the humid air, which may lead to the larger resistance to fatigue cracking than is observed in SA-P specimen (Fig. 7).

3.5 Microstructures

Fig. 9 shows the TEM images of microstructures in DA-U specimen. It is obvious from the bright field image that there are two types of precipitates having rod and spherical shapes, which are homogeneously distributed in grains. The analysis of diffraction patterns show that the rod-shaped particles are Ni_3Ti, as is shown by the dark field image (Fig. 9(b)). The fine particles of spherical shape have much larger density than that of rod-shaped Ni_3(Ti, Mo) particles. These features are common to the specimen one-step-aged to peak-hardening stage (SA-P) and the specimens two-step-aged at 673 K (DA series). The size and number of Ni_3Ti particles do not seem to differ significantly between these specimens.
The electrolyte extraction technique revealed that all of the specimens except SA-U1 specimen contained the particles of Ni_3Ti, Ni_3Mo, Ni_3Al, FeMo and Fe_2Mo [15]. In particular, the fractions of Ni_3Ti, Ni_3Mo and FeMo are much larger than that of Fe_2Mo. However, the contents of these phases were much less in SA-U1 specimen. This suggests that the under-aging state of SA-U1 specimen contains much more solute atoms or finer precipitates of which content cannot be measured by the electrolyte extraction technique. Over-aging at 753 K in one-step-aging led to a drastic decrease in FeMo content and a marked increase in Fe_2Mo instead, though the fractions of Ni_3(Ti, Mo) particles increase very slightly. Thus it is suspected that FeMo particles dissolve and more stable Fe_2Mo particles are formed at longer duration. On the other hand, no significant change was observed in the nature and contents of precipitates between SA-P and DA-P specimens. The similarity in the nature and contents of precipitates was also observed in DA-O specimen and the two-step-aged specimen in which the second-step-aging was conducted at 473 K. These results suggest that the static and dynamic hardening due to the second -step-aging at 473 K and 673 K are caused by very fine microstructures which are not identified by TEM observation and electrolyte extraction technique.

(a) Bright field image and (b) dark field image.

4. Discussion

The present results clearly indicate that the hardness of one-step-aged maraging steels is increased by the addition of static aging at 473 K and 673 K. The rapid increase in fatigue strength within the duration of 0.4 ks at these temperatures also suggests that the microstructural change is promoted by the motion of dislocations. As mentioned in section 3.2, both of the static and dynamic agings are

considered to be related with the precipitation which occurs via the pipe diffusion of substitutional solute atoms. In this case it is considered that the segregation of the solute atoms at dislocations precedes the precipitation at the initial stage of aging. It is well known that the misfit parameters of solute atoms in atomic size and modulus determine the magnitude of the elastic interaction of the solute atoms with dislocations. The analysis of the hardness data of ferrous alloys measured by Stephans and Witzke [16] indicate that Mo atoms have the second largest interaction with dislocations, which is comparable to that of Ti atoms [15]. From the thermodynamical viewpoint, the degree of supersaturation of solute atoms is another significant factor which enhances the segregation at dislocations. According to the phase diagrams of Fe-Mo alloy [17] and Fe-Ti alloy [18], the solubility of Ti and Mo decreases rapidly as the temperature is lowered below 773 K. It is expected that more excess Mo atoms are present during the second-step-aging or the fatigue tests at 473 K and 673 K than Ti atoms, since the content of Mo is much larger than that of Ti in the maraging steels used here. Thus such excess Mo atoms play a predominant role in interacting with dislocations at these temperatures. One can see from Fig. 3 that under-aging state accelerates the increase in hardness due to the following second-step-aging. Since the degree of supersaturation of solute atoms is expected to be larger in the under-aging state, the driving force for the segregation increases.

According to Nitta *et al*. [19] the coefficient of lattice diffusion of Mo in Fe is given by D_{Mo} = 0.0148exp(−282.6 kJ/mol/RT) m^2/s. The diffusion coefficient at 473 K is too small to explain the static and dynamic agings observed at this temperature. The present results rather indicate that the pipe diffusion of solute atoms is attributable to the static aging, as mentioned in section 3.2. It is considered that Mo atoms very close to dislocations migrate to the dislocations with the assistance of their elastic interaction and then diffuse along the dislocations. The stress-induced migration followed by pipe diffusion may serve effectively at 473 K. Thus the evaluated values of Q_d are considered to involve the contribution of stress-induced diffusion of solute atoms close to dislocations. Recently Christien *et al*. [20] have shown by using neutron diffraction that the dislocation density of 4 x 10^{15} /m^2 are generated during martensitic transformation of 17-4PH steel and it is kept nearly constant with increasing aging temperature up to 773 K. The dislocation density measured by them agrees well with 7 x 10^{15} /m^2 in Fe-18mass%Ni evaluated by Nakashima *et al* [3]. Nakashima *et al*. also reported that the dislocation density was lowered to 4 x 10^{15} /m^2 by plastic deformation. Assuming that these results are applicable to the maraging steels investigated here, the mean spacing of dislocations becomes about 16 nm and the stress level between dislocations is 1 GPa. It is therefore considered that such high dislocation density enables the stress-induced and pipe diffusions of solute atoms to operate effectively at low temperatures.

The present results clearly show that hardness is a good measure to get insight into the microstructural change with aging time or testing temperature. Viswanathan *et al*. [21] measured the Rockwell hardness (H_{RC}) of 350G maraging steel aged at temperatures from 673 K to 823 K for various time. In order to compare their result with the present Vickers hardness data, the Rockwell hardness measured by Viswanathan *et al*. is converted into the Vickers hardness in GPa by using the hardness conversion table for steels given in ASTM E140-7. Fig. 10 shows the aging time-temperature-hardness (TTH) diagram deduced from the converted Vickers hardness data. The TTH curves have a nose-shape which is oriented toward higher temperature at shorter time. This indicates the general tendency of aging in which the nucleation and growth of precipitates proceed from the supersaturation of solute atoms to the peak aging and then decomposition and coarsening take place. It should be noted that the hardness increases to its maximum value at 673 K and 1000 ks, as the temperature is lowered. Tewari *et al*. [22] proposed a time-temperature-transformation (TTT) diagram for 350G maraging steel which is shown by broken curves in Fig. 11. The TTT curves proposed by them are conceptual ones and do not present exact profiles. The overlapping of the TTT curves on the TTH contours, however, provides a general trend pertinent to the dependence of hardness on microstructure at temperatures of 673 K ~ 823 K over a wide range of aging time.

The TTT diagram suggests that, at 753 K used as one-step-aging temperature in the present study, Ni_3(Ti, Mo) particles precipitates first and these particles grow accompanying the formation of fine Fe_2Mo particles which leads to the peak hardening. Our microstructural investigation, rather, indicates that Ni_3(Ti, Mo) and FeMo particles with much larger contents than that of Fe_2Mo are attributable to the peak hardening at 753 K. Tewari *et al*. reported that S phase was initially formed at 673 K, which was followed by the precipitation of ω phase in 10 ks. Sha *et al*. [23] found ω phase ($Ni_{47}Fe_{12}Co_1Mo_{40}$) in Fe-Ni-Mo-Co model alloy aged at 687 K for 57 ks by using APFIM. They also showed that Fe_7Mo_6 particles were formed at this aging condition. According to these results, very fine particles of S phase, ω phase and Fe_7Mo_6 are considered to play a major role in the slow hardening at 673 K.

The low-temperature boundaries of TTH curves suggests the possibility that age-hardening continues as the temperature is lowered below 673 K, and it requires longer time with the decrease in temperature. The extrapolation of the boundaries to 473 K, however, does not predict the hardness observed at this temperature. It is rather considered that the solute atoms absorbed at dislocations migrate along them to agglomerate as very fine clusters as the aging time is increased, as shown schematically in Fig. 11. Dissimilar to the aging at 673 K where lattice diffusion may also contribute to the growth of precipitates for prolonged duration, the transition from such clusters to precipitates is considerably retarded at 473 K. In fatigue tests at 473 K, however, dislocations encounter excess solutes atoms during their motion. This leads to the quick formation of solute atmosphere around the dislocation, which in turn impedes the dislocation motion and increases the resistance to fatigue cracking.

It has not been made clear why the second-step-aging improves the fatigue strength in humid air. The specimens tested in 85%RH air showed that cleavage-like facets in several grains were formed at the initiation of cracks and the cracks propagated along lath boundaries, irrespectively of the aging conditions. On the other hand, the crack initiation in 25%RH air was associated with slip in grains, followed by the crack propagation along lath boundaries. These fractographic features obtained in the previous study [24] do not provide the information on the effects of second-step-aging on fatigue cracking. The present results, however, suggest that the increase in fatigue strength in humid air is also closely related with the microstructures formed by the second-step-aging.

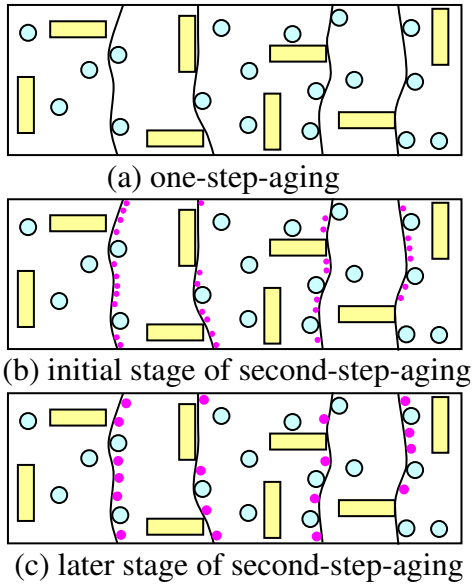

Fig. 11. Segregation and precipitation process during second-step-aging.

5. Summary

In the present study, the effects of the artificial second-step-aging prior to deformation as well as the effects of dynamical aging during deformation in Fe-18Ni maraging steels (300 and 350 grades) were investigated. The analysis of the increase in hardness with aging time in the second-step-aging at 473 K and 673 K showed that the activation energy of second-step-aging is 113 kJ/mol for initially under-aged 300G steel and 82.9 kJ/mol for initially peak-aged 350G steel. This activation energy corresponds to that of the pipe diffusion of solute atoms along dislocations. The solute atmosphere is considered to form around dislocations via the pipe diffusion and impede the motion of dislocations. Particularly the dynamic aging process takes place in the fatigue tests at 473 K and 673 K, of which effect is nearly the same. This also indicates that the fast diffusion of solute atoms to mobile dislocations causes the dynamic aging which improves the fatigue strength markedly. The microstructural observations do not provide clear evidence that new precipitates are formed during the second-step-aging. This fact also is indirect evidence that the evolution of solute atmosphere, very fine clusters or precipitates invisible in TEM are responsible for the hardening during the static and dynamic aging. The improvement in fatigue strength in humid air by the second-step-aging may be correlated closely with the microstructural change and hardening mechanism mentioned above.

Abstract Hydrogen-induced ductility loss in ductile cast iron (DCI) was studied by conducting a series of tensile tests with three different crosshead speeds. By utilizing the thermal desorption spectroscopy and the hydrogen microprint technique, it was found that most of the solute hydrogen was diffusive and mainly segregated at the graphite, graphite/matrix interface zone and the cementite of pearlite in the matrix. The fracture process of the non-charged specimen was dominated by the ductile dimple fracture, whereas that of the hydrogen-charged specimen became less ductile by accompanying the interconnecting cracks between the adjacent graphite nodules. Inside of the hydrogen-charged specimen, the interspaces generated by the interfacial debonding between graphite and matrix are filled with hydrogen gas in the early stage of the fracture process. In the subsequent fracture process, such a local hydrogen gas atmosphere coupled with a stress-induced diffusion attracts hydrogen to the crack tip, which results in a time-dependent ductility loss.

Keywords Hydrogen, Hydrogen embrittlement, Ductile cast iron, Ductility loss

1. Introduction

Ductile cast iron (DCI) is widely used for pipes in city gas pipelines and is a prospective candidate material for hydrogen gas pipes. However, to the authors' knowledge, there exist few studies about the effect of hydrogen on the strength properties of cast irons. On the other hand, with respect to the hydrogen-induced ductility loss in the ferritic or ferritic-pearlitic steels (*e.g.* carbon steels), a number of studies have examined the degradation process in the tensile properties [1-8]. These studies clarified that the ductility loss was mainly attributed to the hydrogen-induced acceleration of the fracture process (*e.g.* nucleation of voids or cracks and their subsequent growth). In addition to the ferritic-pearlitic matrix, DCI contains numerous spheroidal graphites, which can serve not only as stress-concentration sites but also as hydrogen-trap sites. Therefore, the process of hydrogen-induced degradation in cast iron, if any, could be more complex than carbon steels due to the presence of graphites. In this study, as a first attempt to understand the hydrogen effect on the various strength properties of DCI, our focus is primarily on the ductility loss due to internal hydrogen. A unique degradation process associated with solute hydrogen behavior is demonstrated and discussed based on the observations of the fracture process and the microscopic hydrogen segregation behavior.

2. Material and experimental methods

2.1. Material and specimen

The test specimens were cut out from a ductile cast iron pipe that was produced by centrifugal casting. The chemical composition in mass% was 3.70 C, 1.78 Si, 0.34 Mn, 0.058 P, 0.007 S and bal.

Fe. The microstructure was composed of a ferrite/pearlite matrix in conjunction with spheroidal graphites. The volume fraction of each phase, which was measured at a mirror-finished section, was 21 % for pearlite, 15 % for graphite and bal. ferrite. The average value of the Vickers hardness, *HV*, measured with a load of 9.8 N, was 169 in the ferrite section and 217 in the pearlite section. The round bar specimens, having a diameter of 5 mm and a gage length of 30 mm, were used for the tensile tests. The surface of the specimen was finished by polishing with emery papers and then by buffing with an alumina paste.

2.2. Hydrogen-charging, TDS analysis and microscopic visualization of solute hydrogen

The specimens were charged with hydrogen by soaking them in an aqueous solution of 20 mass% ammonium thiocyanate at 313 K for 48 hours. The hydrogen-charged specimens were re-polished before tensile tests to remove the corrosion layer produced by the charging. A number of studies (*cf.* [9-12]) have reported that cast irons as well as steels are vulnerable to surface cracking due to hydrogen-charging. To confirm the presence or absence of a crack in the specimen after the charging, the surface was mirror-polished with buff and then etched with nital. In this study, no crack was detected on the specimen surface.

The hydrogen content in the specimens was measured by the thermal desorption spectroscopy (TDS). Circular disks of 0.8 mm-thick were sliced from the specimen cross section and used for the TDS analysis. The measurements were carried out up to a temperature of 873 K (600 °C) at a heating rate of 0.5 K/s.

The hydrogen emission from the cast iron was visualized by using the hydrogen microprint technique (HMT) [13-15].

2.3. Tensile test

Displacement controlled tests were carried out with three different crosshead speeds (CHSs) of 50, 1 and 0.02 mm/min by using a hydraulically-controlled testing machine in ambient air. By assuming that crosshead displacement is equal to the elongation of the test section, the strain rate $\dot{\varepsilon}$ for each CHS is rendered as 2.8×10^{-2}, 5.6×10^{-4} and 1.1×10^{-5} s^{-1}, respectively. During the experiment, strain was measured with a clip gauge extensometer.

3. Results and discussion

3.1. Hydrogen content in specimen and the desorption behavior

Figure 1 displays the residual hydrogen content, $C_{H,R}$, as a function of the total hold time after hydrogen-charging, Δt. The content decreased gradually while the charged specimen was exposed to ambient air. After 200 hours, the content reduced to the same level of hydrogen content as in the non-charged specimen. From the reduction of hydrogen content, an apparent hydrogen diffusion coefficient at room temperature, D', was estimated by means of Demarez *et al.'s* solution for the hydrogen diffusion from a finite cylinder [16]. The least-square fitting rendered the coefficient to be $D' = 9.1 \times 10^{-13}$ m^2/s, which is relatively smaller than the diffusion coefficient in steels. In the hydrogen-charged specimens, all the tensile tests were initiated within 2 hours after hydrogen-charging, and they were finished within 3 hours after the initiation of the test; *i.e.* around 3-5 mass ppm of hydrogen seemed to be present in the specimen during the tensile test.

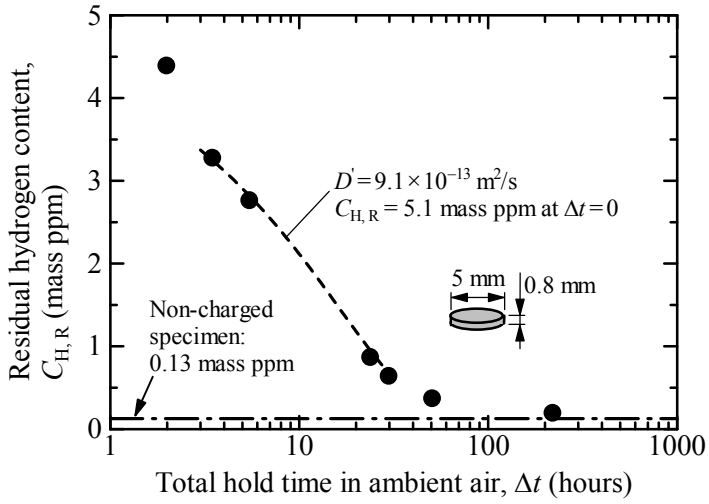

Figure 1. Residual hydrogen content as a function of total hold time in ambient air (Broken line shows the least-square fitting with Demarez et al.'s solution for the hydrogen diffusion from a finite cylinder [16])

3.2. Hydrogen segregation in microstructure

Figure 2 shows the result of HMT observation on a longitudinal section of a hydrogen-charged specimen. Numerous white spots in the photographs represent the silver particles to which the silver bromide particles were reduced by emitted hydrogen. The silver particles were mainly observed at the cross section of graphite nodules as exhibited in Figure 2(a). The particles were also observed along the cementite lamellae in pearlite colonies as shown in Figure 2(b), but were barely observed at ferrite. It is noted that in the non-charged specimens, no hydrogen emission was detected by the HMT.

Figure 3 shows the HMT images on the fracture surface of the hydrogen-charged specimen. The HMT was applied right after the tensile test. As shown, hydrogen emission was observed not only at the graphite nodules, but also at the concaves apart from the graphite nodules. This result implies that a great amount of hydrogen exists at or near the graphite/matrix interface as well as in the graphite itself.

(a) Spheroidal graphite (b) Concave apart from graphite (c) Less ductile surface

Figure 3. HMT images on the fracture surface of the hydrogen-charged specimen (Crosshead speed: 1.0 mm/min)

3.3. Results of tensile testing under different CHSs

Figure 4 displays the engineering stress-strain curves. As demonstrated, hydrogen-charging markedly reduced the percentage elongation after fracture. In addition, Figure 5 illustrates the relationship between the percentage reduction of area (%RA) and CHS. For the sake of more general illustration of the experimental data, the approximated scale of strain rate, $\dot{\varepsilon}$, is additionally indicated on the top of the figure. It is noted that the strain rate was calculated by the CHS divided by the gage length of the specimen. In the non-charged specimen, %RA was nearly constant irrespective of CHS. On the other hand, in the hydrogen-charged specimen, %RA was gradually reduced with a decrease in CHS, *i.e.* a strain-rate-dependent ductility loss was manifested.

3.4. Fracture process

Figure 6 shows the SEM micrographs at the central part of fracture surfaces, and the non-charged (left-hand side) and the hydrogen-charged (right-hand side) specimens are compared. In the non-charged specimens, the ductile fracture with dimples was dominantly observed regardless of CHS. In the hydrogen-charged specimen tested at a CHS of 50 mm/min, the ductile dimple fracture was still dominant, but a small fraction of less ductile fracture surface appeared. In contrast, in the hydrogen-charged specimen tested at a CHS of 0.02 mm/min, the fracture morphology apparently became much less ductile.

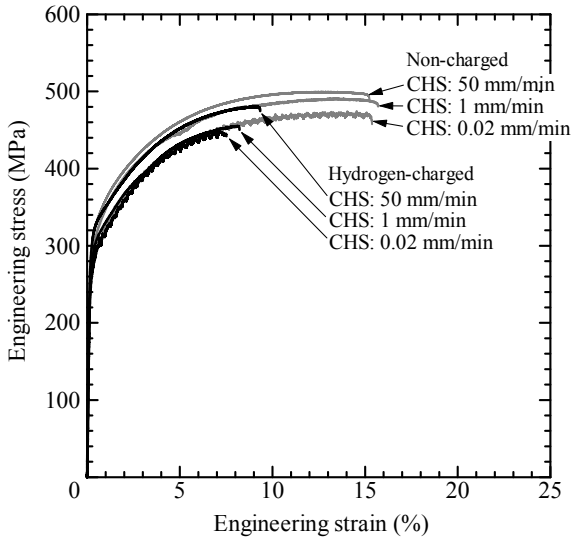

Figure 4. Engineering stress-strain curves

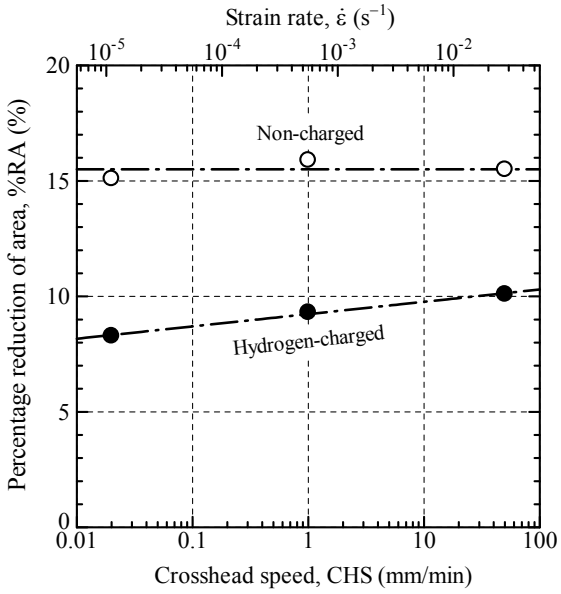

Figure 5. Relationship between the percentage reduction of area and the crosshead speed

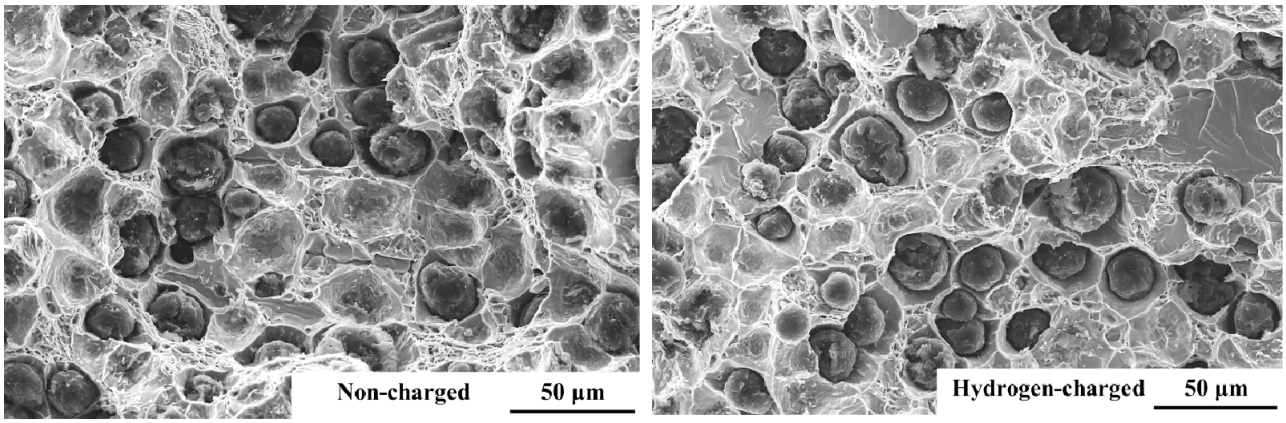
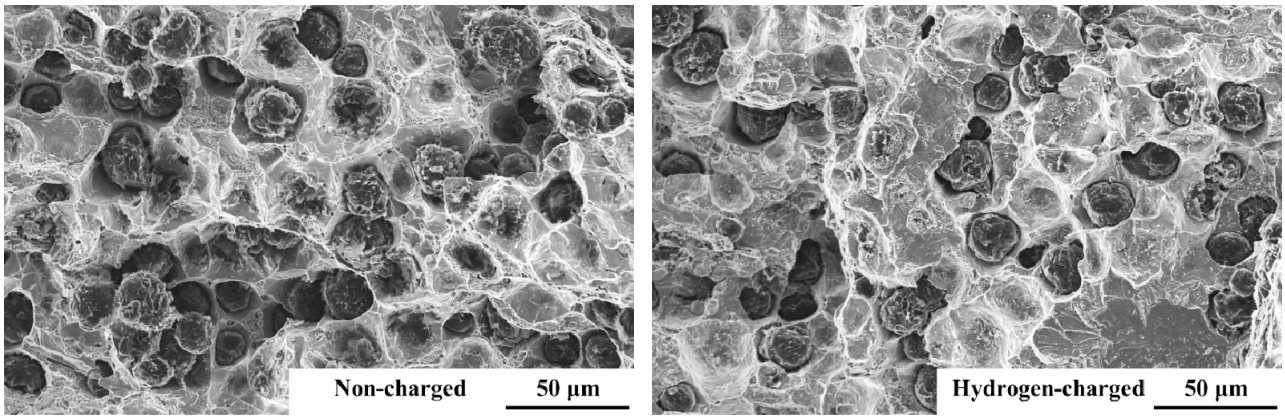
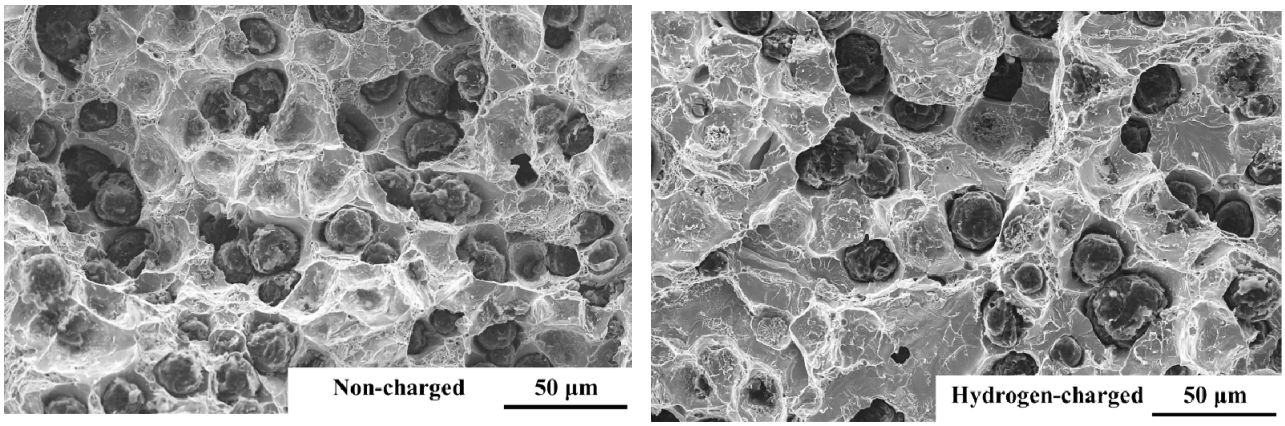


(a) CHS: 50 mm/min ($\dot{\varepsilon} \approx 2.8\times10^{-2}$ s^{-1})

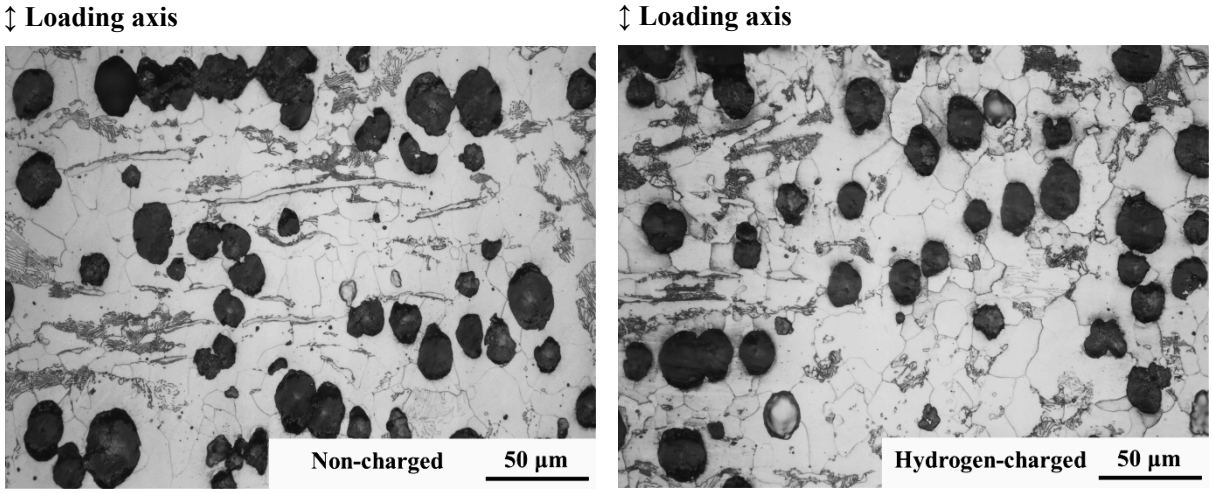


(b) CHS: 1 mm/min ($\dot{\varepsilon} \approx 5.6\times10^{-4}$ s^{-1})

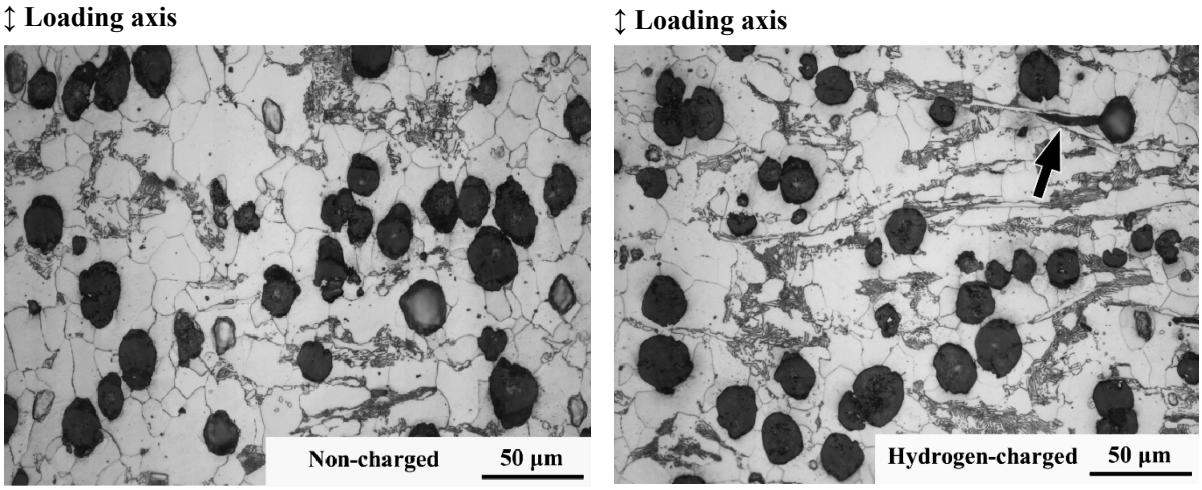


(c) CHS: 0.02 mm/min ($\dot{\varepsilon} \approx 1.1\times10^{-5}$ s^{-1})

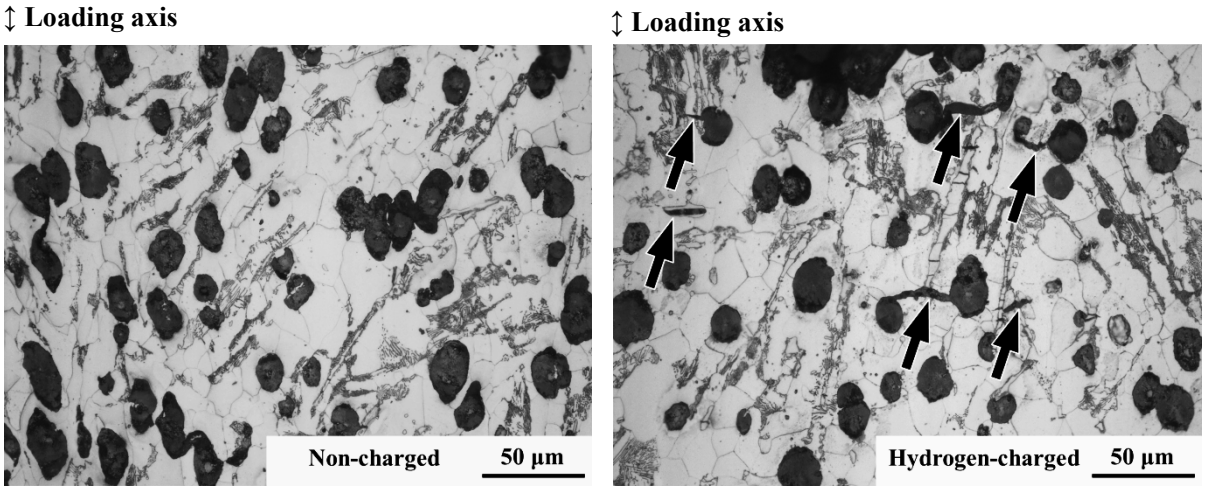
Figure 6. SEM micrographs at the central part of the fracture surfaces (CHS: Crosshead speed)



(a) CHS: 50 mm/min ($\dot{\varepsilon} \approx 2.8\times10^{-2}$ s^{-1})



(b) CHS: 1 mm/min ($\dot{\varepsilon} \approx 5.6\times10^{-4}$ s^{-1})

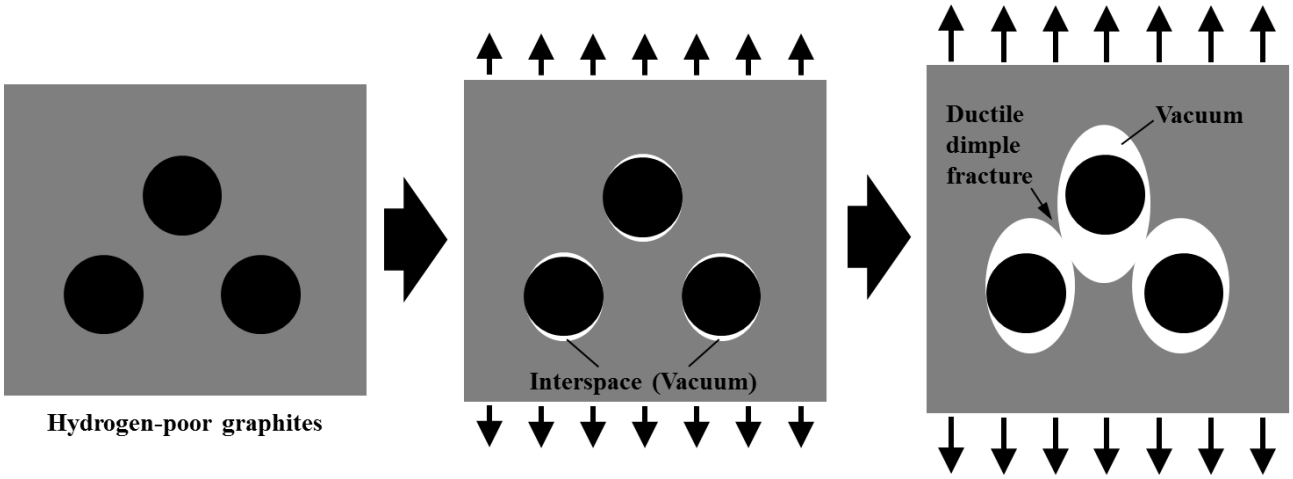


(c) CHS: 0.02 mm/min ($\dot{\varepsilon} \approx 1.1\times10^{-5}$ s^{-1})

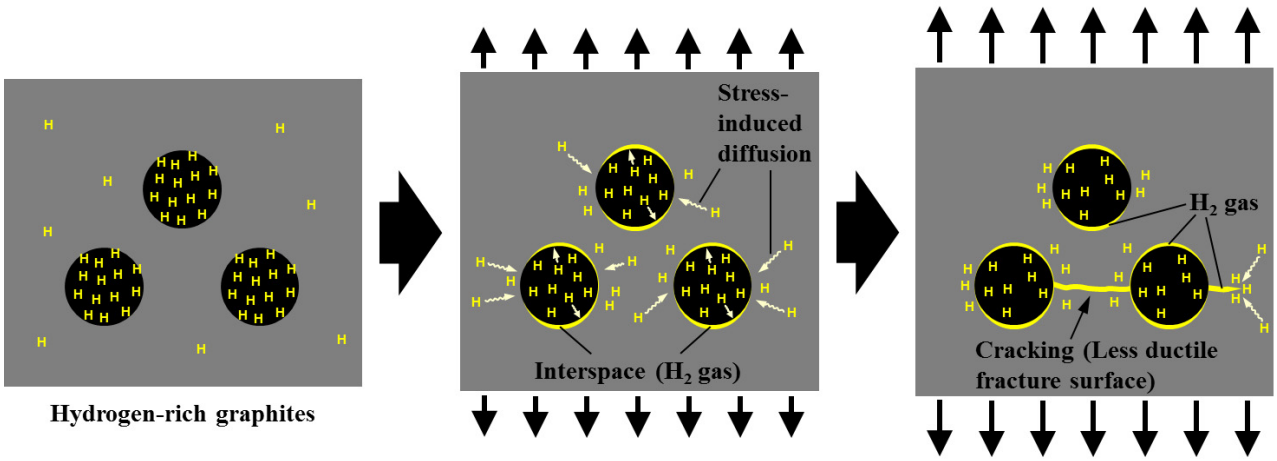
Figure 7. Fracture morphology on the etched cross sections just beneath the fracture surfaces (Arrows indicate interconnecting cracks. CHS: Crosshead speed)

Figure 7 exhibits the fracture morphology on the etched cross sections just beneath the fracture surfaces. In the non-charged specimens (left-hand side), most of the graphites coalesced with each other leading to a typical ductile behavior, regardless of CHS. On the other hand, in the hydrogen-charged specimens (right-hand side), the fracture process was accompanied with the interconnecting cracks between adjacent graphites. This tendency appeared prominently at lower CHS (*cf*. Figure 7(c)).

Figure 8 illustrates two distinct fracture modes in the non-charged and the hydrogen-charged specimens, which were based on the observation of fracture processes. As illustrated for the hydrogen-charged specimen, in the presence of the interconnecting cracks between graphites, less graphite nodules tend to appear on the fracture surface.



(a) Ductile dimple fracture (Non-charged specimen)



(b) Cracking in local hydrogen gas environment (Hydrogen-charged specimen)

Figure 8. Two typical fracture processes in the non-charged and the hydrogen-charged specimens

3.5. Influencing factors for degradation

Considering the hydrogen segregation and fracture process together with the strain-rate-dependent degradation in the hydrogen-charged specimen, it is possible to postulate the role of graphite in the degradation process as follows. In the deformation process of the non-charged specimen, an interspace generated by interfacial debonding between graphite and matrix maintains a vacuum environment. In this case, the surrounding matrix material can be relatively ductile; thereby, the fracture surface exhibits the dimple fracture accompanied with the interconnection of graphites (*cf*. Figure 8(a)). On the other hand, in the hydrogen-charged specimen, a great amount of hydrogen exists at or near the graphite/matrix interface zone, as illustrated by Figures 2 and 3. Therefore, in the early stage of the fracture process, the interspace between graphite and matrix is immediately filled with hydrogen gas (*cf*. Figure 8(b)). It is noted that the hydrogen in the interspace is of molecular in nature. Then, a certain amount of hydrogen as atom can spread into the surrounding matrix near the graphite nodule. Simultaneously, the stress-induced hydrogen diffusion inside the matrix can also contribute to increase the hydrogen concentration near the graphite. It has been shown that solute hydrogen enhances a localization of plasticity [17, 18], which hinders the formation of ductile dimple by facilitating the cracking [5-7, 17]. After the crack initiation from a graphite nodule, hydrogen is incessantly outgassed from the inside of the graphite nodule and supplied to the crack tip via the local hydrogen gas environment. The stress-induced hydrogen diffusion can also attract a certain amount of hydrogen to the crack tip. Such a process results in the localization of plasticity at the crack tip and thereby facilitates the crack growth [17]. As a consequence, smaller CHS enables more hydrogen to be concentrated to the crack tip. This time-dependent process causes the ductility loss associated with a decrease in CHS only for the hydrogen-charged specimen.

As was discussed, the DCI possesses the unique characteristics regarding the influence of hydrogen. Therefore, for proper evaluation of the hydrogen-induced degradation in DCI, the pivotal role of graphites as a *local hydrogen supplier* should be taken into consideration.

4. Conclusions

The effect of hydrogen-charging on ductility loss in the ductile cast iron (DCI) was investigated by conducting a series of tensile tests with three different crosshead speeds (CHSs). According to the present study, the following conclusions were obtained:

(1) Hydrogen-charging led to a marked decrease in the percentage reduction of area (%RA). In the non-charged specimens, %RA was nearly constant irrespective of CHS, whereas in the hydrogen-charged specimens, %RA was reduced with a decrease in CHS.

(2) Thermal desorption spectroscopy (TDS) and the hydrogen microprint technique (HMT) revealed that most of solute hydrogen in the hydrogen-charged specimen was diffusive, and they were mainly segregated at the graphite, graphite/matrix interface zone and the cementite of pearlite.

(3) Hydrogen-charging accelerated the coalescence of graphites during the fracture process. In the non-charged specimen, the fracture process involved the ductile dimple fracture associated with the coalescence of neighboring graphites. On the other hand, in the hydrogen-charged specimen, the fracture process involved interconnecting cracks between neighboring graphites, which appeared prominently at lower CHS.

(4) The variation in fracture morphology is attributed to a great amount of hydrogen stored in the

graphite and graphite/matrix interface zone. In the early stage of the fracture process in the hydrogen-charged specimen, the interspace generated by interfacial debonding between graphite and matrix is filled with hydrogen gas, which hinders the formation of ductile dimple by facilitating the cracking. Even in the subsequent fracture process, hydrogen is incessantly emitted from graphites. Such a local hydrogen gas atmosphere coupled with a stress-induced hydrogen diffusion inside the material attracts hydrogen to the crack tip. Accordingly, the delayed hydrogen supply causes the time-dependent degradation. To evaluate the hydrogen-induced degradation in DCI, the pivotal role of graphite as a *local hydrogen supplier* should be taken into consideration.

Abstract The size effect of the threshold stress intensity K_{TH} for hydrogen-precharged specimens of SAE52100 were investigated. Four types of tensile specimens were used: (i) smooth specimens and (ii) specimens having various shapes of artificial defects with sizes of about 35 ~ 500 μm. In the smooth specimens, fracture origins were nonmetallic inclusions with the size of 10 ~ 30 μm (*e.g.* $Al_2O_3{\cdot}(CaO)_x$, TiN and TiC). The fracture toughness determined for the small defects at fracture origin, *i.e.* the K_{TH} calculated from the defect size $\sqrt{area}$ and the fracture tensile stress σ_f, showed a defect size dependence, where, *area* denotes the area of the domain defined by projecting the defect on a plane normal to the cylindrical axis of the specimen. The values of K_{TH} for both the nonmetallic inclusions and artificial defects were much smaller than those for large cracks measured by the standard WOL and CT specimens.

Keywords Threshold stress intensity, Defect size, Nonmetallic inclusion, Hydrogen embrittlement, High strength steel

1. Introduction

Hydrogen causes degradation of various strength properties, such as tensile strength, ductility, fatigue strength, fracture toughness and *etc*. [1-3] Among them, the fracture toughness such as K_{IC} and J_{IC} is recognized as one of the most important property for the structural integrity of high-pressure hydrogen storage vessels and hydrogen supply systems. Moody *et al.* [4] showed how the fracture toughness K_{TH} of low alloy steels varies with yield strength and hydrogen pressure. Figure 1 schematically shows the relationship between K_{TH} of a steel in hydrogen gas as a function of the yield strength σ_{YS} [1]. Once σ_{YS} exceeds about 1500 MPa, K_{TH} reachs a lower limit between 10 and 20 MPa$\sqrt{\text{m}}$. Similar results on the hydrogen effect on the fracture toughness have been reported also by the other researchers [5 and others].

In most cases, K_{TH} for various materials has been measured for *large cracks* by using standard specimens, *e.g.* WOL and CT. On the other hand, in order to evaluate the effect of small defects on the fracture toughness of high strength steels, Murakami *et al.* [6] carried out a series of tensile tests using hydrogen-precharged (H-precharged) specimens. They determined the K_{TH} values from the fracture stresses and sizes of the nonmetallic inclusions at fracture origins. They reported the followings:

(i) K_{TH} was decreased with an increase in the residual hydrogen content in the material.
(ii) K_{TH} was decreased with a decrease in the defect size. This crack size dependence was similar to that of ΔK_{th} for the small fatigue crack or defect [7, 8].

Above experimental facts caution that the use of the threshold values measured for the *large cracks* leads to an unconservative estimation in the fracture toughness design against *small cracks* or *small defects*. However, the significance of the size effect has not been well recognized despite the presence

of detrimental flows, *e.g.* nonmetallic inclusions and small fatigue cracks, in the real components [9].

In this study, for a more extended understanding of the defect size dependence on the fracture toughness of H-precharged high strength steels, tensile tests of SAE52100 were carried out using specimens having various shapes of artificial surface defect with sizes of about 35 ~ 500 μm. The smooth specimens were also tested to investigate the fracture toughness for subsurface nonmetallic inclusions with sizes of about 10 ~ 30 μm.

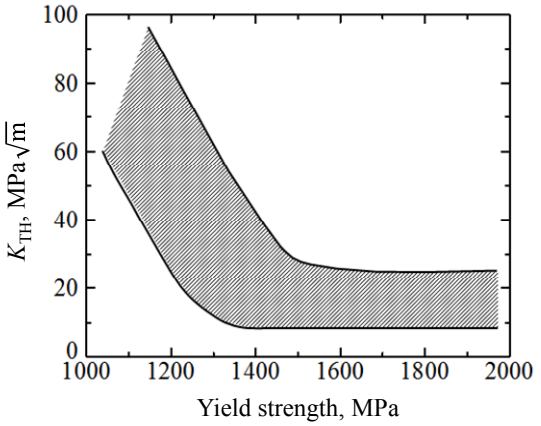

Figure 1. Schematic relationship between the threshold stress intensity factor K_{TH} of a steel in hydrogen gas as a function of the yield strength σ_{YS} [4]

2. Experimental

2.1. Material and specimen

A commercial grade SAE52100 bearing steel was used. The chemical composition in mass% is 1.00 C, 0.26 Si, 0.38 Mn, 0.013 P, 0.001 S, 0.10 Cu, 0.08 Ni, 1.40 Cr, 0.03 Mo, 0.0016 Ti, 0.0005 O and bal. Fe. The steel was heat-treated so that he average Vickers hardness, *HV*, measured with a load of 9.8 N had 712.

Figure 2 shows the shape and dimensions of specimen. In some specimens, the following four types of artificial defects with various sizes were introduced onto the specimen surface; (i) a rectangular slit made by the focused ion beam (FIB) technique, (ii) a semi-circular slit made by the electrical discharging, (iii) a drilled hole which has crack-like thin slits made by the FIB technique and (iv) a hole made by the electrical discharging having the FIB slits. Figure 3 shows the shapes and dimensions of the defects, which are designated as Type A ~ D, respectively.

2.2. Hydrogen precharging (H-precharging) and Tensile testing

The specimens were charged with hydrogen by soaking them in an aqueous solution of 20mass % ammonium thiocyanate at 313 K for 48 hours.

Displacement controlled tests were carried out under a crosshead speed V of 1 mm/min corresponding to the strain rate $\dot{\varepsilon}$ of about 6.5×10^{-5} s^{-1} by using a hydraulically-controlled testing machine in ambient air. All the tensile tests were initiated within 2 hours after the charging. The *time after the H-precharging* means the total hold time in ambient air.

2.3. Measurement of hydrogen content

After each tensile test, the residual hydrogen content $C_{H,R}$ in the specimen was measured by the thermal desorption spectroscopy (TDS). Right after the final fracture of the specimen, circular disks of 2.0 mm-thick were sliced from the broken specimen and used for the TDS analysis.

2.4. Characterization of fracture origins and nonmetallic inclusion rating

The size of the defect was represented by the $\sqrt{area}$, where *area* denotes the area of the domain defined by projecting the crack or defect on a plane normal to the cylindrical axis of the specimen [7, 8, 10].

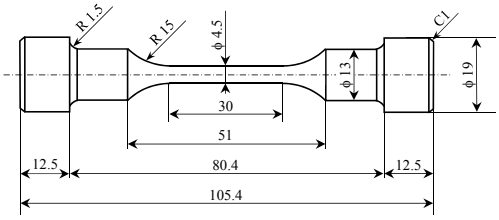

Figure 2. Shape and dimensions of test specimen in mm (Control volume: V_s = 477 mm^3)

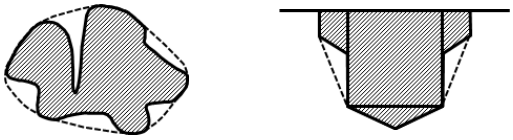
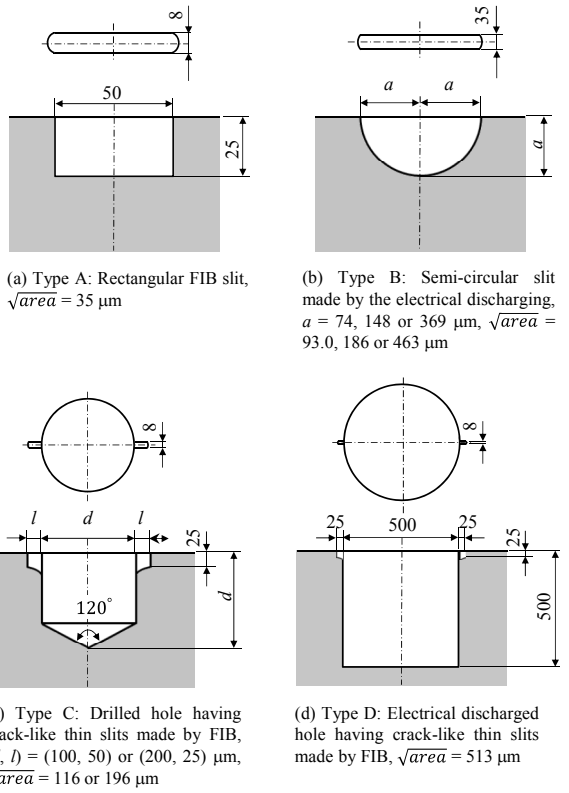


(a) Non-metallic inclusion (b) Artificial defect

Figure 4. Irregularly shaped defects and estimation method for effective area [8]



(a) Type A: Rectangular FIB slit, $\sqrt{area}$ = 35 μm

(b) Type B: Semi-circular slit made by the electrical discharging, a = 74, 148 or 369 μm, $\sqrt{area}$ = 93.0, 186 or 463 μm

(c) Type C: Drilled hole having crack-like thin slits made by FIB, (d, l) = (100, 50) or (200, 25) μm, $\sqrt{area}$ = 116 or 196 μm

(d) Type D: Electrical discharged hole having crack-like thin slits made by FIB, $\sqrt{area}$ = 513 μm

Figure 3. Shapes and dimensions of artificial defects

The effective area for the defect size $\sqrt{area}$ was estimated by considering a contour which envelopes the original irregular shape of the defect, as shown in Fig. 4 [8].

A newly proposed inclusion rating method [11] based on the statistics of extremes was used.

3. Results and discussion

3.1. Hydrogen content in specimen and the desorption behavior

Figure 5 shows the hydrogen thermal desorption spectra for the H-precharged specimen [12]. Figure 6 displays the residual hydrogen content, $C_{H,R}$, as a function of the total hold time after the charging, Δt, in laboratory air. The content decreased gradually with the hold time. After 100 hours, the content reduced to almost the same level of hydrogen content as in the non-charged specimen. From the reduction of hydrogen content shown in Fig. 6 [12], an apparent hydrogen diffusion coefficient at room temperature, D', was estimated by means of Demarez *et al.'s* solution [13]. The least-square fitting rendered the coefficient to be $D' = 8.6 \times 10^{-13}$ m^2/s. In the H-precharged specimens, all the tensile tests were initiated within 2 hours after the charging, and they were finished within 2 minutes after the initiation of the test; *i.e.* around 4 mass ppm of hydrogen seemed to be present in the specimen during the tensile test.

3.2. Fracture data and fracture origins

Figure 7 shows examples of the uniaxial tension stress-strain curves [12]. All the H-precharged specimens failed at a much lower stress as compared to the non-charged specimens irrespective of the presence or absence of the artificial defect, as shown in Fig. 7, *i.e.* the so-called *hydrogen embrittlement* was demonstrated in the H-precharged specimens. Moreover, the presence of an artificial

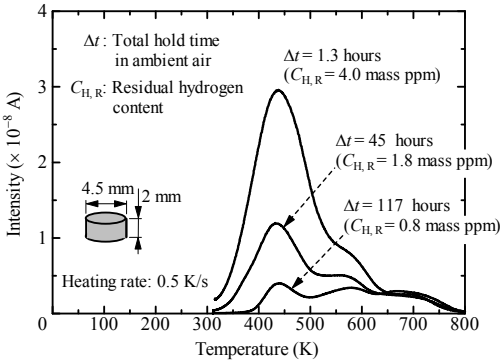


Figure 5. Hydrogen thermal desorption spectra for the hydrogen-charged specimen [12]

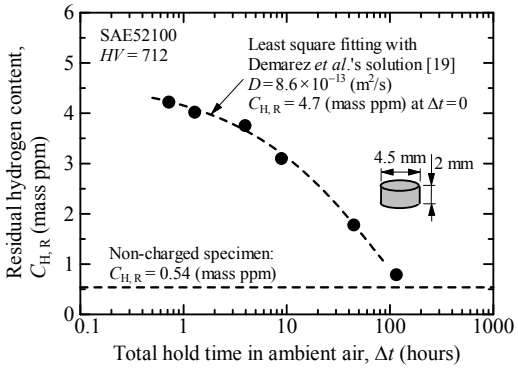

Figure 6. Residual hydrogen content as a function of total hold time in ambient air [12]

defect significantly decreased the nominal stress at the final fracture of specimen, σ_f, which was decreased with an increase in the defect size.

Table 1 lists the chemical compositions of all the inclusions at fracture origin together with a series of experimental data. The inclusion size $\sqrt{area}$ ranged from about 10 to 30 μm. The fracture processes of specimens originated from two types of inclusions, *i.e.* $Al_2O_3 \cdot (CaO)_x$ and TiN, has been reported in a separate paper [6]. Figure 8 illustrates crack initiation processes from the two kinds of nonmetallic inclusions in the non-charged and H-precharged specimens [6]. In an early stage of the fracture process from the $Al_2O_3 \cdot (CaO)_x$ type inclusion, an interfacial cracking occurs at the pole of the inclusion/matrix interface where the tensile stress becomes maximum owing to a large modulus of the inclusion. Subsequently, the complete separation of the interface between the inclusion and matrix creates a spherical-like cavity, which shifts the location of the highest tensile stress from the pole to the equator of the cavity. On the other hand, the fracture process from the TiN type inclusion is initiated by the cracking of inclusion itself. These processes for two types of inclusions take place while the overall deformation of the specimen is elastic as shown in [6].

Figure 9 [12] shows the statistics of extremes distribution of nonmetallic inclusions at the fracture origin of the H-precharged tensile specimens, where y' is the reduced variant, F is the cumulative distribution fraction and T' is the return period. The distribution of the extreme value $\sqrt{area}_{max}$ shows a good linearity and provides a justification for the use of the distribution of extremes.

In the H-precharged specimens having artificial defect, the fracture was originated from the defect. It is worth noting that there was an exception, *i.e.* the fracture of the specimen having the smallest artificial defect (*cf.* Fig. 3(a)) was not originated from the artificial defect but from a nonmetallic inclusion, though the size of the inclusion was definitely smaller than that of the artificial defect,

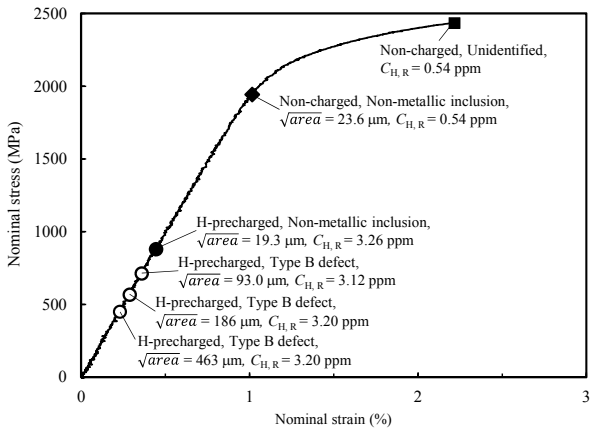

Figure 7. Example of the stress-strain curve and fracture points

as compared in Table 1 [12]. This is due to the non-uniform distribution of hydrogen concentration in the specimen from the surface to the center.

3.3 Dependence on the threshold stress intensity on defect size and hydrogen concentration

In order to quantitatively characterize the hydrogen effect together with the defect size dependence on the fracture toughness, the fracture data will be analyzed in terms of the macroscopic fracture stress σ_f, the defect size $\sqrt{area}$ and the residual hydrogen content $C_{H,R}$.

3.3.1. Smooth specimens

Firstly, we associate the fracture stress σ_f with K_{TH} for the onset of a crack from a spherical inclusion. After the interfacial debonding between inclusion and matrix, the spherical inclusion can be regarded as a traction free cavity (*cf.* Fig. 8). Figure 10 shows the normalized stress intensity factor $K_I/\sigma_0\sqrt{a'+\lambda}$ for a crack emanating from an ellipsoidal cavity as a function of the parameter λ/a',

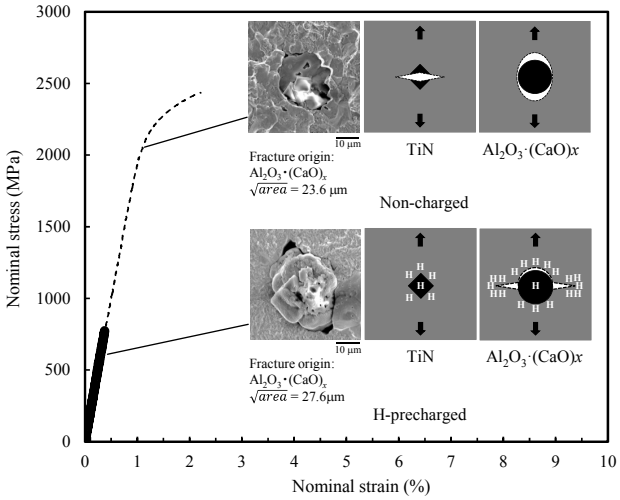

Figure 8. Illustration of crack initiation processes from two kinds of non-metallic inclusions [6]

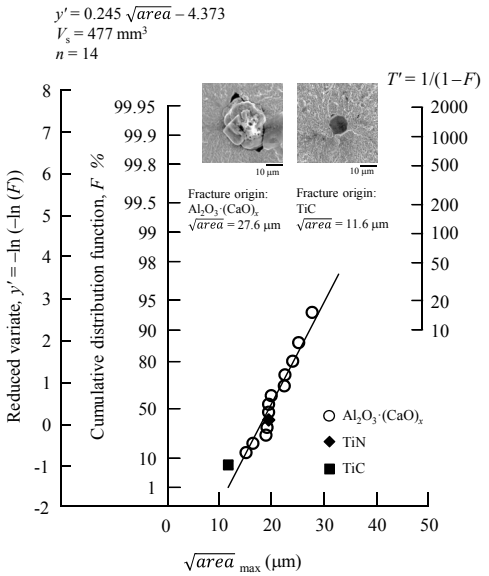

Figure 9. Statistics of extremes distribution of inclusions at the fracture origin [12]

where σ_0 is the remote tensile stress, a' is the large semi-axis of the ellipsoid and λ is the crack length measured from the equator of the ellipsoid [15]. As shown in Fig. 10, K_I for a crack with λ/a' of 0.2 is approximately equal to the stress intensity factor for a penny shaped crack with the radius of $a'+\lambda$. By considering such a steep growth in K_I value together with the presence of the interfacial cracking or cracked inclusion in the early stage of the fracture process (*cf.* Fig. 8), it can be deemed that the ellipsoidal nonmetallic inclusions are mechanically equivalent to a penny-shaped crack. Such an equivalence has experimentally been confirmed for the small fatigue cracks and defects [7, 8, 10]. Accordingly, we approximate K_{TH} in terms of σ_f and the inclusion size as follows:

$$K_{TH} = (2/\pi)\ \sigma_f \sqrt{\pi a'} \tag{1}$$

As illustrated in Fig. 8, most of the $Al_2O_3\cdot(CaO)_x$ type inclusions yield a spherical-like cavity [6]. The shape of the cavity is determined by the inclusion shape, which is not perfectly spherical but is irregular in nature. Also in the case of the TiN type inclusion, the shape of the original crack generated

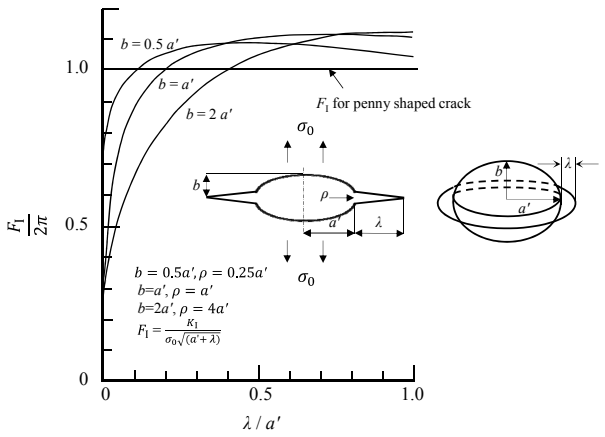

Figure 10. Normalized stress intensity factor for an annular crack emanating from an ellipsoidal cavity [15]

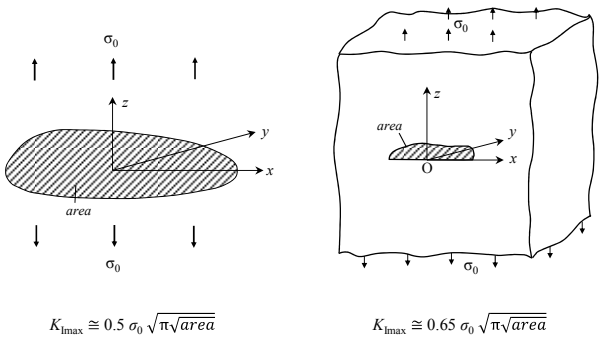


(a) Internal crack (b) Surface crack

Figure 11. Stress intensity factor for planer cracks with arbitrary shapes [7, 8, 10]

by the cracking of inclusion itself is not circular but somewhat angular in accordance with the inclusion shape. Hence, we approximate the cracks forming at nonmetallic inclusions as planar cracks by projecting the 3-D shape of the inclusion onto the plane perpendicular to the tensile axis of the specimen [7, 8, 10]. For a planar internal crack with arbitrary shape under tension shown in Fig. 11(a), K_{Imax} along the crack front is approximately given by [7, 8, 10].

$$K_{\mathrm{Imax}} = 0.5\sigma_0\sqrt{\pi\sqrt{area}} \tag{2}$$

Thus, K_{TH} for H-precharged smooth specimens associated with K_{Imax} is expressed by

$$K_{\mathrm{TH}} = 0.5\sigma_{\mathrm{f}}\sqrt{\pi\sqrt{area}} \tag{3}$$

K_{TH} obtained through this equation yields a magnitude which differs from that of Eq. (1) for the perfectly penny-shaped crack by only about 4%. All the fracture data are listed in Table 1.

The primary objective in this study is to determine the initiation threshold K_{TH} for the onset of crack propagation from small cracks in components exposed to high pressure hydrogen gas. It is well known in metal fatigue that ΔK_{th} for small cracks is not a material constant; ΔK_{th} for small cracks is smaller than that for long crack [7, 8, 10, 16]. In this study, we will explore whether such a size dependence exists or not in the case of small cracks in H-precharged specimens under static loading. Figure 12 shows K_{TH} plotted respectively against the inclusion size $\sqrt{area}$ and the residual hydrogen content measured right after the final fracture of each specimen $C_{\mathrm{H,\,R}}$ [12]. Regardless of some visible scatter in the experimental data in Fig. 12, one can note the following trends:

- K_{TH}, decreases with an decrease in the inclusion size $\sqrt{area}$.
- K_{TH}, decreases with an increase in the residual hydrogen content $C_{\mathrm{H,\,R}}$.

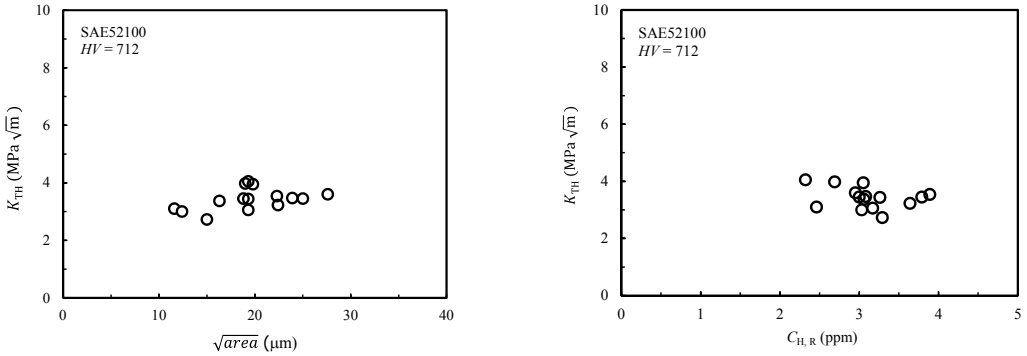
By means of these two dominant factors, the experimental data shown in Fig. 12 can be linearly interpolated by

$$K_{\mathrm{TH}} = 3.89 + 0.0555\sqrt{area} - 0.494C_{\mathrm{H,\,R}} \tag{4}$$

Where, $\sqrt{area}$ is in μm and $C_{\mathrm{H,\,R}}$ is in mass ppm. Figure 13 replots the data in Fig. 12 modified based on Eq. (4) [12]. Equation (4) is expressed as a linear function of $\sqrt{area}$ and $C_{\mathrm{H,\,R}}$, because the variation range of these variables are small such as 10-30μm of inclusion size. However, the equation applicable to wider variation range of these variables must be reconstructed as described later.

The reason for the dependence of K_{TH} on the inclusion size is explained as follows. Recall that the distribution of tensile stress along the axis of symmetry (x direction) ahead of the crack of length $2a$ in an infinite plate under remote tensile stress σ_0 in the y direction is described by

$$\sigma_{\mathrm{yy}} = \frac{\sigma_0 x}{\sqrt{x^2 - a^2}} \tag{5}$$



(a) K_{TH} as a function of $\sqrt{area}$ (b) K_{TH} as a function of $C_{H,R}$

Figure 12. K_{TH} data plotted respectively against $\sqrt{area}$ and $C_{H,R}$ [12]

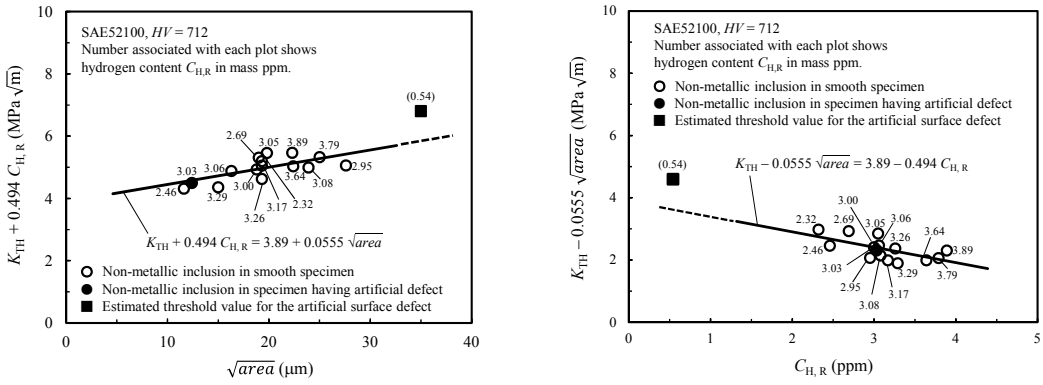


Figure 13. Threshold K_{TH} for SAE52100 expressed in terms of $\sqrt{area}$ and $C_{H,R}$ [12]

Particularly for very small distances, r, from the crack tip along the axis of symmetry, Eq. (5) yields

$$\sigma_{yy} = \frac{K_I}{\sqrt{2\pi r}} \tag{6}$$

Where, $K_I = \sigma_0 \sqrt{\pi a}$ is the stress intensity factor. Figure 14 shows an example of the comparison of stress field ahead of the tip of two different sizes of cracks under a stress intensity factor K_I of 10 MPa$\sqrt{m}$ which were obtained by Eq. (5). In both cases, σ_0 was determined so that K_I is equal to 10 MPa$\sqrt{m}$. In the *large crack* (*e.g.* $2a$ = 20 mm), the singular stress field decays very fast from the crack tip. In this case, Eq. (5) can be well represented by Eq. (6) to characterize the stress field near the crack tip. On the other hand, in the *small crack* (*e.g.* $2a$ = 0.02 mm), a large discrepancy arises between the stress fields in these two cracks. Such a discrepancy in the stress field near crack tip between small crack and large crack also arises even if the material is not the perfectly elastic but the elastic-plastic. For this reason, the tensile stress field ahead of the tip of small crack cannot be determined uniquely through the stress intensity factor alone, and therefore the calculated threshold values for small cracks show a crack size dependence.

3.3.2. Specimens having artificial surface defects

For a planar cracks with arbitrary shape at specimen surface (*cf.* Fig. 11(b)), K_{Imax} along the crack front can be approximated by [7, 8, 10].

$$K_{\mathrm{Imax}} = 0.65\sigma_0\sqrt{\pi\sqrt{area}} \tag{7}$$

Thus, considering the mechanical equivalence between small crack and defect as discussed in the previous section, K_{TH} for surface defects associated with K_{Imax} is expressed by

$$K_{\mathrm{TH}} = 0.65\sigma_{\mathrm{f}}\sqrt{\pi\sqrt{area}} \tag{8}$$

Figure 15 shows the K_{TH} values both for the artificial surface defects and nonmetallic inclusions as a function of the defect size $\sqrt{area}$ [12]. The data are shown in a double logarithmic diagram, as has widely been used for the arrangement of ΔK_{th} data of the small fatigue cracks [7, 8, 10, 16]. It is well known that in fatigue crack the threshold stress intensity factor range ΔK_{th} has the following relation with the defect size in the small crack regime, *e.g.* $\sqrt{area} < 1$ mm.

$$\Delta K_{\mathrm{th}} \propto (\sqrt{area})^{1/3} \tag{9}$$

Also in the present results for K_{TH}, we can see a definite size dependence in the range between about 10 and 500 μm in Fig. 15, *i.e.* K_{TH} was reduced with a decrease in $\sqrt{area}$. However, the exact dependence of the threshold value on the defect size is not clear at present since the threshold value can be varied also with the hydrogen concentration at the location of fracture origin, as will be discussed in the next section. As a reference data, in Fig. 15, the shaded area shows the Moody *et al.*'s K_{TH} data for a large crack in the standard CT and WOL specimens of AISI4340 steel with the yield strength σ_{YS} of 1500 ~ 1900 MPa, which was determined from tests in hydrogen gas, NaCl solutions and H-precharged specimens [4]. The values of K_{TH} for both the nonmetallic inclusions and artificial defects were definitely smaller than those for the large cracks, though the effect of some influencing factors, *e.g.* material type, strength level, hydrogen content, strain rate *etc*., should further be clarified in the future.

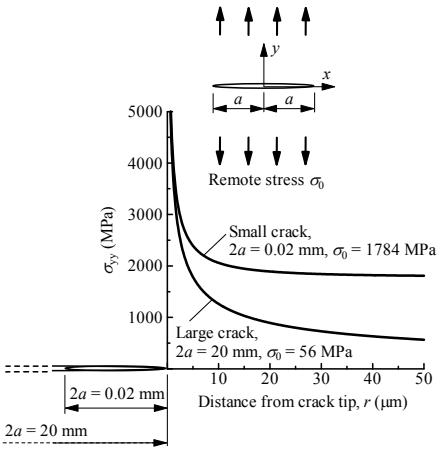

Figure 14. Comparison of stress field ahead of tip of *large* and *small* cracks under a stress intensity factor $K_{\mathrm{I}} = 10$ MPa$\sqrt{\mathrm{m}}$

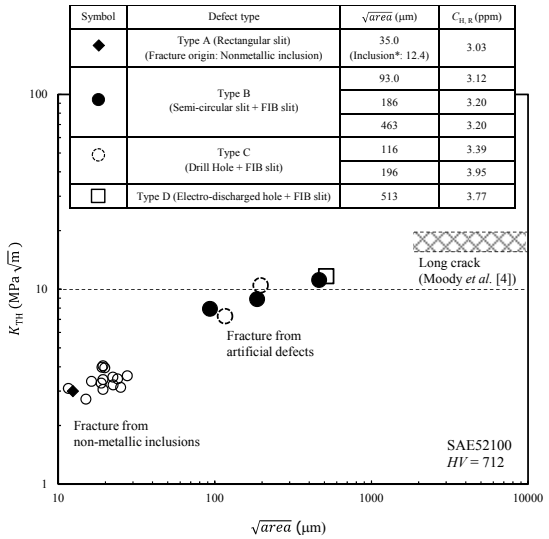

Figure 15. Relationship between K_{TH} and $\sqrt{area}$ for both short and long cracks in SAE52100. ◆: The specimen had the artificial defect, but was fractured from a non-metallic inclusion [12]

4. Conclusions

A series of uniaxial tensile tests of a H-precharged SAE52100 steel were carried out to determine the fracture toughness for the failure originated from nonmetallic inclusions and small artificial defects. The results are summarized as follows:

(1) All the H-precharged specimens failed in the elastic regime irrespective of the presence or absence of the artificial defect.
(2) In the smooth specimens, fracture origins were nonmetallic inclusions with the size of 10 ~ 30 μm (*e.g.* $Al_2O_3{\cdot}(CaO)_x$, TiN and TiC).
(3) Fracture of specimens having the artificial defect with sizes of about 100 ~ 500μm were originated from the defects.
(4) The threshold intensity factor K_{TH} was decreased with a decrease in defect size in the small crack regime. The values of K_{TH} for small defects were much smaller than those for large cracks in the standard specimens such as CT and WOL. For the safer design against the fracture toughness for small cracks, the crack size dependence should be taken into consideration.

Abstract Fatigue crack growth rates in different notched fiber metal laminates under constant amplitude fatigue loading were studied experimentally and numerically. An modified numerically approach was used for predicting the crack growth rate with delamination growth, where the effective stress intensity factor in the metal layer is modulated by a bridging stress intensity factor. Then, fatigue lives of different notched fiber metal laminates were calculated. Good agreement was achieved between the predictions and experimental results.

Keywords Fiber metal laminates, crack growth , delamination growth, bridge stress, fatigue lives

1.Introduction

In modern aircraft fuselage design, advanced composite materials are increasingly utilized. A special family of such materials are the hybrid composites, also known as fiber metal laminates (FMLs), consisting of alternating layers of Al alloy and glass fiber reinforced epoxy. This material provides improved fatigue characteristics, considerable fire resistance and provides improved damage behaviour[1].

This paper deals with a numerical approach of this material, focusing on the fatigue crack growth rates in different notched FMLs. The numerical approach developed by Alderliesten[2] for predicting the fatigue crack propagation of FMLs is modified, and good agreement is achieved between the predictions and experimental results.

2.Experiments

The FMLs studied in this paper were consists of three layers of Al alloy 2024-T3 with the thickness of 0.254mm per layer and two layers of [0/90/0] glass/epoxy prepreg with the thickness of 0.15 mm per glass fiber layer. The dimensions of the specimens are 700 mm in length (L) and 140 mm in width (W). FMLs specimens were designed with 3 different notch sizes($2a_s$): 5mm, 10mm and 20mm. Constant amplitude fatigue testing was conducted using an MTS testing machine, as is shown in Fig 1. Fatigue tests were performed according to ASTM E 468-2004 at room temperature with a frequency of 10 Hz and a stress ratio of R = 0.1. The maximum applied stress was 160 MPa. Crack lengths and the cycles correspondingly were recorded. Crack growth rates were plotted in Fig 2.

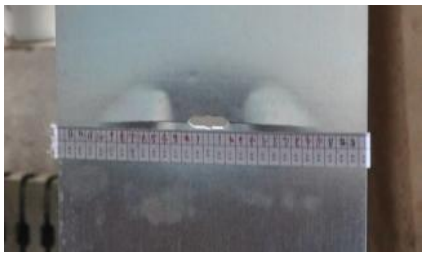

Fig 1 Delamination shape in FML during testing

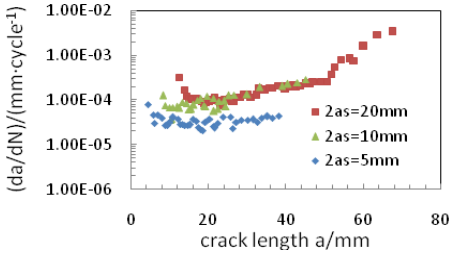

Fig 2 Crack growth rates

3.Model development

In this study, some details of the numerical approach developed by Alderliesten[2] were modified so that the predictions will have a better agreement with the experimental results. The numerical approach is based on a crack opening displacement relationship, as shown in Fig 3.

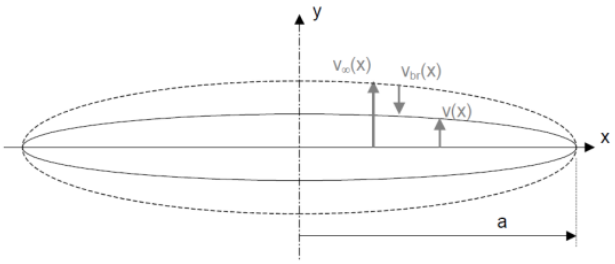

Fig 3 Definition of the crack opening displacement

$$v_\infty(x) - v_{br}(x) = \delta_f(x) + \delta_{pp}(x) \tag{1}$$

where $v_\infty(x)$ and $v_{br}(x)$ denote the crack opening displacement due to the remote applied stress and bridging stress in Al layer, respectively. $\delta_f(x)$ and $\delta_{pp}(x)$ are the deformation in the glass/epoxy prepreg and adhesive layers, respectively. The crack opening displacement away from the notch caused by the remote stress can be expressed as below

$$v_\infty(x) = 2\frac{S_{al}}{E_{al}}\sqrt{a^2 - x^2} \tag{2}$$

where E_{al} and S_{al} are the elastic modulus and the remote stress of the Al layer, respectively. The crack opening displacement $v_{br}(x)$ caused by bridging stress in Al layer can be calculated

$$v_{br}(x) = \int_0^a v(x, x_p)dx_p \tag{3}$$

The crack opening displacement $v(x, x_p)$ caused by point load is expressed as equation (4) and (5).

If $|x| < x_p$

$$v(x, x_p) = \frac{4S_{br,al}dx_p}{\pi E_{al}}\left(\tanh^{-1}\sqrt{\frac{a^2 - x_p^2}{a^2 - x^2 + b^2(x)}} + \frac{\frac{1}{2}(1+\upsilon)b^2(x)}{x_p^2 - x^2 + b^2(x)}\sqrt{\frac{a^2 - x_p^2}{a^2 - x^2 + b^2(x)}}\right) \tag{4}$$

and if $|x| > x_p$

$$v(x, x_p) = \frac{4S_{br,al}dx_p}{\pi E_{al}}\left(\tanh^{-1}\sqrt{\frac{a^2 - x^2}{a^2 - x_p^2 + b^2(x)}} + \frac{\frac{1}{2}(1+\upsilon)b^2(x)}{x_p^2 - x^2 + b^2(x)}\sqrt{\frac{a^2 - x^2}{a^2 - x_p^2 + b^2(x)}}\right) \tag{5}$$

where υ is Poisson ratio of the Al layer. $b(x)$ is the delamination shape function. $S_{br,al}$ is the bridging stress in Al layer.

The deformation caused by the elastic fiber extension is expressed as (6)

$$\delta_f(x) = \frac{S_f + S_{br,f}(x)}{E_f}b(x) \tag{6}$$

where E_f is the elastic modulus of glass/epoxy prepreg, and $S_{br,f}$ is the bridging stress in glass/epoxy prepreg. S_f is the stress in glass/epoxy prepreg at the notched zone. The bridging

stress in Al layer and glass/epoxy prepreg has a relationship given as(7)

$$\frac{S_{br,al}}{S_{br,f}} = \frac{n_{f1}t_{f1} + n_{f2}t_{f2}}{n_{al}t_{al}} \tag{7}$$

For the numerical solution, the crack geometry is divided into N elements with equal width $w = \frac{a - a_s}{N}$.

The stress intensity factor as a result of the far field stress present in the Al layers follows from the linear elastic theory for monolithic metals

$$K_{farfield} = S_{al}\sqrt{\pi a} \tag{8}$$

Since the bridging stress in Al layer for a given delamination shape is calculated, the stress intensity factor caused by the bridging stress is expressed as followed

$$K_{bridging} = 2\sum_{i=1}^{N} \frac{S_{br,al}(x_i)w}{\sqrt{\pi a}} \frac{a}{\sqrt{a^2 - x_i^2 + b^2(x_i)}} \left(1 + \frac{1}{2}(1+\upsilon)\frac{b^2(x_i)}{a^2 - x_i^2 + b^2(x_i)}\right) \tag{9}$$

The bridging stress in Al layer impedes the crack growth, so the stress intensity factor at the crack tip is expressed as(10)

$$K_{tip} = K_{farfield} - K_{bridging} \tag{10}$$

In order to calculate the crack growth rate with Paris equation, an effective stress intensity factor range must be determined. Take the effect of stress ratio and the geometry into consideration, the effective stress intensity factor is expressed as(11)

$$\Delta K_{eff} = \left(1 - R^{1.35}\right) K_{tip} \sqrt{\sec\left(\frac{a\pi}{W}\right)} \tag{11}$$

where W is the width of the specimen.

Now, the crack growth rate can be obtained as (12)

$$\frac{da}{dN} = C_{cg}\Delta K_{eff}^{n} \tag{12}$$

4.Results and conclusions

All the equations above are solved by MATLAB. Triangle is chosen as the delamination shape, that is $b(x) = b(a_s) \times \left(1 - \frac{x - a_s}{a - a_s}\right)$. $b(a_s)$ is a ratio of maximum delamination length to crack length, which is based on experimental observations. $b(a_s)$ for the FMLs with notch length of 20mm is 0.35 . $b(a_s)$ for the FMLs with notch length of 10mm is 0.35. $b(a_s)$ for the FMLs with notch length of 5mm is 0.175. Bridging stresses distributions in the FMLs with 3 differernt notch sizes along the crack length was plotted in Fig 4 when crack lengths comes to 65mm.The comparisons between experimental and predicted crack growth rates are plotted in Fig 5, Fig 6, Fig 7 when notch length is 20mm,10mm,5mm ,respectively.

The fatigue lives of FMLs can be obtained by the equation (13)

$$N = \int_0^a \frac{1}{C_{cg}\Delta K_{eff}^{n}} da \tag{13}$$

Using above equations, the fatigue lives for the notched fiber metal laminates can be calculated, as is plotted in Table 1.

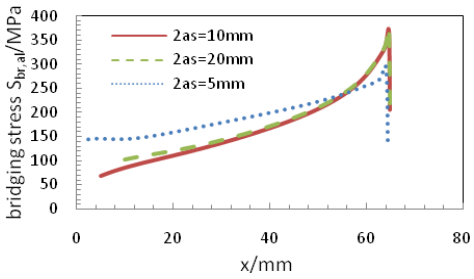

Fig 4 Bridging stresses distributions in t

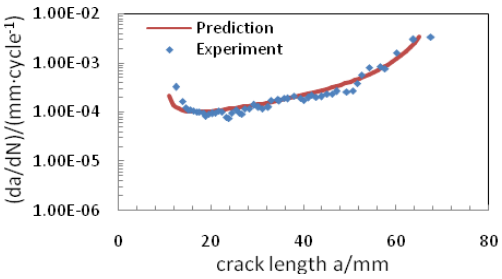

Fig 5 Comparison for as is 20mm

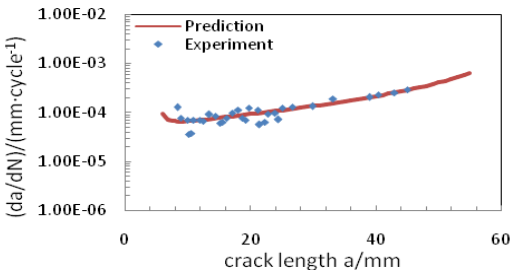

Fig 6 Comparison for as is 10 mm

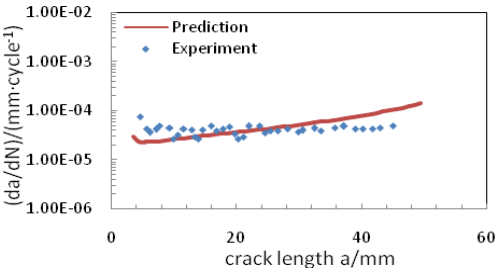

Fig 7 Comparison for as is 5mm

Table 1 The comparisons between experimental and predicted fatigue lives of FMLs

$2a_s$ (mm)	Experiments （N）	Predictions （N）	Errors（%）
5	1024000	1067019	4.2
10	355600	363672	2.3
20	296000	277720	6.2

Actually, the accuracy of this numerical approach depends on the delamination shape and the ratio . The delamination shape can be ellipse, parabola, triangle and cosine. Through the calculation, triangle seems to be the best delamination shape, cosine to be the second, parabola and triangle don'tfit well with the experimental results. The predictions are also sensitive to the radio .But a range of the radio can be determined by experimental observations so that the errors can be controlled.

This paper proposes a modified numerical approach for predicting the fatigue crack growth rates in different notched FMLs. By using MATLAB, the fatigue crack growth rates and the fatigue lives of different notched FMLs are calculated, and good agreement is achieved between the predictions and experimental results.

Abstract

Underground accessibility includes several steps which the cutting step is the one of most basic and most important of them. Indentation of TBM disc cutters into the rock and producing of the chips in different scales are well known as an indentation process. This phenomena passé from producing the micro cracks to the coalescing into macro cracks. The present research focuses on the linear elastic fracture mechanics of rock and maximum shear stress criterion to investigate the micro crack propagation and its direction under disc cutters. A higher order indirect boundary element method (using quadratic displacement discontinuity elements) is used to estimate the stress intensity factors in rocks under single disc cutter. Also to eliminate errors caused by stress and displacement singularity near the crack tip, three special crack tip elements are used. As the TBM disc cutters will be eroded after a period of working, the effects of eroded and not eroded discs are numerically modeled, analyzed and compared with each other. To create the eroded disc model, we considered 4 small elements to generate the curvature of the cutter tip, which reducing the computing efficiency and increasing the required specific energy for chips formation.

Keywords: eroded disc, micro crack propagation, specific energy, SDDM, TBM

1. Introduction

One of the most complex engineering problems is cutting and indentation of mechanical tools into the rock which has been considered by human primitively. The investigation on rock fracture mechanics with mechanical tools in mining and civil operations is significant duo to its widespread applications. These investigations can be used to predict and estimate rock fracture mechanism for optimization and risk-reducing of planning, temporal and economic schematization [1]. The key parameters in TBM head design are head diameter, number of cutters, thrust force, rolling force, RPM, penetration depth, and cutter spacing [2, 3 and 4]. Many experimental studies and numerical simulations have been reported for the breakage mechanism of rock under disc cutters of tunnel boring machines (TBMs) [5-16]). Recently, Cho et al [4] investigated the optimum spacing of TBM

disc cutters using numerical simulations. Their results are in good agreement with those obtained from experimental studies (LCM). Propagation and coalescence mechanism of micro cracks due to indentation of TBM disc cutters into the rock and production of chips in indent process is highly complex and important. The mechanism of micro crack propagation and coalescence has not been widely studied and its real reasons (micro crack propagation and coalescence) have not been fully found. Because of the complexity of the micro crack propagation and coalescence problem under TBM disc cutters, nowadays, numerical or analytical-numerical approaches are mostly used for simulating the rock breakage mechanism [17]. A numerical model, the higher order semi-infinite displacement discontinuity ($HOSDD_{2D}$) code, a two-dimensional code based on the linear elastic fracture mechanics (LEFM) which uses quadratic displacement discontinuity formulation with three special crack tip elements at each micro crack initial and end is used to simulate the rock breakage mechanism. Based on this numerical method, stresses near the crack tip and distribution of displacements can be clearly defined to determine the accurate strain energy release rate and stress intensity factors. There are three important fracture initiation criteria, which are applicable in action: the maximum tangential stress (σ_θ-criterion), the minimum energy density criterion (S-criterion) and the maximum energy release rate (G-criterion) or any modified form of those mentioned issues, (e.g. F-criterion which is A modified energy release rate criterion) has mostly been used to study the breakage mechanism of rock [18-24,14]. Although this criteria act prosperously for predicting the crack initiation under TBM disc cutters, the maximum tangential stress criterion is used here to predict the direction of micro crack initiations resulted from artifact cracks of TBM disc cutters. In the present research, the rock breakage mechanism under eroded disc cutters of tunnel boring machines (TBMs) is modeled and studied by the proposed method. A comparison of results between eroded and non-eroded disc models is presented.

2. Higher Order Displacement Discontinuity In a Half-plane

The semi-infinite displacement discontinuity method (SDDM) is an indirect boundary element method that is solved problems on the basis of fracture mechanics principles given the boundary conditions and calculates stresses and displacements at discontinuities in all boundary elements. cruch and starfield [25] used the analytical solution of a constant element displacement discontinuity, over the line segment $|x| \le a$, $y = 0$ in the semi-infinite area $y \le 0$ as shown in Fig. 1. For complete computaion of displacements and stresses in semi-infinite body, due to the real displacement discontinuity, its portrait and its resulting from the supplementary solution are denoted by u_i^R and σ_{ij}^R, u_i^P *and* σ_{ij}^P, u_i^S and σ_{ij}^S, respectively.
The complete solution for the semi-infinite plane $y \le 0$ can be expressed as:

$$u_i = u_i^R + u_i^P + u_i^S \qquad \text{and} \qquad \sigma_{ij} = \sigma_{ij}^R + \sigma_{ij}^P + \sigma_{ij}^S \tag{1}$$

$\bar{x}, \bar{y}$ and x, y are local coordinates and global coordinates, respectively, that can be transformed by the following two formulas:

$$\begin{aligned} \bar{x} &= (x - c_x)\cos\varphi + (y - c_y)\sin\varphi \\ \bar{y} &= -(x - c_x)\sin\varphi + (y - c_y)\cos\varphi \end{aligned} \tag{2}$$

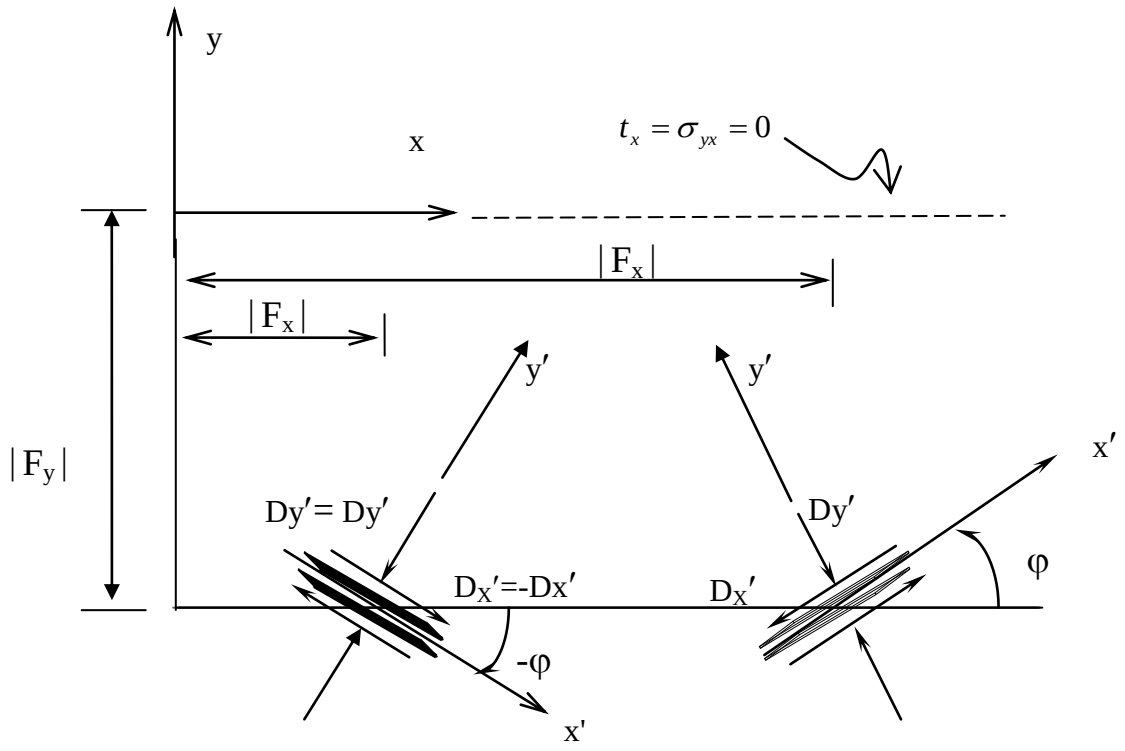

Figure 1. Real and portrait displacement discontinuities in half-plane $y \leq 0$, with a traction-free surface (after Crouch and Starfield [25]).

In the present study, in order to obtain high precision, quadratic collocation displacement discontinuity modified for half plane crack problems with a traction free surface are used. $D_k(\xi)$ is equation that can be used to calculate two fundamental variables of each element (the opening displacement D_y and sliding displacement D_x).

$$D_j(\xi) = \sum_{i=1}^{n} \Pi_i(\xi) D_i^k, k = x, y \tag{3}$$

Where $D_1^k (i, e. D_1^x$ and $D_1^y)$, $D_2^k (i.e. D_2^x$ and $D_2^y)$, $D_3^k (i.e. D_3^x$ and $D_3^y)$ are the quadratic displacement discontinuities, and using the equal length of each sub element $a_1 = a_2 = a_3$

$$\begin{aligned}
\Pi_1(\xi) &= -(3a_1^3 - a_1^2\xi - 3a_1\xi^2 + \xi^3)/(48a_1^3), \\
\Pi_2(\xi) &= (9a_1^3 - 9a_1^2\xi - a_1\xi^2 + \xi^3)/(16a_1^3), \\
\Pi_3(\xi) &= (9b_1^3 + 9a_1^2\xi - a_1\xi^2 - \xi^3)/(16a_1^3)
\end{aligned} \tag{4}$$

are their quadratic element shape functions.

In Fig. 2, A quadratic displacement discontinuity (DD) element is divided into three equal sub-elements (each sub-element contains a central node for which the nodal displacement discontinuities are evaluated numerically) [26].

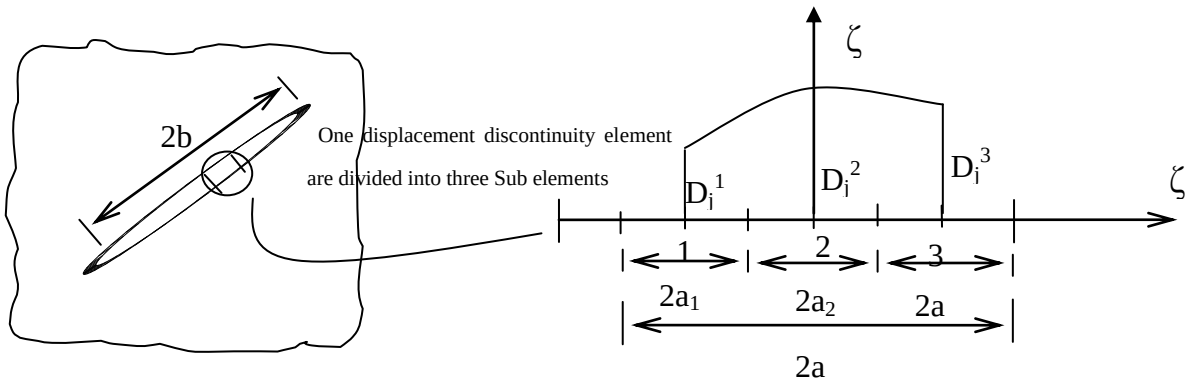

Figure 2. Higher order displacement discontinuity (HODD) elements by quadratic elements

To increase the accuracy in computing of the displacement discontinuities and stresses near original crack tips, the special crack tip elements are used. In previous works, usually, one or two special elements for crack tip were used, but in the present research, three special elements are used. Following equation can be used three elements, particularly for crack tip:

$$D_i(\xi) = [\Pi_{T1}(\xi)]D_i^1(b) + [\Pi_{T2}(\xi)]D_i^2(b) + [\Pi_{T3}(\xi)]D_i^3(b) \tag{5}$$

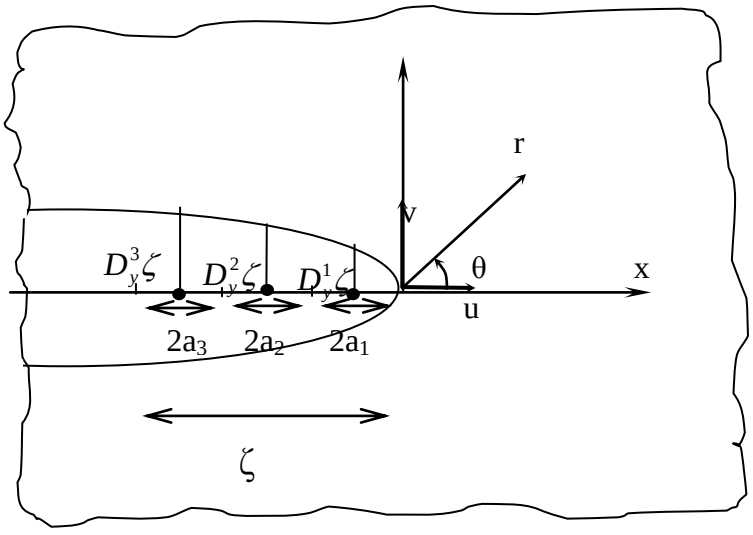

Figure 3. Quadratic element for the higher order displacement discontinuity variation

3. Verification of the semi-infinite displacement discontinuity method (using quadratic elements)

Verification of this method is made through the solution of a simple example problem i.e. a center inclined micro crack in a semi-infinite body which is shown in Fig. 4. The tensile stress is acting parallel to the x axis at infinity. Considering a 30 degrees center inclined micro crack under uniform normal tension σ= *10 MPa*, a half micro crack length b= 1 meter, fracture toughness K_{IC}= *2 MPa*

√m, modulus of elasticity *E=10 GPa*, Poisson's ratio *v= 0.2* are assumed. The analytical solution of mode I and mode II stress intensity factors, K_I and K_{II}, for the infinite body problem are given as [27]:

$$K_I = \sigma(\pi b)^{\frac{1}{2}} \sin^2 \beta \; and \; K_{II} = \sigma(\pi b)^{\frac{1}{2}} \sin \beta \cos \beta \tag{6}$$

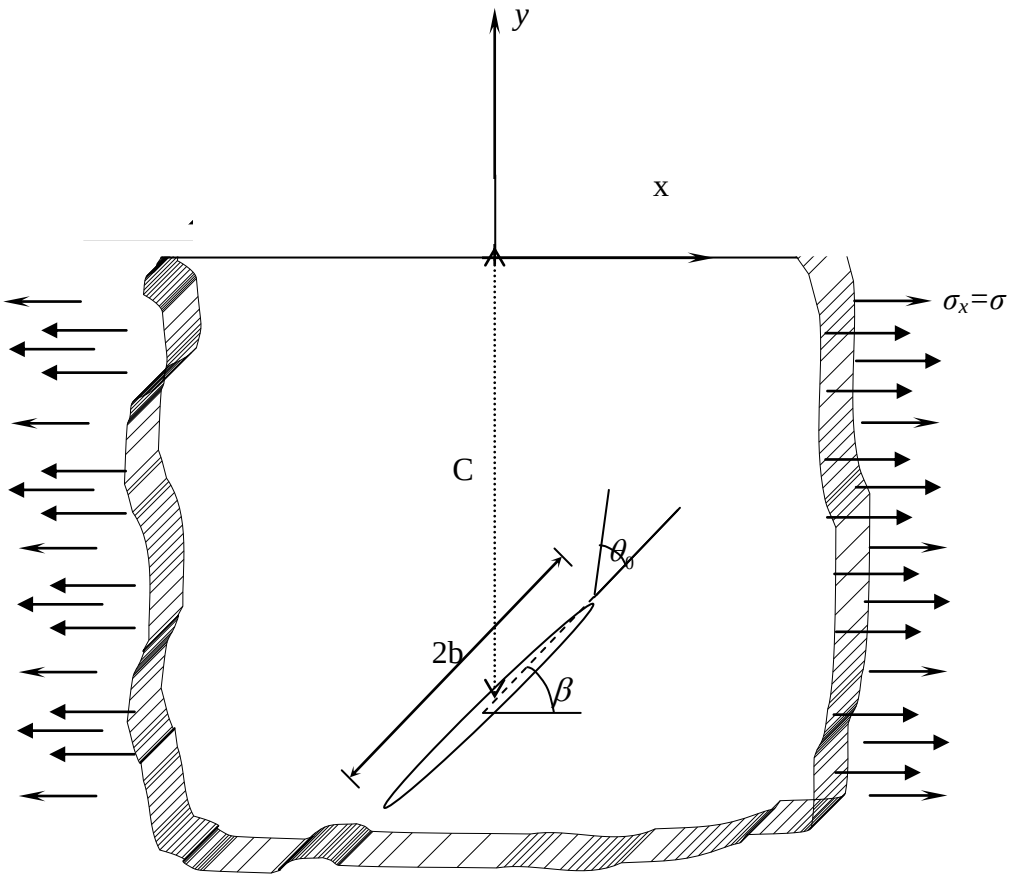

Figure 4. A center inclined micro crack in a semi- infinite body.

The semi-infinite center inclined micro crack problem is selected to verify the proposed code (see Fig. 4).

Fig.5 is based on the normalized stress intensity factors which compare the different results obtained for the upper cracks (the cracks near to the free surface of the half plane), and the lower cracks, with the available analytical results of the center inclined micro crack in an half plane.

The numerical results show that as the depth of the micro crack (*C/R* ratio) increases the mixed mode stress intensity factors K_I and K_{II}, and the crack initiation angle θ_0 tend to their corresponding analytical values of the center inclined micro crack in an infinite plane.

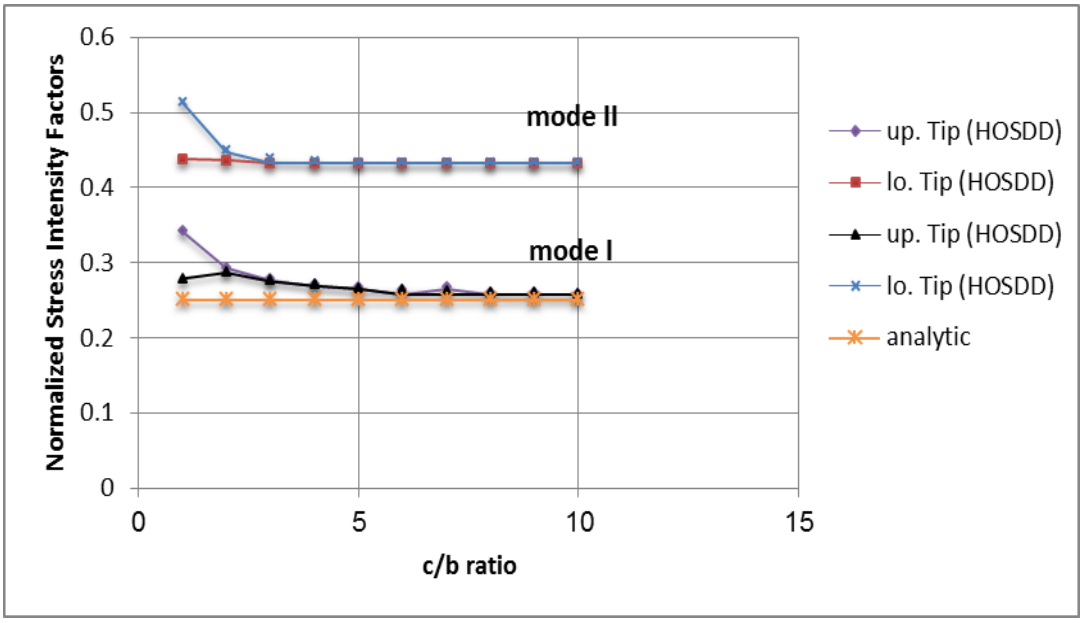

Figure 5. The normalized stress intensity factors $K_I/(p\sqrt{\pi\rho R})$ and $K_{II}/(p\sqrt{\pi\rho R})$, for different *C/R* ratios, for a center inclined micro crack , in a semi-infinite plane

4. Modeling of eroded disc cutter

Since, after a while, TBM disc cutters erosion caused by contact with the rock, therefore, the effect of erosion is modeled numerically. For this purpose, four special elements are used to simulate the disc cutter tips. This model estimates the required curvature near the disc cutter tips, reducing the computing efficiency and increases the required specific energy for chips formation under disc cutters during a rock indentation process. In the Figure 6, the micro crack propagation path for artifact cracks of AC1, AC2, AC3 and AC4 which represents the coalescing of propagated micro cracks from artifact cracks, and also this path for $S/P_d=10$, disc edge angle $\psi=60$, $P_d=6mm$ and extended length of $\delta=4mm$ (8 iteration) are estimated. Micro cracks propagate with respect to direction of the artifact cracks, then after several (8) iteration propagated micro cracks from artifact cracks coalesce to each other at the region between cutters. Considering a typical TBM with a thrust of *250 kN* per cutter, with disc cutters of 15 mm width and 432 mm diameter. The typical rock is the Aspo diorite with the Mode I and Mode II fracture toughnesses $K_{IC}=3.83\ MPa\ m^{1/2}$, and $K_{IIC}=5.09\ MPa\ m^{1/2}$ respectively. The other parameters of this rock as quoted by Backers (2004) are: $\sigma_t = 15$ *MPa*, $\sigma_C = 220$ *MPa*, and $E= 68\ GPa$ and $\nu = 0.24$ [20].

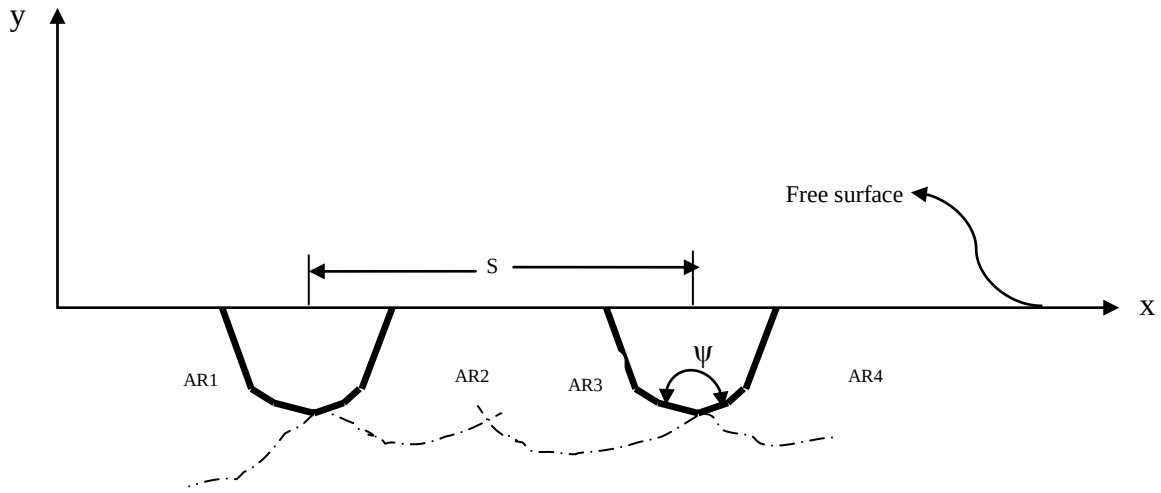

Figure 6. The micro crack propagation path for *S/Pd=10* edge angle *ψ =60, Pd=6*, mm and extended length of *δ=4mm* (8 iteration).

In order to investigate the effect of erosion on the TBM, the results of modeling as illustrate in Figs. 7- 9. According to the Fig. 7, because the cutters are blunted under erosion, as a result, more specific energy for eroded cutters than non-eroded cutters is required. The figure shows that in both cases, the optimum ratio *S/Pd* is in range of 7.5–15, which is in well agreement with the experimental results. Figs. 8 shows comparison between eroded and non-eroded disc cutters for the Mode I and Mode II stress intensity factors, K_I, K_{II} *(MPa* $m^{1/2}$*)* versus different *S/Pd* ratios. Figs. 9 shows comparison between eroded and non-eroded disc cutters for the Mode I and Mode II stress intensity factors, K_I, K_{II} *(MPa* $m^{1/2}$*)* versus different *Pd* ratios.

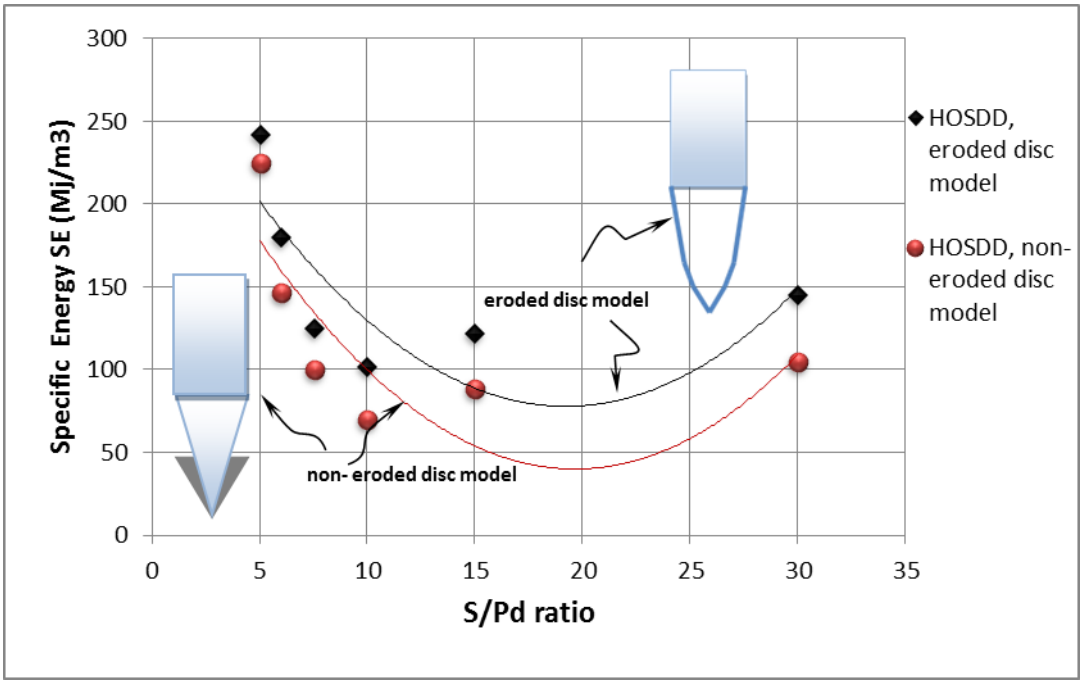

Figure 7. Comparison between eroded and non-eroded disc cutters for specific energy *SE (Mj/*m^3*)* versus different *S/Pd* ratios

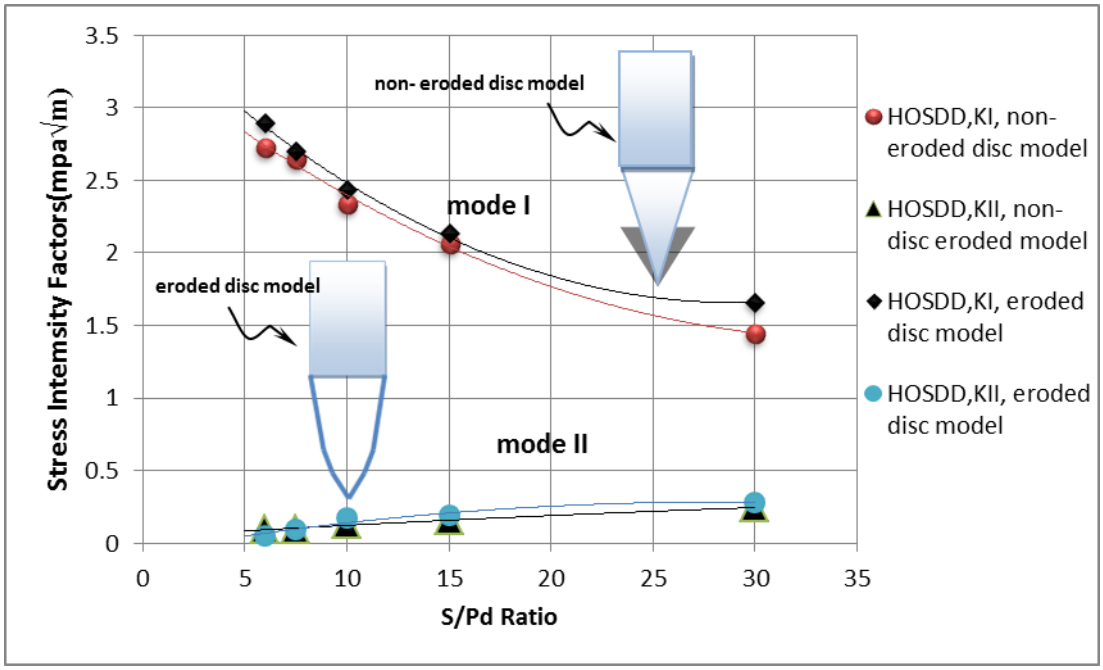

Figure 8. Comparison between eroded and non-eroded disc cutters for the Mode I and Mode II stress intensity factors, K_I, K_{II} ($MPa\ m^{1/2}$) versus different *S/Pd* ratios

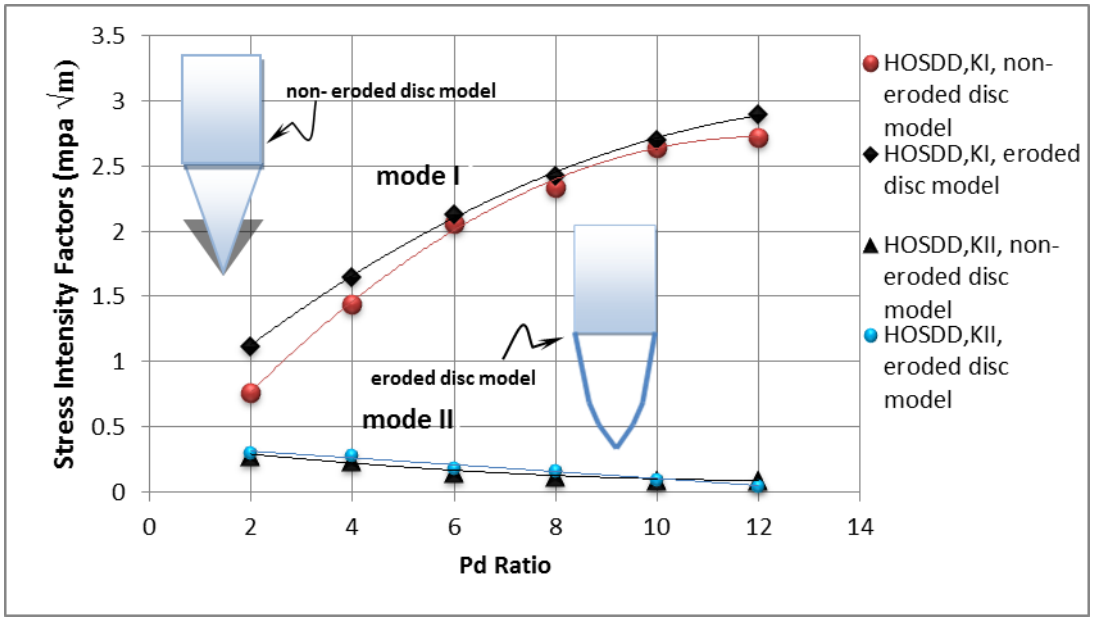

Figure 9. Comparison between eroded disc cutter and non-eroded disc cutters for the Mode I and Mode II stress intensity factors, K_I, K_{II} ($MPa\ m^{1/2}$) for various penetration depths *Pd*

5. Conclusions

A two-dimensional code based on a semi-infinite displacement discontinuity method (Known as $HOSDD_{2D}$) is used to simulate rock-cutting behavior under TBM disc cutter during rock indentation. The produced micro cracks under the disc cutters are coalesced during their propagation into the

underneath rock mass. The disc edges are assumed to behave as artifact cracks. The propagation and coalescence mechanism of the micro cracks emanating from each artifact crack tips are investigated by discretizing it into three ordinary and three special crack tip elements at the tip. The maximum tangential tensile stress criterion (σ_θ-criterion) is implemented into $HOSDD_{2D}$ code. In the present research, the effects of erosion on the Mode I and Mode II stress intensity factors and specific energy (SE) for TBM disc cutters are investigated by simulating the penetrating artifact cracks (disc cutters) into a rock mass. The main purpose of the present modeling was to compare the results obtained for the eroded disc cutters with those of non-eroded disc cutters. As a result, for the eroded disc cutters, higher forces (more specific energy) are required to propagate the micro cracks emanating from the artifact cracks compared to those for non-eroded disc cutters

Abstract

The breakage mechanism of brittle substances such as rocks under uniform tensile loading is considered. The random micro cracks are mostly produced in all of Polycrystalline substances resulting from stress concentration. This paper focuses on the interaction of two pre-existing micro cracks. The quality of the growing and coalescing of micro cracks in rock-like specimen are studied by using a Fortran Code $HDDMCR_{2D}$ which is based on a two dimensional displacement discontinuity method for the crack analysis (a boundary element computer code based on the linear elastic fracture mechanics (LEFM) theory). In order to improve the accuracy of the results and reduce the errors in calculating displacement discontinuity in the proposed model, the higher-order elements (quadratic elements) are used to discretize a sufficient number of boundary elements. Also to eliminate errors caused by stress and displacement singularity near the crack tip, three special elements has been used to discretize each crack end. In this research, the problems of wing cracks propagated at different angles from the original micro crack tips in an infinite specimen under uniform tension are considered.

Keywords micro crack interaction, crack initiation, LEFM, BEM, crack coalescence

1. Introduction

The presence of micro cracks in brittle substances may have higher effect on their macro mechanical behavior. It has been observed that the macro mechanical behavior of rocks is due to their micro mechanical structure [1]. The micro cracks initiate from their tips and extend at an angle with respect to the original micro crack plane [2]. In the path of development of micro cracks, the kinked and curved cracks may be produced and these types of cracks usually occur under shear or mixed mode loading [3]. The breakage mechanism of brittle substances with random micro cracks depends on the degree of their interaction and coalescence path that may leads to the formation of a macro crack [4].

In studying the breakage mechanism of brittle substances under uniaxial tensile stress, crack initiation and specimen breakage may happen very soon and the crack initiation is normally expected to occur in a direction perpendicular to the maximum tensile stress. In rocks, crack initiation in tension is preferred due to the lower toughness of rock substances in tension than in shear [5]. The mechanism of propagation and coalescence of micro cracks in forming of macro cracks or rupture of rock is still not a well understood subject and the problem of interaction between the micro cracks and macro cracks is always noted by the researchers [6]. A number of

experimental investigations on the propagation and coalescence of micro cracks in rock-like specimens under uniaxial and biaxial compression have been published [7-14]. Some useful and modern numerical models such as FROCK code, damage model, Rock Failure Process Analysis ($RFPA^{2D}$) are used in this field [5, 15-19]. There has never been a random investigation on the effect of fracturing in brittle substances altering positions of random micro cracks which is under tension. In this research, a numerical model is proposed using a higher order displacement discontinuity code for micro crack analysis ($HDDMCR^{2D}$ code). This model is designed on the basis of the linear elastic fracture mechanics (LEFM) principles so that it is able to simulate the micro crack interaction of specimens containing random micro cracks. In this paper, the numerical analysis of the growth of wing cracks from pre-existing micro cracks in rock-like specimens under uniform normal tensile stress is studied. In order to verify the validity of proposed numerical model, the experimental and numerical results of the wing crack initiation directions (given by Guo et.al. [20]) for different micro crack inclination angles of a center slant micro crack under uniform tension have been used. The crack propagation mechanism of two pre-existing micro cracks are investigated (for a specimen under uniform tension) in which the propagation direction of micro cracks is estimated by using the maximum tangential stress fracture criterion (σ-criterion) proposed by Erdogan & Sih [21].

2. The higher order displacement discontinuity method

In the higher order displacement discontinuity method, the boundaries are discretized into multiple segment elements. The formulations of three types of displacement discontinuity variations with: a constant variation of the displacement along the elements, a linear variation, and a quadratic variation were previously mentioned and used in the literature [22-24]. The quadratic element displacement discontinuity is fundamentally based on integrating the quadratic element shape functions over collinear, straight-line displacement discontinuity elements.

Fig. 1 shows the displacements distribution at quadratic collocation point ‘m’, which can be calculated as:

$$D_j(\zeta) = \sum \Omega_m(\zeta) D_j^m \ for\ m = 1, to 3,\ j = x, y \tag{2}$$

where D_j is the fundamental variable. It should be noted that two fundamental variables are calculated in each collocation point. Using $c_1 = c_2 = c_3$, it can be written:

$$\Omega_1(\varepsilon) = \zeta(\zeta - 2c_1)/8c_1^2,\ \Omega_2(\zeta) = -(\zeta^2 - 4c_1^2)/4c_1^2,\ \ \Omega_3(\zeta) = \zeta(\zeta + 2c_1)/8c_1^2 \tag{3}$$

which are the shape functions of the quadratic collocation point ‘m’. In the quadratic collocations, there are three collocation points for each element, for which the displacements are typically calculated. These collocations are located in the center of the elements (Fig. 1).

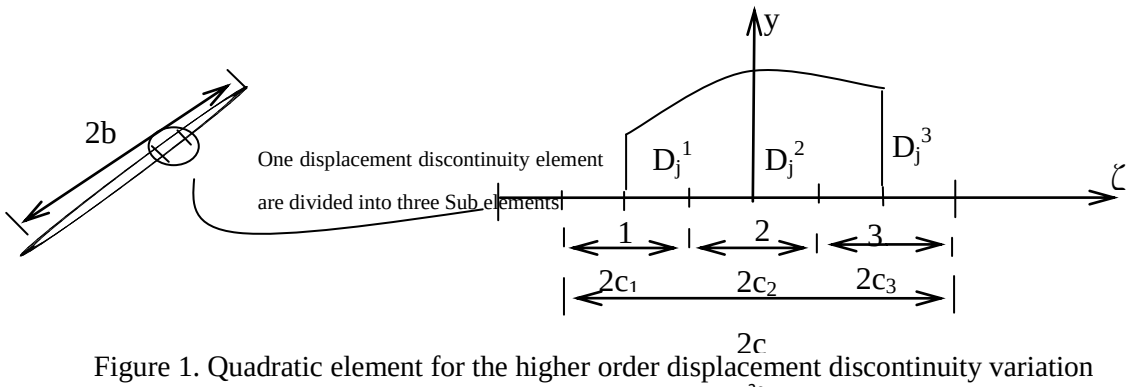

Figure 1. Quadratic element for the higher order displacement discontinuity variation

To eliminate the singularity of the displacements and stress calculation near the micro crack ends and increase the accuracy of order higher displacement discontinuity method around the original micro crack tip, a special treatment of the micro crack at the tip is necessary [24-27]. In this research three special crack tip elements at the end and initiation of each micro crack are used in the general higher order displacement discontinuity method. As shown in Fig. 2, using a special crack tip element with the length of 2c.The displacement discontinuity variations along this element can be written in the following form [24]: given as:

$$D_j(\zeta) = [\Omega_{T1}(\zeta)]D_j^1(c) + [\Omega_{T2}(\zeta)]D_j^2(c) + [\Omega_{T3}(\zeta)]D_j^3(c) \tag{4}$$

The crack tip element has a length $c = c_3 + c_2 + c_1$. Considering $c_1 = c_2 = c_3$, the shape functions $\Omega_{T1}(\zeta)$, $\Omega_{T2}(\zeta)$ and $\Omega_{T3}(\zeta)$ can be written as:

$$\Omega_{T1}(\zeta) = \frac{15\zeta^{\frac{1}{2}}}{8c_1^{\frac{1}{2}}} - \frac{\zeta^{\frac{3}{2}}}{c_1^{\frac{3}{2}}} + \frac{\zeta^{\frac{5}{2}}}{8c_1^{\frac{5}{2}}}, \qquad \Omega_{T2}(\zeta) = \frac{-5\zeta^{\frac{1}{2}}}{4\sqrt{3}c_1^{\frac{1}{2}}} + \frac{3\zeta^{\frac{3}{2}}}{2\sqrt{3}c_1^{\frac{3}{2}}} - \frac{\zeta^{\frac{5}{2}}}{4\sqrt{3}c_1^{\frac{5}{2}}} \quad \text{and}$$

$$\Omega_{T3}(\zeta) = \frac{3\zeta^{\frac{1}{2}}}{8\sqrt{5}c_1^{\frac{1}{2}}} - \frac{\zeta^{\frac{3}{2}}}{2\sqrt{5}c_1^{\frac{3}{2}}} + \frac{\zeta^{\frac{5}{2}}}{8\sqrt{5}c_1^{\frac{5}{2}}} \tag{5}$$

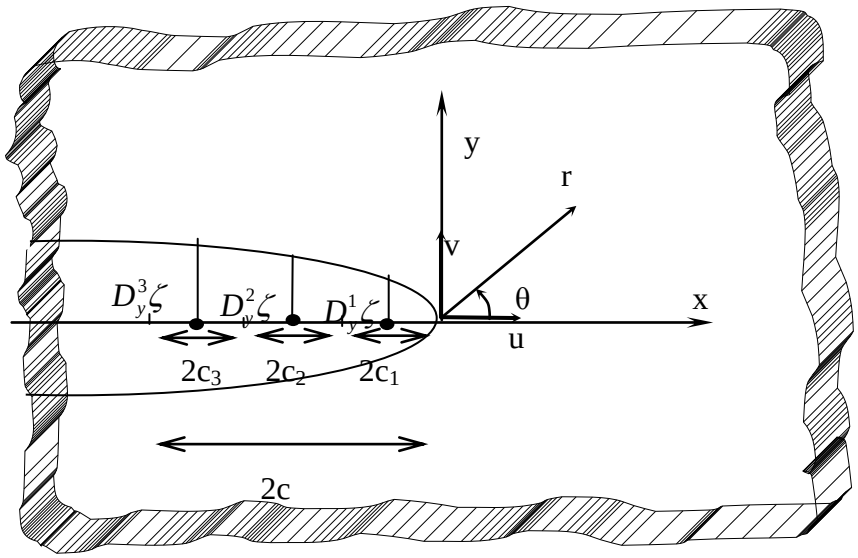

Figure 2. Quadratic element for the higher order displacement discontinuity variation

The mode I and Mode II stress intensity factors k_I and k_{II} can be estimated based on LEFM theory as the opening and sliding displacements [23]:

$$K_I = \frac{\rho}{4(1-\nu)}\left(\frac{2\pi}{c}\right)^{\frac{1}{2}} D_y(c), \quad \text{and} \quad K_{II} = \frac{\rho}{4(1-\nu)}\left(\frac{2\pi}{c}\right)^{\frac{1}{2}} D_x(c) \tag{6}$$

3. Verification of DDM with quadratic elements

A simple problem for verifying the numerical results and the proposed code is presented in this paper. This problem is the center slant micro crack in an infinite specimen shown in Fig. 3. The slant angle ψ, changes counter clock wise from the x (horizontal) axis, and the tensile stress σ^{∞} = 10 MPa is acting. Half of the micro crack length, b= 1 meter, modulus of elasticity E=10 GPa, Poisson's ratio $\nu = 0.2$, fracture toughness K_{IC}= 1.8MPa $m^{1/2}$ are assumed.

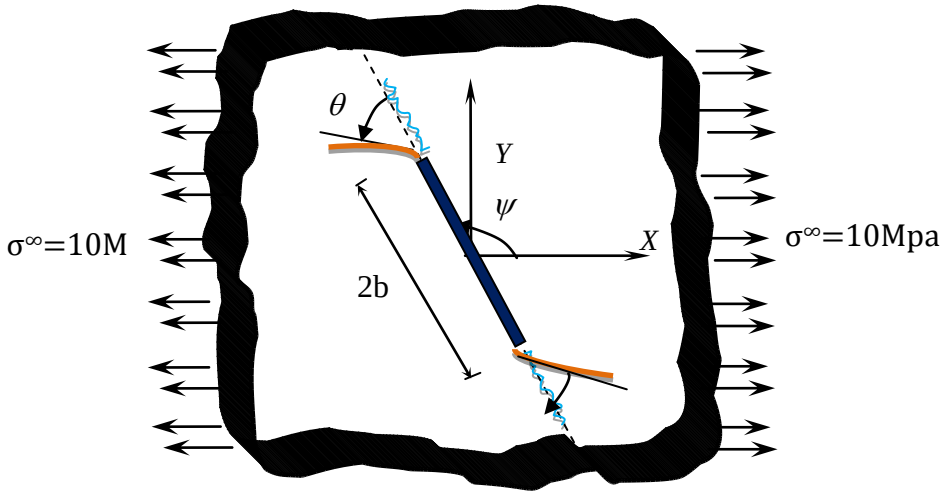

Figure 3. A center slant micro crack in an infinite body under uniform tension (parallel to the x axis)

The center slant micro crack problem has been solved by different researchers e.g. Guo et.al [20] to get a simple analysis, also these researchers used the constant element displacement discontinuity with a special crack tip element for angles 30, 40, 50,60,70,80 degrees. To evaluate the micro crack initiation angle θ_0, they used two initiation criteria: Maximum tangential tensile stress criterion (σ_θ-criterion), and Minimum strain energy density criterion (S-criterion), and compared their results with the results from other models. Fig. 4 compares the numerical results for the wing crack initiation directions θ_0 (obtained by $HDDMCR_{2D}$ code) and the results given by Guo et. al [20].

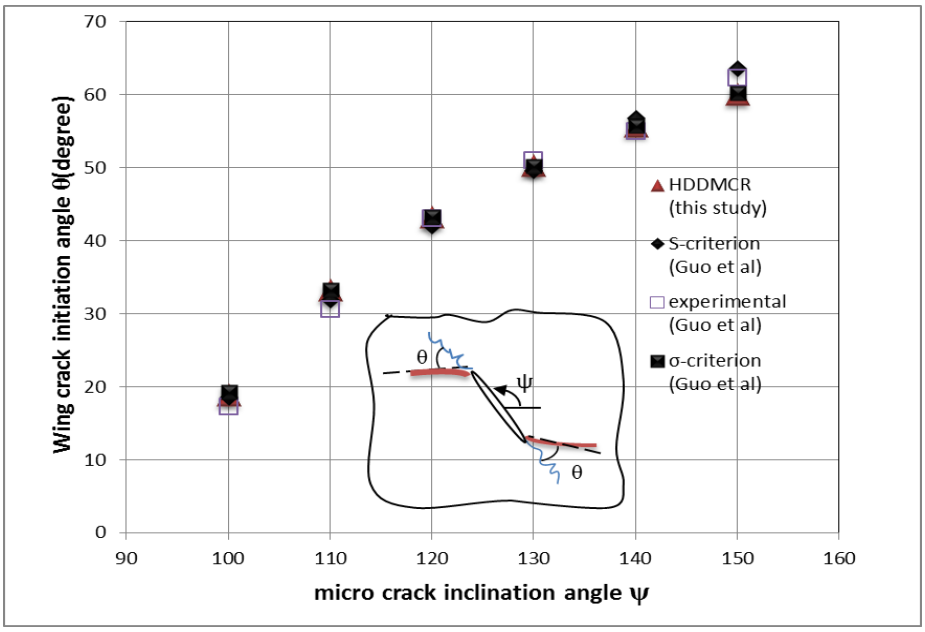

Figure 4. The micro crack initiation angle θ_0 as a function of micro crack inclination Angle ψ

4. The initiation and propagation of two non-parallel pre-existing micro cracks

In addition to the formation and growth of micro cracks in a rock mass, the reciprocal effects among the micro cracks may also be considered in the breakage process of the rock. The micro crack interactions can be modeled by the present numerical method which may allow micro cracks to interact reciprocally. It can be concluded that by increasing the number of micro cracks, the induced stresses among the original micro crack tips may have a significant effect on their initiation and some new micro cracks may also be produced. In fact, in rock specimens a series of micro cracks may remain closed during loading and propagation. In order to find out how the micro cracks connect under uniform tension (parallel to y axis), two micro cracks (of the same size as shown in Fig. 5), are considered. The body containing the micro cracks is an infinite plane, and the plane strain condition is assumed. It is under a uniform far field tensile stress, $\sigma^{\infty} = 10mpa$ with modulus of elasticity, $E=10\ GPa$, Poisson's ratio, $\nu=0.2$, fracture toughness, $K_{IC}=1.8MPa\ m^{1/2}$. In the present research, the effects of micro cracks randomness and spacing are considered.

The mode I and mode II stress intensity factors, K_I and K_{II}, near the original tips of two random micro cracks are estimated numerically. The non-dimensional mode I and mode II stress intensity factors, $\frac{k_I}{\sigma^{\infty}\sqrt{(\pi b)}}$ and $\frac{k_{II}}{\sigma^{\infty}\sqrt{(\pi b)}}$ are mainly used in the micro crack analyses. The negative sign of K_I value shows the micro crack closure, while the positive and negative signs in K_{II} only show the direction of relative shear between the two surfaces of micro crack.

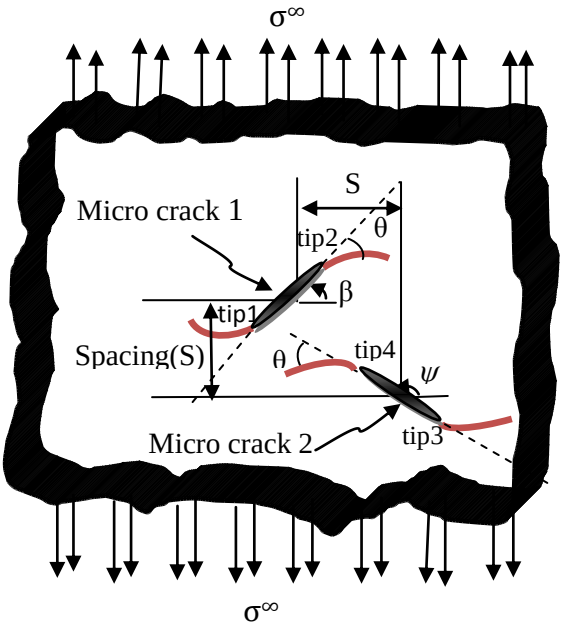

Figure 5. Two randomly slant micro cracks in an infinite specimen under uniform tension with the spacing, S=2b

4.1. Effects of inclination and randomness of micro cracks on SIF

Two random and completely non-parallel micro cracks are shown in Fig. 5. These micro cracks are known as micro crack 1 and micro crack 2. Their vertical and horizontal distances (center to center) are defined by S, and their inclination angles are denoted by β and ψ. The micro cracks are located in an infinite specimen under uniform tension (parallel to y axis). The normalized stress intensity factors $\frac{k_I}{\sigma^\infty\sqrt{(\pi b)}}$ and $\frac{k_{II}}{\sigma^\infty\sqrt{(\pi b)}}$ are shown graphically in Figs. 6 and 7. These normalized intensity stress factors are evaluated for four original tips of the two micro cracks (keeping a constant inclination angle, β=60°, for micro crack 1 but different angles, ψ= 150°, 140°,120°, 100°,80° and 60° for micro crack 2). For the original micro crack tips 3, 4, which have the most effect compared to other original tips, k_I value has decreased with an increase in the inclination angle of micro crack 2 (angle ψ) from 50° to 90°. In fact, k_I gets negative values when ψ is close to 90°. In tension field, the closing of micro crack is due to shear stress because shearing mode occurs sooner than opening mode in this field. The stress intensity factor k_I increases considerably as the inclination angle ψ increases from 90° to 150°. For the original micro crack tips 1 and 2, the effects of randomness are lower than those of other tips. The maximum value of k_I (~0.772) occurs at ψ=150° due to the complete non-orientation of both the micro cracks. The behavior of mode II SIFs of four original tips of micro cracks is notably different from that of mode I SIFs. For original tips 3, 4, $|k_{II}|$ value

has increased in the inclination angle ψ from 50° to 130° and decreased from 130° to 150°, when the micro crack 1 and micro crack 2 are completely non-oriented. For original micro crack tips 1 and 2, there aren't any noticeable effects with a change in the micro crack inclination angle ψ. As it was shown in Figs. 6 and 7, the most changes were in original micro crack tips 3 and 4, when the original tips 3 and 4 are close to the other of original micro crack tips, both of modes I and mode II stress intensity factors, k_I and k_{II} are increased. In nearly vertical micro cracks, k_{11} plays a more important role than k_I. Fig. 8 shows the wing crack initiation angle of four tips versus the changes of inclination angle ψ. This figure shows that in tips 3, 4, wing crack initiation angle θ has increased in the inclination angle ψ from 60° to 90° and decreased from 90° to 150°. The maximum of wing crack initiation angle θ occurs at ψ= 90°. And also for tips 1 and 2, the changes of ψ are not noticeable due to non-orientation of micro cracks and it is assumed that there is zero interaction.

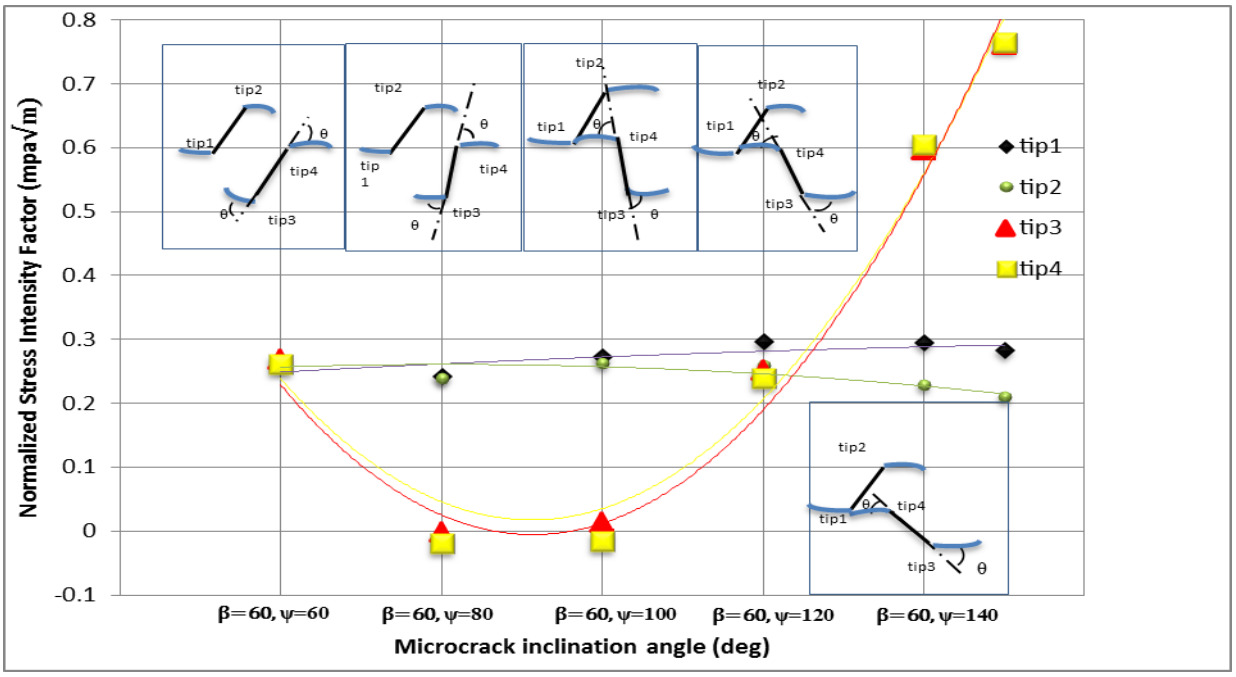

Figure 6. Treatment of mode I SIFs versus the locations of two micro cracks, under uniform tension (parallel to the y axis), for L/b=0.1 and 360+6 nodes for each micro crack

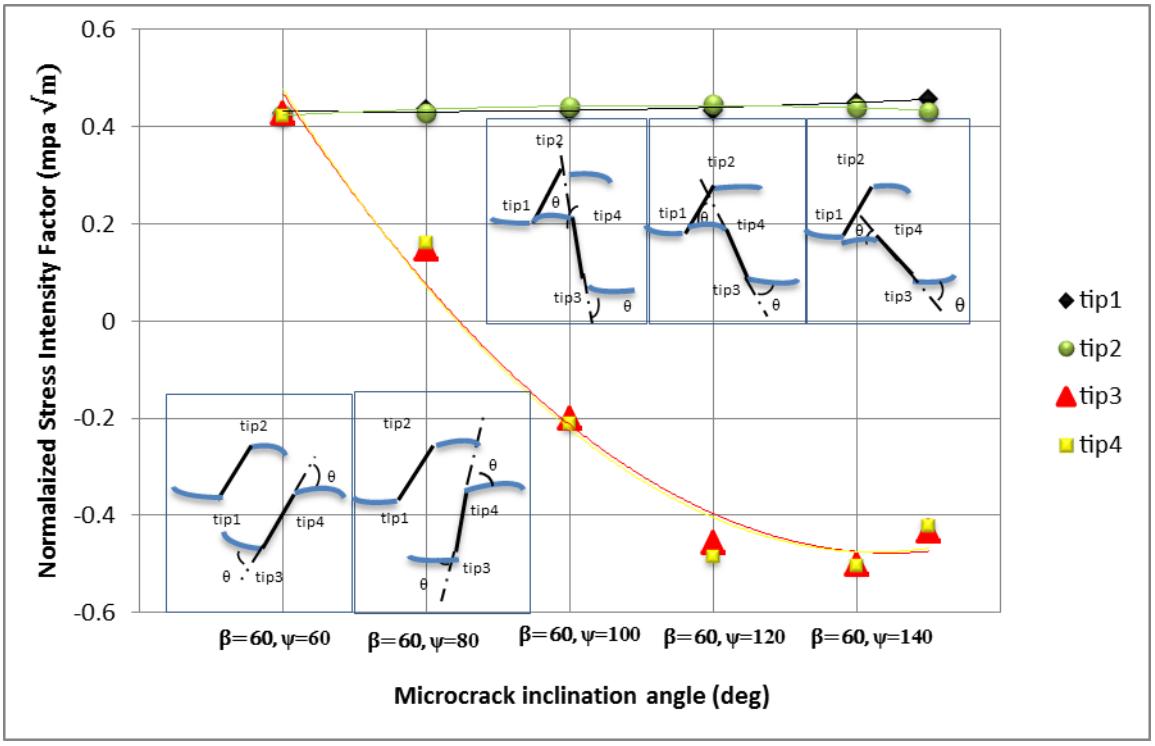

Figure 7. Treatment of mode II SIFs versus the locations of two micro cracks, under uniform tension (parallel to the y axis), for L/b=0.1 and 360+6 nodes for each micro crack

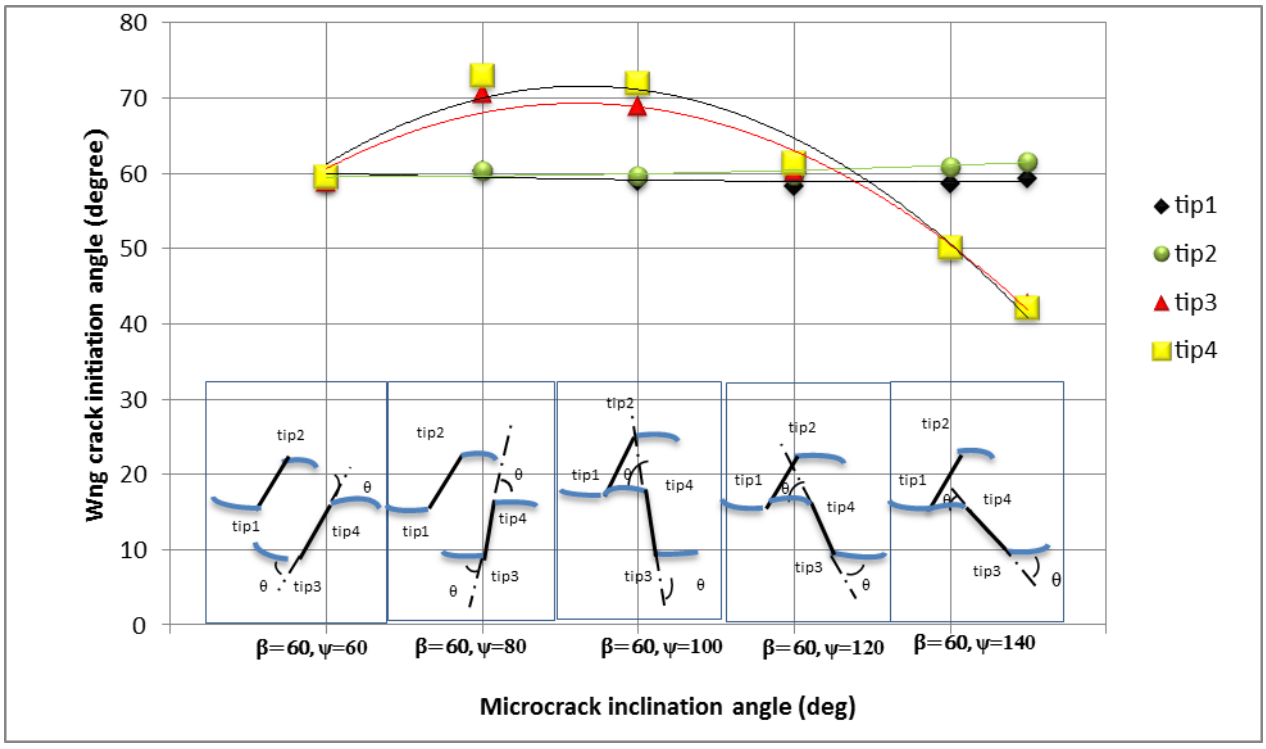

Figure 8. Wing crack initiation angle versus the locations of two micro cracks, under uniform tension parallel to the y axis, for L/b=0.1 and 360+3 nodes for each micro crack

5. Conclusions

A numerical model on the basis of computing the stress intensity factors and wing crack initiation angles for cracked substances under normal uniform tension is presented. In the present work, based on the Linear Elastic Fracture Mechanics (LEFM), the maximum tangential stress criterion or σ-criterion is implemented into code HDDMCR to investigate the interaction of micro cracks. In order to verify the validity of the proposed model, analytical solution of a typical sample problem e.g. a center slant micro crack under uniform tension is used, and its propagation mechanism is compared with numerical solution. In the present model, quadratic collocations with three special crack tip elements for each micro crack tip at the same time are implemented into code $HDDMCR_{2D}$. The numerical simulation is carried out considering infinite planes with two micro cracks under uniform tension. Comparing the parallel and non-parallel micro cracks, the effects of inclinations of two micro cracks show that these factors have a strong influence on the breaking path.

Abstract A controlled crack growth in PMMA was achieved in Wedge-Splitting Test (WST) by regulating the cross-head speed of loading by a computer-driving testing device. The fracture behavior of a crack propagating was investigated quantitatively by both numerical modeling and experiment using Finite Element Method (FEM) and Digital Image Correlation (DIC). A two-parameter fracture mechanics approach, describing the near-crack-tip stress field, was applied to determine the stress intensity factor (SIF) and the coefficient of higher order term (T-stress). In both methods, it was shown that the stress intensity factor versus crack length remains constant whereas the T-stress varies from negative to positive. This later variation is similar to the three point bend beam, but different from the compact tension specimen, for which the T-term is always positive. Using Digital Image Correlation (DIC), the stress intensity factor and T stress were estimated with 10% and 15% uncertainty in a complex loading set-up without having to do a numerical modeling of the experiment.
Keywords Crack path propagation, Digital Image Correlation, Finite Element Method, Stress intensity factor, T-stress

1. Introduction

Fracture propagation in brittle or quasi brittle material is dominated mainly by the near-tip stress field. The stress intensity factors "K" gives the magnitude of the stress field ahead of a crack tip and fracture propagates when a critical stress intensity factor is reached. There are experimental evidences that the stress contributions acting at largest distance from the crack tip may affect fracture mechanics properties [1]. The constant stress contribution (first "higher-order" term of the Williams stress expansion, denoted as the T-stress term) is the next important parameter. It is well known that for crack growth under mode I loading (i.e., $K_{II} = 0$) the straight crack path is stable when $T < 0$ and unstable for $T > 0$ [2]. In the brittle or quasi-brittle materials, the determination of a two-parameter fracture mechanics "K" and T-stress as function of crack length or crack velocity is often difficult. To measure the stress field during the fracture propagation, we need to perform stable fracture tests beyond the maximum load. This is not an easy task! Sophistical and expensive test stability control apparatus (i.e. closed loop control unit with e.g. crack tip opening displacement as a feedback signal) may be used to perform such tests. . However, these systems are often not available inlaboratories.
The wedge-splitting test (WST), first used by Linsbauer and Tscheg [3] and later developed by Brühwiler and Wittmann [3], is a test that permits to propagate stable cracks. . The WST has been extensively used for experimental (e.g. [5-6]), numerical (e.g. [7-8]) and inverse analysis studies (e.g. [9]). In spite of its advantages, the fracture parameters for the WST are not widely reported. The purpose of this paper is to study, using both numerical and experimental approaches, the variation of stress intensity factor or T-stress as function of crack path position. Digital Image Correlation (DIC) is used to follow the crack propagation. Based on displacements evaluation, crack tip position, Stress intensity factor "K" and T-stress are determined. Secondly, we performed by means of a constraint-based two-parameter fracture mechanics approach, a numerical analysis of near-crack-tip stress field using the Finite Element Method (Abaqus 6.6 software) [10]. In the numerical approach, the wedge

displacement load versus crack tip position data was used as boundary load conditions to calculate both stress intensity factor "K" and T-stress. Their values are compared with the result obtained by the Digital Image Correlation (Q4-DIC software) [11]. Finally, the performances of the two global approaches are compared.

2. Experimental configuration

The experimental setup is shown in Figure 1a and b. A vertical load is applied by means of a metallic wedge at the mouth of the notched sample. The sample is supported along its basis. To minimize friction between wedge and lateral supports, two lines of rollers are used. During testing, the wedge pierces the sample and the crack generated at the tip of the notch propagates in stable way. The crack grows until it reaches the bottom of the sample, splitting it into halves.

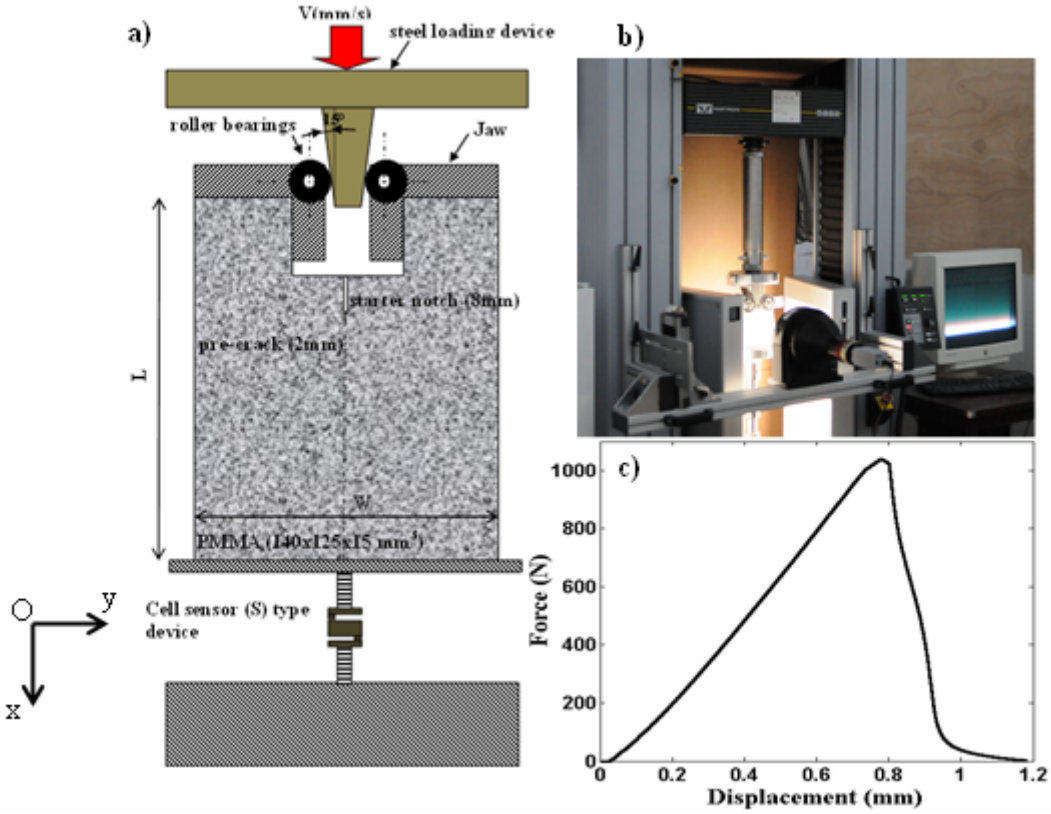

Figure 1. a) Experimental set-up of the Wedge Splitting loading. b) A telecentric lens is used to minimize artifacts induced by out-of-plane motions. c) Typical load- wedge displacement curve from PMMA fracture test.

Due to the compressive stresses in front of the crack tip and due to the small amount of elastic energy stored in the specimen, the crack propagates with a velocity proportional to V_{wedge}. The elastic energy stored in the testing device is much lower compared to other common test methods because the wedge angle (here choose to 15°) enhances the effect of the vertical force applied by the machine. The material used is Polymethyl methacrylate (PMMA) from Altuglas International (Perspex sheets). This material is brittle with a Young's modulus E= 2800 MPa and Poisson's ratio ν=0.33. The specimen is prepared from rectangular plates of length L=140mm, width W=125mm, and thickness H=15mm. A notch is machined i) by cutting out a 25x25x15mm^3 parallelepipeds from the middle of one of the WxH edges; ii) by subsequently adding a 8 mm long 800 µm thick groove with a diamond saw; and

iii) by finally introducing a seed crack (~2mm-long) with a razor blade. The test is conducted at room temperature (20 °C), under displacement control at 1 µm/s using a testing machine of 1 kN capacity (Instron 5882). The specimens exhibited a linear load–displacement diagram prior to fracture, confirming the predominantly linear elastic behavior of the material (Figure 1c). During the test, the surface of the sample is observed, with a CCD camera, (pixeLINK®, definition: 2500 x 1600 pixels, digitization: 8 bits) operating at 0.1 Hz and equipped with a telecentric objectif (GO Edmund, Techspec® gold series, Max distorsion: 0.35%, telecentricity: < 0.2°). The telecentric is used to minimize artifacts related to out-of-plane motions. The physical pixel size corresponds to 44.2 µm. Prior to the experiment, surface of the sample is painted in white and speckled with black paint. Two halogen lights are used for illuminating. For a realistic simulation, we need to obtain the typical wedge displacement-crack length curve from mechanical test and the crack path trajectory. These informations are directly measured from the location of crack tip via the camera using Digital Image Correlation (Figure 2a and b).

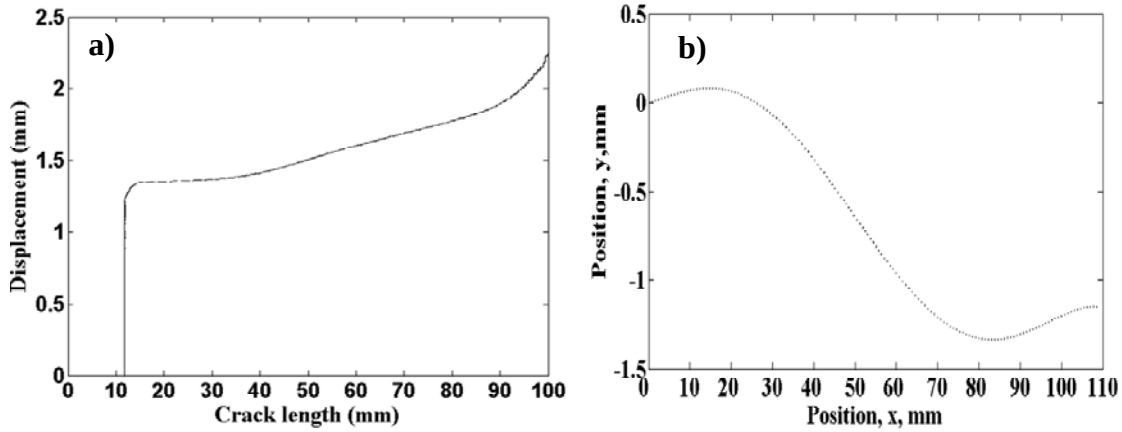

Figure 2. a) Displacement-crack length curve from PMMA fracture test, b) Crack path trajectory determined by DIC.

3. Finite element analysis (Abaqus)

Two-dimensional linear elastic fracture mechanics is retained to model the Wedge Splitting Test (WST) using a finite element method (Abaqus 6.6 software). To be in agreement with the experimental conditions, the choice of plane-stress state conditions was assumed. The computation of the stress intensity factor (K) and T-stress based on the domain integral "J" is carried out using six contours [10,12]. Apart from the first contour, the J-integral is path independent for the remaining 5 contours surrounding the crack tip. The material model was linear elastic, with the same properties for the experimental tests. The loading wedge is modeled as rigid bodies. The specimen is loaded by applying a displacement to the wedge in the vertical direction using an experimental displacement versus crack length data in the loading boundary conditions and taking under consideration the crack path trajectory (see Figure 2a and b. All other motions of the wedge are restrained. Surface-to-surface contact with a finite-sliding formulation is defined between the wedge and the rolling specimens, on the one side, and the specimen and the support, on the other. We assume that the contact is frictionless. Two analysis steps are used. In the first step, contact is established between the wedge and the rolling specimen by applying a small displacement (1×10^{-3} mm) in the vertical direction. In the second step controlled displacement loading of the wedge is applied. The virtual crack extension direction is specified with the q-vector. In the present model, it is defined with the starting point at the crack tip and the end point at the red dot, as shown in Figure 3.

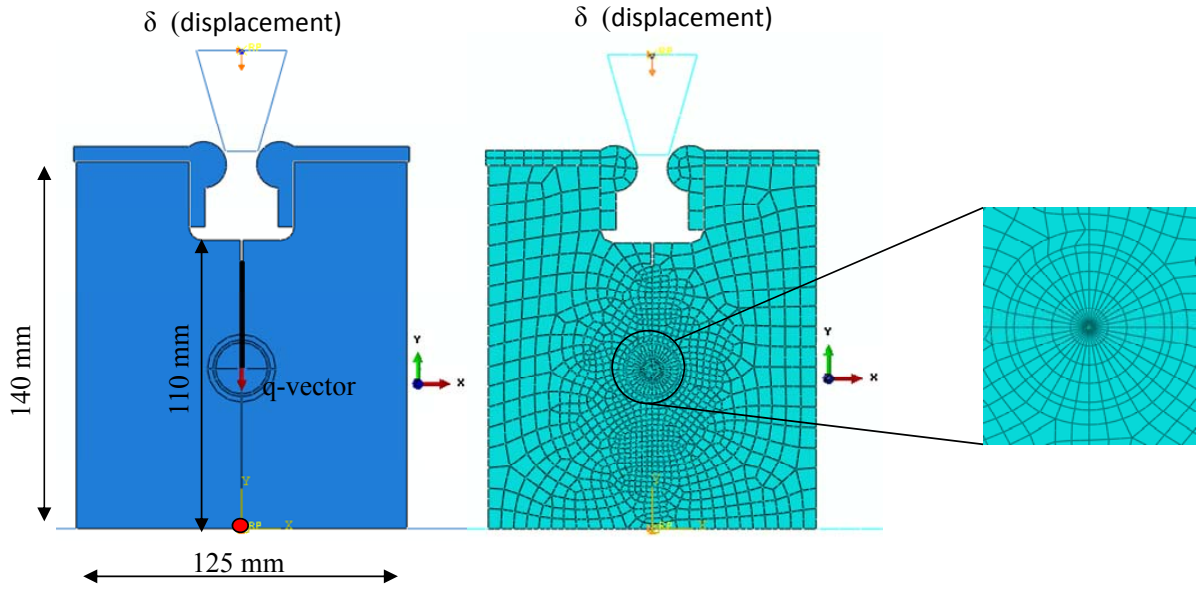

Figure 3. Partitioned two-dimensional Wedge Splitting Test and mesh strategy adopted around crack-tip.

For a sharp crack, the strain field becomes singular at the crack tip. Including the singularity at the crack tip for a small-strain analysis improves the accuracy of strain calculations, the J-integral and stress intensity factors. The partitioning of the geometry is defined by the circular lines centered on the crack tip (Figure 3); this partitioning strategy facilitates the generation of a focused mesh. The remaining portion of the model is free meshed using the "medial axis" meshing algorithm. The crack tip is meshed using a ring of collapsed 8-node bilinear, reduced integration (CPS8R) elements. To obtain a $1/\sqrt{r}$ singularity term, the following conditions must be met:

1. The elements around the crack tip must be focused on the crack tip. One edge of each element must be collapsed to zero length so that the nodes of this zero length edge are located at the crack tip.
2. The "midside" nodes of the edges radiating out from the crack tip of each of the elements attached to the crack tip must be placed at one-quarter of the distance from the crack tip to the other node of the edge.

4. Digital Image Correlation Analysis (Q4-DIC)

Digital image correlation is a technique that allows one to retrieve displacement fields separating two digital images of the same sample at different stages of loading.
We summarize the main points here, for more information the reader shall refer for instance to [11, 15]. Generally, it is not possible to find the correspondence of a single pixel in an image in the deformed state to the image in the reference state. This is because there is not a unique correspondence. The subsets which are comprised of finite number of pixels are utilized to locate the same material point between deformed and reference states. To correlate the deformed image $\boldsymbol{g}$ to the undeformed reference image $\boldsymbol{f}$, each image is divided into small subsets and the correlation algorithm is executed from subset to subset. A digital image of a body is simply a discrete intensity record of the light levels present at various positions of the body in the smallest unit of digitization, the pixel. In an eight-bit system, light intensity at each pixel ranges in value from 0 to 255 (represented as $0 < p(x,y) < 255$). The point P(x,y) in

the reference image becomes P'(x^*,y^*) in the deformed image and Q(x,y) becomes Q'(x^*,y^*). DIC is run by comparing group of similar light intensity numbers between the two digital images to track points P and Q. Depending on the use of a first or second order approximation, 6 or 12 unknowns are available and can be found by correlation between the two images. This can be done by minimizing the global residual between the reference image f and the deformed image corrected by the displacement field g(x+u(x)) over the whole region of interest:

$$\eta^2 = \iint_\Omega \left[g(x+u(x)) - f(x)\right]^2 dx \tag{1}$$

In the following, 4-noded elements are considered (*i.e.* a Q4-DIC approach [11]). The DIC procedure applied herein consists in measuring displacement field discretized with quadratic Q4 elements. The elements size was chosen to be equal to 8 pixels. This value is a good compromise between measurement uncertainly and spatial resolution. Extracting some mechanically meaningful information using the detailed map of displacement can be performed by identifying the amplitudes of relevant reference displacement fields namely, William's series [13]. These field $\mathbf{u}=u_x+iu_y$ take the following expression in the crack frame (crack tip at the origin, and crack path along the negative x axis) resorting to the complex plane, $z=re^{i\theta}$

$$u(z) = \sum_n \left[\omega_n \Omega_n(z) + \upsilon_n \psi_n(z)\right] \tag{2}$$

With, for a mode I regime:

$$\Omega_n(z) = \frac{(-1)^{(1-n)/2}}{2\mu\sqrt{2\pi}} r^{n/2}\left[\kappa \exp\left(\frac{in\theta}{2}\right) - \frac{n}{2}\exp\left(\frac{i(4-n)\theta}{2}\right) + \left((-1)^n + \frac{n}{2}\right)\exp\left(-\frac{in\theta}{2}\right)\right] \tag{3}$$

And a mode II regime:

$$\Psi_n(z) = \frac{i(-1)^{(1-n)/2}}{2\mu\sqrt{2\pi}} r^{n/2}\left[\kappa \exp\left(\frac{in\theta}{2}\right) + \frac{n}{2}\exp\left(\frac{i(4-n)\theta}{2}\right) + \left((-1)^n - \frac{n}{2}\right)\exp\left(-\frac{in\theta}{2}\right)\right] \tag{4}$$

Where μ is Lamé's modulus, and κ is a dimensionless parameter dependent on Poisson ratio ν (*i.e.* $\kappa = \frac{3-\upsilon}{1+\upsilon}$ in plane stress, or 3-4ν in plane strain condition).

Amplitudes ω_1 and ν_1, associated with field Ω_1 and Ψ_1, are the mode I and II SIFs, K_I and K_{II}, respectively. Amplitudes ω_0 and ν_0 correspond to rigid body translations. Amplitudes ω_2 and ν_2 give access to the T-stress component, and the rigid body rotation. The crack-tip is located by canceling out amplitude ω_{-1} of the first supersingular field.

5. Results and discussion

Experimental results were obtained from the displacement fields obtained with a mesh size of 8 pixels (1 pixel→44.2 μm), over a region of interest of 2500 x 350 pixels (Figure 4).

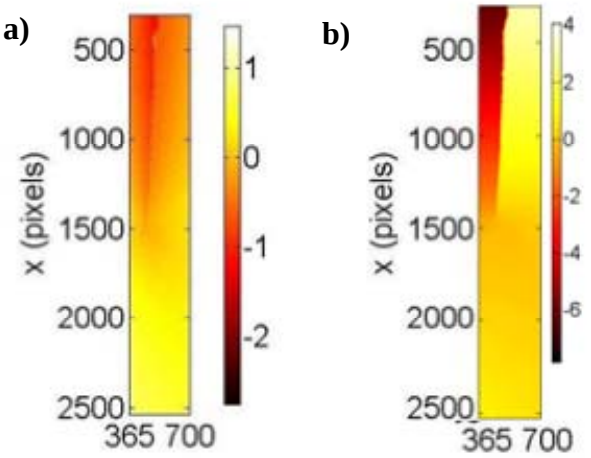

Figure 4. Horizontal (a) and vertical (b) component of the displacement field expressed in pixels as projected onto the basis of suited functions in post-processing of the measured displacement (1 pixel → 44.2 μm).

From the amplitudes ω_n and ν_n, it is possible to plot the SIF and T-stress as function of crack length. In figure 5a and 5b, the SIF obtained by DIC are shown together with the SIF obtained by Abaqus. In average the differences is 9%. For the DIC method, an error bars was estimated by extracting extreme positions of crack tip and measuring the corresponding change in K (average error bars were 11 %). For both methods, we found that K_I is constant from 40 mm to the end of sample, demonstrating that the crack propagation is stable (ie. The cracks propagates with a constant velocity), whereas K_{II} fluctuates around zero (Fig 5b). Despite an average difference of 22 %, a good agreement is found in the case of the T-stress component when compared to the FE results. This difference is compensated by error bars (an average error bar were 15%) (Fig 5c). In both case, the T-stress varies from negative value for short cracks to positive value for crack lengths above 5 mm, contrary to the compact tension geometry, where T values are always positive [14]. Compared to the stress intensity factor, the error bar in the case of T-stress is higher because the T-stress is the coefficient of higher order terms of the displacement field expansions.

Without surprise, those measures confirms Irwin's criterion $K_I=K_c$ during stable propagation and the Principle of Local Symmetry $K_{II}=0$. It confirms also Cotterell and Rice crack path stability criterion. As soon the T-stress becomes positive, the crack path doesn't remain straight (fig. 2b) and find another, not straight, path which satisfies nevertheless Irwin's criterion and the Principle of Local Symmetry. This is one more [16] experimental demonstration that this double criterion doesn't lead to a unique solution: the observed crack path is not the trivial straight one but another more stable bifurcated one.

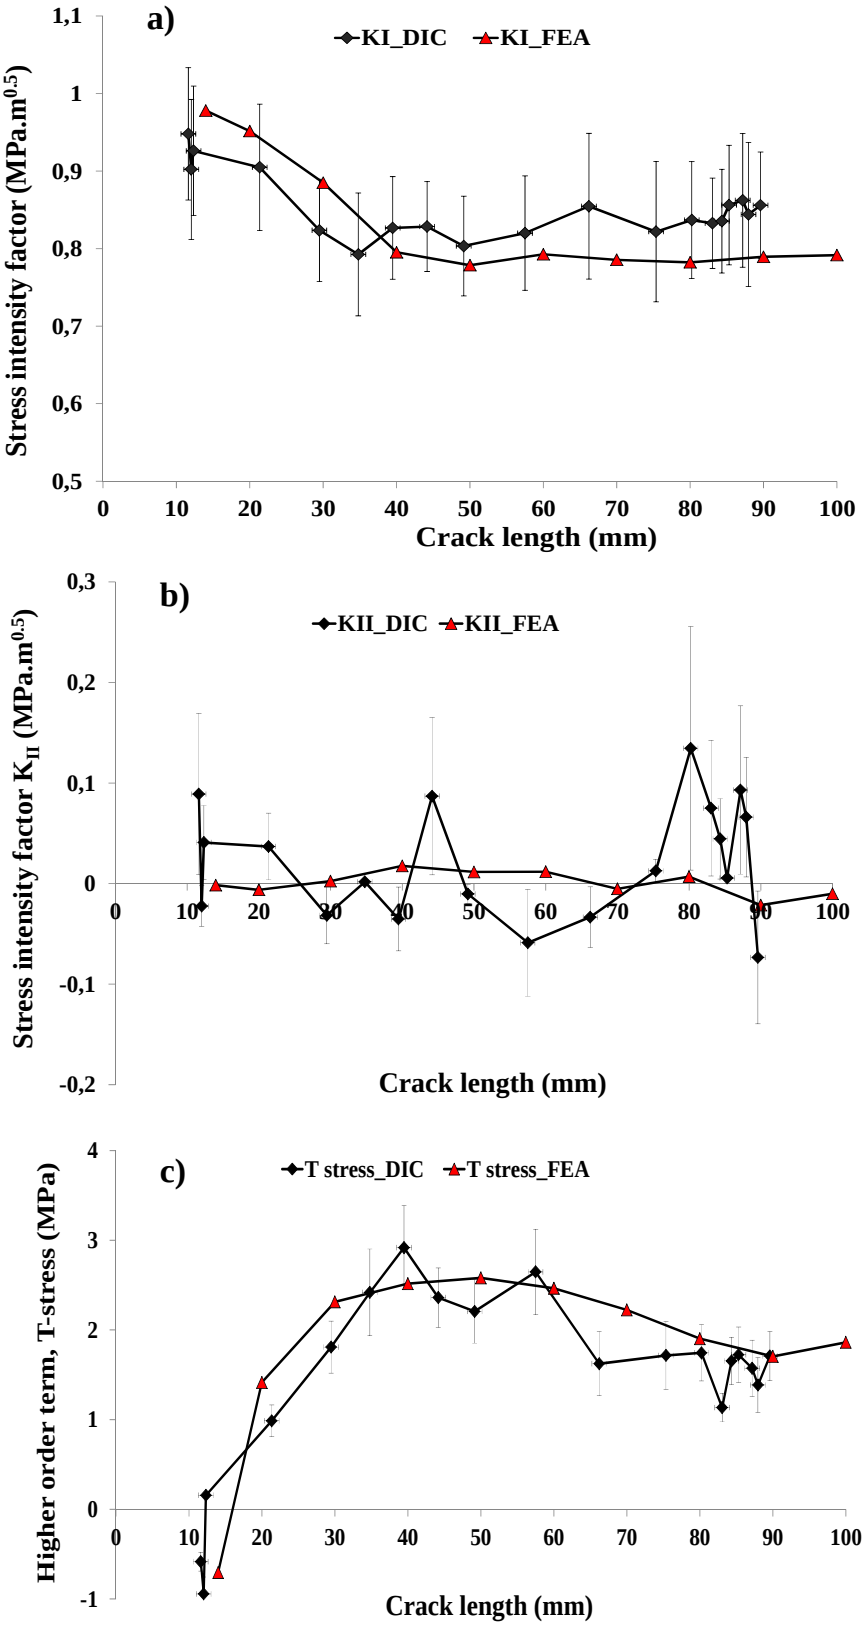

Figure 5. Comparison of (a)-(b) stress intensity factor, (c) T-stress determining using Finite Element Analysis and Digital Image correlation.

6. Conclusions

The Finite element Analysis and Direct measurement of the crack tip displacement field is performed using Abaqus software and Digital Image Correlation (Q4-DIC). In Finite Element Analysis, the two parameter fracture mechanics approach, describing the near–crack-tip stress field (SIF and T-stress) were calculated using the domain integral "J". In Digital Image Correlation, these parameters were obtained by adjusting the first supersingular term of William's series. One the crack tip was determined, the crack growth increment is estimated in addition to other global parameters such as the stress intensity factor range and T-stress. In both method, good agreement is shown and finite element analysis can be validated. The stress intensity factor versus crack length remains constant whereas the T-stress varies from negative to positive. This later variation is similar to the three point bend beam, but different from the compact tension specimen, for which the T-term is always positive. Using Digital Image Correlation (DIC), the stress intensity factor and T stress were estimated with 10% and 15% uncertainty in a complex loading set-up without the need for a numerical modeling of the experiment. The displacement and crack extension at the onset of crack propagation is important. It is expected that any model that can match all the experimentally observed features of the test will provide a significant enhancement to our present capability to predict any fracture parameter. Our wedge splitting test is particularly attractive for fundamental research and model validation because of the enhanced length of stable crack propagation. This advantage allows us the identification of crack propagation parameters during all propagation from one single test.

Abstract
Commonly, for components under creep loading, the maximum tolerable inelastic strain is limited to 1 %. The strains are calculated for components which are free from defects, using appropriate material models. Within the fabrication process internal defects such as crack or cavities cannot be avoided, especially for large thick-walled components. For these internal defects fracture mechanic concepts must be applied for safety assessment.
Existing fracture mechanics concepts such as the Two-Criteria-Diagram or the Time-Dependent-Failure-Assessment-Diagram do not include the effect of the material's ductility which has a clear effect on crack initiation process. Under creep load, the strains within the crack tip region dominate local material separation. Therefore a concept is introduced, which formulates a deformation exhaustion rule. With this procedure a better material utilisation is achieved.
In a next step, crack initiation is calculated using an internal damage variable, which can be used as a life time parameter. Within this approach, the influence of a multiaxial state of stress on the damage evolution must be implemented. This procedure simplifies crack initiation assessment, replacing fracture mechanic methods by the evaluation of the damage variable.

Keywords Creep, crack initiation, failure criterion, creep strain

1. Introduction

For components under creep loading, the maximum tolerable accumulated inelastic strain must be limited, [1]. This limitation in strain is well-founded on evaluations of the remaining life-span with reference on microstructural damage, [2]. If an inelastic strain of 1 % is accumulated, monitoring arrangements must be established. This does not account for internal defects or cracks. For a safe operation of the component, the assessment must include the description of crack initiation and crack growth. If now the period to crack initiation is longer, than the period to accumulate the limit strain, the assessment procedure could be simplified. This can be described by the relation of the time to crack initiation t_A to the time, say for 1 % inelastic strain, $t_{1\%}$:

$$t_A \geq t_{1\%}. \tag{1}$$

The aim of this work was to identify crack sizes for which **Eq. (1)** is met. Therefore the time to crack initiation t_A must be identified, which requires an appropriate assessment concept. Commonly used concepts, such as the Two-Criteria-Diagram, [3], (TKD, see **Figure 1**) or the Time-Dependent-Failure-Assessment-Diagram, [4], [5], are based on stress relations. The TKD differs between three damage modes. Within the crack-tip-damage region the specimens or components have large cracks with a low mean stress. Within the ligament-damage region there are small cracks with a high mean stress and a high accumulated strain within the far-field region of the specimen. In between there is the mixed-mode damage region. Ligament damage is defined by accumulation of 1 % strain in the farfield of the specimen, [3], [4]. The analysed specimens within this work are aimed to have an $R_\sigma = 0.75 \div 1$ and $R_K \approx 0{,}5$ and lie on the edge of the ligament-damage field.
Over the past decade, there have been analysed various steels used in power plant operation generating a wide database for describing the material's behaviour and crack initiation, [5], [6], [7], [8], [9]. Modern high chromium steels however, exhibit a high creep ductility influencing strongly the

crack initiation behaviour. The ductility in this case is represented comfortably by the material's creep rupture strain. The more deformation within the region of the crack tip is attainable, the later the crack initiation will start. Therefore it is sensible to set up a strain based criterion to describe crack initiation. With this, the influence of ductility is directly implemented. To gain a concept which is valid for either high or low ductility, materials differing in their ductility must be analysed to validate the concept. Describing crack initiation applying a stress formulated concept - such as the commonly used assessment procedures- will be too conservative. The influence of ductility on crack initiation have been analysed theoretically or have been approximated, [10], [11], [12], [13]. Concerning the TKD, a modification based on the creep rupture strain has been proposed in [13]. This was done mainly for the crack-tip-damage region. For the ligament-damage mode a dependency of ductility could not yet be established.

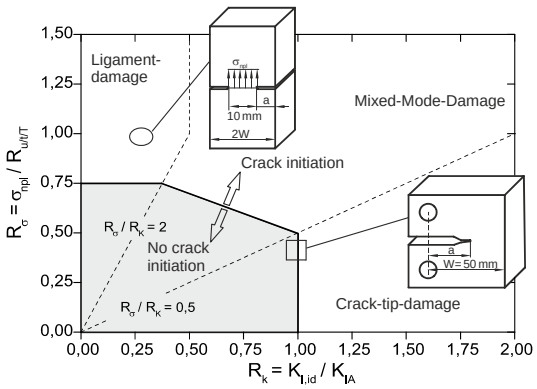

Figure 1. Creep rupture strains of a 10Cr-steel at T = 600 °C, different heats

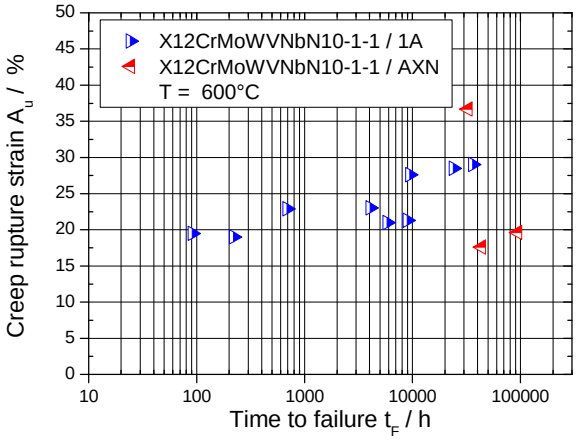
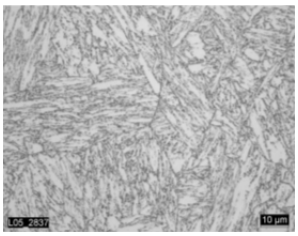
The specimens investigated will have Double-Egde-Notched-Tension (DENT) in different sizes or compact-tension (CT) geometry. The loading times for the numerically treated specimens are up to operational relevant times of 200.000 h. The aim is the determination of initial crack sizes as a function of the creep rupture strain for different specimen sizes which account for Eq. 1. Below this limit of initial crack size a_{limit}, a fracture mechanics assessment is not necessary. The creep data used to set up the material law is available up to 140.000 h for uniaxial creep tests. The fracture mechanics experiments are available up to 20.000 h.

2. Investigated materials

To account for the influence of the material's ductility, one 10Cr-steel and two 1Cr-steels have been considered. The creep rupture strain of the 10Cr-steel is shown in **Figure 2**.





X12CrMoWVNbN10-1-1

Figure 2. Creep rupture strains of a 10Cr-steel at T = 600 °C, different heats

There are two heats shown, which differ only with respect to the initial heat treatment. Due to the loading times up to 100.000 h the material properties are not supposed to differ. As shown, the creep rupture strain is about 20%-25% and can be approximated by a constant.
The creep rupture strain of the two 1Cr-steels is shown in **Figure 3**. It can clearly be seen, that the rupture strain is decreasing with increasing loading time. Both steels differ in the initial heat treatment.
The creep rupture strain itself, however, is not an appropriate measured variable, due to the influence of the reduction of area gained in creep tests on materials with high ductility. Concerning thick-walled components, no transverse strain is observed. To meet this problem a reference strain was introduced, which does not include the influence of the reduction of area on the creep rupture strain value, see **Figure 4**. Two different formulations have been analysed. One is based on the volume of the creep test specimen. This method was preferred for the implementation of the failure criterion. The second method is based on the strains at the onset of the tertiary creep stage.

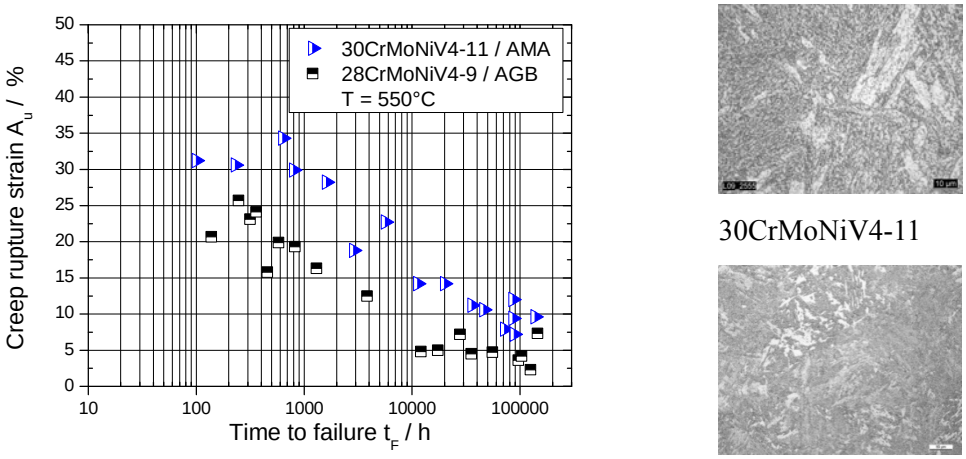


Figure 3. Creep rupture strains of 1Cr-steels at T = 550 °C

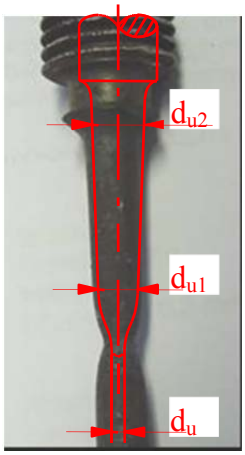

$$\varepsilon_{r,1} = \left(\frac{2 \cdot d_0}{(d_{u1} + d_{u2})} \right)^2 - 1 \qquad (2)$$

$$\varepsilon_{r,2} = \varepsilon_{2/3} + \dot{\varepsilon}_{min} (t_u - t_{2/3}) \qquad (3)$$

with: t_u – time to failure,

$\varepsilon_{2/3}$ – Strain at onset of tertiary creep

$t_{2/3}$ – Timepoint at onset of tertiary creep

Figure 4. Definition of a reference strain

The reference strain according to **Eq. (2)** is used as material parameter within the failure criterion, which relates a characteristic strain within the specimens to the reference strain. The reference strain is referred as ε_r. The reference strain can be plotted over the creep rupture strain, see **Figure 5**. This yields the correlation of the creep rupture strain and the calculated initial limit crack length a_{limit}.

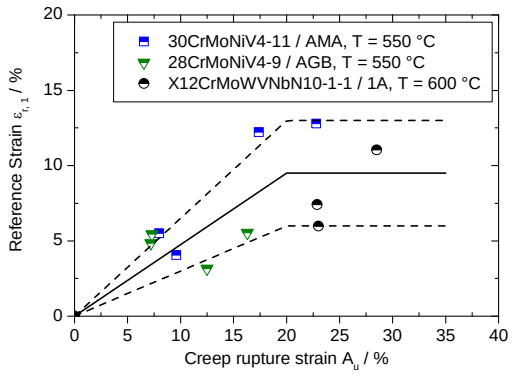

Figure 5. Correlation between reference strain and creep rupture strain

3. Investigation of small cracks

To analyse the dependence of the pre-loading crack size a_{limit} on the material's ductility, 3D models of specimens with DENT geometry have been used. The crack was modelled with a crack tip radius of 0.1 mm, which is valid for the experiments. The crack tip was meshed with a fine mesh to represent the stress and strain gradients correctly. For the description of the material's behaviour a modified Graham-Walles formulation have been implemented, [14]. The calculations were conducted with the Finite-Element-Code ABAQUS ©.

The numerical analysis of specimens with loading times up to 200.000 h requires a failure criterion to correlate with crack initiation. Within the creep regime and with respect to the dependence on ductility, a strain based formulation of the failure criterion is appropriate. Since the creep deformation and the creep damage is dependent on the multiaxiality of the stress state, this must also be considered, [15], [16], [17], [18]. With higher multiaxiality, the deformability is reduced. To account for that effect, the concept of Cocks&Ashby is applied, [19].

To correlate the calculated strains with the material dependent reference strain, a characteristic point within the crack tip region to evaluate the strains and the multiaxiality must be chosen. The calculated strains were evaluated at the point of maximum triaxiality near the modelled crack tip. Due to the high constraints, crack initiation begins at this point by formation, growth and coalescence of creep cavities. In addition a definition of crack initiation in the experiment must be set up. Crack initiation is defined for a crack growth of $\Delta a = 0.1$ mm.

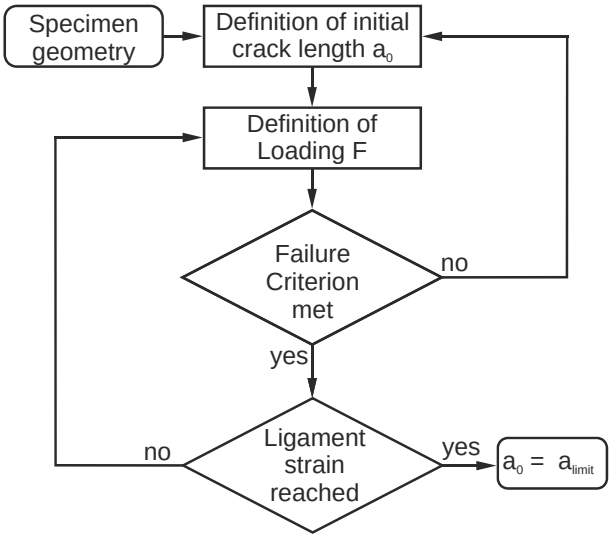

Figure 6. Schematic overview of calculation of a_{limit}

This value was chosen on the one hand to avoid the need of modelling crack propagation in the FE-calculations and on the other to be able to detect crack initiation within the experiments. In **Figure 6** the calculation procedure is schematically shown. The optimisation of the results with respect to the initial crack length and the accumulated strain within the ligament are done iteratively.

The concept for describing crack initiation was first validated by applying on already run experiments. In **Figure 7** are the results shown for the analysed 10Cr and 1Cr-steels. The results of the FE-calculations are in good agreement with the defined reference strain for all materials and different ductility. The failure criterion now can be applied to find out, if there is a limit crack size below a fracture mechanics assessment is not necessary. The limit of initial crack size a_{limit} will be determined in correlation to the creep rupture strain corresponding to loading times of 100.000 h and more, which cannot be done experimentally. The creep rupture strain for the 10Cr-steel is assumed to be constant between 100.000 h and 200.000 h. For the 1Cr-steels the low creep rupture strain at 100.000 h is extrapolated as constant up to 200.000 h.

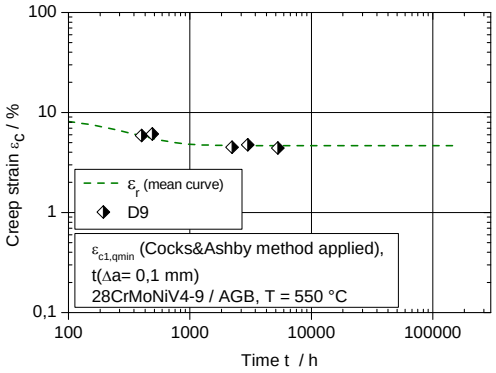
b) 30CrMoNiV4-11



c) 28CrMoNiV4-9

Figure 7. Validation of the strain based failure criterion for 10Cr and 1Cr-steels

The limit of initial crack size a_{limit} sought, is defined dependent on the accumulated inelastic strain within the ligament of the specimen. It is that size of surface type crack for the DENT specimen, when simultaneously the failure criterion in the crack-tip region is met and the selected creep strain is reached. To quantify the influence of specimen geometry and size, these have been varied. The results of the calculations are shown in **Figure 8**. It can be seen, that there is small scatter of the data with respect to geometry and size of the specimens at a constant creep rupture strain. In general it can be stated, that with increasing size (especially breadth) the limit of initial crack size increases, too. An increasing ductility also leads to a higher limit of initial crack size. Also different levels of ligament strain have been analysed. This is derived for the operation of different components. A strain level of 1 % within the net section stress area is valid for thick-walled components and is

founded on [1]. For turbine runners, this strain would lead to component failure due to the component tolerances. In this case a strain level in the ligament of the components of 0.2 % is discussed.

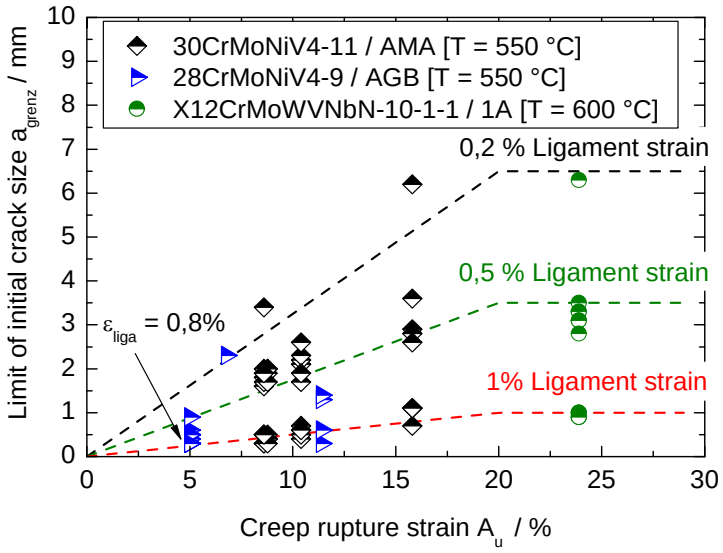


Figure 8.

With a decreasing ligament strain, the net section stress is reduced, which results in a reduced crack tip loading for constant crack length. As it is shown in Figure 8, the limit in initial crack size therefor increases. It is clear, that with growing of a_{limit}, the wall thickness must have a minimum larger than a_{limit}.

For the creep-brittle 1Cr-steel 28CrMoNiV4-9 a ligament strain of 1 % could not be attained even for crack sizes of 0.3 mm. Instead of modelling initial crack sizes below 0.3 mm a ligament strain of 0.8 % was accepted, too.

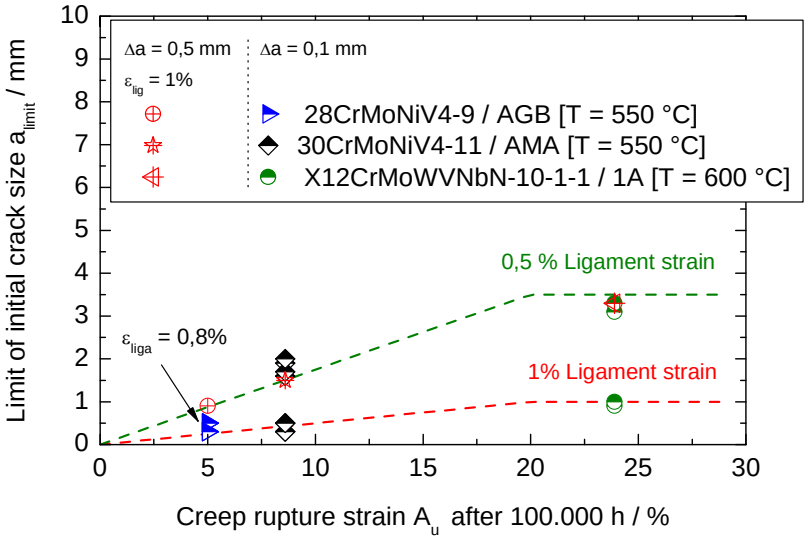

Figure 9.

Considering the relation between the reference strain and the creep rupture strain (see Figure 5) it correlates well with the observed dependence of the initial crack size and the creep rupture strain, i.e. above 20 % of creep rupture strain a_{limit} and ε_r remain constant.

This analysis was conducted defining crack initiation at a crack growth of 0.1 mm. In general a crack propagation of 0.5 mm is assumed. So the above applied strain based failure criterion is met

at earlier loading times, i.e. it is more conservative, if a crack growth of 0.5 mm is tolerable. Otherwise, for a fixed loading time and net section stress, a larger initial crack size is tolerable if at crack initiation a defined ligament strain is reached. This was investigated for a fixed loading time of 100.000 h, shown in **Figure 9**. It can clearly be seen, that the initial crack sizes increase if crack initiation occurs for a crack growth of 0.5 mm at the same ligament strain.
Since no crack propagation was modelled in the numerical analysis, the crack growth was approximated using:

$$\frac{da}{dt} = m \cdot (C^*)^k \tag{4}$$

With the C*-parameter, see [14], [22]. The parameters C and m are dependent on the material and are listed in Table **1**.

Table 1. Crack propagation parameters

	X12CrMoWVNbN10-1-1	30CrMoNiV4-11
	T = 600 °C	T = 550 °C
m	0,25	0,25
k	0,18	1,05

Within the small crack propagation of 0.4 mm a constant crack growth rate can be assumed. The total time span of 100.000 h is then the sum of the time to reach the strain based failure criterion with a crack propagation of 0.1 mm and the crack growth to $\Delta a = 0.5$ mm.

4. Summary

Modern steels for high temperature operation, e.g. in power plants, are showing high deformability. Classical methods, determining failure formulated on the stress field, are highly conservative. Improving the assessment aiming at a better material usage requires a concept which includes the actual deformability. Additionally, for high ductile materials, crack initiation does not readily start before a certain strain within the net section stress region is accumulated, defining monitoring measures or the replacement of the component. To be able to determine this crack size dependent on the material´s ductility a more accurate failure criterion is needed.
A strain based concept has been introduced and applied on three 10Cr- and 1Cr-steels with different ductility. It correlates a characteristic strain within the crack tip region of the specimen and a material dependent reference strain. Determining the stress and strain field within the crack tip at a certain loading time requires Finite-Element modelling and calculations to crack initiation. With a crack initiation criterion with a crack growth of 0.5 mm modelling of the crack propagation is essential. To avoid this effort, crack initiation was attained for a smaller crack growth of 0.1 mm. The concept was validated on fracture mechanics specimens with loading times up to 20.000 h.
It could be shown that the initial crack sizes of interest, i.e. such sizes which does not show crack initiation before a certain strain is reached within the ligament section, is dependent on the materials ductility. For a ligament strain of 1 % the limit of initial crack size is up to 1 mm for creep rupture strains of 20 % and more. Reducing the ligament strain is leading to an increase of the limit of initial crack size.

5. Discussion and conclusions

Within the creep regime, local failure can be described through the available deformability of the material. With regard to crack initiation it would lead to a less conservative concept, than using stress based formulations, since the deformability does markedly have impact. The formulation of failure set up could be validated on fracture mechanics experiments, providing a limit of initial crack size for practical operation times. This limit characterises crack sizes for which crack initia-

tion does not occur before a certain strain within the ligament (in the net section stress region) is reached. If now the operation period of the component is defined by these creep strains within the net section stress area, pre-loaded cracks would not tend to initiate. For this cracks and internal defects, a fracture mechanics assessment is not necessary. So, the results of this work can be used to simplify the assessment of components, depending on the ductility, i.e. the creep rupture strain at a given loading period. In addition for materials with a high ductility a more precise failure assessment could be provided.

CMOD-Based J Integral Measurement for Surface Cracked Specimens

Xudong Qian[1,*], **Ya Li**[1]

[1] Department of Civil and Environmental Engineering, National University of Singapore, Singapore 117576, Singapore
* Corresponding author: qianxudong@nus.edu.sg

Abstract This paper proposes an experimental approach based on the measured crack-mouth opening displacement (CMOD) to determine the mode I energy release rate for surface cracks in plate specimens subjected to four-point bending. The proposed experimental scheme measures the load versus CMOD relationships in a surface cracked specimen under four-point bending, and computes the relative rotation, θ, between the two crack planes based on the measured CMOD, and the bending moment (M) applied on the cracked cross section based on the measured load. The energy release rate, measured by the J-integral value, computes from the area under the M-θ curve, similar to the eta-approach originally proposed by Rice and co-workers for single-edge-notched bend, SE(B), specimens. This study examines the above approach for four plate specimens with fatigue pre-cracked, machined surface notches. The measured J value shows close agreement with the energy release rate computed using the domain integral approach.

Keywords surface crack, crack-mouth opening displacement, energy release rate, domain integral, compliance.

1. Introduction

The standard procedure to derive the fracture resistance curve, namely the J-R curve restricts to small-scale planar specimens with a straight, through-thickness crack front [1-2] under high-constraint, small-scale yielding conditions. The fracture resistance thus measured characterizes the capabilities of the material in resisting fracture failure in an idealized, plane-strain condition. In contrast, realistic cracks in structural details often entail a complex topology with a curved crack-front, sometimes resembling a semi-elliptical shape. The varying crack-extensions along the curved crack fronts impinge inevitably on the resistance against crack growth at individual crack-front locations, due to the stress redistribution caused by the non-uniform crack extensions along the curved crack front. The plane-strain fracture resistance obtained using the conventional through-thickness fracture specimens may not, therefore, represent the fracture resistance reserved at different crack-front locations in curved surface cracks. The fracture resistance measured from the through-thickness specimens may thus not provide an accurate description of the evolving fracture resistance as the surface crack grows in the integrity assessment for engineering structures, *e.g.*, the level 3C ductile tearing assessment. An experimental method to measure the J-integral values for surface crack specimens becomes much-needed to overcome the transferability of the J-R curve from the material level to the specimen/structural level.

This study proposes such an experimental approach to determine the energy release rate for surface cracked plate specimens. The calculation of the energy release rate utilizes the CMOD-based approach, frequently used in the conventional through-thickness fracture specimens in evaluating the energy release rate. The experimental procedure determines the gross energy release rate along the entire crack front using the area under the moment-rotation curve of the crack plane, similar to the η-approach originally proposed by Rice *et al*. [3]. The rotation of the crack plane derives from a numerically determined center of rotation. The dimensionless η-value is, on the other hand, determined by coupling the numerical strain energy (the area under the M-θ curve computed from finite element [FE] models with a stationary crack) and the domain-integral values. The energy release rate determined from the compliance method agrees closely with the energy release computed using the domain-integral approach implemented in WARP3D [4].

2. Proposed *J*-Measurement for Surface Cracks

The proposed approach to measure the energy release rate, quantified by the *J*-integrals, predicates the fundamental principle prescribing the variation of the strain energy with respect to the crack extension,

$$J = -\frac{1}{B}\frac{dU}{da}, \tag{1}$$

where B refers to thickness of the conventional planar fracture specimen with a through-thickness straight crack. The definition of the J value in Eq. (1) requires that the parameter B characterizes the length of the crack front, as the physical interpretation of the J refers to the energy released per extended crack area. Replacing B by the crack-front length for a curved surface crack, Eq. (1) becomes,

$$J_{avg} = -\frac{\partial U}{\partial A_{crack}}, \tag{2}$$

where A_{crack} denotes the crack area. The J-value determined from Eq. (2) thus represents the energy release rate averaged over the entire curved crack front in the surface crack specimens.

To facilitate the experimental measurement of the energy release rate, previous researchers [3, 5] have developed an η-approach for different fracture specimens with a through-thickness crack,

$$J = \frac{\eta U}{Bb}, \tag{3}$$

where η remains as a dimensionless parameter dependent on the specimen geometry, and equals 2.0 for SE(B) specimens [3]. The parameter b in Eq. (3) denotes the length of the remaining ligament in a fracture specimen with a through-thickness crack. The η parameter needs to be re-calculated for surface cracked specimens. Equation (3) provides a convenient calculation of the energy release rate based on some simple geometric parameters and the strain energy U, which often derives from the area under the load versus the load-line displacement. The denominator in Eq. (3) quantifies the remaining net area of the cracked cross section in the fracture specimen. When applied to specimens with a surface crack, Eq. (3) becomes,

$$J_{avg} = \frac{\eta U}{A_{net}}, \tag{4}$$

where A_{net} refers to the net intact area of the cracked cross section, or,

$$A_{net} = A_{total} - A_{crack}, \tag{5}$$

where A_{total} denotes the gross cross-sectional area of the specimen.

Equation (4) allows the determination of a single characteristic energy release rate for a surface crack in the experimental procedure. In contrast, the numerical domain integral approach often computes the varying energy release rates along the curved front for a surface crack. The energy release rate, averaged over the entire crack front, thus derives from the individual J-values along the crack front,

$$J_{avg} = \frac{\sum_{i}^{n} B_i J_i}{B_{total}}. \tag{6}$$

In calculating the average energy release rate along the crack front, Eq. (6) divides the curved crack front into multiple segments, each with a length B_i and a corresponding energy release rate J_i. B_{total}

in Eq. (6) denotes the total crack-front length. Equating Eqs. (4) and (6) allows the determination of the value of the dimensionless parameter η.

3. Experimental Validation

3.1. Specimen Configuration and Set-up

The experimental program includes four specimens made of high-strength steels extracted from a large-scale circular hollow section joint [6]. Figure 1 illustrates the geometric configuration of the steel plate specimens with a machined surface notch. The shape of the surface notch follows a semi-elliptical configuration with the crack aspect ratio (a/c) equal to 0.5, *i.e.*, the machined crack depth equals 10 mm.

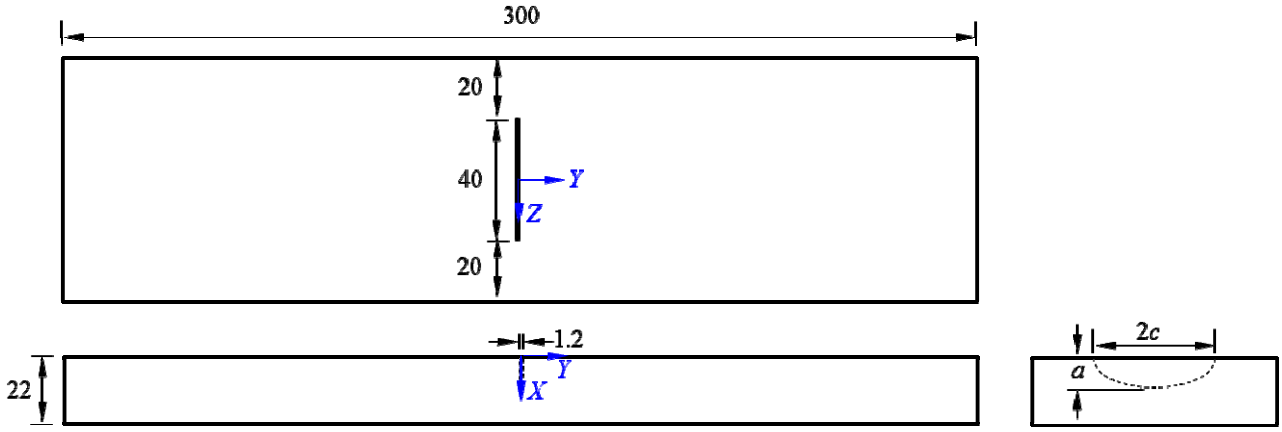

Figure 1. Configuration of the surface cracked plate specimens.

Figure 2 shows the uniaxial true stress-true strain curve obtained from the axial tension test following the ASTM E-8M [7]. The steel material has a specified grade of S690, with a measured yield strength equal to 810 MPa, and a tensile strength of 866 MPa. The Young's modulus of the material equals 206 GPa, with a Poisson's ratio of 0.3.

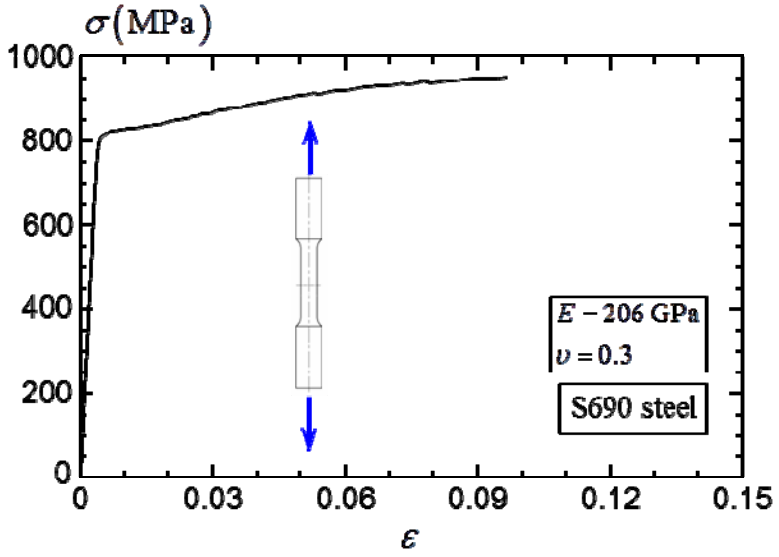

Figure 2. True stress-true strain curve of the S690 steel.

Figure 3 illustrates the four-point bend test set-up for the plate specimens. This four-point bend set-up, in contrast to the three-point bend set-up, prevents the plastic deformation caused by the indentation of the loading point to impinge on the plastically deformed crack tip under large deformations, which has frequently occurred in SE(B) specimens made of highly ductile materials.

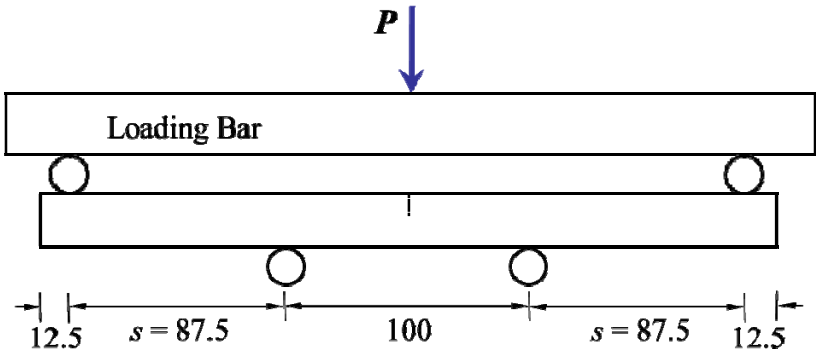

Figure 3. The four-point bend test set-up for the plate specimens.

3.2. Experimental Procedures

The experimental procedure separates into two stages: 1) a load-controlled fatigue pre-cracking cyclic load to generate a sharp crack-front along the machined notch; 2) a displacement-controlled monotonic loading coupled with multiple unloading-reloading cycles to monitor the compliance of the specimen, measured by the ratio of the measured CMOD range over the corresponding range of the applied load, throughout the procedure. The increasing compliance measured during the test indicates a growing crack during the test.

The experimental procedure monitors the specimen compliance during the fatigue pre-cracking stage, which terminates as the compliance increases by 20% to 30% of the initial compliance of the specimen. Table 1 lists the fatigue pre-cracked sizes for all four specimens.

Table 1. Fatigue pre-cracked sizes for the plate specimens

Specimen	Machined Crack Size		Fatigue Pre-crack	
	a (mm)	a/c	a (mm)	a/c
SP1	10	0.5	12.0	0.497
SP2			12.0	0.496
SP3			12.4	0.484
SP4			12.3	0.483

Figure 4 shows the load-CMOD measured during the experiment for the specimen SP1 shown in Table 1. The CMOD in Figure 4 refers to the crack mouth opening displacement measured at the center of the surface crack (Z = 0 in Figure 1).

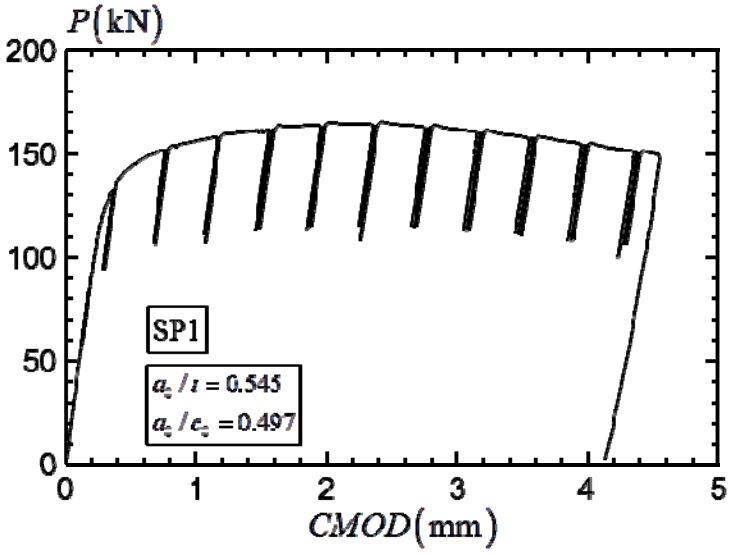

Figure 4. Definition of the crack-plane rotation angle θ.

3.3. Evaluation of Energy Release Rate

The calculation of the energy release rate in the plate specimens shown in Figures 1 and 3 depends on the evaluation of the strain energy U for the surface cracked specimens. The strain energy U, for the four-point bend specimens, follows,

$$U = 2\int_0^{\theta} M d\theta \,, \tag{7}$$

in which the angle θ defines the rotation of one of the two crack planes and M refers to the bending moment applied on the cracked section. Assuming a center of rotation at a distance of r ($W - a$) away from the crack tip, the rotation of the crack plane thus derives from the measured crack-mouth opening displacement (CMOD),

$$\theta = \frac{CMOD}{2\left[a + r(W-a) + h\right]}, \tag{8}$$

where h denotes the thickness of the knife-edge aluminum plate glued to the surface of the plate specimens in order to mount the crack-opening displacement (COD) gauge, as shown in Figure 5.

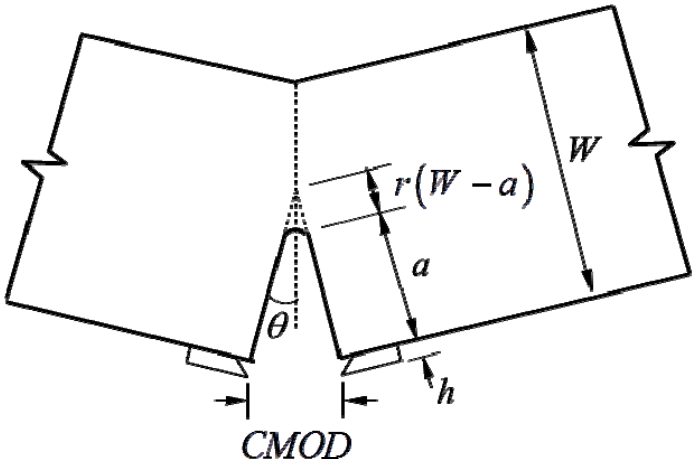

Figure 5. Definition of the crack-plane rotation angle θ.

The value of r in Eq. (8) equals 0.44 for SE(B) specimens, as outlined in standard material testing procedures [1]. This value of r, however, requires re-evaluation for the plate specimens subjected to the four-point bending shown in Figure 3. This study determines the r value through a detailed, large-deformation finite element analyses for plate specimens with a stationary crack. Figure 6 compares the deformed crack plane computed from the finite element analyses (represented by the discrete symbols) with the deformed shape calculated from a regressed rotation center with $r = 0.18$. The displacement u_Y in Figure 6 refers to the displacement in a direction perpendicular to the crack plane (see Figure 1 for the coordinate system X-Y-Z), while the Z value defines the crack-front position corresponding to which the displacements on the crack plane are measured. The results in Figure 6 indicates that the deformed crack plane aligns along a rotated plane with the rotation center calculated using $r = 0.18$.

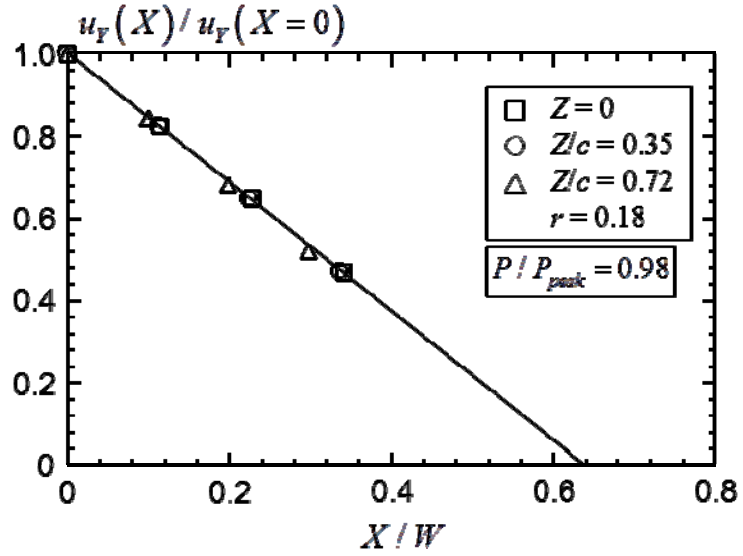

Figure 6. The r value for the plate specimens subjected to four-point bending.

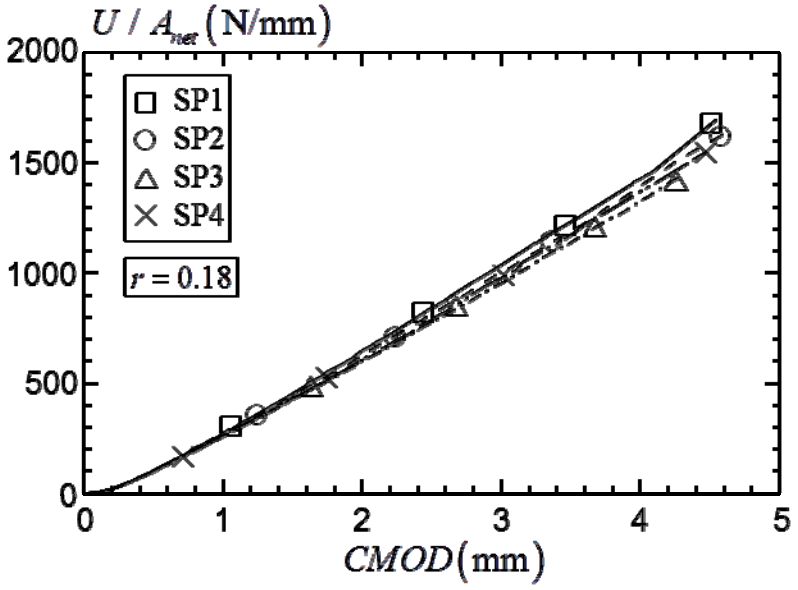

Figure 7. Evolution of the strain energy U for the four plate specimens.

Using an r value of 0.18, the strain energy U for the plate specimen can now derive from Eqs. (7)

and (8). Figure 7 presents the evolution of the strain energy U with respect to the crack mouth opening displacement measured at the center of the crack ($Z = 0$) for all four plate specimens.

The evaluation of the energy release rate requires the determination of the dimensionless η-value. This study determines the η-value using FE models with stationary cracks via equating Eqs. (4) and (6). The strain energy value U in Eq. (4) is computed using the strain energy derived from the area under the moment-rotation curve of the crack plane computed from the large-deformation finite element analyses, as shown in Eq. (7). Figure 8 illustrates the variation of the η-value as the applied load increases for the four plate specimens. The η-value remains approximately at the same magnitude at different load levels in all four specimens. The current study utilizes, therefore, a constant η-value of 1.1 for all plate specimens.

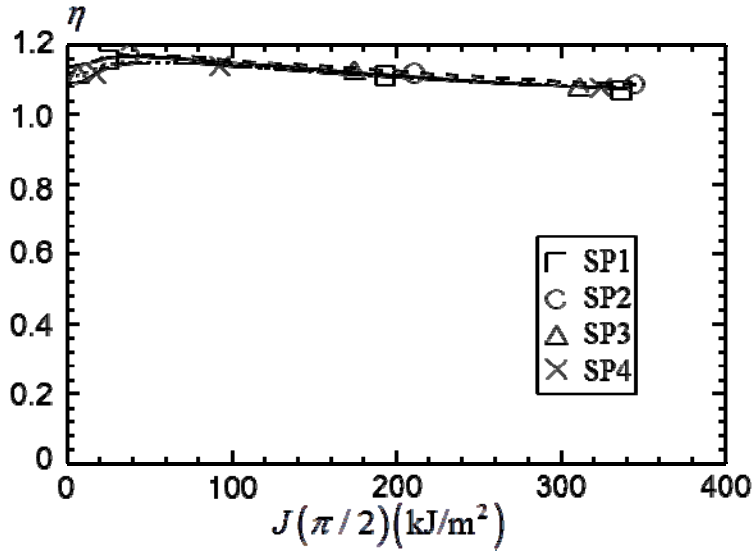

Figure 8. The dimensionless η-values for the plate specimens.

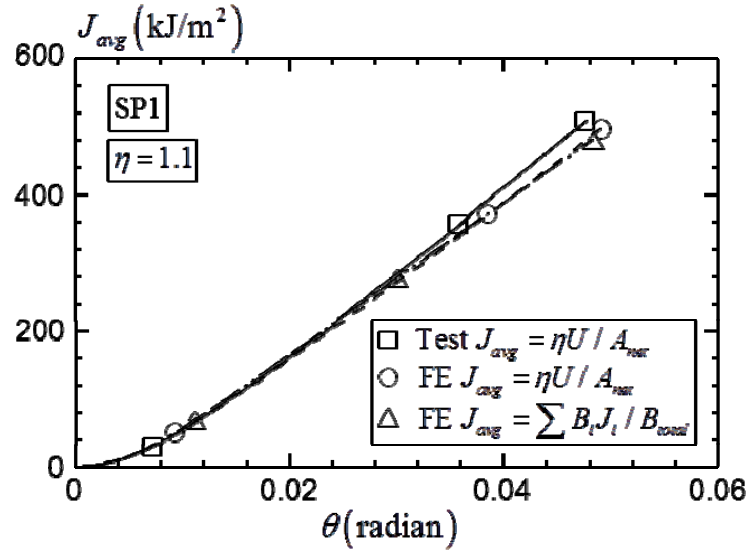

Figure 9. Comparison of the energy release rate for the surface cracked plate specimen SP1.

Figures 9 and 10 compare the energy release rate computed from the finite element model and those measured from the experiments for two selected specimens SP1 and SP4. The average J-values computed from the finite element analysis in Figures 9 and 10 correspond to the plate models with a stationary crack. The comparison in Figures 9 and 10 therefore limits the comparison for the

experimental energy release rate to a small deformation level, at which the amount of ductile crack extension remains small. For both specimens, the numerically computed energy release rate agrees closely with those measured from the experiments.

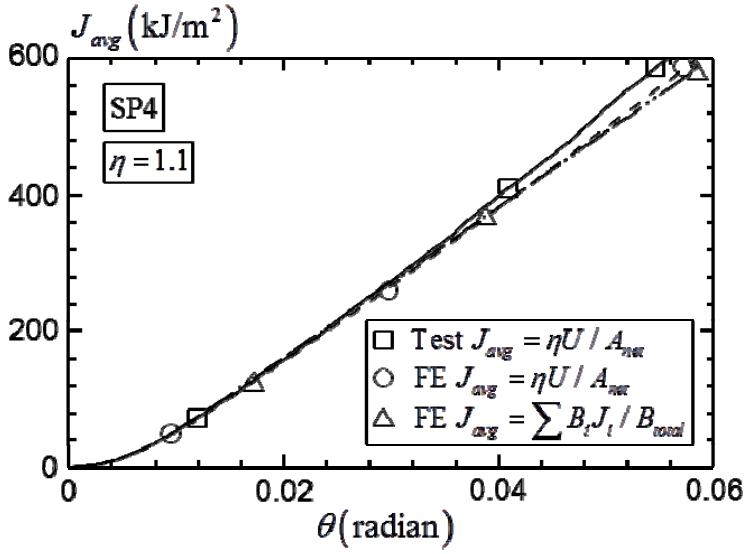

Figure 10. Comparison of the energy release rate for the surface cracked plate specimen SP4.

4. Summary and Conclusions

This study describes a compliance-based procedure to measure the energy release rate for surface cracks in plate specimens subjected to four-point bending. The average energy release rate along the crack front derives from the η-approach using the area under the M-θ curve for the cracked section. The center of rotation for the crack plane remains at about 18% of the remaining ligament measured from the crack tip at the deepest crack-front location, for the four surface cracked specimens considered in this study. This value, however, requires further validation when the η-approach is extended to other types of surface cracked specimens under different loading conditions. The energy release rate calculated using the η-approach based on the area under the numerical moment-rotation curves of the cracked section matches closely with the average energy release rate based on the domain-integral values computed in the large-deformation, elastic-plastic analyses. The energy release rate estimated using the η-approach from the experimental M-θ curves agrees well with that estimated using the numerical M-θ curve, before substantial crack extensions occur in the experimental specimen. Together with a compliance based method to determine the crack size in the surface cracked plate specimen, the approach proposed here provides a basis to determine the J-R curve for surface cracked specimens [8].

Abstract A radial crack emanating from a semi-circular notch is of significant engineering importance. Accurate determination of key fracture mechanics parameters is essential for damage tolerance design and fatigue crack growth life predictions. The purpose of this paper is to provide an efficient and accurate closed-form weight function approach to the calculation of crack surface displacements for a radial crack emanating from a semi-circular notch in a semi-infinite plate. Results are presented for two load conditions: remote applied stress and uniform stress segment applied to crack surfaces. Based on a correction of stress intensity factor ratio, highly accurate analytical equations of crack surface displacements under the two load conditions are developed by fitting the data obtained by using the weight function method. It is demonstrated that the Wu-Carlsson closed-form weight functions are very efficient, accurate and easy-to-use for calculating crack surface displacements for arbitrary load conditions. The method will facilitate fatigue crack closure and other fracture mechanics analyses where accurate crack surface displacements are required.

Keywords: Radial crack, Semi-circular notch, Dugdale strip-yield model, Crack surface displacement, Weight function method.

1. Introduction

In fracture mechanics analysis and fatigue crack growth life predictions for structural components, the strip-yield model (modified Dugdale models) [1] have been employed for crack configurations like middle-crack tension [1-5] and compact specimens [6-8]. Reference [9] discussed the application of the model to analyze double radial cracks emanating from a circular hole. This crack configuration and a radial crack emanating from a semi-circular notch are among the most important crack types for aircraft structures. Stress intensity factors for such cracks under various loading conditions can be found in the literature [10-11]. However, crack surface displacements for various load conditions, preferably in analytical form, which are needed in crack-closure-based fatigue crack growth life prediction models and other fracture mechanics analyses, are rarely available.

A modified Dugdale model is proposed by Newman [1]. The modification is to leave plastically deformed materials in the wake of the crack. The primary advantage in using this model is that the plastic-zone size and crack surface displacements are obtained by superposition of two elastic problems: a crack in a plate subjected to a remote uniform stress and a uniform stress applied over a segment of the crack surfaces. In the Newman model, crack surface displacements under remote applied stresses and a segment uniform pressure (partial loading) in the immediate wake of the crack tip are both required for calculating the crack opening stress, S_{op}. The accuracy of these displacements will significantly influence S_{op}, and further, fatigue crack growth rates.

The motivation of the present paper is to explore an analytical approach, based on the closed-form weight functions, to the calculation of crack surface displacements for a radial crack emanating from a semi-circular notch in a semi-infinite plate. Results are presented for the two loading conditions: remote applied stress and uniform segment stress (partial load) applied to a segment of the crack surfaces. Based on a correction of stress intensity factor ratio, highly accurate analytical equations of the crack surface displacements are developed to fit the data from weight function

method. It is envisaged that the closed-form weight function approach will provide an efficient and reliable method for calculating crack-surface displacements under arbitrary loadings. The analytical equations of the crack surface displacement can contribute to a more rapid and reliable fatigue crack growth life predictions for a radial crack emanating from a semi-circular notch in a semi-infinite plate.

2. Theoretical procedures

The weight function method [10] is a very powerful method for the determination of key fracture mechanics parameters for cracks under arbitrary load conditions, e.g. stress intensity factors and crack surface displacements. The high efficiency of this method lies in that the weight function is a property of crack geometry only, and is independent of loading. For given crack configuration, once the weight function is obtained, fracture mechanics parameters for the same crack configuration under arbitrary loadings can be easily determined through a simple quadrature.

For stress intensity factors [10]:

$$K = f\sigma\sqrt{\pi a} \tag{1}$$

$$f = \int_0^a \frac{\sigma(x/a)}{\sigma} \cdot \frac{m(a,x)}{\sqrt{\pi a r}}\,\mathrm{d}x \tag{2}$$

where $m(a, x)$ is the weight function for the given crack geometry, which can be derived from the crack opening displacements $u(a, x)$ for a reference load case.

$$m(a,x) = \frac{E'}{K(a)}\frac{\partial u(a,x)}{\partial a} \tag{3}$$

where $E' = E$ for plane stress and $E' = E/(1-\eta^2)$ for plane strain.

For the corresponding crack surface displacements [10]:

$$u(a,x) = \frac{\sigma}{E'}\int_{a_0}^{a}[f(s)\sqrt{\pi s}]\cdot m(s,x)\mathrm{d}s \tag{4}$$

From the above equations, it is seen that the central issue in the weight function method is the determination of weight function $m(a, x)$ for the crack geometry in consideration. Various approaches have been used for determining $m(a, x)$. One effective way is to derive $m(a, x)$ through a reference load case. With this procedure, systematic derivations for the weight functions $m(a, x)$ for a large number of two-dimensional crack configurations have been given by Wu and Carlsson [10], which can be readily utilized for the present analysis.

For the edge crack configuration, which is applicable to the present case, i.e. a radial crack emanating from a semi-circular notch in a semi-infinite plate, the stress intensity factor and the corresponding crack face loading for the reference load case are expressed in polynomials of the type:

$$f_r(\frac{a}{r}) = \sum_{i=0}^{I}\alpha_i(\frac{a}{r})^i \tag{5}$$

$$\frac{\sigma_r(\frac{x}{r})}{\sigma} = \sum_{m=0}^{M} S_m(\frac{x}{r})^m \tag{6}$$

where r is the notch radius, and the coefficients α_i and S_m for the present crack configuration are given in Section 3.

The weight function was expressed in closed-form by Wu and Carlsson [10], as

$$m(a,x) = \sqrt{\frac{r}{2\pi a}}\sum_{i=1}^{4}\beta_i(\frac{a}{r})\cdot(1-\frac{x}{a})^{i-\frac{3}{2}} \tag{7}$$

where

$$\left.\begin{aligned}
\beta_1(\frac{a}{r}) &= 2.0 \\
\beta_2(\frac{a}{r}) &= \frac{[4\frac{a}{r}f_r^{'}(\frac{a}{r}) + 2f_r(\frac{a}{r}) + \frac{3}{2}F_2(\frac{a}{r})]}{f_r(\frac{a}{r})} \\
\beta_3(\frac{a}{r}) &= \frac{\left\{\frac{a}{r}F_2^{'}(\frac{a}{r}) + \frac{1}{2}[5F_3(\frac{a}{r}) - F_2(\frac{a}{r})]\right\}}{f_r(\frac{a}{r})} \\
\beta_4(\frac{a}{r}) &= \frac{[\frac{a}{r}F_3^{'}(\frac{a}{r}) - \frac{3}{2}F_3(\frac{a}{r})]}{f_r(\frac{a}{r})}
\end{aligned}\right\} \tag{8}$$

where

$$\left.\begin{aligned}
F_1(\frac{a}{r}) &= 4f_r(\frac{a}{r}) \\
F_2(\frac{a}{r}) &= \frac{15\left[\sqrt{2}\pi\phi(\frac{a}{r}) - E_1(\frac{a}{r})\cdot F_1(\frac{a}{r})\right] - E_3(\frac{a}{r})\cdot F_1(\frac{a}{r})}{15E_2(\frac{a}{r}) - 3E_3(\frac{a}{r})} \\
F_3(\frac{a}{r}) &= \frac{E_2(\frac{a}{r})\cdot F_1(\frac{a}{r}) - 3\left[\sqrt{2}\pi\phi(\frac{a}{r}) - E_1(\frac{a}{r})\cdot F_1(\frac{a}{r})\right]}{15E_2(\frac{a}{r}) - 3E_3(\frac{a}{r})}
\end{aligned}\right\} \tag{9}$$

with

$$\phi(\frac{a}{r}) = \frac{1}{a^2}\int_0^a (s\cdot\left[f_r(\frac{s}{r})\right]^2)\mathrm{d}s \tag{10}$$

$$E_j(\frac{a}{r}) = \sum_{m=0}^{7}\frac{2^{m+1}m!S_m(\frac{a}{r})^m}{\prod_{k=0}^{m}(1+2j+2k)}, \quad j=1,2,3 \tag{11}$$

where r is the radius of the semi-circular notch; f_r and S_m are defined in Eq. (5) and Eq. (6).

3. Crack surface displacements for a radial crack emanating from a semi-circular notch in a semi-infinite plate

For a radial crack emanating from a semi-circular notch in a semi-infinite plate, uniform remote tension is chosen as the reference load case, and the corresponding non-dimensional stress intensity

factor and the reference crack face loadings are expressed in Eq. (5) and Eq. (6) with the following coefficients, respectively:

a_i : 3.4345, -6.9715, 14.5781, -19.9230, 16.9424, -8.5301, 2.3134, -0.2595. ($a/r \leqslant 2.0$)

S_m : 3.0643, -6.6864, 13.1677, -16.9513, 13.7335, -6.6293, 1.7273, -0.1861. ($x/r \leqslant 2.0$)

3.1. Uniform remote tension

The normalized stress intensity factor of a radial crack emanating from a semi-circular notch in a semi-infinite plate under uniform remote tension, $f_{B,S}$, is given in Eq. (5), as:

$$f_{B,S} = \sum_{i=0}^{7} \alpha_i \left(\frac{a}{r}\right)^i \tag{12}$$

With the information of $f_{B,S}$ and $m(a, x)$, the crack surface displacements can be easily calculated from Eq. (4). Figure 2 shows the normalized crack surface displacements of a radial crack emanating from a semi-circular notch in a semi-infinite plate under uniform remote tension for non-dimensional crack length a/r = 0.05 to 1. The circular symbols in Fig. 2~3 are obtained by the crack surface displacement analytical equations, which will be explained later.

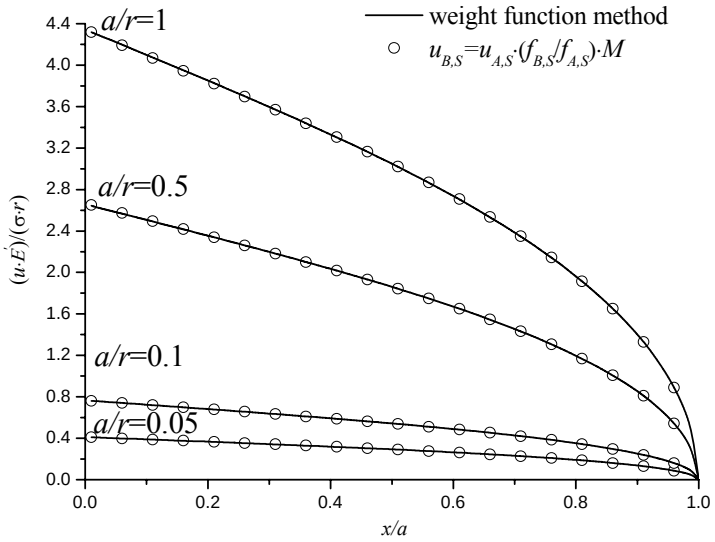

Figure.2 Non-dimensional crack surface displacements for a radial crack emanating from a semi-circular notch in a semi-infinite plate subjected to uniform remote tension.

3.2. Partial crack surfaces subject to Dugdale loading

For partial crack surfaces subject to Dugdale loading (see Fig. 1(a), $b_2=a$), the stress distribution is expressed in a simple form:

$$\sigma(x) = \sigma \qquad (b_1 \leq x \leq a) \tag{13}$$

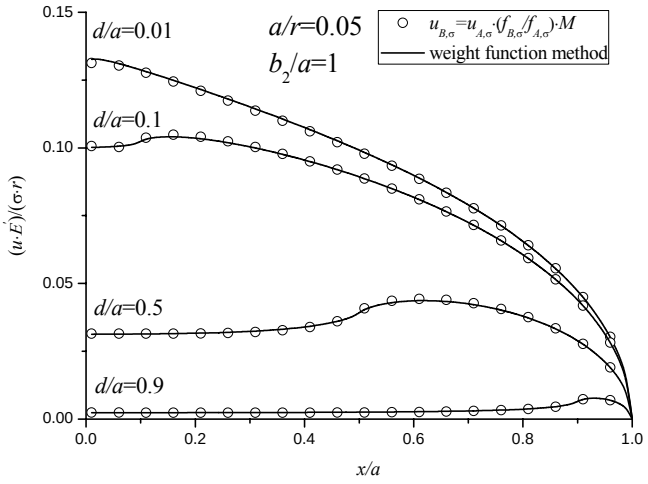
For partial crack surfaces subject to Dugdale loading, the normalized stress intensity factor of a radial crack emanating from a semi-circular notch in a semi-infinite plate is easily calculated by inserting Eq.(13) and Eq. (7) into Eq. (2), with

$$f_{B,\sigma}=\frac{\sqrt{2}}{\pi}\left[\sum_{1}^{4}\frac{1}{(2i-1)}\beta_i(\frac{a}{r})\cdot(1-\frac{b_1}{a})^{i-\frac{1}{2}}\right] \tag{14}$$

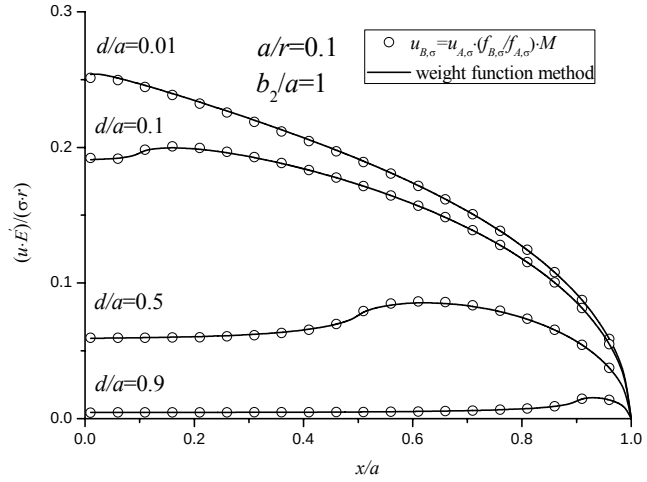
With the above $f_{B,\sigma}$-expression and $m(a, x)$, the crack surface displacements (Eq. (4)) for partial crack surfaces subject to Dugdale loading can be readily calculated from the following equation:

$$u_{B,\sigma}=\frac{\sigma}{E'\pi}\int_{a_0}^{a}\left(\left[\frac{1-\frac{b_1}{s}}{1-\frac{x}{s}}\right]^{\frac{1}{2}}\cdot\sum_{i=1}^{4}\frac{\beta_i(s/r)}{2i-1}\cdot(1-\frac{b_1}{s})^{i-1}\cdot\sum_{i=1}^{4}\beta_i(s/r)\cdot(1-\frac{x}{s})^{i-1}\right)\mathrm{d}s \tag{15}$$

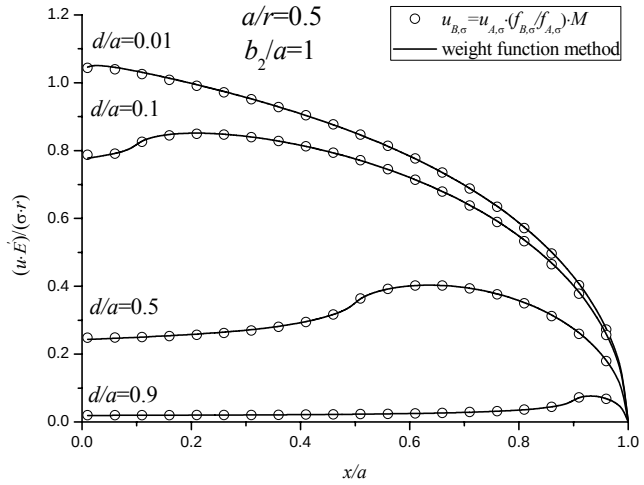
Figure 3 present the results, the normalized crack surface displacements of a radial crack emanating from a semi-circular notch in a semi-infinite plate with crack surfaces subject to Dugdale loading (b_2=a，b_1=d). The non-dimensional crack lengths in Fig. 3 are: a/r=0.05, 0.1, 0.5 and 1.0.



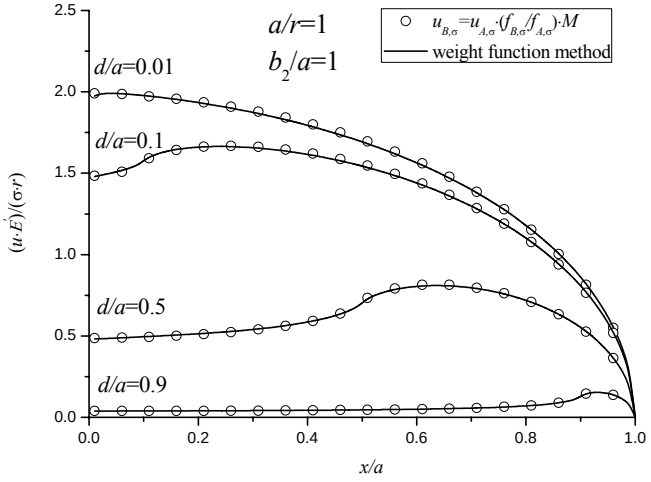
(a)



(b)



(c)



(d)

Figure.3 Non-dimensional crack surface displacements for a radial crack emanating from a semi-circular notch in a semi-infinite plate subjected to Dugdale loading in the immediate wake of crack tip, with (a) a/r=0.05. (b) a/r=0.1. (c) a/r=0.5. (d) a/r=1.0.

4. Analytical crack surface displacement equations for a radial crack emanating from a semi-circular notch in a semi-infinite plate

It has been a common practice in the literature that the crack surface displacements for one case (B) can be estimated from available crack surface displacements for a similar known case (A), by multiplying a correction factor. Recently, Tong and Wu proposed a general expression for an edge crack in a semi-infinite plate and double radial cracks at a circular hole with good success [12,13]. The correction is composed of two parts: the ratio of stress intensity factors for the two cases, f_B /f_A and a fitted correction factor M, as the following:

$$u_B = u_A \cdot \frac{f_B}{f_A} \cdot M \tag{16}$$

where the subscripts A and B represent the two load cases.

Because the crack surface displacements of a center crack in an infinite plate (see Fig. 1(b)) have exact solutions, this case (see Fig. 1(b)) is selected as load case A, a radial crack emanating from a semi-circular notch in a semi-infinite plate is selected as load case B.

For a center crack in an infinite plate under uniform remote tension, the exact crack surface displacement equation is [11]

$$u_{A.S} = \frac{2(1-\eta^2)S}{E}\sqrt{a^2 - x^2} \quad |x| \le a \tag{17}$$

The normalized stress intensity factor is

$$f_{A,S} = 1 \tag{18}$$

For a center crack in an infinite with crack surfaces subject to Dugdale loading, the exact crack surface displacement equation is [11]

$$u_{A,\sigma} = h(x) + h(-x) \quad |x| \le a \tag{19a}$$

$$h(x) = \frac{2(1-\eta^2)\sigma}{\pi E}\left[\begin{array}{l}(d-x)\operatorname{arccosh}\left(\dfrac{a^2 - dx}{a|d-x|}\right) + \\ \sqrt{a^2 - x^2}\,\arcsin\left(\dfrac{d}{a}\right)\end{array}\right]_{d=b_1}^{d=a} \tag{19b}$$

The normalized stress intensity factor is [11]

$$f_{A,\sigma} = \left[\frac{2}{\pi}\sin^{-1}\left(\frac{d}{a}\right)\right]_{d=b_1}^{d=a} \tag{20}$$

4.1. Analytical crack surface displacement equation for uniform remote tension

For a radial crack emanating from a semi-circular notch in a semi-infinite plate under uniform remote tension, the crack-surface displacement analytic equation can be expressed as

$$u_{B,S} = u_{A,S} \cdot \frac{f_{B,S}}{f_{A,S}} \cdot M_{B,S} \tag{21a}$$

where $f_{B,S}$, $f_{A,S}$ and $u_{A,S}$ are given in Eq. (12), Eq. (18) and Eq. (17), respectively. The factor $M_{B,S}$ is determined by fitting the crack opening displacement results obtained from the weight function method. The fitted expression is

$$M_{B,S}=\frac{1+3.52\cdot\frac{a}{r}+0.12\cdot\frac{x}{a}+0.38\cdot(\frac{a}{r})^2+0.645\cdot(\frac{x}{a})^2+2.15\cdot\frac{x}{a}\cdot\frac{a}{r}}{0.774+2.364\cdot\frac{a}{r}+0.45\cdot\frac{x}{a}+0.44\cdot(\frac{a}{r})^2+0.545\cdot(\frac{x}{a})^2+3.28\cdot\frac{x}{a}\cdot\frac{a}{r}}\quad (a/r\le 1.0) \tag{21b}$$

Figure 2 shows that this analytical expression fits the weight function results very well. The maximum error is 0.36% (for $a/r = 0.5$).

4.2. Analytic crack surface displacement equation for Dugdale loading

For a radial crack emanating from a semi-circular notch in a semi-infinite plate with crack surfaces subject to Dugdale loading, the analytical crack-surface displacement equation is

$$u_{B,\sigma}=u_{A,\sigma}\cdot\frac{f_{B,\sigma}}{f_{A,\sigma}}\cdot M_{B,\sigma} \tag{22a}$$

where $u_{A,\sigma}$, $f_{A,\sigma}$ and $f_{B,\sigma}$ are given by Eq. (19), Eq. (20) and Eq. (14), respectively. The factor $M_{B,\sigma}$ is determined by fitting the crack opening displacement results obtained from the weight function method, Eq.(15):

$$M_{B,\sigma}=\frac{0.921-0.713\cdot\frac{a}{r}-0.728\cdot\frac{d}{a}+0.63\cdot\frac{x}{a}+2.98\cdot\frac{a}{r}\cdot\frac{d}{a}+1.65\cdot\frac{a}{r}\cdot\frac{x}{a}-2.26\cdot\frac{d}{a}\cdot\frac{x}{a}-0.14\cdot(\frac{a}{r})^2+0.454\cdot(\frac{d}{a})^2+3.1\cdot(\frac{x}{a})^2}{0.718-0.287\cdot\frac{a}{r}-0.594\cdot\frac{d}{a}+0.723\cdot\frac{x}{a}+2.91\cdot\frac{a}{r}\cdot\frac{d}{a}+1.544\cdot\frac{a}{r}\cdot\frac{x}{a}-2.33\cdot\frac{d}{a}\cdot\frac{x}{a}-0.37\cdot(\frac{a}{r})^2+0.392\cdot(\frac{d}{a})^2+3.2\cdot(\frac{x}{a})^2} \tag{22b}$$

Figure 3 shows some typical comparisons between the fitted expression, Eq. (22), and the weight function results. For a radial crack emanating from a semi-circular notch in a semi-infinite plate, Eq. (22) represented by the circular symbol, is in very good agreement with the results from weight function method (the solid curves) for all points along crack surface. The maximum difference occurs in the loading segment (a/r=0.05, b_1/a=0.9), and is about 2.4%.

With this analytical equation of crack surface displacements for the Dugdale loading, crack surface displacements for a segment (width Δb) pressure acting at an arbitrary location along the crack faces can readily be obtained by using the same procedure as Ref [12,13], i.e. taking the difference between two Dugdale loadings with $b_2=a$, b_1 and $b_1+\Delta b$ in Fig.1.

$$u_{\mathrm{B},\sigma,\Delta b}=(u_{\mathrm{A},\sigma}\cdot\frac{f_{\mathrm{B},\sigma}}{f_{\mathrm{A},\sigma}}\cdot M_{\mathrm{B},\sigma})\Big|_{d=b_1}-(u_{\mathrm{A},\sigma}\cdot\frac{f_{\mathrm{B},\sigma}}{f_{\mathrm{A},\sigma}}\cdot M_{\mathrm{B},\sigma})\Big|_{d=b_1+\Delta b} \tag{24}$$

Equation (23) will not only significantly improve the accuracy of fatigue crack closure analysis for the specific crack geometry in consideration, but also will improve the computational efficiency for the modified strip-yield-model-based fatigue crack growth predictions by eliminating the time -consuming numerical integrations for crack surface displacements under partial loading.

5. Summary and conclusions

Crack surface displacements for a radial crack emanating from a semi-circular notch in a semi-infinite plate are determined, and analytical equations have been developed. Two load cases have been treated, i.e. uniform remote tension and crack face Dugdale loading. The weight function method was used for the analysis. The following conclusions can be drawn.

(1) The closed-form weight function method provides a powerful means for accurate determination of crack surface displacements under arbitrary load conditions.

(2) Based on a correction of stress intensity factor ratio, highly accurate analytical equations of the crack surface displacements for a radial crack emanating from a semi-circular notch in a semi-infinite plate are developed, which fit the results from the weight function method very well.

Abstract Understanding failure mechanisms of construction materials as well as their damage evolution are two key factors to improve design tools of structures. Depending on failure modes to be highlighted, and studied, several tests methods, and analysis tools have been developed, in particular AET. This latter is an experimental tool well suited for characterizing material behavior by monitoring fracture process. Despite the wide use of AET to characterize and monitor damage evolution of composite materials, few research studies focused on using AET to characterize the mechanical behavior of wood materials.
In this work, the failure process in wood material under monotonic loading is studied by confronting three experimental methods; by analyzing stress-strain curves, AE measurements, and digital image acquisition. First, results show good correlation and complementarity between the used methods. Second, simple approach in analysis of AE signals (cumulative event and energy) gives important information about crack initiation and growth without the material. Moreover, advanced analysis of AE data (determination of source locations and the study of mechanism of individual events; study of amplitude distributions; investigation of frequency characteristics of emission events) will allows us to understand some key damage mechanisms such as the fracture process zone.

Keywords Acoustic Emission, Cracking, Wood, Fracture Energy

1. Introduction

Knowledge of the failure mechanisms of construction material as well as their damage evolution are two key factors to improve design tools of structures. In this context, Seismic **N**on-**D**estructive **T**echniques **(NDT)** which are based on stress wave propagation are interesting techniques for monitor structural integrity and characterize the behavior of materials when they undergo deformation, fracture, or both. These techniques can be divided into two methods: passive and active. This paper focuses on the **A**coustic **E**mission **T**echnique (**AET**) which is a passive method. Acoustic emission may be defined as transient elastic waves generated by the rapid release of strain energy in a material. A number of micro and macro processes contribute to both the deformation and the deterioration of a material under strain, resulting to a series of acoustic events. Thus, the events released by the material contain information regarding the general deformation process.
Kawamoto and Williams [1] reported literature review on the feasibility of AET for monitoring defects in wood. The advantages and the disadvantages of this technique were also described. It was noted that the AE investigations for wood products can be classified into five fields: (i) monitoring and control during drying; (ii) prediction of deformation; (iii) estimation of strength properties; (iv) fracture analysis, and (v) machine control.

This introduction focuses on fracture analysis by AET. Ansell [2] related the AE-strain characteristic from three softwoods tested in tension to mechanisms of deformations observed by scanning electron microscopy. The authors also reported correlation of EA total count with fracture toughness. Similar relationship was obtained by Suzuki and Schniewind [3] during cleavage failure in adhesive joints. Landis and Whittaker [4] compared the energy released by a mode I crack propagation in wood with the resulting acoustic emission energy. Results of the energy comparison indicated a good correlation. Reiterer et al., [5] investigated the mode I fracture behavior of softwoods and hardwoods under the splitting test associated to acoustic emission measurements. The measured AE parameters included cumulative counts, amplitude and frequency spectra. The results showed that

the AE counts until the maximum force was reached are much higher for the softwoods supporting the interpretation that the softwoods behave more ductile and therefore build a process zone containing much more microcracks. It was also shown that the differences in macrocrack formation and propagation can be visible in the shape of the cumulated AE counts and the AE amplitudes. More recently, Ando et al., [6] used AET to examine the microscopic process of shearing fracture of old wood.

In conclusion, the potential of laboratory AET to examine the fracture process in wood has been clearly demonstrated in the literature review. Simple AE approaches were used, for example: recording the events by expressing them in the form of event rate or cumulative events; study of amplitude distributions; investigation of frequency characteristics of emission events. All these approaches were performed by considering AE events without determination of source locations. The purpose of this study is to investigate mode I fracture of wood using determination of the position of developing cracks with AE measurements. The AE source is determined from the time differential of AE signals among two piezoelectric transducers (linear location). The determination of source locations associated to the attenuation curve in the tested sample allows correction of the output signal amplitude of the AE transducer. In this study, AE measurements were associated to digital image acquisition during the tensile test.

2. Experimental Procedure

For the present study specimens were cut from softwood (Douglas) and conditioned, in climate-controlled room, to constant moisture content for about 10%. The temperature and relative humidity were regulated at 20 °C and 40% RH, respectively. The specimens had the following dimensions: W = 80 mm; L = 170 mm; T = 15 mm (Fig. 1). Next, a 50 mm notch was cut along the grain to create a mode I double cantilever configuration. The starter notch was introduced with a band saw (3mm) and the notch orientation was chosen such that crack propagation took place in longitudinal direction.

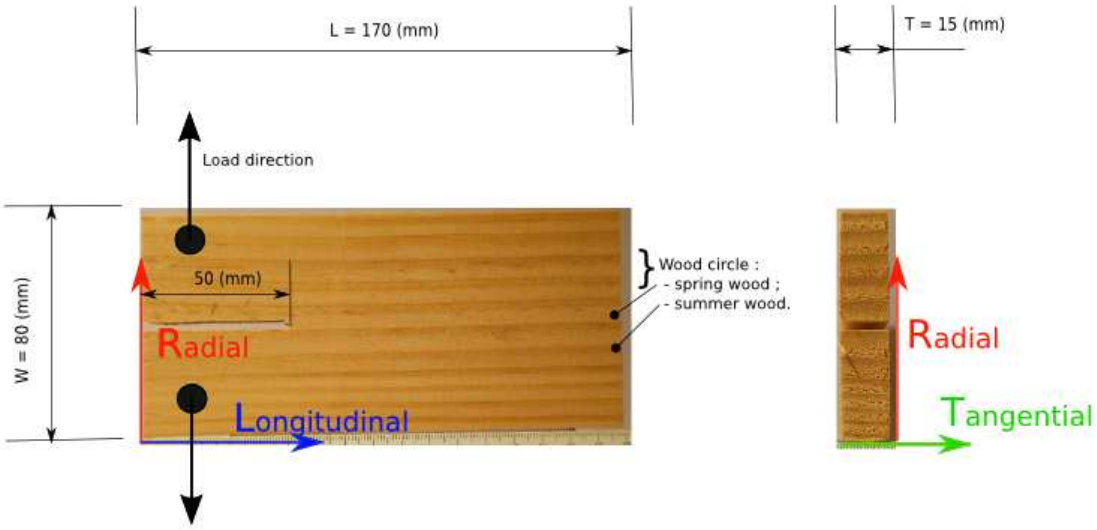

Figure 1. Photography of mode I fracture specimen.

The specimens were loaded under displacement control in an universal testing machine with a 50 kN load capacity. Load was applied to the specimen through the use of shafts that are pushed into holes drilled through the top and bottom cantilevers. A total of 4 specimens were tested at constant displacement-rate of 0.5 mm/min. Synchronized with the testing machine, an 8-bit Charge-Coupled Device camera measured the displacement fields. Thanks to this full-field optical method, the displacement evolution on the specimen surface could be recorded throughout the test. Also note that the image rate of the camera was set at 2 frames/s.

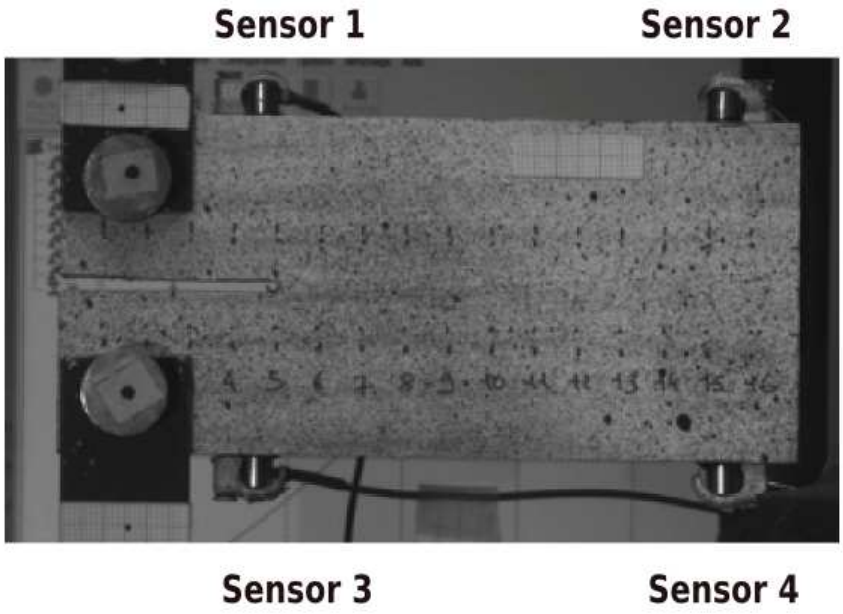

Figure 2. Photography of a specimen instrumented with AE sensors

During the test, AE event signals were monitored and recorded using a Euro Physical Acoustics (EPA) system:

- Four piezoelectric transducers (Nano30), with a band characteristic from 125 to 750 kHz, and 140 (and 300) kHz resonant frequency, were mounted on the specimen (Fig. 2). The transducers were coupled to the specimen with a silicon grease to avoid loss of acoustic signal at the transducer-sample interface;
- Pre-amplification of the AE signals was provided by four preamplifiers (IL40S model) with a gain set for 40 dB;
- AE signals were sampled at 20 MHz and filtered with amplitude threshold about 40 dB. It is clear that the detected events depend on the value of this threshold. Before the loading test, the effective propagation velocity of the longitudinal waves was determined by generating an elastic wave using the conventional pencil lead breaking.
- A signal conditioner and software that allow recording the AE features in a computer for further analysis.

3. Data Analysis and Discussion

3.1. Calibration of Acoustic Emission Measurements

For wood, the wave velocities are very dependent on propagation direction. Consequently, conventional AE source location techniques such as 2D planer location mode, which assume isotropic velocity, cannot easily be used for wood. Thus, AE source location, the most identifiable and beneficial factor of the AE technique for homogenous materials, is difficult to use on wood. In order to overcome these difficulties, we adopted in this study a liner location mode combined with a specific calibration procedure. The value of effective AE wave velocity (5350 m/s) was evaluated by the conventional pencil lead breaking.

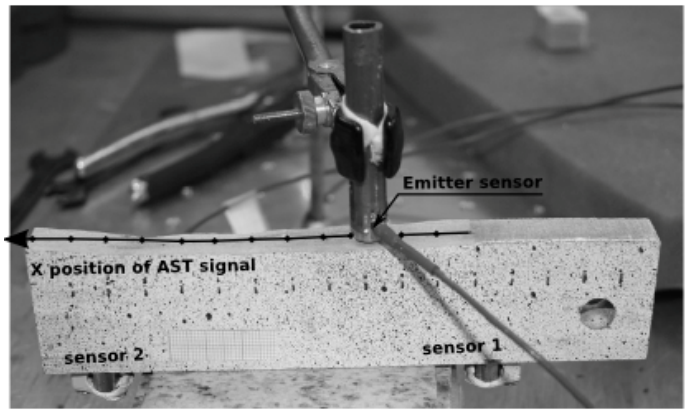
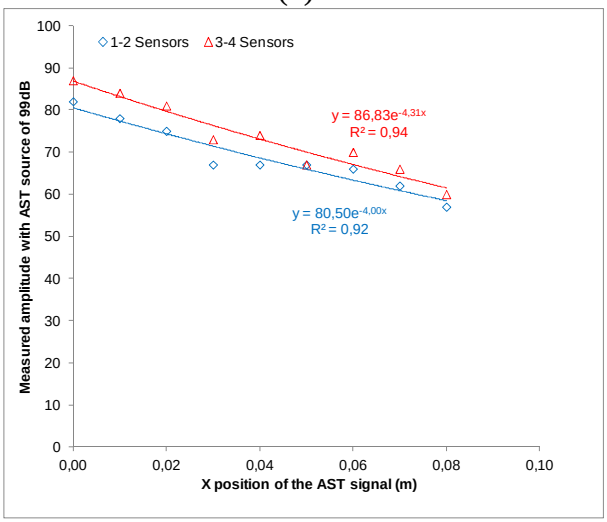
(b)



(c)



(d)

Figure 3. Calibration of Acoustic Emission Measurements. a) Photography of the pencil lead break method. b) calibration curve of the acoustic emission location. c) Photography of the AST method for attenuation measurements. d) Attenuation profile of the AE response on the wood sample.

All specimens were tested, after the fracture loading, using pencil lead break to simulate the burst signal propagation. The device (pencil lead break) is an aid to simulate an acoustic emission event using the fracture of a brittle graphite lead in a suitable fitting. This generates an intense acoustic signal, quit similar to a natural AE source, which the sensors detect as a strong burst. Figure 3 presents the principle of the pencil lead break method preformed on the fractured sample (Fig. 3.a) and the calibration curve of the acoustic emission location (Fig. 3.b).

The amount of AE wave attenuation depends on the proprieties on the material. For the tested samples, attenuation curve (Fig. 3.d) is performed by using the AST procedure (Auto Sensor Test, Fig. 3.c). AST provides an automated means of pulsing and receiving of simulated AE burst that is coupled to the structure. Similar results of attenuation curve can be also obtained by using the pencil lead break method. The attenuation curve plotted in figure 3.b is the consequence of several phenomena taking place as AE waves propagate along the sample: dispersion, scattering and eventually dissipation. The results presented in these figures highlight the importance of the AE calibration procedure in the analysis of AE data.

3.2. Analysis of Energy Balance

The energy approach states that crack extension occurs when the energy available for crack growth is sufficient to overcome the resistance of the material. The material resistance may include the surface energy, plastic work, or other type of energy dissipation associated with a crack propagation. Figure 4.a illustrates the load-displacement behavior of tested wood specimens with a growing crack. Consider point A on the presented curve. The crack has grown with Δa length from initial length a_0. The crosshatched area represents energy that would be stored in the material where considering linear elastic behavior; the remainder is the energy dissipation associated with a propagation crack.

Examination of the plot of figures 4.c&d illustrates a number of things. First, crack growth initiation detected by image analysis occurs closely after the end of the linear elastic behavior. The progression of the crack front propagation according to the displacement loading is quasi-linear showing stable crack growth in the tested specimens. A second point to observe is the over shape similarity when we compare the fracture energy curve and the crack front propagation curve. Thus we can assume validity of the initial hypothesis, linear release of stored elastic energy, used in the energy balance analysis.

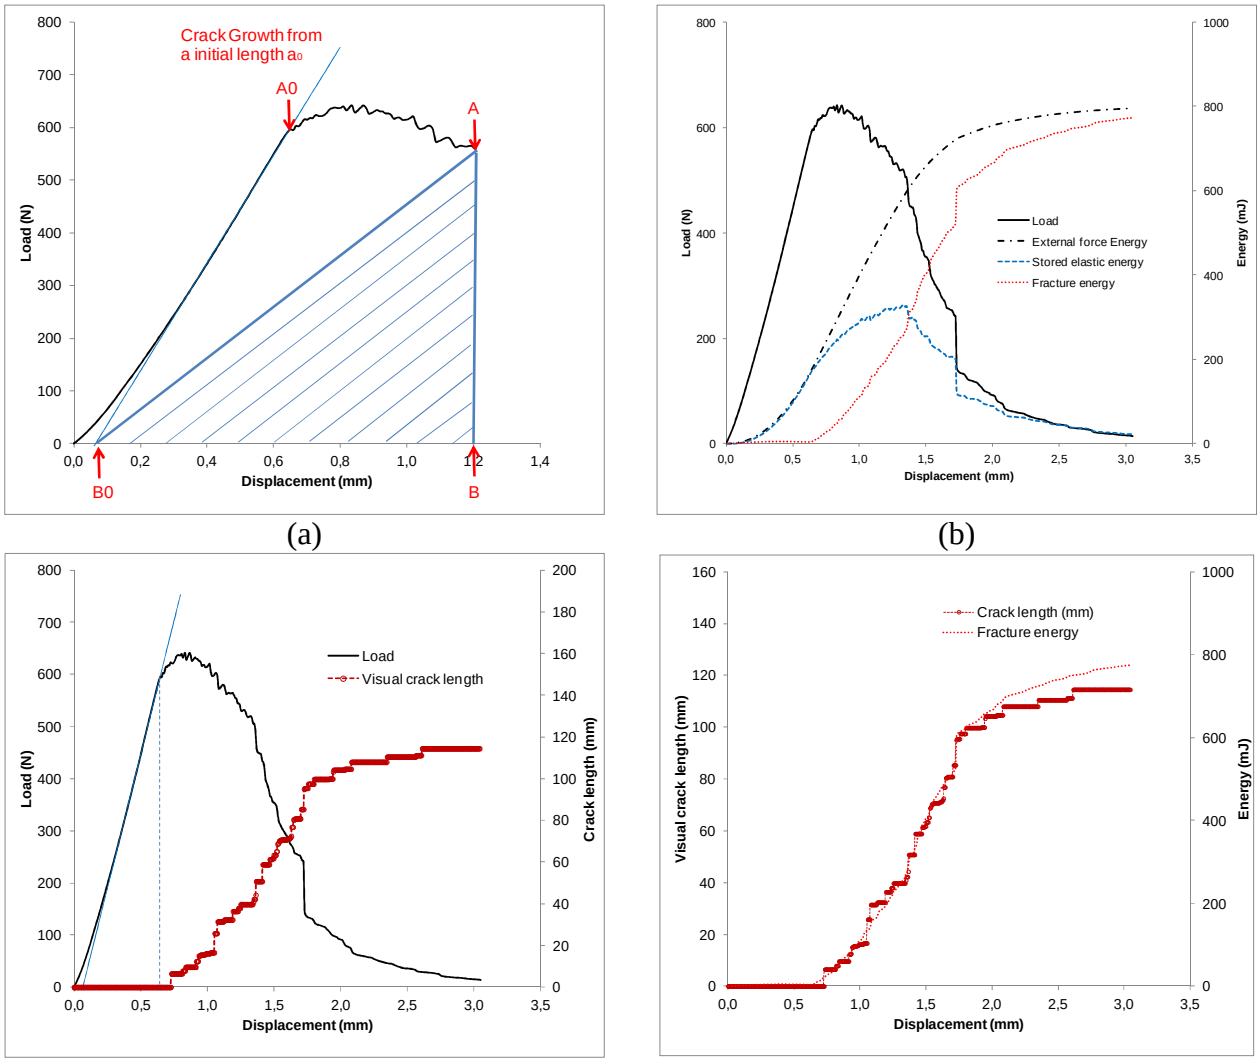


Figure 4. a) load-displacement curve for a specimen with a crack that grows with Δa length from initial length a_0: A_0ABB_0 (External force energy); ABB_0 (Stored Elastic Energy) and B_0A_0A (Fracture energy). b) Energy balance according to the displacement loading. c) Plot of load-displacement curve and crack front propagation measured by image analysis. d) Plot of fracture energy curve and crack front propagation.

3.3. Acoustic Emission Analysis

The recorded AE data are presented with respect to both AE-event (located material change giving rise to acoustic emission) and AE-hit (detected and measured signal for each cannel). To perform comparison with the mechanical results (energy balance) we consider one of the most important characteristic parameter of the AE in the amplitude-time domain, namely AE energy. With conventional AE energy analysis, the AE waveforms are squared and integrated over time. Although that analysis produces an energy measure, the resulting units do not lend themselves to direct comparisons with other energy analyses.

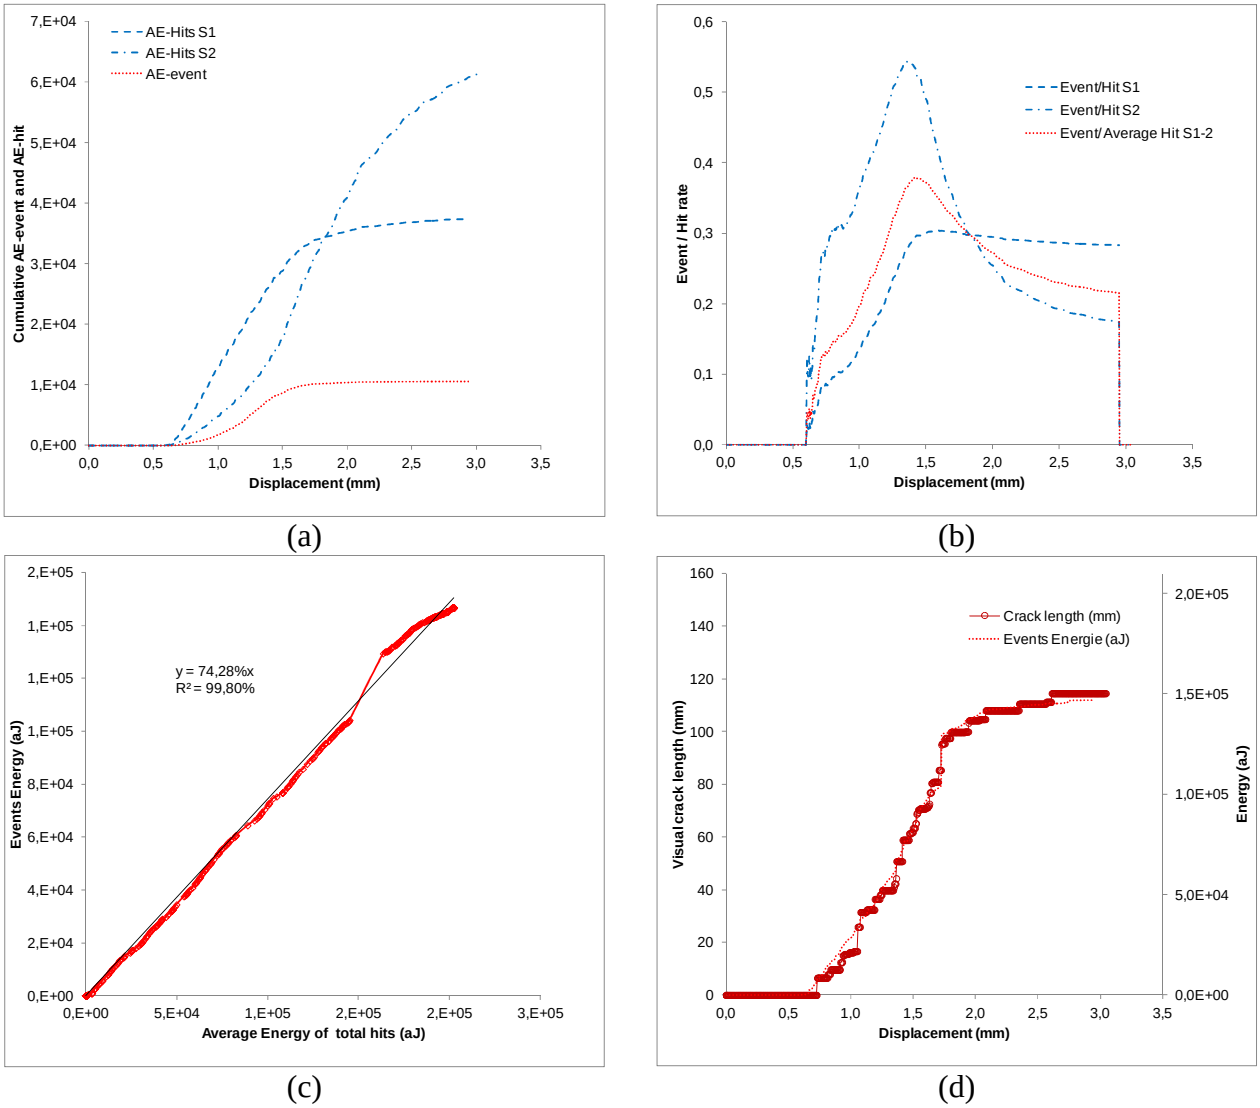

Figure 5. AE data. a) Cumulative AE-event and AE-hit for 1-2 sensor's group location. b) ratio between cumulative AE-event and cumulative AE-hit. d) Comparison of AE-event energy and AE-hit energy. d) Plot of AE-event energy curve and crack front propagation.

Plotted in figure 5 is, for each AE sensor, the cumulative AE-event along with the cumulative AE-hit. Similar results was observed between 1-2 sensor's group location and 3-4 sensor's group location, and only data from the first group are plotted. For linear location mode of AE source, calculation of x-position of each event is based on the measurement of the differences in first wave arrival times between two recorded AE-waveforms (Hits). The first wave arrival time is detected as the first threshold crossing by AE signal. Another parameter necessary for time difference location method is effective velocity. It can be established experimentally with or without considering different wave propagation modes (longitudinal, shear and Rayleigh waves). In this study, the value of effective AE wave velocity was evaluated by the conventional pencil lead breaking, and the obtained value is 5350m/s. The propagation modes were not separated inducing AE-hits which cannot be located. Indeed, figures 5.a&b show that approximately 30% of the average recorded hits from the 1-2 sensor's group location are located. However, figure 5.c shows a good correlation between AE-event energy and AE-hit energy. It should be noted that AE-hit energy is not corrected according to the attenuation curve. Some part of the no-located events can be caused by external noise such that caused by the loading system. Finally, if we compare figures 4.d and 5.d it can be shown that greater correlation between the energy release and the crack front propagation is obtained

from the AE measurements.

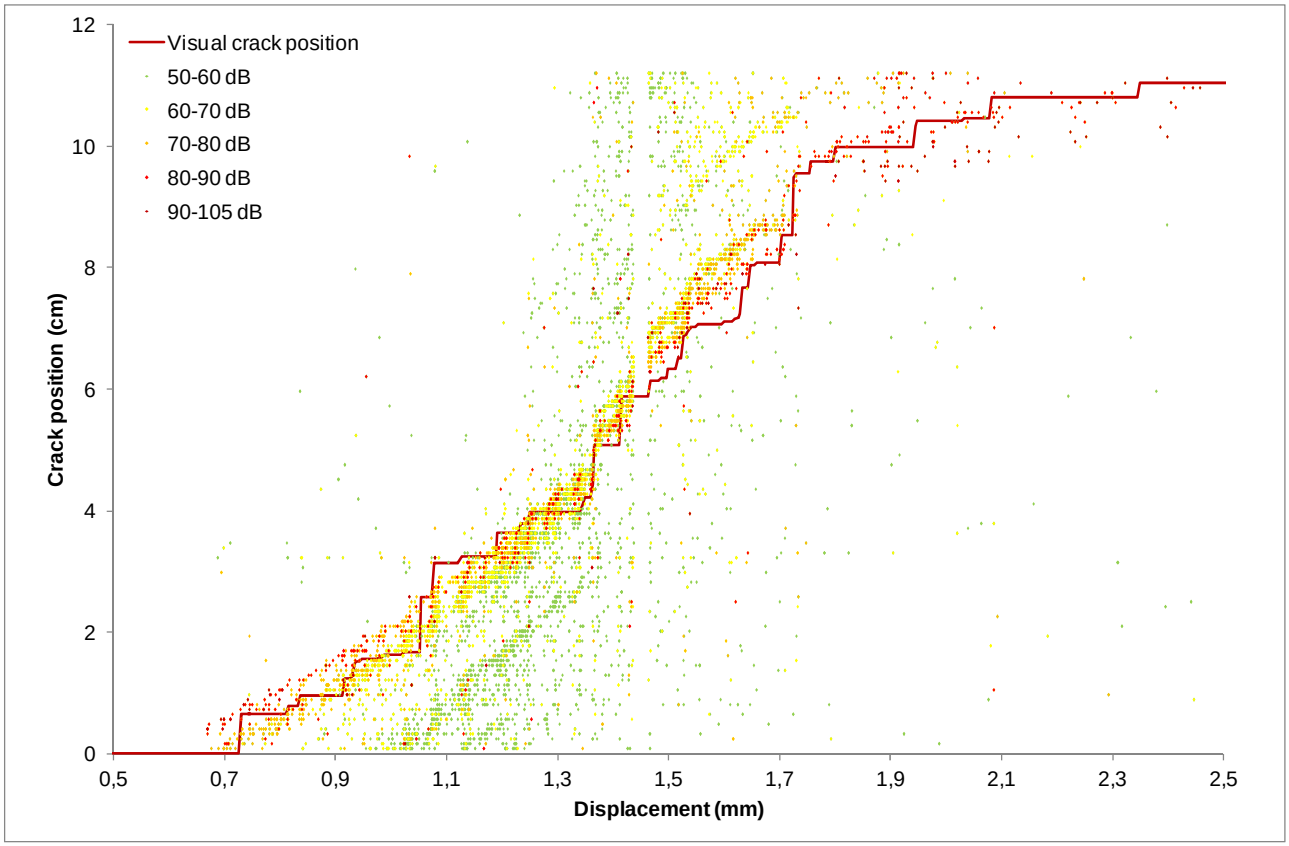

Figure 6. AE-events location and visual crack position vs. displacement loading.

In figure 6 is presented the crack front propagation curve obtained from the AE location process. The dynamic of the crack propagation is in good agreement with the results obtained with the image analysis. In addition, it was observed that the crack front appears to be associated with a Fracture Process Zone. Future works, based on AE waveform analysis using moment tensor components, will allow the crack classification and understand the mechanisms of this localized area.

4. Conclusion

In this study, we observed that the AE technique is an efficient tool for characterizing the failure process in wood materials. First, the experiment showed that crack initiation and crack growth detected by the AE activities is in a good agreement with the image analysis results. A second point to observe is that progress in AE-energy, during the test, is very similar to changes in fracture energy calculated from the load-displacement curve. These results were obtained for the both approaches used in the analysis of acoustic data: global approach with considering AE-hit signals and localization approach by using AE-event signals. For future works, this experimental investigation shows that the use of the localization approach seems to be a very promising method to investigate the cracks mechanisms such as the process zone.

Analysis of Metallic Ductile Fracture by extended Gurson models

Wei Jiang[1,*], Yazhi Li[1], Yixiu Shu[1], Zhenxing Fan[1]

[1] Department of Aeronautics, Northwestern Polythchnical University, 710000, China

Abstract Ductile fracture of metallic materials is usually the result of void nucleation, growth and coalescence. The original Gurson-Tvergaard (GT) model deals with the homogenous deformation related to void nucleation and growth. However, it takes no consideration on the localized deformation due to the void coalescence. In this paper extended GT damage models incorporating two different void coalescence criteria are developed, respectively. One of the void coalescence criteria is based on the plastic limit load model by Thomason; the other decides the onset of void coalescence by a critical equivalent plastic strain as a power law of stress triaxiality (defined by the ratio of the hydrostatic stress over the equivalent stress). Hence, void coalescence is controlled by physical mechanisms, rather than by a critical void volume fraction which cannot be taken as a constant. The extended constitutive models are implemented into an implicit finite element code via a user defined material subroutine (UMAT) in ABAQUS. Detail analyses are performed for a series of notched round tensile bars. The predictions of the fracture behavior based on the proposed approach, from void nucleation to final material failure, are compared with experiment data. Both results agree pretty well. In the end, the effects of stress triaxiality are discussed.

Keywords ductile failure, mechanism-based approach, Gurson model, void coalescence

1. Introduction

Mechanism-based fracture mechanics attempts to link micro-structural variables and continuum properties of material to macroscopic fracture behavior. The macroscopic ductile fracture process due to the presence of voids can be separated into two phases, the homogenous deformation with void nucleation and growth, and the localized deformation due to void coalescence (Zhang et al., 2000) [1].The famous porous material model for analyzing the ductile failure, in which the material yielding is coupled with damage (void volume fraction, f) and hydrostatic stress, was proposed by Gurson (1977) [2]. Tvergaard (1981, 1982) [3], [4] modified Gurson model by introducing two adjustment factors to account for void interaction effects and material strain hardening. Needleman and Tvergaard (1984) [5] extended Gurson model to simulate the rapid loss of load carrying capacity during void coalescence. Chu and Needleman (1980) [6] supplemented it by various kinds of void nucleation criteria.

In the early research, the criterion for the onset of void coalescence states that void coalescence starts at a critical void volume fraction f_c which has tend to be regarded as a material constant. However, further studies show that f_c depends strongly on parameters such as initial void volume fraction, void shape, void spacing, stress triaxiality, as well as strain hardening, etc.(Zhang et al., 2000; Pardoen and Hutchinson, 2000) [1], [7]. Thomason (1985, 1998) [8], [9] proposed a plastic limit load model for void coalescence. In this model, the start of void coalescence is controlled by the mechanism of the plastic localization in the void ligament, which is able to unify the material and stress states dependencies. Bao (2005) [10] conducted a series of experiments and finite element analyses on an aluminum alloy 2024-T351 and obtained a coalescence criterion in terms of the critical equivalent strain E_c as a function of the stress triaxiality ratio T. When the macroscopic equivalent strain reaches the critical value E_c, void coalescence occurs and the material quickly loses its load carrying capacity. However, Gao and Kim (2006) [11] argued that the extra parameter lode angle θ should be introduced and the critical equivalent strain should have the

form $E_c(T,\theta)$.

In this paper, two different void coalescence criteria are combined with the original GT model to simulate the whole process of voids nucleation, growth and coalescence. Axisymmetric round tensile bars with different notch root radii are simulated using the extended damage models to investigate the variation of critical damage at coalescence as a function of stress triaxiality.

2. Extended Damage Models

2.1. Modeling the void growth process

The growth of a void and the associated macroscopic softening is adequately captured by GT constitutive relationship. The most widely used form, which applies to strain hardening materials under the assumption of isotropic hardening, has the shape

$$\Phi=\left(\frac{q}{\bar{\sigma}}\right)^2+2q_1 f\cosh\left(-\frac{3q_2}{2}\frac{p}{\bar{\sigma}}\right)-1-q_3 f^2=0, \tag{1}$$

where p represents the macroscopic hydrostatic pressure

$$p=-\frac{1}{3}\sigma:I, \tag{2}$$

q denotes the macroscopic Mises equivalent stress

$$q=\sqrt{\frac{3}{2}s:s}, \tag{3}$$

σ is stress tensor; s is stress deviator; I is the second order identity tensor; $\bar{\sigma}\left(\bar{\varepsilon}_m^p\right)$ is the current flow stress of the fully dense matrix material as a function of $\bar{\varepsilon}_m^p$, the equivalent plastic strain in the matrix; and f is the current void volume fraction in the material. Tvergaard (1980, 1981) [3] introduced the constants q_1, q_2 and $q_3=q_1^2$ to account for void interaction effects due to multiple-void arrays and to give a better agreement with experimental data.

The hardening of the matrix material is described through $\bar{\sigma}=\bar{\sigma}\left(\bar{\varepsilon}_m^p\right)$. The evolution of $\bar{\varepsilon}_m^p$ is assumed to be governed by the equivalent plastic work expression:

$$(1-f)\bar{\sigma}d\bar{\varepsilon}_m^p=\sigma:d\varepsilon^p, \tag{4}$$

where $d\varepsilon^p$ is the macroscopic plastic strain rate tensor; $d\bar{\varepsilon}_m^p$ is equivalent plastic strain rate of the matrix material.

The change in volume fraction of the voids is due partly to the growth of existing voids and partly to the nucleation of voids. It can be expressed as [12]:

$$df=df_{growth}+df_{nucleation}, \tag{5}$$

with

$$df_{growth}=(1-f)d\varepsilon^p:I, \tag{6}$$

Nucleation of voids can occur as a result of micro-cracking and/or decohesion of the particle-matrix interface. It can be assumed to be strain controlled, so that the rate of increase of void volume fraction due to nucleation of new voids is given by

$$df_{nucleation}=Ad\bar{\varepsilon}_m^p, \tag{7}$$

The void nucleation intensity, A is a function of $\bar{\varepsilon}_m^p$ the equivalent plastic strain in the matrix material, and is assumed to follow a normal distribution as suggested by Chu and Needleman (1980) [6]:

$$A = \frac{f_N}{s_N\sqrt{2\pi}} \exp\left[-\frac{1}{2}\left(\frac{\bar{\varepsilon}_m^p - \varepsilon_N}{s_N}\right)^2\right], \tag{8}$$

where f_N is determined so that the total void volume nucleated is consistent with the volume fraction of particles; ε_N is the mean equivalent plastic strain for void nucleation; and s_N is the standard deviation of the distribution.

2.2. Void coalescence criterion

2.2.1 Plastic limit load criterion

Thomason (1985, 1998) [8] found that the localized deformation mode by intervoid matrix necking can be characterized by a plastic limit load which is not fixed but is strongly dependent on the void geometry and stress states. The condition for void coalescence can be written as:

$$\sigma_1 = \sigma_1^L, \tag{9}$$

where σ_1^L represents the capacity of the material to resist void coalescence; and σ_1 is the maximum principal stress at current yield surface of a material point.

Using a 3D unit cell containing an axisymmetric ellipsoidal void, Thomason acquired the plastic limit load to void coalescence with the following form

$$\frac{\sigma_1^L}{\bar{\sigma}} = \left(\alpha\left(\frac{R_z}{X - R_x}\right)^{-2} + \beta\left(\frac{R_x}{X}\right)^{-1/2}\right)\left(1 - \frac{\pi R_x^{\,2}}{X^2}\right), \tag{10}$$

where R_x, R_z and X are the current radii of the ellipsoidal void in the x- and z- axes and the current length of the cell in the x-axis, respectively; the local coordinates system is constructed so that x-, y- and z- axes represent the minor, medium and maximum principal stress directions. α and β are constants which are suggested as 0.1 and 1.2 by Thomason. Pardeon and Hutchinson (2000) [7] conducted a large number of cells calculations and found the dependence of α and β on hardening exponent n. Their simulation results showed that β is almost a constant and can be taken as 1.24 while

$$\alpha(n) = 0.1 + 0.217n + 4.83n^2 \quad (0 \le n \le 0.3), \tag{11}$$

If the void is assumed to be always spherical, the void/matrix geometry in Eq. 10 can be directly determined from the current void volume fraction f and current principal strain $\varepsilon_1, \varepsilon_2, \varepsilon_3$ by following equations (Zhang, 2001)[13]:

$$R_x = R_y = R_z = \sqrt[3]{\frac{3}{4}\frac{f}{\pi}e^{\varepsilon_1+\varepsilon_2+\varepsilon_3}}, \tag{12}$$

$$X = Y = \sqrt{e^{\varepsilon_1+\varepsilon_2}}/2, \tag{13}$$

2.2.2 Equivalent plastic strain criterion

By assuming the existence of a periodic distribution of voids, the material can be considered as an array of cubic blocks with each block being a unit cell having a void at its center. Failure of the unit cell occurs when localization of plastic flow takes place in the ligament (Koplik and Needleman,

1988) [14]. In macroscopic, a critical value of equivalent plastic strain is always used as a measurement of material ductility. Therefore, critical equivalent plastic strain can be used to denote material failure by void coalescence. To implement this concept, a possible approach is to establish a failure criterion based on equivalent plastic strain at the location where failure is most likely to initiate.

In practical, for axisymmetric round tensile bars, failure always initiates in the center of the minimum section in specimens, where corresponds to the site with the highest stress triaxiality. In addition, stress triaxiality is often used as the sole parameter to characterize the effect of the triaxial stress states on ductile fracture. So the critical equivalent plastic strain can be established as a function of the stress trixiality ratio T .

The power law form of the equivalent plastic strain criterion for API X65 steel proposed by Oh et al. (2007) [15] can be written as:

$$E_{ef} = 3.29e^{-1.54T} + 0.10, \tag{14}$$

with

$$T = -\frac{p}{q}, \tag{15}$$

where E_{ef} represents the critical equivalent plastic strain. This criterion is also used to develop extended damage model in this paper.

2.3. Post coalescence response

The f^* function, introduced by Tvergaard and Needleman (1984) [5], is adopted, to account for the effects of rapid void coalescence at failure. After void volume fraction reaches critical value determined by voids coalescence criteria, f is replaced by f^* in the extended damage models.

$$f^* = \begin{cases} f & for \quad f < f_c \\ f_c + \dfrac{f_u^* - f_c}{f_F - f_c}(f - f_c) & for \quad f \geq f_c \end{cases}, \tag{16}$$

where f_c is the critical void volume fraction at which voids begin coalesce; $f_u^* = 1/q_1$ is the f^* value at zero stress; and f_F denotes the void volume fraction at final complete failure.

3. Finite element applications

API X65 steel which is main pipe material largely utilized in gas transportation networks is discussed in this paper. To investigate the effect of triaxial stress states on tensile ductility of the material, three tensile round bar specimens with different notch root radii are analyzed, see Fig. 1. These specimens are also analyzed by Oh et al. (2007) [15] and the present simulation results are compared to their experimental data.

The extended damage models described in the previous section are implemented in ABAQUS via a user defined material subroutine (UMAT). Two critical numerical procedures are involved in the finite element implementations. The integration of the rate form constitutive equations is following the backward Euler method by Aravas (1987) [16]. In an implicit code, the linearization modulus is needed to construct the stiffness matrix (Jacobin) for Newton scheme which is used to solve the global equilibrium equations. The explicit consistent tangent modulus based on a return mapping

algorithm provided by Zhang (1995) [17] is adopted in this paper. The coalescence criterion 1, the plastic limit load criterion, and the coalescence criterion 2, the equivalent plastic strain criterion, are totally incorporated into the extended damage model, respectively.

As the specimens are axisymmetric, eight-node axisymmetric element with reduce integration (CAX8R) are used in the finite analyses. The finite element meshes of specimens are presented in Fig. 2. The element length of the minimum section where failure will first initiate in the specimen is 0.15mm.

API X65 steel is high strength and low alloy and the tensile properties of the present material are Yong's modulus, $E = 210.7\,\text{GPa}$; Poisson ratio, $\nu = 0.3$; initial yield strength, $\sigma_0 = 464.5\,\text{MPa}$. The uniaxial true stress-strain relationship of the present API X65 steel is approximated using the Ramberg-Osgood form fitted to the test data by Oh et.al (2007) [15].

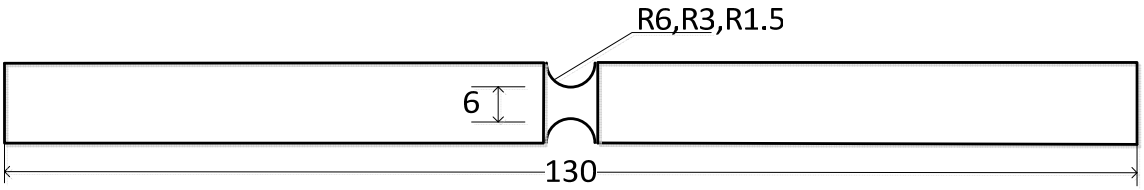

Figure 1. Geometries of notched tensile specimens

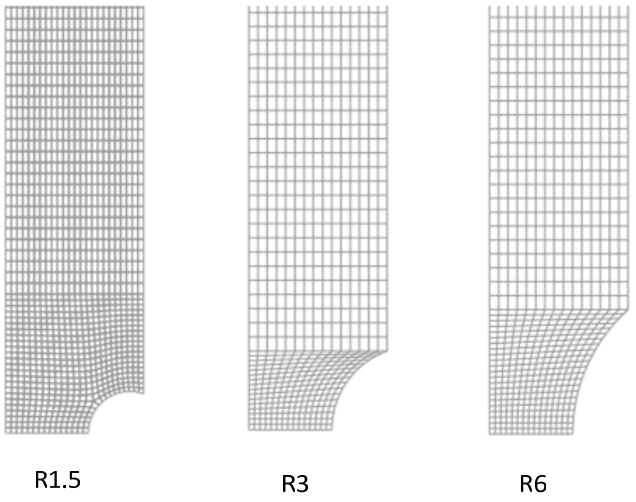

Figure 2. Axisymmetric finite element meshes for notched tensile bars

3.1. Determination of damage model parameters

In order to apply the present extended damage models to simulate ductile fracture, eight parameters should be first determined, including two adjustment factors for Gurson yield function (q_1, q_2); six parameters related to void volume fraction (f_0, f_c, f_F, ε_N, s_N and f_N).

The classic values ($q_1 = 1.5$ and $q_2 = 1.0$) given by Tvergaard (1982) [4] have been applied by many researchers as the constants for the GT model. Koplik and Needleman (1988) [18] carried out micromechanics studies about void growth and coalescence and found that the values of $q_1 = 1.25$ and $q_2 = 1.0$ provide best agreement between the GT model and the finite element results of voided cells calculations. Faleskog et al. (1998) [19] found that the q-values exhibit dependence

on both the hardening exponent (n) and the ratio of initial yield strength over Young's modulus (σ_0 / E). The studies of Kim et al. (2004) [20] have shown that, for a given material, the q-parameters should vary with stress triaxialities.

The nucleation parameters, ε_N and $s_N = 0.1$, determined by Chu and Needleman (1980) [6], are considered reasonable values for the current application. $f_N = 0.04$ is also suggested and is widely used by many researchers. However, the API x65 steel is a high-grade pipeline steel which is very clean steel and thus void nucleation is not significant and also delayed until very late in the deformation process. For this reason a much smaller value of f_N, 0.0008 is adopted in this study.

Some authors suggests that, as a first approximation, initial void volume fraction f_0 could be taken as the volume fraction of MnS inclusions, which is estimated from Franklin's formula [21]

$$f_v = 0.054\left(S\% - \frac{0.001}{Mn\%} \right), \tag{18}$$

where, $S\%$ and $Mn\%$ are the weight-% of sulfur and manganese, respectively. While voids coalescence is automatically determined by two type's criteria in the extended damage models, f_0 is the only unknown parameter and is to be fitted.

The void volume fraction at final fracture f_F is strongly dependent on f_0. Since f_F has been considered as an unimportant parameter, it can be extrapolated from the empirical equation by Zhang (2001) [13]:

$$f_F = 0.15 + 2 f_0, \tag{19}$$

In the present study, two sets of damage model parameters are involved. For these two groups, ε_N, s_N and f_N are to be take the same values as discussed previously; f_0 is determined by fitting to the experiment results for one notched tensile bar and then with this f_0, the void volume fraction at final fracture, f_F is obtained by Eq. 19. The critical coalescence porosity f_c is decided by the two coalescence criteria: plastic limit load criterion and equivalent plastic strain criterion. The q-values are also disparate for the two groups. The classic values ($q_1 = 1.5$ and $q_2 = 1.0$) are adopted in the first group. For the second, $q_1 = 1.704$ and $q_2 = 0.846$ are interpolated from the Faleskog's tabulated results based on the measured values of hardening exponent (n) and the ratio of initial yield strength over Young's modulus (σ_0 / E). Both sets of damage model parameters are illustrated in Table 1.

Table 1. Damage models parameters

	ε_N	s_N	f_N	f_0	f_c	f_F	q_1	q_2
Set1	0.3	0.1	0.0008	0.000125	Criteria1	0.15025	1.5	1.0
Set2	0.3	0.1	0.0008	0.0005	Criteria2	0.151	1.704	0.846

3.2. Comparison with experimental results

The finite element analyses are applied to predict mechanical behavior for the notched tensile bars that had notch root radii of 6mm, 3mm and 1.5 mm. These specimens have different levels of stress triaxiality. Porous metal material based on Gurson plasticity theory is also provided by ABAQUS in both implicit and explicit code; however, the failure definition is only available in

ABAQUS/Explicit. Therefore, it is essential to develop a complete damage model with the ability of simulating the whole process from void nucleation to the final damage. Finite element predictions both using the developed damage models and porous metal material provided by ABAQUS, and experimental results given by Oh et al. (2007) [15] are presented in Fig. 3. Since the axial displacement is monitored with the length of 25mm in experiments, the nominal strain and nominal stress of FEM results are derived from the mean nodal displacements and total nodal force at the section which is 12.5mm from the middle section, respectively.

It can be seen from Fig. 3 that the extended damage models with two different coalescence criteria can give almost identical predictions that are very close to the experimental results for all the specimens, irrespective of geometry. Simulations without the coalescence model can still predict the experimental curve very well before void coalescence. The FEM predictions without the coalescence response definition, however, cannot predict the sharp reduction in the slope of the nominal stress versus nominal strain curve after instability.

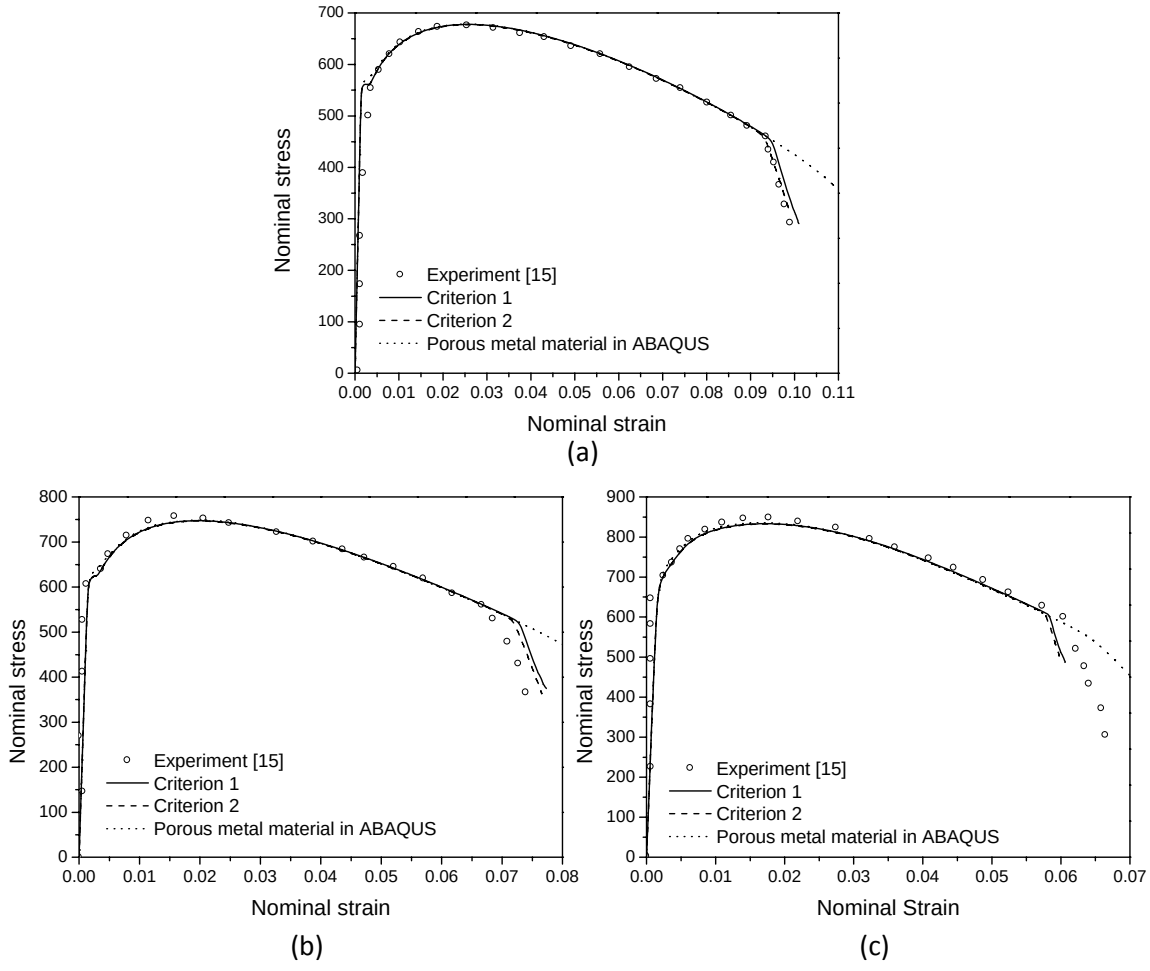

Figure 3. Comparison of FEM results with notched tensile tests: (a) R6; (b) R3; (c) R1.5

3.3. Crack formation in the notched bars

One of advantages of the developed model is that both the crack initiation site and propagation path can be simulated. Fig. 4 (a) shows the crack initiation location of the R6 notched tensile bar, the center site in the minimum section, which is in accordance with results observed from experiments.

Fig. 4 (b) illustrates the crack growth path, from the center to the free surface through the minimum section of the specimen. The void volume fraction at crack initiation is presented in Fig. 4 (c) and the highest void volume fraction site appears in the center of notched bars with no surprise.

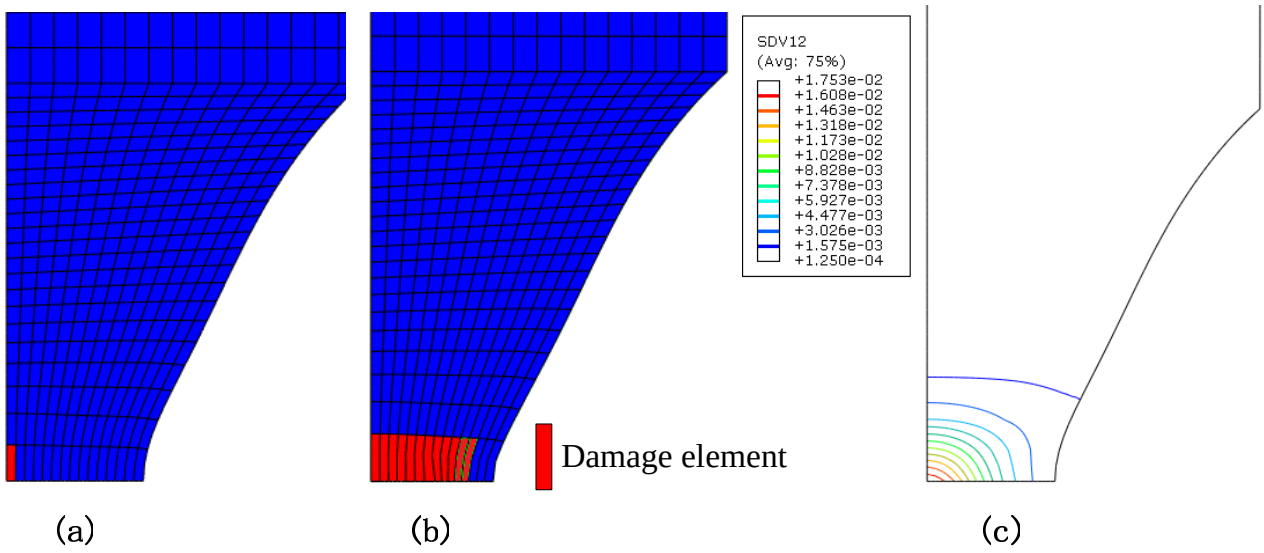

Figure 4. The FEM results of R6 notched tensile bar: (a) (b) Damage elements at and after crack initiation; (c) The void volume fraction at crack initiation

3.4. The effect of stress triaxiality

For each specimen, stress triaxiality is highest at the center and lowest at the free edge. Fig. 5(a) demonstrates the stress triaxiality value along the minimum section at the loading level corresponding to the onset of crack. Higher values of stress triaxiality together with increased plastic deformation in the center region of notched specimens accelerate crack initiation and growth according to the GT constitutive relationship. Thus, it is not surprising to find that crack initiates at the center of specimens.

For specimens with different notch root radii, various stress triaxialities are determined by geometry. Larger notch root radii results in smaller stress trixiality ratio. The curve of stress triaxiality ratio T versus equivalent plastic strain $\bar{\varepsilon}_{ef}$ at the center of specimen with load proceeding is presented in Fig. 5(b). Various stress triaxialities lead to void coalescence at different plastic deformation measured by equivalent plastic strain, illustrated in Fig. 6.

4. Concluding remarks

By incorporating two coalescence criteria, the extended damage models succeed in simulating the ductile failure in round tensile bars and also provide a practical approach to simulate the crack formation and propagation in small-scale tensile specimens. The present predictions show that:

(1) The extended damage models with two different coalescence criteria can give almost identical predictions that are very close to the experimental results for all the specimens.
(2) For each round tensile bar, crack initiates in the center of specimen where the highest stress triaxiatity and largest void volume fraction appear. In addition, crack propagation along the minimum section in specimens.
(3) Distinct geometries represent different stress triaxiatities and different stress triaxiatities lead

to void coalescence starting at diverse equivalent plastic strain.

Abstract: High strength woven fabrics are ideal materials for use in structural and aerospace systems where large deformations and high-energy absorption are required. Their high strength to weight ratio and ability to resist high-speed impacts enables them to be more efficient than metals in many applications, including ballistic armors, propulsion engine containment systems and fabric-reinforced composites. In order to facilitate the design and improvement of such applications, this study investigates the mechanical behavior of Kevlar 49 fabric and single yarn under quasi-static and dynamic tensile loadings. The experimental results show that the fabric exhibits non-linear in tension, and can deform up to 20% before complete failure under quasi-static loading. The fabric has identical Young's modulus in warp and fill directions, but has different crimp strain, tensile strength and ultimate strain. The sample size has little effect on the mechanical properties of the fabric. The dynamic tensile behaviors of the fabric and single yarn were investigated at strain rates from 25 to 170 s^{-1} by using a high rate servo-hydraulic testing machine. Results show that their dynamic material properties in terms of Young's modulus, tensile strength, maximum strain and toughness increase with increasing strain rate.

Keywords: Fabrics, Dynamic, Strain rate, Kevlar 49

1. Introduction

High strength woven fabrics are ideal materials for use in structural and aerospace systems where large deformations and high energy absorption are required. Their high strength to weight ratio and ability to resist high speed impacts enables them to be more efficient than metals. Materials loaded at high strain rates can exhibit mechanical characteristics that are different from those obtained under quasi-static loading. High strain rate applications are quite varied and include structural, military, aerospace, and sports disciplines. Aramid and other high strength fibers and fabrics have been studied extensively in a wide range of applications, creating a demand for numerical modeling of fibers, yarns, and fabrics. While quasi-static tensile strength data for the single fibers is available, results cannot be extrapolated and scaled up for yarns consisting of many fibers, woven, knitted, or bonded fabrics with a 2-D or 3-D microstructure. Furthermore, the strain rates observed in static experiments is not in the same order of magnitude as those observed in ballistic applications [1]. Five types of testing systems are commonly used in generating the rate dependent material data: the conventional screw drive load frame, servo-hydraulic system, high rate servo-hydraulic system, impact tester and Hopkinson bar system. However, the experimental techniques to generate stress-strain data at the medium strain rates in the range of 1~100 s^{-1} are not well established [2]. Two types of equipment have been used to generate data in this strain rate range: high rate servo-hydraulic testing machines [3-5] and drop-weight impact machines [6, 7].

The primary objective of our research is to investigate the effects of gage length and strain rate on the mechanical properties of Kevlar 49 fabric and single yarn, as a part of the project on explicit finite element modeling of multi-layer composite fabric for gas turbine engine containment systems [8-12]. In the next section we present the experimental procedure and results of fabric and single

yarn specimens under quasi-static and dynamic tensile loadings and the results of Weibull statistical analysis. Images captured during loading process are used to study the deformation and failure mechanisms of the fabric and yarn.

2. Experimental Program

2.1. Specimen preparation

The plain-woven Kevlar® 49, a high performance fabric for ballistic protection application, made by EI du Pont de Nemours & Co., is used in this study. The fabric is manufactured using a plain-weave of 17×17 yarns (per linear inch) each consisting of hundreds of filaments. The bulk density (mass per unit of volume) and linear density (mass per unit of length) are 1.44 g/cm^3 and 1.656 × 10^{-3} g/cm, respectively. The cross-sectional area of each yarn was calculated as 1.15 × 10^{-3} cm^2 by dividing the linear density of the material by its bulk density [13]. This value is then taken as the total c/s area of individual fibers within the yarn.

To make a strip specimen for quasi-static tests, the fabric was first cut into an oversized rectangular strip, and then a number of yarns along the fabric length were removed from both sides, thereby producing a sample without yarn crossovers along the edges. This step is necessary to ensure that the edge defects are minimized and that the loaded yarns will not slip out of the cross yarns during the test. The final sample dimension had a length of 250 mm with two alternate widths of 30 mm and 60 mm. In each set, yarns are removed from both sides of the strip such that the samples are left with 17 and 34 longitudinal yarns, respectively. The initial gage length was 200 mm. The total cross-sectional area of a specimen was defined as the cross-sectional area per yarn multiplied by the number of yarns within the width. In order to investigate the effect of gage length on the mechanical properties of the fabric, additional specimen sizes of 25 × 280 mm and 25 × 355 mm were also tested in warp direction under the same loading rate.

Smaller specimens were used for dynamic tensile tests. The fabric was cut to the width using an electric scissor allowing eight yarns in the section of gage length. Thin aluminum sheets were glued using high-strength epoxy to the ends of the test specimen to reduce the stress concentration and improve load transfer in grips so as to prevent any slippage, as shown in Fig. 1. The single yarn specimen was constructed to contain one yarn in the central position by removing the rest of the yarns as shown in Fig. 2. Two different gage lengths of 25 mm and 50 mm were tested for both fabric and single yarn specimens.

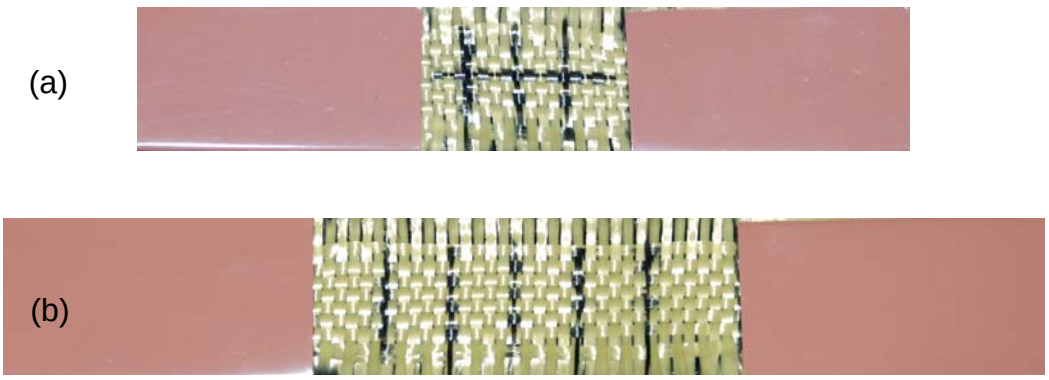

Figure 1. Fabric specimens with (a) 25mm and (b) 50mm gage length for dynamic tensile tests

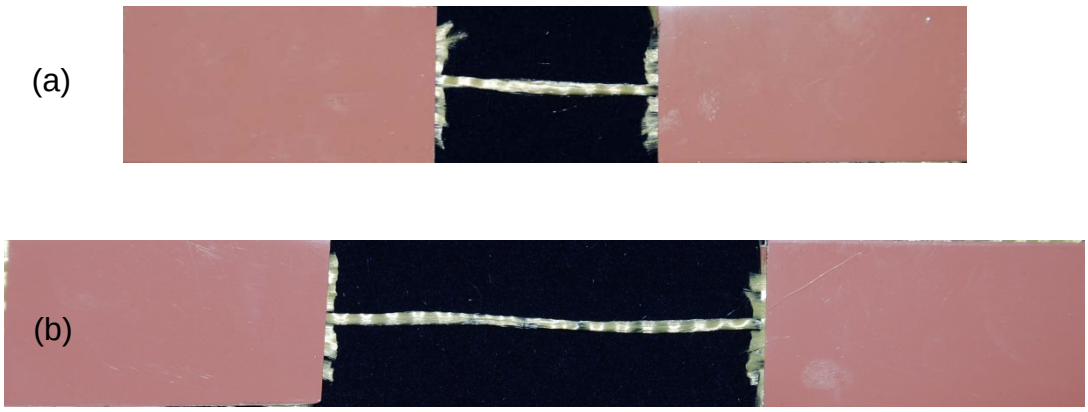

Figure 2. Single yarn specimens with (a) 25mm and (b) 50mm gage length for dynamic tensile tests

2.2. Quasi-static tensile testing

Quasi-static tensile tests of Kevlar fabric were performed on a 90 kN INSTRON machine operated under closed-loop displacement control with a displacement rate of 2.5 mm/min. Digital data acquisition was used to collect data at a sampling rate of 2 Hz. The test was continued until complete failure of the specimen. The overall specimen deformation was measured by stroke movement. The two plates were held together within the hydraulic grips to ensure uniform pressure application and prevent any fabric slippage (more details in Naik et al. [9]). Five replicates were tested for each specimen size in both warp and fill directions, and the deformation and failure behaviors of the specimens were recorded by a CCD monochrome camera.

In order to measure the mechanical properties of the yarn, single yarns were extracted from fabrics and only the warp yarns were tested. A low capacity load cell (275N) was used to record the force. A universal joint was connected to the testing frame to allow rotation of the grip and remove any potential bending moment. The universal joint also helped in the alignment of yarn during test. To avoid any slipping of test sample during testing, the yarn was wrapped around the upper and lower mandrels and aligned using a laser beam alignment level [14]. Ten replicate samples of six different gage lengths (50, 125, 200, 275, 350, 425 mm) were tested on an MTS test frame under displacement control at a strain rate of 4.2×10^{-4} s^{-1} (quasi-static).

2.3. Dynamic tensile testing

Dynamic tensile tests were conducted on an MTS high rate servo-hydraulic testing machine operated in open-loop control [3]. The speed of the stroke is controlled by the opening and closing of the servo-valve of hydraulic supply. By manually turning the servo-valve, the rate of flow of hydraulic fluid can be controlled, resulting in different stroke speeds. However there are some differences in the actual stroke speeds between individual tests although the opening of servo-valve is not changed, especially at higher stroke speeds. The actual stroke speeds of individual tests are determined by the slopes of real-time displacement-time curves obtained from the tests. A description of the high strain rate testing system, test setup and data processing procedure are

provided in the references [3, 13]. The fabric samples of two different gage lengths (25mm and 50 mm) were tested at strain rates ranging from 25 to 170 s^{-1}. The Young's modulus, tensile strength, maximum strain, and toughness were investigated at these strain rates. Single yarn samples were tested at strain rates of 30, 50 and 100 s^{-1} for the 25 mm gage length, and at strain rates of 20 and 60 s^{-1} for the 50 mm gage length. It should be noted that the strain rates listed above are the average values and the actual strain rate of an individual test may be slightly different.

3. Results and Discussion

3.1. Quasi-static response

The typical stress versus strain relationship and the fabric deformation under uniaxial tension are shown in Fig. 3. There are four distinct regions in the stress-strain behavior of both warp and fill directions: crimp region, linear pre-peak region, linear post-peak region and non-linear post-peak region. In the undeformed, but undulated state (strain ε=0), the warp and fill yarns are orthogonal to each other and free of any stretch. In the crimp region, the stress increase is relative low due to the straightening of the undulated yarns in loading direction with limited yarn stretching. The maximum strain in crimp region in warp and fill directions is only 0.0065 mm/mm and 0.0025 mm/mm, respectively. These strain values are negligible when compared with the strain at failure. As the strain increases, the yarns in the loading direction are extended, and when fully straightened (ε=0.01 to 0.02), the fabric exhibits a linear response with no visible failure signs. The Young's modulus (elastic stiffness) is defined by the slope of the stress-strain curve in this region. Both the crimp and pre-peak regions are fitted by linear curves to obtain corresponding stiffnesses [9]. As the stress level reaches the strength of the constituent yarns, the yarns in the loading direction start to fail, resulting in a dramatic decrease in the fabric load-carrying capacity until reaching a transition point at about 200 MPa (the end of linear post-peak region) where the yarns/fibers are broken. After that the stress decreases gradually to zero when the strain increases up to about 0.2 mm/mm, representing the nonlinear post-peak region where the failed yarns/fibers slip out of the fabric and the load is carried by the friction between sliding fibers (ε=0.02 to 0.04). The toughness of the fabric is defined by the area under the entire stress-strain curve.

Analysis of the stress versus strain curves in both warp and fill directions for both specimen sizes (50 mm × 200 mm and 25 mm × 200 mm), indicates that the pre-peak elastic stiffness (Young's modulus) of warp direction is almost identical to that of fill direction, and the stiffness in the crimp region for warp and fill directions is as much as 6% and 20% of the elastic stiffness (Young's modulus) in pre-peak region, respectively. The absolute value of the stiffness in linear post-peak region of warp and fill directions is 2.2 and 5.6 times of the elastic stiffness in pre-peak region. Comparing the stress-strain behavior between warp and fill directions, the major difference is the crimp strain, tensile strength (peak stress) and the ultimate strain (strain at peak stress) in both directions. The crimp strain in warp direction is about 2.6 times larger than that of fill direction. The tensile strength in warp direction is approximately 10~15% lower than that in fill direction, while the ultimate strain in warp direction is approximately 7~12% higher than that in fill direction. This

is due to the fact that the warp yarns have sustained more damage from weaving process and have higher initial crimps. The stress-strain curves of specimens tested are highly repeatable for both sizes and directions.

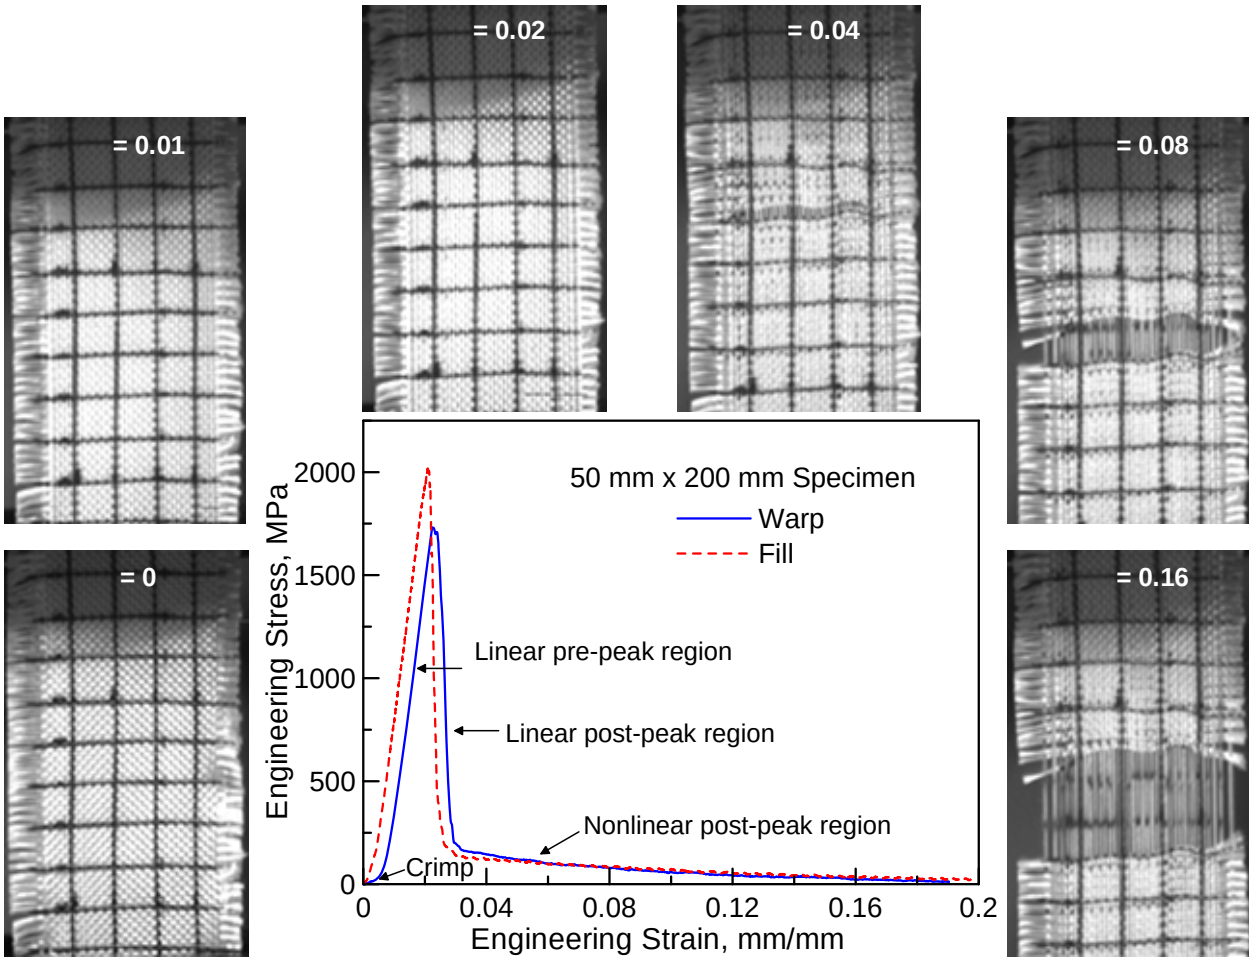

Figure 3. Typical stress-strain relationship and fabric deformation under quasi-static uniaxial tension

Table 1 Summary of Tensile Properties of Kevlar 49 Fabric

Specimen Size (mm × mm)	Material Direction	Tensile Strength (MPa)	Young's Modulus (GPa)	Toughness (MPa)	Ultimate Strain (mm/mm)
50×200	Warp	1748 ± 56	117.2 ± 3.3	32.4 ± 3.0	0.0223 ± 0.0012
	Fill	2013 ± 44	117.1 ± 3.0	33.9 ± 1.3	0.0201 ± 0.0010
25×200	Warp	1859 ± 109	117.9 ± 2.5	32.9 ± 1.4	0.0215 ± 0.0015
	Fill	2055 ± 72	119.7 ± 4.0	33.2 ± 1.2	0.0200 ± 0.0009
25×280	Warp*	1776 ± 100	126.5 ± 4.6	26.9 ± 1.7	0.0197 ± 0.0014
25×355	Warp*	1811 ± 61	132.1 ± 5.8	27.1 ± 1.8	0.0181 ± 0.0008

*These tests were stopped once the load acting on the specimen fell below 222N.

Tables 1 summarizes the tensile properties of both specimen sizes in both warp and fill directions. There is no apparent size effect in terms of Young's modulus, toughness and ultimate strain, but the average tensile strength of 50 mm wide specimens is slightly lower (2~6%) than those of 25 mm wide specimens in both directions. For longer specimens (25 × 280 mm and 25 × 355 mm), the tests were stopped once the load on the specimen fell below 222N (corresponding to approximately 10% maximum strain). Toughness in these samples is underestimated as much as 16~20% lower than those of 200 mm long specimens. However, the toughness remains almost same when the gage length increases from 280 mm to 355 mm, so does the tensile strength, Young's modulus, and ultimate strain, indicating that gage length effect on the fabric's mechanical properties is negligible.

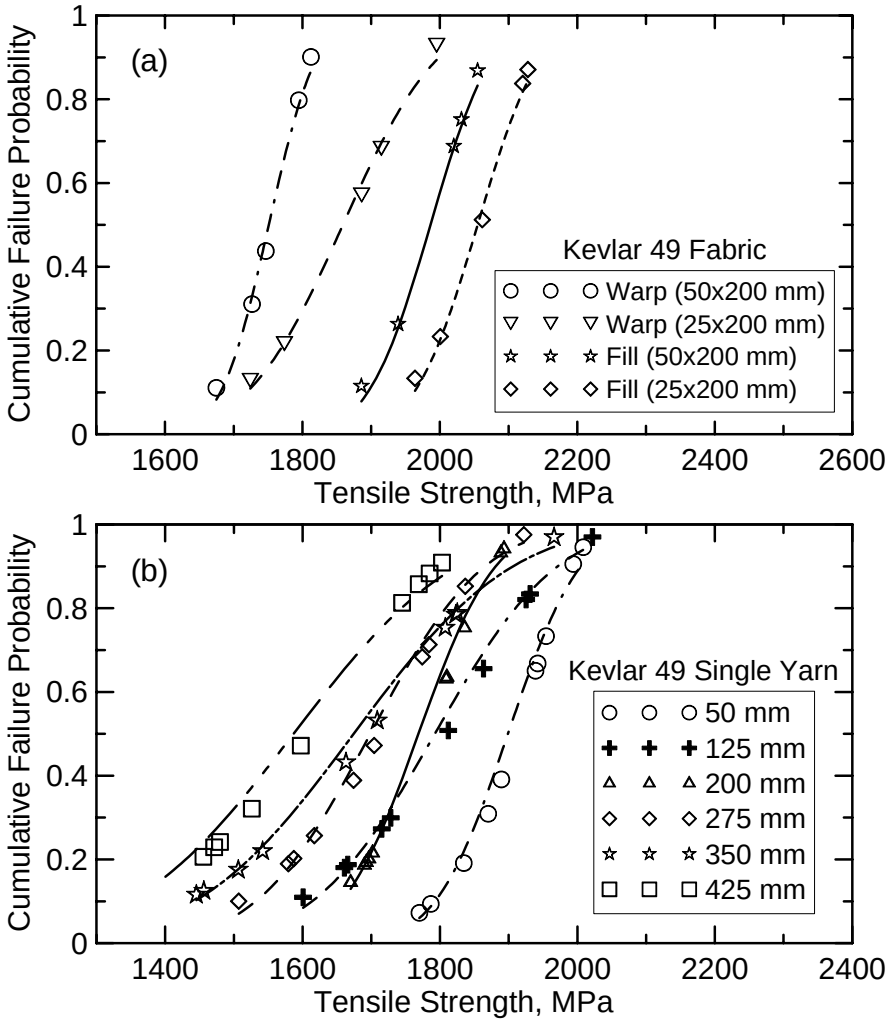

Figure 4. Comparison of cumulative failure probability versus tensile strength: (a) fabric and (b) single yarn under quasi-static loading

Weibull parameters were obtained using a 2-parameter Weibull equation:

$$P_f(\sigma) = 1 - \exp\left[-\left(\frac{\sigma}{\sigma_0}\right)^m\right] \tag{1}$$

where σ_0 is the characteristic yarn strength and m is the shape parameter, characterizing the spread

in the distribution of strengths. P_f was estimated using the following equation:

$$P_f = \frac{i}{N+1} \tag{2}$$

where N is the total number of tests and i is the current test number [15].

Figure 4a and b shows the Weibull curve fitting to experimental data of both fabric and single yarn samples, respectively. The fabric data clearly indicate that the fabric breaks at lower stress in warp direction than in fill direction, and wider samples (50 mm) have lower tensile strength. For the single yarn data, as the gage length increases, the cumulative probability plot shifts towards lower stress values, which is a clear indicator of dependence of tensile strength on the gage length. The Weibull parameters identified from both fabric and single yarn tests are presented in Table 2.

Table 2. Weibull Parameters of Kevlar 49 Fabric and Single Yarn under Quasi-Static Loading

	Fabric				Single Yarn					
Size (mm)	25 × 200		50 × 200		50	125	200	275	350	425
Material Direction	Warp	Fill	Warp	Fill	Warp					
σ_0 (MPa)	1857	2064	1759	2001	1933	1829	1795	1724	1726	1652
m	13.3	27.0	27.5	27.4	21.7	11.5	14.3	11.9	7.9	8.8

3.2. Dynamic response

Figure 5(a-d) shows the dependence of the dynamic material properties of Kevlar 49 fabric, defined in terms of Young's modulus, tensile strength, maximum strain and toughness on strain rates, respectively. There is an apparent dependence of the dynamic material properties on the strain rates discussed as follows: For 25 mm gage length specimen, the Young's modulus increases from 120 ± 14 GPa at initial strain rate of 30 s^{-1} to 131 ± 23 and 147 ± 10 GPa at strain rates of 100 s^{-1}, and 170 s^{-1} respectively. The tensile strength increases from 1489 ± 54 MPa at a strain rate of 30 s^{-1} to 1968 ± 109 and 2340 ± 134 MPa at strain rates of 100 s^{-1}, and 170 s^{-1} respectively. Maximum strain increases from 2.92 ± 0.17% to 3.27 ± 0.32% and then to 3.66 ± 0.27%, and toughness increases from 24.6 ± 2.6 MPa to 30.6 ± 1.5 MPa and to 41.4 ± 4.8 MPa when the strain rate increases from 30 to 100 and then to 170 s^{-1}. For 50 mm gage length specimen, the Young's modulus increases from 127 ± 16 GPa to 144 ± 12 GPa and then to 162 ± 11 GPa, the tensile strength increases from 1677 ± 136 MPa to 1954 ± 104 MPa and then to 2108 ± 83 MPa, the maximum strain increases from 2.58 ± 0.34% to 2.82 ± 0.18% and then to 2.83 ± 0.28%, and toughness increases from 21.6 ± 3.8 MPa to 22.2 ± 3.3 MPa and then to 25.8 ± 1.8 MPa when the strain rate increases from 25 to 60 and then to 100 s^{-1}.

Figure 6(a-d) shows the dependence of the dynamic material properties of Kevlar 49 single yarn on the strain rate. There is an apparent dependence of the dynamic material properties on the strain rate; however there is no clear dependence between the properties and gage lengths investigated. For the

25 mm gage length specimen, the Young's modulus increases from 109 ± 11 GPa at a strain rate of 30 s^{-1} to 111 ± 10 and 128 ± 11 GPa at strain rates of 50 s^{-1}, and 100 s^{-1} respectively. The tensile strength increases from 1622 ± 104 MPa at a strain rate of 30 s^{-1} to 1675 ± 51 and 1707 ± 82 MPa at strain rates of 50 s^{-1}, and 100 s^{-1}, respectively. Maximum strain increases from 0.0245 ± 0.003 mm/mm to 0.0253 ± 0.0017 mm/mm and then to 0.0282 ± 0.0022 mm/mm, and toughness increases from 20.1 ± 2.6 to 20.5 ± 1.4 MPa and to 26.0 ± 4.3 MPa when the strain rate increases from 30 to 50 and then to 100 s^{-1}. For the 50 mm gage length specimen, the Young's modulus increases marginally from 118 ± 28 to 121 ± 22 GPa when the strain rate increases from 20 to 60 s^{-1}. While the tensile strength increases by as much as 23.5% from 1579 ± 100 to 1874 ± 110 MPa, the maximum strain increases about 15% from 0.0217 ± 0.003 mm/mm to 0.025 ± 0.0026 mm/mm, and toughness increases about 29 % from 18.8 ± 2.5 MPa to 24.3 ± 4.0 MPa.

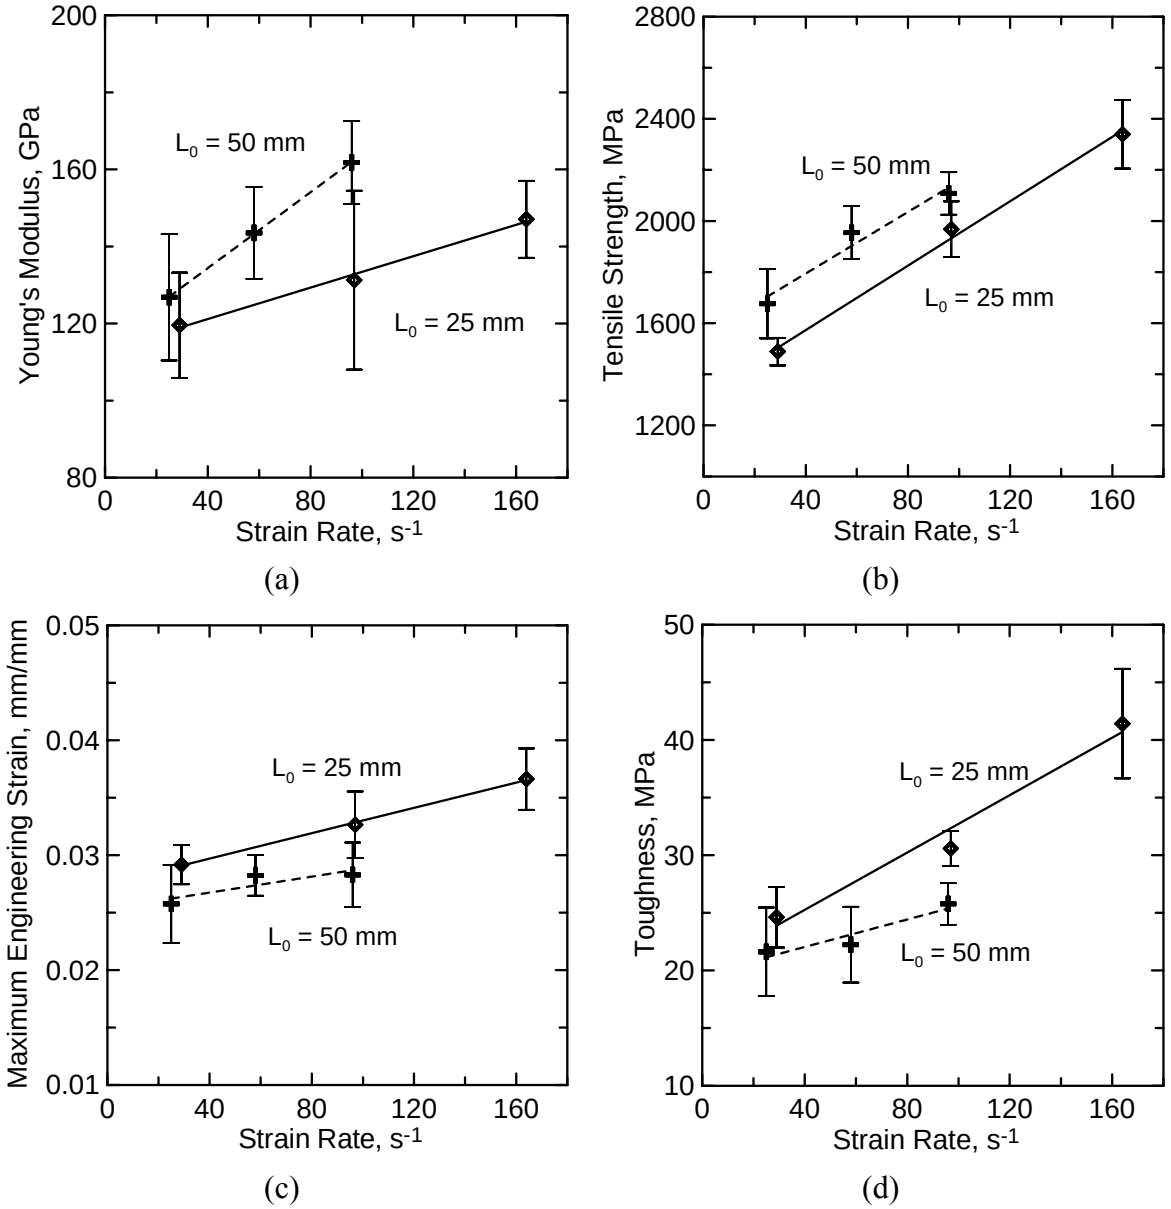

Figure 5. Strain rate effect on the dynamic material properties of Kevlar 49 fabric: (a) Young's modulus, (b) tensile strength, (c) maximum strain, and (d) toughness. L_0 is the gage length.

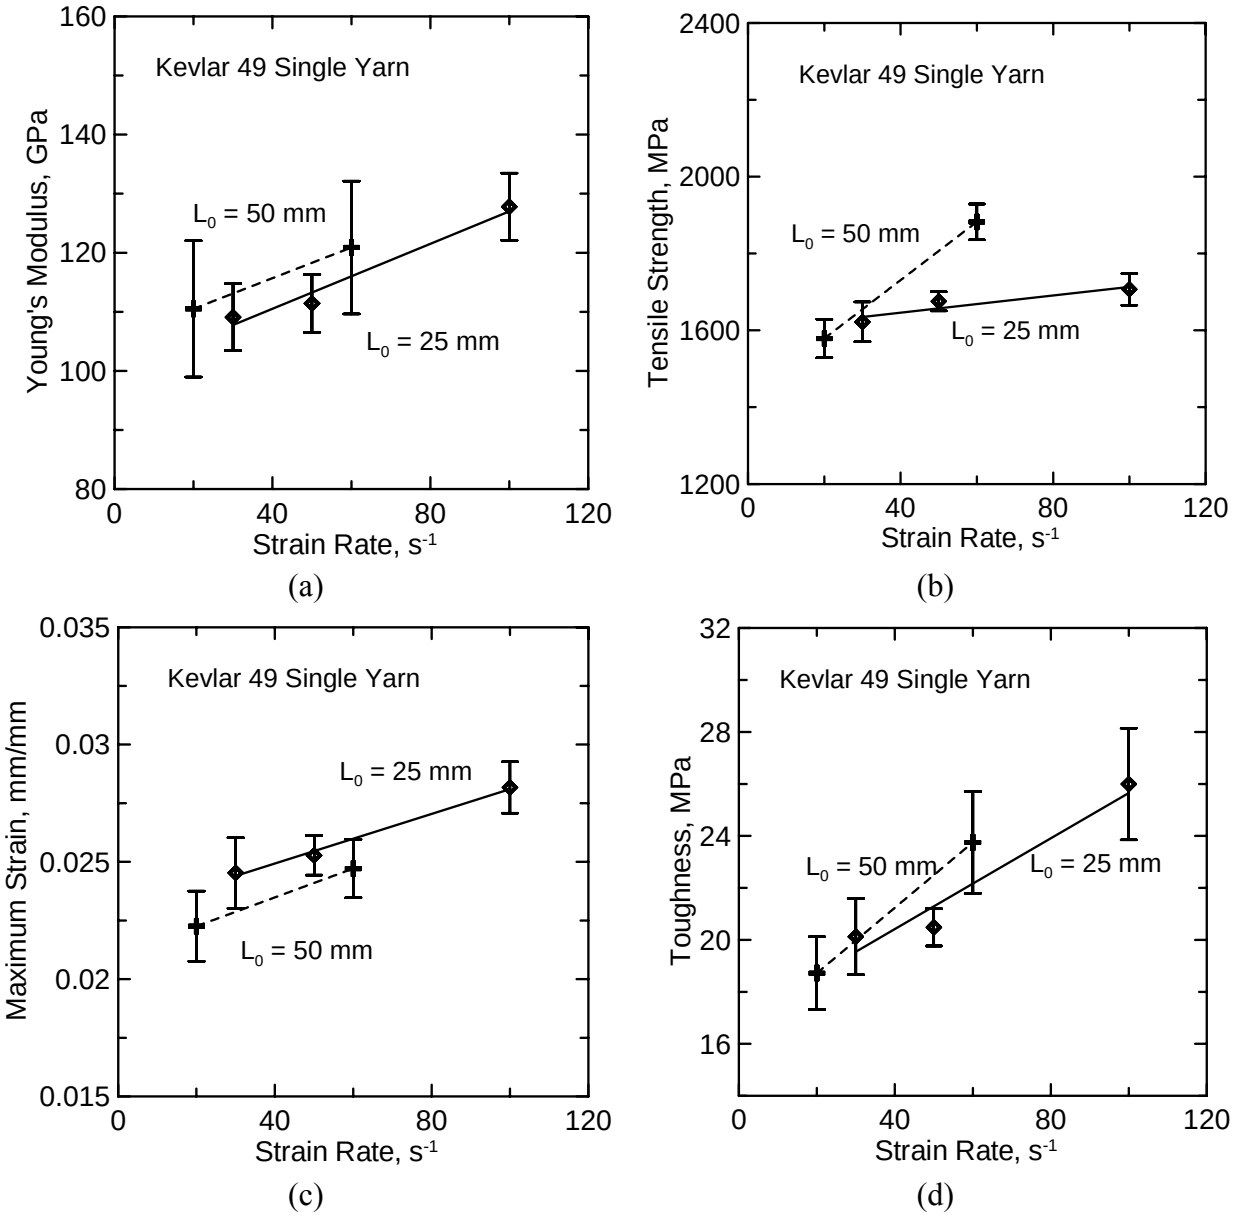

Figure 6. Strain rate effect on the dynamic material properties of single yarn: (a) Young's modulus, (b) tensile strength, (c) maximum strain, and (d) toughness

4. Conclusions

This work investigated the mechanical behaviors of Kevlar 49 fabric and single yarn under quasi-static and dynamic tensile loadings. Weibull parameters have been obtained to characterize the considerable scatter in the mechanical properties due to different amount and distribution of imperfections in the fabric and yarn specimens. The following conclusions can be reached:

(1) Under quasi-static loading, the stress-strain response of Kevlar 49 fabric exhibits non-linear and orthogonal behavior in both warp and fill directions, and the fabric can deform up to 20% before the stress decreases to zero. The Young's modulus is almost identical to one another in both directions. The major difference between warp and fill directions is the crimp strain, the tensile

strength and the ultimate strain. The tensile strength of single yarn decreases with increasing gage length.

(2) Under dynamic loading, Young's modulus, tensile strength, maximum strain and toughness of the fabric and yarn increase with increasing strain rate over the strain rate range from 20 to 170 s^{-1}. However, based on the current results, it is not clear what the effect of the gage length is on the dynamic properties.

Abstract This paper presents a 3D dynamic failure analysis of linear elastic body by using particle discretization scheme finite element method (PDS-FEM). PDS-FEM uses two sets of non-overlap characteristic function to discretize function and function derivative. Unlike ordinary FEM, PDS-FEM can easily calculate crack, which is the discontinuity in displacement function. The target is a thin epoxy plate with two anti-symmetric notches under uni-axial tensile boundary condition. A time depend failure criterion, called Tuler - Butcher criterion is applied. The simulation results are compared with the experimental results, which are captured by an image sensor at the rate of one million frames per second. In real world, no ideal isotropic homogeneous body exists. Disturbances exist everywhere. Crack is sensitive to local heterogeneity. Since the mesh configuration determines the candidate crack distribution in PDS-FEM, the uncertainty can be modeled by adding disturbance to the mesh configuration. By using Monte-Carlo simulation, the crack patterns observed in experiment, including bending, kinking and bifurcation are successfully simulated by using PDS-FEM.

Keywords Three dimensional dynamic simulation of fracture, stochastic model, brittle failure, photo-elastic experiment

1. Introduction

The simulation of fracture has been a challenging problem in solid continuum mechanics [1-2]. There are two difficulties in reproducing experiment results numerically: 1, accuracy and efficient numerical method is needed; 2, due to the limitation of observing technology, a stochastic model, which can represent the uncertainties, needs to be carefully designed.

For simulation of crack growth, varieties of numerical methods have been developed, such as E-FEM, X-FEM [3], discontinuous Galerkin method and meshfree methods. However, the original version of these methods has two common drawbacks: (1), the bifurcation or branching could not be calculated, which is essential for brittle materials, such as epoxy resin, rock and concrete; (2), the crack configuration is simple, normally in one dimension, so complex and detail configuration cannot be expressed. Recently, the improved version of above methods has been proposed by many researchers. The static, quasi-static and dynamic analysis can be successfully carried out [4-7].

Besides aforementioned methods, the newly developed method, called particle discretization scheme finite element method (PDS-FEM) is another candidate [8], for its numerical efficiency and capability of calculating bifurcation. In order to verify the accuracy and numerically efficiency of this method, a thin epoxy resin plate with two notches located anti-symmetrically in the middle under uni-axial tensile has been carried out numerically and experimentally. The quasi-static state of PDS-FEM has been developed by Oguni et al [9]. The comparison results show similarity between the simulation and experiment results.

In order to study the dynamic crack growth, we extend PDS-FEM to dynamic state [10]. PDS-FEM is originally formulated for Lagrangean at quasi-static state, and hence the extension to dynamic state is straightforward. Special attentions, however, have to be paid to time integration since

cracking releases strain energy and changes stiffness matrix drastically. High robustness is required for the time integration, and we adopt Hamiltonian formulation so that most robust algorithm which is proposed in the field of computational quantum mechanics can be employed for the time integration.

In real world, there is no ideal isotropic homogeneous body. Various kinds of disturbances exist everywhere. Due to limitation of the observation technology, the material property and boundary condition can hardly measure accurately. The difference between numerical setting and reality is called disturbance. Since crack is sensitive to local heterogeneity, even with the same setting, the crack paths of experimental samples are still somehow different from each other. In this paper, the authors try to reproduce a fracture experiment of a thin epoxy resin plate. In order to model the heterogeneity, a stochastic model is proposed, which introduces certain perturbation to the homogeneous body. Then, a Monte-Carlo simulation is carried out, from which, the crack patterns observed from corresponding experiments are successfully simulated.

The content of the present paper is as follows: section 2 briefly explains the extension of PDS-FEM to dynamic state. We formulate the dynamic extension of PDS-FEM by using discretized Hamiltonian, so that a robust algorithm can be applied to the time integration. Section 3 is devoted to discuss modeling of weak heterogeneity. The modeling is made by using different candidates of possible crack extensions, which is realized by using different meshes. Section 4 contains a Monte-Carlo simulation for a thin epoxy resin plate with a pair of anti-symmetric notches located in the middle. Also, the simulation results are compared with corresponding experiments, which are captured by a high frequency image sensor at the rate of 1 million frames per second. Concluding remarks are pointed out in section 5.

2. Extension of PDS-FEM to dynamic state

On the viewpoint of the numerical computation, it is not easy to analyze the crack growth, since cracking not only releases strain energy, but also changes the stiffness matrix. A robust algorithm that can handle such a change is required. The algorithm is also required to guarantee symplecticity, i.e., the total energy and momentum should be conserved during the crack growth.

A robust algorithm of time integration has been studied in the field of computational quantum mechanics [11]. To implement such an algorithm, we formulate the dynamic extension of PDS-FEM using Hamiltonian. We start from the following Lagrangean of a linearly and isotropically elastic solid, denoted by B, with elasticity $\mathbf{c}$, density ρ, displacement $\mathbf{u}$, stress $\boldsymbol{\sigma}$ and strain $\boldsymbol{\varepsilon}$:

$$L[\mathbf{u},\dot{\mathbf{u}};\boldsymbol{\varepsilon},\boldsymbol{\sigma}]=\int_B \frac{1}{2}\boldsymbol{\varepsilon}:\mathbf{c}:\boldsymbol{\varepsilon}-\frac{1}{2}\rho\dot{\mathbf{u}}\cdot\dot{\mathbf{u}}+\boldsymbol{\sigma}:(\nabla\otimes\mathbf{u}-\boldsymbol{\varepsilon})\,dv\,. \tag{1}$$

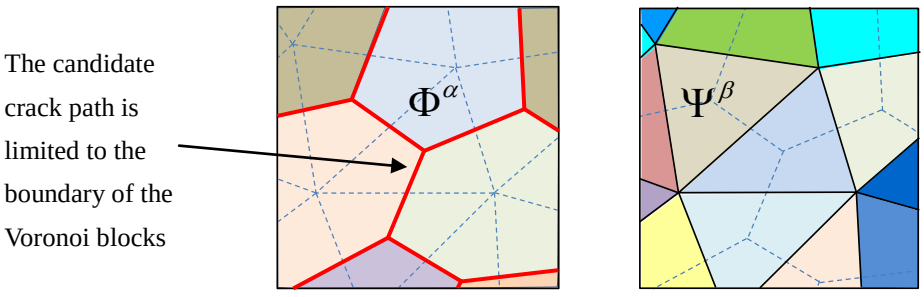

Figure 1. Two dimension decomposition by using particle discretization scheme

The discretization is made by using dual Voronoi $\{\Phi^{\alpha}\}$ and Delaunay tessellations $\{\Psi^{\beta}\}$, and their characteristic functions $\{\phi^{\alpha}\}$ and $\{\psi^{\beta}\}$ are used as basis functions. Note that, the displacement is discretized by Voronoi tessellations, while strain and stress are discretized by Delaunay tessellations:

$$\begin{aligned} u(x,t) &= \sum_{\alpha} u^{\alpha}(t)\phi^{\alpha}(x), \\ (\varepsilon,\sigma)(x,t) &= \sum_{\beta} \left(\varepsilon^{\beta},\sigma^{\beta}\right)(t)\psi^{\beta}(x). \end{aligned} \tag{2}$$

The following discretized wave equation is derived from L and the discretized functions:

$$M^{\alpha}\ddot{\mathbf{u}}^{\alpha}(t) + \sum_{\alpha'} \mathbf{K}^{\alpha\alpha'} \cdot u^{\alpha'}(t) = 0, \tag{3}$$

where M^{α} is the mass of the α^{th} Voronoi tessellation, the superscript α' stands for the α'^{th} adjacent Voronoi tessellation. Note that $\mathbf{K}^{\alpha\alpha'}$ is the stiffness matrix of PDS-FEM. This $\mathbf{K}^{\alpha\alpha'}$ coincides with an element stiffness matrix of FEM with linear tetrahedron elements [8]. Also, it should be noted that Eqn. 3 automatically leads to a lumped mass matrix. No approximation is needed to derive the lumped mass matrix, unlike ordinary FEM. This is the advantage of PDS-FEM, since, as shown in Eqn. 3, displacement is discretized as a set of rigid body displacement, or a continuum is regarded as an assembly of rigid body particles.

From this discretized wave equation, a discretized Hamiltonian of the following form is defined:

$$H = \sum \frac{1}{2}\mathbf{q}^{\alpha} \cdot \mathbf{K}^{\alpha\alpha'} \cdot \mathbf{q}^{\alpha} + \frac{1}{2\mathbf{M}^{\alpha}}\mathbf{p}^{\alpha} \cdot \mathbf{p}^{\alpha}, \tag{4}$$

where $\mathbf{p}^{\alpha} = \dfrac{\partial L}{\partial \dot{\mathbf{u}}^{\alpha}}$ and $\mathbf{q}^{\alpha} = \mathbf{u}^{\alpha}$ are the momentum and displacement of the α^{th} Voronoi tessellation.

We take advantage of the bilateral symplectic algorithm [12] as a robust algorithm of the time integration of Eqn. 4. The main advantage of this algorithm is that in order to achieve the accuracy of the order of Δt^N with Δt and N being time increment and an integer, it needs $2N$ times iteration for the interval of $2\Delta t$. Until now the highest order derived for this algorithm are four. In this paper, the fourth order is used.

3. Modeling of weakly heterogeneity for cracking

For brittle materials, it is usually observed that a crack propagates in an unpredictable manner, when subjected to dynamic loading. For instance, kinking and brunching are induced during the process of crack growth, or shattering due to multiple cracking is observed at high loading rate.

The key task of this paper is a numerical experiment that uses a set of weakly heterogeneous bodies. In the numerical model, several parameters, such as failure criteria, material properties, flaws' positions, can hardly be obtained accurately. However, it is not necessary at all to make all these parameters to be the stochastic variables, we can assign only a few to be stochastic variables, and others can be assigned as constants according to experience for simplicity. In this way, all the variability of unknown parameters can be represented by the designed stochastic variables.

Generally speaking, two methods can be used to model heterogeneity, adding perturbation to material properties of either deformation or fracture. PDS-FEM takes a simple treatment of weak heterogeneity, as: material properties are uniform except for a parameter for fracture, and cracking are allowed only on some of predetermined weak plane segments.

PDS-FEM uses a boundary facet as a set of pre-determined weak plane segments for possible crack extensions. The location of the weak plane is pre-determined by mesh configuration. In order to model the weak heterogeneity, we add disturbance to the location of mesh mother points, from which, a lot of samples with slightly different fracture property can be generated. However, there are two difficulties in this method: generating unbiased distribution may result in ill-shaped Delaunay elements, i.e., some elements with large aspect ratio; a simple solution of forcing the aspect ratio of the Delaunay elements in a certain range leads to biased distribution of some clusters of Voronoi mother points. The unbiased distribution of the Voronoi mother points and the aspect ratio control of the Delaunay elements are in a trade-off relation. As a compromise, we start from one distribution of the Voronoi mother points with majority of the Delaunay elements being well shaped, and modify this distribution randomly to generate other distributions without changing the geometry of the target model.

The mesh size is regarded as a parameter which represents the degree of material heterogeneity; the size becomes smaller as the distribution of material parameters is closer to being uniform. For designing the stochastic model of a real experiment, we need to identify the degree of material heterogeneity or the mesh size. However, with limited observation equipment, the degree of heterogeneity of real samples cannot be measured easily. Therefore, the authors try to start from a standard mesh configuration, which takes a balance between the accuracy and computation overload. If the crack path solutions of the numerical experiments show that the variability is not large enough to include the experimental results, then we have to find ways to increase the degree of heterogeneity in the stochastic model: (1), apply larger mesh size, while ensuring the required accuracy; (2), add additional perturbation to material properties of deformation. Thus, in the numerical experiment presented in section 4, we start from a standard mesh configuration as this: finer meshing is used near the crack tip, to allow a wider choice of crack extension, while meshing becomes coarser farther from the crack tip to save computation overload.

4. Monte-Carlo simulation of crack propagation

This section carries out a numerical experiment of executing Monte-Carlo simulation of heterogeneous samples, in order to reproduce the real experiments' phenomena.

4.1. Problem setting

We study a thin plate of 5×24.5×140 mm, which includes two anti-symmetric parallel notches of height 0.6 mm; see Fig. 2. It is assumed that the material is linearly elastic; see Table 1. For dynamic analysis of brittle material we need to consider the time effect, since dynamic fracture is a time-dependent phenomenon [13-14] which depends on the stress pulse duration, also from experiment study, it is observed that, the material strength is higher than static strength for high loading rate [15-16]. Concerning about this, a time dependent material strength failure criterion called Tuler Butcher criterion [17] is adopted in this paper:

$$\int_0^{\tau_f} \left(\sigma_1 - \sigma_0\right)^{\beta} dt \geq K_f , \tag{5}$$

for $\sigma_1 \geqq \sigma_0 \geqq 0$, where σ_0 and σ_1 are a threshold stress and the maximum stress, τ_f is fracture duration and K_f is the stress impulse for failure. This criterion means that a crack grows if accumulated stress in fracture duration reaches a critical value. It is assumed that $\beta = 2$ and $K_f = 10^{-8}$, σ_0 is equal to the static tensile strength, and τ_f is assigned to be the time step used in time integration; these parameters should be calibrated according to experimental data, which are not

available at this moment. However, as mentioned above, the variability of the parameters can be presented by the disturbance in mesh configuration.

Table 1. Material properties of epoxy resin

Young's modulus (Mpa)	3300
Poisson's ratio	0.38
Tensile strength (Mpa)	35.0
Epoxy density (kg/m^3)	1180

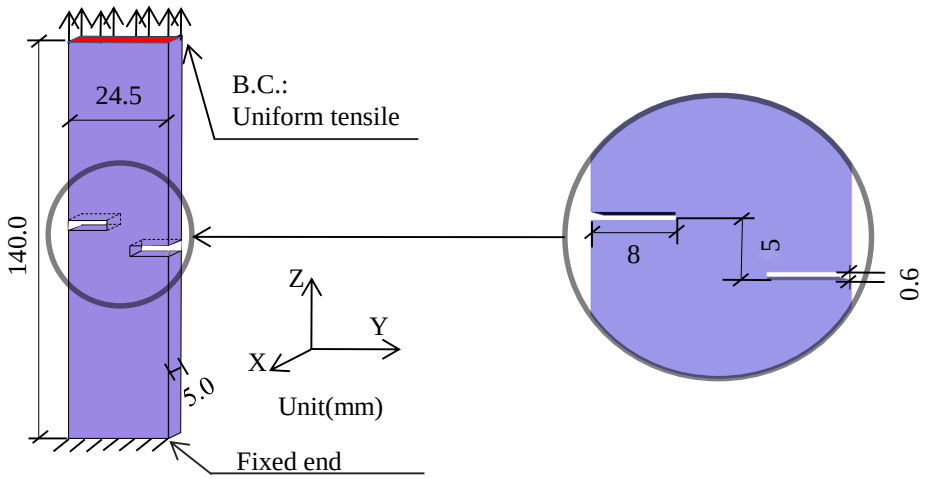

Figure 2. Analysis model

The force boundary condition is posed. The bottom end of the model is fixed, and the top end is pulled up in longitudinal direction. The loading rate is set to be 5N/s. Since the loading rate is small, the initial load of simulation is set to be 135N to save computation time. No element failure exists under this initial load. Following the PDS-FEM discretization, the crack tip is modeled as a notch with 0.6 mm height; the vertical surface of the notch is discretized by using 2 elements. The average mesh size is 1.0 mm at the top and bottom surfaces of the model to save computational overload. The time increment is set to be $\Delta t = 5.0 \times 10^{-9}$s.

200 samples with slightly different mesh configurations or distributions of candidate crack path for PDS-FEM are prepared for Monte-Carlo simulation. The number of samples is decided by checking the convergence of average crack path position through the specified cross-sections.

4.2. Simulation results and experimental comparison

For numerical simulation, the crack patterns can be classified into two groups: (1), the crack paths are symmetrically distributed; (2), one crack is fully developed horizontally from either of the notches. Fig. 3 shows eight typical crack path solutions of the model with small heterogeneity. Bifurcation is also observed in the simulation results; see Fig. 3.5~Fig.3.8.

In order to record the development of crack growth and stress changes of the epoxy resin thin plate, an ultra high speed video camera, which can capture images at the rate of 1 million frames per second, is used herein [18]. The photo-elastic technology [19] is used to show the stress distribution of experimental samples. Fig. 4 shows the final stages of four typical photo-elastic fringe patterns.

Within 16 samples, no sample with perfect anti-symmetric distribution of the two crack paths has been found. This is because the number of experimental samples is too few to include a sample with sufficiently homogenous material property and symmetrical boundary condition at the same time. The typical crack patterns can be classified into two groups: (1), one main crack path develops from either one of the two notches; (2), the two crack paths are more or less anti-symmetrically distributed. From experiments, some cracks bifurcate at the end of experiments.

3.5 3.6 3.7 3.8

Figure 3. The typical crack paths projection into YZ plane
under force boundary condition of loading rate 5N/s

Among 200 numerical samples, we find the samples, whose crack paths coincide with experimental results. In order to make further comparison between the simulation results and experimental results, the stress distribution of simulation has been converted into photo elastic fringe patterns. Fig. 5 and 6 shows the experimental photo-elastic fringe patterns and the numerically synthesized fringe patterns. From these comparisons, the crack growth processes of these two samples are successfully simulated by the method proposed in this paper.

(c), crack growth process of numerical sample 3.6

Figure 6. Bifurcation

(The colour of all images in Fig. 6.a and b has been reversed, since the records are too dark to see.)

Before crack starts, the experimental fringe patterns and simulation results show significant similarity. However, when crack develops, the stress distribution of the simulation becomes blurred. There are three possible reasons for this:

(1) The mesh density is not large enough near the crack tips. In the simulation, the element size is still large, so the energy of the stress wave released from broken elements is significant. On the contrary, the granularity of the epoxy resin is small, and the energy released from the broken of crystalline grain is small and continuous in real experiments.

(2) Friction, thermal as well as acoustic energy consumption mechanics due to cracking have not been considered in this simulation. The released strain energy blurs the simulated photo-elastic fringe patterns.
(3) Ductile fracture may happen in the experiments under indoor temperature.

5. Conclusion

There is no ideal homogeneous body in the world. In order to model the heterogeneity, PDS-FEM offers a nature way by adding disturbance in the mesh configuration. This paper conducts a tensile fracture experiment of a thin epoxy resin, and builds a stochastic model with the distribution of candidate crack path set as stochastic variables. Monte-Carlo simulation is carried out. With specified basic mesh configuration, the simulation results reproduce the crack growth of corresponding experiments, including bending, kinking and bifurcation. The heterogeneity is successfully modeled.

Before crack develops, the stress distribution of simulation shows great similarity with experimental photo-elastic fringe patterns captured by a high speed camera. When crack begins, the fringe patterns of simulation become blurred. Three possible reasons have been proposed and more realistic problem setting is needed to increase the similarity between the results of simulation and experiment in future study.

Abstract Based on the previously proposed simple bar hypothesis, the fracture surfaces can be assumed to be composed of independent rectangular bars. In this paper, by dividing the plastic deformation into single bars, the original lengths of these bars were deduced and then the global strains of these bars during the course of failure were calculated. According to the relationship between true stress and true strain of the material, the normal stress on the cross section of each bar was determined. Multiply the stress with the cross section area, the load acted on each single bar was obtained. Adding all loads on all bars together led to the total applied load of the specimen.

Keywords Fracture surface; FRASTA; Fatigue load

1. Introduction

To investigate the fractured surfaces always reveals a lot of useful information. For example, details of the processes that lead to failure can be determined from these surfaces, making it useful to investigate their morphology.

In order to investigate the reasons for a material's failure, it is necessary to know the temperature, environment and load imposed on it. Since these records are often unavailable, the reasons for failure must be deduced by analyzing fracture surfaces.

Dr. Kobayashi firstly proposed fracture-surface topography analysis (FRASTA) in 1987 [1]. FRASTA considers that as the crack extends, the material immediately beneath the newly formed fracture surfaces undergoes no further inelastic deformation. Based on this understanding, the process of fracture can be rebuilt from the conjugate fractured surfaces. Using the FRASTA technique, the details of the void nucleation and growth, the coalescence of the voids and cracks, and the crack propagation process can be clarified visually [2]. However, the FRASTA application has previously focused on smaller size scales and localized behaviors [3].

A novel method [4] of measuring the CTOA and determining the J integral using FRASTA was proposed in 2006. It extended the application of FRASTA to global fracture surfaces. Software [5] was developed for researching the global fracture surfaces based on this principle. The relationship between J integral and fracture surface average profile [6] and the relationship between J integral and COD [7] were proposed respectively based on FRASTA reconstruction.

The main goal of this paper is to propose a new method to calculate the specimen applied load during failure from the fracture surfaces. Based on the above researches especially the proposed simple bar hypothesis, the fracture surfaces will be divided into independent rectangular bars. The calculation of elongation, global strain, cross-section normal stress and so on of these bars will be deduced. By adding the applied force of each bar together, the total applied force of the specimen during the course of failure will be derived.

2. Method for calculating the applied loads of fractured specimens

The simple bar hypothesis was firstly proposed for determining the J integral [4]. Then it was used in the research of relationship between J integral and fracture surface average profile [6]; and relationship between J integral and COD [7] respectively. Results in these researches verified the validity of the proposed simple bar hypothesis. Based on the hypothesis, a new method for determining the applied loads of fractured specimens during the course of failure will be proposed and experiments will be performed to verify it.

It is well known that, by means of Mises yield criterion, for the Mode Ⅰ stress field, the boundary of plastic zone around crack tip for plain strain [8] can be expressed as Eq. (1)

$$r(\theta)=\frac{K_{\mathrm{I}}{}^{2}}{2\pi\sigma_{y}{}^{2}}\cos^{2}\frac{\theta}{2}\left[(1-2\nu)^{2}+3\sin^{2}\frac{\theta}{2}\right]. \tag{1}$$

where K_{I} is the stress intensity factor and ν is the Poisson's ratio. In plastic zone, the distribution of strain component that perpendicular to fracture surface is

$$\varepsilon(y)=\frac{K_{\mathrm{I}}}{2G(1+\nu')\sqrt{2\pi r}}\cos\frac{\theta}{2}\left[(1-\nu')+(1+\nu')\sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right]. \tag{2}$$

where $\nu'=\nu$ and $\nu'=\nu/(1-\nu)$ for plain stress and plain strain respectively, G is shear modulus.

Introduction of Eq. (1) into Eq. (2) leads to Eq. (3)

$$\varepsilon(y)=\frac{\sigma_{y}}{2G(1+\nu')\sqrt{(1-2\nu)^{2}+3\sin^{2}\dfrac{\theta}{2}}}\left[(1-\nu')+(1+\nu')\sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right], \tag{3}$$

where σ_{y} is the yielding stress. It is clear that, on the boundary of plastic zone, for certain material, $\varepsilon(y)$ is only relative to θ. And for $\theta=\pi/2$, $\varepsilon(y)$ can be represented as Eq. (4),

$$\varepsilon(y)_{\frac{\pi}{2}}=\frac{\sigma_{y}}{2G(1+\nu')\sqrt{(1-2\nu)^{2}+\dfrac{3}{2}}}\left(\frac{3}{2}-\frac{\nu'}{2}\right). \tag{4}$$

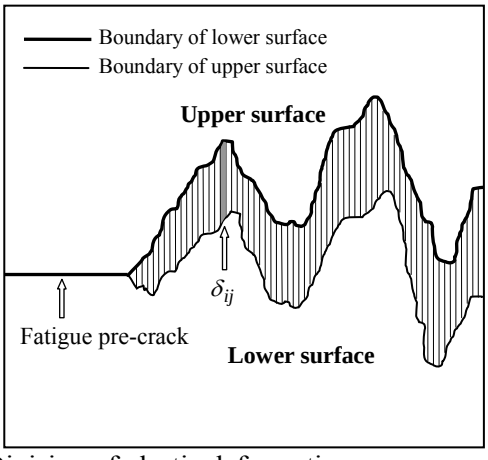

Figure 1. Division of plastic deformation on cross-sectional plot

This paper defines

$$\varepsilon_y = \varepsilon(y)_{\frac{\pi}{2}}. \tag{5}$$

It is obvious that ε_y is a constant. According to elastic-plastic fracture mechanics, at the crack tip, when the strain component along y axis direction reaches some certain value, crack extends. This certain value is defined as ε_f in this paper.

Fig. 1 displays a cross-sectional plot of a compact tension specimen. The hatched area is the overlap of the upper and lower fracture surfaces when driven to the initial position (state before test started) after being broken. It refers to the plastic deformation left on the specimen. In order to simplify the calculation, this paper supposes the plastic deformation is symmetry about the fracture surface as shown in Fig. 2. It means that the specimen fractures along x axis. Furthermore, this paper defines the area which is plastically deformed during the course of testing as plastic field. It is worth noting that plastic field is different from plastic deformation as shown in Fig. 2.

In this paper, according to the simple bar hypothesis, the fracture surfaces are assumed to be composed of independent rectangular bars. The sizes of these bars in the X and Y directions (the directions of crack extension and specimen thickness, respectively) are determined by the resolution of the laser microscope for the X and Y axes (represented by p and q, respectively). In this paper, they are both 50 μm. Thus, along the direction of crack extension, the amount of plastic deformation which is gray-scaled in Fig. 2 can be considered as the elongation of the bar. This paper supposes the original half length of the bar is l and the half elongation is Δl.

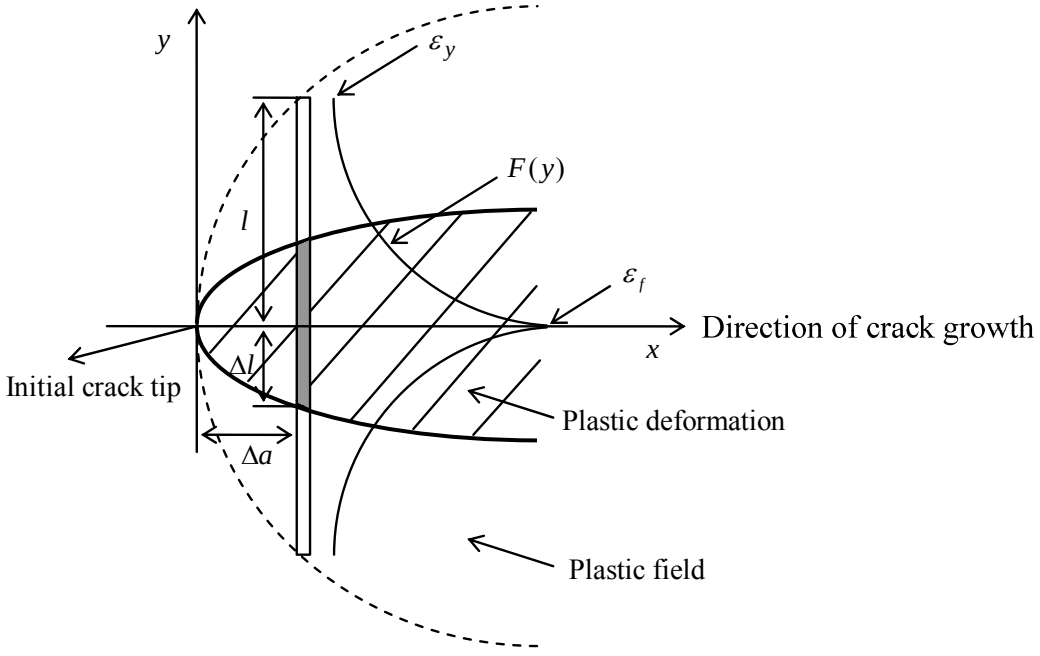

Figure 2. Principle of determining plastic field left on specimen

As introduced in [4], the strain distribution of a simple rectangular bar along the axis can be expressed as the curve shown in Fig. 2. The function of curve was supposed to can be written as Eq. (6),

$$F(y) = a\exp(by). \tag{6}$$

According to what discussed above,

$$F(0) = \varepsilon_f ,$$

$$F(l) = \varepsilon_y . \tag{7}$$

The substitution of Eq. (7) into Eq. (6) provides Eq. (8),

$$a = \varepsilon_f ,$$

$$b = \frac{1}{l} \ln \frac{\varepsilon_y}{\varepsilon_f} . \tag{8}$$

So, the elongation of the bar can be expressed as Eq. (9),

$$\Delta l = \int_0^l F(y)\, dy = \frac{\varepsilon_f - \varepsilon_y}{\ln \varepsilon_f - \ln \varepsilon_y} l . \tag{9}$$

Thus, the ratio of elongation of the bar can be expressed as Eq. (10),

$$P = \frac{\Delta l}{l} = \frac{\varepsilon_f - \varepsilon_y}{\ln \varepsilon_f - \ln \varepsilon_y} . \tag{10}$$

Because ε_f and ε_y are material constants, P is a constant, too. That is to say, the dimension of plastic field left on specimen is in proportion to the plastic deformation. At the same time, because Δl can be acquired from FRASTA, the plastic field left on specimen can be determined.

Return to the state as shown in Fig. 1, δ_{ij} represents the elongation of the bar at (x_i, y_j), where i and j represent the number of position along x and y axis respectively. The sizes of these bars along x and y direction (the direction of crack extension and specimen thickness respectively) are determined by the step lengths of laser microscope, which are represented by p and q respectively in this paper. Then, the original length l_{ij} of each bar should be

$$l_{ij} = \frac{\delta_{ij}}{P} , \tag{11}$$

the length of each bar after being broken is

$$l_{ij}' = \frac{\delta_{ij}}{P}(1 + P) . \tag{12}$$

In order to calculate the load applied to the specimen during the course of fatigue, based on the above simple bar hypothesis, the fracture surfaces are assumed to be composed of independent rectangular bars. Once the normal stress on the cross section of each bar was obtained, the force applied on the bar can be determined by multiplying the normal stress with the cross section area. By this means, adding the force applied on each bar together, the load applied on the specimen can be obtained.

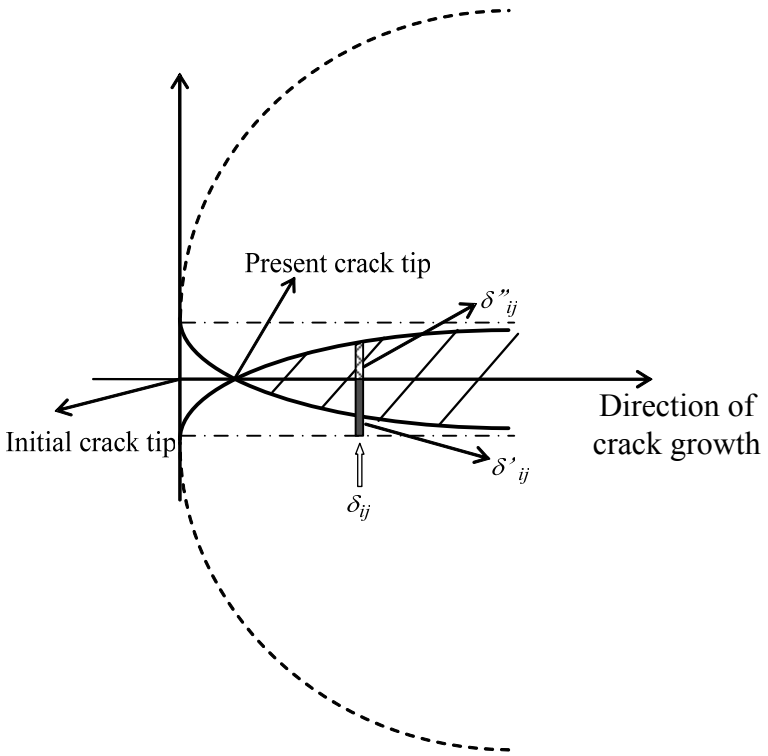

Figure 3. Two parts of the elongation of a single bar

According to this idea, we should firstly determine the global strain of each single bar during the course of failure. As shown in Fig. 3, using FRASTA to reconstruct the process of fracture, considering that the crack has extended to the "present crack tip", that is material behind the present crack tip (between the "initial crack tip" and the "present crack tip" in Fig. 3) has been fractured, thus forces acting on the bars composing this part had been released. While for material in front of the "present crack tip", it still bears load before failure. Add the loads acting on these bars together, the applied load of the specimen can then be determined. As shown in Fig. 3 and introduced above, suppose the final elongation of the bar is δ_{ij} and divide the elongation into two parts, δ'_{ij} and δ''_{ij}, where δ'_{ij} represents the elongation of the bar when the crack extends to the "present crack tip" and δ''_{ij} represents the residual elongation of the bar with the crack extending further from the "present crack tip" until final failure.

As introduced above, it is easy to get δ_{ij}, δ'_{ij} and δ''_{ij} by reconstructing the process of crack extension using FRASTA. According to Eq. (11), the initial length of the bar can then be calculated and the global strain of the bar when the crack reaches to the "present crack tip" can be calculated as Eq. (13),

$$\varepsilon_{ij} = \frac{\delta'_{ij}}{l_{ij}}. \tag{13}$$

Furthermore, the relationship between true stress σ and true strain ε can be expressed as Eq. (14),

$$\sigma = K\varepsilon^n, \tag{14}$$

where K is a constant and n is work hardening exponent.

Introduction of Eq. (13) into Eq. (14) leads to Eq. (15),

$$\sigma_{ij} = K\varepsilon_{ij}^{\ n}, \tag{15}$$

where σ_{ij} is the normal stress on the cross section of the single bar l_{ij}. Thus the applied load of the specimen can be calculated as Eq. (16),

$$F = \sum p \times q \times \sigma_{ij} = p \times q \times K \times \sum \varepsilon_{ij}^{\ n} \tag{16}$$

In order to simplify the calculation, use the average deformation of the fracture surfaces for instead, that is to add all deformations of the single bars with the same x coordinate together and divide it by the number of bars. By this means, Eq. (16) can be converted into Eq. (17),

$$F = p \times q \times K \times k \times \sum \varepsilon_{i}^{\ n} \tag{17}$$

where ε_i is the average strain at x_i and the k is the number of bars with the same x coordinate .

3. Conclusions

From the results presented in this paper, it is clear that by using FRASTA reconstruction, that is recording the elevation data of fracture surfaces and reconstructing the process of crack extension, it is possible to obtain the plastic deformation with crack extension. Based on the simple bar hypothesis and by dividing the plastic deformation into single bars, the original lengths of these bars can be determined thus the global strains of these bars during the course of failure can also be calculated. According to the relationship between true stress and true strain of the material, the normal stress on the cross section can thus be determined. Multiply the stress with the cross section area, the load acted on each single bar can be got. Adding all loads on all bars together leads to the total applied load of the specimen.

Abstract This paper provides some critical review of the history and state of two elastic fracture mechanics (K and T) and relationship to crack paths. A particular attention is given in the case of hydrogen embrittlement. A fracture toughness transferability curve ($K_{\rho c}$-T_{ef}) has been established for the X52 pipe steels described by a linear relationship where T_{ef} is the average value of T stress over the characteristic length of the fracture process. A mechanism involving influence of the $T_{ef,c}$-stress on void growth for ductile failure is proposed; the effects of hydrogen on crack paths from the viewpoint of microstructural aspects are disputed.

Keywords crack paths, hydrogen embrittlement, transferability curve, fracture toughness, T-stress

1. Introduction

Fracture toughness is now considered as not intrinsic to material but depends on geometry, thickness, loading mode and more generally to constraint. Recent numerical and experimental studies have attempted to describe fracture in terms of two or three fracture parameters [1-3].The elastic stress fields in a region surrounding the crack tip can be characterized by the following solution [1]:

$$\sigma_{ij} = \frac{K_I}{\sqrt{2\pi r}} f_{ij}(\theta) + T\delta_{xi}\delta_{xj} + A_3\sqrt{2\pi r} + 0(r) \qquad (1)$$

where K_I is the stress intensity factor, $f_{ij}(\theta)$ is the angular function, δ_{ij} is the symbol of Kronecker's determinant. A polar coordinate system (r,θ) with origin at crack tip is used. Several methods have been proposed in literature to determine the T-stress for cracked specimen. The stress difference method has been proposed by Yang et al. [4]. It was noted [5-8] that T-stress characterizes the local crack tip stress field for elastic linear material, and the elastic plastic material with the restriction of small-scale yielding conditions. Various studies have shown that T-stress has significant influence on fracture toughness, crack growth direction, A_3 has some influence crack stability [9-15].

The K-T and K-A_3 approaches lead to a two-parameter fracture criterion. With K as the driving force and T or A_3 a constraint parameters, a master failure curve can be successfully used to take into account the constraints of stress fields for various proposed geometry and loading structure configurations. Recently, the master curve has been evolved into a mature technology for characterizing the notch fracture toughness to quantify constraint effects for different testing specimen and structures [16].

The effect of T-stress on crack paths has been investigated for various specimen configurations and materials [17-19]. But some results of the crack path estimation give ambiguous data; for example, it was shown [20] that if the T-stress in front of a flat crack is negative then the crack grows along the crack plane. In the case of a positive T-stress, the crack deviates from its initial plane. It was also observed that the crack did not turn immediately when the T-stress became positive but at a considerably higher value. The method employed in Ref. [21,22] was developed for a kink which is formed at a given angle to the main crack [23]. Actual attention has been paid to problem of hydrogen pipeline systems due to strong world asking in energy and environmental problems. One future way is to use hydrogen as energy vector. In one European project [24], hydrogen transport will be provided way by adding hydrogen to natural gas in existing networks. Experience shows that the majority of pipeline failure initiates from defects or cracks [25-27]. Effects of transported hydrogen affect material mechanical properties, namely, hydrogen embrittlement [28,29]. The external environmental conditions cause free corroding processes, where hydrogen is product on metal surface as result of cathodic counterpart of the anodic dissolution reaction [30,31]. The gas pipeline industry recognizes this well as a major problem.

The aim of present work is to study the influence of hydrogen coupled with constraint (T stress is used as constraint parameter) on master failure curve and crack path direction and stability. In the first part the influence of hydrogen on master failure curve determined from fracture tests performed on different specimens geometries (CT, SENT, RT and DCB) has been studied. In a second part, fracture path under low constraint (negative T-stress) has been studied. Fracture has been obtained by burst tests under hydrogen pressure of pipes. In the third part, fracture path under high constraint (positive T-stress) has been studied from fracture of DCB specimens. Finally, a proposed mechanism of crack extension with constraint and hydrogen embrittlement has been proposed.

2. Material

The material used in this study is an X52 steel meeting requirements of API 5L standard. API X52 steel was the most common gas pipeline material for transmission of oil and gas during 1950-1960. Chemical composition of the studied steels is given in Table 1. In table 2, the mechanical properties of API X52 steel have been presented. E, σ_Y, σ_u, A%, n, k and K_{Ic} are the Young's modulus, yield stress, ultimate stress, elongation at fracture, strain hardening exponent and hardening coefficient of Ramberg-Osgood law, and fracture toughness, respectively. Stress strain curves of X52 steel have been determined with and without hydrogen absorption and reported in Figure 1. Classical tensile properties such as yield stress and ultimate strength increases also when hydrogen is absorbed in steel as indicated in Table 2. A small increase of yield stress has been noted (2.5%) as an important reduction of elongation at failure (38%). Static stress-strain is obtained by fitted tensile test results using hardening power law $\sigma = K.\varepsilon^n$. Microstructure of API 5L X52 steel in the longitudinal and transverse orientation is shown in Figure 2 (a) and Figure 2 (b), respectively. These pictures show the distribution of the ferrite and pearlite with respect to orientation. The distribution of pearlite in

upper surface (Figure 2.a) appears to be relatively isotropic when compared to the pearlite bands in inner the surface (Figure 2.b). However, Figure 2 shows pearlite bands in different sections of the API 5L X52 specimen.

3. Influence of Hydrogen on Master Failure Curve

Due to the assumptions, that pipes failure emanates mainly from external interferences i.e. that defect promoting failure are considered as notch, the notch fracture toughness (critical notch stress intensity factor) $K_{\rho,c}$ and the critical effective T-stress ($T_{ef,c}$) were employed to describe the material failure curve $K_{\rho,c} = f\left(T_{ef,c}\right)$. The critical notch stress intensity factor $K_{\rho,c}$ is determined by the Volumetric Method (VM) [32]. Averaging the T-stress distribution inside the effective distance (determined by Volumetric Method), the effective T-stress (T_{ef}) can be defined in the following

form:

$$T_{ef} = \frac{1}{X_{ef}} \int_0^{X_{ef}} T_{xx}(r).\Phi(r).dr \tag{3}$$

$K_{\rho c}$–$T_{ef,c}$ has been determined with [6] and without[2] the presence of hydrogen. Different specimens geometries (CT, SENT, RT and DCB) are used, all with a notch and a depth ratio of 0.5 (a/t = 0.5). Specimens have been submitted to hydrogen environment during 30 days. Fracture initiation is detected by acoustic emission and provides load for crack initiation P_i, more details are given in [12]. Results are compared with results of [2] and summarized in Figure 3. The material master curve is approximated by the following equation

$$K_{\rho,c} = a\, T_{ef,c} + b \tag{4}$$

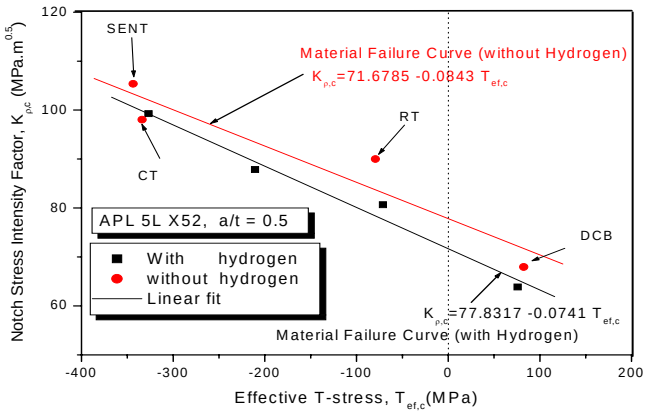

Figure 3. The experimental assessment points ($K_{\rho,c}, T_{ef,c}$) and the material failure curve $K_{\rho,c} = f\left(T_{ef,c}\right)$ for X52 pipe steel with and without hydrogen effect [6].

where a = -0.0843 and b =71.6785 for the X52 pipe steel without hydrogen embritlement and a =-0.0741 and b = 77.83 for the X52 pipe steel with hydrogen embrittlement. One notes a small decreases of fracture toughness decreases in the range [5.8 %– 9.8 %] when T_{ef} increases in the range [- 400 MPa- +100 MPa] with a small difference for SENT specimen and larger for DCB specimen (about 10 %). One note a parallel with the decrease of fracture resistance in term of master failure curve and increase of the yield stress after hydrogen introduction. A small increase of yield stress has been noted (2.5%), as an important reduction of elongation at failure (38%). Also one notes that increasing the yield stress increases the constraint parameter.

4. Hydrogen and Constraint Effect on Kinking Direction

4.1 Fracture under low constraint

Fracture of pipe under internal pressure is performed under low constraint. Notched tubes were used for burst tests under pressure of hydrogen gas. Tubes were manufactured with steel X52, which

chemical composition, mechanical properties at elongation and environmental conditions of tests are given in [33].

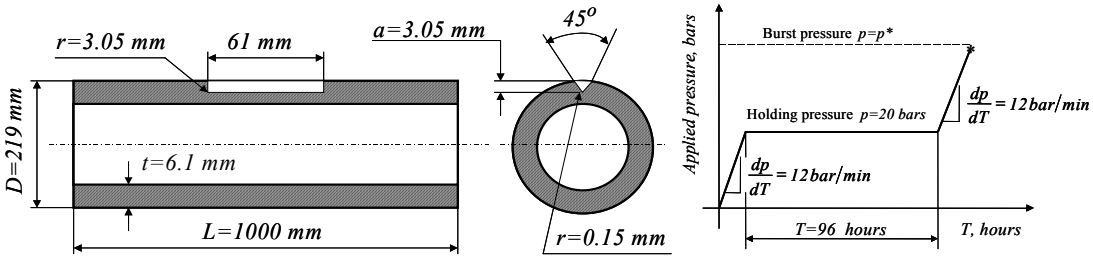

Figure 4. Tubes- Specimen for test

a) b)

Figure 5. Burst tests of the model specimens made from Ukrainian tube:
a - elastoplastic failure; b – catastrophic brittle fracture.

Tubes-specimens have a longitudinal notch on the outer surface and their geometry is given in Figure 4. Pipes were tested until burst according to the test sequence described in Figure 5. T-stress distribution indicates that T stress is negative and increases with internal pressure (see Fig.6). Test results showed that burst pressure for test in methane is equal $p_{max} = 118\ bar$ and burst pressure for test in hydrogen is equal $p_{max} = 122bar$. Therefore, there is no gaseous hydrogen effect on the strength of notched pipes for considered testing conditions. At this critical pressure effective T-stress T_{ef} is equal to – 22.268 MPa. This negative value indicates a relatively low constraint.

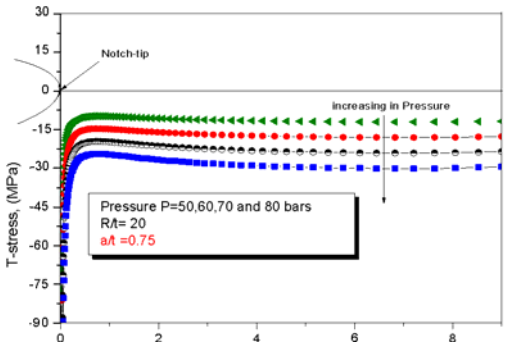

Figure 6. Evolution of T- stress versus distance over ligament. Pipe submitted to internal pressure. Diameter 400 mm thickness 10 mm (pressure 50-80 bars)

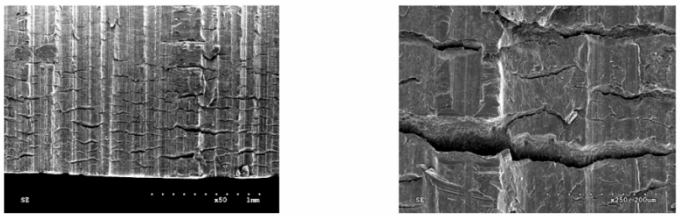
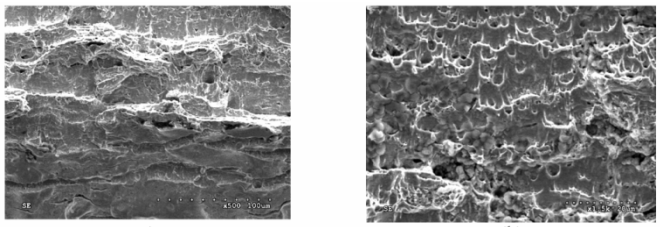
After burst tests, fracture surfaces were examined with a Scanning Electron Microscopy (SEM) for determination of fracture initiation points and also for checking of eventual fracture surface modification under influence of hydrogen. It has been found for hydrogen tests, inner fracture surface is characterized by an array of surface cracks (see Fig. 7-a). Careful examination shows that, surface cracks density is higher and average crack length is smaller. View of surface cracks under hydrogen conditions is given in Fig. 7.b at magnification X250.



(a) (b)

Figure 7. (a) surface cracks mesh at the edge of fractured notch for test in hydrogen. (b) magnification X250.

Examination of the notch bottom shows that fracture is originated at centre of notch (± 1 at 2 *mm*).The mechanism of fracture initiation is developing of micro cracks from notch bottom (Fig. 7.a). Generally fracture surface consist of two parts. First part is a flat surface created by micro cracks growth from notch bottom and second part is final failure surface, which is made by shear mechanisms. This second part prevails at the inner surface of tube along notch and it may be considered as final ductile failure (Fig. 8.a). For test in hydrogen, the following aspect was observed. There is alternation of brittle and ductile sites of fracture character (Fig.8.b). The depth of particular surface aspect doesn't exceeds a distance of about 50 μm from notch bottom. No crack bifurcation was observed with or without hydrogen and this fact is considered as the result of fracture occurring under low constraint.



a) (b)

Figure 8. (a) Micro cracks at the notch bottom as source of fracture initiation for test in hydrogen. (b) fracture character at the inner surface.

4.2 Fracture under high constraint

Fracture tests have been made on DCB specimen made in X52 steel. Geometry and dimensions of specimen ~~is~~ aregiven in figure (9).

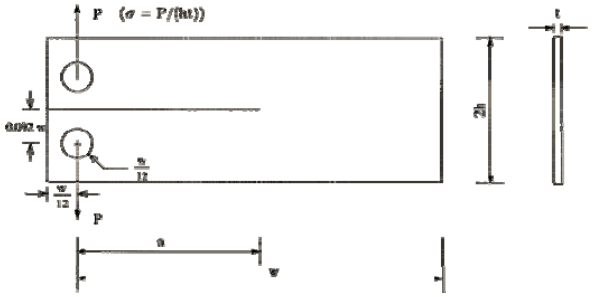


Figure 9**.** Geometry and dimensions of DCB specimens made in X52 steel.

Effective T stress has been determined by computed T stress distribution by Finite Element method along ligament and applying the Stress Difference Method, SDM [4]. Effective T stress distribution is presented in Figure 10. T is positive and indicates a low of constraint. $T_{ef,c}$ at failure is equal to (+151.657 MPa). Observation of hydrogen effects by SEM on crack paths is shown in Figure 11 on CT and DCB specimens. Presences of hydrogen also induce another feature on crack growth that will contribute to the acceleration effect. A comparison is made with CT specimen which develops higher constraint. For CT in air and hydrogen crack grows perpendicular to the principal opening stress in mode I. For DCB under hydrogen, there is facility to extend crack in perpendicular direction and this could cause microscopic deviations in the crack path (Figure 11). These deviations can lead into crack branching or kinked crack paths [12].

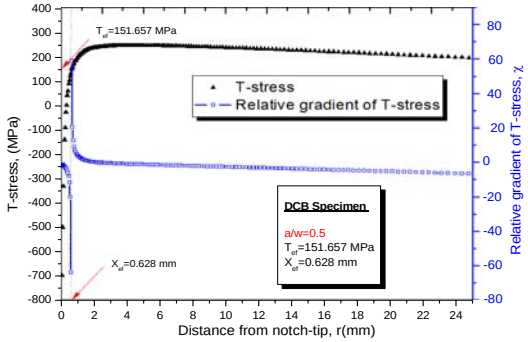

Figure 10. Evolution of the T-stress along of ligament for DCB specimen.

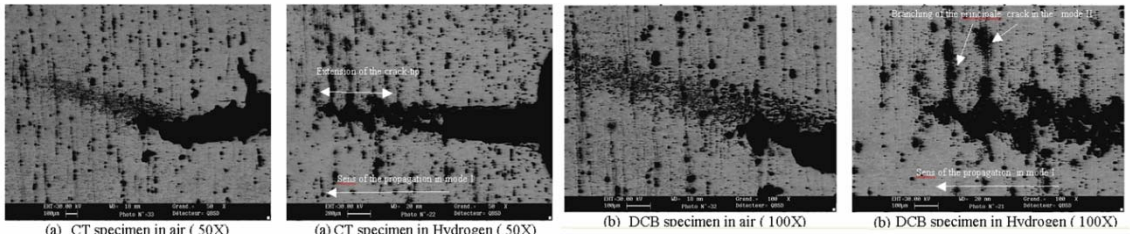

Figure 11. Observation by SEM of the cracks formation in pipeline during its service in different environments: air and hydrogen for CT and DCB specimens.

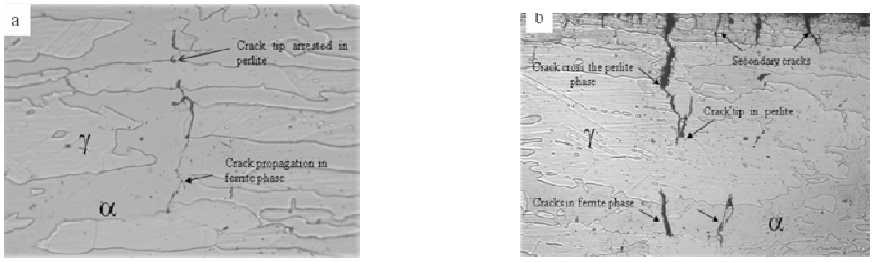
Crack propagation in air shows perlite debonding and ferrite matrix cracking as in Figure 12. In air, crack propagates by mode I in ferrite phase. Somes cracks are arrested in the perlitic phase, and continue as second crack in ferrite. Extension of second crack, is probably prolongation of the first crack in third dimension. The perlite phase play the role of crack arrestator.



(a) 40µm (50X) (b) 100µm (20X)

Figure 12. Optical photographs for cross section through the cracks and secondary cracks (a) –without hydrogen & (b) –hydrogen environment

With hydrogen environment, fracture is sometimes initiated from secondary cracks and very close to the surface due to pitting under hydrogen attack as shown in Figure 12.b. The crack stress field will produce a strain magnification in adjacent micro-cracks and penetration of hydrogen atoms will result in further cracking of ferrite phase at the crack tip. The crack cross the perlitic phase and will propagate in the straight direction, facilitating hydrogen propagation and weeping.

5. Discussion

It can be seen that critical effective $T_{ef,c}$-stresses have ~~the~~ influence on crack paths. Pipe submitted to internal pressure has higher negative critical value of the T-stress, $T_{ef,c}$, range and consequently lower constraint in comparison with bending specimens. SENT and CT specimens have also a high negative value of the $T_{ef,c}$-stress for cracks emanating from notch tip but lower than a notched pipe. For these specimens and pipe submitted to internal pressure, crack extension is observed along x direction, i.e. perpendicular to the principal tensile stress (Fig. 13.a). DCB specimens exhibits a particular positive $T_{ef,c}$-stress values (Fig. 13.b). In this case, crack bifurcation appears after fracture initiation.

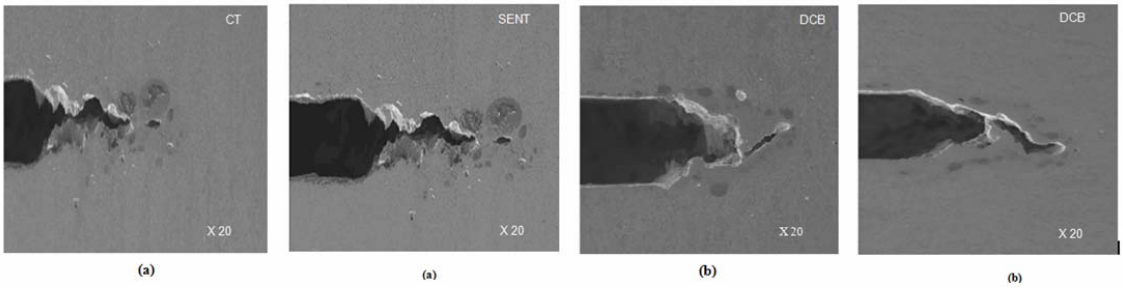


Figure 13. Kinking direction for (a) SENT and CT specimen, (b) DCB specimen.

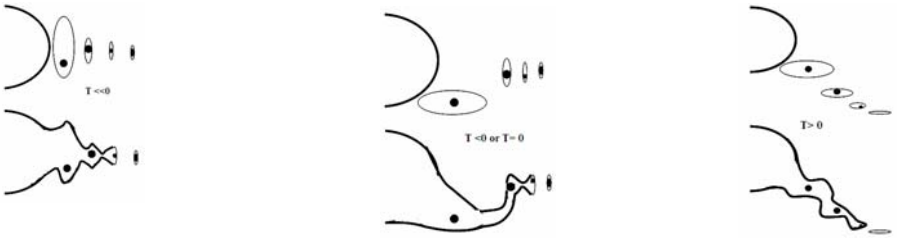
Crack extension in API 5L X52 steel is governed by ductile failure mechanism, namely, nucleation of microvoids, growth and coalescence of these microvoids. However, pipe under internal pressure, CT, and SENT specimens, voids close to the notch are not elongated along the direction of loading but are elongated along shearing stress direction component which induced failure by mode II superimposed with mode I. Therefore, crack extension has a zigzag path characteristic of mixed mode (I + II failure mode). This zigzag mechanism can be seen on Figure 14.a with and without the hydrogen effect.



(a) strong negative T stress (b) low negative T-stress (c) positive T-stress

Figure 14. Proposed mechanisms for ductile crack extension under negative or positive $T_{ef,c}$ -stresses.

For DCB specimen, the T-stress component is positive and voids are elongated closed to shearing direction. Crack path is linear along a direction which is close to pure mode II bifurcation angle (70°) (see Fig. 14.b). Therefore, ductile crack extension is governed by the intensity of shearing mode induced by the T-stress. Thus, the following model of crack extension can be assumed to describe crack paths as a function of the critical effective T-stress. Due to hard particles inside voids (these particles promote voids nucleation by stress concentration), voids cannot be closed by compressive (negative) T-stress and crack extension is then stable in notch direction according to scheme in [12]. If the T-stress is positive and higher than opening stress at some distance ahead of the notch tip, void extension then occurs in x direction which is corresponding to the maximum $T_{ef,c}$-stress direction. In this case, crack extension is made by bifurcation.

6. Conclusion

Fracture toughness is not really intrinsic to material but depend on constraint. The critical notch stress intensity factor versus the effective T stress build up a master curve which coupled the fracture driving force gives the critical conditions for any kind of geometry and loading mode. For the pipe steel API X52,the master curve exhibits a linear decreasing behavior. Slope and value at origin are few affected by hydrogen embrittlement. Crack path after fracture initiation is affected by constraint evaluated by T stress. A loss of constraint corresponds to high negative T effective value. This situation occurs in notched pipe submitted to internal pressureand crack path remains normal to maximum principal stress. This is unchanged after hydrogen embrittlement but fracture appearance is then modified. Over a short distance ahead of notch tip , there is a mixture of dimples and brittle facets. Fracture of DCB specimens occurs under high constraint characterized by a positive value of T stress. Crack kinking occurs due to mixed mode I +II induced by superposition of T stress. It has been seen on CT specimen with a lower constraint than DCB specimen that hydrogen embrittlement promotes this crack kinking. Further works are required to understand the shift of critical T effective value to promote crack kinking to lower value. The assumption of decreasing shearing mode cohesion energy with hydrogen will be investigated. Following the same idea, evolution of ratio of shearing and opening mode cohesion energy will be determined by appropriate experiments.

Abstract Carbon nanotube (CNT) can be used as a good reinforcement embedded into polymer matrix. However, properties of composites reinforced by CNT can't be improved efficiently, because of the damage of interface between CNT and polymer in CNT composites. In this paper, the cohesive zone model (CZM) was employed to express the damage and fracture of interface between CNT and the epoxy matrix. The key parameters of the bilinear CZM were deduced based on the existing theory work. The whole deformation and fracture process of the interface has been revealed through the FE simulation results. The performance of the interface decides the mechanical property of the CNT composites and the stress-strain curve of composites has been plotted. It is with great importance to study the mechanical property of the interface to improve the performance of CNT composites.

Keywords Carbon nanotude, Composite, Interface, Damage, Crack Growth

1. Introduction

Since the discovery of carbon nanotube (CNT) by Iijima [1], CNT has wide application potential because of their wonderful physical and mechanical property, it has been thought as a promising candidate as the ideal reinforcing fibers for advanced composite with high strength and low density. However, mechanical property of composites reinforced by CNT can't be improved efficiently, owing to the deep affect of interface between CNT and polymer in CNT composites. The damage and fracture of the interface leads to stress redistribution in CNT composite, and decides the effective mechanical property of the composite. The mechanical property of the interface is the key factor of the CNT reinforced composite [2].

The Cohesive zone Model (CZM) describes material separation with a traction-separation law (T-S law) and links the micro-structural failure mechanism to the effective properties of the composite [3,4]. Because of the nano-scale interface in CNT composite, the van der Waals force plays an important role in the property of the interface [5,6]. The Cohesive zone Model(CZM) can reflect the characteristic and working principles of the van der Waals force phenomenologically, by two important parameters, the cohesive strength Tc and the energy release rate Gc, as shown in Fig.1[7]. The effective separation and damage parameter from view point of stiffness reduction are employed. The different T-S law has been developed with continuous study of the cohesive model, and the CZM has been widely used in interface decohesion and crack growth.

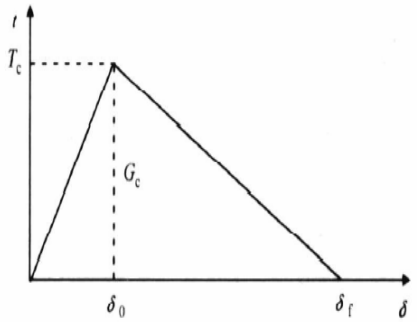

Figure 1. Bilinear cohesive law

Nowadays, many researchers have realized the significance of the van der Waals force in the

interface between the CNT and the matrix, and study mechanical property of the interface of CNT composite with various method, such as the experimental method and the Melecular Dynamics (MD) method [8]. There are still many technical limitations in experimental method, and the calculation cost of the MD method is too huge. The Finite Element Method (FEM) combined with the CZM is the effective and economy method to study mechanical property of the interface of CNT composite, and the CZM was utilitied in this paper to predict local damage initiation and fracture propagation.

2. CZM Model of Interface

The key problem of the CZM is the definition of the two important parameters, the cohesive strength *Tc* and the energy release rate *Gc* . There is few experimental data providing the interface parameters accurately and directly for the CZM. Gou[9] has calculated the shear strength by the MD simulation of the CNT's pull out from the matrix. The result 75MPa was adopted to be the shear strength .Tan[6] has deduced the normal strength 470MPa and the energy release rate 0.107Jm^{-2}, from the Lennard-Jones potential from the van der Waals interactions, the results was adopted as the normal cohesive strength and the energy release rate *Gc* . The interface between the CNT and the matrix was modeled by the 2 dimension, 4 node cohesive element COH2D4 to reproduce the damage of interface between the CNT and polymer. The Young's modules of the CNT and the epoxy matrix are respectively 1 TPa and 4GPa.
The FEM model of the CNT composite was established by the generally used software ABAQUS. It is with three phases: the CNT fiber phase, the cohesive interface phase employing the CZM and the epoxy matrix phase. The unit cell was extracted to represent the effective properties of CNT composite based on the homogenization theory, as is shown in Fig. 2.

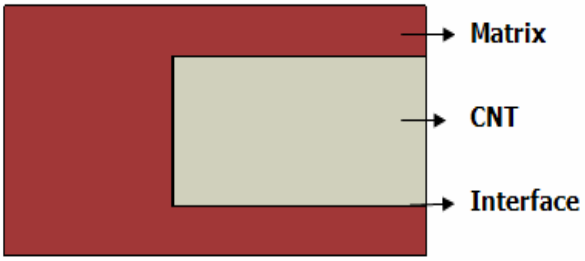

Figure 2. Unit cell of CNT composite

Since composite structures are usually designed for the loading in the reinforcement orientation, the displacement load was exerted at one side of the unit cell, and the other side was fixed, the boundary conditions of the unit cell was demonstrated in Fig. 3.

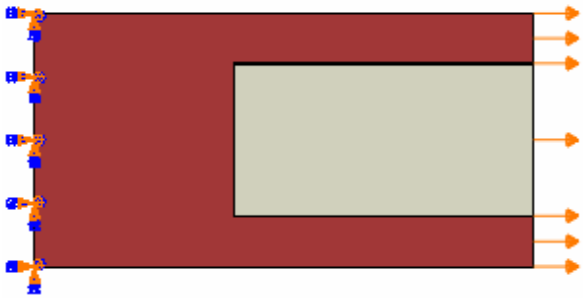

Figure 3. Boundary conditions of unit cell

3. Results and discussion

One of the advantages of the FE simulation is that the whole deformation and damage process can be observed clearly in the simulation. From the FE results, three obvious stages of mechanical properties of the interface were found: the linear elastic stage, the damage initiation stage and the crack propagation stage, as is shown in Figs. 4-6. The unit of the labels of the stress distribution nephogram is GPa.

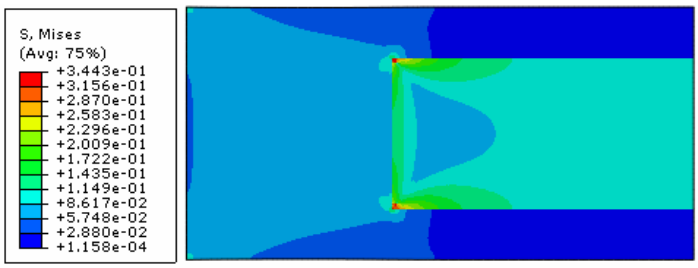

Figure 4. Stress distribution at linear elastic stage

In the linear elastic stage, the epoxy matrix and the CNT were bonded by the interface. The high cohesive strength ensures the effective transfer of the stress between CNT and the matrix. CNT takes more load than the matrix, the properties of CNT composites have been improved by the strong interface. The stress in the matrix where near by the CNT end is larger than the other positions in the matrix, and the stress in the CNT where near by the interface is larger than the other positions in CNT. In addition, the stress concentration appears at the corner of the CNT end.

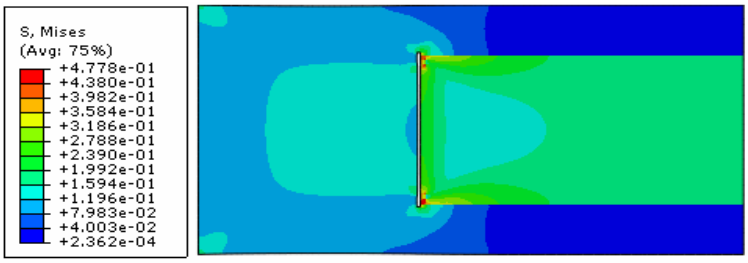

Figure 5. Stress distribution at damage initiation stage

As the displacement increasing, the damage initiation stage comes up, the damage initiated at the corner of the interface due to stress concentration. The damage of the interface leads to the stiffness reduction and stress redistribution in the composite, although the composite still has the capacity to bear the load. Then the microcracks at the corner grows, the crack extends to the end side of the interface.

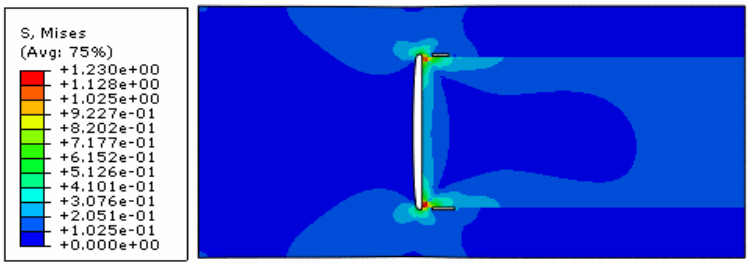

Figure 6. Stress distribution at crack propagation stage

At the crack propagation stage, the shear sliding comes up after the normal debond in the corner of

the interface, as can be seen from the Fig.6, the normal crack hasn't connected to the shear crack, the shear crack initials at a position near the interface end . For the damage and the debond of the interface, the CNT composite has been failed to take the load. The interface plays an important role to the mechanical property of the composites. The maximum stress appears in the corner of the interface, the stress concentration effect should be considered to predict the damage initiation and the crack propagation.

4. The discussion of mechanical property of CNT composites

The crack progress and the fracture mechanism of the interface has been studied by the CZM model. The influence of the interface to the CNT composites can be reflected in the stress--strain curve of the whole unit cell, as is shown in Fig.7. Because of the effect of the interface, the relationship between stress and strain is nonlinear. At first, the composite displays linear characters, on account of the valid function of the interface before the stress gets to its strength value. The effective modules of the composites in the linear stage is 9.44GPa, CNT has the obvious reinforcing performance. Then accompanies with the crack propagation in the interface, the stress has an abrupt drop. The performance of the interface decides the mechanical property of the CNT composites.

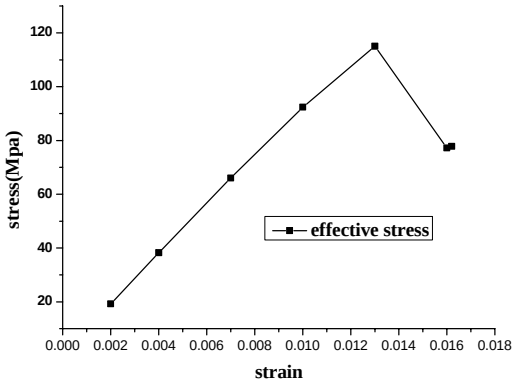

Figure 7. Stress-strain curve of CNT composites

5. Conclusion

1. The CZM of the interface between the matrix and CNT has been established to predict the mechanical property of interface, and it is proved that CZM is effective in the nanocomposites.
2. The whole deformation and damage process of the interface has been studied through the FE simulation results.
3. The stress--strain curve of composites has been plotted to research the mechanical properties of the composites. It is with great importance to study the mechanical property of the interface to improve the performance of CNT composites.

Abstract A series of critical fracture toughness of two kinds of rock materials under different temperature which varied from -50°C to 240 °C are measured by I-II-III mixed mode fracture experiments adopting atypical three point bending specimens. Relative stress intensity factors of crack initiation are calculated by finite element method. Combining with calculated values, the experiment result shows that, the mixed mode fracture toughness of the rocks decreases with the increase of temperature. The experimental and calculated results can be used in the design of deep underground engineering and disaster prevention and mitigation engineering。

Key words rock crack fracture, I-II-III mixed mode , temperature, experiments, finite element method.

1. Introduction

The rock mass whole structure failure in underground engineering is the process of damage, crack fracture and propagation. Deep mining engineering and geological disposal engineering such as nuclear waste, carbon dioxide and garbage deeply buried belong to the underground geotechnical engineering combining with temperature variation. Therefore, the investigation of the propagation behavior of rock crack under different temperature will be very important. Preliminary studies on temperature effect are mainly concentrated in mode I rock crack[1-3], a small amount of studies are concentrated in mixed-mode I-II rock crack[4-7]. About three-dimensional propagation behavior of rock crack which containing mode III stress intensity factor, the authors have done some researches under the room temperature in the recent time [8-9]. But the research about mixed mode I-II-III rock crack fracture coupling with temperature effect, there is almost no published paper, but it has important significance in deep underground engineering, for this mixed mode crack coupling with temperature is the basic existence in deep underground engineering. Consider of this, three point bending I-II-III mixed mode fracture experiments of two kinds of granite were carried out under 6 temperature levels in this paper. The variation law of critical fracture load v.s. temperature was measured. Combined with finite element method (FEM) calculation, the stress intensity factors in crack tip line under the critical load were got. The results of the paper both in experiments and in numerical calculation can provide a valuable reference for the deep underground engineering design and disaster prevention engineering design.

2. Experimental investigation

2.1. Preparation of specimen

The rocks used in this experiment investigation are two kinds of granite: white linen granite and red linen granite. They have different grain sizes. The grain size of the former is smaller than later. Specimen contours are both 140mm×40mm×24mm (Figure 1). From specimen central section, in the position L=15mm and L=30mm, an edge crack which width is not more than 1mm were cut by diamond wheel blade. Crack length a=20mm.

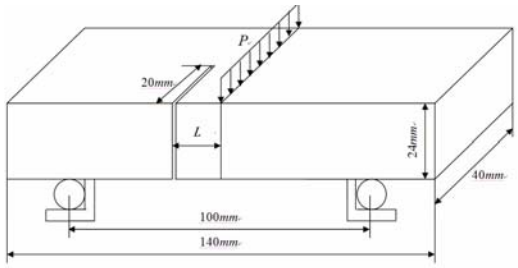

Figure 1 Specimen diagram and loading mode

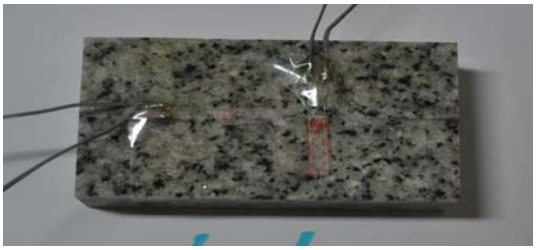

Figure 2 Uniaxial compression experiment specimen

2.2. The process of experiment

For the finite element method (FEM) calculation subsequently in this paper, the elastic modulus of two rocks under different temperature was measured by uniaxal compression experiments. The contour of uniaxal compression specimen and test situation is shown in Figure 2 and Figure 3. The elastic modulus E measured under different temperature are listed in Table 1. Due to the difficulty of test technique，the Poisson's ratio of the two rocks under different temperatures were not measured except under ambient temperature. And then, about the variation law of Poisson's ratio in different temperature was not mentioned in published documents. So in this paper Poisson's ratio are assumed that it has no change when temperature changes; and it is measured under ambient temperature that: for white linen granite μ = 0.26 and for red linen granite μ = 0.3.

The loading way of abnormal three point bending test is shown in Figure 1. The experimental situation is shown in Figure 4. For the two kinds of granite, under different temperature and different crack position L, the critical fracture loads F measured by experiments are listed in Table 2.

Table 1 ： Elastic modulus E of two kinds of granite under different temperatures

Type of specimen	Elastic modulus E/GPa					
	-50^0C	-25^0C	Room temperature	80^0C	160^0C	240^0C
White linen granite	18.8685	17.643	15.3455	17.1	18.3985	17.087
Red linen granite	17.033	15.992	17.713	17.56	17.9665	19.196

Whether in high temperature test or in low temperature test, before a test, the specimen must be placed in the oven in which temperature has arrived demand level half an hour in order to get a well-distributed temperature within specimen. In the experimental process, the loading way of test machine was controlled by displacement. Loading rate is 0.015mm/min. In experiment it can be observed that the crack tip point at the bottom of the specimen starts fracture, it leads the specimen failure. The fracture section of specimen is not a plane, and presents a three-dimensional

morphology. The failure pattern of the specimen is shown in Figure 5. The critical fracture loads under different temperature are shown in Table 2. The relative variation rate η which was compared with the critical fracture load under ambient temperature, the values of η v.s. temperature are listed in Tab. 3. η is defined as:

$$\eta=(F-F_0)/F_0 \quad (1)$$

F_0 and F are the critical fracture load under ambient temperature level and other temperature levels. η can reflect the deviation extent between F and F_0 under different temperature.

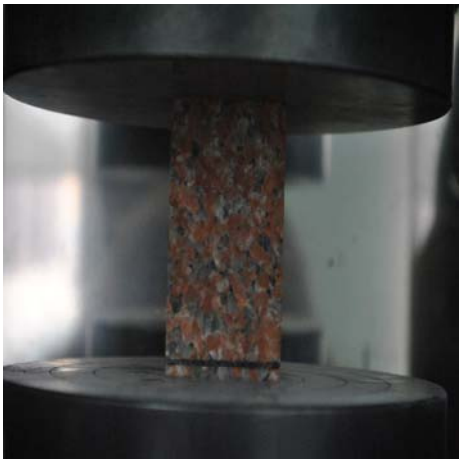

Figure 3 Uniaxial compression test

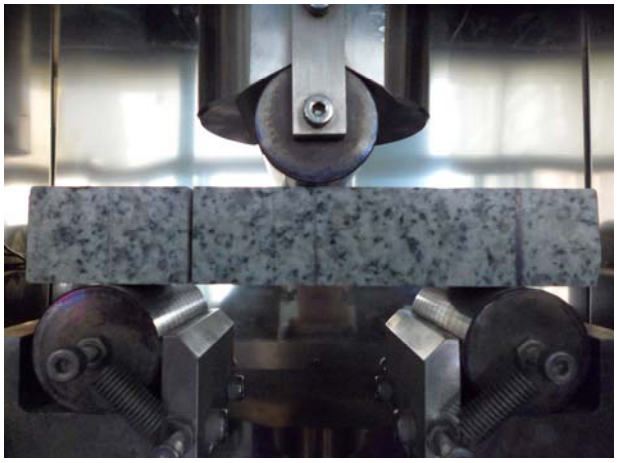

Figure 4 Abnormal three point bending experiment

Table 2 The critical fracture load F v.s. temperature

Type of specimen	Distance from the central position/mm	The critical fracture load F/（kN）					
		-50^{0}C	-25^{0}C	Room temperature	80^{0}C	160^{0}C	240^{0}C
White linen granite	L=30	2.67	-	2.07	2.01	1.71	1.62
	L=15	1.47	1.51	1.25	1.17	1.06	0.84
Red linen granite	L=30	2.35	1.90	1.72	1.27	0.95	0.97
	L=15	1.55	1.21	1.21	1.42	0.99	0.75

Table 3 The deviation rate η between F and F_0 under different temperature.

Temperature /^{0}C	White linen granite		Red linen granite	
	L=30mm	L=15mm	L=30mm	L=15mm
-50^{0}C	28.95%	17.86%	37.02%	27.95%
-25^{0}C	-	21.10%	10.61%	-0.47%
Room temperature	0	0	0	0
80^{0}C	-2.86%	-6.20%	-26.02%	17.28%
160^{0}C	-17.32%	-15.12%	-44.53%	-18.25%
240^{0}C	-21.71%	-33.07%	-43.39%	-37.82%

2.3. The relationship between parameters and temperature

It can be seen from Table 1 that in the range of -50^{0}C to 240^{0}C, with the temperature increases, the variation of elastic modulus E is not obvious. It has only a little volatility.

From Table 2, for the same type of specimen, It can be seen that the critical fracture load reduce with the temperature increase. It is unconcerned with the crack location and the type of rock. Under the same temperature, the value of the critical load is related with the crack position. The shorter the distance between crack and central position of the specimen is, the lower the critical load is.

In the rang of -50^{0}C to 240^{0}C, for different specimens, with the temperature increase, the deviation rate η between F and F_0 gradually reduce. For white linen granite, when L = 30 mm, η gradually reduce from 28.95% down to -21.71%. when L = 15 mm, η gradually reduce from 17.86% down to -33.07%. For red linen granite, when L = 30 mm, η gradually reduce from 37.02% down to -43.39%. When L = 15 mm, η gradually reduce from 27.95% down to -37.82%.

Figure 5 Specimen after fracture

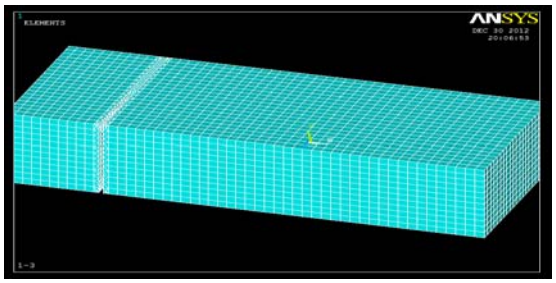

Figure 6 Divide grid

3. Finite element analysis

For abnormal three point bending I-II-III mixed mode fracture specimens in this paper, numerical solution of stress intensity factors for every point in crack tip line were not got in other documents, no more than analytic solutions. In this paper the distribution laws of stress intensity factors K_{I}、K_{II}、K_{III} and their critical values in crack fracture initiation point were obtained by FEM calculation under different temperatures.

3.1.Finite element modeling

By try of FEM calculations many times, it had been known that if the short sections outside the two lower supports of the specimen were ignore, it did not affect the simulation results obviously, so in this paper, the sections between the two lower supports of specimen were choose into FEM calculation. By this modeling way, unnecessary elements can be reduced. It can improve the calculation speed. Cartesian coordinate system was defined as follows: X axis is along the length of the specimen, Y axis is up along the specimen thickness direction, Z axis is forward along the width direction (Figure 6). The width of edge crack is not more than 1mm. The crack surface is a free surface, and the crack front is a rectangular shape. It is consistent with the crack front in the specimens of experiments. Scanning grid division is used. In order to get accurate stress values near crack tip, refined grids around crack tip are also used. Divided elements situation are shown in Figure 6. Substitute the material parameters E, μ and critical load F into the FEM program, critical values (mixed mode critical fracture toughness) of K_{I}, K_{II}, K_{III} in failure crack tip can be calculated.

3.2. The relation between stress intensity factors of initiation points and temperatures

After the stress field calculated within the specimens by the finite element method, the three formulas following can be directly applied to calculate the stress intensity factors of the crack tip[10-11]:

$$K_{\mathrm{I}} = \lim_{r\to 0}\sqrt{2\pi r}\sigma_x \tag{2}$$

$$K_{\mathrm{II}} = \lim_{r\to 0}\sqrt{2\pi r}\tau_{xz} \tag{3}$$

$$K_{\mathrm{III}} = \lim_{r\to 0}\sqrt{2\pi r}\tau_{xy} \tag{4}$$

r is the short distance from stress point to the crack tip

Put r values and stress values of every point on crack extension cord into the formulas, and drew a straight line of K_{I}、K_{II}、K_{III} v.s. r, through the straight line, the real values of K_{I}、K_{II}、K_{III} can be got at the point $r = 0$[10-11].

In abnormal three point bending experiments (Figure 4), the crack fracture just initiated from the tension point which was on the crack tip point located on the bottom of specimen (Figure 4), so the relations between critical stress intensity factors and temperatures are listed in Table 4 and Table 5, and shown in Figure 7 to Figure 10.

Table 4 Critical stress intensity factors v.s. temperature (white linen granite)

Figure 10 The critical stress intensity factors v.s. temperature (red linen granite, L =15mm)

3.3.Result analysis

From the Figures above，it can be seen that the absolute values of critical stress intensity factors decrease with the temperature increase. It is unconcerned with rock type and crack positions L. The reason is the critical fracture loads decrease with the temperatures increase, so the critical stress intensity factors K_{I}、K_{II}、K_{III} decrease relevantly.

From the Tab. 4 and Tab. 5, it can be seen that the K_{I} (>0) values at the initiation points for L=30mm specimen are generally smaller than the K_{I} (>0) values for L=15mm specimen. And the critical loads of the former are generally bigger than the latter. From this it can be known that, let the L=30mm specimen failure is more difficult than let the L=15mm specimen failure. But the relevant absolute values K_{II} and K_{III} of former are bigger than latter. It shows that, if K_{I} value who dominates the crack fracture initiation is not big enough, a I-II-III mixed mode rock crack tip can begin to expand, it has to have bigger K_{II} and K_{III} values. This result reflects a comprehensive effect of mixed mode rock crack fracture sufficiently.

4. Conclusion

(1) In the range of -50^{0}C to 240^{0}C, with the increase of temperature, the variation of elastic modulus E of two kinds of granite is not obvious; i.e. E values had no obvious differences between ambient temperature and some other temperature levels.

(2) For the same kind of rock crack specimen, with the increase of temperature, the critical fracture load is gradually reduced. The deviation rate η decrease gradually from (20% to 40%) under -50^{0}C to (-20% to -40%) under 240^{0}C, i.e. at the lower temperature -50^{0}C, the crack initiation load will be higher (20% to 40%) than at ambient temperature; at the higher temperature +240^{0}C, the critical fracture load will be lower (20% to 40%) than at ambient temperature .

(3) For the same specimen, the critical stress intensity factor K_{I}, K_{II}, K_{III}, at the crack fracture point, decrease with the temperature increase.

(4) At the same temperature, the longer the distance between crack and center of the specimen, the value of K_{I} (caused by tensile stress) in crack fracture point will be lower; and the critical load will be higher. It reflects the rock crack fracture initiation is mainly caused by tensile stress. If the K_{I} value is smaller, is the higher absolute value of K_{II}, K_{III} at crack fracture initiation point required. It reflects the comprehensive effects in I-II-III mixed mode rock crack fracture.

Abstract

Consider two planar circular cracks embedded in an infinite linear elastic media and submitted to mode I tensile loading. Bueckner-Rice weight functions theory allows us to update the stress intensity factor when the crack fronts are slightly deformed in their plane. Using an incremental numerical method based on this theory, we study the propagation of these two cracks when they interact each other taking into account the non-linearities induced by their deformations. The advantage of this method in comparison to more standard finite element methods is that only the crack fronts have to be meshed. Using a Griffith threshold law, we notice important deformations of the crack fronts are observed and a drastically decreasing threshold loading when the fronts approach each other.

Keywords: Brittle fracture, Toughening, Finite element method, Elastic line model

The present study focuses on the coalescence phenomenon of two circular cracks. What is the critical loading to reach the coalescence? Is the crack advance facilitated due to the presence of the secondary crack? What is the shape of the cracks during their propagation? Those questions are considered in the present article. To do it accurately, the main difficulty is to calculate the three-dimensional stress intensity factors along all the fronts by taking into account the crack shape changes induced by the interaction between the cracks.

In the literature, we can find papers treating of interacting cracks but they never take into account the cracks fronts deformation during propagation (see [2 − 5] and [8]).

Here, the effects of the crack front shape changes are analized independently of the edge effects. For this purpose, two small cracks are considered, so we can make the assumption that the medium is infinite and subjected to remote loading. For this reason, methods based on integral equations are adapted here: the sole cracked area is needed. Moreover, in the present case of in-plane propagation, it is just necessary to mesh the 1D outline of the cracks. Using Bueckner-Rice formalism [7], the work of Bower and Ortiz [1] provides some examples of this approach in mode I. More recently, Lazarus [6] developped a simplified variant of their method without significant loss of accuracy. All these works only deal with a sole crack. In the present paper, we extend to two cracks in order to study their final coalescence.

1. Objectives

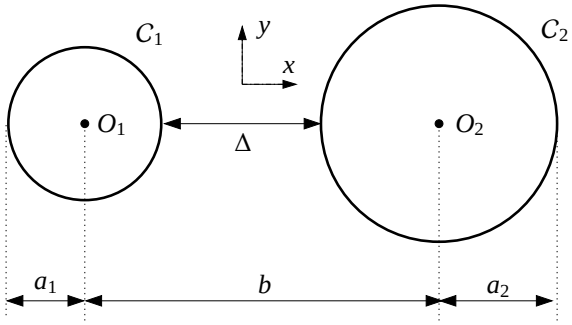

Figure 1: Two circular cracks.

Let us consider two circular coplanar cracks embedded in an isotropic elastic body (such as depicted in figure 1). The aim of this paper is to predict the in-plane propagation of these cracks subjected to remote tensile stress σ_∞ at infinity in brittle fracture. The method consists in coupling the Bueckner-Rice formalism with a propagation law starting from a configuration for which the needed quantities, namely the stress intensity factor (SIF) along the front and a certain kernel, are known. The procedure consists of different steps:

- Determination of the SIF for a given geometry:
  Knowing the geometry and the loading, how to calculate the SIF along the fronts?
- Propagation problem with a threshold:
  In brittle fracture, it is assumed that the propagation law is given by Irwin's criterion:

$$\left\{ \begin{array}{lcl} K < K_c & : & \text{no propagation} \\ K = K_c & : & \text{possible propagation} \end{array} \right. \tag{1}$$

  For a given crack geometry, there is a critical loading σ_∞^c such as: if $\sigma_\infty < \sigma_\infty^c$ then $K(M) < K_c$, $\forall\, M$ and if $\sigma_\infty = \sigma_\infty^c$, there is at least one point M of the front that verifies $K(M) = K_c$. We want to determine this stability threshold σ_∞^c all along the propagation.

2. Numerical approach

2.1. Adimensionalization

Let us define the dimensionless problem for which the distance between cracks centers b is taken at 1. The quantities of interest become: a_1/b and a_2/b, with a loading unit $\sigma_\infty = 1$, letting $K(M) = \sqrt{b}\,\sigma_\infty\,\widehat{K}(M)$, where $\widehat{K}$ is a dimensionless quantity.

2.2. Rice incremental formulae

Suppose that the crack geometry is slighty perturbed in its plane and consider a point $M_i \in C = C_1 \bigcup C_2$.

Let us set $\alpha = (1\,,\,2)$ and $\beta = (1\,,\,2)\,,\,\beta \neq \alpha$.

Then Rice's first formula reads ([7]):

$$\begin{aligned} \delta\widehat{K}_\alpha(M_i) &= \frac{1}{2\pi}\ VP \int_C \frac{W(M_k, M_i)}{D^2(M_k, M_i)} \widehat{K}(M_k)[\delta a(M_k) - \delta_* a(M_k)] ds(M_k) \\ &= \frac{1}{2\pi}\ VP \int_{C_\alpha} \frac{W_{\alpha\alpha}(M_i, M_k)}{D^2_{\alpha\alpha}(M_i, M_k)} \widehat{K}_\alpha(M_k) \delta a_\alpha^{(\alpha)}(M_k) ds(M_k) \\ &+ \frac{1}{2\pi} \int_{C_\beta} \frac{W_{\alpha\beta}(M_i, M_k)}{D^2_{\alpha\beta}(M_i, M_k)} \widehat{K}_\beta(M_k) \delta a_\alpha^{(\beta)}(M_k) ds(M_k) \end{aligned} \tag{2}$$

with:

$$\delta a_{\alpha}^{(\gamma)}(M_k) = \delta a_{\gamma}(M_k) - (\delta a_{\alpha}(M_i)\overrightarrow{n_{\alpha}}(M_i)).\overrightarrow{n_{\gamma}}(M_k) \quad , \quad \gamma = 1,2$$

and where $W_{\alpha\gamma}(M_i, M_k)$ is a kernel expressing the effect of the advance of $M_i \in C_\alpha$ over the SIF at point $M_k \in C_\gamma$. Rice's second formula can be written of the form:

- if $M_i \in C_\alpha$ and $M_k \in C_\alpha$ (points belong to the same crack front):

$$\begin{aligned}\delta W_{\alpha\alpha}(M_i, M_k) &= \frac{D^2(M_i, M_k)}{2\pi}\ VP \int_C \frac{W(M_i, M)W(M; M_k)}{D^2(M_i; M)D^2(M; M_k)}\,[\delta a(M) - \delta_{**}a(M)]ds(M) \\ &= \frac{D^2_{\alpha\alpha}(M_i, M_k)}{2\pi}\ VP \int_{C_\alpha} \frac{W_{\alpha\alpha}(M_i, M)W_{\alpha\alpha}(M_k, M)}{D^2_{\alpha\alpha}(M_i, M)D^2_{\alpha\alpha}(M_k, M)}\delta a^{(\alpha)}_{\alpha\alpha}(M)ds(M) \\ &+ \frac{D^2_{\alpha\alpha}(M_i, M_k)}{2\pi} \int_{C_\beta} \frac{W_{\alpha\beta}(M_i, M)W_{\alpha\beta}(M_k, M)}{D^2_{\alpha\beta}(M_i, M)D^2_{\alpha\beta}(M_k, M)}\delta a^{(\beta)}_{\alpha\alpha}(M)ds(M)\end{aligned} \tag{3}$$

- if $M_i \in C_\alpha$ and $M_k \in C_\beta$ (points belong to different crack fronts):

$$\begin{aligned}\delta W_{\alpha\beta}(M_i, M_k) &= \frac{D^2_{\alpha\beta}(M_i, M_k)}{2\pi}\ VP \int_{C_\alpha} \frac{W_{\alpha\alpha}(M_i, M)W_{\alpha\beta}(M, M_k)}{D^2_{\alpha\alpha}(M_i, M)D^2_{\alpha\beta}(M, M_k)}\delta a^{(\alpha)}_{\alpha\beta}(M)ds(M) \\ &+ \frac{D^2_{\alpha\beta}(M_i, M_k)}{2\pi}\ VP \int_{C_\beta} \frac{W_{\alpha\beta}(M_i, M)W_{\beta\beta}(M_k, M)}{D^2_{\alpha\beta}(M_i, M)D^2_{\beta\beta}(M_k, M)}\delta a^{(\beta)}_{\alpha\beta}(M)ds(M)\end{aligned} \tag{4}$$

with: $\delta a^{(\gamma)}_{\alpha\beta}(M) = \delta a_{\gamma}(M) - \overrightarrow{V_{i,k}}(M).\overrightarrow{n_{\gamma}}(M)$, where $\overrightarrow{V_{i,k}}$ is a geometric transformation such as:
$\delta a^{(\gamma)}_{\alpha\beta}(M_i) = \delta a^{(\gamma)}_{\alpha\beta}(M_k) = 0$.

These formulae give us the first order perturbation of the SIF and kernels, knowing the perturbation δa and the initial SIF and W. Here comes the natural idea of an iterative procedure to predict the propagation. For this purpose, it's necessary to start from a configuration for which the quantities $\widehat{K}_\alpha$ and $W_{\alpha\gamma}$ are known. We assume that for two circular cracks which are distant enough, the SIF and functions $W_{\alpha\gamma}$ are those for single crack that is :

$$\begin{cases} \widehat{K}_\alpha(M) = 2\ \sqrt{a/\pi} \\ W_{\alpha\alpha} = 1 \\ W_{\alpha\beta} = 0 \end{cases} \tag{5}$$

This situation will serve as starting point of our method, corresponding to two circular cracks of size $a_0/b << 1$.

2.3. Propagation

Assumption is made that propagation is governed by the SIF so that we have:

$$\delta a\,(M) = \delta a_{max}\left[\frac{K(M)}{K_{max}}\right]^{\beta} \tag{6}$$

where δa_{max} is a small given quantity.

It is presumed here that this law simulates brutal fracture if $\beta \gg 1$ and fatigue propagation otherwise.
Subjected to Irwin's criteria, cracks are supposed to propagate in a quasistatic way under a remote loading σ_∞, varying

at each numeric step such as: $\max_{M \in C} K(M)/K_c = 1$. This condition ensures that $K(M) < K_c, \forall M \in C$ and that there is always an "active" part of the front. The loading is thus recalculated at each numerical step:

$$\sigma_\infty \sqrt{b} = \frac{K_c}{\max_{M \in C} \widehat{K}} \tag{7}$$

We can define here the real nondimensionalized loading as follows:

$$\sqrt{b} \frac{\sigma_\infty}{K_c} = \frac{1}{\max_{M \in C} \widehat{K}(M)} \tag{8}$$

3. Determination of the SIF along two coplanar circular cracks of same radius $a_1 = a_2 = a$

In this section, the SIF values obtained for two coplanar penny-shaped cracks in interaction are presented. Unfortunately, to our knowledge, no 3D analytical solution exists for this problem that should serve as benchmarks. For weakly interacting cracks (that is the SIF remains close to their value for one single crack), Isida et al. [4], Fabrikant [3], Kachanov and Laures [5], Chen and Lee [2] and Zhan and Wang [8] provide numerical results that are in agreement with each other. We thus believe that those values must be correct and shall serve to validate our code and test the influence of our numerical parameters a_0/b, N and $\delta a/a$ (section 3.1). For closely spaced cracks, the numerical approximations are more questionable and few studies exist. Among them those of Fabrikant [3], Kachanov and Laures [5] and Zhan and Wang [8] will serve to compare with our simulations (section 3.2).

3.1. Weak interaction

Figures 2 reflect the influence of different parameters: the number of nodes N on each front, the initial adimensionless radius a_0/b and the crack advance $\delta a/a$. In this section, cracks are subjected to a uniform advance defined as follows: $\frac{\delta a}{a} = \gamma \; min\left(a \,, \frac{\Delta}{2}\right)$.
All the figures 2 represent K_{max}/K_0 as a function of $\Delta/2a$ in the same y-range to make easier comparisons. Moreover it shall be noticed that the SIF of all points within the frame are less diffent than 10 % from the ones for a single isolated crack.

The initial cracks should not be too small because of the incremental nature of the method, numerical errors would accumulate. Typically, one shall choose a_0/b between 0.05 and 0.1.

There is a few dependence on the number of points, provided that $N > 100$. Moreover we notice that $K(s)$ presents some irregularities for $N < 160$. Thus values of $N \geq 160$ shall be used. Since the CPU depends on N, we shall be reasonable. Typically $N = 160$ seems a good compromise.

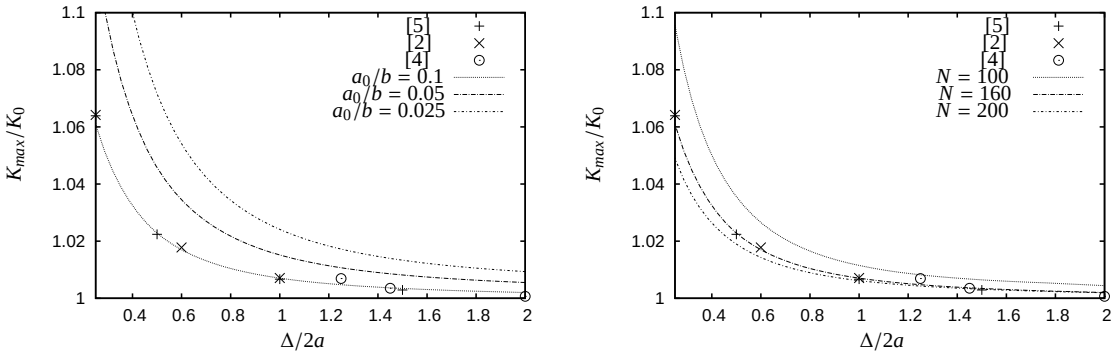
Once again due to the incremental nature of the method, we notice on figure (2c) that $\delta a/a$ shall be not too small but enough to use the first order perturbation formulae. Typically, $\delta a/a \in (0.025 - 0.1)$ is acceptable.

We shall use $a_0/b = 0.1$, $N = 160$, $\delta a/a = 0.025$ in the sequel.

3.2. Strong interaction

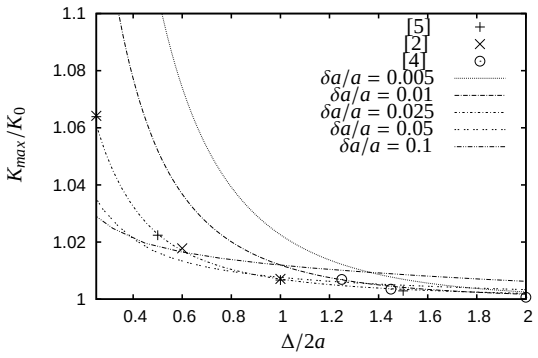
In the sequel, let's define: $l = \min(a, \Delta)$.
It shall be noticed that the method is unstable for some set of parameters. It is linked to the incremental nature of the method and to the amplification of K as soon as some angular points appear along the crack front. For instance, one can notice on figure (3c) that for $N = 160$, ($a_0/b = 0.1$, $\delta a/l = 0.01$ the value of K_{max} diverges. In the sequel, we consider those calculations as ill and arrange to find well suited set of parameters. A systematic study of numerical stability is under consideration and will be published in the future.

From those results, we can conclude that the method is able to give qualitatively correct values of K but quantitatively, is quiet sensitive to the numerical parameters. In particular for cracks as close as $\Delta/2a < 10^{-4}$, a relative dispersion (standard deviation/mean value) can be observed of approximately 100 % by choosing reasonable parameters ($N = 100 - 200$, $a_0/b = 0.1 - 0.2$, $\delta a/l = 0.01 - 0.05$). For higher values of $\Delta/2a$, the dispersion decreases. It is of 50 % for $\Delta/2a \sim 10^{-2}$, 10 % for $\Delta/2a \sim 10^{-1}$, 1 % for $\Delta/2a \sim 0.5$, 0.1 % for $\Delta/2a \sim 1$.



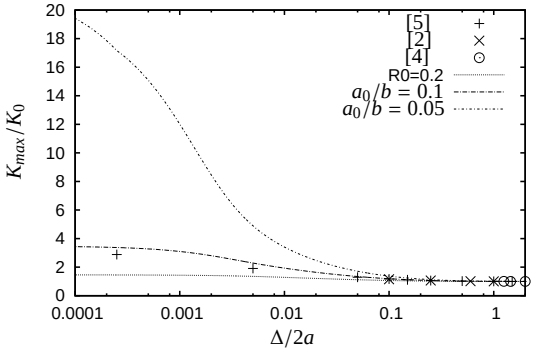
(a) $N = 160$, $\delta a/a = 0.025$

(b) $\delta a/a = 0.025$, $a_0/b = 0.1$

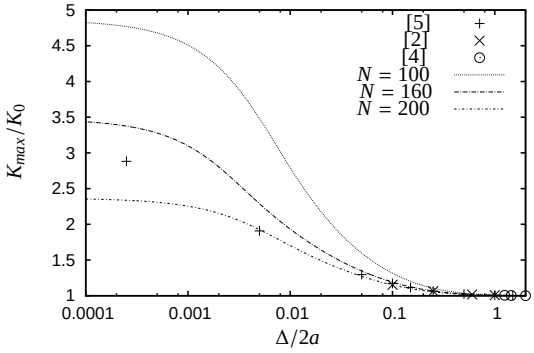


(c) $\delta a/a$ ($N = 160$, $a_0/b = 0.1$

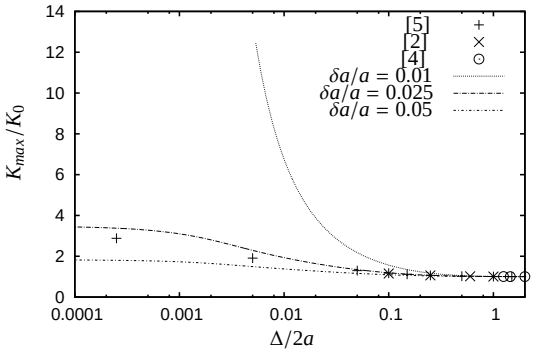
Figure 2: Dependance on the initial size a_0/b (a), on the number N of points in the mesh (b), on the crack advance (c)



(a) $N = 160$, $\delta a/a = 0.025$



(b) $\delta a/l = 0.025$, $a_0/b = 0.1$



(c) $\delta a/l = 0.025$, $a_0/b = 0.1$

Figure 3: Dependance on the initial size a_0/b (a), on the number N of points in the mesh (b), on the crack advance (c)

Nevertheless we achieve to obtain very similar results than previous authors Fabrikant [3], Kachanov and Laures [5] and Zhan and Wang [8] by choosing $a_0/b = 0.1$, $N = 160$, $\delta a/a = 0.025$ (see figure 4 where *phi* is the polar angle). We shall use those parameters as reference in the sequel.

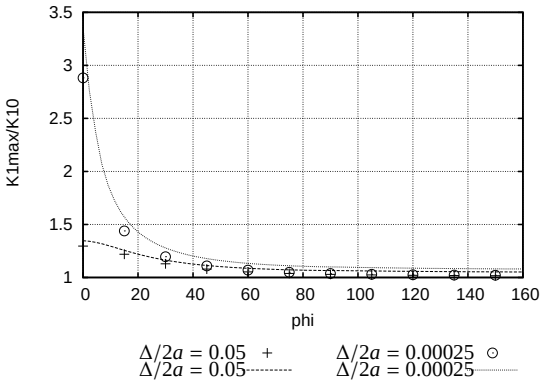


Figure 4: Points corresponds to the values of Kachanov and Laures [5] given in table 1. Lines correspond to our simulations for $a_0/b = 0.1$, $N = 160$, $\delta a/l = 0.025$.

4. Propagation of two circular cracks in brittle fracture

We present here our results for simulations in brittle fracture. For numerical purposes, Irwin's law can be remedied by a Paris type law provided to choose an exponent β large enough. In practice, above $\beta = 30$, results are very close and become independent of β. That is why the sole case $\beta = 30$ is presented here. Crack deformation is consequent so that we had to set up a remesh procedure to redistribute nodes.

Figure (5a) shows the successive positions of the fronts for different values of the dimensionless loading $\sigma_\infty \dfrac{\sqrt{b}}{K_c}$. When the cracks are distant, threshold is reached for the entire set of points because the SIF values are almost uniform along the fronts.

When a/b reaches about $1/4$, interaction between cracks leads to an increase in SIF of points near the opssite crack. In consequence, the threshold is only achieved at these nodes whence a pronounced front deformation. It should be noted that coalescence couldn't be reached because of the values larger and larger of the SIF. Indeed, SIF values are asymptotically infinite at the vinicity of the "interaction area".

Figure (5b) represents the real loading in terms of cracks advance, characterized by the dimensionless quantity a_{int}/b for the case of coalescence and for the isolated crack. It can be noticed that the loading strongly decreases during propagation and tends to almost disappear when cracks are close to one another.

5. Conclusion and perspectives

The purpose of this work was to apply Lazarus's numerical code to study the coalecence of circular cracks.
To validate the code, we compared the SIF values, obtained for different configurations, with those found in the literature. Good agreements with Fabrikant [3], Kachanov and Laures [5] and Zhan and Wang [8] were achieved. After validation with literature, brittle propagation was experimented. It shoud be emphasized that each front was highly perturbed by the presence of the other crack. Our simulations showed cracks with a strongly elongated profile within the "interaction area". It can also be observed a significant decrease of the fracture loading as soon as the interaction between cracks was felt.
The possibility of extending the code to more complex geometries is considered.

Failure Analysis Procedure of Steel Wire Drawing Fracture

LIU Lihua, SUN Jie*, WANG Huan

Jiangsu Fasten Hopesun Group Co., Ltd., 214434, China
* Corresponding author: jason8246@163.com

Abstract Failure analysis procedure of steel wire drawing fracture process was introduced, which includes background information collection, visual inspection and low magnification test, microscopic analysis, metallographic examination, etc. The importance of each step on fracture failure analysis results was also explained. In accordance with the stress condition in drawing process of steel wire, the typical characteristics of the mainly drawing fracture failure modes including pencil-point shaped, plane shaped and inclined shaped were investigated. The process of microscopic analysis and metallographic examination were optimized with macro morphology characteristics, and a faster and more precise analytical approach of metallic wire drawing fracture failure was proposed which was of important engineering significance and practical value to improve product competitiveness.

Keywords failure analysis, fracture, drawing, SEM, metallographic examination

1. Introduction

This is a template to prepare the full paper manuscript for the 13th International Conference on Fracture, which will be held at Beijing, China, June 16–21, 2013.
Fracture failure was inevitable during steel wire drawing which was affected by equipment, weather, operation, etc [1]. Many researchers had made great efforts to investigate the causes of fracture failure, the major fracture morphology included pencil-point shaped, plane shaped, and inclined shaped fracture [2]. And microstructure of wire rod, drawing die, lubrication and other factors which lead to fracture were analyzed.

An optimized procedure of circle section steel wire fracture failure analysis which was depended on macroscopic fracture morphology was proposed. The importance of every step of failure analysis was emphasized, and failure analysis of the pencil-point shaped, plane shaped, and inclined shaped fracture were introduced respectively.

2. Failure Analysis Procedure

The main procedure failure analysis procedure of steel wire drawing fracture was: background information, visual inspection and low magnification test, microscopic analysis, metallographic examination, chemical analysis and mechanical tests if necessary [3].

2.1. Background Information

The object of failure analysis was not only the fracture wire but an integration of wire, equipment, environment and person. Failure analysis should consider the relationships include: fracture wire and normal wire of the same batch, fracture wire and drawing equipment, fracture wire and production environment, fracture and operating person.

First of all, make sure the location of fracture wire, number of drawing pass, reduction of fracture pass and other relevant information as much as possible. Generally, fracture wire located in drawing die hole, around the reel, post-straightener, or take-up device. That information was used to judge the stress condition of fracture. Secondly, find out the fracture frequency of the same batch and

other similar fracture samples. Then, make sure whether the drawing equipment was well, such as broken of drawing die, hole eccentric of die, water shortage of die case would lead to wire fracture. Because the influence of temperature and humidity on wire drawing performance, production environment and operating person would not be ignored.

2.2. Visual Inspection and Low Magnification Test

The purpose of visual inspection and low magnification test were to determine the fracture mode by the macro morphology and surface defects, and photo with relevant information should be recorded. For circle section steel wire fracture, visual inspection and low magnification test included: (1) Original surface defects, such as fold and pitting. (2) Surface defects caused by drawing, such as broken of drawing die, hole eccentric of die, water shortage of die case, etc. (3) Color of wire surface, such as corrosion and welding joints.

2.3. Microscopic Analysis and Metallographic Examination

The purpose of microscopic analysis and metallographic examination was to find microstructural characteristic which caused wire fracture.

Scanning electron microscope (SEM) was used to observe fracture and surface morphology. The feature of wire fracture could be divided into two categories: (1) Dimple character, which was composed of round or oval holes with different sizes, sometimes inclusions or second-phase particles could be found in dimple. (2) Cleavage character, which included river pattern, scallop pattern, grainy pattern and intergranular fracture character.

Metallographic examination was used to analysis internal cracks, grain size, decarburized layer, defect microstructure, etc. And typical defect microstructure included: martensite, net carbide, widmanstatten, etc.

3. Drawing Fracture Analyses

Steel wire was under drawing force, pressure and friction during the drawing that was a plastic deformation. If the drawing equipment had poor lubrication, shortage of cooling water, or die eccentric, wire drawing would be caused to fracture. Fracture and surface morphology were very important to failure analysis of wire drawing fracture. Generally, fracture modes were corresponded to macro fracture morphology and surface state of wire.

Failure analysis procedure of typical macro fracture morphology was optimized, such as, pencil-point shaped, plane shaped and inclined shaped fracture.

3.1. Pencil-point Shaped Fracture

One end of the pencil-point shaped facture was conical tip, and the other conical hole which was matched with each other. The conical surface was angel of 45° to drawing direction and its morphology was shown in Fig. 1. Many investigations showed that the cause of pencil-point shaped fracture was central brittle phase. During wire drawing, brittleness microstructure in center could not be well deformed with outer steel wire, cracks firstly initialized surround the brittle phase, then the cracks which extended along 45° direction to wire axis leas to fracture [4,5]. Central brittle microstructure of wire that was shown in Fig.2 consists of inclusion, net carbide, martensite, etc.

The above research showed that defects of pencil-point shaped fracture usually in center of wire, therefore the procedure of microscopic analysis and metallographic examination should be: (1) SEM was used to search inclusion or pin of it in conical tip. (2) Longitudinal metallographic examination was used to seek central brittle phase. Transversal metallographic examination was also used by some researchers to judge brittle microstructure. Longitudinal metallographic examination was suggested that could found brittle phase and its discontinuous deformation (shown in Fig. 3) more easily.

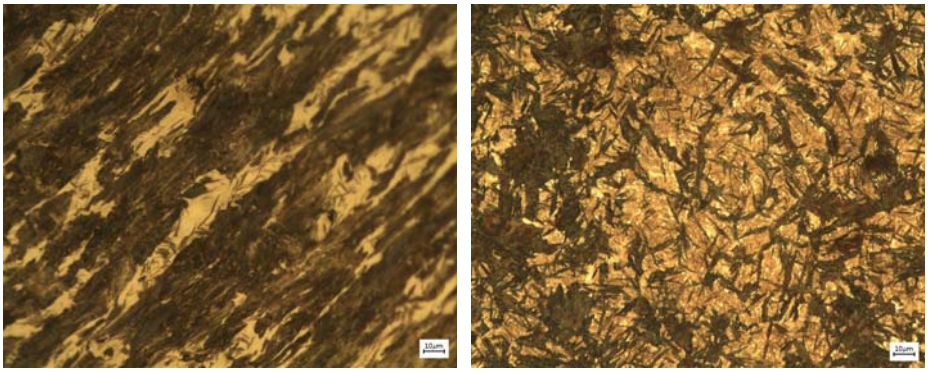
(a) Inclusion (b) net carbide



(c) martensite (longitudinal) (d) martensite(transversal)

Figure. 2 Central brittle microstructure of pencil-point shaped fracture

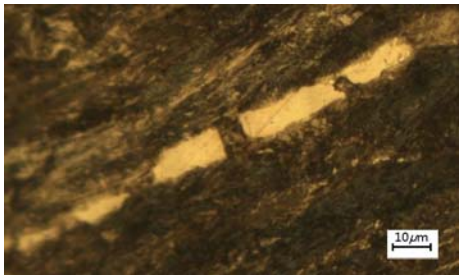


Figure. 3 Discontinuous martensite in center of steel wire

3.2. Plane shaped fracture

There was almost no necking or significant surface defects of plane shaped fracture, whose fracture surface was likely a plane shown in Fig. 4, so called as plane shaped fracture. Generally, the cause of plane shaped fracture was abnormal microstructure or larger grain which increased brittleness of wire [6]. Cleavage character and its microstructure of a plane shaped fracture were shown in Fig. 5.

Bad welding zone could lead to plane shaped fracture as well [7], and the unusual color of blue or white could be the proof of joint. There were cleavage character, inclusion and dimples of different region of fracture, and longitudinal metallographic examination could show variation tendency of grain size which were shown in Fig. 6.

Therefore microscopic analysis and metallographic examination procedure of plane shaped fracture should be: (1) wire surface should be inspected whether had defects or unusual color. (2) SEM was used to observe cleavage character, dimple, inclusion or other microstructural feature. (3) Transversal metallurgical examination should be adopted if cleavage character was found. Longitudinal metallurgical examination should be adopted if there were more than one microstructural character or unusual color of wire surface.

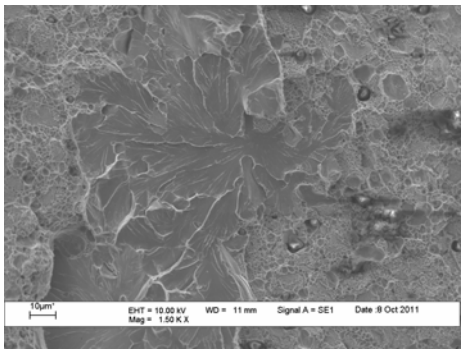
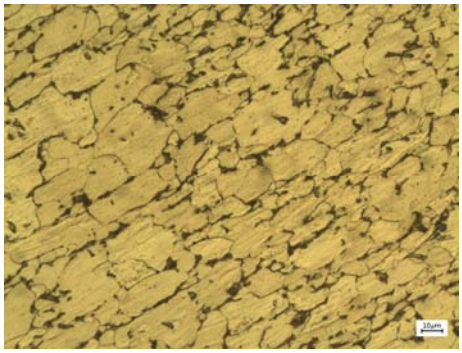
Figure. 5 Cleavage character and Metallurgical analysis of plane shaped fracture

(a) Unusual color



(b) Microscopic character



(c) Variation trend of grain size

Figure. 6 Plane shaped fracture of bad welding

3.3. Inclined shaped fracture

The fracture surface of inclined shaped was an angle to wire drawing direction, and crack, little hole or other defects would be found nearby fracture. Different wire surface defects corresponded to fracture cause which included scratching, abrasions, die broken, poor lubrication, etc [8]. Morphology of inclined shaped facture and a typical surface defect was showed in Fig. 7 and Fig. 8, respectively.

Microscopic analysis of inclined shaped fracture was brittle fracture feature, shown in Fig. 9. Trend of surface crack and poor deformability microstructure would be observed by longitudinal metallographic examination, shown in Fig. 10.

Microscopic analysis and metallographic examination procedure of inclined shaped fracture should be: (1) Wire surface of fracture should be examined to find defect of crack, scratches and so on. (2) SEM would be used to identify microstructural character and defect mode. (3) Longitudinal metallurgical examination would be used to observe trend of crack and poor deformability.

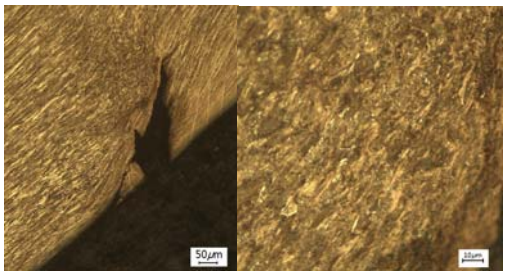

Figure. 10 Poor deformability microstructure of inclined shaped facture

4. Conclusion

Failure analysis procedure of steel wire drawing fracture was proposed and the significance of every step was explained. Microscopic analysis and metallographic examination of pencil-point shaped, plane shaped and inclined shaped fracture were optimized by fracture modes and investigation of fracture failure.

The Effect of the Changing State of Stress Around the Crack Tip on the Determination of Stress Intensity Factors by the Method of Caustics

Emmanuel Gdoutos*

Civil Engineering, Democritus University of Thrace, GR-671 00 Xanthi, Greece
* egdoutos@civil.duth.gr

Abstract The state of stress in the vicinity of the crack tip changes from plane strain at the tip to plane stress at a critical distance (about half the specimen thickness) from the tip through an intermediate region where the state of stress is three-dimensional. In the optical method of caustics, the caustic is the image of a circle on the specimen centered at the crack tip, and, therefore, yields information on the stress state along this circle. In the method conditions of plane stress are assumed along this circle. This condition imposes restrictions on the geometrical dimensions of the optical arrangement, specimen thickness, crack length and applied loads for the correct determination of stress intensity factors. In the present work the limits of applicability of the method of caustics are studied. The use of optically anisotropic materials is introduced to obtain a double caustic which provides the correct state of stress (plane strain, plane stress or three-dimensional) along the initial curve. When the state of stress is known the proper values of stress-optical constants can be used for the correct determination of stress intensity factors.

Keywords Cracks, Stress intensity factors, The method of caustics, Triaxial state of stress

1. Introduction

The optical method of caustics is sensitive to stress gradients, and it has extensively been used for the determination of stress intensity factors in crack problems [1-6]. According to the method the stress singularity at the crack tip is transformed to an optical singularity. A highly illuminated curve, so-called caustic, is obtained on a viewing screen at a distance from the crack tip. The dimensions of the caustic are related to the state of stress near the crack tip. Thus the stress intensity factor which governs the stress field can be determined by measuring characteristic dimensions of the caustic, usually, its diameter perpendicular to the crack. The method is based on the assumption that the state of stress near the crack tip is plane stress. However, experimental and analytical solutions have shown that the state of stress changes from plane strain near the crack tip to plane stress away from the tip through an intermediate region where the stress state is three-dimensional. The changing state of stress results to changing values of stress-optical constants which enter in the equations for the determination of stress intensity factors. In the present work the method of caustics is critically reviewed, and its limits of applicability are studied. Furthermore, the use of optically anisotropic material is introduced for the determination of stress intensity factors.

2. The Optical Method of Caustics

In the optical method of caustics a specimen is illuminated by a light beam and the reflected or transmitted rays undergo a change of their optical path dictated by the stress field (Fig. 1). The change of the optical path is caused by the variation of the thickness and refractive index as the specimen is loaded. At stress gradients resulting at crack tips, the reflected or transmitted rays generate a highly illuminated three-dimensional surface in space. When this surface is intersected by a reference screen, a bright curve, the so-called caustic curve, is formed. For transparent

materials three caustics are formed by the light rays reflected from the front and rear surfaces and those transmitted through the specimen. For opaque materials, only one caustic is formed by the reflected light rays from the front surface of the specimen. The dimensions of the caustic are related to the state of stress near the crack tip. For the case of a mode-I through-the-thickness crack the stress intensity factor K_{exp} is given by [1]

$$K_{exp} = 0.0934 \frac{D^{5/2}}{z_0 c t m^{3/2}} \tag{1}$$

where z_0 is the distance between the specimen and the viewing screen where the caustic is formed, c is the stress optical constant of the specimen under conditions of plane stress, t is the specimen thickness, m is the magnification factor of the optical arrangement defined as the ratio of a length on the reference screen where the caustic is formed divided by the corresponding length on the specimen and D is the transverse diameter of the caustic at the crack tip. The above equation is valid when the state of stress in the vicinity of the crack tip is plane stress, so that the value of stress-optical constant under conditions of plane stress is used.

For optically isotropic materials, the caustic is created by the light rays reflected from the circumference of a circle, the so-called initial curve, which surrounds the crack tip. The radius of the initial curve is given by

$$r = 0.316\ m\ D \tag{2}$$

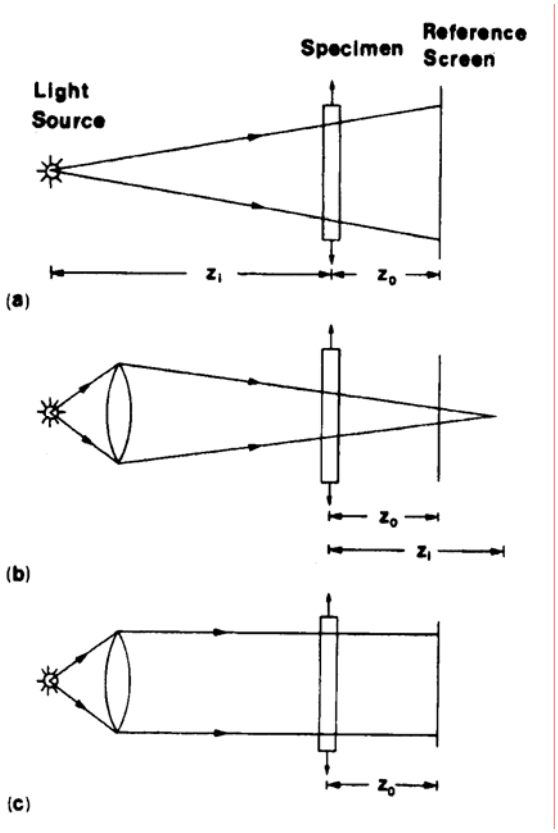

Figure 1. Optical arrangement for divergent (a), convergent (b) and parallel (c) light

3. Experimental

Specimens made of Plexiglas, of thickness d = 3.0, 4.5, 9.5 and 12.5 mm and width w = 42.4, 47.5, 51.5 and 63.5 mm, with an edge notch of length a = 15.5 mm were subjected to a progressively increasing tensile loading in an Instron testing machine. The specimens were illuminated by a convergent, divergent or parallel monochromatic light beam produced by a Ne-He laser. The caustic curves obtained from the light rays reflected from the front or rear faces of the specimen, or those transmitted through the specimen, were recorded on a viewing screen placed at a distance z_0 from the specimen. Caustics were obtained at different load levels for various values of the magnification factor of the optical arrangement, m, and the distance z_0. In this way, a host of caustics were obtained from different values, r, of the initial curve from the crack tip.

Experimental values of stress intensity factor, K_{exp}, were obtained. These values were compared with theoretical values of stress intensity factor K_{th} given by [7]

$$K_{th} = \sigma\sqrt{\pi a}\left[1.12 - 0.23\left(\frac{a}{w}\right) + 10.55\left(\frac{a}{w}\right)^2 - 21.72\left(\frac{a}{w}\right)^3 + 30.95\left(\frac{a}{w}\right)^4\right] \quad (3)$$

Note that the experimental values of stress intensity factor are obtained under the assumption that the initial curve of the caustic lies in the region near the crack tip where plane stress conditions dominate. Thus, if the values of K_{exp} and K_{th} coincide, this means that the initial curve of the caustic lies in the region where the state of stress is plane stress. In case the values of K_{exp} and K_{th} do not coincide, this implies that the initial curve lies in the region where the state of stress is three-dimensional

Fig 2 present the variation of K_{exp}/K_{th} versus r/d for a value of the specimen thickness d = 4.5, and different values of specimen width. Points in figure correspond to different values of the applied load, P, the magnification factor of the optical arrangement, m, the distance between the specimen and the viewing screen where the caustic is formed, z_0, and the specimen thickness, d. Note form figure that the ratio K_{exp}/K_{th} increases with r/d and reaches a plateau value equal to one as the radius of the initial curve takes a limiting value r_c. At that value of $r = r_c$ the state of stress in the neighborhood of the crack tip becomes plane stress. For distances r smaller than r_c the state of stress is three-dimensional, while for values of r larger than r_c plane stress conditions dominate. It was obtained that the critical value of r for which the state of stress becomes plane stress depends not only on d, but also on the geometrical characteristics of the cracked plate, especially the ratio of the crack length to specimen thickness.

4. Limit of Applicability of the Method of Caustics

The condition that the initial curve of the caustic should lie at distances from the tip approximately greater than half the specimen thickness introduces limitations in the parameters (distance between the specimen and the viewing screen where the caustics is formed, the magnification factor of the optical arrangement, the specimen dimensions and thickness, and applied loads) entering in the determination of stress intensity factors. These factors should be properly selected so that the initial

curve lies in the region where plane stress conditions dominate. In that case the value of stress-optical constant corresponding to plane stress should to be used.

In order to obtain caustics generated from the region of plane stress the radius of the initial curve of the caustic should be larger than a fraction of the specimen thickness. By taking this distance equal to half the specimen thickness we obtain

$$\left(\frac{3.385 z_0 cK}{m}\right)^{2/3} > d \tag{4}$$

Inequality (4) establishes a condition the quantities, z_0, c, K, m, d should satisfy in order to obtain caustics generated by an initial curve that lies in the plane stress region Fig. 3 presents the variation of the critical (minimum) value of specimen thickness, z_0, versus K_I for a parallel light beam illuminating a notched Observe that the critical thickness z_0 increases as the thickness of the specimen increases and K_I decreases. Fig. 4 presents the variation of r_0 versus stress intensity factor K_I for a Plexiglas specimen of thickness d = 1 mm illuminated by a parallel light beam. The caustic is created by transmitted light rays (c_t = 1.08x10^{-10}m^{2}N^{-1}) and the reference screen is placed at distances z_0 = 0.1,1 and 10 m from the specimen. K_I varies up to 1 MPa√m corresponding to the value of fracture toughness of Plexiglas. In the same figure the line r_0 = d/2 is drawn. Observe that r_0 increases as K_I and z_0 are also increased. Only for the part of curves above the line r_0 = d/2, does the radius of the initial curve lie in the region of plane stress. It is observed that the realm of validity of the method of caustics under conditions of plane stress increases with K_I and z_0.

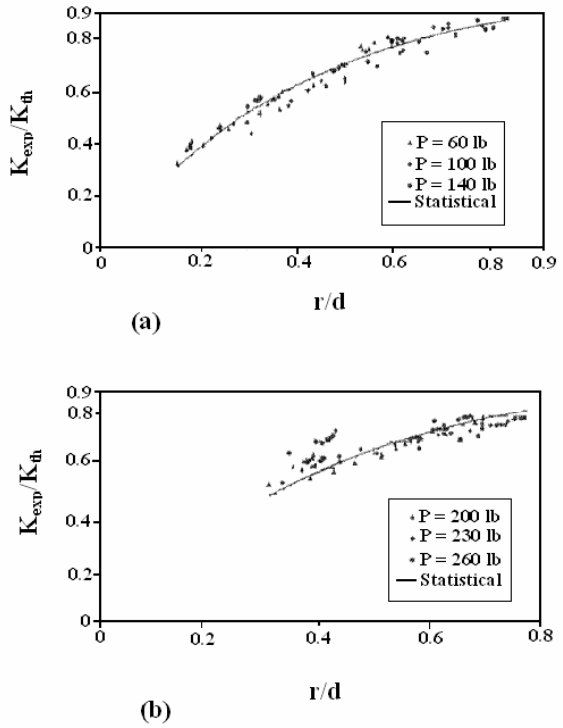

Figure 2. Variation of K_{exp}/K_{th} versus r/d for a = 15.5 mm, d = 4.5 mm and w = 47.5 mm (a) and w = 63.5 mm (b)

5. Determination of Stress Intensity Factors

When the initial curve of the caustic lies at distances where three-dimensional effects dominate the proper value of the stress-optical constant, c, should be used. The value of the stress-optical constant changes from its plane strain value near the tip to its plane stress value at distances away from the tip approximately equal to half the specimen thickness. In order to characterize the three-dimensionality of the stress field near the crack tip an empirical triaxiality factor k is introduced, such that

$$\sigma_z = k\,\nu\,(\sigma_x + \sigma_y) \tag{5}$$

where σ_z is the normal stress perpendicular to the plane of the specimen, and σ_x and σ_y are the in-plane stresses. k takes the values of 0 and 1 for plane stress ($\sigma_z = 0$) and plane strain [$\sigma_z = \nu\,(\sigma_x + \sigma_y)$], respectively.

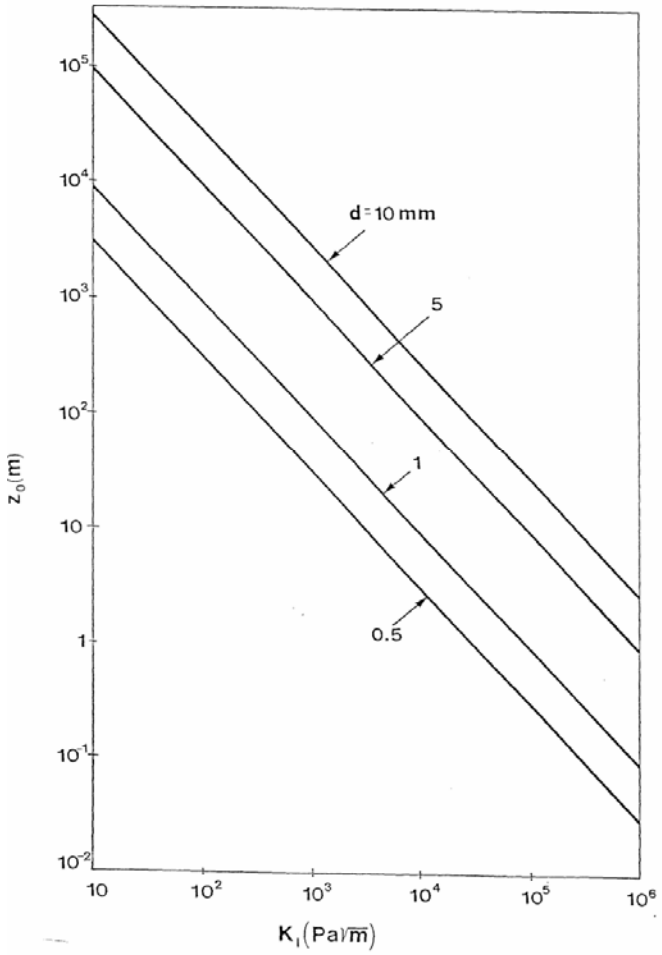

Figure 3. Variation of minimum value of z_0 versus K_I for parallel light. d= 0.5, 15 and 10 mm.

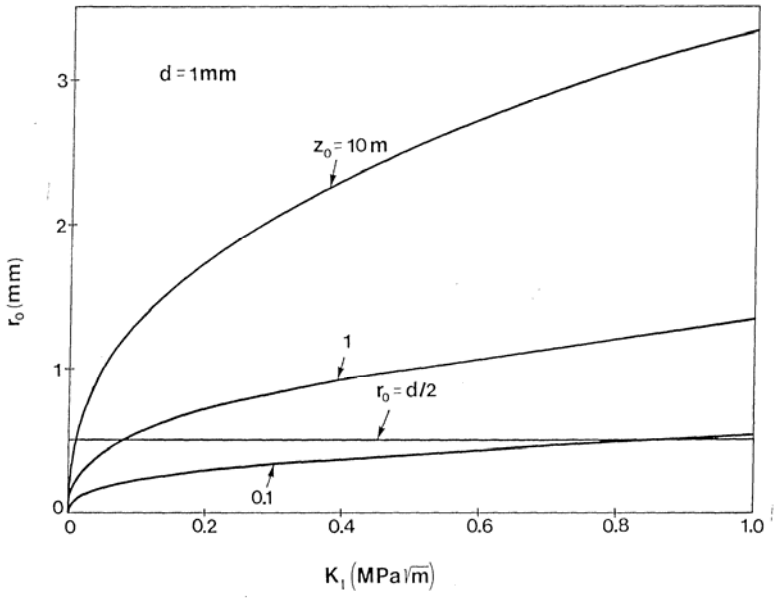

Figure 4. Variation of r_0 versus K_I for parallel light. d = 1 mm, z_0 = 0.1, 1 and 10 m

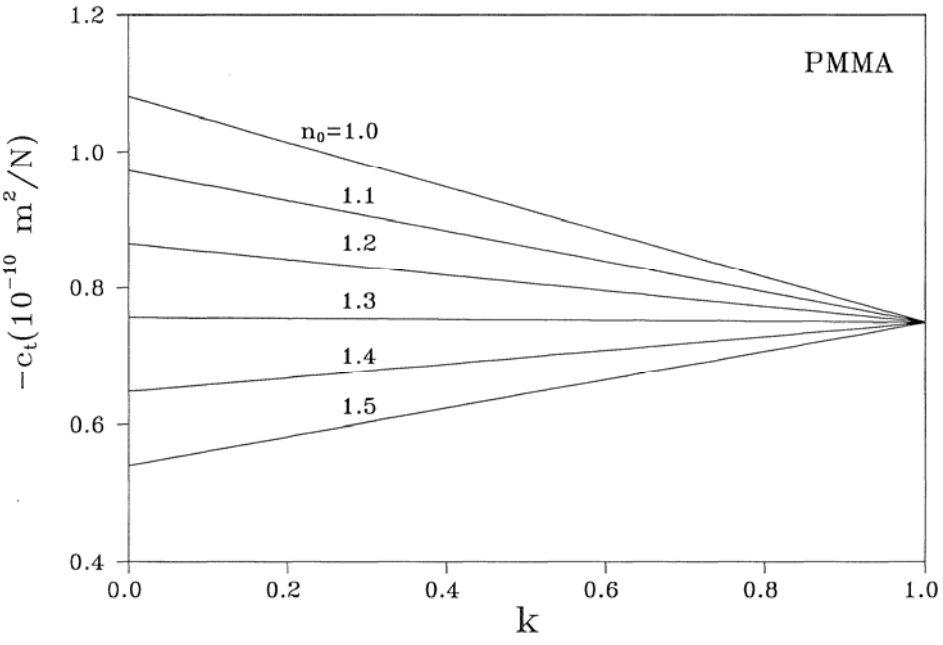

Figure 5. Variation of stress-optical constant c_t versus triaxiality coefficient k for PMMA for various values of the index of refraction n_0 of the surrounding medium. k = 0 and 1 correspond to conditions of plane stress and plane strain, respectively.

When the triaxiality factor is determined the corresponding value of the stress-optical constant, c, is calculated which subsequently is used for the determination of stress intensity factor. Fig. 5 presents the variation of the stress-optical constant c_t for transmitted light for Plexiglas (PMMA) versus the triaxiality coefficient k from its plane stress (k = 0) to its plane strain value (k = 1) for various

values of the index of refraction n_0 of the surrounding medium. Note that c_t varies linearly with k. From Fig. 5 it is observed that c_t remains almost constant for $n_0 = 1.35$. This means that when the index of refraction of the medium surrounding the specimen is equal to $n_0 = 1.35$ the stress-optical constant c_t is independent of the state of stress near the crack tip. Under such circumstances Eq. (1) can be used for the correct determination of stress intensity factor K_I for any values of the parameters entering in Eq. (1). Analogous results for the stress-optical constant c_r are shown in Fig. 6. Note that in this case c_r does not become constant for any value of n_0.

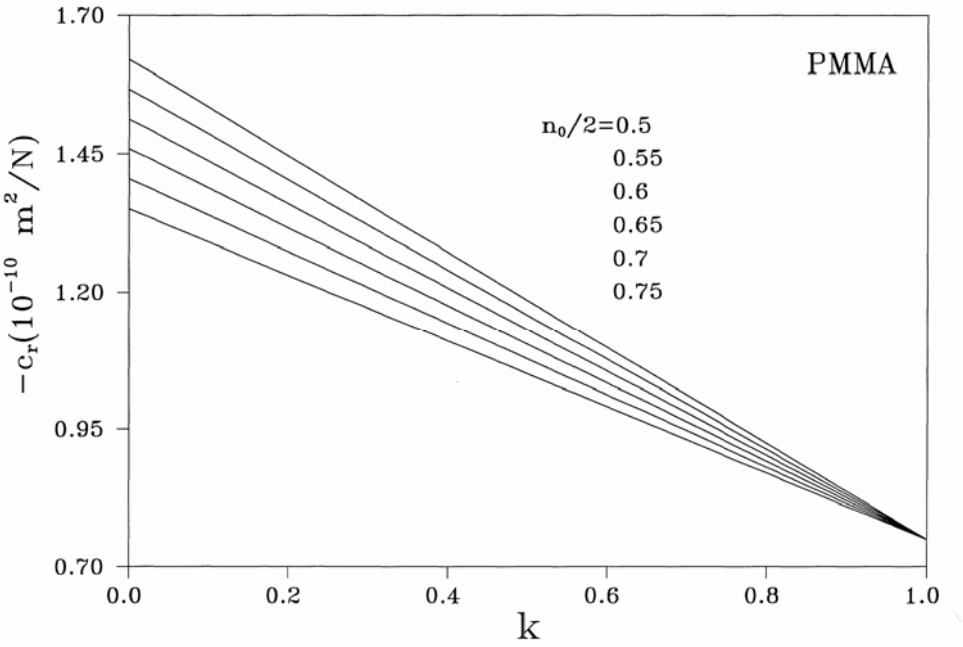

Figure 6. Variation of stress-optical constant c_r versus triaxiality coefficient k for PMMA for various values of the index of refraction n_0 of the surrounding medium. k = 0 and 1 correspond to conditions of plane stress and plane strain, respectively.

6. Use of Optically Anisotropic Materials

In optically anisotropic materials the variation of the optical path of a light ray traversing the specimen along the two principal stress directions is given by:

$$\Delta s_{t1,2} = c_t \left[(\sigma_1 + \sigma_2) \pm \xi_{r,t} (\sigma_1 - \sigma_2) \right] d \tag{6}$$

where the coefficient $\xi_{r,t}$ characterizes the optical anisotropy of the material for light rays reflected from the rear face (r) or traversing (t) the specimen. The plus and minus signs in equation correspond to the values σ_1 and σ_2 of the principal stresses. Under such conditions the parametric equations of the caustic are given by [8]:

$$X_{r,t} = \left(\frac{3}{2}C_{r,t}\right)^{2/5}\left[A^{2/5}\cos\theta + \frac{2}{3}A^{-3/5} + \left\{\left(\cos 3\theta/2\right) \pm \frac{3}{4}\xi_{r,t}\sin 2\theta\right\}\right] \tag{7a}$$

$$Y_{r,t} = \left(\frac{3}{2}C_{r,t}\right)^{2/5}\left[A^{2/5}\sin\theta + \frac{2}{3}A^{-3/5} + \left\{\left(\sin 3\theta/2\right) \pm \frac{1}{4}\xi_{r,t}\left(1+3\cos 2\theta\right)\right\}\right] \tag{7b}$$

where:

$$A = \pm\frac{1}{4}\xi_{r,t}\sin\theta + \left[1 \pm \frac{1}{4}\xi_{r,t}\left\{\left(7\sin\theta/2 + \left(\sin 3\theta/2\right)\right\} + \frac{1}{32}\xi_{r,t}^2\left(25+9\cos 2\theta\right)\right]^{1/2} \tag{8}$$

$$C_{r,t} = \frac{\varepsilon z_0 dc_{r,t}K_I}{\left(2\pi\right)^{1/2}} \tag{9}$$

The equation of the initial curve is given by:

$$r = r_0 = \left\{\frac{3}{2}C_{r,t}A\right\}^{2/5} \tag{10}$$

Equations (7) express the equations of the caustic curve for optically anisotropic materials. Two caustics are obtained corresponding to the plus and minus signs in equations. These caustics are referred to the two principal stress directions. Note that for $\xi_{r,t}$ = 0 equations (7) and (9) reduce to the equations of the caustic for optically isotropic materials. Fig. 7 shows the initial curves and respective caustics in a plate with crack subjected to tension made of birefringent materials with ξ = 0, 0.2, 0.4, 0.6, 0.8 and 1.0 [8]. Observe that as ξ increases the shapes of the initial curves and caustics are progressively distorted. The distance between the two caustics increases as ξ also increases. The value of ξ depends on the state of stress, being plane strain, plane stress or three-dimensional. Thus the experimental caustics obtained can be used for the determination of the triaxiality factor k and the subsequent calculation of the stress-optical constant for the correct determination of stress intensity factors.

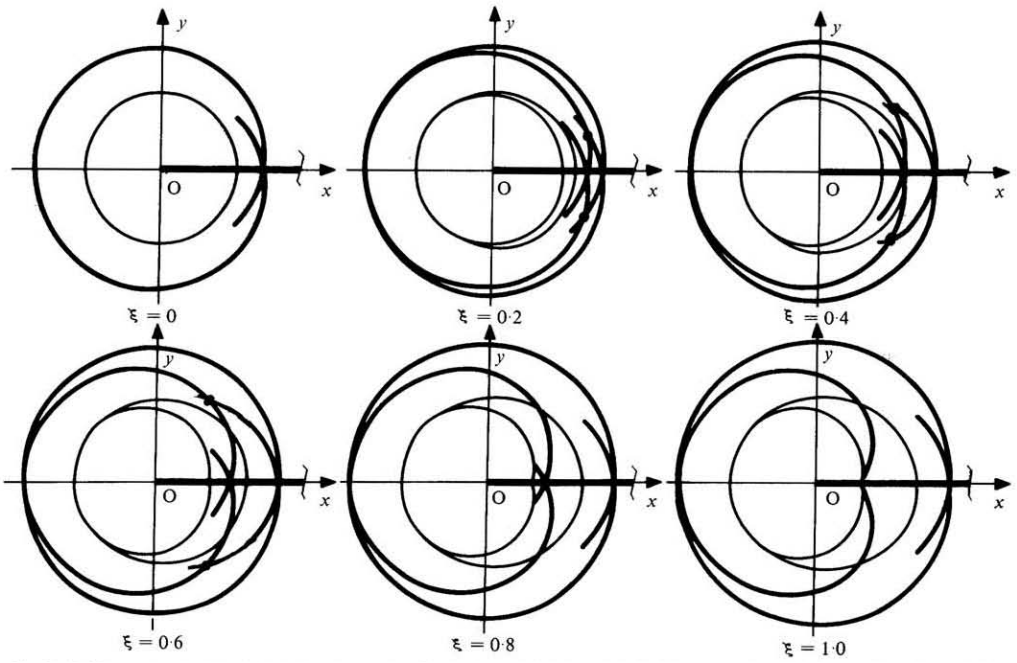

Figure 7. Initial curves and respective caustics in a plate with crack subjected to tension made of birefringent materials with ξ = 0, 0.2, 0.4, 0.6, 0.8 and 1.0

7. Conclusions

From the results of the present work the following conclusions may be drawn:

a. Direct application of the method of caustics without taking special precautions for the determination of stress intensity factors may lead to erroneous results.
b. The material, dimensions of the specimen, applied loads and geometrical dimensions of the optical arrangement should be properly selected to ensure that the initial curve lies in the plane stress region.
c. For specimens made of Plexiglas the stress-optical constant for transmitted light rays is independent of the state of stress around the crack tip for a value of the index of refraction of the medium surrounding the specimen approximately equal to 1.35. Under such condition the plane stress stress-optical constant of the material can be used for any location of the initial curve of the caustic. On the contrary, for light rays reflected from the rear face of the specimen the stress-optical constant does not become independent of the state of stress around the crack tip for any value of the index of refraction of the medium surrounding the specimen.
d. Optically anisotropic materials can effectively be used for the determination of the state of stress around the initial curve of the caustic and the correct determination of stress intensity factors. For such materials the two caustics formed can be used for the determination of the triaxiality coefficient and the subsequent calculation of the corresponding stress-optical constant.

Abstract Globally, steel pipelines are widely used to transport energy in the form of liquid petroleum and natural gas. The steel used in the manufacture of these pipelines must have high strength and toughness, and high resistance to fracture. The Drop Weight Tear Test (DWTT) is the most widely used test to assess brittle fracture characteristics in steel. The zones of ductile and brittle fracture during DWTT characterize the quality of pipeline steels. In this paper, the Gurson-Tvergaard-Needleman (GTN) fracture models are coupled in a Finite Element model. The ductile and brittle fracture zones in the samples are analyzed under different conditions. The results show that the change in fracture mode during the DWTT is from the brittle to the ductile, then again to the brittle. The calculated absorbed energies during DWTT compare well with experimental findings. Finally, we present an analysis of the transition from ductile to brittle fracture under different conditions.

Keywords Energy pipeline; ductile fracture; brittle fracture; DWTT

1. Introduction

Oil and gas provide 60% of the world's primary fuel and a large proportion is transported in pipelines. There is more than 33,000 km of high-pressure steel pipelines in Australia. The pipelines are designed, built and operated to well-established standards and rules, because the products they carry can pose a significant hazard to the surrounding population and environment. A combination of good design, adequate material properties and sound operating practices are therefore necessary, to ensure that transmission pipelines operate safely and efficiently.

Line pipe specifications specify minimum requirements for the shear area in a Drop Weight Tear Test (DWTT) to ensure the arrest of a long running brittle fracture. The DWTT, as specified in API RP 5L3 [1] or ASTM E436 [2], was developed by Battelle Memorial Institute in 1962 during the course of the American Gas Association NG-18 Research Program [3] to overcome some limitations of the Pellini drop-weight test which was developed by the US Naval Research Laboratory. In a DWTT, the test specimen is a rectangular bar with a length of 305 mm, a width of 76 mm and of the full material thickness (up to at least19mm). The specimen has a shallow pressed notch and is subjected to three-point bending, as shown in Fig. 1. The standards specify a 5 mm deep notch made by a sharp indenter with a 45° included angle resulting in a tip radius that is normally between 0.0127 to 0.0254 mm [1]. A series of specimens are broken under impact loading at various temperatures and the proportions of ductile fracture (shear) and brittle fracture (cleavage) on the fracture surfaces are measured. From correlations with full-scale pipe burst tests, a transition temperature corresponding to about 85 percent shear is normally defined in application standards as the fracture propagation transition temperature (FPTT) [4-5].

In this paper, a numerical method has been used to simulate the fracture behavior of pipelines. The most commonly used fracture model in computational fracture mechanics to characterize the toughness of line pipe steels is the modified Gurson model [6]. The Gurson model includes the influence of micro-voids on the plastic flow in a constitutive framework. The Gurson model was later modified extended by Tvergaard [7] and Needleman [8]. The modified Gurson- Tvergaard-Needleman(GTN) model is used to describe the acceleration of void growth. In this model, the

material is regarded as a continuum, composed of a ductile matrix with microvoids. There have been a limited number of studies applying this model to ductile materials [9-11].

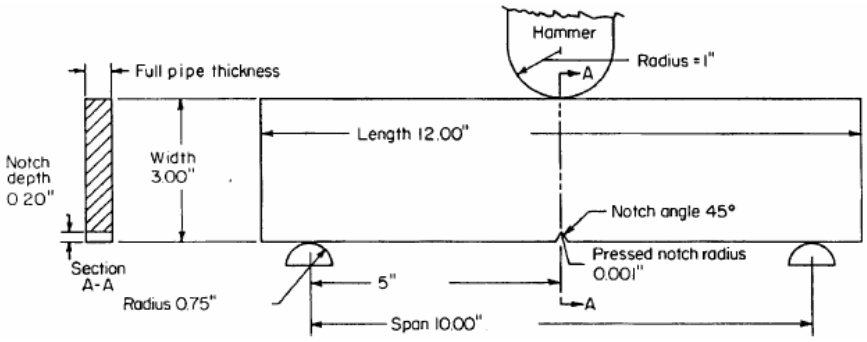

Fig. 1 Drop weight tear test (DWTT) specimen [2]

As opposed to simulations of the DWTT, simulations of Charpy tests are widely carried out to characterize the toughness of line pipe steels. Koppenhoefer and Dodds [12] investigated specimen size and loading rate effects on cleavage fracture of ferritic steels tested in the ductile-to-brittle transition region in pre-cracked Charpy specimens. The probability distribution for fracture of a cracked solid is defined by a two-parameter Weibull distribution [12]. Eberle et al. [13] developed 2D as well as 3D explicit dynamic finite element analyses, in combination with the rate-dependent Gurson model, to simulate Charpy tests. The simulated load-displacement curve and crack front are in close agreement with experimental observations. Tanguy et al. [14] conducted a numerical simulation of the Charpy V-notch test in the ductile-brittle transition regime using a modified Gurson-type model for ductile damage and Beremin model for cleavage fracture. Folch et al [15] also developed a local coupled brittle/ductile fracture approach model to predict either Charpy energy or fracture toughness and to investigate conditions for correlations between them using the Beremin and Gurson models. The modified Beremin model is based on the principles of Weibull statistics for the distribution of the defects and their size as is the standard Beremin model. The modified Gurson model, which incorporates a yield function for porous metal plasticity, was utilized in this work in conjunction with the Lemaitre and Beremin models. Thibaux and van den Abeele [16] reported on the fracture mechanics of instrumented Charpy tests performed on an X70 material. The tests were then simulated using a finite element method and the GTN constitutive model. Damage is represented by an internal variable, f, representing the void volume fraction which is assumed to be isotropic.

There have been very few reports on studies of the ductile-to-brittle transition region during a DWTT. Nonn et al [17] performed numerical simulations of a DWTT by applying the GTN model and compared the simulation results with experimental results from an instrumented DWTT. The results show that GTN model gives a reliable prediction of the load level variation with time when considering strain rate dependence. By applying GTN parameters validated on quasi-static fracture mechanics tests, the maximum load level including the beginning of the load drop for a DWTT can be well described quantitatively. The model equations were not provided in the publication.

In this paper, we used the GTN model to simulate the fracture behavior during DWTT. The stress at the notch was included as an initial condition in this model for the first time. The equivalent stress, nucleation of voids, void size distribution, etc, were analyzed. We found that the fracture propagates in a triangular shape at the crack tip, and the inverse fracture occurs when the fracture propagated about 3/4 of sample width in current study case. Some of the cases show that the transition during DWTT test is from the brittle to the ductile and then again to the brittle zone.

2. Models and simulation

The GTN damage model could be used to analyze the ductile fracture behavior under tension loads. In this paper, we also used the model to predict the damage behavior, as shown in Eq. (1),

$$\Phi = \frac{\sigma_{eq}^2}{\sigma_0^2} + 2q_1 f^* \cosh\left(-q_2 \frac{3p}{2\sigma_0}\right) - \left(1 + q_1^2 f^{*2}\right) \quad (1)$$

where p the hydrostatic pressure, σ_{eq} the effective Von Mises stress, σ_0 the yield stress of the matrix (function of the plastic deformation), q_1, q_2 are material parameters and f^* is the effective porosity. Material grade API 5L X80 was adopted in the models and the parameters are listed in Table 1.

Table 1 Main material parameters

Parameters	Value
Density, kg/m^3	7850
Young's Modulus, GPa	206
Yield stress, MPa	610
f^*	0.06
q_1,q_2	1.5,1.0

As specified in the ASTM E436 [2], the DWTT specimen is loaded in three-point bending by a drop hammer with 400kg weight and loading span of 254 mm. The simulated fracture test comprises two steps employed, as shown in Fig. 2: (1) pressing the notch and, (2) fracturing the sample under the action of the hammer. A three-dimensional geometrical model of the DWTT process was created with a pressed crack was set up with the above parameters and computational meshes with 8-node elements. The elements around the expected fracture zone are much finer than elsewhere in order to accommodate steeper gradients in parameters. In the models, there are 124864 elements and 127002 nodes. In the DWTT process, the hammer descends with an initial impact speed of 7 m/s.

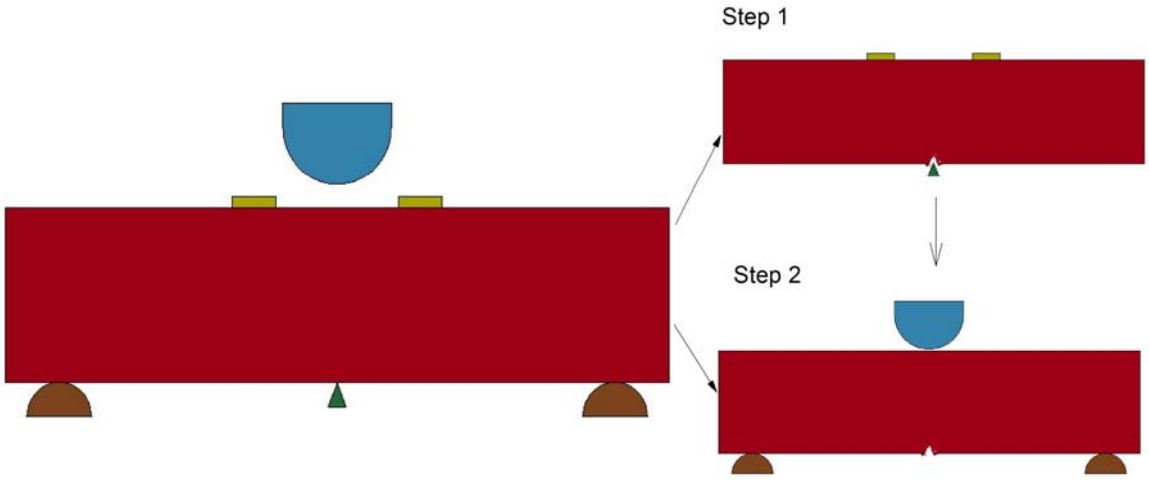

Fig. 2 Geometry of the full simulation process

3. Results and discussion

Fig.3 shows the equivalent stress distribution around the pressed notch position. After the pressed notch was introduced (step 1) at the centre of the specimen, stress concentration in the notch tip

area is observed prior to commencement of fracture. In the figure, we observe the maximum initial stress appeared in the notch tip zone, and this will affect the fracture behavior during the DWTT process.

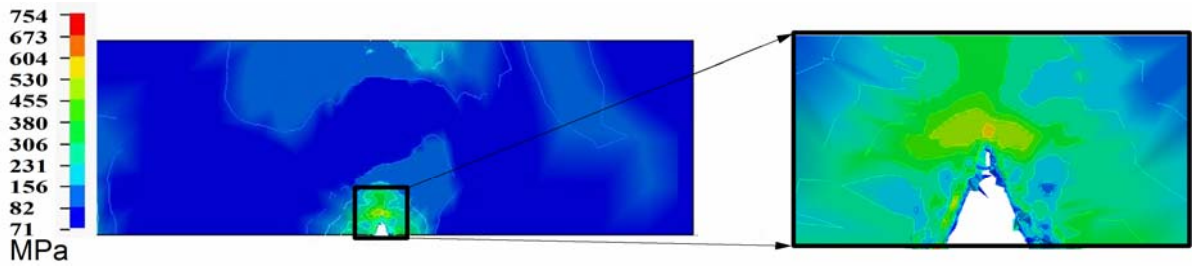

Fig. 3 Equivalent stress distribution and detail around the notch (MPa)

Fig.4 shows the equivalent stress distribution sequence during crack propagation (step 2). The equivalent stress is a three-dimensional stress calculated by Eq.(2). A maximum stress of 813 MPa is found at the notch tip and at the loading point, due to high stress concentration at these places. The stress value in the central area between the notch tip and the loading point is relatively small. A 'butterfly-wing' stress distribution is observed at the crack tip and at the loading point. The stress distribution is almost symmetrical about the loading line. As the crack propagates, the maximum stress distribution extends along the loading line till the specimen fractures.

$$\sigma_v = \sqrt{\frac{3}{2} s_{ij} s_{ij}} \qquad (2)$$

Where S_{ij} are the components of the stress deviator tensor.

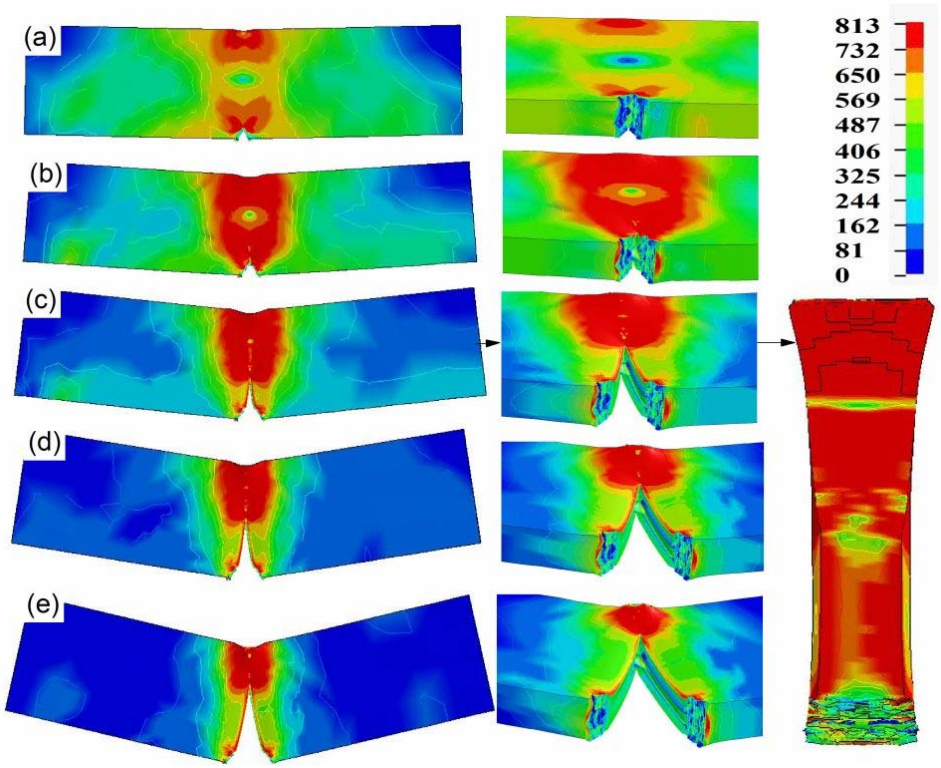

Fig.4 Equivalent stress distribution in DWTT sample (MPa)

Figure 5 shows the development of void nucleation during crack propagation from the notch tip to the impact side. The maximum void density always occurs at the two sides of the fracture surface where fully ductile fracture is seen. The voids appear to peak faster near the plane of symmetry. Which implies that the plasticity at the two sides of the sample is larger than that near the plane of symmetry.

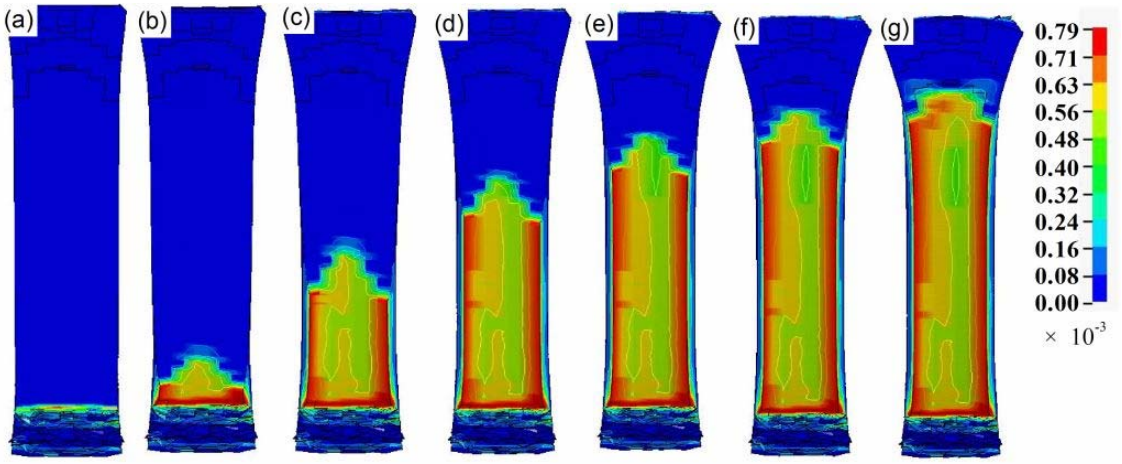

Fig.5 Nucleation of voids in DWTT samples

Fig.6 shows the void volume fraction distribution in the DWTT sample at different stages. It is seen that the void volume fraction in the pressed notch zone is slightly larger than in the other zone, suggesting that the process of notch pressing affects the initiation of fracture in the test sample. Hong et al. [18] concluded that the stress was less concentrated at the notch tip in the pressed-notch specimens compared to a Chevron notch, and this makes the initiation of fracture of pressed-notch specimens more difficult, and accordingly the deformation preceding the fracture initiation resulted in strain hardening in the hammer-impacted region increased.

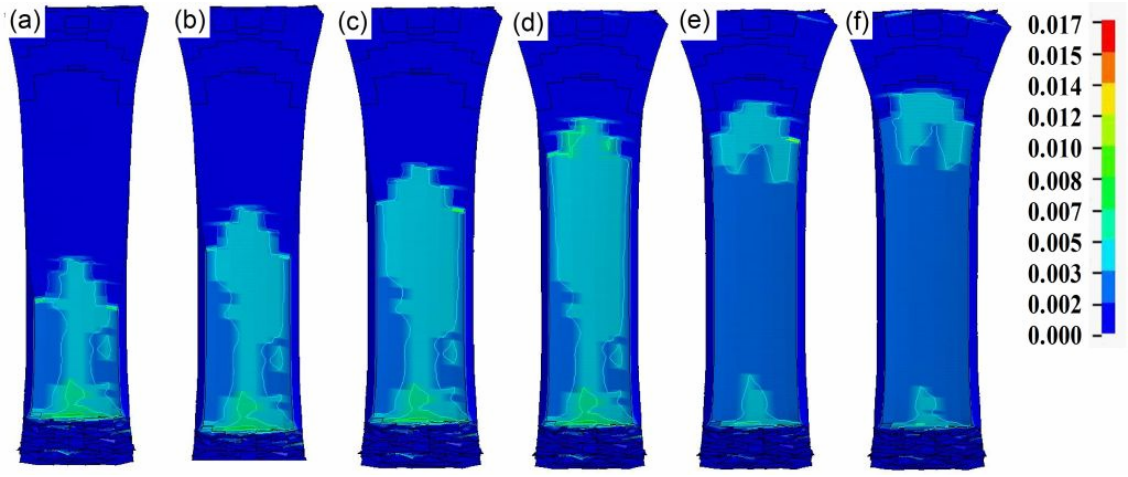

Fig. 6 Void volume fraction distribution in DWTT samples

As seen in Fig.7, the effective strain rate shows a peak near the plane of symmetry until the specimen fractures. This is consistent with the higher crack growth rate due to stress concentration near the surface of symmetry. As expected, the shape of effective strain rate distribution is found to be similar to the shape of the voids distribution. In Fig. 7 (g), it was observed that the inverse

fracture occurred when the fracture propagation reached 3/4 of sample width. The fracture also occurred at impact zones at same time.

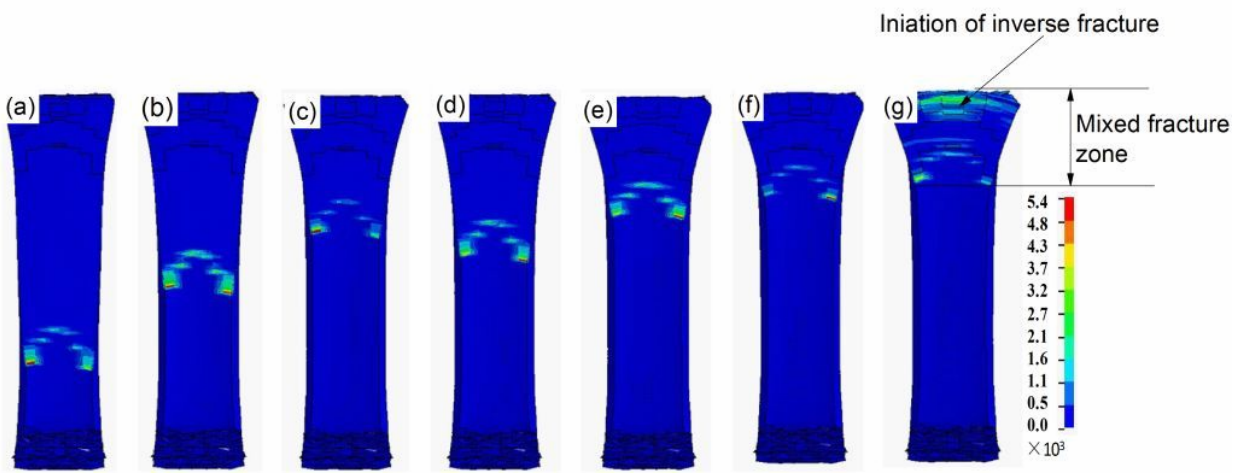

Fig. 7 Effective strain rate distribution in DWTT samples (s^{-1})

The appearance of the simulated fracture surface is in close agreement with the experimental results [18] in terms of stress distribution and fracture morphology as shown in Fig.8. Fracture was initiated as cleavage fracture followed by shear fracture, and then an inverse fracture occurred at the impact zone of the sample. Further analyses on ductile-brittle transition will be carried out by developing a coupled brittle/ductile fracture model in the near future. The relationship between the initiation of inverse fracture and the length of mixed fracture zone need to be further investigated.

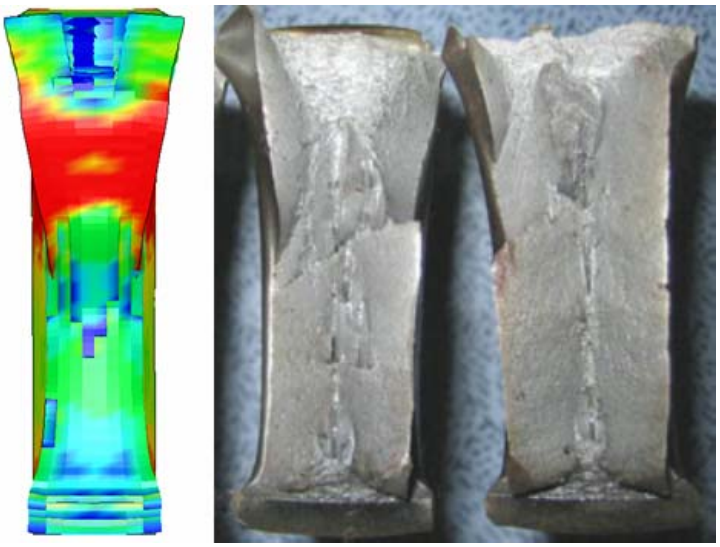

Fig. 8 Simulated results versus the experimental results obtained in ref 18.

4. Conclusions

(1) A finite element model using the Gurson-Tvergaard-Needleman damage model was employed to simulate the fracture process of pipeline steel during DWTT, in particular, considering the state of initial stress around the pressed notch.

(2) During DWTT, the fracture follows a triangular shape in the sample due to higher constraint at

the mid-thickness. This is compatible with the simulation results for void nucleation distribution and effective strain rate distribution.

(3) The simulated results are in good agreement compared with the experimental results in terms of stress distribution and fracture morphology. The relationship between the initiation of inverse fracture and the length of mixed fracture zone need to be further investigated.

Abstract In this paper, applications of friction stir welding in the integral fuselage structure are studied. In order to compare with the traditional riveted stringer panel, the integral panels are joined by two ways: one is by single-row rivets and the other one is by friction stir welding. Two kind finite element models are built by Abaqus 6.10. Stress distributions are analyzed and compared. For welded panel, a FORTRAN program of the SIGINI subroutine is made to input the residual stress profile to the finite element model of friction stir welded panel. Compared with the rivet joint, friction stir welded joint can reduce the weight of fuselage. In the same applied stress, the sample joint with rivets has the higher stress areas around the rivet hole, the sample joint with friction stir welding avoids the stress concentration in junctions.

Keywords Friction stir weld; riveted stringer panel; welded panel; stress distribution.

1. Introduction

Friction stir welding (FSW) is a solid state welding process that has received the world wide attention, particularly for joining aluminum alloys. Because FSW has a lower heat input than the traditional fusion welding, the plastic shrinkage of joint induced by heat in FSW is also lower, which will help to reduce the welding residual stress and distortion of structure. Consequently, FSW has been widely used in modern aero structures.

A significant amount of work has been conducted in the past few years to understand the properties of friction stir welding joints. Aidy studied the crack coalescence in 2024-T351 Al alloy friction stir welded joints and discussed the fatigue endurance of FSW joint [1]. Zhang established the two-dimensional numerical models of friction stir welding and gave the numerical simulation of FSW process [2]. Dinaharan studied the effect of friction stir welding on microstructure, mechanical and wear properties of AA6061/ZrB_2 [3]. Xu studied the residual stress in thick aluminum friction stir welded butt joints [4].

2. Numerical Simulation

2.1 Parameters settings

Finite element analysis is run by Abaqus 6.10. The riveted stringer panel and the welded panel are of the same size (shown in Fig.1). The length of the panel is 1113mm, the width in the middle is 200mm and in both ends is 288mm, and the thickness is 2mm. There are three rows of rivet hole along the direction of the riveted stringer panel width, one of which is located in the middle and the other two rows are located on both sides, 150 mm from the middle rivet holes. Three stringers (shown in Fig.2) will be fixed on the panel by 30 rivets. The width of the surface of the stringer which contacts with the panel is 28mm, the height of the stringer is 28mm, and the thickness is always 2mm in every part of the stringer. The material of panel and stringers is aluminum-lithium alloy, the Young's modulus is 77000 and the Poisson's ratio is 0.33. The material of rivet is 45 steel; two parameters are 210000 and 0.269. Welded panel is joined by welding instead riveting to joint panel and stringers, and the size of the welded panel are the same with the riveted stringer panel except using 10 mm width weld zone to replace the three rows of rivet hole. The material parameters in the weld zone are 55000 and 0.33. After assembly, contact surface between different

parts of the panel has been set up. In the riveted stringer panel, each group of mutually contacting surface are defined as an contact pair, then four contact pairs in the riveted stringer panel were built. In the welded panel, the constraint tie were set up to characterize the welded areas in panel and stringers, other contact areas were defined as contact pairs in same parameters with riveted stringer panel.

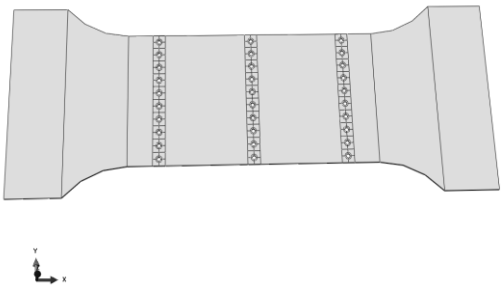

Fig.1 Riveted stringer panel

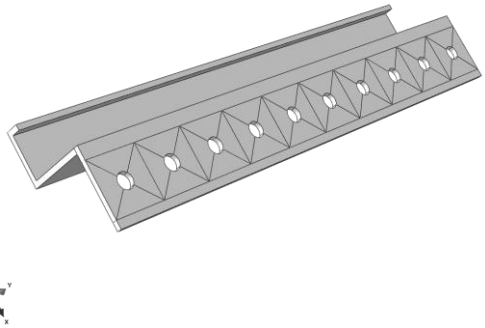

Fig.2 Stringer

2.2 Mesh

Reasonable mesh of complex structure need appropriate partition (Fig.1 illustrates the partition of each part of this panel). In order to get a more accurate calculation result, the rivet must be meshed carefully. The areas around the rivet holes are critical areas where stress concentrate will emerge in tensile load, so these areas also need meticulous grid. Based on this principle, the panel were meshed carefully (shown in Fig.3). Mesh of the welded panel is easier because there is no rivet in welded model.

2.3 Loads

The same load is applied to the two models. 200MPa tensile pressure is loaded along the x direction, in addition, a FORTRAN program of the SIGINI subroutine is made to input the residual stress profile to the finite element model of friction stir welded panel before tensile pressure is loaded.

2.4 Results

Fig.4 shows the numerical simulation result of riveted stringer panel, the high stress areas appears around the rivet holes (especially the middle row) and the curved areas on both sides, the stress in stringers is lower compare with the panel. The maximum stress around the rivet holes reaches more than 600MPa (exceed the ultimate strength of the material) and the stress in the curved areas reaches from 400MPa to 500MPa (shown in Table.1), stress in other areas is much lower than these areas. So the rivets connection areas on the panel may be the first to be destroyed in proper tensile load.

Fig.5 shows the numerical simulation result of welded panel, the high stress areas appears in the top of the welded areas and the curved areas on both sides, stringers are also the low stress areas. The maximum stress in the curved areas is nearly 400MPa, a little higher than 350MPa in the top of the welded areas, however, the tensile strength of the welded area is much lower than the base material (about 70% of the base material), and so the welded areas will be weak zone.

After comparison of the results of two different models show in Table 1, under the same tensile load，stress profile in welded panel is uniform and much lower than it in riveted stringer panel, so we can predict that the welded panel could withstand the larger tensile load than riveted stringer panel.

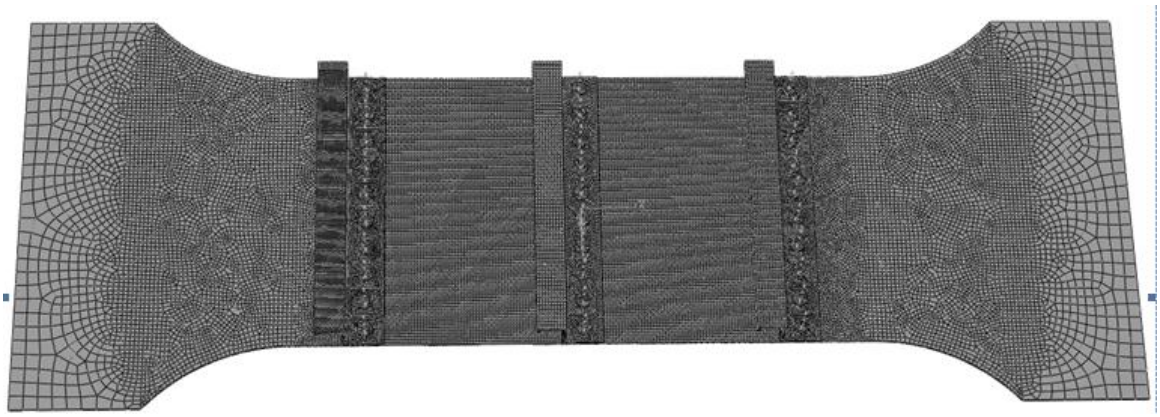

Fig.3 Mesh of riveted stringer panel

Table.1 Comparison of stress

Stress in Riveted panel (MPa)			Stress in Welded Panel (MPa)		
Panel	Around Holes	Stringers	Panel	Welded Areas	Stringers
<300	>600	<100	<300	200~400	<200

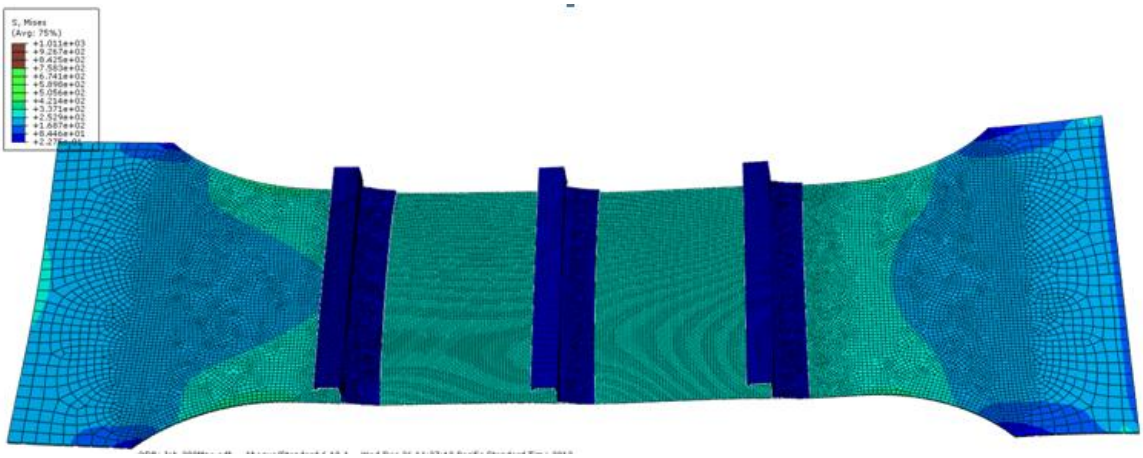

Fig.4 Riveted stringer panel

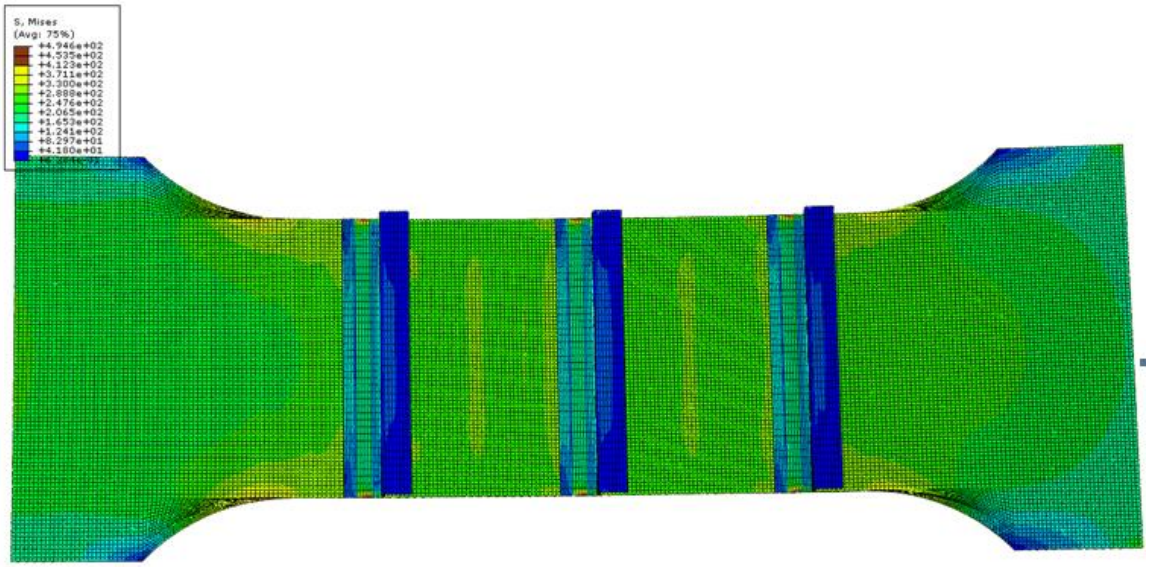

Fig.5 Welded panel

3. Comparison with the Test Results.

Tests were performed to compare this two kinds of structures in tensile load. Six panels consist of three riveted stringer panels and three welded panels were tested by MTS, and the results are shown in Table.2. Two of riveted stringer panels were destroyed in rivet holes on one side and the other one is destroyed in the middle row of rivet holes, the welded panels are all destroyed in welded areas. These results can be used as validation of the numerical simulation.

Table.2 Testing and simulation results

			Simulation Result
	Number	Failure Position	High Stress Area
Riveted panel	1	Left holes	Around holes
	2	Left holes	
	3	Middle holes	
Welded panel	1	Left weld	Welded areas
	2	Middle weld	
	3	Middle weld	

4. Summary

In this study, the main conclusions are

(1) A more uniform stress distribution in welded panel than riveted stringer panel under the same applied stress, the sample joint with friction stir welding avoids the stress concentration in junctions.

(2) The tensile strength of welded structure is higher than riveted stringer structure in certain situation.

Abstract This paper presents the modeling of deformation and failure behavior of dissimilar resistance spot welded joints (RSW) between hot-stamped ultra-high strength (22MnB5) and microalloyed (HC340LAD) steels. To determine the deformation and failure behavior of the different material zones of the weld, tensile and shear specimens, which were cut from the base metals, the weld nugget and heat treated sheets were tested and modeled using the Gologanu-Leblond model coupled with the fracture criteria of Thomason and Embury. The joints were modeled using detailed 3-dimensional finite element models taking into account the different weld zones, i.e. base metal (BM), heat affected zones (HAZ) and weld metal (WM), their dimensions and their mechanical properties. Simulations of the spot welded joints' behavior under shear, axial and combined axial and shear loading were carried out and compared to experimental results such as force vs. displacement curves, load bearing capacities, fracture mode and fracture locations. Maximum loads and force vs. displacement curves from experiments and simulations showed good agreements for all loading situations examined. Despite of its superior strength compared to the microalloyed steel, pull-out fracture of the joints took place in the coarse grain HAZ of the hot-stamped ultra-high strength steel in experiments and simulations.

Keywords Resistance spot welding, Mechanical properties, Combined loading, Failure criterion, Ultra-high strength steel

1. Introduction

With several thousands of spot welds in a body-in-white, spot welding still represents the most widely used thermal joining process in steel-based automotive production. With the development of hot-stamped ultra-high strength steels, new light-weight potentials have been created, that combine thin steel sheets and thereby reduce weight, with a simultaneous optimization of passive safety requirements. To implement these potentials joining technologies have been adapted to ensure a combination of optimized material and joint strength. At present hot-stamped manganese-boron steels (22MnB5) are widely used, especially for load-bearing structural components in parts of the passenger cabin, where deformation and intrusion should be kept at a minimum.
To increase the reliability and accuracy of crash-simulations failure of the joints has to be taken into account using simplified models like solid or beam elements [1][2][3] in combination with simplified mostly force based failure criteria depending on the occurring axial and shear loads acting on the joints. To identify the model parameters of such criteria, failure of the joints can be characterized experimentally under different loading situations, as e.g. shown in [4][5]. For different welding parameters, which lead to a change in the joints' geometry in terms of different diameters of the weld nugget and the heat-affected zone [6], the procedure has to be repeated to determine the load bearing capacities of each particular joint.
In this work the deformation, fracture and load bearing capacity of dissimilar spot welds between hot-stamped and microalloyed steels is investigated in detailed finite-element simulations in several loading situations such as pure shear and pure axial loading as well as combined axial and shear loading. Material data for the modeling of the different material zones of the weld were obtained in tensile, notched tensile and double notched shear tests. The material models calibrated based on these tests are used for the simulation of experiments on spot-welded tensile-shear, KS2- and coach-peel specimens.

2. Experimental results

2.1. Dissimilar spot welded joints between ultra-high strength and low-alloyed steels

The joints investigated in this work are dissimilar resistance spot welded joints between a hot-stamped ultra-high strength steel (22MnB5) with a nominal ultimate tensile strength (UTS) of 1500 MPa and a microalloyed high strength low-alloy steel (HC340LAD) with an UTS of 415 MPa. Spot welding and testing of spot welded KS2-specimens was carried out at the Laboratory for Materials and Joining Technology (LWF) at the University of Paderborn [7].
On the left Fig. (1) shows the etched cross section of the dissimilar joint. The upper sheet shows the microalloyed HC340LAD with a sheet thickness of 1.5 mm. The hot-stamped 22MnB5 steel sheet with a thickness of 1.0 mm can be seen as the lower sheet in Fig. (1) (left). The averaged weld nugget diameter measured from cross-sections of three different spot welds was 5.2 mm.

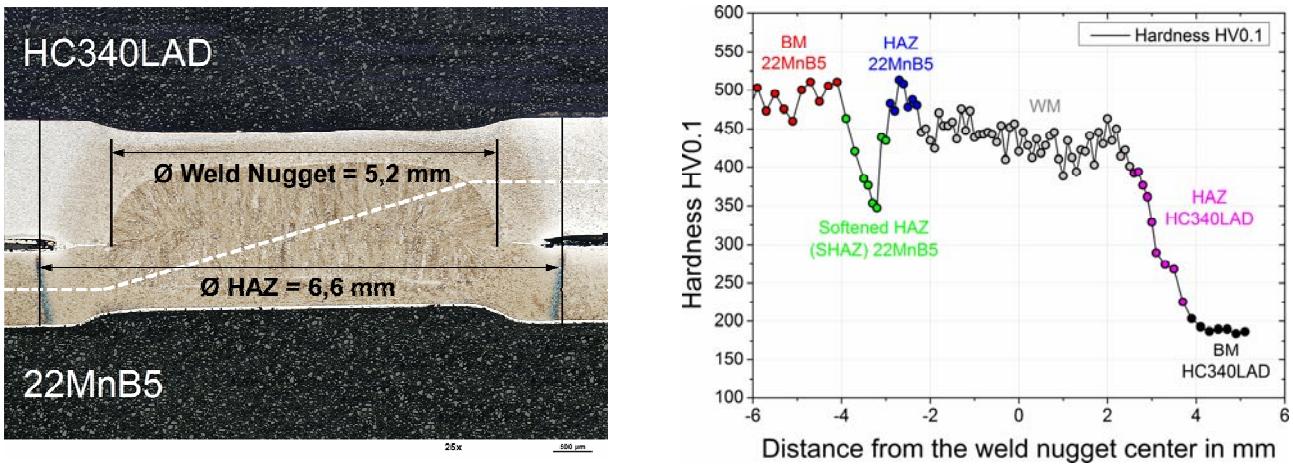

Figure 1. Etched cross section (left) and hardness measurements along the dashed white line shown in the cross section of the investigated spot welded joint between hot-stamped 22MnB5 and HC340LAD (right)

The base metal (BM) of the microalloyed steel shows a ferritic-perlitic microstructure with a hardness of 190HV0.1. Inside its HAZ the microstructure is ferritic-bainitic and a continuous increase in hardness up to 380HV0.1 adjacent to the weld nugget can be observed. The microstructures of the BM and the HAZ of the hot-stamped 22MnB5 are fully martensitic with averaged hardness values of 475HV0.1. Inside the subcritical HAZ a significant decrease in hardness can be seen. Due to the heat input during spot welding tempering of the martensitic microstructure occurs in this region (SHAZ) and leads to softening of the material. This phenomenon has also been observed during spot or laser welding of dual-phase steels as e.g. shown in [8]. The microstructure of the weld metal (WM) of the dissimilar weld is martensitic and has slightly lower hardness values than the BM and the HAZ of the hot-stamped manganese-boron steel.

2.2. Testing of dissimilar spot welded joints

The mechanical behavior of the dissimilar spot welded joints was characterized under shear, axial and combined axial and shear loading conditions using different tests and specimens such as tensile-shear- (TS), LWF-KS2- and coach-peel (CP) specimens. The LWF-KS2 concept [9] is based on double-U formed specimens, which are spot welded in their center and tested under different loading angles and/or velocities using different clamping conditions. The CP- and the KS2-specimen as well as the fixtures of the KS2-specimen for tests with different loading angles

are shown in Fig. (2). By using a pin-joint connecting the grips with the specimens fixtures no additional constraining forces arise during loading and only the applied vertical force acts on the joint.

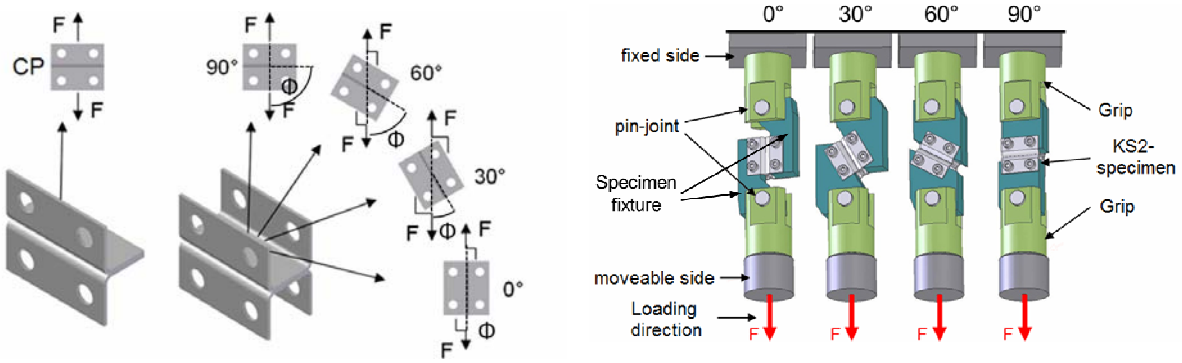

Figure 2. Coach-peel and KS2-specimens with loading angles 0°, 30°, 60° and 90° (left). Clamping conditions for the KS2-specimens tested under different loading angles (right) [9]

Assuming constant loading angles Φ, defined as the angle between the joining plane and the loading direction during deformation of the specimens, the measured forces F in KS2-experiments can be decomposed into their axial F_N and shear F_S parts as

$$F_N = F \cdot \sin\phi\,, \qquad F_S = F \cdot \cos\phi\,. \tag{1}$$

Based on this decomposition simplified force-based failure criteria for spot welded joints as proposed by several authors [4][10][11] can be constructed. Fig. (3) (left) shows the force vs. displacement curves of all the KS2-experiments carried out on the investigated dissimilar spot welded joint. The decomposition of their load bearing capacities assuming constant loading angles is shown on the right. The gray dashed circular lines in Fig. (3) (right) indicate lines of constant resulting forces. The highest maximum load of the joint was measured under shear loading conditions in experiments on KS2-0° specimens. With increasing loading angles the load bearing capacity of the joint decreases to a minimum of 4.2 kN under pure axial loading in KS2-90° tests. Fracture of all tested specimens occurred as pull-out fracture from the hot-stamped 22MnB5 sheets. Cross-sections of failed specimens, loading capacities and results of TS- and CP-specimens will be shown in section 3.3.

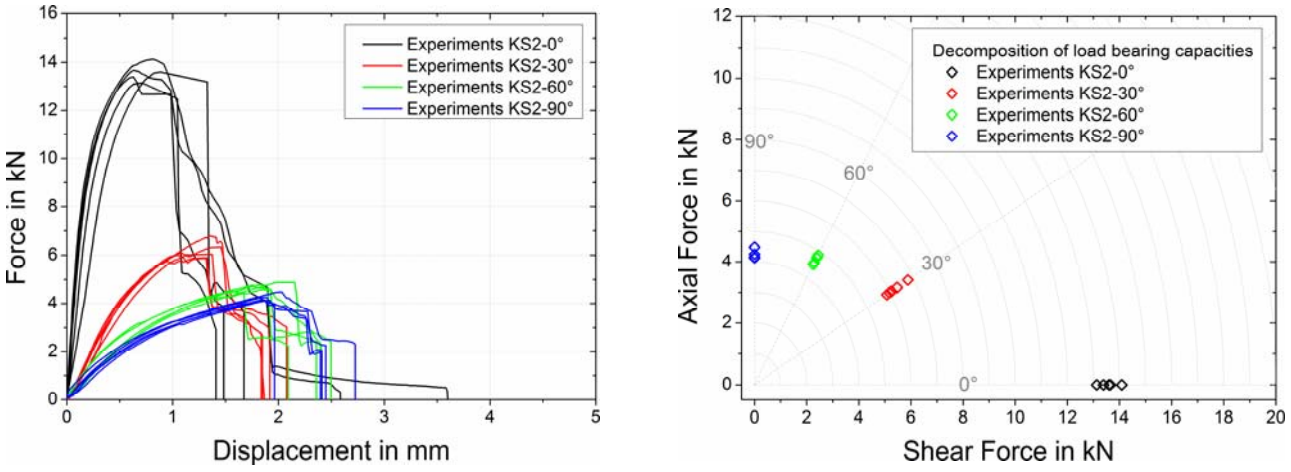

Figure 3. Force vs. displacement curves of KS2-specimens with loading angles 0°, 30°, 60° and 90° (left). Decomposition of load bearing capacities of the KS2 experiments into axial and shear forces (right)

3. Modeling of deformation and failure behavior of dissimilar spot welded joints

3.1. Material model

The constitutive model developed by Gologanu and Leblond [12] for porous media is an extension of the Gurson model [13] which takes into account the effect of void shape. In addition to the porosity *f*, the void shape *S* or *w* is considered in the flow potential of the model. Considering an oblate or prolate axisymmetric spheroidal void, shown in Fig. (4), with the semi-axes a along the x_2-(axial direction) and b along the x_1- and x_3-direction (radial direction), *w* and the *S* are defined as $w=a/b$ and $S=ln(a/b)=ln(w)$. Spherical voids are characterized by $S = 0$ and $w = 1$ respectively. The shape parameters for prolate voids are $S > 0$ and $w > 1$, while $S < 0$ and $w < 1$ is true for oblate voids.

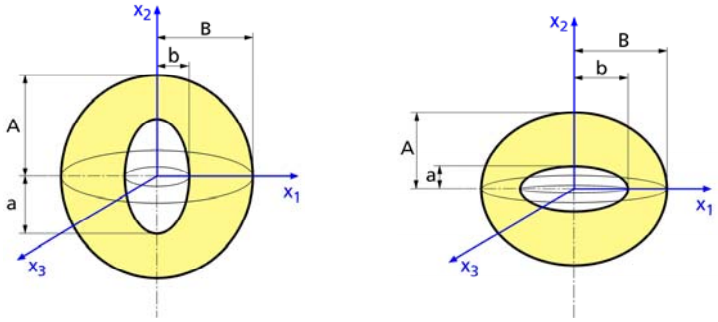

Figure 4. Spheroidal axisymmetric prolate (left) and oblate (right) void in a representative volume element with the shape of a confocal spheroid with the semi-axis A along x_2 and B along x_1 and x_3

The porosity of the representative volume element is given by

$$f = \frac{ab^2}{AB^2}. \tag{2}$$

The functional form of the flow potential, which was derived by Gologanu using an approximate load limit-analysis, is given in Eq. (3).

$$\Phi = C\frac{\|T_{ij}\|^2}{\sigma_M^2} + 2q_1(g+1)(g+f)\cosh\left(\frac{\kappa\Sigma_h}{\sigma_M}\right) - (g+1)^2 - q_1^2(g+f)^2 = 0 \tag{3}$$

with

$$\|T_{ij}\| = \sqrt{\frac{3}{2}T_{ij}T_{ij}} \tag{4}$$

T_{ij} and Σ_h are anisotropic generalizations of the deviatoric and the hydrostatic stresses. σ_M is the equivalent yield stress of the matrix material. The parameters *C*, q_1, *g* and κ are functions of the void volume fraction *f* and the void shape *S*. The evolution of the void shape $\dot{S}$ and the porosity in terms of the rate of void growth $\dot{f}_{growth}$ and nucleation $\dot{f}_{nuc}$ are given in Eq. (5) and Eq. (6) – (8).

$$\dot{S} = S_a\dot{\varepsilon}_a^{p'} + S_b\dot{\varepsilon}_{kk}^{p} \tag{5}$$

The parameters S_a and S_b are functions of the void shape and the stress triaxility. $\dot{\varepsilon}_a^{p'}$ and $\dot{\varepsilon}_{kk}^{p}$ are the deviatoric part of the plastic strain rate in the direction of the semi-axis a and the rate of

volumetric strain. Compared to the Gurson model, no modifications are needed to describe the evolution of porosity. The rate of f consists of two terms describing growth and nucleation of voids.

$$\dot{f} = \dot{f}_{growth} + \dot{f}_{nuc} \tag{6}$$

Void growth is governed by the rate of volumetric plastic strain, whereas void nucleation is assumed to be controlled by the equivalent plastic strain $\varepsilon_{pl,M}$ of the matrix material. Under the assumption that void nucleation follows a normal distribution, its rate is given by Eq. (8).

$$\dot{f}_{growth} = (1-f)\dot{\varepsilon}_{kk}^{pl} \tag{7}$$

$$\dot{f}_{nuc} = \frac{f_n}{S_N\sqrt{2\pi}} \exp\left(-\frac{1}{2}\left(\frac{\varepsilon_{pl,M}-\varepsilon_N}{S_N}\right)^2\right)\dot{\varepsilon}_{pl,M} \tag{8}$$

f_n denotes the overall volume fraction of void nucleating inclusions, ε_N is the mean value of the equivalent plastic strain, at which inclusions nucleate voids and S_N is the standard deviation of the normal distribution.

Together with the Gologanu model the fracture criteria of Thomason [14], in a modified version of Pardoen and Hutchinson [15], and Brown and Embury [16] are used. The Thomason model assumes that void coalescence begins once the plastic limit load on the ligament between the voids is reached. The limit load is derived using an axisymmetric unit-cell containing one ellipsoidal void of a regular array shown in Fig. (5).

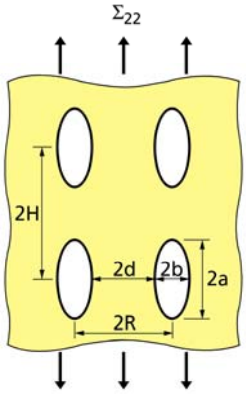

Figure 5. Geometrical quantities of the void distribution used for the Thomason model

The coalescence criterion is then expressed by Eq. (9), where α and β are material parameters. Unit cell analyses suggest to choose α = 0.1 and β = 1.2 [15]. Based on the geometry the ligament size ratio can be written as Eq. (10).

$$C_{\text{Thomason}} = \frac{\Sigma_{22}}{\sigma_M} - \left(1-\left(\frac{b}{R}\right)^2\right)\left(\alpha\left(\frac{R/b-1}{w}\right)^2 + \beta\left(\frac{R}{b}\right)^{1/2}\right) = 0 \tag{9}$$

$$\frac{\mathrm{b}}{\mathrm{R}} = \left[\frac{3}{2}\frac{\mathrm{f}}{\mathrm{w}}\frac{\mathrm{H}_0}{\mathrm{R}_0}\exp\left(\tfrac{3}{2}\varepsilon'_{22}\right)\right]^{1/3} \tag{10}$$

The Gologanu model calculates f, w, Σ_{22} and σ_M in Eq. (9) and (10). The initial aspect ratio H_0/R_0 can be considered, besides α and β, as a third material parameter of the failure criterion.

To model material failure at low stress triaxilities, the criterion of Brown and Embury [16] is used here. This model is based on the assumption that the formation of shear bands takes place in the ligament between two voids and leads to ductile fracture, if the mean radius of a void equals half the distance between the centers of the two voids. Using the void aspect ratio w, calculated by the

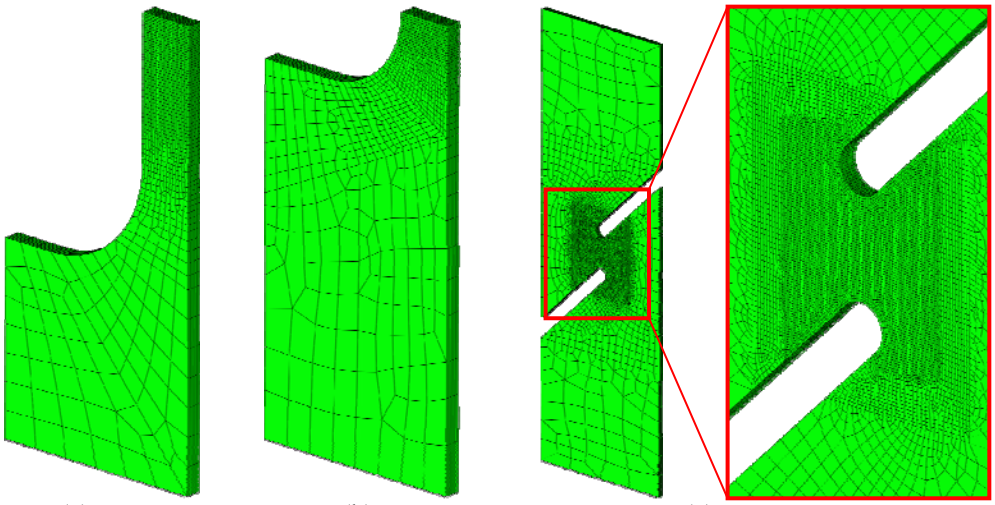
Gologanu model, this criterion can by written as

$$C_{Embury} = \sqrt{1+w^2} - \frac{R}{b} = 0\,. \tag{11}$$

The model has been implemented by Andrieux [17] into the finite element code ABAQUS/Explicit.

3.2. Identification of model parameters of the different weld zones

The parameters of the Gologanu model and the fracture criteria were identified by inverse simulations of smooth and notched tensile specimens as well as double notched shear specimen, which were cut from the base materials, the weld nugget itself and heat treated sheets with microstructures corresponding to the heat affected zones. In case of the specimens cut from the weld nugget reduced dimensions have had to be used, due to the geometry of the weld nuggets. All specimens have been modeled using detailed finite element models meshed with 3-dimensional brick elements with edge lengths of 0.1 mm in the regions of interest. Using the symmetry of the specimens only one eighth of the smooth and notched tensile specimen and half of the double notched shear specimen has been modeled. The finite element models are shown in Fig. (6).



(a) (b) (c)

Figure 6.Finite element models of smooth (a) and notched tensile (b) and double notched shear (c) specimens

Up to uniform elongation the true stress-strain curves of the base material, heat affected zones and the weld metal were measured in smooth tensile tests. Subsequently the true stress vs. true strain curves are determined in simulations of the smooth tensile tests. The damage and failure parameters for the different material zones of the weld were identified by simulating the smooth and notched tensile tests and the shear tests on double notched shear specimens and adjusting the parameters to match the numerical results with the experimental ones. The parameters identified are given in Table (1).

Table 1. Parameters of the material model and the failure criteria

	f_0	ε_N	f_N	S_N	q	S_0	H_0/R_0	α	β
22MnB5 BM	0.002	0.20	0.02	0.1	1.5	0.0001	1.2	0.1	1.2
22MnB5 SHAZ	0.002	0.30	0.008	0.1	1.5	0.0001	1.2	0.1	1.2
HC340LAD BM	0.002	0.85	0.003	0.1	1.5	0.0001	0.5	0.1	1.2
HC340LAD HAZ	0.002	0.15	0.005	0.1	1.5	0.0001	0.5	0.1	1.2
WM	0.002	0.15	0.02	0.1	1.5	0.0001	1.8	0.1	1.2

The comparison of experimental and numerical results for the 5 different material zones is shown in Fig (7) – Fig. (9). The simulation results show good agreements with the experimental measurements for all loading conditions and stress triaxilities. It should be noted that the specimens for the characterization of the weld metal and the smooth tensile specimens from the HAZ of HC340LAD have been manufactured and tested with reduced dimensions and gauge lengths to obtain valid experimental data. The materials' ductility in terms of technical fracture strains in tensile tests cannot be compared in these cases.

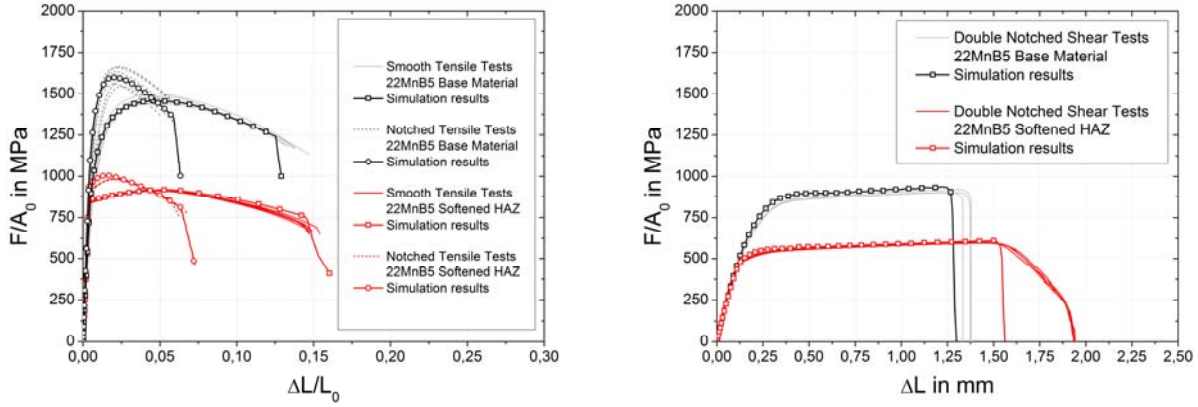


Figure 7. Comparison of measured and calculated F/A_0 vs. $\Delta L/L_0$ curves of smooth and notched tensile tests (left) and F/A_0 vs. ΔL curves of double notched shear tests (right) for 22MnB5 (BM and softened HAZ)

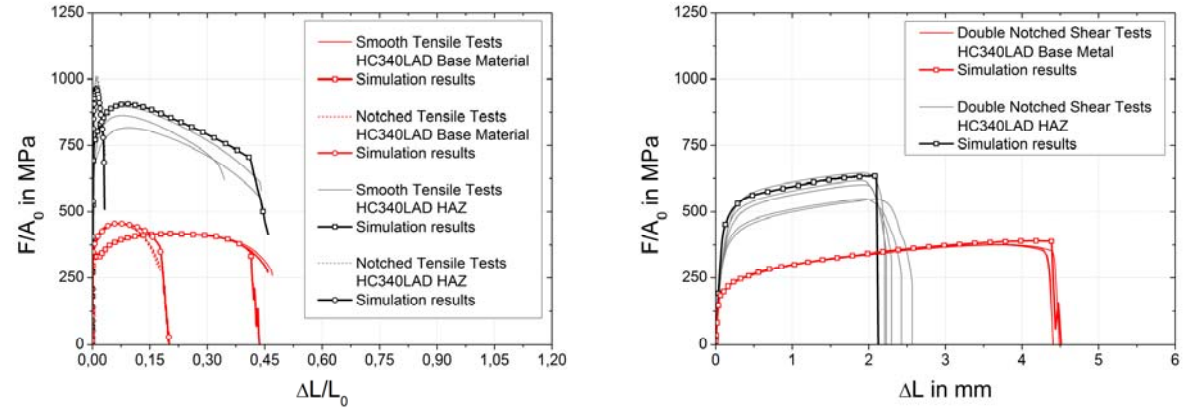

Figure 8. Comparison of measured and calculated F/A_0 vs. $\Delta L/L_0$ curves of smooth and notched tensile tests (left) and F/A_0 vs. ΔL curves of double notched shear tests (right) for HC340LAD (BM and HAZ)

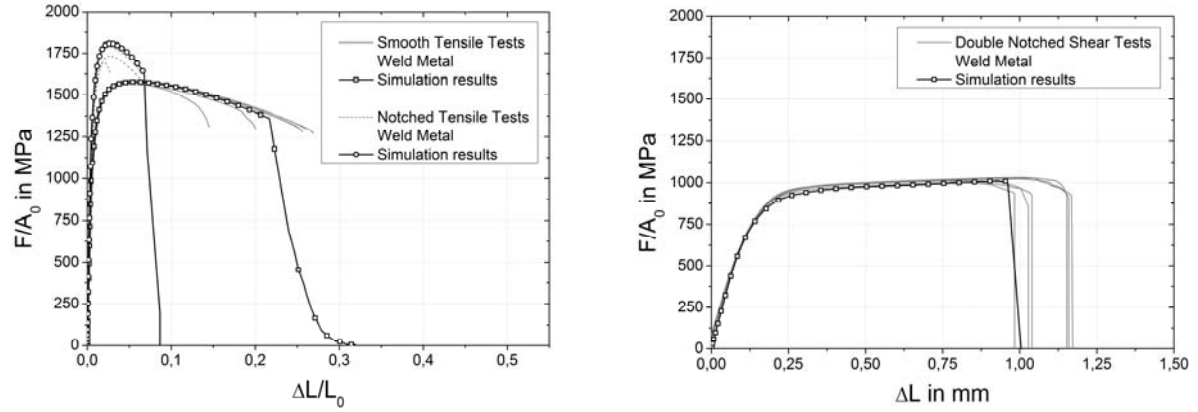

Figure 9. Comparison of measured and calculated F/A_0 vs. $\Delta L/L_0$ curves of smooth and notched tensile tests (left) and F/A_0 vs. ΔL curves of double notched shear tests (right) for the WM

3.3. Simulation of tensile-shear-, KS2- and coach-peel tests

For the simulation of deformation and failure behavior of dissimilar spot welded joints in tensile-shear- (TS), KS2- and coach-peel (CP) tests, the calibrated material and failure models were used for the different material zones of the weld. Due to the negligible differences in the mechanical behavior between the base material of 22MnB5 and the weld metal as well as the similar hardness values of the base metal, the weld metal and the non-softened HAZ in 22MnB5, the mechanical properties of the non-softened HAZ were assumed to be identical to those of the weld metal. A detailed finite-element model of the spot weld, shown in Fig. (10), was built up taking into account the geometry of the weld and its material zones measured in etched cross-sections and hardness measurements of spot welded specimens (see Fig.(1)). The nugget diameter and the diameter of the HAZ of the spot weld were modeled as 5.2 mm and 6.6 mm respectively. The softened HAZ in the hot-stamped 22MnB5 sheet was modeled with a width of 0.6 mm. The edge length of the elements in the spot welded region is approximately 0.1 mm.

Figure 10. Detailed finite element model of the spot weld between 22MnB5 and HC340LAD

The finite-element models of TS-, KS2- and CP-specimens are shown in Fig. (11). Due to the symmetry only one half of each specimen was modeled. The parts of the specimens that are clamped in the experiments, shown in dark gray, are taken as rigid bodies. The grips and the specimen fixtures of the KS2-tests were not explicitly taken into account. Instead of that the clamping conditions of the specimens have been modeled by connecting all nodes of the clamped rigid bodies via kinematic constraints to one node representing the pin-joint between the specimen fixtures and the grips (see Fig. (2)). This is shown schematically in Fig. (11).

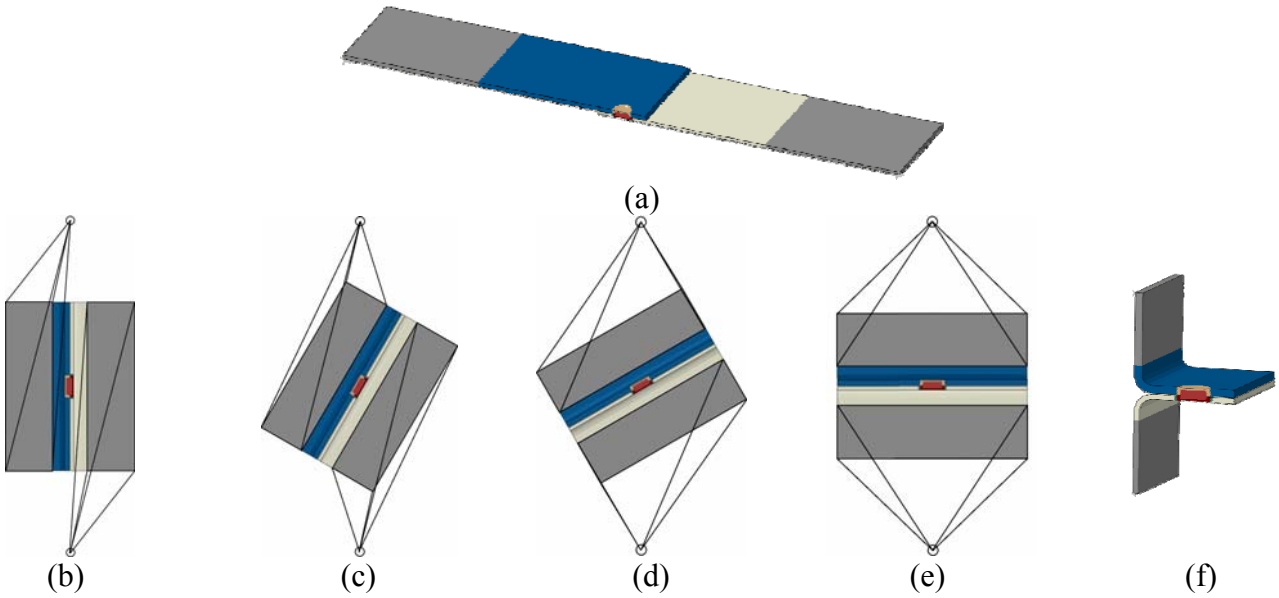

Figure 11. Detailed finite element models of the spot welded tensile-shear specimen (a), KS2-0° (b), -30° (c), -60° (d), -90° (e) specimens and the coach-peel specimen (f)

All simulations were performed using the finite element code ABAQUS/Explicit version 6.9. The calculated force vs. displacement curves for the six different loading situations of the spot welded joints are shown together with the corresponding experimental data in Fig. (12). The measured force vs. displacement curves of all specimens are reproduced well by the numerical results. Also the calculated and experimental load bearing capacities (see Table (2)) agree well.

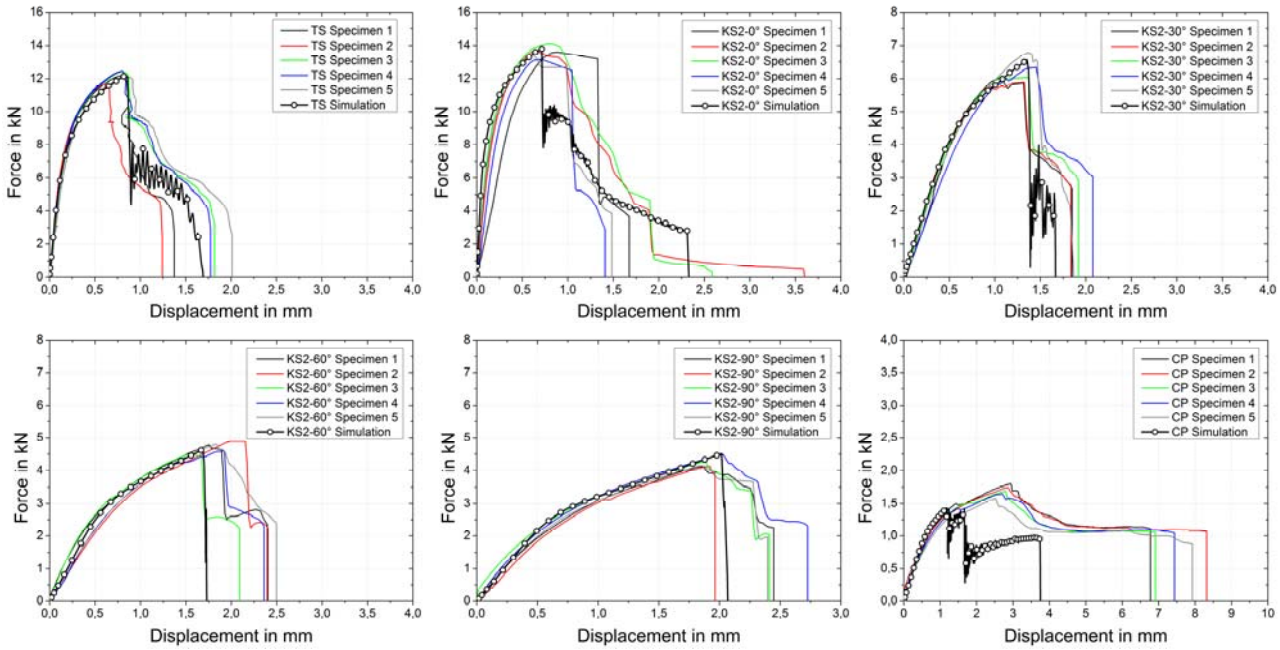

Figure 12. Comparison of measured and calculated force vs. displacement curves for tensile-shear- , KS2-0°, -30°, -60° and -90° and coach-peel specimens

Failure of the joints in shear tests, i.e. TS- and KS2-0° tests, is calculated as pull-out fracture inside the softened HAZ of the hot-stamped 22MnB5. During loading of both of the shear-specimens deformation localizes inside the SHAZ of 22MnB5 leading to pull-out fracture of the joint. Failure of the SHAZ occurs due to the Thomason criterion. The calculated fracture location was confirmed in observations of polished and etched cross-sections of the tested TS-specimens (see Fig. (13)).

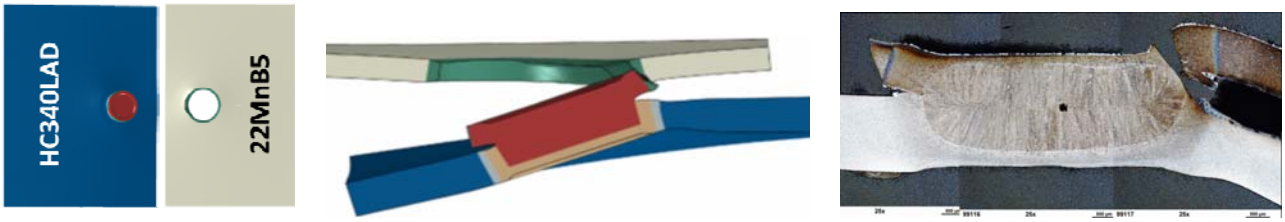

Figure 13. Calculated pull-out fracture of TS-specimen inside the softened HAZ of 22MnB5 (left and middle) Polished and etched cross-section of a tested TS-specimen showing pull-out fracture inside the SHAZ (right)

In pure axial loading situations in KS2-90° tests, pull-out fracture of the joints does not initiate inside the softened HAZ, but occurs inside the coarse grain HAZ of 22MnB5 directly adjacent to the weld nugget. The same fracture behavior is observed under combined loading conditions in KS2-30° and KS2-60° tests as well as in CP-tests. Fracture occurs in the ultra-high strength steel due to the lower sheet thickness and the lower ductility of its HAZ compared to that of the microalloyed steel. In all cases the critical criterion for failure initiation of the joints in simulations was found to be the Thomason criterion. As an example Fig. (14) shows the comparison between calculated and experimentally observed fracture appearance and locations for KS2-90° specimens.

Table 2. Comparison of measured and calculated load bearing capacities of the dissimilar joints

	TS	KS2-0°	KS2-30°	KS2-60°	KS2-90°	CP
$F_{max,av}$ Exp.	12.16 kN	13.57 kN	6.20 kN	4.67 kN	4.20 kN	1.66 kN
F_{max} Sim.	12.19 kN	13.78 kN	6.56 kN	4.64 kN	4.51 kN	1.43 kN
Deviation in %	+ 0,25	+ 1,55	+ 5,81	- 0,64	+ 7,38	-13,86

Figure 14. Calculated pull-out fracture of KS2-90° specimen (left and middle). Polished and etched cross-section of a tested KS2-90° specimen showing fracture inside the coarse grain HAZ of 22MnB5 (right)

Based on the simulations of TS- and KS2-specimens the applied loads were decomposed into axial and shear forces according to the current loading angles during deformation of the specimens as shown in Fig. (15). It can be seen that the loading angles of all specimens, except the KS2-90° specimen, which is loaded under pure axial forces, deviate from their original values due to rotation of the weld nuggets during deformation. In KS2-60° and KS2-30° tests only minor rotations of the weld occur. Therefore the deviation from their original loading angle is negligible. In this case the measured load bearing capacities from experiments could be directly decomposed into their components to be used as values for the adjustment or construction of force-based failure criteria. In shear loading conditions larger weld rotations were observed. Up to the maximum forces rotations of 12.2° and 9.6° were calculated for TS- and KS2-0° specimens respectively. Caused by the rotation the axial forces acting on the joints increase to 2.6 kN for TS- and 2.3 kN for KS2-0° specimens. The assumption of constant loading angles for the adjustment or the construction of simplified force based failure criteria should not be made in this case, but can be taken from numerical simulations.

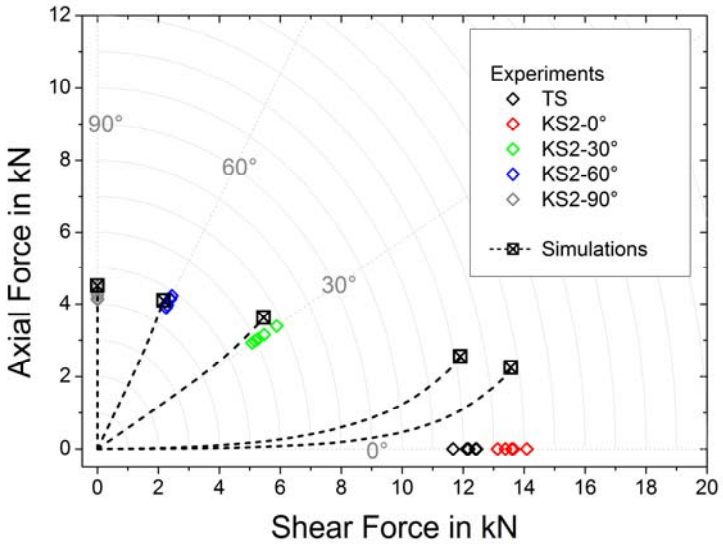

Figure 15. Decomposition of measured and calculated load bearing capacities into axial and shear forces acting on the joint. The evolution of axial and shear forces during deformation of the specimens in simulations are shown by the dashed black lines

4. Conclusion

Based on the calibrated Gologanu material models and failure criteria of Thomason and Brown and Embury for the different material zones of resistance spot welded joints between the hot-stamped ultra-high strength steel and the microalloyed HSLA steel, the joints' behavior in terms of force vs. displacement curves, load bearing capacities, fracture mode and fracture locations can be calculated using detailed finite-element models according to the joints geometry. In the cases investigated pull-out fracture of the joints under shear loading took place inside the softened HAZ of 22MnB5 due to localization of plastic deformation. Under combined axial and shear loading as well as under pure axial loading situations a change in fracture location can be observed. In these cases fracture occurred as pull-out fracture in the coarse grain HAZ of 22MnB5 directly adjacent to the weld nugget. Fracture initiation of all joints is calculated due to the Thomason criterion.
The evolution of axial and shear forces acting on the weld during different loading situations could be obtained by decomposing the applied loads into their axial and shear components according to their true loading angles. Such results can be used for the adjustment or the identification and construction of simplified force based failure criteria used for simplified spot weld models in crash simulations. Furthermore, factors influencing the load bearing capacity of the joints, as e.g. sheet thickness, weld nugget diameter or other geometrical quantities can be investigated by means of detailed finite-element modeling of spot welded joints between the investigated materials without further experimental effort.

Abstract Friction Stir Welding (FSW) is a new type of solid-state connection which can reduce structural weight significantly. In this paper, fatigue tests and finite element analysis were employed to study fatigue properties of aerial aluminum alloy 2524-T3 FSW joint and lap joint. The S-N curves of specimens show that the fatigue strength of FSW joint is better than that of lap joint. Finite element models of two joints were established by ANSYS software. The residual stress of FSW joint were obtained by a nonlinear direct coupled-field analysis, and the detailed stress distribution of lap joint which under pulling force were simulated. On the basis of finite element analysis results, the fatigue lives of two types of joints were estimated. It is verified that the analytic and estimated results agree with that of experiment. The residual stress is the main factor affecting the fatigue life of FSW joint and the failure of lap joint is mainly caused by stress concentration of hole edge.

Keywords Friction stir welding, Fatigue test, S-N curve, Finite element analysis, Lap joint

1. Introduction

Friction stir welding (FSW) [1] is a new solid-state joining technology invented at the welding institute (TWI) of Britain in 1991. It is a technique well suit for joining many hard-to-weld metals without filler materials. Compared with traditional bolt or rivet jointing techniques, FSW can reduce connective weight significantly and has higher link efficiency. In order to reduce design, manufacture, and maintenance costs, FSW is applied to the fabrication of aircraft primary structures. In North America, Eclipse Aviation has developed the Eclipse 500 business jet, utilizing FSW in both wing and fuselage skin-stiffener-frame fabrication [2].

Extensive research has been carried out on FSW with the wide application of this technology. In order to improve the mechanical properties of FSW joint, many studies have been performed on welding procedure and microstructure of joint, and many researchers have explored the thermomechanical numerical simulation technology of FSW.

Thermal and mechanical behaviors are mutually dependent during the FSW process. Many researchers [3-7] have simulated this process by finite element method and have obtained the distribution of residual stress, but they didn't discuss the relationship between residual stress and fatigue life of FSW joint. Furthermore, reference [8] pointed out that the influence of residual stress on fatigue life of FSW joint is a problem need to be solved.

Reference [9] has studied the fatigue properties of aerial aluminum alloy 2524-T3 base metal specimens and three different sizes of FSW joints, fatigue tests have been carried out and the S-N curves have been obtained. Although the fatigue properties of base metal specimens and FSW joints have been compared, the fracture mechanism of FSW joints has not been identified.

Nowadays, structures such as skins and stringers are jointed together by bolts or rivets in most aircrafts, however, the comparative study on fatigue properties of FSW joint and bolt or rivet

connected joint is rare. In this paper, fatigue tests and finite element analysis (FEA) were employed to study the fatigue properties of 2524-T3 FSW joint and riveted lap joint. Test results show that the fatigue strength of FSW joint is better than that of lap joint. The residual stress of FSW joint and the detailed stress distribution of lap joint were obtained by FEA. Furthermore, the fatigue life of FSW joint was estimated according to the result of residual stress distribution and base metal S-N curve; the fatigue life of lap joint was estimated according to the results of stress-strain distribution and local stress-strain method.

2. Experiments

Fatigue tests of FSW joint specimens and lap joint specimens were made by machine MTS-810-500 at room temperature, just as shown in Fig.1 and Fig.2.

Figure 1. Fatigue test of FSW joint specimen

Figure 2. Fatigue test of lap joint specimen

2.1. Specimens and Fixture Design

Two types of specimens, which simulate different connective types of skins in airframe, are shown in Fig.3 and Fig.4. Pieces of specimens are made of aluminum alloy 2524-T3 and rivets are made of titanium alloy TC4. FSW joint specimens were produced by machine FSW2-4CX-006. The tool shoulder diameter is 8mm. The pin is cylindrical with a hemispherical tip, its dimensions are 2.6mm in diameter and in 1.7 mm length. The tool rotation speed is set at 1000 rpm, and the translation speed is fixed at 100mm/min. While the rotating tool moves along the welding line, a forging pressure of 1.5kN is applied. Lap joint specimens are connected by staggered rivets.

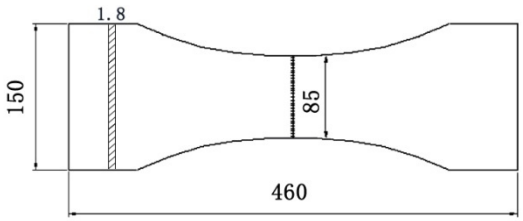

Figure 3. FSW joint specimen (mm)

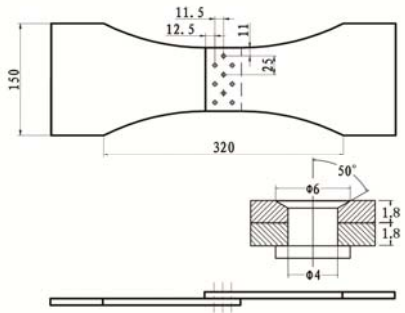

Figure 4. Staggered riveted lap joint specimen (mm)

The weight of lap joint specimen and FSW joint specimen are 297g and 271g separately. This means the FSW technique could reduce structural weight significantly than traditional jointing techniques.

For the purpose of simulating the actual force condition, anti-bend fixtures were designed for lap joint specimens, just as shown in Fig.5. The anti-bend fixture I and II are designed to prevent out-of-plane bending and the function of shims is to ensure specimens loaded in the same plane. In order to reduce the friction between specimens and fixtures during test, some effective measures were applied such as injecting lubricant oil or inserting plastic films between contact surfaces.

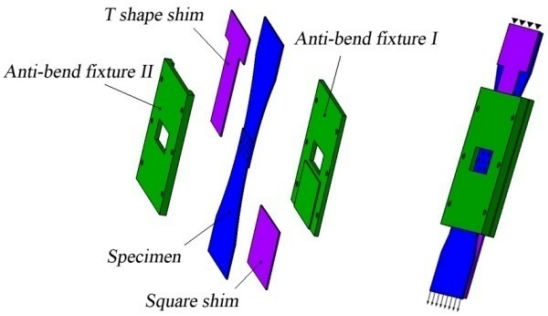

Figure 5. Configuration of anti-bend fixtures

2.2 Fatigue test

All specimens were subjected to constant amplitude loads; the stress ratio R=0.06 and the load frequency f=10. In order to obtain S-N curves, each type of specimens were divided into three groups, which loaded under different stress levels (illustrated in Table 1).

Table 1. The maximum stress endured by different types of specimens during fatigue test (MPa)

	FSW specimen	Lap joint specimen
1	240	150
2	210	120
3	180	100

2.3 Test results

Fig.6 shows the fracture forms of specimens. The fracture position of FSW specimens locates on the thermomechanical affected zone and the lap joint specimens break on the line of the first row of rivets.

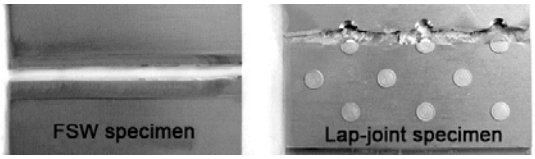

Figure 6. Fracture forms of two type specimens

Chauvenet criterion was used for all test results to abandon dubious data. And S-N curves of two

type specimens were obtained by group test method, the formulas of S-N curves are,

$$\text{FSW specimen:} \quad N=1.89\times10^{11}(S-122)^{-3.36}, \tag{1}$$

$$\text{Lap joint specimen:} \quad N=1.18\times10^{8}(S-72.9)^{-1.84}. \tag{2}$$

S-N curves are illustrated in Fig.7.

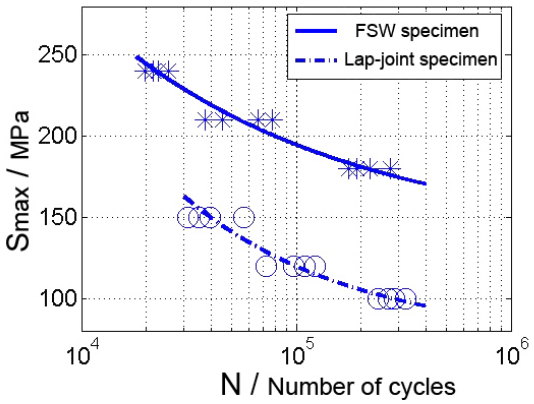

Figure 7. S-N curves of two type specimens

The S-N curves show that the fatigue strength of FSW joint is better than that of lap joint. At the fatigue life of 1×10^5 cycles, the fatigue strength of FSW joint (195MPa) is about 61% higher than that of lap joint(120MPa).

3. Finite element analysis

In order to reveal the fracture mechanism of two jointing techniques, three-dimensional elasticplastic FEA for two types of specimens was conducted by ANSYS 14.0 software.

Through FEA, the residual stress of FSW joint and detailed stress distribution of lap joint were obtained, and both of them provide necessary conditions for life prediction.

3.1 FEA of FSW joint

FSW is a coupled-field (structural-thermal) process. The temperature field affects the stress distribution during the entire process. Also, heat generated in structural deformation affects the temperature field. In this paper, a direct FEA of coupling is developed using a coupled-field element SOLID226. The simulation occurs over three load steps, representing the dwell, traverse and cool phases. The schematic diagram of FEA model is shown in Fig.8.

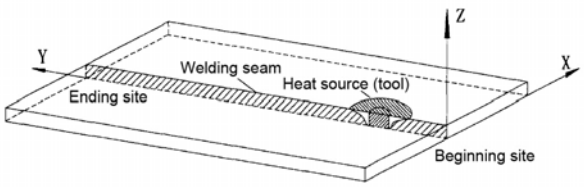

Figure 8. Schematic diagram of FEA model

The material properties of aluminum alloy 2524-T3 are shown in Table 2.

Table 2. Material properties of aluminum alloy 2524-T3

Temperature(℃)	25	150	300	500
Young's modulus(GPa)	68	60	51	38
Poisson's ratio	0.31	0.32	0.33	0.35
Density(kg/m^3)	2810	2785	2750	2708
Coefficient of thermal expansion(um/m℃)	23	25.5	29	33
Yield stress(MPa)	370	330	115	50
Tangent modulus(GPa)	23.5	22	19.8	17
Thermal conductivity(W/m℃)	120	134	146	159
Specific Heat(J/kg℃)	860	920	980	1050

The temperature rises at the contact interface due to frictional contact between the tool and workpieces. FSW generally occurs when the temperature at the weld line region reaches 70 to 90 percent of the melting temperature of the workpiece material [10].

A moving heat source was used to simulate the heat generated by friction. Meanwhile, a moving pressure of 1.5kN is applied synchronously to simulate the forging pressure of tool.

According to reference [11] and [12], the heat flux density of shoulder is expressed as,

$$q_s = \frac{\pi\omega\mu P(R_1^2 + R_1R_2 + R_2^2)}{45(R_1 + R_2)}, \tag{3}$$

and the heat flux density of stirring pin is,

$$q_p = \frac{\pi\omega\mu PR_2(1.5h+1)}{45}. \tag{4}$$

where,

ω: Rotating speed of tool, μ: Friction coefficient, P: Forging pressure of tool,

R_1: Radius of shoulder, R_2: Radius of stirring pin, h : Height of stirring pin.

The boundary conditions include thermal boundary conditions and mechanical boundary conditions. On the top and side surfaces of the workpiece, convection and radiation account for heat loss to the ambient [4], the value of the convection coefficient is set as 30 W/m^2℃. Conduction losses also occur from the bottom surface of the workpiece to the backing plate, and a high heat-transfer coefficient of 300 W/m^2℃ is set. The workpiece is fixed by clamping plate [4], and the clamped portions are constrained in all directions. To simulate support at the bottom of the backing plate, all bottom nodes of the workpiece are constrained in the Z direction.

The simulated FSW process consists of three primary phases: dwell, traverse and cool. Three load

steps are applied corresponding with the three phases. Dwell phase means the heat source dwells at the initial position until the temperature reaches to the value required for the welding. Traverse phase means the rotating tool moves along the welding line, this is the most important phase during FSW. During the cool phase, the temperature of workpiece drops to initial value (25 ℃) and then the fixture will be removed; accurate residual stress of FSW joint will be obtained after this phase.

The temperature distribution during the second load step is shown in Fig.9. The melting temperature of aluminum alloy 2524 is about 550℃, and the maximum temperature at the welding line is well below it.

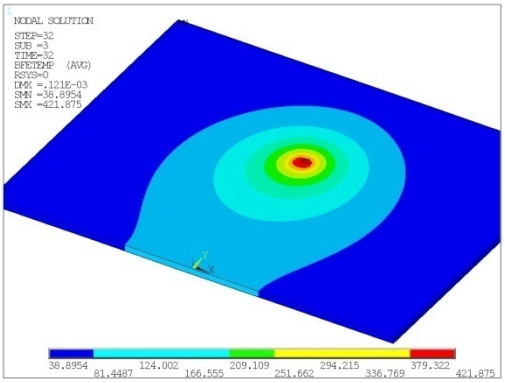

Figure 9. Temperature distribution during load step 2

The distribution of residual stress (X direction) after the third load step is shown in Fig.10. The residual stress distribution of middle site is different from that of the beginning and ending site. Because the FSW joint specimens are cut out from a big workpiece, the residual stress distribution of specimens can be considered as that of middle site.

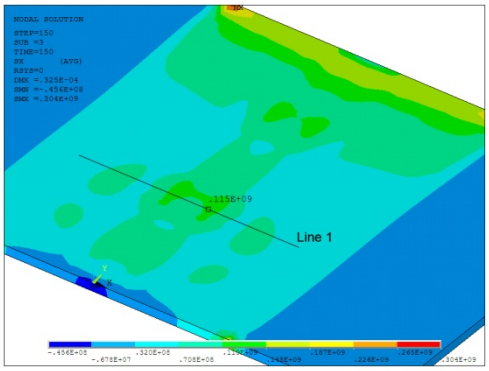

Figure 10. Distribution of residual stress (X direction)

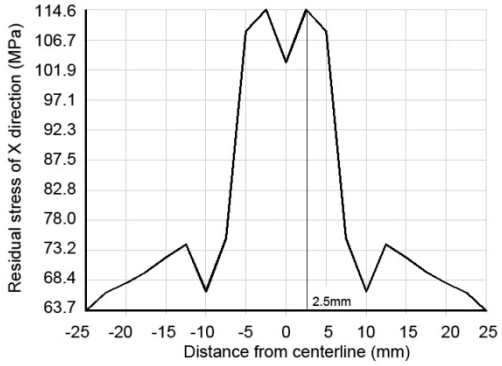

Figure 11. The residual stress distribution of line 1

Fig.11 shows the distribution of residual stress of line 1 (Fig.10). The maximum stress is 115MPa at the point of 2.5mm from the weld center, which shows a good agreement to the fracture position of FSW specimen.

3.2 FEA of lap joint

Three-dimensional lap joint specimen model is created as shown in Fig.12. The full scale joint is modeled considering the features of material nonlinearity, out-of-plane bending, pin-load and friction contact.

Both the pieces and rivets are meshed by 10 nodes tetrahedron solid element SOLID92. All the possible contact areas are modeled, and the rivets are modeled as 'neat fit' to holes and plates. The surface of model has the same displacement restriction as the specimen for the best boundary condition approximation.

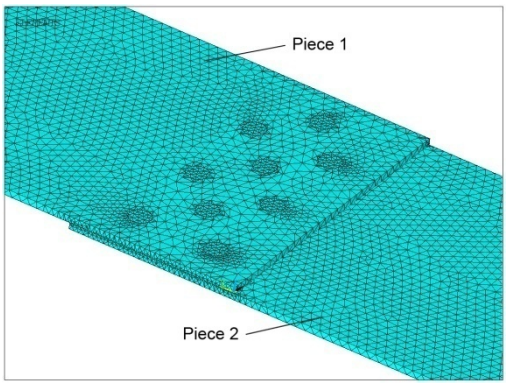

Figure 12. Finite element model of lap joint specimen

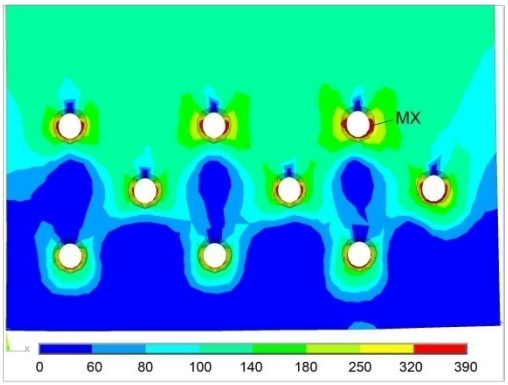

Figure 13. Von Mises stress of piece1

Three-DOF constrain was applied on one side of the model, and pulling stress (120MPa) was evenly applied on the other side. Fig.13 shows the stress distribution of piece 1.

The maximum stress concentration of lap joint locates on the right hole's edge of the first rivets row, it shows an excellent accordance with the crack initiation locations observed in tests. The maximum stress is 385MPa and the maximum strain is 0.0068 when the pulling stress is 120MPa; the maximum stress is 59.8MPa and the maximum strain is 0.00088 when the pulling stress is 7.2MPa.

4. Fatigue life estimate

In order to verify the validity of simulation method and establish links between FEA and test, fatigue lives of two different joints were estimated.

4.1 Fatigue life estimate of FSW joint

The fatigue life of FSW joint is estimated according to residual stress result and base metal S-N curve [9] on the bridge of *Goodman formula*.

We have known that the maximum residual stress of FSW joint is 115MPa. When the FSW joint under the constant amplitude load spectrum which maximum stress is 180MPa and stress ratio is 0.06 (accord to Fig.7, the fatigue life is 224566), the maximum local stress of joint is 295MPa ($\sigma'_{max}=180+115$) and the stress ratio is 0.42 ($R'=\frac{180\times 0.06+115}{180+115}$).

Assume the decline of fatigue performance of FSW joint is only affected by residual stress. We can estimate the fatigue life of FSW joint by base metal S-N curve according to the maximum local stress of FSW joint.

Goodman formula is used to establish the relationship between the maximum local stress and the base metal S-N curve. *Goodman formula* is a constant life formula, which is expressed as,

$$S_a = S_{-1}[1-\frac{S_m}{\sigma_b}]. \tag{5}$$

where,

S_a : The stress amplitude of load spectrum, S_m : The mean stress of load spectrum,

S_{-1} : Stress amplitude when the stress ratio is -1, σ_b : The ultimate strength of material.

Through calculation, the fatigue life of FSW joint is equal to that of base material specimen under the constant amplitude load spectrum which maximum stress is 247.6MPa and stress ratio is 0.06.

According to Fig.4 in reference [9], the fatigue life of base material specimen which considering the influence of residual stress is 252674 cycles, with an error of 12.5%. This result is basically identical with the experimental one, means that the residual stress is the main factor affecting the fatigue life of FSW joint.

4.2 Fatigue life estimate of lap joint

The fatigue life of lap joint is estimated according to stress-strain results and *local stress-strain method*. Calculation formulas of local *stress-strain method* are shown as,

$$\varepsilon_a = (\varepsilon_{\max} - \varepsilon_{\min})/2, \tag{6}$$

$$\sigma_m = (\sigma_{\max} + \sigma_{\min})/2, \tag{7}$$

$$\varepsilon_a = \frac{\sigma_f^{'} - \sigma_m}{E}(2N)^b + \varepsilon_f^{'}(2N)^c. \tag{8}$$

where,

$\varepsilon_{\max}$, $\varepsilon_{\min}$: The maximum and minimum strain, $\sigma_f^{'}$, $\varepsilon_f^{'}$, E, b, c : Material parameter,

$\sigma_{\max}$, $\sigma_{\min}$: The maximum and minimum stress, N : Fatigue life.

According to the simulation results of FEA, the fatigue life of lap joint is 90400 cycles under the constant amplitude load spectrum which maximum stress is 120MPa and stress ratio is 0.06. The

estimate error is 8.2%, which satisfies engineering demands. The coincidence of estimate result and test result prove that the failure of lap joint is mainly caused by stress concentration of hole edge.

5. Conclusions

This paper has studied the fatigue properties of aerial aluminum alloy 2524-T3 FSW joint and lap joint by fatigue tests and FEA.

The S-N curves of different specimens have been obtained by fatigue tests to compare the fatigue strength of them. It has been shown that the fatigue strength of FSW joint is better than that of lap joint. At the fatigue life of 1×10^5 cycles, the fatigue strength of FSW joints is about 61% higher than that of lap joint.

The three-dimensional elasticplastic FEA for two types of specimens have been developed to explore the fracture mechanism of two jointing techniques. The residual stress of FSW joint were obtained by a nonlinear direct coupled-field analysis, and the detailed stress distribution of lap joint which under pulling force were simulated. The maximum residual stress of FSW joint is 115MPa at the point of 2.5mm from the weld center, and the maximum stress concentration of lap joint locates on the right hole's edge of the first rivets row.

Finally, fatigue lives of specimens have been estimated, and both estimated results agree with that of experiment. Results show that the residual stress is the main factor affecting the fatigue life of FSW joint and the failure of lap joint is mainly caused by stress concentration of hole edge.

Abstract Based on the residual strength diagram of non-stiffened plate construction, a residual strength diagram of hull steel in stiffened plate construction was proposed using the linear-elastic fracture mechanic theory in this work, the effects of loading rate and temperature on the crack arrest behavior of the stiffened plate construction were discussed, the lower limit of the residual strength and the dimension of a valid arrested crack were obtained via the theoretical analysis. The results demonstrated that, whether loading rate or temperature significantly influence the lower limit of the residual strength of the hull steel in a stiffened plate construction; under the conditions of 273K and 293K, the stiffened plate construction is a stiffener critical construction when the applied loading rate $\dot{K}$ is in the order of $\sim 10^5 MPa\sqrt{m}/s$, while under the loading rate of $\sim 10^6 MPa\sqrt{m}/s$, it becomes a skin critical construction due to the decrease of the fracture toughness of the full steel, the lower limit of residual strength is reduced to one fourth of the steel yield strength under this loading condition. In this case, the stiffened shipping construction is no longer adaptable to such a high loading rate, the crack arrest design is therefore highly desirable for protecting the full plate construction.

Keywords stiffened plate, residual strength, crack arrest, loading rate and temperature effect

1. Introduction

In order to enhance strength and stiffness, the stiffened plate construction is always often used in the structure design of the hull. Therefore, it must be considered the effect of stiffener when analyzing the deformation and fracture behavior of hull structure. Vliege and Brock studied the crack propagation behavior and crack arrest characteristic in stiffened plate structure of the plane, and proposed the residual strength diagram of non-stiffened plate structure to analyze and predict the crack propagation characteristic of the stiffened plate structure [1, 2]. The design of crack arrest is an important aspect of ship design, while the study associated with of the crack arrest behavior of hull steel under dynamic loading is quite limited at present. The ships especially naval vessels are often subjected to impact load in their service processing. The fracture toughness of hull steel may be reduced due to the effect of high loading rate, for example, the fracture toughness (K_{IC}) of hull steel used in this paper is $\sim 180 MPa\sqrt{m}$ (loading rate $\sim 10^0 MPa\sqrt{m}/s$) under the temperature ~273K, while the fracture toughness decreases to $\sim 64 MPa\sqrt{m}$ under the loading rate $\sim 10^6 MPa\sqrt{m}/s$, which is one third of static fracture toughness. Thus, it is essential to design ships in terms of crack arrest principle. Based on the linear-elastic fracture mechanic theory and residual strength diagram (when temperature is 273K, $\sim 10^5 MPa\sqrt{m}/s$ and 293K, $\sim 10^6 MPa\sqrt{m}/s$) of the hull, the present paper discusses the crack arrest behavior of the stiffened plate structure of the hull, the conclusions drawn from this work can be used as the reference for the design of crack arrest of the hull steel.

2 Mechanical properties of materials and stiffened plate construction

The hull steel used for skin plate and stiffener of stiffened plate structure is a low alloy steel in this paper, and its mechanical properties of the hull steel are listed in Table 1,

Table 1 The mechanical properties of hull steel

material	σ_s (MPa)	σ_b (MPa)	δ(%)	φ(%)
hull steel	480	580	21.4	74
weld metal	400	505	28	74

The Charpy impact specimens were used in experiments, which firstly were cut notch ~3mm by EDM (electrical charge machine), and then pre-fatigue for achieving a relative crack length a/W≈0.5. The dynamic fracture toughness of hull steel under different loading rate conditions were tested by pendulum impact test ($\sim 10^5 MPa\sqrt{m}/s$) and Hopkinson bar apparatus ($\sim 10^6 MPa\sqrt{m}/s$), respectively. The experimental results are shown in Table 2. The impact energy tested by pendulum impact experiment can be used to calculate the dynamic fracture toughness by the following Equation [3]:

$$K_{\mathrm{Id}}^2 = 1290.17 + 108.03\mathrm{CVN} \tag{1}$$

It can be seen from Equation (1) that the dynamic fracture toughness under loading rate $\sim 10^5 MPa\sqrt{m}/s$ can be obtained using the value of CVN. The dynamic fracture toughness of tested material under higher loading rate $\sim 10^6 MPa\sqrt{m}/s$ can be gained using Hopkinson bar loading apparatus, details for testing procedures can be found elsewhere [4].

Table 2 The dynamic fracture toughness and dynamic strength of hull steel

loading rate	$\sim 10^5 MPa\sqrt{m}/s$		$\sim 10^6 MPa\sqrt{m}/s$	
Temperature (K)	273	293	273	293
$K_{Id}(MPa\sqrt{m})$	119	128	64	74
$K_d(MPa\sqrt{m})$	282	343	71	89
$\sigma_{Yd}(MPa)$	567	565	640	638
$\sigma_b(MPa)$	691	678	774	768

As the dynamic yield strength of tested material is a necessary parameter in next analysis, the dynamic yield strengths under different strain rate and temperature were carried out using dynamic compression test in Hopkisnon bar apparatus in order to investigate the rate sensitivity of this material. Thus the dynamic compression test was carried out on the Hopkinson pressure bar test for determining the dynamic yield strength of hull steel. The relationship between dynamic yield strength and strain rate and temperature can be established as following according to our experimental data:

$$\sigma_{yd} = \sigma_s\left[1+\left(\dot{\varepsilon}/59213\right)^{0.281}\right]\left[1.13\exp\left(-0.0004T\right)\right] \tag{2}$$

Where T is the experimental temperature, σ_s is the yield strength under quasi-static, $\dot{\varepsilon}$ is the strain

rate. Using the Equation (2), the dynamic yield strengths of hull steel under different strain rate and temperature were evaluated and listed in Table 2.

The data listed in Table 2 and the thickness of skin were confirmed to be meet the plane strain condition in terms of ASTM E-399 standard. Therefore, it needed to use the Irwin Equation to transform the data listed in table 2 to plane stress fracture toughness K_d [5, 6]:

$$\beta_{Id}=\frac{1}{B}(\frac{K_{Id}}{\sigma_{yd}})^2 \quad , \quad K_d^{\,2}=K_{Id}^{\,2}(1+1.4\beta_{Id}^{\,2}) \tag{3}$$

The value of plane stress fracture toughness K_d transformed were also listed in Table 2.

The simple stiffened plate construction with two stiffeners was analyzed, as shown in Figure 1. The stiffeners are symmetrically distributed at both sides of central crack 2a, and the crack plane passes through the rivet hole. The stiffener and skin plate are connected by rigid rivet. The corresponding construction parameters are as following: thickness of the skin plate B=24*mm*, sectional area of stiffener A_s=20*mm*×80*mm*, interval of stiffeners b=600*mm*, interval of rigid rivet p=b/12=50*mm*, modulus of elasticity E_s=E=2.1×10^5*MPa*, Reinforcement ratio [7]:

$$\mu=A_sE_s/(A_sE_s+EbB) \tag{4}$$

where E_s is elastic modulus of stiffeners, E is elastic modulus of skin plate. The value of μ is calculated using Equation (4) to be 0.1.

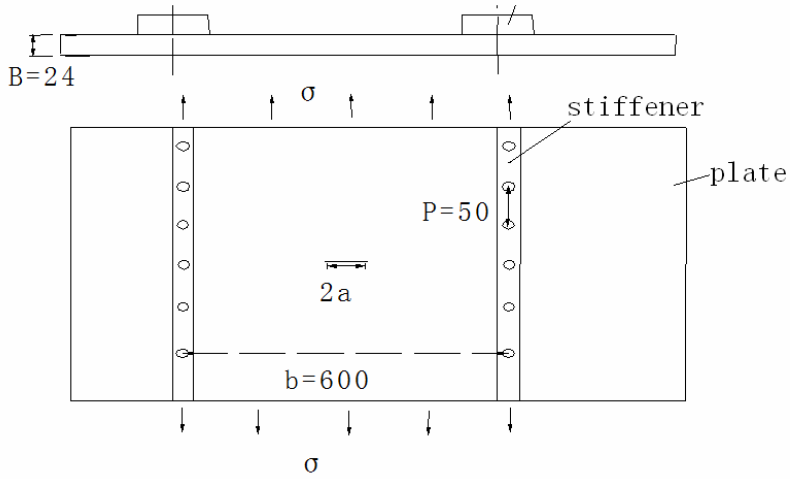

Figure1. Construction diagram of stiffened plate construction

3 The residual strength of stiffened plate construction

According to linear-elastic fracture mechanical theory, the relationship between stress and plane strain fracture toughness is following for the infinite wide plate with a penetrated central crack that bears the average tensile stress in both surface [8].

$$\sigma_c=K_{Ic}/\beta\sqrt{\pi a_c} \text{ (for infinite width plate, a<<w, } \beta=1) \tag{5}$$

Here, σ_c is fracture stress, a_c is the half length of critical crack and K_{Ic} is quasi-static plane strain fracture toughness. If the dynamic fracture toughness does not meet the plane strain condition, the equivalent value must be calculated by Equation (3). According to the Equation (5), the curve of

residual strength of non-stiffened plate can be calculated, that is to say the curve of $\sigma_c - a$ can be computed. However, it must be modified by Fedderson revision [9] when the crack length is quite small.

When stiffened plate construction is subjected to load, partial load would transfer to stiffeners by way of rivet, which lower the stress intensity factor in the crack tip of stiffened plate. Simultaneously, the stress concentration occurs around the stiffeners. The decreasing coefficient of stress intensity factor of crack tip of stiffened plate C is calculated as [10,11] ,

$$C = K_{stiffened} / K_{nonstiffened} \quad (6)$$

where, $K_{stiffened}$ is the stress intensity factor of stiffened plate construction with crack, $K_{nonstiffened}$ is the stress intensity factor of non-stiffened plate construction with crack. It can be seen from Equation (6) that the value of C is less than 1, i.e. C≤1. The coefficient of stress concentration L is written as,

$$L = \sigma_{max} / \sigma \quad (7)$$

where, σ is nominal stress of stiffened plate construction, σ_{max} is concentrated stress of stiffener, the parameters of C and L can be found in the stress intensity factor manual [8].

If the stiffened plate and non-stiffened plate construction with the same crack length fracture under the same stress intensity factor, the following Equation will be exist:

$$\sigma_{cstiffened} = \sigma_{cnonstiffened} / C \quad (8)$$

where， $\sigma_{cstiffened}$ is fracture stress of stiffened plate construction, $\sigma_{cnonstiffened}$ is fracture stress of non-stiffened plate construction. It can be seen from Equation (8) that the fracture stress of stiffened plate increases by 1 / C times. Using the Equation (8), the residual strength curve of stiffened plate construction can be calculated by that of non-stiffened plate construction.

Under the non crack condition, when the stress of stiffeners reaches to tensile strength σ_b, the stiffeners will fracture. Contrary, if the concentrated stress σ_{max} reaches to tensile strength σ_b, stiffeners would fracture. The following Equation can be derived from Equation (7):

$$\sigma = \sigma_b / L \quad (9)$$

Where, σ is nominal stress of stiffeners. According to the Equation (9), failure curve of stiffeners can be attained.

The residual strength curve of stiffened plate construction can be achieved by putting the residual strength curve of non-stiffened plate and stiffened plate construction and the failure curve of stiffener together into a common coordinate system， as shown in Figures 2 and 3.

4 Analysis of the crack arrest behavior of the stiffened plate construction

The residual strength diagram of stiffened plate construction of the hull under the loading rates $\sim 10^5 MPa\sqrt{m}/s$ and $\sim 10^6 MPa\sqrt{m}/s$ at the temperature of 273K and 293K can be determined using

the related data listed in table 2 and Equations (3)-(8), as shown in Figures 2 and 3.

Whether Figure 2(a) and (b) or Figure 3(a) and (b), all of them indicate that for stiffened plate construction with penetrable crack in center, the residual strength curve nearly coincides with that of non-stiffened plate construction when the crack length is small, which shows that reinforcement effect of stiffener is not obvious. When the crack propagated near the stiffener, the amplitude decrease of stress intensity factor become larger due to the load beard by stiffeners increasing, and the stress intensity factor reaches to maximum value while the crack propagates to the central line of stiffeners. At the same time, the residual strength curve of stiffened plate construction is much higher than that of non-stiffened plate construction. The reinforcement effect of stiffener decreases again and the residual strength curve of stiffened plate construction falls with increasing crack

According to the relative position between the failure curve of stiffeners and the residual strength diagram of stiffened plate construction, the crack arrest behavior of the stiffened plate construction includes a stiffener critical construction (Figure 2) and a skin critical construction (Figure 3). In skin critical construction (Figure 3), the unstable expansion of crack is arrested when the lengths reaches a_1' under stress state of σ_1 and the initial length of crack satisfying $a_0<a_1<a_s$. Under this condition, the crack is in stable state. That is to say, any expansion of crack would lead to further increase of the fracture resistance. It can be concluded that crack is in controlled state or crack arrest state. As the stress increased to σ_0, crack would steadily spread to a_s and then unsteadily propagate. Following, the stiffener would fracture because of the high stress applied, which results in structural failure. However, in the skin critical construction, as shown in Figure 2, when crack spread to a_s, since the stress of stiffener reaches its fracture stress, fracture would occur and the reinforced influence of stiffener released. As a result, crack of skins spread instability and led to structural failure.

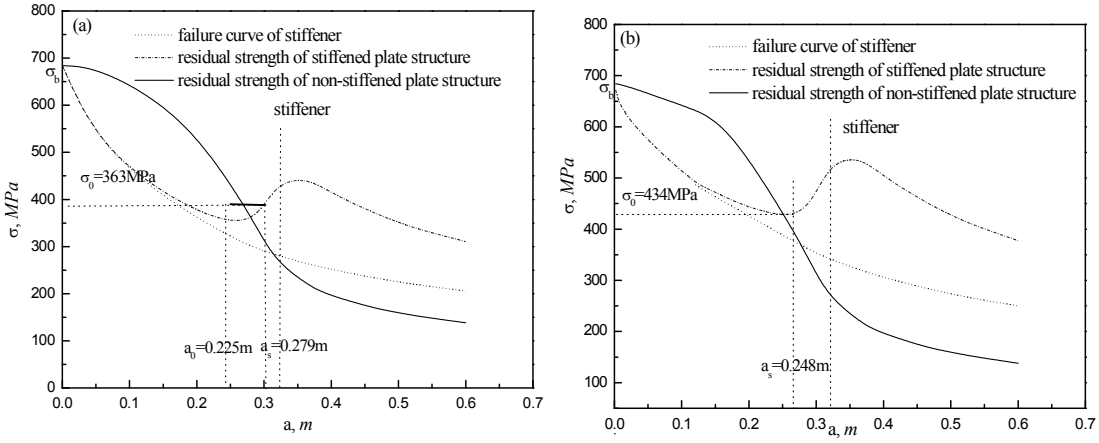

Figure2. Residual strength diagram of stiffened plate construction of the hull under loading rate $\sim 10^5 MPa\sqrt{m}/s$ and temperature 273K (a) and 293K (b)

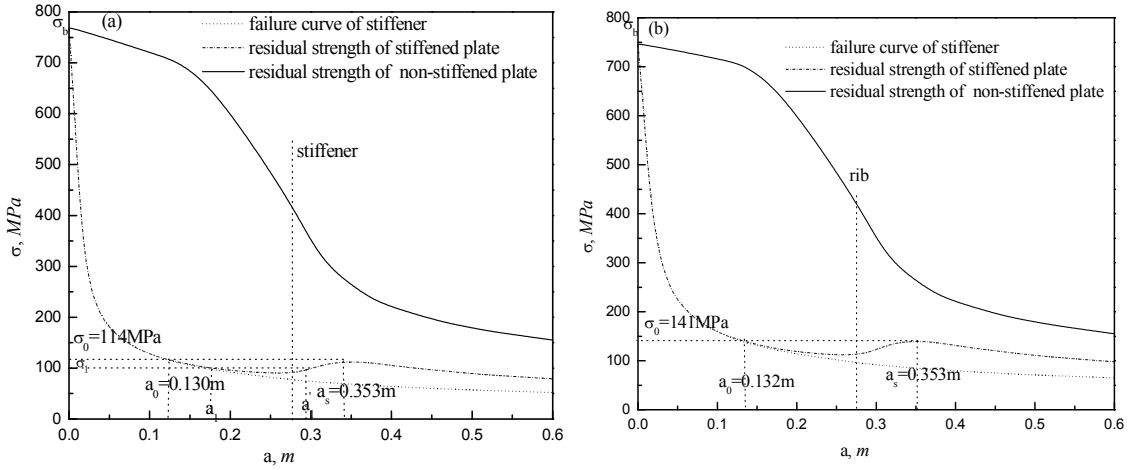

Figure3. Residual strength diagram of stiffened plate construction of the hull under loading rate $\sim 10^6 MPa\sqrt{m}/s$ and temperature 273K (a) and 293K(b)

The above analysis with respect to the crack behavior shows that the residual strength of stiffened plate construction has a "platform" stress σ_0 to which corresponding the range of cracks length $a_0 \sim a_s$. At this scope, the stiffened plate construction can play a part in crack arrest. Therefore, it can be obtained that the lower limiting value of residual strength of stiffened plate construction is σ_0, and the effective range of crack length for crack arrest is $a_0 \sim a_s$.

The stiffened plate construction of the hull analyzed in this paper shows elastic-plastic fracture with large plastic deformation under the loading rate $\sim 10^5 MPa\sqrt{m}/s$ and temperature 273K and 293K. At this condition, the stiffened plate construction belongs to a stiffener critical construction (details seen in Figure 2). For example, when the loading rate is $\sim 10^5 MPa\sqrt{m}/s$, the fracture toughness of hull steel are $282 MPa\sqrt{m}$ and $343 MPa\sqrt{m}$ under temperature 273K and 293K, respectively. While, under the loading rate $\sim 10^6 MPa\sqrt{m}/s$, the fracture toughness obviously decrease to $71 MPa\sqrt{m}$ and $89 MPa\sqrt{m}$, which is only quarter of the fracture toughness under quasi-static loading rate (seen Table 2). Thus, the residual strength curve of stiffened plate construction decreases largely. As a result, under the loading rate $\sim 10^6 MPa\sqrt{m}/s$, the stiffened plate construction belongs to a skin critical construction (Figure 3). The lower limiting value σ_0 and the range of crack length for crack arrest $a_0 \sim a_s$ for stiffened plate construction of the hull are listed in Table 3.

Table 3 $\sigma_0 (MPa)$ and $a_0 \sim a_s (m)$ of stiffened plate construction of the hull

loading rate	$\sim 10^5 MPa\sqrt{m}/s$		$\sim 10^6 MPa\sqrt{m}/s$	
temperature (K)	273	293	273	293
$\sigma_0 (MPa)$	363	434	114	141
$a_0 \sim a_s (m)$	0.225-0.279	0.248	0.130-0.353	0.132-0.353

It can be seen from Table 3 that the lower limiting value of residual strength is strongly dependent

upon the loading rate and temperature, which is the same as the fracture toughness of steel. That is to say, at the same loading rate, the lower limiting value of residual strength under temperature 293K is higher than that under temperature 273K; on the other hand, at the same temperature, the lower limiting value of residual strength decreases drastically with increasing loading rate, especially under loading rate $\sim 10^6 MPa\sqrt{m}/s$, the lower limiting value of residual strength reduces to the level of a quarter of σ_s. Suggesting the hull construction is no long suitable for use under impact condition with a loading rate $\sim 10^6 MPa\sqrt{m}/s$. Thus, it is necessary to use stiffened plate construction according to the strength level. However, it is worth noting that the stiffened plate construction is the skin critical construction that has a limit crack arrest capacity. Therefore the stiffened plate construction is needed to modify to enhance the crack arrest performance of the construction.

The data listed in Table 3 indicates that the crack length range of effective crack arrest in the skin critical construction is more than that in the stiffener critical construction. Under the loading rate $\sim 10^5 MPa\sqrt{m}/s$, the crack length range at temperature 273K is 0.225 *m* ~0.279 *m*, while at temperature 293K there is no crack arrest after the crack instable state. Under the loading rate $\sim 10^6 MPa\sqrt{m}/s$, the crack length range of effective crack arrest is 0.130 *m* ~ 0.353 *m* whether temperature 273K or 293K because the stiffened plate construction belongs to the skin critical construction.

5 Conclusions

Based on the linear-elastic fracture mechanic theory and the residual strength diagram of non-stiffened plate construction, the residual strength diagram of stiffened plate construction of the hull was proposed, and the crack arrest behavior, temperature and loading rate effects in the stiffened plate construction were discussed. The following conclusions can be drawn:

(1) The lower limiting value of residual strength of stiffened plate construction is significantly influenced by temperature and loading rate.

(2) The stiffened plate construction belongs to the stiffener critical construction at temperature 273K and 293K under loading rate $\sim 10^5 MPa\sqrt{m}/s$. While stiffened plate construction belongs to the skin critical construction because the fracture toughness of hull steel decreases sharply under loading rate $\sim 10^6 MPa\sqrt{m}/s$.

(3) The lower limiting value of residual strength of stiffened plate construction discussed in this paper and the crack length range of effective crack arrest are found to be 0.225 *m* ~ 0.279 *m* for the loading rate $\sim 10^5 MPa\sqrt{m}/s$ and temperature 273K and 0.130 *m* ~ 0.353 *m* for the loading rate $\sim 10^6 MPa\sqrt{m}/s$ and temperature 273K or 293K.

Abstract

The natural gas produced from subsea wells is processed through different stages before being supplied through pipelines for local market or export. Processing of the produced natural gas is started with separation of gas and liquid using a slug catcher that is connected to a flare system. The flare system consists of piping made of 16" diameter branches connected to 20" diameter header using circumferential weld with a total of seven joints. The pipe work of the flare system is made of 316L stainless steel and it is operated in an interrupted mode. Design and operation pressures are 142 bar g and 88 bar g while design and operation temperatures are -40^{o}C and 20^{o}C, respectively. After five years of normal service, one of the seven joints of 16" branch/20" header has experienced failure. Based on different non-destructive and destructive tests, it is concluded that this premature failure is attributed mainly to fatigue damage. It is believed that acute or sharp angle of 16" branch/20" header connection that acts as a local stress raiser played a remarkable role in initiation of fatigue damage on outer surface, just beside circumferential weld. In addition, low stress high frequency vibration of the subject pipe work, due to mainly several emergency shut down operations, has accelerated initiation of fatigue damage. In order to minimize the possibility of such failure in future, design of 16" branch to 20" header connection was modified where a compensation plate fitted was used to minimize stress concentration at this connection zone.

1. Background

A natural gas production plant has been set into operation about twelve years ago. The natural gas produced from subsea wells is processed through different stages before being supplied through pipelines for local market or export. Processing of produced natural gas is started with separation of gas and liquid using a slug catcher that is connected to flare system to be used in case of emergency plant shutdown. The flare system consists of piping is made of 16inch diameter pipes connected to 20inch diameter header using circumferential weld with a total of seven joints. Nominal thickness of 16" pipes is 4mm while that of 20" header is 6mm. The pipe work of the flare system is made of 316L stainless steel and it is operated in an interrupted or irregular mode. Design and operation pressures are 142 bar g and 88 bar g, respectively. Design and operation temperatures are -40^{o}C and 20^{o}C, respectively.

After five years of normal service, one of the seven joints of 16" pipe/20" header has experienced failure where

fracture has occurred at its conjunction zone. A spool including fracture zone was subjected to different non-destructive and destructive investigations for failure analysis.

2. Investigations

The failed spool was subjected to different non-destructive and destructive tests including visual investigation, liquid penetrant test, radiographic test, chemical analysis, thickness measurement, macro-, optical and scanning electron microscopic examinations, hardness measurements, tensile and impact tests. General and enlarged views of the fracture zone of the spool are shown in Fig. 1. The important notice is that fracture had occurred at the acute or sharp angle zone of 16" pipe/20" header assembly, just beside its circumferential weld. Based on visual investigation, it can be deduced that fracture was started at its mid-length then, propagated in tow opposite directions along circumference. The fracture extended less than half way around the circumference of 16" pipe/20" header. Visual and dye penetrant inspections indicated surface cracks on both sides of the fracture termination zones (Fig. 1-b). Generally, the outer surface of the failed spool is clean and free from deposits or indications for corrosion. Visual investigation of the weld face and root sides of the circumferential weld of 16" pipe/20" header as well as that of 16" pipe showed less weld quality. However, dye penetrant test of both root and face sides of circumferential weld of 16" pipe showed no surface cracking.

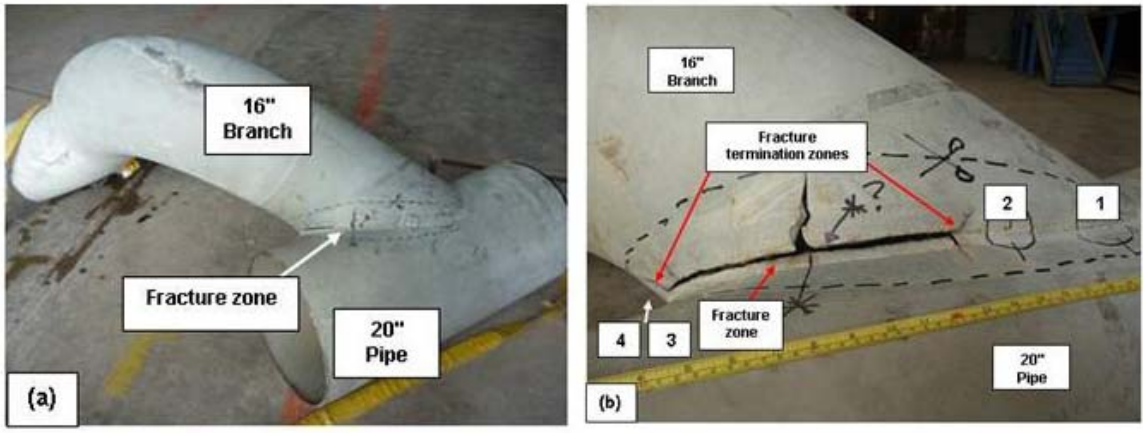

Figure 1. General (a) and enlarged (b) views of fracture zone of the spool. Note that fracture had occurred at sharp angle zone of 16" pipe/20" header assembly, just beside its circumferential weld.

Visual investigation of the internal surface of the failed spool showed damage at the inner surface of 16" pipe, which could be related to mechanical action. Except that, the internal surface of the spool showed smooth surface with no indications for internal corrosion. In other words, no thinning or variation in the wall thickness was observed, where almost uniform wall thickness (~6.0mm for 20" pipe and ~4mm for 16" branch) was obtained at both fractured and non-fractured zones. Macro- and microscopic investigations of a cross section taken from mechanically damaged zone showed internal localized reduction of about 0.6mm depth in the wall thickness of mechanically damaged zone. Optical microscopic investigation showed no indication for cracking at mechanically damaged zone.

Surface cracks zones observed around the fracture termination zones (zones 1, 2, 3 & 4, in Fig. 1-b) were subjected to detailed investigation. Close-up views of zones 4 and 1 at front of the fracture termination zones are shown in Fig. 2-(a) and (b). It can be noticed that surface cracks are existed just beside

circumferential weld of 16" pipe/20" header. Visual and dye penetrant examinations of zones 3 and 4 showed similar results.

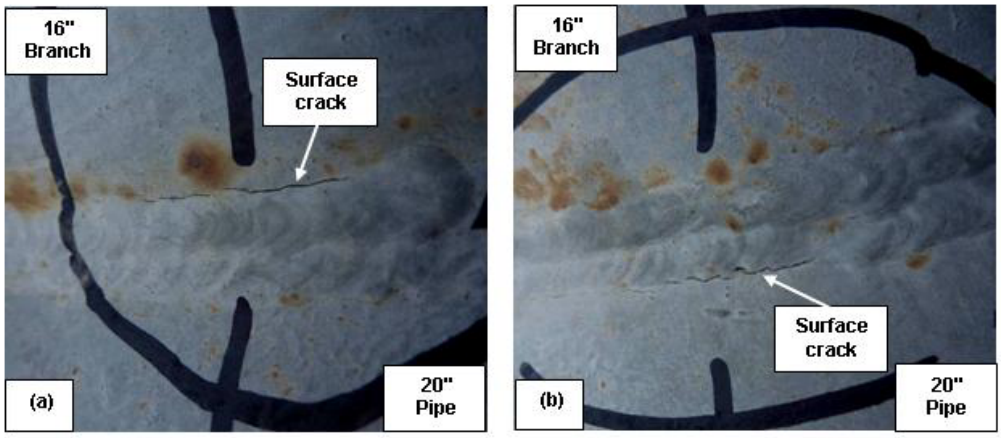

Figure 2. Close-up views of zones 4 and 1 at front of fracture termination zones of Fig. 1-b. Note surface cracks on both sides of circumferential weld of 16" pipe/20" header.

After detailed visual and dye penetrant investigations, specimens from both fractured and non-fractured zones of the spool were cut out and prepared for chemical analysis, macro- and microscopic examinations, scanning electron microscopic examination, hardness measurements, tensile and impact tests. Results of chemical analysis of the failed spool together with the specified chemical composition range for type 316L stainless steel are shown in Table 1. It is obvious that the chemical composition of the used spool is a typical for the austenitic stainless steel type 316L.

Table 1. Results of chemical analysis (wt%) of the failed spool together with the specified chemical composition range for ASME-SA213, 316L stainless steel.

Material	C	Si	Mn	S	P	Cr	Ni	Mo
Failed spool (BM)	0.017	0.41	1.45	0.018	0.031	17.73	11.26	2.16
Failed spool (WM)	0.017	0.37	1.23	0.006	0.029	16.91	10.18	2.01
316L St. St.	<= 0.03	<= 1.0	<= 2.0	<= 0.03	<= 0.04	16.0~ 19.0	9.0~ 12.0	2.0 ~ 3.0

Cracked zones 1, 2, 3 and 4 in Fig. 1-(b) were cross sectioned where its cracking features were clarified. Macrographs of a cross section taken from cracked zone 2 are shown in Fig. 3. It is clear that the observed cracks are weld toe cracking type. Similar results were obtained for samples taken from zones 1, 3 and 4 in Fig. 1-b. Weld toe cracks of zones 2 and 3 (~18cm away from fracture termination zones) were propagated through thickness of 16" pipe. Weld toe cracks of zones 1 and 4 in Fig. 1-b (~35cm away from fracture termination zones) were propagated through thickness of 20" header. It is obvious that cracks were initiated at weld toe on outer surface then, propagated through thickness. Optical micrographs with high magnification of cross sections taken from zones 1 and 4 in Fig. 1-b are shown in Fig. 4. It can be noticed that normal austenitic microstructures for both base metal, HAZ and weld metal were obtained and cracks were propagated through grain boundaries. Survey of the hardness measurements indicated

reasonable hardness values for the base metal, HAZ and weld metal, where average hardness values of 181HV, 183HV and 179HV were obtained for base metal, HAZ and weld metal respectively (Table 2). The given hardness values are the average of five readings. Results of the tensile test for both base metal and welded joint of the failed spool are shown in Table 3. The given tensile values are the average of three specimens. Results of the impact test, at different temperatures, of the base and weld metals of the failed spool are shown in Table 4. The given impact values are the average of three specimens. Results of both tensile and impact tests showed normal values based on specified properties for the used material.

ASME-SA 213, 316L St. St.	88-134 J (65-100 Ft.lb) at 23°C		

The given values are the average of three tested samples.

In order to help in identification of failure mechanism, fracture surface was carefully examined using stereoscope and scanning electron microscope. Low magnification photographs of fracture surface of 16" pipe side of the spool are shown in Fig. 5. Crack initiation zones and fracture propagation directions are highlighted with arrows. It is obvious that multi-cracks were initiated at the outer surface, where smooth fracture surface can be seen, then propagated toward inner surface. In other words, crack suspected initiation zones at the outer surface appeared relatively smooth and associated with beach marks and a propagating ductile crack. Crack termination zones at the inner surface had a rough texture associated with the final fracture.

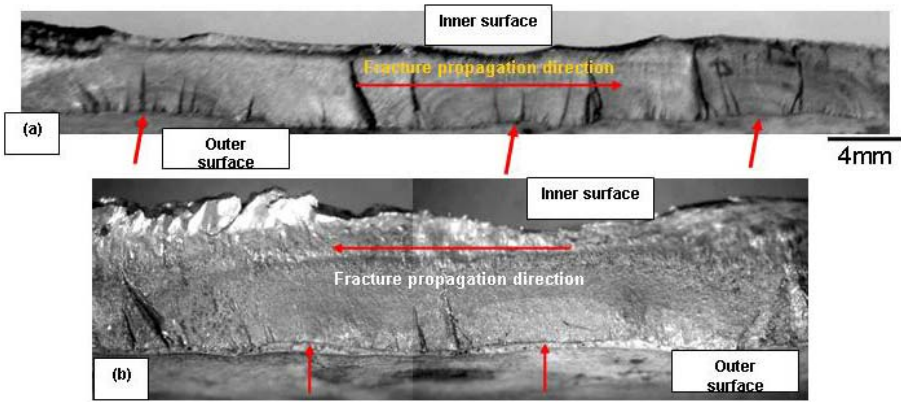

Figure 5. Low magnification photographs of fracture surface of 16" pipe side of spool. Crack initiation zones and fracture propagation directions are highlighted with arrows. Note beach marks at crack suspected initiation zones.

Scanning electron microscopic photographs with different magnifications of fracture surface including suspected initiation zones are shown in Fig. 6. Crack initiation sites can be seen on the outer surface, where a single macroscopic direction of crack propagation is impossible to be defined. This is because crack size is still in the microcrack zone, where multiple cracks form at the surface, initiating at different locations and with different orientations. The important notice is the unclear fatigue striations at the fracture initiation zones.

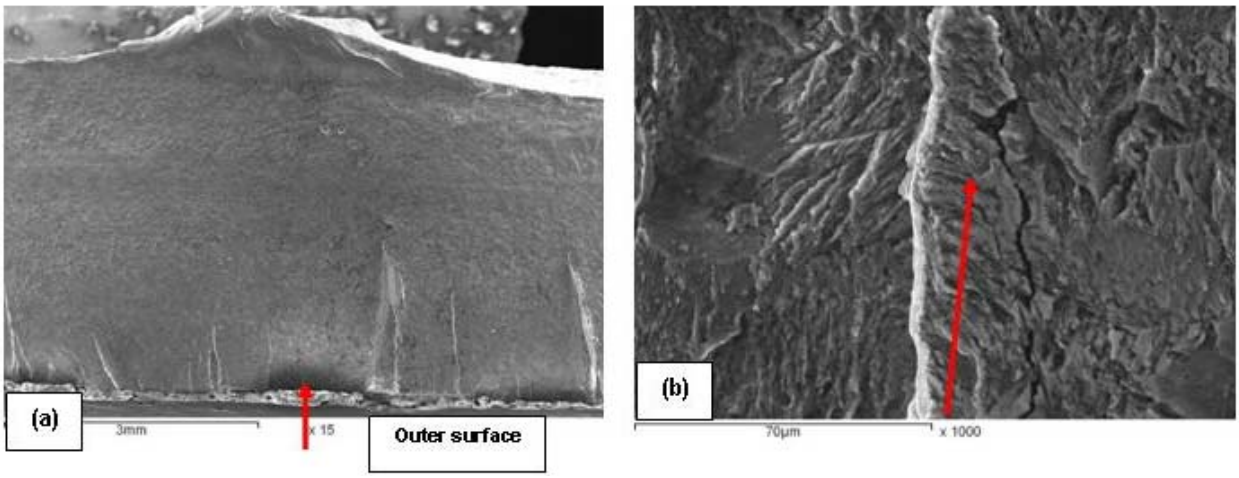

Figure 6. Scanning electron microscopic photographs of fracture suspected initiation zones at outer surface showing unclear fatigue striations.

3. Discussion

Visual and dye penetrant examinations of the failed spool showed that the fracture zone was confined to the acute or sharp angle of 16" pipe/20" header assembly, just beside circumferential weld line. Such sharp angle is considered as stress concentration zone. The fracture was initiated at the outer surface and propagated through thickness in two opposite directions where it was extended less than half way around the circumference. No indications for corrosion attack were observed on spool outer or inner surface. Only, mechanically damaged zone was observed at the inner surface of 16" pipe and this could be occurred long time ago during construction or repair works. However, such mechanical damage played no role in the current failure. In general, non-destructive investigations showed less weld quality. Meanwhile, fracture was not directly related to welding defects since fracture had occurred in the base metal just beside weld line.

Based on the results of chemical analysis, hardness measurements, tensile and impact tests and microscopic examination of the failed spool, materials of both base and weld metals were found to be within the specification of type 316L austenitic stainless steel. Macro- and microscopic examinations of cross sections around the fracture zone showed multi-cracks initiated at the weld toe that is considered as another stress concentration zone. Stereoscopic examination of the fracture surface showed that multi-cracks were initiated at the outer surface where smooth surface with beach marks was observed. Scanning electron microscopic investigation of the fracture surface showed unclear fatigue striations at the fracture suspected initiation zones. These findings support fatigue damage as a failure mechanism [1-5].

Fatigue failure is the phenomenon leading to fracture under repeated or fluctuating stresses that are less than the tensile strength of the material. Fatigue fractures are progressive, beginning as minute cracks that grow under the action of fluctuating stress. There are three stages of fatigue failure: initiation, propagation, and final fracture. The location of the initiation is at a stress concentration [6-9]. It is believed that stress concentration in the subject case is attributed mainly to the acute or sharp angle zone of 16" pipe/20" header assembly. In other words, such acute or sharp angle worked as site for initiation of fatigue damage at weld toe on outer surface of 16" pipe/20" header assembly, just beside its circumferential weld line.

The current piping system is subjected to more than just static forces. They can have severe vibrations induced mainly due to several start up operations. Vibration can be also induced due to temperature change. Since the piping system is operated in an interrupted or irregular mode, it is subjected to low stress high cycles fatigue. Under such repeated conditions, fatigue crack could be initiated at the highest stress concentration zone (acute angle zone). After the original fatigue crack is formed, it becomes an extremely sharp stress concentration that tends to drive the crack ever deeper into the metal with each repeating of the stress. The local stress at the tip of the crack is extremely high because of the sharp “notch,” and with each crack opening, the depth of the crack advances by one “striation”. Fatigue striation is not clear at the fracture initiation zone due to low stress cycles. As the propagation of the fatigue crack continues, gradually reducing the cross-sectional area, it eventually weakens the material so greatly that final, complete fracture occurs.

Conclusions and Recommendations

Based on the results obtained in this investigation, it can be concluded that the subject premature failure is attributed mainly to fatigue damage. High stress concentration at the acute or sharp angle of 16" pipe/20" header assembly and low stress high frequency vibration due to mainly several start up-shut down operations, both have shortens the lifetime of the spool. Fatigue failure is the phenomenon leading to fracture under repeated or fluctuating stresses that are less than the tensile strength of the material. The initiation site of fatigue failure is minute, never extending for more than two to five grains around the origin. The location of the initiation is at a stress concentration. It is believed that the acute or sharp angle of 16" pipe/20" header assembly that acts as local stress raiser played a remarkable role in initiation of the fatigue damage on the outer surface, just beside circumferential weld. It is obvious that the fracture initiated at the outer surface and propagated across the thickness in two opposite directions. As the propagation of the fatigue crack continues, gradually reducing the cross-sectional area, it eventually weakens the material so greatly that final, complete fracture occurs.

As a preventive measure, the other six connections of 16" pipe/20" header were subjected to visual and dye penetrant tests where absence of external surface cracks was confirmed. In order to minimize the possibility of such failure in future, the design of 16" pipe to 20" header connection was modified, where a compensation plate fitted was used to minimize stress concentration at this connection zone. Besides, circumferential welds were made with a better quality even it had no direct relation with the failure.

Abstract The fracture behavior of blends of poly(ninylidene fluoride) (PVDF) and poly(methyl methacrylate) (PMMA) was investigated by gradually increasing the PVDF content. The study focuses on semi-crystalline blends. The trends of net stress versus crack opening displacement curves were analyzed. From these plots, two fracture energies were defined: the fracture energy to crack initiation corresponding to the area under the curve up to the maximum net stress and the fracture energy to crack propagation considering the last part of the curve where the load continuously decreases. Fracture surface inspections confirmed typical semi-crystalline polymer features. Critical values of the degree of crystallinity corresponding to brittle to ductile transition were determined, depending on the selected fracture energy.

Keywords Blends, Poly(methyl methacrylate), Poly(vinylidene fluoride), Fracture toughness, Brittle to Ductile transition

1. Introduction

Mechanical parameters at failure are key factors to assess the durability of engineering components. For structural polymeric materials, fracture toughness is often characterized by the impact strength (Charpy or Izod tests). These are dynamic tests, accurate for brittle failure characterization. They might be inappropriate when the material exhibits significant ductility. Theoretically, fracture mechanics approaches suggest a methodology to define fracture toughness, whatever the mechanical response of the material. Whereas comprehensive research has been carried out for years on metallic materials concerning the equivalence between impact strength and fracture toughness, there is no such amount of work on polymers. Some attempts were made in this way but failed because, for instance, of the difficulty to fulfill requested plane strain conditions. Nevertheless, impact strength or toughness of polymeric materials was currently plotted as a function of the test temperature, in order to find a ductile to brittle transition temperature. The essential motivation of such a plot is to check whether the modification of the material process actually leads to an improvement of the toughness or the impact strength, by shifting the brittle to ductile transition temperature away from in-service temperature.

The present contribution focuses on blends of poly(vinylidene fluoride) (PVDF) and poly(methyl methacrylate) (PMMA). Indeed, in recent years, PMMA/PVDF blends got a renewal of interest with studies aiming at assessing their mechanical response. In terms of processing, they exhibited a transition from miscible amorphous to semi-crystalline structures. At room temperature and for approximately the same given crosshead speed, PMMA is basically brittle and neat PVDF exhibits ductile failure. By gradually increasing the PVDF content, toughening effects were evidenced according to a given fracture mechanics parameter based on fracture energy. The motivation here is then to determine a critical degree of crystallinity able to characterize the transition between brittle (low fracture energy) and ductile (high fracture energy) failures, for the same test conditions (room temperature/ crosshead speed). It was demonstrated that depending on the fracture energy definition,

corresponding to either fracture toughness or impact strength, the value of this critical degree of crystallinity was changed.

2. Experimental procedure

2.1. Materials - Specimen

The PVDF/PMMA blends were prepared from the homopolymers PVDF Kynar® 721 and PMMA Oroglas® V825, both provided by the company Arkema France. Blending was achieved by co-precipitation from a homogeneous solution [1]. Depending on the fraction of PVDF, either amorphous or semi-crystalline blends were produced. Typically, the blends remain amorphous when their PVDF content is less than about 50 wt%. In the following, blend identification was based on weight composition. For instance, %F = 20 or F/M 20:80 deals with a blend containing 20 wt. per cent of PVDF and 80 wt. per cent of PMMA. Of course, blend composition influenced the values of the glass transition temperature. Moreover, the presence of amorphous PVDF segments constrained by the crystallites was evidenced in the crystalline blends [1].

Table 1. Blends characteristics

Sample	%F	T_g (°C)	χ (%)
M	0	110	0
F/M 20:80	20	85	0
F/M 30:70	30	77	0
F/M 40:60	40	58	0
F/M 50:50	50	66	14
F/M 60:40	60	54	19
F/M 70:30	70	45	27
F/M 80:20	80	54	36
F/M 90:10	90	53	45
F	100	-40	55

Table 1 recalls the main characteristics of the blends under study, namely overall wt percentage of PVDF, %F, glass transition temperature, T_g and the degree of crystallinity, χ.

The blends were compression-molded in the form of 5 mm-thick sheets. Then, single edge notch bending (SENB) specimens were machined out of the sheets. Their characteristic dimensions were kept constant: thickness T = 5 mm, width W = 12 mm, crack depth a = 5 mm (thus a/W = 0.42), length L = 70 mm, span S = 50 mm. The pre-crack was machined with a notch root radius of approximately 250 µm.

2.2. Fracture energy measurements

Fracture tests on SENB specimen were carried out at room temperature on an Inströn testing machine with a constant crosshead speed of 0.5 $mm.s^{-1}$ for all tests. For the sake of reproducibility, all tests were repeated twice. The load F, the notch opening displacement δ and the crosshead displacement were recorded as a function of the running time. The net stress (σ_{net}) is defined as the

load F divided by the area of the initial net section: T (W –a).

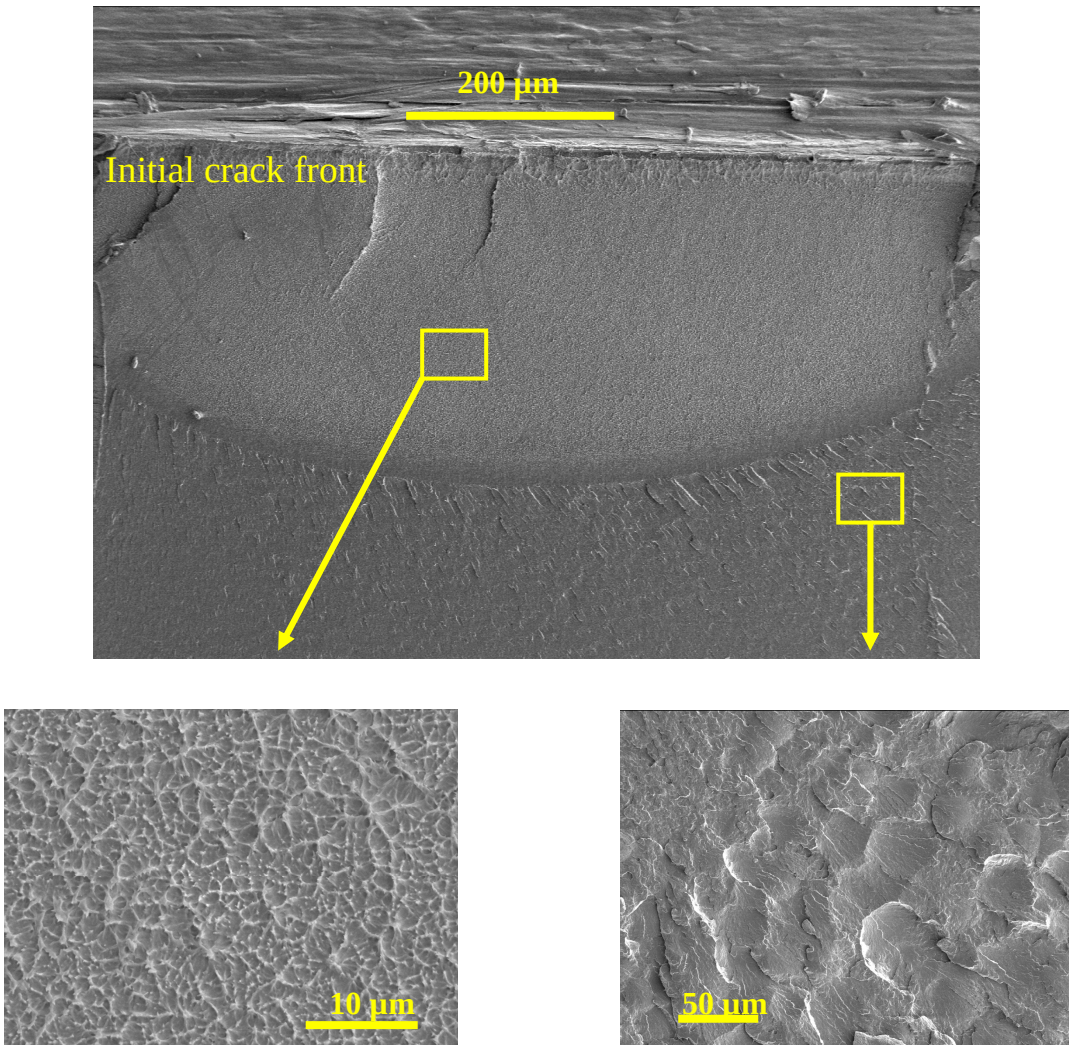

Figure 1. Typical features of semi-crystalline fracture surfaces for 50 ≤ %F ≤ 80

Following fracture mechanics theory [2], the energy release rate G can be expressed as:

$$G = f(a/W)\, U \qquad (1)$$

where $f(a/W)$ is a function of the crack depth ratio and the specimen geometry; U the area under the load versus δ plot. Here both a/W and specimen geometry were kept constant so G was assumed to be proportional to the area under σ_{net} versus δ. Note that this area is homogeneous to an energy density and can be directly calculated from experimental data. In the following, it will be integrated and split into two fracture energies: E_i during the loading path up to the maximum σ_{net} and E_p corresponding to the consecutive decrease in σ_{net}. For brittle fracture $E_p = 0$, E_i is therefore related to the critical energy release rate. It is representative of the toughness of the material. For the general case where $E_p \neq 0$, the total fracture energy $E_t = E_i + E_p$ can be linked to the Charpy impact fracture strength [3-5] but adapted here to quasi-static loading of the specimen. Both E_i and E_t will then be considered here to follow the toughness improvement according to the PVDF content.

3. Results

3.1. Fractography

In Table 1, the degree of crystallinity χ is zero for %F ranging from 0 to 50. Additionally, T_g values were "stabilized" for %F ≥ 50. As already mentioned, the blends were considered as semi-crystalline when their PVDF content was more than 50 wt%. By examining fracture surfaces of broken SENB specimens (fig.1), it was demonstrated that typical semi-crystalline features were identified on blends corresponding to 50 ≤ %F ≤ 80. Accordingly, investigations focused on blends for which %F ≥ 50, *that is* 14% ≤ χ ≤ 55%. Indeed, to better assess the transition between brittle (low fracture energy) and ductile (high fracture energy) fractures, the failure mechanisms should be ensured to be the same. Moreover, since T_g does not vary so much for semi-crystalline blends and since all tests were carried out the room temperature, the degree of crystallinity χ was selected as the relevant parameter allowing for the characterization of this transition.

3.2. Mechanical parameters

3.2.1. Net stress versus δ curves

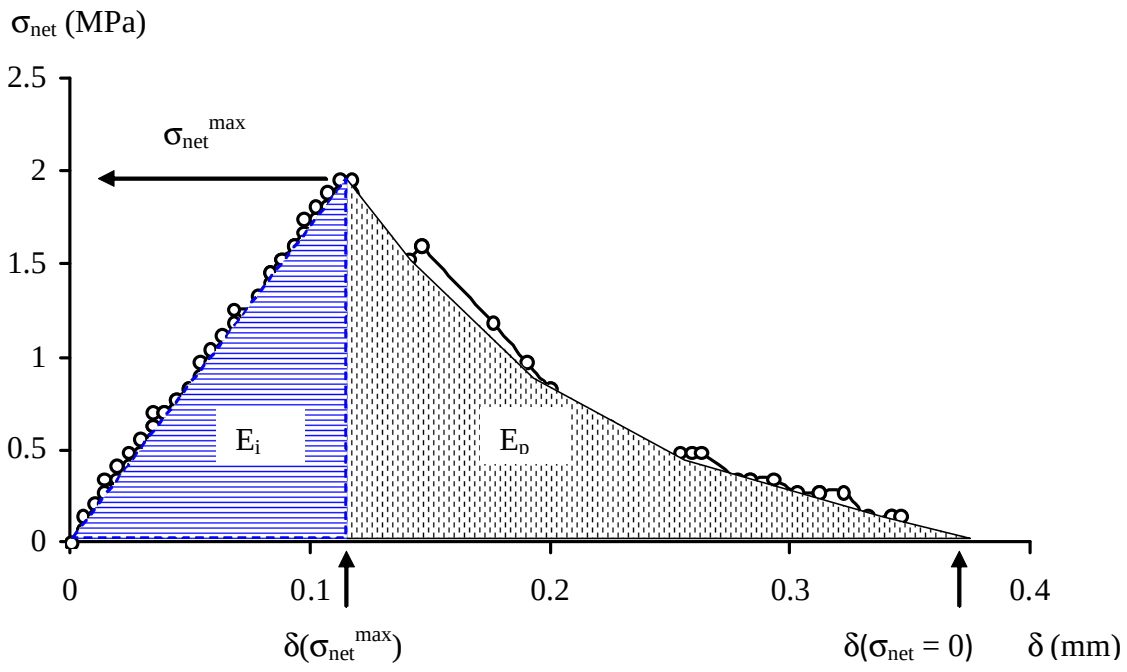

Figure 2. Typical net stress versus opening displacement curve for %F = 50.

The main mechanical parameters were derived from the curve of net stress versus the opening displacement δ as illustrated in fig.2. The definitions of σ_{net}^{max}, $\delta(\sigma_{net}^{max})$ and $\delta(\sigma_{net} = 0)$ were clearly indicated. Moreover, two specific steps could be distinguished in this plot: i) the loading stage (up to maximum net stress), where the crack is supposed to be stationary at the initial value of a/W = 0.42. This part is concerned with "crack initiation" process and therefore to E_i; ii) the crack

growth stage, characterized by the decrease of net stress, related then to E_p.

3.2.2. Maximum net stress

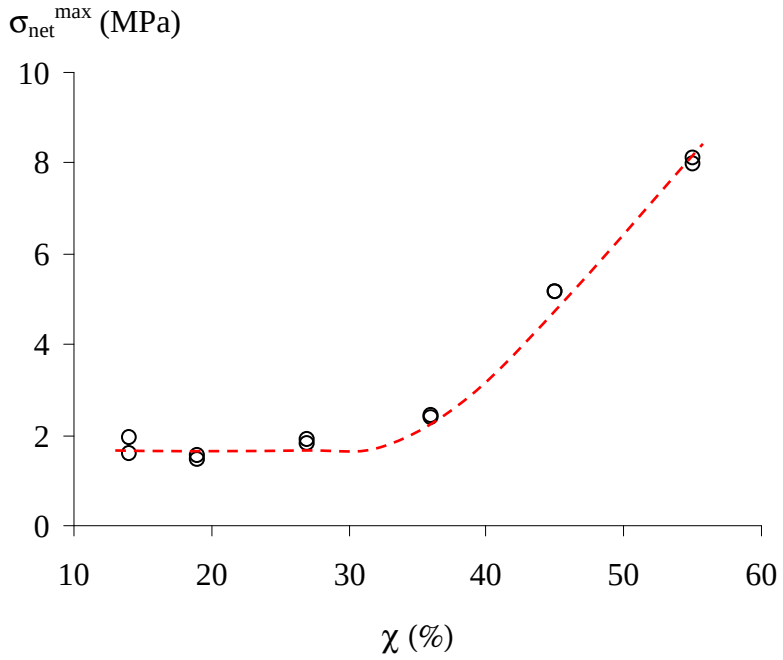

Figure 3. σ_{net}^{max} as a function of the degree of crystallinity χ (%)

The maximum values of the net stress (σ_{net}^{max}) were plotted as a function of χ (%) in fig.3. A continuous increase in σ_{net}^{max} is observed, slightly between 14% and 35% then significantly for the last values of the degree of crystallinity. Moreover, excellent reproducibility of (σ_{net}^{max}) values could be noticed.

3.2.3. Opening displacements: $\delta(\sigma_{net}^{max})$ and $\delta(\sigma_{net} = 0)$

Fig.4 displays the crack opening displacements δ corresponding to respectively, $\sigma_{net} = 0$ at the complete failure of the specimens (first Y-axis) and σ_{net}^{max} (second Y-axis). The same trend as in fig.3 is observed for $\delta(\sigma_{net}^{max})$. This similarity indicates that during the loading step, the net stress versus δ curve was quasi-linear.

Instead, the evolution of $\delta(\sigma_{net} = 0)$ versus χ (first Y-axis) exhibited a jump between 20% and 30%. Actually, this jump was essentially due to the propagation stage where additional deformation of the crack tip (blunting) was observed. For $\chi \geq 35\%$ a saturation of $\delta(\sigma_{net} = 0)$ value was observed.

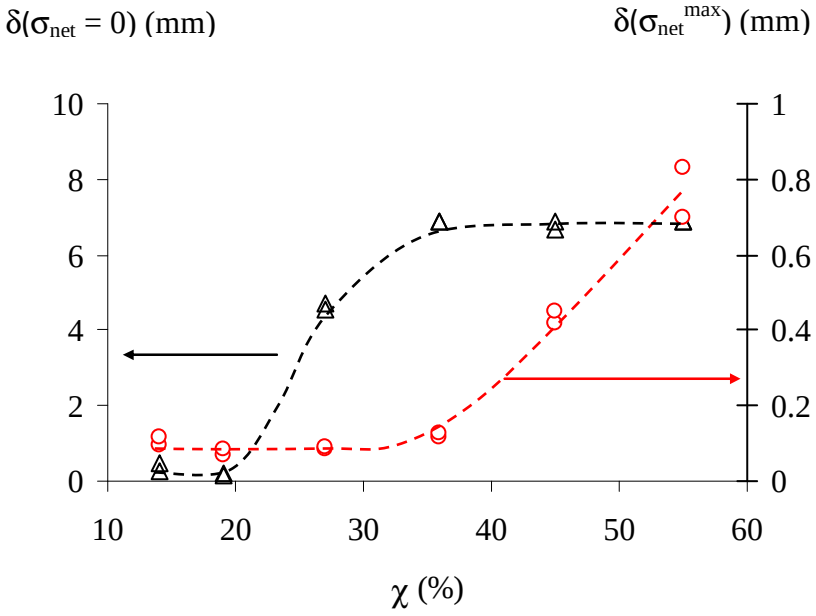

Figure 4. $\delta(\sigma_{net}^{max})$ and $\delta(\sigma_{net} = 0)$ as a function of the degree of crystallinity χ (%)

3.2.3. Fracture energies E_i and E_t

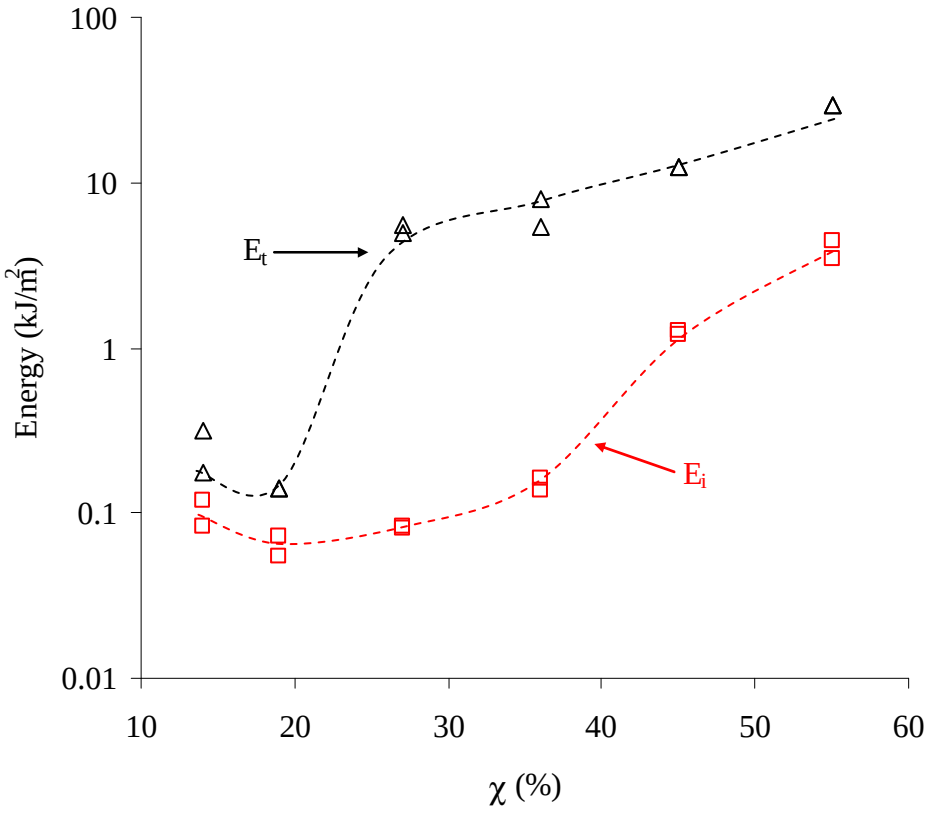

Figure 5. Fracture energies plotted as a function of the degree of crystallinity χ (%)

Fig.5 displays the fracture energies E_i and E_t in a semi-logarithmic scale versus χ. For E_i, the trend was the same as that of σ_{net}^{max} and $\delta(\sigma_{net}^{max})$, whereas the jump of E_t between 20% and 30%

coincided to that of $\delta(\sigma_{net} = 0)$. Furthermore, fig.5 showed that at low values of fracture energy ($\chi \leq$ 20%), $E_t \approx 2E_i$. This was due to that E_i and E_p had approximately the same value. In the upper shelf of the fracture energy ($\chi > 40$) E_p was of higher order of magnitude than E_i.

4. Discussion

The effects of the PVDF content on the fracture energies were analyzed for %F ≥ 50 corresponding to $\chi \geq 14\%$. Depending on the selected fracture parameter, the observed gain in fracture energy may significantly differ in their absolute value (factor 10). Indeed, a jump in the total fracture energy E_t was clearly established whereas a smoother increase in E_i was evidenced at the same time. It should be recalled that E_t is representative of the Charpy impact strength. The "gain in toughness" observed for both parameters was shown to be of the same order of magnitude. In practice, the shape of E_t suggests that the degree of crystallinity corresponding to the brittle to ductile transition was estimated at about $\chi = 23\%$. Around this transition, E_t value drastically increased from 0.13 kJ/m^2 to 5.3kJ/m^2 (factor 40). It is to be noted that for higher values of χ, E_t was still growing from 5.3 kJ/m^2 to 29 kJ/m^2.

For the fracture toughness parameter E_i, a slight and progressive transition was observed at χ values ranging from 30% to 45%. In this χ range, E_i increased from 0.08 kJ/m^2 to 1.2 kJ/m^2 (factor 10).

5. Conclusion

Consideration of the blends of PVDF and PMMA all over the composition range proved to be a powerful tool to assess the characteristics that govern the fracture behavior of polymers. The amorphous blends (PMMA-rich materials) corresponding to PVDF content lower than 50% exhibited zero degree of crystallinity, low values of fracture energy and no particular pattern on their fracture surfaces. They were not taken under consideration in this work.

The PVDF-richer blends exhibited higher degrees of crystallinity $\chi \geq 14\%$. The fracture surfaces issued from tested SENB samples showed dimples characteristics of semi-crystalline polymers. Transitions from brittle to ductile fracture behavior of these semi-crystalline blends were identified, in terms of critical degree of crystallinity χ. The value of such a transition was found to depend on the fracture mechanics parameter: either the fracture toughness (fracture energy to crack initiation E_i) or the equivalent of the Charpy impact strength in quasi-static case (total fracture energy E_t).

The transition for E_i and E_t was estimated at $\chi \sim 38\%$ and $\chi = 23\%$, respectively. At these χ-transitions, E_i was found to increase from 0.08 kJ/m^2 to 1.2 kJ/m^2 (factor 10) whereas E_t jumped from 0.13 kJ/m^2 to 5.3kJ/m^2 (factor 40).

Abstract

A study on the destruction of thin aluminum and copper samples in a wide range of loading times was made. Static loading of samples in the form of strips on a tensile testing machine was carried out. For dynamic loading magnetic-pulse method with a period of 1 μs loading and 7,5 μs applied. The samples were made in the form of rings. The mechanism of fracture in each time range, and the peculiarities of the behavior of materials was studied. A mathematical model for fracture process was proposed. Comparison of the mechanical properties of materials under static and dynamic range tests was realized.

Keywords: static loading, dynamic loading, fracture, magnetic pulse technique, metallic ring samples.

1. Introduction

A large number of experiments on loading of continuum shows fundamental differences between destruction process under the influence of slow quasistatic loadings and "fast" dynamic destruction. In case of quasistatic deformation critical value of strength parameters is much less dependent on experimental conditions, than at dynamic influence. As observed critical characteristics of destruction at dynamic deformation it is essential volatile and behave it is rather unpredictable, one of the main objectives at definition of dynamic strength characteristics is research of interrelation of the limit power parameters conducting to destruction of a material with duration, amplitude and growth rate of enclosed loading. Results of microstructural research of the destroyed samples. The mathematical model, allowing to describe destruction of materials both at static, and under dynamic conditions of loading is considered.

Results of a experimental study on a rupture of thin aluminum and copper samples in the form of narrow strips as in the conditions of static loading by breaking machine, and at dynamic harmonic stretching impact with the period 1μs are given in this work. In the second case the magnetic-pulse method of loading was applied, and samples were carried out in the form of rings. The destroying static tension of materials is determined and the assessment of their dynamic breaking points with use of the offered method of measurement of time from the beginning of loading until destruction is made. Comparison of breaking points in static and dynamic conditions is carried out. Results of microstructural research of the destroyed samples are given. The mathematical model, allowing to describe destruction of materials both at static, and under dynamic conditions of loading is considered.

2. Deformation and destruction of thin aluminum and copper samples at quasistatic loading

2.1. The methodology of the experiments

The experimental study on mechanical deformation and strength properties of aluminum (Al) and copper (Cu) condenser foils by h=0,015 mm thickness in solid (cold-worked [1]) condition is conducted at stretching of strips in the breaking machine Tinius Olsen H10KN (fig. 1) at a speed of movement of mobile grab of the breaking machine of 10 mm/min.

Fig. 1. General view of the test machine: 1 - frame, 2 - PC 3 - moving cross-arm, 4 – machine`s grabs, 5 - sample clips, 6 – sample.

Control of operation of the machine and data acquisition was carried out by the computer. Charts of stretching of samples were received: "effort - lengthening" and "stress – deformation". The test machine`s computer automatically chose scales of charts in the set size of speed of deformation, thickness and sample width, its working length. Start of movement of mobile grab (cross-arm) was carried out at not completely straightened condition of samples - foils, because of complexity of exact definition of the effort beginning in them. Therefore at charts there was an initial area (fig. 2, 3), having, generally small nonzero ordinates (efforts and stress), the achievements caused by process by samples of the straightened condition, and also operation (friction) of additional tiny hinged devices (clips) for samples mount. Further, when processing charts, this area excluded.

2.2. About a type of samples and their production

In [2] requirements to aluminum foils for condensers, a view and sizes of samples (length of 150 mm, width of 15 mm) and conditions of mechanical (quasistatic) tests are provided. However, for an exception of influence of a large-scale factor by comparison of these quasistatic tests in comparison with dynamic experiments on the ring samples received by gluing together or the soldering of strips foils, in our case the sizes of samples – strips for quasistatic tests were accepted considerably the less size, namely: rather close with sizes of strips applied to rings. Preparations – strips for quasistatic tests of an aluminum foil were cut out 60 mm long and width b about 6 mm,

and copper - respectively, 50 and b=1,7 mm, with width deviation no more, than $\pm 0{,}05$ mm. The choice of bigger width (and lengths) aluminum preparations was connected with considerably smaller durability of this material, in comparison with copper, - for providing a sufficient correctness of tests. Length of working part of aluminum samples equaled l_0=28 mm, copper 20 mm. Thus, the speed of relative deformation of samples equaled $\dot{\varepsilon}(t) = \frac{\Delta l}{l_0}$ aluminum samples it was equal 0,357 min^{-1}, copper – 0,5 min^{-1}. Conditional stretching tension stress in samples was determined by a formula $\sigma = \frac{P}{h \cdot b}$ with initial values h and b. Other parts of samples (ends) were used for fastening of samples in grabs of the test machine so that the rupture of a sample was carried out not in capture zone, and in its working zone. For this purpose the ends were bent before acceptance of double thickness, with placement of cardboard laying in a bend, and, then, the ends were pasted over with a paper adhesive tape. Before the placing of samples in the test machine on these ends tiny aluminum clips with the hinges, necessary for more exact axial loading of samples that it is difficult to provide at direct use of large rigid grabs of the test machine Were attached. At test samples fastened in test machine grabs through tiny clips.

2.3 . Results of quasistatic experiments

In fig. 2 are provided received by means of the computer of the test machine the chart of "loading - lengthening" and "stress - deformation" for one sample from an aluminum foil, and on fig. 3 – for one of a copper foil.

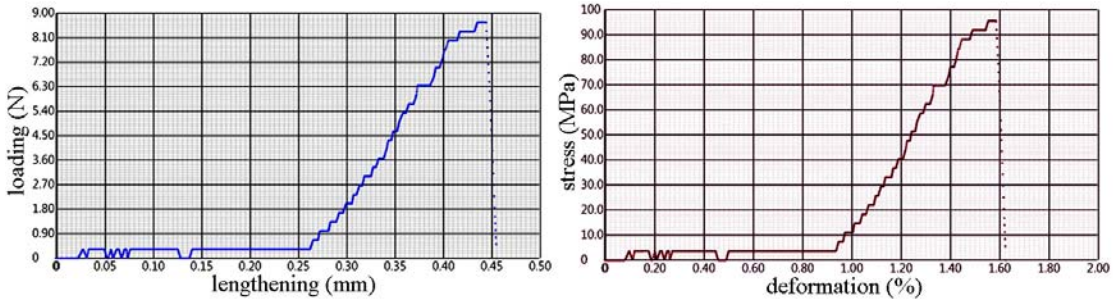

Fig. 2. Charts of stretching of an aluminum foil

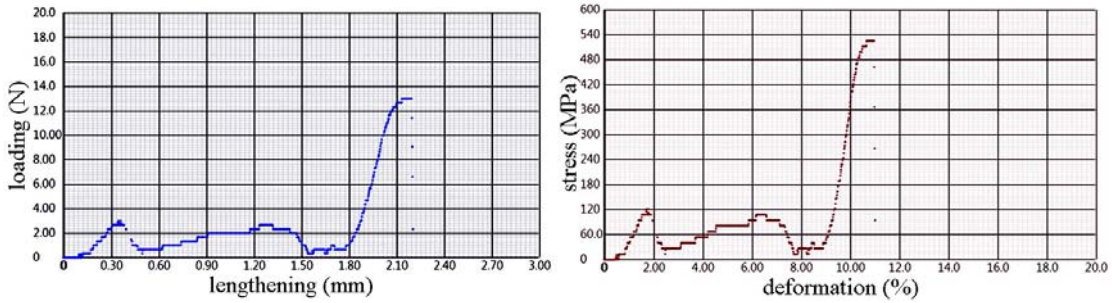

Fig. 3. Charts of stretching of a copper foil

When processing initial areas of the charts "stress - deformation" (0 – 0,9) for aluminum and (0 – 9) for copper were excluded. The same was carried out when processing charts of all other samples.
Stretching charts σ - ε aluminum and copper foils have an appearance typical for plastic materials: with an initial site of elasticity, viscoplasticity and destruction. On the chart for a copper foil before destruction small falling of conditional stress ((increase of true stress) before a direct prompt macrorupture of a sample – germination of the main crack, the events for an aluminum foil in time ~ 0,12 sec., and for copper 0,05 sec. is observed.

In table 1 are provided average on three measurements (to charts σ - ε) data on mechanical characteristics aluminum and copper foils at stretching with speeds of $\dot{\varepsilon}(t) = 0{,}357$ min^{-1} and 0.5 min^{-1} respectively, in parentheses – discrepancy in %. Designations are accepted: E - Young's modulus; σ_e - elasticity limit; $\sigma_{\max}$ - the maximum conditional stress on the chart "stress - deformation"; σ_c - conditional stress of destruction (temporary resistance) corresponding to the moment of the beginning of a macrorupture of a sample; ε_c - destruction deformation; t_c - destruction time.
Essential distinction of all mechanical characteristics foils is established to Al and Cu.

Table 1. Mechanical characteristics of an aluminum and copper foils

Material	E, GPa	σ_e, MPa	$\sigma_{\max}$, MPa	σ_c, MPa	ε_c, %	t_c, s
Al	13 (±12%)	60 (±15%)	99 (±1%)	99 (±1%)	0,76 (±14%)	1,275 (±14%)
Cu	38 (±28%)	400 (±18%)	527 (±3%)	508 (±3%)	2,27 (±18%)	2,730 (±18%)

Very insignificant dispersion of characteristics attracts attention $\sigma_{\max}$ and σ_c. It is possible to claim about experimental stability of these characteristics.

2.4. The microstructural analysis of destruction at quasistatic loading

The type of two samples of an aluminum foil and two samples of a copper foil after destruction is presented on figs. 4. In fig. 4 destruction of samples on a working site is noticeable l_0.
Research of destruction surfaces of aluminum and copper samples after tests was carried out on an optical microscope of Axio-Observer-Z1-M in a dark field, and research of structure cross microsection – in a light field or polarized light. The structure was studied on cross microsection after the corresponding etching. The size of grain and quantity of a pores defined on a surface microsection.
Microstructural studying is carried out on three aluminum and three copper destroyed samples. The analysis of samples structure of copper and aluminum showed that samples mainly collapse viscously – have a “cup” break. Comparison of samples of copper and aluminum revealed that the

Fig. 4. The destroyed samples aluminum (at the left) and copper (on the right) foils

fiber percent in a break of statically loaded copper is less, than in aluminum, i.e. copper collapses is more fragile in these conditions.

On fig. 5 structures of aluminum samples after static tests are presented. Porosity in a sample 4, cracks in a sample 5 and the main crack in a sample 6 is visible.

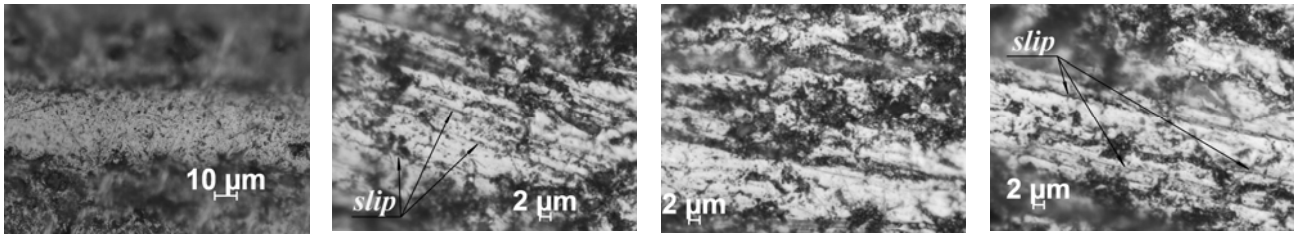
In figure 6 structures of samples of copper after static tests are presented.



a b c d

Fig. 6. Structure of copper samples after static tests: a – in an initial condition; b – sliding strips in a sample 4; c– homogeneous structure in a sample 5; d – sliding strips in a sample 6.

In samples 4 and 6 sliding strips are observed, and in a sample 5 the homogeneous structure prevails, as is noticeable by appearance of samples in fig. 4. The sample 5 is destroyed at an angle about 45^0, i.e. in the direction of the maximum tangent stress on the planes of more dense packing.

3. Deformation and destruction of aluminum and copper samples at dynamic loading

Experiments on deformation and destruction of samples were carried out with use of the modified magnetic-pulse method on the basis of the generator of short high-voltage impulses of GKVI-300 providing formation of electric voltage with amplitudes of 30 - 300 kV. As samples rings from thin aluminum and copper foils with a diameter of 28,6 mm and 1 - 2 mm wide were used.

On fig.7 the loading scheme is shown. The current passing on the coil on which the ring sample coaxially settles down, directs in it induction current, and interaction of these currents generates pushing away force between the solenoid and a ring.The coil is made of a copper wire by diameter 1mm, has 5 rounds, diameter of the coil - 25 mm. The current passing through the coil, was measured by a Rogovsky coil (RC) and displayed on a digital oscillograph (OSC) information with which registered on the electronic carrier. At a rupture of the ring (Sample) which has been coaxially fixed on the middle of the coil (L), there was a spark which allowed to fix the moment of destruction of a sample by means of the photo diode (PD). At test of samples installation when via the coil current with the period of fading fluctuations T=1μs was passed was applied. Its flowchart is provided on fig. 8.

Appearance of installation is given on fig. 9.

On fig. 10 current oscillograms via the coil and a signal from the photo diode fixing the moment of a rupture of a sample are represented.

Experiments on rings from aluminum and copper foils 0.015 mm thick and 1.0 - 2.0 mm wide were made. Samples tested with a cut and without a cut.

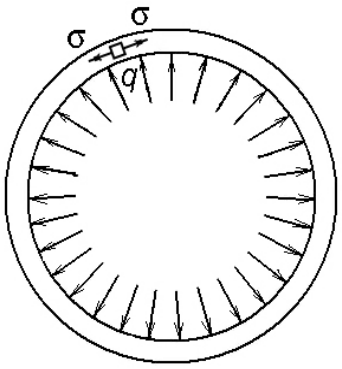


Fig. 7. Scheme of sample loading
(q – loading, σ– the stretching stress)

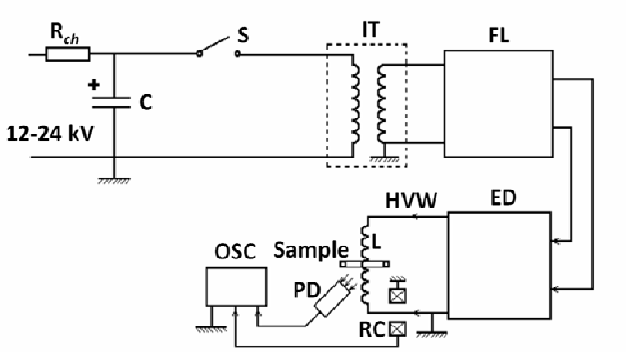

Fig. 8. The block-scheme of the setup for sinusoidal electromagnetic load of period 1 μs: Sample – a sample; IT – the pulse transformer; FL – the forming line; ED – the output device; HVW – a high-voltage electrode; PD – the photo diode; RC – a Rogovsky coil; OSC - an oscillograph

The assessment of the radial force operating on a ring from rounds of the coil, was carried out by a technique stated in work [3], submitted on ICF 13. Tangential stretching stress was calculated on Laplace's formula for thin-walled covers

$$\sigma(t) = \frac{q(t)R}{h},$$

where $q(t) = F(t)/c -$ the distributed radial loading acting on an internal surface of a ring, F (t) – force acting on a ring, c, R, h – width, internal radius and ring thickness, respectively.

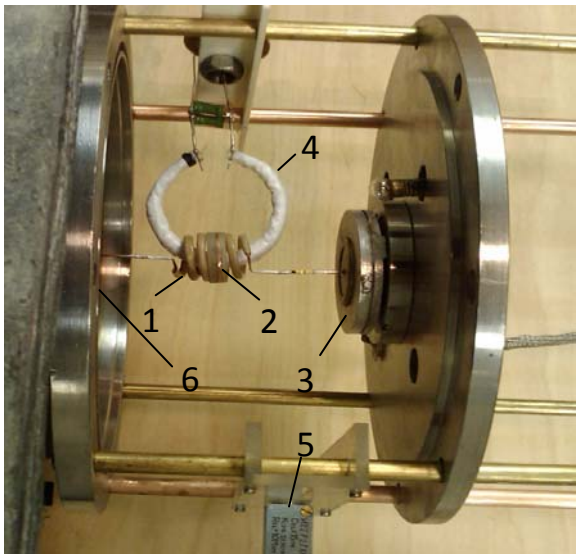

Fig. 9. General view of installation,
1 – solenoid; 2 – sample; 3 - Rogovsky coil, measuring current in the coil; 4 – Rogovsky coil, measuring current in a ring;
5 – photo diode; 6 – output device.

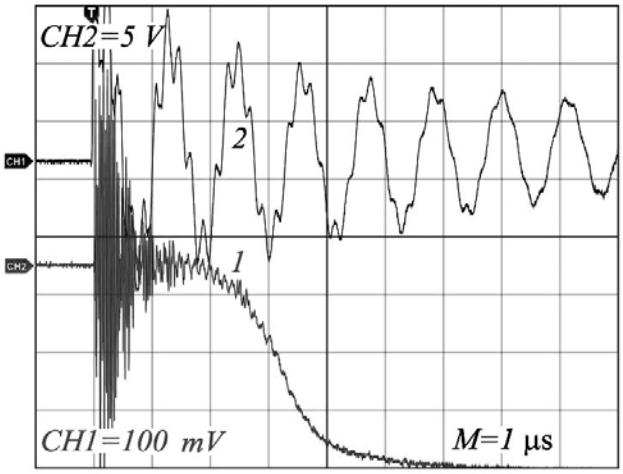

Fig. 10. Oscillograms from the photo diode 1 and current from a Rogovsky coil 2.

At determination of the stretching tangential stress its pulsing value $\sigma(t)$ it was replaced average in the form of a rectangular impulse with an amplitude σ_0 and duration equal to time from beginning of giving of current in coil until rupture of a ring t_c:

$$\int_0^{t_c} \sigma(t)dt = \sigma_0 t_c, \quad \sigma_0 = \frac{\int_0^{t_c} \sigma(t)dt}{t_c}$$

Time t_c was measured in experiences.

Characteristics of samples, conditions of experiments and results are provided in table 2, where: T - the period of fluctuations of current in the coil; h - ring thickness; c - ring width; ∅ - diameter of a ring; U - tension of a charge of the condenser; σ_0 - the stretching stress of a ring rupture; τ - time before destruction; W - energy of the charged condenser; I - current amplitude via the coil.

Table 2. Characteristics of samples, conditions of experiments and results

Material	T, μs	h, mm	c , mm	∅, mm	U, kv	σ_0, MPa	τ, μs	W, J	I, A
Al	1	0,015	1,50	28,6	20	162	4,17	100	4200
Cu	1	0,015	1,00	28,6	20	577	4,68	100	5800
Cu notch	1	0,015	1,55	28,6	20	376	6,60	100	8400

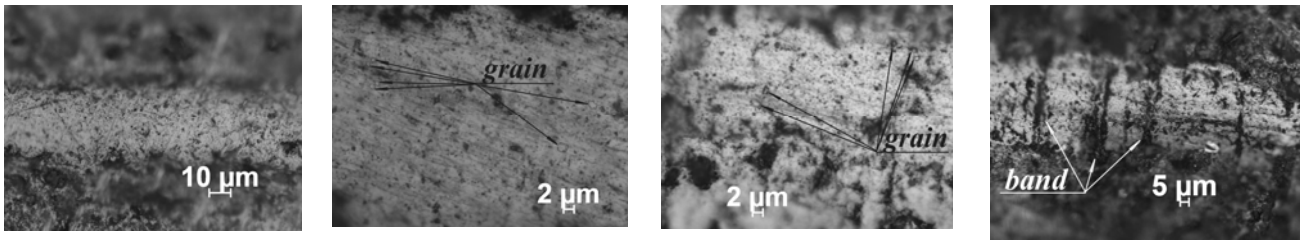
3.1. Results of microstructural research

Microstructural studying is carried out by the same technique that is presented in item 2.4. Microhardness measured on the PMT-3 device at loading 20g. Results of microstructural researches are given in photos (фиг.11) and in table 3, where: T - the period of fluctuations of current in the coil; S=hxb - sample section; D - grain size; n - quantity of a time on the area 400 μm2; HV – microhardness.

Table 3. Results of microstructural researches

Material	T, μs	hxb, μm^2	D, μm	n, 1/400 μm^2	HV, MPa
Al	1	$68,4\times10^3$	3,0	70	639,1
Al initial		120 x10^3	4,6	53	720,4
Cu	1	$29,9\times10^3$	2,5	96	340,2
Cu notch	1	75,8 x10^3	0,8	380	103,3
Cu initial		15 x10^3	-	282	644,6

The copper sample before loading represented a monocrystal, and after loading as a result of dynamic recrystallization there are fine grains – the size – 0,8-2,5 μm. And dynamic recrystallization in a sample with a cut – here grains smaller is more developed. Quantity of a time in a sample with a cut too much more, than in a sample without a cut. Besides, in a sample with a cut a large number of strips of shift (fig.11d).



a b c d

Fig. 11. Copper structure: (a) - in an initial condition; (b) - after loading with the period of T=1μs (S=0,03mm2); (c) – sample with a cut after loading with the period of T=1μs (S = 0,08 mm2); (d) - sample with a cut after loading with the period of T=1μs (S = 0,08 mm2). Designations: grain – the recrystallized grains, band – shift strips.

4. Results comparison of static and dynamic materials destruction

It should be noted essential distinction of dynamic and static strength characteristics.
Comparison of structural changes at static and dynamic loading shows that at short-term influence there is a dynamic recrystallization – formation of new fine grains. Extent of dynamic recrystallization the greatest in samples with the bigger duration of loading and the maximum cross section (a large-scale factor). Aluminum samples after loading show big tendency to cavitation at increase in the period of loading in comparison with the initial. Besides, at increase in duration of influence in samples there is an origin of a multiple splitting off.

5. Conclusion

1. Techniques of experimental studying of quasistatic and dynamic properties metal foils are developed and applied.
2. Deformation and strength characteristics aluminum and copper foils are defined.
3. Analytical expressions for mechanical characteristics of materials are received.
4. The microstructural analysis of destruction zones is made at quasistatic and dynamic loading.
5. Comparison of properties of materials in the conditions of the static and dynamic loading, shown their essential distinction is carried out.

Abstract: As resourceful stress states, high strain rates, and large plastic deformation were involved, the Taylor test can be used to identify the most suitable fracture criterions for high velocity impact problems. A systematic evaluation is carried out for the maximum principal stress, the maximum principal strain, equivalent plastic strain and Johnson–Cook fracture models by numerical simulations. The applicability of the ductile fracture models are discussed, finally.

Keywords: Taylor impact, Ductile fracture, Johnson–Cook fracture model

1. Introduction

Considering high temperature and high strain rates, strength models and fracture criterions are needed in impact response calculation of metal material. There are J-C, ZA, MTS strength models and the maximum principal stress, the maximum principal strain, equivalent plastic strain and Johnson–Cook fracture models to chose from. It is necessary to evaluate these fracture models.

The Taylor test can get high strain rate (10^4~10^6), in which a deformable flat-nosed cylinder is fired against a fixed, rigid wall and was originally proposed to determine dynamic yield stresses of materials [1]. Taylor test results are used to validate or to estimate coefficients for phenomenological strength models needed for simulating dynamic loading processes using inverse identification procedures[2-4].

When Taylor bar runs fast, cracks and fragmentation phenomenon are very common. Couque (1998)[5] observed several spiral cracks which formed on the lateral surface of the cylinder in symmetric Taylor tests on swaged tungsten alloys.

Material mechanics performance test of Q235 was taken to calculate parameters of fracture criterions. The display dynamic analysis software AUTODYN was used to forecast failure modes of Taylor tests. The differences and limitations of the ductile fracture models are discussed, finally.

2. Mechanical property testing of Q235

To get parameters of the fracture criterions, cold quasi static single axis tensile test was done on MTS. Specimens were processed according to <GB/T228-2002>, whose diameter was 10mm, length of test part was 100mm (see Fig.1). Loading rate of this test was 0.6mm/min (strain rate was 2×10^{-4}/s).

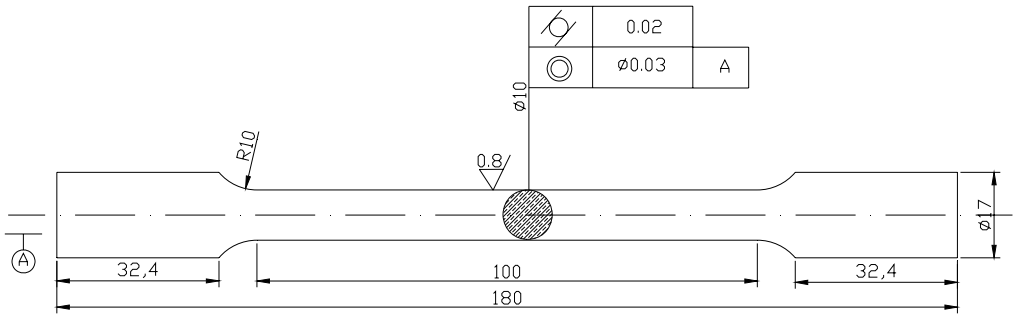

Fig.1 Schematic of specimen for quasi static single axis tensile tests

Engineering stress strain curve was got by the load-displacement curve. Parameters of the maximum principal stress, the maximum principal strain, equivalent plastic strain and Johnson–Cook fracture models were got by Stress triaxial degree test and tensile test at high temperature.

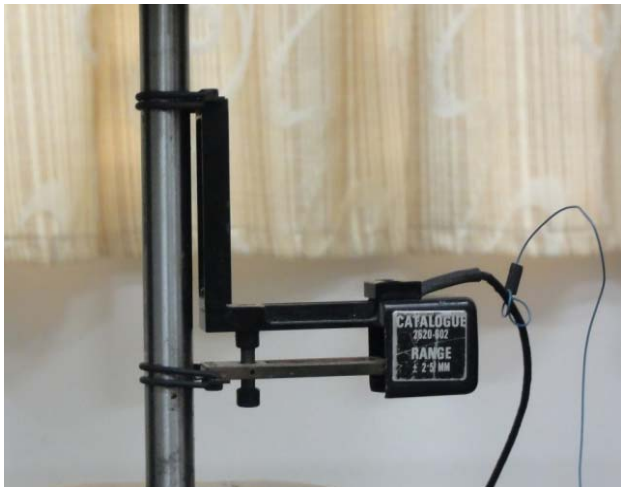

Fig.1 quasi static single axis tensile test

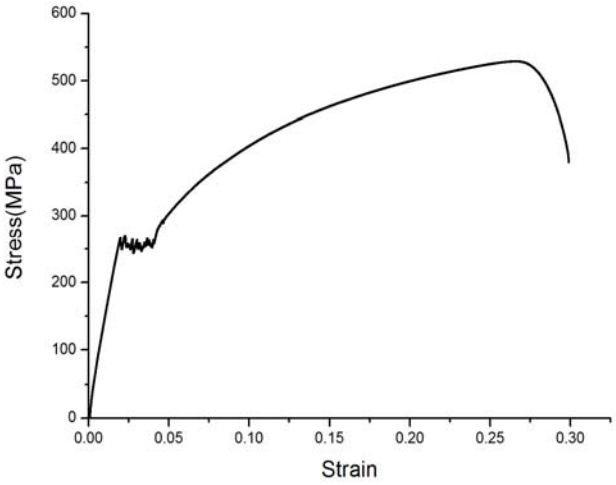

Fig.2 stress-strain curve of Q235

3. The numerical simulation model and the strength model

3.1 The numerical simulation model

Generally, in the Taylor test a deformable flat-nosed cylinder is fired against a fixed rigid wall (see Fig. 3). The cylindrical projectile is of the diameter d= 6mm and the length l= 30mm. The friction coefficient between the front surface of the projectile and the rigid wall is assumed to be $\mu = 0.1$.

Smoothed Particle Hydrodynamics method (SPH) was used to simulate the failure phenomena of cylinder. A 3-D solid finite element model was built rather than an axisymmetric model (see Fig. 4).

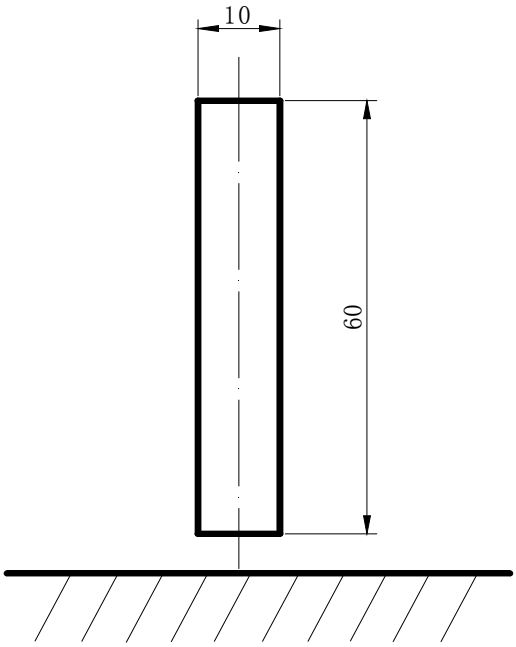

Fig. 3 Schematic of a cylindrical projectile impacting a rigid wall

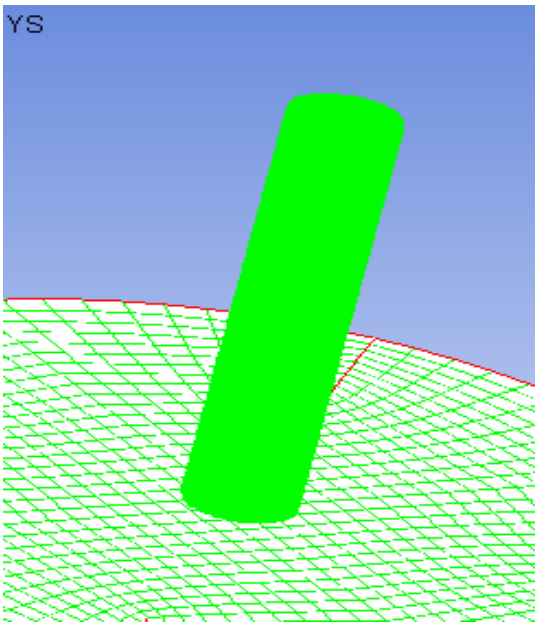

Fig.4 Finite element model of the projectile-target system

3.2 The strength model

Due to simplicity and availability of material coefficients, the Johnson–Cook (JC) material model implemented in AUTODYN was used in the present calculation. The material model should not be confused with the fracture model which will be discussed later. In the JC model the equivalent stress σ is an explicit function of the equivalent plastic strain ε_{eff}, the temperature T, and the plastic strain rate $\dot{\varepsilon}$.

$$\sigma = (A + B\varepsilon^{n})(1 + C\ln\dot{\varepsilon}^{*})(1 - T^{*m}) \tag{1}$$

Where the reference plastic strain rate $\dot{\varepsilon}^{*} = \dot{\varepsilon}/\dot{\varepsilon}_{0}$, $T^{*} = (T - T_{r})/(T_{m} - T_{r})$, T_{r} and T_{m} are the room temperature and the material melting temperature respectively, and A, B, n, C, and m are five material constants. The JC model accounts for isotropic strain hardening, strain rate sensitivity, and thermal softening in the uncoupled form. The first term of the right hand side of Eq. (1) represents the quasi-static stress–strain relation at room temperature; the second term signifies the strain-rate hardening; the third term means the temperature dependence of the stress–strain relation. It should be pointed out that in the computation, the material behaves elastically up to the point of initial yield and then follows Eq.(1).

The material parameters in the JC model for Q235 were listed in Table 1.

Table 1 Material parameters for Q235

Material	A（MPa）	B（MPa）	n	C	m
Q235	249.2	45.6	0.875	0.32	0.76

4. Results and analysis

4.1 The maximum principal stress failure criterion

Refering to quasi static tensile tests, the maximum principal stress of Q235 was 560MPa , The maximum shear stress of Q235 was 448MPa. With the simulation computation, failure mode of the maximum principal stress for different velocity is showing in Fig.5 and 6.

After impacting on the rigid wall, the Taylor bar was smashed. The fragments were very small and almost in the same volume (v=400m/s).

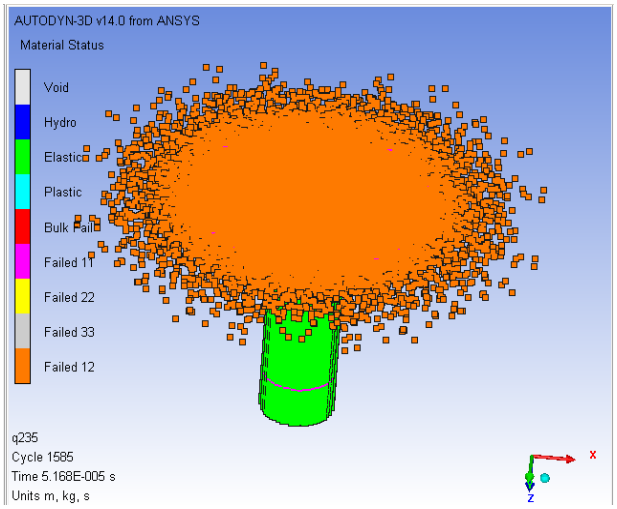

Fig.5 Failure mode of the maximum principal stress (v=300m/s)

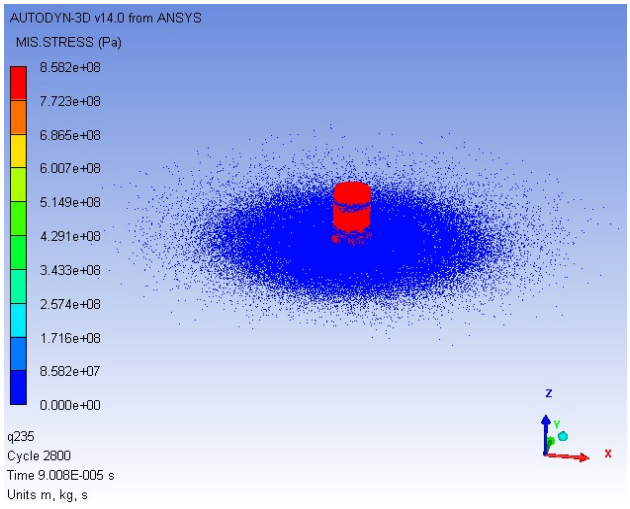

Fig.6 Failure mode of the maximum principal stress (v=400m/s)

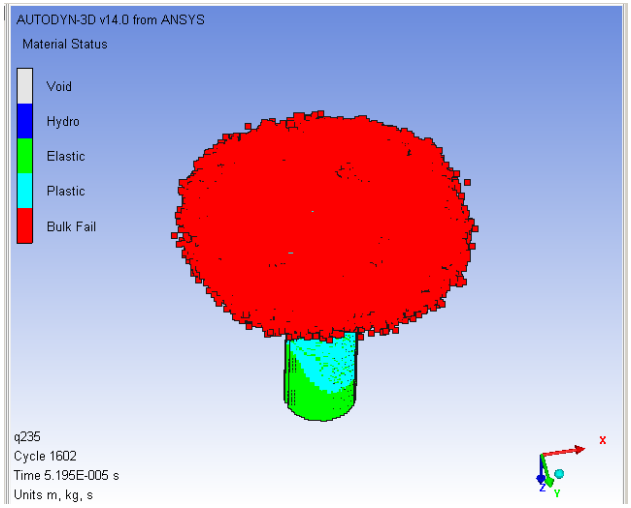
4.2 The equivalent plastic strain failure criterion

Refering to quasi static tensile tests, the equivalent plastic strain, $\varepsilon_f = 2\ln\left(\frac{d}{d_0}\right)$, for Q235 $\varepsilon_f = 1$.

Through the simulation, failure mode of equivalent plastic strain for different velocities (v=300m/s, 400m/s) are showing in Fig.7and 8.



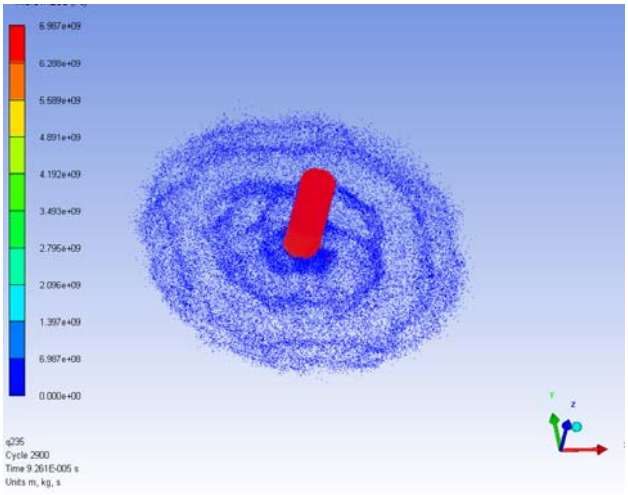


Fig.7 Failure mode of equivalent plastic strain (v=300m/s)

Fig.8 Failure mode of equivalent plastic strain (v=400m/s)

4.3 The maximum principal strain fracture criterion

Refering to quasi static tensile tests, The maximum principal strain was 0.33. Through the simulation, failure mode of the maximum principal strain in different velocities (v=300m/s, 400m/s) are showing in Fig.9 and 10.

About thirty fragments produced in this process, and the fragment volume was larger than that of above two fracture criterions.

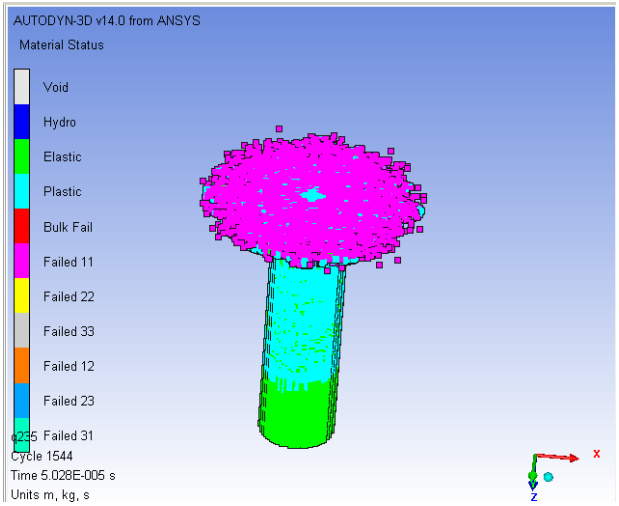

Fig.9 Failure mode of the maximum principal strain (v=300m/s)

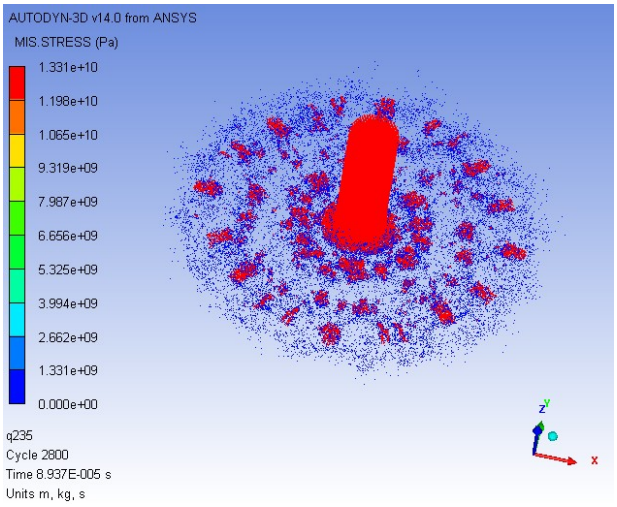

Fig.10 Failure mode of the maximum principal strain (v=400m/s)

4.4 J-C fracture criterion

The influence of the stress triaxiality in these models is based on the void growth equation proposed[6, 7].The expression of J-C fracture strain ε_f is[3]

$$\varepsilon_f = \left(D_1 + D_2 e^{\left(D_3 \sigma^*\right)} \right)\left(1 + D_4 \ln \dot{\varepsilon}^*\right)\left(1 + D_5 T^*\right) \tag{2}$$

D_1, D_2, D_3, D_4 and D_5 are material parameters; $\sigma^* = p/\sigma_{eff} = -\sigma_{kk}/\sigma_{eff} = -R_\sigma$, p is pressure, σ_{eff} is equivalent stress, R_σ is stress triaxiality; $\dot{\varepsilon}^* = \dot{\varepsilon}/\dot{\varepsilon}_0$ is dimensionless plastic strain rate, $\dot{\varepsilon}_0$ is Referenced plastic strain rate; $T^* = (T - T_r)/(T_m - T_r)$, T_r and T_m are the room temperature and the material melting temperature. For Q235, D_1=0.38, D_2=1.47, D_3=2.58, D_4=-0.0015, D5=8.07.

Through the simulation, failure modes of J-C in different velocities (v=300m/s, 400m/s) are showing in Fig.11 and 12.

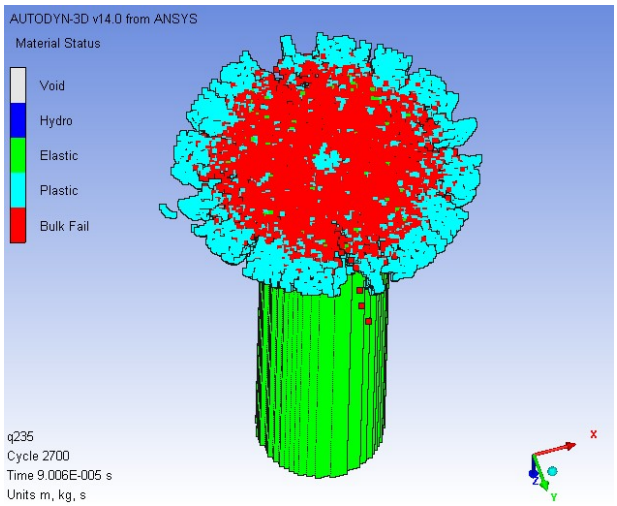

Fig.11 Failure mode of J-C(v=300m/s)

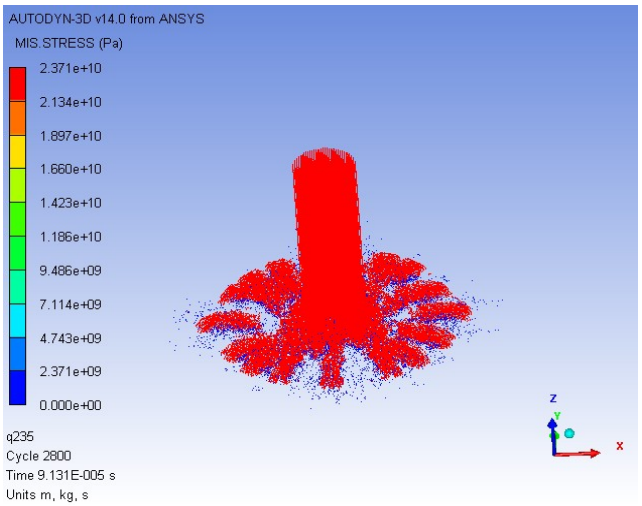

Fig.12 Failure mode of J-C(v=400m/s)

4. Conclusion

Through the above analysis and Taylor test, in which the Taylor bar was broken like petals, Finally, conclusions are summarized:
(1) Failure modes in high velocity impact problems are quite different because of choosing different fracture criterions.

(2) J-C fracture criterion is the most accurate fracture criterion in four fracture criterions for ductile metal in high velocity impact problems.

(3) The maximum principal stress and the equivalent plastic strain failure criterions lead to many fragments for ductile metal in high velocity impact problems.

Several kinds of Calculation Methods on the Crack growth Rates for Elastic-Plastic Steels

Yangui Yu*

Zhejiang GuangXin New Technology Application Academy of Electromechanical and Chemical Engineering
Hangzhou, 310007, China
* gx_yyg @126.com

Abstract Research interdependent correlations among various calculations models, relationship between their calculations parameters, and relationship between their materials constants in equations on strengths and life predictions, which are elastic-plastic steels with cracks. Thereby obtain and suggest to adopt several new calculations models and their calculations methods on crack propagation rates, which are respectively suitable for calculations of crack propagation rates under different stress ratio loading, or are suitable for calculations under symmetrical and unsymmetrical cyclic loadings, the work stresses less than or greater than the yield limit. Also the material constants B_2 in new models are defined as comprehensive material constants and give also out their physical meaning and geometric significances that are having a function relation with other parameters. Moreover provide yet a calculation example of crack propagation rate. Anticipate that the works will be having practical significances for fatigue - damage - fracture tests to save experimental times, fund inputs and to expand engineering applications.

Keywords Elastic-Plastic-materials, Comprehensive material constants, Crack growth rate, Calculation methods

1. Introduction

In the engineering fields, loading conditions are very complicated. In the engineering designs and calculations, there are a lot of calculating models are applied. In traditional design methods, for their calculating parameters, for their material constants adopted in the models, in addition to some key calculating parameters, in addition to some limited materials constants which are showing the material properties, they must be by means of the experiments to take data. However there are also some of the traditional calculating models, their calculating parameters and material constants had been already extensively applied, which had been derived usually from the relationships between various calculation parameters or from the relationships between all kinds of material constants, afterwards again applied to engineering design calculation and analysis.

The same, for including cracks structures and materials undergone to very complicated loadings, the calculations on their strengths, crack propagation rates and service life, in all kinds of calculation models also must refer to many calculation parameters and material constants, but these required parameters of designs and calculations got from experiments are always limited. In fact, between these calculations parameters or between these materials constants each other, there are also usually some functional relations. So that to research and analyze these calculations models, their calculations parameters and materials constants, of course, some new models and their parameters and constants can also be derived from them and would be applied to designs and calculations in engineering.

The author researches various strengths, crack propagation rates and life calculations models, to analyze and find interdependent relationships between the various calculation parameters and all kinds of material constants, proposes respectively several new calculation models and calculation methods for the elastic-plastic steels with cracks. But also puts forward specially the new concepts of comprehensive material constants and their calculation methods, its purpose is in combination

with limited experimental data and conventional material constants, thereby to realize the calculations for the crack growth rates and to do the life predictions which are in different stress ratio under complicated loading conditions. Moreover, provides yet homologous calculation examples. Anticipate that the works will be having practical significances for fatigue - damage - fracture tests to save experimental times, fund inputs and to expand engineering applications.

2. The calculations of crack growth rate for elastic-plastic steels

In references [1，2] provide the relation between the fracture life N_{2fc} and half-cycle of amplitude value $\Delta\delta_t/2$ of crack tip open displacement at crack growth stage,

$$\frac{\Delta\delta_t}{2} = \delta_{fc} \times 2N_{2fc}^{c'_2} \tag{1}$$

But if it is expressed to adopt one-cycle of crack tip open displacement range $\Delta\delta_t$, it become as following form

$$\Delta\delta_t \times N_{2fc}^{-c_2} = B_2^{c_2} \tag{2}$$

And relation between the crack growth rate da_2/dN_2 and one-cycle of crack tip open displacement range $\Delta\delta_t$ is as discussed [3~4],

$$da_2/dN_2 = B_2\Delta\delta_t^{\lambda_2} \tag{3}$$

Where the equations (1) and (2) can be described as the reversed beeline C_2C_1 in bidirectional combined coordinate system and bidirectional curves in the whole process(Fig.1) ［5~7］, that is predigested by logarithm transacting just is showed the relation between the life and the crack tip open displacement. And the equations (3) can be described as the positive direction beeline C_1C_2, it just is showed for the relation between the crack growth rate and the crack tip open displacement.

Research and discover that in fact the relations among equations (1), (2) and (3) are consistent. Here the parameters λ_2, c_2 and B_2 are all material constants. λ_2 and c_2 are exponents of equations, $\lambda_2 = -1/c_2$, its geometrical meaning is the slope of force triangle bevel edge. Of course some key material constant in the engineering calculations must be obtained from experimentations. But actually in a number of calculation models, there are functional relationps between some parameters or between some material constants each other, so that we can use the kinds of having

important significances of correlations, can derive a number of beneficial formulas, obtain some calculation methods on the strengths, crack propagation rates and life predictions. For example between the material constant B_2 and other constants are having functional relations as formulas below,

$$B_2 = 2(2\delta_{2\,fc})^{-\lambda_2}(a_{2c} - a_{02})/(N_{2c} - N_{02})\ (\sigma_m = 0) \tag{4}$$

$$B_2 = 2\left(2\delta_{2\,fc}(1 - \frac{\delta_m}{\delta_{2\,fc}})\right)^{-\lambda_2} \times (a_{2c} - a_{02})/(N_{2c} - N_{02}),(\sigma_m \neq 0) \tag{5}$$

Where $\delta_{2\,fc}$ in (4~5) are critical value of the crack tip open displacement, $\delta_{2\,fc} = \delta_c$, the B_2 is defined as comprehensive material constants. Its physical meaning is a concept of power, is a maximal increment value, and also is given out energy in one cycle made specimens to failure. Its geometrical meaning is a maximal micro-trapezia area to approximate to beeline, and is also an intercept between $O_3 - O_4$ (Fig.1). And slope of micro-trapezium bevel edge just is corresponding to the exponent λ_2 of formula (4, 5). a_{2c} is a critical crack size, a_{02} is initial (or precrack) crack size. N_{02} is initial life, $N_{02} = 0$; N_{2c} is a critical life. δ_m is a mean value of the crack tip open displacement, $\delta_m = (\delta_{\max} + \delta_{\min})/2$, here $\delta_{\max}$ and $\delta_{\min}$ are the maximal and minimal values of the crack tip open displacement. Moreover if its unit of the parameter B_2 is calculated by 'mm', then the value of B_2 must be again multiplied by 1000.

For the sake of safety, the comprehensive constant B_2 should be calculated as following form,

$$B_{2eff} = 2\left(2\delta_{2eff}(1 - \frac{\delta_m}{\delta_{2\,fc}})\right)^{-\lambda_2} \times (a_{2eff} - a_{02})/(N_{pv} - N_{02}) \tag{6}$$

Where B_{2eff} is also an effective comprehensive material constant, its physical meaning is a given out effective energy in one cycle made specimens before failure. Here $(a_{2eff} - a_{02})/(N_{pv} - N_{02}) = v_{pv}$, v_{pv} is defined to be the virtual rate, $v_{pv} = v^*(m/cycle)$ [6,8]. $v_{pv} \approx 3\times10^{-8} \sim 3\times10^{-7} = v^*,(m/cycle)$. a_{eff} is an effective size during steady growth course. N_{pv} is a virtual life. δ_{2eff} is an effective value of crack tip open displacement, that is the parameters during steady growth course, they must be all obtained from experiment. Here suppose that

$\delta_{2eff} = (0.3 \sim 0.4)\delta_c$.

It should point that for elastic-plastic materials, the calculating validity of the crack tip open displacement is restricted by different work stresses σ, their calculation expressing forms would be different for work stress under $\sigma < \sigma_s$ or $\sigma > \sigma_s$ condition. Such, calculations of the crack growth rate in equation (3), in addition to directly calculate from the experiment achieved data, and can also use the following varied calculation methods to calculate it.

2.1 Calculations for crack growth rate under work stress $\sigma < \sigma_s$ condition

According to the D-M' as discussed by [9] mathematical model to calculate the crack tip open disparagement δ_t, it can be adopted as following equation.

$$\delta_t = \left(\frac{8\sigma_s a_2}{\pi \cdot E} \ln \sec \frac{\pi \times \sigma}{2\sigma_s} \right) \tag{7}$$

Under $\delta_t -> \delta_c$, $K_1 -> K_{1c}$ condition, and the work stress $\sigma / \sigma_s << 1$ ($\sigma \le 0.5\sigma_s$), for the D-M' model is made by simplify treatment, it is

$$\delta_t = \beta \frac{y_2 K_2^2}{E \cdot \sigma_s} \tag{8}$$

Here y_2 is correction coefficient related to crack size and shape. The coefficient β is $\beta = 1$ under plane stress condition, and $\beta = (1 - \nu^2)/2$ under plane strain condition. ν is Poisson's ratio. If $\beta = 1$ and under cyclic loading, the crack tip open displacement can adopt three of kinds calculations methods as following forms.

(1) The calculations methods used by the stress intensity factor $K_2 (= K_I)$

For this method, the comprehensive material constant B_{2eff} and the crack tip open displacement $\Delta\delta_t$ range in the crack propagation rate equation da_2 / dN_2 are all to adopt the stress intensity factor to express. Here the crack tip open displacement range $\Delta\delta_t$ can be [9],

$$\Delta\delta_t = \frac{y_2 \Delta K_2^2}{2E \cdot \sigma_s} \tag{9}$$

$$\frac{da_2}{dN_2} = B_{2eff} \times v_{pv} \times \left(\frac{y_2 \Delta K_2^2}{2E \cdot \sigma_s} \right)^{\lambda_2}, (m/cycle), (\sigma_m = 0) \tag{10}$$

Here for $\sigma < \sigma_s$, and under the symmetrical cyclic loading ($R_\delta = \delta_{\min} / \delta_{\max} = -1$),

$$B_{2eff} = 2 \left(\frac{K^2{}_{eff}}{2E \cdot \sigma_s} \right)^{-\lambda_2} \times v_{pv} \tag{11}$$

But for $R_\sigma = \sigma_{\min} / \sigma_{\max} \neq -1$ (or $R_\delta = \delta_{\min} / \delta_{\max} \neq -1$), for $\beta = 1$, the parameters δ_m in equations (6) should be also changed as follow forms,

$$B_{2eff} = 2 \left\{ \frac{K^2{}_{eff}}{2E \cdot \sigma_s} \times \left(1 - \frac{K_{1\max}^2 + K_{1\min}^2}{2K_{1c}^2} \right) \right\}^{-\lambda_2} \times v_{pv} \tag{12}$$

$$K_{eff} \approx \sqrt{K_{th} K_{1c}} \quad \text{or} \quad K_{eff} \approx (0.25 \sim 0.55) K_{1c} \tag{13}$$

Where K_{eff} is an effective stress intensity factor, K_{th} is threshold stress intensity factor. $K_{1\max}$ and $K_{1\min}$ are respectively the Maximums and minimums value of stress intensity factor. E is a modulus of elasticity. In fact the (12) is consistent with (6).

(2) The calculation methods used by the stress σ

For this method, the comprehensive material constant B_{2eff} and the crack tip open displacement $\Delta\delta_t$ range in the crack propagation rate equation are all to use the stress to express. Here the crack tip open displacement δ_t and $\Delta\delta_t$ are as below [10]

$$\delta_t = \pi \sigma_s y_2 (\sigma / \sigma_s)^2 a_2 / E, (m) \tag{14}$$

Under cyclic loading, and for stress ratio $R_\delta = \delta_{\min} / \delta_{\max} = -1$, the crack tip open displacement

range is,

$$\Delta\delta_t = \frac{y_2 \Delta\sigma^2 \pi a_2}{4\sigma_s E}, (m) \tag{15}$$

Then equation of crack growth rate is

$$\frac{da_2}{dN_2} = B_{2eff} \times \left(\frac{y_2 \Delta\sigma^2 \pi a_2}{4\sigma_s E} \right)^{\lambda_2}, (m/cycle) \tag{16}$$

And for different stress ratio, the B_{2eff} are respectively,

$$B_{2eff} = 2\left[4(\pi\sigma_s(\sigma_{meff}/2\sigma_s)^2 a_{meff}/E)\right]^{\lambda_2} \times v_{pv}, (\sigma_m = 0) \tag{17}$$

$$B_{2eff} = 2\left\{4(\pi\sigma_s(\sigma_{meff}/2\sigma_s)^2 a_{meff}/E)\left(1 - \frac{a(\sigma_{\max}^2 + \sigma_{\min}^2)}{2a_{meff}\sigma_s^2}\right)\right\}^{-\lambda_2} \times v_{pv}, (\sigma_m \neq 0) \tag{18}$$

Where σ_{meff} is maximal effective stress, $\sigma_{meff} = (0.5 \sim 0.55)\sigma_s$. a_{meff} is a maximal effective crack size,

$$a_{meff} = \frac{K_{eff}^2}{\sigma_s^2 \pi} = \frac{(0.5 \sim 0.55)K_{1c}^2}{\sigma_s^2 \pi}, (m) \tag{19}$$

(3) Calculation method of combination of the stress and the stress intensity factor

For this method, the comprehensive material constant B_{2eff} in the crack propagation rate equation adopts the stress intensity factor to express, and the crack tip open displacement $\Delta\delta_t$ range adopts the stress to express. So their forms are as bellows

$$\frac{da_2}{dN_2} = 2\left(\frac{K^2{}_{eff}}{2E \cdot \sigma_s} \right)^{-\lambda_2} \times v_{pv} \times \left(\frac{y_2 \Delta\sigma^2 \pi a_2}{4\sigma_s E} \right)^{\lambda_2} (\sigma_m = 0) \tag{20}$$

$$\frac{da_2}{dN_2} = 2\left(2(K_{eff}/\sigma_s)^2 \times \frac{\sigma_s}{E}\left[1 - \frac{K_{2\max}^2 + K_{2\min}^2}{2 \cdot K^2{}_{1c}}\right] \right)_{eff}^{-\lambda_2} v_{pv} \times \left(\frac{y_2 \Delta\sigma^2 \pi a_2}{2\sigma_s E} \right)^{\lambda_2} (\sigma_m \neq 0) \tag{21}$$

It must point that the equations (10), (16), (20) and (21) can also only apply to work stress $\sigma/\sigma_s << 1$($\sigma \le 0.5\sigma_s$).

2.2 Calculations for crack growth rate under work stress $\sigma => \sigma_s$ condition

On the other hand, for work stress $\sigma => \sigma_s$ condition, it must be changed to use as following calculating equations. Here there are also two kinds of methods

(1) The calculation methods used by the stress σ

It also can directly use the stress σ to calculate the δ_t and $\Delta\delta_t$ [10]. Here the crack tip open displacement δ_t and $\Delta\delta_t$ are as bellows [10]

$$\delta_t = \frac{0.5\pi\sigma_s y_2(\sigma/\sigma_s + 1)a_2}{E} \quad (m) \tag{22}$$

$$\Delta\delta_t = \frac{\pi\sigma_s y_2(\Delta\sigma/2\sigma_s + 1)a_{02}}{E}, (m) \tag{23}$$

$$\frac{da_2}{dN_2} = B_{2eff} = \left(\frac{\pi\sigma_s y_2(\Delta\sigma/2\sigma_s + 1)a_2}{E}\right)^{\lambda_2}, (m/cycle) \tag{24}$$

$$B_{2eff} = 2\left\{2\left[(\pi\sigma_s(\sigma/\sigma_s + 1)a_{meff}/E\right]\right\}^{-\lambda_2} \times v_{pv} \ (\sigma_m = 0) \tag{25}$$

$$B_{2eff} = 2\left\{\left[2(\pi\sigma_s(\sigma/\sigma_s + 1)a_{meff}/E\right] \times \left(1 - \frac{a(\sigma_{\max}^2 + \sigma_{\min}^2)}{2a_{meff}\sigma_s^2}\right)\right\}^{-\lambda_2} \times v_{pv} \ (\sigma_m \neq 0) \tag{26}$$

$$a_{meff} = \frac{E\delta_{eff}}{\pi\sigma_s(\sigma/\sigma_s + 1)}, (m) \tag{27}$$

Where $\delta_{eff} = (0.3 \sim 0.35)\delta_c$.

(2) The calculation methods combined by stress and strain

Its method is that the comprehensive material constant B_{2eff} to adopt the δ_{eff} to express, and the crack tip open displacement to adopt the stress σ to express, its form as follow

$$\frac{da_2}{dN_2}=2\left(2\delta_{eff}(1-\frac{\delta_m}{\delta_c})\right)^{-\lambda_2}\times v_{pv}\left(\frac{y_2\pi\sigma_s(\Delta\sigma/2\sigma_s+1)a_2}{E}\right)^{\lambda_2},(\sigma_m\neq 0) \tag{28}$$

Here can take $\delta_m\approx 0$.

3. Calculation example

A pressure vessel is made with steel 16MnR, its strength limit of material $\sigma_b=573MPa$, yield limit $\sigma_s=361MPa$, modulus of elasticity $E=200000MPa$. Critical stress intensity factor $K_{2c}=K_{1c}=92.7\text{MPa}\sqrt{\text{m}}$. Suppose shape correcting coefficient of long crack $y_2=1.01$. Its local stress $\sigma_{\max}=450\,MPa$ at stress concentration point, $\sigma_{\min}=0$. Other computing data is all in table 1. Try to calculate the growth rate da_2/dN_2 at crack size $a_2=0.001m$ under $\sigma=450MP>\sigma_s=391\ \ MPa$ conditions.

Table 1. Calculation data

$K_{1c},MPa\sqrt{m}$	$K_{eff},MPa\sqrt{m}$	$K_{th},MPa\sqrt{m}$	v_{pv}	m_2	$\delta_{2\,fc},m$	λ_2	y_2	β
92.7	28.23	8.6	2×10^{-7}	3.91	0.00018	2.9	1.01	1

(1) Calculations for relevant parameters

1) According to table 1, take the virtual rate, $v_{pv}=2\times10^{-7}\,(\text{m/Cycle})$.

2) Take effective crack tip open displacement,

$\delta_{eff}=0.35\times\delta_c=0.35\times0.00018m=6.3\times10^{-5}(m)$; Take $\delta_m\approx 0$.

3) Calculation for effective crack size

$$a_{eff}=\frac{\delta_{eff}E}{\pi\sigma_s(\sigma/\sigma_s+1)}=4.94537\times10^{-3}(m)$$

4) According to (26), calculation for comprehensive material constant B_{2eff}

$$B_{2eff}=2\left[2\times(\pi\sigma_s(\sigma/\sigma_s+1)a_{eff}/E)\right]^{\lambda_2}\times v_{pv}$$
$$=2\left[2\times3.1416\times361(450/361+1)\times0.00494537/200000\right]^{2.9}\times2\times10^{-7}=84151(m^{\lambda_2}\cdot m/cycle)$$

The experiment value of Steel 16MnR, $B_2=84570$, and here its calculation value 84151, so that it is close to experimental data.

5) According to equation (23), computing for crack tip open displacement range $\Delta\delta_t$

$$\Delta\delta_t = \frac{y_2\pi\sigma_s(\Delta\sigma/2\sigma_s+1)a_2}{E} = \frac{1\times3.1416\times361(450/2\times361+1)0.001}{200000} = 9.204\times10^{-6},(m)$$

(2) Calculation for crack growth rate under $\sigma = 450MPa > \sigma_s$ condition.

According to equation (24), at $a_2 = 0.001m$, its crack growth rate is

$$\frac{da_2}{dN_2} = 2\left[2\times(\pi\sigma_s(\sigma/\sigma_s+1)a_{eff}/E)\right]^{\lambda_2}\times v_{pv}\left[\frac{\pi\sigma_s y_2(\Delta\sigma/2\sigma_s+1)a_2}{E}\right]^{\lambda_2}$$
$$= 2\left[2\times3.1416\times361(450/361+1)\times0.00494537/200000\right]^{2.9}\times2\times10^{-7}$$
$$\times\left[\frac{3.1416\times361(450/2\times361+1)0.001}{200000}\right]^{2.9} = 84151\times2.4869\times10^{-15} = 2.062\times10^{-10},(m/cycle)$$

4. Conclusions

(1) The correlating equation $\Delta\delta_t/2 = \delta_{fc}\times2N_{2fc}^{c'_2}$ between half-cycle of crack tip open displacement amplitude $\Delta\delta_t/2$ and life N_{2fc}, the correlating equation $\Delta\delta_t\times N_{2fc}^{-c_2} = B_2^{c_2}$ between one-cycle of crack tip open displacement range $\Delta\delta_t$ and life N_{2fc} and the correlating equation $da_2/dN_2 = B_2\Delta\delta_t^{\lambda_2}$ between one-cycle of crack tip open displacement range $\Delta\delta_t$ and crack growth rate da_2/dN_2, which the interrelations among three of kinds relation- expressions actually are consistent.

(2) The crack growth rate equations (10), (16), (20), (21), (24) and (28) of suitable for elastic-plastic steels are also consistent with the rate equation (3) in [3, 4]. But the material constant B_2 in latter (3) is obtained from experiment under constant stress ratio condition, so that only applying to corresponding loading. And the former, they can respectively do calculations for cracks growth rates of suitable for different stress ratio and loading conditions which they are only in combination with a small number of experiment data, Therefore they can expand the application ranges, and increase the calculating reliabilities and safeties.

(3) The comprehensive materials constants B_2 and B_{2eff} in crack growth rate equations are to have interdependent functional relationships with parameters δ_{eff}, λ_2, δ_m and v_{pv}. Its physical

meaning of the B_{2eff} is to give out effective value of energy in one cycle made specimens before to failure. Its geometrical meaning is a maximal micro-trapezia area to approximate to beeline.

(4) The crack growth rate equations (24) and (28) are generally suitable for under $\sigma => \sigma_s$; and the (10), (16), (20) and (21) can only applied to under $\sigma <= 0.5\sigma_s$. If the (10), (16), (20), (21) are applied to under $\sigma > 0.5\sigma_s$ and $\sigma < \sigma_s$, their calculation error are larger.

Abstract Corrosion fatigue is identified as one of the main failure mechanism for structures working in corrosive environment. The existing study on pit corrosion showed that cracks do not necessarily initiate from the bottom of the pit. Where the crack initiate from pit depends on the pit shape (aspect ratio), loading and the corrosive environment. In this study, firstly, the corrosion pit development in size and shape and its effect on fatigue life were reviewed. Fatigue tests were conducted on pre-pitted and smooth samples to further investigate the pit effect. Then various aspect ratios of pits were modeled to calculate the SCF in a round bar under tension and bending loadings.In addition, the SCF of a wide range of aspect ratios of pits were calculated, by which it is expected to offer the engineering practice and researchers convenience to find SCF value.

Keywords Corrosion pits 1; Aspect ratio 2; Stress concentration factor 3; Fatigue life 4

1. Introduction

Pitting corrosion is considered to be one of the principal degradation mechanisms for many metallic materials subjected to corrosive environment. The fatigue life was shortened due to formation of corrosion pits on surface of the material causing the initial damage and then cracks initiated from these pits. Pit development and its effect on corrosion fatigue crack growth have been extensively studied, but there is little consensus with regard to the exact relationship between the pit size and the time due to the interaction of environment and loading and the dependence on microstructural state and stress level.

The main purpose of the present paper is to provide a review of the pit formation and its effect on fatigue lives, attempting to develop a generalized understanding of how the pits develop. Then fatigue tests were conducted on pre-pitted and smooth samples to further investigate the pit effect. Finally, various aspect ratios of pits were modeled to calculate the SCF in a round bar under tension and bending loadings.

2. Corrosion pit development

2.1 Pit size development

Corrosion pit size varies as exposure time in solution increases and depends on electrochemical and mechanical conditions. Many researchers have conducted extensive studies on pit development and various relationships between and pit size and time were proposed. Sriraman et al [1] developed a model that considers the coexistence of corrosive environment and fatigue loading conditions and took into account the influence of cyclic stresses in the pitting corrosion process. Boag et al [2] observed stable pit formation on AA2024-T3 in a NaCl environment, and indicated that local clustering played an important role in pit initiation. Ryuichiro Ebara [3] emphasizes initiation and growth of corrosion pits in the corrosion fatigue crack initiation process. The pit size distribution

data in [4] suggests that the depth of the pits in alloys such as 7075-T6 increases by the interconnection of the pits that have nucleated at constituent particles at various depths through the thickness of the exposed alloy. Rybalka's study [5, 6] on pitting development on Stainless Steel 403 Steel and 20Kh13 showed that the size of pit is affected by the PH and temperature of the solution and the electrode rotation. Additionally, the depth of growing pits as a function of time can be described by the equation $h = 2.25+3.39t^{1/2}$. While the depth h of growing pits on 20Kh13 steel in 0.01 M NaCl solution at ΔE= 30 mV increases with the time as $h \sim t^{1/2}$, and an average pit diameter d obeys the relationship $d = d_0(1-e^{-0.07t})$. P. Ernst [7, 8] proposed that the pit width increases almost linearly with time, and the pit growth in depth follows a parabolic law with time ($\propto \sqrt{t}$) and is independent of the potential, whereas lateral pit growth is linear with time and dependent upon potential. Harlow and Wei [9] assumed that the pit maintained hemispherical geometry and grew at a volumetric rate determined by Faraday's law, and the aspect ratio is a continuous function of time. The relationship between the depth (a) and the diameter ($2c$) of pits was studied by Kondo [10] and showed that the pit growth occurred at the same aspect ratio $a/c \approx 0.7$. The corrosion pit growth law can be formulated as $2c \propto t^{1/3}$. Cavanaugh [11] used optical profilometry and Weibull functions to characterize pit depth and diameter distributions and found pit growth kinetics varied by environment, but most followed approximately $t^{1/3}$ kinetics. Sriraman [12] proposed the depth a_p is considered proportional to the cube root of t through the relationship of $a_p = Bt^{1/3}$. Buxton [13] described the pit growth law following a typical power law curve ($x = Bt^{\beta}$) with a relatively large exponent value of 0.596. Turnbull [14] also assumed that the depth can be described by $x = \alpha t^{\beta}$, and examples of the results [15] for three environmental exposure conditions in terms of the variation of aspect ratio with pit depth are illustrated.

As illustrated above that various relationship was developed for pit depth and width. But the literature mostly suggests that the pit width follows a linear relationship with time shown in Fig. 1 (left) and the pit depth is linearly proportional to the square root of time in Fig. 1 (right).

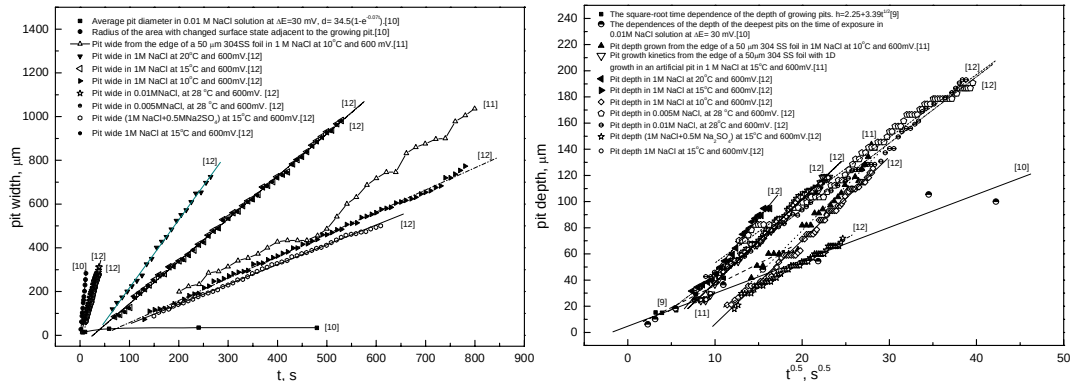

Fig. 1. Corrosion pit width vs t and depth vs $t^{0.5}$.

2.2 Pit shape development

Pidaparti et al [16] noted that the pit/defect profile changing its shape (both depth and width) from slightly conical to more hemispherical shape with increasing corrosion time and stress distribution and levels vary non-linearly around a single pit/defect. Melchers [17] proposed that the sequence consists of the development of anodic areas, development of small pits and shallow broad pits, the apparent coalescence of small pits into larger localized corrosion and eventually the appearance of

stepped or benched, perhaps irregular shaped broad or macro-pits. Ernst [7, 8] carried out a semi-quantitative model to explain lacy pit cover formation and pit growth, representing the shape of a pit and pits within pits grown from the edge of a 50 μm 304 SS foil in 1 M NaCl at 15℃ and 600 mV. An SEM microfractograph of a typical nucleating corrosion pit on the fracture surface of a specimen that had been precorroded for 384 h was given by Dolley [18]. And elliptical pits developed from the artificial pit were given in [19].

3. Effect of the corrosion pit on fatigue lives (crack initiation)

3.1 Effect of the corrosion pit on crack initiation and propagation.

Corrosion pits acted as pre-existing flaws in the material to nucleate fatigue cracks. Burstein [20] and Li Lei [21] indicated that the evolution of corrosion pit followed three stages: nucleation, metastable growth and stable growth. The pit size observed on the fracture surface is considered to give the critical pit size that depends on the cyclic stress amplitude at which the transition occurred [10]. A comprehensive seven-stage model is developed in [22, 23] for pitting corrosion fatigue damage process, including pitting nucleation, pit growth, transition from pit growth to short crack, short crack growth, transition from short crack to long crack, long crack growth, and fracture. Bastidas-Arteaga [24] assessed the total corrosion-fatigue life as the sum of three critical stages: corrosion initiation and pit nucleation; pit-to-crack transition, and crack growth. Turnbull [14, 15] noted that fundamental steps in the overall process of crack development include pit initiation, pit growth, the transition from a pit to a crack, short crack growth and long crack growth, and suggested that cracks do not necessarily initiate from the bottom of the pits, for the reason that there were many cracks with a depth smaller than that of the corresponding pit. While Ebara [25] found that the crack initiated at the bottom of corrosion pit where stress concentration is large and is presumably electrochemically active, and indicated that corrosion fatigue cracks essentially nucleated and grew from one or two large pits at the circular hole surface near the area of maximal stresses [26]. It is indicated that the largest pits did not nucleate cracks, which is due to the result of a combination of the ‘bluntness’ of the larger pits, and they were not located at the root of the notch, where the stress concentration is highest [27]. As regards to the SUS 630 specimen, the fracture surface showed that the fatigue crack propagation displayed high non-linear in route [28].

The initiation and growth of corrosion pit, crack initiation from corrosion pit and the crack propagation appearance can be vividly identified in [25]. Based on the modeling results of Bastidas-Arteaga [24], G. S. Chen [26] and Medved [27], two criteria are proposed to describe the transition from pit growth to fatigue crack growth: (1) the stress intensity factor of the equivalent surface crack has to reach the threshold stress intensity factor, ΔK_{th}, for fatigue crack growth, assuming that a corrosion pit may be modeled by an equivalent semi-elliptical surface crack; (2) the time-based corrosion fatigue crack growth rate also exceeds the pit growth rate.

The results of Sriraman and Pidaparti [1, 12] indicated crack initiation from pit sites can be extremely fast at high stress levels and can occur even from relatively small pits. And Kondo [10] pointed that at higher stress levels, transition occurred at fairly small pit sizes. On the other hand, at lower stress levels, transition occurred at larger pits. Medved [27] arrived at the conclusion that pits were deeper than wide with aspect ratios up to 4, many of which nucleated fatigue cracks were not

singular pits, but rather comprised of multiple needlelike pits. The observed synergistic effects of environmental, material and loading parameters on the environmental acceleration of fatigue crack growth in low-alloy RPV steels are discussed in [29]. Sivaprasad [30] noted the mechanism of corrosion fatigue crack growth for the two HSLA steels changes with attendant change in the Paris slope, and temperature, water flow speed, ionic concentration, material quality, and load condition play a crucial role in the behavior of fatigue crack propagation of SUS 630 [28]. Bjerkén [31] examined the manners in which the cracks grow and coalesce on the surface and showed that the cracks avoid each other initially and coalesce crack tip to crack side.

3.2 Stress intensity factor/ stress concentration factor around corrosion pits

Ramsamooj [32] suggested the parameters needed to predict corrosion fatigue might be the crack velocity caused by stress-corrosion, the applied mechanical stress, frequency, and the threshold stress intensity factor. Cerit and Genel [33] investigated the stress distribution at the semi-elliptical corrosion pits and pointed out that the aspect ratio is the main parameter affecting the stress concentration factor (SCF). The initiation and propagation of the non-propagating crack at the bottom of the artificial corrosion pit, were explained with the stress concentration factor of the pits and the stress intensity factor (SIF) range of the crack tip in [34]. Sankaran et al [4] concluded that the effects of pitting corrosion on fatigue lives can be related to the effects of equivalent stress concentration factors that are routinely used in structural design. Eduardo R. de los Rios [35] proposed an equation to evaluate the stress concentration as a function of distance from the pit center. Carpinteri et al [36-38] calculated the SIF of elliptical-arc surface cracks and the maximum stress-intensity factor is obtained at the deepest point on the crack front. W. Guo [39] showed that the SIF is strongly dependent on SCF, and the influence of notch geometry is negligibly weak for a given stress concentration coefficients. Toribio's [40] review on SIF for surface cracks in round bars under tension loading indicated that SIF increases with the crack depth and decreases with the crack aspect ratio and changes continuously from the crack center to the crack surface.

3.3 Effect of the corrosion pit on fatigue life

The influence of the pitting was on initiation and very early growth stages of fatigue. Further reductions in fatigue lives were associated with increases in pit size. And corrosion fatigue lives were reduced by 40-50% from those of pristine samples [27]. Y. Kondo [10] proposed a residual life prediction method for fatigue crack initiation for the case where crack initiation is controlled by pitting. P. Shi [22] studied on the damage tolerance approach for probabilistic pitting corrosion fatigue life prediction and found that pit nucleation time and the material constant for short crack growth are the two most important random variables affecting corrosion fatigue life. Emilio Bastidas-Arteaga [24] developed a model to predict the corrosion fatigue lifetime. The results showed that the coupled effect of corrosion-fatigue on structures strongly affects its performance, leading to large reduction in the expected lifetime.

Together with the rotating bending fatigue tests with various loads on shaft specimens in various extent of pitting corrosion conditions and the fatigue fracture surface analyses, the fatigue lifetime of SUS 630 shaft under various extent of pitting corrosion condition is found to be in a range of

only 2.5-27% of that of the uncorroded condition [28]. Sriraman [12] presents a simple integrated deterministic model for life prediction in a high-strength aluminum alloy subject to pitting corrosion under cyclic stresses. The overall corrosion-fatigue life is the sum of crack initiation and propagation. At higher stress levels, there is not enough time for pits to develop and hence failure is not associated with stress concentration at the base of a pit, whereas life prediction at low stress amplitude is possible using only pit growth times [13]. Dolley [18] interpreted the reduction in fatigue life depending upon the pre-corrosion time and in turn the initial pit size. Rokhlin [19] established an empirical relation to predict fatigue life $N = N_{th}(d/h)^{-3/4}$. Yongming Liu [41] predicted the probabilistic fatigue life by using an equivalent initial flaw size (EIFS) distribution, which is independent of applied load level and only uses fatigue limit and fatigue crack threshold stress intensity factor. A method for estimation of the cumulative distribution function (CDF) for the lifetime is demonstrated to predict the lifetime, reliability, and durability beyond the range of typical data by integrating the CDFs of the individual RVs into a mechanistically based model [42].

4. Corrosion fatigue testing

To further illustrate the effect of corrosion pit on fatigue life, the test on pre-pitted in air and in corrosion solution of 3.5% NaCl were conducted. Fig.2 shows the *S-N* data for air and corrosion fatigue tests. It can be seen that the air fatigue P1200 samples have the longest fatigue lifetimes. The stress concentration factor of the pre-pitted samples, with a pit aspect ratio of 0.11, is around 1.5 [33]. This geometry of defect significantly reduces the fatigue life by over 60%. At 298 MPa, the air fatigue life of the pre-pitted sample is only 16% of that of the P1200 samples, while the corrosion fatigue lives are further reduced. The corrosion fatigue strength reduced from 279 MPa (in air) to 126 MPa (in 3.5 % NaCl) at 10^7 cycles. A previous study by Masaki et al [34] showed that the fatigue strength of pitted specimens for 316NG at 10^8 cycles is approximately half that of unpitted specimens, where the SCF of the pre-pit was assumed to be approximately 2, almost equivalent to the fatigue strength reduction factor. However, the present study shows that the fatigue strength reduction factor is much greater than the stress concentration factor.

The corrosion pits have smaller stress concentration factor than the pre-pit due to their smaller depth [33], implying that pre-pitted samples having longer fatigue lives than initially-smooth samples that develop pits within a corrosive solution. Furthermore, the smooth samples in 3.5%NaCl have shorter fatigue lives than the pre-pitted samples in air, indicating that electrochemical effects, i.e., localized corrosion, has a greater effect on fatigue life than mechanical effects, especially as stress levels fall below the in-air fatigue limit.

5. Modeling of corrosion pit development

As literatures stated above that the corrosion pits can be simplified as semi-elliptical pits. Cracks originates from pits where the SCF is the biggest. To calculate the SCF around pits, a 3-D model is developed on a round bar under uniaxial tension and bending loading by using FEM. The 3-D model has various pit diameter ($2c$) and depth (a) ranging from 80 to 1000 μm. A total of 82878 finite elements and 118406 nodes are employed.

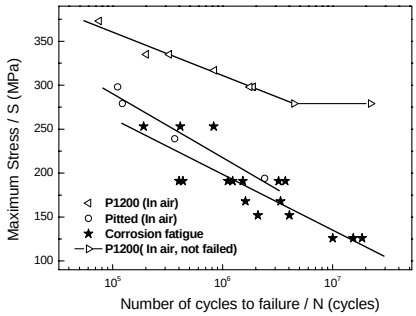

Fig. 2. S-N data for air and artificial seawater environments.

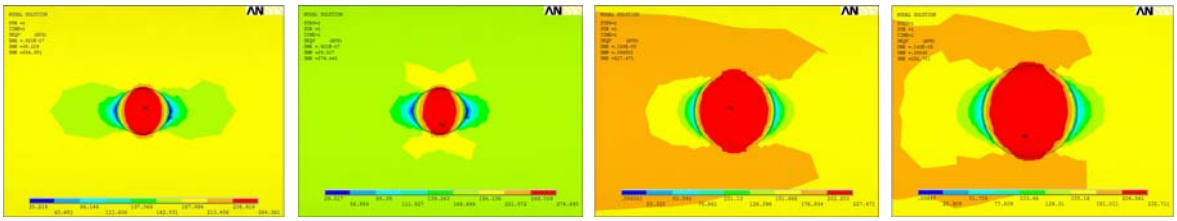
Figs. 3 show the maximum stress within the pit. The maximum stress is not always at the bottom of corrosion pit and it moves to the mouth with the aspect ratio *a/2c* increasing. The maximum stress occurs at the bottom when *a/2c* is less than 1/7 under tension loading and *a/2c* less than 1/10 under bending loading.



(a) *a/2c* =1/7 (b) *a/2c* =1/6 (c) *a/2c* =1/10 (d) *a/2c* =1/9

Fig. 3.The maximum stress distribution at various aspect ratios under tension (a), (b) and bending (c), (d).

Cracks initiate from the point where the stress concentration is highest. Then the corrosion pit transfers to crack when the stress intensity factor for the equivalent surface crack growth for the pit reaches the threshold stress intensity factor for the fatigue crack growth, and the corrosion fatigue crack growth rate exceeds the pit growth rate.

The SCF is largely influenced by the aspect ratio (*a/2c*) and the type of loading mode, as shown in Fig.4. The SCF increases greatly with increasing aspect ratio when *a/2c* is less than 1, and slow down when *a/2c* is between 1-2. It remains unchanged as *a/2c* is greater than 2. The tension loading produces bigger SCF than the bending. Also compared is the depth effect and width effect, illustrated in Fig. 5. The pit depth has much bigger effect than the pit width.

6. Conclusion

The corrosion pit size and shape development and its effect on crack initiation and fatigue life were reviewed. It suggested the following:

1) Various relationships were developed for corrosion pit depth and pit width. But the literatures mostly suggest that the pit width follows a linear relationship with time and the pit depth is linearly proportional to the square root of time.

2) The higher the stress amplitude the more corrosion pits formed. Compared to artificially-induced pits, real corrosion pits have a smaller stress concentration factor, but lead to shorter fatigue lifetimes.

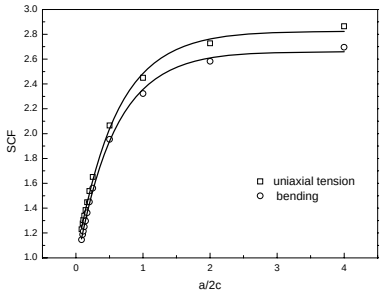


Fig. 4 SCF variation with *a/2c* Figure.

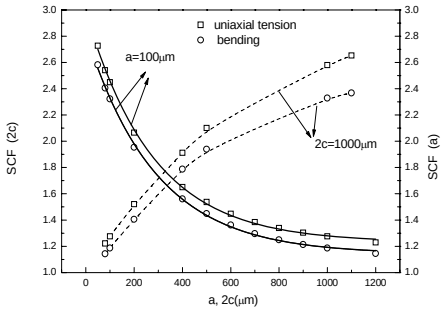

Fig.5 SCF variation with *2c* and *a*

3) Cracks do not necessarily originate from the bottom of the pit. Rather, it starts from the point which has the biggest SCF. The aspect ratio affects the SCF greatly when *a/2c* is less than 1 but almost has no effect when *a/2c* is greater than 2. The pit depth has much bigger effect on SCF than the pit width does.

Abstract: Cohesive zone models (CZM) are widely used for material fracture analysis. In monotonic loading process, the cohesive parameters are remarkably dependent on the specimens' triaxiality conditions. A cyclic CZM is now introduced for crack initiation life and fatigue crack growth analysis. These two types of fatigue phenomena - crack initiation and fatigue crack growth - are to be described by the cyclic CZM with a unique set of parameters. Fatigue crack initiation is usually investigated using smooth specimen and fatigue crack growth is measured using compact tension specimen. The triaxiality condition in the CZM of these two standard specimens is strongly different. Realistic modelling of the phenomena therefore requires taking the triaxiality into account in the damage evolution law of the cyclic CZM. As a consequence in this paper a cyclic CZM combined with triaxiality dependent characteristic is proposed. This new model can be applied for specimens with different triaxiality conditions. The computation results including crack initiation life and fatigue crack growth simulation are compared with experimental data. In the very low cycle fatigue regime, a reasonable accordance of experimental and calculated results is achieved.

Keywords: Cohesive zone model, Triaxiality dependence, Low cycle fatigue, Damage evolution

1. Introduction

In actual engineering, fracture of the materials and structures is a very dangerous failure form and usually causes serious consequence. Thus, research on mechanisms of material fracture, controlling and reducing occurrence of fracture accidents are always important issues. Fracture mechanics provides the theoretical basis and application approaches for material fracture research. But sometimes the modelling expenses are very high for fracture mechanics concepts and other ideas should be introduced. Among all these methods, the cohesive zone model is very attractive for researchers.

Cohesive zone model (CZM) is an interface damage model, it simplifies the fracture process zone into a narrow cohesive strip. Originally, the concept of CZM has been proposed by Dugdale [1] and Barenblatt [2]. In 1976, the CZM was firstly used by Hillerborg [3] in finite element calculation for concrete material. From then on, the CZM was applied widely as a numerical simulation model for material fracture. In the last 30 years, the CZM was developed by many investigators and scientific groups [4-10]. Now, it becomes a universal tool for material fracture analysis. Especially for material fracture under monotonic loading, the applications of the CZM are successful.

However, using the CZM in material fatigue fracture is still at a starting stage. In the late 1990's, the CZM was firstly extended by De-Andrés et al. [11] for fatigue crack growth simulation. A damage parameter was introduced to indicate the irreversible damage process. But in this model no description about the damage evolution is supplied. Soon afterwards, Yang et al. [12] developed a damage locus in the CZM to simulate fatigue crack growth. However, in this model the unloading and reloading stiffness have different definitions and the damage evolution is just dependent on the damage locus, these treatments are not convenient and accurate for application. Then the cyclic CZM proposed by Roe and Siegmund [13] explicitly introduced a damage variable and a damage evolution equation. The stiffness and traction of the cohesive zone degraded with the damage variable. The numerical calculation results of this model can reproduce many basic characteristics which are similar to the experimental phenomena in fatigue fracture. Nevertheless, there is no experimental verification for the damage evolution process and the other important factors for CZM

are not considered, such as surrounding continuum element influence, element friction influence and constraint condition influence. Base on Roe and Siegmund's method, some authors did further research work [14-16].

2. Cohesive zone model

2.1. Fundamentals

The CZM intends to describe the real physical fracture process by phenomenological equations. It treats the material separation in the fracture process zone as material damage. Separation is the displacement jump occurring in the cohesive element. In the CZM, the material separation behaviour is described within a constitutive equation relating the cohesive traction T to the material separation δ, called traction separation law (TSL). The TSL represents the material deterioration occurring in the damage zone under the monotonic loading condition. For the shape of the TSL many proposals have been given, but no one can easily decide which is right or wrong. For all TSLs, two parameters are contained: maximum traction T_0 and critical separation δ_0. The area under the TSL represents the cohesive energy Γ_0. If the shape of the TSL is selected, the cohesive parameters should be determined from the correlative experiment. In this paper, the TSL from Scheider et al. is taken as a basis (Equation (1) and Figure 1). More details on application of this CZM can be taken from references [8-9].

$$T(\delta)=T_0 f(\delta)=T_0\begin{cases}2\left(\dfrac{\delta}{\delta_1}\right)-\left(\dfrac{\delta}{\delta_1}\right)^2 & \delta<\delta_1\\ 1 & \delta_1\le\delta\le\delta_2\\ 2\left(\dfrac{\delta-\delta_2}{\delta_0-\delta_2}\right)^3-3\left(\dfrac{\delta-\delta_2}{\delta_0-\delta_2}\right)^2+1 & \delta_2<\delta\le\delta_0\end{cases} \tag{1}$$

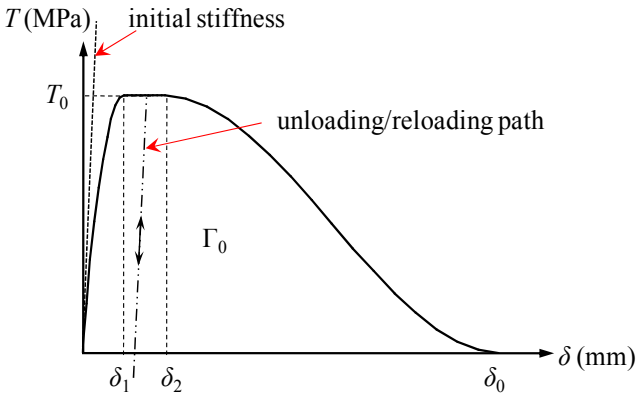

Figure 1. Traction separation law according to Scheider et al. [8], given by Equation (1)

2.2. Triaxiality dependent behaviour

When the phenomenological TSL is applied for ductile fracture analysis, it is possible to find a fundamental relationship between this TSL and micromechanics. A micromechanical model - GTN model [17] is used to simulate a biaxial tension test for one volume element, a cohesion-decohesion curve can be obtained. Such cohesion-decohesion curve is considered as the micromechanical TSL and can be used to fit the phenomenological TSL. For this micromechanical traction separation curve, some investigators found that it was strongly dependent on the triaxiality condition of the

element. Here, the triaxiality value means the ratio between the hydrostatic stress and the von Mises equivalent stress, see Equation (2).

$$H = \frac{\sigma_h}{\sigma_{Mises}} \tag{2}$$

H is the triaxiality value for unit volume element. σ_h is the hydrostatic stress in the element. σ_{Mises} is the von Mises equivalent stress in the element.

The conclusions for triaxiality dependent behavior can be summarized as: the cohesive parameters are not pure material constants but dependent on the triaxiality conditions. With increasing the triaxiality value, the material maximum traction T_0 becomes bigger but the material critical separation δ_0 and cohesive energy Γ_0 become smaller. Details about this investigation can be consulted in references [18-20]. When the triaxiality dependent behaviour is implemented into the CZM, the triaxiality value can only be obtained from the surrounding continuum element and has to be transferred to the cohesive element.

3. Extended CZM for fatigue fracture

3.1. Overview

The ordinary TSLs just describe the material fracture failure under monotonic loading condition. For material fatigue fracture properties, other approaches need to be introduced. By reviewing some ideas from pioneers, a tentative method of Roe and Siegmund [13] is chosen as starting point. Considering the theory of continuum damage mechanics, a damage variable and a corresponding damage evolution law are introduced in the CZM following ideas of Scheider [8]. This cyclic CZM is used for fatigue fracture analysis.

In respect to the fatigue fracture process, the important research topics focus on fatigue crack initiation life and fatigue crack growth rates analysis. In experimental investigation, fatigue crack initiation is usually tested using uncracked smooth specimen and fatigue crack growth is measured using pre-cracked specimen. The triaxiality conditions for these two standard specimens are totally different. When the CZM is applied for simulation of these two fatigue phenomena, it is necessary to take the triaxiality influence into account in the damage process.

So, a triaxiality dependent cyclic CZM is now proposed. The model should be implemented to reproduce fatigue experimental phenomena which contain fatigue crack initiation and fatigue crack growth, just using a unique set of parameters. For simplicity, in this paper just mode-I fracture is considered. This means in the CZM just normal separation contributes to the damage.

3.2. Fatigue damage process

With the damage variable D, the cohesive strength and normal stiffness of the cohesive element will degrade (Equation (3) and Equation (4)).

$$T_0^N = \left[T_{0\,(H)}^N \right] (1 - D) \tag{3}$$

$$k_N = k_N (1 - D) = \frac{2T_0^N}{\delta_1} \tag{4}$$

T_0^N and $\overline{T}_0^N$ are the initial and current normal cohesive strength, the subscript (*H*) represents that the initial cohesive strength is dependent on the triaxiality condition. k_N and $\overline{k}_N^0$ are the initial and current normal stiffness of the cohesive element. δ_1 is a parameter relating to the critical separation δ_0, the meaning is the same as in Equation (1).

For the triaxiality dependent cyclic CZM, it is difficult to judge the loading and unloading conditions because the separation δ and the critical separation δ_0 of the cohesive element alter simultaneously. So, a relative normal separation and its increment are defined by Equation (5) and Equation (6):

$$\delta_{re}^N = \frac{\delta^N}{\delta_{0\,(H)}^N} \tag{5}$$

$$\Delta\delta_{re}^N = \frac{\delta_t^N}{\delta_{0\,(H_t)}^N} - \frac{\delta_{t-\Delta t}^N}{\delta_{0\,(H_{t-\Delta t})}^N} = \delta_{re\,(t)}^N - \delta_{re\,(t-\Delta t)}^N \tag{6}$$

δ_{re}^N and δ^N are the relative and absolute normal separation, respectively. δ_0^N is the critical normal separation, the subscript (*H*) represents that it is dependent on the triaxiality condition. $\Delta\delta_{re}^N$ is the relative normal separation increment. The subscripts *t-Δt* and *t* stand for the previous and current calculation time increment. $\delta_{t-\Delta t}^N$ and δ_t^N, $\delta_{0\,(H_{t-\Delta t})}^N$ and $\delta_{0\,(H_t)}^N$, $\delta_{re\,(t-\Delta t)}^N$ and $\delta_{re\,(t)}^N$ correspond to the absolute normal separation, the critical normal separation and the relative normal separation in the time increment *t-Δt* and *t*, respectively. If in the different time increment the triaxiality condition does not change, the two critical separations $\delta_{0\,(H_{t-\Delta t})}^N$ and $\delta_{0\,(H_t)}^N$ should be the same.

A loading step is indicated by $\Delta\delta_{re}^N > 0$, an unloading step is indicated by $\Delta\delta_{re}^N < 0$. At the first loading step, the traction separation response goes along the monotonic TSL's path (Equation (1)). Afterwards the unloading and reloading process is defined by Equation (7).

$$T_t^N = T_{t-\Delta t}^N + \overline{k}_N^0 \left[\Delta\delta_{re}^N * \delta_{0\,(H_t)}^N \right] \tag{7}$$

$T_{t-\Delta t}^N$ and T_t^N are the normal traction in the time increment *t-Δt* and *t*. The meanings for the other symbols can be checked in the previous paragraphs.

In every loading process a maximum relative normal separation $\delta_{re\,\max}^N$ may be reached. During the reloading process, when the current relative normal separation exceeds this maximum value, Equation (8) is used for the new path.

$$T^N = \begin{cases} \overline{T}_0^N \left[2\left(\dfrac{\delta^N}{\delta_1}\right) - \left(\dfrac{\delta^N}{\delta_1}\right)^2 \right] & \delta_{re}^N \le \dfrac{\delta_1}{\delta_{0\,(H)}^N} \\ \overline{T}_0^N & \delta_{re}^N > \dfrac{\delta_1}{\delta_{0\,(H)}^N} \end{cases} \tag{8}$$

In the unloading process, it is still an open topic how the triaxiality influences the cohesive parameters. In this paper, a simple assumption is made. The triaxiality value keeps constant in the unloading process and a part of the reloading process. The definition about this part of the reloading

process is like Equation (8). When the current relative normal separation is less than δ_{re}^{N}, the triaxiality value keeps constant. Once δ_{re}^{N} is exceeded, the triaxiality value updates again.

After the cohesive element is broken, in the unloading or compression period in order to avoid the adjacent continuum element penetrating each other, a contact condition should be considered. Here, when δ^{N} <0, Equation (9) is used.

$$T^{N} = k_{N}\delta^{N} \tag{9}$$

A new damage evolution equation is proposed here, as Equation (10)

$$\dot{D} = \left(\frac{A^{\frac{1}{H}} e^{(\lambda - H)}}{H} \right) \Delta\delta_{re}^{N} \left[\frac{T^{N}}{\left[T_{0}^{N}{}_{(H)} \right](1-D)} - \frac{\sigma_{e}}{T_{0}^{N}{}_{(H)}} \right]^{m} \qquad \dot{D} \geq 0 \tag{10}$$

D is the damage variable. $\dot{D}$ is the damage evolution. It is always a positive value. $T_{0}^{N}{}_{(H)}$ is the triaxiality dependent normal cohesive strength. T^{N} is the cohesive traction. $\Delta\delta_{re}^{N}$ is the relative normal separation increment. σ_{e} is the material endurance limit. H is the triaxiality value. A and m are the material dependent damage controlling parameters. λ is the material dependent triaxiality influence coefficient.

A schematic illustration for the cyclic process of the CZM is shown in Figure 2. The new cyclic CZM is contained in a user defined subroutine, and it is connected with the commercial finite element program ABAQUS. The fatigue damage is calculated for every time increment.

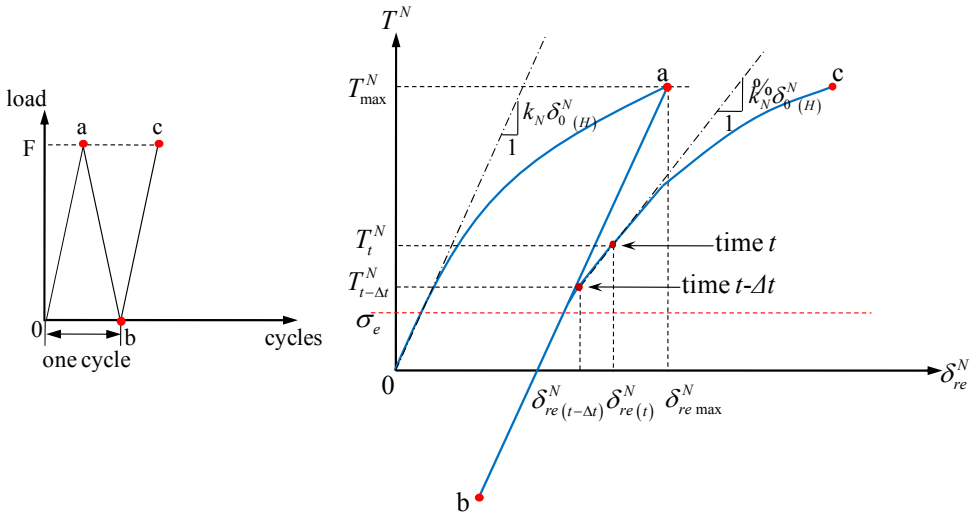

Figure 2. Schematic illustration for cyclic process of the CZM

4. Numerical application

The triaxiality dependent cyclic CZM is applied for fatigue simulation. For triaxiality dependent behavior, some results from literature [20] are used. In reference [20], the examined material is S460N. For convenience, material S460N is chosen for the whole investigations in this paper, too. Some basic mechanical properties for material S460N are shown in Table 1.

Table 1. Mechanical properties for material S460N

Material	E(MPa)	σ_Y(MPa)	R_m(MPa)	K'	n'	σ_e(MPa)
S460N	208000	470	682	1181	0.161	312

E is the material Young's modulus. σ_Y is the material yield stress. R_m is the material ultimate tensile strength. K' is the material cyclic hardening coefficient. n' is the material cyclic hardening exponent. σ_e is the material endurance limit.

4.1. Damage parameters analysis

For the chosen material, the unknown damage parameters in the damage evolution law are just A, m and λ. The material dependent triaxiality influence coefficient λ is fixed first for λ=1.2. The decision for this parameter is based on many trial calculations and a little supposition. The recommendation λ value for material S460N ranges between 0.8 and 1.2, a change of the parameter λ will influence the other two parameters A and m. After λ is chosen, a simple simulation is applied to analyze the material dependent damage controlling parameters A and m. The finite element model consists of two plane strain elements (CPE4) connected by one cohesive element. The model is loaded by cyclic displacement, the loading ratio is R=-1.

In order to reflect the real material response under cyclic loading, the material behavior for continuum element uses a nonlinear kinematic hardening model in ABAQUS. Three different ways are offered by ABAQUS to define the nonlinear kinematic hardening component, specifying the material parameters directly, specifying half-cycle test data or specifying test data from a stabilized cycle. In this paper, nonlinear kinematic hardening model is identified from the stabilized cyclic test. Series of the parameters A and m are investigated and the calculation results are plotted in the material strain-life curve, shown in Figure 3.

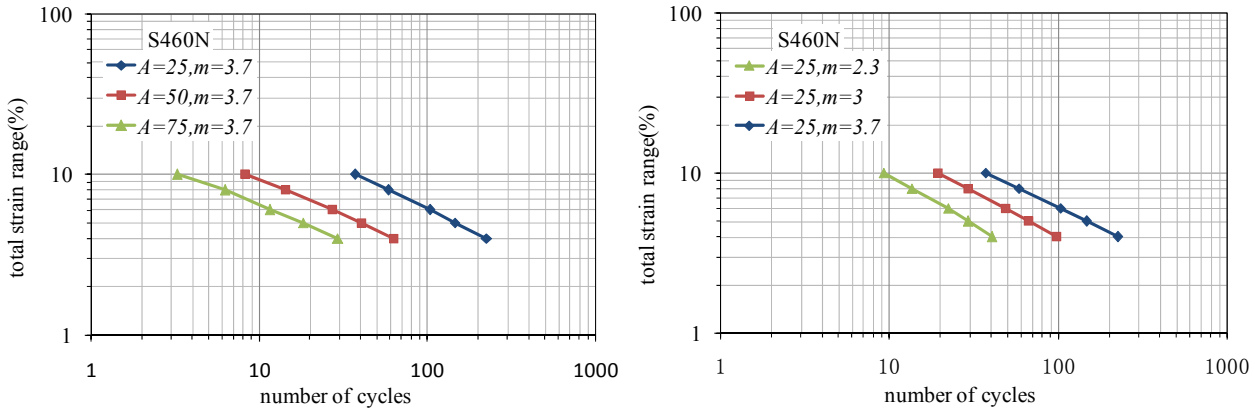

Figure 3. Effect of damage controlling parameters A and m

It is obvious that the parameter m influences the slope of the strain life curve. With increasing the value of m, the slope of the strain-life curve becomes flatter. The parameter A does not influence the slope of the strain-life curve. However, it makes the curve moving parallelly. According to these rules, the parameters A and m can be identified by fitting the numerical results to the experimental strain-life curve.

4.2. Fatigue crack initiation simulation

The strain-life curve of the material S460N is expressed by Equation (11)

$$\varepsilon_a = \varepsilon_{a,el} + \varepsilon_{a,pl} = \frac{\sigma_f'}{E}(2N)^b + \varepsilon_f'(2N)^c \tag{11}$$

ε_a is the strain amplitude. $\varepsilon_{a,el}$ and $\varepsilon_{a,pl}$ are the elastic and plastic part for the strain amplitude. E is the Young's modulus. N is the fatigue life, it stands for fatigue crack initiation life or fatigue fracture life. Here it means the fatigue crack initiation life. σ_f' is the fatigue strength coefficient. b is the fatigue strength exponent. ε_f' is the fatigue ductility coefficient. c is the fatigue ductility exponent. Values are taken from reference [21] and shown in Table 2.

Table 2. Experimental strain-life curve parameters

Material	E(MPa)	σ_f'(MPa)	ε_f'	b	c
S460N	208000	1218	0.452	-0.104	-0.536

In the previous section, the influence rules of the damage controlling parameters A and m are discussed. By fitting the simulation results to the experimental strain-life curve, the parameters A and m can be determined. Here the simulation model is also two plane strain elements connected by one cohesive element. The loading condition and the material behaviour are like in the previous section. The investigations just focus on the very low cycle fatigue regime, so the calculated number of cycles is within 600. For material S460N, the parameters A and m are fitted as: A=25, m=3.7. The experiment and simulation results are plotted in Figure 4.

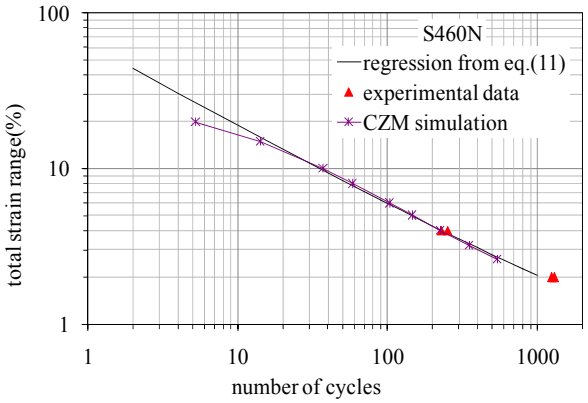

Figure 4. Comparison of strain-life curve for material S460N

4.3. Fatigue crack propagation simulation

For the material S460N, the damage parameters are determined: λ=1.2, A=25 and m=3.7. These parameters need further validation. As an important part of fatigue fracture, the fatigue crack growth simulation is applied here to validate the damage parameters.

The experimental data of fatigue crack growth for the material S460N are taken from reference [22]. The experimental fatigue crack growth rate curve includes four different strain range levels, i.e. $\Delta\varepsilon$=0.4%, $\Delta\varepsilon$=0.6%, $\Delta\varepsilon$=1.0% and $\Delta\varepsilon$=2.0%. Because the investigations focus on very low cycle fatigue regime, just the experimental data at fast crack growth rate are used for comparison.

The numerical model is a two dimensional compact tension specimen. The dimension of the model is width 50mm and height 60mm. The initial crack length a_0 is 25mm and the ligament length is 25mm, too. The type of the continuum element is plane strain. The material behaviour of the continuum elements is the same as in the previous section. The cohesive elements locate along the

ligament and the size of the element is 0.125mm. The details for the finite element model are depicted in Figure 5.

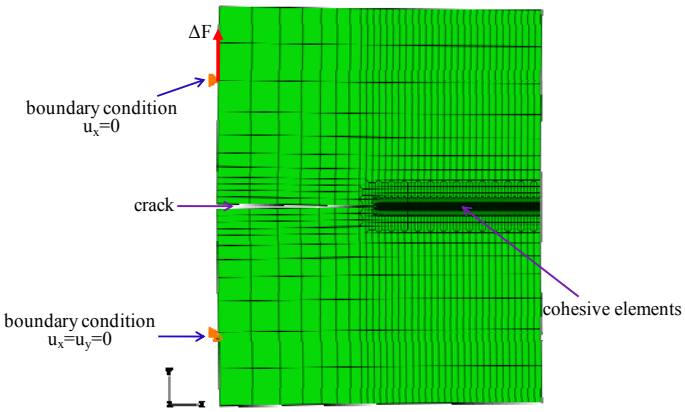

Figure 5. Finite element model for simulated compact tension specimen

In the calculation, three different cyclic loading ranges are used: ΔF=1200N, ΔF=950N and ΔF=800N. All loading ratios are R=0. The fatigue crack growth rate $\Delta a/\Delta N$ can be calculated directly from the numerical model, but the cyclic ΔJ integral will be computed by another approach. A finite element model of the CT specimen without cohesive zone is built. The crack length inserted in this model is $(a_0+\Delta a)$. One cycle is calculated and the cyclic ΔJ integral is computed by Equation (12) [23].

$$\Delta J = \int_{\Gamma}\left(\Delta W dy - \Delta t_i \frac{\partial \Delta u_i}{\partial x} ds\right) \qquad \Delta W = \int_0^{\Delta\varepsilon} \Delta\sigma_{ij} d\Delta\varepsilon_{ij} \tag{12}$$

$\Delta\sigma_{ij}$ and $\Delta\varepsilon_{ij}$ are the cyclic stress and strain range. W is the cyclic deformation energy. x and y are the Cartesian coordinates with the x-axis parallel to the crack surface. Γ is the integration path. ds is the line element lying on the integration path. Δt_i is the cyclic stress vector on the integration path. Δu_i is the cyclic displacement variation.

The simulation results under three loading ranges are plotted together with the scatter band of experimental data in Figure 6.

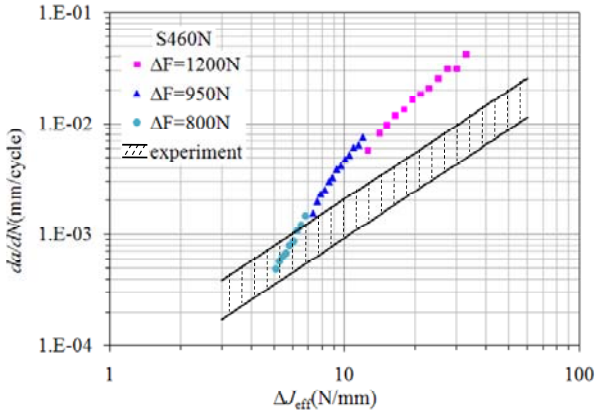

Figure 6. Comparison of fatigue crack growth rates curve for material S460N

A reasonable accordance of experimental and simulated results is achieved. The simulated fatigue crack growth rates are a little bit faster than the experimental data, but the total trend for fatigue

crack growth is very similar. One possible reason for this diversity is from the influence of the model dimension. In experiment, the specimen is a three dimensional model, but in simulation a two dimensional model is used. The calculation about the energy integral ΔJ is bigger for two dimensional problems than for three dimensional problems. The other possible reason is from the new CZM. This numerical model may express the real cyclic process inaccurately.

5. Conclusions

CZM is a very robust numerical tool for material fracture analysis. It is simple enough for theoretical understanding and practical application. For the material monotonic fracture, the implementation of the CZM is particularly mature. But for fatigue fracture analysis, the application is just in developing. In this paper, according to the pioneers' idea [13], a triaxiality dependent cyclic CZM is proposed. This model can be applied for various triaxiality conditions, and only one set of unique material damage parameters is used. In the very low cycle fatigue regime, using the triaxiality dependent cyclic CZM in fatigue crack initiation and fatigue crack growth simulation, the reasonable comparison results between experiment and simulation can be obtained.

However, this new CZM is still in a testing process. Many improvements and developments need to be done in the future. More materials should be chosen in the simulation to validate the new CZM. The cyclic process for the CZM needs more discussions, especially in unloading and compression period. The format of the damage evolution law maybe modified. The triaxiality dependent behavior in the whole cyclic process needs much more investigations.

Abstract A technique to heal a fatigue crack for a stainless steel by controlling a high-density electric current field was studied. The high-density electric current was applied at the crack tip using electrodes. A surface-activated pre-coating technique was used in order to improve adhesion of the crack surface. The crack on the specimen surface was observed by scanning electron microscope (SEM) before and after the application of the high-density electric current to examine the effect of the fatigue crack healing. The experimental results showed that the fatigue crack was closed and the crack growth rate of a healed specimen was decreased by the electrical stimulation.

Keywords Crack Healing, Fatigue, Crack Closure, Electric Current, Stainless Steel

1. Introduction

Fatigue is the main reason of failure accidents in metallic structures. To improve long term durability and reliability of structures, various methods are studied. The techniques to improve the fatigue strength, such as high-frequency quenching, carburizing, nitriding and shot peening, had been developed. They can prolong the fatigue life of materials by suppressing the crack initiation on the material surface. However, the advantages of these methods are limited for the materials where a crack had been existed. If damage of materials can be healed, it is possible to improve the reliability and durability of the industrial materials remarkably. Recently, some researchers have studied crack healing techniques in polymer materials and ceramic materials [1-3]. However, a technique to heal essentially a fatigue crack detected in metallic materials has not been established.

The studies to improve the mechanical properties of metallic materials have been conducted by the application of the electric current for a few decades. Karpenko et al. [4] showed that the fatigue life of a steel was prolonged by the application of the electric current during fatigue loadings. Golovin et al. [5] studied the effect of the high-density pulse current on the crack propagation of a silicon iron during the dynamic tensile loading. They showed that the crack propagation halted when the high-density pulse current was applied just before the crack initiation. Conrad and coauthors [6-10] investigated the influence of high-density pulse current on materials in detail. They showed that the action of drift electrons influenced the dislocation mobility. As other effects, the following phenomena are known, such as the generation of Joule heating [11], the cause of the compressive stress due to Joule heating [12-14], the induction of Lorentz force [15], the cause of the electron wind force due to the flow of the electric current [16].

Although some studies to improve the mechanical and material properties by applying the electric current in metallic materials have been conducted, a method for the essential healing of a fatigue crack has not been established yet. Therefore, the authors developed the technique to heal a fatigue crack in a stainless steel by controlling the high-density electric current field [17, 18]. In these researches, it is revealed that the crack was closed and the bridging by partial melting was formed between the crack surfaces. However, the adhesion between the crack surfaces is prevented due to the oxide layer on the crack surfaces. In this study we proposed to improve the adhesion of the crack surfaces by treating surface-activated pre-coating technique, which eliminates oxide layer and coats Ni on the crack surfaces. In addition, we evaluated quantitatively the healing effect of the

fatigue crack treated with the surface-activated pre-coating method by controlling high-density electric current.

2. Experiments

2.1. Specimens

Austenite stainless steel SUS316 was used as the experimental material. The chemical compositions and the mechanical properties of SUS316 are shown in Tables 1 and 2, respectively. The dumbbell-shaped specimens were used, and the schematic is represented in Fig. 1. A notch was introduced at the center of the one-side edge in the specimens. The specimens were treated with stress relief annealing to remove the residual stress caused in machining process. The heat treatment process is as follows. The specimens are heated to 1173 K for 4 hours, and the temperature is kept at 1173 K for 10 minutes. After that, the specimens are cooled slowly to a room temperature in a furnace. The surfaces of the specimens were polished to a mirror plane by using a buffing machine to observe the surface condition.

2.2. Experimental conditions

2.2.1. Fatigue test conditions

The tensile fatigue tests were conducted to introduce a fatigue crack with the annealed specimen, and were carried out at the room temperature in the atmosphere under load control conditions with a hydraulic driven testing machine. All of the tests were conducted at a stress ratio of R=0.05 and a frequency of f=10 Hz. The details of the fatigue test conditions are shown in Table 3. The crack length under cyclic loading was measured by in-situ observation using a digital microscope. In this paper, the test conditions and results of two major examples were indicated. Each specimen is named Specimen A and B. For comparison, the specimen which is not applied electric current is named Standard specimen.

2.2.2. Surface-activated pre-coatings

The surface-activated pre-coating technique, which eliminates the oxide layer and coats Ni film for preventing reoxidation, was treated on the crack surfaces. The surface-activated pre-coating technique was composed of three stages as follows. The first stage is electrolytic cleaning, the second stage is HCl activating and the third stage is Ni striking. The schematic of surface-activated pre-coating technique is represented in Fig. 2. The specimen is washed by using pure water between every stage. In the stage of the electrolytic cleaning, the specimen is washed in alkali solution. The composition of the alkali solution is 30 g/L NaOH, Na_2Co_3 and Na_4SiO_3. The anode was connected to Al plate and the cathode was to the specimen. The electrolytic cleaning current density is 10 A/dm^2, a time of current duration is 60 seconds and the alkali solution is maintained at a temperature of 60 °C. In the stage of the HCl activating, the oxide layer on the specimen was eliminated in 37 % HCl solutions for 10 seconds. At the stage of Ni striking, the oxide layer on the specimen was eliminated and the Ni film was coated for preventing reoxidation. The composition of the Ni coating solution is 240 g/L $NiCl_2$ and 80 g/L 37%HCl. The anode was connected to Ni plate and the cathode was to the specimen in the coating solution. The current density is 10 A/dm^2 and a time of current duration are 60 seconds.

2.2.3 Conditions of electric current application

The electric current was applied to heal the fatigue crack. The application of electric current was carried out using a transistor type power source. The pulse current was applied through the electrodes striding across the notch as shown in Fig. 3. The chromium cupper electrodes of 5 mm in diameter were used. Two electrodes were connected straddling the notch of the specimen. The distance between two electrodes was 1.3 mm. The conditions of the application of the electric current are shown in Table 4. The pulse electric current was applied to the specimen once and more, and the crack state on the specimen surface was observed with a scanning electron microscope (SEM) before and after every application of the electric current.

3. Experimental results

3.1. Observation of fatigue crack

The elemental components were observed with an auger microprobe to confirm the effect of the surface-activated pre-coating technique. Figure 4 shows the relationship between atomic concentration of O, Cr, Fe and Ni and depth from the specimen surface after Ni striking. The Fe and Cr are the main element of the specimens, SUS316, and Ni is the element coated by the surface-activated pre-coating technique. It is observed that the oxide layer, O is almost eliminated at the surface of the specimen and Ni coating film is approximately 630 nm thick.

The crack state on the specimen surface was observed with SEM. Figure 5 shows the fatigue crack shape before the application of the electric current in Specimen A. The points to measure the change of the crack width were indicated. Figure 6 shows the change of the fatigue crack shape at each application of the electric current in Specimen A. It is observed that the crack was closed for almost every application of the electrical current. Figure 7 is an enlarged picture at the area near the point 3 which is approximately 900 μm away from the crack tip before the application and after the 12th application of the electric current in Specimen A. The adhesion between the crack surfaces was observed and it is observed that the application of electric current also has an effect on the area far from the crack tip. Figure 8 shows the change of crack width for every application of the electric current. Compared to before the application and after the twelfth application of the electric current, the crack width near the notch decreased from approximately 39 μm to 8.5 μm. After the twelfth application of the electric current, the whole crack was closed 75-97 % from original crack, and the whole crack width was less than 10 μm. The bonding of the crack surfaces was confirmed by

cutting the specimen vertically to the direction of the crack propagation.

The elemental components at the inside of the crack were observed with the auger microprobe. Figure 9 shows the auger spectrum at the bridge formation inside of the crack after the application of the electric current. It is observed that the intensity of the spectral line is strong at the electron energy of Fe and Ni, and Fe and Ni are alloyed on the crack surface.

3.2. Evaluation of crack growth behavior

The behavior of the crack growth was evaluated quantitatively in order to research the effect of the crack healing. The crack closure was confirmed at the Specimen B in the same way like Specimen A. Figure 10 shows the crack growth rate as a function of the stress intensity factor range, Paris law, with Standard specimens without the application of the electric current. The fatigue test was conducted at σ_{max} = 150 MPa in the Specimen B after the application of the electric current. Figure 11 shows that before and after the application of the electric current in the Specimen B. The solid line indicates the approximate line of the results of Standard specimens without applying the electric current. The open and solid symbols B show the behavior of the crack growth in specimen B before and after the application of the electric current, respectively. It was observed that the crack growth rate decreased from 3.69×10^{-8} to 2.52×10^{-8} m/cycle just after the application of current compared to that of Standard specimens.

4. Discussions

One of the reasons that the crack was closed and healed as shown in Figs. 6 and 7 is thought to be thermal compressive stress due to Joule heating caused by the high-density electric current field formed at the clack tip. When the electric current is applied as crossing a crack, it flows along the crack because of the electric resistance on the crack surface. Therefore, the high-density electric current field is formed at the crack tip. The area at the tip and the vicinity of the crack is heated rapidly and expands due to Joule heating. On the other hand, the outside area of the crack tip where the high-density electric field is not caused remains intact. Therefore, the direction of expansion is restricted and the thermal compressive stress toward crack closure is caused due to the thermal expansion and it is thought that the crack is closed. Moreover, it is thought that the crack surfaces are easily bonded because the oxide layer preventing the bonding between each crack surfaces is eliminated by the surface-activated pre-coating technique, and the Ni film works as the well-adhesion inner layer. In addition, for every application of the electric current, the crack is closed, and the crack tip transfers to the direction to the notch. Therefore, the area of the current concentration continuously transfers to the direction of the notch and the whole crack was closed by the application of electric current.

On the other hand, the crack growth rate decreased temporarily as shown Fig. 11. The reason the crack growth was decreased is thought that the crack closure and bonding between the crack surfaces influenced on fatigue crack growth by applying electric current. The crack closure reduces the driving force for the crack propagation because of the decrease of the crack opening displacement. The bonding between the crack surfaces also makes the crack opening suppressive.

5. Conclusion

The technique to heal fatigue crack treated with surface-activated pre-coating method by controlling high-density electric current field was researched. The closure of the crack and the bonding between crack surfaces were realized by applying high density electric current. The crack was closed 75-97 % from original crack by improving adhesion between crack surfaces and applying the multiple electric current. Moreover, it was observed that the crack growth rate was decrease temporarily after the application of the electric current. As a result, it was indicated that the technique with the electrical stimulation has the potential to heal a fatigue crack.

Abstract: In the high cycle fatigue, the initiation of fatigue cracks is significantly affected by microstructure, loading conditions, and specimen geometry. However, fatigue life estimation traditionally considers microstructure and geometric effects via semi-empirical methods without explicit consideration of the early stages of crack formation, which tends to dominate the total lives in high cycle fatigue. Such a strategy has been useful for existing materials that have been characterized with extensive fatigue experiments, but is less applicable to the design of fatigue-resistant alloys or modification of existing alloy microstructures to enhance fatigue resistance. This paper employs a framework developed to assess the early stages of crack formation and growth through the microstructure in smooth and notched specimens. The methodology employs finite element simulations that render an unimodal grain-size microstructure and a crystal plasticity-based fatigue model that estimates 3D transgranular fatigue growth on a grain-by-grain basis. The crystal plasticity model parameters were calibrated for Ni-base superalloy RR1000. In these simulations, cracks form in near surface grains with highest slip-based driving force and then propagate through the field of adjacent grains.

Keywords Fatigue Indicator Parameter, Microstructurally Small Cracks, Fatigue Life

1 Introduction

In spite of its significance in industrial applications, the influence of microstructure on the early stages of fatigue cracks in engineering alloys is still poorly understood. The formation and early growth of fatigue cracks can consume a significant portion of the high cycle fatigue life and is strongly influenced by the size and shape of grains, and the crystallographic orientation. Fatigue models have been able to predict the fatigue life as a function of the microstructure by employing parameters aimed at reflecting the role of microstructure without strong physical connections. These methodologies can assess and perhaps compare materials, but they are not fully appropriate to design of fatigue-resistant engineering alloys.

During the past decade computational simulations have been increasingly used for designing materials. These models simulate microstructure-sensitive mechanical responses with the aim of reducing experimental effort. Castelluccio [1][2] developed a computational methodology for predicting the number of fatigue cycles required to crack an individual grain with highest driving force. The algorithm employs finite element simulations and a crystal plasticity framework to compute nonlocal fatigue indicator parameters (FIPs) which are correlated with the cycles required to crack a grain. This methodology has been successfully employed to assess the effect of bimodal

grain size distributions on fatigue resistance [2].

This work employs similar fatigue and crystal plasticity models to assess the effect of multiaxial straining and stress concentration on early fatigue life. The finite element simulations are calibrated to represent RR1000 Ni-base superalloy and render the microstructure explicitly. The fatigue lives are correlated to a variant of the Fatemi-Socie FIP that is averaged over nonlocal volumes that are oriented as bands aligned with the crystallographic slip planes. The model considers the influence of grain size effects for fatigue cracks that nucleate and extend into neighboring grains.

2 Modeling and simulation

2.1 Constitutive model

At the scale of individual grains we employ a physically-based crystal plasticity constitutive model for RR1000 superalloy adapted from the work of Lin et al. [3]. The crystallographic shearing rate is given by

$$\dot{\gamma}^{(\alpha)} = \dot{\gamma}_0 \exp\left[-\left(\frac{F_0}{k_b T}\right)\left\langle 1-\left\langle \frac{\left|\tau^{(\alpha)}-B^{(\alpha)}\right|-S^{(\alpha)}\mu/\mu_0}{\tau_0\mu/\mu_0}\right\rangle^{p}\right\rangle^{q}\right] sgn\left(\tau^{(\alpha)}-B^{(\alpha)}\right), \quad (1)$$

in which $\dot{\gamma}^{(\alpha)}$ is the shearing rate of slip system α, $\tau^{(\alpha)}$ is the resolved shear stress, T is the absolute temperature, F_o, p, q, $\dot{\gamma}_0$, τ_0, μ, and μ_0 are material parameters that may differ for octahedral and cube slip systems, as listed in Table 1 for 650°C, and k_b is Boltzmann's constant. The evolution laws for slip resistance ($S^{(\alpha)}$) and back stress ($B^{(\alpha)}$) are written as

$$\dot{S}^{(\alpha)} = \left[h_S - d_D\left(S^{(\alpha)}-S_0^{(\alpha)}\right)\right]\left|\dot{\gamma}^{(\alpha)}\right|, \quad (2)$$

$$\dot{B}^{(\alpha)} = h_B\dot{\gamma}^{(\alpha)} - r_D^{(\alpha)}B^{(\alpha)}\left|\dot{\gamma}^{(\alpha)}\right|, \quad (3)$$

in which $r_D^{(\alpha)} = \frac{h_B\mu_0}{S^{(\alpha)}}\left\{\frac{\mu_0'}{f_c\lambda}-\mu\right\}^{-1}$ and S_0, h_B, h_S, d_D, μ_0', f_c, λ, are constants that differ for octahedral and cube slip planes (see Table 1). The initial values are specified as S_0 for the slip resistance and zero for the back stress. This formulation considers 12 octahedral and 6 cube slip systems and was implemented as a user-material subroutine (UMAT) in ABAQUS 6.9 [4] using an implicit integration scheme. Discussion of model parameters and their estimation can be found in Ref. [1].

2.2 Fatigue driving force

During crack nucleation and early growth, the local fatigue driving force is affected by the microstructure, which has particular implications for microstructurally small cracks (MSCs). Hence,

Table 1. Parameters of the constitutive model at 650°C for octahedral and cube slip systems.

	F_0 kJ/mol	p	Q	$\dot{\gamma}_0\ s^{-1}$	τ_0 *GPa*	S_0 *MPa*	f_c	h_B *GPa*	h_S *GPa*	d_D *MPa*	μ_0' *GPa*
Oct.	295	0.31	1.8	120	810	350	0.42	400	10	6024	72.3
Cube	295	0.99	1.6	4	630	48	0.18	100	4.5	24	28.6

Other: λ=0.85, μ_0' = 192GPa. Elastic constants: C_{11} = 166.2GPa, C_{12} = 66.3GPa, C_{44} = 138.2GPa.

the driving force for early stage fatigue needs to be characterized with fatigue indicator parameters (FIPs) describing the local fields (rather than far field basis of the stress intensity factor in LEFM). The present approach quantifies the driving force with a crystallographic version of the Fatemi-Socie parameter adapted to evaluate the FIP on each octahedral slip system, i.e.,

$$\mathrm{FIP}^{\alpha} = \frac{\Delta\gamma_p^{\alpha}}{2}\left(1 + k\frac{\sigma_n^{\alpha}}{\sigma_y}\right) \tag{4}$$

where $\Delta\gamma_p^{\alpha}$ is the cyclic plastic shear strain range on slip system α, σ_n^{α} is the peak stress normal to this slip system, σ_y is the cyclic uniaxial yield strength of the polycrystal, and *k=0.5*, as proposed by Fatemi and Socie [5]. Several investigators have successfully employed approaches akin to the Fatemi-Socie parameter along with crystal plasticity formulations for studying the effects of microstructure on fatigue life [6][7]. The value of such a parameter was further explored by Reddy and Fatemi [8], who postulated that the Fatemi-Socie parameter represents the fatigue driving force and plays a role similar to that of the ΔK or the ΔJ in predicting fatigue crack formation and early growth. Recently, Castelluccio and McDowell [9] correlated the Fatemi-Socie parameter with the cyclic crack tip displacement using crystal plasticity simulations. To numerically regularize the FEM discretization and also to represent the finite physical scale of the fatigue damage process zone, the FIP^{α} values are calculated at each integration point and then averaged along bands (i.e., nonlocal FIPs), parallel to slip planes across entire grains, as depicted in Figure 1.

2.2.1 Life estimation

This approach focuses on the interaction between small fatigue cracks and the microstructure at a mesoscale level; therefore, crack growth on a grain-by-grain basis. In other words, the number of cycles to crack the first grain (nucleation) is first computed, and then the cycles required to extend the microstructurally small crack within each of the neighboring grains is computed. Each nonlocal FIP is employed in fatigue life correlations using a hierarchical approach to estimate the life to completely crack a grain along a band. The nucleation relation is assumed to follow the semi-empirical empirical law [6]

$$N_{nuc} = \frac{\alpha_g}{d_{gr}}(FIP^{\alpha})^{-2}, \tag{5}$$

where α_g is an irreversibility coefficient and d_{gr} is a length scale of the current grain calculated as:

$$d_{gr} = D_{st} + \sum_{i}^{n} \omega^i D_{nd}{}^i, \tag{6}$$

in which ω^i is the disorientation factor for grain i, D_{st} is related to the length of the band considered and D^i_{nd} relates to the length of all n intersecting bands in adjacent grains. The values of D_{st} and D^i_{nd} are calculated for each averaging band as the square root of the area of the band. The disorientation factor is computed as

$$\omega = \left\langle 1 - \frac{\theta_{dis}}{20^o} \right\rangle \tag{7}$$

Here, θ_{dis} is the disorientation angle between two grains, and the Macaulay brackets satisfy that $<a>=a$ if $a > 0$, $<a>=0$ if $a \le 0$. Thus, ω = 1 when there is no disorientation (i.e., the grain and the neighbor have exactly the same orientation and should be a single grain) and ω = 0 if the disorientation is 20° or larger. The disorientation factor for randomly oriented grains results in non-zero values for fewer than 10% of the grain boundaries.

The MSC crack growth rate is assumed to be controlled by the mechanical irreversibility of dislocations emitted from the crack tip and proportional to the crack tip displacement range, i.e.,

$$\left.\frac{da}{dN}\right|_{msc}^{\alpha} = \phi \left\langle A \quad \mathrm{FIP}^{\alpha} - \Delta \mathrm{CTD}_{\mathrm{th}} \right\rangle, \tag{8}$$

where $(A \sim 2)$ is a scaling constant that depends on microstructure attributes, $\Delta \mathrm{CTD}_{\mathrm{th}}$ is a threshold that has a value close to the magnitude of the Burgers vector. The factor $\phi=0.077$ measures the mechanical irreversibility at the crack tip process zone and depends on environment. The number of cycles to extend the crack front through the i^{th} grain along slip system α in the MSC regime, $N_{G_i}|_{MSC}^{\alpha}$, is determined by integrating Equation (8) with respect to the crack length. The crack growth rate

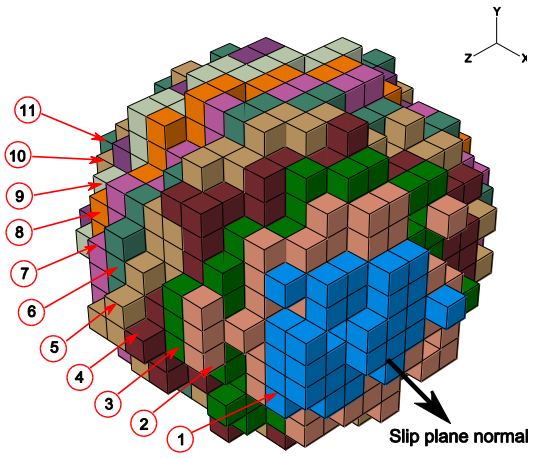

Figure 1: Schematic representation of elements, bands and grains in which FIPs are averaged to estimate transgranular fatigue crack growth. The implementation in a FEM model with unstructured, voxellated meshing is shown, with bands color coded and numbered for a single spherical grain.

depends on the crack length/size within the i^{th} grain, which varies from an uncracked to a fully cracked grain. To integrate analytically Equation (8), we consider that the mean evolution of FIP^{α} inside the grain follows a decreasing law, i.e.,

$$\mathrm{FIP}^{\alpha} = \mathrm{FIP}_o^{\alpha}\left(1-\frac{1}{2}a_i^2\right) \tag{9}$$

Here, a_i is defined here as the *fraction* of the area of the i^{th} grain to have cracked (nondimensional measure of cracked area of slip plane within the grain), and FIP_o^{α} represents the FIP value for the i^{th} grain on the α^{th} slip system along which a_i is measured, *before the grain is cracked*. Interestingly, Equation (9) resembles the empirical laws proposed by Hobson et al. [10] [11] and Miller [12] and has been validated using FEM simulations [1].

After integrating, the total life consumed in the MSC regime (N_{MSC}) is the sum of the lives for each grain involved in the growth process for a given 3D crack, i.e.,

$$N_{MSC} = \sum_i N_i\,|_{MSC}^{\alpha} \,. \tag{10}$$

where
$$N_i\,|_{MSC}^{\alpha} = N_{G_i}\,|_{MSC}^{\alpha} - N_{History} = \frac{1}{\sqrt{c_1 c_2}}\tanh^{-1}\left(D_{st}\sqrt{\frac{c_2}{c_1}}\right) - N_{History} \tag{11}$$

$$c_1 = \phi\,\frac{D_{st}+\sum_i^n \omega^i D_{nd}{}^i}{d_{gr}^{ref}}\,2\mathrm{FIP}_0^{\alpha} - \phi\,\Delta\mathrm{CTD}_{th} \quad \text{and} \quad c_2 = \phi\,\frac{\mathrm{FIP}_0^{\alpha}}{\left(D_{st}+\sum_i^n \omega^i D_{nd}{}^i\right) d_{gr}^{ref}} \tag{12}$$

Here, $N_{History}$ corresponds to the number of cycles undergone since the band considered has intersected the crack perimeter, and is necessary to include since cracks grow in multiple grains along a 3D crack front. Further details can be found in Refs. [1][2].

2.3 Crack growth model

To compute stress redistribution due to an increment in crack length, we employ an isotropic damage model along the bands having FIP values that lead to minimum fatigue lives. For the elements within these bands, the elastic stiffness tensor $\bar{\mathbf{C}}$ is degraded according to damage parameter d_1, i.e.,

$$\bar{\mathbf{C}} = (1-d_1)\mathbf{C} \tag{13}$$

Here, d_1 varies from 0 (uncracked) to 0.99, at which point full damage is assumed. The elastic stiffness is degraded for those elements in bands along which the crack is assumed to grow. The degradation of the elastic stiffness requires a gradual increase of parameter d_1 to achieve convergence of the FEM solution. Accordingly, the degradation is imposed over several time steps, i.e., for the current time step Δt^i we write

$$d_1^{(i+1)} = d_1^{(i)} \pm \nu \, \Delta t^i \tag{14}$$

For example, a value of $\nu = 2$ was enough to increase d_1 up to 0.99 by the end of the 1-second half loading cycle; of course, ν can be varied to accelerate crack stiffness reduction and to allow for convergence while computing stress redistribution effects in the polycrystal over a few computational cycles. Of course, this represents evolution over a much larger number of applied fatigue loading cycles. The plus sign corresponds to the case in which the stress normal to the band is positive and the crack plane is in tension. On the contrary, if the stress normal to the band is in compression, the crack is assumed to be closed and d_1 is decreased to zero at a rate proportional to the time step, as described by the minus sign in Equation (14).

When roughness- or plasticity-induced closure conditions are detected by virtue of compressive traction normal to the crack face on individual elements, the value of d_1 is decreased to 0 such that the initial elastic stiffness is restored. Hence, the degradation of the stiffness tensor is performed on a grain-by-grain basis by increasing the parameter d_1 in all the elements after predicting the path of the crack in the following grain. Such a prediction is performed every two computational loading cycles to allow for stiffness degradation and the update of the stress and strain fields.

In summary, the fatigue algorithm starts by calculating the nonlocal FIP values on every band in every grain over the third computational cycle, and proceeds by calculating the number of expected cycles to nucleate crack on all bands for all grains using Equation (5). The elements within the band with the lowest nucleate life are marked as "cracked," and the model applies again a couple of computational loading cycles to update the FIP values and to degraded (d_1 increased) the stiffness tensor as necessary to represent crack growth. Thereafter, the algorithm computes the MSC life of all FIP averaging bands that intersect the crack perimeter and renders the elements in the band with minimum life as cracked. The simulation proceeds by applying further loading cycles, in which the stiffness tensor is degraded on the cracked elements to redistribute stress and plastic strain, while checking for grain level closure effects of cracked grains, and the MSC life is evaluated again on the remaining grains. Since we seek to describe the dominant crack, only one crack nucleates per realization.

3 Simulation results

3.1 Specimens and loading conditions

Figure 2 depicts the C3D8R-element meshes employed for modeling smooth and notched specimens, each color representing a different crystallographic orientation. The grain size follows a lognormal distribution based on the algorithm by Musinski [13] with a mean value of 18μm. The straining sequence consisted of triangular relative displacement of the upper and lower boundary planes at a 0.05%/s strain rate under shear or tensile mode loading to achieve an overall nominal strain range of 0.8%; lateral faces are free of traction. Simulations with different strain ratios employed a similar strain range to assess only the effect of applied strain ratios (strain/displacement conditions).

To achieve equivalence with tensile straining, the magnitude of the displacement vector in shear straining was computed by assuming an elastic model with cubic symmetry. The value of Poisson's

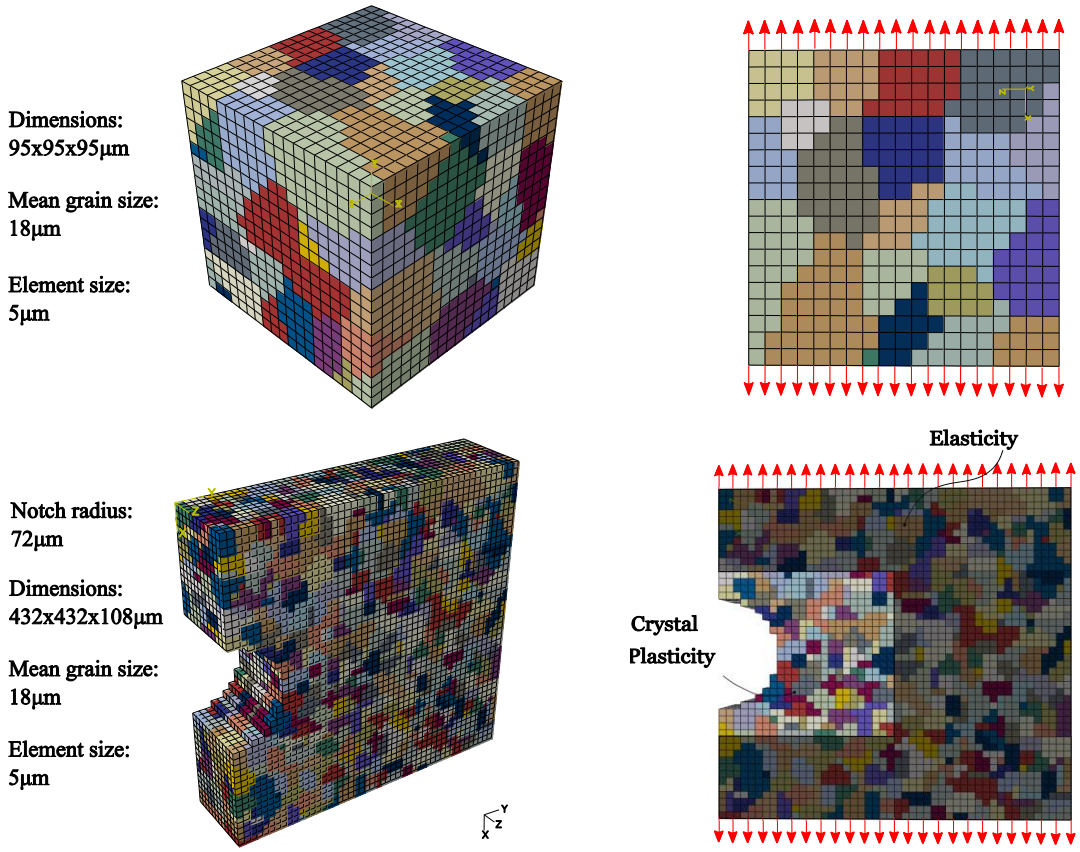

Figure 2. Example of voxellated meshes representing the explicit polycrystalline microstructure for axial straining of smooth (top) and notched (bottom) specimens. Triangular straining sequence is applied by displacing the upper and bottom faces of the meshes at 0.05%/s strain rate.

ratio was deduced to compute the equivalent pure shear strain for $R_\varepsilon = 0$. The 0.8% uniaxial strain range is equivalent in shear to

$$\Delta\gamma_{eq} = (1+\nu)\Delta\varepsilon_1 = (1+\nu)0.8\% = (1+0.3989)0.8\% = 1.119\% \tag{15}$$

Thus, the upper and lower faces were displaced in shear up to a nominal shear strain of 1.119% for equivalence in this particular case. The Poisson's ratio was deduced using an elastic model with cubic symmetry, i.e.,

$$\nu = \frac{C_{12}}{C_{11}} = \frac{66.3}{166.2} = 0.399 \tag{16}$$

3.2 Crack growth vs cycles for smooth specimens

Smooth specimens were employed to simulate shear and tension-compression straining at 650°C for under three strain ratios $R_\varepsilon = \varepsilon_{min} / \varepsilon_{max}$ = -1, R_ε = 0 and R_ε = 0.5, all undergoing an equivalent nominal strain range of 0.8% at 0.05%/s strain rate. For each loading condition, a total of 10 equivalent microstructure realizations were simulated. The simulations considered unidirectional periodic boundary conditions, with lateral faces free of traction. Figure 3 presents crack length vs. life on a semi-log scale. Each data point corresponds to extending the crack by one grain and only lives below 10^9 are considered (otherwise considered as crack arrest, giving rise to run-out

behavior). These results support that uniaxial tension-compression straining is more detrimental than cyclic shear, by a factor of nominally two or greater on life.

Fatigue crack nucleation rather than fatigue crack growth seems particularly influenced for $R_\varepsilon = 0$ and $R_\varepsilon = 0.5$, which suggests that crack nucleation assisted by stress concentration (e.g., notch, pore, or inclusion) might exhibit a reduced dependence on the strain ratio. Furthermore, tension-compression fatigue life results seem to show slightly less variability, and for both displacement conditions, the variability seems to increase with decreasing strain ratio.

Figure 4 presents an example of the stress-strain evolution for one realization in tension after 20 straining cycles for three different strain ratios. As expected, higher strain ratios lead to higher tensile mean stresses. The mean stress evolves slowly and after 20 cycles the change is less 10%; therefore we may consider that the fatigue life estimations are performed at a relatively stable mean stress level for each strain ratio. Even when mean stress assessed may differ from a fully relaxed state, the fatigue model was calibrated under similar conditions [1], which reduces the inaccuracies.

3.3 Crack growth vs cycles for notched specimens

Figure 5 presents the simulation results for three strain ratios using models with a notch root radius of 144 μm and a similar microstructure. Compared to the smooth specimens, the results from models with a notch show a reduction in fatigue life of about an order of magnitude. As expected, the lower the strain ratio, the larger the fatigue life, while tension-compression simulations resulted in lower lives than shear loading. However, the separation in life between tension-compression and shear cases increases with decreasing strain ratio, which was not clearly observed in simulations with smooth specimens. Note that the cracks for the shear case did not nucleate at the notch, but grew in the bulk of the specimen. The computed results for tension-compression, which nucleated the crack at the notch, lie within two orders of magnitude on life. In the case of shear loading, the life is longer and exhibits greater scatter as the cracks formed in the bulk of the specimen.

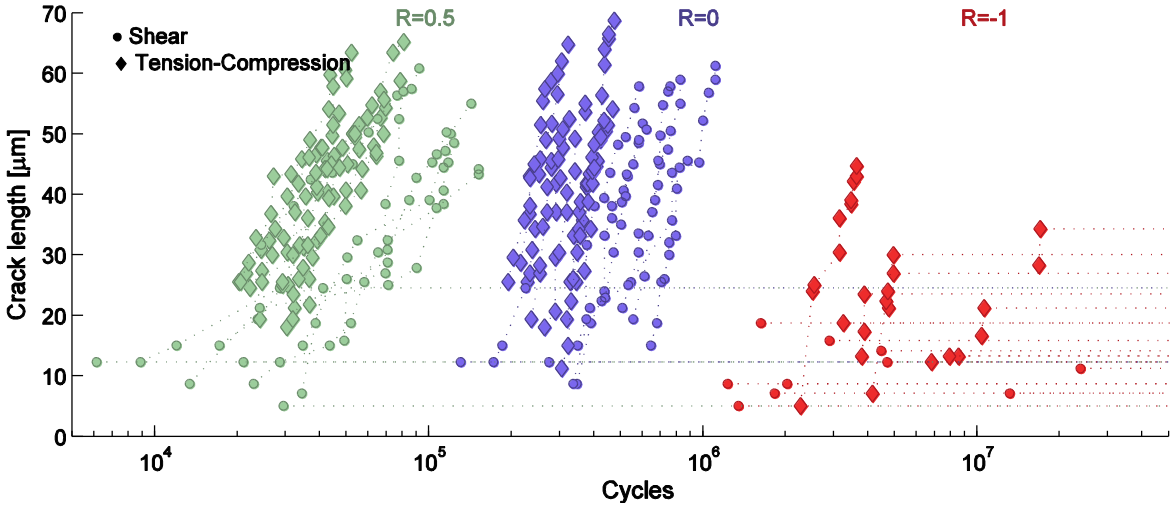

Figure 3. Comparison of the results for strain ratios $R_\varepsilon = 0$, $R_\varepsilon = 0.5$ and $R_\varepsilon = -1$ using simulations with unidirectional periodic conditions undergoing an equivalent nominal strain range of 0.8%.

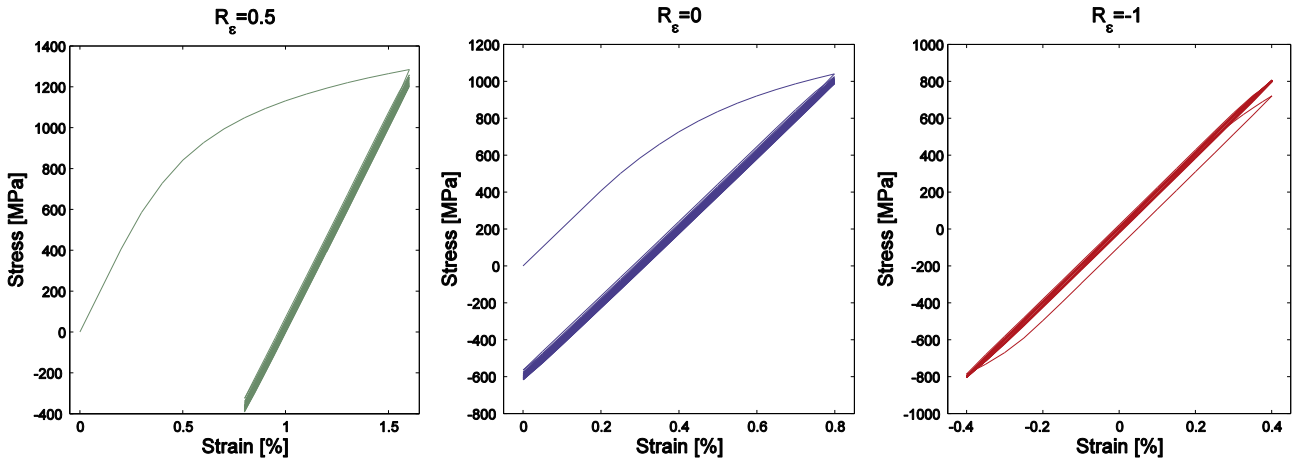

Figure 4. Stress-strain responses of a smooth specimen microstructure realization and three strain ratios over 20 uniaxial straining cycles.

4 Discussion and conclusions

The simulations showed quantitatively the detrimental effects of higher strain ratios, which change orders of magnitude the cycles required to grow a crack of similar lengths. Furthermore, in all cases tension-compression straining was more damaging than shear straining, which has been reported in the literature for other materials [14][15]. The results for smooth specimens exhibited a spread of fatigue life over three orders of magnitude for strain ratios between $R_\varepsilon = 0.5$ and $R_\varepsilon = -1$, for shear and tension-compression loading. Notched specimens under tension-compression loading showed a smaller spread, which is explained by a reduction of the variability in nucleating a crack. This effect dominates over the reduction of the highly strained volume around the notch. In the case of notches under shear, the cracks nucleated within the bulk of the specimen (not at the notch), and the results are comparable to those found for smooth specimens.

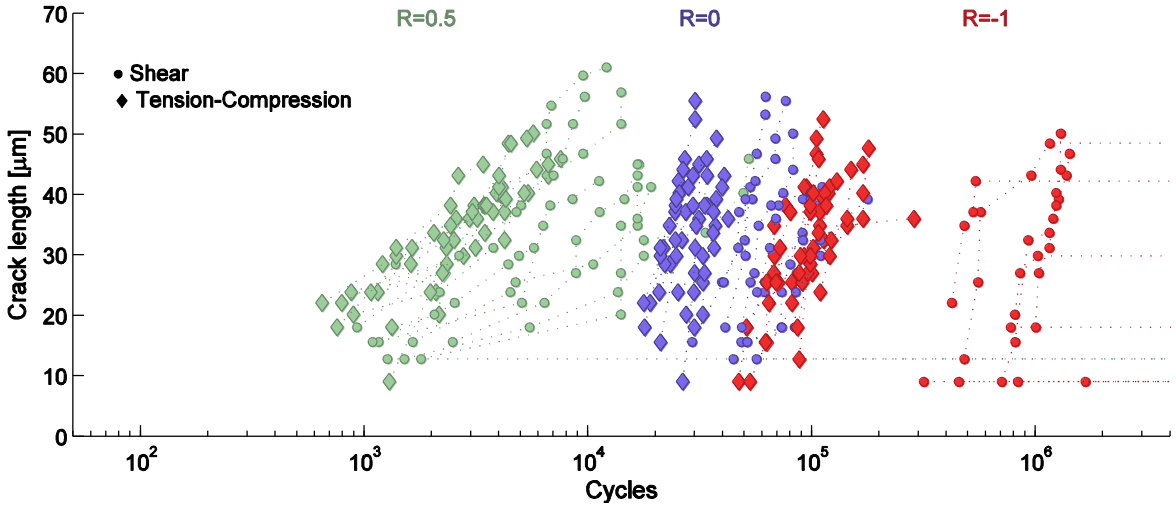

Figure 5. Comparison of the results for strain ratios $R_\varepsilon = 0$, $R_\varepsilon = 0.5$ and $R_\varepsilon = -1$ on a logarithmic scale for notched specimens undergoing an equivalent nominal strain range of 0.8%.

Abstract Experimental studies in the last few decades have exhibited higher fatigue crack growth rates for cracks with size on the order of grains than would be predicted using growth laws based on LEFM. Small crystallographic fatigue cracks are affected by microstructure features that are not captured by traditional homogenous fracture mechanics theories (i.e., LEFM, EPFM). Since far-field driving force parameters cannot capture the intrinsic variability of the local fatigue driving force of small cracks induced by microstructure, alternative measures of the fatigue driving force are sought. This work employs finite element simulations that explicitly render the polycrystalline microstructure to compare nonlocal fatigue indicator parameters (FIPs) averaged over multiple volumes. The model employs a crystal plasticity algorithm in ABAQUS calibrated to study the effect of microstructure on early fatigue life of Ni-base RR1000 superalloy at elevated temperature under constant amplitude loading. The results indicate slight differences in the extreme values of distributions of FIPs for each element, slip plane cross-section (bands) and grain volumes. Furthermore, the grain average FIP better reflects the driving force for cracks on the cross section at the center of the grain while the extremes values of the FIPs averaged along bands tend to be located away from the grain centers.

Keywords Fatigue Indicator Parameter, Microstructurally Small Cracks, Fatigue Driving Force

1 Introduction

Extensive literature shows that fatigue experiments on metals in the high cycle fatigue (HCF) regime present variability in fatigue life of over a factor of 10. Multiple investigators have demonstrated that the underlying microstructural attributes [1][2] (i.e., grain size effects, elastic and plastic anisotropy, pre-existing defects) are usually responsible for the large variation in fatigue life. Indeed, in the HCF regime, the heterogeneous plastic deformation within favorably oriented and/or highly stressed grains controls the nucleation and early growth of fatigue cracks.

Recent finite element approaches that render the microstructure of metallic alloys have estimated the fatigue damage by assessing nonlocal fatigue indicator parameters (FIPs). These parameters typically refer to the value of the FIP averaged over certain mesoscale volumes (e.g., grain volumes). In contrast to local magnitudes within each finite element, these nonlocal FIPS mitigate effects of the mesh sensitivity and represent the physical length scale over which the fatigue damage occurs. Recent work [3][4] pursued definition of the averaging volume in terms of bands

that lie parallel to the crystallographic slip planes and have a width of one element. These bands seek to reflect domains in which cyclic plastic deformation localizes via dislocation dipole structures and in experimentally observed persistent slip bands.

By averaging the local FIPs over bands [3], a methodology was developed that predicts the path of a fatigue crack along bands through multiple grains, considering grain size effects [4]. The fact that FIPs can be averaged over multiple volumes (sizes and shapes) raises questions about the role of volume domains for averaging on the variability of nonlocal FIPs and the influence of grain size effects on the variance of the distribution of fatigue life.

This work employs a crystal plasticity finite element model for RR1000 Ni-base superalloy to compare the variability of the Fatemi-Socie FIPs averaged over grains or bands, and its local magnitudes for a number of realizations of ostensibly the same microstructure. The influence of grain size effects on normalized FIP distributions is also considered.

2 Modeling and simulation

2.1 Constitutive model

At the scale of individual grains we employ a physically-based crystal plasticity constitutive model for RR1000 superalloy adapted from the work of Lin et al. [5]. The crystallographic shearing rate is given by

$$\dot{\gamma}^{(\alpha)} = \dot{\gamma}_0 \exp\left[-\left(\frac{F_0}{k_b T} \right) \left\langle 1 - \left\langle \frac{\left| \tau^{(\alpha)} - B^{(\alpha)} \right| - S^{(\alpha)} \mu/\mu_0}{\tau_0 \mu/\mu_0} \right\rangle^p \right\rangle^q \right] sgn\left(\tau^{(\alpha)} - B^{(\alpha)} \right), \quad (1)$$

in which $\dot{\gamma}^{(\alpha)}$ is the shearing rate of slip system α, $\tau^{(\alpha)}$ is the resolved shear stress, T is the absolute temperature, F_o, p, q, $\dot{\gamma}_0$, τ_0, μ, and μ_0 are material parameters that may differ for octahedral and cube slip systems, as listed in Table 1 for 650°C, and k_b is Boltzmann's constant. This formulation considers 12 octahedral and 6 cube slip systems, the latter representing a zigzag deformation mechanism [6] along octahedral planes, but producing net slip along cube planes. The model was implemented as a user-material subroutine (UMAT) in ABAQUS 6.9 [7] using an implicit integration scheme based on the Newton-Raphson and the backward-Euler methods. Discussion of model parameters and their estimation can be found in Ref. [8].

The slip system shearing rate relation includes a directional slip resistance $S^{(\alpha)}$ that functions as a theshold stress below which no plastic flow occurs and a back stress $B^{(\alpha)}$ that accounts for directional hardening (Bauschinger effects) on the slip system. The evolution laws for slip resistance and back stress are written as

$$\dot{S}^{(\alpha)} = \left[h_S - d_D \left(S^{(\alpha)} - S_0^{(\alpha)} \right) \right] \left| \dot{\gamma}^{(\alpha)} \right| \quad (2)$$

$$\dot{B}^{(\alpha)} = h_B \dot{\gamma}^{(\alpha)} - r_D^{(\alpha)} B^{(\alpha)} \left| \dot{\gamma}^{(\alpha)} \right|, \tag{3}$$

in which $r_D^{(\alpha)} = \frac{h_B \mu_0}{S^{(\alpha)}} \left\{ \frac{\mu_0'}{f_c \lambda} - \mu \right\}^{-1}$ and S_0, h_B, h_S, d_D, μ_0', f_c, λ, are constants that differ for octahedral and cube slip planes (see Table 1). Both evolution equations follow a hardening-dynamic recovery format and the initial values are specified as S_0 for the slip resistance and zero for the back stress.

Table 1. Parameters of the constitutive model at 650°C for octahedral and cube slip systems.

	F_0 kJ/mol	p	Q	$\dot{\gamma}_0 s^{-1}$	τ_0 *GPa*	S_0 *MPa*	f_c	h_B *GPa*	h_S *GPa*	d_D *MPa*	μ'_0 *GPa*

Other parameters: λ=0.85, μ_0= 192GPa.
Elastic constants: C_{11} = 166.2GPa, C_{12} = 66.3GPa, C_{44} = 138.2GPa.

2.2 Simulations

Figure 1 depicts a mesh composed of "brick" elements (C3D8R) employed for modeling smooth specimens, containing 6859 elements and 118 grains, with colors representing different crystallographic orientations. The loading sequence consisted of relative displacement of the upper and lower boundary planes at a 0.05%/s strain rate under tensile mode loading to achieve overall nominal peak strains of 0.8% and strain ratio (R_ε) equal to zero, typical of the HCF regime. The lateral faces are free of traction and the model has unidirectional periodic boundary conditions along the loading direction (Y-axis) such that the sum of the displacement perturbations of the nodes on top and bottom faces relative to the mean is null, leaving only the imposed net relative displacement. The grain size follows a lognormal distribution based on the algorithm by Musinski [9] and has a mean grain size about 18 μm.

2.3 Fatigue driving force measures

Since the local driving force to nucleate and grow fatigue cracks is affected by the microstructure, several FIPs have been proposed to consider these effects. Fatemi and Socie [10] proposed a FIP based on the critical plane approach that plays a role similar to that of the mixed mode ΔCTD or ΔJ-integral in correlating with growth of small fatigue cracks [11][12][13]. Subsequently, several investigators have successfully employed approaches akin to such FIP along with crystal plasticity formulations for studying the effects of microstructure on fatigue crack formation and early growth within the first few grains [14][15][16].

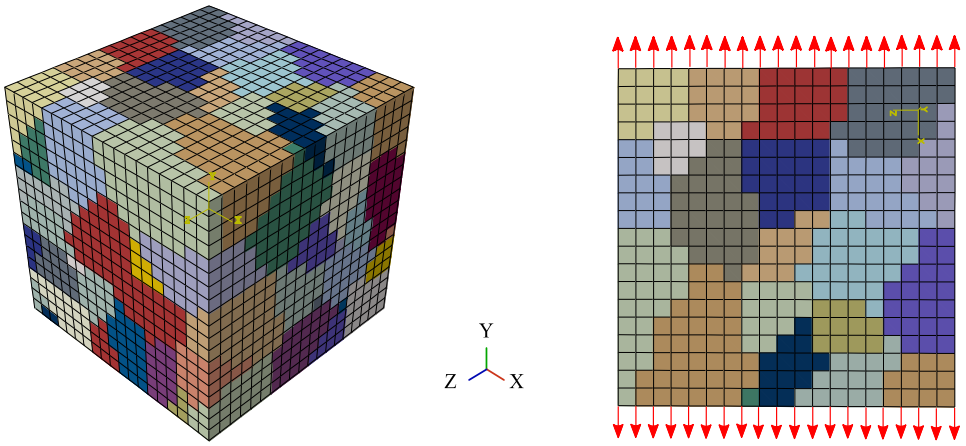

Figure 1. Example of a mesh with the explicit microstructure for axial loading of smooth specimens. Quasistatic mean relative displacement of the upper and lower boundary planes is depicted by the red arrows.

Castelluccio and McDowell [3] proposed to quantify the driving force for transgranular failure with a crystallographic version of the Fatemi-Socie FIP defined for each octahedral slip system, i.e.,

$$\mathrm{FIP}^{\alpha} = \frac{\Delta\gamma_p^{\alpha}}{2}\left(1 + k\frac{\sigma_n^{\alpha}}{\sigma_y}\right) \tag{4}$$

where $\Delta\gamma_p^{\alpha}$ is the cyclic plastic shear strain range on slip system α, σ_n^{α} is the peak stress normal to this slip system, σ_y is the cyclic uniaxial yield strength of the polycrystal, and $k = 1$, as proposed by Fatemi and Socie [10]. The algorithm computes the FIP on each slip system and for each element using the range of plastic strain over the third loading cycle [3]. This methodology allows for an approximate stress redistribution to almost represent "steady state" cyclic conditions in terms of stress and plastic strain redistribution within the polycrystal in the HCF regime, since the microstructure exerts a dominant influence on the transient cyclic plastic deformation fields.

2.3.1 Mesoscale averaging volumes for FIPs

To numerically regularize the FEM discretization and also to represent the finite physical scale of the fatigue damage process zone, the FIPs calculated at each integration point in the mesh are averaged over a selected mesoscale volume. In the present approach we consider three volumes (Figure 2): (i) individual elements, (ii) bands parallel to slip planes, and (iii) entire grain volume. Figure 2 presents a cluster of finite elements that form one grain. Each grain is subdivided in bands of one element of width that are parallel to slip planes as described in Refs. [3][4][8]. The nonlocal FIP is averaged separately over each of these volumes—elements, bands and grains.

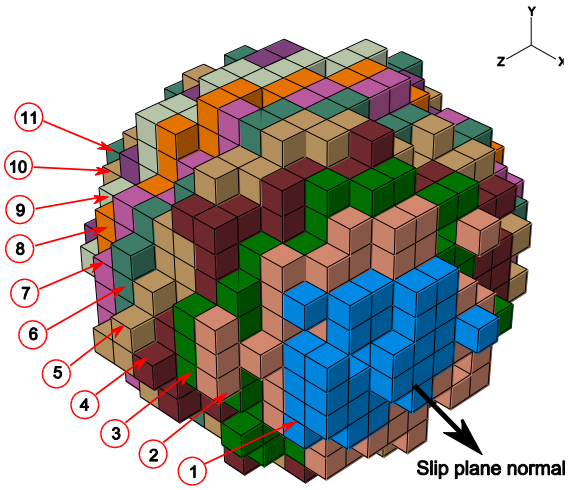

Figure 2: Schematic representation of elements, bands and grains in which FIPs are averaged to estimate transgranular fatigue crack growth. The implementation in a FEM model with unstructured, voxellated meshing is shown, with bands color coded and numbered for a single spherical grain.

3 Assessment of non-local FIP averaging volumes

A total of 50 equivalent realizations with random grain distributions for nominally the same microstructure with mean grain size of about 18 μm were utilized to compare the FIP averaged over grains (FIP_{grains}), bands (FIP_{band}), or the local FIP on every element ($FIP_{element}$). In each case, the average is computed for each octahedral slip system over the corresponding domain.

Figure 3 presents the distributions of the FIP for each element ($FIP_{element}$) and the averages over bands (FIP_{band}) and grains (FIP_{grains}) compiled from 50 equivalent realizations considering all the octahedral slip systems. Since fatigue life is dominated by the extreme distributions, these results consider only values larger than FIP_{thresh} =MAX(FIP_{grains})/1000. The three cases present similar distributions and the extreme value of the three distributions lie between $2x10^{-3}$ and $3x10^{-3}$. Since elements are smaller than the grain scale, the FIPs averaged over elements have somewhat higher extreme values than either grain- or band-averaged FIPs.

Figure 4 presents the distributions of band-averaged FIPs that result from dividing the grain into seven regions, each aligned along slip planes which are oriented perpendicular to the slip plane normal. Note that the number of bands per grain is not constant, so each region may include more than one band from a single grain and slip system. The FIP_{band} presents similar distributions from all sections of the grains, which suggests that there is no dependence of the FIPs on the section from which it belongs (e.g., closer to the center of the grain).

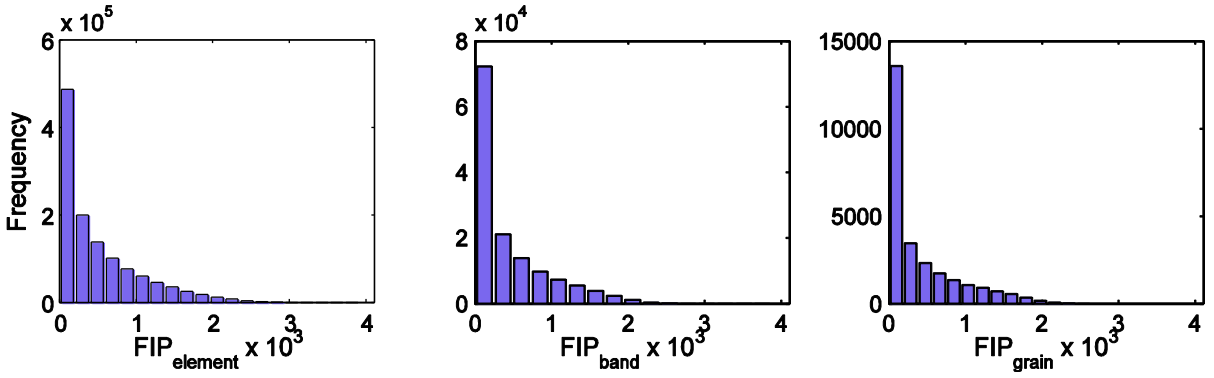

Figure 3. Distributions of the FIP from each element, band and grain for values larger than FIP_{thresh} from 50 equivalent realizations.

To assess the difference between averaging over bands or grains, Figure 5 presents a series of histograms with ratio FIP_{band}/FIP_{grain}; such ratios are presented in a semi-log scale between 0.1 and 10 only considering FIP values larger than FIP_{thresh} for bands or grains. Furthermore, we classified the histograms with the sections from which they belong (rows 1 to 7) or the range of the FIP_{grain} (columns, the FIP increases to the right).

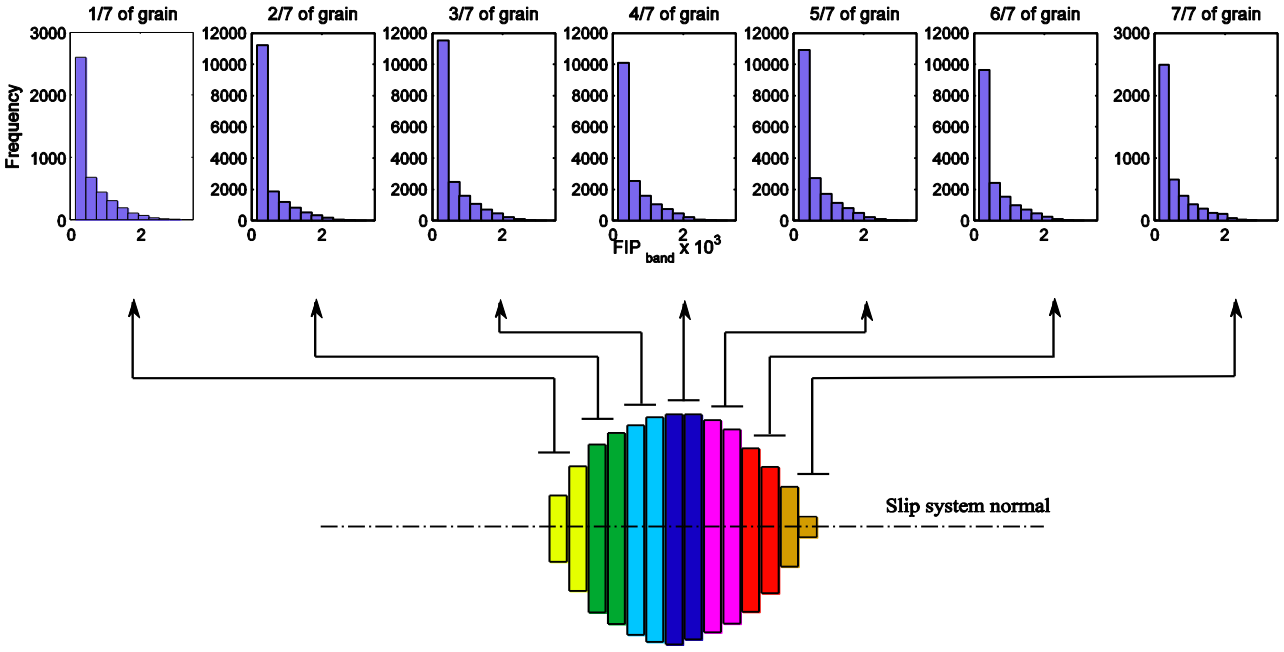

Figure 4. FIP_{band} distributions classified by the region they occupy within a grain, computed from 50 realizations. Only values larger than FIP_{thresh} are considered.

The results show that the variability of the ratio FIP_{band}/FIP_{grain} decreases both towards larger FIPs and the center of the grain. Therefore, the average of the FIP over the entire grain closely mimics the FIP computed at the center cross section of the grain for large values of FIPs.

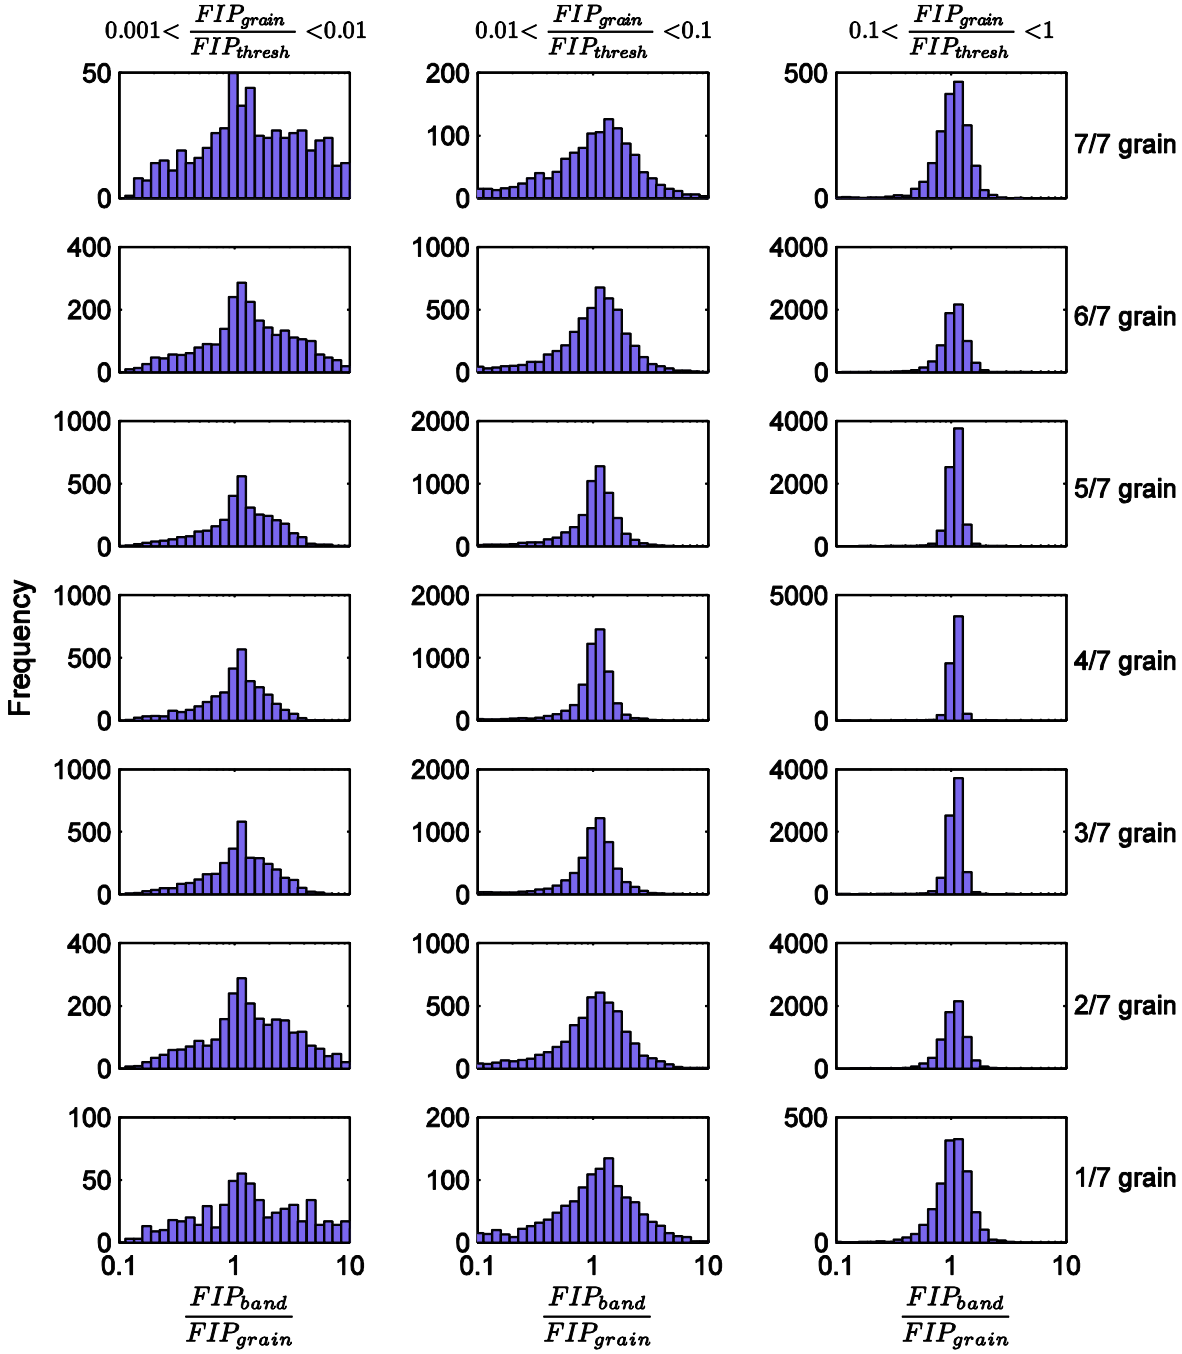

Figure 5. Distributions of the ratio between FIP_{band} and FIP_{grain}, classified by region they occupy in the grain (rows) and the intensity of the FIP_{band} and FIP_{grain} (columns).

3.1 Grain size effects

Grain size effects on fatigue crack formation and early transgranular growth have been modeled by

introducing a dependence of plastic deformation (or the FIP) on the grain size. Such a definition can be ambiguous since the "cross sectional area of the grain" differs for each slip plane that cuts through it. For example, the grain size can be computed for each band as the square root of the cross sectional area or as the diameter of a spherical grain with equivalent volume. Figure 6 presents the distributions of the size of the bands (scales as the square root of the number of elements within) and grains (scales as the cubic root of the number of elements within) normalized by the reference grain size (d_{gr}^{ref} =18μm.); the distributions are clearly different, with the same extreme values but a lower mean value for the band size distribution. In previous work [3][8] we have estimated the fatigue life to nucleate a crack by assuming a proportional dependence of the FIP on the normalized grain size, d_{gr}, (either the size of the band or the diameter of the grains) described by

$$A = d_{gr} \Big/ d_{gr}^{ref} \tag{5}$$

By multiplying A by the FIP we obtain the normalized driving force

$$A \cdot FIP = d_{gr} \Big/ d_{gr}^{ref} \; FIP \tag{6}$$

Distributions in Figure 7 present normalized values of $A \cdot FIP$. It is noted that, because the extreme values associated with FIP_{band} do not tend to be associated with the center of grains, the cross sectional dimension of their associated planes is usually smaller than the grain diameter based the cube root of the grain volume. Accordingly, the distributions of $A \cdot FIP_{band}$ and $A \cdot FIP_{grain}$ are very similar. However, the maximum extreme values of the grain-averaged FIPs are somewhat higher.

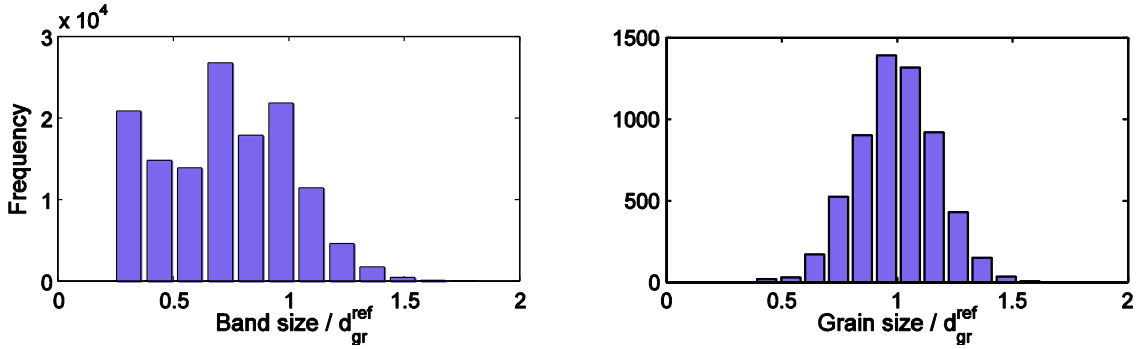

Figure 6. Distributions of the normalized size of bands (left) and grains (right).

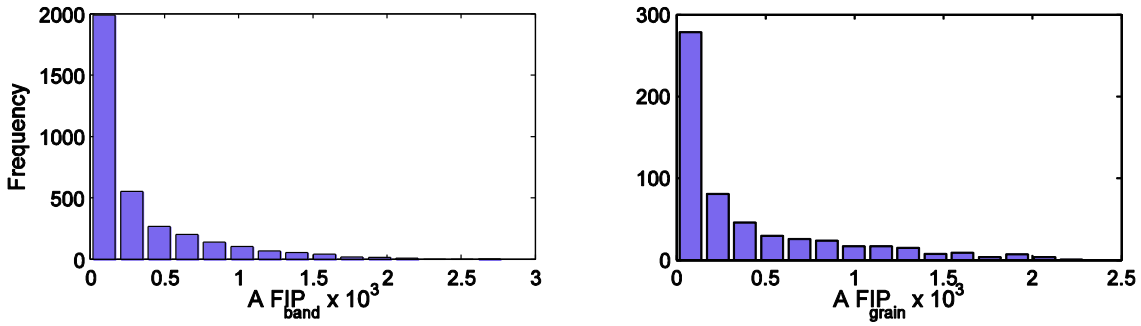

Figure 7. Distributions of the FIPs regularized with the grain size effects for bands, FIP_{band}, (left) and grains, FIP_{grain}, (right).

4 Conclusions

Results of this work support the following conclusions:

- The distributions of FIPs for each element, slip plane cross-section (bands) and the grain volume are very similar with only slight differences in the extreme values.
- Grain averages of FIP represents better the largest cross section representative of the center of the grain.
- The extremes values of the FIPs averaged along the slip plane cross-sectional area tend to be located away from the center of the grains.
- The methodology employed to define grain size effects can affect the variability of the fatigue driving force and modify the distribution of extreme FIP values.

Abstract Research in this paper is about fatigue and fracture behavior of high performance steel HPS485W produced in Wuyang Steel Factory in China. Fatigue crack growth rate (da/dN) test was conducted for HPS 485W compact specimens with thickness of 7.5mm, 12.5mm and 19.5mm under different fatigue load ratio ($R=F_{min}/F_{max}$=0.1, 0.5 and 0.8), respectively. The seven-point incremental polynomial method was adopted for local fitting to obtain fatigue crack growth rate. The test results show that HPS485W has better crack growth resistance compared with traditional steel 14MnNb. What's more, specimen thickness is an influencing factor for crack growth rate, and fatigue crack growth rate increases with the increase of fatigue load ratio R. For 19.5mm specimen under fatigue load with R=0.1, the engineering threshold was tested and numerical calculation was conducted to obtain theoretical threshold. The calculated theoretical threshold is 7.22MPa.$m^{0.5}$. Fatigue life of high performance steel bridge can be predicated based on tested fatigue crack growth rate curve. Study in this paper serve as test basic for the fatigue control and fracture control of high performance steel bridge.

Keywords high performance steel, fatigue crack growth rate, stress intensity factor, threshold value, fracture

1. Introduction

High performance steel (HPS) for highway bridges was developed, which has superior characters in strength, weldability, toughness and corrosion resistance. Compared with steel bridge fabricated by traditional steel, these material characters bring several advantages to HPS bridges such as longer span length, easier fabrication, greater crack tolerance, elimination of painting in operation stage and so forth [1, 2]. Nowadays, about 250 HPS bridges have been constructed in the U.S., and all of these HPS bridges have demonstrated to be structural efficient and economical in whole life cycle [1]. So, the construction of HPS bridge is an attractive choice for modern society. However, with assumption that HPS detail has the same fatigue performance as conventional structural steel, effectively use of HPS may not be possible when fatigue limit state controlling the design [3].

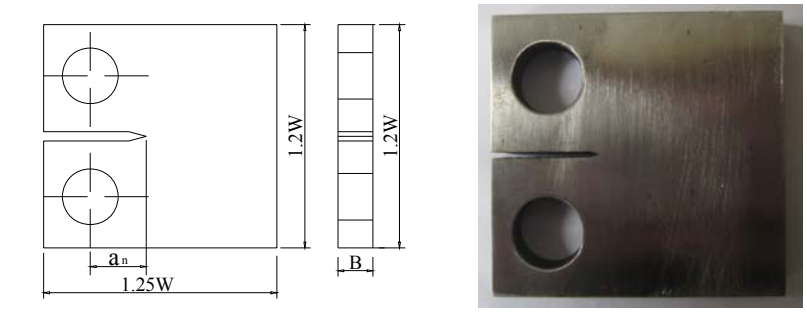
Fatigue and fracture are typical failure mode for steel bridge. With purpose of ensuring high performance steel bridge operation safety, fracture failure control and remaining fatigue life calculation should be studied clearly. Thus, it's necessary in this paper to carry out study for fracture toughness and fatigue characters study for high performance steel Q&T HPS 485W, which is produced by Chinese Wuyang Iron and Steel Co., Ltd. [4]. In this paper, with purpose of remaining life calculation and safety assessment, fatigue crack growth rate test was conducted under different load ratio to acquire fatigue crack growth parameters by Paris equation under cyclic loading, and threshold value was also tested and calculated. The test study in this paper provide important parameters in high performance steel bridge fracture control design and its remaining fatigue life calculation.

2. Fatigue crack growth rate test

Fatigue crack growth rate (da/dN) tests were conducted to determine the fatigue crack growth rate according to ASTM E647-08 and referencing to Chinese GB/T 6398-2000 [5, 6].

2.1. Test specimens

d*a*/d*N* tests were conducted for compact specimen [C(T)] with different HPS 485W thickness under load ratio of *R*=0.1, 0.5 and 0.8. The prefabricated crack for all the specimen is oriented perpendicular to the rolling direction of the steel plate (L-T). The dimension and specimen are shown in Figure 1 and Table 1.



(a) Dimension of C(T) specimen (b) Fabricated C(T) specimens

Figure 1. Dimension of C(T) specimen

Table 1. Specimens dimensions (mm)

B	$1.25W$	$1.2W$	a_n
7.5	50	48	9
12.5	75	72	15
19.5	125	120	23

The loading frequency during test is 15 Hz, considering low frequency of the alternating cycle load in practical traffic transportation. Fatigue crack precracking is conducted before test to provide a sharpened fatigue crack. During the test, the electro-hydraulic servo-controlled fatigue testing machine was used and the crack growth length is read by the microscope with min scale of 0.01mm. The load cycle number and corresponding crack length are recorded at certain intervals from near-threshold to fatigue crack propagate unstably.

2.2. Test result

After the test, the stress-intensity factor range ΔK_i under each crack length is calculated, according to Eq.1. In Eq. 1, $\alpha=a/W$ 错误！未找到引用源。, and $a/W\geq 0.2$.

$$\Delta K = \frac{\Delta P}{B/W}\frac{(2+\alpha)}{(1-\alpha)^{3/2}}\cdot (0.886+4.64\alpha-13.32\alpha^2+14.72\alpha^3-5.6\alpha^4) \quad (1)$$

Using Paris equation to fit tested ΔK_i and $(da/dN)_i$ data. The parameters are obtained including material constant m and C, the standard deviation S, and correlation coefficient. The d*a*/d*N* test result for HPS 485W is shown in Table 2 and Figure 2.

The fracture surface of d*a*/d*N* specimen presents fibrous, and grey or dark grey. Figure 3 shows fracture surface for one of test specimens. The fatigue fracture is composed with crack propagation phase and ultimately quickly failure phase, corresponding to smoothing region and intense coarse region. The fracture surfaces of specimens, shown in Figure 3, are characterized with secondary

cracks. The fracture surface has strong stereoscopic impression.

2.3. Threshold value test

Threshold value (ΔK_{th}) is a significant factor in fracture control design of steel structures and load decreasing procedure is used for ΔK_{th} test. ΔK_{th} for 19.5mm HPS 485W specimen under R=0.1 is tested and the test result is shown in Figure 4 [7]. The calculated theoretical threshold value is 7.22MPa•m$^{0.5}$.

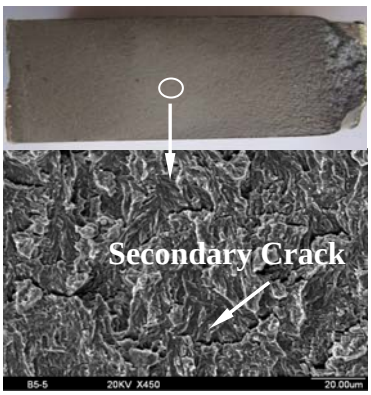

Figure 3. Fracture surface of specimen

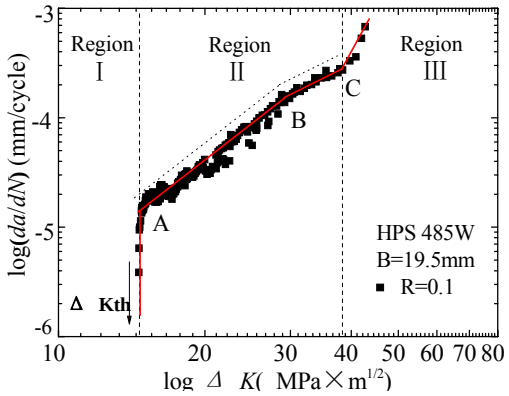

Figure 4. log(da/dN) and log(△K) curve for 19.5mm specimens

3. Test result analysis

Ren et al. conducted da/dN test for 24mm, 32mm and 50mm 14MnNb steel under load ratio of R=0.1, 0.2 and 0.5 [8]. The test result of Ren Weixin is shown in Table 3. Neglecting thickness effect, compare da/dN test result of HPS 485W and 14MnNb was conducted. For R=0.1, the tested m is ranging from 2.53 to 3.28 and C is ranging from 2.29×10^{-12}m/cycle to 2.19×10^{-11}m/cycle for HPS 485W, while the tested m is ranging from 2.67 to 3.74 and C is ranging from 5.83×10^{-10}m/cycle to 1.98×10^{-8}m/cycle for 14MnNb. For R=0.5, the tested m is ranging from 2.72 to 4.13 and C is ranging from 2.37×10^{-13}m/cycle to 1.48×10^{-11}m/cycle for HPS 485W, while the tested m is ranging from 3.39 to 4.08 and C is ranging from 3.08×10^{-10}m/cycle to 1.76×10^{-9}m/cycle for 14MnNb. Learn from comparative result, the tested value of m is similar for traditional bridge steel 14MnNb and HPS 485W, which is about 3. However, the tested value of C for HPS 485W is much smaller than 14MnNb. Fatigue crack growth rate is increasing with the increase of C and m, so compared with traditional 14MnNb, HPS 485W has superior fatigue crack resistance.

The average value of m in Table 3 is 3.17. Using this average value of m=3.17, the log(da/dN) and log(△K) curves are re-fitted by Paris equation for HPS485W specimens. The re-fitting test result is shown in Table 4. The correlated coefficient in Table 4 means the derivation from average value for all the HPS 485W specimens. Learn from Table 4, firstly, for the same load ratio R, thickness of specimen has obvious affection for fatigue crack propagate rate. Secondly, for specimen with same thickness, with the increase of R, value of C is increasing, which means fatigue crack growth rate is increasing.

Table 3. da/dN test result for 14MnNb

Thickness	R	Regression Parameters

Zhang et al. conducted da/dN test for 24mm 14MnNbq at room temperature by three-point loading specimen, which is applied in steel and concrete composite railway bridge in Qinghai-Tibet railway system [9]. For 14MnNbq base steel, the tested parameters in Paris equation is C=1.4763×10^{-10}m/cycle and m=2.1413, which shows HPS 485W has greater fatigue crack growth resistance than 14MnNbq. The comparative results demonstrate better fatigue resistance of HPS 485W.

4. Conclusions

This paper conducted fatigue crack growth rate (da/dN) test to study fatigue resistance of high performance steel HPS 485W. The da/dN test result shows HPS 485W has better fatigue crack growth resistance than traditional steel. The fatigue crack growth rate of HPS 485W is determined by Paris equation, which provides significant parameters in remaining fatigue life calculation of HPS bridge. Research in this paper demonstrates HPS 485W has superior fatigue resistance, and HPS 485W is suggested to be prior used in stress complex part of steel bridge.

Abstract

In this paper, the high-cycle fatigue characterization of 316L stainless steel was studied based on dissipated energy measurement. At first, the dissipated energy per cycle was deduced from temperature field of specimen surface using an experimental mechanical method. Then, variations of dissipation energy per cycle were in-situ monitored during each high-cycle fatigue test under different stress levels. The results show that dissipated energy is mainly constant after the initial 5% cycles of total fatigue lifetime. Dissipated energy versus fatigue lifetime fitting curve shows the same pattern as the traditional stress versus fatigue lifetime curve.

Key words: Dissipated energy, metal material, high-cycle fatigue, fatigue lifetime

1. Introduction

High-cycle fatigue characterization of metal material is a time consuming and expensive statistical process. Thus, various theories and alternative accelerated methods to estimate fatigue characteristics have been of great interest at home and abroad [1] over a number of years. From an energy point of view, under the repeated mechanical energy input provided by the loading, dislocation are created and rearranged into the specific micro-structures. These micro-structural modifications accompanied with heat dissipation energy, lead to progressive energy storage.

By observing the local temperature rise, many authors developed many accelerated methods to estimate fatigue limit or S-N curve, such as one curve method [2]and two curve method [3], Amiri method [4], quantitative thermographic method [5], self-heating method [6] et.al. Unfortunately, fatigue characteristics resulting from these approaches are questionable: the local temperature rise is correlated with heat-conduction, heat-convection and heat-exchange, and especially affected by the environment temperature fluctuation, and the physical reasons leading to these estimations are not yet well understood. A better understanding of the physical origin of dissipated energy is required to better interpret the local temperature rise. The relative dissipated energy was firstly deduced from local temperature

[*]Corresponding author: yuanli@nudt.edu.cn

rise using a two-dimensional convolution local heat conduction equation under fatigue loadings [7, 8]. Considering the environment temperature and the thermo-elastic effect, the accurate dissipated energy per cycle was achieved [9]. In this paper, a precise temperature measurement experiment program was developed to compute dissipated energy. The variation of dissipated energy per cycle was in-situ monitored during each high-cycle fatigue test process under different stress levels.

2. Theory and Experiment Set-up

To achieve the goal of this work, it is necessary to perform precise energy dissipation measurements in high cycle fatigue processing.

2.1. Materials

Stainless steel 316L is a low-carbon stainless austenitic steel. It's composed of 0.03 C, 2 Mn, 0.045 P, 0.03 S, 0.75 Si, 16-18 Cr, 0.01 N, 2-3 Mo, 10-14 Ni (in wt.%). The thermo-mechanical properties of 316L stainless steel are reported in Tab.1. The specimens were machined from a 3mm thick cold rolled sheet and machined in the rolling direction. Before the high cycle fatigue test, three tensile tests was performed to determine the 0.2% yield stress ($\sigma_{0.2\%} = 295MPa$) and ultimate tensile stress ($\sigma_b = 587MPa$).

Table 1: Thermo-mechanical and Mechanical properties(at 20 ^{o}C)

	ρ (kg.m^{-3})	C (J.kg^{-1}K^{-1})	k (m^{-1}.K^{-1})	α (10^{-6}.K^{-1})	E (GPa)	$\sigma_{0.2\%}$ (MPa)	σ_b (MPa)	Ref.
316L	7960	500	14	14.8	195	295	585	[10]

2.2. Dissipated energy measurements

The dissipative source d_1 of the material were computed from the surface temperature fields of the loaded specimen with a rectangular active gauge section (width l=20mm and length lu=30mm). As the surface temperature variations with plastic strain are very small, precise temperature field measurements are required. A step-by-step mathematical description and details about the method performance are available in [9, 11].

A loaded sheet specimen and a dummy specimen were used to dissipated energy measurement. The dummy specimen localized next to the loaded specimen was made from the same material as the loaded one (Fig.1, left picture). It's used to monitor the environment temperature variation during the temperature filed acquisition. Both loaded and dummy specimens were coated with a thin layer of black paint to enhance their emissivity. To lower the environment noise, an insulation equipment was designed and placed around the specimen. Besides, a black curtain was surrounded to avoid external radiative reflections onto the specimens (Fig.1,right picture).

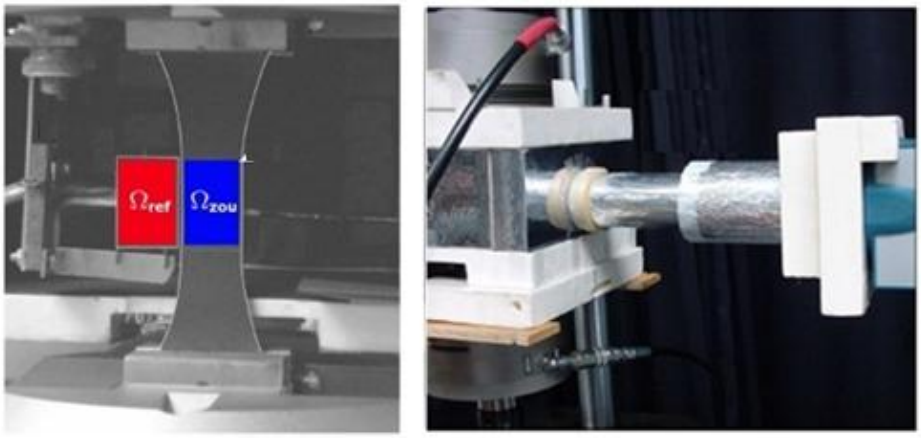

Figure 1: Specimens position (left) under fatigue machine and thermal insulation box (right).

Experiments under cyclic loading were conducted with a INSTRON 8801 axial servo-hydraulic load frame at room temperature. Each high cycle fatigue test was load-controlled. The temperature field of the observed Ω_{sp} and Ω_{dum} were measured using a 350Hz sampling and an integration time of 1200 μs infrared camera (CEDIP Jade MW) with a resolution of 160×120 pixels. The camera, which sensor is cooled down by a Rotary Stirling engine, was started about 4h before the tests in order to ensure its thermal stability. Moreover, the origin manufacturer calibration was used to ensure the precise dissipated energy measurement in this study. Fig.2 shows the dissipated energy $E^i_{d_1}$ obtained with and without the insulation calibration.

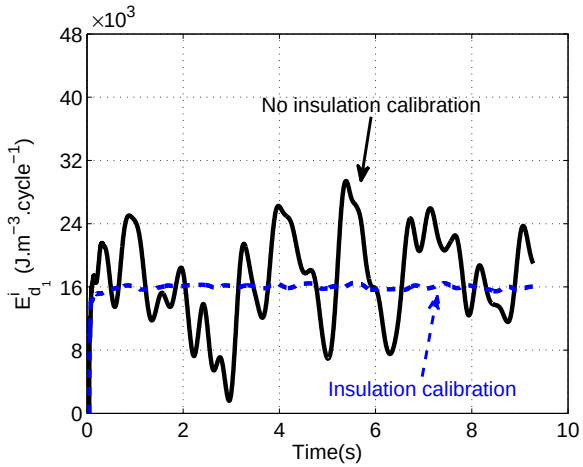

Figure 2: Evolution of dissipated energy difference with and without the insulation calibration.

During each test, the thermal fields of the observed areas Ω_{sp} and Ω_{dum} were stored for 20s (7000 images), which divided in two sequences (Fig.3):

-At the first 5s, the applied stress on the specimen was constant and equal to the mean stress σ_m. The mean stress being small compared to the material yield stress, creep and associated dissipated energy is negligible. Thus, during these 5s, the intrinsic dissipative sources d_1 of both specimen and dummy were assimilated to zero. The measured thermal drifts are due to the convection (loaded specimen and dummy) or conduction (loaded specimen) and represent the initial conditions.

-At the second 15s, the specimen was loaded with a stress such as σ=σ_m+$\sigma_a \cos(2\pi f t)$, where σ_a is the alternate stress amplitude and f is the loading frequency (f=14Hz). The temperature fields acquisition was from t=5s and lasted 15s (210 cycles). The temperature field variations acquired due to the intrinsic thermo-mechanical sources. The alternative temperature variation are due to the thermo-elastic sources S_{th} (thermoelastic coupling effect) while the mean temperature increase is due to the dissipative sources d_1.

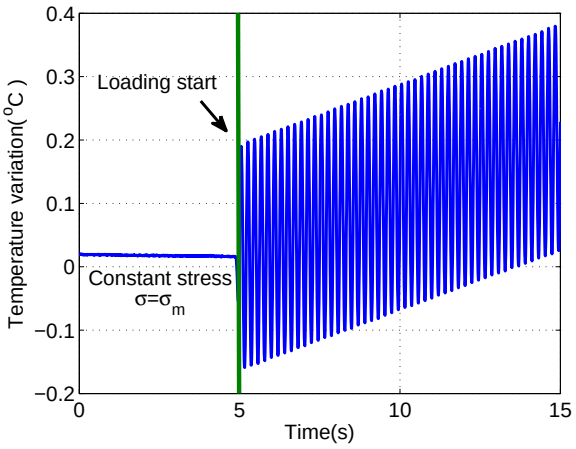

Figure 3: Temperature variation during a temperature field measurement under R_σ=0.2, σ_{max}=380MPa, 316L specimen.

The measured temperature fields were assumed to be representative of the material temperature through the specimen thickness, and the thermo-mechanical sources d_1 and S_{th} were estimated using the local energy balances equations. By combining the balance energy equations before and after the start of the the loading on both loaded specimen and dummy, the following energy balance equation was obtained:

$$\rho C(\frac{\partial \theta}{\partial t} - [\frac{\partial \theta}{\partial t}]_{t=0^-}) - k\Delta_2\theta + \rho C(\frac{\theta}{\tau_{th}^{2D}}) = d_1 + S_{th} \quad (1)$$

where ρ is the material density, C is the calorific capacity, k is the thermal conductivity and Δ_2 is the Laplacian operator, θ is the local temperature variation of the specimen due to the thermo-mechanical sources. Eq.(1) underlines that these thermo-mechanical sources produce three major effects: a change in heat rate ($\rho C(\frac{\partial \theta}{\partial t} - [\frac{\partial \theta}{\partial t}]_{t=0^-})$), energy exchanges by conduction ($k\Delta_2\theta$) and energy exchanges by convection and radiation ($\rho C(\frac{\theta}{\tau_{th}^{2D}})$). τ_{th}^{2D} is here a time constant characterizing the convection and radiation losses.

The dissipative and thermo-mechanical sources are coupled in Eq.(1)(thermo-mechanical coupling effects), although only the dissipative sources d_1 are of interest in this work. The loading signal was used to compute and remove the thermo-mechanical sources S_{th} and associated temperature variations from Eq.(1). As a result, dissipative sources d_1 were obtained. Eq.(1) was also integrated over the observed area Ω_{sp} and Ω_{dum} to lower the measurement noise level.

In this work, the mean dissipative sources were defined as $\bar{\bar{d}}_1$ to underline the spatial averaging. The spatial average $\bar{\bar{d}}_1$ is supposed to be representative of the dissipative sources field over the area Ω_{sp}. This hypothesis has been validated by computing the fields of dissipative sources d_1 using the method described in [9]. Eventually, the dissipated energy per cycle $E^i_{d_1}$ was computed by integrating $\bar{\bar{d}}_1$ over each cycle:

$$E^i_{d_1} = \int_{t_i}^{t_i+1/f} \bar{\bar{d}}_1 dt \tag{2}$$

Where t_i is the starting time of cycle i.

As the dissipated energy measurement is achieved in the elastic hysteretic domain, the dissipated energy should be constant during the test (15s). This characteristic was used a posteriori to check whether the test was performed in the elastic domain. The mean of the dissipated energy per cycle $E^m_{d_1}$ was thus computed over a time t_m=12s to lower the noise level (Fig.4):

$$E^m_{d_1} = \frac{1}{t_m} \int_{t_0}^{t_0+t_m/f} E^i_{d_1} dt \tag{3}$$

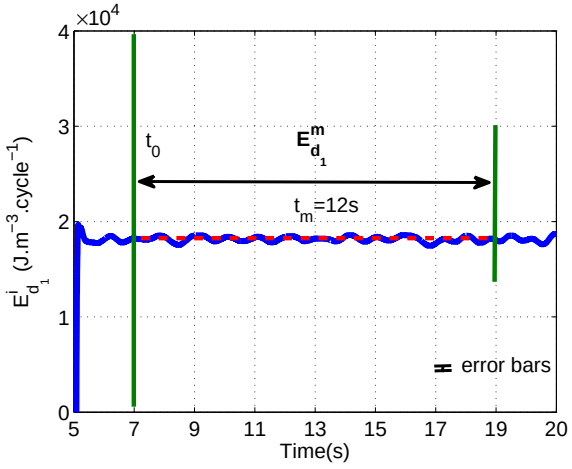

Figure 4: Definition of the mean dissipated energy per cycle $E^m_{d_1}$ (316L specimen).

The dissipated energy measurements have proved to be a reliable method[12]. With this method, the detection threshold of $E^m_{d_1}$ is as small as $\pm 222 J{\cdot}m^{-3}{\cdot}cycle^{-1}$ ($2\sigma_{E^m_{d_1}}$) for a 316L stainless steel specimen.

3. Results and discussion

It's known that in high fatigue test, damage is created slowly by dislocation pile-ups due to the small and gradual changes in the material microstructure. A test sequence was proposed to observe dissipated energy variation during the high cycle fatigue process, to better underline the in-situ thermo-mechanical modifications of materials. Serval specimens were loaded from σ_{max}=280MPa to 440MPa in steps of 20MPa with R_σ=0.2 and f=14Hz.

Different constant amplitude fatigue tests (13 levels,30 specimens) were run until the specimen complete separation under traction-traction loadings (Tab.2). In each fatigue test, serval dissipated energy measurements were performed every 5,000, 10,000 or 30,000 cycles for different stress levels fatigue tests.

Table 2: Fatigue test results of 316L stainless steel (R_σ=0.2, f=14Hz)

Specimen number	σ_{max} (MPa)	σ_m (MPa)	σ_a (MPa)	N_f to failure	$E_{d_1}^m$ at 30,000 cycles $(J{\cdot}m^{-3}{\cdot}cycle^{-1})$	Results

30	280	168	112	2,000,000	3,499	No Failure

Fig.5 and Fig.6 are dissipated energy variations in term of fatigue cycles ratio at different stress levels from

420MPa to 280MPa during fatigue test process, where N is the loading cycle, N_f is the cycles to failure (i.e. fatigue lifetime) and N/N_f represents fatigue loading cycles ratio. Dissipated energy per cycle $E_{d_1}^m$ was almost constant after 10% of total fatigue lifetime (N/N_f=0.10) beyond σ_{max}=370MPa) and 5% of total fatigue lifetime (N/N_f=0.05 in below σ_{max}=350MPa).

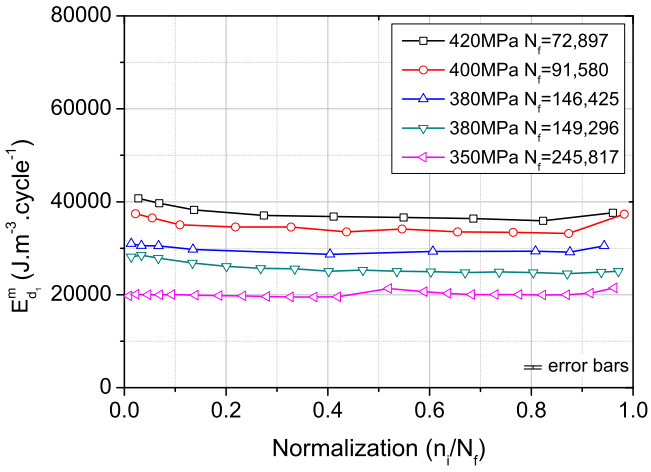

Figure 5: Dissipated energy variation during high cycle fatigue tests from 420MPa to 350MPa (R_σ=0.2, f=14Hz).

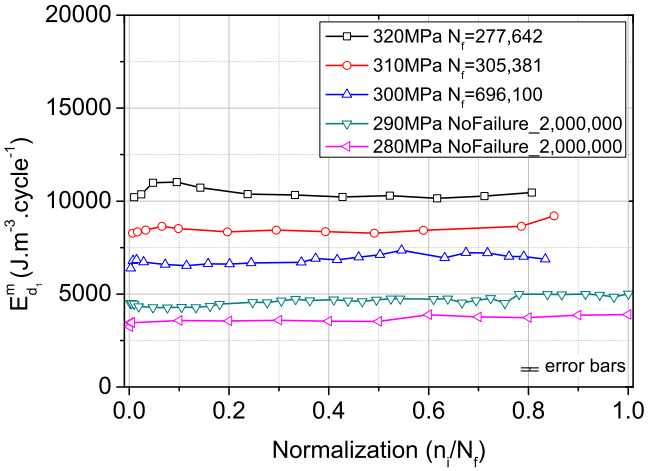

Figure 6: Dissipated energy variation during high cycle fatigue tests from 330MPa to 280MPa (R_σ=0.2, f=14Hz).

The same phenomenon about dissipated energy variation were observed by $Meneghetti, G$ [8, 13]. In his method, the fatigue test must suddenly stop many time to measure the cooling curves to calculate the specific heat loss Q. The

measured values of Q for each specimen were whin 15% with respect to the mean value. Thanks to the precise experiment set-up, the dissipated energy per cycle $E_{d_1}^m$ are with 5% of the mean value in these fatigue tests.

The constant stress amplitude fatigue tests (12 stress levels, 30 specimens in Tab.2) were performed to obtain the S-N curve by the traditional procedure (Fig.7). Meanwhile, Fig.8 shows that the relationship between the dissipated energy $E_{d_1}^m$ and fatigue lifetime N_f is very similar to the S-N curve. This curve was defined as $E_{d_1}^m$-N curve in this work. The scatter bands of the two curves are given for 10% and 90% survival probability.

The linear fitting equation of $E_{d_1}^m$-N curve is written as,

$$log(E_{d_1}^m) = -0.77log(N_f) + 8.33 \tag{4}$$

where the related coefficient $R^2_{E_{d_1}^m - N}$ between $E_{d_1}^m$ and N_f equals to 0.94.

The linear fitting equation of S-N curve is written as,

$$log(\sigma_a) = -0.13log(N_f) + 2.85 \tag{5}$$

where the related coefficient R^2_{S-N} between σ_a and N_f equals to 0.89.

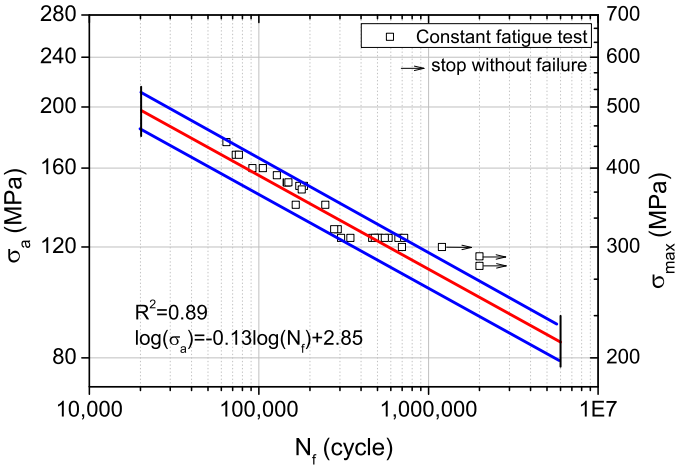

Figure 7: S-N curve by traditional staircase procedure of 316L material (R_σ=0.2, f=14Hz).

As $R^2_{E_{d_1}^m - N} > R^2_{S-N}$, $E_{d_1}^m$-N curve by dissipated energy measurements shows more accurately than S-N curve by traditional fatigue test method. In such a case, it's possible to extrapolate the $E_{d_1}^m$-N curve by dissipated energy measurements to predict the residual fatigue lifetime during various stress amplitude fatigue test under traction-traction cyclic loadings (i.e. R_σ=0.2).

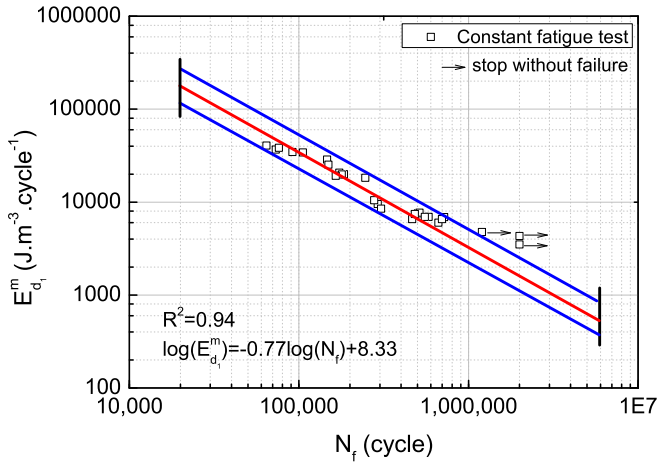

Figure 8: $E_{d_1}^m$-N curve by dissipated energy $E_{d_1}^m$ method of 316L material (R_σ=0.2, f=14Hz).

4. Conclusion

In conclusion, dissipated energy per cycle $E_{d_1}^m$ is constant under traction-traction cyclic loadings during constant and various stress amplitude high cycle fatigue tests of 316L stainless steel while the material reached a stabilized thermo-mechanical state (5% of total fatigue lifetime). Dissipated energy versus fatigue lifetime fitting curve shows the same pattern as the traditional stress versus fatigue lifetime curve. Further studies and specific microstructural analysis are still required to better understand the correlation between the dissipated energy and the microstructural material state.

Abstract A method was proposed for measuring the effective stress intensity factor ranges of Mode II fatigue crack growth by using the hysteresis loop for a specimen's surface strain. Many cases of rolling contact fatigue failure, such as those that occur in railway rails, bearings and gears are due to repeated high shear loads. In order to prevent such fatigue failures, the resistance of a material to repeated high shear loads must be determined. The fatigue crack growth characteristics are dependent on the Mode II stress intensity factor range. However, conventionally measured Mode II fatigue crack growth characteristics vary according to the measurement methods. Therefore, the authors improved the experimental measurement method proposed by Murakami, and proposed a way to measure the Mode II effective stress intensity factor range. Improvements to the jigs and specimen were made based on the ideal mechanical model of the experimental method. Furthermore, to measure the Mode II fatigue crack growth behavior, strain gauges were applied to the specimen and the hysteresis loop of the strain was measured with high accuracy by using a newly developed subtraction circuit.

Keywords Rolling contact fatigue, Friction, Mode II fatigue crack, Effective stress intensity factor, Fracture mechanics

1. Introduction

Mechanical failures such as spalling and pitting can occur in rails, bearings, and other components when they are subjected to heavy repeated rolling contact loading. In order to prevent these types of failures, it is necessary to determine the resistance of certain materials to them. A fatigue crack under repeated rolling contact loading, which is what leads to the failure, propagates in Mode II. Therefore, the resistance to fatigue crack propagation which is caused by stress concentration sources such as flaws or inclusions can be evaluated by using the Mode II fatigue threshold stress intensity factor range, ΔK_{IIth}.

Methods for measuring Mode I fatigue crack propagation have already been established and standardized [1]. However, for Mode II fatigue crack propagation, systematic research is limited because this type of fatigue crack propagation is difficult to produce in a laboratory and there are no standard tests. Early systematic research was conducted by Otsuka et al. [2]. However, the method they developed could only be applied to soft metals such as aluminum alloys, even though hard metals are used for the components for which Mode II fatigue crack become a problem. After this study, Murakami et al. [3, 4] developed an experimental method that could also be applied to hard metals such as bearing steel. Later, Otsuka et al. [5] improved their method so that it could also be applied to hard metals. However, different values were obtained for the threshold stress intensity factor range ΔK_{IIth} when these two methods [4, 5] were used for the same material. It seems that interference by the crack faces affected the result. The study conducted by Matsunaga et al. [6] on the shear mode threshold proved that friction on the crack face increases the value of ΔK_{IIth}. Therefore, it is thought to be necessary to take the friction on the crack faces into account when determining the Mode II effective stress intensity factor range, $\Delta K_{\mathrm{IIeff}}$.

In the previous work by the authors, a new method was proposed [7, 8] to measure the friction at the crack faces and $\Delta K_{\mathrm{IIeff}}$. Moreover, a more appropriate assumption for the friction distribution on

the crack faces was made and a new method was proposed. This paper discusses, Mode II fatigue crack growth experiments that were conducted using the proposed method, along with the obtained results.

2. Experimental procedures

2.1. Mechanical model

Figure 1(a) shows the mechanical model of the Mode II fatigue crack growth experiment that was proposed by Murakami et al. [3]. In this paper, this model is referred to as the "former mechanical model." Load P was applied to the upper cantilever. By inserting a ceramic cylinder in the slit, load P was assumed to be divided into two equal halves and applied to both cantilevers. In a real machine, a Mode II crack propagates under the condition of compressive stress. Therefore compressive load S was applied using the pre-tightening force of bolts. Mode II fatigue crack growth experiments were performed by applying the former mechanical model. However, because of the plastic deformation of the specimen where the ceramic cylinder made contact with it, load P could not be divided as expected. In fact, dents were found on the specimen where the ceramic cylinder inserted into the slit made contact, and a considerable reduction in the slit width was observed during the fatigue experiment. This reduction in the slit width was thought to be caused by a gap formed as a result of plastic deformation when the load was applied and, as a result, the load applied to the lower cantilever was thought to be considerably reduced.
In order to equally divide the load P between the cantilevers, a new mechanical model has been proposed [7, 8]. Figure 1(b) shows this new mechanical model, which was based on the experimental setup shown in Fig. 1(c). The new model was discussed with springs and rigid blocks in the previous study [7, 8]. This discussion showed that if the pre-tightening force S was larger than $P/2$, then the load was divided into two equal halves and applied to the two cantilevers, and the width of the slit did not change during the experiment even if a cylinder was not in place. In addition to the compressive load S by the pre-tightening force of the bolts, compressive load Q was applied on the fatigue crack face in order to avoid crack branching in Mode I during the fatigue crack propagation.

2.2. Material

The experiments were carried out using commercial grade Japanese Industrial Standards (JIS) SS400 steel (400 MPa minimum tensile strength) which is rolled steel designed for general structures. Table 1 presents its chemical composition.

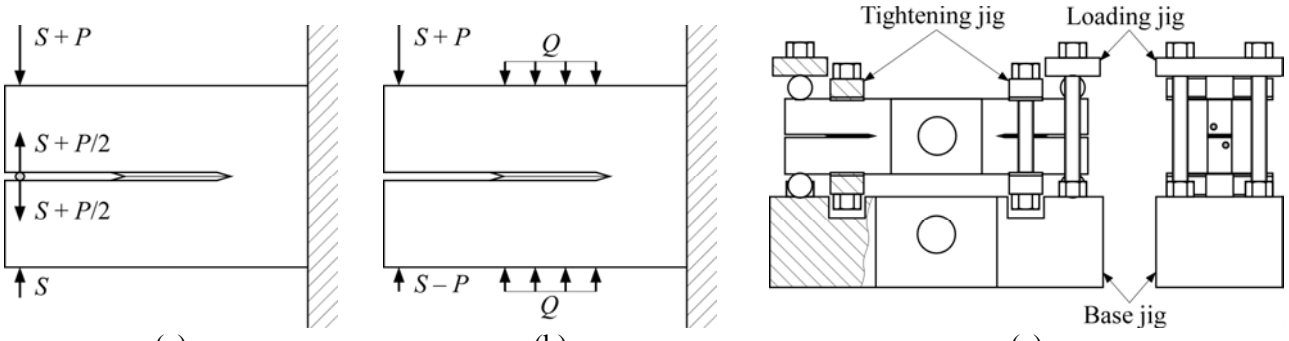

Figure 1. Mechanical models for Mode II experimental method: (a) former mechanical model [3], (b) new mechanical model [7, 8], and (c) new experimental setup

2.3. Specimen

Figure 2 shows the shape and dimensions of the specimen that was used in this study. The specimen had a chevron notch and side grooves. The fatigue crack initiated at the tip of the chevron notch, where the stress intensity factor was high. The groove on the side of the chevron notch caused Mode II fatigue crack growth in the section with the maximum shear stress and prevented crack branching in the direction of the maximum tensile stress, which was a Mode I crack. Two crack propagations were simultaneously carried out on a single specimen. Compressive force Q was applied on the crack face with the middle jigs to avoid crack branching in Mode I. In order to reduce the unexpected horizontal force applied to the specimen, three of the four grooves on the end of the cantilever were made flat and one was made larger with a radius of 1 mm to 4 mm. The three flat grooves allowed for the relative displacement caused by the elastic deformation between the specimen and the jigs. The large circular groove prevented the specimen from moving.

2.4. Experimental setup

Figure 3 shows the setup of the experiment. Four ceramic cylinders were placed between the cantilevers and the loading jigs. As a result, the load applied to the specimen was divided into two equal halves on the cantilevers. A cyclic tensile load P in the form of a sine wave, ranging from 0.5 kN to 10 kN (stress ratio: $R = 0.05$) was applied to the center holes in the jig and specimen through two pins using a servo-hydraulic fatigue testing machine operating at a frequency of 6 Hz. In order

Table 1. Chemical composition of specimen (mass %)

C	Si	Mn	P	S	Fe
0.11	0.27	0.55	0.021	0.023	Bal.

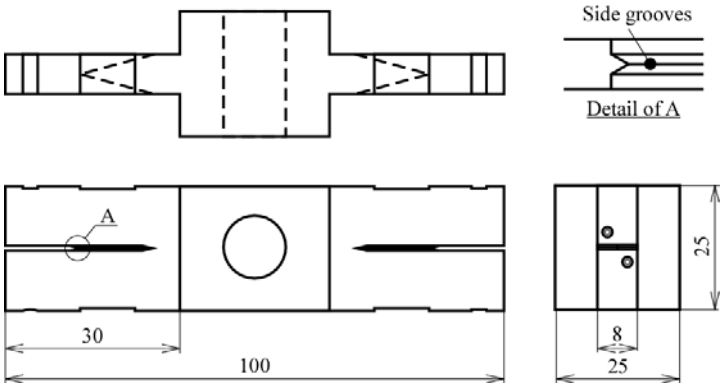

Figure 2. Shape and dimensions of specimen (unit: mm)

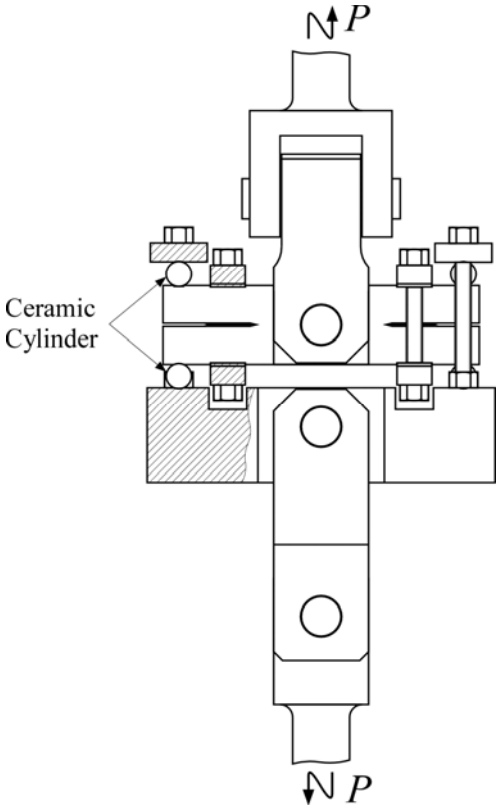

Figure 3. Experimental setup

to suppress the tendency for Mode I crack branching, the pre-tightening load S of a bolt was applied to the ends of the cantilevers and vertical compressive load Q was applied to the crack faces using the loading jigs and tightening jigs. The ceramic cylinder diameter (8 mm) was larger than that used in the former setup (1 mm) in order to reduce the plastic deformation of the specimen on the contact face. Moreover, a set of universal joints was used to cancel out the unexpected moment applied to the specimen.
The specimen and jigs were designed considering their compatibility with the fatigue crack growth experiment equipment using a "CT (Compact Tension) specimen." Therefore, the experimental setup shown in Fig. 3 could be used with environmental experiments equipment that is designed for a "CT specimen."

2.5. Crack length measuring method

The crack length during the fatigue crack growth experiment was measured by using the AC potential method [3]. Two electrodes were connected to the ends of the cantilevers. As the crack between the two cantilevers grew, the electrical resistance between these two electrode points increased. Then, the resistance was measured and converted into the crack length. The ratio of the increase in the electric potential (ΔE) caused by the crack growth to the electric potential at the beginning of the experiment (E_0) correlated with the crack length. Therefore, the crack length could be measured without interrupting the experiment. The specimen was insulated from the jig using the ceramic cylinders.

3. Derivation of friction between crack faces

In order to measure the friction between the fatigue crack faces, two strain gauges (Kyowa Electronic Instruments Co., Ltd., KFG-2N-120-C1) were placed on the specimen surface. Figure 4 shows the strain measurement positions on the specimen. The friction force on the crack face was derived from the load-strain curve over one cycle using the outputs of the strain gauges.
Figure 5 shows the basic model for the derivation of the friction, which represents a mass spring model with a rough ground and a mass subjected to a cyclic load P. The load-displacement curve over a cycle is shown in Fig. 5(b). Because the direction of the friction changes over a cycle, the friction can be derived from the hysteresis in the load-displacement curve.
However, for the real experiment, the curve became more complicated. When the loading began, the portion of the crack faces at the notch began to slide, and all of the other parts of the crack faces soon followed. As a result, the linear part of the curve marked (i) became nonlinear. Thus, because of the plastic deformation that occurred around the crack tip, the portion of the linear part of the curve marked (ii) also became nonlinear. The same phenomena also occurred at the portions marked (iii) and (iv). Therefore, the load-strain curve over one cycle was estimated to be that is shown in Fig. 6. The friction could still be derived from the load-strain curve. The vertical dashed line shown in Fig. 6 starts from point A and intersects at point B with the extended line of the elastic portion of the curve at the unloading. The length of dashed line AB is related to the friction, where the relation is determined using a finite element method (FEM).

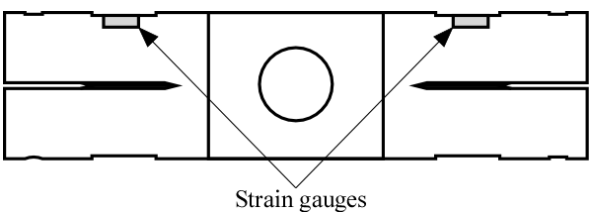

Figure 4. Strain gauges placed on specimen

4. Results and discussion

The fatigue crack growth experiment was ended by the action of the displacement limiter at $N = 2.08 \times 10^6$ cycles. A fatigue crack that nucleated and grew at the root of the cantilever caused the limiter action. Figure 7 shows the displacement range ($\Delta\delta$) of the load piston during the fatigue experiment. Until $N = 1.0 \times 10^6$ cycles, the displacement range maintained a constant value. However, at $N = 2.0 \times 10^6$ cycles, the value rose slightly and then suddenly began to increase. This sudden increase was thought to indicate the fatigue crack growth at the root of the cantilever. Therefore, in this case, the intended fatigue crack growth experiment was performed until around $N = 1.0 \times 10^6$ cycles.

4.1. Mode II fatigue crack growth behavior

Figure 8 shows the relationship between the potential difference and the number of cycles measured using the AC potential method. In this experiment, because the effect of electric noise was not removed, averaged data were considered. From Fig. 8, it can be seen that the crack began to grow from $N = 5 \times 10^3$ cycles, after which the crack growth depended on the number of cycles.

4.2. Fracture surface of Mode II fatigue crack

After the fatigue crack growth experiment, the fracture surface was observed using a scanning electron microscope (SEM). Figure 9 shows the result of this observation. In this figure, lines that were parallel to the crack growth direction and cracks branching in the Mode I direction were found, which are characteristic of a Mode II fatigue fracture surface [3, 4]. Therefore, the success of the Mode II fatigue crack growth experiment was verified.

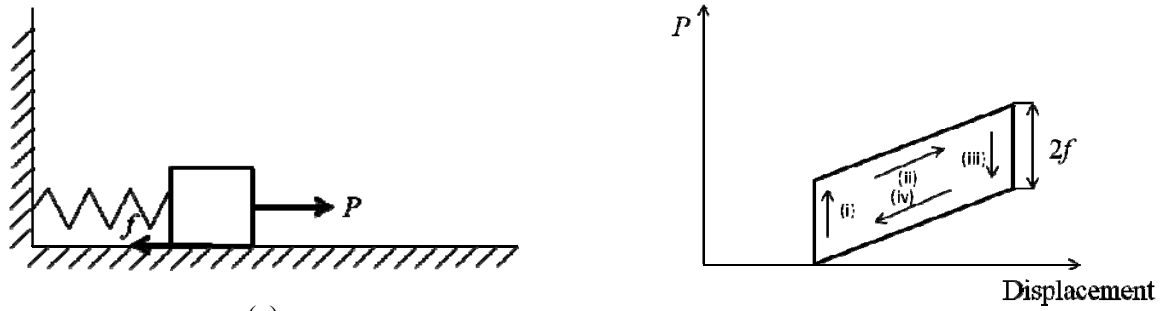

Figure 5. Models for derivation of friction: (a) mass-spring model and (b) load-displacement curve

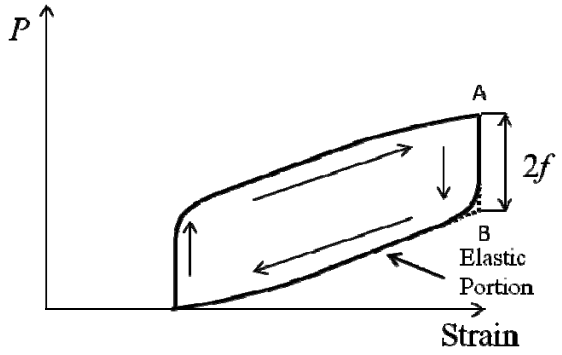

Figure 6. Estimated load-strain curve

4.3. Friction force measurement

Figure 10(a) shows an example of the relationship between the load and the strain at $N = 4.0 \times 10^4$ cycles. In order to measure the hysteresis loop of the strain with high accuracy, a subtraction circuit was developed. The input data were the strain at a jig and the strain at a specimen, as measured by strain gauges. These strains were converted to electric potentials and subtracted in the circuit. Figure 10(b) shows that the relationship between the load and the subtracted strain. From Fig. 10(b), the hysteresis loop was observed during a load cycle. As seen from a comparison of Fig. 10(b) with Fig. 6, the hysteresis loop was the same at a low load, whereas a difference existed at a high load. At present, the exact reason for this result is not known. However, through an analysis of the obtained load-strain hysteresis loop, the friction force and values of $\Delta K_{\mathrm{IIeff}}$ and ΔK_{IIth} could be determined in a future study.

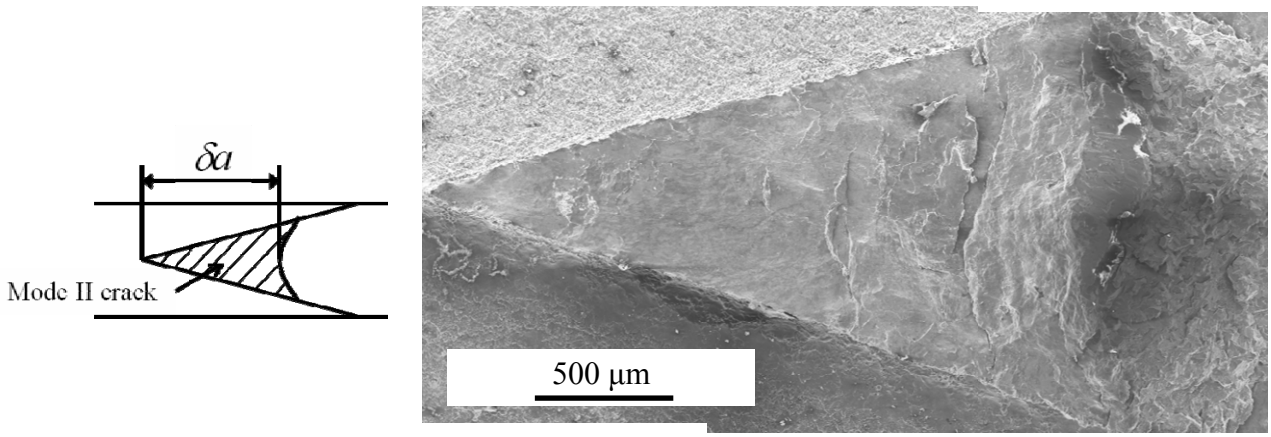

Figure 9. Fracture surface of Mode II fatigue crack

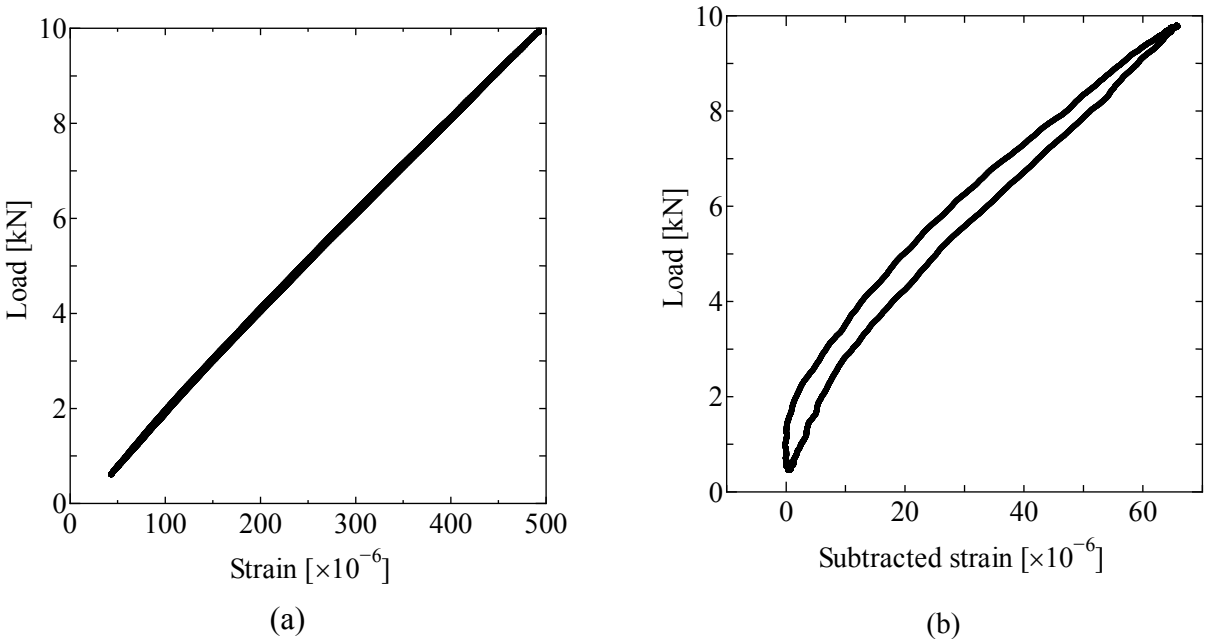

Figure 10. Example of relationship between load and strain (at $N = 4.0 \times 10^4$ cycles): (a) strain is measured strain and (b) strain is subtracted strain

5. Conclusions

The mechanical model for the Mode II experimental method proposed in the previous paper was modified. Thus, the load was considered to be equally divided into two halves and applied to each cantilever of the specimen. Furthermore, a new method for determining the friction between the crack faces was proposed. The crack length and friction between the crack faces were measured using an AC potential method and deduced from the load-strain curve, respectively. From this measurement and deduction, $\Delta K_{\mathrm{IIeff}}$ could be determined. However, the value of ΔK_{IIth} has not yet been determined. It will be determined using this method in a future study.

Abstract
It is well known that it is impossible to guarantee that structural components are really free of cracks smaller than the detection threshold of the non-destructive method. Nevertheless, most components are still designed against fatigue crack initiation using procedures that do not recognize such cracks. Consequently, their "infinite life" predictions may become unreliable when cracks are introduced by any means and not quickly detected or properly removed. Therefore, structural components that must last for very long fatigue lives should be designed to be tolerant to undetectable short cracks. Indeed, continuous work under fatigue loads cannot be guaranteed if any crack can propagate during their service lives. Since most structural components designed for long lives work in spite of not recognizing such cracks, and they certainly are somehow tolerant to short cracks. However, the question "how much tolerant" cannot be answered by traditional fatigue design procedures alone, but such a problem can be avoided by adding proper short crack concepts to their "infinite" life design criteria. This work proposes such a damage-tolerance requirement to quantify the behavior of short cracks. This methodology can also be used to quantify the difference between the fatigue K_f and the static stress concentration factor K_t.
Keywords: Fatigue; Short crack; stress gradient; non-propagating crack; tolerance

1. Introduction

During the manufacture or service of structural components, small defects ranging in length from tens microns to several millimeters are unavoidable. Industrial experiments have shown that the rupture of components is often produced by these "short cracks", which develop in most cases from the instinct faults of these structures and propagate when they are subjected to cyclic loading. As the initiation fatigue life is largely influenced by the behavior of short cracks, not taking into account of the propagation of short cracks can lead to potentially dangerous overestimation of fatigue life [1, 2]. It is therefore essential to thoroughly understand their growth rules and effectively predict the structure life by considering the initiation and propagation of short cracks.

As we know, growing short cracks from sharp notches can stop completely even when the remote applied stress amplitude remains constant. This phenomenon was discovered as early as 1949 by Frost [3] as shown in Fig.2. In the succeeding research of short cracks, inspired by Frost's report about the non-propagating cracks, people normally tend to focus on the behavior of short cracks departing from the sharp notch root which corresponds to the evident notch sensitivity coefficient and significant stress gradient. It has a non-propagating cracks zone where the cracks initiated from a sharp notch ($K_t > 3$); and the driving force ΔK, which should increase along with the short cracks growth, is not high enough to propagate the cracks under the constant remote applied stress and K_t. These analyses contribute to the quantification of fatigue crack initiation life and non-propagating crack length. Hence, it is certainly reasonable to expect that such phenomenon can be used to quantitatively explain why the fatigue stress concentration factor K_f differs from the conventional stress concentration factor K_t of sharp notches. The stop of short cracks has been attributed to the decrease of ΔK as short cracks lengthen, which relates to significant stress gradient at the edge of notch.

Recently, Castro et al. have indicated in [4] that the high stress gradient at the narrow notch root

was drastically reduced due to the short crack growth, which may lead to the non-propagating crack phenomena. In the present paper, based on their analytical methodology, a modified method has been provided to quantify the short crack behavior. And the variation of the stress gradient and the resulting ΔK along with the short cracks growth has been presented.

2. Stress gradient at the sharp notch root along with the short cracks growth

It is well known that the stress concentration is usually caused by geometrical discontinuity or heterogeneity of microstructure which involves an appearance of the maximum stress compared to the calculated median values based on the smooth section. In mechanical design, one attaches rather importance to the high stress fields which arise in the majority of the industrial components (shoulder, holes, fillets etc.). The stress concentrations can be regarded as the origin of the fatigue cracks or the unstable ruptures.

In this paper, the authors are devoted to the investigation of the stress concentrations due to the geometry imposed by the industrial design. The notch effect is modeled by an increase of the local stress in a restricted volume, compared to the distribution of nominal stress. However, the concept of stress gradient can be generalized with any cross-section of a specimen or with any volume element of a mechanical component. Therefore, for a plate containing cracks at the bottom of an elliptic notch as illustrated in Fig. 1, the stress σ_y, which acts in the remaining ligament of an infinite plate with an elliptic hole, is given by Eq. (1) at points ($x \geq b$, 0) (see [5]).

$$\frac{\sigma_y}{\sigma_n} - 1 = \frac{\left(b^2 - 2bc\right)\left(x - \sqrt{x^2 - b^2 + c^2}\right)\left(x^2 - b^2 + c^2\right) + bc^2\left(b - c\right)x}{\left(b - c\right)^2\left(x^2 - b^2 + c^2\right)\sqrt{x^2 - b^2 + c^2}} \tag{1}$$

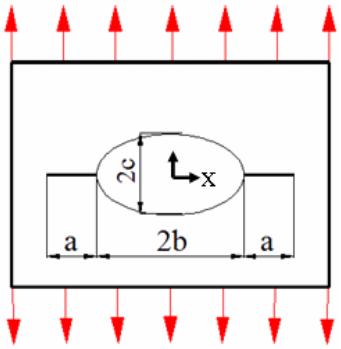

Fig. 1. Centre elliptic notch with a fatigue cracks formed at the notch roots

The σ_y/σ_n can be defined as the stress concentration factor in the presence of short crack K_{tf}. Thus, the gradient of σ_y at the bottom of notch (at the edge of the elliptic hole) is given by the following equation:

$$d\sigma_y / dx\big|_{x=b} = -\left(2K_t + 1\right)\sigma_n / \rho = -\left(3 + 4b/c\right)b\sigma_n / c^2 \tag{2}$$

The stress gradient increases with the increase of K_t and/or the reduction of ρ, where $K_t = 1 + 2\sqrt{b/\rho}$ according to [6]. In this paper, five different configurations with the same dimension of elliptic notch b = 27.5 mm (see Table 1) have been analyzed, and five radii values of which have been

tested on a purely comparative basis (ρ = 0.5, 1, 2.5, 3 and 27.5mm), which correspond to the critical value of the elliptic notch.

ρ (mm)	b (mm)	c (mm)
0,5	27,5	0,5
1	27,5	1
2,5	27,5	2,5
3	27,5	3
27,5	27,5	27,5

Table 1. Notches dimensions

The high value $K_{tf} = \sigma_y/\sigma_n$ in the presence of a short crack is always localized close to the edges of the hole according to the curves of Fig. 2. In fact, in the case of an elliptic notch ($b > c$), the ratio of the stress $\sigma_y(x)$ along the remaining ligament and the nominal stress σ_n, i.e. K_{tf}, is roughly equal to 3 for the distance $x = 1.1b$. This ratio falls to a value of 2 independently of the radius ρ when x reaches approximately $1.2b$. The Eq. (3) enables us to quantify the influence of the stress gradient on the variation of the K_{tf} according to x/b.

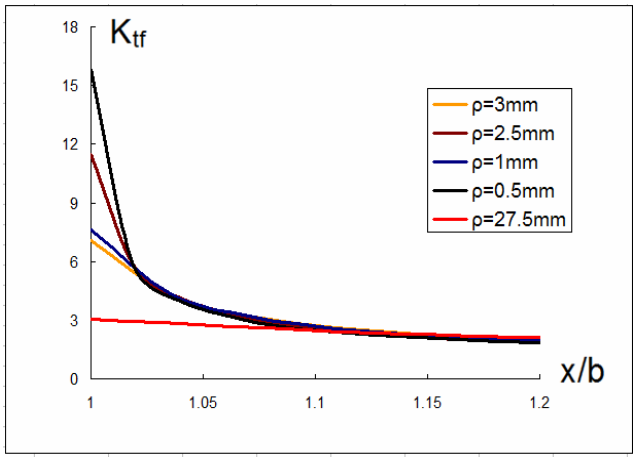

Fig. 2. Evolution of the stress concentration in the presence of a short crack

Fig. 3 illustrates explicitly the relationship between the stress concentration K_t (without crack) and the stress concentration ($K_{tf} = \sigma_y/\sigma_n$) (in the presence of a crack) with respect to the distance away from the edge of the notch. The reduction of K_{tf}/K_t is practically linear and not very sensitive to the value of K_t. The ratio decreases steeply from 1 for a point located at the end of the notch to 0.9 for a point which is very close to the crack length $a = b/20$. This rather high stress gradient can cause an initiation of the fatigue short crack, even in the case of a nominal stress lower than the yield stress.

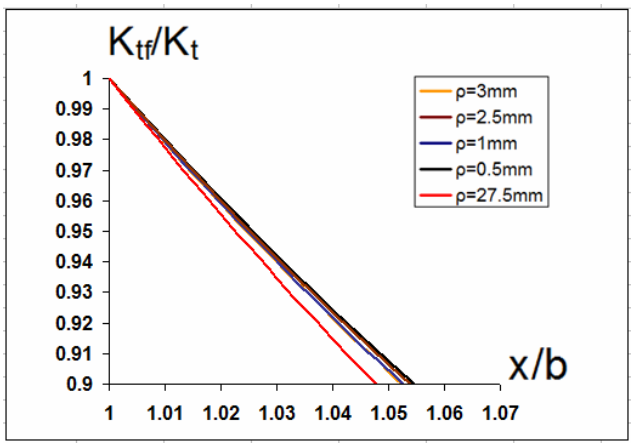

Fig. 3. Evolution of the ratio K_{tf}/K_t with respect to the relative length of the short crack

After the above discussion of the stress gradient with the propagation of short cracks at the sharp notch root, the variation of ΔK which associates with the fatigue stress concentrations K_f can be better understood. The K_f is defined as the ratio of the fatigue limit of a smooth specimen, S_0, to that of a notched specimen, S_0', under the same experimental conditions. Obviously, it is related to the size and geometry of the specimen and dimension of the notch. However, to determine experimentally the K_f with the grand variation of the notch shape (from the blunt notch to the critical condition "crack") is too laborious. Thus the analytical method based on some experimental results to predict the K_f is rather necessary. Indeed, if the crack is regarded as the critical condition of "notch", the nominal stress which can initiate the existing crack will be equal to the value of S_0'. That implies that the K_f is not only the key point for the crack initiation life analysis but also for the short crack growth estimations.

In 1979, El Haddad et al. associated the fatigue limit with the crack threshold through the Eq. (3) – Eq.(4) [7].

$$\Delta K = \eta \cdot \Delta\sigma \sqrt{\pi (a + a_0)} \geq \Delta K_0 (a) = \Delta K_0 \cdot \sqrt{a/(a + a_0)} \tag{3}$$

$$a_0 = (1/\pi) \cdot \left(\Delta K_0 / (\eta \cdot \Delta S_0) \right)^2 \tag{4}$$

Following Bazant's reasoning in [8], a more general threshold expression as Eq. (5) was presented by introducing an adjustable parameter γ to fit experimental data as described by Eq.(5)

$$\Delta K_0(a) = \Delta K_0 \cdot \left[1 + (a_0/a)^{\gamma/2} \right]^{-1/\gamma} \tag{5}$$

For the case where the crack is much smaller or much larger than the notch dimensions, the stress intensity range of a semi-elliptical notch has been mentioned in [9] with the expression in Eq.(6) and Eq.(7).

$$\Delta K = \eta \cdot K_t \cdot \Delta\sigma \cdot \sqrt{\pi (a + a_0)} \qquad \text{for} \quad a << b \tag{6}$$

$$\Delta K = \eta \cdot \Delta\sigma \cdot \sqrt{\pi (a + b)} \qquad \text{for} \quad a >> b \tag{7}$$

For the case of very small crack with $a << a_0$, $\Delta\sigma$ is the notch root stress range; for the long crack with $a >> b$, $\Delta\sigma$ tends to the nominal stress $\Delta\sigma_n$. In most cases, the K_t is used to indicate the stress concentration factor of the notch root without the crack growth. Hence, the function $\varphi(a)$ in Eq. (8)

can be used to reflect the effects of the notch root stress concentration instead of K_t. It is remarkable that the $\varphi(a)$ tends to the notch root stress concentration factor as the crack length a tends to zero.

$$\Delta K = \alpha \cdot \varphi(a) \cdot \Delta\sigma \cdot \sqrt{\pi(a + a_0)} \tag{8}$$

According to these theories, Meggiolaro et al. have proposed an effective method which could analytically estimate the K_f (see [9]). They associated ΔK and $\Delta K_{th}(a)$ so that the short crack will propagate when:

$$\Delta K = \eta \cdot \varphi(a/\rho) \cdot \Delta\sigma\sqrt{\pi a} > \Delta K_{th}(a) = \Delta K_0 \cdot \left[1 + (a_0/a)^{\gamma/2}\right]^{-1/\gamma} \tag{9}$$

Accordingly, a crack propagation criterion was stated using two dimensionless functions φ and g with the following expression:

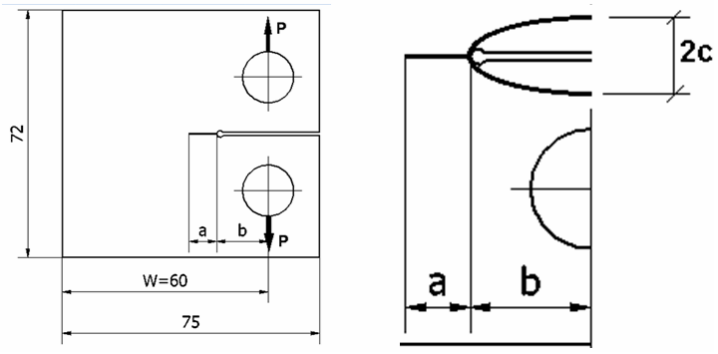
$$\varphi\left(\frac{a}{\rho}\right) > \frac{\left(\Delta K_0/\Delta S_0\sqrt{\rho}\right)\cdot(\Delta S_0/\Delta\sigma)}{\left[\left(\eta\sqrt{\pi a/\rho}\right)^{\gamma} + \left(\Delta K_0/\Delta S_0\sqrt{\rho}\right)^{\gamma}\right]^{1/\gamma}} \equiv g\left(\frac{a}{\rho}, \frac{\Delta S_0}{\Delta\sigma}, \frac{\Delta K_0}{\Delta S_0\sqrt{\rho}}, \gamma\right) \tag{10}$$

The second term $\Delta S_0/\Delta\sigma$ in the function g will be equal to the K_f when the $\Delta\sigma$ corresponds to the minimum stress range that can cause crack initiation and propagation from the notch border by fatigue, without arrest.

In general, K_f and a_{max} can always be found by solving the system

$$\begin{cases} \varphi/g = 1 \\ \partial(\varphi/g)/\partial x = 0 \end{cases} \Rightarrow \begin{cases} \varphi\left(\dfrac{a_{max}}{\rho}\right) = g\left(\dfrac{a_{max}}{\rho}, K_f, \kappa, \gamma\right) \\ \partial\varphi\left(\dfrac{a_{max}}{\rho}\right)\Big/\partial x = \partial g\left(\dfrac{a_{max}}{\rho}, K_f, \kappa, \gamma\right)\Big/\partial x \end{cases} \tag{11}$$

To verify the accuracy of the models to evaluate the tolerance to short cracks, a methodology is proposed to design notched fatigue test specimens specially conceived to induce non-propagating short cracks. The geometric configuration is that of a modified compact tension specimen C(T), having a machined notch with a circular hole with radio ρ at the tip, as is shown in 错误!未找到引用源。a. The line of size a represents the crack length. The external dimensions and the notch length $b = 15(mm)$ is chosen according to ASTM E647 recommendations to assure that the loading condition at the crack tip is not influenced by the loading-pin holes.



(a) (b)

Fig. 4 a) Modified C(T) specimens, dimensions in mm.

b) Approximation to a semi-elliptical notch.

The specimen notch is approximated by a semi-elliptical notch with semi-axes b and c (see **Fig.** b). The value of c can be expressed as a function of the notch root tip ρ, $\rho = c^2 / b$.

From an elastic stress analysis, considering the C(T) as a cantilever beam, the nominal stress range applied at the notch can be calculated as

$$\Delta\sigma_n = \frac{\Delta P}{t \cdot (W - b)} \cdot \left(1 + 3 \cdot \frac{W + b}{W - b}\right) \tag{1}$$

Therefore, after the value of $\Delta\sigma_n$ is determined by solving the system of equations in Eq. (11), the load ΔP to be applied to the specimen will be found by applying Eq. (12), in the next section are presented the numerical results for that combination.

3. Numerical results

Assuming the fatigue limit of smooth specimen as $S_L' = 0.5 \cdot S_u$, for a load ratio $R = -1$ (fully reversed loading), by Goodman it can be interpolated for $R = 0$ (pulsating tension), resulting in $\Delta\sigma_0 = 2 \cdot S_u / 3$.

Following the Frost's statement, it is the difference between K_t and K_f that define the generation of non-propagating cracks. The figure also shows the stress concentration factor K_t and how its value tends to K_f as the notch root ρ increases. Therefore, for this material and specimen configuration, notch with root radii $\rho <\sim 1.5$ will be able to generate non-propagating cracks (see **Fig. 5**).

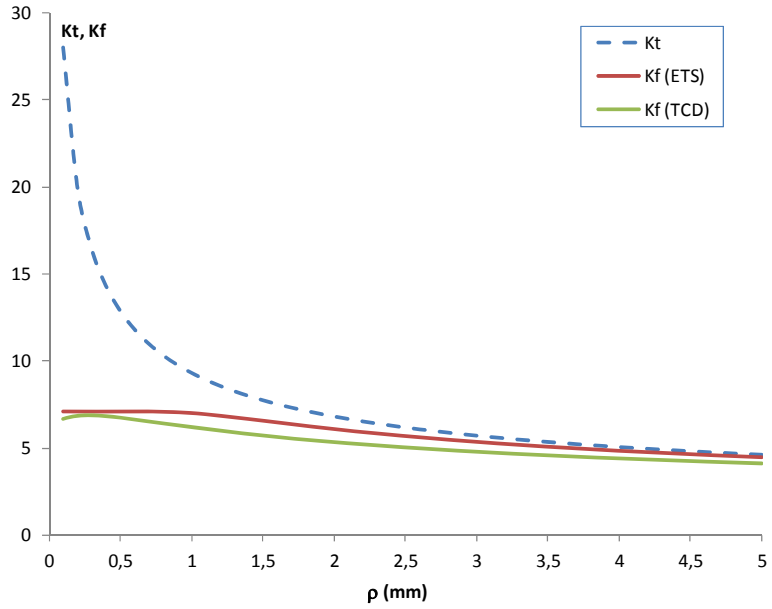


Fig. 5 Comparison of predictions of the notch fatigue factor K_f with the stress concentration K_t as a function of the notch root ρ.

In addition to K_f, the model also allows calculating the largest non-propagating crack $a_{\max}$ that can arise from fatigue alone. **Fig.** shows the value of $a_{\max}$ as a function of the notch root ρ.

Ideally, it would be better to deal with high values of ρ because they are easier to machine at the notch tip. In the other hand, the smaller the notch root radius ρ, the greater the maximum non-propagating crack $a_{\max}$ is, and, consequently, the more reliably the method can be applied to predict non-propagating cracks that can be robustly measured. According to the numerical results shown in **Fig.** , for $\rho <\sim 1.5$ it can be expected that the maximum non-propagating crack size should be $0.309mm < a_{\max} < 0.83mm$. Those values can be easily measured by an optical microscope.

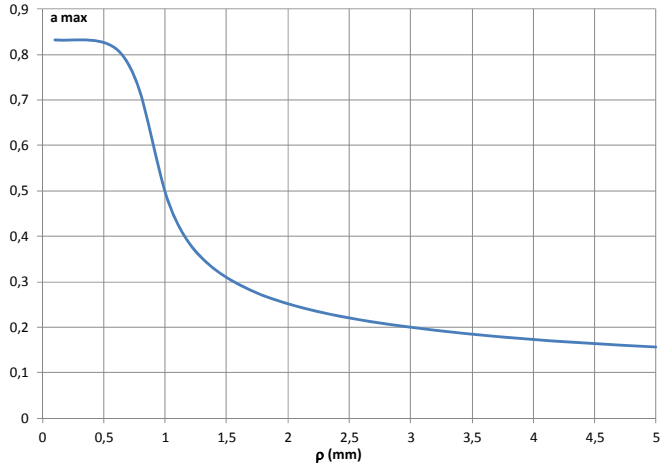

Fig. 6 Comparison of predictions of the maximum non-propagating crack a_{max} as a function of the notch root ρ.

4. Conclusions

A method was used to predict the notch factor K_f and, therefore, the fatigue limit for a notched specimen can be designed to induce non-propagating short cracks at the notch root. The configuration of the notch was approximated as a semi-elliptical notch and its fatigue limit was determined as a function of the radius of the notch root ρ. The largest non-propagating crack length can be calculated.

Abstract Age-hardened 7075 Al alloys are one of the materials which possess large strength and large toughness. Their weight and large resistance to corrosion are also attractive in practical use. We have recently shown that the fatigue behavior of extruded 7075-T6 Al alloy is strongly influenced by the humidity in atmospheric air, and the fatigue strength decreases markedly at the humidity higher than about 60%. In addition, shear-type fracture with high crack growth rate occurs at high humidity, while tensile-type fracture dominates at low humidity. The occurrence of the change in fracture mode, however, depends on the conditions used in fatigue tests. In the present study, microstructures of the 7075 T6 Al alloy subjected to fatigue tests in various conditions and humidity are examined by using electron backscattering diffraction (EBSD) and X-ray diffraction (XRD). The results of EBSD and XRD analyses indicate that the microstructures depend on the history of metalworking and heat treatment and that the fatigue properties in high humidity environment are influenced by the difference of the microstructures in addition to the effect of humidity. A crytallographic geometry model is also shown to interpret the preferential occurrence of the shear-type fracture based upon the EBSD analyses.

Keywords Fatigue, Humidity, Fracture mode, 7075-T6 Al alloy, Microstructure

1. Introduction

Age-hardened Al alloys are very attractive from the viewpoints of those large strength, large fracture toughness and light weight. In particular, Al-Mg-Zn(-Cu) alloys (7000 series) are commonly strengthened by the precipitation of spheric GP zone, hexagonal η' phase ($MgZn_2$) and hexagonal η phase ($MgZn_2$), and the degree of strengthening depends on the heat treatment conditions used for aging [1]. It is well established that 7000 series Al alloys are very susceptible to stress corrosion cracking in aggressive corrosion environment [1]. The fatigue properties of age-hardened Al alloys are very sensitive to environment, and a drastic decrease in fatigue strength occurs in the air of relative humidity (RH) higher than 85% [2]. Our previous studies [3-7] have also shown that the fatigue strength of 7075 T6 alloy decreases markedly as RH is increased to more than about 60 %. Anodic dissolution of particles or stress concentration arising from large particles may become the causes of initiating cracks. However, the previous studies strongly suggest that hydrogen-enhanced local plasticity mechanism plays a major role in the deterioration of fatigue properties.

The difference in microstructure especially due to under-, peak- and over-aging has been considered to be another key issue to understand the susceptibility of age-hardened Al alloys and improve their resistance to environmental attacks. Commercial Al alloys, however, commonly experienced metalwork processes such as rolling and extrusion in order to obtain products with desired strength, shape and size. Thus, we have to consider the effect of these microstructures produced by manufacturing processes. The previous studies have shown that the extruded rods of 7075 T6 alloy exhibit unique deformation and fracture behaviors in cyclic loading. The initiation of crack and its propagation takes place at angles of about 35^o inclined from the loading axis in certain atmospheres and for certain test conditions. In the rotating bend tests with the frequency of 50 Hz, this shear-type cracking is observed in high humidity more than 60% RH at high stress levels, while the decrease in

stress level or the decrease in frequency to 6 Hz alters the shear mode to the tensile mode.
In the present study, microstructural analyses of the extruded 7075 T6 Al specimens subjected to fatigue tests were carried out by EBSD and XRD, in order to obtain an insight into the influence of extrusion texture on the fatigue properties in high humidity environment. Since EBSD analyses are restricted in local regions and insensitive to internal stresses, XRD analyses were also conducted to obtain the information on the macroscopic texture structure as well as the internal stresses remaining due to extrusion. The microstructural analyses were carried out on another specimen into which different microstructures were introduced by using different heat treatment. In order to deepen the understanding of the relation of fatigue properties influenced by humid environment with microstructures, some of the previous results on fatigue tests were reassessed and compared with the results of microstructural analyses.

2. Experimental procedure

Commercial rods of 7075 T6 Al alloy with the diameters of 18 mm were used as a starting material. The alloy has the chemical composition listed in Table 1, but the degree of extrusion was not known. Some of the as-received rods were solution treated at 733 K for 10.8 ks, and some rods were solution treated at 773 K for 118.8 ks. These solution treatments were carried out to increase grain sizes. The solution treated specimens were aged at 393 K for 86.4 ks, *i.e.*, under ordinary T6 temper condition. In order to distinguish the heat conditions, the as-received specimens and the specimens solution treated at 733 K and 773 K will be hereafter called A, B and C specimens, respectively. Table 2 shows the tensile properties and grain size of these rods. It is clear from this table that the solution treatment increased grain size considerably, and lowered the yield strength markedly compared to that of as-received ones.
The fatigue tests were conducted for A and B specimens, while C specimens were used only for the comparison of microstructure with these specimens. A specimens were subjected to rotating bend (RB) tests at 50 Hz and ultrasonic loading (US) tests at 20 kHz. On the other hand, B specimens were RB-tested at 50 Hz and 6 Hz. The shape and size of the fatigue test specimens are shown in Fig. 1. The humidity was varied from 0% RH in N_2 gas to 100% RH in distilled water. The details of the fatigue tests and conditions had been mentioned in the previous studies [3-7]. EBSD and XRD analyses were conducted by using disk specimens with a height of 10 mm cut from A, B and C rods (Fig. 2). The surfaces of these specimens to be used for EBSD analyses were mechanically polished to the final polishing with 20 nm silica particles, followed by low-energy Ar ion etching. XRD profiles were obtained by using Cu Kα beam from the same transverse cross-section as was subjected to EBSD analyses. Subsequently the disc specimens were cut longitudinally at the

distance of 6 ~ 7 mm from the center, and the cut surfaces were polished in the same way and then subjected to EBSD and XRD analyses. In the XRD analyses of the longitudinal cross-sections, the projection of X-ray beam on the cross-section was aligned in directions along *x* and *y* axes to examine the difference in microstructure in these directions. The same procedure was applied to the microstructural analysis of longitudinal cross-sections at the center of disc.

3. Results

3.1 Effect of humidity on fatigue strength

Fig. 3 shows a comparison of *SN* curves obtained for A and B specimens which are subjected to RB tests with 50 Hz in humid atmospheres ranging 0% RH (N_2 gas) to 100% RH (distilled water). Symbols in the figure are experimental data of the stress amplitude (σ_a) and the number of cycles to failure (N_f), and the curves can be expressed by

$$\sigma_a = \sigma_{ao} + k\{(N_f/N_{fo})^{-m} - 1\} \quad (1)$$

where σ_{ao} and k are the strength coefficients, m is a numerical constant and N_{fo} is a reference number of cycles to failure and set to be 10^7 cycles in the present analysis. The as-received A specimens in N_2 gas show the largest fatigue strength among all of the testing conditions, which exhibits larger strength by 30 ~ 60 MPa than that of B specimens fatigue-tested in N_2 gas. This is consistent with the fact that the yield and tensile strengths of A specimens are larger than B specimens. Humidity does not change the fracture strength of B specimens significantly until RH is increased to 50 %, and a marked reduction of fatigue strength occurs at the humidity larger than 50 %. Previous studies showed that this transition appeared distinctly at the humidity of about 60 %. In contrast to B specimens, the humidity-induced deterioration in A specimens is prominent from the RH of 25 %, and the fatigue strength of A specimens at the humidity from 25% RH to 85% RH is lower than that of B specimens for identical RH. These results indicate that A specimens with larger yield strength is more susceptible to the environmentally assisted fatigue cracking.

Fig. 4 shows the change of the fatigue strength (σ_{ao}) for $N_f = 10^7$ as a function of RH. The fatigue strength of A specimens RB-tested at 50 Hz decreases monotonically with increasing RH. The fatigue strength of B specimens tested in the same condition, however, is insensitive to the humidity up to 50 % and shows a rapid decrease at higher humidity. Nevertheless, the fatigue strength of B specimens RB-tested at 6 Hz is kept to be constant up to 85% RH. The application of US loading with 20 kHz to A specimens results in a slight degradation from N_2 gas to 25% RH, a high-stress-level plateau from 25% to 50% RH, a drastic degradation from 50% to 75% RH, and

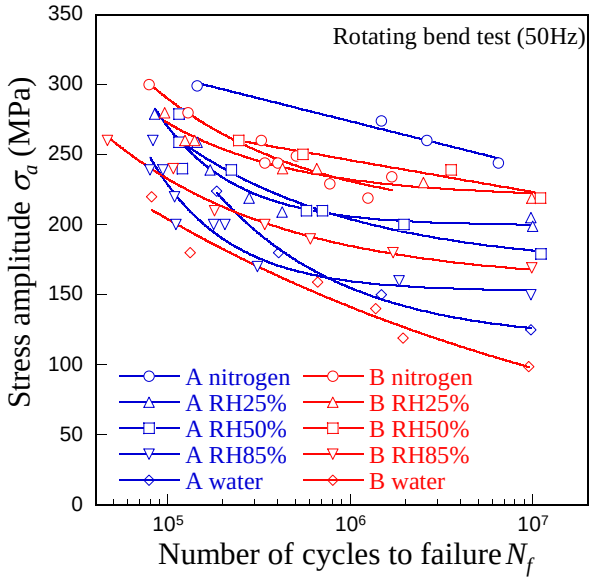

Fig. 3. SN curves of A and B specimens.

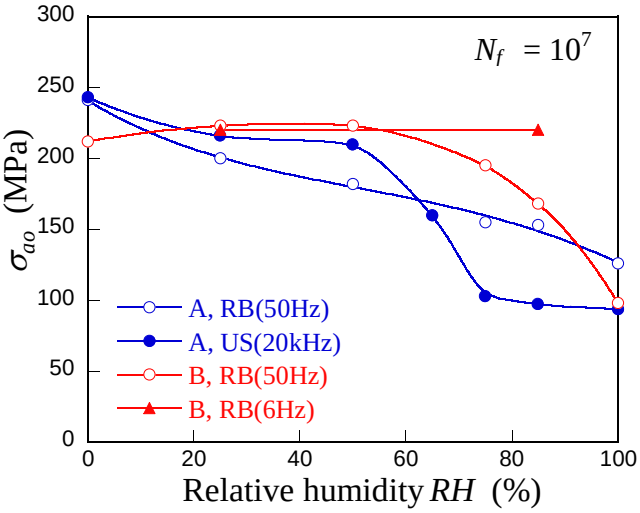

Fig. 4. Dependence of fatigue strength on RH.

then a low-stress-level plateau above 75% RH. It is obvious that these different fatigue behaviors cannot be explained only by the effect of humidity.

3.2 Crack initiation and growth

SEM observations conducted in previous studies [3-7] showed different morphologies of fatigue cracks in extruded 7075 T6 Al alloy, which are depicted schematically in Fig. 5 (a)~(d). These morphologies are macroscopically classified into (a) tensile-mode-initiation followed by tensile-mode-propagation (TT-type), (b) tensile-mode-initiation and shear-mode-propagation (TS-type), (c) shear-mode-initiation and shear-mode-propagation (SS-type), and (d) multiple-shear-mode-initiation followed by coalescence of cracks leading to apparent tensile fracture (MST-type). Typical examples of fracture surfaces are also shown in Fig. 5. In A specimens RB-tested at 50 Hz, crack initiation takes place in tensile manner and their macroscopic fracture mode becomes TT-type in all of the humid conditions and TS-type in N_2 gas. On the other hand, the application of US loading to A specimens changes the crack initiation from tensile mode to shear mode, except at low humidity. Hence US-tested A specimens show TS-type fracture at low humidity and SS-type or MST-type fracture for other conditions. This tendency appears in B specimens RB-tested at 50 Hz, too. The common feature to US-tested A specimens and RB-tested B specimen is that MST-type fracture is induced at 85% RH and in water at low stress level. This fact suggests that many cracks are initiated at the surface exposed to such high humidity for longer time. Both of the initiation and propagation of S-type cracks take place at an angle of about 35^o inclined from the loading axis in both of the RB and US tests. In particular, the morphologies of initial cracks are important, since they may be indicative of the slip prior to the initiation as well as the slip associated with the initiation.

Fig. 6 shows typical examples of T-type and S-Type short cracks observed on the surfaces of B specimens RB-tested at 25% RH and 85 % RH, respectively. The T-type crack exhibits some irregularities in propagation path, some of which are inclined by $\pm 35^o$ from the loading axis, but it develops in a direction perpendicular to the loading axis. On the other hand, the S-type crack develops in a shape of "V" of which edges are symmetrically inclined by $\pm 35^o$ from the loading axis. The symmetry of crack initiation with a definite geometry, which can be microscopically observed in the zigzag path of T-type crack, indicates that slip leading to the crack initiation may take place

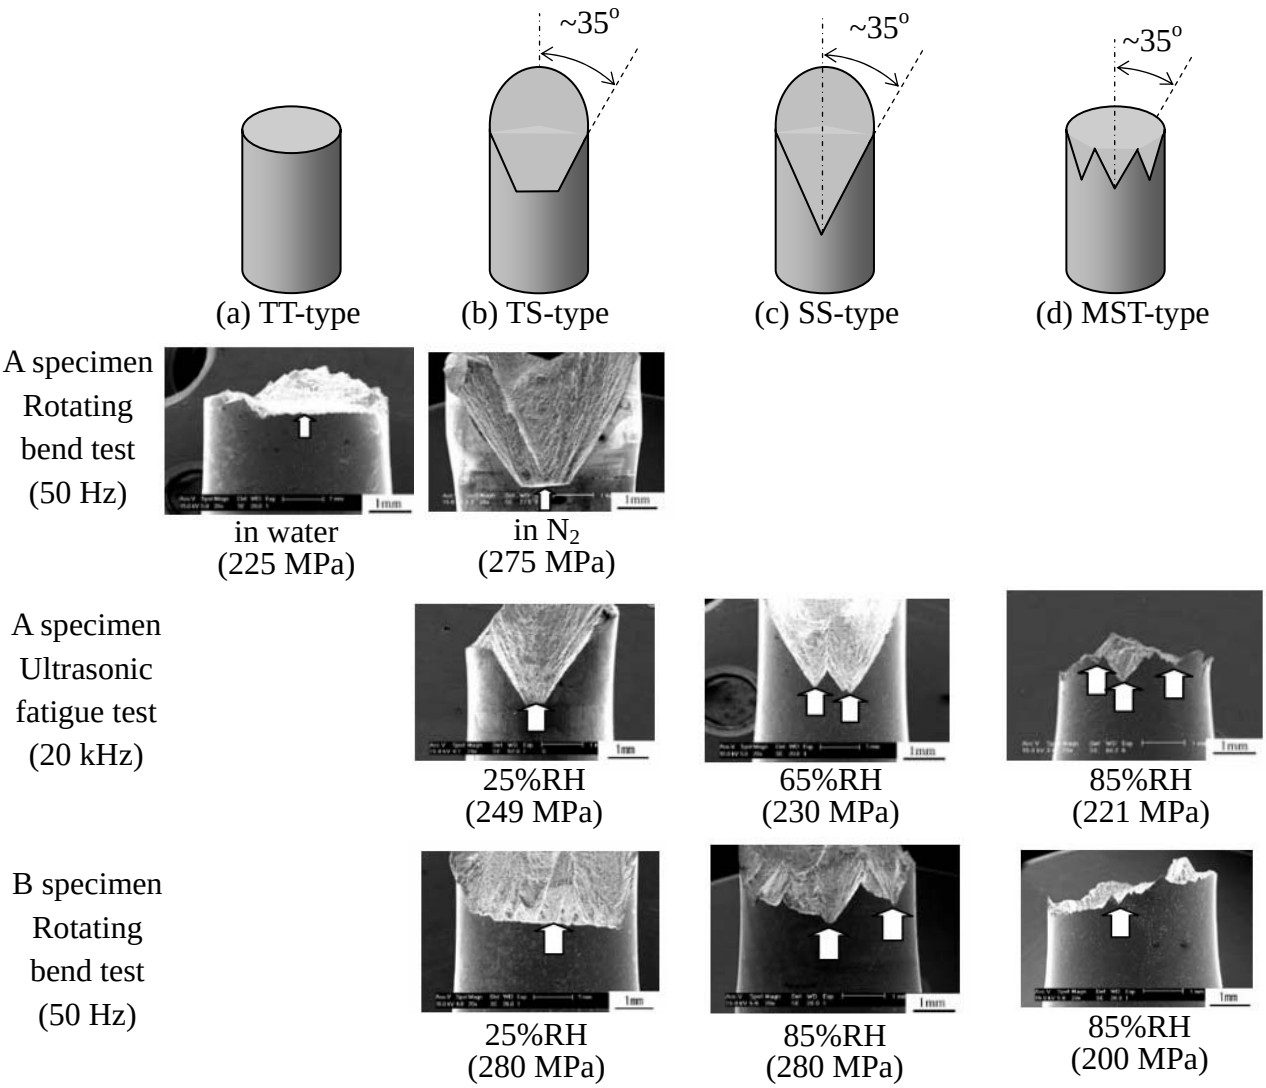

Fig. 5. Macroscopic features of fatigue fracture.

preferentially in this direction. One can see that the crack propagation in macroscopic scale shows the same tendency in certain circumstances. Thus, the evolution of plastic zone in front of crack tip may also have orientation-dependence intrinsic to the microstructure.

Fig. 7 shows typical relations of crack length (l) and number of cycles (N) in B specimens RB-tested at 50 Hz. The values of crack length were measured in transverse direction. Thus the length of a pure S-type crack developing with an angle of 35°, for example, becomes $l/\sin 35^{o} = 1.74l$. As shown in Fig. 5, there are some mixtures of T- and S-type crack propagations so that the real length of crack along its path is always larger than the measured value of l in such mixtures. Reminding this effect, one can see from Fig. 6 that the growth of S-type cracks formed at 85% RH occurs much faster than that of T-type cracks at 25% RH. It is also recognized that the initiation of S-type cracks at such high humidity is induced at very small cycles compared with the initiation of T-type cracks at low humidity. On the other hand, A specimens tested in the same test condition show T-type crack initiation irrespectively of environment, while its sensitivity to humid environment appears from low humidity. US tests with 20 kHz enables A specimens to exhibit the S-type cracking so that the crack growth as a function of N becomes much larger than RB-tested A specimens. This result suggests that the formation and propagation of cracks may be rate-controlled. This was also demonstrated in B specimen; the reduction of frequency from 50 Hz to 6 Hz in RB tests transformed the fracture mode from S-type to T-type [7].

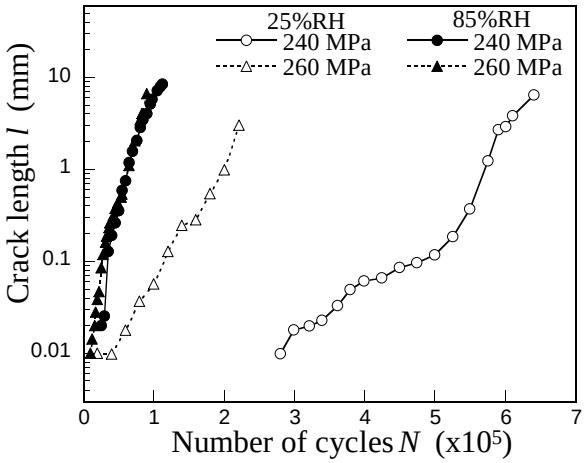

Fig.7. Relation of crack growth with the number of cycles in B specimens.

3.3 Microstructure

Fig. 8(a) shows the SEM image of the transverse cross-section at the center of B specimen, which is inclined by 70° for EBSD analyses. Fig. 8 (b), (c) and (d) are the maps (IPF maps) of crystallographic orientations of grains in *z*, *x* and *y* directions, respectively, which are obtained from the square region depicted in Fig. 8(a). Grains are distinguishable by those relief and contrast in SEM image. The grain size estimated by using the SE image is 12 μm, which is nearly the same as the grain size evaluated by using large misorientation angle. The IPF image along *z* axis shows that the transverse surface are dominated by large grains close to <111> direction (hereafter called <111> grains) and the remaining large grains have orientations close to <001> (hereafter called <001> grains). The areal fraction of <111> grains is estimated to be about 80 %. However, the IPF images along *x* and *y* axes clearly indicate that these large grains involve subgrains, and the average grain size including the subgrains is estimated to be 3.9 μm by using a misorientation angle of 0.5° for grain boundary detection. The IPF (Fig. 7(e)) along *z* axis also shows the largest fraction of <111> grains and the second one of <001> grains. The crytallographic orientations are uniformly distributed along <101>-<112> circle in *x* and *y* directions, as is shown by Figs. 7(f) and 7(g).
Figs. 9 and 10 are the IPF images of A and C specimens, respectively. It is obvious that the grains in C specimens have round corners compared to A specimens, which indicates the grain growth takes place in C specimen by the solution treatment. The grain growth appearing as round grains can be seen in B specimen by comparing Fig. 8(b) with Fig. 9(a). The grain sizes listed in Table 4 show that the as-received A specimen has the smallest grain sizes in both large misorientation and small misorientation including subgrains. In addition the fraction of <111> grains in A specimen is 61 %, while the fraction in the other specimens are nearly 80%. This result indicates that the solution treatments done for B and C specimens induce the preferential growth of <111> grains.
Fig. 11(a), (b) and (c) are the pairs of IPF image and IP figure taken from the longitudinal cross-section at the center of B specimen along *z*, *x* and *y* axes, respectively. The longitudinal cross-section is mainly covered with <111> grains which involve the elongated islands of <001> grains (Fig. 11(a)). The extrusion ratio is estimated to be more than 800 % from the shape of island <001> grains. In contrast to the transverse cross-section, subgrains involved in large <111> grains do not have large misorientation between neighboring ones. It is also noted that some of the <001> grains observed in *z* axis analysis disappear in *x* and *y* axes, which indicate that these disappeared grains have continuous relation with surrounding <111> grains. Thus the texture structure is

consisted of fibrous grains of 3.9 μm diameter elongated in the extrusion direction, but is regarded as having the single-crystal-like nature within several 10 μm in the transverse directions. These trends are common in all specimens investigated. However A specimen exhibits a larger fraction of <001> grains, as is shown in Fig. 9 (a).

3.4 XRD profiles

Fig. 12 shows the XRD peaks taken from the transverse cross-section in B specimen. The height of (111) reflection peak was considerably large in all of the specimens due to the texture of <111>

Table 4. Estimated grain sizes and fraction of <111> grains.

Specimen	Grain size with large misorientation (μm)	Grain size involving subgrains (μm)	Fraction of <111> grains (%)
A	10	1.8	61
B	12	3.9	80
C	50	5.5	85

grains, as is typically demonstrated by Fig. 12. This result is consistent with the results of EBSD analyses mentioned above. However, A specimen has the broadest peaks, while C specimen has the most narrow peaks, as shown in Fig. 13. Since the grain sizes of the present specimens are too large to contribute to the broadening of XRD peaks, the internal stress is attributed to the broadening in A and B specimens [6]. The internal stress due to precipitates is considered to be nearly the same in all specimens, because the same aging condition is applied. Therefore the broadening of XRD peaks is considered to be brought by the difference in the dislocation density; A specimen has the largest dislocation density, the density in B specimen is the second largest and the density in C specimen is comparable to that of the annealed one which shows distinct peaks of $K_{\alpha 1}$ and $K_{\alpha 2}$ X-rays.

4. Discussion

Birnbaum and Solfronis [8] calculated the interaction of H interstitials with dislocations and indicated that the motion of dislocations trapping H interstitials becomes easier and planar. Ferreira *et al*. [9] showed that the cross slip of screw dislocations in pure Al becomes difficult in hydrogen atmosphere. Further, Bond *et al*. [10] showed that the velocity of dislocations is enhanced and therefore the resistance to cracking is reduced in 7050 and 7075 alloys exposed to hydrogen atmosphere. These theoretical and experimental results strongly support that hydrogen-enhanced local plasticity (HELP) accompanying the reduction of flow stress and the planar slip is induced in Al and its alloys, when they are exposed to environments which enable H atoms to enter the materials. It is also considered that H atoms formed by the reaction of H_2O with freshly created surfaces close to crack tips enter the material during the fatigue cracking of 7075 T6 alloy in high humidity. The HELP mechanism works at the crack tips and lowers the flow stress in the plastic zone in front of the crack tips. This deterioration mechanism explains the present results well. However, the difference in the sensitivity to humidity as well as the fracture mode between A and B specimens, which is shown by Figs. 3-7, has not been made clear [13].

As mentioned in sections 3.3 and 3.4, as-received A specimens have finer grains containing dislocations with a high density. In contrast, B specimens solution-treated at 733 K for 10.8 ks exhibit the preferential growth of <111> grains and their dislocation density is lowered. Such grain growth as well as the reduction in dislocation density is manifested in C specimens. These results suggest that the grain size, the structure of texture and the dislocation density influence the HELP mechanism in environmentally assisted fatigue cracking. In A specimens, both of the <111> and <100> grains are relatively hard as is shown by the yield strength in Table 2. In addition, the faction of <100> grains in A specimens is larger compared with that of B specimens. It is hence considered that the propagation of slip between neighboring grains is more difficult in A specimens. On the other hand, the grains in B specimens are softer and mostly governed by <111> grains, and the misorientations between the subgrains are very small (Fig. 11). Therefore it is considered that the texture structure of B specimens enables selected slips to propagate smoothly from grain to grain. This consideration explains well why the shear mode fracture takes place more preferentially in B specimens than in A specimens under the same RB test condition using 50 Hz (Fig. 5).

Kariya [11] found by using etch pit technique that the humidity-induced shear mode cracks propagate in <110> direction and the cracks lie on {001} plane in B specimens RB-tested at 50 Hz. This result seems to be consistent with the morphology of observed S-type cracks, since the angle between <111> and <001> is 35.3^o. On the other hand, the present EBSD analyses yield such angle of S-type cracks in other geometries as shown in Fig. 14. In a <100> grain, the intersections of two slip planes with the specimen surface make the angle of $\pm 35.3^o$, when <110> direction of the grain is normal to the surface (Fig. 14(a)). The "V"-shaped crack can be formed only in this geometry. In a <111> grain, a slip direction makes an angle of 35.3^o with the specimen surface, when this slip direction is parallel to the surface (Fig. 14(b)). It is suspected from these geometries that the cracks of "V" shape are initiated in such <100> grains emerging at the specimen surface. It should be also noted that the "V"-shaped cracks in <100> grains can induce the slip in neighboring <111> grains with the same angle, when <011> directions of both grains are aligned like Fig. 14(a) and (b). Further the slip in <100> grains can be continuously connected with the slips in <111> grains, when the slips on two slip planes involving the selected direction operate simultaneously in <111> grains. This situation leads to the macroscopic {001} slip plane in <111> grains which is microscopically composed of two slip planes (Fig. 14(c)). As a result, {111} and {001} planes become preferential planes for crack propagation in <100> and <111> grains, respectively. It is also considered that edge dislocations glide on these planes so that the interaction of H atoms with the edge dislocations induces the acceleration of inclined crack propagation. It is suspected that the continuous slip propagation between <100> and <111> grains in A specimens is more difficult than in B specimens

for the reasons mentioned above. In the present study, we have not yet obtained the full understanding on the mechanisms by which the fatigue properties are influenced by the test conditions such as RB, US and frequencies. It is believed that such effects involve some rate-controlled processes like the diffusion and trapping of H atoms in different microstructures.

Fig. 14 Crytallographic geometries. Thompson tetrahedron is used in (a) and (b).

5. Summary

The present study shows that extruded 7075 T6 Al alloy exhibits the deterioration of fatigue strength in high humidity environment. However the fracture mode strongly depends not only on the history of the metalworking and heat treatment, but also on the test conditions. The results of EBSD and XRD analyses indicate that these differences may arise from the grain size, texture structure and dislocation density. In particular, the shear mode cracking with the angle of 35^{o} from loading axis can be correlated with the crytallographic geometry of slips which are selected in the texture strongly aligned in <111> direction. In order to interpret the whole phenomena including the test conditions, more analyses taking into the characteristics of microstructures will be needed.

Influence of Surface Rolling Time on Short Fatigue Crack Behavior of LZ50 Axle Steel

Bing Yang*, YongXiang Zhao

State Key Laboratory of Traction Power, Southwest Jiaotong University, 610031, China
* Corresponding author: yb@home.swjtu.edu.cn

Abstract Based on the mean fatigue life of LZ50 axle steel specimens which were unrolled before testing, five surface rolling times were determined according to the fatigue life fraction, i.e., f=0.0, 0.3, 0.5, 0.6, and 0.7. Five groups of smooth hourglass shaped specimens which were turned and rolled at above surface rolling times were tested by a replication technique. Results show that with a given dominant short crack size, crack growth rate after surface rolling occurs much slower than that before rolling. However, the more prolonged the surface treatment is performed, the greater the growth rate occurs at the transition point between the micro-structural short crack (MSC) stage and the physical short crack (PSC) stage. Furthermore, influenced by the change of surface hardness and residual compressive stress, the effective short crack density in all the specimens, which is the average number of short cracks per unit area, decreases significantly after rolling than before. Focusing on the density after surface rolling, it is evident that the highest effective short crack density for the five studied groups of specimens increases from 662 mm^{-2} to 941 mm^{-2} with postponed rolling time. On the other hand, the average fatigue life for each group of specimens decreases with postponed surface treatment time. The average life of the initial rolled specimens was 882,562 cycles, while that of specimens turned and rolled at a 0.7 fatigue life fraction is 618,640 cycles. Therefore, the surface rolling procedure can improve the fatigue performance characteristics of the material. The choice of rolling time may affect the short fatigue crack behavior greatly. The earlier the surface treatment is performed, the better the collective effect of short cracks can be restrained as well as the longer the fatigue life of the material will be.

Keywords Fatigue, short crack, surface rolling time, LZ50 axle steel

1. Introduction

With the development of the high speed and heavy haul railway in China, the service load conditions for structures and components of railway vehicles are much poorer than before[1]. As one of the important parts for vehicle running gear, axle bears complicated alternate loadings in service, and is the component with the highest loading frequency and the most complex failure modes[2]. If the axle failure caused by fatigue damage is uncontrollable, vehicles are likely to derail, and railway operation safety will be gravely affected. For components with smooth surface under alternate loadings, short fatigue crack (SFC) initiation, coalescence and propagation normally occupy more than 70% the fatigue life[3]. For example, with a overhaul cycle of 100,000 km and a reliability of 0.999, the critical size of semi-elliptical crack on the load relieving groove of RD_2 axle is 1.23 mm, and the size of circumferential crack is only 0.94 mm[4, 5]. Thus it can be seen that the fatigue damage process of axle belongs primarily to SFC stage.

The maintenance strategy for load relieving groove of RD_2 axle, for which the final processing method is turning, is finish turning and surface rolling. However, the impact of surface treatment time choice on maintenance effect, i.e., how the surface rolling time affects the short fatigue crack behavior, is still an on-going research issue.

LZ50 axle steel is one of the widely applied axle materials in Chinese railway manufacturing

industry, its production technology adopted the axle standard of AAR M-101[6]. Present research is based on the fatigue tests by a replication technique of this material. Different surface treatment times are chosen for five groups of specimens. The influence of surface rolling time on short crack propagation, crack density, and fatigue life is revealed.

2. Materials, Rolling Simulation, and Replication Tests

2.1. Test Materials and Specimens

Test material of present work is LZ50 axle steel. Its chemical composition and mechanical properties are shown in Tables 1 and 2, respectively. The heat treatment is double normalizing and then tempering in accordance with the Chinese railway standard, TB 2945-1999. After heat treatment, the microstructure of material is coarse ferrite particles and layered pearlite particles. The banded structure is quite obvious (Figure 1a), the mean value of intervals between two rich pearlite bands, d_2, is about 109 μm with high dispersion. Gathering effects exist in both ferrite structure and pearlite structure (Figure 1b). Average equivalent diameters for ferrite grains, d_1, is 14.6 μm[7]. Totally 33 smooth axial hourglass shaped specimens with 10 mm diameter were machined (Figure 2).

Table 1. Chemical composition of LZ50 axle steel (wt. %)

C	Si	Mn	Al	Cr	Ni	Cu	P	S
0.47	0.26	0.78	0.021	0.02	0.028	0.15	<0.014	<0.01

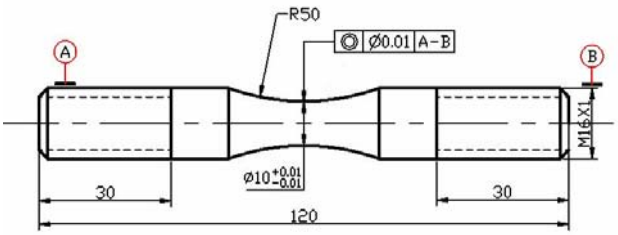

Figure 2. Schematic of shape and dimension of the specimen for fatigue test (Unit: mm)

2.2. Surface Rolling Simulation

The machining technology for load relieving groove of RD_2 axle is listed in Table 3 in detail. The purpose of finish turning is to remove possible surface cracks, while surface rolling is to strengthen the surface of load relieving groove. Surface treatment parameters of present research are also listed in Table 3. It can be seen that the simulation technology meets the maintenance requirements of real RD_2 axle. After rolling, surface Vickers hardness of specimens increases from 201.68 $HV_{0.1}$ to 222.90 $HV_{0.1}$. Meanwhile, absolute value of axial and circumferential compressive stress for specimens after surface rolling is about 170 MPa and 101 MPa higher than that before rolling[8].

Table 3. Practical repair procedure for RD2 axle and simulated surface treatment procedure for specimen

Procedure	Indicator	In practice	In simulation
Finish turning	Equipment	Numerical control machine	Numerical control machine
	Rotate speed of axle	≥350 r/min	=350r/min
	Cutting thickness	≤0.2 mm	≤0.15 mm
	Feeding speed	40~70 mm/min	=50 mm/min
Surface rolling	Equipment	Numerical control machine	Numerical control machine
	Rotate speed of axle	330~400 r/min	=350 r/min
	Rolling time	1	1
	Diameter deformation	≤0.02 mm	≤0.02 mm

2.3. Replication Tests

Replication technique is a widely applied fatigue test method in short crack research field. Test is interrupted at given time intervals (depending on the number of cycles), then replicate specimen surface with softened acetyl cellulose films, and finally these films can be dried and preserved for subsequent observation[9]. Present tests were performed under a stress-controlled sine wave mode on Rumul 250 kN high frequency fatigue test machine. The symmetrical cyclic stress amplitude was 230 MPa. To study the relationship between cracks and micro structures, specimen surfaces were etched by 4% nitric acid alcohol and the metallographic structure was exposed.

Firstly, all specimens without surface rolling were tested according to replication technique. Secondly, when cyclic loading number met predetermined cyclic number for surface treatment, test was suspended and specimens were dismounted. Thirdly, above specimens were turned and surface rolled complying with Table 3. Finally, processed specimens were mounted on test machine again and still tested at 230 MPa by replication method to final failure. Two things are important to note:

(1) Number of loading cycles according to surface rolling time.

Previous test result has shown that the average fatigue life of LZ50 axle steel specimens without surface rolling is 137705 cycles[7]. To investigate the influence of rolling time, surface treatment time for five groups of specimens was determined according to this life. That is, surface rolling was applied when life fraction, f, was 0.0, 0.3, 0.5, 0.6 and 0.7, respectively. To facilitate the presentation, specimens were indexed according to their surface rolling time, i.e., S0.0, S0.3, S0.5, S0.6, and S0.7 specimens.

(2) Test stress amplitude after surface rolling.

After turning and surface rolling, axle diameter will be slightly smaller than before, which will lead to higher local stress level even at same service loading condition. However, the purpose of present research is to investigate the influence of surface treatment time and maintenance technology on short fatigue crack behavior for LZ50 axle steel. Increase of stress amplitude caused by size decrease at changeless test load can make subsequent analysis more complex. Therefore in present study, test load was recalculated based on actual specimen diameter after surface rolling, so that replication test could be finished still at 230 MPa.

Number of effective specimens for S0.0 to S0.7 is 6, 6, 7, 7, and 7, respectively. After tests, dried replication films, which had been flattened with two glass slides, were observed using an

Auto-Montage micro-observation system by an inverted sequence method[10]. Thus, the information of short crack initiation and propagation, such as crack size, number, and angle, was obtained.

3. Results and Discussions

3.1. Comparison of Dominant Short Crack Growth Rate

Inheriting the idea of effective short fatigue crack criterion[10-12], the relation curves between dominant short crack (DSC) growth rate, d*a*/d*N*, and its size, *a*, with five different surface rolling times are shown in Figure 3. Following conclusions can be drawn:

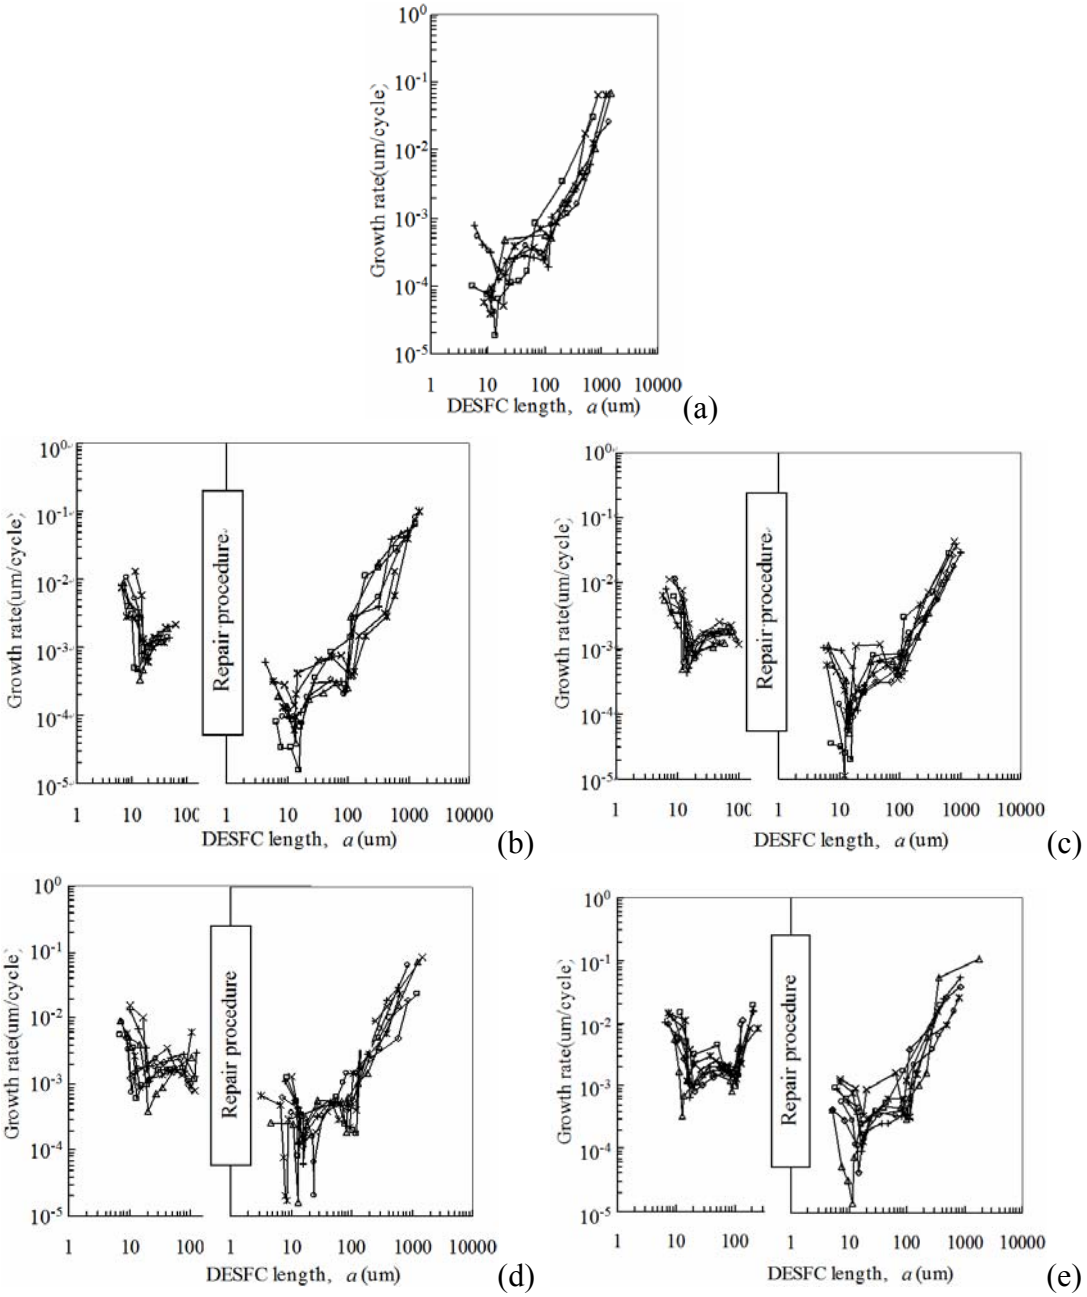

Figure 3. Dominant short crack growth rate for each group of LZ50 axle steel specimens repair times for specimens are (a) *f*=0.0, (b) *f*=0.3, (c) *f*=0.5, (d) *f*=0.6, and (e) *f*=0.7

(1) During crack growth process, the growth rate decelerates once or twice clearly for all these five groups of specimens. If only the crack propagation after surface rolling is taken into

consideration, it is clearly that no matter when surface treatment is performed, the crack growth rate exhibits decelerations twice in MSC stage, and corresponding DSC sizes can be seen in Table 4. At the same time, DSC sizes corresponding to growth rate decelerating time for specimens before rolling are also listed in Table 4. For S0.3 and S0.5 specimens, there are no DSC size data, because the second obvious deceleration has not appeared yet. Combined with previous study results[7], it is evident that whether or not the specimens are rolled, DSC growth rate decelerates when its size approaches ferrite grain boundary firstly and then to the pearlite banded structure. These micro-structural barriers restrain the growth of short cracks. They are inherent resistances of material, and do not change with surface rolling time.

(2) Comparing the crack growth rate curves for specimens before and after surface rolling, it is easy to judge that DSC of unrolled specimens grows much faster than specimens after rolling at the same DSC size. This may due to the difference in specimens surface condition. While surface is not rolled, its hardness and absolute value of residual compressive stress are both smaller than specimens after rolling. Fatigue performance characteristics of the material is not strengthened, thus its constraint force for crack initiation and growth is relatively weak.

Table 4. Mean value of dominant short crack size while crack growth decreases for each group of specimens

Repair time	Before repair		After repair	
	a_1, μm	a_2, μm	a_1, μm	a_2, μm
f=0.0	---	---	15.90	101.43
f=0.3	15.51	---	14.19	91.51
f=0.5	16.08	---	15.34	100.92
f=0.6	15.55	106.90	16.29	97.56
f=0.7	17.62	104.53	15.02	105.16

Note: f---fatigue life fraction according to previous test results[7], a_1, a_2---mean value of dominant short crack size while crack grow decreases for the first and the second time

3.2. Comparison of Effective Short Crack Density

LZ50 axle steel owns the character of two-stages, i.e. MSC stage and PSC stage, for the crack initiation and growth[7, 13]. Effective short crack density is the average number of short cracks per unit area in the initial zone of DSC in MSC stage. While in PSC stage, the observation regions transfer to the two zones ahead of DSC tips. The density can reflect the inherent difference of local micro-structure, and is one of the proper parameters to describe the evolutionary collective effect and statistical scatter of SFC behavior[14]. Higher density indicates the formation of micro-structural conditions for short crack growth, and also reflects the strengthen of SFC collective effect.

The changes in effective short crack density with respective fatigue life fraction for S0.0 to S0.7 specimens are shown in Figure 4. It is clear that crack density of specimens after surface rolling is much less than that of unrolled specimens. Surface treatment effectively limits the collective initiation of short cracks, and consequently weakens the promotive impact of SFC collective effect on crack propagation. However, crack density of all groups of specimens shows the same overall trend, i.e., increases in MSC stage and decreases in PSC stage. It attains the peak value at the transition point from MSC stage to PSC stage. DSC size according to density peak value is about the mean value of intervals for rich pearlite bands. It can be concluded from above discussions that the rich pearlite banded structure instead of the ferrite grain boundary is the strongest micro-structural barrier. When DSC grows to this size, SFC collective effect is further embodied. DSC is about to coalesce with other short cracks through further propagation, and enters PSC stage.

Moreover, the maximum density value for each group of specimens increases with the delay of surface rolling time. For S0.0 specimens, the mean value of maximum density is 662 mm^{-2}, while for S0.7 specimens, surface rolling time, *f*, is postponed to 0.7, and the density increases to 941 mm^{-2}. So postponed rolling time will lead to strengthened SFC collective effect, so that local micro-structure conditions get more and more advantageous to DSC growth.

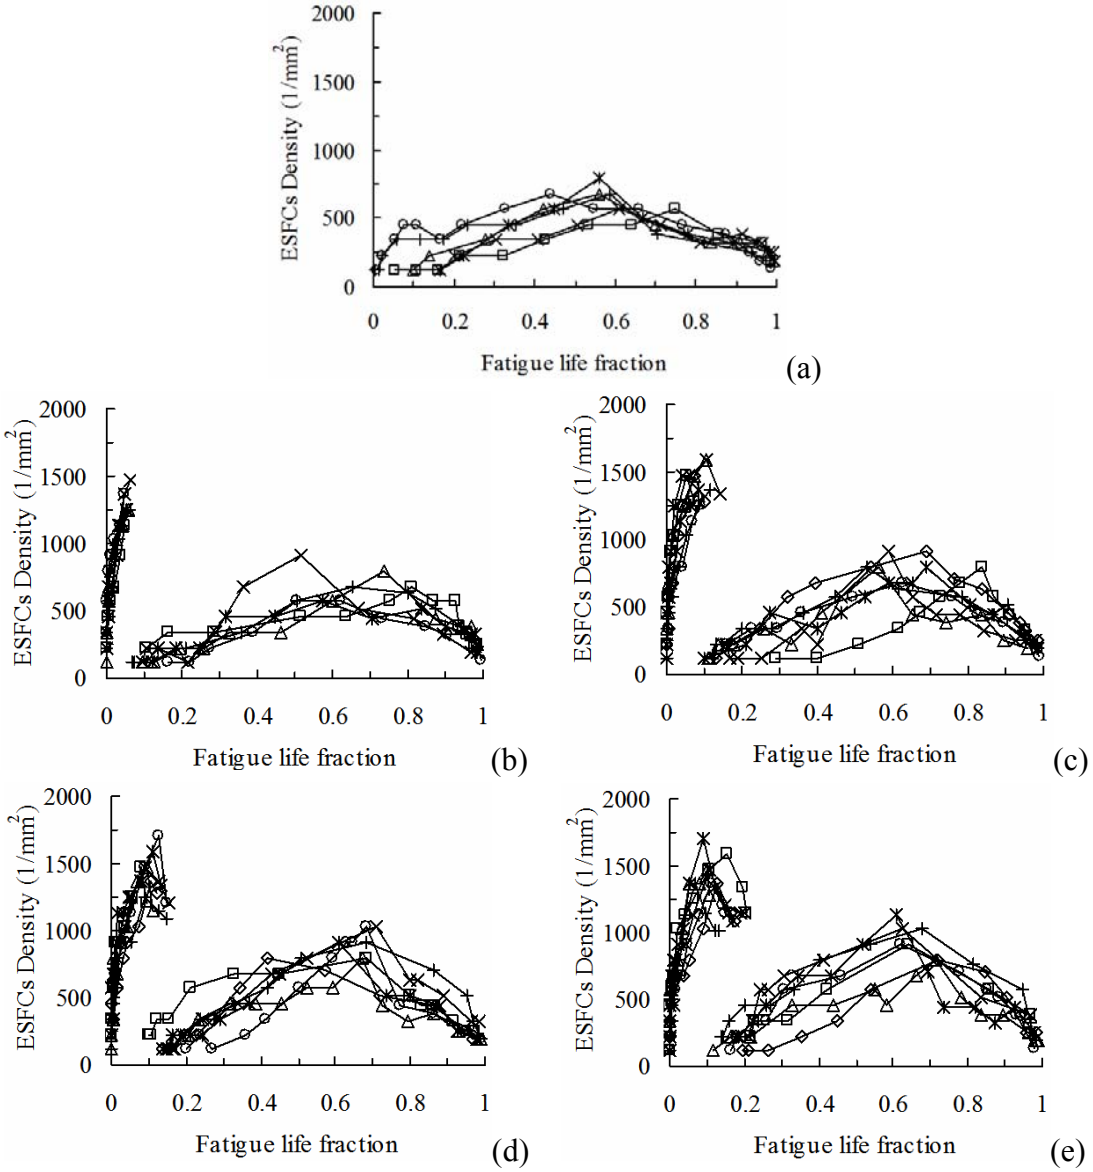

Figure 4. Effective short crack density for each group of LZ50 axle steel specimens repair times for specimens are (a) *f*=0.0, (b) *f*=0.3, (c) *f*=0.5, (d) *f*=0.6, and (e) *f*=0.7

3.3. Comparison of Fatigue Life

Fatigue life is the most direct indicator to reflect surface rolling effect. Table 5 gives the cyclic numbers before rolling, after rolling, and in total. To calculate the prolonged-life rate (defined as the ratio of total cyclic number to standard life), an average fatigue life of 137705 cycles, which was obtained from previous unrolled specimens fatigue tests[7], is cited as the standard life. It can be seen from the table that surface turning and rolling extends the fatigue life greatly than that of

unrolled specimens. The prolonged-life rate increases from 4.49 to 6.41 with the advance of surface rolling time.

Theoretically, average fatigue life for S0.0 specimens to S0.7 specimens should be close to each other due to the same test stress amplitude. However, the choice of surface rolling time makes great difference in life extension effect. For example, the average life of initial rolled specimens (S0.0) is about 1.69 times the cyclic number after rolling of S0.7 specimens. The later surface treatment is performed, the slighter the life extension effect may be. Possible reasons are: Fatigue damage cumulated in material before surface turning and rolling can not be eliminated entirely. This residual damage gets more and more serious with delayed rolling time. Secondly, to remove existed surface cracks as thoroughly as possible, cutting thickness has to be increased with the postponement of rolling time. Thus, diameter and effective section of specimen are also reduced more seriously. Assume the same short cracks initiate in two specimens, local stress level for specimen with smaller diameter is relatively higher.

Table 5. Mean value of fatigue life and corresponding prolonged-life rate for each group of specimens

Repair time	Cyclic number before repair, cyc	Cyclic number after repair, cyc	Total cyclic number, cyc	Prolonged-life rate
f=0.0	--	882562	882562	6.41
f=0.3	41311	720580	761891	5.53
f=0.5	68852	627380	696232	5.06
f=0.6	82623	567379	650002	4.88
f=0.7	96393	522247	618640	4.49

4. Conclusions

(1) Ferrite grain boundary and rich pearlite banded structure are two primary micro-structural barriers to short fatigue crack growth for LZ50 axle steel. No matter surface rolling or not, dominant short crack growth data of all specimens exhibits deceleration twice in MSC stage due to above micro-structural obstacles. Growth rate of specimens after surface rolling is significantly slower than that of specimens before rolling.

(2) Effective short crack density for all five groups of specimens indicates the same overall trend, i.e., first rises then falls. Density after specimen rolling is much less. Surface rolling effect restrains the initiation of collective short cracks. However, this effect is weakened with the delay of rolling time.

(3) Surface turning and rolling to specimens prolongs the fatigue life greatly compared to the life of unrolled specimens. It is because turning cuts off possible existed short cracks in material surface and rolling improve the fatigue performance of new surface. But postponed implementation of surface rolling make the accumulated fatigue damage can not be eliminated thoroughly. In addition, increase of cutting thickness also increase the actual local stress.

In conclusion, for unrolled specimens, the earlier the surface treatment is performed, the better the collective effect of short cracks can be restrained as well as the longer the fatigue life of the material will be.

Abstract Effect of humidity on the propagation mechanism of a fatigue crack in age-hardened Al alloy 2017-T4 was investigated under ultrasonic loading in relative humidity of 25% and 85%, respectively. Plain specimen of both extruded and drawn Al alloys were tested. In the extruded alloy, fatigue cracks that propagated macroscopically in tensile mode in low humidity changed to extend in shear mode to failure, comparing to that fatigue cracks always grew in shear mode in high humidity. On the other hand, in the drawn alloy, fatigue cracks propagated in tensile mode to final fracture in low humidity, and in a combined mode of tensile and shear in high humidity. In the both alloys, the growth of cracks shorter than a specific length, e.g. ~1 mm, which is stress level dependent, was accelerated in high humidity, but it was not or little influenced by humidity beyond that specific length. The difference in fatigue crack propagation behavior between the two alloys and the effect of humidity on the fracture mechanism were discussed based on fractographic and crystallographic analyses.

Keywords Fatigue, Ultrasonic loading, Age-hardened Al alloy, Humidity, Texture

1. Introduction

High strength Al alloys have excellent properties such as high specific strength, corrosion resistance and easiness to recycle, from viewpoint of reduction of environment load. However, Al alloys have no definite fatigue limit, meaning that once a crack initiates it will continue to grow and lead to failure. Therefore, the fatigue property of Al alloys in long life region is important, though the examination of fatigue behavior in long life region is a time consuming task. Recently, ultrasonic fatigue test has attracted much attention because it is a time-saving technology for the evaluation of fatigue properties in long life region in comparison with the conventional low frequency fatigue method [1]. However, the effect of high frequency on fatigue properties has not been fully understood. Especially, the effect of environment such as corrosion is one of important factors to be clarified, because corrosion is a time-dependent damage and high strength metals are highly sensitive to corrosive environment [2-4].

In the present study, fatigue tests at ultrasonic frequency (20kHz) were carried out in relative humidity of 25% and 85% respectively, for two kinds of age-hardened Al alloys 2017-T4 (Al-Cu-Mg alloy), i.e. the extruded and the drawn alloys, which have nearly the same static strengths but different microstructure to investigate the effects of microstructure and atmospheric moisture on fatigue crack propagation behavior under ultrasonic loading.

2. Material and Experimental Procedure

Materials used were an extruded and a drawn bar of age-hardened Al alloy 2017-T4. The chemical

composition (mass %) of each alloy is shown in Table 1. The mean grain sizes of the extruded and the drawn alloys were about 13 μm and 18 μm, respectively. Their mechanical properties are shown in Table 2.

Figure 1 shows inverse pole figure on the cross section of the bars. The extruded alloy has marked texture on (111) plane, but a specified orientation is not observed in the drawn one. This difference in texture may be related to the difference in severity during fabrication processes. From the material properties of both alloys mentioned above, the important difference in both alloys is the degree of texture.

Table 1. Chemical composition (mass %)

	Si	Fe	Cu	Mn	Mg	Cr	Zn	Ti
Extruded	0.42	0.3	4.06	0.73	0.58	0.05	0.02	0.05

Figure 1. Inverse pole figure

Figure 2 shows shape and dimensions of specimens. Prior to fatigue testing, all of the specimens were slightly electro-polished by 40 μm in diameter to remove the work affected layer and secure direct surface observation. The observation of fatigue damage and the measurement of crack length were conducted under a scanning electron microscope (SEM) or under an optical microscope by using the plastic-replica technique. Surface crack length, ℓ, was measured in the circumferential direction of the specimen in both tensile and shear mode propagations. The crystallographic analysis was performed by using Electron Back Scatter Diffraction Pattern (EBSD) method. The fatigue tests were carried out using a 20 kHz piezoelectricity actuated ultrasonic machine in relative

humidity (RH) of 25% and 85%. In addition, rotating bending fatigue tests (50Hz) were carried out in nitrogen gas (N_2>99.995%, O_2<5ppm, H_2O<10ppm) and RH25% to investigate the effects of oxygen and humidity. In the ultrasonic fatigue, pulse-pause tests were employed with a pulse length of 1s and a pause length of 5s to reduce temperature rise under high frequency cycling. By this method, temperature rise during ultrasonic fatigue was controlled below 3K. The humidity conditions were selected by considering the daily humidity and the significant influence of humidity on fatigue strength [4]. The deviation of humidity was controlled in the range of RH±5% with the temperature at 298±3K in each humidity condition.

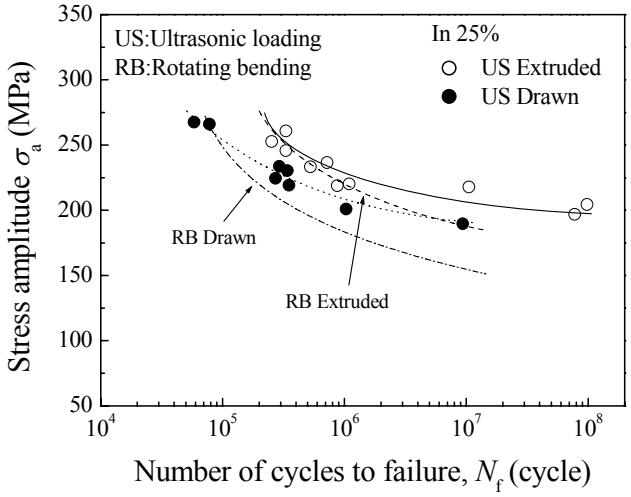
3 Experimental Results and Discussion

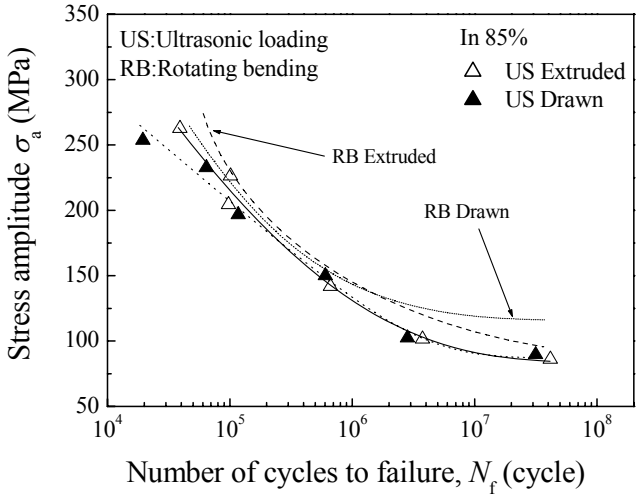
Figure 3 shows *S-N* curves of both alloys in RH25% and RH85%. In Fig. 3, results under rotating bending fatigue tests were also displayed by lines only [5]. Fatigue strength is larger in ultrasonic loading than in rotating bending in both alloys. Moreover, fatigue strengths of both alloys in both fatigue tests were largely decreased in high humidity with the drop in fatigue strength is larger under ultrasonic loading than under rotating bending, though the time consumed at given fatigue life was much shorter in ultrasonic fatigue. The effect of humidity on fatigue strength was larger in the extruded alloy than in the drawn one. For example, fatigue strength at 10^7 cycles of the extruded alloy in RH85% was decreased to about 30% of that in RH25%.

Figure 4 shows crack propagation curves of both alloys. In both alloys, a crack initiated at the early stage of stress repetitions, so most of fatigue life was occupied by the growth life of a crack in both humidity. Moreover, the propagation of cracks shorter than a specified length ℓ_0, e.g. about 1 mm, was accelerated in high humidity, and there was no or little influence of humidity on the propagation of a fatigue crack over ℓ_0. The existence of crack length ℓ_0 is clearly confirmed in RH25%, though the value of ℓ_0 changed with stress level.

Optical feature of surface cracks and SEM morphology of fracture at different stage of crack growth are shown in Fig. 5, in which the results of Fig. 4 are rearranged into two groups so as to better understand whether or not and how the humidity affects crack growth behavior in the two alloys. It is found that the crack growth in each alloy can be classified into two regions, i.e. region I and II. In the region I ($\ell<\ell_0$), crack growth is accelerated by high humidity, while in the region II ($\ell>\ell_0$), no distinct effect of humidity is recognized. In the extruded Al alloy, cracks propagated in tensile mode



(a) In RH25%



(b) In RH85%

Figure 3. *S-N* curves of extruded and drawn Al alloys

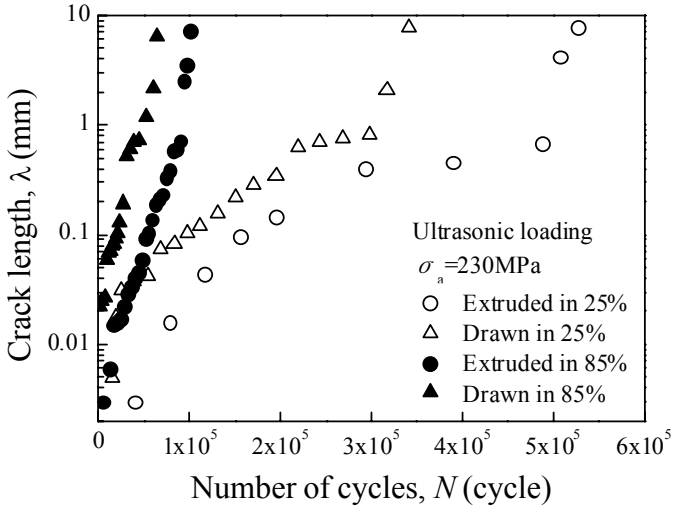


Figure 4. Crack growth curves of extruded and drawn Al alloys

macroscopically, then changed growth mode to shear one in low humidity (D), in comparison with that the whole fatigue crack propagation process was occupied by shear mode cracks in high humidity (C). The crack length corresponding to the above mentioned crack growth mode change coincides with the specific length, ℓ_0, as described before. The angle between the propagation direction of the shear mode crack and the load axis, θ, is about 35°. In the drawn Al alloy, however, fatigue cracks propagated in tensile mode entirely in low humidity (J) and in a combined mode of tensile and shear in high humidity (I). On the other hand, fracture morphology also depends on the microstructure of the alloy and humidity. In the extruded alloy, fracture surfaces are different even in the same propagation of a macroscopic shear mode crack. For example, fracture surfaces in the region II in RH25% (E) and RH85% (A) are mostly occupied by slip planes, while those in the region I in RH85% (B) feature with ripple-like pattern in addition to slip planes. On the other hand, in case of the drawn alloy which is characteristic of a macroscopic tensile mode crack in both humidity, many facets of a grain size and tearing of matrix between facets are observed in the regions I and II in RH25% (K, L), and in the region II in RH85% (G), though ripple-like pattern is also observed in the region I in RH85% (H). These facets are confirmed as slip planes by etch pit method (Fig. 6) and by EBSD analysis. Moreover, there was no brittle facet observed as in the corrosion fatigue of Al alloys [6] and high strength steels [7].

(b-1) RH85% (b-2) RH25%

(b) Drawn Al alloy

Figure 5. Optical photos featuring surface cracks and SEM micrographs characterizing fracture morphology at different stage of crack growth (⟷ :axial direction, ⇒ : crack initiation site)

The observation of fracture surfaces caused by the propagation of a macroscopic tensile mode crack in low humidity, e.g. (F) and (L), was difficult because of the sever contacting at crack tips. However, striations were recognized on the fracture surface of extruded Al alloy 7075-T6 under ultrasonic loading [8], which means that cracks propagated in a ductile manner regardless of humidity. As stated above, fracture mechanism is different depending on humidity when the crack length is smaller than ℓ_0, but there is no difference in fracture mechanism when the crack length is larger than ℓ_0 in both alloys. These findings on the effect of humidity on fracture mechanism agree well with those on crack propagation rate as shown in Fig. 4.
From the results mentioned above, it is concluded that the shear mode crack propagated along slip planes, therefore, cracks in the extruded alloy propagated in shear mode macroscopically because of

its marked texture. This can be explained by considering that the angle between the propagation direction of the shear mode crack and the load axis, 35°, is related to the angle between the composed plane (100) of fracture surface with the plane (111) of texture. On the other hand, the effect of humidity on crack propagation behavior may be explained as follows. A crack whose growth was accelerated in high humidity propagated in a ductile manner, which means that fatigue deformation was assisted by hydrogen because the hydrogen enhanced localized plasticity (HELP) [9] is assumed as the propagation mechanism of a fatigue crack in high humidity. Moreover, the reason for the indistinct effect of humidity on crack propagation behavior in the region II may be related to the high crack growth rate under ultrasonic loading or in other words, atmosphere is difficult to reach at crack tips so that the environment at the crack tips is similar to vacuum. As a result, crack propagation mode changed and the effect of humidity disappeared.

In order to confirm this assumption, fatigue tests under conventional loading frequency (50Hz) were carried out in RH25% and in nitrogen gas as well to simulate vacuum condition. Figure 7 shows fracture surfaces in the region II in both RH25% and N_2 gas after rotating bending fatigue. In both alloys, fracture surfaces of specimens subjected to rotating bending in N_2 gas are similar to those under ultrasonic loading, though definite striations characteristic of general propagation mechanism are observed in RH25%.

4. Conclusions

Fatigue tests under ultrasonic loading frequency (20kHz) were carried out for two kinds of age-hardened Al alloys, extruded and drawn alloys of 2017-T4 (Al-Cu-Mg alloy) with nearly the same static strengths in relative humidity of 25% and 85%, to investigate the effects of microstructure and humidity on propagation behavior of a fatigue crack under ultrasonic loading. The extruded Al alloy has a marked texture with plane (111) in the cross section, but the drawn alloy has not any specified orientation. In the both alloys, the propagation of small cracks shorter than a specific length, e.g. about 1 mm, which is stress level dependent, was accelerated in high humidity, causing large decrease in fatigue strength, though there was no or little influence of humidity on the propagation of a fatigue crack beyond that length. In the extruded Al alloy, fatigue cracks propagated in tensile mode macroscopically, and then changed to grow in shear mode in low humidity, in comparison with that all of fatigue crack propagation process was occupied by the shear mode crack growth in high humidity. On the other hand, in the drawn alloy, a fatigue crack propagated in tensile mode to final fracture in low humidity and in a combined mode of tensile and shear in high humidity. Fracture surfaces caused by the propagation of a shear mode crack were covered with many slip planes. The difference in fatigue crack propagation behavior between the two alloys was mainly caused by the texture. The effect of humidity on crack propagation was yielded through the acceleration to the propagation of a ductile crack.

Abstract A low-cost experimental apparatus has been developed to investigate the Mode I fatigue crack growth behavior of thin metallic foils and sheets. The apparatus utilizes magnetic coupling between a ceramic magnet and a rotating steel disk to induce cyclic tensile loads in notched rectangular test specimens.To illustrate the testing apparatus, Mode I fatigue crack growth in 30 μm thick high purity titanium foils was studied. Experiments were performed at ambient temperature using a loading frequency of 2 Hz and a nominal stress ratio of 0.1. The cyclic crack growth data could be fit to a Paris relationship between crack growth rate and stress-intensity range. The stress intensity factor exponent, *m*, in the Paris relationship was between 4 and 5, which is comparable to the relatively high values found in the literature for the tension-tension fatigue of other metallic bulk materials. Self-similarity analysis was used to explain the observed higher m values for thin metallic foils.

Keywords Fatigue testing, Mode I crack growth, foil

1. Introduction

Foil thickness materials, with a thickness in the range of 10 μm to 250 μm are used in a variety of applications, including micro-electro-mechanical systems (MEMS), integrated circuits, fuel cells and printers. The progressive trend of miniaturization of structural components leads requires knowledge regarding the mechanical behavior and properties of thin metallic materials. As discussed below, the tensile, fracture and fatigue behavior of foil-thickness materials can be very different from that observed in bulk materials. In addition to influencing the tensile properties (ductility and strength) of thin foils, grain size and grain orientation can have a major effect on crack initiation, crack growth and fracture toughness. Compared to bulk materials, microstructural inclusions or precipitates in thin foils will also have a larger impact on fracture toughness and crack growth. Surface damage, in the form of roughness, oxidation or corrosion will also have a much larger effect on the mechanical behavior of thin metallic foils.

Several experimental and theoretical investigations of the mechanical properties of foils have been carried out during last two decades. Klein *et al* [1] studied the stress-strain behavior of Cu and Al with thicknesses ranging from 10 and to 250 μm and observed a thickness effect on fracture strain, which decreased with decreasing specimen thickness. In experiments with thin Cu films, Zhang *et al* [2] observed an increase in yield strength and a decrease in fatigue life as thickness was decreased. In another study, Zhang *et al* [3] found that although the mode of fatigue damage in 25 μm thick 304 stainless steel followed that of the bulk material, the fatigue strength was higher for the 25 μm foils; the increase in fatigue strength was attributed in part to the smaller grain size of the foils

Fracture-mechanics-based test results. In a review of fatigue test techniques and experimental results for materials used in MEMS, Sharp and Turner found that the majority of available fatigue data for foils was in the form of S-N curves obtained from bending fatigue. Limited fatigue data was found for uniaxial loading with a positive mean stress [4]. The cyclic crack growth behavior from a pre-existing notch in free-standing thin foils is still a relatively unexplored area of research.

Holmes *et al* [5, 6] studied the mode I fatigue crack growth behavior of 250 μm thick center-notched Ni-base specimens, which were subjected to tension-tension fatigue at a loading frequency of 2 Hz. Using the Paris relationship, it has been found that the stress intensity factor exponent, *m* was significantly higher than commonly reported for bulk Ni-base specimens [7, 8]. A similar trend was also observed in Ti-6Al-4V foils. The high cyclic crack growth rate in thin foils was attributed to the lower Mode I lower fracture toughness commonly observed for thin metallic foils [5, 6, 9]. In a very informative study, Meirom *et al* [9] observed that ~500 nm thin films exhibit low fracture toughness and inferior resistance to fatigue crack growth when compared to conventional micro-scale-grained bulk forms of the materials. Their studies showed that thickness had a substantial effect on the Paris power law exponent and the estimation of fracture toughness. At first glance, the high crack growth rates found during Mode I testing of thin metallic foil [5, 6] is at odds with observations of higher fatigue strength found from standard (S-N) tests with un-notched thin metallic foils [2,3]. Standard fatigue life (S-N) tests include cycles to crack initiation, which may be strongly influenced by yield strength and residual stresses as well as surface finish and microstructural features such as grain size. However, fracture toughness can play an important role in the cyclic crack growth behavior of materials. For certain metals, fracture toughness exhibits a “bell-shaped” dependence on thickness, with fracture toughness reaching a maximum at intermediate thickness. In experiments with Cu, Wang *et al* [10] observed that J_c initially increased with increasing thickness, reached a maximum at a thickness of about 0.3 mm, and decreased at larger thicknesses.

Because of the very low applied loads, the cyclic crack growth behavior of metallic foils requires specialized testing approaches. For lower frequency testing (up to 1000 Hz with specially designed load frames) servo hydraulic and electro-mechanical load frames can be used for tension-tension fatigue loading histories [11, 12]. However, because of the low load levels required, the use of servo hydraulic load frames for fatigue testing is generally limited to foil thicknesses above 50 μm. Moreover, because of high cost, servo hydraulic and electro-mechanical load frames are generally not used for long duration testing of materials. The cost to perform long duration fatigue and fatigue crack growth experiments is of particular concern for low loading frequencies in the range of 0.01 to 5 Hz, which is a frequency range of general interest for many practical devices which utilize foil-thickness materials, including MEMS, fuel cells with metallic interconnects, and printer drives.

The objective of the present investigation was to develop a reliable low-cost experimental apparatus to study the low frequency high cycle Mode I cyclic crack propagation behavior of thin foils under tension-tension loading. The approach, which involves use of magnetic coupling between a clamped rectangular specimen and a rotating steel disk, is well suited for studies of Mode I fatigue crack growth. In order to illustrate the test apparatus, the cyclic crack growth rate of 30 μm thick edge-notched high-purity (99.6%) annealed titanium (Ti) foils was investigated at RT.

2. **Development of Testing Apparatus**

The overall design goal was to develop fatigue test apparatus using commercially available components and conventional machining. As shown in Figures 1, this was accomplished by magnetic coupling between a magnet attached to a sliding grip and a rotating eccentric steel disk mounted to a DC motor. As shown in Fig. 1, the specimen is clamped in face-loaded (friction) grips. One of the specimen grips is attached to a linear bearing slide, which is free to translate parallel to the specimen centerline; motion perpendicular to the centerline is constrained by the linear rail. The grip at the other end of the specimen was fixed to a load cell (Honeywell Model 41) which was rigidly fixed to the test frame. A ceramic magnet attached to the end of the translating specimen grip provides magnetic coupling with a rotating eccentric steel rotor. The strength of the couple, and

hence tensile force in the specimen, is controlled by the magnet strength and the air gap between the rotor and magnet. The air gap varies with the rotation of the eccentric rotor; therefore, the force varies in a cyclic manner. A mean tensile stress is achieved by use of a weight applied through a cable and pulley attached to the sliding grip/magnet assembly. To control the cyclic loading frequency, the eccentric steel rotor is driven by variable speed DC motor. For the test apparatus shown, the DC motor had a power rating of ½ HP, and a maximum rotational speed of 34 RPM.

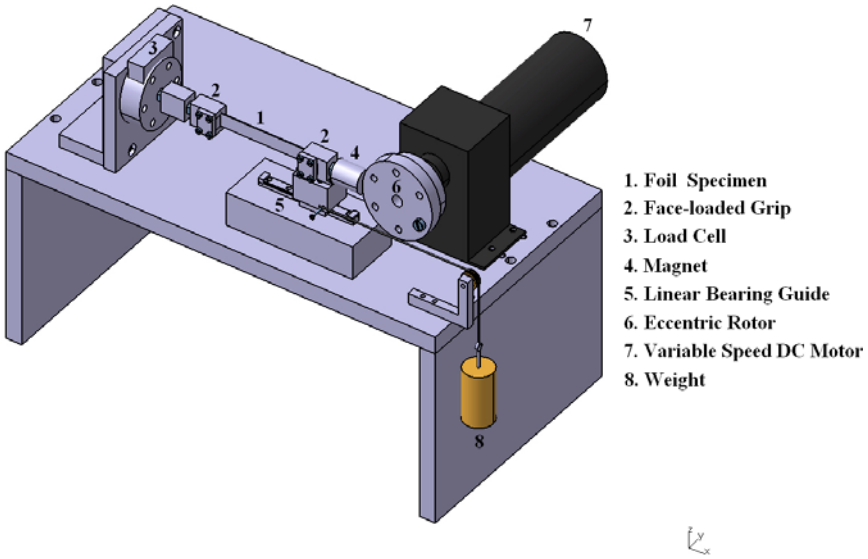

Figure 1. Schematic illustration of the fatigue testing apparatus.

For a given magnet strength and rotor speed, the waveform of the applied axial load is determined by the geometry of the rotor (shape and number of lobes). For the current test configuration, the motor speed was adjusted to provide a loading frequency of 2 Hz. Although a simple eccentric rotor was used in the present investigation, a multi-lobed rotor can also be used to increase the fatigue loading frequency or provide different peak and mean load levels within a given cycle. The shape of the rotor lobe (s) can also be changed to produce other load *versus* time waveforms. Alternatively, the shape or number of magnets that interact with the rotor can be altered to achieve a desired waveform.

Signal monitoring. An impulse counter was used to record the number of fatigue cycles. The load cell and impulse counter signals were monitored by a data acquisition board and DASYLAB software.[1] By monitoring the load cell signal, the DA board also enabled stopping the motor when the specimen failed. Figure 2 shows a close-up view of the actual fatigue testing apparatus with a 30 μm thick specimen installed.

3. Experimental Procedure

3.1. Material and Specimen Preparation

The material used for this study, commercially available annealed Ti foil (99.6% purity), was obtained as 30 μm thick sheets.[2] General information regarding the composition and mechanical

[1]Measurement Computing Corporation, Norton, MA USA.
[2]Goodfellow Corp., 125 Hookstown Grade Road, Coraopolis, PA 15108-9302 USA.

behavior of 99.6% purity Ti foil can be found in Refs [13, 14]. Single-edge-notched specimens were cut from the foil sheets using a single-blade paper cutter. To determine if differences in specimen geometry with the same notch to width ratio would affect test results, specimens with widths of 12 mm and 10 mm were tested. The first type of specimen (Group A) had a nominal thickness of 30 μm, a width of 12 mm and an overall length of 120 mm. Group A specimens had a notch length of 1.6 mm along one edge of the specimen. A second group of specimens (Group B), with the same thickness and length, but a smaller 10 mm width and shorter 1.35 mm long edge-notch were also tested. Note that both specimen groups had the same notch-to-width ratio of 0.13.

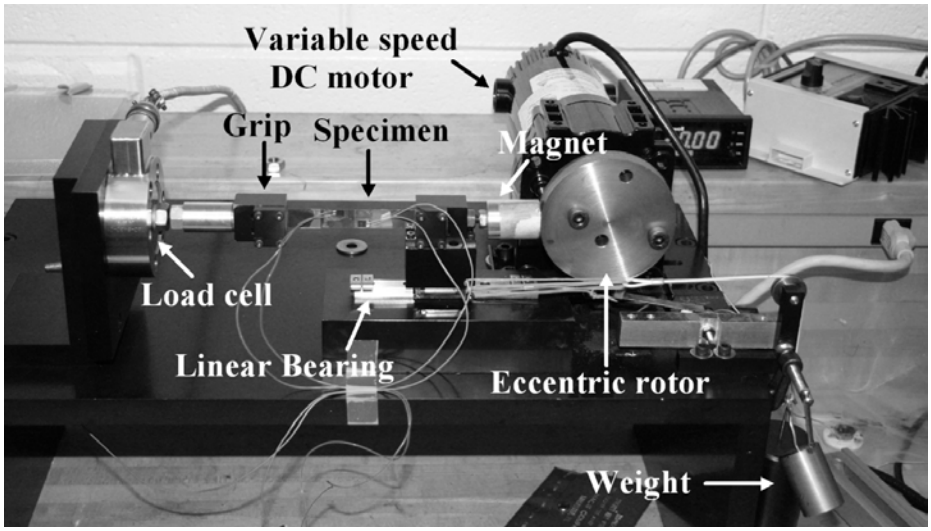

Figure 2. Close-up of the experimental setup

3.2 Experimental Procedure

All fatigue experiments were performed at room temperature at a nominal stress ratio of 0.1 and loading frequency of 2 Hz. At the start of each experiment, and with a specimen installed, the distance between the rotor and magnet was adjusted to achieve the desired maximum stress level in the specimen; in parallel, the tensile mean stress (and therefore the minimum load level) was adjusted by use of a weight applied through the cable attached to the moving grip/magnet assembly.

Table 1. Overview of the test conditions used to investigate the Mode I fatigue crack growth rate of thin titanium foils

	Type A	Type B
Loading mode	Tension-Tension	Tension-Tension
Stress ratio, R	0.1	0.1
Frequency, f	2 Hz	2Hz
Max stress, σ_{max}, MPa	111~124	122~ 124

Table 1 summarizes the specimens and test conditions that were used in the investigation. Two types of specimens having different width. For specimen in fatigue tests, crack length was measured with a 20X optical microscope attached to a video camera and digital micrometer. During the fatigue tests, crack length was measured at the end of each fatigue loading block. The optical microscope had a resolution of 0.002 mm and a repeatability of 0.005 mm. At the completion of testing, fracture surface characteristics were examined by optical and scanning electron microscopy.

4. Data analysis

As discussed in the results section, the cyclic crack growth behavior of the Ti foils could be described by the Paris relation between cyclic fatigue crack growth rate (*da/dN*) and applied stress intensity, ΔK :

$$\frac{da}{dN} = C\Delta K^m \tag{1}$$

C and m are obtained from a linear curve fit to the experimental data. For a single-edge-notched specimen, the applied stress intensity range, ΔK, is related to the far field stress amplitude, $\Delta\sigma$ and the crack length, a, by

$$\Delta K = Y\Delta\sigma\sqrt{\pi a} \tag{2}$$

Y is a geometry correction factor defined in terms of the ratio of the crack length a to the specimen width w. The determination of the geometry correction factor depends on the specimen's geometry and the applied loading type. For a single-edge-notched specimen, *Y* is given by

$$Y = 1.12 - 0.231\left(\frac{a}{w}\right) + 10.55\left(\frac{a}{w}\right)^2 - 21.72\left(\frac{a}{w}\right)^3 + 30.39\left(\frac{a}{w}\right)^4 \tag{3}$$

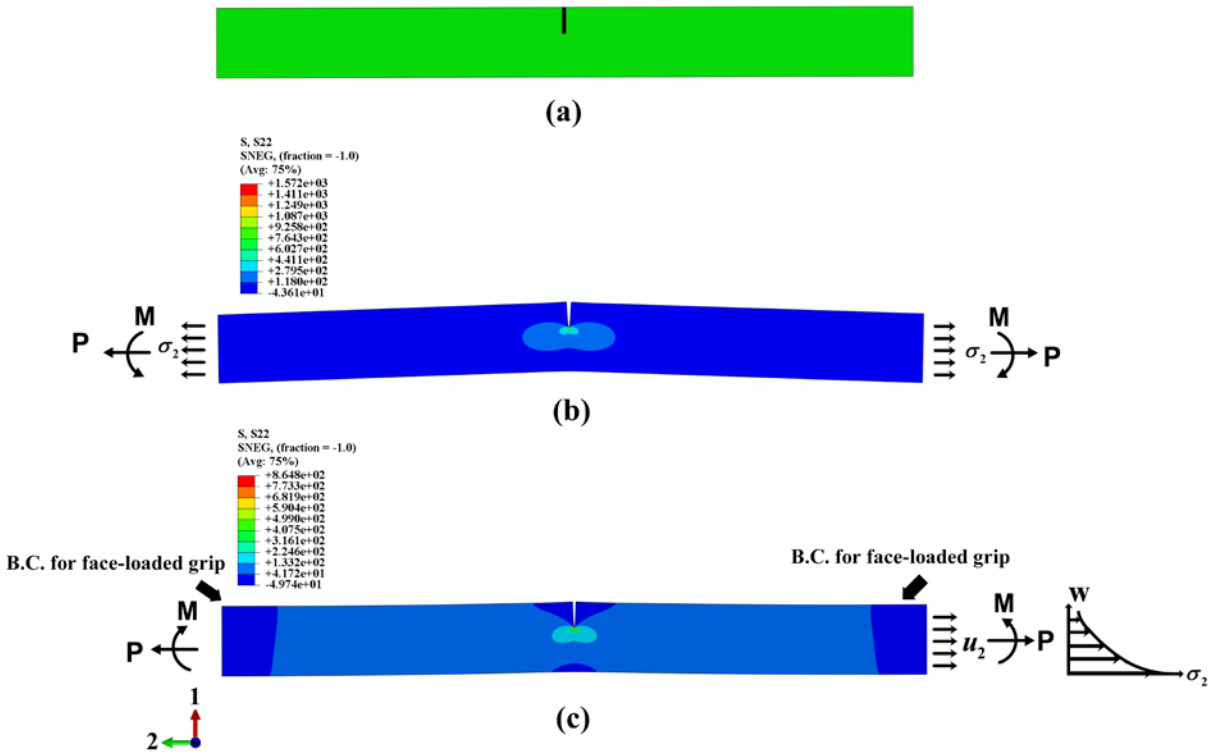

Figure 3. FEM models of the foil specimen. (a) FEM model of unloaded foil specimen. (b) Foil specimen under a uniform stress, which represents the condition used for the intensity factor given by Eq. 3. (c) Foil specimen loaded through the face-loaded grips with a uniform displacement u_2 boundary condition is applied along the right grip.

Correction of the effective stress intensity factor

Eq.3 is limited to loading configurations which can provide a uniform stress throughout the specimen cross section. In the present investigation, the foil specimen is constrained to move parallel to the applied tensile load by the linear bearing; this most closely represents a fixed-displacement end condition. The application of Eq. 3 to a fixed-end displacement loading configuration can overestimate the applied stress intensity factor [15]. The center line of the specimen shift can cause a bending moment which increases the applied Mode I stress intensity factor. This overestimation is of particular importance as a crack grows and the

crack-depth-to-width ratio increases.

To estimate a corrected K_I, a finite element analysis of the end conditions for the magnetic-driven fatigue apparatus was performed. The foil, which is rigidly clamped by the face-loaded grips along its ends, is under a uniform fixed-end displacement boundary condition (Figure 3c). Due to the non-uniform tensile stress σ_2 distribution along the specimen width, a closing moment is imposed on the specimen, which reduces the effective stress intensity at the crack tip. A summary of the results of the analysis for the loading cases examined is provided in Figure 4. The corrected stress intensity factors obtained from the FEM analysis were used in the subsequent analysis of ΔK versus crack growth rate presented below.

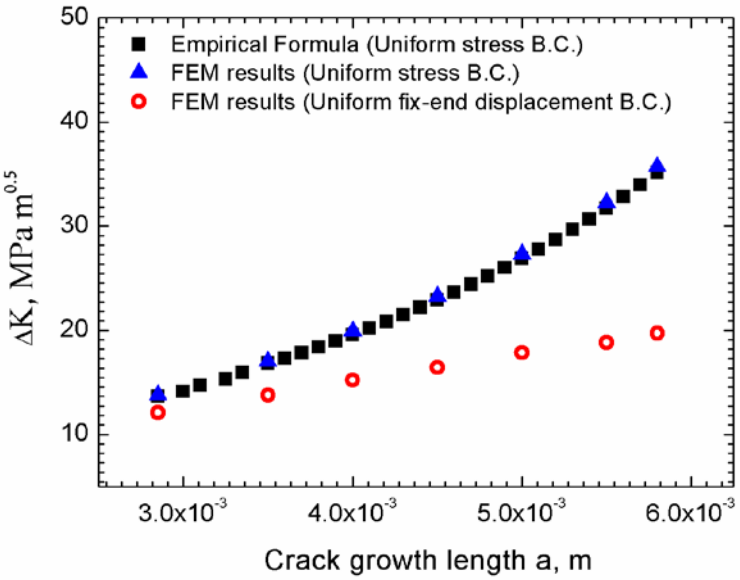

Figure 4. Variation of stress intensity factor K_I with the crack length. The data defined by solid squares represents K_I calculated from the empirical Eq. 2; the triangular data point represents K_I is determined by FEM analysis. A comparison of the data shows that the overestimation of K_I by Eq. 2 increases as crack length increases.

5. Results and discussion

5.1 Results

All fatigue cracks started from the root of the machined notch; cyclic crack propagation behavior, which remained perpendicular to the applied load, was similar for all specimens, indicating adequate alignment of the specimen was achieved during the experiments. Figure 5 shows typical results for crack length versus number of cycles. All specimens behaved in a similar manner, and the amount of scatter was limited for similar test parameters.

Figure 6 shows crack growth rate *vs.* corrected stress intensity for all specimens. The double-logarithmic plot shows that the data can be fit reasonably well using a simple Paris-equation relationship between crack growth rate and applied stress intensity range (corrected with FEM analysis). The measured stress intensity factor exponent m ranged from 3.94~5.08 for the eight specimens tested (Table 2). The small change in specimen width from 12 mm to 10 mm (Group A and Group B), did not have a measurable influence on the test results. The crack growth rate data for thin foils is quite limited and the Paris “m” value for similar pure Ti foils is not available. However, the m values found in the current investigation are similar to elevated m values of around

4~5 reported for other metals [5,6].

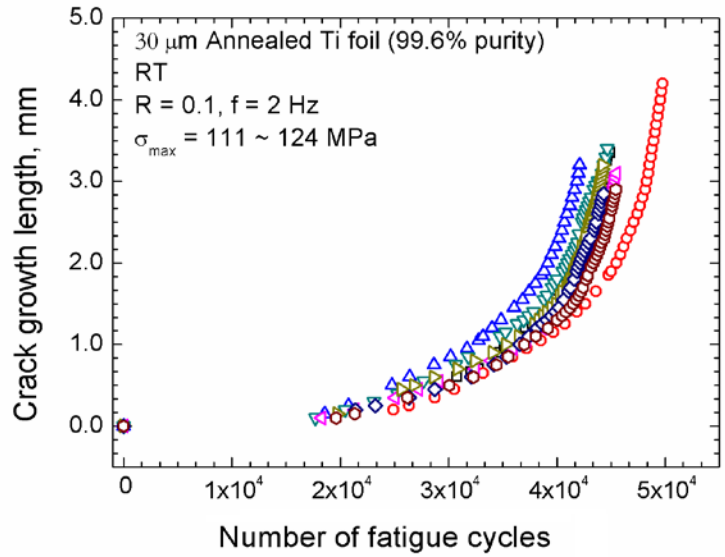

Figure 5. Crack growth length versus fatigue cycles for 30 μm thick single-edge notch Ti foil specimen foil specimens subjected to tension-tension fatigue at RT. The data scatter is very limited for similar experimental conditions.

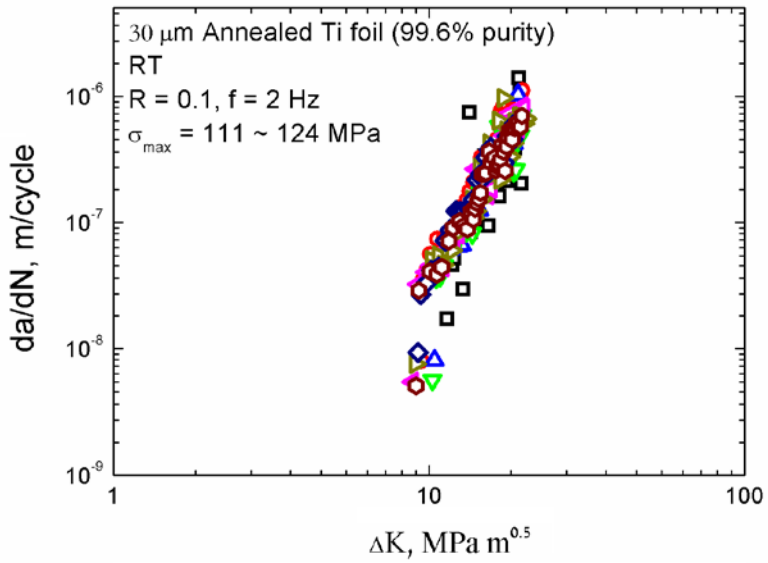

Figure 6. Cyclic crack growth rate data for 30 μm thick Ti foil specimens subjected to tension-tension fatigue loading at room temperature.

The typical crack growth path is observed after specimen failure; these images show the side view of the flat fracture surface in crack growth region II, and the corrugated facture surface in the high crack growth rate region prior to failure. The crack growth was generally perpendicular to the tensile loading direction until a final shear slip forms during failure. According to experimental measurements, the stable crack growth length was around 7~8 mm, which covers two crack growth regimes. For instance, in crack growth region II, the applied ΔK is lower than 30 MPa $m^{1/2}$ and the crack growth rate is less than 10^{-6} m/cycle. In this crack growth regime, the crack growth rate *vs.* applied ΔK can be described by the Paris relationship with the exponent value m between 4~5. With the crack growth length increasing, the applied ΔK increases and the crack propagation fit in very high crack growth regime (crack growth region III). The angle of the "knife edge" fracture surface ranges between 44° and 48°. To evaluate the morphological characteristics of Ti foil fracture

surface, fractography for foil specimens was investigated by scanning electron microscopy (SEM). All SEM images exhibited similar fracture surface appearances. Representative SEM images taken of specimens that failed during cyclic loading are shown in Fig. 7. These images show the complicated fracture surface appearance for crack growth within the Paris region with occasional striations visible. Fractography features also indicate a ductile, void rupture along with indications of transverse (through thickness) necking.

5.2 Similarity Analysis

Incomplete self-similarity of higher crack growth rate for foils

The crack growth rate can be correlated with the corrected stress intensify factor ΔK_I by a power-law relationship (Paris relationship), which is a notable scaling law [16], between the fatigue-crack growth rate per cycle, *da/dN*, and the stress intensity factor range, ΔK. This relationship has been shown to apply over a wide range of cyclic crack growth rates for metallic, polymeric and ceramic materials. For the limited number of foil-thickness materials that have been studied, the m value of is higher than that commonly found for bulk (thicker) samples [5,6].

The Paris relationship (Eq. 1) is an empirical equation that provides little information of the effect that other parameters might influence cyclic crack growth behavior. Obviously, the average crack growth depends on (i) fatigue loading parameters, *i.e.* loading ratio *R* and frequency *f*, (ii) material properties, such as yield strength, σ_y and fracture toughness, K_c and (iii) specimen size. To examine the effect of various parameters on fatigue crack growth behavior, following the mathematical similarity approach from the work of Barenblatt *et al* [17] and Ritchie [18] crack growth rate can be expressed as:

$$\frac{da}{dN} = \left(\frac{\Delta K}{\sigma_y}\right)^2 \Phi\left(\frac{\Delta K}{K_c}, R, z, f t\right) \tag{4}$$

z is the basic similarity parameter, given in terms of material constants and a characteristic specimen length scale *h*:

$$z = \frac{\sigma_y \sqrt{h}}{K_c} \tag{5}$$

If incomplete similarity is assumed in the parameter $\Delta K << K_c$, then

$$\Phi = \left(\frac{\Delta K}{K_c}\right)^{\alpha} \Phi_1(R, z), \quad \frac{da}{dN} = \frac{(\Delta K)^{2+\alpha}}{\sigma_y^2 K_c^{\alpha}} \Phi_1(R, z) \tag{6}$$

Comparison with the Paris relation (Eq. 1) gives,

$$C = \frac{\Phi_1(R, z)}{\sigma_y^2 K_C^{\alpha}}, \quad m = 2 + \alpha(R, z) \tag{7}$$

where α is a function of loading ratio R and similarity parameter *z*. From Eqs. 6 and 7, the incomplete self-similarity infers that the constants C and m in the Paris power law relationship depend not only experimental parameters, such as ΔK, and material parameters, but also (through the similarity parameter *z*) on a specimen length scale h. For a set of loading parameters, the exponent α (and therefore m in Eq. 7) depends only on the parameter *z*.

It has been first reported by proposed *et al* [17] and interpreted by Ritchie [18] that there is a trend of increasing Paris exponents *m* with increasing *z* corresponding to the transition from ductile (low *m* value) to brittle fracture (high *m* value). For the fatigue crack growth behavior of the Ti foils investigated, the experimentally measured Paris constant *m* varied between 4 to 5, which is slightly higher than the *m* value typically associated with bulk metal materials. The result implies accelerated fatigue crack growth rate due to foil thickness effect. According to incomplete self-similarity method, higher *m* value occurs with increasing *z* value and it corresponds to a transition from ductile fatigue fracture (m = 2~4) to more brittle fatigue fracture (m > 4). The higher *m* value induced by higher *z* value results from the competing mechanism between decreasing sample characteristic dimension *h*, fracture toughness K_c and increasing yield strength σ_y in the similarity parameter of *z*. Taking specimen thickness as the characteristic length scale *h*, would lead

to the conclusion that foil thickness materials should have smaller *z* values, however compared to the dependence on yield strength and fracture toughness, *z* has a weaker, square-root, dependence on *h*. Although the mode I fracture toughness K_{Ic} and yield strength σ_y of 30 μm pure Ti foil were not determined in the present investigation, it can be expected, in line with results for foil-thickness metals, that the mode I fracture toughness K_{Ic} *decreases* with decreasing sample thickness [10]. Therefore it is indicated from the slightly higher value of m that although the sample thickness *h* decreases for foils, the effect of σ_y/K_{Ic} on the similarity parameter of *z* is more significant. The foil samples investigated also demonstrated complicate ductile combined brittle fatigue fractures features (Fig. 7). The fatigue behavior of the Ti foils, which was characterized by slightly elevated *m* values and both ductile and brittle fracture surface characteristics, is consistent with the speculation that the higher *m* value induced by higher *z* value with decreasing sample characteristic dimension *h*, fracture toughness K_c and increasing yield strength σ_y.

To summarize, a preliminary incomplete self-similarity analysis, indicates that that the slightly higher *m* values observed for the Ti foil specimens, and in other metal foils [5, 6] is related to a the reduction in the fracture toughness and the rising in the yield strength with decreasing metal thickness. It can also be inferred from the incomplete similarity that with a further decrease in fracture toughness with decreasing thickness even higher values of m indicative brittle crack growth could occur.

6. Conclusions

A new experimental approach to study the tensile fatigue behavior of ultra-thin metal foils was developed. The technique, which involves magnetic coupling between an eccentric steel rotor and a ceramic magnet attached to a specimen grip mounted to a linear bearing slide. Cyclic tensile loads are induced in the specimen during rotation of the eccentric disk which is attached to a variable speed DC motor. The apparatus can be readily fit with a small furnace for testing at elevated temperatures. For the proof-of-concept experiments, fatigue crack growth tests were performed with commercially pure 0.03 mm thick Ti foils. Based on the observations, test results and a preliminary similarity analysis, the following conclusions can be made:

1. The test apparatus shows considerable promise as a low-cost method to study tensile fatigue and mode I cyclic crack growth of thin foils and wires at ambient and elevated temperatures.

2. Analysis showed that a shift in the centerline of loading can occur when testing edge-notched specimens, which induces an opening moment at the crack tip. If not accounted for, this effect can lead to overestimation of the mode I stress intensity factor.

3. Crack growth data for specimens with the same notch-to-width ratios, exhibits similar trends and fatigue crack growth parameter values. For all test cases, stable crack growth was observed.

4. The effective stress intensity factor ΔK_I corrected by FEM analysis for face-loaded specimens were used to correlate the crack growth rate *da/dN*. The crack growth rate can be described by a Paris relationship with a *m* value between 4~5. The results are consistent with other studies of thin metal foils where high m values are commonly observed.

An incomplete self-similarity theory was used to gain additional insight to the higher *m* value in Paris law and possible trends with decreasing specimen thickness. It is proposed that due to a significant reduction in fracture toughness K_{Ic} for foil thickness metals, the basic similarity parameter *z* increases, which leads to an increasing *m* value. This also infers that there is a transition

from ductile fracture to brittle facture behavior with decreasing thickness. It is suggested that with continuing decreasing specimen thickness, *m* could increase until a constant maximum value is achieved and brittle fatigue fracture behavior dominates the crack growth process.

Determination of statistical secured residual lifetime based on sensitivity analysis and stochastic crack propagation simulation

Jens Lebahn*, Manuela Sander

Institute of Structural Mechanics, University of Rostock, Rostock 18059, Germany
* Corresponding author: jens.lebahn@uni-rostock.de

Abstract To consider uncertainties due to the scattering of input parameters common residual lifetime calculations are deduced from conservative deterministic crack propagation simulations. Conclusions about the reliability of the residual lifetime are not possible in general. Those can be obtained from stochastic crack propagation simulations. Therefore the significant input parameters have to be identified and statistically modelled. In the present investigations quantil curves of the crack propagation data of 42CrMo4 are derived. From those the fracture mechanical material parameters were statistically modelled. After identifying the significant material parameters by performing a sensitivity analysis stochastic input vectors of the relevant input parameters are generated. Using the Monte Carlo simulation and the analytical crack propagation software NASGRO stochastic residual lifetime calculations are performed and statistically analyzed. Afterwards residual lifetimes can be related to survival probabilities.

Keywords residual lifetime calculation, sensitivity analysis, Monte Carlo method, *Forman*/*Mettu*-equation

1. Introduction

The residual lifetime of components and structures can be calculated by crack propagation simulations [1]. Those are mostly performed analytically due to the low computational effort. Therefore, deterministic simulations are commonly used. Uncertainties through the scattering of input parameters e.g. the crack propagation curves are considered by conservative appreciated material parameters and safety factors [2]. As a result of this approach, it is not possible to derive conclusions about the failure probability of the calculated residual lifetimes. Alternatively stochastic crack propagation simulations e.g. the Monte Carlo simulation [3–5] can be performed instead of deterministic ones. Therefore, the significant stochastic input parameters must be statistically characterized. From those, independent input vectors are calculated and a multiplicity of crack propagation simulations are performed. Afterwards the residual lifetimes are statistically analyzed.

To identify the significant stochastic input parameters a sensitivity analysis [6–8] was used in the present study. Therefore, only scattering of the crack propagation curve was considered. From crack propagation curves of 42CrMo4 for different stress ratios quantile curves were deduced. By fitting those curves with the *Forman/Mettu*-equation [9] its parameters and the related distribution functions of the parameters could be obtained. Hereby, stochastic input vectors were calculated and crack propagation simulations performed by use of the analytical crack propagation software NASGRO 6 [9]. The sensitivity analysis respectively the robustness analysis provided the significant input parameters of the resistance against cyclic crack propagation. Those were used to perform stochastic crack propagation simulations.

2. Theoretical background

In this chapter some basics of analytical crack propagation simulation, sensitivity analysis and Monte Carlo simulation are provided.

2.1. Analytical crack propagation simulation

The basic requirements for an analytical crack propagation simulation are the solution of the stress

intensity factor (SIF) and a relationship between the cyclic SIF ΔK and the crack propagation *da/dN* [1]. An equation to describe the crack propagation curve is the *Forman*/*Mettu*-equation

$$\frac{da}{dN} = C \cdot \left(\frac{1-\gamma}{1-R} \cdot \Delta K\right)^n \cdot \left(1 - \frac{\Delta K_{\mathrm{th}}}{\Delta K}\right)^p \cdot \left(1 - \frac{K_{\max}}{K_{\mathrm{C}}}\right)^{-q}. \tag{1}$$

This function, which is implemented in NASGRO [9], characterizes the whole crack propagation curve. The empirical coefficients C, n, p and q have to be fitted to test data. K_{C} is the fracture toughness. The R-dependence in eq. (1) is explained by the crack closure effect and considered by *Newman*'s crack closure function

$$\gamma = \frac{K_{\mathrm{op}}}{K_{\max}} = \begin{cases} \max(R, A_0 + A_1 \cdot R + A_2 \cdot R^2 + A_3 \cdot R^3) & R \geq 0 \\ A_0 + A_1 \cdot R & -2 \leq R < 0 \end{cases} \tag{2}$$

with the coefficients

$$\begin{aligned} A_0 &= (0{,}825 - 0{,}34\alpha_{\mathrm{CF}} + 0{,}05\alpha_{\mathrm{CF}}^2) \cdot \left[cos\left(\frac{\pi}{2} \cdot \frac{\sigma_{\max}}{\sigma_{\mathrm{F}}}\right)\right]^{\frac{1}{\alpha_{\mathrm{CF}}}} \\ A_1 &= (0{,}415 - 0{,}071\alpha_{\mathrm{CF}}) \cdot \frac{\sigma_{\max}}{\sigma_{\mathrm{F}}} \\ A_2 &= 1 - A_0 - A_1 - A_3 \\ A_3 &= 2A_0 + A_1 - 1. \end{aligned} \tag{3}$$

The constraint factor α_{CF} varies between 1 for the plane-stress condition and 3 for the plane-strain condition. The constraint factor and the ratio of maximum stress $\sigma_{\max}$ and yield stress σ_{F} are also considered as fitting coefficients [9]. To describe the R-dependence of the cyclic threshold value

$$\Delta K_{th} = \Delta K_1 \cdot \sqrt{\frac{a}{a + a_0}} \cdot \left(\frac{1-R}{1-\gamma}\right)^{\left(1 + C_{th}^{+} \cdot R\right)} / (1 - A_0)^{(1-R) \cdot C_{th}^{+}} \tag{4}$$

for $R \geq 0$ and

$$\Delta K_{th} = \Delta K_1 \cdot \sqrt{\frac{a}{a + a_0}} \cdot \left(\frac{1-R}{1-\gamma}\right)^{\left(1 + C_{th}^{-} \cdot R\right)} / (1 - A_0)^{\left(C_{th}^{+} - C_{th}^{-} \cdot R\right)} \tag{5}$$

for $R < 0$ again *Newman*'s crack closure function is used. The cyclic threshold value ΔK_1 for $R \to 1$ as well as C_{th}^{+} and C_{th}^{-} are fitting coefficients. All in all ten parameters are needed to describe the resistance against cyclic crack propagation by the *Forman*/*Mettu*-equation.

2.2. Sensitivity analysis

With a sensitivity analysis the significance of input parameters X_{i} or rather factors and their effects on an output value Y is investigated [6]. The importance of a factor is denoted as sensitivity S_{i}. The effect is distinguished in main effect (first order effect) and interaction effect, which describes the effect of a factor according to the properties of another factor. Sensitivity analysis can be divided in factor screening, local and global sensitivity analysis [8]. While with factor screening only qualitative influences of factors are investigated with local and global sensitivity analysis also quantitative influences are analyzed. If the effect of a factor on an output value is investigated in a small domain of the factor with consideration of its distribution function a local sensitivity analysis or rather a robustness analysis is performed [8]. To determine sensitivities different methods e.g. the contrast method, the regression analysis or the analysis of variance (ANOVA) exists [7, 8].

The regression analysis is based on a regression model in which the dependencies between input and output factors are described analytically [8]. Therefore, linear or quadratic models are used commonly. For n_f input factors without error term a linear regression model

$$\hat{y} = b_0 + \sum_{i=1}^{n_f} b_i \cdot x_i + \sum_{i=1}^{n_f-1} \sum_{j=i+1}^{n_f} b_{ij} \cdot x_i \cdot x_j \tag{6}$$

contains one constant b_0, n_f regression coefficients b_i and $n_f \cdot (n_f - 1)/2$ independent regression coefficients b_{ij}. If the domain of the input factors is normalized on [-1 , 1], the coefficients b_i are a measure of the main effects and the coefficients b_{ij} are a measure of the interaction effects [8]. Here the scattering of the input and output factors is not considered *Saltelli* et al. [7] recommend

$$S_i = b_i \cdot \frac{s_i}{s_y} \tag{7}$$

as a measure of the sensitivity. Herein, s_i and s_y are the standard deviations of the input factor X_i and the output value Y.

To check the predictive of the regression model and thus the accuracy of the calculated sensitivities the coefficient of determination

$$R^2 = \frac{\sum_j (\hat{y}_j - \bar{y})^2}{\sum_j (y_j - \bar{y})^2} \tag{8}$$

is calculated. For a linear regression model a small coefficient of determination can be caused by non-linear effects. In such a case a transformation of the output value can lead to a better accordance. To find a valid transformation the Box-Cox-transformation [8]

$$z = \begin{cases} \dfrac{y^\lambda - 1}{\lambda \cdot g^{(\lambda-1)}} & ,\lambda \neq 0 \\ g \cdot ln(y) & ,\lambda = 0 \end{cases} \tag{9}$$

with the geometric mean value

$$g = (y_1 \cdot y_2 \cdot \ldots \cdot y_{n_r})^{\frac{1}{n_r}}. \tag{10}$$

can be performed. For different values of λ a multiplicity of transformations is realized. For each of them the coefficients of determination can be calculated to find the optimum transformation.

2.3. Monte Carlo simulation

The Monte Carlo simulation is a numerical method for the approximate solution of mathematic tasks by use of random input vectors [3]. It is e.g. used to solve multi-dimensional integrals. The generation of linear independent random vectors x_{ij} based on the input factor's distribution functions $g_i(x)$ is the main object of the Monte Carlo simulation. If $f(x)$ is a function of the factor X and $g(x)$ its' distribution function the expected value

$$E[f(x)] = \int_{-\infty}^{+\infty} f(x) \cdot g(x) dx \approx \frac{1}{N} \cdot \sum_{j=1}^{N} f(x_j) \pm \sqrt{\frac{\sigma^2}{N}} = \frac{1}{N} \cdot \sum_{j=1}^{N} f(x_j) \pm s_{\bar{F}} \tag{11}$$

of $f(x)$ can approximately calculated by the mean of the function values of the N random input values x_j [3]. The sum converges against the integral, if the standard error $s_{\bar{F}}$ of the expected value of $f(x)$ gets small. Therefore, a high number N of samples is required, depending on the variance σ^2

of the function $f(x)$. However, the accuracy of the Monte Carlo simulation is independent of the number n_f of input factors [3, 5] so it becomes attractive for systems with a multiplicity of factors.

For the basic Monte Carlo simulation the input vectors are generated by a random number generator based on the factor's distribution functions. Therefore, taking into account a statistical error of 10 %

$$N = \frac{100}{P_A} \tag{12}$$

samples are required [5]. It is obvious that the computational effort is high for small probability of failure P_A. Against this background different variants of the Monte Carlo simulation were developed to minimize the variance and therefore to increase the computational efficiency. Some of them are the Latin Hypercube sampling and the Importance sampling [5].

3. Analysis of crack propagation data

For the crack propagation simulation an analytical relationship $da/dN = f(\Delta K, R)$ is required. To obtain its coefficients this function is fitted through experimental crack propagation data. Therefore, visual criteria and a conservative approximation are commonly used [2]. An automated adaption of the *Forman*/*Mettu*-equation is not documented. This is also the case for a complete statistical analysis of its coefficients and building on a sensitivity analysis or rather a robustness analysis referred to the residual life. To consider the scattering of crack propagation data of metallic materials usually the coefficients C [2,10 – 14], ΔK_0 [2, 10, 11, 13] and K_C [2, 11] are statistically analyzed. ΔK_0 is the cyclic threshold value for $R \rightarrow 0$ which is related to ΔK_1 [9].

3.1. Automated adaption of fitting parameters

To perform an automated analysis of crack propagation data by the *Forman/Mettu*-equation a MATLAB program was developed. The adaption of the fitting coefficients on the experimental data is divided in two steps. First the threshold values against cyclic crack propagation are calculated for different stress ratios and therewith the coefficients ΔK_1, C_{th}^{+} and C_{th}^{-} of equations (4) and (5) are determined. Next the coefficients C, n, p and q of the *Forman/Mettu*-equation (1) are calculated. The remaining coefficients a, a_0, α_{CF}, σ_{max}/σ_F and K_C have to be supported for the adaption.

After loading the crack propagation data the threshold values for the different stress ratios are calculated by use of the DLR-method [15]. Therefore the user has to set an upper bound da/dN_{max} of the crack propagation data used for the analysis of the threshold value. This limit should be below the transition from the threshold to the *Paris*-domain [15]. The threshold data are analyzed in a linear scaled coordinate system, Figure 1. Every data set with R = constant is fitted by a linear function. Therewith, the threshold value is obtained for $da/dN = 0$. The crack propagation data of 42CrMo4 contains of the stress ratios $R = 0{,}1$, $R = 0{,}3$ and $R = 0{,}5$. The analyzed threshold values for each stress ratio are plotted in Figure 2.

Referring to the determination of the experimental threshold values the coefficients ΔK_1, C_{th}^{+} and C_{th}^{-} for the analytical threshold value calculation are adapted. Therefore two algorithms are available in the program. The first one is a simple search algorithm, in which the search domain is divided into intervals. The second one is a gradient based algorithm. For both methods start values of the fitting coefficients must be set. Furthermore, the coefficients $a = 45$ mm, $a_0 = 0{,}0381$ mm, $\alpha_{CF} = 1{,}9$ and $\sigma_{max}/\sigma_F = 0{,}3$ are pretended. At the beginning the number of stress ratios is checked. If only positive stress ratios are available at least two otherwise three discrete threshold values are required. Since the crack propagation data only contains positive stress ratios C_{th}^{-} could not be analyzed, see equation (4) and (5). The adaption of the threshold value is visualized in Figure 2.

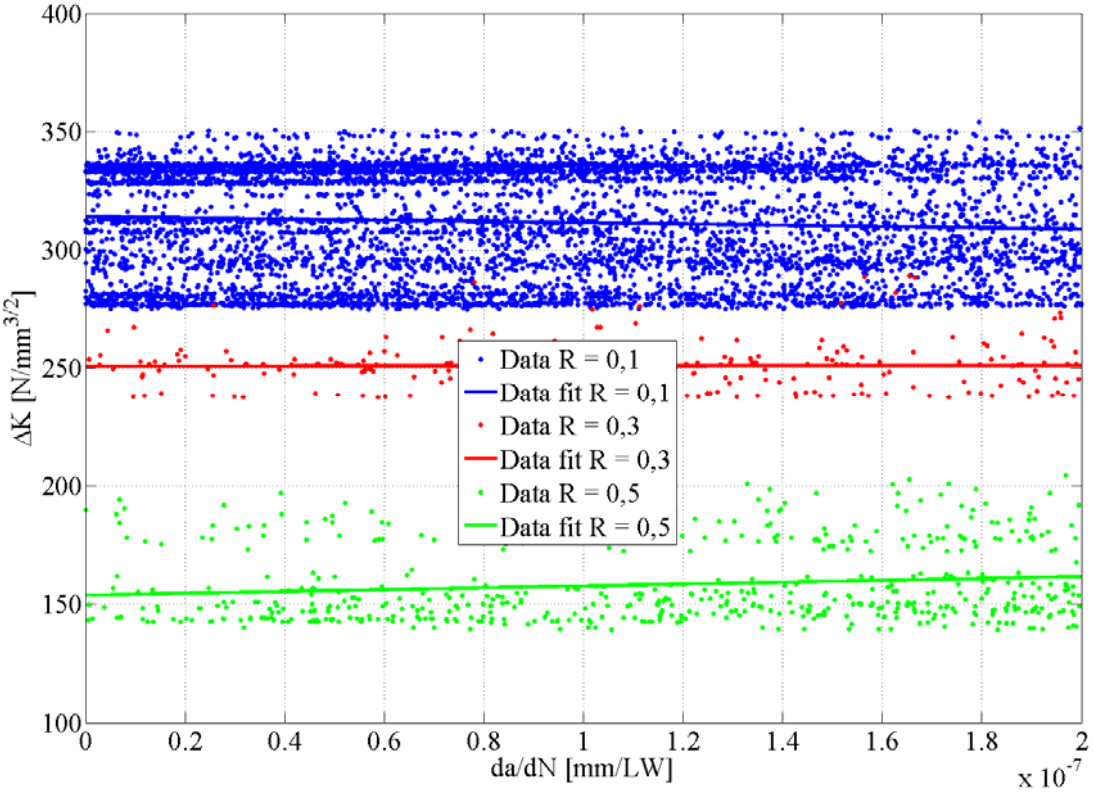

Figure 1: Determination of threshold values from crack propagation data by DLR-method

In the second step of the adaption the coefficients C, n, p and q are calculated by use of a search algorithm with nested intervals. Therefore, the four-dimensional search domain is divided into intervals. In every iteration loop a weighted effective error is calculated for every parameter combination. The parameter combination leading to a minimum error is used as center for the search domain of the next iteration loop. Additionally, the search domain is reduced, so that the intervals become smaller. Due to the nested intervals a convergence behavior of the algorithm is realized. Since error values of the threshold domain are much smaller compared to those of e.g. the K_C-domain the error values are weighted with the inverse of the crack propagation. For the adaption a fracture toughness $K_C = 4.200$ N/mm$^{3/2}$ is used. The results of the adaption together with the crack propagation data of 42CrMo4 are shown in Figure 3. The appropriated mean fitting coefficients are listed in Table 1 and consists with a probability of survival $P = 50$ %.

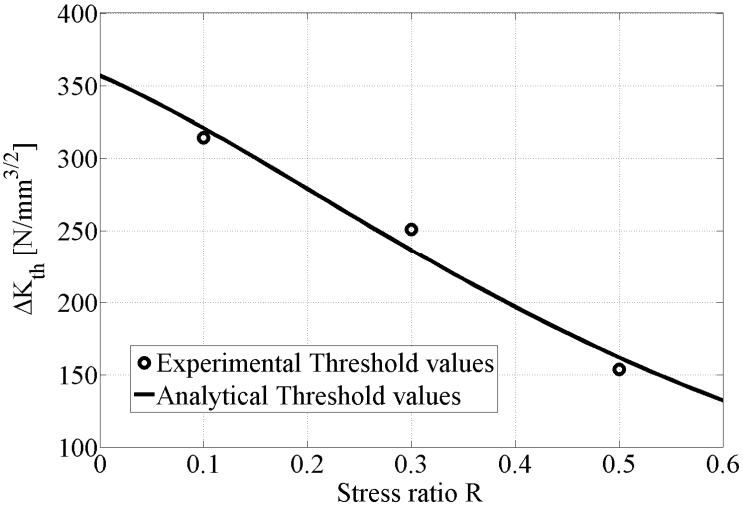

Figure 2: Experimental and analytical threshold values

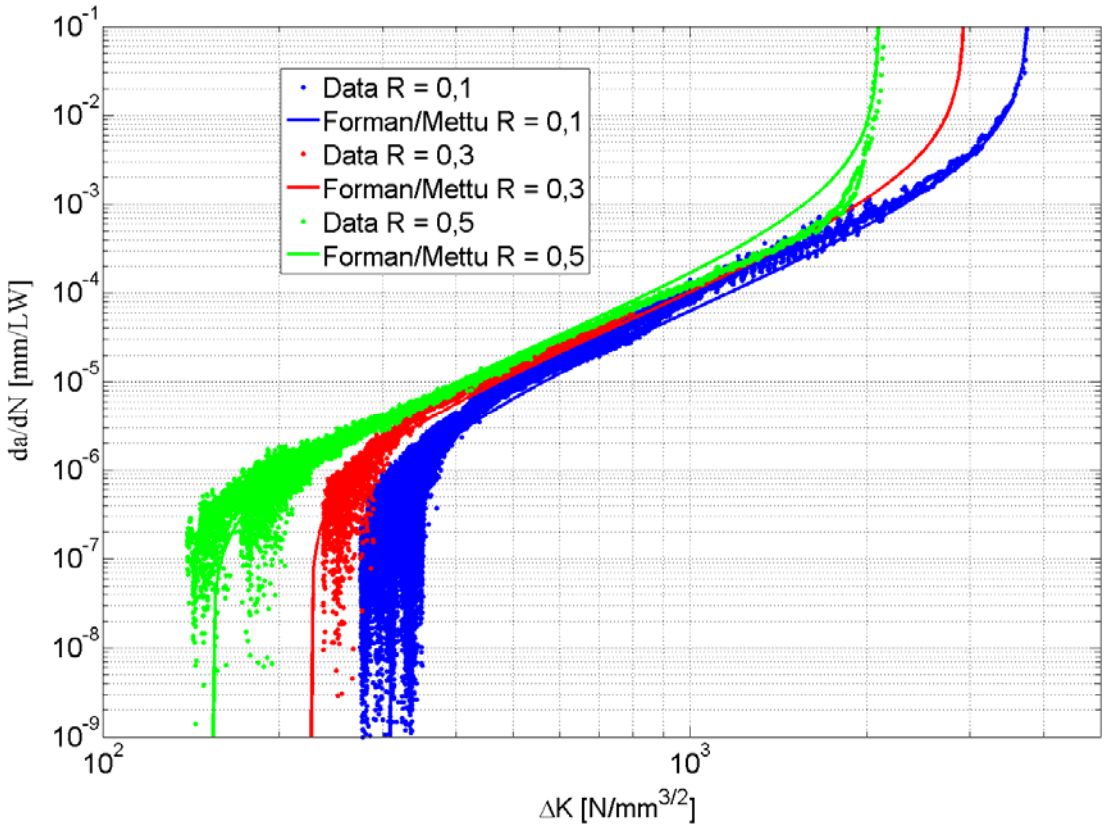

Figure 3: Crack propagation data of 42CrMo4 and the adaption by the *Forman/Mettu*-equation

3.2. Statistical analysis

The statistical analysis of the crack propagation data is divided in three steps. First for each stress ratio quantile curves are calculated for different probabilities of survival. Next, for each probability of survival the quantile curves are fitted by the *Forman/Mettu*-equation to obtain the fitting coefficients. Those are statistically analyzed in the last step to obtain their distribution functions.

To determine quantile curves the logarithm is taken from the crack propagation data. Afterwards the co-domain of the crack propagation data is divided into intervals. For each interval a polynomial regression function and a confidence interval for a pretended confidence probability are calculated. Therewith and for each domain discrete values are calculated for the mean and the upper and lower bound of the confidence interval. By use of interpolation functions the transition between the domains is smoothed and equidistant spaced values are calculated. Taking the antilogarithm the three quantile curves are obtained e.g. for a stress ratio $R = 0{,}1$, Figure 4. This procedure is also applied to the crack propagation data of the other stress ratios.

Every quantile curve corresponds to a probability of survival P. Taking the quantile curves for one probability of survival the fitting coefficients of the threshold value and the *Forman/Mettu*-equation are determined by use of the adaption program. For the statistical analysis of the crack propagation data of 42CrMo4 the probabilities of survival $P = 5\,\%$, $P = 50\,\%$ and $P = 95\,\%$ are used. The corresponding fitting coefficients are listed in Table 1. As can be seen the analytical crack propagation curve is shifted to top left with increasing probability of survival.

In the last step every fitting coefficient is statistically analyzed. This contains the choice of a distribution function and the calculation of the mean value and the standard deviation. For all fitting coefficients a normal distribution is used to describe the scattering, except of the coefficient C, Table 1. Here, a logarithmic normal distribution leads to the best results.

Table 1: Fitting coefficients of the *Forman/Mettu*-equation and their distribution functions

Parameter	ΔK_1 [N/mm$^{3/2}$]	C_{th}^{+}	C [mm/LW]	n	p	q	K_C [N/mm$^{3/2}$]
P = 5 %	71,0	3,1	$8{,}6 \cdot 10^{-12}$	2,5	0,65	1,1	4350
P = 50 %	55,75	3,4	$1{,}2 \cdot 10^{-11}$	2,4	0,8	0,9	4200
P = 95 %	42,0	3,83	$1{,}8 \cdot 10^{-11}$	2,3	1,0	0,7	4050
Distribution	normal	normal	log-normal	normal	normal	normal	normal
μ	56,3	3,44	-10,91	2,4	0,82	0,9	4200
s	8,81	0,22	0,0975	0,06	0,11	0,12	91,2

4. Stochastic crack propagation simulation

To perform a sensitivity analysis of the fitting coefficients and to deduce statistical secured residual lifetimes stochastic crack propagation simulations were carried out by use of the analytical crack propagation software NASGRO 6.0 [9]. In a MATLAB script random input vectors of the fitting coefficients were generated using the determined distribution functions and a random number generator. To assure a probability of failure P_A = 1 % the input vectors contain of 10.000 elements, according to equation (12). For every element the MATLAB script generates an input file, starts the crack propagation simulation and reads in the residual lifetime.

The crack problem is a semi-elliptical surface crack in a hollow cylinder. The cylinder is loaded by a positive constant mean stress and a reverse bending stress. The amplitude of the bending stress is defined by a load frequency distribution. The initial crack size and the load were adapted, that the

frequency distribution is at least repeated 30 times to prevent load sequence effects [16]. The non-interaction material model was used.

4.1. Sensitivity analysis of the fitting coefficients on the residual lifetime

To identify the dependencies of the residual lifetime a sensitivity analysis was performed by use of the software Visual-XSel 12.0 [17]. The input factors are the seven fitting coefficients C, n, p, q, ΔK_1, C_{th}^+ and K_C. The output factor is the residual lifetime. To derive the sensitivities a regression analysis was performed by use of a quadratic model with interaction effects [17]. To increase the accuracy of the regression model the output factor was transformed by the natural logarithm, which followed from the Box-Cox-transformation. The reduced model, containing only the significant factors, explains 99,8 % of the data. The relative effects of the input factors are plotted in Figure 5. As can be seen the coefficients C, n and q are inversely proportional to the residual lifetime.

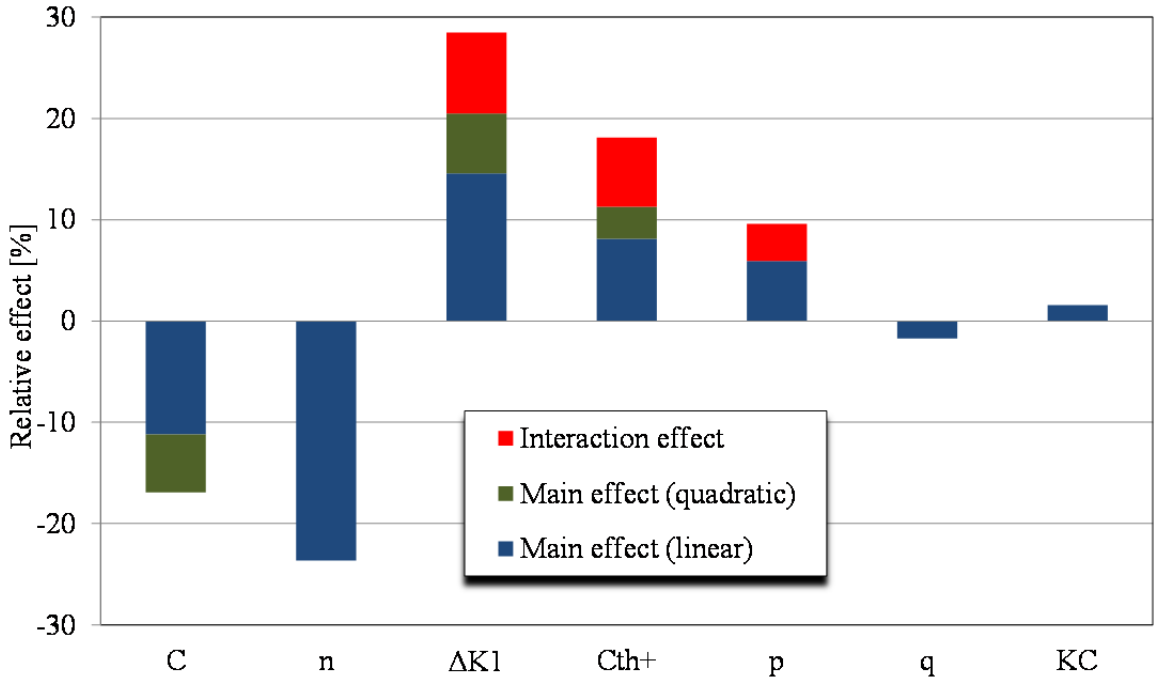

Figure 5: Relative effects of the fitting coefficients on the residual lifetime

Furthermore, it is obvious that the coefficients q and K_C are less significant and thus are not required as stochastic parameters in the stochastic crack propagation simulation. The coefficients C, n, ΔK_1, C_{th}^+ and p are significant. That means they have to be statistically analyzed and are required for the stochastic crack propagation simulation. Although, p has a small effect it cannot be neglected, due to the interaction effects between ΔK_1 and C_{th}^+.

The results of the sensitivity analysis are inconsistent to the statistical analysis of crack propagation data in literature [2, 10 – 14]. On the one hand it is not necessary to statistically analyze K_C in terms of a residual lifetime calculation. On the other hand a statistical analysis should include the coefficients n, p and C_{th}^+.

4.2. Determination of statistical secured residual lifetime

The stochastic crack propagation simulations with stochastic input vectors, created by a random number generator correspond to a basic Monte Carlo simulation. Additionally and based on the results of the sensitivity analysis a second stochastic crack propagation simulation was performed in

which only the five significant parameters were stochastically modeled. Afterwards, the residual lifetimes were statistically analyzed by use of the distribution fitting toolbox in MATLAB. The scattering of the residual lifetimes corresponds to a logarithmic normal distribution, Figure 6. By knowledge of the distribution function residual lifetimes can be calculated for arbitrary probabilities of failure. Furthermore it is able to determine the range of scattering

$$T_N = 1{:}\frac{N_{P=90\%}}{N_{P=10\%}} = 1{:}\frac{3{,}0 \cdot 10^6}{0{,}83 \cdot 10^5} = 1{:}3{,}6 \tag{13}$$

which is equal for both stochastic simulations. So the results of the sensitivity analysis are confirmed and the coefficients q and K_C are insignificant.

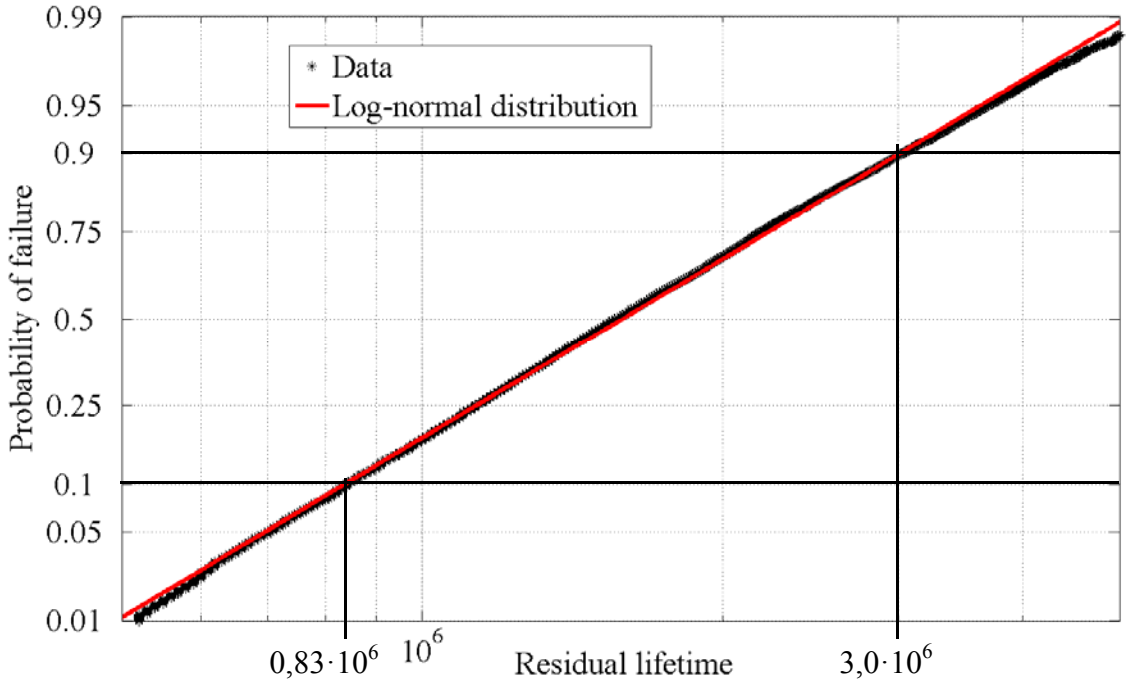

Figure 6: Residual lifetimes of stochastic crack propagation simulation with 7 stochastic parameters

5. Conclusion

In the current investigations crack propagation data of 42CrMo4 are analyzed. This includes the determination of fitting coefficients of the *Forman/Mettu*-equation which describes the crack propagation curve analytically. For the automated adaption of the crack propagation curve a MATLAB program was developed. Herewith, first the experimental threshold values are calculated and analytically described by use of a one criteria concept. Next the whole crack propagation curve is adapted by the *Forman/Mettu*-equation. Therefore, the limits of cyclic crack propagation (threshold value and fracture toughness) are required. For the determination of the optimum fitting coefficients a search algorithm with nested intervals is used. Problematically in this context is the calculation of an error value by reason that the co-domain reaches about eight decades.

Furthermore, the crack propagation data is statistically analyzed. By dividing the co-domain in several intervals regression functions and confidence intervals are calculated for each domain. Therewith, discrete quantile curves for pretended probabilities of survival are calculated using interpolation functions. From the adaption of quantile curves with constant probability of survival by the *Forman/Mettu*-equation the corresponding fitting coefficients are determined. The statistical analysis of these fitting coefficients leads to its distribution functions.

To obtain statistically secured residual lifetimes stochastic crack propagation simulations are

performed by use of MATLAB and the analytical crack propagation software NASGRO. Therefore, the significant parameters are stochastically modeled. To identify the significant parameters of the *Forman/Mettu*-equation a sensitivity analysis was performed. The results are inconsistence to the statistical analysis of crack propagation data used in literature. For instance the fracture toughness is insignificant to the scattering of the residual lifetime and can be neglected in the stochastic crack propagation simulation. As simulation method the basic Monte Carlo simulation was used. The stochastic input vectors are determined by a random number generator. After the simulation the residual lifetimes are statistically analyzed. Thus, it is possible to obtain residual lifetimes for pretended probabilities of survival.

Abstract Fatigue crack growth in a metastable austenitic stainless steel was investigated in thin specimen under positive stress ratio. Annealed conditions were used to test the influence of the microstructure. The influence of load ratio on propagation threshold and propagation behavior was analyzed using the Elber`s closure approach, the Donald and Paris partial crack closure and the empirical Kujawski $(\Delta K \bullet Kmax)^{\alpha}$ parameter. Results show that load ratio effects are not completely explained by these approaches. It was found that the threshold of the material in the annealed condition depends on the load history, especially when the load ratio is low. It seems that the amount of martensite transformation is responsible for the observed differences in fatigue crack growth resistance.

Keywords: Fatigue, crack propagation, thresholdMetastable austenitic stainless steel

1. Introduction

In the last years, the competitiveness in the automotive sector and the compliance with higher environmental standards has forced the development of new light-weight materials. One of the materials that fulfill with the exigencies of automotive sector are the metastable stainless steels because of they combine good corrosion resistance with versatile mechanical properties [1,2]. Due to his high ultimate strength, metastable stainless steel allows the use of components of less thickness. One of the more important aspects in the automotive sector is the design again fatigue damage.Traditionally, the approach to fatigue design based on the cyclic stress range ΔShas been used [3]. However, thin walled light components must be designed using more conservative approach, basedmainly in linear elastic fracture mechanics.

AISI 301LN steels belong to the metastable austenitic steels and have an austenitic structure in annealed conditions which confers them an excellent ductility. Besides, they have an extraordinary strain hardening because of the transformation of austenite to martensite during deformation. This particular class of steels are called TRIP steels [4]. Significant researches have been conducted on the fatigue behavior of TRIP steels [4-12], and depending of the testing condition, different behaviors have been reported. In the high cycle (HCF) regime, i.e. test under load control or test under K control, the conclusion of the studies show that exists a relationship between the martensitic transformation around the crack tip and the decrease in the fatigue crack growth rate (FCGR) [4-8,10,12], with the exception of reference [9], where it attributed the decrease in the FCGR to the slip characteristic rather than the martensitic transformation. Until now various mechanisms have been proposed trying to explain how the martensitic transformation can affect the FCGR. However, there is no mechanism that can explain satisfactorily the effect of the martensitic transformation over the FCGR having accounted the entire picture of the stress state.

The most recurrent mechanism to explain the crack growth retardations in fatigue is the crack closure, which was introduced by Elber in 1971 [13], after observing that fatigue crack surfaces contact under cyclic tensile loading. Even direct measurements have not been achieved, is felt that the martensitic transformation cause crack closure because of the involved volume expansion of 1-4 % [14]. The first mechanism used to explain the premature contact between the faces of the crack is the plasticity induced crack closure. However, others mechanisms induced crack closure

have been identified, as oxide induced crack closure or roughness induce crack closure. The vast majority of mechanisms to explain crack closure are explained, for instance, in the book "Fatigue of Material" written by S.Suresh [3]. Traditionally, in some expression obtained from experimental investigations have been indicated that the crack opening stress intensity factor K_{op} is only function of the stress ratio R [13,15]. However, some authors recognized that K_{op} is also influenced by the specimen geometry, the stress state, the stress intensity factor range and the environment. Some models have been theoretically developed in order to explain how the crack opening stress is influenced by the stress ratio R, the maximum applied stress or load level P_{max}, and the crack front constraint (plane stress or plane strain behavior).

In this work the fatigue crack growth behavior of an annealed metastable austenitic stainless steel was investigated in thin specimen under positive stress ratio. The influence of load ratio on propagation threshold and propagation behavior was analyzed using the Elber`s closure approach, the Donald and Paris partial crack closure approach and the empirical Kujawski $(\Delta K \bullet Kmax)^{\alpha}$ parameter. Results are analyzed in order to look for answers about the influence of the martensitic transformation on the fatigue behavior of this kind of steel and for a unique relationship between fatigue crack propagation rate and the applied driving force.

2. Experiments

The material utilized in the current study was an annealed austenitic stainless steel AISI 301LN provided by OCAS NV, Arcelor-Mittal R&D Industry Gent (Belgium) The chemical composition of this material is shown in Table 1. The microstructure of the material is shown in figure 1. The α'martensite content was calculated by mean of X-ray diffraction and results showed that the martensite content was less than 2%.

Table 1.Chemical Composition

*For AISI 301 stainless steel.

Single edge notch test specimen (SENT) of 1 mm thickness and a width of 35 mm and 40 mm, were

machined with the rolling direction parallel (T-L) and perpendicular (L-T) to the notch. The specimens were fatigued in air and at room temperature.

The FCGR test were conducted in an Instron‘s servo-hydraulic machine with closed loop to computers for automatic test control and data acquisition. The crack extension was measured with a krak-gages® technique, which is principally an indirect DC potential measurement procedure. The krag-gages® theory is explained in reference [16]. For instance, the crack gauge KG-B20, whose full scale is 20 mm, has a sensitivity of measurement to crack extension that is better than 0.02mm [17]. The crack extension was also measured using the compliance technique by means of a clip gage in the crack mouth and a strain gauge fixed in the back surface.

The crack closure measurementwere made by using a sampling rate of 400 data pairs (load and displacement) per cycle according to some of the recommendations made by Song et al. [18]. The signal noise was reduced by using low-pass digital filters [19]. The determination of the opening force was done by comparing slope segments of 10 percent of the load- displacement data with the linear region of the load-displacement curve.

The fatigue tests were performed at a frequency of 20 Hz. Three different values of load ratio R ($=\sigma_{min}/\sigma_{max}$) 0.1, 0.3, 0.5, 2 different stress level at the same load ratio, and 3 decreasing ΔK at different load ratio were employed. For ΔK decreasing test the rate of force shedding with increasing crack size was according to the ASTM standard (20). The details of the experiments are listed in table 3.

The martensite transformation around the crack tip was observed by optical microscopy. The material was ground in the surface where the fatigue crack was going to appear with SiC emery paper up to a roughness of 1200 grit and then polished. Because of the mechanical grinding can induce martensitic transformation,the material was electro-polished with a solution consisting of 5vol% perchloric acid and 95% ethanol at 45V for 15 s. The martensitic phase was revealed by chemical etching in a solution of 100 ml ethanol, 20 ml HCl, 1.5 g K_2S2O_5 and 2 g $NH_4F{\cdot}HF$. The electro-polished was used until no peak (100) (200) (211) (α`martensite peak according to M. Karimi et al [21]) was found by X-ray diffraction.

Table 3.Details of test configuration

	Specimen	R ($\sigma_{min}/\sigma_{max}$)	Load level [N] (P_{max}- P_{min})	Notch [mm]	Test Type	w [mm]	C [mm^{-1}]
1	NL2	0.5	2625	8.729	Constant amp. load	35	-

8	NNL4	0.7	variable	9.088	ΔK decreasing	35	-0.055
9	NNL7	0.7	variable	8.897	ΔK decreasing	35	-0.09
10	NNL1	0.5	variable	8.912	ΔK decreasing	35	-0.08

3. ΔK expressions

In situations where the linear elastic fracture mechanics theory (LEFM) is valid the crack driving force is traditionally represented by using the stress intensity factor ΔK. For the specimen type used in this investigation and for the grid constraint of our test‘s machine, the stress intensity factor for the specimen of this investigation is not tabulated in books, therefore the finite element method (FEM) was employed to obtain the value of the stress intensity factor. Figure 2 shows the ΔK solutions used for the two configurations that have been used for test. The typical solution available in literature for SENT specimens is also shown and the difference in the given *K* values for a given crack length can be clearly observed. The curve was normalized by dividing the stress intensity factor by the applied stress and the crack length by the specimen length.

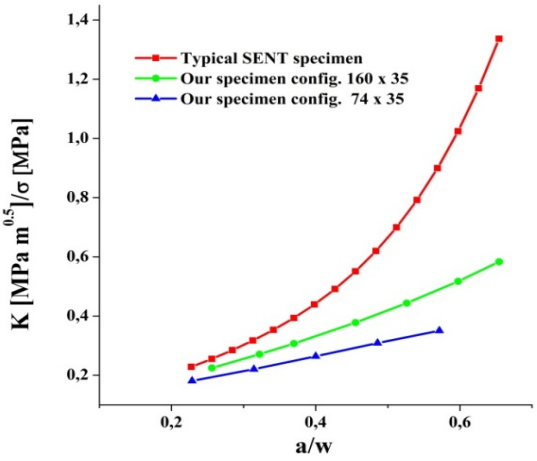

Figure 2. Stress intensity factor obtained by finite element models for the used configurations.

4. Experimental Results

4.1. Results using the range of the stress intensity factor

The fatigue crack growth rates of austenitic stainless steel 301LN at room temperature, at 3 different load ratios and different load levels are shown in Fig. 3(a). For all test conditions the crack growth rate increases with increase in ΔK. The curves show a trend that can be considered linear with positive and constant slope. The influence of load level is negligible, in spite of we found some papers that mention that some austenitic stainless materials in specimen with thin section [7,22] suffer the influence of stress level on fatigue crack growth rate.

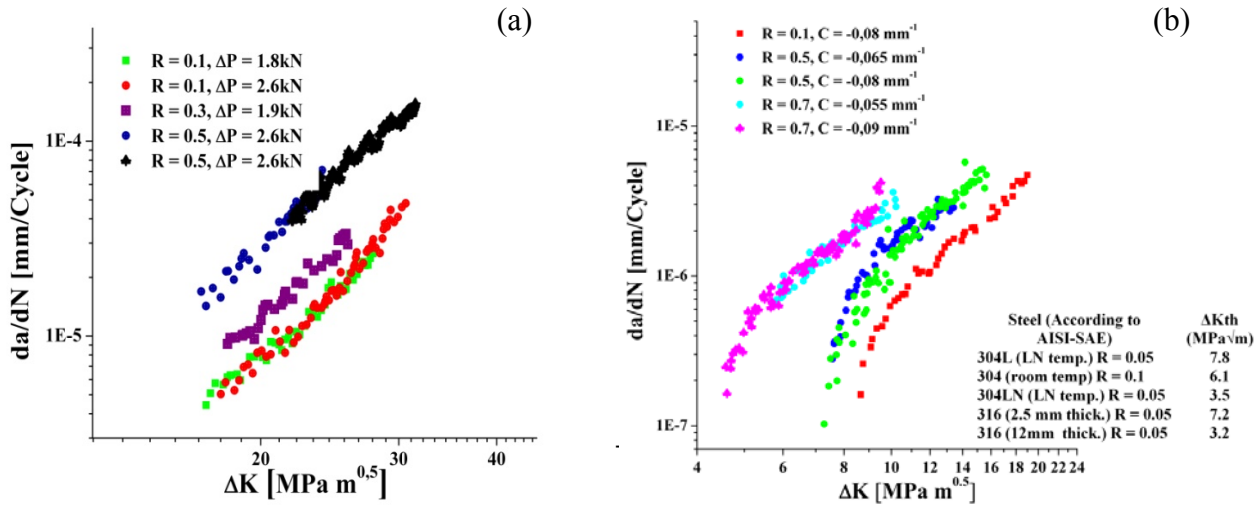

Figure 3. Fatigue crack growth rate vs stress intensity factor range at different load ratios (a) in the stable crack propagation region and (b) in the near threshold region.

The influence of R values on near threshold crack growth rates is shown in Fig. 3(b). It can be seen how the ΔK_{th} decreases with the increment in load ratio. The values of ΔK_{th} are relatively high, especially at R = 0.1 and R = 0.5, in comparison with other austenitic stainless steel alloys or even other steel alloys. However the results are not surprising, according to the results found for other austenitic stainless steel that are shown in the table of Fig.3(b), where it can be observed that materials with martensitic transformation and/or in conditions of plane stress, produce high thresholds.

4.2. Results using the effective stress intensity factor

The fatigue crack growth rate was plotted also by using the conventional Elber's approach and defining the effective stress intensity range as:

$$\Delta K_{eff} = K_{max} - K_{op} \tag{1}$$

Fig. 4 shows the obtained results. They show that in the stable region (far from thresholds) the crack closure is practically constant in the total range of crack propagation for the same test. It is only observes the same average value of $S_o/S_{max} \approx 0.35$ for both cases at low load ratio (R = 0.1 and 0.3). The analysis was based in the work of J. Song et al [18], from which the offset criterion that better estimate load ratio effects in the Paris region is 4% (this analysis will be detailed in a paper that will be soon submitted for publication).

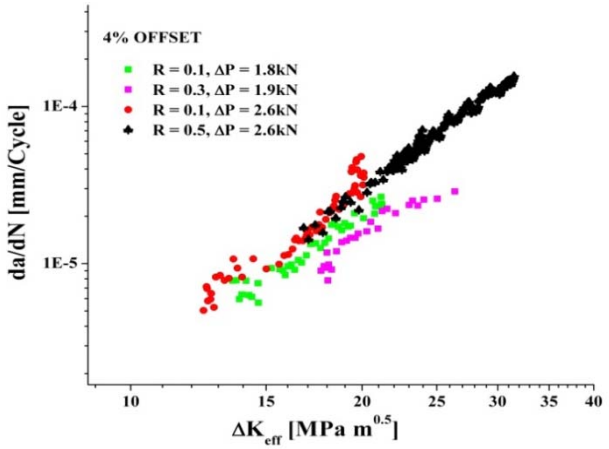

Figure 4. Fatigue crack growth rate as a function of the effective stress intensity factor

Fig. 5 shows the correlation obtained using Eq. (1) for the near threshold behavior. It shows that with the use of crack closure concepts the curves move closer each other but it is still not possible to join them in a unique curve. In this region of slow growth rate the relation of K_{op}/K_{max} increase with decreasing the range of the stress intensity factor (approaching the threshold).

4.3. Results using the Donald`s effect

The original concept of crack closure indicates that the crack cannot grow if the crack is not fully open. However Donald and coauthors have shown that the interference of crack faces does not

shield completely the crack tip from fatigue damage [23]. Based on this concept, Donald proposed to calculate an effective stress intensity factor range as:

$$\Delta K_{2/PI} = \Delta K_{app} - \frac{2}{\pi}\left(K_{op} - K_{min}\right) \quad (2)$$

This is one of several methods that have been used to estimate ΔK_{eff}, although this method distinguishes over other because of his simplicity and because has provided successful correlation of the crack growth rate data for aluminum alloys. Fig. 6 shows the fatigue crack growth rate as a function of the effective stress intensity factor proposed by Donald. It can be observed that for our analyzed material the Donald`s effect does not provide a better correlation of the R-ratio effects than the traditional ΔK_{eff} calculated by using the Eq. (1).

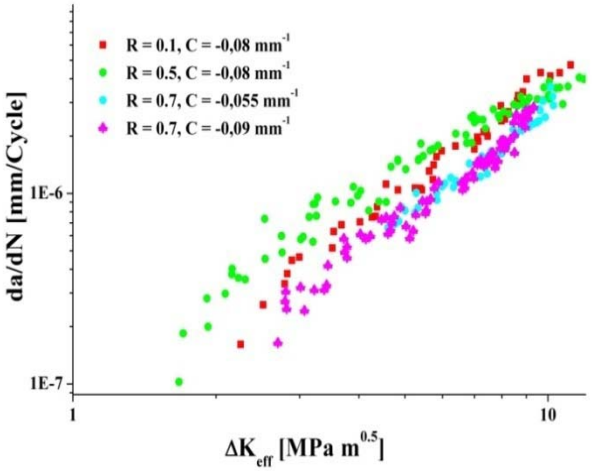

Figure 5. Fatigue crack growth rate as a function of the effective stress intensity factor

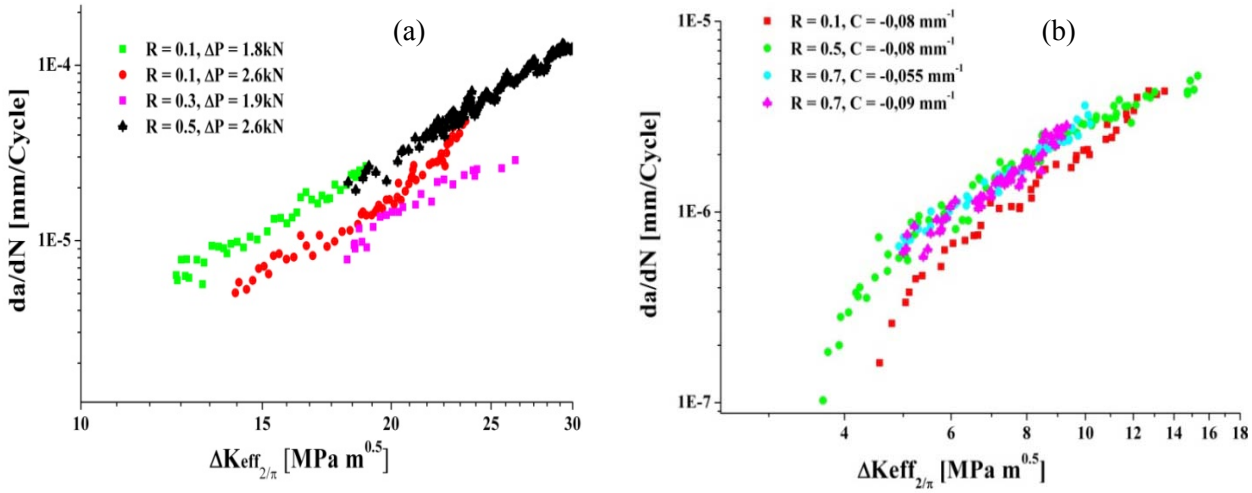

Figure 6. Fatigue crack growth rate as a function of the effective stress intensity factor proposed by Donald et al. (a) in the stable crack propagation region and (b) in the near threshold region.

4.3. Results using the Kujawski`s Parameter

To explain the load ratio effects in fatigue crack growth, and because of the inconsistency in the measurement of crack closure and the difficulties to determine the fatigue damage associated to a crack partially open, Kujawski proposed a crack driving force parameter that is calculated by using

K_{max} and ΔK [24] as follow:

$$K^* = (K_{max})^{\alpha}(\Delta K)^{1-\alpha} \tag{3}$$

Where ΔK is the positive part of the range of the applied stress intensity factor. This parameter is characterized, among other things, by the use of two separate variables that could describe unambiguously the load cycle at least if the load ratio is positive and K_{max} is greater than 0, like in the present case. The α value is a factor that determines the importance of K_{max} or ΔK and it is calculated by means of the following expression:

$$\alpha = \frac{log(\Delta K_1/\Delta K_2)}{log((1-R_1)/(1-R_2))} \tag{4}$$

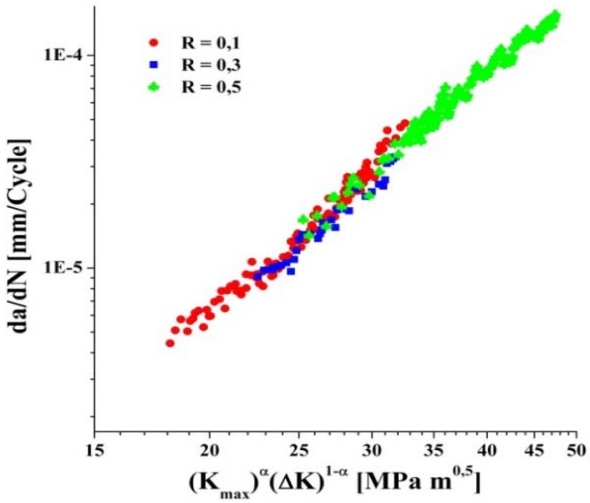

Figure 7. Fatigue crack growth rate as a function of the Kujawski`s parameter with α equal to 0.6.

Using Eq. (4) the average α value, for the AISI 301 LN in the paris region, was equal to 0.6. This was the same α value found for the metastable austenitic stainless steel AISI 304L tested at 77K [8], although in that case the scatter was higher. Fig. 7 shows the correlation obtained by plotting the fatigue crack growth rate vs the Kujawski`s parameter far from the threshold region. It is seen that kujawski`s parameter can unify the curves of the test performed to constant load ratio into a master curve that can be described by using Eq (5) with C = 1.33×10^{-11} [mm/cycle MPa $m^{0.5m}$] and m = 3.619.

$$\frac{da}{dN} = C(\Delta K^{1-\alpha}K_{max}^{\alpha})^m \tag{5}$$

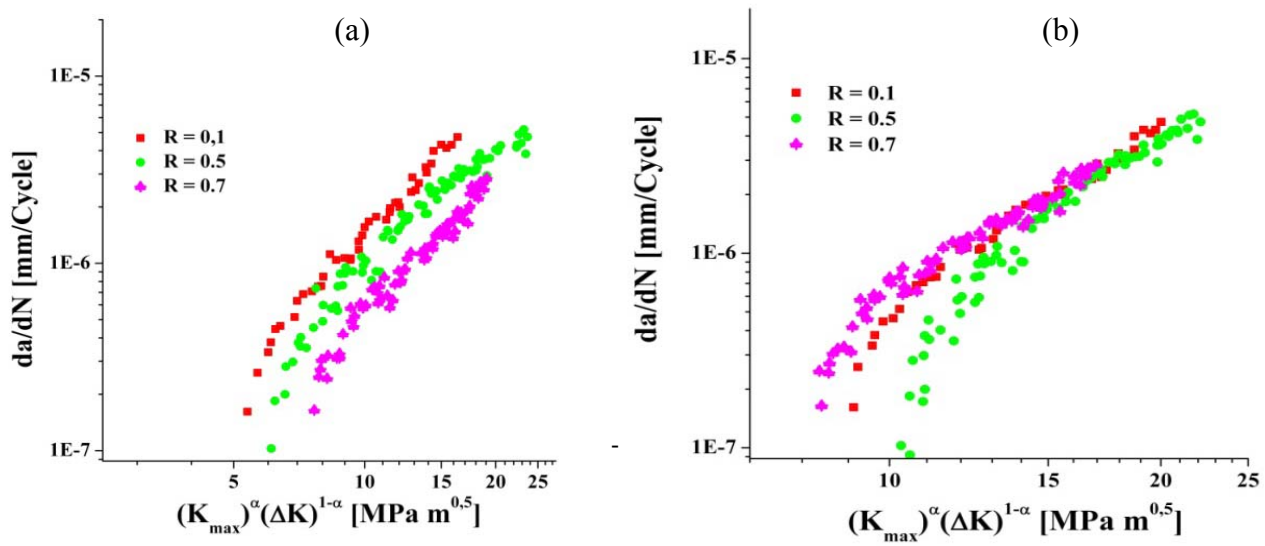

Figure 8.Fatigue crack growth rate as a function of the Kujawski`s parameter with (a) α equal to 0.6 and (b) α equal to 0.5

The same parameter α that was found to correlate the fatigue crack growth rate curves in Fig. 7 has been used to analyze the near threshold region, and results are shown in Fig 8(a). It can be observed that in this case the approach cannot success as in Fig. 7. Fig.8(b) shows results obtained by using an α value equal to 0.5. Even though results seem to be somehow better, the approach does not success.

It is interesting to note that the value of α parameter calculated for the AISI 301LN decrease with the decrease of the stress intensity factor range and/or with the decrease of the martensite content. This result agree with those of the work of S.Kalnaus et al [11], were they estimated an α parameter equals to 0.36 for an austenitic steel without transformation. According to our measurements, the martensite content decreases in the near threshold region of crack propagation with respect to measurement made in the relative high ΔK fatigue crack propagation region. It is clear that further and more detailed analyses are needed in order to explain the influence of the load ratio R in this region.

5. Concluding remarks

Fatigue crack growth of aannealed metastable austenitic stainless steel was investigated in thin specimen under positive stress ratio. The influence of load ratio on propagation threshold and propagation behavior was analyzed using the Elber`s closure approach, the Donald and Paris partial crack closure and the empirical Kujawski $(\Delta K \bullet Kmax)^{\alpha}$ parameter.

Results show that load ratio effects are not completely explained by these approaches. The crack closure effect approaches (both, the traditional Elber approach and its modification by Donald and Paris) cannot explain the influence of the stress ratio R on the fatigue crack propagation rate on the analyzed thin specimens of a TRIP material.

The two parameter crack driving force $(\Delta K \bullet Kmax)^{\alpha}$, with $\alpha = 0.6$, seem to be a proper parameter to uniquely explain the fatigue behavior of the analyzed TRIP steel for positive R ratios far from the threshold region. However, it seems to fail in the threshold region, where the crack closure levels are important, and a unique α value cannot be found. So, further investigation should be carried out in order to explain these results.

Abstract A three-term crack growth model was developed by adding a creep-fatigue interaction term to the traditional linear superposition law. It is based on the hypothesis that the maximal creep-fatigue interaction occurs when creep and fatigue crack growth rates are comparable. Thereby a novel exponential form of interaction intensity factor was proposed. In order to verify the model, the creep-fatigue crack growth behaviour of a nickel-based powder metallurgy superalloy (FGH97) was experimentally investigated. Creep-fatigue crack growth rates were obtained at 750 °C with various dwell times. Comparison of the crack growth rates between fitted and measured values at 0s, 90s, 450s and 1500s dwell times show great agreement. Encouragingly, excellent predictive ability of the model was verified by the experiment at 25s dwell time. Furthermore, to test the applicability of the interaction law on other materials, experimental data of two additional superalloys from references, namely Alloy 718 and Hastelloy® X, were used to fit the model. The results are also satisfactory.

Keywords Crack growth rate modelling, high temperature, dwell time, nickel-based superalloys

1. Introduction

As for the quantitative description of creep-fatigue crack growth rate, several models have been developed. Tong et al. [1] proposed single term models, in which creep damage is taken into account by modifying the coefficient of the basic fatigue model. Other researchers [2] have used an alternative approach. They assumed that creep-fatigue behaviour is governed by competing mechanisms of creep and fatigue crack growth, and whichever gives a higher growth rate dominates the entire crack growth process. A more universal model is based on simple linear superposition of creep crack growth and fatigue crack growth [3]. However, such methods tend to overlook the effect of creep-fatigue interaction, which cannot be ignored by many materials.

For this reason, a three term model considering the interaction effect separately was referred in [4], expressed in the form of linear superposition of fatigue crack growth rate, creep crack growth rate and their interactions. However, the quantitative relationship between the creep-fatigue interaction and the loading condition for certain materials is still an open question. The work of Grover and Saxena [5] indicated that the intensity of the creep-fatigue interaction is directly related to the relative sizes of the creep zone and cyclic plastic zone.

Recently, the authors [6] presented an exponential formed interaction intensity factor to help describing the interaction effect. The accuracy of the model proposed was experimentally confirmed by a nickel-based superalloy FGH97. The study presented here is a continuation of that work and applicability of the model on other materials was verified.

2. Creep-fatigue interaction model

The simple linear superposition equation, as shown in Eq. (1), is preferentially considered to model the creep-fatigue crack growth rate[3].

$$\frac{\mathrm{d}a}{\mathrm{d}N} = \left(\frac{\mathrm{d}a}{\mathrm{d}N}\right)_{\text{fatigue}} + \left(\frac{\mathrm{d}a}{\mathrm{d}N}\right)_{\text{creep}} \tag{1}$$

where $(\mathrm{d}a/\mathrm{d}N)_{\text{fatigue}}$ denotes the fatigue crack growth rate, including the effect of environment (oxidation for example). It can be achieved by Eq. (2) according to the Paris law. $(\mathrm{d}a/\mathrm{d}N)_{\text{creep}}$ represents the creep crack growth rate. Selecting K as the creep crack growth dominant parameter due to its practicability, $(\mathrm{d}a/\mathrm{d}N)_{\text{creep}}$ is thereby expressed by Eq. (3).

$$\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right)_{\text{fatigue}} = C(\Delta K)^n \tag{2}$$

$$\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right)_{\text{creep}} = A(K_{\max})^m t_{\mathrm{h}} \tag{3}$$

where $K_{\max} = \Delta K / (1 - R)$, C, n, A and m are material related parameters.

In order to take the creep-fatigue interaction into account, a three-term crack growth model was developed by adding a third-term to the traditional linear superposition equation, see Eq. (4).

$$\frac{\mathrm{d}a}{\mathrm{d}N} = \left(\frac{\mathrm{d}a}{\mathrm{d}N}\right)_{\text{fatigue}} + \left(\frac{\mathrm{d}a}{\mathrm{d}N}\right)_{\text{creep}} + \left(\frac{\mathrm{d}a}{\mathrm{d}N}\right)_{\text{interaction}} \tag{4}$$

where $(\mathrm{d}a/\mathrm{d}N)_{\text{interaction}}$ denotes the influence of creep and fatigue interaction on the crack growth rate, and the expression should be discussed.

As Grover and Saxena [5] indicated, at short t_{h}, the creep zone size is small relative to the cyclic plastic zone size during all the crack growth period since the creep zone grows very slowly, resulting in fatigue dominating cracking. At long t_{h}, the creep zone grows larger than cyclic plastic zone size, and the crack growth rate becomes time dependent. In between, the cracking will rely on both creep and cyclic plastic damage. The most significant interaction occurs when creep and cyclic plastic damage size are comparable. Also provided in their study is that the ratio of the creep and cyclic plastic zone sizes is dependent on the dwell time t_{h}, load ratio R and the material related parameters. This implies that the creep fatigue interaction should also depend on these parameters. Based on these, a factor, η, was proposed to characterize the intensity of the creep and fatigue interaction, as shown in Eq.(5).

$$h = \exp(- p_1(\ln f + p_2 \mathrm{D}K + p_3)^2) \tag{5}$$

where, p_1, p_2 and p_3 are material related parameters, $f = (T+t_h)^{-1}$ is the frequency of the load waveform and T is the load period of the baseline triangular waveform. It can be seen that there are two extreme cases. On one extreme, η approaches zero, indicating that there is almost no interaction between creep and fatigue. For the other extreme case in which η approaches 1, it implies that the interaction reaches the most significant.

Accordingly, taking $D(\Delta K)^q$ as the basic term, $(da/dN)_{interaction}$ can thereby be expressed as following:

$$(\frac{da}{dN})_{interaction} = D(\Delta K)^q \cdot h \tag{6}$$

where $K_{max} = \Delta K / (1 - R)$, D and q are material related parameters.

3. Crack growth experiment on FGH97

The material in this study is a nickel based PM superalloy, named FGH97, taken from a turbine disk. It was strengthened by the formation of γ′ precipitates based on Ni_3Al and received both the solid-solution-strengthening and age-hardening treatment. The nominal chemical composition is as follows (wt%): C 0.02-0.06, Cr 8.0-10, Mo 3.5-4.2, W 5.2-5.9, Al 4.8-5.3, Ti 1.6-2.0, Co 15.0-16.5, Nb 2.4-2.8, Hf 0.1-0.4, Mg ≤ 0.02, Zr ≤ 0.015, B ≤ 0.015, Ce ≤ 0.010 and the balance nickel[7]. Compact tension (CT) specimens were employed, where width W = 50 mm and initial crack length a_0 = 22.5 mm. More details can be found in Ref.[6].

The baseline loading cycle is a triangular wave of load ratio R = 0.05. Different dwell time t_h = 90s, 450s and 1500s at the maximum load are superimposed to the baseline loading cycle to obtain a trapezoidal creep-fatigue loading condition, see Fig. 1. The baseline triangular fatigue loading cycle can be reasonably regarded as t_h = 0s reasonably. A typical service temperature of 750°C was conducted.

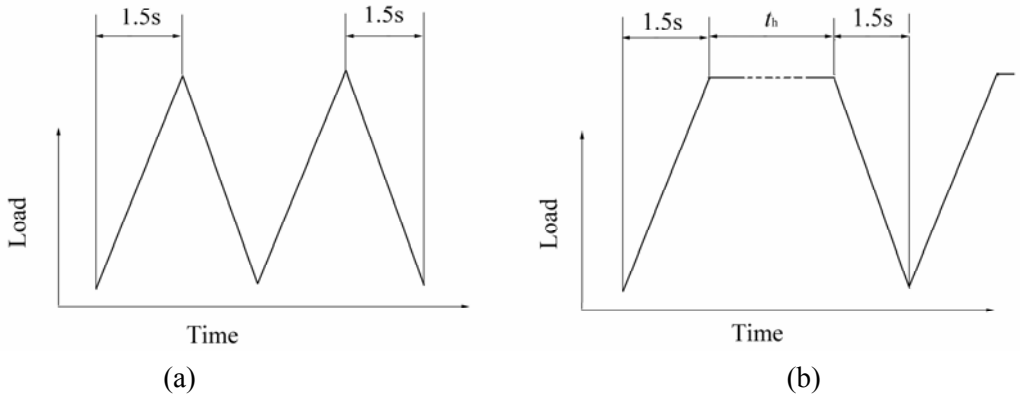

Figure 1. Schematic of loading waveforms (a) Triangular; (b) Trapezoidal

In order to clarify the creep-fatigue interaction, the da/dN vs. f data of the present alloy at four specified ΔK in log-log scale is plotted in Figure 2(a). For pure fatigue loading, according to Eq. (2), the crack growth rate showing no influence by f, therefore, ln(da/dN) vs. ln(f) curves should be parallel to the abscissa f at specified ΔK. And for pure creep crack growth, according to Eq. (3), the da/dN is proportional to t_h at certain stress level, hence, the gradients for ln(da/dN) vs. ln(f) curves should be -1. Thereby, the solid lines in Figure 2(a), calculated by Eq. (1), denote the simple linear superposition of the fatigue and creep components. The experimental data at four specified ΔK are also provided in the figure by various symbols.

It can clearly be seen from that, first, the t_h effect on da/dN is nonlinear in the log-log scale. With the t_h increases, the effect is initially increased and then decreased, especially at low ΔK stage. Second, the experimental data in the medium ΔK and t_h are much greater than the solid lines. Comparisons between the fitted and experimental crack growth rates are presented in Figure 2(b). The results show good agreements at all four dwell times, ignoring slight deviation in the quite low ΔK and ln(f) stage. Thereby, interaction intensity factor η, as expressed in Eq.(5), can depict this interaction satisfactory.

Comparisons between the fitted and experimental crack growth rates are presented in Figure 2(b). The results show good agreements at 0s, 90s, 450s and 1500s. Furthermore, to verify the predictive capability of the model, additional crack growth rate for t_h = 25s is computed by Eq. (4) and are compared with the experimental data, also shown in Figure 2(b). Excellent correlation between the predicted and observed growth rates was obtained. It appears that the model can provide accurate descriptions of the influence of t_h and ΔK on the crack growth behaviour at 750°C.

4. Applicability on Alloy 718 and Hastelloy® X

In order to verify the applicability of the model on other materials, two additional nickel-based superalloys from the references, namely Alloy 718 and Hastelloy® X, were analysed. Alloy 718 is a wrought polycrystalline nickel based superalloy with a large amount of Fe and Cr. The crack growth experiments [8] were conducted on Kb-type specimens with rectangular cross sections of 4.3×10.2 mm. Hastelloy® X alloy is a solid-solution strengthened nickel-based superalloy that combines exceptional oxidation resistance, good fabricability, and excellent high-temperature strength. And the experiments [9] were conducted on CT specimen with thickness of 3.2 mm, height of 61.0 mm and width of 63.5 mm. Here, two temperatures with three or four dwell times were involved for each material. Details of the experiments can be found in references [8] and [9], respectively.

Figure 3 and Figure 4 present the comparisons between the fitted and experimental d*a*/d*N* of Alloy 718 and Hastelloy® X, respectively. Where, the solid lines in the figures were fitted by Eq. (4). Encouragingly, the results show excellent correspondences for these two alloys.

5. Summary

Key results and conclusions drawn from this investigation are summarized below: (1) The exponential form of interaction factor, η, could successfully characterize the intensity of the creep and fatigue interaction. (2) The established three-term crack growth model is capable of accurately representing and predicting the creep-fatigue crack growth behavior of FGH97. (3) The applicability of the three-term model on the nickel-based superalloys Alloy 718 and Hastelloy® X is satisfactory.

Residual stress effects on the propagation of fatigue cracks in the weld of a CA6NM stainless steel

Alexandre Trudel[1,*], Myriam Brochu[1], Martin Lévesque[1]

[1] Department of Mechanical Engineering, École Polytechnique de Montréal, Montreal, Canada

Abstract The fatigue crack growth behavior in an automatic flux core arc weld was investigated for stainless steel alloy CA6NM. As-welded and heat treated compact tension specimens were prepared with the crack propagation plane perpendicular to the weld. Constant stress intensity factor range tests were performed at a load ratio R = 0.1 to reveal intra-specimen fatigue crack growth rate variations and differences between the fatigue crack growth behavior of as-welded and heat treated specimens. Comparing the fatigue crack growth rate of as-welded and heat treated specimens revealed that the crack propagates at a faster rate in the as-welded specimens where indications point to the existence of tensile residual stresses acting on the crack tip by inhibiting crack closure. As for the heat treated specimens, when the crack is in the base metal, the fatigue crack growth rate decreases accompanied by an increase in crack closure levels. Tensile residual stresses that may have remained after the post-weld heat treatment and their subsequent relaxation with crack growth could explain this behavior.

Keywords Welding, Stainless Steel, Fatigue Crack Growth, Residual Stresses, Crack Closure

1. Introduction

Cast martensitic stainless steel alloy CA6NM has been used to manufacture hydraulic turbine runners for many decades. Its high strength, weldability and resistance to corrosion and cavitation damage make it a prime candidate for this application. Turbine runners are manufactured by welding cast blades to a cast core using a matching filler metal such as 410NiMo. During service, the cyclic loads acting on the runners can lead to fatigue failures [1]. A damage tolerance approach for the stress analysis of turbine runners can be an efficient strategy to account for the discontinuities, such as casting and welding defects as well as partial penetration weld joint designs, found in these components. A good knowledge of material resistance to fatigue crack growth is therefore needed.

During welding, residual stresses develop and are believed to have a significant influence on the fatigue crack growth behavior of CA6NM welds. Weld-induced residual stresses arise from the elastic interactions between the constraining base metal and the weld metal shrinkage upon solidification and cooling. In stainless steel CA6NM, the volumetric expansion resulting from the austenite to martensite transformation, in conjunction with the low transformation temperature, contributes to the buildup of residual stresses during the welding process [2]. Previous studies have shown that significant tensile and compressive residual stresses can be found in as-welded CA6NM welds [2, 3]. These studies have also shown that post-weld heat treatment (tempering) can reduce the residual stress level. Thibault and al. obtained a 75 percent reduction of the maximum tensile residual stress measured in a five beads V-preparation weld (534 MPa to 136 MPa) [2]. Moisan and al. also showed that the maximum average tensile residual stress in a multi-pass T-joint was reduced after post-weld heat treatment by an amount of 73 percent (204 MPa to 56 MPa) [3].

A fatigue crack growing in a weld can be under the influence of tensile or compressive residual stresses, depending on the geometry of the joint and the position of the crack tip. Under tensile residual stresses, the crack tip is submitted to higher maximum and minimum loads resulting in a higher effective load ratio. This can also affect the effective stress intensity factor range as it can prevent closure, often resulting in higher fatigue crack growth rates (FCGR) [4-6]. On the other hand, compressive residual stresses can accentuate crack closure and be beneficial if they reduce the effective stress intensity factor range and thus the fatigue crack growth rate [5].

The main objective of this study was to characterize the effect of residual stresses on the fatigue crack growth behavior of a flux-cored arc weld consisting of alloy CA6NM and filler metal 410NiMo. Intra-specimen fatigue crack growth rate variations between the filler metal (FM), heat affected zone (HAZ) and base metal (BM), as well as the effect of post-weld heat treatment on fatigue crack growth behavior were studied. Microhardness profiles and metallographic observations were realized on as-welded (AW) and heat treated (HT) specimens encompassing the three zones (FM, HAZ and BM) in order to position the fusion line and determine the width of the heat affected zone. Fatigue crack growth tests were carried out at constant stress intensity factor ranges in order to highlight the effect of residual stresses on the fatigue crack growth behavior. The results are discussed based on the effect of the residual stresses as well as crack closure.

2. Experimental procedure

2.1. Materials

The materials used in this study are base metal martensitic stainless steel alloy CA6NM, and the matching filler metal 410NiMo. The chemical composition and mechanical properties of the CA6NM alloy used are given in Table 1 and Table 2, respectively. Using a fully automated flux-cored arc welding (FCAW) process, 40 mm of weld was built up at the surface of a 50 mm thick CA6NM plate. The welding parameters are given in Table 3. The welded plate was cut in two parts, one of which underwent a post-weld heat treatment at 600°C for two hours. Specimens were prepared from both plates for microhardness measurements and fatigue testing.

Table 1. Chemical composition of base metal CA6NM (weight %) [7]

Material	C	Mn	Si	S	P	Cr	Ni	Mo
CA6NM	0.02	0.66	0.59	0.008	0.031	13.04	4.07	0.53

Table 2. Mechanical properties of base metal CA6NM [7]

Yield strength	Tensile strength	Young's Modulus	Elongation	Reduction Area
763 MPa	837 MPa	206 GPa	27.0 %	58.8 %

Table 3. Welding parameters

Process	Shielding gas	Wire diameter	Voltage	Current	Speed	Heat input
FCAW	75% Ar, 25% CO_2	1.6 mm	27.5 V	260 A	5 mm/s	1.4 kJ/mm

2.2 Microhardness measurements and metallographic observations

As-welded (AW) and heat treated (HT) specimens encompassing the three zones (FM, HAZ and BM) were sampled for microhardness measurements and metallographic observations. A rough polish was performed with abrasive paper of grit sizes ranging from 240 to 600, followed by a final polish using polycrystalline diamond suspension of sizes 6 μm, 3 μm and 1 μm. Vickers microhardness profiles were taken across the as-welded and heat treated specimens using a force of 100 gf and a dwell time of 15 seconds. The indentation spacing was 100 μm and measurements were taken on a length of 12 mm starting in the filler metal up to the unaffected base metal. A modified Fry's reagent was used to chemically etch the specimens and metallographic observations were realized to position the fusion line.

2.3. Fatigue testing

Compact tension (CT) specimens having a width of 50.8 mm and a thickness of 12.7 mm were machined from heat treated and as-welded plates in accordance with ASTM E647 [8]. The notches were aligned perpendicularly to the welding direction to allow for the crack to grow through each zone of the joint (FM, HAZ and BM). As seen in Fig. 1, the crack tip was positioned in the filler metal at 7 mm from the fusion line (FL). Constant stress intensity factor range tests in river water environment were performed at a constant load ratio R = 0.1 and at a frequency of 20 Hz using a 100 kN MTS servo-hydraulic machine. As-welded and heat treated specimens were tested at stress intensity factor ranges of 8 MPa·m^{½} and 20 MPa·m^{½}. The crack length was continuously monitored using the compliance method with a crack mouth clip gauge. The load and crack opening displacement (COD) were recorded for every cycle and used to determine the closure loads. The closure stress intensity factor (K_{cl}) was defined for a compliance offset of 2 percent [8]. The effective stress intensity factor range (ΔK_{eff}) was calculated by the difference between the maximum applied stress intensity factor (K_{max}) and the closure stress intensity factor (K_{cl}).

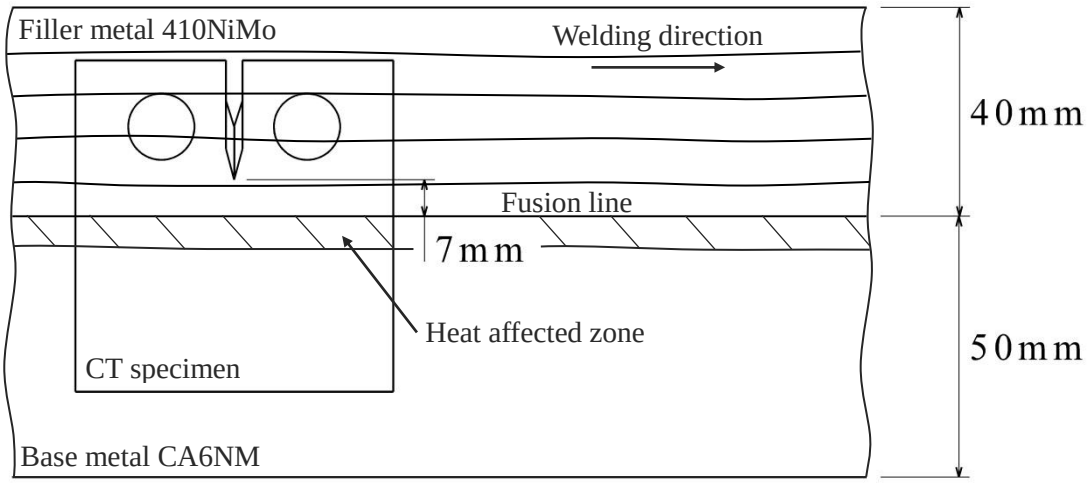

Figure 1. Compact tension specimen sampling layout. Starter notch aligned perpendicularly to the welding direction. Crack tip positioned at 7 mm from the fusion line in the FM.

3. Results

3.1. Microhardness measurements and metallographic observations

The microhardness profiles of the as-welded and heat treated specimens are shown in Fig. 2a and b, respectively. Metallographic observations were realized to identify the position of the fusion line as shown in Fig. 3 for an as-welded joint. The microstructure of the heat treated joint is visually similar and has been omitted. The heat affected zone extends from the fusion line to the microhardness plateau characterizing the base metal, as indicated in Fig. 2. The shape of the microhardness profile is similar for both specimens. The microhardness has its highest value in the filler metal and decreases from the fusion line down to characteristic values of the base metal. The heat affected zone extends up to about 5 mm from the fusion line. The main difference between the two profiles is the microhardness of the filler metal, which is 360 HV on average in the as-welded condition and 325 HV following the tempering heat treatment. These results are in good agreement with what was measured by Thibault and al. from a FCAW CA6NM joint using filler metal 410NiMo [9].

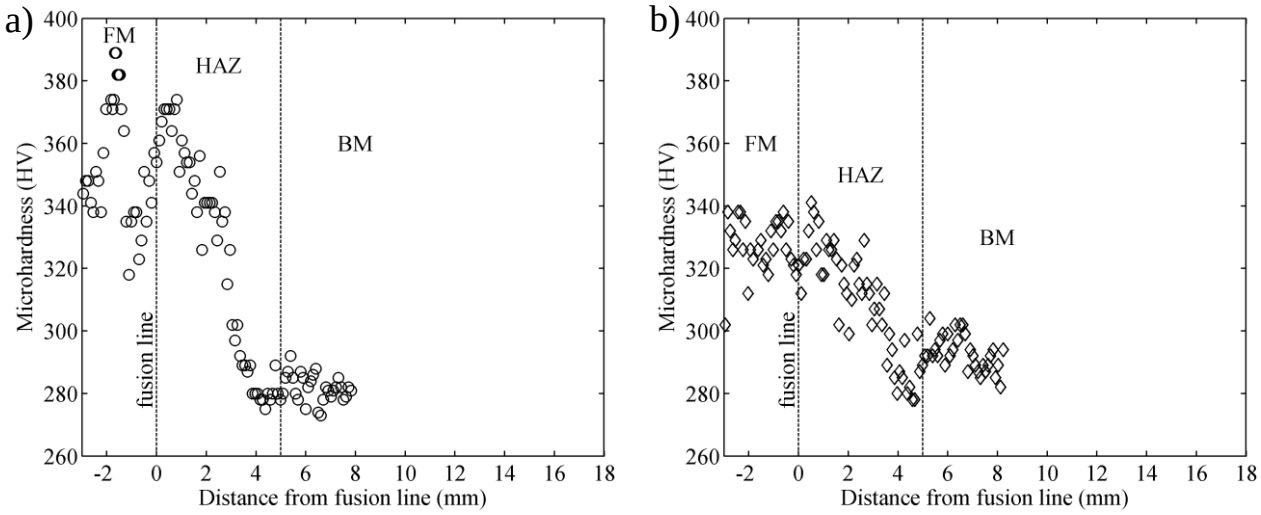

Figure 2. Microhardness profiles a) As-welded specimen b) Heat treated specimen, 2 hours at 600°C

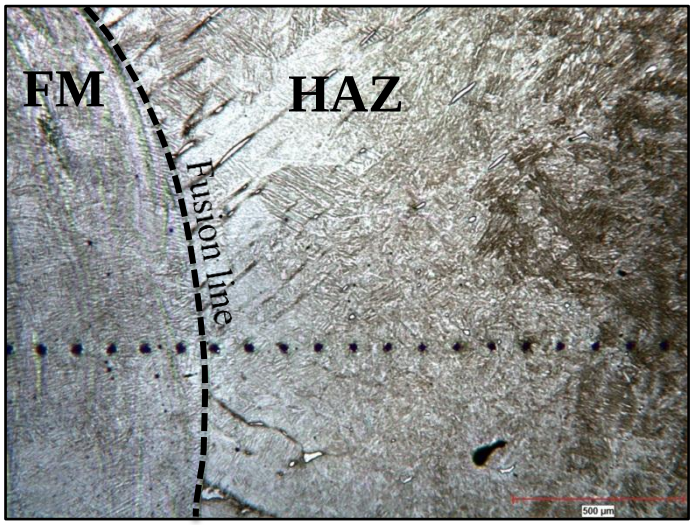

Figure 3. As-welded joint microstructure near the fusion line revealed by etching (50X).

3.2 Fatigue tests

Fig. 4 shows the results of the fatigue tests for as-welded and heat treated specimens at $\Delta K = 8$ MPa·m^{½} and $\Delta K = 20$ MPa·m^{½}. Table 4 shows the mean fatigue crack growth rate in the three zones (FM, HAZ and BM) of as-welded and heat treated specimens. When comparing a given zone at a given stress intensity factor range, the fatigue crack growth rate is always lower in the heat treated specimens than in the as-welded specimens, suggesting that the post-weld heat treatment improves the fatigue crack growth resistance. Pukasiewicz et al. found a similar behavior where the fatigue crack growth rate in the fusion zone of an as-welded CA6NM welded joint was considerably lowered after post-weld heat treatment [10]. In as-welded specimens, the fatigue crack growth rate decreases regularly from the filler metal and into the heat affected zone, before stabilizing in the base metal for both stress intensity factor ranges. These intra-specimen variations are believed to be attributed to microstructural effects and are the subject of an ongoing research. The gradual decrease of the fatigue crack growth rate is not observed in the heat treated specimen. At $\Delta K = 8$ MPa·m^{½}, the fatigue crack growth rate remains fairly constant up to 9 mm from the fusion line (4 mm into the base metal), then decreases by approximately 50 percent and stabilizes at 13 mm from the fusion line. The same behavior, though less pronounced, is also observed at $\Delta K = 20$ MPa·m^{½}, where the fatigue crack growth rate decreases by approximately 20 percent.

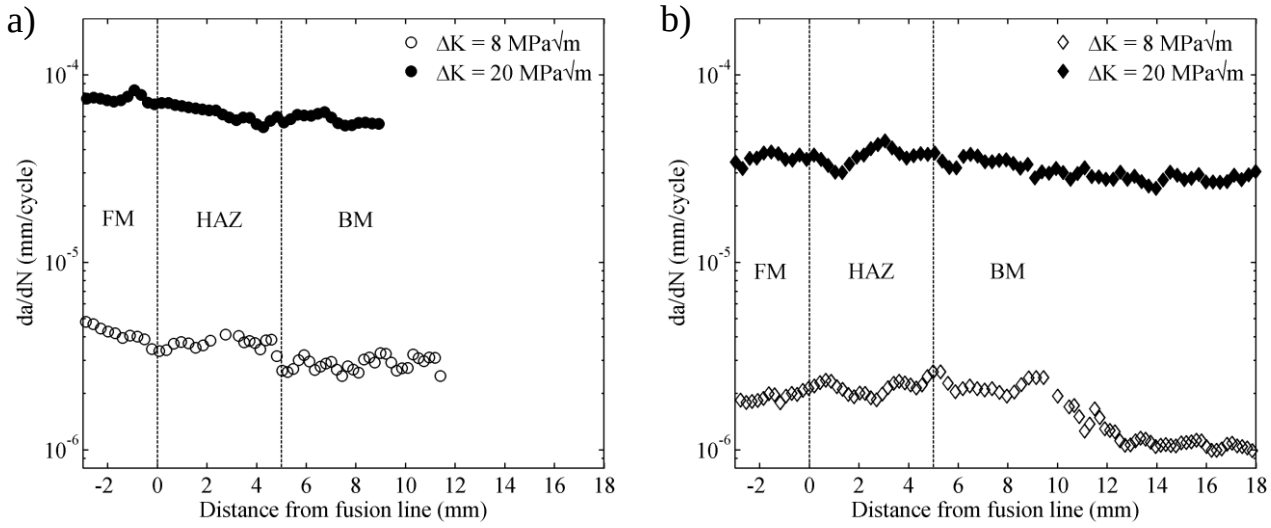

Figure 4. Constant ΔK test results a) As-welded specimens b) Heat treated specimens

Table 4. Mean FCGR in the FM, HAZ and BM of as-welded and heat treated specimens

ΔK (MPa·m^{½})	Fatigue crack growth rate (mm/cycle)						
	As-welded specimens			Heat treated specimens

4. Discussion

This section presents an analysis of the constant stress intensity factor range tests results. The higher fatigue crack growth rates found in the as-welded specimens are discussed in terms of tensile residual stresses causing the opening of the crack. The fatigue crack growth rate variations observed in the heat treated specimens are discussed in terms of residual stress relaxation and crack closure.
Fig. 5 shows the base metal fatigue crack growth curves obtained at load ratios R = 0.1 and R = 0.7 [1], along with the mean fatigue crack growth rate obtained in the base metal from the constant stress intensity factor range test results (Table 4). The mean fatigue crack growth rate in the base metal of the heat treated specimens was calculated from the stabilized data starting at 13 mm from the fusion line. For the heat treated specimens, a good agreement is found between the R = 0.1 base metal fatigue crack growth curve and the fatigue test results, for both stress intensity factor ranges. These results, along with the intra-specimen fatigue crack growth rate variations noted in the last section (Fig. 4b), are discussed further in terms of residual stress relaxation and crack closure. Furthermore, the fatigue crack growth rates in the as-welded specimens at $\Delta K = 8$ MPa·m^{½} (empty circles) and $\Delta K = 20$ MPa·m^{½} (filled circles) correlate well with the R = 0.7 base metal baseline. Several indications suggesting the presence of tensile residual stresses responsible for the higher effective load ratio seen by the as-welded specimens are discussed next.

4.1. Fatigue crack growth behavior of as-welded specimens

The typical load-compliance offset curve for as-welded specimens is shown in Fig. 6a. For both stress intensity factor ranges and at all crack lengths, the specimen's response does not deviate from the fully-open crack compliance. This indicates that the crack remains fully-open and that the effective stress intensity factor range is equal to the applied stress intensity factor range. This corresponds to an effective stress intensity factor range ratio ($U = \Delta K_{eff}/\Delta K$) equal to unity in Fig. 6b (circles). It is well known that, for ductile materials free of residual stresses, plasticity-induced crack closure plays a significant role in reducing the effective stress intensity factor range [11].

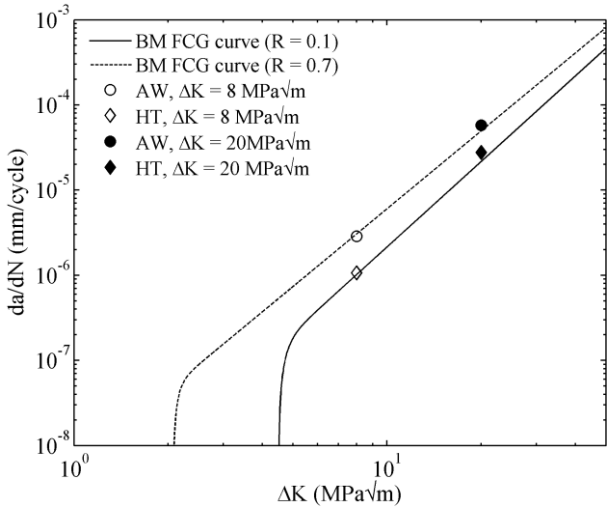

Figure 5. Comparison between the mean FCGR in the BM obtained from the constant ΔK tests and the BM fatigue crack growth curve in the Paris regime at load ratios R = 0.1 and R = 0.7 [1]

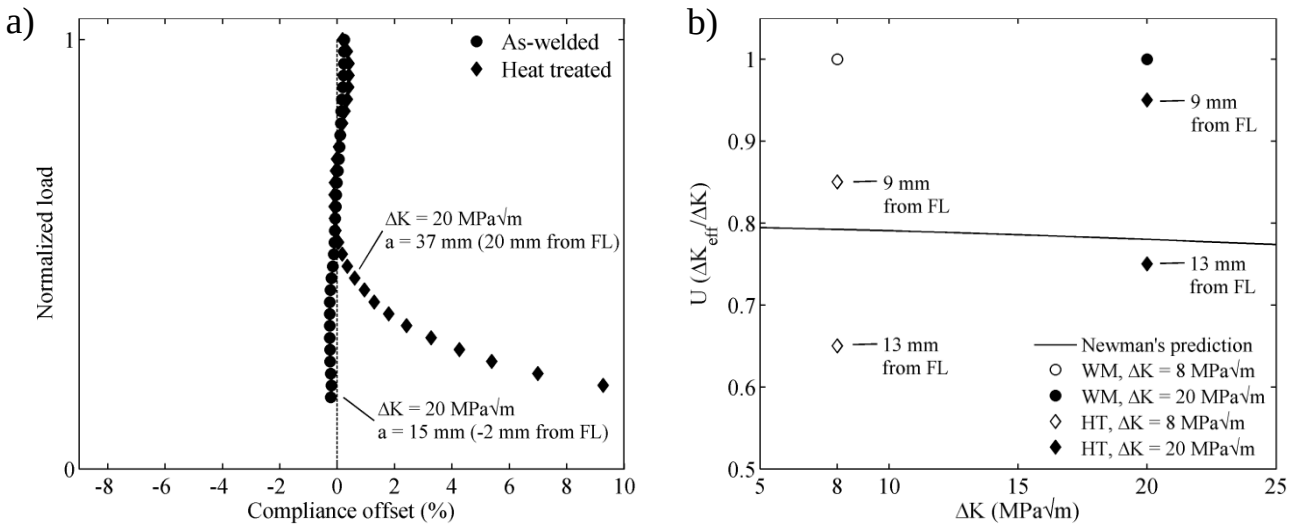

Figure 6. a) Typical load-compliance offset curves for as-welded and heat treated specimens. b) Comparison between experimental values of U and Newman's prediction

The solid line in Fig. 6b was calculated using Newman's plasticity-induced closure stress equation [12, 13] and represents an upper bound of the effective stress intensity factor range ratio. Experimental data above this upper bound indicate the existence of a crack opening mechanism. Tensile residual stresses are believed to act as such a mechanism in the as-welded specimens, since tensile residual stresses are typically found in CA6NM welds.

To further assess the presence of tensile residual stresses, an as-welded compact tension specimen with a crack length of 20 mm was incrementally loaded from 500 N to -12000 N and the crack opening displacement was recorded (Fig. 7). A closure load of -1000 N was found with a 2 percent compliance offset criterion. The existence of a negative closure load is another strong indication that tensile residual stresses are acting on the crack by preventing it to close at positive loads. A similar behavior has been observed in the welds of three different kinds of steels where tensile residual stresses caused the crack to remain fully open at a load ratio R = 0, resulting in higher fatigue crack growth rates than that of the base metal [5].

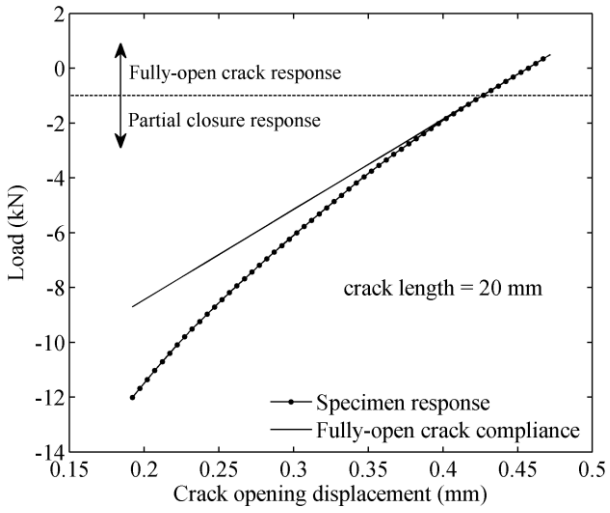

Figure 7. As-welded specimen load-COD curve from a single compression excursion (a = 20 mm)

4.2. Fatigue crack growth behavior of heat treated specimens

The crack closure behavior of the heat treated specimens is different. Crack closure was observed at both stress intensity factor ranges and for all crack lengths and the typical load-compliance offset curve is shown in Fig. 6a. Fig. 6b shows the effective stress intensity factor range ratio for the heat treated specimens when the crack is at 9 mm from the fusion line and at 13 mm from the fusion line. As a first observation, crack closure is more important at $\Delta K = 8$ MPa·m^{½} for equal crack lengths. This is expected since crack closure is more pronounced for low stress intensity factor ranges [14]. Furthermore, up to 9 mm from the fusion line, the effective stress intensity factor range ratio remains above Newman's theoretical upper bound for both stress intensity factor ranges. This is an indication that tensile residual stresses may have remained after post-weld heat treatment, partially inhibiting crack closure. These results are consistent with previous studies that showed that the post-weld heat treatment may not completely eliminate the residual stresses in CA6NM welds [2, 3]. On the other hand, the effective stress intensity factor range ratio of the crack at 13 mm from the fusion line is below the upper bound predicted by Newman for plasticity-induced crack closure for both stress intensity factor ranges. This is an indication that tensile residual stresses at the crack tip may have relaxed with crack growth and that crack closure is not inhibited. Tensile residual stresses are known to redistribute and eventually relax following the growth of a fatigue crack [15]. After complete relaxation of the tensile residual stresses, common closure mechanisms such as plasticity-induced, roughness-induced and oxide-induced crack closure become fully active and the global closure level is increased.

The evolution of the measured effective stress intensity factor range ratio against the crack length is shown in Fig. 8 (triangles). Crack closure is rather constant up to 9 mm from the fusion line, than it increases as the crack grows and eventually stabilizes. A good correlation is observed between the profiles of the fatigue crack growth rate (circles) and the effective stress intensity factor range ratio (triangles). This shows that the fatigue crack growth behavior of the heat treated specimens is directly affected by the variation of crack closure.

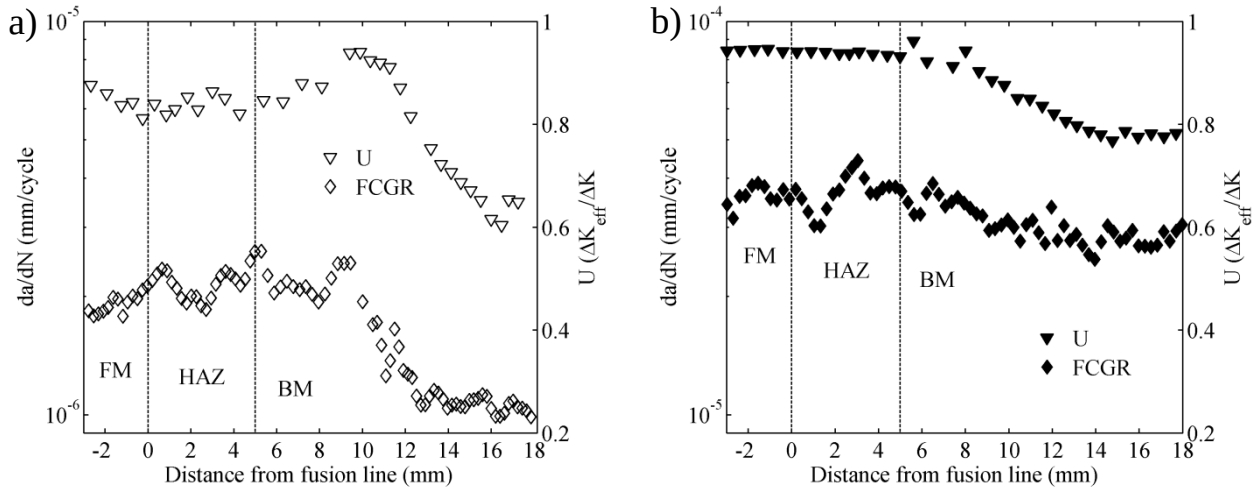

Figure 8. Relationship between U and the FCGR against the crack length for heat treated specimens a) $\Delta K = 8$ MPa·m^{½} b) $\Delta K = 20$ MPa·m^{½}

5. Conclusion

The main objective of this study was to investigate the effect of residual stresses on the fatigue crack growth behavior of a stainless steel alloy CA6NM welded joint. From the results, the following conclusions can be drawn.

In as-welded specimens, many clues point to the fact that tensile residual stresses are present at the crack tip and are having an effect on the fatigue crack growth behavior. This hypothesis is supported by: (1) A higher effective load ratio indicated by the agreement between the mean R = 0.1 experimental base metal fatigue crack growth rate and the R = 0.7 base metal fatigue crack growth curve. (2) An effective stress intensity factor range ratio equal to unity for all crack lengths meaning that a crack opening mechanism is present. (3) A negative closure load on an as-welded specimen at a crack length of 20 mm.

It is also believed that some tensile residual stresses remain after post-weld heat treatment, as evidenced by the effective stress intensity factor range ratio being superior to Newman's prediction for plasticity-induced crack closure. In addition, an increase in crack closure when the crack is in the base metal points to the fact that the tensile residual stresses were relaxed with crack growth and that closure mechanisms become fully active.

This study showed that tensile residual stresses, which are strongly believed to be present in the as-welded specimens, caused the crack to remain fully open, this having a detrimental effect on the fatigue crack growth resistance of CA6NM welds. Moreover, the fatigue crack growth resistance was found to be improved in the heat treated specimens compared to the as-welded specimens. This is attributed to the residual stresses relaxation after tempering and with crack growth, allowing closure mechanisms to become active and reducing the fatigue crack growth rates. This shows the importance of a good residual stress level control through post-weld heat treatment.

Acknowledgements

This study was made possible by the support of Alstom Hydro, Hydro-Québec and the National Science and Engineering Research Council of Canada (NSERC). The authors wish to thank Prof. Yves Verreman for his invaluable technical insights as well as technologists Carlo Baillargeon and Benedict Besner for their help with the fatigue testing procedure.

Abstract Fatigue crack growth in thin sheets of 7075 T651 aluminium alloy and S355 steel were characterized in 3D, using crack front markings and topographic reconstructions of fracture surfaces. Tests performed in air or in salt water produced different crack paths for similar mechanical conditions, shear lips being reduced by the corrosive environment, in the aluminium alloy as well as in steel. Before the onset of shear lips development, tunnelling crack fronts were observed, due to the difference in closure effects at mid-thickness and near the free surfaces. Tunnelling was progressively reduced and cancelled as slanted crack growth developed, even though ΔK_I was reduced locally by crack twisting. This indicates a significant contribution of shear modes to the crack driving force, even though mode I striations are present in the slanted zones. Elastic three-dimensional X-FEM computations were performed to analyse the observed crack growth kinetics, based on ΔK_I, ΔK_{II} and ΔK_{III}. The crack growth rates correlated much better to $\Delta K_{eq} = \sqrt{\Delta K_I^2 + \Delta K_{II}^2 + \frac{\Delta K_{III}^2}{(1-\nu)}}$ than to ΔK_I. Elastic-plastic finite element simulations and the local application of a fatigue criterion with an amplitude-dependent critical plane were found to capture qualitatively the transition in fracture mode.

Keywords fatigue crack, shear lips, thin sheet, mixed-mode, X-FEM, slanted crack

1. Introduction

Fatigue crack growth normal to the tensile axis becomes unstable in thin metallic sheets, above a material, environment and frequency-dependent amplitude, even though, in many cases, small scale yielding conditions still prevail. Shear lips development has been investigated mainly in aluminium alloys by Schijve and coworkers [1-2] Zuidema et al. [3-4] or Shanyavsky and Koronov [5], while a few studies were devoted to steel [6] or titanium alloys [7]. Walker et al [7] first reported an influence of environment on shear lips development in titanium alloys. The corrosive environment appeared to postpone crack twisting in Ti-8Al-1Mo-1V, while no systematic effect was found in Ti-6Al-AV. Vogelesang and Schijve [2] observed complete crack twisting in 7075 T651 aluminium alloy for a lower apparent ΔK_I in vacuum than in air and for a higher apparent ΔK_I in 3,5%NaCl solution. Horibe et al [6] reported a similar effect of salt water in low strength steel, but a less pronounced effect of environment for high strength steel. Shanyavsky and Koronov [5] measured the shear lips width in thin aluminium alloy cruciform specimens cyclically loaded in two orthogonal directions and reported that a positive biaxiality ratio reduced the shear lips, while a negative ratio increased it. They also observed a reduction in shear lips width when the R ratio increased. This observation conflicts with the conclusion of Zuidema et al. [3-4] that the

"steady-state" shear lips is a linearly increasing function of the effective ΔK, which usually increases with R.

The analyses of experimental data in the literature are essentially two-dimensional. Slanted crack growth kinetic data is analysed as if it was mode I and as if the growth rate and driving force were uniform along the front. Based on "constant ΔK_I tests", empirical relations between the steady-state shear lips width, the loading frequency and the "effective ΔK_I" were derived for aluminium alloys [3-4]. This parameter will be denoted below by "apparent ΔK_I", since it is computed in 2D for a normal crack of same length as that observed on the free surface, with an empirical correction for closure effects deduced from the R ratio. The meaning of "constant ΔK_I tests" is also questionable in view of the large gradient in K_I, K_{II} and K_{III} along the front of a partially or completely slanted crack and of the reduction in ΔK_I associated with crack twisting.

In an effort toward 3D analysis, Pook [8] performed finite element computations of the stress intensity factors along the front of a fully slanted crack in specimens of different thickness. He found that K_I was 0.51 to 0.71 smaller than its apparent value (computed in 2D for a normal crack of same length). He also found that K_{III} had the same order of magnitude as K_I, while K_{II} raised near the free surfaces with a skew-symmetric profile. Bakker [9] performed 3D computations of stress intensity factors for fully or partially slanted crack. However, as in the case studied by Pook, a straight crack front was considered, while tunnelling probably plays a role in crack twisting in fatigue.

The present work re-examines the problem from a 3D perspective, in order to determine what mechanical parameters control the onset of crack deviation and the kinetics of slanted crack growth. Since environment seemed to influence shear lips development, a 3D experimental characterization of the crack paths and kinetics was performed, both in air and in salt water and the crack paths were compared. A 3D numerical analysis of the crack growth rates was done, based on linear elastic fracture mechanics, taking mode-mixity into account. Elastic-plastic computations of stress and strain fields ahead of the crack front were used to rationalize the observed crack paths. A method to predict the onset of crack twisting and the twist angles was proposed.

2. Experimental procedures

Fatigue crack growth tests were performed with a frequency of 5Hz and R=0.1 on 6mm-thick, 100mm-wide, 300mm-high Center-Cracked Panels (CCP) specimens. Two material were investigated: 7075-T651 aluminium alloy ($\sigma_{0,2}$= 376MPa, σ_u= 537MPa, E= 75 GPa) and S355 low-alloy steel ($\sigma_{0,2}$= 349MPa, σ_u= 510MPa, E= 205 GPa). Both sides of the specimens were polished to allow crack propagation monitoring with an optical microscope, at a magnification of one hundred. The tests were performed in air or in a transparent reservoir filled with 3,5g/l NaCl solution, under different loading amplitudes indicated in Table 1. Marker block loading sequences with and increased K_{min} but the same K_{max} were periodically applied, so that the R ratio became temporary 0.7, until approximately 100 μm propagation was achieved, in order to mark the position of the crack front and be able to derive the mean crack growth rate between consecutive markings, for any point along the front. Ten to twelve marker blocks were applied at 20Hz. To characterize crack front tunnelling, the difference in crack length between the mid-thickness and the average length on free surfaces was measured and denoted by Δa.

Table 1: Test conditions

Material	7075 T651			S355 steel	
Test n°	CCP7a	CCP7Na	CCP5a	CCP2a	CCP2Na
Environment	air	NaCl	air	air	NaCl
Range of apparent ΔK_I (Mpa$\sqrt{m}$)	7-18	7-18	9-20	18-35	18-35
Stress range (MPa)	34	34	40	100	100
Cycles for crack initiation	30000	10000	15000	35000	27000
Cycles of crack growth until fracture	202440	110260	59000	157730	138730

Fracture surface topographies were reconstructed using a digital optical microscope. The results were obtained as (x, y, z) triplets, where x denotes the distance from the notch root, y, the position in depth, and z the height from the notch plane. Transverse height profiles, z(y) were derived. Polynomial expressions were fitted to these profiles and used to compute the local twist angle as arctang (dz/dy). The shear lips width, denoted by t_s, was deduced from these height profiles.

3. Experimental results

Salt water reduced the number of cycles for crack initiation by a factor of 3 in the aluminium alloy and 1.3 in steel. Crack growth was significantly accelerated in the aluminium alloy, but not in steel. Figure 1 shows examples of crack transverse profiles, z(y), and twist angle profiles at different stages of crack growth.

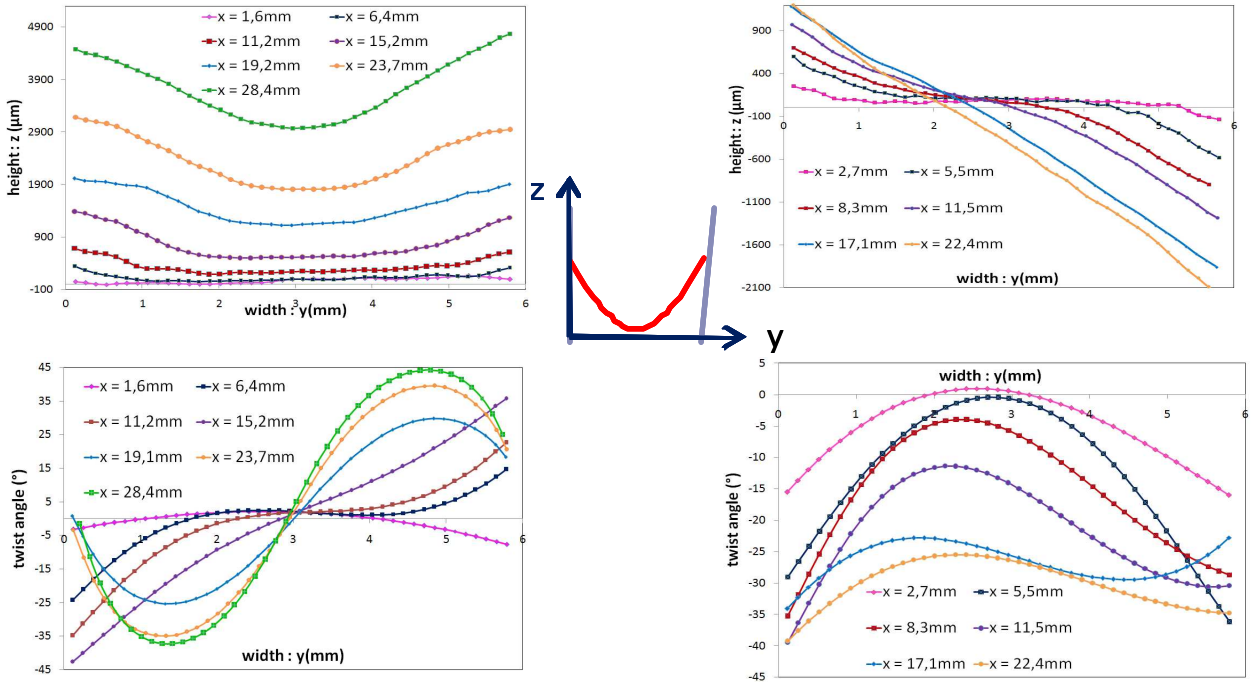

Fig 1: Topographic reconstructions of fracture surfaces. a) transverse profiles and b) twist angles for specimen CCP5a. c) transverse profiles and d) twist angles for specimen CCP2a.

The twist angle is neither uniform along the shear lip, nor constant as the crack grows. It is substantially less than 45°. In some cases, the peak value is not observed at the free surface but up to 1mm in depth. The evolutions of the shear lips width in air and NaCl solution under the same mechanical conditions are compared on Fig 2.

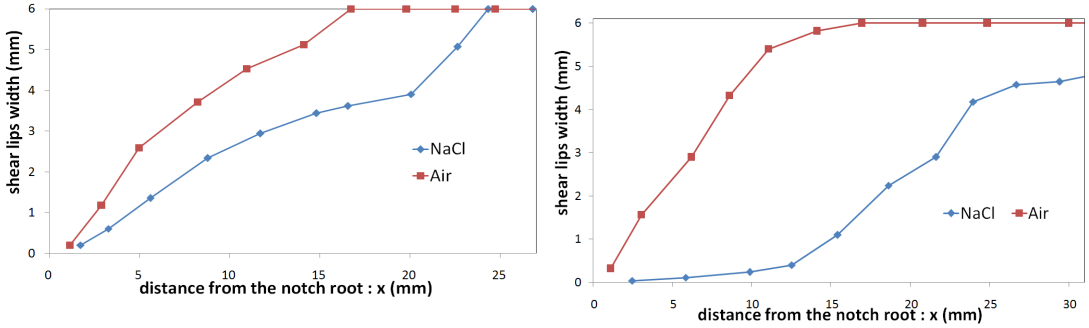

Fig 2: Evolution of shear lips width in air and NaCl solution under similar loading conditions
a) specimens CCP7a and CCP7Na and b) steel specimens CC2a and CCP2Na

Shear lips development was delayed and less complete in the NaCl solution, in agreement with some observations from the literature [2, 6]. The evolution of crack front tunnelling, Δa, is plotted on Fig 3.

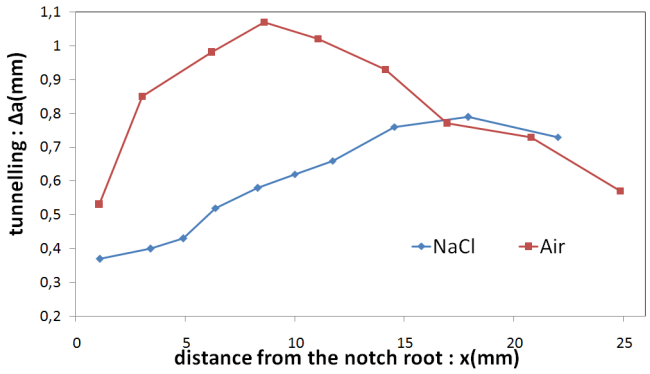

Fig 3: Evolution of crack front tunnelling, in steel specimens, in air or NaCl solution

In air, tunnelling was progressively reduced and cancelled by the development of shear lips, in spite of a drop in nominal ΔK_I in the slanted zones and of a probable local increase in closure effects, generally more important at low ΔK_I. Both factors should reduce the crack growth rate near the free surfaces and thus increase the convexity of the front. A reverse effect is observed. The reduction of tunnelling provides evidence for an effective contribution of shear modes to the crack driving force. However, fractographic observations revealed fatigue striations in normal zones as well as in slanted areas, where a few isolated rubbing marks were also observed near the side surfaces. Hence mode I still contributed to crack growth in the slanted zones and it would be incorrect to describe crack twisting as a transition from tension to shear-mode, as sometimes done in the literature.

4. Numerical study

The numerical study is constituted of two parts: 1) an elastic analysis in an extended finite element code (X-FEM, implemented in *Code_Aster* at EDF R&D, *www.**code-aster**.org/*) well fitted to

estimate the stress-intensity factors (SIFs) taking into account the real geometry of slanted cracks, but not suitable for the simulation of cyclic plasticity and 2) an elastic-plastic analysis carried out in the framework of the classical finite element method with Cast3M software (*www-**cast3m**.cea.fr/)*, therefore limited to flat tunnelling cracks. The stress-intensity factors issued from the X-FEM computations will be used to analyse the measured crack growth rates and to determine the parameter which best correlates the data. But the SIFs are considered useless for the prediction of crack paths, since none of the bifurcation criteria based on those parameters can predict that a fatigue crack loaded in mode I changes its path to grow in mixed-mode along a shear lip. In the present case, the crack paths are believed to be determined by the stress and strain fields just ahead of the crack front, which must be computed by elastic-plastic cyclic computations.

4.1 ***The X-FEM computation***

4.1. a General framework

The extended finite element method, introduced by Moes et al. [10], allows the simulation of complex crack shapes where the structural finite element mesh does not have to conform to the crack surface. The crack surface and its front are defined geometrically by two signed distance functions named “level sets”. In order to take into account the displacement jump due to the presence of the crack and the crack tip singularity the discretized displacement field is “enriched” with discontinuous shape functions. The displacement field is approximated as follows:

$$u(x) = \sum_{i \in I_0} N_i(x) u_i + \sum_{i \in I_H} N_i(x) H(x).a_i + \sum_{i \in I\gamma} N_i(x) \left(\sum_{k=1,4} \gamma_k(x).b_{i,k} \right) \quad (1)$$

In which H denotes the Heavyside function: $H(x) = \begin{cases} -1 \, if & x < 0 \\ +1 \, if & x > 0 \end{cases}$ (2)

I_0 is the set of the standard finite element nodes, I_H the set of nodes whose support is completely cut by the crack and I_γ the set of nodes whose support contains the crack front, a_i and $b_{i,k}$, the corresponding additional degrees of freedom. N_i are the standard finite element shape functions, u_i the nodal displacements and γ_k is the base of Westergaard’s solution representing the asymptotic displacement field at the crack tip of a semi-infinite crack in an infinite medium:

$$\gamma_k(x) = \left\{ \sqrt{r} \sin(\frac{\theta}{2}), \sqrt{r} \cos(\frac{\theta}{2}), \sqrt{r} \sin(\frac{\theta}{2}) \sin(\theta), \sqrt{r} \sin(\theta) \cos(\frac{\theta}{2}) \right\} \quad (3)$$

4.1. b Representation of the crack.

One of the ways to generate the level–sets used to represent the crack is to mesh both the crack surface and the crack front. This mesh is used only for the geometrical description of the crack and not for the resolution of the problem. An algorithm was thus developed to turn the measured topographic data, that is: a set of (x, y, z) triplets plus polynomial fits of crack front markings, into a mesh representative of the crack. The first step is to fit a polynomial interpolation to the cloud of points extracted from the topography, using the least square method, in 3D. Then a regular, flat grid of points is deformed, using both the equation of the crack surface z(x, y), and the polynomial fit of its front, x(y) (Fig. 4). This grid is then meshed with quadrangles and the linear elements of the

crack front are extracted.

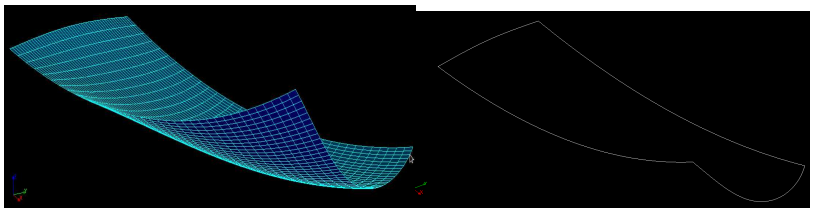

Fig 4: example of mesh of a crack surface used for level-sets computation

The G-θ method proposed by Destuynder et al. [11] was used to compute the SIFs. Due to corner point singularities, the values computed at surface points were not included in the analysis.

4.1. c The structural mesh.

Half of the CCP specimen was modelled with linear hexahedral (50µm*50µm*50µm) elements in a parallalepidal zone centered at the crack tip, linked to tetrahedral elements, via pyramidal elements, out of the process zone. The boundary conditions are indicated on Fig. 5.

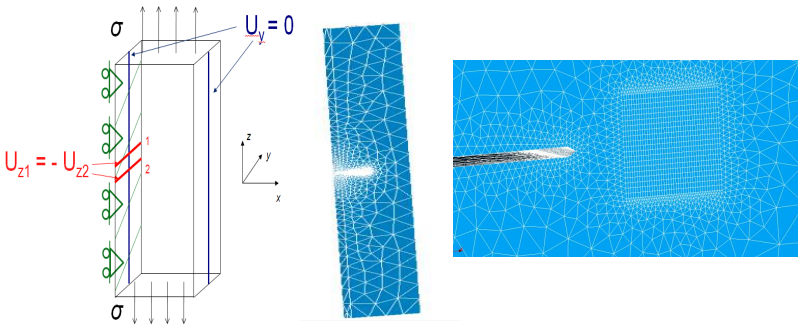

Fig 5: Boundary conditions and mesh of the CCP specimen in the X-FEM model

4.2. Elastic-plastic finite element analysis

This part focuses on the onset of crack twisting and thus considers flat, normal cracks, but takes tunnelling into account. Only a quarter of the CCP specimen was modelled, taking advantage of the symmetries. A 3D mesh with a straight crack front was first prepared, using linear elements, 30*30*150µm-wide near the crack front, which was then deformed, using the polynomial equation describing best the observed tunnelling front (Fig 7).

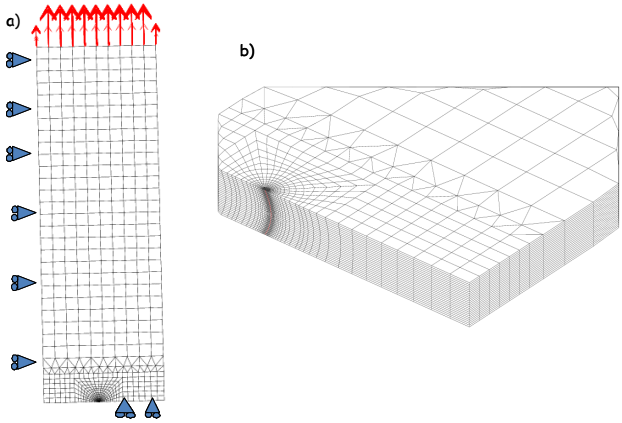

Figure 7: a) F.E. mesh of a quarter CCP specimen and boundary conditions, b) tunnelling crack front

Elastic-plastic constitutive equations with isotropic and non-linear kinematic hardening, identified from the stress-strain loops obtained from push-pull tests were used. Cyclic loading with R=0.1 was simulated. The stress and strain fields computed at maximum and minimum load were used for a local application, ahead of each node of the front, of a fatigue criterion derived from that identified by Zhao and Jiang from an extensive multiaxial fatigue database on 7075 T6 [12]. Their criterion successfully captured the transition in fracture mode observed in torsion as well as in push-pull or combined loading: when the loading range increases, fatigue damage changed from normal-stress-driven to shear-driven, yet with an assistance of an opening stress. Their damage function (DF) was thus:

$$DF = 2b\Delta\varepsilon_n \left\langle \sigma_{n\max} \right\rangle + \frac{1-b}{2}\Delta\tau\Delta\gamma \tag{4a}$$

$$b = \left\langle a_1 - a_2 \Delta\sigma_{eq} \right\rangle \tag{4b}$$

in which <x> denotes the positive part of x, a_1 and a_2 two fitted constants (0.862 and 0.00125), $\Delta\varepsilon_n$, $\Delta\gamma$, $\Delta\tau$, σ_{nmax}, respectively the normal strain, shear strain and stress range and peak opening stress, all computed along the critical plane. The latter is that for which the damage function, DF is maximum. As a consequence of Eq. 4b, the normal stress and strain play a major role at low stress range, but their influence decreases as the stress range increases, down to a transition stress range above which damage is merely driven by shear (b=0). In the present study, this criterion was slightly modified. The transition in fracture mode occurs in the low-cycle fatigue regime, where fatigue tests are usually strain-controlled, while the equivalent stress range evolves due to cyclic hardening. The value of $\Delta\sigma_{eq}$ which enters equation 4b was thus not clearly defined. The parameter b was thus considered to be more clearly related to the applied equivalent strain range, rather than to the stress range. Equation 4b was therefore turned into:

$$b = \left\langle 1 - \frac{2.\Delta\varepsilon_{eq}}{\Delta\varepsilon_{eq\,trans}} + \left(\frac{\Delta\varepsilon_{eq}}{\Delta\varepsilon_{eq\,trans}}\right)^2 \right\rangle \tag{5}$$

in which $\Delta\varepsilon_{eq,trans}$ corresponds to the equivalent strain range for which the transition from one fracture mode to the other is observed. A smoother evolution of b is predicted, compared to Eq. 4b. In addition, b tends toward 1 when the strain range vanishes, so that fracture is controlled merely by the normal stress and strain, which was not the case in the original criterion, for which the maximum value of b was 0.862. To apply the criterion ahead of each node of the crack front, $\Delta\varepsilon_{eq}$ was first averaged over a 90μm-long segment parallel to the x axis, comprising three elements. The local value of b was then computed using Eq. 5 with $\Delta\varepsilon_{eq,trans}$=0.92% for the aluminium alloy and 0.45% for steel. For each node, the damage function was computed, using the local value of b, along all potential twisted planes, for a twist angle θ ranging from 0 to 45°. The value of θ corresponding to the maximum of DF was considered as the local direction of crack extension. Here again stresses and strains were averaged over a distance of 90μm. This arbitrary distance, which influences the predicted crack paths should be considered as an adjustable parameter.

5. Numerical analysis of the experimental results

5.1. Computed SIFs and analysis of crack growth rates

Figure 8 shows the computed K_I, K_{II} and K_{III} computed at peak load along the 7th crack fronts in specimens CCP5a and CCP2a.

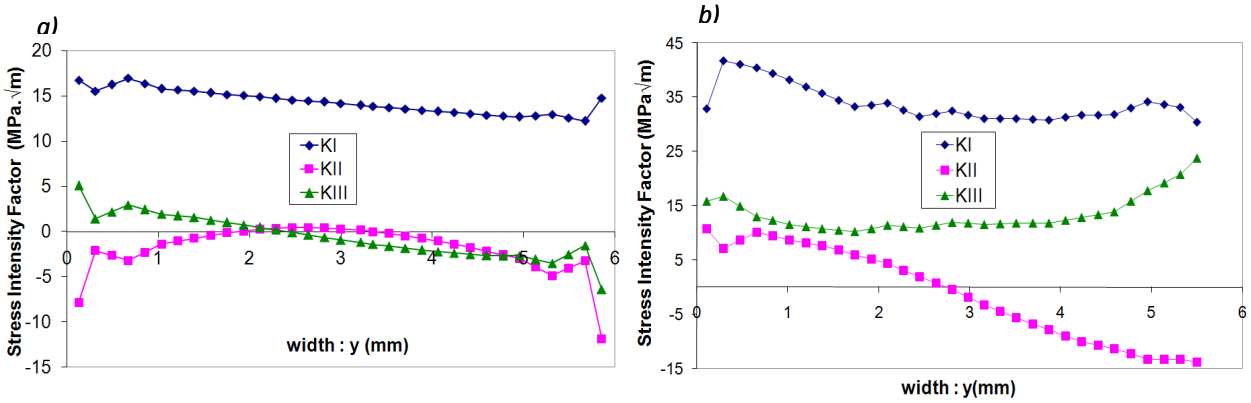

Figure 8: SIFs at peak load along the 7th crack fronts in a) Al specimen CCP5a b) steel specimen CCP2a.

The crack growth rates measured at various depths in these specimens are plotted versus ΔK_I on Fig. 9a and versus $\Delta K_{eq} = \sqrt{\Delta K_I^2 + \Delta K_{II}^2 + \frac{\Delta K_{III}^2}{(1-\nu)}}$ on Fig. 9b. While ΔK_I fails to correlate all the data, ΔK_{eq} provides a much better correlation, which gives additional evidence that opening and shear modes cooperate for slanted crack growth.

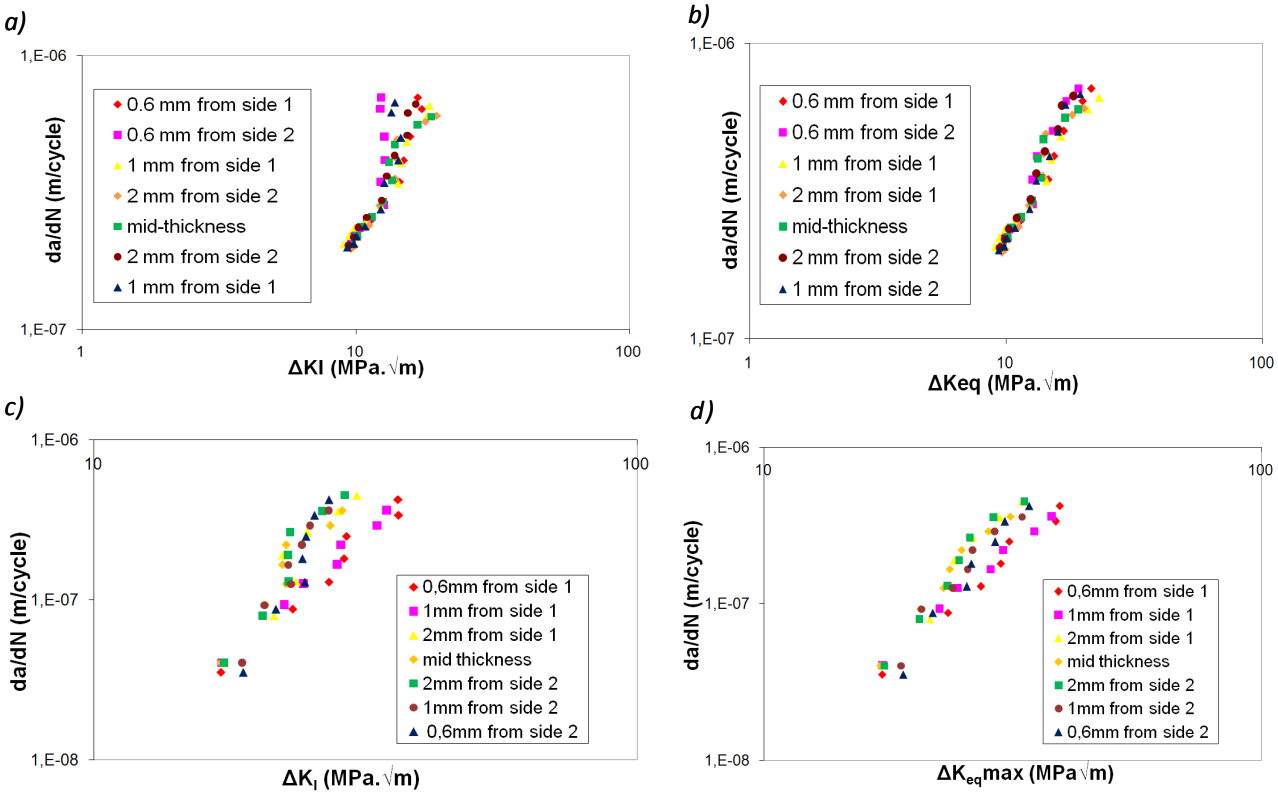

Figure 9: Correlation of measured crack growth rates in 7075-T6 with a) ΔK_I or b) ΔK_{eq} and in S355 steel with c) ΔK_I and d) ΔK_{eq}

5.2. Analysis of crack paths based on the local approach

Figure 10 shows the computed profiles of von Mises equivalent strain range ahead of the successive crack fronts for specimens CCP5a and CCP2a. Since ΔK increases as the crack grows, so does the equivalent strain range. $\Delta\varepsilon_{eq}$ rises near side surfaces. According to the fatigue criterion presented above, this should trigger a change in fracture mode (normal to slanted crack growth) there.

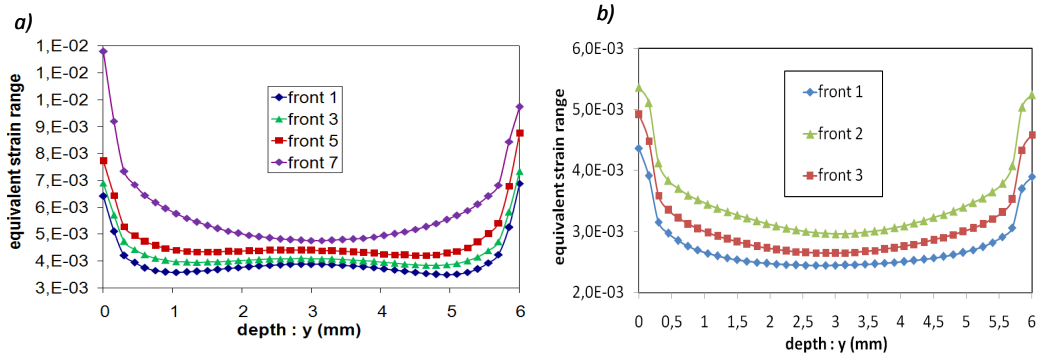

Figure 10: Profiles of Δ∈eq ahead of various crack fronts for a) specimen CCP5a and b) specimen CCP2a

Figure 11 shows the profiles of predicted twist angles. A progressive increase in twist angle as the crack grows is predicted near side surfaces. In some cases, as for the measured twist angles shown on Fig. 1b and 1d, the peak value of θ was not found at the free surface but somewhat inside.

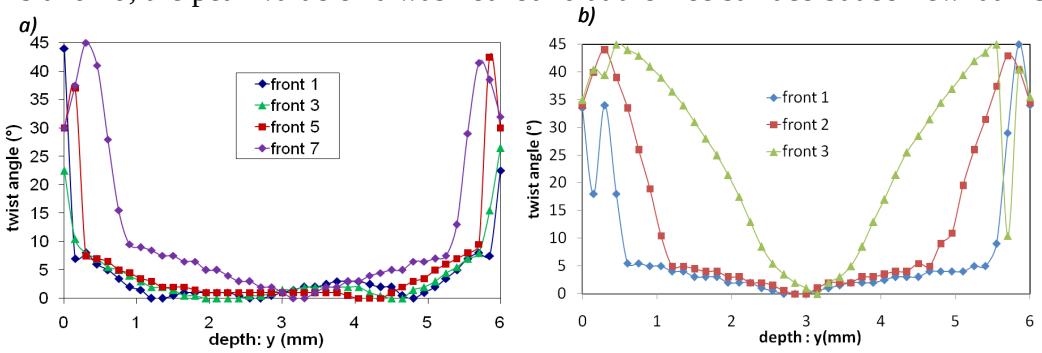

Figure 11: Profile of predicted twist angles for a) specimen CCP5a and b) specimen CCP2a

The shear lips width, t_s, was computed from such profiles, as the width of the part where $\theta \geq 4°$ in average. Figure 12 compares the predicted and measured evolutions of t_s. The model qualitatively captures the progressive increase in t_s.

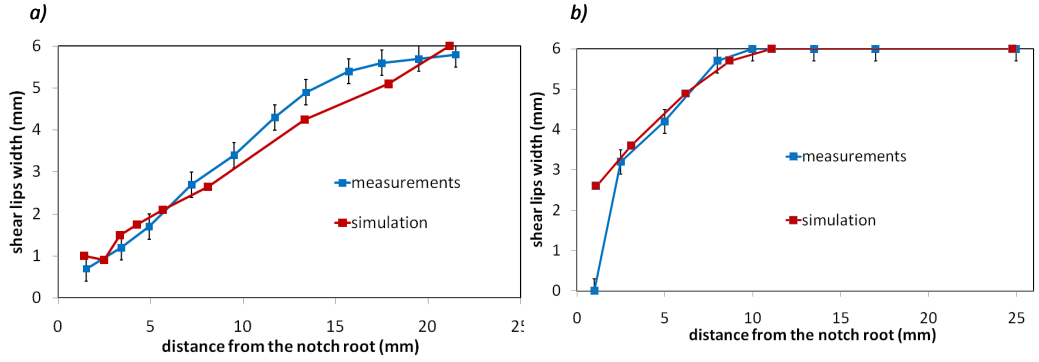

Figure 12: Predicted and measured evolution of shear lips width. a) ccp5a and b) ccp7a.

6. Conclusions and further work

Fatigue crack paths in thin sheets of aluminium alloy and mild steel were characterized in 3D in air and salt water. Crack twisting was delayed by a corrosive environment, which makes normal mode I crack growth more stable. Real 3D crack geometries were taken into account in an X-FEM model allowing the computation of K_I, K_{II}, K_{III} at any point along the front. Both the opening and shear modes contribute to slanted crack growth, whose rate correlates much better with $\Delta K_{eq} = \sqrt{\Delta K_I^2 + \Delta K_{II}^2 + \frac{\Delta K_{III}^2}{(1-\nu)}}$ than with ΔK_I. 3D elastic-plastic F.E. simulations and a local application of a fatigue criterion with a strain range-dependent critical plane qualitatively predicted the transition in crack growth mode and the twist angles. The challenge is now to develop incremental 3D simulations of mixed-mode slanted crack growth in a unified framework. The X-FEM method has to be modified to incorporate cyclic plasticity. This should allow predictions of both the crack growth kinetics and crack paths, based on the local approach mentioned above.

Abstract

Ceramic coatings are generally used on the facades of buildings. These materials provide acoustic and thermal insulation, achieving a reasonable comfort in buildings. The coatings are run in layers: plaster, adhesive mortar, grout and ceramic. They are subject to different weather and thus prompted the actions coming from sudden temperature variation or thermal shock. When you combine these actions with different physical and mechanical characteristics of the materials used, states of stress and strain on the facades are produced, creating different pathologies, such as peeling parts, which can cause accidents on pedestrians. This paper presents a methodology for evaluating the fatigue resistance, using experimental, analytical and numerical analysis via Finite Elements and considering the system under the action of heat loss shock temperature characteristic in the city of Brasilia. Studies are in particular the influence of thermo mechanical stresses in fatigue failure of the adhesive mortar. Experimentally a Whöler curve (or "SN" curve) is obtained for the adhesive mortar. With the appropriate models for fragile materials, the fatigue strength of the mortar under compressive and tensile-compression is deduced. With the values of temperatures and correspondent stresses obtained via analytical and numerical analysis it is possible, with this methodology, to assess the fatigue resistance of the adhesive mortar on the coating system.

Keywords: Fatigue coating, Coatingsystem, Stress facades

1. Introduction

Coatings on facades of buildings are used, among other purposes, for protection against the weather which have aggressive agents that reduce its lifespan. They also, have the property to give thermal and acoustic comfort to the user inside the building. Thus, the facades are exposed to various situations of thermal loads, arising from changes in temperature and isolation, which results in thermal stresses requested by the materials that make up the coating.

A ceramic coating system is an element for presenting different materials in different applications that must always maintain a balance between the stresses acting on the system and tension resistance of the materials so as not to compromise the integrity of the facade. In this paper we present the stresses inside the structure produced by outside thermal shock, when using clearceramic (low energetic absorption of heat) and dark ceramic (high-energetic absorption of heat), evaluating the structure performance against thermal shock cycles, which cause fatigue. The fatigue is evaluated by tracing the experimental curve or Wöhler SN, based on the principle that the thermal stresses acting on the system tend to cause their rupture by fatigue and using a coating structure composed of ceramic pieces and groutconstituting the outermost layer, connected with a thin layer of adhesive mortar in turn connected to a base composed of plaster. These structures are superposed on a masonry wall, which is coated with a layer of plaster facing the inside of the building. We tried to represent such a constructive disposition commonly used in Brazil.

2. Fatigue

The degradation process by fatigue is linked to deterioration under cyclic loading which leads to the emergence and development of microcracks or microfissures on the pre-existing material, and may cause rupture of the structure. The higher the stress level used, the lower the number of cycles achieved, and thus more rapidly deteriorate the mortar by fatigue, for the same frequency of loading. Coating systems are subject to an increase of stress due to temperature differences between the top and bottom of the wall and the coating system, causing large thermal differential that origin the warpage of the coating.

For the static fatigue analysis breakthrough curves are usually used that can be adapted to cyclic loading. In the analysis of fatigue strength material such as mortar which is a brittle material a classical curve that may be used is the Mohr-Coulomb curve. This curve defines the fatigue resistance of the material and the expected life of the material can be used with the stresses generated by the thermal shock on the system, and indicate whether there is a risk of collapse due to fatigue mortar.

3. Characterization of mortar

In this work the mortar ACII Votomassa was used, prepared according to the manufacturer's recommendations.

3.1. Definition of the body-of-evidence

Fatigue tests in compression, body-of-proof cylindrical 10x20cm were chosen according to the study by SUELEN, 2009.

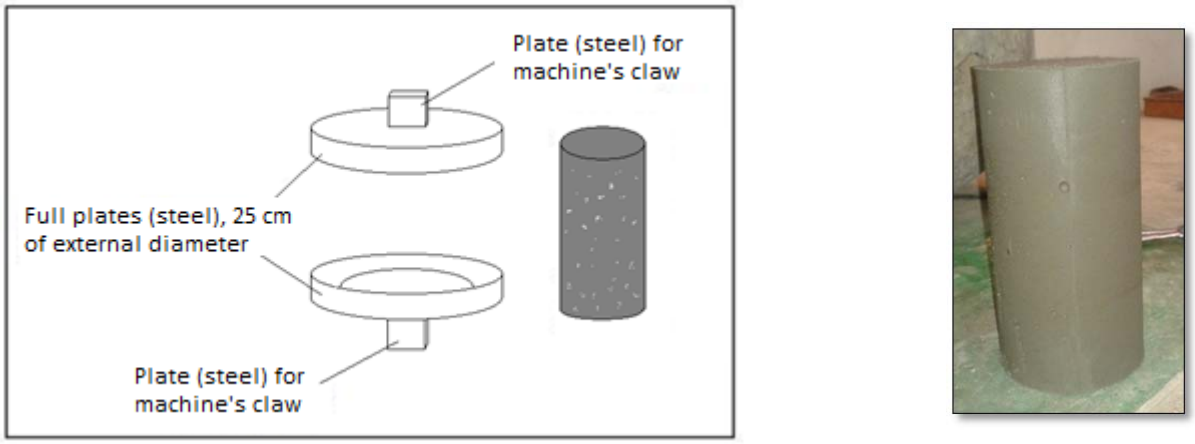

Figure 1 - Mechanism to support the fatigue test and compression test specimen.

3.2 Fatigue Testing

The fatigue test consists in applying a cyclic compression load on a body-of-evidence in order to measure how many cycles the body-of-evidence resists before rupturing. Thus, we obtain the Wöhler curve or SN curve. This assay is also capable of supplying a characteristic alternated stress for each material, below which the body of the test piece no longer breaks. The main results of this assay are: Narrow fatigue resistance (σ_{Rf}), ie the alternating stress value below which the body of

the test piece not further ruptures by fatigue; Life fatigue (N_f), or the number of cycles that rupture occurs in the body of the test piece for a particular alternated stress level (S) above (σ_{Rf}).
After sizing the body-of-evidence, the realization of the mortar compression fatigue test is next. The tests were performed on a universal testing machine MTS 810, being made via control force which results in constant amplitude alternating stress across the tests.
The body of the test piece was cast in a mold iron, running in three layers of 4 cm each, and applying 25 blows on each layer. The procedure for determining the body-of-evidence to the MTS 810 was given as follows: initially, for the specimen used in the compression test, we used two circular steel plates holding the specimen fixed. As can be seen in Figure 2a and Figure 2b.

(a)

(b)

Figure 2– (a) - (b)Endurance test compression.

4. Thermal Analysis

The purpose of the thermal analysis was to determine how the temperature distribution behaves inside the wall, and therefore inside coating structure, after the incidence of atmospheric thermal shock abroad. The first mathematical simplification was made to adopt an equivalent wall composed of only one material, which replaces the conventional wall, composed of five layers of materials. Thus it was possible to work with only one equivalentthermal diffusivity parameter(α_{eq}).
The temperature distribution analyticalequation$U(y,t)$varies in function of the wall thickness (direction$y$) and time (t).It was obtained from the problem depicted in partial differential equation of heat diffusion:

$$\alpha_{eq}\frac{\partial^2 U}{\partial y^2}=\frac{\partial U}{\partial t} \tag{3}$$

The boundary conditions of the problem, then, represent the heat exchanges by conduction and convectionat the faces facing the interior and exterior of the building:

$$-K_{eq}\frac{\partial U(d,t)}{\partial y}=h_e\big(U(d,t)-U_\infty(t)\big)-\gamma I_g(t) \tag{4}$$

$$-K_{eq}\frac{\partial U(0,t)}{\partial y}=h_i\big(U_i-U(0,t)\big) \tag{5}$$

Where$U_\infty(t)$is the air temperature outside the building, and$I_g(t)$represents the supply of thermal energy from the sun to the facade over time, modeling it as a source of heat within the system. Having in mind that τ is the time instant at which occurs the heat shock, these features were modeled as it follows:

$$U_{\infty}(t) = U_a + (U_c - U_a)H(t-\tau) \tag{6}$$

$$I_g(t) = \gamma I_g\big(1 - H(t-\tau)\big) \tag{7}$$

Where,$H(t-\tau)$is the Heaviside mathematical function (step function) definedby

$$H(t-\tau) = \begin{cases} 0, & t < \tau \\ 1, & t \geq \tau \end{cases} \tag{8}$$

Other variables of the problem are:

- $K_{eq} = 1{,}19$ W/m°C: Thermal Conductivity of the equivalent wall;
- $\alpha_{eq} = 6{,}33 \times 10^{-7}$m²/seg: Equivalent Thermal diffusivity. Single value of thermal diffusivity for the entire coating structure;
- $d = 25{,}15$cm: Total thickness of the wall where the structure of ceramic coating, outward looking;
- $l_1 = 2$cm: Thickness of plaster layer facing the interior of the building. Not part of the structure of the ceramic coating;
- $l_2 = 20$cm: Thickness ofthe masonry wall layer. Substrate where theceramic coating structure is applied;
- $h_i = 9$W/m² °C: Coefficient of air heat transfer from inside the building into the wall structure where the internal plaster layer lays;
- $h_e = 18$W/m² °C: Coefficient of atmospheric air heat transfer from outside the building into the wall structure where the ceramic coating lays;
- $U_i = 21$°C: air temperature inside the building where is the wall subjected to thermal shock;
- $U_a = 34{,}60$°C: Temperature of the atmospheric air outside the building moments immediately prior to the occurrence of thermal shock;
- $U_c = 22{,}14$°C: Temperature of the atmospheric air outside the building moments immediately following the occurrence of thermal shock;
- λ_n:∶ Eigenvalues obtained numerically by the following equation:

$$\lambda \cos \lambda d - \frac{\lambda^2 K_{eq}}{h_i} \sin \lambda d + \frac{h_e}{K_{eq}} \sin \lambda d + \frac{\lambda h_e}{h_i} \cos \lambda d = 0 \tag{9}$$

- CF_n: Coefficients of Fourier Series describing the temperature distribution;
- γ: Coefficient of Solar Radiation Absorption of ceramic coating. Worth 0.45 to 0.95 for clear anddark ceramic pottery.
- $I_g = 692$ W/m²: Solar Thermal Energy Incident on the ceramic surface, moments immediately prior to heat shock.

The values of the parameters described were obtained in Saraiva (1998), Moaveni (2008), Uchôa (2007) and Rosa (2001). Thus the modeled thermal shock itself contains a mathematical simplification, which consists in the instant change of atmospheric conditions in contact with the

outer face of the wall. A further simplification is the admission that before the heat shock event, the wall is in a steady state temperature distribution, simplification considered conservative.
Thus, solving the problem has been that the coating structure in equation ($t \geq 0$) is given by:

$$U(y,t) = \frac{h_e U_c K_{eq} + h_i U_i K_{eq} + h_i h_e U_i d + [h_e h_i (U_c - U_i)](y + l_1 + l_2)}{K_{eq}(h_e + h_i) + d h_e h_i} - \sum_{n=1}^{\infty} CF_n e^{-\alpha_{eq} \lambda_n{}^2 t} \left(\sin \lambda_n (y + l_1 + l_2) + \frac{\lambda_n K_{eq}}{h_i} \cos \lambda_n (y + l_1 + l_2) \right) \quad (10)$$

$$CF_n = \frac{2\lambda_n{}^{-1} h_i \left[h_i{}^2 (\sin \lambda_n d - \lambda_n d \cos \lambda_n d) + \lambda_n{}^2 K_{eq} \sin \lambda_n d \, (h_i d + K_{eq}) \right] \left[h_e (U_c - U_a) - \gamma I_g \right]}{\left(2\lambda_n K_{eq} h_i (\sin^2 \lambda_n d) + \left(\lambda_n{}^2 K_{eq}{}^2 - h_i{}^2 \right) \sin \lambda_n d \cos \lambda_n d + \lambda_n d \left(\lambda_n{}^2 K_{eq}{}^2 + h_i{}^2 \right) \right) \left(K_{eq}(h_e + h_i) + d h_e h_i \right)} \quad (11)$$

Therefore, we obtain values of temperature in each wall layer in the form of one-dimensional distribution.

5. Adopted numerical model

To evaluate the stresses that arise in the three outer layers of the wall(which characterize the structure of the coating)regarding the temperature distribution described by the analytical equation obtained, we choose to model the coating structure with a finite element mesh. Modeling in a coating system of 4.90 m length in each direction, having in mind that Fiorito (1994) suggests that, on a wall, positioning the drive joints should be at least every 4.90 m distance. However, as been done in previous studies of Uchôa (2007) and Saraiva (1998), it is appropriate to focus the analysis in only a small region of that piece of facade. Therefore, a region containing only three ceramic riding up a region equivalent shell around the three ceramics is choosen, as shown in Figure 3 below:

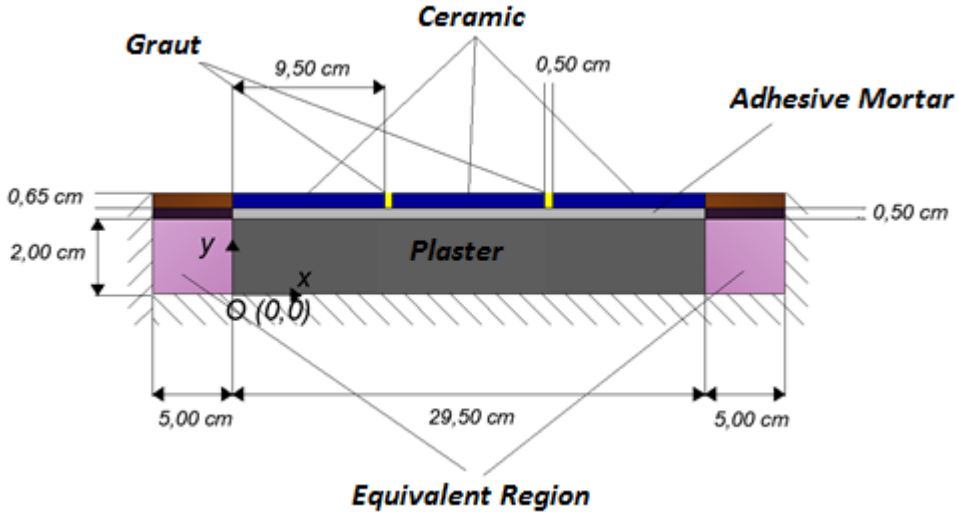

Figure 3-Structure model to be analyzed and dimensions.

The boundary condition used to simulate the structure is based in the assumption that the substrate is rigid.Thus, in the boundary between the coating and the substrate the displacements in the y-axis must be equal to zero. The equivalent regions and their very neighborhoodare not considered objects of study, being focus the central regions of the system. The idea would be to avoid disturbances generated at the boundary, which does not produce consistent results, as argued by Saraiva (1998).

Table1- Material properties of the coating structure and facade equivalent.

Material	**ElasticityModulus - E (GPa)**	**Thermal Expansion Coefficient - α ($°C^{-1}$)**	**Poisson'sRatio - ν**
Plaster	5,499	$11,5 \times 10^{-6}$	0,2
Mortar	3,562	$8,7 \times 10^{-6}$	0,2
Graut	7,879	$4,2 \times 10^{-6}$	0,2
Ceramic	41,600	$6,8 \times 10^{-6}$	0,2
Eq.Plaster	0,11941	530×10^{-6}	0,2
Eq.Mortar	0,07735	400×10^{-6}	0,2
Eq.CeramicandGraut	0,78891	310×10^{-6}	0,2

Once modeled of the facade, the application ANSYS (1994) is ran to convert it into finite elements. Among the factors contained in the library of ANSYS (1994) the element named PLANE42 was used, which has four nodes having two degrees of freedom per node: the displacements in the directions *"x"* and *"y"*.The PLANE42 element accepts temperature as charging, and allows inputting parameters such as elasticity modulus, thermal expansioncoefficient of, Poisson's ratio in the materials and structures modeled with the element.

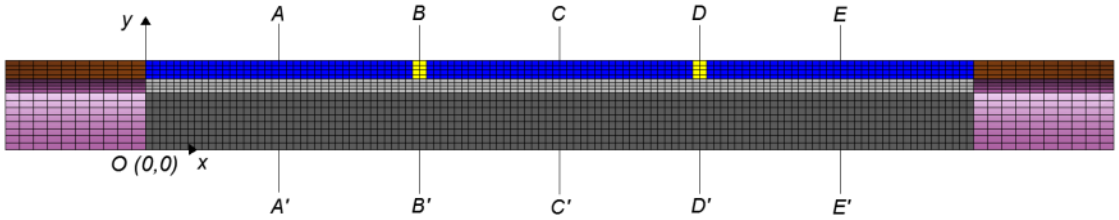

Figure 4 - Finite element mesh structure characterizing the coating studied.

6. Results Presentation

After insertingnodal temperatures in each nodal layer the model, obtained through the temperature distribution equation, the application ANSYS (1994) is ran again, outputtingthestresses that affect the coating structure. The stresses obtained were: SX to the normal stresses in the x direction; SY to the normal stress in the y direction; SXY for the shear stresses; and S1 and S2 to the principal stresses.

According to the above, two constructive situations were studied: using clear ceramic, and using dark ceramic. In each case were evaluated three sections shown in Figure 4: AA ', passing through

the center of the first ceramic; BB' passing through the layer of grout, and CC 'passing through the ceramic core. Therefore, the influence of ceramic and cross-sectional analysiswere evaluated.

6.1 Temperature Distribution

As explained in the item 4, we adopted the simplifying assumption that, before the heat shock, the coating structure presented steady state temperature distribution. Therefore the most critical condition in which the structure has higher temperatures is the initial. When the thermal shock atmospheric occurred, the coating structure begins to gradually lose heat to the air, seeking new situation of steady state, with higher speed of temperature decrease in the first few minutes. The clear ceramic shows lower temperatures than the dark because it has a lower coefficient of thermal absorption.

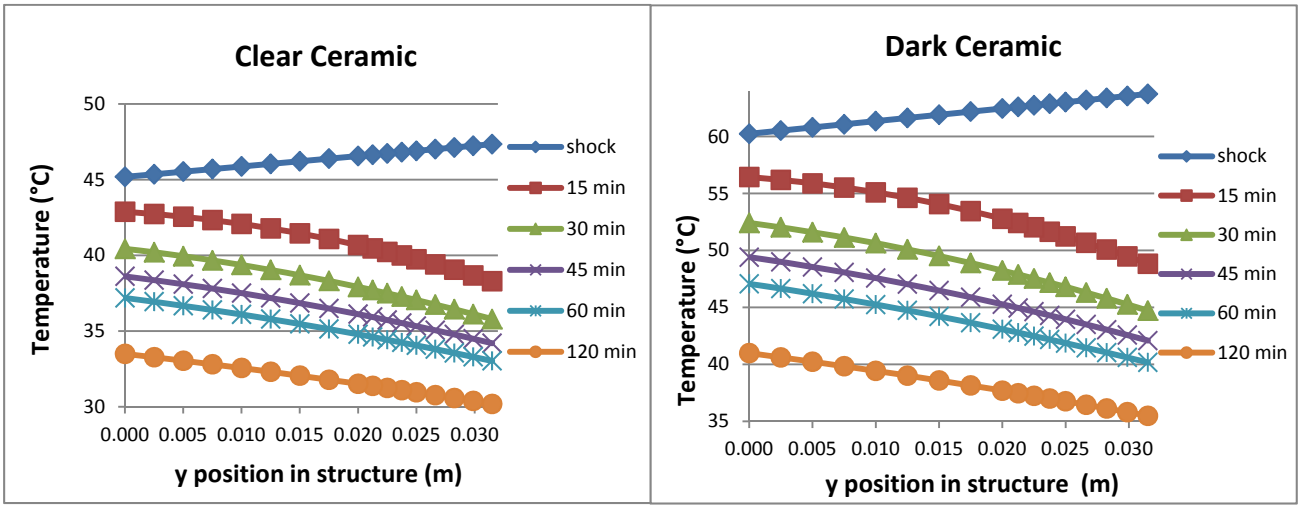

Figure 5 – Temperaturesobtained for ceramics dark and clear

6.2Analysis of stresses

Considering that the highest temperatures are shown at the beginning, also the highest stressesare present at that moment. Because the model with clear ceramic works with lower temperatures, stresses values in this model were lower when compared with the dark ceramic. During the cooling of the layers of the structure, due to thermal shock, there is also the relief of the stresses that request it. Negative values indicate compressive stresses, and the positive tensile stresses.

With regard to stresses SX, it was found that the models worked with compressive stresses in all three layers. This is due to the fact that when the structure is heated before heat shock, it tends to swell; however, their deformation is prevented by the boundary conditions of zero displacement at the ends. From here the compressive stress analysis are originated. The ceramic pieces in sections AA 'and CC' have the highest stress values because they have the higher modulus of elasticity (41.6 GPa). Because of high modulus of elasticity, the ceramic ultimately absorb much of the compressive stress that would be passed on to lower layers. Moreover, the grout atBB' top is significantly less rigid than the ceramic (modulus of 7.879 MPa) and therefore ends up being compressed by the ceramic part, deforming and allowing major deformations, thus,allowing the passage of more stresses for the subsequent layers of adhesive mortar and plaster, which is why

tensions SXin plaster and adhesive mortarof BB’ section are higher than observed in sections AA’ and BB’.

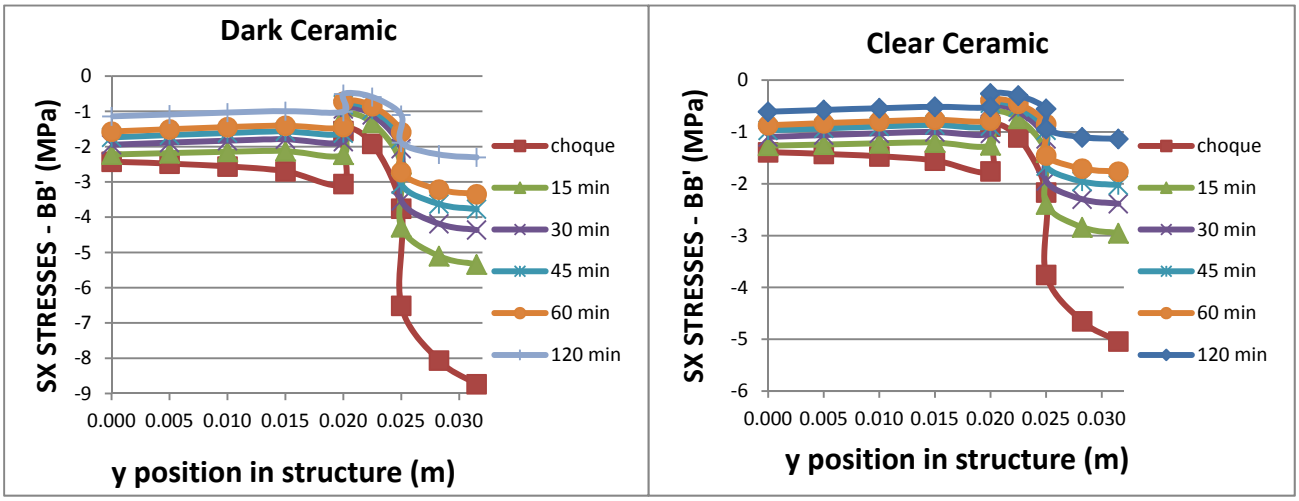

Figure 6 –SX stresses in section BB’ after thermal shock, ceramicsclear and dark

Regarding the SY stresses, due to the compressive stress in the x direction, the sections AA’ and CC’ there were tensile stresses in the sense tendency to detachment between layers of the structure. The highest stress values were observed in these layers beneath the layer of plaster, where was restrictionof no movement. Moreover, layers of plaster and adhesive mortar section BB’ worked with SY compression stresses, and the main reason is because the ceramic parts are compressing the grout in the x direction. In response, crushed grout spreads up and down in the vertical direction, compressing both the adhesive mortar as the plaster situated below it.

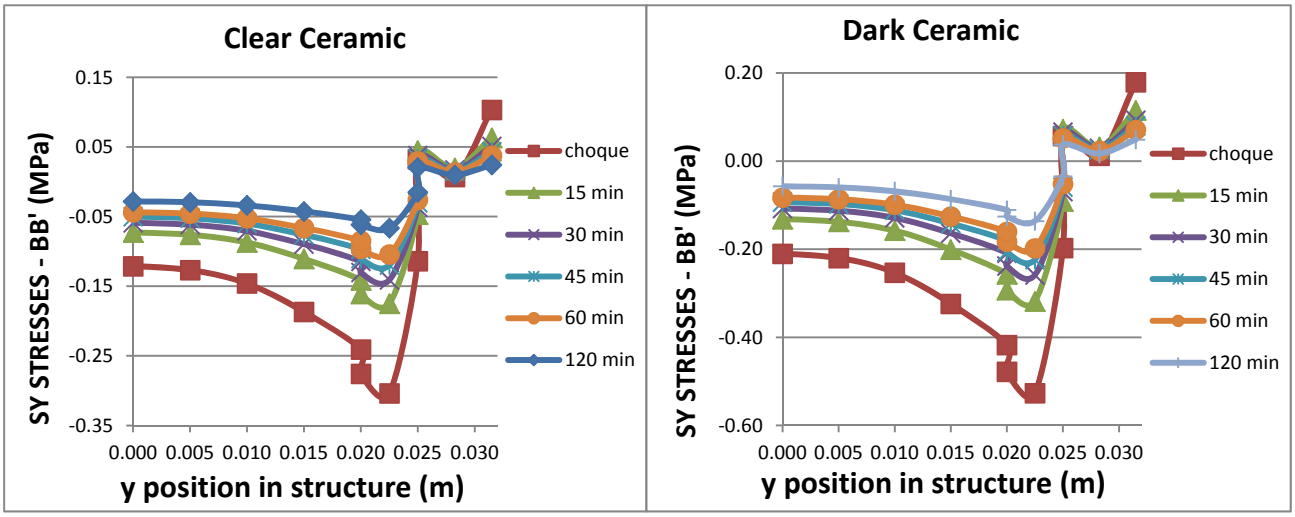

Figure 7 – SY stresses in section BB’ after thermal shock, ceramicsclear and dark.

TheSXY shear stresses encountered to the coating structure in both models were very low compared to the stresses SX and SY. In section CC’ the values were effectively zero, due to the central position of this section. The reason for the low values of SXY is because of the deformations within the structure are of thermal nature, which normally do not produce shear stresses. As a result, the values should be more restrictions on movement imposed on the structure than the thermal loading

properly. So, it follows that the principal stresses S1 and S2 have almost the same values SY and SX, respectively.

6.3Performance of the mortar layer on the fatigue

Given that the thermal shock is a transient phenomenon, which produces variation in the stress state along time, one can understand the difference between the final state and the initial state of stresses as the alternated loads that affect the structure. Then it is appropriate to evaluate the performance of the structure (specifically the adhesive mortar) as fatigue, determining how many cycles of alternating stresses (S) are necessary to the rupture.
In this paper, only the performance of the layer of adhesive mortar is evaluated. For this, Equations 12 and 13 are used, which displays the linearized equation of SN curve (or Wöhler curve) for the adhesive mortar, obtained under test. The critical situations, where the highest stresses occurred, in the mortar, were on top of layer (grout interface) to the stresses S2, and at the base of the layer (plaster interface) to stress S1, both in section BB' section.

$$S = 9{,}5771 - 0{,}7523\log(N), \quad N < 1{,}1 \times 10^6 \tag{12}$$

$$S = \sigma_{Rf} = 5{,}06\,MPa, \quad N > 1{,}1 \times 10^6 \tag{13}$$

Table 3 – Calculation of alternatedstress

CASE1 (CLEAR CERAMIC)			
	PRINCIPAL STRESSES (MPa)		ALTERNATED STRESSES(MPa)
	during shock	120 min	ΔS = S (120 min) - S (Shock)
S1	-0,27579	-0,06181	-0,06181 – (-0,27579) = 0,21398
S2	-2,16630	-0,55252	-0,55252 – (-2,16630) = 1,61378
CASE2 (DARKCERAMIC)			
	PRINCIPAL STRESSES (MPa)		ALTERNATED STRESSES(MPa)
	during shock	120 min	ΔS = S (120 min) - S (Shock)
S1	-0,47798	-0,12571	-0,12571 – (-0,47798) = 0,35227
S2	-3,75780	-1,10190	-1,10190 – (-3,75780) = 2,65590

So for both cases, there is no risk of fatigue failure in any of the directions of principal stress, because the variation of both principal stresses ΔS1 and ΔS2 is smaller than the threshold fatigue resistance (σ_{Rf}=5,06 MPa).

7. Final Thoughts

The methodology consisted of three phases: characterization tests of the behavior of the adhesive mortar when subjected to cyclic loading; the conception of an analytical equation to explain the temperature distribution inside the coating structure, in responseto the incidence of heat loss shock;

and using numerical model in finite elements to determine the stresses arising within the coating due to the temperature distribution over time.

In step test was determined the 5,06Mpavalue as the limit of fatigue resistance of the adhesive mortar. In consequence, as the alternated stresses levels in the mortar layer does not reach this value, according to this methodology there is no risk of breakage of this layer to either case. This is due to the fact that among the materials that compose the structure, the mortar is the one with the lowest value of elasticity modulus.

However, it is recommended to apply the methodology also for the other layers, especially layers of grout (subjected to large compression caused by the movement of ceramics) and ceramic (because they are subject to the higher stress levels, including bending stresses). Consequently, it is necessary to perform characterization tests for types of grout, besides testing flexural behavior for ceramic pieces.

Statistical Model of Submicrocrack Evolution under Cyclic Loading

Oleg Plekhov*, **Oleg Naimark**

Institute of continuous media mechanics Ural Branch Russian academy of science, 614013, Perm, Russia
*poa@icmm.ru

Abstract To describe the damage evolution under high- and gigacyclic fatigue we develop a generalization of statistical model of microcrack evolution. The statistical model combined with a stochastic description of damage accumulation process allows us to describe the interaction of microplastisity and damage (submicrocracks) under cyclic deformation and propose a model of fatigue crack initiation. Considering a fatigue crack initiation as a blow-up regime of damage accumulation we propose a method for prediction of SN-curves of materials. The SN-curve has dual form caused by shift the location of crack initiation from surface to the bulk of specimen.

Keywords statistical model of defects, gigacyclic fatigue, dual Woller curve

1. Introduction

It is now well known that real metals have complex structure, which is a hierarchy of different levels. Under deformation process the structural evolution observed at all scale levels and leads to irreversible deformation and destruction. The most interesting situation observed under gigacyclic fatigue when the stress amplitude is less than the yield stress of materials and fracture emergence under macroscopic “pure” elastic conditions. One of most critical issue of the gigacyclic fatigue is the location of fatigue crack initiation. The decreasing of stress amplitude leads to the shift of crack initiation from specimen surface to the bulk.

To develop a model of defect evolution under small stress amplitude we have to choice of the basic physical level of description of the material microstructure and describe the geometry of the elementary defects. Analysis of the experimental results of the study of structural levels of plastic deformation and fracture [1,2] and resent experimental investigation of damage evolution of fine grain metals can hypothesize that scale level with the size of submicrocracks 0.1-0.3 mm plays a key role in this process [3]. The failure process includes both the nucleation of new microcracks and their development. The contribution of these processes in the failure varies depending on the structure of the material conditions of its loading.

The defect kinetics is different near specimen surface and in the bulk. The rate of microcracks nucleus initiation in the surface layers of one to three orders of magnitude higher than in the bulk material. It is also well known that for high concentration the defect ensemble exhibits both collective and nonlocal effects.

One of the possible descriptions of defect kinetics is the statistical model of defect ensample. This model has to take into account the stochastically properties of defect initiation, their nonlinear integration and link between micropalsticity and damage accumulation.

This work is devoted to the development of such model in the application to cyclic loading of metals. The paper is organized as follow. The first part is devoted to the statistical description of submicrocrack ensemble. The statistical description was developed based on the mean field approximation of defect interaction and allows us to investigate the effect of initial nucleus concentration of defect evolution process and determine the equilibrium state of materials with

defects.

The second part of the paper devoted to the thermodynamic description of deformation process. Based on the results of solution of the statistical problem we introduce a new thermodynamic variable and derive the constitutive equation for metals with submicrocracks.

In the last part the proposed constitutive equation applied for the description of defect kinetics near specimen surface and in the bulk. The model allows us to describe the shift of crack initiation location from the specimen surface to the bulk and numerically obtain dual S-N curve for 2023 T3 aluminum alloys.

The discuses about physics of the investigated process and proposition for father experimental verification of the model presented in conclusion.

2. Statistical description of damage accumulation in metals

The data obtained from systematic studies of defects evolution, carried out at Physical technical institute named after A.F. Ioffe RAS shows that the volume defects (submicrocracks with characteristic size about 0.1 mkm) play the important role in deformation process [3]. These defects emerge at the early stage of deformation and effect on the microplasticity and failure processes. The same situation could be observed under cyclic loading. The best materials for the experimental proofing of this hypothesis are the fine grain metals which contained the high concentration of volumes defects (micropores) after manufacturing procedures (equals channel pressing).

The value, geometrically representing the real microcracks with allowance made for a variety of their shapes, sizes and arbitrary orientations as well as or the crack initiated material loosening, can be introduced in terms of the dislocation theory [4].

The dislocation loop D, bounding the surface S, where the displacement vector undergoes a finite increment equal the Burgers vector b, is characterized by the tensor of the dislocation moment $S\nu_i b_k$. The sum of N dislocation loops, which is equivalent to a microcrack, introduces the tensor of dislocation moment of a microcrack:

$$s_{ik} = \sum_{l=1}^{N} S^l \nu_i^l b_k^l, \tag{1}$$

where $\vec{\nu}^l$ is the vector of a normal to the surface S of the 1-th loop. Small sizes and multiple character of microcrack nucleation as well as size and orientation distributions of microcracks permit averaging of their parameters over elementary volume to obtain the macroscopic tensor

$$p_{ik} = n\langle s_{ik} \rangle, \tag{2}$$

where n is a concentration of microcracks.

A solution of equation (2) was presented in [4]. The solution depends on structural parameter δ and defect concentration n. Figure 1 presents two solutions of the equation (2) for $\delta = 1.1$ and different values of initial defect concentration (curves 1,2).

To describe a real deformation process which characterized by the growth of defect concentration we propose that the representative material volume V_r contains $n_0 V_r$ defects

nucleuses. Following [5] we propose that the applied stress activates the defects and this process can be described as a stochastic Poisson point process with intensity function $n(\Sigma)$.

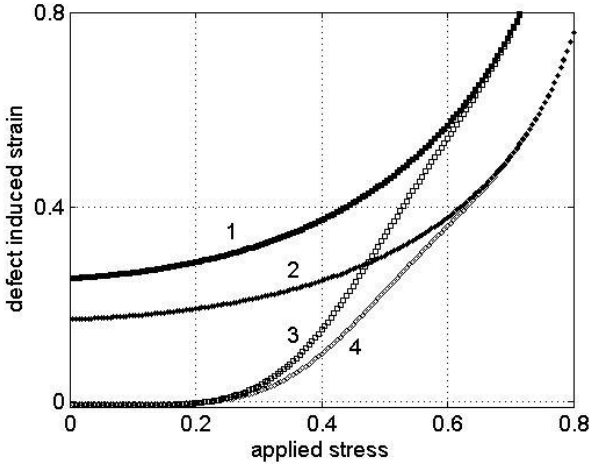

Figure 1. Equilibrium defect induced strain versus applied stress for different values of initial defect concentration (curves 1,2) and the mean values of defect induced strain during deformation process (curves 3,4).

Intensity function describes both the growth of active defects (which contribute to the defect induced strain) and growth defect nucleuses. Following the experimental data [5] about evolution of microcrack concentration we can assume the following approximation for intensity function

$$n(\Sigma)=\frac{\alpha_0}{2}\left(1+Erf\left(\frac{\Sigma-\Sigma_0}{\Sigma_1}\right)\right)(n_0+\alpha_1\Sigma), \tag{3}$$

where $\alpha_0,\alpha_1,\Sigma_0,\Sigma_1$ - material constants.

The probability of find N active defects in representative material volume is $P(N)=\frac{n(\Sigma)^N Exp(-n(\Sigma))}{N!}$.

The stochastic consideration of defect evolution process change the self-consistency equation for defect induced deformation. The solution of equation (2,3) is presented in figure 1 (curves 3,4). For small stress values we observe a pure elasticity which passes to the plastic deformation with different intensity. The intensity of plastic deformation and damage accumulation depends on the initial concentration of defect nucleuses.

3. Thermodynamics of metals with defects

A thermomechanical process of plastic deformation obeys the momentum balance equation and the first and second laws of thermodynamics. In the case of small deformation, these equations involve the following thermodynamic quantities: volumetric mass ρ, specific internal energy e, strain and stress tensors ε_{ik} and σ_{ik}, heat supply r, heat flux vector $\vec{q}$, specific Helmholtz free

energy F, and specific entropy η. The energy balance and the entropy can be written as

$$\dot{e} \equiv \left(\dot{F} + \eta\dot{T} + \dot{\eta}T\right) = \frac{1}{\rho}\sigma_{ik} : \dot{\varepsilon}_{ik} + r - \overline{\nabla} \cdot \overline{q}\,, \tag{4}$$

$$\dot{\eta} - \overline{\nabla} \cdot \left(\frac{\overline{q}}{T}\right) - r' \geq 0\,,$$

where $\overline{\nabla} = \left(\frac{\partial}{x_1}, \frac{\partial}{x_2}, \frac{\partial}{x_3}\right)$, the superposed dot stands for the material time derivative.

We assume the following kinematical relationship for the material under study

$$\tilde{\varepsilon} = \tilde{\varepsilon}^{e} + \tilde{\varepsilon}^{p} + \tilde{p} + \tilde{\beta}\left(T - T'\right), \tag{5}$$

where ε_{ik}^{e} is the elastic strain tensor, $\tilde{\varepsilon}^{p}$ is the plastic strain tensor (related to the defect motion), $\tilde{\beta}$ is the thermal expansion coefficient tensor, and T' is the reference temperature.

To introduce the list of independent variables for the free energy $F\left(\tilde{\varepsilon}^{e}, T, \tilde{p}\right)$ the equations (4) give

$$-\vec{q} \cdot \frac{\overline{\nabla} T}{T} - F_{\tilde{p}} : \dot{\tilde{p}} + \frac{1}{\rho}\tilde{\sigma} : \left(\dot{\tilde{\varepsilon}}^{p} + \dot{\tilde{p}}\right) \geq 0\,, \tag{6}$$

$$c\dot{T} = \overline{\nabla}\overline{q} + r + Q^{e} + Q^{p}\,, \tag{7}$$

where $Q^{e} = TF_{T\varepsilon^{e}} : \dot{\tilde{\varepsilon}}^{e}$ - heat production due to thermoelastic effect; $Q^{p} = TF_{Tp} : \dot{\tilde{p}} + \frac{1}{\rho}\tilde{\sigma} : \dot{\tilde{\varepsilon}}^{p} + \left(\frac{1}{\rho}\tilde{\sigma} - F_{p}\right) : \dot{\tilde{p}}$ - represents the inelastic part to the heat production; $c = -TF_{TT}$ - the specific heat capacity.

To assume the linear links between thermodynamic forces and the thermodynamics fluxes, we obtain the constitutive equations

$$\dot{\tilde{\varepsilon}}^{p} = l_{\varepsilon^{p}} F_{\tilde{\varepsilon}^{e}} + l_{\varepsilon^{p}p}\left(F_{\tilde{\varepsilon}^{e}} - F_{\tilde{p}}\right), \tag{8}$$

$$\dot{\tilde{p}} = l_{p}\left(F_{\tilde{\varepsilon}^{e}} - F_{\tilde{p}}\right) + l_{\varepsilon^{p}p} F_{\tilde{\varepsilon}^{e}}\,, \tag{9}$$

where the function F_{p} follows from the presentation of free energy given by the statistical model of solid with mesodefects.

The specific free energy of the system can be calculated as $F = -n_0 Q \cdot \ln Z$ or

$$F(p) = \frac{1}{2}\lambda p_{ik}^2 - n(\sigma_{ik})Q \cdot ln \int exp\left\{\left[(\gamma\sigma_{ik} + \lambda p_{ik})s\nu_i\nu_k - \alpha s^2\right]/Q\right\} ds d^3\vec{\nu}. \quad (10)$$

The equation (10) request a determination materials constants at micro level and complex calculation. At macroscopic level the equation (10) can be approximated by corresponding function [4].

To consider the influence of diffusion processes on defect nucleation and evolution and to study the localization effects of the damage accumulation, we have introduced in the expression of the total free energy F the term describing spatially-nonuniform distribution of microcrack density tensor p_{ik}

$$\mathrm{F} = \frac{1}{2}K\varepsilon_{ll}^{e\,2} + \mu\left(\varepsilon_{ik}^e - \frac{1}{3}\varepsilon_{ll}^e\delta_{ik}\right)^2 + F(p_{ik}) + \frac{1}{2}\kappa\left(\frac{\partial p_{ik}}{\partial r}\right)^2. \quad (11)$$

In order to evaluate tensor F_p, we have to consider the equation (11) as a functional determined for a representative material volume. For one dimension problem we can write

$$F_p = \frac{\delta \mathrm{F}}{\delta p_{ik}} = \frac{\partial \mathrm{F}}{\partial p_{ik}} - \frac{\partial}{\partial x_l}\left[\frac{\partial \mathrm{F}}{\partial(\partial p_{ik}/\partial x_l)}\right]. \quad (12)$$

The system (8)–(9) in the case of uniaxial cyclic loading ($\sigma_{zz} = \sigma$, $e_{zz} = e$, $p_{zz} = p$) takes the form

$$\dot{\varepsilon}^p = l_{\varepsilon^p}\sigma + l_{\varepsilon^p p}\left(\sigma - \frac{\partial F}{\partial p} - \frac{\partial}{\partial x}D\frac{\partial p}{\partial x}\right), \quad (13)$$

$$\dot{p} = l_p\left(\sigma - \frac{\partial F}{\partial p} - \frac{\partial}{\partial x}D\frac{\partial p}{\partial x}\right) + l_{\varepsilon^p p}\sigma, \quad (14)$$

where D is the coefficient of self-diffusion which is known to obey the Arrenius law, $D = D_0\, exp(-E_{sd}/T)$ (E_{sd} is the activation energy of self-diffusion) and largely depends on the defect concentration.

4. **Defect evolution under cyclic loading**

To describe the defect evolution in bulk and near specimen surface let us to reduce the equations (13,14). Under high cyclic and gigacyclic fatigue we can propose a weak interaction of defect accumulation and microplastisity processes ($l_{\varepsilon^p p} -> 0$) and write the equation (14) in the form

$$\dot{p} = l_p\left(\sigma - \frac{\partial F}{\partial p} - \frac{\partial}{\partial x} D \frac{\partial p}{\partial x}\right). \tag{15}$$

Let us to consider two representative material volumes V_{sur}, V_{bulk} located near specimen surface (part of the surface volume coincides with specimen surface) and into specimen volume, respectively. If we introduce a mean defect induced strain in the considering volume as $p_m = \frac{1}{v_i}\int_{v_i} p dv$ we can rewrite the equation (15) as

$$\dot{p}_m + \frac{h\, l_p}{V} p_m = l_p\left(\sigma - \frac{\partial F}{\partial p}\right)_m, \tag{16}$$

where we used the following boundary conditions

$$D \frac{\partial p}{\partial x}\bigg|_{p\in S} = -\frac{h}{V}\int_{v_i} p dv\,. \tag{17}$$

The equation (16) requests an approximation of function $\sigma - \frac{\partial F}{\partial p}$ which determined the equilibrium states of materials with defects. Taking into account the solution of equations (2) we can propose the following approximation for defect evolution law

$$\dot{p}_m + \frac{h\, l_p}{V} p_m = l_p\left(\frac{n\sigma^2}{n_0 E^2}\left(p_m + p_0\right)^2 - a\, p_m\right), \tag{18}$$

where n is initial defect concentration, σ is mean stress for the considered volume, p_0, l_p, a are materials constants, h the constant which determine the boundary conditions for considered volumes.

To explain the different mechanisms of crack initiation on specimen surface and in the bulk we have to consider a surface as a physical object with high concentration of incomplete atomic planes and other defect of different nature. As a result we can consider the surface as negative source with infinite capacity which has a great influence on the defect evolution. This influence can be described by the value of constant h in the boundary condition (18).

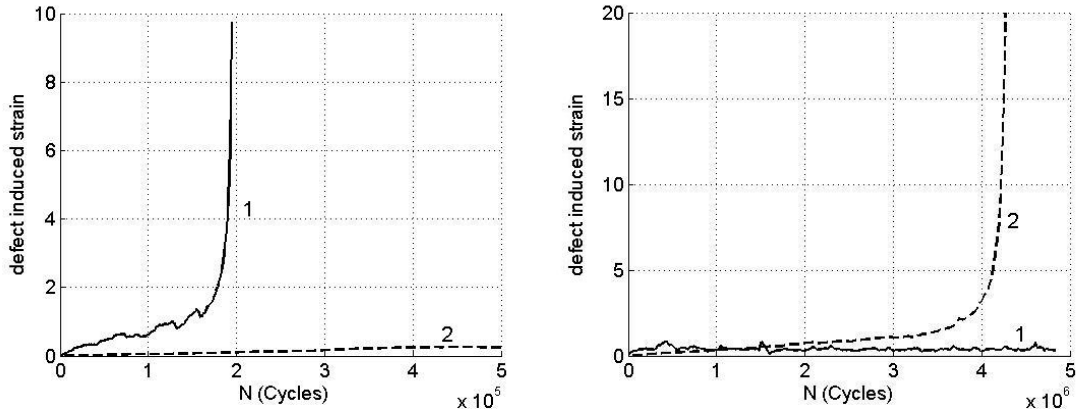
There are two limiting cases for equation (18). The first case is $h \to \infty \Rightarrow p\big|_{p\in S} = 0$. It means the surface is the sink of infinite capacity and this condition can be used for the description of defect evolution close to specimen surface (V_{sur}). The second case is $h \to 0 \Rightarrow D\frac{\partial p}{\partial x}\Big|_{p\in S} = 0$. The surface is closed for the defect diffusion. This condition can be used for the description of defect evolution in the bulk of specimen (V_{bulk}).

Let us to introduce the following dimensionless variables $\tau = t\, l_p a$, $n' = n / n_0$, $\Psi = \sigma /(E a)$, $h' = h /(V a)$, taking into account the fact that the initial defect (submicrocrack) concentration near specimen surface is in one or two order high then in the bulk of specimen [6] ($n'_{sur} >> n'_{bulk}$) and the difference in boundary conditions we can write the equation (18) for V_{sur}, V_{bulk} as

$$\dot{p}_m = n'_{sur}\Psi^2\left(p_m + p_0\right)^2 - \left(1 + h'\right)p_m, \tag{19}$$

$$\dot{p}_m = n'_{bulk}\Psi^2\left(p_m + p_0\right)^2 - p_m. \tag{20}$$

Under one dimension loading the stress is equal for both representative volumes and can be written as $\Psi = \Psi_0 \cos(\omega\tau)$. The numerical solutions of equations (19,20) are presented in figure 2.



a) b)

Figure 2. Defect induced strain evolution near specimen surface (1) and in the bulk of specimen (2) for high (a) and small stress amplitudes (b).

At high stress amplitude the initial defect concentration plays the main role and leads to the sharp increasing of defect density near specimen surface (Fig.2a). The blow-up regime of defect accumulation can be considered as damage to fracture transition and can manifest the emergence of macroscopic crack.

At small stress amplitude the defect diffusion and defect annihilation on specimen surface lead to the low defect growth near specimen surface and blow-up regime of defect accumulation can be observed in the bulk of specimen (Fig. 2b).

The calculation of critical times corresponding the blow-up of defect accumulation allows us to determine the S-N of the material which describes the two possibilities of fatigue crack initiation. The materials constants l_p, a, p_0, n_0, h, V were selected to describe the two stage S-N curve experimentally obtained by C. Bathias and P. Paris for 2023-T3 aluminum alloy [6]. The numerical result presented in figure 3.

The S-N curve has dual form. First branch describes the ordinary surface fatigue crack

initiation. The second part has high fracture times and describe the volume fatigue crack initiation.

The equation (19,20) allows as to propose the analytical representation for S-N curve of material. To obtain the upper bound for life time we can take into account the stress amplitude, only.

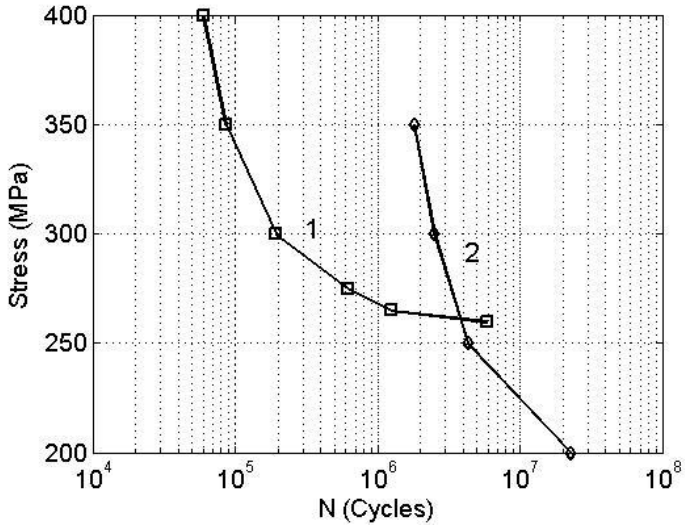


Figure 3. S-N curve for aluminum alloy 2024-T3. Failure caused by surface crack initiation (1), failure caused by under surface crack initiation (2).

In the case of proposed approximation of equilibrium solution of (2) the critical time in the equation (19) can be estimated as follows

$$t_f = \int_0^{\infty} \frac{(1+h')p_m}{n'_{sur}\Psi^b(p_m + p_0)^b}\,dp\,. \tag{21}$$

To describe the full S-N curve we have to use several equation (19) with different values h', n' which could be connected with initial heterogeneity of materials. The equation (21) gives the traditional representation of S-N curve in Basquin form

$$ln(N_f) = a - b\,ln(\Psi), \tag{22}$$

where $a = \nu \int_0^{\infty} \frac{(1+h')p_m}{n'_{sur}(p_m + p_0)^b}\,dp$, ν is loading frequency.

5. Conclusion

Analysis of experimental data devoted to the study of microcracks kinetics in the bulk and surface layer of the metals allowed us to choice of scale level for description of fracture of metallic materials - the level of submicrocracks with the size of 0.1-0.3 microns. To describe the geometry of these defects, as well as their effect on the mechanical material properties were used dislocation theory.

The high initial concentration of these defects in metals and their initiation during initial stage of deformation process allows us to propose the importance of the consideration of their evolution

under cyclic loading. The high concentration of these defect experimentally observed in fine grain metals after equals channel pressing allows us to propose the fine grain metals as model materials for verification of the theoretical predictions obtained in this work.

The small size and high concentration of submicrocracks in metals, the existing of their size and orientation distributions allows us to develop a statistical description of microcrak evolution in metals under cyclic loading and introduce a new thermodynamical variable – defect induced strain. The new variable gives a natural description of thermodynamics of metals with microcracks and allows one to describe the interaction of plasticity and failure processes.

The combination of statistical description of microcrack ensemble with stochastic consideration of defect initiation process allows us to describe the effect of initial nucleus concentration of the deformation process. This model coupled with a description of nonlocal effect in the defect ensemble gives us a key parameter for the description of defect kinetics in the bulk and near specimen surface under cyclic loading.

Based on the developed model the new equation for defect kinetics in the bulk and near specimen surface have been proposed. The surface was considered as a physical object with high concentration of incomplete atomic planes and other defect of different nature. It allows us to explain the difference in the defect kinetics far and close to specimen surface and describe the damage to fracture transition both in the bulk and near specimen surface.

It was show that the stress amplitude can influence on the location of macro fatigue crack initiation. At small stress amplitude the defect induced strain reaches an equilibrium value near specimen surface due to the defect diffusion and annihilation processes. It can be considered as an infinite fatigue life but in this case there is possibility of blow-up regime of defect kinetics in the bulk of specimen. It leads to the shift of location of crack initiation from the surface to the bulk of specimen.

These two modes of crack initiation leads to dual form of S-N curve of materials. The calculated S-N curve has a good quantitative agreement with experimental data obtained by C. Bathias and P. Paris for 2023-T3 aluminum alloy [6]. Each part of the dual S-N curve has the traditional Basquin representation. The micromechanical model allows as to propose the link of macroscopic parameters a, b with defect accumulation kinetics and used the experimentally determined S-N curve for the estimation of microscale model variables.

The developed theoretical model describes the important role of specimen surface and its physical state in the process of defect accumulation under cyclic loading. This model proposes a physical mechanism of the shift of crack initiation location from specimen surface to the bulk that experimentally observed under gigacyclic fatigue (cyclic loading with small stress amplitude). It is interesting to note that the best experimental verification of the model could be carried out based on the structural investigation of microcrack accumulation in fine grain metals (materials with high concentration of initial submicrocracks) under gigacyclic fatigue.

Formulation and Characterization of Fatigue Strength Diagrams of Notched Specimens Based on Equivalent Cyclic Stress Ratio, Attending Especially to Material Dependence and Notch Size Effects

Hiroshi Matsuno[1,*]

[1] Department of MECHANICAL ENGINEERING, SOJO University, Kumamoto 860-0082, Japan
* Corresponding author: hi-matsuno@par.odn.ne.jp

Abstract In the present paper, a fatigue strength diagram is formulated and characterized as a function of an equivalent cyclic stress ratio (named as R_{EQ}-ratio). The R_{EQ}-ratio is derived from a hypothesis of plastic adaptation that reflects micro-mechanical behavior of a fatigue slip band, and it was proposed as a corresponding parameter between cyclic stress-conditions of notched and un-notched specimens in the previous paper. The R_{EQ}-ratio is given as a function of a theoretical stress concentration factor K_t and a nominal cyclic stress ratio R_N, and it is noteworthy that the R_{EQ}-ratio materializes a similitude relation between the fatigue strength diagrams of notched and un-notched specimens in the case where the notch depth is greater than about 1*mm* (where the notch size effect is negligible). Therefore, the R_{EQ}-ratio can be applied as a main variable to the formulation of the fatigue strength diagram. The formulation is extended to the case of the extremely shallow notch where the size effect is dominant, and finally the generalized equations expressing the fatigue strength diagrams are proposed. These equations are applied to regression analyses on fatigue data of practically used metallic materials. Consequently, the material- and size-dependence in notch effects are considered and characterized.

Keywords Fatigue strength diagram, Cyclic plastic-adaptation, Equivalent cyclic stress ratio (R_{EQ}-ratio), Notch behavior map, Notch size effect

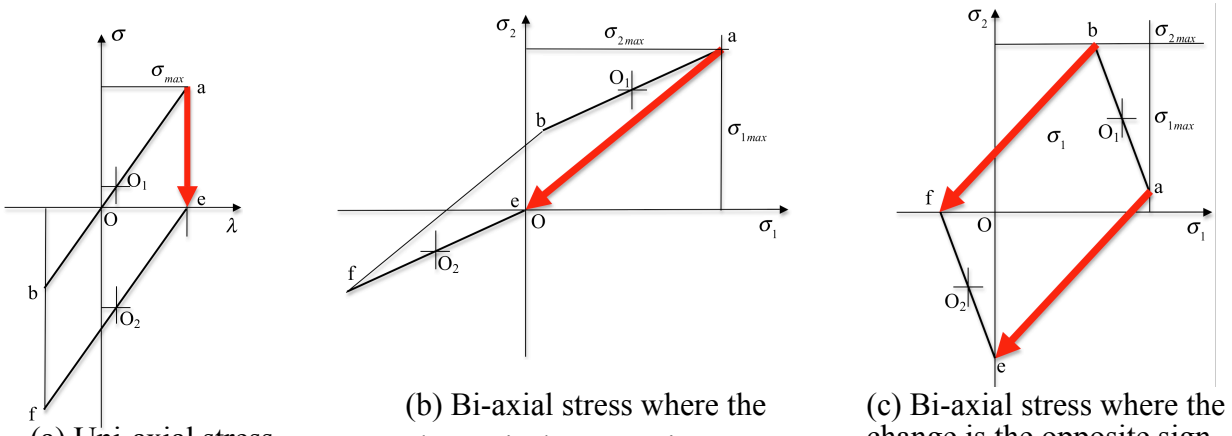
1. Introduction

A fatigue strength diagram is formulated and characterized as a function of an equivalent cyclic stress ratio (named as R_{EQ}-ratio). The R_{EQ}-ratio is derived from a hypothesis of cyclic plastic adaptation that reflects micro-mechanical behavior of a fatigue slip band, and it was proposed as a corresponding parameter between cyclic stress condition of notched and un-notched specimens in the previous paper [1]. A graphic method estimating the R_{EQ}-ratio on the basis of the hypothesis is developed in the present paper. It is described that the R_{EQ}-ratio materializes a similitude relation between the fatigue strength diagrams of the notched and un-notched specimen in the case where the notch depth is comparatively large size of *mm*-order (where the notch size effect is negligible). It means that the R_{EQ}-ratio can be applied as a main variable to the formulation of the fatigue strength diagram. Next, the notch behavior is characterized and mapped by making the notch root radius and depth into variables. The notch size effect is discussed on the basis of the notch behavior map and the size effect factors are introduced. As a result, the formulation of the fatigue strength diagram can be extended to the case of the extremely small size notch, such as the depth of 10 and 100 μm-order, where the size effect is dominant, and finally the generalized equations expressing the fatigue strength diagrams are proposed. These equations are applied to regression analyses on fatigue data of practically used metallic materials.

2. Graphic method estimating an equivalent cyclic stress ratio (R_{EQ}-ratio)

2.1. A hypothesis of cyclic plastic-adaptation

Irreversible microscopic expansion developing in the slip direction of a crystal of a persistent slip



(a) Uni-axial stress (b) Bi-axial stress where the change is the same sign (c) Bi-axial stress where the change is the opposite sign

Fig. 1 Change of the stress path under cyclic plastic-adaptation

band is released on the surface and forms surface relief [2-4]. On the other hand, it is inside restrained and produces inherent compressive stress. A hypothesis that reflects such microscopic mechanical behavior in the persistent slip band is introduced from a viewpoint of macro-mechanics as follows. At the weakest spot of a surface layer, a notch root and a fatigue crack tip, the elastic expansion arising at the maximum stress is transformed into the irreversible expansion inherent in fatigue. As a result, the maximum stress at the weakest spot is substantially decreased and the elastic energy is relieved. Therefore, it is termed as the hypothesis of cyclic plastic-adaptation by author. Such stress relief is materialized for each maximum principal stress in a multi-axial stress condition, too. The expansion arising by the plastic adaptation behaves as a mechanical misfit and lowers the mean stress of substantial cyclic stress. Accordingly, the cyclic behavior of stress can be imaged as shown in Figs. 1(a)-(c). They show the cases of uni-axial stress (a), bi-axial stress where the change is the same (b) and opposite sign (c). At the weakest spot of the surface layer, the stress path moves from a site *ab* to a site *ef*, in common in each figure, though the outward path remains at a site *ab*. The cyclic plastic-adaptation is accomplished completely at the site *ef*. As mentioned later, it should be noted that the movement of the stress path caused by growth of irreversible expansion means not a change of itself but the movement of the potential field that it has.

2.2. Derivation of the equivalent cyclic stress ratio (R_{EQ}-ratio)

How to reproduce the cyclic stress potential field at a notch root as that in the surface layer of the un-notch condition is illustrated based on the hypothesis of cyclic plastic-adaptation. Concretely speaking, the cyclic stress that activates microscopic slip behavior in the un-notch condition as much as the cyclic stress does at the notch root is pictured on the diagram of the stress path. From this diagram, the equivalent cyclic stress ratio R_{EQ} and the equivalent mean stress $\sigma_{mean\,EQ}$ are graphically estimated. R_{EQ} and $\sigma_{mean\,EQ}$ behave just like a hydrostatic stress ratio and hydrostatic mean stress in the process of the cyclic plastic-adaptation, respectively. This is due to the following reasons; (1) the irreversibility of expansion caused by cyclic plastic-adaptation and (2) the addibility of volume expansion which is produced under each principal cyclic stress. These two matters give the important hint to quantitative interpretation of cyclic plastic-adaptation; it is the potential described by Mises' equivalent stress that generates a driving force advancing cyclic plastic adaptaion and it is the algebraic sum of the maxmum value of principal stresses that provides the capability producing the cyclic plastic-adaptation. So, in the present study, in order to estimate the

potential at the notch root, Mises' equivalent stress concentration factor K_{teq} is defined by Eq. (1) where $\sigma_{xN},\cdots,\tau_{zxN}$ are the stress components of the nominal condition and $\sigma_{xNR},\cdots,\tau_{zxNR}$ are those of the notch root. Moreover, Eq. (2) that has been rewritten by principal stresses is obtained by dividing Eq. (1) with K_{teq}. Then, the principal stresses σ_{iNR} (i=1-3) are already not those arising actually at the notch root but those of which nominal values σ_{iN} (i=1-3) are expanded to the same potential level as the notch root has. After all, the principal stress of the un-notch condition where the potential is equal to that of the notch root is given by σ_{iNR} (i=1-3) in Eq. (3). The difference in the stress path of the nominal condition (magnified by K_{teq}) and the notch root condition is disregarded in the present method. As it is mentioned in the following section 2.3, such disregard does not affect the correspondence between fatigue strength of the notch and un-notch condition.

$$
\begin{aligned}
K_{teq} &= \frac{\sigma_{eq\,NR}}{\sigma_{eq\,N}} \\
&= \frac{\left(1/\sqrt{2}\right)\sqrt{\left(\sigma_{x\,NR}-\sigma_{y\,NR}\right)^2+\left(\sigma_{y\,NR}-\sigma_{z\,NR}\right)^2+\left(\sigma_{z\,NR}-\sigma_{x\,NR}\right)^2+6\left(\tau_{xy\,NR}^2+\tau_{yz\,NR}^2+\tau_{zx\,NR}^2\right)}}{\left(1/\sqrt{2}\right)\sqrt{\left(\sigma_{x\,N}-\sigma_{y\,N}\right)^2+\left(\sigma_{y\,N}-\sigma_{z\,N}\right)^2+\left(\sigma_{z\,N}-\sigma_{x\,N}\right)^2+6\left(\tau_{xy\,N}^2+\tau_{yz\,N}^2+\tau_{zx\,N}^2\right)}} \\
&= \frac{\left(1/\sqrt{2}\right)\sqrt{\left(K_{tx}\sigma_{x\,N}-K_{ty}\sigma_{y\,N}\right)^2+\left(K_{ty}\sigma_{y\,N}-K_{tz}\sigma_{z\,N}\right)^2+\left(K_{tz}\sigma_{z\,N}-K_{tx}\sigma_{x\,N}\right)^2+6\left(K_{ts\,xy}^2\tau_{xy\,N}^2+K_{ts\,yz}^2\tau_{yz\,N}^2+K_{ts\,zx}^2\tau_{zx\,N}^2\right)}}{\left(1/\sqrt{2}\right)\sqrt{\left(\sigma_{x\,N}-\sigma_{y\,N}\right)^2+\left(\sigma_{y\,N}-\sigma_{z\,N}\right)^2+\left(\sigma_{z\,N}-\sigma_{x\,N}\right)^2+6\left(\tau_{xy\,N}^2+\tau_{yz\,N}^2+\tau_{zx\,N}^2\right)}}
\end{aligned}
\tag{1}
$$

$$
1=\frac{\sigma_{eq\,NR}}{K_{teq}\sigma_{eq\,N}}=\frac{\left(1/\sqrt{2}\right)\sqrt{\left(\sigma_{1\,NR}-\sigma_{2\,NR}\right)^2+\left(\sigma_{2\,NR}-\sigma_{3\,NR}\right)^2+\left(\sigma_{3\,NR}-\sigma_{1\,NR}\right)^2}}{\left(1/\sqrt{2}\right)\sqrt{\left(K_{teq}\sigma_{1N}-K_{teq}\sigma_{2N}\right)^2+\left(K_{teq}\sigma_{2N}-K_{teq}\sigma_{3N}\right)^2+\left(K_{teq}\sigma_{3N}-K_{teq}\sigma_{1N}\right)^2}} \tag{2}
$$

$$
\therefore\quad \sigma_{1\,NR}=K_{teq}\sigma_{1N},\quad \sigma_{2\,NR}=K_{teq}\sigma_{2N},\quad \sigma_{3\,NR}=K_{teq}\sigma_{3N} \tag{3}
$$

One example of the process of the cyclic plastic-adaptation at the notch root of material subject to cyclic torsion is shown in Fig.2, where plane stress is assumed. The segments *ab* and *cd* show the stress path of the nominal condition and the expanded one of the un-notch condition of which the potential is equal to the notch root, respectively. The segment *ef* shows the stress path where the

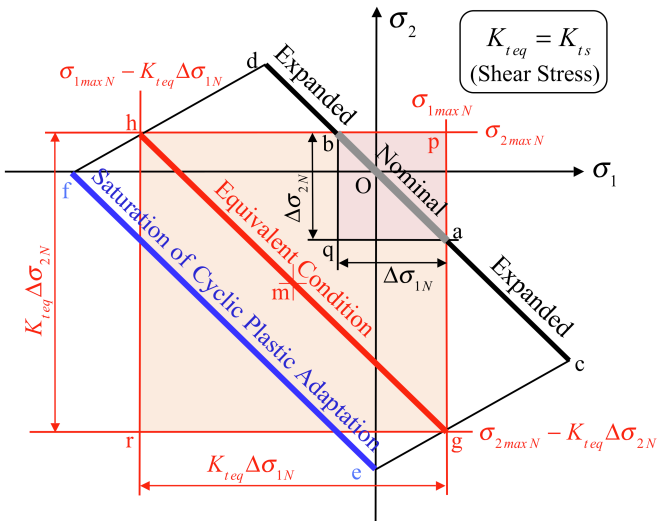


Fig. 2 Illustration of the graphic method of how to estimate R_{EQ} and $\sigma_{mean\,EQ}$ (cyclic torsion)

cyclic plastic-adaptation is accomplished completely. On the way of the cyclic plastic-adaptation process, as it is shown by the segment *gh*, each maximum values of the principal stress become equal to that of the nominal stress path, respectively. This is an important matter which should be mentioned specially; for, it means that, if the cyclic stress shown by the segment *gh* is applied to the un-notched material, the cyclic plastic-adaptation process at the notch root can be reproduced at the surface layer of the un-notched material. Therefore, it can be said that the segment *gh* corresponds to the equivalent cyclic stress condition between the notched and un-notched specimens. In the present study, the stress ratio R_N^* is newly defined for multi-axial stress condition other than the usual nominal stress ratio R_N. The R_N^* is formulated as a ratio of the algebraic sum of the x/y-coordinate value for each of the peak point *p* and *q* of the rectangle *paqb* with the line segment *ab* as a diagonal line (henceforth, the basic equations are shown with the three-dimensional form);

$$R_N^* = \frac{\left(\sigma_{1\,max\,N} - \Delta\sigma_{1N}\right) + \left(\sigma_{2\,max\,N} - \Delta\sigma_{2N}\right) + \left(\sigma_{3\,max\,N} - \Delta\sigma_{3N}\right)}{\sigma_{1\,max\,N} + \sigma_{2\,max\,N} + \sigma_{3\,max\,N}} \tag{4}$$

Next, the equivalent cyclic stress ratio R_{EQ} is formulated as the ratio of the algebraic sum of the x/y-coordinate values for each of the peak points *p* and *r* of the rectangle *pgrh* with the line segment *gh* as the diagonal line, and the expression is moreover simplified by using Eq. (4);

$$\begin{aligned} R_{EQ} &= \frac{\left(\sigma_{1\,max\,N} - K_{t\,eq}\Delta\sigma_{1N}\right) + \left(\sigma_{2\,max\,N} - K_{t\,eq}\Delta\sigma_{2N}\right) + \left(\sigma_{3\,max\,N} - K_{t\,eq}\Delta\sigma_{3N}\right)}{\sigma_{1\,max\,N} + \sigma_{2\,max\,N} + \sigma_{3\,max\,N}} \\ &= R_N^* - \left(K_{t\,eq} - 1\right)\left(1 - R_N^*\right) \end{aligned} \tag{5}$$

Last, the equivalent mean stress $\sigma_{mean\,EQ}$ is formulated as the algebraic sum of the x/y-coordinate values of the middle points *m* of the rectangle *pgrh* with the line segment *gh* as a diagonal line;

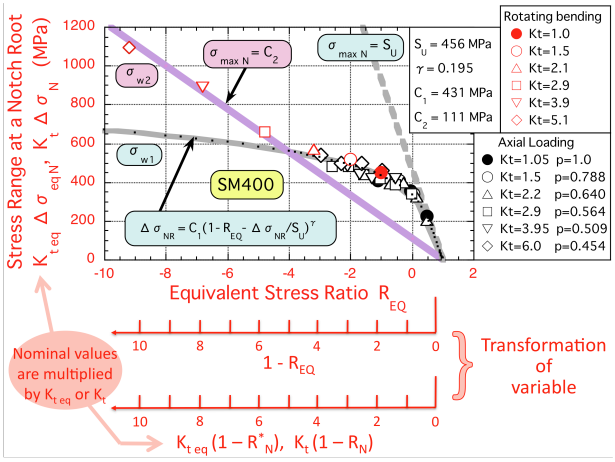
$$\begin{aligned} \sigma_{mean\,EQ} &= \left(\sigma_{1\,max\,N} + \sigma_{2\,max\,N} + \sigma_{3\,max\,N}\right) - K_{t\,eq}\left(\Delta\sigma_{1N} + \Delta\sigma_{2N} + \Delta\sigma_{3N}\right)\Big/2 \\ &= \left(\sigma_{1\,max\,N} + \sigma_{2\,max\,N} + \sigma_{3\,max\,N}\right) - K_{t\,eq}\left(\sigma_{1a\,N} + \sigma_{2a\,N} + \sigma_{3a\,N}\right) \end{aligned} \tag{6}$$

where, $\sigma_{i\,a\,N}$ (i=1-3) are the principal stress amplitude of the nominal condition. Saying again, R_{EQ} and $\sigma_{mean\,EQ}$ behave just like a hydrostatic stress ratio and hydrostatic mean stress in the process of the cyclic plastic-adaptation, regardless whether the stress components constituting them synchronizes or not, respectively. For the un-notch condition of $K_{t\,eq} = 1$, $\sigma_{mean\,EQ}$ of Eq. (6) is coincident with the mean hydrostatic stress that Sines introduced into his criterion [5].

2.3. Applicability of the R_{EQ}-ratio to fatigue strength diagramming

In order to prove the applicability of the equivalent cyclic stress ratio R_{EQ} and the equivalent mean stress $\sigma_{mean\,EQ}$, the fatigue strength of the specimen containing a comparatively large size notch (from the reason why influence of the notch size effect is little) is plotted on the diagram where the abscissa shows R_{EQ} and $\sigma_{mean\,EQ}$ and the ordinate does the notch root stress range $\Delta\sigma_{NR}$. Fig. 3 shows the fatigue test result concerning the notched and un-notched round-bar specimen of SM400 (low carbon structural steel) subject to cyclic axial loading under mean stress of tension side [1] and suject to rotating bending. Fig. 3(a) and (b) represent the R_{EQ}-based and $\sigma_{mean\,EQ}$-based fatigue strength diagram, respectively. The depth of the circumferential notch t is 3 *mm* for axial cyclic loading test and 1.5 *mm* for rotating bending test. The notch root radius ρ is changed in the range

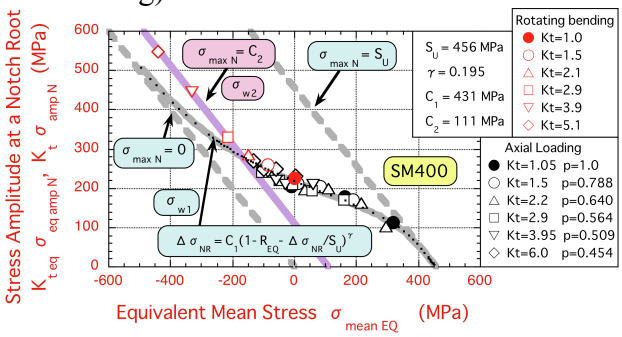
from 0.1 to 3 *mm*. The R_{EQ} for axial cyclic load is estimated by FEM based on Mises' equivalent



(a) R_{EQ} *vs.* $K_t\Delta\sigma_N$ diagram and similarity

(b) $\sigma_{mean\,EQ}$ *vs.* $K_t\sigma_{amp\,N}$ diagram and identity with that of the un-notch condition

Fig. 3 Fatigue strength diagram of SM400 steel round-bar specimen with the large-size notch (The fatigue tests were performed by cyclic axial load under mean stress [1] and rotating bending)



stress and the factor p done as the ratio of the average equivalent stress in the notch section $\bar{\sigma}_{eq}$ to the nominal stress σ_N [1]. In Fig. 3, the colored plot represents the experimental result. From the dispersion state of a plot, it is found, the fatigue strength is systematically arranged in spite of differences of stress concentration factors and mean stress, and it is clearly separable into the two groups of σ_{w1} and σ_{w2}. The curved and straight lines represent the fatigue strength diagrams of σ_{w1} and σ_{w2}, respectively, and they are drawn on the basis of the regression equations derived in the following chapter. The horizontal axis of the graph in Fig. 3(a) can be converted from the scale of R_{EQ} to the scale of $K_{t\,eq}\left(1-R_N^*\right)$ and $K_t\left(1-R_N\right)$ as shown in the lower berth of the graph;

$$1-R_{EQ}=K_{t\,eq}\left(1-R_N^*\right)=K_{t\,eq}\left(\Delta\sigma_{eq\,N}/\sigma_{eq\,max\,N}\right)=\Delta\sigma_{eq\,NR}/\sigma_{eq\,max\,N} \quad \text{(for axial load)} \quad (7)$$

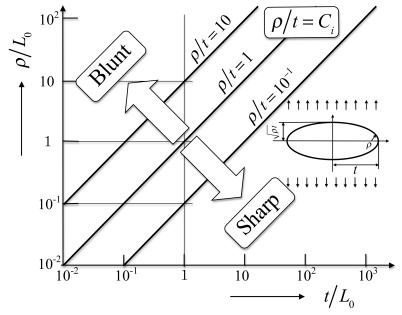
$$1-R_{EQ}=K_t\left(1-R_N\right)=K_t\left(\Delta\sigma_N/\sigma_{max\,N}\right)=\Delta\sigma_{NR}/\sigma_{max\,N} \quad \text{(for rotating bending)} \quad (8)$$

Both the axes of the graph take the scale proportional to K_t. Therefore, it can be said that a similitude relation between the diagrams is materialized. This means that R_{EQ} is very useful as the correspondence parameter between the fatigue strength of the notched and un-notched specimen. The coincidence of a diagram in Fig. 3(b) means that the $\sigma_{mean\,EQ}$-based fatigue strength diagram obtained from the fatigue data of the notched specimen turns into the $\sigma_{mean\,N}$-based fatigue strength diagram of the un-notched specimen as it is.

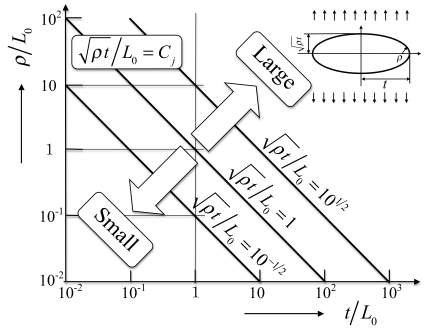
3. Formulation of the fatigue strength diagram based on the R_{EQ}-ratio

3.1. Characterizing and mapping of the notch behavior

The notch is characterized by two parameters of ρ/t and $\sqrt{\rho t}/L_0$ as shown in Fig. 4(a) and (b), where the notch depth t and the notch root radius ρ are expressed as the co-ordinates after normalized by the size L_0. L_0 is introduced as an index for judging large size or small size notch. In the present study, $L_0=1mm$ is set emprically. The parameter ρ/t shows the sharpness of the notch which K_t depends on and the parameter ρt does the scale of the notch which the size effect depends on. Taylor classified the character of the notch behavior into three and drew the



(a) Notch sharpness: ρ/t



(b) Notch size scale: $\sqrt{\rho t}/L_0$

Fig. 4 Index parameter of notch sharpness and notch size scale: ρ/t and $\sqrt{\rho t}/L_0$

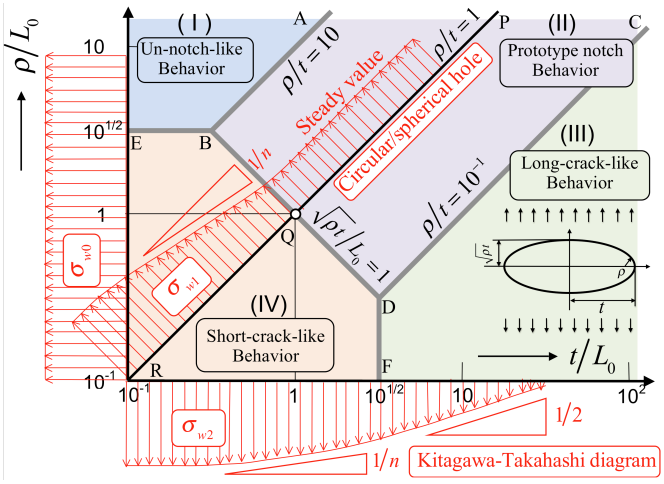


Fig. 5 Notch behavior map and a few typical distributions of fatigue strength threshold stress

distribution map on the key map [6]. His map seems to be rather suitable for expressing the characteristic of the fatigue strength σ_{w2}. So, a new map is created so that it can express the characteristic of the fatigue strength inclusive of the fatigue strength σ_{w1}. The new map is shown in Fig. 5, where the character of the notch behavior is classified into four domains; (I) Un-notch-like behavior, (II) Prototype notch behavior, (III) Long-crack-like behavior and (IV) Short-crack-like behavior. The four domains are partitioned with three characteristic lines AB, CD and BD and with the outgoing lines BE and DF drawn in the horizontal and perpendicular directions from the two intersections. The characteristic lines AB, CD and BD are expressed by the following simple formulas, $\rho/t=10$, $\rho/t=10^{-1}$ and $\sqrt{\rho t}/L_0=1$, respectively. A straight line PR formulated as $\rho/t=1$ expresses the size change of the circular or spherical hole that represents typical notch behavior. The distribution of the fatigue strength can be diagramed in a logarithmic scale by taking the z-axis in the direction perpendicular to space of the map. Three examples are schematically shown in Fig. 5. One is the diagram of the fatigue strength σ_{w1} for the circular or spherical hole. The diagram makes $\sqrt{\rho t}/L_0$ a variable and it is shown as a $\sigma_{w1}-\sqrt{\rho t}/L_0$ diagram on the line where $\rho/t=1$. As mentioned later, a $\sigma_{th}-\sqrt{area}$ diagram that makes Murakami's parameter of $\sqrt{area}$ a variable is a particular case of the $\sigma_{w1}-\sqrt{\rho t}/L_0$ diagram where $\rho/t=1$ and $\sqrt{\rho t}/L_0<1$. Another is Kitagawa-Takahashi diagram that makes a crack length a/a_2 a variable and the diagram is known as a $\sigma_{th}-a/a_2$ diagram [7]. The $\sigma_{th}-a/a_2$ diagram is depicted as a $\sigma_{w2}-t/L_0$ diagram on the horizontal axis (x-axis) in Fig. (5) where the crack length a/a_2 is replaced by the notch depth t/L_0. Moreover, Kitagawa and Takahashi prepared another critical size a_1 that represents the substantial transition from large size crack to small size one. This type of transition size on the fatigue strength σ_{w2} is expressed by replacing a_1/L_0 by t_0/L_0; the transition notch size is shown as $t_0/L_0=10^{1/2}$ in Fig. (5). The third is the fatigue strength of the un-notch condition σ_{w0} that is distributed on the vertical axis (y-axis) as a uniform value. This value is thought to be materialized in common where both ρ/L_0 and t/L_0 are extremely small.

3.2. Primary equations at the onset of formulation and their modification (Domain II)

The fatigue strength diagram is formulated first for the prototype notch of the domain II ($\sqrt{\rho t} \geq L_0$), where the notch size effect is not taken into consideration. In the following section 3.3, the equation is developed into a general form including the short-crack-like notch of the domain IV ($\sqrt{\rho t} < L_0$), where the notch size effect is taken into consideration. Primary equations that become a starting point of formulation are as follows, where Eq. (9) is quoted from Ref. [8];

$$\left(\Delta\sigma_{NR}\right)_{w1} = C_1\left(1 - R_{EQ}\right)^{\gamma}, \qquad \text{(Fatigue strength } \sigma_{w1}\text{)} \tag{9}$$

$$\left(\Delta\sigma_{NR}\right)_{w2} = C_2\left(1 - R_{EQ}\right). \qquad \text{(Fatigue strength } \sigma_{w2}\text{)} \tag{10}$$

Eq. (10) is rewritten by using the conversion expression of Eq. (8), as follows;

$$\left(\sigma_{max\,N}\right)_{w2} = C_2. \qquad \text{(Fatigue strength } \sigma_{w2}\text{)} \tag{11}$$

Eq. (12) is adopted as an asymptotic equation of Eq. (9) on σ_{w1}, so that the ultimate strength of material S_U may be gradually approached with an increase of the value R_{EQ};

$$\left(\sigma_{max\,N}\right)_{w1} = S_U \quad \text{i.e.} \quad \left(\Delta\sigma_{NR}\right)_{w1} = S_U\left(1 - R_{EQ}\right). \tag{12}$$

Solving Eqs. (9) and (12) about $\left(1 - R_{EQ}\right)$ and susequently transposing those algebraic sum to new $\left(1 - R_{EQ}\right)$, Eq. (13) can be expressed;

$$\left(\Delta\sigma_{NR}\right)_{w1} = C_1\left\{1 - R_{EQ} - \frac{\left(\Delta\sigma_{NR}\right)_{w1}}{S_U}\right\}^{\gamma}. \qquad \text{(Fatigue strength } \sigma_{w1}\text{)} \tag{13}$$

Eq. (13) is a very important as the expression which not only improves the precision for calculating the fatigue strength σ_{w1} but also explains how the tensile strength of material S_U relates quantatively with σ_{w1}. The equation expresses that the SCF-criterion (K_t-criterion) is materialized for σ_{w1} by using the equivalent cyclic stres ratio R_{EQ}. On the otherhand, for the fatigue strength σ_{w2}, Eq. (10) and (11) is used in a form as it is. It should be noted that, at this stage, γ, C_1 and C_2 are not material constants but variables. Strictly speaking, C_1 includes free boundary correction and C_2 includes a function of the notch depth t.

3.3. The equations generalized by incorporation of notch-size effects (Domain IV)

The factor of a notch size effect is incorporated into the euations derived in the foregoing paragraph. The judgement whether it is necessary to take the notch size effect into consideration or not is performed according to the value of a notch size $\sqrt{\rho t}$. In the present study, the value of $\sqrt{\rho t} = L_0$ is selected as the critical value as shown in Fig. 5. As it is mentioned in the foregoing section 3.1, the fatigue strength σ_{w1} depends on the notch size $\sqrt{\rho t}$ and the fatigue strength σ_{w2} does on the notch depth t. Therefore, the size factors F_{S1} and F_{S2} are introduced in the forms of the functions of $\sqrt{\rho t}$ and t, respectively;

$$F_{S1} = f_1\left(\sqrt{\rho t}\right), \tag{14}$$

$$F_{S2} = f_2\left(t\right). \tag{15}$$

Generally, the nominal stress of the plate and round-bar specimen containing a hole, a defect and a pre-crack is shown by gross-sectional stress. On the other hand, that of the plate and round-bar specimen containing an edge and circumferential notch is shown by net-sectional stress. These specimens are often furnished with the net-sectional area unified for different K_t and accordingly their gross-sectional area is different every specimen. Such difference has serious influence for the asymptotic process ofthe fatigue strength σ_{w1} to the ultimate strength of material S_U. So, a factor of F_G is introduced for the fatigue strength σ_{w1} expressed by the net-sectional stress, as follows;

$$F_G = A_{G0} / A_G\ , \tag{16}$$

where, A_{G0} and A_G are the gross-sectional area for $\sqrt{\rho t} = L_0$ and $\sqrt{\rho t} < L_0$, respectively. Also, it should be noted that the fatigue strength σ_{w2} in torsion is not subjected to the influence of the notch depth t. A concrete form of the function of F_{S1}, F_{S2} and F_G is summarized in Table 1. By using these factors, Eq. (9) and (12) are rewritten for the σ_{w1} as Eq. (17) and (18), respectively;

$$F_{S1}\left(\Delta\sigma_{NR}\right)_{w1} = C_1\left(1-R_{EQ}\right)^{\gamma}, \tag{17}$$

$$F_G\left(\sigma_{max\,N}\right)_{w1} = S_U \quad \text{i.e.} \quad F_G\left(\Delta\sigma_{NR}\right)_{w1} = S_U\left(1-R_{EQ}\right). \tag{18}$$

Eq. (18) is adopted as an asymptotic equation of Eq. (17) so that the ultimate strength of material S_U may be gradually approached with an increase of the value R_{EQ}. The final equation on the fatigue strength σ_{w1} is obtained as follows;

$$F_{S1}\left(\Delta\sigma_{NR}\right)_{w1} = C_1\left\{1-R_{EQ}-\frac{F_G\left(\Delta\sigma_{NR}\right)_{w1}}{S_U}\right\}^{\gamma}. \tag{19}$$

Eq. (19) is obtained by solving Eqs. (17) and (18) about $\left(1-R_{EQ}\right)$ and subsequently transposing those sum to new $\left(1-R_{EQ}\right)$. The final equation for the fatigue strength σ_{w2} is shown as follows;

$$F_{S2}\left(\Delta\sigma_{NR}\right)_{w2} = C_2\left(1-R_{EQ}\right) \quad \text{i.e.} \quad F_{S2}\left(\sigma_{max\,N}\right)_{w2} = C_2\,, \tag{20}$$

Table 1 Summary of the notch size correction factors

σ_w	F	Center hole (Gross-sectional stress)		Edge/circumferential notch (Net-sectional stress)		Small-size defect
σ_{w1}	$\sqrt{\rho t}$	$\sqrt{\rho t} \ge L_0$	$\sqrt{\rho t} < L_0$	$\sqrt{\rho t} \ge L_0$	$\sqrt{\rho t} < L_0$	$\sqrt{area} < L_0$
	F_{S1}	$F_{S1}=1$	$F_{S1}=\left(\sqrt{\rho t}\right)^{1/8}$	$F_{S1}=1.12$	$F_{S1}=1.12\left(\sqrt{\rho t}\right)^{1/8}$	$F_{S1}=\left(\sqrt{area}\right)^{1/6}$
	F_G	$F_G=1$		$F_G=1$	$F_G=\frac{A_{G0}}{A_G}=\left(\frac{d+2L_0}{d+2\sqrt{\rho t}}\right)^2$	$F_G=1$
σ_{w2}	t	$t \ge t_0$	$t < t_0$	$t \ge t_0$	$t < t_0$	$\sqrt{area} < L_0$
	F_{S2}	$F_{S2}=t^{1/2}$	$F_{S2}=t^{1/7}$	$F_{S2}=1.12t^{1/2}$	$F_{S2}=1.12t^{1/7}$	$F_{S2}=\left(\sqrt{area}\right)^{1/7}$

Note 1) $L_0 = 1mm$.
2) $t_0 = \sqrt{10}\,L_0 = \sqrt{10}\,mm$.
3) A value of 1.12 means a free boundary correction (F_0).

where, γ, C_1, C_2: Material constants.

4. Regression analysis on the fatigue data currently introduced in literature

Eq. (19) and (20) are applied to the regression analyses of fatigue data picked up from literatures. It is confirmed whether the function form of the equation derived in the preceding chapter 3 is appropriate as a regression equation. A part of the result is described below. Fig. 6 shows the result of a rotating bending test of S45C annealed steel with a round-bar specimen containing a small drill-hole. In the experiment [9], the diameter of a hole d was changed in the range from 0.04 to 0.5 *mm* and the depth t changed from 0.04 to 1 *mm*. The fatigue strength σ_{w1} is shown as a function of $\sqrt{area}$ -parameter in Fig. 6. The plot represents the experimental result and the curve shows the calculated result from the regression equation. The horizontal line represents the strength level of an un-notched specimen σ_{w0} is calculated backward from the regression equation. It turns out that the regression equation fits the experimental result very well. Fig. 7 shows the result of a rotating bending test of S45C annealed steel with a round-bar specimen containing an extremely shallow circumferential-notch. In the experiment [10], the notch root radius ρ was changed in the range from 0.01 to 0.6 *mm* and the depth t changed from 0.005 to 1.5 *mm*. The fatigue strength σ_{w1} and σ_{w2} were measured and they were shown as a function of a stress concentration factor K_t in Fig. 7(a) and (b), respectively. The colored plot represents the experimental result and the colored thin curve/line shows the calculated result. The horizontal thick gray line represents the strength level of an un-notched specimen σ_{w0} calculated backward from the regression equation. The thick gray curve obtained by dividing σ_{w0} by K_t is drawn for reference. In both Fig. 7(a) and (b), it turns out that the regression equation fits the experimental result very well. The regression analysis using the proposed equation has applied to the fatigue testing result of the total

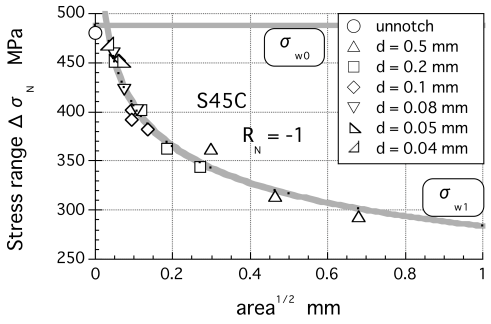

Fig. 6 Result of a regression analysis on rotating bending fatigue strength of S45C round-bar specimens containing small drill-holes (data from Ref. [9])

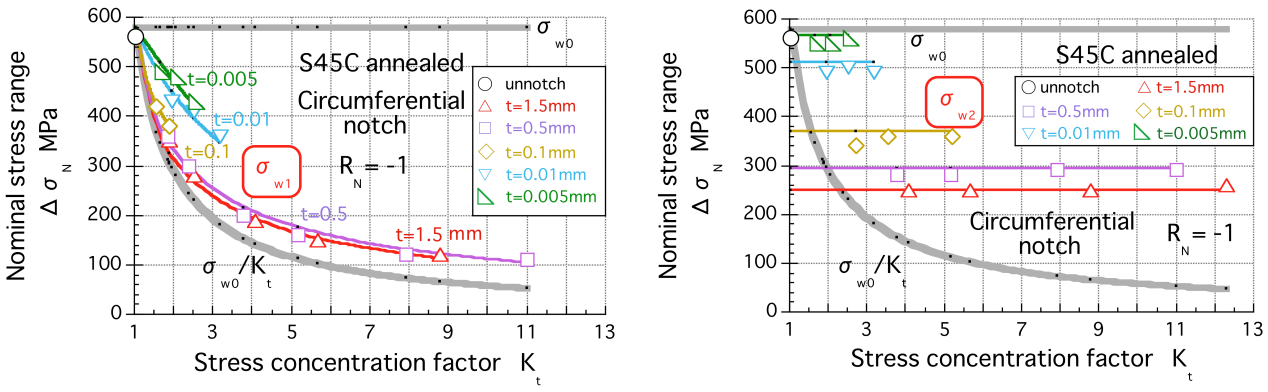

(a) Fatigue strength σ_{w1} (b) Fatigue strength σ_{w2}

Fig. 7 Result of a regression analysis on rotating bending fatigue strength of S45C round-bar specimens containing small size circumferential notches (data from Ref. [10])

number of about 25 sorts of ferrous materials and their heat-treatment conditions in the present stage. As a result, it is found that the equation is materialized with less than 10% of error.

5. Conclusions

(1) A fatigue strength diagram is formulated and characterized as a function of the equivalent cyclic stress ratio (R_{EQ}-ratio). The R_{EQ}-ratio is derived from a hypothesis of cyclic plastic adaptation that reflects micro-mechanical behavior of a fatigue slip band.

(2) The graphic method estimating R_{EQ}-ratio based on the hypothesis of the plastic adaptation is developed in the present paper. R_{EQ}-ratio materializes a similitude relation between the fatigue strength diagrams of the notched and un-notched specimen in the case where the notch depth is comparatively large size of *mm*-order (where the notch size effect is negligible). It means that R_{EQ}-ratio can be applied as a main variable to the formulation of the fatigue strength diagram.

(3) The notch behavior is characterized and mapped by making the notch root radius and depth into variables. The notch size effect is systematically considered on the basis of the notch behavior map and the size effect factor is proposed for each of the fatigue strength σ_{w1} and σ_{w2}.

(4) The formulation of the fatigue strength diagram can be extended to the case of the extremely small size notch, such as the depth of 10 and 100 μm-order, where the size effect is dominant, and finally the generalized equations expressing the fatigue strength diagrams are proposed. These equations are applied to regression analyses on fatigue data of practically used metallic materials. As a result, it is found that the equations are materialized with less than 10% of error.

Abstract 2.0 mm thick 2198-T8 Al-Li alloy sheets with the parallel friction stir welds in the middle were used in this work. The center cracked tension (CC(T)) specimens with transverse welds were designed and welded by different welding parameters. Fatigue tests were performed and fatigue crack growths in the nuggets were measured and compared. Effects of rotation speed and welding speed on fatigue crack growth rates parallel to the friction stir welds were studied. It was shown crack growth rate in the nuggets can relate to the welding parameter. Residual K (K_{res}) approaches was used to predict fatigue crack growth rates in residual stress fields. Finite element models of the samples were built and the measured residual stress data put into the model. The virtual crack closure technique was used to calculate K_{res} and then K_{res} was used to calculate effective R values. Predicted crack growth rates were compared with experimental results.

Keywords Friction stir weld, Welded nugget, Fatigue crack growth rate, different R ratio.

1. Introduction

Friction stir welding (FSW), invented at The Welding Institute (TWI) in 1991, was widely used in modern aerospace industry. This new welding technique have successfully taken the pilot study stage and developed into a useful alternative in the manufacture of industrialized aluminum structures solid phase connection technology. Compared to traditional welding techniques, FSW strongly reduces the presence of distortions and residual stresses [1-4]. Also, the FSW performed well in the strength, fatigue and fracture resistant of aerospace aluminum welds, which has long inhibited the widely use of those alloys such as 2XXX and 7XXX series [5, 6]. These aluminum alloys are generally classified as non-weldable because of the poor solidification microstructure and porosity in the fusion zone [7]. Previous studies show that the grain size of the weld nugget has a strong effect on the mechanical properties [8]. In 2007, the air bus published a report which claimed that the FSW application in fuselage longitudinal seam connection of A340-500s and A340-600s has reduced 0.9 kg weight per meter relative to traditional riveting technology. A similar instance occurred in Boeing that the production efficiency in the manufacture of C-17 Global/MasterⅢ has improved tenfold with the FSW application.

2. Experimental procedure

2.1. Fatigue test procedure

2198-T8 Al-Li alloy plates were friction stir welded. The welding directions are perpendicular to the rolling direction. Cracks are the weld centre and grow in the weld. Center cracked tension (CC(T)) specimens ware chosen for the fatigue experiment. All samples have been cut into 220mmX70mm. The specimens have different rotation speed and welding speed: 800(rpm)/400(mm/min), 600(rpm)/200(mm/min) and 400(rpm)/100(mm/min). Fig.1 shows the sample geometries.

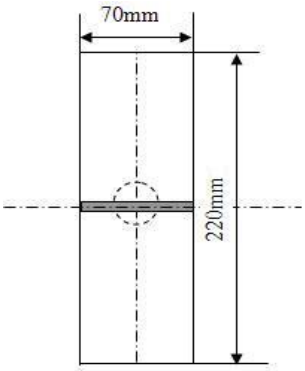

Fig.1 Sample size

Instron8872 hydraulic servo fatigue testing machine was used. Samples with different rotation speed and welding speed were tested in three different R ratio: R=0.1, R=0.3 and R=0.6. Δ P was set a constant value 6.3 KN.

2.2 Results

In Fig.2, crack growth rates under three different R ratio fatigue loads were shown. For three different welding parameters, crack growth rates at R=0.1, 0.3 were shown in Fig. 3.
The experimental data from all specimens was compared in Fig.2 and Fig.3, for samples with crack, da/dN versus $\Delta K_{applied}$. Even though had different rotation speed, welding speed and R ratio, the crack growth rate of these samples tended to be the same tendency. Previous studies [9] indicated that the fatigue life was based on the R ratio, which shown the stress level played an important role in crack growing. However, the fatigue life of the three kinds of samples certificated that even in different rotation speed and welding speed, the microstructure was the primary factor controlling the crack propagation for cracks grow in the welded nugget.

Fig. 3 Crack growth rate under different ratios for three different welding conditions

3. Numerical simulation

3.1 Numerical solution of K_{res}

The evaluation of residual K (K_{res}) was considered as a mature method of predicting fatigue crack growth rates in residual stress fields. Finite element analysis was used to calculate the stress intensity factor K_{res} from residual stress by using ABAQUS 6.10. The models were built using C3D8R (an 8-node linear brick, reduced integration, hourglass control.) entity elements around the notch tip and along the crack lines. The unit size gradual transition from 2.5mm to 0.5mm length. The virtual crack closure technique (VCCT) [10] was used for calculating strain energy release rate for unit sample thickness.

For plane stress, the relation between the strain energy release rate and stress intensity factor (SIF) was as follows:

$$K_{res} = \sqrt{GE} \tag{1}$$

$$\Delta K = \frac{\Delta P}{B}\sqrt{\frac{\pi\alpha}{2w}\sec\frac{\pi\alpha}{2}} \tag{2}$$

$$R_{eff} = \frac{K_{res}+K_{min}}{K_{res}+K_{max}} \tag{3}$$

If residual stresses were input to this model, K_{res} can be derived from Eqs. (1), R_{eff} can be derived from Eqs. (2) and (3). The crack growth rate can be calculated with the Paris formula.

3.2 Fatigue life in simulation

The fatigue life in weld nugget were compared to the experimental data, as shown in Fig.4 For ΔK less than 10MPa $\sqrt{m}$, the experimental data was consistent with the parent material. When ΔK grew breakthrough 10MPa $\sqrt{m}$, the experimental data was more in line with simulations.

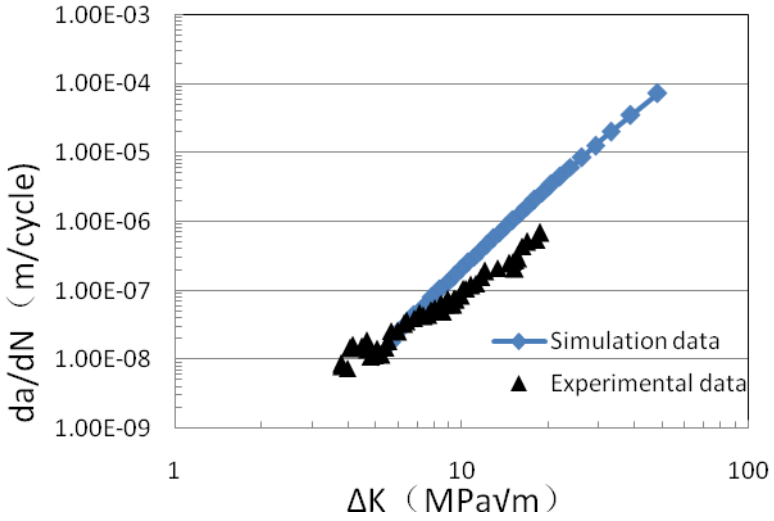

Fig.4 The crack growth rate in parent material and weld nugget

4. Conclusion

The crack growth rate in weld nugget of Al-Li alloy 2198-T8 friction stir welded was mainly decided by the microstructure, not the R ratio as common understanding.

Abstract Ultrasonic testing method has allowed some impressive improvements in order to better grasp fatigue properties of various metallic materials the latest 20 years. It is particularly the case in the very high cycle regime since ultrasonic fatigue tests are conducted at very high stressing frequencies. However, the question of a potential difference of fatigue strengths due to huge frequency gap between ultrasonic method (usually carried out at 20 kHz) and servo-hydraulic one (usually in the range of 1~100 Hz) is still unclear and needs to be studied for a various kind of metallic materials. The case of low carbon steels presents a singularity, as fatigue properties are significantly different between these two fatigue tests methods. It seems particularly interesting to study this kind of materials in order to get a better overview of frequency effect in metallic materials fatigue. Aim of the present work, which consists of a general survey of JIS S15C steel (0.15% C) fatigue properties, is firstly to reconfirm such a frequency effect. Secondly, based on several experiments related to micro-plasticity behavior, some discussions will be held in order to explain this frequency effect in the case of low carbon steels.

Keywords Frequency effect, Low carbon Steel, Ultrasonic test, Cyclic hardening, EBSD observations

1. Introduction

The past 20 years in the field of fatigue test marks increase of ultrasonic testing method for various industrial uses. Since study of the very high cycle regime has become a topical issue, ultrasonic stressing frequency allowed by this fatigue testing method is essential to conduct fatigue test in a definite time. It is indeed almost impossible to reach 10^9~10^{10} cycles with a conventional fatigue testing machine.

However, question of a potential influence of stressing frequency on fatigue test result, usually known as “frequency effect”, have been studied by numerous literatures and is still unclear, except for some particular materials. Low carbon steels reveal usually a clear difference of fatigue strength between usual fatigue testing (servo-hydraulic as instance) and ultrasonic testing method.

As a consequence, it was decided to make a focus on the effect of loading frequency on low carbon steels. The present work discusses some phenomenon possibilities involved in frequency effect of low carbon steels.

2. Experimental Procedure

In the present study, material tested is JIS S15C steel, extracted from as rolled material. Chemical composition and mechanical properties are indicated in Tables 1 and 2, respectively. Figure 1 shows the microstructure of this steel, with typical ferritic and pearlitic composition. One can see that grains are elongated in the rolling direction.

Table 1. S15C chemical compositions (mass %)

C	Si	Mn	Cu	Ni	Cr	Fe
0.15	0.21	0.40	0.02	0.02	0.15	*Re*

Table 2. Mechanical properties of S15C steel

Mechanical properties	Value
Lower yield stress (MPa)	273
Tensile strength (MPa)	441
Young modulus (GPa)	207
Elongation (%)	40.2
Reduction of area (%)	65.8
Vickers hardness (HV)	161

Fatigue tests have been conducted at several frequencies: 20 kHz using an ultrasonic type machine, under displacement control; 140 Hz using an electro-magnetic type machine under stress control; 20 Hz, 2 Hz and 0.2 Hz using servo-hydraulic type machine under stress control. An air-cooling system and intermittent loading conditions were admitted to avoid temperature rising of specimen in the case of ultrasonic fatigue tests. For fatigue tests performed at 140 Hz, an air-cooling system has been also added for the same reason.

All fatigue tests were performed in air, at room temperature, with a stress ratio R = -1. Configurations of fatigue specimens are presented in Fig. 2. Diameter of tested portion was fixed at 5 mm, whatever the testing method used. After machining, center portion of specimens are electro-polished to remove residual stresses. As a consequence, we avoid any size effect and residual stress effect on the *S-N* properties of S15C steel.

One can see that servo-hydraulic and electro-magnetic specimens present a cylindrical shape at center rather than usual hour glass shape. It allows us to carefully attach a 4-strain gauge system in order to follow micro-plasticity behavior during fatigue test. Choice of this type of full-bridge system has been done in order to obtain accurate measures and to avoid heating influence on strain measures.

3. Experimental Results

3.1. *S-N* data

S-N diagram of JIS S15C steel used here is depicted in Fig. 3. One can see a clear difference of fatigue strength between ultrasonic 20 kHz fatigue test results and other results from servo-hydraulic and electro-magnetic machines. Fatigue limits found under these four fatigue tests conditions are 248 MPa, 200 MPa for 20 kHz and 140 Hz respectively, and a similar fatigue limit of 185 MPa has been found in the case of servo-hydraulic fatigue tests at a testing frequency of 2 and 20 Hz. This kind of large discrepancy between fatigue tests performed in usual testing frequency range and ultrasonic frequency has been also found in several other literatures as Kikukawa *et al.*[1], Yokobori *et al.*[2] or Setowaki *et al.*[3] for different other kinds of low carbon steels.

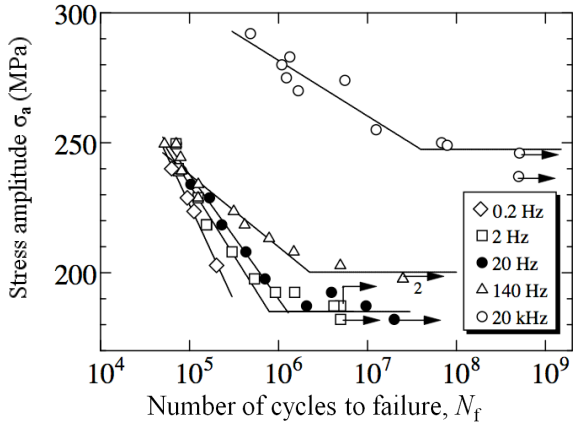

Fig.3. General *S-N* property of S15C steel

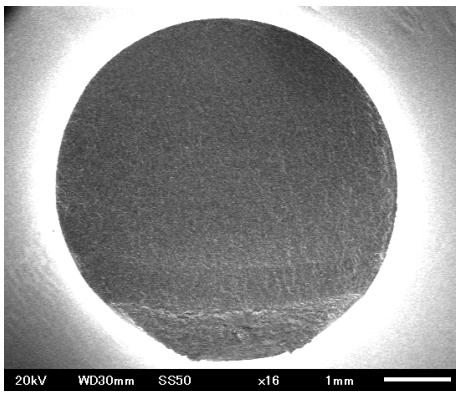
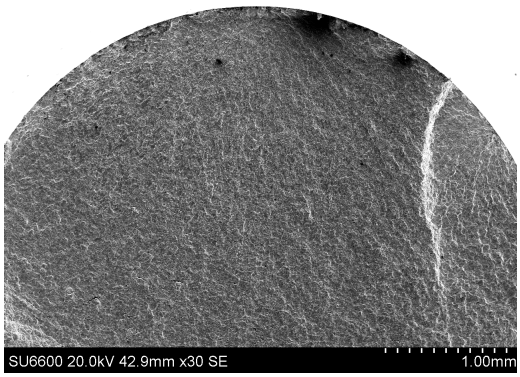
In addition, one can see that there are some fatigue strength differences between tests performed in the range from 0.2 Hz to 140 Hz. The fatigue properties are equivalent for high stress tests in this frequency range. However, as the stress level decreases, some fatigue life differences can be seen. In a general way, the higher is frequency, the higher becomes the fatigue strength. Particularly, even though tests performed at 2 and 20 Hz reveals the same fatigue limit, a relatively higher fatigue limit is found for 140 Hz tests. Nevertheless, those fatigue strength differences are far smaller than compared with ultrasonic fatigue test results.

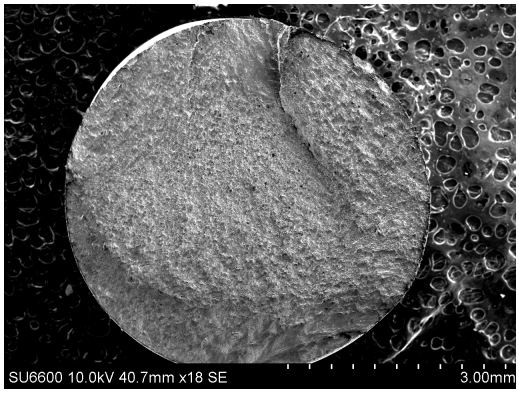
3.2. Fracture surface observation



(a) f=20 kHz, σ_a=255 MPa, N_f=1.25×10^7



(b) f=2 Hz, σ_a=228.8 MPa, N_f=1.25×10^5



(c) f=140 Hz, σ_a=244.4 MPa, N_f=7.29×10^4

Fig. 4 Typical examples of fracture surface

Fracture surface observation reveals that, for all the fatigue tests conducted up to failure, fracture has been initiated from the specimen surface, even under ultrasonic fatigue loading. This fact is usual for this kind of low strength steels, where number of inclusions, and so main factor of fish-eye fracture occurrence, is low. Figure 4 shows some typical examples encountered in the present study. Two kinds of fracture conditions have occurred. On the one hand, Fig. 4(a) presents a fracture behavior initiated by only one crack. On the other hand, Figs. 4(b) and (c) depict a clear multiple cracks conditions before specimen's failure. In order to gather such these data, Fig. 5 is an *S-N* diagram, which makes clearly distinction between simple and multiple cracks behavior found.

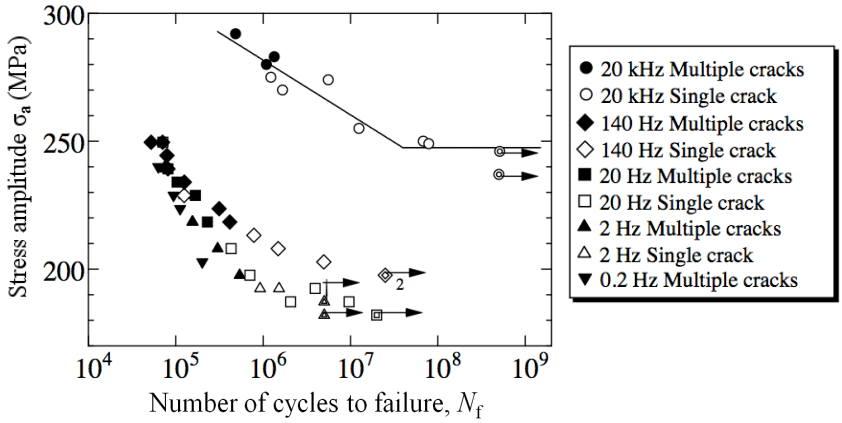


Fig.5. General fracture crack behavior

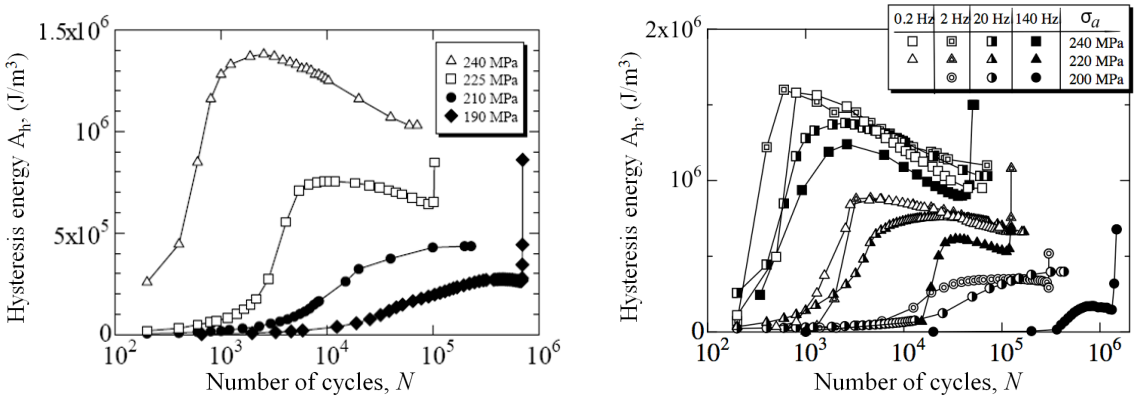
It is not surprising at all to see that multiple crack behavior is able to occur only for relatively high stress level tests, whereas simple crack condition is more likely to happen for low stress levels. One important finding related to this fracture behavior is that the transition between multiple to single crack appears around fatigue strength of 10^6 cycles, regardless testing frequency. In other words, this fracture behavior is not directly related to the stress level, but is mainly governed by the fatigue strength at a specific fatigue test condition. As fatigue strength of S15C steel is dependent of the testing frequency, the stress level where takes place this fracture behavior transition tends also to increase when testing frequency is increasing.

3.3. Stress-strain hysteresis

Stress-strain behavior in the present study has been studied for 0.2, 2, 20 and 140 Hz loading frequencies; as such a study is not possible in the case of ultrasonic method. Stress signal was directly recorded from testing machine load cell, whereas strain was measured from strain gauge system introduced before. As failure of fatigue specimen occurs almost all the time at the extremity of central cylindrical shape due to a slight stress concentration factor K_t=1.04, crack propagation does not influence measures on strain gauge at the center.

General evolution of stress-strain hysteresis loop of S15C studied here is presented in Fig. 6. In this diagram, hysteresis loop's area A_h from some fatigue tests is plotted against the number of cycles. One can clearly see on Fig. 6(a) that an increasing general trend occurs. In other words, as those tests are stress controlled, S15C is generally softening when fatigue goes. This result can be explained by the fact that this material is as rolled, and so has a hardened initial condition.

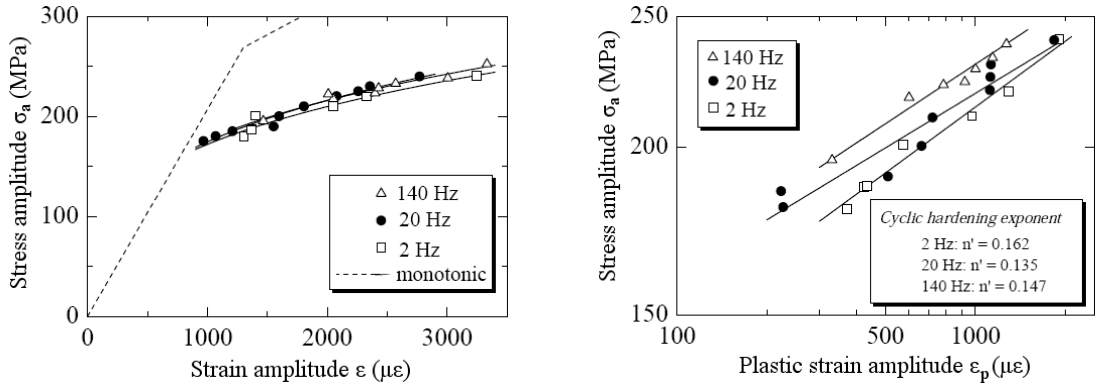
In addition, it is obvious that increasing trend becomes dramatic as the stress level increases. This result is natural, since cyclic softening phenomenon becomes usually more remarkable when material is subjected to higher stress amplitude. One can note that softening get to saturation at a certain number of cycles and then a slight cyclic hardening behavior is observed, as hysteresis loop's area tends to decrease. This phenomenon is particularly obvious for high stress tests.



(a) Hysteresis area under 20 Hz tests (b) Hysteresis area for several tests conditions

Fig.6. Evolution of stress-strain hysteresis loop's area

Figure 6(b) allows a comparison of hysteresis loop's area value between 0.2 Hz, 2 Hz, 20 Hz and 140 Hz fatigue tests at three different stress amplitudes. One can see clearly that hysteresis loop's area is dependent of the fatigue test as the smaller is the frequency, the higher becomes hysteresis energy. In addition, primary cyclic softening behavior is also more severe when frequency decreases.



(a) Comparison Monotonic and CSSC (b) Determination of cyclic hardening exponent

Fig.7. Comparison of CSSC under 2 and 20 Hz

Let us pay now a particular attention on the cyclic stress-strain curve (CSSC). Figure 7(a) allows a comparison of monotonic and cyclic stress-strain curves from fatigue tests at 2, 20 and 140 Hz. One can find that cyclic stress-strain data are lower than monotonic ones. This behavior is in accordance with general cyclic softening already mentioned[4].

In addition, if we consider only plastic strain of hysteresis loops as in Fig. 7(b), the cyclic hardening exponent is equal to 0.162, 0.135 and 0.147 for 2, 20 and 140 Hz fatigue tests respectively. One can note that theses values are close to the usual estimation 0.15 for most of metallic materials[5], regardless its initial conditions. Even though CSSC from 20 and 140 Hz fatigue tests are really close one to each other, one can see that for a similar stress amplitude, total strain amplitude and particularly plastic strain amplitude decreases when the testing frequency is increasing. This fact is of course correlated with the decrease of hysteresis energy already highlighted.

4. Discussion

A clear effect of the testing frequency on the fatigue properties of JIS S15C steel has been reconfirmed in the previous section. Now let us make a discussion on some phenomena, which can be involved in fatigue behavior for the present material.

4.1. Yield stress influence

Effect of strain rate on the yield stress value for this kind of low carbon steels has been reported in some publications[3,6]. This phenomenon is most of the time considered as one of the main phenomena that can explain frequency effect observed.
Figure 8 shows results of tensile tests conducted at different speeds in order to assess the strain rate effect on the present S15C steel. These tensile tests have been conducted according to JIS Z2201 standard, with a 14 mm diameter tested section. Results are compared with data from Tsuchida[7].

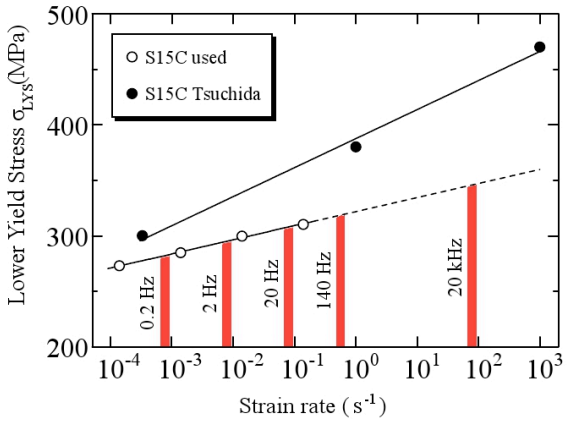


Fig.8. Strain rate effect on yield stress

One can easily find that S15C lower yield stress tends to increase when strain rate is increasing. This trend may be certainly linked with resistance of deformation, which decreases under high-speed tests.
Accordingly to literature from Tsuchida, a logarithmic law has been chosen. Difference of slope between the present work and Tsuchida's results may comes from that tensile test specimens in the case of very high stain rate are significantly smaller than those in usual strain rate range.
The present S15C used shows a regression with a correlation coefficient of 0.998, in the strain rate range from 10^{-4} to 10^{0} s^{-1}. This regression was extrapolated up to a strain rate of 10^{2} s^{-1} in order to assess yield stress value under equivalent ultrasonic fatigue strain rate. For instance, by this means, we obtain a difference of lower yield stress value between 20 Hz and 20 kHz fatigue test conditions of nearly 40 MPa.
This difference has been compared with the fatigue properties of S15C steel already introduced in Fig. 3. The following diagram, in Fig. 9, takes into consideration variation of yield stress by using normalized stress amplitude σ_a by the lower yield stress σ_{LYS} previously assessed.

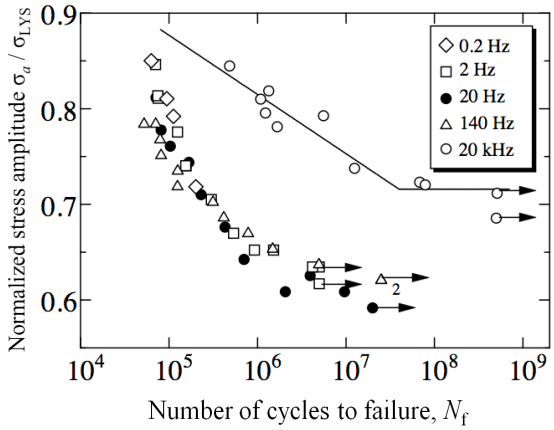

Fig.9. Evaluation of yield stress variation on *S-N* properties

Such a diagram gives us two very interesting points, which have to be discussed. First, if we consider only results from tests performed at 0.2, 2, 20 and 140 Hz, one can see that fatigue strength of S15C steel gathers in a thin area. Besides, fatigue limits from 2 and 140 Hz fatigue tests become really close each other. As a consequence, such a diagram is significant in order to evaluate the yield stress influence on the *S-N* property of S15C steel.

The second main point is of course the case of fatigue results from ultrasonic tests. Due to relatively high difference of yield stress introduced before between ultrasonic tests conditions and usual test frequency conditions, the huge gap of fatigue strength seen in Fig. 3 is significantly lower by taking into consideration the effect of strain rate. Nevertheless, it is not enough to claim that *S-N* properties are similar with other results from usual range frequency. So, the strain rate effect on yield stress is not sufficient to give an entire explanation of fatigue strength gap found in Fig. 3.

4.2. Cyclic hardening / softening behavior

In Figs. 6 and 7, a difference of stress-strain hysteresis phenomenon can be highlighted between 0.2, 2, 20 and 140 Hz fatigue tests. In other words, cyclic softening and hardening behavior seems to be slightly influenced by fatigue test frequency in this range. Of course, it is impossible to undertake similar stress-strain hysteresis study in the case of ultrasonic testing method, as real stress applied on specimen in unknown under ultrasonic technique. So, we cannot assess in the same way a potential discrepancy between ultrasonic and fatigue tests conducted in usual frequency range.

In order to highlight anyway a possible frequency effect on the cyclic hardening and softening, misorientation observation by EBSD method has been performed. This comparison involves 20 kHz and 20 Hz fatigue tests.

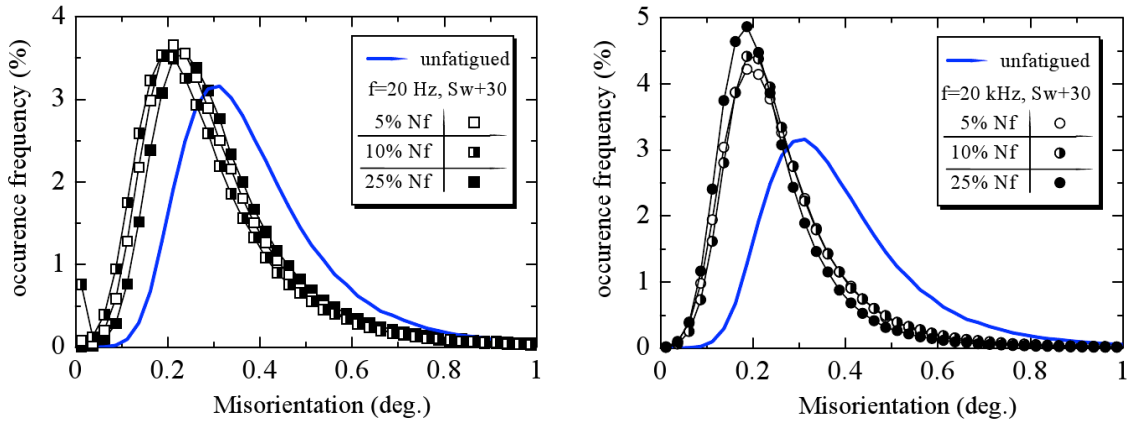
The samples used in this study have been prepared following hereafter instructions. For each frequency, two particular stress levels have been chosen, which are the fatigue limit plus 10 and 30 MPa. These stress levels are called S_w+10 and S_w+30 in the rest of the present paper.

For each stress level, corresponding fatigue strength is given by *S-N* model shown in Fig. 3. Three different specimens were stopped at 5%, 10% and 25% of the calculated fatigue strength. So, 12 different specimens have been fatigued in this process considering both 20 kHz and 20 Hz fatigue tests. After fatigue test has been stopped, center section of the specimen has been extracted, and then polished. Sample final condition has been prepared by OP-AA polishing method in order to

prepare samples for EBSD observations.

Aim of these observations is to determine how lattice misorientation in ferrite phase evolves when fatigue goes. As well-known, cyclic hardening / softening behavior has an impact on dislocation structure[8-9]. This type of experiments can be considered as a first step to evaluate dislocation changes, before conducting direct observation of dislocations.

For each sample, two distinctive map scans of a 200x180 μm^2 area have been conducted. Misorientation curves presented in Figs. 10 and 11 are the average of these two scans. Figure 10(a) reveals that misorientation distribution does not significantly change between stages 5 and 25% of N_f for 20 Hz tests. This is less the case of ultrasonic tests, according to Fig. 10(b), even though dramatic change cannot be seen between these three fatigue stages. However, main result that has to be pointed out here is the drift of distribution into lower misorientation values for fatigued specimens, compared to the condition before fatigue test.



(a) Case of 20 Hz loading frequency (b) Case of 20 kHz loading frequency

Fig.10. Change of misorientation distribution for S_w+*30* stress level

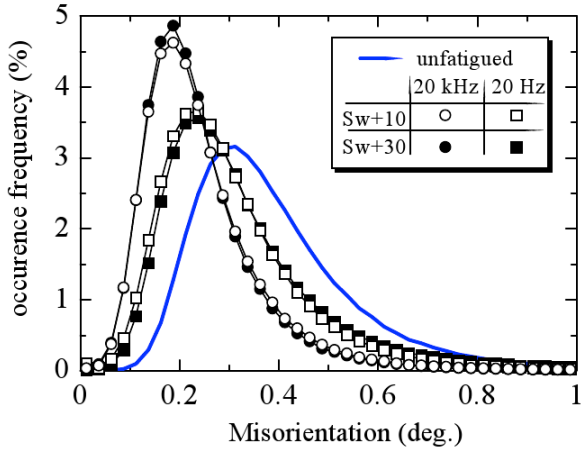


Fig.11. Comparison of misorientation distributions for 20 Hz and 20 kHz conditions at N=25% N_f

Such a result is confirmed in Fig. 11, where results at N=25% N_f for both stress levels studied are presented. It is found at a same frequency, distribution from S_w+*10* and S_w+*30* are similar. However, mode of distributions from 20 kHz tests is obviously lower than 20 Hz. This significant change of mode is certainly linked with dislocation structure changes. More precisely, such a result is an

indication that dislocation structure changes due to fatigue loading at 20 Hz and 20 kHz is not equivalent. A possible explanation of this fact is the time allowed to dislocations to move is necessarily different for a same material fatigued under 20 Hz and 20 kHz conditions.
As a consequence, we can assess that fatigue frequency has an effect on cyclic behavior of S15C steel. Nevertheless, other results are needed to conclude in this way. It is particularly expected to undertake direct dislocations observation in order to be able to detect such a discrepancy in dislocations substructures.

5. Conclusions

(1) Frequency effect on fatigue properties of S15C low carbon steel has been reconfirmed. Fatigue strength tends to increase when testing frequency is increasing.
(2) Strain rate has a clear effect on yield stress value of S15C steel. This phenomenon is involved in the trend described before and explains the slight change of fatigue strength between 0.2 and 140 Hz. However, it is not sufficient to explain the *S-N* properties gap found from ultrasonic method.
(3) Comparison of stress-strain hysteresis loops and EBSD observations indicate a frequency dependence in cyclic behavior. This fact urges us to consider the cyclic hardening / softening properties as one other main phenomenon involved in frequency effect of S15C steel.
(4) Some other works have to be conducted to finalize the study of frequency effect on S15C steel. Particularly, further experiments on cyclic hardening / softening behavior will be undertaken, like dislocation observations.

Abstract In metals, during plastic strain, a significant part of the plastic energy is converted into heat. This generates a heterogeneous temperature field around the crack tip which depends on the intensity of the heat source associated with the plasticity and the thermal boundary conditions of the cracked structure under cyclic loading. Due to the thermal expansion of the material, the temperature gradient near the crack tip creates thermal stresses which contribute to stress field around the crack tip. This paper shows how this thermal effect modifies the mode one stress intensity factor for two cases: (i) the theoretical problem of an infinite plate with a semi-infinite through crack and (ii) a finite plate specimen with a central through crack. The comparison of the two cases allows the authors to discuss the effect of convection. The comparison of the simulated and experimental temperature field variation at the specimen surface (infra-red measurement on a mild steel) leads to identify the heat flux in the reverse cyclic plastic zone. This is the key parameter of the problem. Finally, the consequences of the calculation on the range, the ratio and the maximum and the minimum values of the stress intensity factor are discussed.

Keywords: stress intensity factor, plastic dissipation, reverse cyclic plastic zone, thermal stress

1. Introduction

During experimental study of fatigue crack propagation (for example the characterization of the propagation velocity versus the range of the stress intensity factor) the heating effects associated with the crack propagation are often neglected and the tests are considered as isothermal. This assumption is all the more legitimate when the loading frequency is small. However currently it is increasingly necessary to study the fatigue behavior of materials for long and very long life. Experimental techniques of accelerated tests thus are often carry out in order to reduce test durations : electromagnetic resonance fatigue testing machine with a loading frequency of about hundred Hertz and even ultrasonic fatigue machine with a loading frequency of about several tens of kHz. It is then necessary to know if the assumption of an isothermal process is always valid under these test conditions.

In metals, during plastic strain, a significant part of the plastic energy (around 90% [1,2]) is converted in heat. During a cyclic loading of a cracked structure, the plasticity is located in the reverse cyclic plastic zone near the crack tip [3,4]. This heat source generates a heterogeneous temperature field which depends on the intensity of the heat source associated with the plasticity and the thermal boundary conditions of the cracked structure. Due to the thermal expansion of the material, the temperature gradient near the crack tip creates thermal stresses which contribute to the stress field in this region and on the global stress intensity factor.
The objective of this communication is to propose a method in order to quantify the thermal contribution on the stress intensity factor. In a first part the identification of the heat source associated with the crack propagation will be detailed. In a second part the estimation of the thermal effect on the stress field near the crack tip and on the stress intensity factor will be made for the two geometries: an infinite plate with a semi-infinite through crack and a finite plate specimen with a central through crack and with convection boundary conditions on all the specimen faces. Finally, in the last part, all these results will be compared and discussed.

2. Heat source identification associated with the fatigue crack propagation

In order to identify the heat source associated with the crack propagation a cracked specimen which geometry is given in fig. 1, is subjected to a cyclic loading with a stress intensity factor range of about $20\,MPa\sqrt{m}$ and a stress ratio of 0.1. The loading frequency is about 100Hz and the material is a C40 mild steel with an ultimate tensile strength UTS=600 MPa. The mechanical and thermal properties of this steel are summarized in table 1.
The temperature field at the specimen surface was measured with an infrared camera (CEDIP Jade III MWR) whose spectral range is in the near infrared domain. The acquisition frequency and the aperture time of the camera were respectively 5Hz and 1100µs. In order to reduce the effect of the emissivity of the surface on the temperature determination, the specimen was covered with a fine coat of mat black paint.

Table 1. Mechanical and thermal properties of C40 steel

Material properties	density	Yield stress	Young Modulus	Poisson ratio	Thermal expansion	Heat capacity	Heat conduction	Heat diffusivity
Notation	ρ	σ_y	E	ν	α	C	k	a
Unit	kgm^{-3}	MPa	GPa		K^{-1}	$JK^{-1}kg^{-1}$	$WK^{-1}m^{-1}$	m^2s^{-1}
Value	7800	350	210	0.29	$1.2x10^{-5}$	460	52	$1.4x10^{-5}$

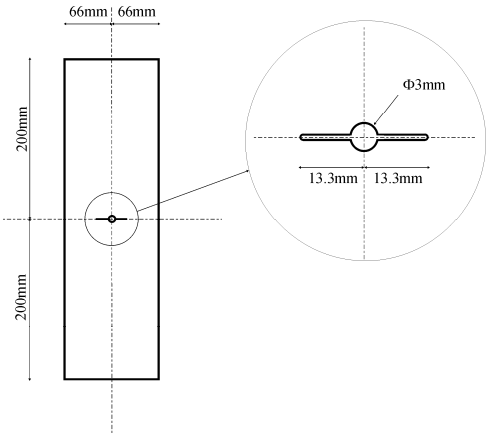

Figure 1. Cracked specimen geometry

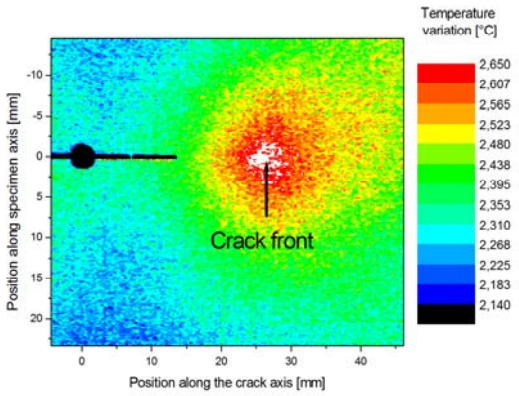

Figure 2. Temperature field near the crack front after 680s

Fig. 2 and fig. 3 show respectively the temperature variation field near the crack tip at time 680s and the temperature evolution according to time at a distance of 5mm from crack front. The temperature evolution on fig. 3 exhibits a superposition of a high frequency evolution of the temperature due to the thermoelasticity and a low frequency signal evolution corresponding to the dissipated power in the reverse cyclic plastic zone. Fig. 2 shows that the temperature distribution remains heterogeneous due to the highly localized form of the heat source in the reverse cyclic plastic zone. The total increase of the temperature in the specimen between the beginning and the end of the test corresponds to the heat source related to the plastic dissipation in the reverse cyclic plastic zone. This total increase in the temperature at a distance of 5mm from the crack front is about 2.5°C.

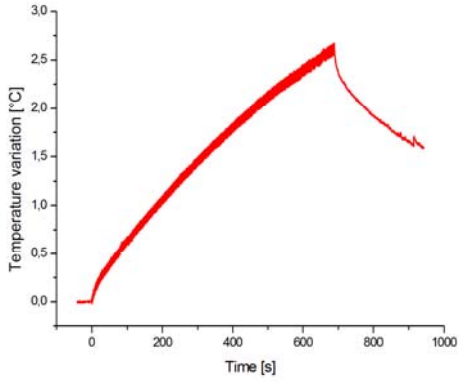

Figure 3. Temperature evolution versus time at a distance of 5mm from the crack front

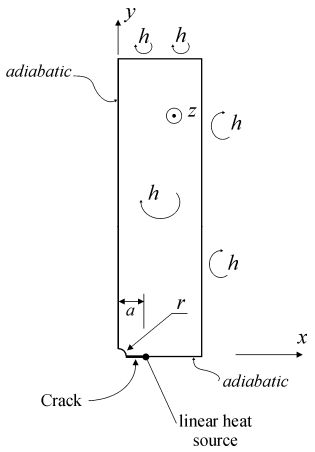

Figure 4. Thermal model, geometry and boundary conditions

In order to determine the heat source associated with the crack propagation. Under plane stress condition the radius of the reverse cyclic plastic zone can be quantified with the relation:

$$r_R = \frac{\Delta K^2}{8\pi\sigma_y^2} \tag{1}$$

For a stress intensity factor of $20\,MPa\sqrt{m}$ the radius of the reverse cyclic plastic zone is about 130µm. This value remains small compared to the size of the specimen. The heat source distribution will be thus considered as linear and centered in the reverse cyclic plastic zone.

For a slow moving crack, the heat source associated with the fatigue crack propagation can be considered to be motionless. This assumption can be justified by the calculation of the Péclet number, noted *Pe*, which compares the characteristic time of thermal diffusion with the characteristic time associated to the heat source velocity (i.e. the velocity of the reverse cyclic plastic zone at the crack tip). In our case the Péclet number is expressed by $Pe = Lv/a$ where L is the characteristic length of crack propagation, v the crack velocity and a the thermal diffusivity. For a crack length of around 1mm, a crack velocity of $0.1 mms^{-1}$ and a thermal diffusivity of 1.4×10^{-5} m^2s^{-1} the Péclet number is 6×10^{-3}. This value remains small compared to unit and therefore the heat source can also be considered as motionless.

In order to identify the heat source a thermal model of the plate was made and solved with the finit element method. The geometry and the thermal boundary conditions are detailed in fig. 4. The heat convection coefficient on the specimen faces and the room temperature are respectively taken equal to $10Wm^{-2}K^{-1}$ and 20°C. For C40 mild steel, the thermal and mechanical properties are given in table 1. A unit line heat source (q=$1Wm^{-1}$) is imposed on the crack front line. For a steady state regime the temperature variation at a distance of 5mm of the crack front is about 0.0163°C. Thanks to the linearity of the heat equation with the heat source, it is possible to deduce a heat source of $153Wm^{-1}$ associated with the fatigue crack loaded with a stress intensity factor range of $20\,MPa\sqrt{m}$.

3. The stress field and stress intensity factor due to the heterogeneous temperature field near the crack tip

2.2. An infinite plate with a semi-infinite through crack

This section is focused on the theoretical problem of an infinite plate with a semi-infinite through

crack loaded in fatigue in mode I. The main advantage of this problem is that it can be solved analytically. In the associated thermal problem, the thermal losses due to convection and radiation are neglected and the steady state regime is only considered. This problem is axi-symetric and the temperature variation distribution $\vartheta(r,t)$ is given by the heat equation:

$$\rho C \frac{\partial \vartheta}{\partial t} = q\delta(r) + k \frac{\partial^2 \vartheta}{\partial r^2}, \tag{2}$$

with δ the Dirac function. A solution of this equation is given in [5]:

$$\vartheta(r,t) = \frac{-q}{4\pi k} \mathrm{Ei}\left(-\frac{r^2}{4at}\right), \tag{3}$$

with $-\mathrm{Ei}(-x) = \int_x^\infty \frac{\mathrm{e}^{-u}}{u} \mathrm{d}u$ the integral exponential function and a the heat diffusivity.

In order to estimate the thermal stresses the thermo-mechanical problem with the temperature variation field previously calculated needs to be solved. The behavior of the material is considered elastic and perfect plastic. It is supposed that the plastic strain occurs only in the reverse cyclic plastic zone. With alternating plasticity, the boundary condition on the reverse cyclic plastic zone radius is radial stress equal to zero.

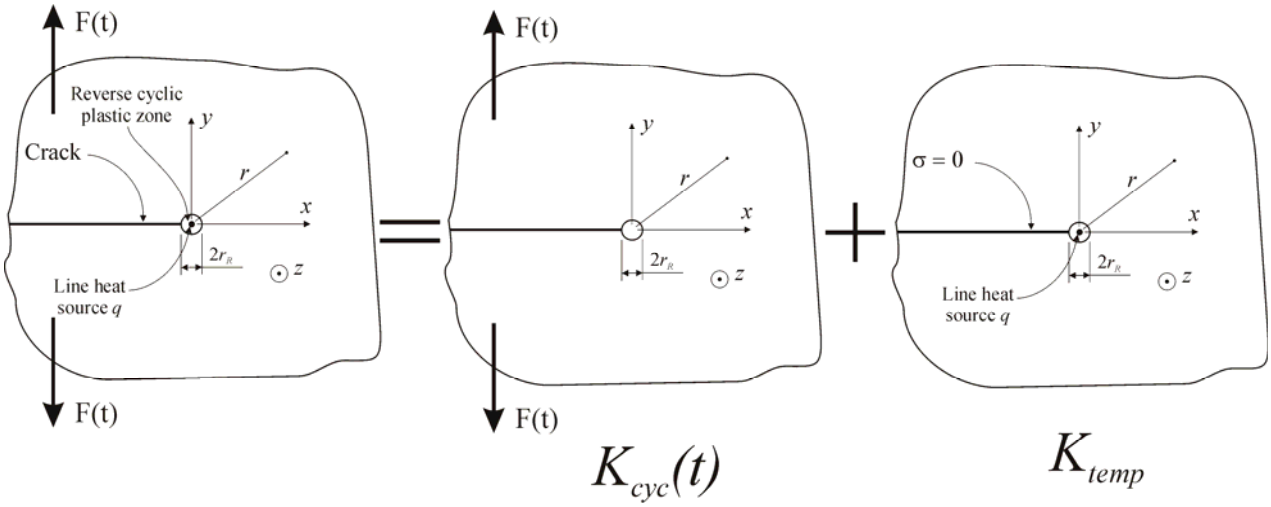

Figure 5. Decomposition of the thermomechanical problem

First the thermomechanical problem can be decomposed into two problems: the first problem (purely mechanical problem) is the cracked specimen subjected only to the cyclic loading $F(t)=F_m+F_a \sin(2\pi f\, t)$ without heat source due to the crack. The stress field associated with this problem is related to a mode one stress intensity factor $K_{cyc}(t)$. The second problem (purely thermal problem) is the cracked specimen subject to the line heat source q. The thermal stresses associated with this thermal loading create to a stress intensity factor named K_{temp}. The thermal effect generates a compressive stress field near the crack front and thus creates a negative contribution on the stress intensity factor ($K_{temp} < 0$) [6]. This decomposition is correct if crack closure due to the thermal effect is neglected and if the thermal effect does not affect significantly the reverse cyclic plastic zone radius. This assumption is realistic if the thermal correction remains small compared to the mechanical loading. The first pure mechanical problem is solved in a classical way and enable us to estimate the mode I stress intensity factor $K_{cyc}(t)$ according to the applied force $F(t)$. In order to solve the second problem, another decomposition is necessary. This second decomposition is illustrated in fig. 6.

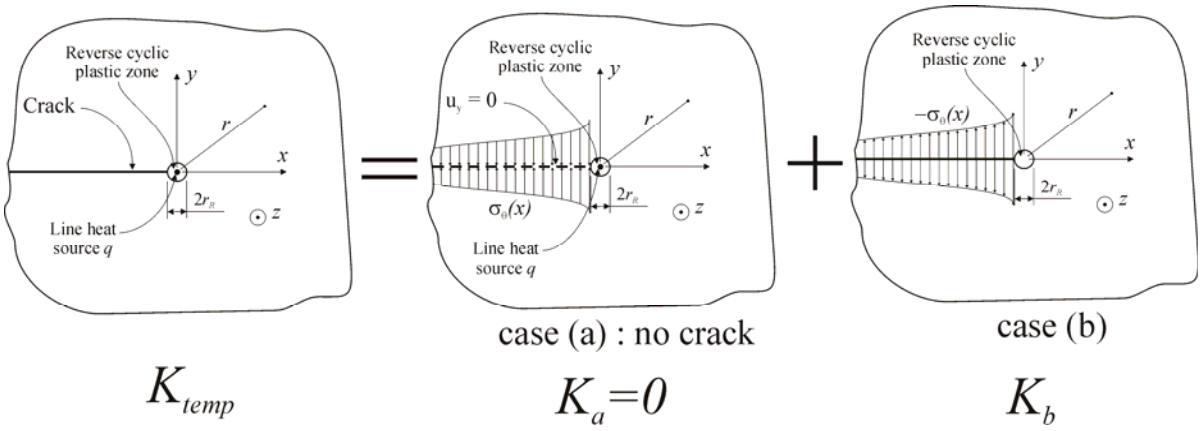

Figure 6. Decomposition of the thermal problem

In the first case (a) a normal stress $\sigma_\theta(r)$ is applied on the crack lips in order to imposed a crack opening equal to zero ($u_y = 0$). This stress $\sigma_\theta(r)$ is calculated from a thermoelastic problem without crack and with the heat source q. The stress intensity factor of case (a) is equal to zero and the stress intensity factor of case (b) is calculated with the Green function:

$$K_{temp} = \sqrt{\frac{2}{\pi}} \int_{r_R}^{\infty} \frac{\sigma_\theta(r,t)}{\sqrt{r - r_R}} \mathrm{d}r \,. \tag{4}$$

The case (a) thermo-mechanical problem is symmetric because both the geometry and the temperature field are symmetric. Only the case of plane stress is considered hereafter but plane strain solution is given in [6]. Further, outside of the reverse cyclic plastic zone since the constitutive behavior of the material is supposed to be elastic, it is expected in first approximation that the basic equations of thermo-elasticity will govern. The equilibrium equation is:

$$r\frac{\partial \sigma_r}{\partial r} + \sigma_r - \sigma_\theta = 0 \tag{5}$$

For which σ_r is the radial normal stress and σ_θ is the circumferential normal stress.
The isotropic elastic stress strain law gives with plane stress hypothesis:

$$\varepsilon_r = \frac{\partial u_r}{\partial r} = \frac{\sigma_r}{E} - \nu\frac{\sigma_\theta}{E} + \alpha\vartheta(r,t) \tag{6}$$

$$\varepsilon_\theta = \frac{u_r}{r} = \frac{\sigma_\theta}{E} - \nu\frac{\sigma_r}{E} + \alpha\vartheta(r,t) \tag{7}$$

A solution of this equation is given in [6] and the circumferential stress can be expressed with the following relation:

$$\sigma_\theta(r,t) = \frac{-\alpha E q}{8\pi k r^2}\left\{4at\left[\exp\left(\frac{-\mathrm{r}_\mathrm{R}^2}{4\mathrm{at}}\right) - \exp\left(\frac{-\mathrm{r}^2}{4\mathrm{at}}\right)\right] - \left[r_R^2 \mathrm{Ei}\left(\frac{\mathrm{r}_\mathrm{R}^2}{4\mathrm{at}}\right) + r^2 \mathrm{Ei}\left(\frac{r^2}{4at}\right)\right]\right\} \tag{8}$$

This circumferential normal stress is then calculated for a line heat source of 153 Wm^{-1} and at time $t = 680$s and this is represented in fig. 7. Near the reverse cyclic plastic zone ($r = r_R = 130\mu$m) the circumferential stress is negative (about -8.24 *MPa*) because the temperature is high and through the circumferential direction, the material is under compression due to the thermal expansion and the constraint effect.

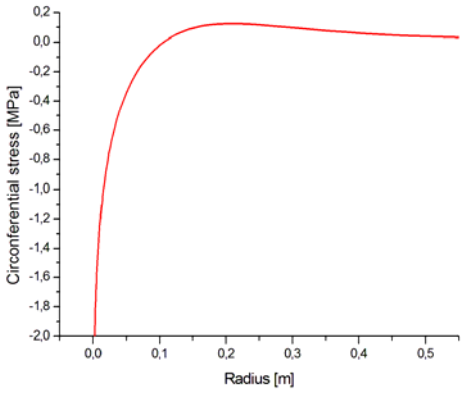

Figure 7. Circumferential stress distribution along radial axis

From equation (1) and (8) it is possible to expressed the associated stress intensity factor K_{temp}. We obtain after integration:

$$K_{temp} = \frac{-\alpha E q}{80k}\sqrt{\frac{2}{\pi}}\left\{40\sqrt{r_R} + \frac{20at\left(\exp\left(\frac{-r_R^2}{4at}\right)-1\right)}{r_R^{3/2}} + \sqrt{r_R}\,\mathrm{Ei}\left(\frac{-r_R^2}{4at}\right)\right.$$

$$+\frac{10(at)^{1/4}}{\Gamma\left(\frac{7}{4}\right)}\left(3{}_2F_2\left[\left(\frac{-1}{4},\frac{1}{4}\right),\left(\frac{1}{2},\frac{3}{4}\right),\frac{-r_R^2}{4at}\right]\right)+\frac{10(at)^{1/4}}{\Gamma\left(\frac{7}{4}\right)}\left({}_2F_2\left[\left(\frac{1}{4},\frac{3}{4}\right),\left(\frac{1}{2},\frac{7}{4}\right),\frac{-r_R^2}{4at}\right]\right)$$

$$\left.-\frac{8r_R}{(at)^{1/4}\Gamma\left(\frac{1}{4}\right)}\left(5{}_2F_2\left[\left(\frac{1}{4},\frac{3}{4}\right),\left(\frac{5}{4},\frac{3}{2}\right),\frac{-r_R^2}{4at}\right]\right)-\frac{8r_R}{(at)^{1/4}\Gamma\left(\frac{1}{4}\right)}\left({}_2F_2\left[\left(\frac{3}{4},\frac{5}{4}\right),\left(\frac{3}{2},\frac{9}{4}\right),\frac{-r_R^2}{4at}\right]\right)\right\}, \quad (9)$$

With the hypergeometric function

$${}_pF_q = \left(\{a_1,\ldots,a_p\},\{b_1,\ldots,b_q\},z\right) = \sum_{i=1}^{+\infty}\frac{(a_1)_i\ldots(a_p)_i}{(b_1)_i\ldots(b_q)_i}\frac{z^i}{i!},$$

where $(a)_i = \dfrac{\Gamma(a+i)}{\Gamma(a)} = a(a+1)(a+2)\ldots(a+i-1)$ is the Pochhammer symbol and $\Gamma(x) = \int_0^{+\infty} u^{x-1}\mathrm{e}^{-x}\mathrm{d}u$ the Euler Gamma function.

The value of K_{temp}, the thermal correction on the stress intensity factor, is estimated for a line heat source of 153Wm^{-1} and the typical material characteristics detailed in table 1. Eq. (9) gives a thermal correction on the stress intensity factor of -0.521 $MPa\sqrt{m}$.

2.2. A finite plate with a central through crack

For being representative of a real crack propagating problem let us now consider a finite plate with a central through crack. In such case thermal losses due to convection on the specimen faces, the effect of the temperature gradient near the crack front and thus the thermal correction of the stress

intensity factor cannot be neglected. For this type of thermomechanical problem it is not possible to find an analytical solution. That is the reason why computations of both the temperature field and the associated stresses and strains have been carried out by a finite element analysis.
First, the temperature field is calculated with the same model presented in section 2 for the thermal source identification. The steady state temperature field is thus calculated and represented on figure 8 for a line heat source of 153Wm^{-1}.

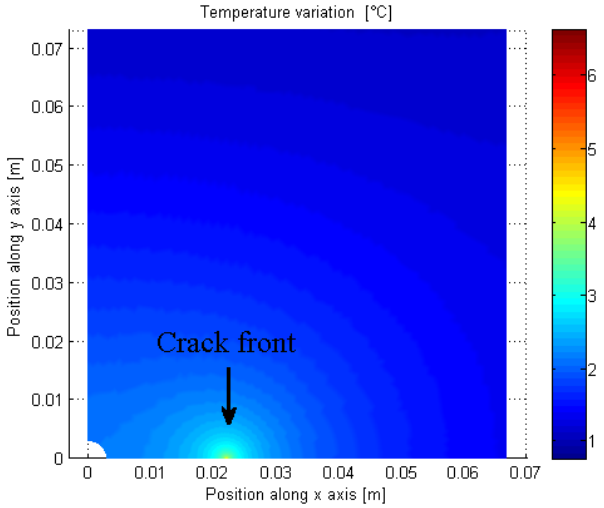

Figure 8. Temperature field near the crack front

The same type of decomposition and assumptions as presented for the previous geometry are used to calculate the stress field in the specimen. These two decompositions are detailed in figure 9 and 10.

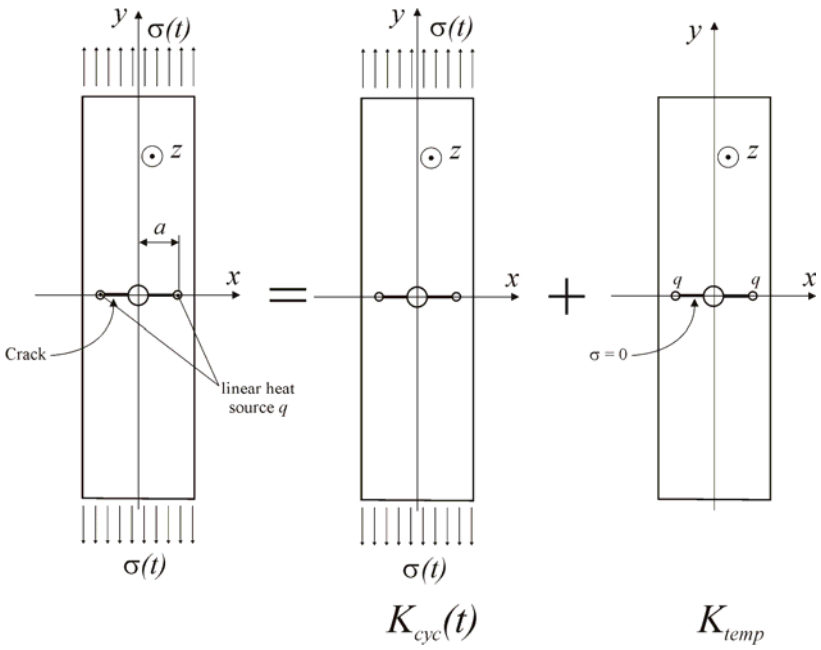

Figure 9. Decomposition of the general problem

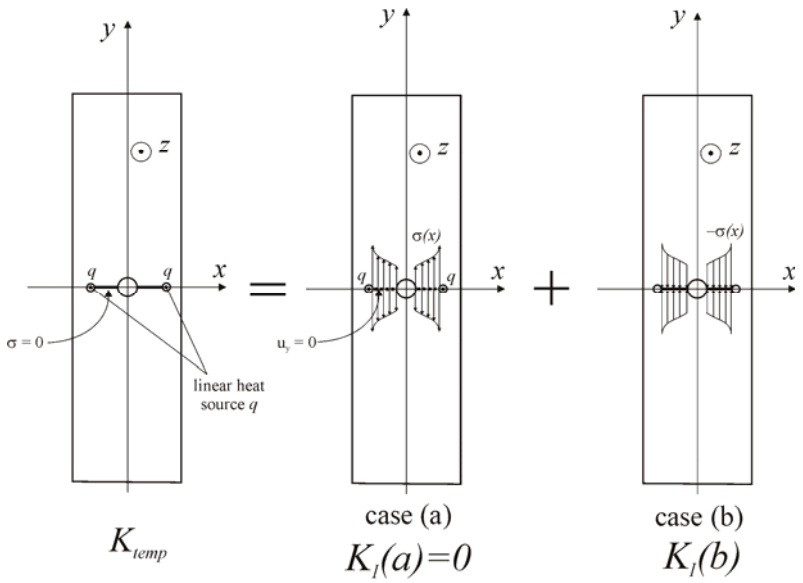

Figure 10. Decomposition of the thermal problem

Figures 11 and 12 show the normal stress in the direction of the y axis. The thermal effect on the stress intensity factor, K_{temp}, is calculated from the case (a) with the Green function and the stress field along the x axis calculated with the case (b) :

$$K_{temp} = \frac{2}{\sqrt{\pi}} \int_0^a \sigma(x) \frac{\sqrt{a}}{\sqrt{a^2 - x^2}} \mathrm{d}x \tag{10}$$

with a the crack length. The value of the thermal correction of the stress intensity factor K_{temp} for the plane problem with an centered through crack for a line heat source of 153Wm^{-1} is about -0.316 $MPa\sqrt{m}$.

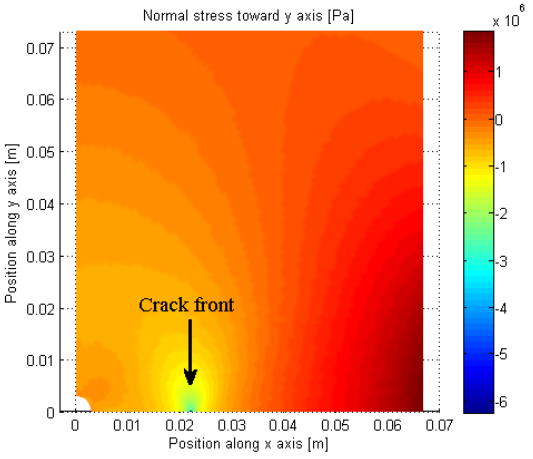

Figure 11. Normal stress field in the direction of the y axis

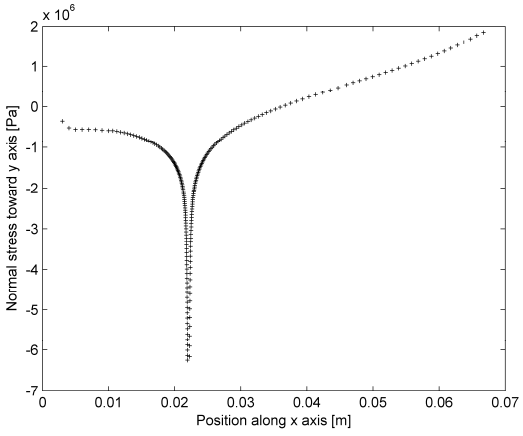

Figure 12. Normal stress in the direction of the y axis distributed along the x axis

2. Conclusion

The correction on the mode one stress intensity factor, K_{temp}, determined in the two previous sections is a value superimposed on the usual stress intensity factor due to the fatigue cyclic loading, noted K_{cyc}(t), which varies at each cycle between a maximum, $K_{cyc,max}$, and a minimum, $K_{cyc,min}$, of the stress intensity factor. As written before, due to the compressive thermal stresses around the

crack tip it has been shown that the stress intensity factor during a fatigue loading has to be corrected by the factor K_{temp}. This thermal effect on the stress intensity factor varies slowly with time and can be considered as constant during one cycle. Consequently the temperature has no effect on the stress intensity factor range ΔK but it has an effect on both the maximum, K_{max}, and minimum, K_{min}, values of the stress intensity factor:

$$K_{max}=K_{temp}+K_{cyc,max} \tag{11}$$

$$K_{min}=K_{temp}+K_{cyc,min} \tag{12}$$

However, K_{temp} can affect crack closure by changing the load ratio (equation 13) and because of the compressive nature of the thermal stresses around the crack tip:

$$R_K = \frac{K_{min}}{K_{\max}} = \frac{K_{temp} + K_{cyc,\max}}{K_{temp} + K_{cyc,\min}} \neq \frac{K_{cyc,\max}}{K_{cyc\min}} \tag{13}$$

In the two problem geometries presented in this paper, the results on the thermal correction of the stress intensity factor are very closed. For a stress intensity factor range of $20\,MPa\sqrt{m}$ and a stress ratio of 0.1 the thermal correction is about $-0.521\,MPa\sqrt{m}$ for an infinite plate with a semi-infinite through crack and $-0.316\,MPa\sqrt{m}$ for a finite plate with a central through crack with considering thermal losses due to convection. In conclusion the geometry of the specimen and the thermal boundary conditions have a very small effect on the results. For test on mild steel at a loading frequency of 100Hz, the values of K_{temp} remain very small and a new stress ratio of 0.087 (compared to 0.1, the initial stress ratio) can be calculated.

However, since the dissipated energy rate per unit length of the crack front is proportional to both the loading frequency and to $\Delta K^4/\sigma_y^4$ this effect should be more important for ductile metals (low yield stress) loaded under high stress intensity range. Revisiting the frequency effect on the fatigue crack growth could be also interesting by taking this thermal correction consideration.

Abstract: The aim of this study was to evaluate the influence of plasma nitriding process on the fatigue limit of PH-42 Supra steel provided by Schmolz + Bickenbach of Brazil. The paper presents the experimental results of rotating bending fatigue tests for specimens as received and treated by plasma nitriding process with a nitrided layer of 0.3mm. This material is employed in manufacturing polymer injection molds and inserts, and offers high hardness and good machinability. The fatigue tests were carried out by a rotating bending fatigue machine which allowed to plot and compare the Wöhler's curve for both types of steel specimens. Moreover, the hardness of the nitrided layer and substrate, the hardness of the non-nitrided specimens, the ultimate strength from simple tensile tests were determined experimentally. The fatigue testing results were used to obtain the material empirical Basquin's fatigue life equations. Photographs by SEM of the fractured surface were obtained and provided a visual aspect analysis of nitrided and non-nitrided specimens in tensile and fatigue testing. The fatigue limit stress increased from 440 MPa to 710 MPa for non nitrided and plasma nitrided PH-42 steel respectively. In addition, the fatigue limit behavior and fracture mechanisms, depending on the application of advanced plasma nitrided layer, are also discussed.

Keywords: PH-42 steel, rotating bending test, plasma nitriding, fatigue limit.

1. Introduction

Rupture in a structural or mechanical component frequently initiate at metal surface under two loading conditions, owing to metal fatigue process. Firstly, it is related to high loading cycles of component, leading to resultant stresses greater than the material fatigue limit. Under this type of high loading, rupture occur at shorter number of cycles due to the inception of surface micro-cracks which are originated from shear bands in preferential sliding atomic planes and directions in the material.

Secondly, there are situations of fracture occurring in components due to surface crack nucleation which are originated from surface defects such as grooves, scratches, pores, holes or metallic inclusions, even for low stresses. However, fatigue cracks can also be originated from non-metallic inclusions and defects situated in sub-layers just below the component surface [1]. This kind of rupture has been referred in literature to explain the behavior of high strength steels. In surface treated steels, fatigue limit is expected to increase proportionally to hardness increase. However, it is worth to recall that for steels with hardness above 400 Vickers there is a reduction of fatigue limit which is related to non-metallic inclusions. This can be observed in Fig. 1, showing the fatigue limit of various steel grades versus hardness [2]: fatigue limit increases up to a maximum and then falls with increasing hardness.

Moreover, there are other issues related to fatigue resistance of steels such as the presence of profile of residual stresses near the surface site of crack nucleation due to machining and shot peening processes [3].

In metal fatigue, tensile stresses act to open crack tip and promotes crack growth. However, compressible stresses can increase the fatigue limit or have little or no contribution to crack generation and propagation. In this context, it is important to study the fatigue limit of machined steel components of high hardness and steel components with plasma nitriding surface treatment which increase even more the surface hardness.

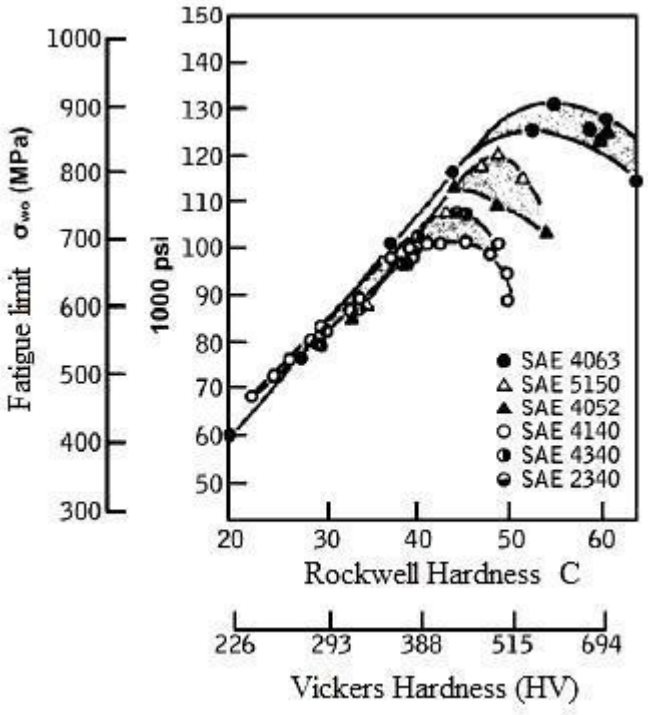

Figure 1. Fatigue limit of various steel grades versus hardness [2].

Hence, the main goal of this work is to present and compare the experimental results of rotating bending fatigue tests of PH-42 Supra steel plasma nitrided and non-nitrided which is low carbon steel and are employed to fabricate plastic injection molds and inserts.

2. Material and Experimental Procedure

Fatigue tests were performed using specimens of PH-42 Supra steel delivered by Schmolz + Bickenbach of Brazil. According to the steel supplier, the material had limit strength of 1250 MPa, elasticity modulus of 206 GPa and Rockwell hardness of 40HRC [4]. For the plasma nitrided steel specimens the attained surface hardness was 60HRC. The material chemical composition is shown in Table 1.

Table 1. Chemical composition of PH-42 Supra steel, according to supplier [5].

C %	Mg %	Ni %	Cu %	Al %
0.15	1.5	3.0	1.0	1.0

25 fatigue test specimens as received (non-nitrided) and 25 plasma nitrided specimens with a nitriding layer of 0.3mm, were tested in a rotating bending fatigue machine and the results were plotted and compared by Wöhler's curve for both types of steel specimens. Besides, the surface hardness of non-nitrided and plasma nitrided specimens and the limit strength were obtained by hardness and tensile tests respectively. Photographs by SEM of the fractured surface specimens were obtained and provided a visual analysis of fracture of nitrided and non-nitrided specimens in tensile and fatigue tests.

The fatigue test specimens were machined from one bar, according to the dimensions seen in Fig.2. Each specimen were polished to surface average roughness of Ra = 0.11μm in the useful region which had lower specimen diameter of 7.0mm.

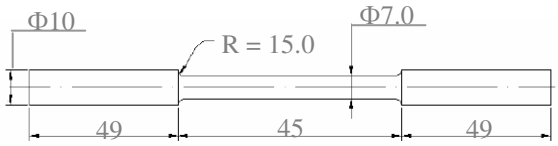

Figure 2. Geometry dimensions of rotating bending fatigue test specimens.

Figure 3 shows a photo of a non-nitrided specimen employed in the rotating bending fatigue test which attained a fatigue life over 10^6 cycles.

Figure 3. Photo of a rotating bending fatigue test specimen which attained fatigue life over 10^6 cycles.

2.1. Fatigue Tests

Fatigue tests were carried out in the rotating bending fatigue machine, type TYP RM 506, Budapeste/Hungary, seen in Fig. 4. The specimen bending load was applied by a load arm existing in the machine. The true bending load applied on the fatigue specimen corresponds to 10 times the load applied on the plate situated at the opposite arm end.

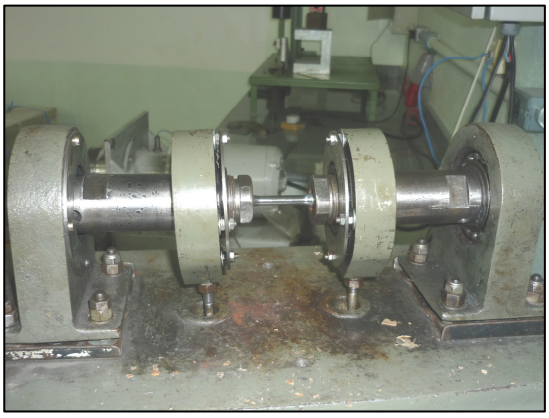

Figure 4. Photo of the rotating bending fatigue machine, type TYP RM 506, utilized in the fatigue tests.

Hence, the tensile and compression stresses on the specimen surface were calculated by the equation,

$$\sigma = 160\frac{P\,a}{\pi D^3} \quad (kgf/mm^2) \tag{1}$$

where D (= 7mm) is the diameter of the useful region in the specimen, P (kgf) is the applied load on the plate at the load arm end and "a" is the distance from the point of bending support (ball bearing) to the point of load application. For the nitrided specimens, the load varied from 4.8 to 8.0kgf and for non-nitrided specimens the load varied from 2.72 to 5.2kgf. The electric motor rotating velocity was fixed and equal to 3000 rpm.

The fatigue tests were initiated for high applied load until the specimen rupture. This high load was gradually reduced for the following specimens till obtaining the fatigue limit for the material. The fatigue limit was defined as the maximum stress for fatigue life of 10^6 cycles.

3. Results and Discussions

3.1. Vickers Micro-Hardness

Tables 2 and 3 shows the average Vickers micro-hardness (mHV), using indenter load of 500g, for the PH-42 Supra steel fatigue specimen plasma nitrided at two distinct regions: measured on the plasma nitrided surface layer of 0.3mm, Table 2, and at the substrate or bulk of material, Table 3. In addition, the correspondent Rockwell C hardness conversion is also presented. In Table 4, the average Vickers micro-hardness measured at surface, indenter load of 500g, for the non-nitrided specimen of PH-42 Supra steel fatigue specimen is presented. The nitriding process has increased the substrate material hardness from 454 to 885 mHV as can be observed from Table 3 and 4.

Table 2. Vickers micro-hardness of nitrided surface layer of PH-42 Supra steel nitrided specimen.

Load 500g	Vickers micro-hardness (mHV0.5)	Conversion to Rockwell C hardness (HRC)
	861.22	65.9
	900.56	67.0
	893.77	66.8
Average	885.2	66.6

Table 3. Vickers micro-hardness of substrate of PH-42 Supra steel nitrided specimen.

Load 500g	Vickers micro-hardness (mHV0.5)	Conversion to Rockwell C hardness (HRC)
	680.41	59.2
	588.70	54.6
	599.54	55.2
	727.31	61.2
Average	648.99	57.7

Table 4. Vickers micro-hardness of PH-42 Supra steel non-nitrided specimen.

Load 500g	Vickers micro-hardness (mHV0.5)	Conversion to Rockwell C hardness (HRC)
	446.0	45.0
	434.0	44.0
	484.0	48.0
	506.0	45.6
Average	454.2	45.6

3.2. Surface Roughness

Before fatigue tests, the arithmetic average surface roughness Ra of plasma nitrided and non-nitrided specimens were measured, utilizing a profilometer Supertronic 25 Taylor Robson, with total sliding distance of 4.0mm and Gausian filter of 0.8mm [5]. The experimental results for three specimens and total average Ra are presented in Table 6 for 10 measurements on each specimen. The plasma nitrided specimens have increased the surface roughness Ra in relation to the non-nitrided specimens, but they both can be considered polished for their very low values. This is due to the formation of precipitates and nitrides on the nitriding layer [6].

Table 7. Arithmetic average surface roughness Ra of plasma nitrided and non-nitrided specimens.

Specimen	Ra (μm) Plasma nitrided	Ra (μm) non-nitrided
1	0.31	0.14
2	0.44	0.11
3	0.29	0.08
Total average	0.35	0.11

3.2. Rotating Bending Fatigue Test Results

The fatigue limits for as received (non-nitrided) and plasma nitrided specimens were obtained directly from the plotted Wöhler's curve, seen in Fig. 5, which is the curve of fatigue life for the alternate bending stress tests versus total number of cycles to specimen fracture [7]. According to ASTM E466 standard recommendation, fatigue limit correspond to the maximum rupture stress for the number of cycles equal or superior to 10^6 cycles. The average values are presented in Table 5.

Table 5. Fatigue Limit Stress for PH-42 Supra steel specimens plasma nitrided and non-nitrided. Average values obtained from the plotted Wöhler's curve for fatigue life (1kgf/mm^2 ≅ 10 MPa).

Specimen	Fatigue Limit Stress σ_{fad} (MPa)
Ph-42 Supra steel plasma nitrided	710.0
Ph-42 Supra steel non-nitrided	440.0

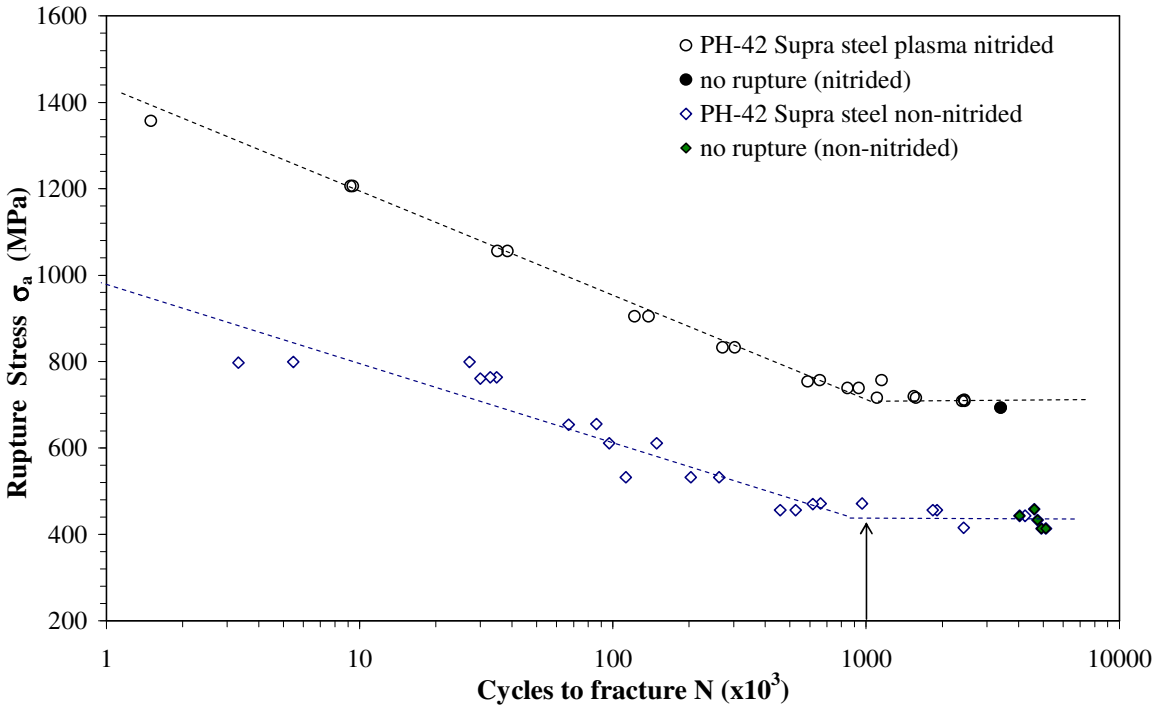

Figure 5. Stress versus number of cylces N to fracture curves for rotating bending fatigue test for PH-42 Supra steel non-nitrided and plasma nitrided with layer of 0.3mm. Fatigue limit is for $N=10^6$ cycles.

In Fig. 6, some fractured non-nitrided specimens after the rotating bending fatigue tests can be observed which fracture site is similar to the plasma nitrided specimens.

Figure 6. Photo of three non-nitrided specimens after the fatigue test.

3.3. Tensile Tests

Tensile tests were also performed, using the same fatigue test specimens of PH-42 Supra steel plasma nitrided with nitriding layer of 0.3mm and non-nitrided as seen in Fig. 2. The ultimate tensile strength values are shown in Table 6.

Table 6. Ultimate tensile strength obtained experimentaly from tensile tests.

Sperimen	Ultimate tensile strength σ_t (MPa)
Ph-42 Supra steel plasma nitrided	1174.3
Ph-42 Supra steel non-nitrided	1150.0

3.4. Basquin's Equation

The empiric law of Basquin for fatigue life [8] of PH-42 Supra steel plasma nitrided specimens obtained from the plotted mean curve in Fig. 5 is given by,

$$\sigma_a = 2921\ N_f^{-0.1024}\ (\text{MPa}) \tag{2}$$

and for PH-42 Supra steel non-nitrided specimens, the Basquin's equation is given by,

$$\sigma_a = 2182.7\ N_f^{-0.1159}\ (\text{MPa}) \tag{3}$$

where σ_a is the bending cyclic stress amplitude and N_f is the number of cycles to rupture.

3.5. Fractograph by SEM

Fracture surface by SEM of PH-42 Supra steel plasma nitrided tensile test specimens are shown in Fig. 7a and 7b. Surface cracks initiated in the nitrided layer and at 90 degree to the load line are seen. Hence, the fracture mechanism of the nitrided layer was brittle fracture due to principal maximum tensile stress. The measured plasma nitrided layer thickness was 337.87μm.

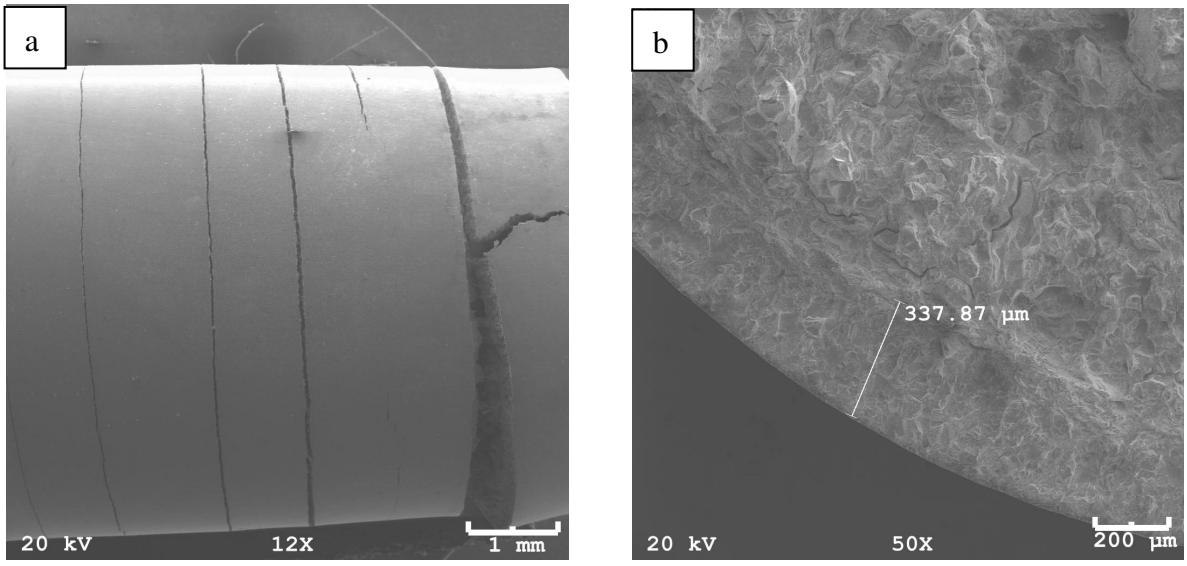

Figure 7. SEM photos of fractured PH-42 Supra steel plasma nitrided tensile test specimen: a) surface cracks and b) fracture surface showing the plasma nitrided layer thickness of 337.87μm.

In Fig. 8, fracture surface of fatigue test specimen of PH-42 Supra steel non-nitrided are presented. Brittle fracture mechanism in Fig. 8a and 8b and the fatigue crack length near the specimen surface can be observed. In Fig. 9a and 9b, fracture surface of fatigue test specimen of PH-42 Supra steel plasma nitrided are shown. Instantaneous rupture by brittle fracture and a very small fatigue region

near specimen surface are seen. The fatigue crack length near the specimen surface can be evaluated in Fig. 9b, approximately 20μm owing to plastic compressive deformations.

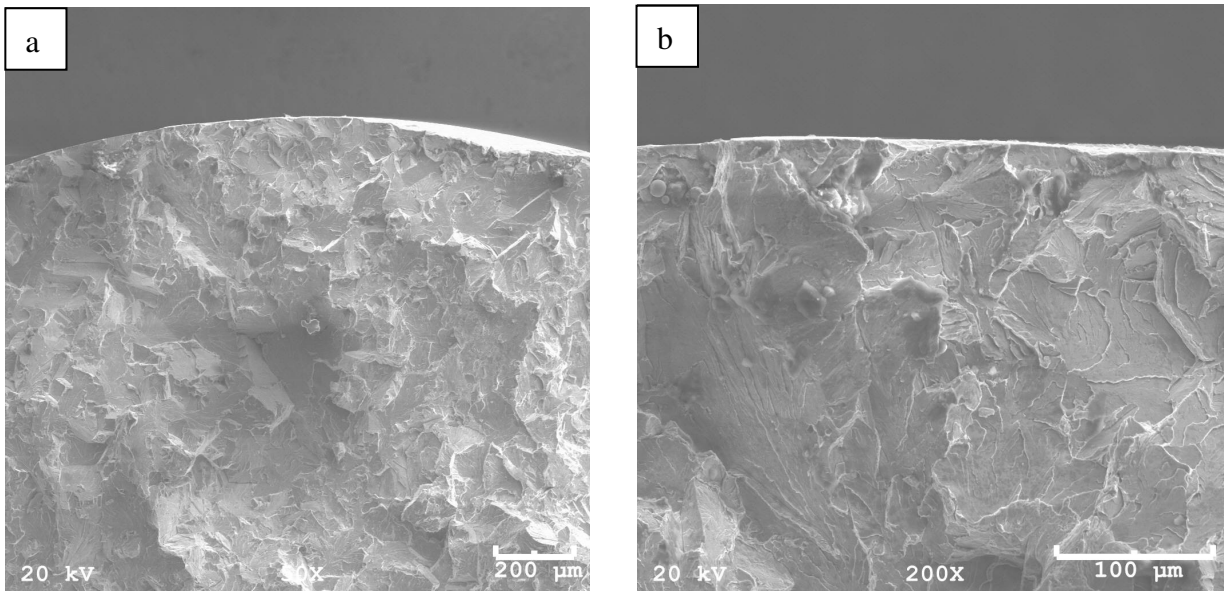

Figure 8. SEM photos of fracture surface of PH-42 Supra steel non-nitrided fatigue test specimen in rotating bending test: a) rupture by brittle fracture and b) detail of beginning of fatigue crack at specimen surface.

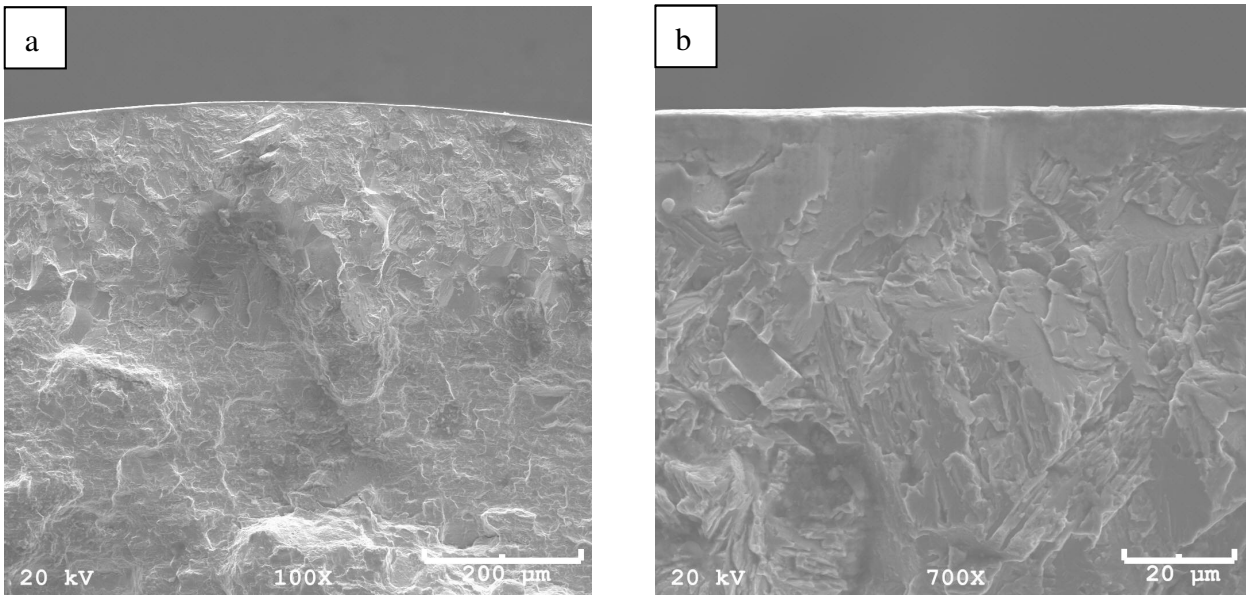

Figure 9. SEM photos of fracture surface of PH-42 Supra steel plasma nitrided fatigue test specimen in rotating bending test: a) rupture by brittle fracture and b) detail of fatigue crack growth at specimen surface.

4. Conclusions

From the experimental results of PH-42 Supra steel (Schmolz + Bickenbach do Brasil) plasma nitrided, nitriding layer of 0.3mm, and as received (non-nitrided) specimens tested in tensile test, Vickers micro-hardness and rotating bending fatigue testing and analysis of fracture surface by SEM, the following conclusion can be drawn,

a) Fatigue limit stress of PH-42 Supra steel plasma nitrided was 710 MPa which is much higher

than the bulk material or non-nitrided specimen of 440 MPa. Hence, the plasma nitriding process has increased the fatigue limit stress by 61%.

b) The plasma nitriding process has increased the material hardness from 454 to 885 mHV.

c) Basquin's empiric law for fatigue life of PH-42 Supra steel plasma nitrided specimens was $\sigma_a = 2921\ N_f^{-0.1024}$ (MPa) and for non-nitrided specimens, $\sigma_a = 2182.7\ N_f^{-0.1159}$ (MPa).

d) SEM analysis of fracture surface of fatigue test specimen of PH-42 Supra steel non-nitrided presented brittle fracture mechanism: the fatigue crack length near the surface was very small.

e) SEM analysis of fracture surface of fatigue test specimen of PH-42 Supra steel plasma nitrided had shown rupture by brittle fracture and a very small fatigue region near specimen surface. The fatigue crack length near the specimen surface was evaluated approximately 20μm owing to plastic compressive deformations.

f) The plasma nitrided specimens have increased the surface roughness Ra in relation to the non-nitrided specimens from Ra = 0.11μm to 0.35μm for non-nitrided and plasma nitrided respectively, but they both can be considered polished for their very low values.

g) In tensile tests, surface cracks initiated in the nitrided layer and at 90 degree to the load line are seen. Hence, the fracture mechanism of the nitrided layer in tensile test was brittle fracture due to principal maximum tensile stress.

Abstract The presented work is devoted to the experimental study of heat dissipation process caused by fatigue crack propagation. To investigate a spatial and time temperature evolution at the crack tip, set of experiments has been carried out using plate titanium specimens with pre-grown centered fatigue crack. An original mathematical algorithm for experimental data treatment has been developed to obtain a power of heat dissipation caused by plastic deformation at the crack tip. The algorithm includes spatial-time filtration and relative motion compensation procedures. The time dependence of the stored energy was calculated as difference between work caused by plastic deformation near the crack tip and heat dissipation energy obtained from experimental data. As a result, it has been shown that the stored energy has to accumulated during the fatigue test and has to be equal to zero when the crack reaches the critical length corresponding to the sample failure.

Keywords stored energy, plastic work, fatigue test, heat dissipation, infrared thermography

1. Introduction

Infrared thermography is the simple way to measure the temperature of surface and to monitor of crack propagation during cycling test. It is well know that the changing of the temperature correlates to the physical processes of damage and failures in metals [1]. The application of infrared thermography as a non-destructive method to detect the damage accumulation and to investigate the fatigue process of materials has become popular and has been wildly investigated in literature in last 25 years.

In materials under cyclic deformation, fatigue cracks are initiated in the area of plastic deformation localization and lead to an intensive heat dissipation [2]. Investigation of the heat dissipative and absorption laws can take information about dissipative ability of material and current state of structural evolution.

This work is devoted to investigation the time evolution of the stored energy during fatigue test using infrared technique and specially developed methods of data processing. Proposed approach allows us to measure parts of plastic work that dissipated as heat and stored in metals at fatigue crack tip. Study of these tasks enables to obtain information about the evolution laws describing the irreversibility of the fatigue process.

2. Materials and conditions of experiments

Experimental study of temperature evolution at the fatigue crack tip was carried out on the plane specimens of titanium Ti-4.2Al-1.6Mn. The specimens were manufactured from a commercial titanium sheet 3 mm thick.

Mechanical properties of material are modulus of elasticity - 64 GPa, yield stress - 800 MPa, ultimate stress 900 MPa, fatigue limit (R=-0.051) – 460 MPa, fracture toughness – 75.6 MPa$\sqrt{m}$.

The geometry of specimen is shown in Fig. 1. The specimens were weakened by holes to initiate fatigue crack at the specimen center. The fatigue crack (about 10 mm) was initiated at the initial stage of the experiment by high amplitude cyclic loading of the specimens at the average stress of 215MPa, stress amplitude of 238 MPa and loading frequency of 20 Hz. Then the load was decreased to slow down the rate of crack propagation, which allows a detailed analysis of the heat generation processes at the crack tip. The surface of the specimens was polished in several stages by

the abrasive paper (at the final stage of polishing the grit size does not exceed 3 μm). Before starting the experiment, the polished surface was covered by a thin layer of amorphous carbon.
The temperature evolution was recorded by infrared camera CEDIP Silver 450M. The spectral range of the camera is 3-5 mm. The maximum frame size is 320×256 pixels; the spatial resolution is 10^{-4} meters. The temperature sensitivity is 25 mK at 300 K. Calibration of the camera was made based on the standard calibration table.
Mechanical tests were carried out at 100 kN servo-hydraulic machine Bi-00-100. The test conditions comply with the conditions of the experiment was described in [3]. The process of crack propagation was studied at 5 Hz loading frequency.
The selected frequency of loading provides a close to adiabatically condition at crack tip. At low frequency (less that 5 Hz) the heat transfer process plays a great role and doesn't allow one to calculate the right value of heat source. The investigation of high loading frequency requests the high frame rate and treatment of large amount of infrared data.

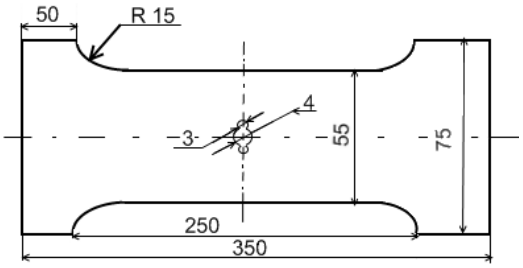

Figure 1. Geometry of sample (all sizes are in millimeters).

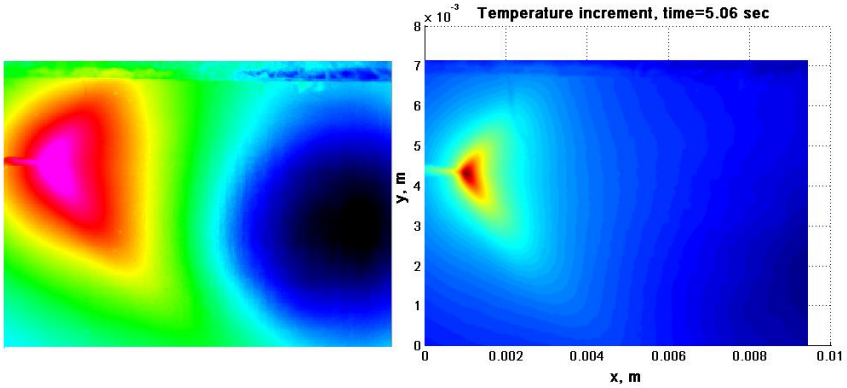
3. Experimental data processing and determination of the stored energy

At the beginning of data processing procedure, the first frame was subtracted from the film to eliminate the influence of infrared radiation from the camera lens on the determined temperature field. Due to the relative motion of the specimen and infrared camera lens under cyclic tests, there is the problem of motion compensation in order to obtain the correct temperature data at a given point on specimen surface. Compensation of relative motion was made based on the algorithm described in details in [4]. The main idea of this algorithm is the selection of marker-zone on the studied surface and searching this area on the surface in each next time step. Farther, displacement of each point on the surface is calculated for each time step. As a result of data processing, we obtained the temperature increment field (Fig. 2) based on which the heat sources field was determined.



A **B**
Figure 2. Infrared image of sample before data processing (A) and obtained temperature increment field (B).

To calculate the specific power of the heat source, we have used a finite difference scheme of the equation for heat sources evolution (Eq. 1).

$$s = \rho c\left(\dot{T} + \frac{T}{\tau}\right) - k\Delta T, \tag{1}$$

where T – temperature, ρ – density (4550 kg/m^3), c – heat capacity (600 J/(kg·K)), k – heat conductivity (6.5 W/(m·K)), s – unknown specific power of the heat source (W/m^3), τ – a constant related to the losses of heat by heat exchange with the surroundings (10^3 J/(m^3·K)).
The heat power of sources close to fracture moment (at 5.06 sec after beginning of the last stage of test) is shown in Fig. 3. At the last moments before fracture, we can observe pronounced plastic deformation at crack tip and plastic zone has a "butterfly form" near the crack tip as it is presented in Fig. 3.

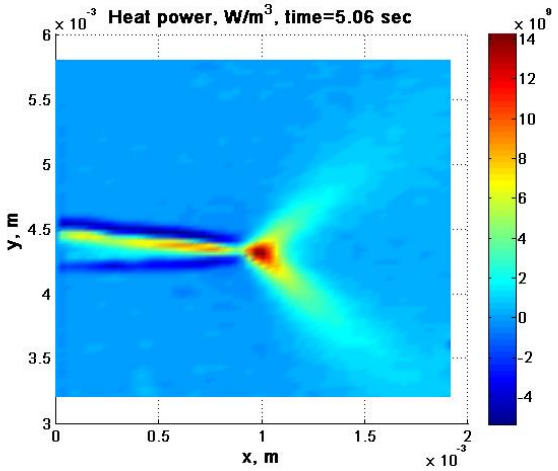


Figure 3. Experimental data of heat power field near the crack tip at the beginning of unstable crack propagation.

Taking into account assumption from [5, 6], we also suppose that some of the irreversible plastic work contributes to heat generation while the rest is stored as energy of crystal defects accompanying plastic deformation, traditionally known as the stored energy of cold work.
To define the plastic work near the crack tip we used the solution for stress distribution at crack tip obtained by Hutchinson, Rice and Rosengren (HRR-solution). Specific plastic work in the direction of crack propagation can be written as [7]:

$$w_p(x,t) = \int_0^{\varepsilon_p} \sigma d\varepsilon = \frac{n}{n+1}\frac{J(t)\sigma_e^{n+1}}{I_n x}, \tag{2}$$

where n – hardening coefficient (in our case n=4), I_n – function of hardening coefficient, x – distance from the crack tip, σ_e – tabulation function, $J(t)$ – energy J-integral that is the function of applied cycling loading and crack length. Time dependence of J-integral is presented in Fig. 4.

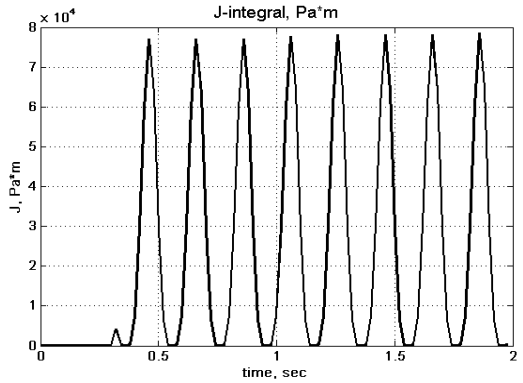

Figure 4. Time dependence of energy J-integral during cycling loading.

The stored energy was obtained as difference between accumulated plastic work (Eq. 3) and accumulated heat dissipation energy (Eq. 4) calculated at the point of the crack tip x_0 during all time moments of experiment as follows:

$$W_p(t) = \int_0^{t_i} w_p(x_0, t)dt \tag{3}$$

$$Q(t) = \int_0^{t_i} s(x_0, t)dt \tag{4}$$

The time dependence of accumulated plastic work, dissipative energy and stored energy that was calculated at the moving fatigue crack tip is shown in Fig. 5. Comparing time evolution of the plastic work and dissipative energy, the deformation process during cycling loading can be divided into three parts. The first one is about 1.3 seconds when two curves have a good correlation that can be connected with thermoelastic effect and existence the elastic part of the mechanical work.

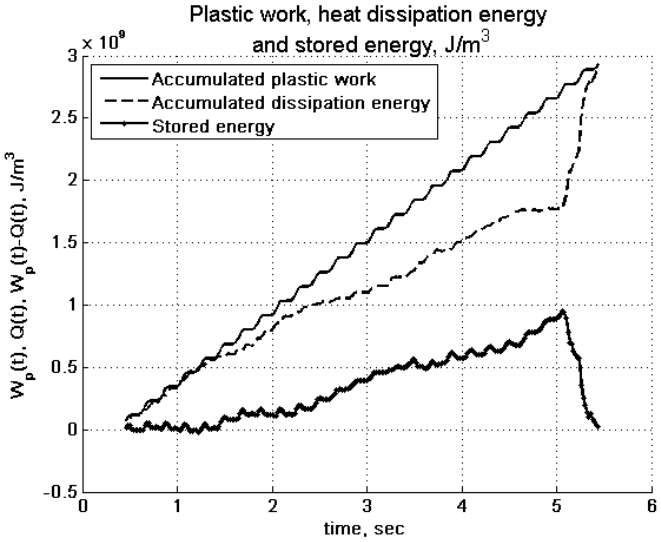

Figure 5. Time dependence of plastic work, heat dissipation energy and stored energy.

From 1.3 second to 5 second, dissipation energy increases slower than plastic work. In this period stored energy is monotonically accumulated in deformed material and spent on the potential energy of lattice distortion. At the last moments before fracture the heat dissipation energy increases explosively and reaches the value of the plastic work. The stored energy aims to the zero and material goes to the fracture stage when macroscopic displacements play important role and it is accompanied significant energy dissipation.

Data obtained for studied material displays that value of the stored energy increases to a critical point after that all mechanical energy goes to the heat and stored energy decreases explosively to zero, which ultimately leads to the destruction.

4. Conclusion

The effect of heat dissipation at the crack tip under cyclic loading has been studied based on the infrared thermography. To calculate the values of heat dissipation at crack tip an original data processing algorithms were applied. The algorithms include the relative motion compensation and spatial-time filtration procedures. As a result of infrared data treatment we determine the characteristics associated with the heat dissipation processes at the crack tip, which allowed us to propose method for determining the current values of the heat dissipation energy and stored energy

during cycling loading.
As a result, it has been shown that the value of the stored energy has to accumulate during the fatigue test and has to be equal to zero when the crack reaches the critical length corresponding to the sample failure. So, it can be used as a criterion for prediction of damage.
The set of developed mathematical algorithms and methods of the experiment allows us to develop in a future engineering methods for analyzing the current crack state inside of real constructions in a wide range of applied loads.

Abstract Ti-6Al-4V was experimentally investigated in two different forged conditions with respect to fatigue crack initiation mechanisms and growth characteristics of microstructurally short fatigue cracks. The experimental findings show that the stage of short fatigue crack propagation is strongly affected by the microstructure and widely controls fatigue life under the testing conditions applied. The observations obtained were implemented into a mechanism-based short-crack model, which describes crack propagation as a partially irreversible dislocation glide on a crystallographic slip plane. The numerical model is based on dislocation dipole boundary elements. The non-uniform, oscillating propagation behaviour of short cracks is dealt with by defining grain boundaries and phase boundaries as obstacles to plastic slip and crack propagation. The model prediction in terms of short crack propagation behaviour allows for a quantitatively representation of the crack growth characteristics. Moreover, the simulation of short crack propagation was successfully used for the purpose of life assessment. Finally, by means of virtual microstructures, microstructural parameters such as grain size and volume fractions were systematically varied. Crack growth simulation calculations in these virtual microstructures are helpful to define those microstructural modifications which are desirable for improving the fatigue resistance.

Keywords Ti alloy Ti-6Al-4V, fatigue crack initiation, short fatigue crack propagation, microstructural barriers, fatigue life assessment, boundary element method

1. Introduction

The Ti6Al4V alloy is still by far the most common titanium material in use. It is used in many different fields, however the most important applications are probably found within the aerospace industry, where airframes and aero engine components are made of titanium alloys [1]. These employments are mainly driven by the superior structural efficiency of this alloy caused by an excellent combination of high strength and low density. Hence, a selection of high strength titanium forgings will always be found in the internal structure of planes.

A proper fatigue assessment is of course a crucial requirement for all structural components in flight service, since fatigue loading conditions always occur in these assemblies. Many approaches only consider the propagation of long cracks (damage tolerant approach) and thus make use of phenomenological equations such as Paris Law in classical linear elastic fracture mechanics [2]. As an alternative, total life approaches are used with S-N curves as basis for a fatigue life prediction according to Basquin/Coffin/Manson [3-5]. These methods do generally not distinguish between

crack initiation, short crack propagation and long crack propagation, which might be important in some cases. Another option, which is linked to physical properties of the material, is a microstructural-based short fatigue crack propagation model for lifetime prediction [6]. Since the loads arising in components associated with the internal structure are usually in the area of high cycle fatigue, up to 99% of the total lifetime can be spent with crack initiation and the propagation of short fatigue cracks. Thus, modeling short crack propagation in virtual microstructures promises a flexible and reliable approach for lifetime calculations. This paper presents firstly some selected experimental results from a study of the crack initiation and microstructurally short fatigue crack propagation mechanisms in two forged Ti6Al4V alloys. Then a mechanism-based model will briefly be introduced which tries to describe quantitatively the phenomena observed. This model will be verified by comparing experimental and predicted results. Finally it will be shown that by means of the generation of virtual microstructures the model is capable to identify microstructural parameters which are significant for a purposeful microstructure optimization with respect to fatigue resistance.

2. Material and experimental details

The Ti6Al4V alloy under investigation was delivered by Böhler Schmiedetechnik, where round bar stocks were forged into “V-shaped” pieces from which all specimens were machined. Two different heat treatments were applied after the forging process, (i) mill-annealing (ma) and (ii) solution heat treatment (sht). The most important chemical elements of the composition are given in Tab. 1. The analysis was done using spark emission spectroscopy. The figures represent mean values from three measurements and are within normal scatter. Some Fe content was found probably resulting from impurities of the alloying elements or from the process routine.

Table 1. Chemical composition in wt.%

Element	Al	V	Fe	Ti
Concentration	6.5	3.52	0.133	bal.

Micrographs using a scanning electron microscope with backscattered electron detector giving a channeling grain contrast of the resulting microstructures are shown in Fig. 1. A typical bi-modal microstructure was obtained in both conditions, thus no distinctive differences are present. The microstructures consist of primary alpha grains (α_p-grains) and colonies of secondary alpha lamellae (α_s-lamellae). A little content of remaining β-phase (app. 5-8%) can be found between the lamellae or at triple points.

The primary alpha grains of the sht microstructure are fully recrystallized due to the applied dwell time at a high temperature near the forging temperature, while the ma condition was cooled directly after forging, so some grains are only partially recrystallized. This can be deduced from orientation measurement data exhibiting large misorientation variations in single primary alpha grains along with subgrain boundaries.

The final heat treatment step was the same for both microstructures consisting of a plain stress relieve annealing above the Ti_3Al solvus temperature. The phase fractions are slightly different (α_p: 71% ma, 61% sht), and the mean grain sizes are larger for the sht condition (α_p: 3.1µm ma, 7.3µm sht; α_s: 3.3µm ma, 11.3µm sht). It should be mentioned that no subgrains were accounted for in the ma condition and that the α_s size refers to the colonies, meaning lamellae of the same orientation. Of course the mean lamella thickness is much smaller in case of the ma condition.

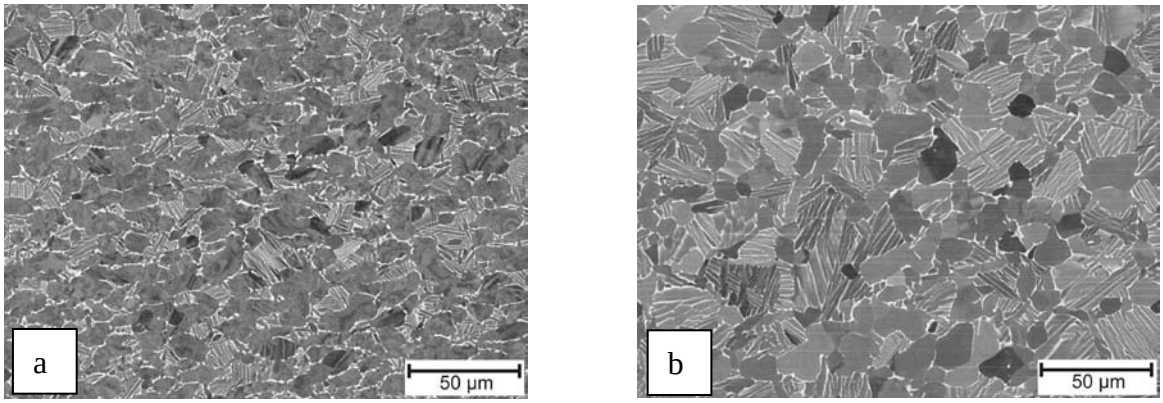

Figure 1. Microstructure of (a) ma condition and (b) sht condition.

All specimens except of the micro-sections were electro-chemically polished in a solution of perchloric acid and methanol prior to testing to meet the requirements for electron backscattered diffraction (EBSD) experiments. The surface should be as smooth as possible without any residual stresses from machining. This requirement can be perfectly met by grinding and vibration polishing (which was done in case of flat specimens for micro-sections), but is impossible for cylindrical specimens, where electrolytic polishing is the only possibility available. It should be pointed out that a slight surface roughness results from different metal removal rates of the different phases. The topography, measured by atomic force microscopy (AFM), was about 400nm from peak to valley.

Fatigue experiments were carried out in symmetrical push-pull with a servohydraulic MTS 810 test system under load control at a frequency of 20Hz. All experiments were stopped by specimen failure or at $6x10^6$ cycles. The samples which survived this number of cycles are referred to as run-out specimens. Cylindrical specimens with a milled shallow notch in the gauge length were used for the crack initiation and short crack growth investigations in order to limit the area to be observed. Some tests were interrupted after certain numbers of cycles to enable studying several cracks in the scanning electron microscope (SEM) together with EBSD. A Philips XL30 microscope equipped with automated orientation imaging microscopy (OIM^{TM}) was employed for all analytical research work. A FEI Helios DualBeam Microscope was used for sectioning cracks into the depth.

3. Experimental results

Two types of crack initiation sites were observed. Firstly, crack initiation is observed at the interface between two lamellae. Because of the Burgers relationship between alpha and beta phase

during phase transformation, this interface plane is parallel to one prismatic plane in the hcp crystal of the alpha phase, which is a possible slip system [7]. Secondly, cracks are found to initiate on slip bands inside of primary alpha grains.

Once initiated, different growth mechanisms were found for the short crack propagation in stage I. Inside of primary alpha grains or single lamellae, the crack grows on slip bands. By means of EBSD-measurements the cracks are identified to be either on the basal plane or the prismatic plane. The active slip bands are favorably orientated slip systems characterized by a high Schmid factor *S*. An example of such a crack is shown in Fig. 2a; the crack starts to grow on the basal plane with a Schmid factor of $S = 0.43$. After crossing a grain boundary the crack is slightly deflected and propagates on a prismatic plane, once again characterized by a high Schmid factor $S = 0.46$. Thus, the crack propagation rate is controlled by crack tip slide displacement range $\Delta CTSD$. The grain boundaries act as obstacles to crack propagation, as they prevent a transmission of slip into the neighboring grain. This yields a dislocation pile up in front of the barrier resulting in a decreased crack growth rate. If the boundary is overcome, the stress intensity will be relieved by slip in the next grain and the crack propagation rate will increase again, resulting in an oscillating crack growth rate. In addition to that, crack growth is also found on grain boundaries, as can be seen at the right crack tip in Fig. 2a. Here, the crack path is in a plane perpendicular to the applied load so that the normal stress, which causes a crack opening, seems to be responsible for crack propagation.

The crack in Fig. 2b grows on the interface between two lamellae. As this plane is equal to a prismatic plane with a Schmid factor of $S = 0.49$ the crack growth mechanism can be explained by slip as well. However, cracks were also found between two lamellae oriented normal to the applied load, where the Schmid factor on the respective prismatic plane is small.

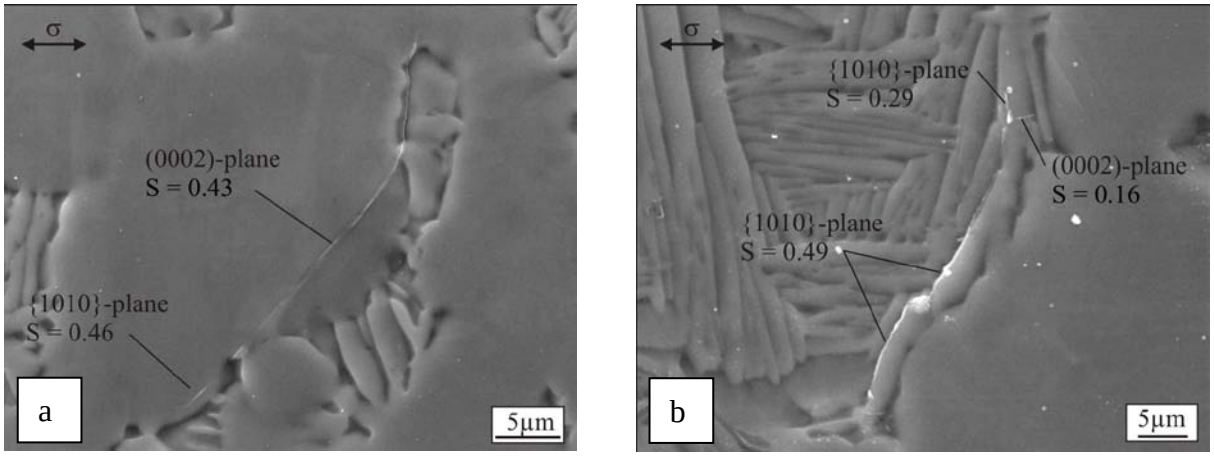

Figure 2. (a) Stage I-crack in primary alpha on slip plane and (b) crack growth on lamellae interface .

Since orientation data from the surface was used to calculate the possible slip plane, FIB sectioning was applied to determine the crack path direction into the interior (Fig. 3). A comparison between the calculated tilt angle of the slip plane with the surface and the crack path in the depth shows a good agreement. This strongly supports the assumption of crack growth occurring on a single slip system. However, as soon as a grain boundary is crossed (indicated by the white line) the crack is slightly deflected as can be observed on the surface as well.

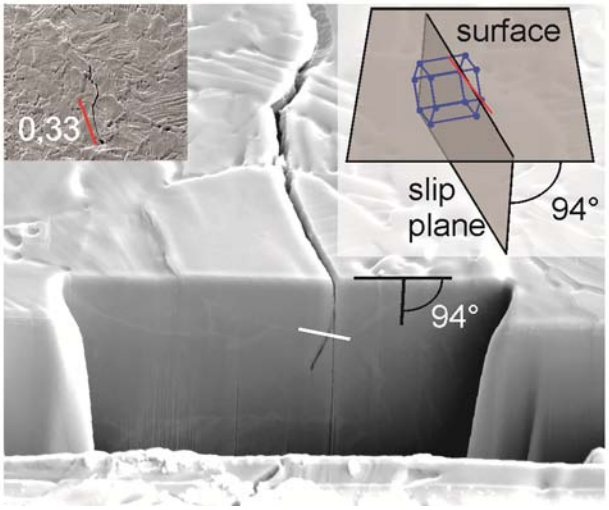

Figure 3. Cross section of a crack in primary alpha.

4. Short crack model

Several models for stage I-cracks have been presented, which consider the abnormal propagation behaviour of short cracks described above. Very promising one-dimensional analytical models for stage I-crack growth have been developed by Taira [8] and Navarro and de los Rios [9]. These models account for the barrier effect of grain and phase boundaries by blocking the extension of the plastic zone at the next grain boundary. Only if the stress on a dislocation source behind the grain boundary reaches a critical value, slip is transferred over the barrier resulting in an increased crack propagation rate. In order to take real microstructures with arbitrary grain shapes and orientations into account the analytical approaches have been extended to a two-dimensional model, which has been applied successfully to simulate crack growth in a duplex stainless steel [6,10]. This model is taken as the basis for the simulation of short crack growth in forged Ti6Al4V.

The crack problem is solved numerically by means of a discretisation with dislocation dipole boundary elements (see Fig. 4). Such a dipole element consists of a negative and a positive dislocation and represents a constant relative displacement over the element. Within a crack element two dipoles with a Burgers vector normal and tangential to the crack are combined to allow for an opening and a tangential displacement. On a slip band only a slide deformation is possible, so the respective boundary elements only consist of a dipole representing a tangential displacement. To monitor the stress state behind the grain boundary sensor elements with a constant length are positioned at the intersection point between active slip band and grain boundary. The sensor orientations match those of possible slip planes so that it is possible to calculate, in which direction a slip band is activated.

As grain boundaries act as obstacles to plastic deformation, the extension of the plastic zone is blocked by the next grain boundary. Thus, the crack propagation rate, which is controlled by the plastic deformation at the crack tip, decreases. Only if a critical stress intensity is reached on a dislocation source beyond the barrier in the neighbouring grain, the respective slip band is activated and the plastic zone extends into the new grain. The dislocation pile up in front of the grain

boundary is released resulting in a significant increase of the crack tip slide displacement and the crack propagation rate. This mechanism yields an oscillating crack growth rate that is characteristic of microstructurally short fatigue cracks.

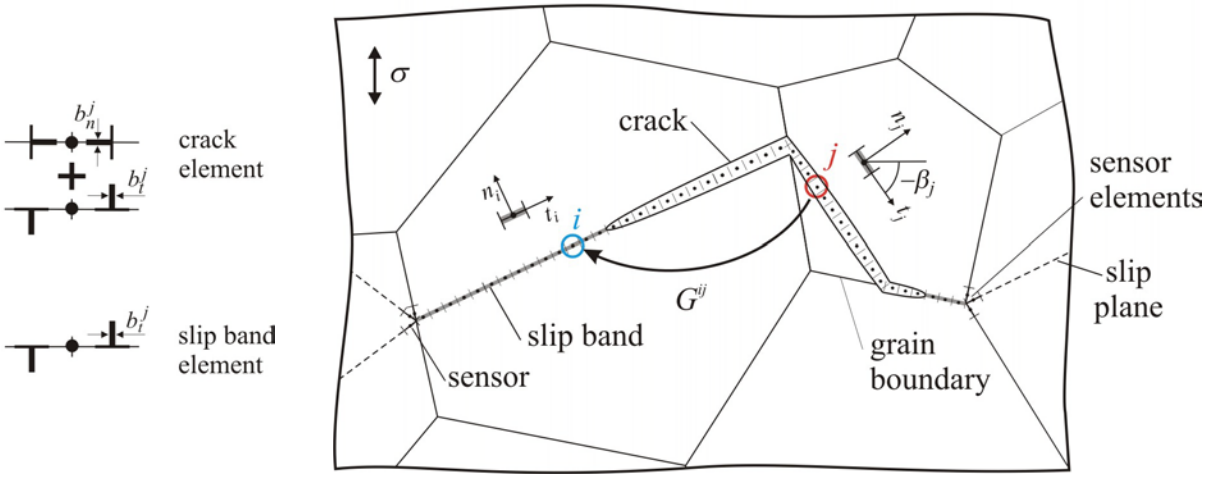

Figure 4. Stage I-crack model with boundary element discretisation.

In the plastic zone in front of the crack tip a differentiation between two cases is made, which results in different crack growth mechanisms. In the first case the crack propagates on a slip band and plastic slip occurs on this slip plane, if the resolved shear stress τ reaches the critical value for dislocation motion τ^b. In the second case the crack grows on a grain boundary, which does not represent a slip system of the crystal. Therefore, the only way to reduce the stress intensity in front of the crack tip is a plastic deformation inside the neighboring grains leading to a crack tip opening displacement. As the grains at each side of the grain boundary have different orientations, in general it is likely that more than one slip system is activated in each grain in order to ensure a compatible plastic deformation (Fig. 5a). In the model this plastic deformation is projected onto the yield strip on the grain boundary where both a tangential and a normal relative displacement is possible. As the plastic deformation occurs on multiple slip systems in the neighboring grains, the von Mises stress σ^m is used as the criterion for plastic deformation (Fig. 5b).

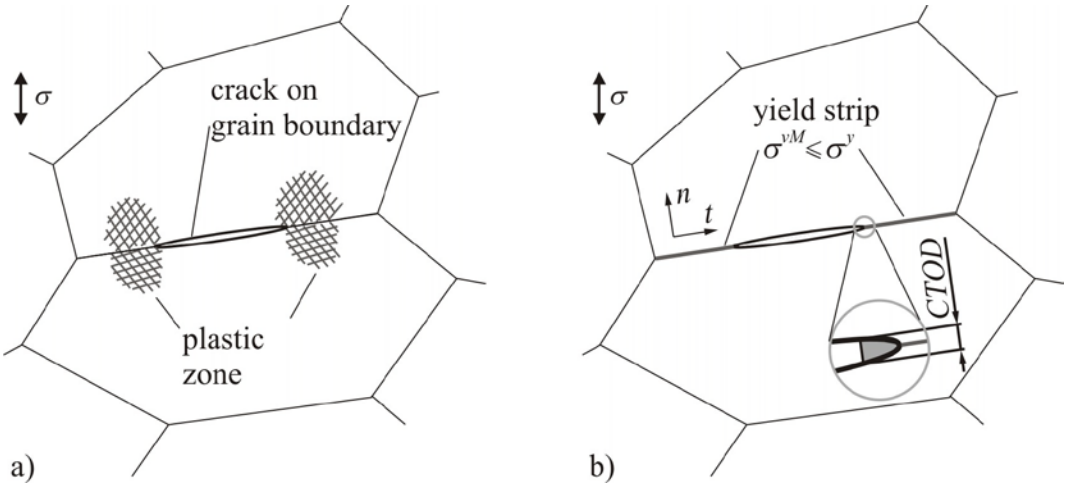

Figure. 5. Crack on grain boundary: a) plastic zone around the crack tip and b) yield strip model of the plastic zone.

The crack propagation on a slip band is calculated from the range of the crack tip slide displacement *ΔCTSD* by a power law function, which is analog to the model of [9]. A physical explanation for the mechanism of crack propagation is given in [11]. During the loading and the unloading cycle dislocations of opposite sign are created in a dislocation source in front of the crack tip and move towards the crack. Thus, vacancies are generated, which lead to a crack advance. For crack propagation on a grain boundary the crack growth is related to the range of the crack tip opening displacement *ΔCTOD*.

5. Virtual microstructure

The simulation model can be used for a virtual optimization of the microstructure for maximum high-cycle-fatigue strength. The aim is to carry out crack growth simulations in virtual microstructures with different properties to find out, how the stage I-crack growth resistance can be improved. Therefore, an algorithm for the generation of virtual microstructures has been developed, which is based on the Voronoi technique. Initially, such a Voronoi diagram has a normal distribution of the grain diameter and is single-phased. By assigning different phases to individual grains, a microstructure consisting of primary alpha grains and colonies of alpha lamellae is created. Furthermore, the average grain size and grain size distribution is modified by dividing selected grains.

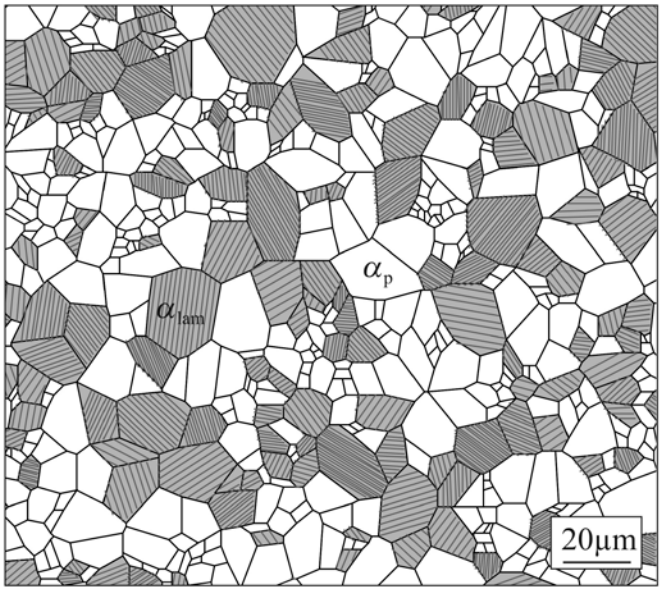

Figure 6. Virtual microstructure of forged Ti6Al4V in the sht condition.

In a first step a virtual microstructure has been generated, which represents the real microstructure of the ma condition shown in Fig. 1a. The virtual microstructure is shown in Fig. 6 and has a primary alpha volume fraction of 70.5%, compared to 70.9% of the real one. A good agreement is found in the mean diameter of the α_p-grains and lamellar grains, which are 10.0µm and 6.8µm for the virtual and 9.9µm and 6.8µm for the real microstructure. Also the grain size distribution shows a reasonably good agreement.

The slip systems in the model are chosen based on the experimental observations during the fatigue

tests. As cracks were found both on the basal plane and on prismatic planes in α_p-grains, the respective systems are considered in the model. In reality a lamellar colony consists of parallel alpha plates in a beta matrix and the orientation relation between both phases is defined by the Burgers relationship. This means that there are two parallel slip systems in both phases, and therefore slip can be easily transferred over the interface between alpha plate and beta matrix so that the effective slip length is equal to the colony diameter. As the effective slip length is the crucial parameter for crack initiation and crack growth, a lamellar colony is modeled as one grain in the virtual microstructure without resolving each single lamella.

6. Model capability

First, the model is verified by comparing simulation results to real fatigue crack propagation behavior. For this purpose the geometry of the crack shown in Fig. 7b is given as an input into the simulation model. Then, the simulation is started from the initial crack length until the crack tip reaches the end of the slip band. In Fig. 7a the projected crack length of the left and the right half is plotted over the number of cycles. It can be seen that the crack propagates fast on the left hand side on a slip band favorably oriented for slip. However, when the crack tip approaches the grain boundary the propagation rate decreases. On the right hand side the crack grows significantly slower on a grain boundary. The comparison of simulation and experimental data shows satisfying agreement.

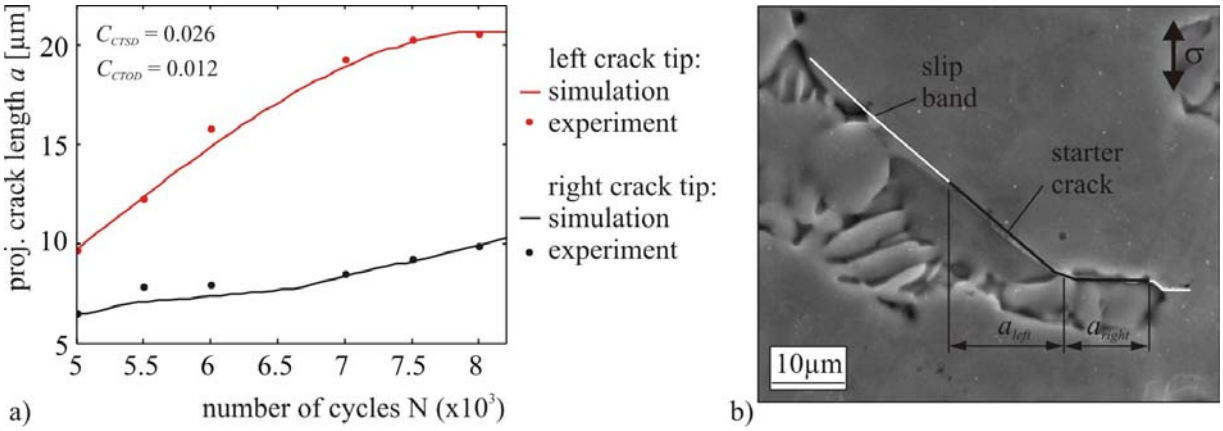

Figure 7. (a) Comparison between simulation and experimentally observed fatigue crack and (b) crack geometry.

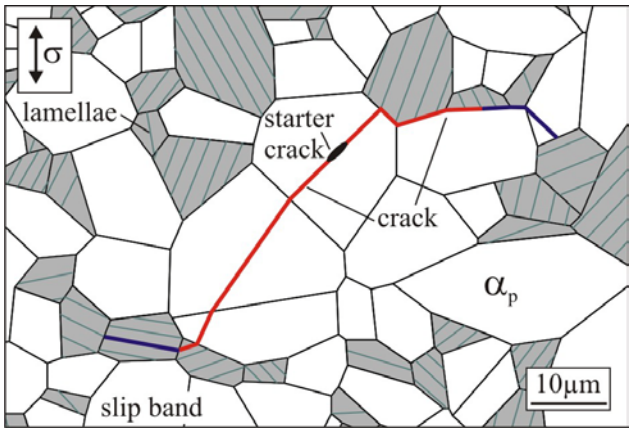

Figure 8. Crack growth simulation through several grains in virtual microstructure.

Crack growth simulations were carried out in virtual microstructures (Fig. 8). The simulation is started with an initial crack on a slip band in an α_p-grain. Then the crack grows autonomously through the microstructure. On the left hand side the crack propagates on a slip band, whereas intercrystalline crack growth on grain boundaries occurs on the right hand side.

On the basis of these calculations a fatigue life assessment is possible. For this purpose 100 calculations were carried out for each stress amplitude considered. A starter crack of 0.2µm in length is assumed to lie in the middle of an α_p grain, which is randomly selected from all α_p grains exhibiting a Schmid factor of higher than 0.4. In Fig. 9 the growth of the projected crack length with the number of cycles is shown for stress amplitudes of 500MPa and 600MPa. At the lower stress amplitude most of the cracks stop at microstructural obstacles.

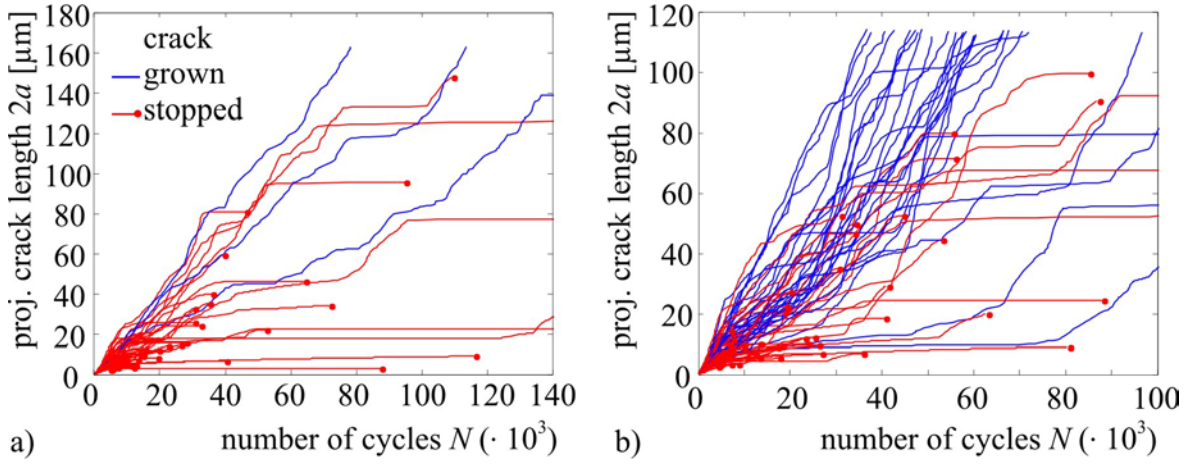

Figure 9. Crack growth simulation results for stress amplitudes of (a) 500MPa and (b) 600MPa (ma condition).

In these calculations, failure is defined to occur, when a critical value of the stress intensity factor at the crack tip is reached. This value is assumed to be 8 MPa $m^{½}$. In order to take into account that a real fatigue sample forms numerous fatigue cracks and that the fastest growing crack determines fatigue life, 20 cracks were randomly selected from the 100 cracks simulated and the one that fulfils the failure criterion first defines cyclic life. Hence 5 data points result for stress amplitude. This data is depicted in Fig. 10 together with the experimentally observed number of cycles until failure for both heat treatment conditions. The agreement appears very promising.

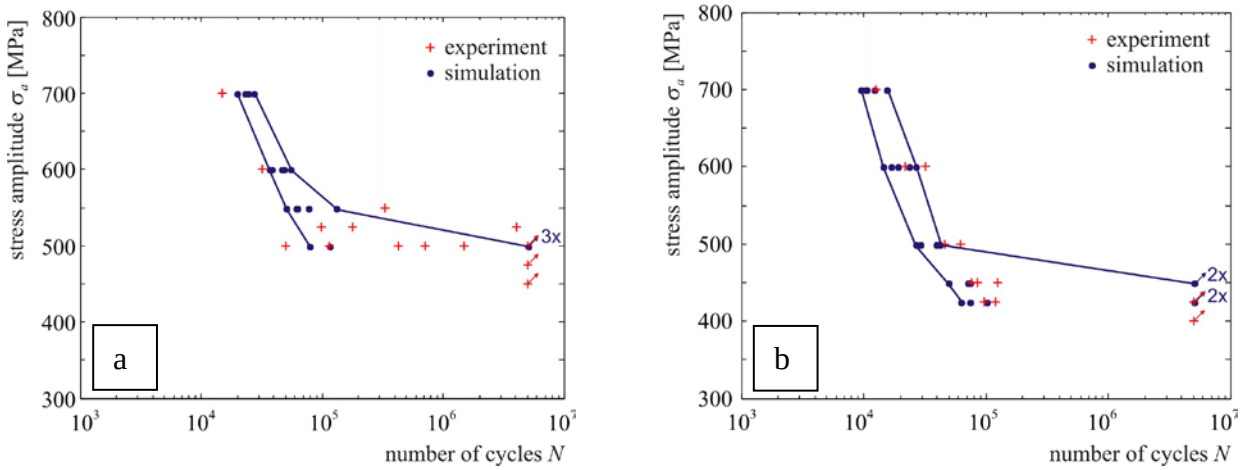

Figure 10. Comparison of observed and predicted fatigue lives for (a) ma condition and (b) sht condition.

7. Conclusions

This paper presents experimental investigations on crack initiation and short crack propagation in Ti6Al4V and shows, how the results are used in a numerical model. Crack growth mainly occurs on single slip systems (basal or prismatic) although in some cases cracks are found on boundaries where no slip system could be assigned. The numerical approach considers these crack growth mechanisms and uses either the range of the crack tip slide displacement or the crack tip opening displacement to describe the crack propagation rate. The modeling results show excellent agreement with propagation data of observed cracks. By means of calculations of the microstructurally controlled short fatigue crack growth in artificially generated “virtual” microstructures the significance and effect of microstructure parameters can be identified and analyzed, providing a mechanism-based foundation for a purposeful material development towards higher fatigue resistance. Moreover, a statistical treatment of the calculation results in terms of the evaluation of the distribution of the number of loading cycles necessary to reach a critical stress intensity factor under given loading conditions forms a sound methodology for fatigue life assessment.

Abstract Symmetrical push-pull low circle fatigue tests were carried out with conventional and high-strain X80 linepipe material respectively. Micro-analysis was performed for deformation mechanism as well. Results showed that high-strain X80 linepipe material exhibited a lower cyclic softening rate and a longer low-circle fatigue life than those of conventional X80 linepipe material. Cyclic response curves showed that the cyclic softening occurred at all strains amplitude (0.4%~1.4%) on two X80 line pipe materials. For conventional X80 linepipe material, cyclic softening was found after slight cyclic stress saturation at high strain amplitude of 1.0% ~1.4%. however, for high-strain X80 linepipe material, cyclic softening was observed after slight cyclic hardening at high strain amplitude of 1.0% ~1.4%. Fractography analysis suggested that transgranular fracture with well-developed fatigue striations and obvious second crack is the predominant failure mode. The amount of second crack was fewer detected in high-strain X80 linepipe material than that in conventional X80 linepipe material. TEM examination reveals that the primary deformation mode of two kinds of material was dislocation slipping. Abundant dislocation glide bands and dislocation cells were formed at grain boundary as strain amplitude increased. The number of dislocation blocked and wall thickness of dislocation cells in conventional X80 linepipe material are much greater than that in high-strain X80 linepipe material. The better cyclic deformation resistance of high-strain X80 linepipe material was ascribed to relative more M/A islands distributed inside the grains or grain boundaries.

Keywords High-strain line pipe; Low-circle fatigue; Strain amplitude; Dislocation; M/A

1. Introduction

Fatigue is a common failure mode of oil & gas pipeline. Fatigue fracture of pipeline is mainly caused by various alternating stress, which derives from pressure oscillation, layering of gas medium and all sorts of external variable load, such as vibration led by vehicle on the buried pipeline, fluvial abrasion of river, quicksand migration in desert and waves wash in offshore pipeline [1, 2]. Alternating stress can lead to local and alternative plastic deformation where stress concentration occurs, then fatigue failure of pipeline. In addition, since a lot of long distance, high pressure and large throughput pipeline set up in the harsh geological area, such as landslide, permafrost and seismic, buckling always caused by serious local plastic deformation of pipeline by bending, axial compression and axial tension stress. However, fracture can not be accomplished only once, low circle fatigue always becomes the final reason for the fracture of pipeline [3, 4]. Therefore, investigation on fatigue behavior of pipeline, especially low circle fatigue behavior is very significant for providing the theoretical suggestion for design, material selection and lifetime prediction of pipeline operating in the harsh condition. In this paper, the difference of low-circle fatigue performance between two X80 linepipe materials has been discovered by sub-structure evolution observation as well.

2. Experimental

The material of X80 conventional and high-strain line pipe used in this paper is obtained by TMCP and UOE forming technology. The microstructure of both X80 linepipe material mainly consists of granular bainite, polygonal ferrite and M/A as show in figure 1. While comparing the detailed

feature of conventional and high-strain X80 linepipe material, some differences can be detected that the grain size of first one is much finer and the content of polygonal ferrite and M/A of second one is much higher. The tensile properties of both X80 pipe are listed in table 1. It can be found that the tensile strength, ductility and strain hardening property of X80 high-strain pipe are much better than conventional pipe.

Since cyclic load that leads to fatigue failure always derives from axial stress, such as bending, compression and tension stress, round bar specimen with uniform section is cut from the pipe body along the longitudinal direction where is adjacent to the weld seam with 90° and machined with a gauge length of 12.5mm as shown in figure 2. Low circle fatigue test has been conducted on electro hydraulic servo fatigue testing machine Instron 1341 in terms of GB/T 15248-2008, in which tension-compression symmetric cycle and total axial strain control has been used. Triangle wave loading is adopted in tests to ensure a stable strain rate during the process of cyclic tension and compression and an obvious inflection point of sluggish loop. Strain amplitude of tests are 0.4%, 0.6%, 0.8%, 1.0%, 1.2% and 1.4%, strain rate used in tests is 4×10^{-3}mm/s, and strain ratio is -1.

Fatigue fracture has been investigated on SEM JSE-6700F. Specimen for TEM investigation was cut from the specimen in the range of gauge length along section direction after fatigue tests with EDM and machined by mechanical thinning and electrode polishing. Deformation microstructure observation has been carried out on the TEM JEM-200CX using an accelerating voltage as 200Kv.

3. RESULTS

3.1. Cyclic stress response behavior

The relationship between stress amplitude and lifetime of two X80 linepipe steel material has been investigated with different strain amplitude 0.4%~1.4% as shown in figure 3. Comparing figure 3 (a) and (b), some common cyclic fatigue characteristics of X80 linepipe material suffered with different strain amplitude can be concluded: i. the stress amplitude of two X80 linepipe materials declines with the increment of cyclic time Nf, which means that material shows a general cyclic softening during the process of cyclic deformation with different strain amplitude. ii. softening rate is relative lower when material suffers with low strain amplitude 0.4%~0.8%, softening rate greatly increases as strain amplitude exceeds 0.8%, total softening rate of material shows an incremental tendency as strain amplitude increased. iii. cyclic fatigue lifetime is gradually shortened as strain amplitude increases. According to figure3, some different cyclic deformation feature also can be found: i. in the earlier phase of cyclic deformation, e.g. Nf lower than 4, two X80 linepipe material shows an obvious cyclic softening feature when materials suffer with lower strain amplitude 0.4%~0.8. However, as strain amplitude exceeds 0.8%, X80 conventional linepipe material shows a cyclic saturation feature, while X80 high-strain linepipe material presents a cyclic hardening behavior in which hardening level is prompted as stress amplitude increased. ii. the softening rate of X80 high-strain linepipe material is much higher than X80 conventional linepipe during the whole process of cyclic deformation with different strain amplitude. iii. under the same strain amplitude, cyclic stress amplitude of X80 high-strain linepipe material is always higher than X80 conventional linepipe material, which maybe ascribes to the much higher strength of X80 high-strain linepipe material.

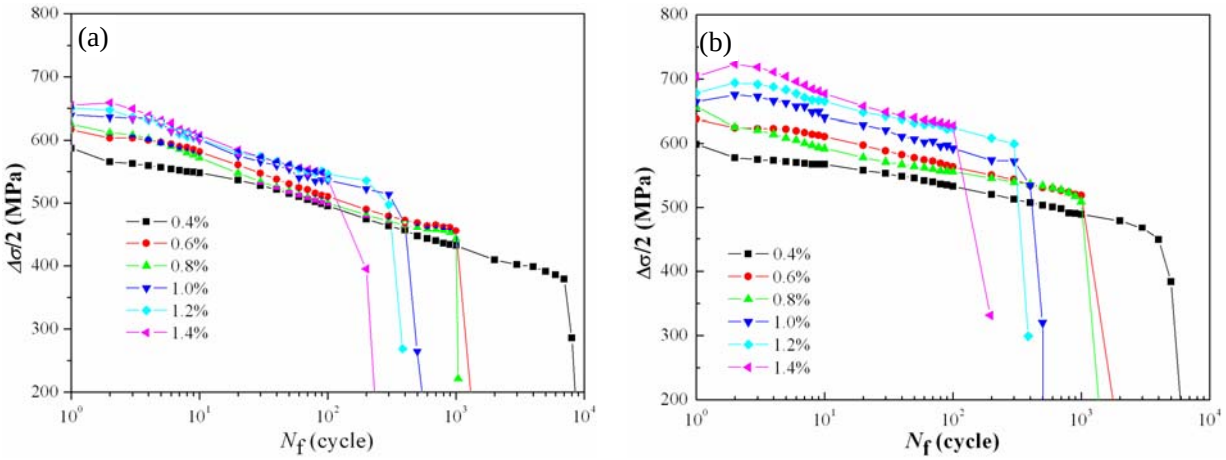

Figure 3. Relationship between stress amplitude and lifetime of X80 linepipe: (a) conventional, (b) high-strain

3.2. Cyclic stress strain behavior

Cyclic strain resistance in steady state of metallic material always can be indicated by cyclic stress strain curve. When comparing it with static tension curve, the feature of cyclic strain behavior can be found. In terms of relationship between $\Delta\sigma/2$ and $\Delta\varepsilon_p/2$, cyclic stress strain curve can be obtained after test data linear fitted in the logarithmic coordinates by least square method. Static tension curve and cyclic stress strain curve of two X80 linepipe material is shown in figure 4. It is found that two materials present cyclic softening characteristic in the range of strain amplitude. Softening level is much stronger under lower strain amplitude, while, softening level decreases with

the increment of strain amplitude. It can be observed that cyclic hardening rate of two X80 linepipe material is higher than that of static tension. It means that although the material apparently presents cyclic softening, since uniform distribution ability of deformation elevated by hardening, cyclic level is declined with the increment of strain amplitude [5].
Cyclic stress strain curve of two X80 linepipe material has been compared as figure 5 shown, it displays that cyclic softening level of X80 high-strain linepipe material is much lower than X80 conventional linepipe material under the same strain amplitude and the difference of stress amplitude between them gradually enhances as strain amplitude increases, which implies that X80 high-strain linepipe material has a much better cyclic strain resistance.

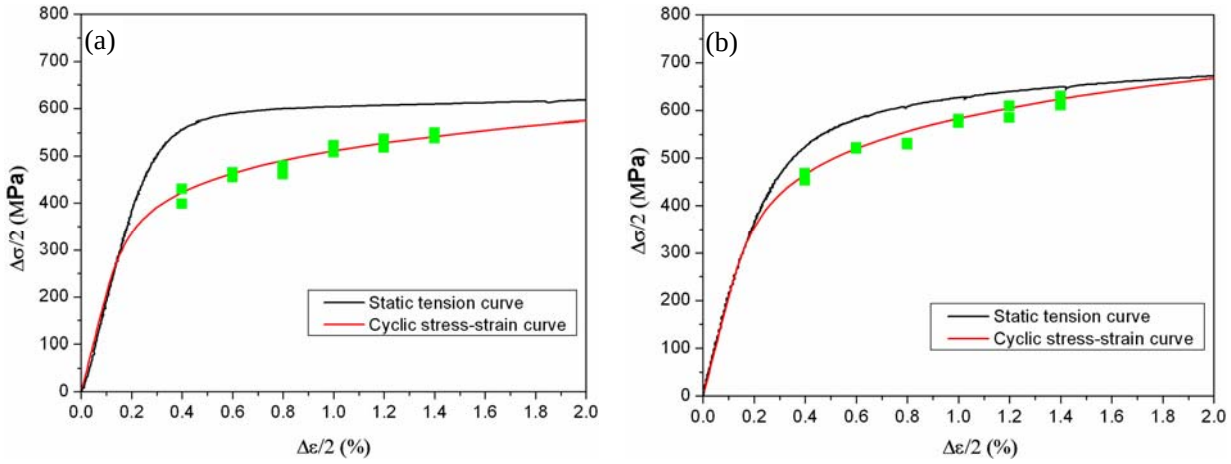

Figure 4. Cyclic strain stress curve and static tension curve of X80 linepipe material: (a) conventional, (b) high-stain

3.3. Fatigue lifetime

According to Manson-coffion equation, the relationship between strain and lifetime of X80 conventional and high strain linepipe material can be extrapolated as equation (1) and (2) after test data linear fitted in the logarithmic coordinates by least square method.

$$\frac{\Delta\varepsilon_t}{2}=\frac{\Delta\varepsilon_e}{2}+\frac{\Delta\varepsilon_p}{2}=0.0044(2N_f)^{-0.0677}+0.3171(2N_f)^{-0.5572} \quad \text{(conventional)} \quad (1)$$

$$\frac{\Delta\varepsilon_t}{2}=\frac{\Delta\varepsilon_e}{2}+\frac{\Delta\varepsilon_p}{2}=0.0073(2N_f)^{-0.1158}+0.2159(2N_f)^{-0.5032} \quad \text{(High-stain)} \quad (2)$$

Figure 6 shows the strain-lifetime curve of two X80 linepipe materials. It indicates that lifetime of X80 high-strain linepipe material is much higher than X80 conventional linepipe material when stain amplitude is much lower as 0.4%~1.0%. When strain amplitude exceeds 1.0%, the lifetime of two X80 linepipe materials almost has no difference. Generally, the lifetime of X80 high-strain linepipe material is much higher than X80 conventional linepipe material.

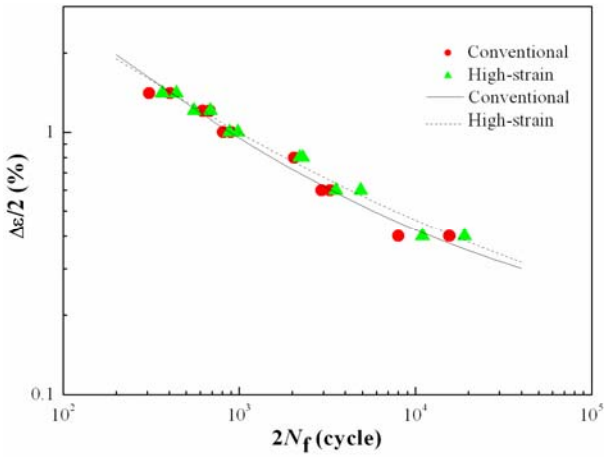

Figure 6. Strain-lifetime curve of X80 linepipe material

3.4. Fractography analysis

Fracture of low-circle fatigue specimens of two X80 linepipe material has been investigated by SEM. Figure 7 shows the facture appearance of specimen suffered with 1.2% strain amplitude. It is observed that fatigue fracture consists of 3 zones, including fatigue crack initiation, propagation and final fracture. Fatigue crack always initiates at surface and propagates along the direction perpendicular to the normal tensile stress (axial of specimen). The excircle edge of fracture fully distributes with fatigue steps presented with a radial pattern, and the amount of fatigue step increases with the increment of strain amplitude, which implies that the quantity of fatigue source increases accordingly. Comparing figure 7 (a) and (b), it can be found that the amount of fatigue step and radial stripe of X80 conventional linepipe material is much more than X80 high-strain linepipe material. Since fatigue specimen suffered tension-compression load, the zone adjacent to crack initiation presents obvious trail of extruding and grinding which resulted by the mutual extruding and rubbing between upper and lower surface of crack when fatigue crack stretched and closed repeatedly. Extruding and grinding become much heavier with the increment of strain amplitude and load applied on material, which makes the zone near the crack initiation much smoother as shown in figure 8. It also indicates that in initiation zone of X80 high strain linepipe material has a much smoother feature than X80 conventional linepipe material and its step is also much lower, which implies that high-strain linepipe material has a relative lower crack initiation rate.

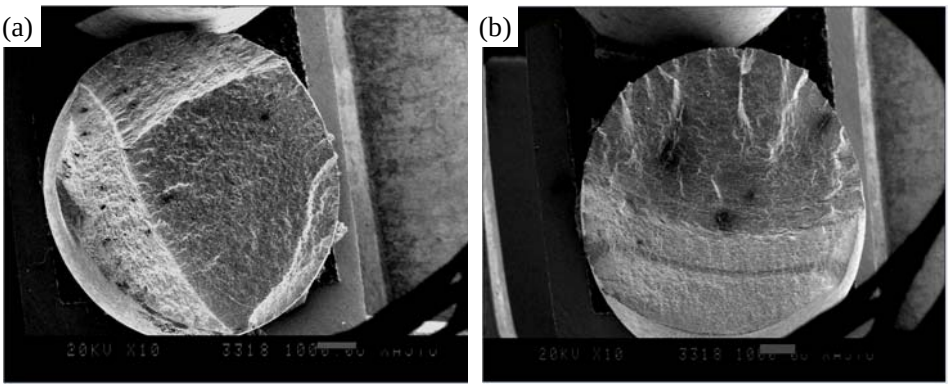

Figure 7. Macro-appearance of low-circle fatigue fracture of X80 linepipe material ($\Delta\varepsilon / 2$ =1.2%): (a) conventional, (b) high-strain

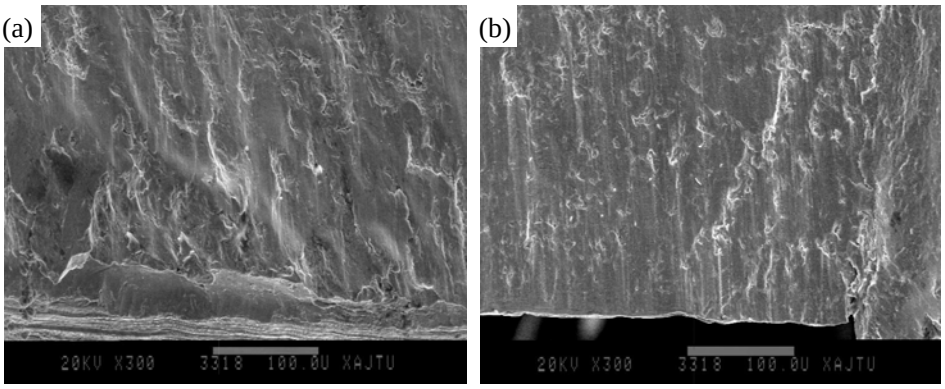

Figure 8. Micro mophology of fitigue crack intiation zone of X80 high-strain linepipe material ($\Delta\varepsilon/2$ =1.2%)

Micro-morphology of fatigue crack propagation zone of X80 linepipe material under the condition of different strain amplitude is shown in figure 9 and figure 10. It is found that the typical characteristic of propagation zone of specimen is fatigue striations and second crack which induced by cyclic load with the strain amplitude of 0.4%, as shown in figure 9. Comparing with figure 9 (a) and figure 9 (b), it can be found that the amount of second crack and the spacing of fatigue striation of X80 conventional linepipe material is much higher than X80 high-strain linepipe material, which means that fatigue crack propagation rate of X80 conventional linepipe material is much higher.

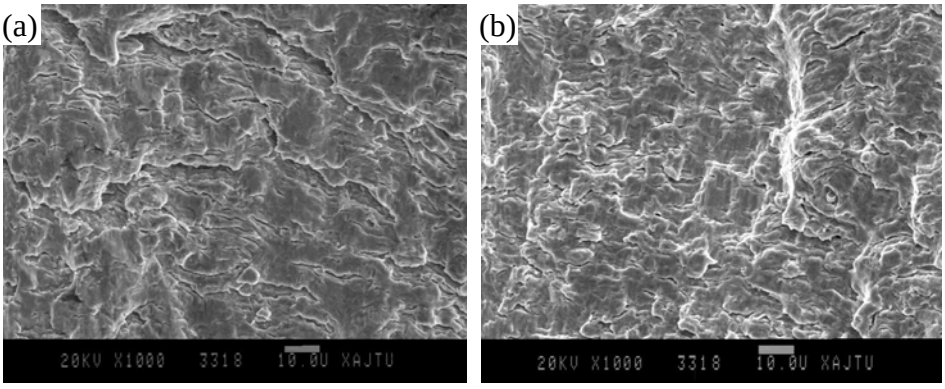

Figure 9. Micro mophology of fitigue crack propagation zone of X80 high-strain linepipe material ($\Delta\sigma/2$ =0.4%): (a) conventional，(b) high-stain

When strain amplitude increases to 1.2%, much more second cracks appear since load enhanced. Since the heavy extruding and grinding of fracture surface, propagation zone turns to be much smoother, tire-shaped pattern presents and fatigue striations almost disappears as shown in figure 10. The emergence of tire-shaped pattern means that fatigue crack speed dramatically increases under the condition of high strain amplitude which can enormously shorten the fatigue lifetime of material [6]. According to figure 10, X80 high-strain linepipe material presents a much obvious tire-shaped patter in crack propagation zone which presents a typical brittle fatigue feature.

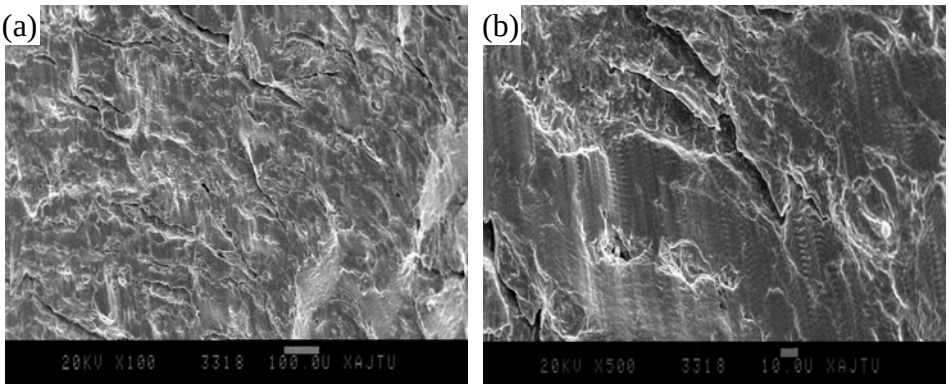

Figure 10. Micro mophology of fitigue crack propagation zone of X80 linepipe material ($\Delta\sigma/2$ =0.4%): (a) conventional，(b) high-stain

4. Sub-structure observation and Discussion

Low-circle fatigue tests results of two X80 linepipe materials as presented above show that cyclic deformation behavior of both X80 linepipe materials is cyclic softening. In addition, the softening rate of X80 high-strain linepipe material is much lower than that of X80 conventional linepipe material, the fatigue lifetime of X80 high-strain line pipe material is much longer as well. Generally, cyclic softening behavior always decides by the evolution of micro sub-structure of material suffered for cyclic loads. Usually, possible reasons for cyclic softening are reduction of dislocation density resulted by opposite screw dislocation meetion and counteraction, dislocation realignment and formation of sub-grain or dislocation cell, decline of friction stress induced by dislocation off-pining which original pinned by solute atoms. Therefore, some investigations on both X80 linepipe materials after cyclic deformed have to be performed to discover the different cyclic strain behavior of both X80 linepipe materials.

Since ferrite is relatively soft and has much fewer precipitated carbide, plastic deformation always preferentially happens inside it. Therefore, dislocation motion in ferrite can reflect the substructure evolution of material. Figure 11 presents substructure morphology of two ruptured X80 linepipe materials which suffered with lower cyclic strain amplitude 0.4%. X80 conventional linepipe material has a much heavier density of dislocation inside ferrite, and an incomplete dislocation cell is has formed by tangled dislocation as shown in figure 11 (a). However, it can be observed from figure 11 (b) that dislocation in ferrite and bainite is fairly higher and abundantly tangled on the grain boundary, while dislocation cell has not formed yet. The presence of dislocation of X80 high-strain linepipe material mainly is outcrop and dislocation line in ferrite due to much higher density of M/A constituent that can improve the deformation coordinate capability of material and postpone the occurrence of dislocation cell in ferrite. The difference of dislocation configuration between two materials results in the lower cyclic softening rate of X80 high-strain linepipe.

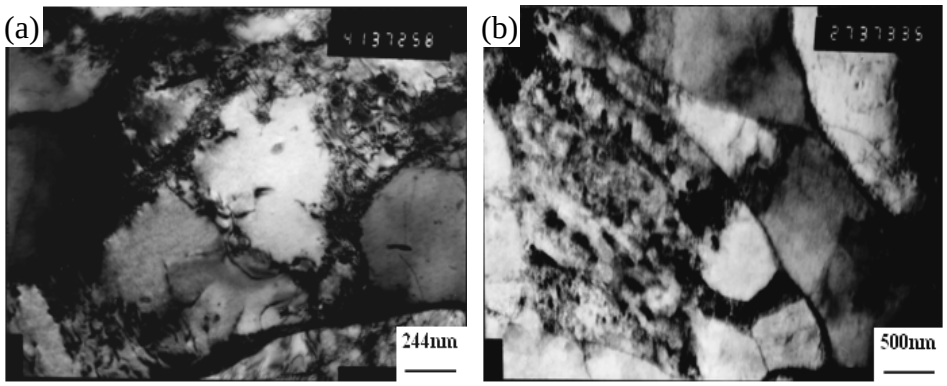

Figure 11 Substructure morphology of X80 linepipe material by 0.4% strain amplitude: (a) conventional (*Nf* =7800), (b) high-strain (*Nf* =9500)

Figure 12 (a) ~ (b) shows the dislocation configuration of X80 conventional linepipe material. With the increment of strain amplitude up to 0.8%, dislocation density in ferrite of X80 conventional linepipe material further decreases, single dislocation line almost disappears and complete dislocation has been formed as figure 12 (a) shown. Dislocation in M/A island begins to be polygonzaition and dislocation cell is going to be formed, in the same time, the amount of dislocation which bypasses second particles and accumulates around increases as shown in figure 12 (b) which results the realignment of dislocation. The formation of dislocation cell and declines of dislocation density causes the cyclic softening rate increase of material under 0.8% strain amplitude. Figure 12 (c) ~ (d) shows the dislocation configuration of X80 high-strain linepipe material. An obvious variation of dislocation configuration happens in X80 high-strain line pipe material with the increment of strain amplitude. Dislocation cell with relative thinner wall has started to be formed in ferrite in some area, which implies that with the occurrence of cellular structure, cyclic softening rate of X80 high-strain line pipe material suffered 0.8% strain amplitude is significantly improved comparing with 0.4% strain amplitude. Furthermore, it also can be observed that the tendency of dislocation cellular structure formation is much more obvious in ferrite surrounded by M/A as shown in figure 12 (c). While, the dislocation configuration in ferrite not surrounded by M/A is dislocation line or tangled dislocation as show in 12 (d). The reason for this phenomenon is that deformation inside material focuses primarily on coordinating deformation among structures. That is to say, deformation firstly happens on ferrite with a lower strength which can induce dislocation annihilation or formation of dislocation cell after dislocation movement and occurrence of ferrite softening [7]. Meanwhile, since deformation of ferrite is restrained by plenty of M/A constituent, once ferrite has been deformed to a certain level, deformation on M/A island begins. Furthermore, since much more ferrite exits in X80 high-strain linepipe material, the resource for dislocation movement is much more than X80 conventional linepipe material. Therefore, deformation in ferrite is further suppressed and the formation of dislocation cell in ferrite is accordingly delayed, which results in the reduction of softening rate of ferrite. Perhaps, that is certain reasons for inducing of much lower softening rate of X80 high-strain line pipe material [8].

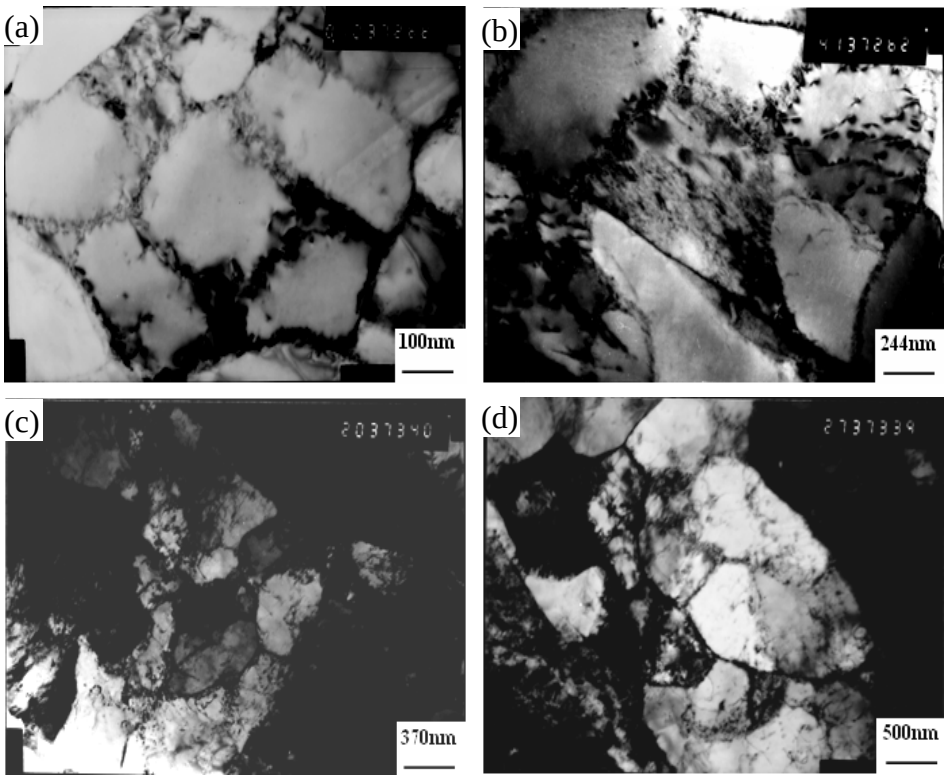

Figure 12. Substructure morphology of X80 linepipe material by 0.8% strain amplitude: (a)~(b) conventional (*Nf* =1027), (c)~(d) high-strain (*Nf* =1145)

Figure 13 presents the substructure morphology of two X80 linepipe material suffered 1.2% strain amplitude. For X80 conventional linepipe material, dislocation cell has been rapidly formed and cell wall-thickness obviously increases due to the dislocation pilling up nearby as indicted by figure 13(a). It is observed in figure 13 (b) that dislocation cell has been formed in ferrite surrounded by M/A, which further demonstrated the decrease of softening rate resulted by M/A that can obstruct deformation and postpone the development of dislocation cell in ferrite of X80 high-strain linepipe material.

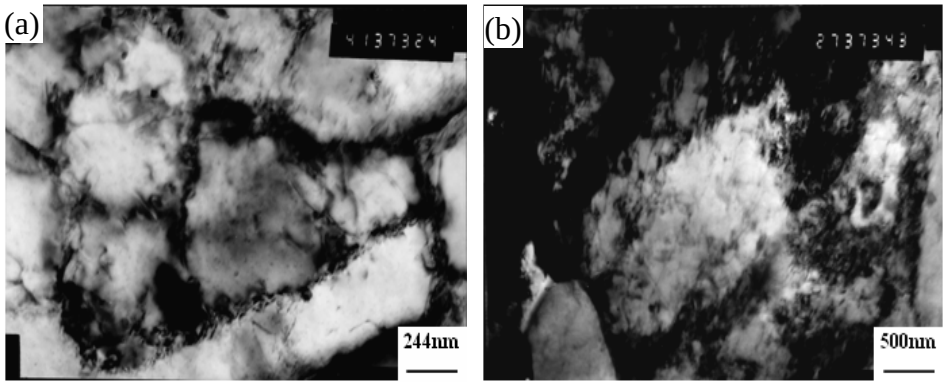

Figure 13. Substructure morphology of X80 linepipe material by 1.2% strain amplitude: (a) conventional (*Nf* =340), (b) high-strain (*Nf* =343)

5. Conclusion

Generally, two X80 linepipe materials exhibit a cyclic softening behavior under the cyclic load. Softening rate of two X80 linepipe materials show an incremental tendency as strain amplitude

increased. Cyclic fatigue lifetime of two X80 linepipe materials is gradually shortened as strain amplitude increases. In the earlier phase of cyclic deformation with strain amplitude exceeding 0.8%, X80 conventional linepipe material shows a cyclic saturation feature, while X80 high-strain linepipe material presents a cyclic hardening behavior. The softening rate of X80 high-strain linepipe material is much higher than X80 conventional linepipe during the whole process of cyclic deformation. Under the same strain amplitude, cyclic stress amplitude of X80 high-strain linepipe material is always higher than X80 conventional linepipe material, which maybe ascribes to the much higher strength of X80 high-strain linepipe material.

Cyclic softening level of X80 high-strain linepipe material is much lower than X80 conventional linepipe material under the same strain amplitude and the difference of stress amplitude between them gradually enhances as strain amplitude increases, which implies that X80 high-strain linepipe material has a much better cyclic strain resistance. The fatigue lifetime of X80 high-strain linepipe material is much higher than X80 conventional linepipe material.

In initiation zone of X80 high strain linepipe material has a much smoother feature than X80 conventional linepipe material and its step is also much lower, which implies that high-strain linepipe material has a relative lower crack initiation rate. the amount of second crack and the spacing of fatigue striation of X80 conventional linepipe material is much higher than X80 high-strain linepipe material, which means that fatigue crack propagation rate of X80 conventional linepipe material is much higher. X80 high-strain linepipe material presents a much obvious tire-shaped patter in crack propagation zone which presents a typical brittle fatigue feature.

Substructure evolution investigation reveals that the primary deformation mode of two X80 linepipe material is islocation slipping. As strain amplitude increased, dislocation cell developed gradually from dislocation line and tangled dislocation in two X80 linepipe materials. Dislocation density in X80 high strain linepipe material is much higher than X80 conventional linepipe material under various strain amplitude. The formation of dislocation cell or dislocation realignment of X80 high-strain linepipe material is always later than X80 conventional linepipe material. Ferrite deformation has been restrained in X80 high-strain linepipe material due to the higher amount of M/A and ferrite which postponed the formation and development of dislocation cell and caused a much lower softening rate.
