Abstract Ni-base superalloy IN718 is known to display time-dependent intergranular crack growth under dwell time mechanical loading at high temperature under atmospheric conditions. Oxygen has been pointed out as a cause of the intergranular damage causing embrittled crack growth during both cyclic and hold time loading. Investigation of the mechanisms responsible for the embrittlement should not only focus on the effect of environment but also on the combined action of fatigue, creep, temperature and time. In this work material from experiments with fatigue crack growth in combination with hold times of different length at different temperatures has been investigated. Fractographic studies and metallographic cross sections of fatigued specimens has been subjected to careful analysis using ECCI- imaging in order to shed light on the fracture mechanisms. The results show that the damage is caused by the influence of a combination of environment and severe local damage manifested as a transformation of the microstructure into sub cells, micro twins and recrystallised areas close to the crack tip. The damage mechanism is thus influenced by a combination of oxidation and severe local plastic deformation.

Keywords Intergranular damage, Dwell time, ECCI, Fatigue, Fractography

1. Introduction

Ni-base superalloys are widely used in high temperature and for applications like rotating discs in gas turbines where IN718 is a popular alloy due to relatively low price/performance ratio, good corrosion resistance and mechanical properties with excellent weldability. The high temperature performance is limited to 650°C and an increase in temperature needed to increase efficiency has created demands of increasing temperature in steps of 50°C. Since IN718 has a strengthening phase of DO_{22} based on Ni and Nb called γ'' the max temperature is 650°C while a similar precipitate based on Ni and Al (γ') dissolves at a higher temperature. A newly developed γ'-former called Allvac718plus [1] is a replacement candidate for IN718.

The Ni-base superalloys are during service subjected to a combination of static loading and fatigue loading controlled by stress as well as strain. In addition to that high temperature and environment will act to reduce service life. The growth of fatigue cracks will be affected by temperature and environment so that the mode of crack growth is shifted from transgranular to intergranular. This embrittlement effect that most superalloys have in common [2] has been analysed in a great number of publications [3-8]and reviews [9-11] [12]. The fact that not only fatigue fracture crack growth is influenced by, frequency, temperature and environment but also growth of a static crack in conjunction with fatigue has been subject to analysis [13, 14]. The conclusions have so far been that the significance of the effect is minor under present service conditions but with increasing service temperature and load the effect might be a serious matter for the future.

The aim of this work is to study the effect of growth of fatigue cracks at high temperature in IN718 and Allvac718Plus in order to better understand the mechanisms behind the growth of fatigue

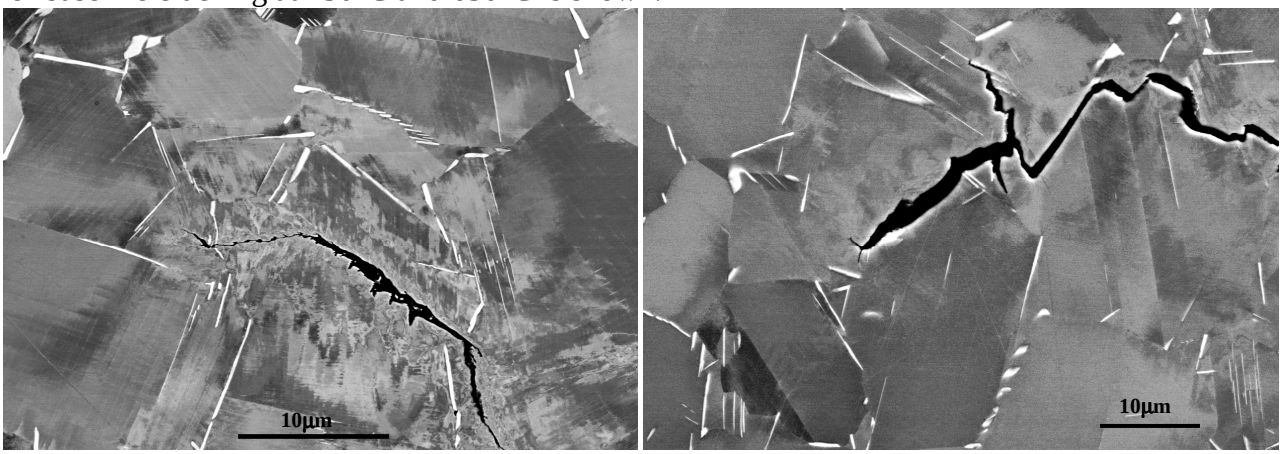
cracks especially dwell time cracking at hold times with varying length.

2. Experiments

Two alloys IN718 and Allvac718Plus have been subjected to fatigue testing with dwell time. The testing was performed in servohydraulic testing machines at constant stress amplitude using SEN specimens [8] with DCPD crack monitoring at high temperature using a radial furnace or induction heating [8, 15, 16]. Specimens with a crack were studied either as cross sections or as fracture surfaces using an Hitachi S70 analytical SEM with an annular Back scatter detector making it possible to produce images by Electron Channeling Contrast Image (ECCI). This method has been used with great success to study damage mechanisms in super alloy single crystals [17, 18]. The studied specimens have been chosen from crack growth experiments performed with Kb-type of specimens with cross sections of 4.3 X 10.2 mm with a 0.2 mm sparc cut starter notch. A baseline series of specimens were run at 0.5 Hz, R=0.005and the hold time testing (90s, 2160s and 21600s) was performed at 450, 550, 650 and 700°C in lab air environment except for Allvac718Plus that was also tested in pure oxygen atmosphere and the results presented as crack growth curves in ref. [5, 16, 19-21].

3. Results

In order to be able to distinguish between crack growth at different temperatures with and without dwell the results from crack growth without dwell will be presented first. In figure 1 the crack zone for baseline cracking at 450°C and 650°C is shown.

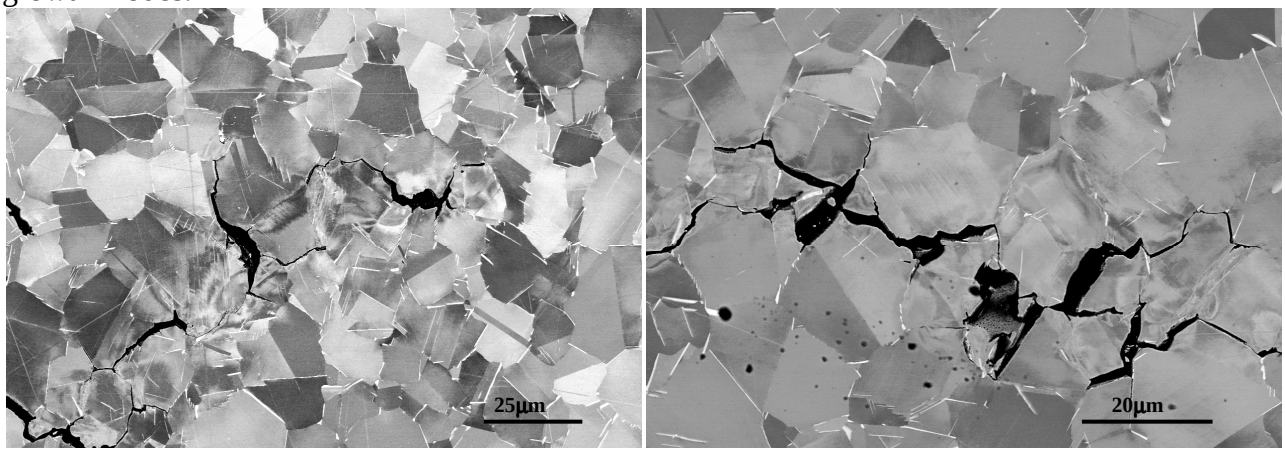


a b

Figure 1. SEM-ECCI micrograph showing cross section of the crack tip region of IN718 subjected to base line fatigue at a) 450°C showing high slip activity and 650°C with lower slip activity.

The lower temperature shows clear channeling contrast from plastic deformation caused by homogeneous slip on primary slip systems and in a narrow zone close to the crack localized more concentrated multiple slip. The crack path is transcrystalline with slight crack branching. The crack growth mechanism seems to be based on a weakening of interface at the crack tip by plastic deformation. For the higher temperature the crack path is more intergranular with more crack branching and the slip intensity is less pronounced.
The specimens subjected to dwell show more intergranular fracture and branching Figure 2 and the plastic deformation is more pronounced at 550°C but the fracture mode is varying along the crack

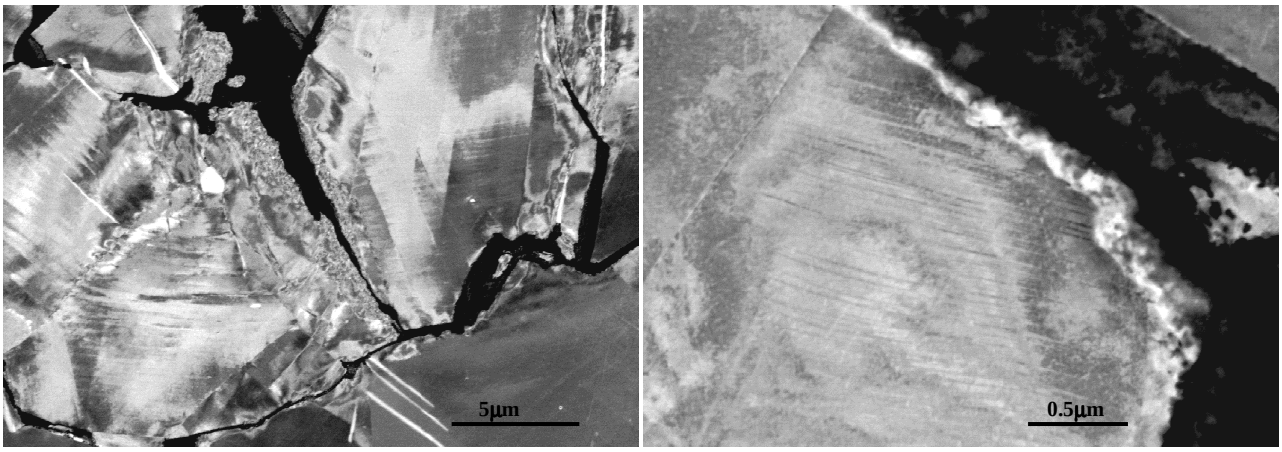
path and the crack growth seems to be assisted by both slip, plasticity induced dynamic recrystallisation sometimes with twins or formation of voids and cracking oxide at the crack tip. Although the crack growth is considered intercrystalline it can be divided into three different growth modes.



a b

Figure 2. SEM-ECCI micrographs showing cross sections of specimens with hold time at a) 550°C with intergranular branched cracks and clear signs of slip and b) 650°C with intergranular cracking and less pronounced plasticity.

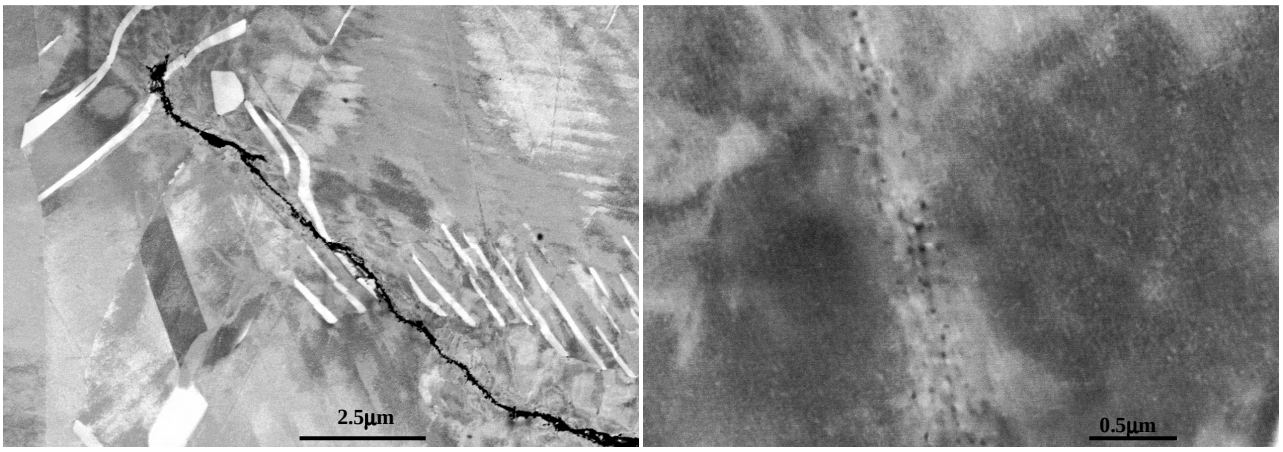
The first one is the growth along grain boundaries where the mating grains are subjected to planar slip on one or two slip systems Figure 1a. The second growth mode is along grains with heavier homogeneous slip and a narrow zone close to the fracture surface with heavy non planar dislocation structure and sometimes twins and recrystallisation structure nicely shown in ECCI mode in the SEM Figure 3.



a) b)

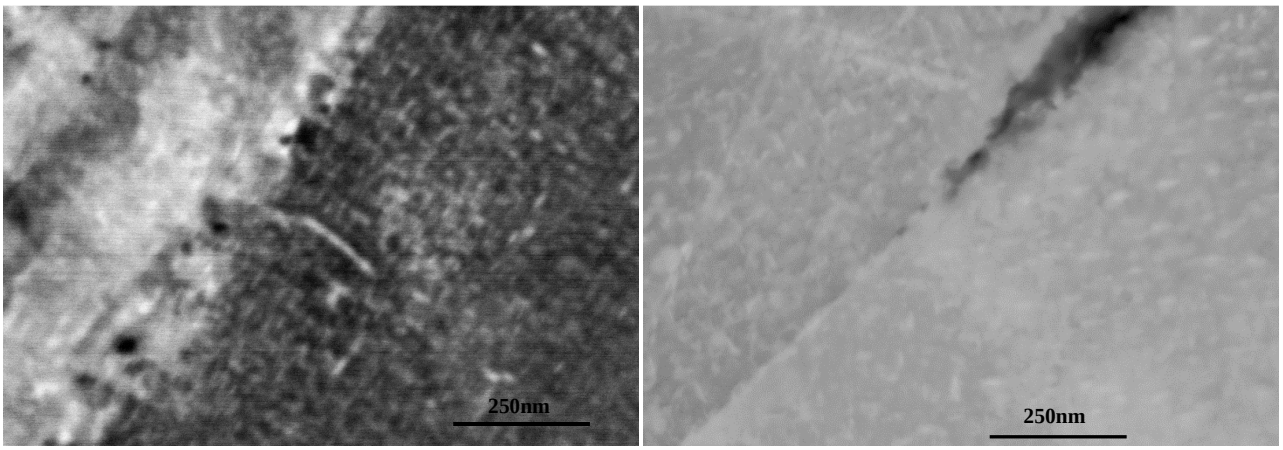
Figure 3. SEM-ECCI micrographs showing a) the plastically damaged zone with sub grains and beginning recrystallisation close to the crack surface and b) deformation twins.

The third growth mode is cracking along δ-phase often oxidized into a sponge like structure in the interface between a δ-plate and the crack. It is thus difficult to say anything about the time-sequence of these events but the nanometric oxidized pores present at crack tips with a smallest size in the order of the hardening precipitates could trigger the onset of intercrystalline failure and the stress state and dislocation structure contributing factors Figure 4, 5, 6. The separate dwell time cracking



a b

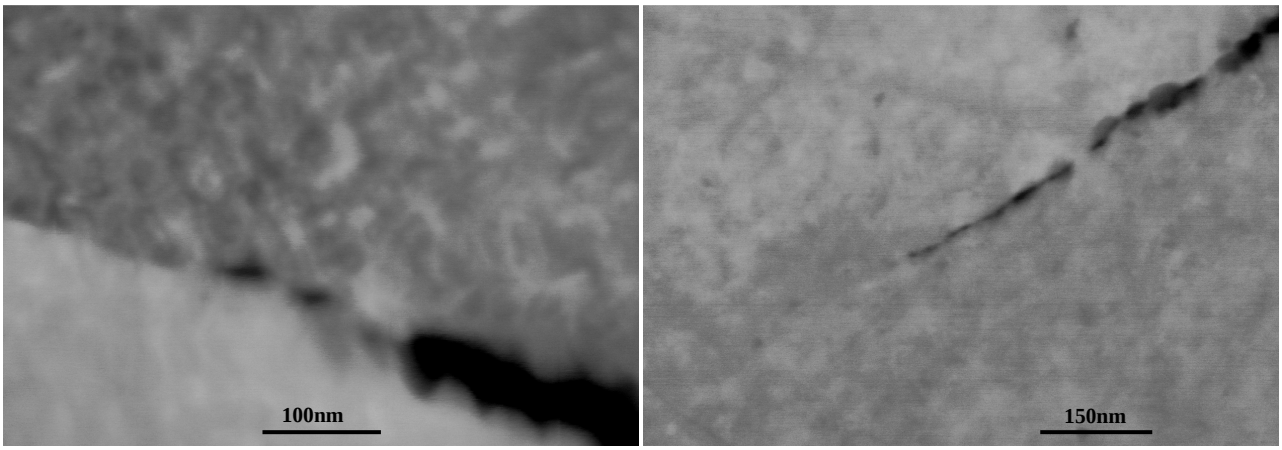
Figure 4. SEM-ECCI micrograph showing a) the crack tip region and b the damage zone in front of the crack tip at higher magnification with stringers of pores.



a b

Figure 5. SEM-ECCI picture of the damaged zone in IN718 at 550°C temperature close to the crack showing a) the hardening precipitates along with nano sized pores in an area with high plastic deformation and b) pores in a grain boundary with no plastic deformation.

events caused by unloading between each hold time are difficult to distinguish along the crack front. The crack front seems to have the character of a spherical discontinuous process zone (fig.2) with branched intergranular cracks rather than a single crack moving through the microstructure. Crack growth could then consist of environmental oxygen induced intercrystalline growth of cracks along sensitized paths in different directions and an interlinking between embrittled areas showing ligaments with more severe slip. The ligaments are severely plastically deformed to a level that is very close to dynamic recrystallization with characteristic pores shown as black dots in Fig. 4b, Fig. 5 indicating a future crack path. The growth of the main crack is also influenced by interaction with δ-plates acting either as a crack path or as a crack stopper (fig 4a) depending on orientation. The fact that the δ-phase is ductile makes it less probable as a crack path but the interface between δ and matrix is often acting as a crack [10] path through severely oxidized pores in the interface as observed in this work. Non propagating branched cracks are stopped due to blunting and/or geometrical reasons like going into mode II. Residual stress built up during growth manifested by a closure of the crack along the front also plays a role for the path taken by the crack.



a b

Figure 6. SEM-ECCI micrographs of a) IN718 650°C during hold and b) ALVAC718plus 700°C during hold. Both alloys show voids in front of the crack tip. The smallest voids are in the same range of size as the hardening precipitates that are clearly visible in a).

The macroscopic crack path often shows a mismatch orthogonally indicating shear or grainboundary sliding along the crack growth direction. SEM ECCI pictures taken at a very high magnification of non propagating secondary cracks is shown in Fig. 6 where nanometric voids in the same size range as the clearly visible hardening precipitates Fig 6a are seen along the grain boundary. This type of voids is often seen along the crack front for longer cracks being coarser and more oxidized.

The dwell time cracking of Alvac718Plus in pure oxygen atmosphere shows (Fig. 7b) more clearly the intercrystalline character of the crack growth due to the absence of δ-plates (black in Fig. 7a) in this condition. The observable environmental action manifested by growth of oxidized pores in the grain boundaries seems to be the same as for IN718. The completely flat grain boundary surface has still slip bands and microscopic pores. The fatigue cycling in oxygen atmosphere at 700°C before the start of the dwell time cycle show clear striation like arrest markings indicating a continuous crack growth mode. Studying the fracture surfaces in higher magnification show signs of nano sized voids at the tip of branched cracks. The intergranular facets giving a smooth appearance at lower mag. (Fig 7b) show signs of voids at higher magnification (Figure 8, 9).

4. Discussion

The results from studies of the crack growth process of IN718 and Allvac718Plus under fatigue and dwell time loading conditions at high temperature will be discussed. The focus will be put on the effects of events taking place during the hold time periods.

The crack growth under the influence of temperature and cyclic loading is transgranular at 450°C with clear evidence of planar slip in the grains surrounding the crack going over to intense slip close to the fracture surface with phenomena like nano twins and local recrystallisation appearing. The crack path is sometimes branched and not as transgranular as during room temperature cycling indicating that the grain boundaries play a role even during base line cracking. With increasing temperature the crack path becomes more branched and the plastic deformation is less pronounced. This indicates that the environmental effect is gradually increasing with temperature.

The hold time experiments consist of applied constant load cycles between 90 to 21660 s where each cycle is separated by unloading to zero load level. The observed macroscopic change in growth rate caused by those events can unfortunately not by traced on a micro level. The reason for that is probably that the crack advance is a non continuous process. Gas phase embrittlement, GPE by oxygen is by far the most proposed damage mechanism in this case [12]. Still very little is

known about the damage on a micro scale. The conditions at the crack tip are probably controlled by the environment and the diffusion of oxygen towards and into the grain boundaries. This process is in turn controlled by the conditions at the grain boundary where slip bands, local stress, voids, oxide formation and local chemistry will affect the diffusion of embrittleing elements like oxygen. Depending on the local condition at the grain boundaries micro cracks will form and propagate till they are interfering and sometimes arrested by microstructure like δ phase or blunted at different locations in different directions creating a damaged volume where the final crack path will be formed when the ligaments between the micro cracks will break after plastic deformation or embrittlement. This crack model can explain the apparent non continuous crack growth and all the other phenomena like oxidized voids and plastic deformation together with embrittlement. Crack closure caused by local plasticity and observed mixed mode character along the crack path may also play a role both due to the unloading cycle between the cycle but also due to plasticity and oxide formation[10]. The environmental crack propagation during dwell at 700°C in Allvac718plus is observed as close to purely intergranular with limited fractographic information of microscopic direction of growth while the fatigue crack growth during the same conditions show clear crack arrest markings during intergranular growth. The fact that the there are virtually no crack arrest markings present during dwell does unfortunately not answer the question if the crack growth is continuous or not. Analysis of the crack tip with [15] advanced methods (SIMS) has shown that the penetration of oxygen is very limited in the crack tip region in front of the crack tip so the triggering of the crack growth event is probably caused by oxidation and growth of nano sized voids in the crack tip region. The voids can either be pure creep nano voids or γ'' or γ´particles from the matrix identified in this study. The origin of the voids found in this study could be from γ'' and/or γ´ growing under the influence of local stress and dislocation activity [10] and subsequently close to the crack tip being opened up and oxidized to form the observed pores. The oxidation of γ'' is probable in this environment since the δ-plates exposed to oxygen, with the similar composition as γ'' or even sometimes could be transformed to δ by dislocation particle [11] shearing, have been observed to be severely oxidized. Since the analysis with SIMS has shown that diffusion of oxygen in front of the crack tip is nonexistent a growth mechanism based on oxygen diffusion must be extremely local in character. This supports a mechanism where nanometric voids are created by a combined action of creep, transformation/oxidation of γ'' or γ´ into pores where the pore walls are thin enough to allow transportation of oxygen before they break and gradually open up the crack. In a review by Woodford [12] the cavities are supposed to be created by oxidation of carbon into gas phase where the voids are created from gas bubbles. The bubbles are not only acting as creep cavities but also to reduce the grain boundary sliding that normally takes place to relive stress concentrations in the grain boundary at higher temperatures. This is not contradicted by the observations in this work and could also explain the lack of expected oxide in front of the crack tip and also the fact that no oxygen at all was found by SIMS in ref. [16]. This also supports the observations in this work that there is a large amount of plastic deformation involved together with intergranular fracture in IN718 and no signs of embrittlement since the oxygen is not primarily causing embrittlement according to this model. Unfortunately evidence of a possible carbon source for the creation of gas bubbles to support the model proposed in Woodford has not been observed in this study but on the other hand not specifically been a subject of study.

Generally the growth of a crack during hold time constant loading is for IN718 a result of a number of growth mechanisms where microstructure together with plastic deformation and environment preferably oxygen are acting. For Allvac718Plus the dwell time effect at high temperature is more clear with pure intergranular growth mode but the growth mechanism during intergranular growth is very similar to IN718 with signs of oxidized pores in the [11]crack tip region.

5. Conclusions

A study of the growth of hold time cracks in IN718 and Allvac718Plus at high temperatures has led to the following conclusions.

- Growth of cracks in IN718 during dwell time show a mix between different growth modes with a marked shift in crack growth mode towards intergranularity with branching compared to fatigue crack growth under the same conditions.
- The growth mode during dwell time cracking is shifting towards more intergranular with increased branched cracking with increasing temperature for IN718 but local plasticity is still present.
- The dwell time cracking mode for Allvac718Plus is pure intergranular at high temperature with less pronounced local plasticity.
- Intergranular nanosized voids observed close to the crack tip region could be the responsible for intergranular cracking in both alloys.
- The origin of the nanosized voids is either pure mechanical or a result of oxidation of grain boundary precipitates

Abstract Wrought Inconel 718 DA superalloy disk zones present a wide range of behavior in fatigue life due to the variability of the microstructure. In order to link the effect of the forging conditions and achieved microstructure to the fatigue life, two microstructures have been tested in fatigue. Fatigue tests under strain control were performed at 450°C. Grain size distributions and phase distributions were characterized in the specimens and related to fatigue failure initiation modes. Fatigue crack initiation was seen to occur on large grains in stage I for the larger grain material whereas for the material with slightly smaller grains initiation from internal nitrides caused failure via so-called fish-eye cracks. The different steps of these failure modes are discussed using data from the literature to gather the ingredients for a quantitative assessment of the fatigue lifetime using fracture mechanics.

Keywords Inconel 718, Microstructure, Fatigue, Crack initiation, Propagation mechanism

1. Introduction

Inconel 718 is widely used in aircraft industry. Because of a good combination of formability fatigue and weldability properties and low price/performance ratio, this superalloy is widely used for aerospace applications like turbine disks [1, 2]. This wrought material is produced by forging followed by different heat treatments in order to obtain the desired microstructure. The fatigue behavior at high temperature of this superalloy was widely studied [3-6], the main objective is to predict the lifetime of aircraft engine disk by calculation according to microstructures parameters [7, 8].

To improve the fatigue durability, it is important to obtain the finest possible microstructure. A specific heat treatment called Direct Aging (DA) was developed to obtain this kind of microstructure [9]. Contrary to a classical heat treatment, here the material is directly quenched after forging then aged without adding an annealing step. Fatigue tests were carried out on 718DA and even if the fatigue life was improved thanks to a finer grain size, a strong scatter in test results was observed [10]. Fractography revealed that this scatter is linked to different microstructures and crack initiation mechanisms [11]. Two mechanisms were identified, one for the fine grain size material (5-10µm) and another one for the large grain size material (150µm). For the fine microstructure, initiation sites were systematically related to the presence of second phase particles (carbides and nitrides) on the specimen surface with a size of 10-20µm, then Stage II crack propagation occurs until the breaking point. On the other hand, in the larger grain size material, conventional Stage I crack initiation was observed along the slip bands. In conclusion of this work [11], crack initiation always occurs in the larger microstructural phase. For the fine grain size material, it corresponds to the particles. When the grain size is larger than the particles, crack initiation occurs within the grains themselves. Also, in the previous study, the fatigue properties

were compared at 600°C, and strong oxidation effects are observed in particular on the NbC particles. This oxidation mechanism increases the volume of the particles and allows the initiation and propagation of local cracks because of stress concentration [9].
In the present study, the two materials which were investigated have a mean grain size smaller than the particles size because of the forging parameters used and the DA heat treatment. Two grain sizes were selected. In the case of small grain size the scatter of fatigue life is always present [10]. So it is necessary to understand which one of these parameters really affects the fatigue life.
In the present study the microstructural features are assessed via experimental observation methods. Mechanical fatigue tests are carried out and fatigue crack initiation mechanisms assessed via fractography observations. The various modes of crack initiation encountered and subsequent propagation are discussed using data from the literature to gather the ingredients for a quantitative assessment of the contributions of each crack progression step on the fatigue lifetime.

2. Materials and experimental methods

The experimental pancakes used in this study were forged by Snecma. The pancakes, which were water quenched after forging, have been directly aged with the standard aging treatment, and will be designated as DA718 in the following. The standard aging treatment is: 720°C /8h/ Furnace cooling (50°C/h) down to 620°C/8h and subsequent air cooling. In the present study, two kinds of forging parameters have been investigated (such as temperature, strain amplitude or cooling speed). Indeed material 1 presents a cooling speed slower, as well as a hold time at temperature higher than the delta phase solvus temperature longer than the material 2.

Inconel 718 is a nickel based superalloy hardened by γ'' (Ni_3Nb) and γ' ($Ni_3[Ti,Al]$) precipitates. This alloy also contains δ (Ni_3Nb) phase. The δ phase particles are located both along the grain boundaries and within the grains, depending on the heat treatment applied to the alloy. Another category of coarse second phase particles present in the alloy are nitrides (TiN) and carbides (NbC) with a typical size ranging from 5 to 20 μm. These particles are preferentially located at grain boundaries [14].

Table 1 : Chemical composition of Inconel 718 in weigth %

Al	B	C	Cr	Co	Cu	Fe	Mn	Mo	Ni	Nb+Ta	Ti	O	N
0.56	0.0041	0.023	17.97	0.14	0.03	17.31	0.08	2.97	54.18	5.40	1.00	0.001	0.0062

Microstructures were assessed in term of grain size, particle (carbides and nitrides) and δ phase sizes and their distributions. Samples were polished up to 1μm diamond paste. Micrographs of these samples were taken using a Scanning Electron Microscope (SEM), LEO VP 1450 SEM. To measure precipitates and particles size and their distributions, image analysis software, ImageJ®, was used.
Electron back scatter diffraction (EBSD) scans were also carried out on polished samples. EBSD patterns were collected using a Hikari digital camera, installed on a LEO SEM system. LEO VP 1450 SEM is equipped with an EDAX TSL OIM EBSD data acquisition and processing software and a Hikari digital camera. Operating conditions: high voltage 30 kV, probe current 2000 pA, working distance 22.5 mm, tilt angle 70 deg, step size 0.5 micrometers (hexagonal grid). Four areas of 500μm² were scanned on each material. Data cleanup by "Grain dilation" with threshold values of grain size and misorientation angle of 2 pixels and 5 degrees, respectively.
All the mechanical tests were performed on specimens taken from the two forged material which were submitted to DA heat treatment. The specimens were oriented along the tangential direction of the pancakes.
Fatigue tests were performed using a servo-hydraulic MTS testing machine with a maximum loading of 250kN. This machine was equipped with a resistance heating furnace allowing a

maximum temperature of 1200°C. The fatigue tests were carried out in air at 450 °C ± 2 °C. The temperature control was realized with thermocouple welded on each head of the sample surface (outside the gauge length). These specimens had a diameter of 5 mm and a gauge length of 13 mm. The specimens were tested under 1Hz triangular cycles under strain control. SEM observations of the fracture surfaces allowed us to identify the nature of the fatigue crack initiation sites using a Zeiss Gemini SEM.

3. Results and discussion

3.1. Microstructure

Figure 1 shows EBSD data for the two materials. Differences in grain size are observed. In material 1, the average size of grains is about 10µm whereas it is only about 7µm in material 2. The distribution of the grain size is also different (Figure 2); the scatter of the distribution of grain size is larger in material 1. EBSD data also show that both materials do not have a preferred crystal orientation (i.e. texture in Figure 3).

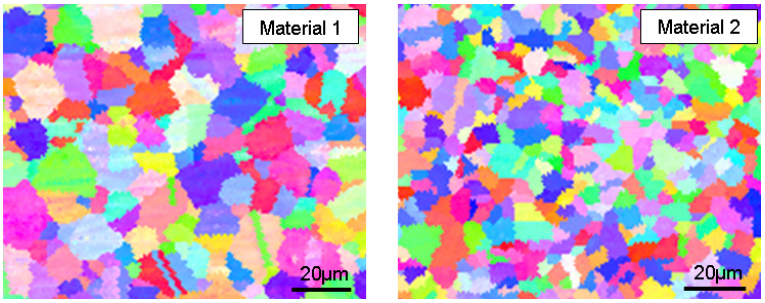

Figure 1 : Grain microstructures observed by EBSD scans with a step of 0.5 µm for a) material 1 and b) material 2

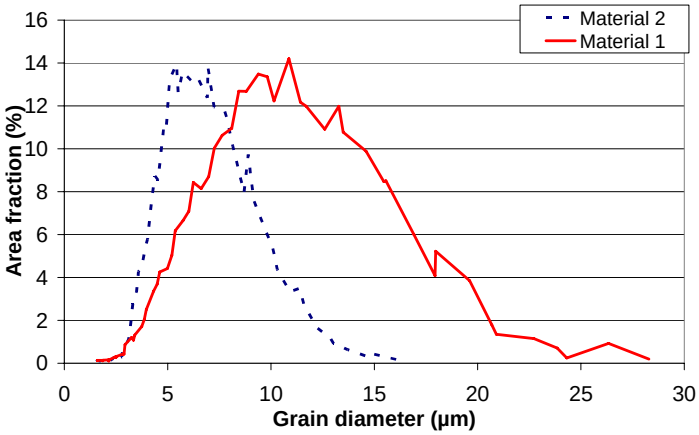

Figure 2 : Grain size distributions of the 2 materials calculated from the EBSD data on 1mm² zones

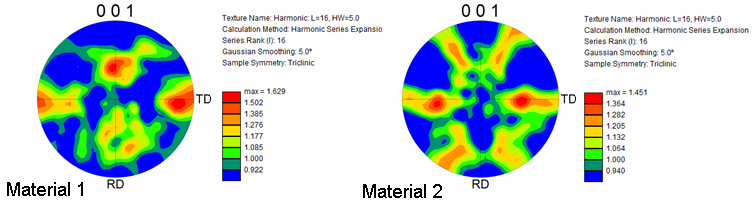

Figure 3 : Pole figure of the texture of the two materials

The size and the distribution of the particles (carbides and nitrides) were also determined by SEM observations on cut-sections first (Figure 4). Carbides are bigger in the initial, non-wrought material

than in the wrought materials, which is consistent with the fact that the carbides were “cut” during the forging process (Table 2). During forging, clusters of smaller carbides are formed that are oriented according to the fibre direction. These results were obtained from a 1mm² surface.

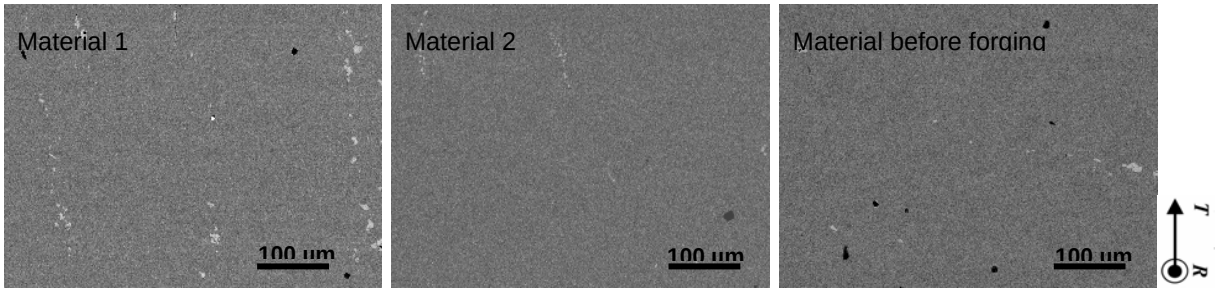

Figure 4 : Microstructures of the different materials, comparison of the distribution of carbides and nitrides, in the radial direction.

Table 2 : Comparison of the distribution and the size of the carbides in the three materials, analysis zones of 1mm².

	Numbers of carbides	Average size	Average diameter	Maximal size	Maximal diameter
	(±5)	µm² (±0,5)	µm	µm² (±0,5)	µm
Material 1	185	13.3	6.5	139.0	20.9
Material 2	115	16.9	7.3	121.5	19.5
Material before forging	95	25.6	9.0	220.5	26.3

The same analysis was carried out for the nitrides which are particles with sharper angles than the carbides (Figure 4). Their density seems similar in both materials, only their size differs weakly. To carry this study further, and compare the distribution of the nitrides in the two materials, a larger area of analyses should be used to assess enough particles for a statistical study.

Table 3 : Comparison of the distribution and the size of the nitrides in the three materials, analyse zones of 1mm².

	Numbers of nitrides	Average size	Average diameter	Maximal size	Maximal diameter
	(±5)	µm² (±0,5)	µm	µm² (±0,5)	µm
Material 1	23	33.3	10.2	204.1	25.3
Material 2	24	27.2	9.2	154.9	22.1
Material before forging	22	17.9	7.5	101.0	17.8

The last microstructural comparison concerns the proportion of δ phase in the two materials of the study (Figure 5). The fraction of δ phase is three times higher in material 2 compared to material 1; they are respectively of 3.0% and 1.1%. This δ phase precipitates preferentially on grain boundaries.

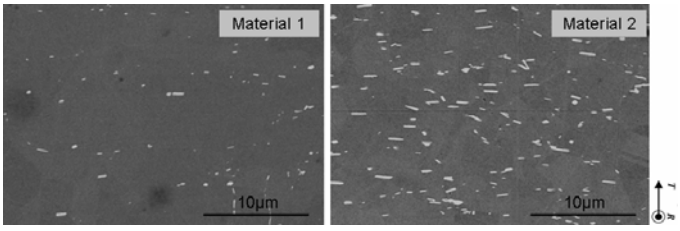

Figure 5 : Comparison of the delta phase distribution between the two materials.

3.2. Mechanical test results

The difference of yield stress between the material 1 and 2 is observed; they are respectively 1170 MPa and 1250MPa. Fatigue properties of these two materials are compared in relation with the grain sizes. The results are presented in Figure 6, the pseudo-stress values are normalised by the Young modulus divided by the mean yield stress of the material, and for proprietary reason this

value cannot be indicated. As shown in Figure 6, for tests conducted at 450°C, the small grain size material achieves significantly higher fatigue lives than the larger grain size material. The fatigue life of material 2 is at least twice superior to that of the material 1.

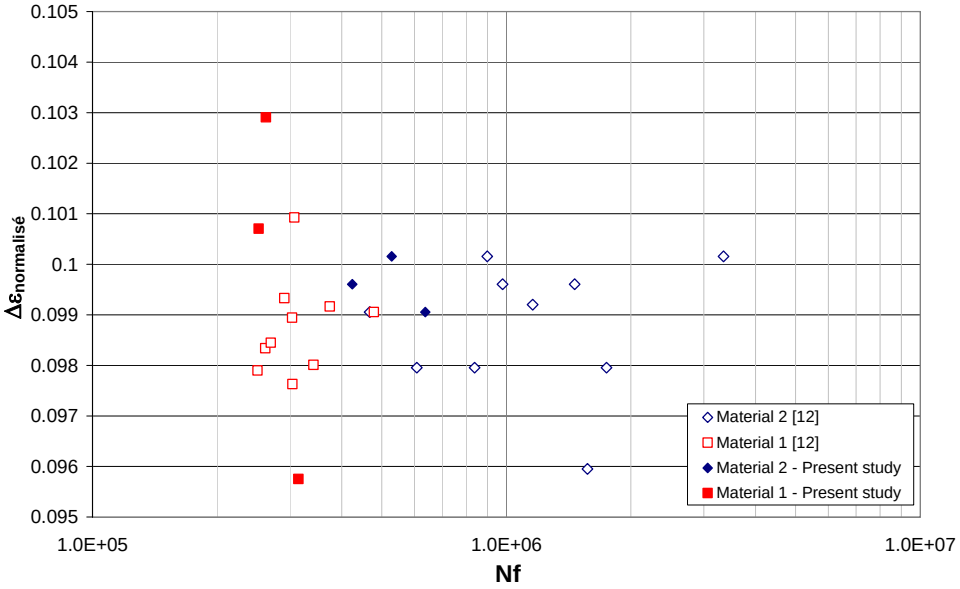

Figure 6 : Repartition of the fatigue life at 450°C, Comparison of the two microstructures**.**

3.3. Discussion of the fatigue crack initiation scenarios and crack propagation steps

In this section the different crack initiation and propagation scenarios are discussed in detail and compared with the literature to gather the elements necessary for a quantitative study of the contribution of each crack progression mechanism to the total fatigue lifetime.

Inconel 718 DA presents at least two known modes of crack initiation [9, 11] modes depending of the microstructure for smooth round bars:
1. Crack initiation on the surface particles for the lowest fatigue life
2. Stage I crack initiation for the longest fatigue life.
In this study, a supplementary crack initiation mode is observed:
3. Internal crack initiation on nitrides leading to fish-eye cracks.
This third crack initiation mode appears for long fatigue lifes and will be discussed in detail.

3.3.1. Crack initiation on surface particle

This type of fatigue crack initiation phenomenon is not shown here but it was clearly observed in the F. Alexandre's work [9, 11] for larger strain amplitude and temperature. These brittle particles may fracture during loading. In addition, the niobium carbides particles on the surface are strongly oxidized and transformed into Nb_2O_5 type oxide [9, 15], as shown in Figure 7. The increased volume of carbides and the stress concentration associated with the oxidation of carbides may lead to early crack initiation. The surface crack initiation probability is dependent of the probability to encounter a large oxidized particle on the specimen surface. This probability increases for large specimens. The fatigue life is then mainly spent in Stage II propagation from an initial crack size equal to the size of the larger grain.

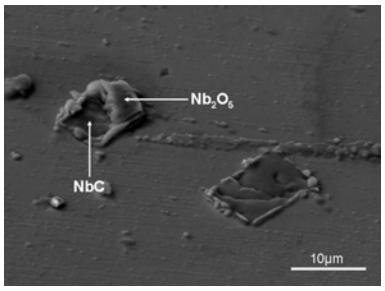

Figure 7 : SEM micrograph of the outer specimen surface away from the fracture surface after specimen failure; oxidized carbides surrounding nitrides are seen

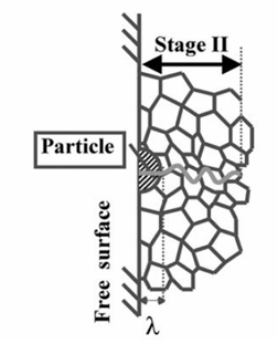

Figure 8 : Schematic representation of the fracture mechanisms for crack initiation from a surface particle [11]

3.3.2. Stage I crack initiation on large grains via persistent slip bands (PSB)

For the larger grain size material 1, the fatigue crack initiation corresponded to typical Stage I crack initiation along persistent slip bands as shown in Figure 9 for two specimens. The stage I crack initiation takes place over several grains, it occurs from the larger grains of material 1. This type of crack initiation was already observed in a previous study [9, 11] for larger mean grain size material, about 50µm.

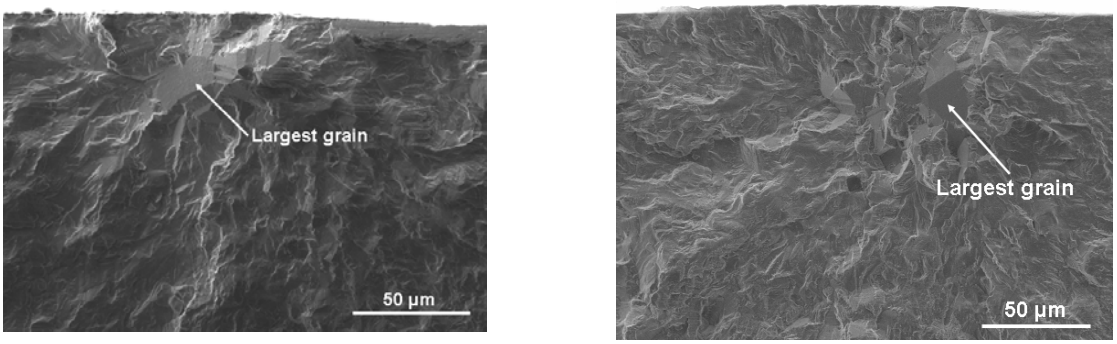

Figure 9 : Fatigue crack initiation sites on microstructure 1 with the biggest mean grains size (11 µm) : Stage I crack initiation across an area of several grains of (a) 70µm of diameter and (b) 150µm of diameter

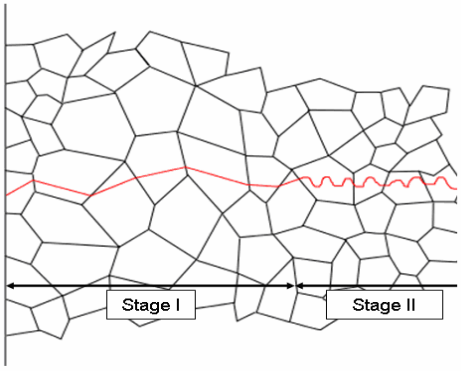

Figure 10 : Schematic representation of the fatigue crack initiation and propagation mechanisms for stage I initiation (for the material with larger grains in the present study)

A probabilistic life model was described by F. Alexandre [11] for this mechanism. The number of crack initiation cycles has been assessed using a Tanaka-Mura [16] type formulation with a modification to account for grain size effect.

$$N_i = \frac{1}{d}\frac{A_{StageI}}{(\Delta\varepsilon_p)^2} \quad (1)$$

where N_i is the number of cycles to initiation, d is the grain size (here, 7µm), $\Delta\varepsilon_p$ is the strain plastic amplitude (in our study, the macroscopic plastic strain is almost equal to zero), and A_{stageI} a constant depending on temperature. This model accounting for grain size effect is consistent with the findings of our study because crack initiation occurs on the largest grains for the material with the larger grains.

This stage I crack initiation is known to be sensitive to the size of the γ'' precipitates [17]. Indeed the γ'' precipitates influence the homogenization on the slip bands. Reducing the risk of crack initiation via PSBs [18].When the grain size is small, the size of the γ'' precipitates increases and the slip bands are more homogeneously distributed in the grains. So this theory may explain why stage I crack initiation occurs on the biggest grain of the material. The dislocation structure and the precipitate size have an effect on the fatigue life [19].

3.3.3. Internal crack initiation on particles leading to a fish-eye crack

This last mechanism is observed in material 2 with smaller grains; crack initiation occurs on an internal particle (nitrides) leading to a fish-eye crack. The mechanism was widely observed for other materials, like in steels for very cycle fatigue [20, 21]. Only a semi-quantitative discussion of crack initiation and propagation steps is presented here.

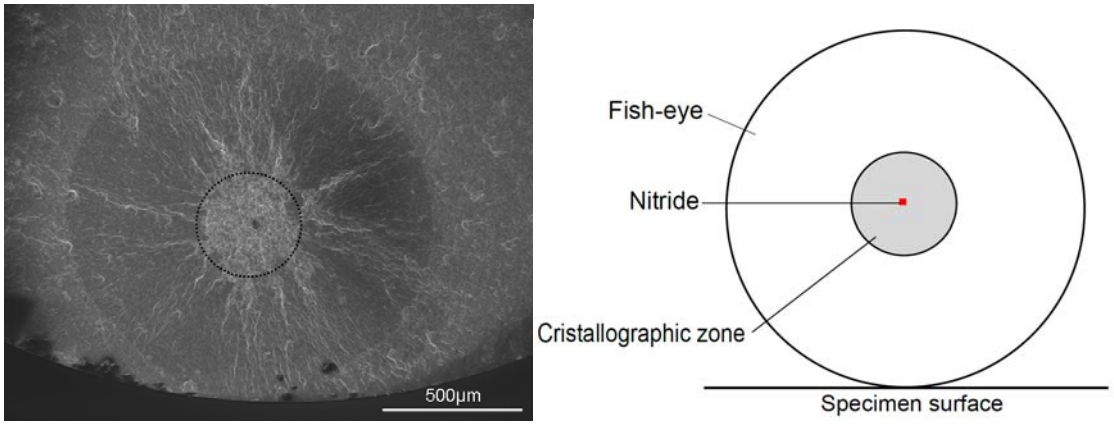

Figure 11 : SEM micrography of a fish-eye crack with a dark nitride particle in its centre for the small grain material 2 and the schematic representation

SEM observations (Figure 11) show an example of a fish-eye pattern formed on the fracture surface and the nitride at the centre of the fish eye. The difference of contrast between the three zones observed on the fracture surface suggests different crack growth mechanisms. At the centre of the fish-eye mark, a bright-facet area was found around the inclusion at the fracture origin as shown in Figure 12. The bright-facet area reveals a very rough topology compared to the area inside the fish-eye.

The propagation mechanism can be classified in five steps:

I. fracture of the large nitride during loading (or during forging)
II. Near threshold micropropagation with crystallographic character, under vacuum
III. vacuum stage II propagation (few striations),
IV. Air propagation with marked striations when the crack reaches specimen surface,
V. final ductile fracture

All these steps will be studied to gather elements to better understand the contribution of the

fracture phenomena on fatigue life.

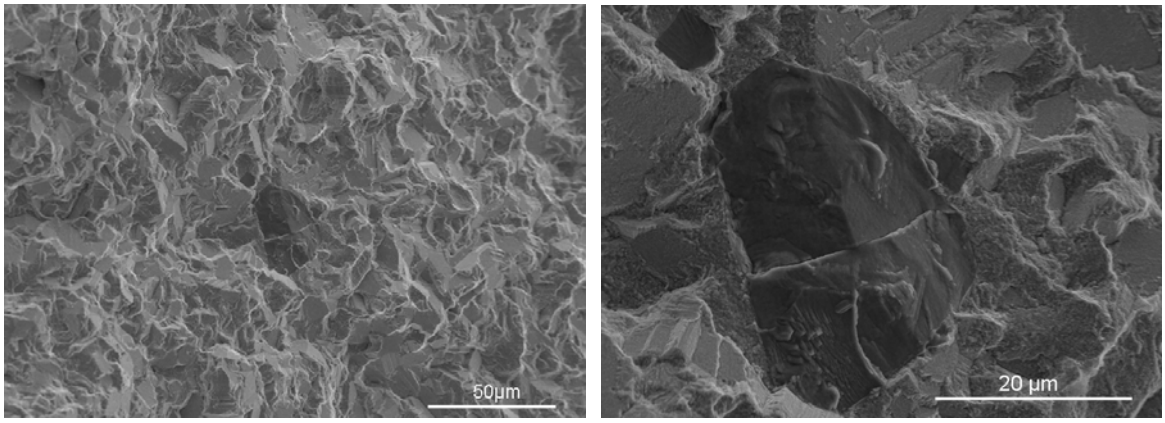

Figure 12 : SEM micrograph showing a zoom in the centre of the fish-eye crack displaying the fractured nitride particle and the rough micro-propagation with crystallographic character

I. Large nitride broken during loading (or during forging)

The nitride cracking is dependent on the particle size and applied stress [9, 11]. As a consequence the distribution of the nitrides through the material plays a role on the fatigue life of a structure. The crack initiation always occurred on the largest nitrides for the present study when comparing according to surface characterization of the nitrides distribution realised (Table 3).

II. Vacuum near threshold micropropagation with crystallographic character

The question is if a cracked nitride leads to crack propagation from the first load cycle onwards. If the value of stress intensity factor generated by the cracked nitride is superior to the threshold value this will be the case. Based on the size of the particles found in the crack initiation site, the initial stress intensity factor range, $\Delta K_{ini,}$ can calculated for a penny shaped crack in a cylinder using the following formula [22]:

$$\Delta K_{ini,inclusion} = 0{,}5\,\sigma_a\,\sqrt{\pi\sqrt{area_{inclusion}}} \qquad (2)$$

Where, σ_a is the stress amplitude. The initial stress intensity factor calculated from a nitride size is between 4MPa√m and 6MPa√m for different specimens displaying internal crack initiation. According to Lawless and King's studies [23, 24], the stress intensity threshold in air for 718 DA, at 538°C and 550°C respectively, is about 8MPa√m. At 427°C in air [19] the threshold for a fine microstructure varies between 5MPa√m and 9MPa√m depending of the heat treatment and the stress ratio. This threshold decreases when the grain size decreases [19, 23]. These values have been found for crack propagation in air; the initiation of the internal fish eye crack occurs, however, in vacuum. Few studies about propagation threshold were performed in vacuum. In [25] the threshold seems to be closed from the one in air when extrapolating the given curve. Material 2 of this study has a small mean grain size (about 7µm) which can reduce the propagation threshold. In addition the residual stress around the particle may be in tension and lead to an effective stress intensity factor which is higher than the one calculated here which would facilitate the propagation.

Furthermore most the threshold values given in the literature have been obtained for long cracks. However, for the fish eye crack initiation, the initial crack is the cracked nitride which is a short crack. It may be assumed that due to the short crack behavior crack progression may occur below threshold values obtained for long cracks [26].

The last parameter which can influence the initial stress intensity factor is the shape of the particle. The corners of the cubic nitrides may generate a stress intensity factor that is superior to the one obtained by the equation (2) for a penny shaped crack

The propagation speed and consequently the fatigue life of this step is certainly low because of the

roughness of the crystallographic surface [1, 13]

III. Vacuum stage II propagation (little striations)

The second area inside the fish-eye presents a classic stage II fracture surface, but the striations are not marked. This can be explained by the fact that this propagation step still occurs in vacuum [13]. Utilisation of Pedron's data [25] is certainly suitable in this step of the propagation. This step propagation stops when the crack reaches the specimen surface.

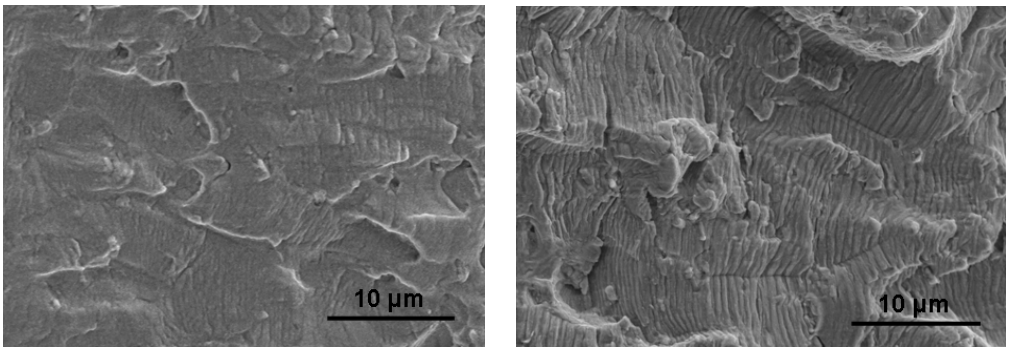

Figure 13 : SEM fractography of the stage II fatigue a) vacuum crack propagation in the fish eye b) air crack propagation beyond the fish-eye.

IV. Crack reaches specimen surface air propagation with marked striations

When the fish-eye crack reaches the specimen surface, the ligament between the penny-shaped fish-eye crack and the specimen surface will break very quickly due to the high local stress intensity factor.

In this step the surface crack can approximately be considered as semi-elliptical. The propagation occurs in air:

$$K = \sigma\sqrt{\pi d}\ F_I \quad (3)$$

Where σ is applied stress, *d* the crack depth from the surface and F_I the correction factor depending on the geometry of the specimen and crack. Values of this factor F_I can be found in handbooks [22]. The last step on the fracture mode corresponds to final ductile fracture.

In conclusion, 3 different crack initiation scenarios have been identified for Inconel 718. The likelihood of the occurrence of each of these scenarios depends on the microstructural heterogeneities, such as e.g. grain size distributions, particle size distributions and their spatial distributions. The link between the probability to encounter each crack initiation scenario and the total fatigue life of the specimens is schematically sketched in **Figure 14**. Further analysis of the resulting distributions in fatigue life is under progress.

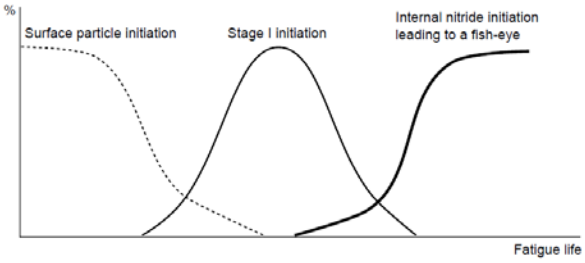

Figure 14 : Schematic representation of the relationship between probability to encounter each crack initiation scenario function with the total fatigue life of the specimen for a specific loading value (the relative position of the stage I initiation curve and the internal nitride initiation curve is dependent of a scale effect. These curves can be translated.)

Conclusions

The differences in fatigue life behavior in Inconel 718DA are studied here for two different microstructures. In both microstructures of the present study, the average grain size is smaller than the particle (nitrides) size and nevertheless crack initiation sites are different. In the larger (10μm) grain size material, stage I crystallographic cracking at or near the surface is initiated on the large grains of the material located at the free surface and having a diameter about 30 μm. In small (7μm) grain size material, crack initiation occurs preferentially on internal TiN particles followed by crack propagation with crystallographic character and subsequent Stage II crack propagation. A fish-eye crack is formed. The particles initiating the internal fatigue cracks are substantively larger than the largest particles observed on cut section from microstructural analyses. The internal crack occurs on nitrides of a mean diameter of 30μm. The different stages of the fish eye cracks are identified with: I. fracture of the large nitride during loading (or during forging), II. vacuum near threshold micropropagation with crystallographic character, III.vacuum stage II propagation (few striations), IV.crack reaches the specimen free surface, and propagation in air with marked striations and V.final ductile fracture. These crack progression stages are discussed using data from the literature to gather elements for quantitative assessment of the contribution of each crack progression step to the total specimen lifetime.

Abstract The Ultrasonic nanocrystal surface modification (UNSM) was employed to enhance the fatigue strength of S45C steel with different pre-plasma nitriding (un-nitrided, nitriding 8 h and 48 h) by improving the surface roughness and producing nanocrystalline on the sample surface. The parameters of UNSM were two different strike numbers, 34000 mm^{-2} and 68000 mm^{-2}. Different experimental processes including microstructure observation, microhardness, roughness and X-ray diffraction measurements have been performed to characterize the treated surface of specimens. The results shown that after UNSM treatment an improvement can be obtained for surface microhardness, surface roughness, and compressive residual stress. Under the same UNSM conditions more surface defects can be produced with the increasing strike number and with increase of surface hardness the effect to surface roughness decreased. For the higher hardness surface sample, smaller nanocrystalline can be obtained compared with other sample through XRD results. Higher compressive residual stress was found for un-nitrided S45C steel with increasing strike number, but a decrease was found for the nitriding sample. Rotating bending fatigue test was carried out to evaluate the effect UNSM to the fatigue strength. An improvement of fatigue strength for un-nitrided and nitriding 8 h sample was found and the surface defects were the main reason inducing the fatigue failure. However, for N48 samples, no improvement of fatigue strength as little effect of UNSM on the sub-surface crack induced by inclusion.

Keywords UNSM, Plasma nitriding, Surface Hardening, Fatigue

1. Introduction

Ultrasonic nanocrystal surface modification (UNSM), as one of severe surface plastic deformation (S^2PD) methods to improve material surface properties, has been used on many materials treatments [1-5]. The properties of wear [4, 5], fatigue [1-3] of materials can be improved as the reason of high surface hardness and compressive residual stress produced by the UNSM treatment. In the study of Cao [2], with the increase of strike number higher fatigue strength can be obtain and small fatigue crack can be restrained as the compressive residual stress produced by UNSM treatment. Suh's study [3] shows that the grain in the top surface zone can be refined into nano-size and the depth of gradual grain refined layer about 100 μm can be produced by UNSM treatment with the applied static force of 100 N. Amanov [5] has found that high impact load can get a lower friction and well wear characteristics and smaller nano-grain size can be obtained at the same time. So we can see that the processing parameters (the applied static force, the strike number per mm^{-2}, the size of tip ball) can be controlled accurately and all of these parameters have a close connection with the characters of specimen's surface zone after the UNSM treatment. Also the structure of the material receiving surface treatment plays an important role for the formation of microstructure in the surface processing layer. Zhou [6] showed that the SMAT steel sample has a thicker refined layer (with grain size < 100 nm) compared with pure Fe. Cho [7] and Lee [8] found that with more hard

phase smaller sized grain can be induced due to the easier formation of dislocation around the hard phase.

Although a few studies have been conducted on the UNSM treatment with many kinds of materials, few studies about the UNSMed sample with different surface hardness were found. In this paper, the specimens of S45C steel with different surface hardness introduced by pre-surface treatments were processed by the UNSM treatment under the same conditions. The surface morphology, microstructure, residual stress, microhardness and fatigue properties were investigated and the effect of different pre-hardening surface to the UNSM treatment on the surface properties was discussed.

2. Experiment

2.1. Materials preparation

The material used was a medium-carbon steel S45C shaft with a chemical composition (in wt.%) of 0.45%C, 0.15%~0.35%Si, 0.6~0.9%Mn, ≤0.03%P, ≤0.035%S, ≤0.3%Cu, ≤0.2%Ni, and ≤0.2%Cr, balanced with Fe. To test the fatigue properties, the specimens were machined to the dimensions shown in Fig. 1, resulting in a stress concentration factor, K_t, of approximately 1.08. The specimens were first quenched (austenitized, 1113 K, 150 min; oil quenched, room temperature, 60 HRC) and tempered (tempered, 773 K, 270 min, 31 HRC). The specimens were then polished by using sandpaper from grade 400 to grade 2000. Subsequently, the specimens were nitrided in a mixture gas (40%N_2-60%H_2) and at 400 Pa. Two nitriding time durations, 8 h (N8) and 48 h (N48), were used to obtain different nitriding properties.

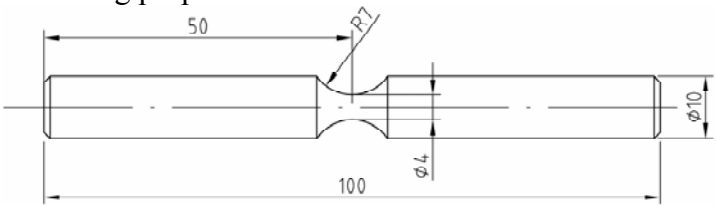

Figure 1. Dimension of the test specimen for S45C steel.

2.2. Surface treatment

After plasma nitriding, the surface layer (approximately 12 μm) was removed to avoid the effect of the nitriding layer on the subsequent UNSM treatment. The UNSM technique details have been previously published. An ultrasonic generator (a 30 μm amplitude and 20 kHz) and air compressor devices were used to produce a static force with a dynamic load to strike the material surface with a tungsten carbide (WC) ball (the diameter: 2.4 mm). Accurate surface strike numbers can be obtained by calculating the speed of the surface being treated when the specimen is rotated by a turning lathe. Thus, it is easy to process the material surface and control the static loads and strike numbers. Throughout the process, cold liquid was used to avoid high specimen surface temperatures.

Table 1. Specimen treatment conditions

Specimens	Untreated	U1	U2	N8	N8U1	N8U2	N48	N48U1	N48U2
34000 mm^{-2}	–	Y	–	–	Y	–	–	Y	–
68000 mm^{-2}	–	–	Y	–	–	Y	–	–	Y

To study the effect of strike number on the fatigue properties of the nitrided sample, two treating

parameters were selected: (U1) strike number of 34000 mm^{-2}; static load of 50 N; revolution rate of 37 rpm, feed rate of 0.07 mm/rev; and (U2) strike number of 68000 mm^{-2}; static load of 50 N; revolution rate of 18.5 rpm, feed rate of 0.07 mm/rev. The specimen processing conditions are listed in Table 1.

2.3. Materials characterization

To examine the grain-refined layer and the nitriding layer, the cross-section of the all specimens were observed by an optical microscope (Olympus BN2). Before test, the samples were mechanically polished with the sandpapers (from grade 150 to grade 2000) and then a polish cloth with a liquid suspension of alumina. The saturated picric acid solution was used to etch the specimens in this test.

X-ray diffraction (XRD) was employed to measure residual stress of all sample varieties, utilizing Cr-Kα radiation for a longer wavelength and deeper penetrating power. The test was carried out on a Rigaku XG-4026A1 using the classical sin2ψ method. Cu-Kα (on a Rigaku Rint-2000) was used to analyze the state of the surface layer nanostructure and the compound layer of nitrided samples to a depth of approximately 5 μm.

The microhardness of the plastic deformation zone and nitriding layer was measured on a micro-Vickers hardness tester (MVK-E3, Akashi). The parameters used in the microhardness test were 50 gf and a duration 15 s.

The surface roughness of the S45C specimens before and after the UNSM treatment was tested on a contact surface profiler (ULVAC DEKTAK3).

To compare the fatigue properties of S45C with the two process methods, a rotating bending fatigue test was carried out on a dual-spindle rotating bending fatigue test machine under atmospheric conditions. The rotating frequency used was 52.5 Hz, and the stress ratio was -1.

The failure fracturing of the samples was observed using scanning electron microscopy (SEM) (S-4700, Hitachi). Energy-dispersive X-ray spectroscopy (EDX), with the same machine, was used to detect the composition of any inclusions that induced the sub-surface fish-eye crack initiation.

3. Results and discussion

The surface morphology of before and after UNSMed specimens was shown in Figure 2. It is obvious that UNSMed processing marks were produced on the specimen surface. As the processing principle, these marks show parallel and as the increase of processing number these marks become more obvious. For the parallel marks, the distance between each other was approximately 70 μm. This value equals to the processing parameter of the feed rate which is 0.07 mm/rev. During surface treatment, only the surface under the center of the tip can receive most severe plastic deformation as the reason of ball shape of the process tip. Comparing the surface morphology results of UNSM samples with different pre-surface hardness, it can be seen that for the softest surface sample (un-treated) the UNSM process marks show the most obvious after the process of 68000 mm^{-2}. The surface roughness was test and shown in Figure 3. It can be found that the surface roughness (Ra) for the all UNSMed sample has an improvement and even there are a few of obvious UNSMed process marks on the UNSMed sample surface. As the increase of strike number, a little growth can be observed with the surface roughness. Combined with results of surface morphology it is easy to find that the UNSMed process marks produced during surface process were the main reason.

Though from magnified surface morphology results the region between two UNSMed marks was smoother the process of more strike number, the UNSMed marks mainly lead to the worse of the surface roughness. For the nitriding samples, the UNSMed marks show unobvious as the reason of nitrides within top surface region reducing the plastic deformation of sample surface. Compared with the soft un-nitriding sample, better surface roughness can be obtained for the sample surface with higher hardness. It also means fewer surface defects produced on the nitriding sample surface.

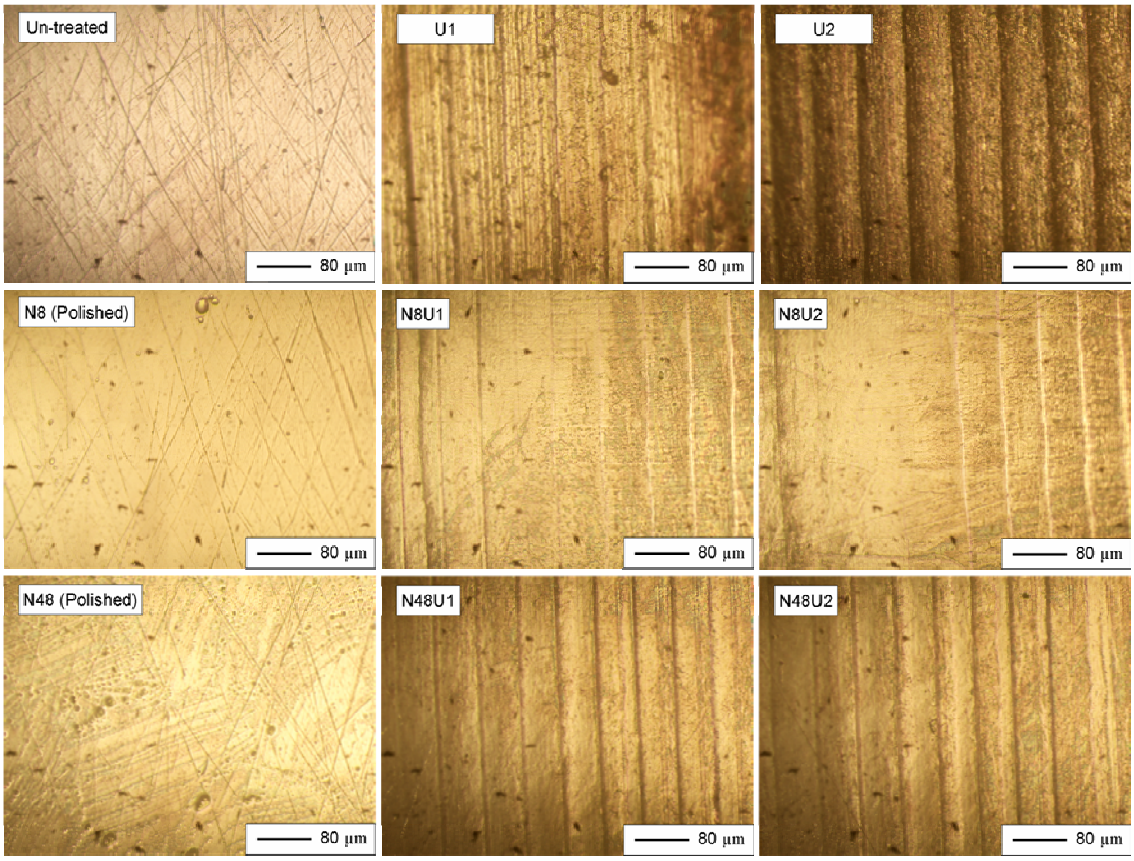

Figure 2. The surface morphology of specimens before and after UNSM.

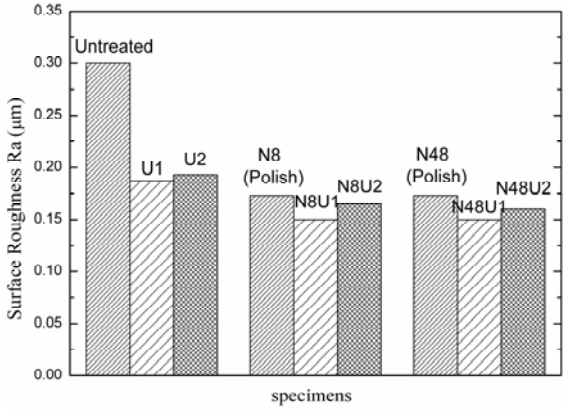

Figure 3. The surface roughness of specimens before and after UNSM.

The microstructures of the samples before and after UNSM treatment were shown in Figure 4. Through the other studies [3, 6] it can be seen that a gradual change microstructure from nano-sized grain in the sample top surface to the grain size of base material can be produced by the S^2PD treatment. With picric acid solution the grain boundaries can be etched easily. For the un-UNSMed samples the grain can be distinguished from top surface to interior and no difference between each

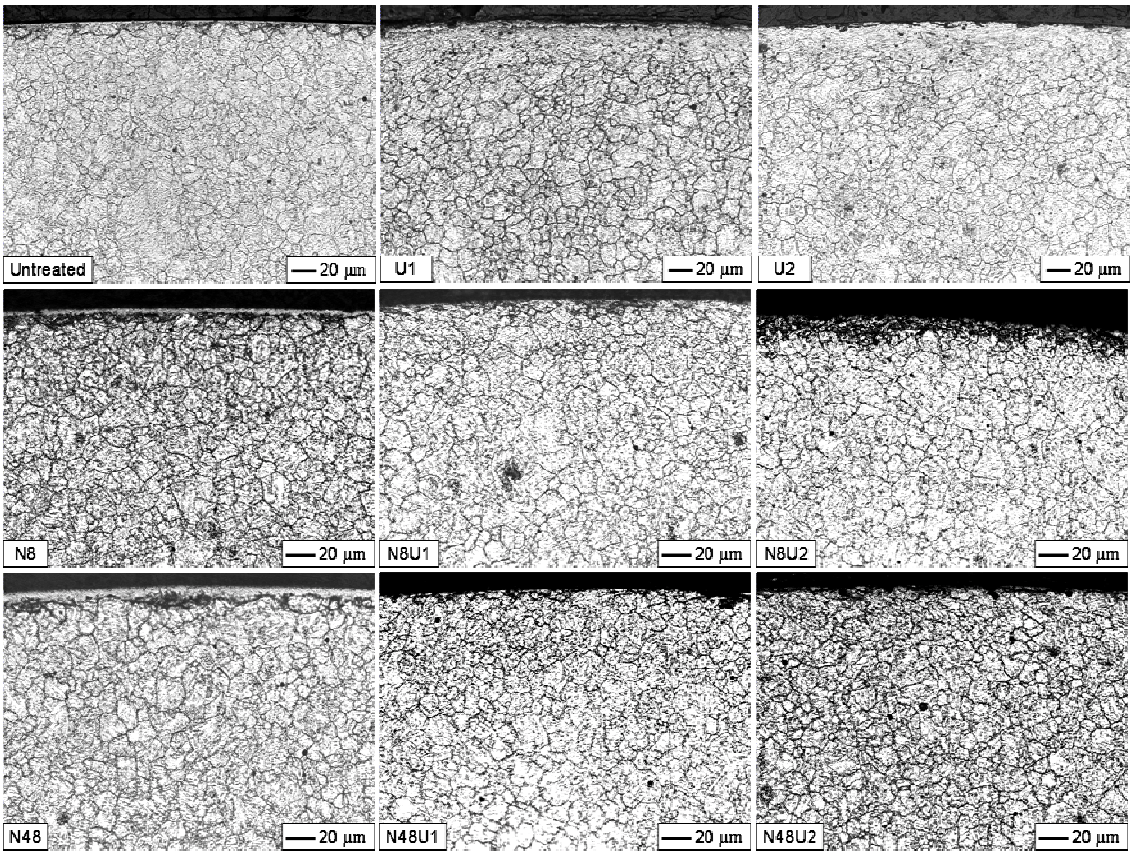

Figure 4. The microstructure of cross-section of specimens before and after UNSM.

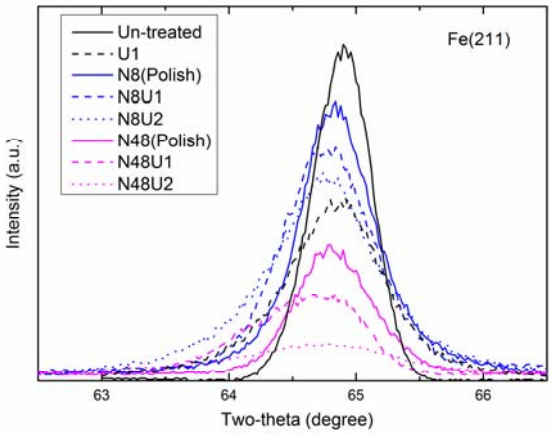

Figure 5. The XRD pattern of Fe (211) diffraction angles for the specimens before and after UNSM.

other can be observed. For the nitriding sample, a compound layer can be found on the nitriding sample surface (approximately 3 μm for N8 and approximately 8 μm for N48 sample). All the UNSMed samples can be found a grain refined layer at the edges of the cross-section. The refined layers are obvious for U1 and U2 samples approximately 40 μm for U1 specimens and approximately 70 μm for U2 specimens. However for the pre-nitriding samples, this layer is difficult to be distinguished and only some deformed grains can be found and the results show that the deformed layer induced by UNSM decreases with the increase of pre-sample surface hardness. The XRD was employed to scan the sample surface and the Fe (211) diffraction angles were scanned slowly and shown in Figure 5. Analyzing the XRD results and we can find that the Bragg diffraction peaks for all samples can be broadened by the UNSM. That means a grain refinement was induced on the sample surface according relation between grain size and the full width at half

maximum (FWHM). With FWHM results of all samples it can be found that though the nitrides within the sample surface zone and the XRD intensity of all un-UNSMed samples is different, the values of FWHM are close. And the degrees of the change are different. It is easy to find that the N48 samples were broadened easily compared with the un-treated and N8 samples. In many references [6-8], the hard phase can enhance the ability of the refinement of ferrite as different mechanism. So we can see that with the growth of nitrides concentration, harder sample surface can be obtained. More easy grain refinement can be found the harder sample, but thinner grain refined layer would be obtained as the reason of the surface with high hardness hindering the transfer of the plastic deformation energy produced by UNSM.

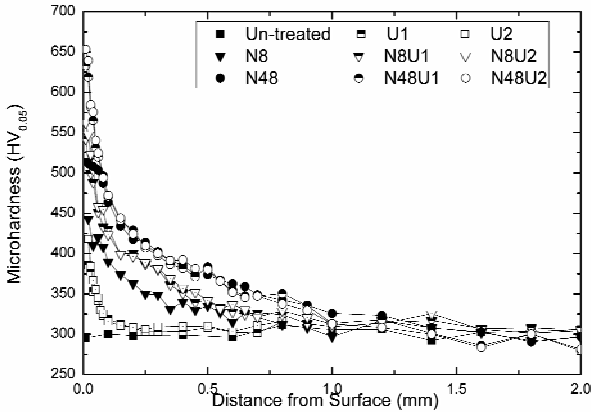

Figure 6. The microhardness of cross-section of specimens before and after UNSM.

The microhardness results of the all samples along the cross-section were shown in Figure 6. After UNSM treatment not only was surface hardness improved but also a gradual enhancement in the sub-surface region also can be observed. For the UNSM samples, the microhardness in the top nanostructured layer is 372 Hv for U1 sample and 418 Hv for U2 sample. For the N8 specimens, the surface hardness increased from 443 HV to approximately 540 HV after U1 treatment and to 560 HV after U2 treatment. These values were even higher than that of the N48 samples without UNSM treatment. For the N48 specimens, the surface hardness increased from 510 HV to 630 HV after U1 treatment and to 650 HV after U2 treatment. For all UNSMed samples the top surface hardness and the depths of effect increase with more strike number. It also can be found that the depths of effect regions are different with the change of samples. After the UNSM treatment, the materials surface was subjected to a severe plastic deformation induce a grain refinement. With the UNSM treatment, increased number of grain boundaries as the refined grains and generation of high density dislocation with strain hardening restrict the dislocation motion and render the material harder and stronger. According the microstructure results, we can also infer that the concentration of nitrides has a close connection with the hardening depth. Zhou [6] has found that compared with the strain-induced grain refinement in the pure Fe under the same SMAT processing, not only was refinement of ferrite much facilitated by the presence of dispersed cementite particles but also a thicker nanostructured layer can be obtained. The hard phase has the ability of transfer energy during S^2PD treatment. For soft surface materials, as the amplitude of 30 μm during UNSM processing energy of UNSM can not transfer too far as the absorption of energy by the top surface to have a plastic deformation. With the increase of nitrides concentration the hard phase of nitrides can transfer the energy to the deeper region. However when the surface hardness is too high, it is difficult to have a plastic deformation in the top surface and only induce a refinement of grains. So with just enough nitrides concentration, a deeper hardening layer can be produced.

The top surface residual stress was measured and shown in Figure 7. Before UNSM treatment un-treated and plasma nitriding samples all have a compressive residual stress on the surface

induced by QT (quenching and tempering) and nitriding process. After UNSM treatment the surface stress for all UNSMed samples was improved. However different trends with the increase of strike number can be observed for the UNSMed samples. For the un-treated sample, the surface residual stress increase from -217.4 MPa to -318 MPa with U1 and -395.1 MPa with U2 and it can be found that higher compressive residual stress can be obtained as the increase of UNSMed striking number. For the nitriding samples, the residual stress has a growth from -171.9 ~ -161.2 MPa (N8 and N48) to -925 MPa for N8 samples and -1089 MPa for N48 samples with U1 treatment. However a decrease (to -750 MPa for N8 samples and -778 MPa for N48 samples) was found with U2 treatment. This means that though with the growth of surface hardness higher compressive residual stress can be produced, a decrease was found as the increase striking number. This phenomenon is different from the U1, U2 results and other studies [2]. This may be the reason of the grain refinement of the nitrides in the surface zone inducing a relaxation of the surface stress.

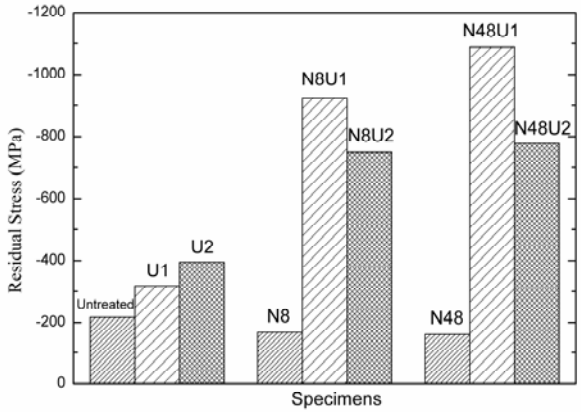

Figure 7. The residual stress on the surface of specimens before and after UNSM.

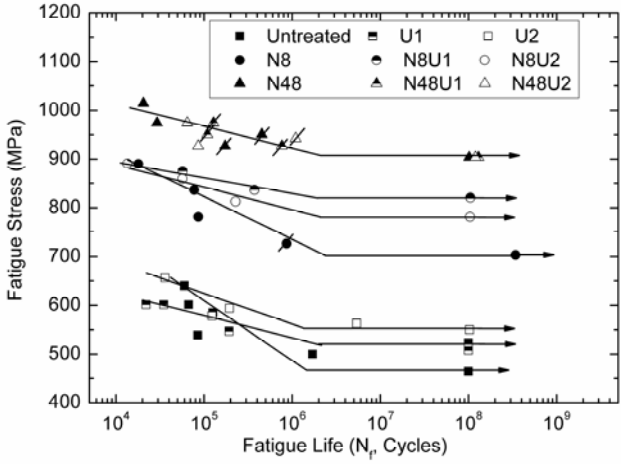

Figure 8. S-N curves of rotating-bending fatigue test

The fatigue test was employed on a rotating bending test machine and the S-N results are shown in Figure 8. The results show that after UNSM treatment the fatigue strength was enhanced for un-treated and N8 samples, but no improvement for the N48 samples. Compared with un-treated sample, more enhancements were obtained for N8 samples. At the same time the improvements of UNSMed samples have a close connection with the value of surface residual stress. Foe ever un-treated or N8 samples, the fatigue strength has a linear relation with the surface residual stress and with the higher residual stress, higher fatigue strength can be obtained. So we can find that a higher fatigue limit of N8 sample can be obtained after U1 treatment than after U2 treatment. It shows opposite compared with un-treated sample after UNSM treatment. This means that though

harder surface can be obtained by U2 treatment, the fatigue strength mainly depends on the level of surface stress. For the N48 samples, U1 process also introduced a higher compressive residual stress but the sub-surface fatigue crack initiation induced by inclusions hinders the improvement of fatigue strength.

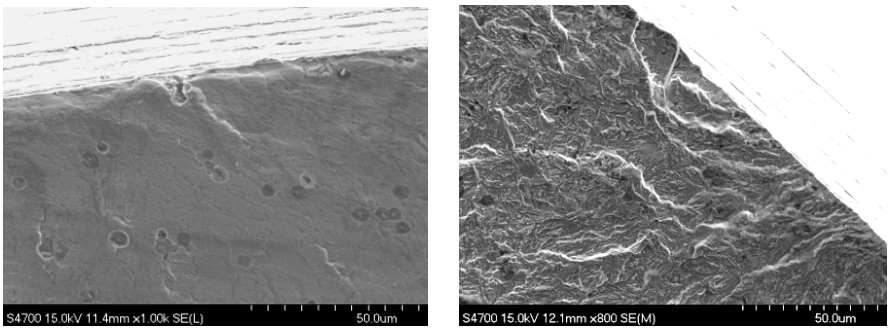

Figure 9. The fatigue crack initiating from surface defects (U2, 562MPa, $5.4x10^6$, left; N48U2, 974MPa, $6.46x10^4$, right)

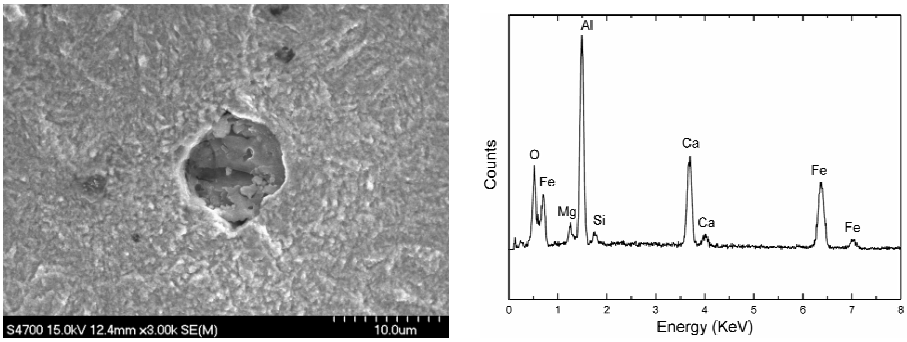

Figure 10. The sub-surface fatigue crack induced by inclusions (N48U1, 974.2MPa, $1.3x10^5$) (Left); EDX data on the inclusion.

The observations of the fatigue fractures were shown in Figure 9 and Figure 10. It obviously can be seen that the fatigue crack inducing the material's failure can be divided into two modes: one is the surface crack initiation induced by the persistent slip bands (PSBs) or surface defects; another is the sub-surface crack induced by the inclusions within materials. After plasma nitride, the surface of S45C steel can be enhanced effectively and the fatigue crack initiating from sample's surface becomes difficult. With the high cycle loading the inclusion within the sub-surface can induce a stress concentration and a fine granular area (FGA) (Figure 10, left), which was composed by the aluminum oxide, calcium oxide and magnesium oxide or other hard phases (Figure 10, right), was produced and expand to fracture. The mechanism of the formation of FGA is not clear and there are many theories explaining this phenomenon, for example, the theory of hydrogen diffusion, the dispersive decohesion of carbide and the grain refinement induced by stress concentration [9-11]. From the observations of fractures results, the UNSM treatment not only can improve the fatigue strength but also has an influence on the fatigue crack initiation. For the un-treated samples, the surface cracks transfer form surface crack induced by PSBs to the crack induced by the UNSM process marks (Figure 9, left) which we also can found in the surface morphology results. So we can also find that with increase of the test loading the fatigue life decreases as the reason of relaxation of residual stress and the stress concentration induced by the surface defects. For the nitriding samples, also were surface cracks induced by surface defects (Figure 9, right) found and the fatigue strength decreases with the increase of striking number (U2) as the reason of decrease of surface residual stress and more surface defects induced by the UNSM treatment after U2 process. We can also find more surface fatigue crack initiations for N48 samples with U1 treatment than U2

treatment. Combined with the results of surface roughness, it can be found that more surface defects can be introduced to the N48 samples' surface. So the fatigue strength is difficult to be enhanced as these defects inducing stress concentration easily. For the N48U1 samples, though high compressive residual stress and little defects were introduced, the inclusions within the sub-surface of samples still can form a fish-eye crack and hinder the improvement of fatigue strength. Also we found that as the high compressive residual stress induced by UNSM treatment the position of inclusions trend a deeper depth beneath the samples' surface [1]. With above results we can conclude that with the high loading during fatigue test the fatigue strength is more sensitive to the surface state of samples. At the same time, though high compress residual stress can be introduced by UNSM treatment, the sub-surface cracks induced by inclusions with materials are difficult to be hindered as the reason of limited depth of enhanced zone improved by UNSM treatment.

4. Conclusions

(1) With the increase of strike number, deeper UNSM processing marks can be introduced on the specimen surface; for the specimen with the higher surface hardness, little effect of UNSM to the surface roughness can be found.
(2) A gradual refined grain layer can be produced by the UNSM as multiple strikes to specimen surface; the thickness of the refined layer increases with the strike number and decreases as the growth of surface hardness; the top surface grains can be refined in to nano-size and for the sample with higher surface hardness grain refinement become easier.
(3) The surface hardness can be effectively improved by UNSM treatment and increases as the increasing strike number; N8 sample has a larger zone for the hardness increase as the effect of nitrides within sample.
(4) Higher compressive residual stress can be found for the nitriding specimens; increase of the residual stress can be obtained for un-nitriding samples as the increase of strike number; however opposite phenomenon was found for nitriding samples and residual stress decreases with the increasing strike number.
(5) The enhancement of fatigue strength mainly depends on the residual compressive stress in the surface zone produced by UNSM treatment; as the increase of fatigue strength the surface defects and sub-surface inclusions hinder the increase of fatigue strength definitely.

Abstract The fatigue damage and fracture of GH4133B superalloy used in turbine disk of aero-engine are studied. Firstly, the fatigue limit is measured, and the relation between electric resistance change ratio and number of fatigue loading cycles is investigated for smooth samples. Then, the fatigue crack propagation tests are carried out at various stress ratios, and the fatigue crack propagation threshold values are measured for standard compact tension samples. The research results indicate that the theoretical fatigue limit agrees well with experimental one, the modified Chaboche model can predict the fatigue damage preciously, and the Paris formula considering fatigue threshold can describe the crack propagation behavior accurately. Finally, the crack propagation equations and loads are derived using the inverse deducing method based on the fractography of smaples. It is suggested that the inverse deduced equations can predict the crack propagation behavior, and the predict results can effectively prevent the occurrence of fatigue fracture.

Keywords Fatigue, Damage, Crack propagation, Fractrography, GH4133B superalloy

1. Introduction

In the fracture accidents of engineering components and structures, the fracture caused by fatigue accounted for about 70% to 80% of all the fracture accidents [1]. In the field of aviation industry, the damage tolerance design criterion has been introduced into the structural design of the aircraft and aero-engine, instead of the traditional minimum safe life design criterion [2, 3]. As far as the fatigue damage mechanism is concerned, from the point of view of damage mechanics, the process of crack growth in material from initiation to propagation to ultimate failure is a one of continuous damage evolution. The damage evolution equation is stated by the relationship between the change of damage variable and the number of loading cycles. Therefore, constructing a suitable damage evolution equation becomes a key issue of the damage tolerance design. Many damage theories for various metals and their alloys under different conditions had been devoloped, and these models were reviewed, and they were grouped into six categories: linear damage rules; nonlinear damage curve and two-stage linearization approaches; life curve modification methods; approaches based on crack growth concepts; continuum damage mechanics models; and energy-based theories [4]. In general, the elastic modulus, fatigue cycles, microhardness, interface shrinkage, as well as electric resistance, etc., can be used to describe the fatigue damage of material. For most of the metals and their alloys, the electric resistance change method can be adopted to charaterize the fatigue damage evolution, which has better accuracy and sensitivity [5–7].

Fatigue crack growth in metals and alloys is a process controlled by many variables, which includes both external factors such as temperature, frequency, loading rate, stress ratio, mean stress, and internal factors such as content, microstructure, and inclusion. GH4133B is a nickel-based superalloy. Such alloy is selected to manufacture components operated at high temperature, such as turbine disk of aero-engine, for its resistance to sensitization, adaquate high temperature tensile strength and creep resistance. Hu [8] investigated the creep-fatigue interaction and the effect of loading history on the creep-fatigue damage of GH4133B superalloy at 600ºC in three cases of loading as continuous cyclic loading (CF), prior fatigue followed by creep loading (F+C), and prior

creep followed by fatigue loading (C+F), and found that the creep-fatigue damage in the cases of CF and F+C was larger than unity, while that was smaller than unity at C+F. Luo [9] carried out a statistical analysis on the mechanical parameters of GH4133B superalloy at room temperature, and found that the three-parameter Weibull distribution was fit for the reliability assessment of this superalloy. Padula II [10] investigated the effect of grain size on high frequency fatigue crack propagation of nickel-based superalloys at various stress ratios. The results indicated that there is no effect of frequency on the fatigue behavior at ambient temperature. The threshold stress intensity for fatigue crack propagation decreases with decreasing grain size and with increasing stress ratio.
In this paper, the fatigue damage and fracture tests of GH4133B superalloy used in turbine disk of earo-engine are carried out at room temperature. The fatigue limit is measured for smooth samples at various stress amplitudes, and the fatigue crack growth rates are detected for standard compact tension samples under different stress ratios. A modified Chaboche model is applied to predict the accumulated damage of smooth samples of GH4133B superalloy at symmetrical cycle loading, and a Paris formula considering threshold stress intensity factor range is deduced to describe the fatigue crack growth behavior. The fracture surface morphologies of standard compact tension samples of GH4133B superalloy are investigated using scanning electron microscope, and the crack growth equations and loads are derived using the inverse deducing method.

2. Material and samples

The material used in this research is a nickel-based GH4133B superalloy with following chemical composition in % weight: C 0.06, Cr 19~22, Al 0.75~1.15, Ti 2.5~3.0, Fe 1.5, Nb 1.3~1.7, Mg 0.001~0.01, Zr 0.01~0.1, B 0.01, Ce 0.01, Mn 0.35, Si 0.65, P 0.015, S 0.007, Cu 0.07, Bi 0.0001, Sn 0.0012, Sb 0.0025, Pb 0.001, As 0.0025, and the balance nickel. The superalloy samples are machined from a turbine disk. The heat treatment process is as follows: 1080±10ºC, 8 hours, air cooling with 750ºC±10ºC, 16 hours air cooling. The samples for fatigue damage tests are machined in rod shape, as shown in Fig. 1. The samples for fatigue crack growth tests are machined in the shape of standard compact tension sample, as shown in Fig. 2.

3. Fatigue life and fatigue damage analysis

3.1. Fatigue life test

At room temperature and atmospheric pressure, the fatigue tests for smooth samples of GH4133B superalloy are performed on a servo hydraulic test machine (CSS-280S-20) of ±20kN loading capacity. Under symmetrical cyclic loading condition (30 Hz sine wave, stress ratio R=–1), the fatigue life tests are carried out at various stress amplitudes. The fatigue limit is defined as 10^7 cycles. The stress amplitudes are assigned as 256MPa, 320MPa, 400MPa, 432MPa, 462MPa and 538MPa, respectively. In the case of stress amplitude as 256MPa or 538MPa, only one fatigue test for a smooth sample is carried out, while for the other stress amplitudes, four fatigue tests are performed for eight smooth samples of GH4133B superalloy. During the process of fatigue tests, a multi-parameter measurement mode is adopted, that is, except for recording the number of fatigue loading cycles, the values of electric resistance of smooth sample are measured every certain number of loading cycles by a QJ-57 type DC resistance bridge whose scale overs the range from 0.01μΩ to 1.1111kΩ, which is producted by Shanghai Sute Electrical Appliance Limited Company. Therefore, the accumulated fatigue damage for the sample of GH4133B superalloy during the fatigue process is monitored by measuring electric resistance change.

3.2. Fatigue life analysis

Using the up-down stress amplitude method, the fatigue life measured in the tests is determined as 288MPa, which is the mean value of stress amplitude 256MPa and 320MPa. The three-parameter power function expression is adopted to describe the fatigue *S-N* curve, that is

$$N_{\mathrm{f}} = \sigma_{\mathrm{f}}(\sigma_{\mathrm{a}} - \sigma_{\mathrm{ac}})^{-m}, \tag{1}$$

where, N_{f} is fatigue life, σ_{f}, σ_{a} and m are undetermined coefficients, and σ_{ac} is theoretical fatigue limit. Usually, the value m is obtained as 2 to 4. In this work, the value m is set as 2. Taking logarithm on both sides of above equation, and the equation can be rewritten as

$$\lg N_{\mathrm{f}} = \lg \sigma_{\mathrm{f}} - 2\lg(\sigma_{\mathrm{a}} - \sigma_{\mathrm{ac}}), \tag{2}$$

Eq. (2) shows a linear relationship between logarithmic fatigue life $\lg N_{\mathrm{f}}$ and $\lg(\sigma_{\mathrm{a}}-\sigma_{\mathrm{ac}})$, and the slope is 2. According to the experimental data obtained from the fatigue life tests, using a standard normal distribution function to calculate the values of fatigue life at survival probabilities as 50%, 90%, 95% at various stress amplitudes, the *P-S-N* equations at survival probabilities as 50%, 90% and 95% are individually achieved by using nonlinear regression method as

$$N_{\mathrm{f}} = 2.987\times10^{10}(\sigma_{\mathrm{a}} - 233.43389)^{-2}, \tag{3}$$

$$N_{\mathrm{f}} = 2.008\times10^{10}(\sigma_{\mathrm{a}} - 229.50659)^{-2}, \tag{4}$$

$$N_{\mathrm{f}} = 1.795\times10^{10}(\sigma_{\mathrm{a}} - 228.36174)^{-2}, \tag{5}$$

It can be seen that the theoretical fatigue limit σ_{ac} in Eq. (1) is calculated as 233.43389MPa, and the experimental one is measured as 288MPa, the relative error is about 18.95%. According to Eq. (3), Eq. (4) and Eq. (5), the *P-S-N* curves at survival probabilities as 50%, 90% and 95% are individually plotted, and are compared with the estimated values of fatigue life, as shown in Fig. 3. It can be found from Fig. 3 that the theoretical *P-S-N* curve is well fitted with the estimated values of fatigue life at survival probability as 50%, while at survival probabilities as 90% and 95%, there are some difference between the theoretical curves and the estimated values.

3.3. Fatigue damage analysis

As aforementioned above, during the process of fatigue life tests, the multi-parameter measurement

mode is applied to measure the electric resistance of GH4133B superalloy samples every certain numerber of loading cycles at various stress amplitudes. According to the definition of damage variable, the damage variable D charaterized by electric resistance can be written as

$$D = 1 - \frac{R_0}{R}, \text{ or } D = \frac{\Delta R}{R_0 + \Delta R}, \tag{6}$$

where, R_0 is the electric resistance before damage, R is the electric resistance after damage, and ΔR is the difference between R and R_0, which is called as electric resistance change. In this work, a modified Chaboche damage model is derived to describe the damage evolution, that is

$$D = 1 - \left(1 - \frac{N}{N_f}\right)^{1/(1+\beta_1(\sigma_a)+\beta)}, \tag{7}$$

Substituting Eq. (6) into Eq. (7), the fatigue damage evolution equation characterized by electric resistance change can be written as

$$\frac{\Delta R}{R_0} = \left(1 - \frac{N}{N_f}\right)^{-1/(1+\beta_1(\sigma_a)+\beta} - 1, \tag{8}$$

where, N is the number of fatigue loading cycles, N_f is the fatigue life, β and β_1 are the fatigue parameters, and the parameter β_1 is the function of the stress amplitude σ_a.

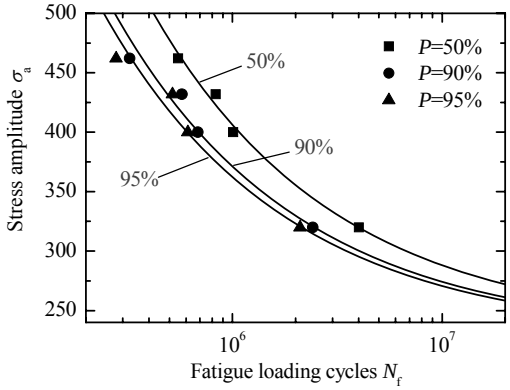

Figure 3. *P-S-N* curves at different survival probabilities

According to Eq. (8), the theoretical damage evolution equations at various stress amplitudes are derived using the nonlinear regression analysis of experiment data obtained in the electric resistance tests. Corresponding to stress amplitudes applied as 320MPa, 400MPa, 432MPa and 462MPa, the values of damage parameter $1+\beta+\beta_1(\sigma_a)$ are determined as 26.543, 31.571, 40.177 and 46.822, respectively. The comparisons between theoretical fatigue damage evolution curves and test data are shown in Fig. 4. Corresponding to the various stress amplitudes, the accumulated fatigue damages of two samples in each group are collected. In Fig. 4, the square symbols denote the test date obtained from the first sample, while the circle symbols denote the test data obtained from the second sample of each group, and the solid lines represent the theoretical results. It can be found from Fig. 4 that the theoretical predicted values are in good agreement with the experimental data, which indicates that the electric resistance change ratio under cyclic loading can be used to describe the process of fatigue damage evolution of GH4133B superalloy.

In the fatigue nucleation and small crack propagation stage (stage I), the fatigue damage is mainly dominated by a process of microdamge nucleation. Furthermore, due to the tension-pressure mode of cyclic loading, the action of compressive stress results in some small crack interfaces colsed, leading to the corresponding electric resistance change smaller, which can be reflected from Fig. 4(a) to (d), that is, the damage increases slowly with number of cycle in the early part of damage evolution curve. With the propagation and coalescence of small cracks, the damage degree becomes

larger, following with increasing electric resistance, and the electric resistance change ratio transits from a relatively flat stage to an acceleration stage, which is called stable fatigue crack propagation stage (stage II). With increasing number of loading cycles, the fatigue propagation moves from a stable stage to an acceleration stage (stage III), and finally leads to fracture failure. In this stage, the damage change rates very large, and the corresponding electric resistance change ratios are also large, as shown in the last parts of fatigue damage evolution curves.

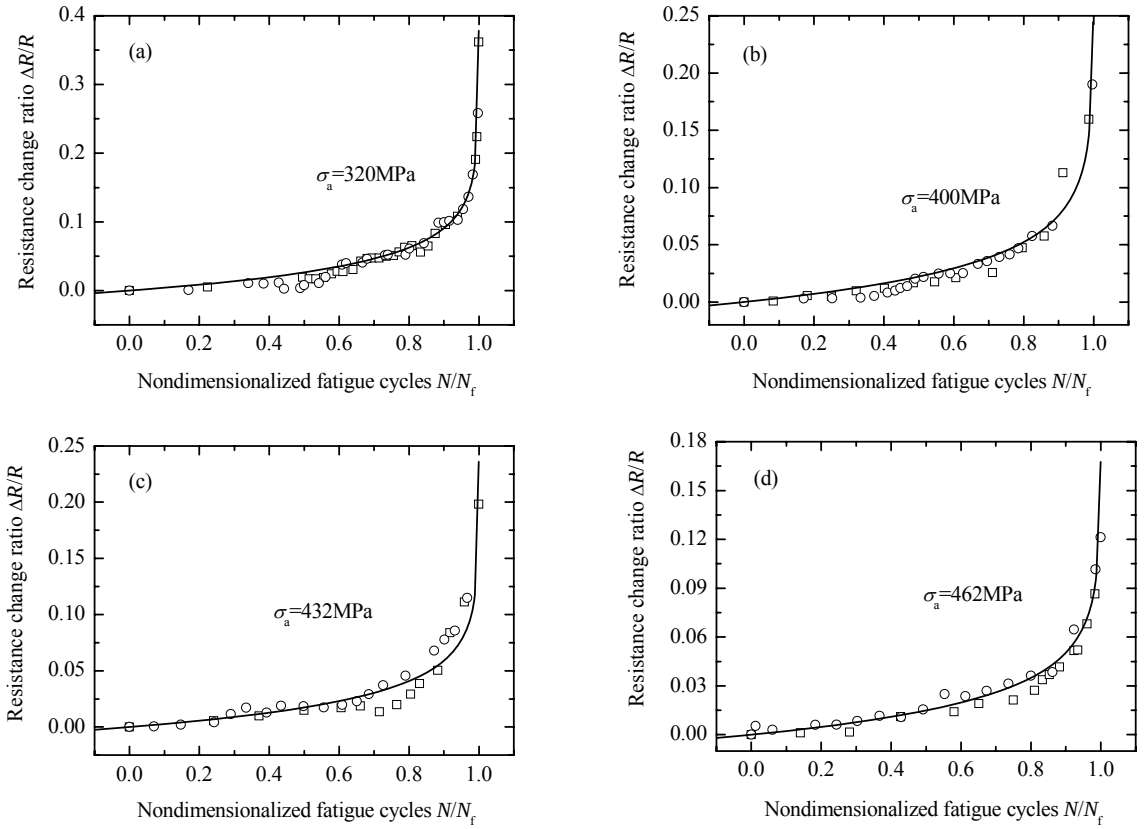

Figure 4. Fatigue damage evolution curves at various stress amplitudes

As aforementioned above, when the stress amplitude σ_a increases from 320MPa to 462MPa, the value of parameter $1+\beta+\beta_1(\sigma_a)$ increases from 26.543 to 46.882. However, the chang rate of electric resistance change ratio is reversed with increasing stress amplitude, which indicates that when the stress amplitude becomes higher, to achieve the same degree of damage as that at lower one, the proportion of consumed fatigue life over the total fatigue life will increase. That is, in the fatigue tests, as the stress amplitude increases, the proportion of fatigue life in the stage II and stage III of crack propagation will decrease, and the total fatigue life is mainly consumed in the stage I of fatigue crack initiation and small crack propagation. Therefore, the change rate of electric resistance change ratio is also relatively slow.

4. Fatigue crack propagation behavior and fractography reverse model

4.1. Fatigue crack propagation tests

The fatigue crack propagation tests for standard compact tension samples of GH4133B superalloy are performed on the CSS-280S-20 test machine. Under cyclic loading conditions (6Hz sine wave, stress ratio R=0.02, 0.1, 0.2, 0.4), the fatigue crack propagation tests are carried out. According to the different values of stress ratio, the tests are categorized as four groups, and two samples prepare

for each group. The approach of specified number of fatigue loading cycles is applied to determine the threshold stress intensity factor range ΔK_{th}, and an EVO scanning electron microscope is applied to investigate the fracture surface morphologies of samples of GH4133B superalloy.

4.2. Fatigue crack propagation behavior

As the stress ratio R=0.02, 0.1, 0.2 and 0.4, the threshold stress intensity factor ranges ΔK_{th} measured in the tests are 11.842MPa·m$^{1/2}$, 11.313MPa·m$^{1/2}$, 9.773MPa·m$^{1/2}$ and 7.440MPa·m$^{1/2}$, respectively. The relationship between the crack propagation rate da/dN and stress intensity factor range ΔK is shown in Fig. 5(a). It can be found from Fig. 5(a) that the crack propagation rate da/dN increases with increasing stress intensity factor range ΔK, and with increasing stress ratio. However, under the condition of low stress intensity factor ranges, the differences among the experimental data of crack propagation rate at different stress ratios are very small, which indicates that the effect of stress ratio on fatigue crack propagation rate are weak at low stress intensity factor ranges.

The Paris formula is applied to carry out a regression analysis for experimental data of fatigue crack propagation at various stress ratios. The Paris formula is written as

$$\frac{\mathrm{d}a}{\mathrm{d}N} = C(\Delta K)^m, \tag{9}$$

where, a is crack length, N is number of fatigue loading cycles, C and m are parameters determined by the crack propagation tests. Taking logarithm both sides of Eq. (9), Eq. (9) can be rewritten as

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = \lg C + m\lg(\Delta K), \tag{10}$$

It can be seen from Eq. (10) that the relationship between crack propagation rate da/dN and stress intensity factor range ΔK shows a linear one in double-logrithmic coordinates, and the slope and intercept are individually m and lg$C$. At stress ratio R=0.02, 0.1, 0.2 and 0.4, the experimental data of fatigue crack propagation are analyzed by Eq. (10) using the least square regression method, and the crack propagation rate equations are individually derived as

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -8.229 + 2.700\times\lg(\Delta K), \tag{11}$$

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -8.403 + 2.858\times\lg(\Delta K), \tag{12}$$

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -8.807 + 3.171\times\lg(\Delta K), \tag{13}$$

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -8.587 + 3.176\times\lg(\Delta K), \tag{14}$$

According to Eq. (11), Eq. (12), Eq. (13) and Eq. (14), the theoretical curves of crack propagation rate versus stress intensity factor range are plotted, as shown the solid lines in Fig. 5(a). It can be found from Fig. 5(a) that the theoretical results are in good agreement with the experimental data, and the value of slope m increases monotonously from 2.700 to 3.176 with increasing stress ratio from 0.02 to 0.4, indicating that the crack propagation rate increases with increasing stress ratio, which is consistent with the aforementioned experiment results. Therefore, the Paris formula can be used to describe the fatigue crack propagation behavior of GH4133B superalloy.

Intending to describe the crack propagation behavior in the fatigue tests of GH4133B superalloy at any stress ratio more precisely, a threshold stress intensity factor range ΔK_{th} is introduced into Eq. (9), and the Paris formula is modified as

$$\frac{\mathrm{d}a}{\mathrm{d}N} = B(\Delta K - \Delta K_{th})^n, \tag{15}$$

where, B and n are material parameters determined by the fatigue crack propagation tests. Taking logarithm both sides of Eq. (15), Eq. (15) can be rewritten as

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = \lg B + n\lg(\Delta K - \Delta K_{\mathrm{th}}), \tag{16}$$

It can be found from Eq. (16) that the relation between logrithmic crack propagation rate lg(da/dN) and lg(ΔK–ΔK_{th}) shows a linear one, and the slope and intercept are individually m and lg$B$. As aforementioned above, in the cases of stress ratio R=0.02, 0.1, 0.2 and 0.4, the threshold stress intensity factor ranges (ΔK_{th}) measured in the tests are 11.842, 11.313, 9.773 and 7.440MPa·m$^{1/2}$, respectively. The linear regression analysis on the experiment data is performed by using Eq. (16), and the crack propagation rate equations considering ΔK_{th} are individually derived as

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -6.858 + 2.055\times\lg(\Delta K - 11.842), \tag{17}$$

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -6.994 + 2.192\times\lg(\Delta K - 11.313), \tag{18}$$

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -7.326 + 2.457\times\lg(\Delta K - 9.773), \tag{19}$$

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -7.376 + 2.571\times\lg(\Delta K - 7.440), \tag{20}$$

Considering the threshold stress intensity factor range ΔK_{th}, and in double-logrithmic coordinates, the theoretical curves of crack propagation rate da/dN versus stress intensity factor rang ΔK are plotted by using Eq. (17), Eq. (18), Eq. (19) and Eq. (20), as shown the solid lines in Fig. 5(b).

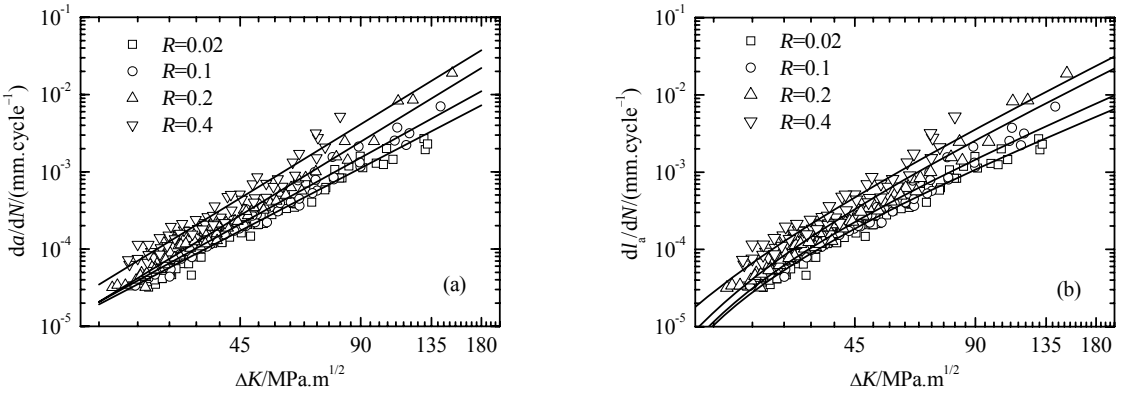

Figure 5. Curves of crack propagation rate: (a) by Paris formula; (b) by modified Paris formula

It can be found from Fig. 5(b) that the theoretical results are well fitted with test data, especially in the case of small values of stress intensity factor range ΔK, comparing with Eq. (11) to Eq. (14), the precise theoretical results are obtained by using Eq. (17) to (20), which can be seen from the comparison between theoretical curve and experimental data in Fig. 5 and Fig. 6. Therefore, the modified Paris formula can not only be used to predict the value of threshold stress intensity factor at different stress ratio, but also can describe the fatigue crack propagation behavior accurately.

4.3. Fractography reverse model

As aforementioned above, the fracture surface morphologies of standard compact tension samples of GH4133B superalloy are investigated using an EVO scanning electron microscope, and a series of fatigue striations are found in the crack steady propagation region. According to these fatigue striations on the fracture surface, the crack propagation rate equations and loads are derived using

the inverse educing method. For mode I crack, the expression of stress intensity factor range ΔK is

$$\Delta K = Y\Delta\sigma\sqrt{\pi a}\,, \tag{21}$$

where, $\Delta\sigma$ is external stress range, a is crack dimension parameter, Y is shape factor which relates to structure shape, crack location and dimension as well as load condition. Substituting Eq. (9) into Eq. (21), the expression of external stress range $\Delta\sigma$ is derived as

$$\Delta\sigma = \frac{1}{Y\sqrt{\pi a}}\left(\frac{1}{C}\cdot\frac{\mathrm{d}a}{\mathrm{d}N}\right)^{1/m}, \tag{22}$$

It can be found from Eq. (22) that if the values of crack propagation rate are measured, then the external stress range acted on the sample can be calculated using the inverse educing method. For standard compact tension sample (Fig. 2), the expression of stress intensity factor range ΔK is

$$\Delta K = \frac{\Delta P}{B\sqrt{W}}F(\alpha),\quad F(\alpha) = \frac{2+\alpha}{(1-\alpha)^{3/2}}\times(0.886+4.46\alpha-13.32\alpha^2+14.72\alpha^3-5.6\alpha^4), \tag{23}$$

where, ΔP is external load range, B is thickness, W is width, and α is the ratio of crack length a to width W. Substituting Eq. (9) into Eq. (22), the expression of external load range ΔP is derived as

$$\Delta P = B\sqrt{W}\left(\frac{1}{C}\cdot\frac{\mathrm{d}a}{\mathrm{d}N}\right)^{1/m}\Big/F(\alpha), \tag{24}$$

For example, in the case of R=0.4, the fracture surface morpologies in the steady propagation region at various stress intensity factors are shown in Fig. 6. Measuring the widths of damage striations on the fracture surface, and recording the corresponding number of loading cycles, thus the crack propagation rates are calculated. Using Eq. (23) and Eq. (24), the stress intensity factor ranges and external loads relating with crack propagation rates are derived.

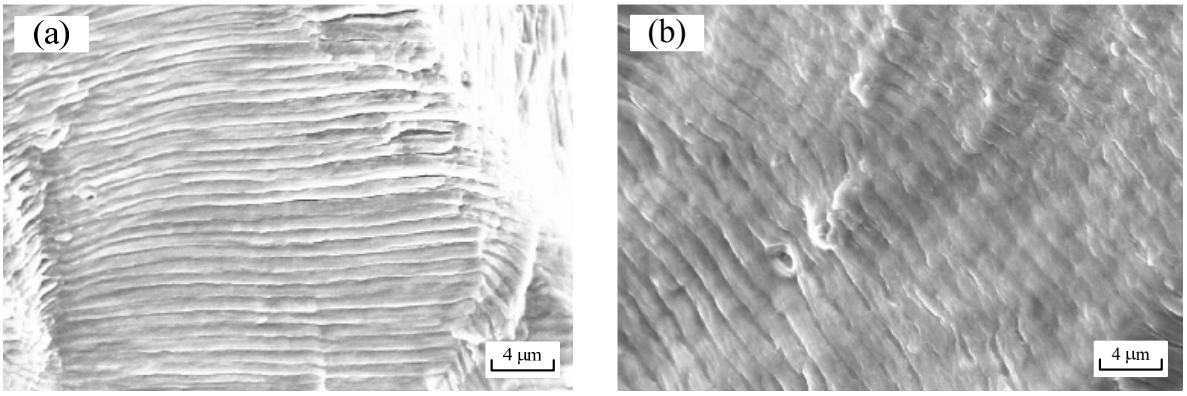

Figure 6. Fracture surface morpology: (a) ΔK=60.69MPa·m$^{1/2}$; (b) ΔK=80.53MPa·m$^{1/2}$

According to Eq. (16), the regression analysis on the calculated data obtained from the fractography is performed, and the inverse deduced equations on fatigue crack propagation are derived. In the cases of stress ratio R=0.02, 0.1, 0.2, 0.4, the inverse deduced equations are individually as

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -7.633+2.619\times\lg(\Delta K-11.842), \tag{25}$$

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -7.544+2.498\times\lg(\Delta K-11.313), \tag{26}$$

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -7.595+2.500\times\lg(\Delta K-9.773), \tag{27}$$

$$\lg\left(\frac{\mathrm{d}a}{\mathrm{d}N}\right) = -8.003+2.647\times\lg(\Delta K-7.440), \tag{28}$$

The comparison between the theoretical curves predicted by inverse deduced equations and analysis data obtain from the fractography is shown in Fig. 7. It can be seen from Fig. 7 that the theoretical curves are well fitted with analysis data, which indicates that the inverse deduced equations can be used to accuratelly describe the crack propagation behavior in the steady propagation region.

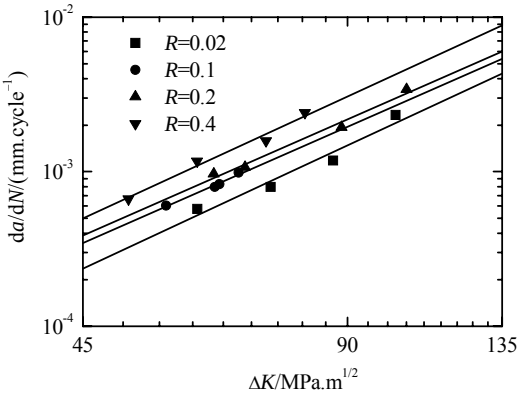

Figure 7. Inverse deduced curves of crack propagation rate

Following, these inverse deduced equations (from Eq. (25) to Eq. (28)) are generalized to describe the whole process of fatigue crack propagation. At various stress ratios, the comparisons between theoretical curves of fatigue crack propagation rate and experimental data are shown in Fig. 8.

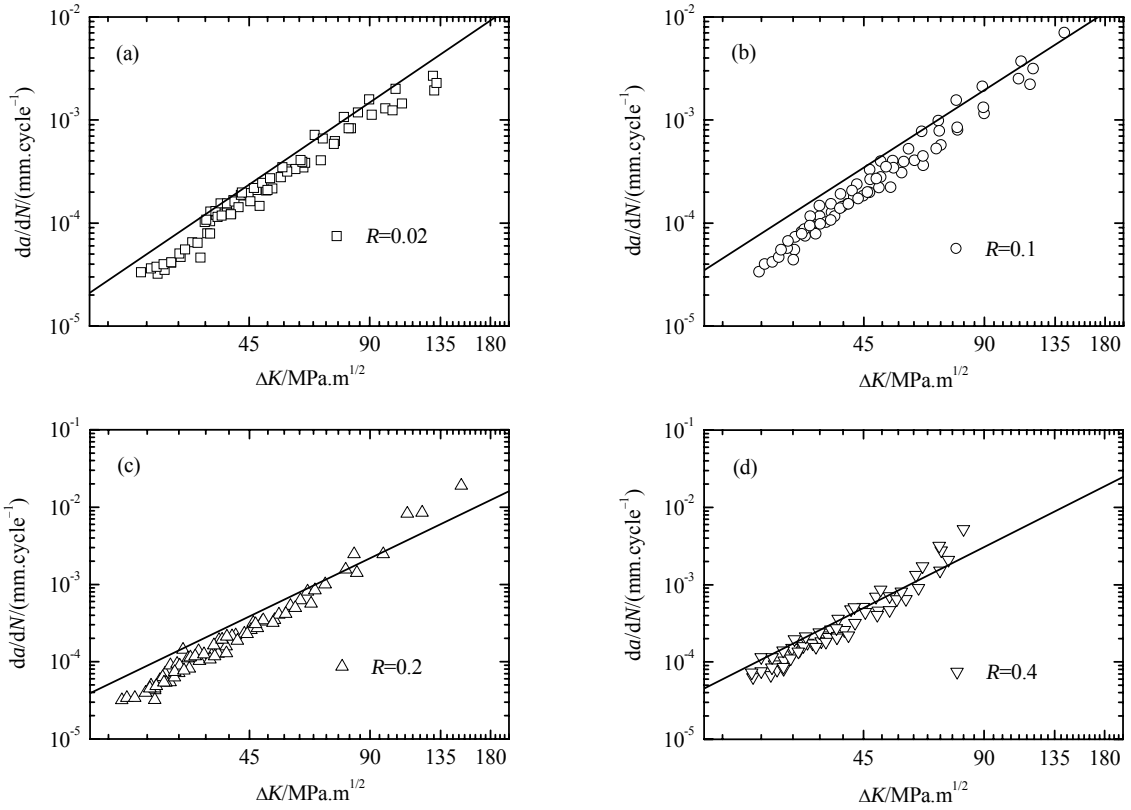

Figure 8. Crack propagation rate curves obtained by inverse deduced equations

It can be seen from Fig. 8 that the theoretical curves are basically consistent with experimental data, indicating that the inverse deduced equations derived from the analysis data obtained by measuring damage striations in steady propagation region of fracture surface, can still be used to predict the whole process of fatigue crack propagation. Furthermore, it can be found that if only the stress

intensity factor range ΔK is not too large, in other words, if only the fatigue crack is not at the later stage of accelerated growth region, the theoretical values are totally larger than that of experimental data, so the predicted results obtained by the inverse deduced equations tend to security.

5. Conclusions

(1) The fatigue life of GH4133B superalloy is measured, and the theoretical fatigue life is calculated, and the *P-S-N* curves at various survival probabilities are obtained. It is found that the theoretical fatigue limit agrees well with experimental one, and the fatigue life of GH4133B superalloy can accurately be estimated by the *P-S-N* curves.
(2) The modified Chaboche model can predict the accumulated damage of GH4133B superalloy preciously. Higher stress amplitude will result in a higher proportion of the fatigue life in stage I of fatigue crack initiation and small crack propagation to the total fatigue life, which is unfavorable to monitor the accumulative fatigue damage and to prevent fatigue fracture in the components.
(3) A modified Paris formula is achieved by introducing a threshold stress intensity factor range. The comparison between theoretical curves and experiment data shows that the modified Paris formula can not only be used to predict the value of threshold stress intensity factor range at different stress ratio, but also can describe the fatigue crack propagation behavior accurately.
(4) Based on the measurement data of fatigue striations and the modified Paris formula, the crack propagation rate equations and external loads are inversely deduced and calculated. It is found that the inverse deduced equations based on the fractography inverse model can predict the fatigue crack propagation behavior, and the predicted results tend to security.

FATIGUE CRACK GROWTH SIMULATION OF SURFACE CRACKS UNDER ARBITRARY CRACK FACE LOADING

Xiaobin Lin

HBM (nCode) United Kingdom Limited, UK
Xiaobin.Lin@hbmncode.com

Abstract Fatigue crack growth was simulated for a surface crack subjected to arbitrary crack face loads. The simulation was based on the step-by-step integration of a proper fatigue crack growth law along the crack front, enabling complex crack shape changes to be directly predicted. The three-dimensional finite element method with the inverse square singularity near the crack tip considered was employed to calculate the stress intensity factors along the crack front, and the contact elements were also introduced into the cracked surface to avoid the possible overlapping between the crack faces. Several typical crack face loads were analysed, and the results including crack shape development, aspect ratio changes and stress intensity factor variations were given to validate the simulation technique. The results showed that the crack shape is dependent on the applied load and non-semielliptical surface crack profiles may be adopted by fatigue cracks. The simulation is particularly useful and necessary for the fatigue crack growth analysis in a residual stress field.

Keywords fatigue crack growth, stress intensity factor, surface crack, crack shape change

1. Introduction

Fatigue crack growth for surface cracks in plates has been extensively investigated both theoretically and experimentally. Surface cracks are very common in many engineering components and structures, such as pressure vessels, pipeline systems, off-shore and aircraft components *et al*. It has been widely observed from experimental investigations [1, 2] that a surface crack under fatigue loading always changes its crack front as it grows, and the shape by the fatigue crack subjected to both tension and bending loads is close to a semi-ellipse if neglecting the possible retardation of crack growth along the free surface.

Some efforts have been made to establish reasonable models to predict the fatigue crack growth of a two-dimensional surface crack, in which an experimental fatigue crack growth relation obtained from small specimen tests is employed. A typical model is that a surface crack is treated to have a semi-elliptical shape, and the change in crack aspect ratio is predicted. Newman and Raju [3] presented a two degree-of-freedom model, in which the change of crack aspect ratio is calculated by coupled integration of a Paris type of fatigue crack growth law along both crack depth and surface directions. In their model, the stress intensity factor (SIF) range at the free surface point was modified by the reducing 10% its value to consider the effect of the surface layer when the retardation of crack growth is often observed, and their own closed-form SIF equations were used.

For cracks subjected to a complex stress gradient, a method similar to those mentioned above is probably suitable if SIF solutions corresponding to such a stress distribution are available. Generally, these solutions are likely to be obtained by using a weight function method, or by superposing the SIF results for a series of polynomial stress distributions. However, this method is obviously incomplete. First, it includes a semi-elliptical shape assumption which is not adequate in some situations to define the actual shape adopted by the crack. Second, crack contact is not taken into account almost in all SIF solutions reported. This may happen if there are compressive stresses acting on the crack face. Using the SIF results obtained without considering crack contact might cause a big error in fatigue crack growth calculations. In this paper, a numerical method developed

by the author [4, 5] has been employed to simulate the fatigue crack growth of surface cracks under several typical and complex crack face loads. The method can directly predict, in a step-by-step way, the crack shape change without having to make a semi-elliptical crack shape assumption, and also take possible crack face contact into account. Various results are given to validate the numerical method for simulating fatigue crack growth with complex crack shape change.

2. Numerical simulation technique

It is usually considered reasonable to apply a fatigue crack growth law from small specimens that have a straight front to a curved crack front along which the stress intensity factor varies. The fatigue crack growth rate can then be expressed as a function of crack front position as follows

$$\frac{\mathrm{d}a(\xi)}{\mathrm{d}N} = f(\Delta K(\xi)) \tag{1}$$

where $a(\xi)$ and $\Delta K(\xi)$ are the local normal crack growth increment and the SIF range at an arbitrary crack front position, ξ, as shown in Fig.1. The crack growth increment can be written as

$$\Delta a(\xi) = \frac{f(\Delta K(\xi))}{f(\Delta K_{\max})} \Delta a_{\max} \tag{2}$$

where $\Delta a_{\max}$ is the maximum increment along the crack front, occurring at the point where the SIF is the largest. Fatigue cycles can then be calculated as follows

$$N_{\mathrm{i+1}} = N_{\mathrm{i}} + \frac{\Delta a_{\max}}{f(\Delta K_{\max})} \quad (\mathrm{i} = 0,1,...) \tag{3}$$

By choosing an appropriate small value of $\Delta a_{\max}$, both the crack shape change and the corresponding number of fatigue cycles can be predicted if the SIF solutions along the crack front are available. For a Paris type fatigue crack growth law, we have

$$\Delta a(\xi) = \left(\frac{\Delta K(\xi)}{\Delta K_{\max}}\right)^m \Delta a_{\max}, \quad N_{\mathrm{i+1}} = N_{\mathrm{i}} + \frac{\Delta a_{\max}}{C(\Delta K_{\max})^m} \quad (\mathrm{i} = 0,1,...) \tag{4}$$

The above equations have been used in the present simulation. However, it is worth indicating that a general fatigue crack growth rate equation including crack threshold and fracture toughness can be readily incorporated.

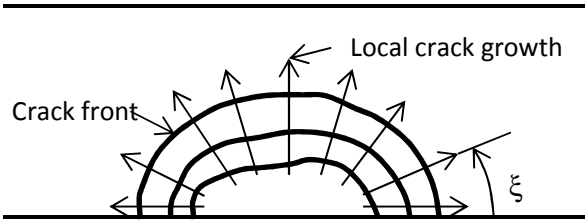

Figure 1. Illustration of fatigue crack growth of a surface crack

Stress intensity factors along the crack front were estimated by using the finite element (FE) method. The 1/4-point displacement method was used to achieve the inverse square-root stress singularity at the corner of a wedge element, and particularly possible contact between crack faces in a compressive stress field was taken into account in FE analyses. The method of estimating the SIF was detailed in [5]. Figure 2 illustrates a typical mesh created in the simulation. The mesh comprises both cracked and un-cracked blocks. Between them the “multiple point constraint” equations are applied to maintain the displacement compatibility. Both cracked and un-cracked blocks are filled with 20-node iso-parametric elements. In particular, three rings of elements are arranged surrounding the crack tip. In the simulation, the cracked block is recreated as the crack

grows whilst the un-cracked block remains unchanged.

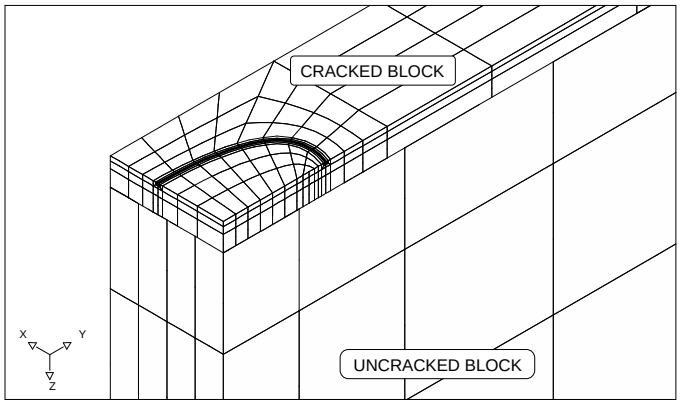

Figure 2. Type mesh configuration for stress intensity factor estimation

Local fatigue crack growth increments were calculated using the equation mentioned above, and a new crack front was established by fitting a cubic spline curve to the positions of the advanced corner nodes. Along the spline curve new corner and midside nodes were then relocated with them distanced properly. This method has been verified to be effective [6]. Automatic re-meshing of the FE model is part of the simulation technique, which makes the step-by-step simulation possible. More details can be found in [4, 6].

3. Analysis examples

Six different stress distributions varying along the plate thickness direction, as shown in Fig. 3, are considered in the present investigation. They are applied to the surface crack face in the plate as the maximum fatigue load. The minimum fatigue load is assumed to be zero.

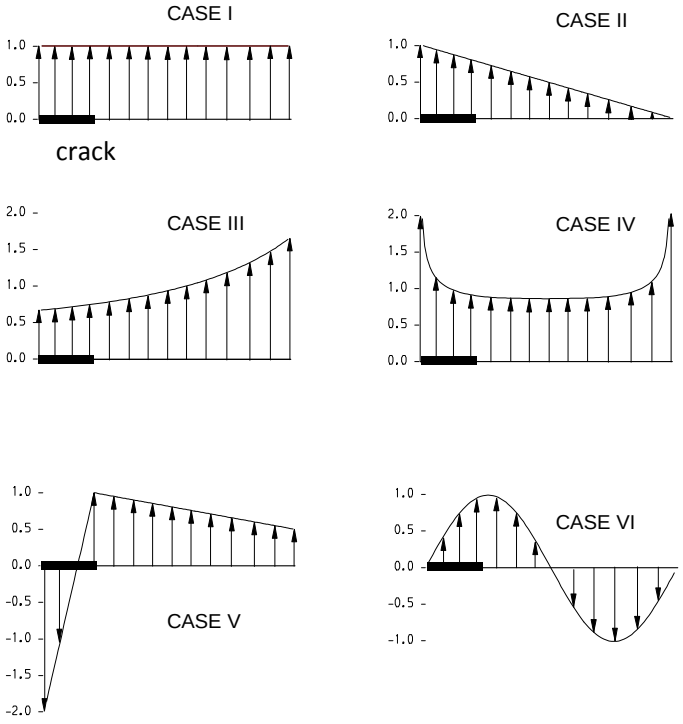

Figure 3. Crack face stresses considered in the investigation

Case I is the extensively studied loading configuration—uniform tension, i.e.

$$s(x)=1 \tag{5}$$

Case II is a combined tension and bending load that decreases linearly from unity to zero,

$$s(x)=-x/t+1 \tag{6}$$

This was selected as a representative of the linear stress variation.

Case III represents a stress variation existing on the wall of a cylindrical vessel subjected to a uniform internal pressure, which can be expressed as

$$s(x)=\frac{pR_{\mathrm{i}}^2}{R_{\mathrm{o}}^2-R_{\mathrm{i}}^2}\left(1+\frac{R_{\mathrm{o}}^2}{(R_{\mathrm{o}}-x)^2}\right) \tag{7}$$

where R_{i} and R_{o} are the inner and outer radii of the vessel, respectively; p is the internal pressure. In the simulation, the ratio of $R_{\mathrm{o}}/R_{\mathrm{i}}$ is chosen to be 2 and p to be 1 MPa. The location where x=0 corresponds to the external wall of the vessel, thus the modelled crack is similar to an external surface crack in a cylinder.

Case IV is a typical stress distribution existing in cruciform fillet welded joints [7], as shown in Fig. 5. Verreman *et al.* [7] proposed the following equations to describe the stress variation occurring at the weld toe

$$s(x)=\left(\frac{x}{t}\right)^{-\alpha}\sum_{i=0}^{4}\lambda_i\left(\frac{x}{t}\right)^i \quad 0\le x/t\le 0.5 \tag{8}$$

$$s(x)=\left(\frac{t-x}{t}\right)^{-\alpha}\sum_{i=0}^{4}\lambda_i\left(\frac{t-x}{t}\right)^i \quad 0.5\le x/t\le 1 \tag{9}$$

The above equations were obtained by fitting them to the two dimensional elastic element results. For the particular cruciform fillet joint shown in Fig. 4, the following parameters have been used: α=0, λ_0=0.414, λ_1=0.815, λ_2=-1.71, λ_3=4.16, λ_4=-3.7. High stress concentration can be found at the weld toe, which is the reason why the crack initiation is often induced there. This crack problem has been received a great deal of attention due to its importance in engineering practice.

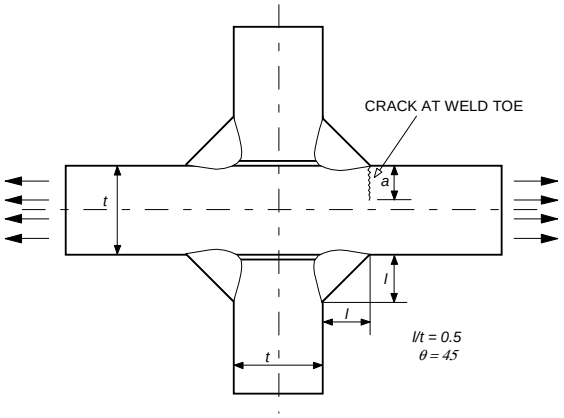

Figure 4. Cruciform fillet welded joint

Case V is used by the author to demonstrate the ability of the numerical technique to simulate the fatigue crack growth in a complex stress field containing compression. It is well known that compressive stresses are often generated on purpose to resist fatigue cracking as well as its subsequent growth. The shot peening is usually considered beneficial to delaying or even avoiding

the crack initiation from the free surface. The stress form devised here, to a certain extent, is similar to the residual stress generated by such a shot peening process. This hypothetical stress is expressed by the following equations

$$s(x)=\frac{15}{t}x-2 \qquad 0\le x\le t/5 \tag{10}$$

$$s(x)=\frac{5}{8t}x+\frac{9}{8} \qquad t/5\le x\le t \tag{11}$$

Case VI is also a hypothetical load case intended to demonstrate the capability of the numerical technique. The following is its stress distribution

$$s(x)=\sin\left(\frac{2\pi}{t}\right)x \tag{12}$$

The initial crack configuration was assumed to be a semi-circle (a/c=1) with depth ratio a/t=0.2. a, c and t are crack depth, crack surface half length, and plate thickness, respectively. The material properties employed in this investigation are: Poisson's ratio ν=0.3, Paris' fatigue crack growth relation $\mathrm{d}a/\mathrm{d}N=1.83\times10^{-13}(\Delta K)^3$

4. Results and discussion

4.1. Crack Shape Development

Figure 5 shows the fatigue crack shape development of the initially semi-circular surface crack in a plate subjected to different crack face loads. It is clear that the shape change is dependent on the load applied. The crack under uniform tension (Case I) grows with a similar growth increment along the crack front. The free surface has a slight effect on crack growth, which makes the crack advance relatively rapidly along the surface. It can be seen that the semi-elliptical shape is adequate to define the front of the propagating cracks in Fig. 5 (Case I). Crack shape change of different initial cracks for this load case has been investigated by the author [8]. It has been numerically confirmed that the widely used semi-ellipse is an adequate crack shape approximation.

The crack in Case II that has a decreasing stress value along the plate thickness propagates more rapidly in the direction of the free surface than in the direction of the plate thickness, gradually leading to a flatter crack profile. The semi-ellipse is also quite acceptable for the shape in this case, as indicated by the author [8] according to a numerical study of crack shape.

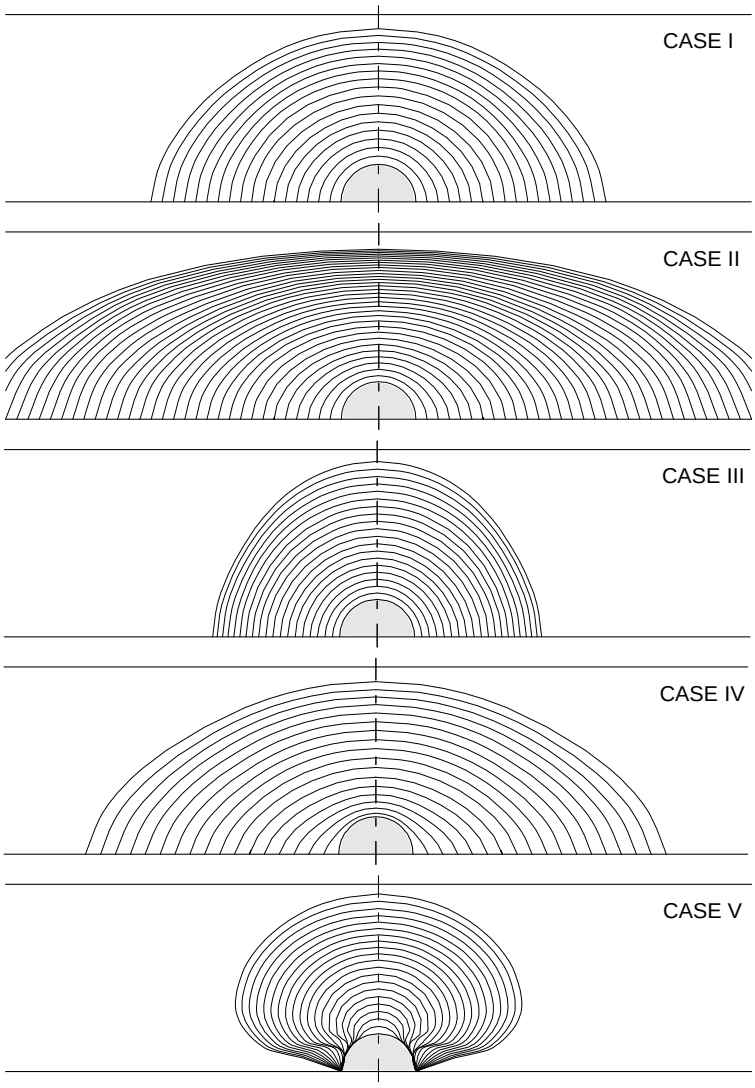
Contrary to Case II, the Case III crack extends faster at the depth than the free surface. This is due to the larger stress in the direction of crack depth. It seems that these crack profiles predicted can still be approximated with high accuracy by the semi-elliptical shape.

The stress concentration at the free surface in the Case IV load permits the crack to grow more easily along the surface compared to the crack under uniform tension fatigue (Case I). It is particularly obvious at the early stage of crack growth. The numerical crack profiles in Fig. 5 (Case IV) are basically in agreement with the experimental results obtained by Pang *et al.* [9, 10] using the beach-mark method. The growing cracks were also treated by them as those of semi-elliptical form during the crack growth calculation.

The crack face load of Case V produces an interesting result of crack shape development. The

initially semi-circular crack gradually evolves into a mushroom-shaped crack. The crack mouth is kept close and the crack, initially, is only given an opportunity of extending in a small region near the crack depth. As the cracked area becomes large, the portion of the crack front in a state of closure gradually shrinks. This is because of the increasing positive resultant stress. The maximum crack dimension can be seen to occur nearly at the *t*/4 position from the front surface, which is in accordance with the loading configuration that has the maximum tensile stress at the *t*/4 position. This phenomenon should be considered to be reasonable although no direct experimental result can be compared. The predicted crack fronts are obviously far from the semi-elliptical shape, and thus the widely used semi-elliptical crack shape assumption is not adequate for such load case. The crack shape evolution in Fig. 5 (Case V) also demonstrates that surface cracks can be effectively delayed by creating a compressive stress field near the plate surface, such as using the shot peening method.

The crack shape change illustrated in Fig. 5 for Case VI also shows that the semi-elliptical shape is not proper to be approximated to the crack fronts in this case. The lagging of crack growth along the surface can be observed, which is due to the zero stress value at the surface. The crack develops mainly in the depth direction at the early stage but the crack growth in this direction is slowed down and even stopped finally by the descending stress level as the crack extends further, see Fig. 3. The maximum crack growth is subsequently transferred to the crack front position, where the highest stress happens, i.e. at the *t*/4 position from the front surface.



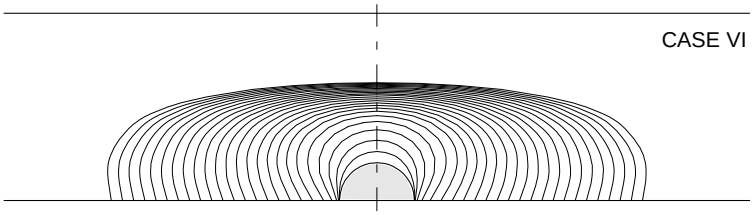


Figure 5. Fatigue shape development starting from an initially semi-circular surface crack under different crack face loads.

4.2. Aspect Ratio Change

The crack shape change is usually described quantitatively by the aspect ratio (*a*/*c*) variation with the crack depth ratio (*a*/*t*), but it should be aware that it is incomplete. The aspect ratio changes are shown in Fig. 6 for all six load cases. Clearly, the aspect ratio relation is strongly dependent on the load, as mentioned previously. The load with decreasing stress along the plate thickness makes the crack advance more difficult in this direction and eventually leads to a smaller *a*/*c* value, as seen for Cases II and IV; whilst the increasing stress along the plate thickness causes more rapid crack growth in this direction than along the surface. This can be seen in Case III. The *a*/*c* value of the Case V crack increases linearly with the *a*/*t* ratio, quickly exceeding the maximum value set in the figure. This is because no crack extension occurs along the plate surface due to the large compressive stress acting in the surface layer of the plate. However, for Case VI, the *a*/*c* value re-drops rapidly after its initial rise similar to the Case V crack, which is caused by the stress distribution with a decreasing value when the crack depth is in the region of *t*/4 and 3*t*/4. Obviously, the aspect ratio cannot give a proper description for the cracks that are not of semi-elliptical shape, like the Cases V and VI cracks.

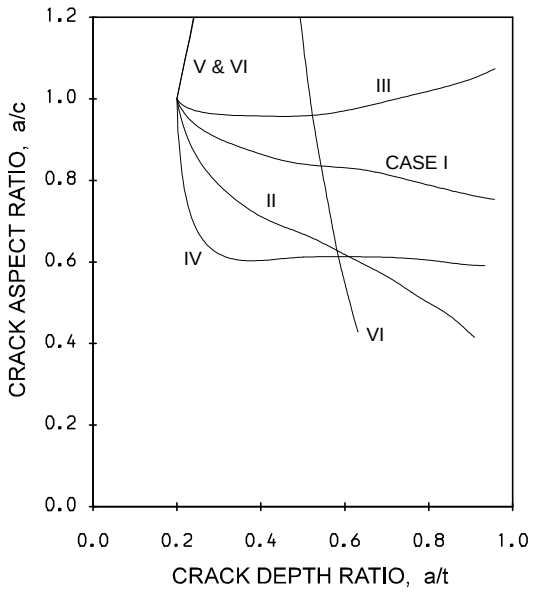

Figure 6. Aspect ratio change for surface crack under different crack face loading

Lin and Smith [8] compared the numerical results of aspect ratio predicted by the simulation technique with the experimental results for the pure tension case, i.e. Case I, and found that both the numerical and experimental results are in good agreement. This indicated that the simulation technique is effective. The numerical aspect ratio result of Case VI can be found to agree well with the experimental results of [9, 10], who carried out the fatigue test of welded joint containing a

surface crack similar to that analysed in this work for both the initial crack and joint geometries, if their result is included in Fig. 6. This further validates the present numerical technique.

4.3. Stress Intensity Factor Variation

Figure 7 shows the SIF distributions along the front of the initially circular crack (a/t=0.2) estimated by the 3D finite element method for all six load cases, where the SIF is normalised by $K_0 = \sqrt{\pi a}$. Obviously, the results vary with the applied load. The distributions along the crack front are basically uniform for Cases I, II and III, but not for Cases IV, V and VI. The SIF for Case IV shows a rapid rise at the plate surface, but that for Case VI drops when the crack front approaches the plate surface. The Case V crack gives a result that the SIF value is zero along the half crack front close to the surface, which means that the crack is in a state of partial closure under the load (Case V). It needs to be indicated that contact elements have been employed for this case. By looking at the crack face load in Fig. 3 for this case, these results are obviously reasonable.

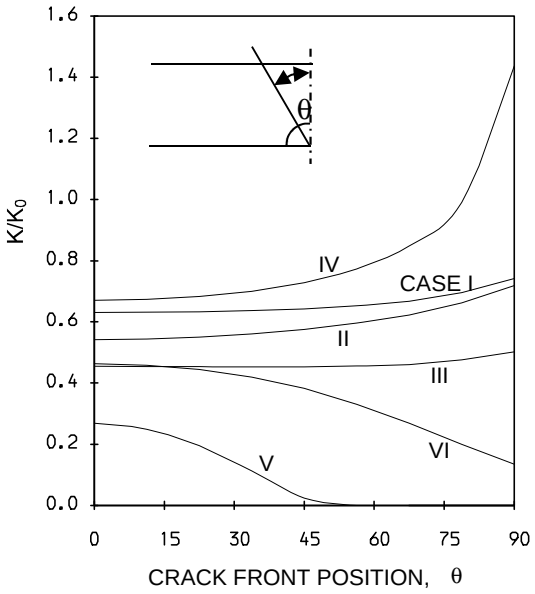

Figure 7. Stress intensity factor distributions along the initially circular crack front

The degree of the SIF non-uniformity along a crack front with crack growth is more clearly represented for all six loads in Fig. 8, where the ratio of $K_{\min}/K_{\max}$ is plotted against the crack depth ratio, a/t. It can be found that the equal K profile (the SIF value is identical around the crack front), generally, cannot be reached for non-uniform loads. Dependent on the load acting on the crack faces, complex variations exist. For Case V, rapid rise and subsequent drop in the $K_{\min}/K_{\max}$ ratio are due to the sine load, whilst for Case VI the zero variation is caused by the existence of partial closure along the crack front.

Figure 9 shows the SIF variations for all load cases at both the depth (θ=0°) and surface (θ=90°) points, where SIF has been normalized by $K_0 = \sqrt{\pi a}$. The SIF value at the depth generally increases with the crack advance except Case VI. The SIF decrease for Case VI is due to the rapid drop in stress after the crack propagates to the region of a/t<1/4. The SIF along the surface also tends to increase during crack growth, but that for Case V retains to be zero.

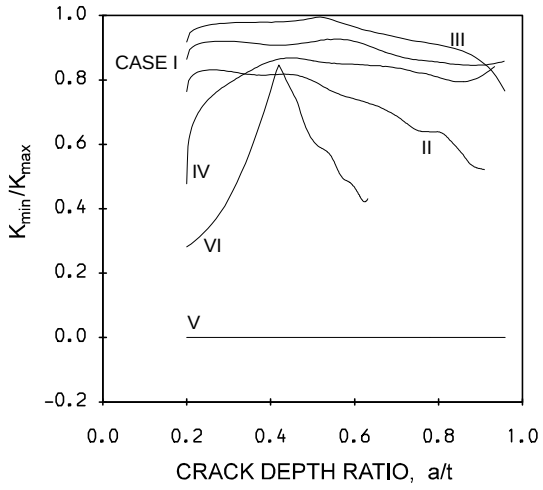

Figure 8. Change of $K_{\min}/K_{\max}$ along the crack front during crack development

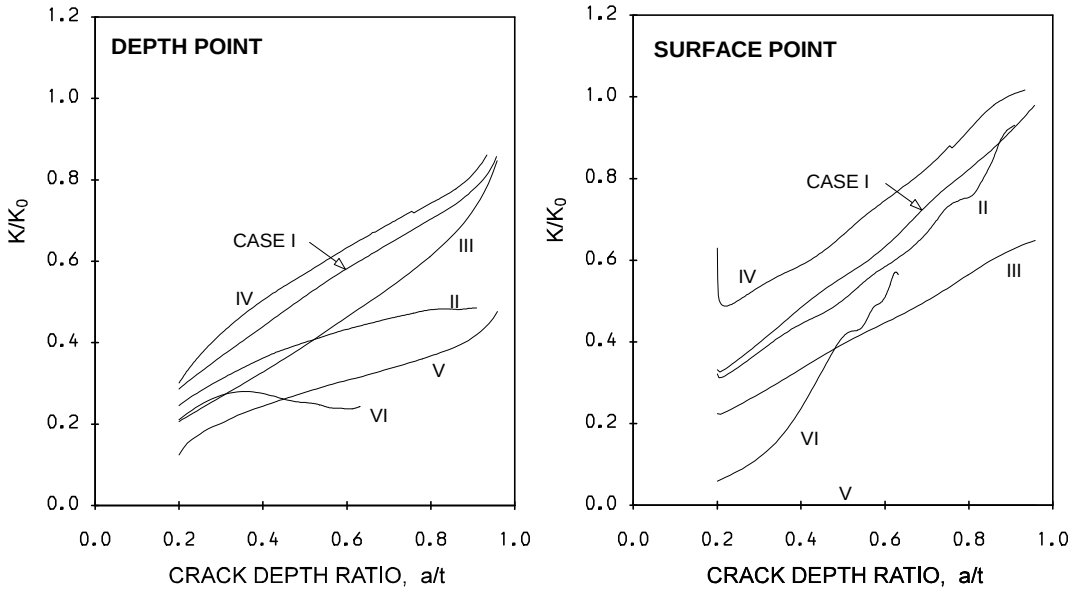

Figure 9. Stress intensity factor variations along both depth and surface points during crack growth

5. Concluding remarks

The effect of different crack face loads on fatigue crack growth of a surface crack in a plate has been investigated by using a multiple degree-of-freedom numerical method, which is based on a series of 3D FE analyses with including contact elements in cracked area and is able to directly obtain the crack shape development in a complex crack face stress field. It has been concluded that complex crack shape evolution in fatigue crack growth can be successfully predicted by the multiple degree-of-freedom numerical method. The crack profiles adopted by cracks are strongly dependent on the applied load. They might significantly deviate from the widely assumed semi-elliptical shape, although in many cases they can be approximated to such a shape. It has been also found that crack surface contact can be simulated by the contact elements introduced in the SIF calculations, so that negative SIF results can be correctly avoided.

Abstract
In the actual work, the fatigue induced damage evolution in brazed steel joints - in particular under the influence of artificial brazing defects - was investigated using digital image correlation (DIC). The brazed joints consist of the soft martensitic stainless steel AISI CA 6-NM as substrate material and Au 18wt.-% Ni as a filler metal. Brazing was performed in a shielding gas furnace with an H_2 atmosphere. Besides the lifetime-oriented investigations, the cyclic deformation behavior was investigated using DIC. The measurements show that it is possible to monitor localized accumulating fatigue damage in an early state of the experiment. Besides the determination of the local strains, the deformation zones in the vicinity of strain concentrations could be characterized in detail. A high frequency camera allowed characterizing the damage evolution in the brazing zone during cyclic loading and investigating crack initiation and crack propagation during cyclic loading. The results are in correlation with SEM investigations and allow a more profound understanding of the failure mechanisms of brazed steel joints.

Keywords brazing, fatigue, defect, fracture, DIC

Nomenclature

Roman Symbols

a	[mm]	Defect size
A	[%]	Elongation at fracture
BSE	[--]	Back scattered electrons
d	[mm]	Thickness of the braze layer
DIC	[--]	Digital image correlation
E	[MPa]	Young's Modulus
N_f	[--]	Number of cycles to fracture
Nmax	[--]	Maximum number of cycles
R	[--]	Load ratio
SEM	[--]	Scanning electron microscopy

Greek Symbols

σ_{UTS}	[MPa]	Ultimate tensile strength
σ_{max}	[MPa]	Maximum applied load for cyclic testing on the defect-free assumed cross section
σ_y	[MPa]	Yield strength

1. Introduction

Brazing has gained increasing importance as a favorable joining technology for many seminal applications in industry in the last years. Generally, brazing plays an essential role because the thermal stress of the joining partners and the processing times can be reduced, compared to e.g. welding. Furthermore, brazing allows joining of dissimilar materials as e.g. metals and ceramics at narrow tolerances. With the use of advanced brazing technologies, as e.g. high temperature (HT) vacuum furnace brazing, brazed joints can also be used for thermally and mechanically heavily loaded components in chemical engineering, power generation and for the production of power electronic components [1-3].

By definition, brazing is performed by heating an assembly over the melting point of the filler metal placed between two substrates without reaching the melting point of the substrate material. The liquid filler metal wets the surfaces of the substrate material and fills the joint gap. Subsequent adhesion and diffusion processes during the cooling of the assembly are essential for the final joint strength. The general differentiation between soldering and brazing is made according to the process temperatures used for the joining process. The above described process at $T < 450$ °C is referred to as soldering, whereas it is named brazing at $T > 450$ °C.

Generally, brazed joints form heterogeneous systems, consisting of base material, filler metal and diffusion zone. Under mechanical loading, the properties of brazed joints vary significantly from those of the individual joining partners. The complex deformation behavior of the brazed joint is characterized by geometrical and microstructural interactions as e.g. by different elastic-plastic properties of substrate material and thin braze layer. Uniaxial loading and the constrained deformation of the thin filler alloy layer can lead to a triaxial stress state which strongly influences the joint performance [4]. To estimate the influence of defects on bulk materials and on welded structures under quasi-static loadings, defect assessment procedures, such as R6, BS7910 or SINTAP have been developed [5 - 8]. In the scope of previous investigations [9], it has been shown that the R6-procedure can also be used to estimate the influence of defects on brazed joints. In previous studies, a rather unusual fatigue crack growth behavior of brazed steel joints, i.e. extremely steep da/dN-ΔK curves in comparison with the ones of bulk materials, was observed [4]. It could be shown that under defined boundary conditions, the influence of defects on the fatigue lifetime can be estimated based on the stress intensity factor caused by the defect [10], but up to date information on the general influence of brazing defects on the fatigue behavior of brazed joints is lacking. Therefore, a better understanding of fatigue crack initiation and propagation is very important for reliable life-time predictions of brazed joints.

Generally, during stress-controlled fatigue tests with metallic materials, fatigue is closely related to the evolution of (local) irreversible strains. In homogenous materials, the strains are relatively equally distributed over a macroscopic length scale and can therefore be averaged using integrating measurement techniques, e.g. with extensometers. However, plastic strains in brazed joints are usually localized in a small volume in or next to the brazing zone. The thickness of braze layers is usually in the range of 50-100 µm, so conventional strain measuring techniques cannot be applied reasonably. To measure local strains during cyclic loading with a sufficiently high resolution, digital image correlations (DIC) were performed. The technique was applied to monitor the fatigue induced damage evolution in brazed steel joints during cyclic loading, in particular under the influence of brazing defects. Furthermore, the fracture surfaces were analyzed by SEM to correlate the experimental results with characteristic deformation features and to obtain information on the underlying failure mechanisms.

2. Testing materials and experimental setup

The brazed joints used for the actual investigations consisted of the steel AISI CA 6-NM (X 3 CrNiMo 13-4) as substrate material and of the gold-nickel alloy Au-18wt.-% Ni as filler metal. The substrate material contains 0.05 wt.-% carbon, 13wt.-% chromium, 4 wt.-% nickel and small amounts of molybdenum. Brazing was performed using foils of the filler metal with a thickness of d = 100 µm. Besides its comparably low melting point of 955°C, the filler metal is characterized by good corrosion resistance and excellent wetting behavior. The brazing process was performed at T ≈ 1000°C in reducing atmosphere with H_2 as a shielding gas. After brazing, a two-step heat treatment procedure was performed at $T_1 \approx 700$°C and $T_2 \approx 650$°C with N_2 was as a shielding gas to optimize the mechanical properties of the brazed joints and to improve the materials resistance against stress corrosion cracking. The mechanical properties of the substrate material, filler metal and brazed joints taken from round specimens are shown in Table 1. The mechanical properties of the filler metal were measured in the scope of in situ SEM investigations [9].

Table 1: Mechanical properties of base material, filler metal and brazed joint

	E [GPa]	σ_y [MPa]	σ_{UTS} [MPa]	A [%]	HV0.05
AISI CA 6-NM	203	726	844	20.0	327
Au-18wt.-%Ni	110	555	940	6.5	271
Brazed, round	200	721	841	10.3	--

Further tensile tests were performed with T-joint specimens. Due to their specimen geometry, conventional strain measurements with an extensometer were not applicable. The experiments show that the σ_{UTS} of brazed T-joints without defects averages 835 MPa.

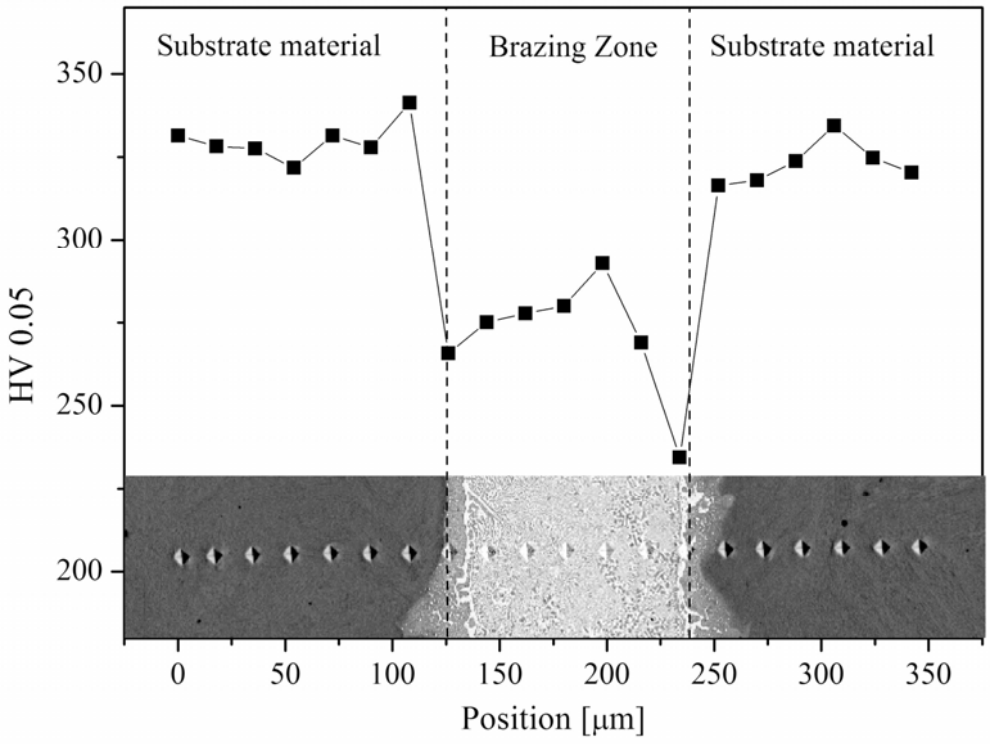

Figure 1: Microstructure and hardness measurements of a brazed joint

As shown in the BSE-micrograph in Figure 1, the joint consists of base material, filler metal and diffusion zone.

In the brazing zone, the filler metal consists of a gold-rich phase and an iron-nickel-rich phase whereas in the region between substrate material and braze layer, the penetration of gold into the substrate material was observed, as is also reported in the literature [11]. Adjacent to the diffusion zone, a layer of the precipitate-free gold-rich phase is formed, that provides the lowest hardness values of 235 HV 0.05.
For the actual experiments T-joints with and without artificial brazing defects were investigated. T-joints are characterized by a sudden change of the cross section area at the brazing zone, as shown in Figure 2. They were designed with respect to the original geometry of a turbo compressor impeller.

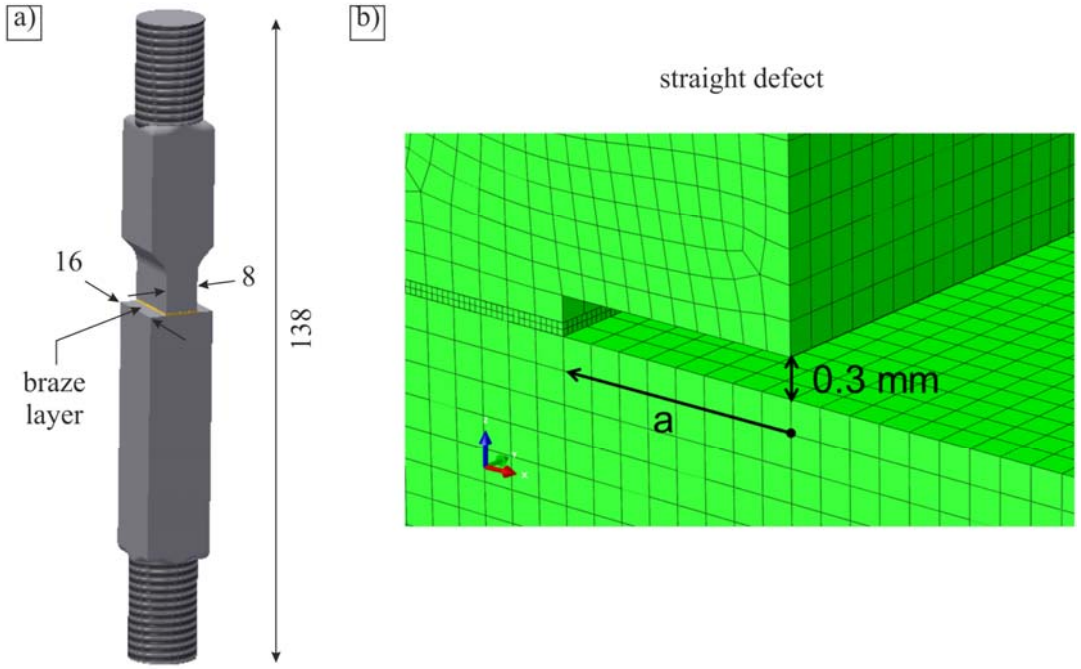

Figure 2: a) Geometry of the T-joint specimen and b) defects introduced into the braze layer

To simulate typical brazing defects like partly unfilled brazing gaps or large pores, straight defects with sizes of a = 0.5 mm, a = 1 mm and a = 2 mm (cf. Fig. 2b) were introduced into the braze layer by electrical discharge machining.
The stress-controlled cyclic loading experiments were performed on a servo-hydraulic testing machine at a frequency of 5 Hz. To simulate the influence of start/stop cycles, the experiments were performed at a load ratio of R = 0.1 until $N_{max}=2\cdot10^4$ cycles. Besides the lifetime oriented investigation of the fatigue behavior, event-oriented experiments were performed with DIC.
The DIC analysis was performed with a black speckle pattern on a white coating on the side surfaces of the T-specimens. To guarantee a sufficient resolution of the object displacements, the pattern was prepared with an average speckle size of 35 µm. The spray painting system used was an airbrush device with a nozzle diameter of 0.2 mm and gravity feed. The image acquisition was performed with a high speed camera (Redlake MotionExtra HG100K) that was focused on the brazing zone. Series of pictures were taken at a recording speed of 500 fps and an aperture time of 500 µs. The DIC was performed with the software Moiree Analysis V0.950© by correlating images of the maximum and the minimum force at defined loading cycles. The use of a high frequency camera allows investigating the development of strains during cyclic loading. Especially for brazed specimen, as a typical representative for heterogeneous systems, this technique allows to study the crack initiation, the crack propagation and the influence of stress concentrations as e.g. defects

locally with an adequate lateral and temporal resolution.
After the experiments, SEM investigations were performed to analyze the fracture surface and to correlate the results with DIC. To distinguish between volumes with different chemical compositions, a BSE detector was chosen for the investigations. Therefore, volumes containing heavy elements as gold are shown in bright contrast whereas comparably light elements are shown in dark contrast.

3. Results

Figure 1 shows the maximum applied loading amplitude of the defect-free assumed cross section as a function of the numbers of cycles to failure.

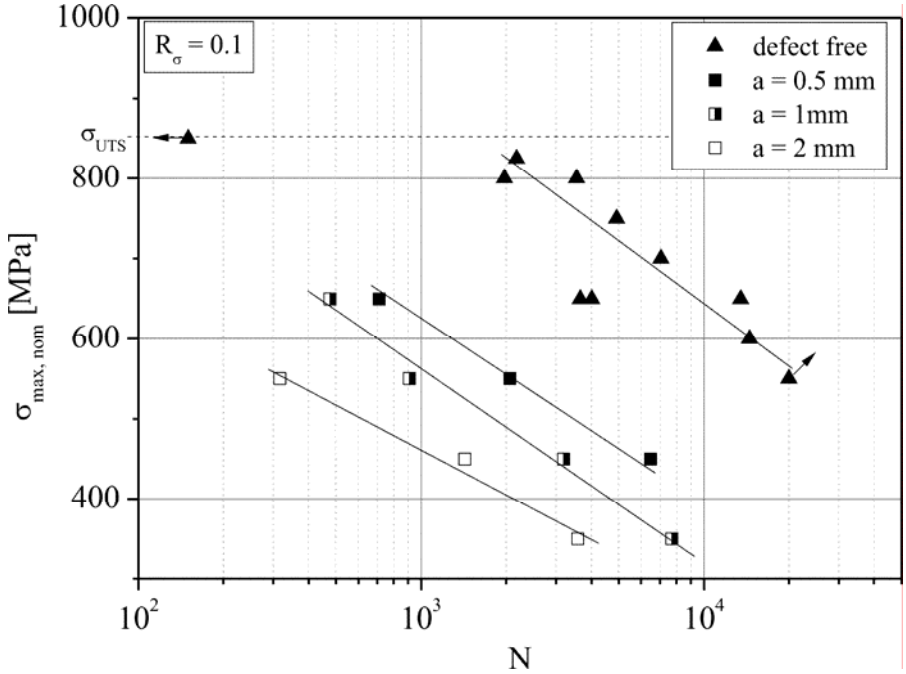

Figure 3: S,N curve of defect-free and defect containing T-joint specimens

The results of the experiments show that defects significantly influence the joint strength. As could be expected, defects lead to a decrease of the joint strength. The larger the defect, the more pronounced the decrease of the fatigue strength. Defect-free specimens can be loaded even up to the ultimate tensile strength of the substrate material for 50 loading cycles, as shown in Figure 3. This can be explained by the ductile deformation and hardening behavior of the substrate material. Loadings around the yield strength of the material lead to failure of the defect-free specimens at approx. 10^4 loading cycles. S,N-curves can be used to describe the influence of one defined defect, but they are not suitable to describe the influence of defects varying in form, shape and position reasonably. In a previous study, a fracture mechanical approach to estimate the influence of brazing defects on a universal scale is based on the stress intensity caused by a defect was successfully applied to make life-time predictions for joints of a less ductile steel [10]. However, this approach did not lead to reasonable results for the material used in this work.

The local strain evolution was characterized experimentally by DIC. Figure 6 shows a defect-free specimen at several stages during cyclic loading at $\sigma_{max} = 650$ MPa until $N_f = 13518$ cycles. The strain distribution in the first and in the loading cycle before failure occurred is shown in Figure 4 together with the speckle in the background.

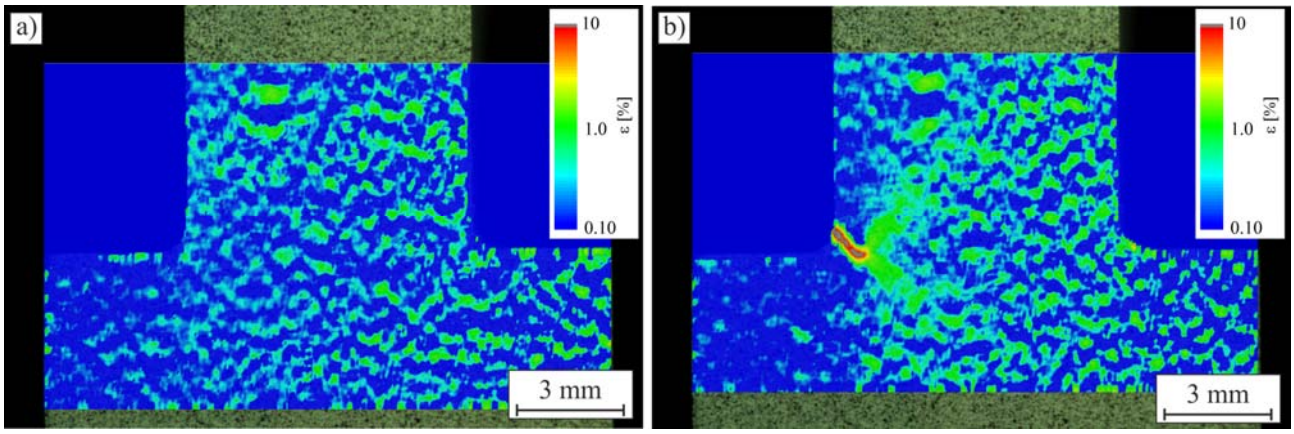

Figure 4: DIC with a defect free specimen

During the first loading cycles, the strains are equally distributed over the whole cross section (Figure 4 a). During further cycling, the fatigue damage accumulation leads to increased local strains and subsequent crack initiation and propagation. Figure 4b shows the deformations in the last cycle before fracture. Furthermore, Figure 4b shows that the crack initiates in the fillet, not directly in the braze layer, as could be expected. Then, it grows at an angle of approximately 45° to the loading direction until it changes its direction and propagates in the vicinity of the brazing zone, perpendicular to the loading direction.

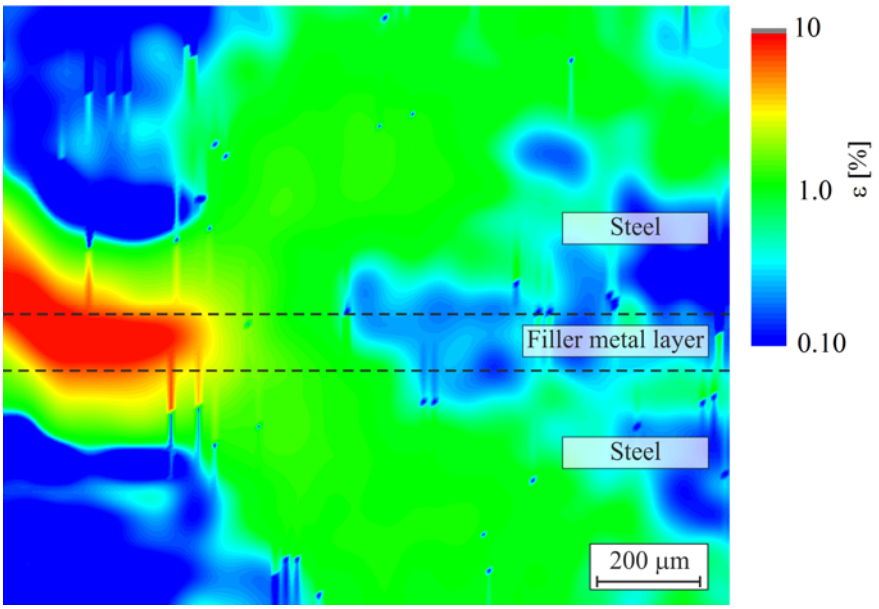

Figure 5: DIC – Strain field in the vicinity of the fatigue crack

Figure 5 shows a close-up image correlation of the crack tip region, the approximate position of the filler metal layer is indicated by dashed lines. Whereas the highest strains are found at the position of the crack due to the crack opening, the volume ahead of the crack tip exhibits also increased strains. With increasing distance these high strains are located in wing-shaped strain fields in the parent material. The filler metal is only subjected to a strain level comparable to the wing-shaped strain fields in a region of 300 µm ahead of the crack tip, whereas in further distance the enhanced stress levels are only observed in the parent material. Some of the data points shown in blue represent regions where no correspondence was found. The strain interpolation with the neighboring values leads to the vertical stripes in Figure 5.

A further experiment was performed with a defect containing specimen with a = 1 mm that was subjected to σ_{max} = 350 MPa. Failure occurred after N_f = 7711 loading cycles.

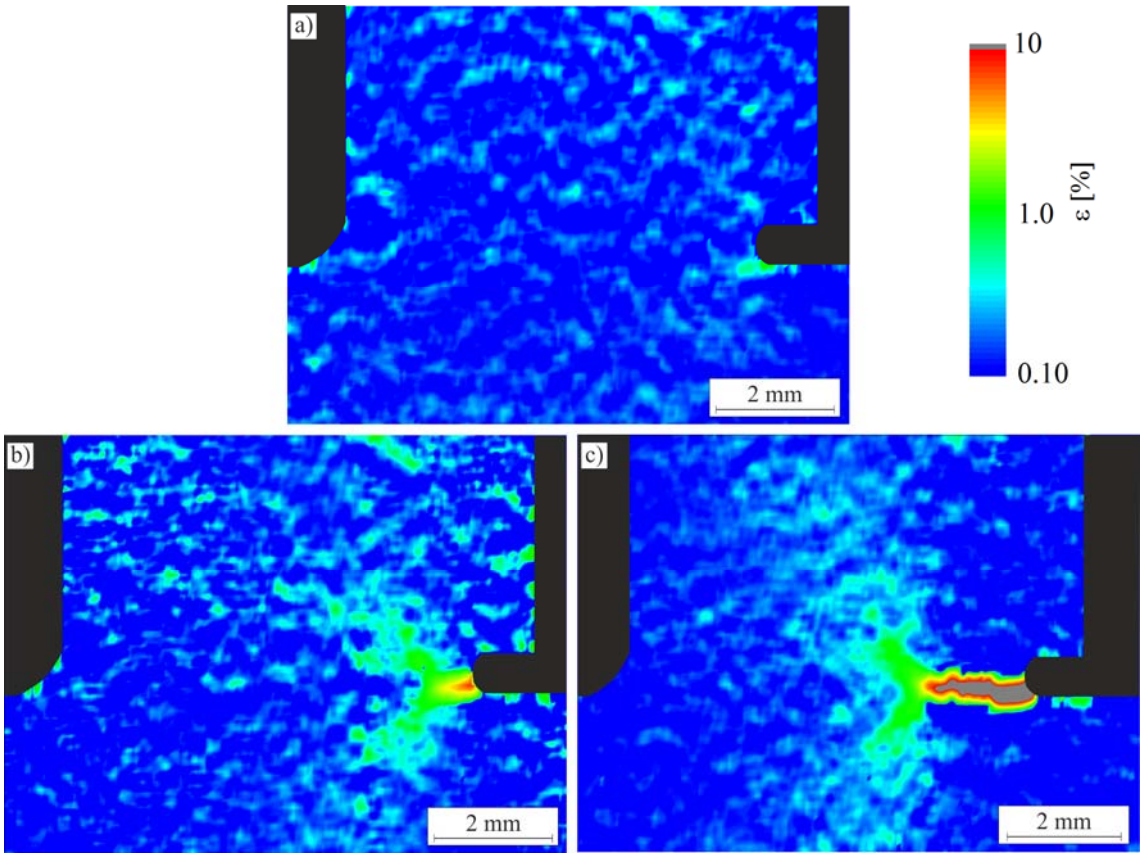

Figure 6: DIC of a defect containing specimen at a) N = 100 b) N = 0.8·N_f and b) N = N_f – 20

The results of the DIC show the inhomogeneous distribution of local strains due to increased stresses at the tip of the defect already in an early state of the experiment. After 100 loading cycles, a slight increase of the strains can be measured at the tip of the defect (Figure 6a) At N ≈ 6200 loading cycles (≈ 0.8·N_f), severe deformations indicate increasing strains as a result of accumulated fatigue damage at the approximate position of the braze layer at the tip of the defect (Figure 6b). Further cycling leads to crack initiation and crack growth. Figure 6c shows the local deformations 20 loading cycles before failure occurred. Due to the lacking possibility of differentiating between crack opening and a black speckle, the results in the direct proximity of the crack should be considered only qualitatively. Especially the volume ahead of the crack exhibits high strains that are distributed over a relatively large volume compared to the layer thickness of d = 100 µm. The wing shaped strain field that expands over 1 mm in front of the crack tip corresponds also to the strain field that has been determined for the defect free specimen (Figure 4b).

To investigate the mechanisms of crack growth, SEM investigations were performed on the fracture surfaces of the specimens shown in Figure 4 and Figure 6.

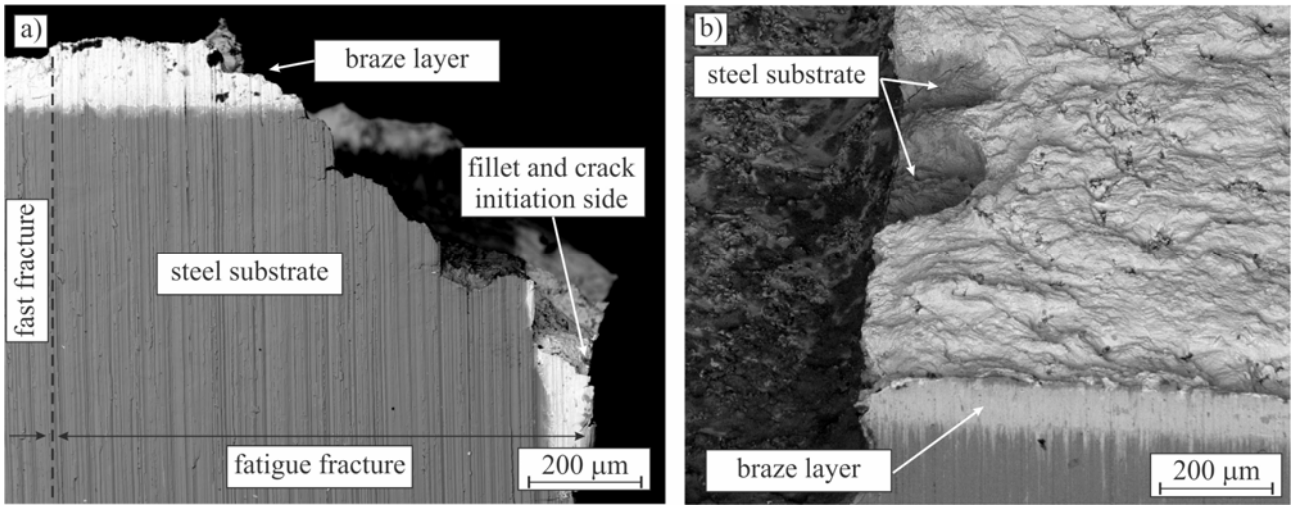

Figure 7: SEM investigations of the fracture surface for a) defect-free and b) defect containing T-joint

The SEM analysis correlates with the DIC calculations considering crack initiation and crack growth. Figure 7a shows the crack initiation side in the fillet and its growth at an angle of 45°, as was also shown in Figure 4b. The crack path through the substrate material is characterized by a discontinuous course. This could be an indicator for inter-crystalline crack growth that could result from the diffusion of liquid gold into the steel substrate between the grain boundaries, as described in [11]. Next to the main crack, multiple secondary cracks were found in the substrate material and in the braze layer. The crack growth follows the same direction until it has passed the braze layer and reached the opposite interface. There, it changes direction and follows the interfacial zone until it has reached a critical length and fast fracture occurs. The fracture surface of the defect containing specimen is shown in Figure 7b. Also for this specimen, the crack passes through the substrate material.

Conclusions

The results show that defects in the brazing zone strongly influence the fatigue lifetime of brazed components. It could be shown that DIC allows measuring local displacements during cyclic loading with a sufficiently high resolution. Continuing fatigue damage is indicated before final failure occurs by increasing strains around structural hot spots. Wing shaped strain fields in front of the crack tip extend over a comparable large volume of the substrate material. Furthermore, the results allow to draw conclusions on the mechanisms of crack initiation and to monitor crack growth during cyclic loading, which is important for braze joints. The results of the DIC show that for defect-free and for the defect containing T-joint specimen, the crack does not necessarily follow the softer filler metal but propagates through both the substrate material and the braze layer. Only when the crack reaches the opposite interface of the braze layer it changes its direction and follows the interfacial regions on its path. Further experiments will be performed to characterize the fatigue behavior of brazed joints with special interest on the influence of defects. In the future, DIC will be performed to investigate the fatigue crack growth behavior more precisely. In correlation with SEM investigations, the presented methods can be used to achieve a better understanding of the mechanisms that lead to failure of brazed steel joints.

Abstract To study crack opening contour and delamination behavior of one kind of advanced hybrid laminates during fatigue crack propagation process, this research accomplished fatigue crack propagation test under R=0.1 for two kinds of saw-cut length and two kinds of stress level, acquired the basic appearance of crack opening contour and delamination, obtained the effect of saw-cut length and stress level on crack opening contour and delamination size. The results indicate that crack opening contour becomes larger as the stress level or saw-cut length rises. Delamination size increases when the stress level becomes larger. The saw-cut length is almost not able to affect delamination size.

Keywords Fiber metal laminates; Advanced hybrid laminates; Delamination; Fatigue crack propagation; Saw-cut

1. Introduction

Fiber metal laminates (FML) have been developed in recent years[1]. Advanced hybrid laminates (AHL) applied to wing load-carrying structures have been developed from ARALL, GLARE and the concept of Selective Reinforcement[2]. One of the AHL, named CentrAl, developed by GTM-advanced structures and Alcoa Technical Center, will be applied in the wing box structure for airliner and cargo plane[3].

Significant research on fatigue crack propagation behavior has been adequately conducted for ARALL and GLARE. And various prediction models have been developed by researchers[4-15]. As Alderliesten said[13], bridging stress, crack opening contour and delamination shape are in balance. As a result of it, in order to calculate bridging stress and then predict fatigue crack propagation behavior effectively, there is significance for studying crack opening contour and delamination behavior deeply.

Existing a few papers[2, 16] present that it is very different from the fatigue crack propagation behavior of AHL and traditional FML. ARALL and GLARE is thin enough to show a nearly same fatigue crack propagation rate in each aluminum alloy sheet layers and a similar delamination shape and size between each layer. But there is a remarkable difference for crack length and delamination size between each layer because of a thickness effect. As the same time, research on the crack opening contour of AHL has not yet been published.

To understand the fatigue crack propagation behavior of AHL, this research accomplished fatigue crack propagation test under different saw-cut lengths and stress levels, recorded crack opening contour, obtained delamination shape and size by etching, got the initial results from the influence of saw-cut length and stress level on crack opening contour and delamination behavior, laid the foundation of validating theoretical analysis results.

2. Experiment

2.1. Materials and Specimen

The lay-up of AHL in this research is shown in Fig. 1. There is a 3/2 lay-up laminate bonded between two 2mm-thick 2A12-T4 aluminium alloy sheets by adhesive film. Central 3/2 lay-up was laid by three 0.5mm-thick LY12-M aluminium sheets and two prepregs. Prepregs are prepared by

HS2 glass fiber and TDE-85 epoxy resin.

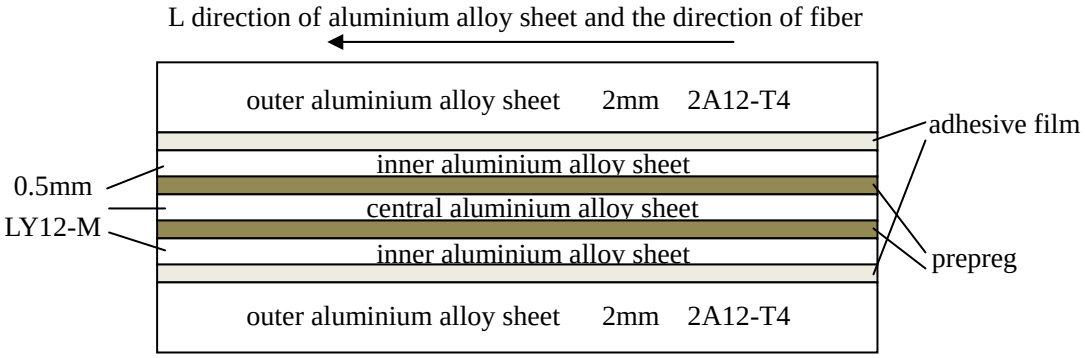

Figure 1. Lay-up of advanced hybrid laminates

Centre crack tension (CCT) specimen was selected for this research, as shown in Fig. 2. Two kinds of saw-cut size, $2a_s$=10mm and 15mm, were processed in order to explore influence of saw-cut length on crack opening contour and delamination behavior.

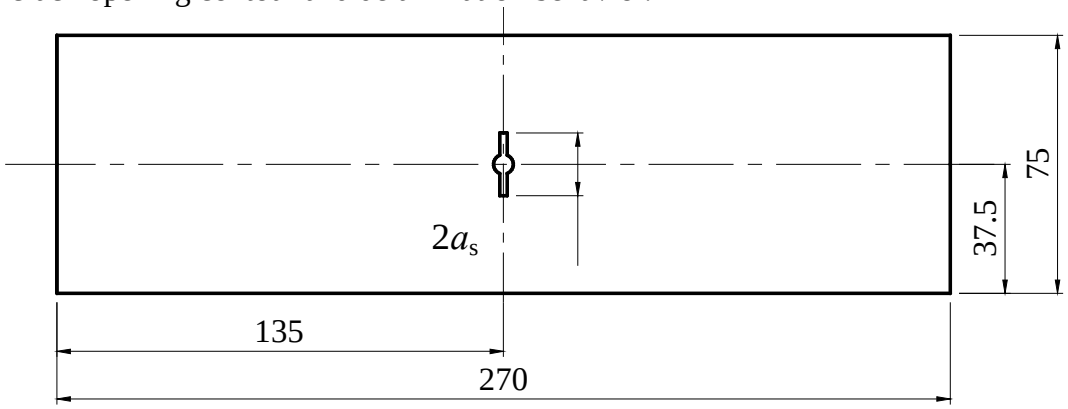

Figure 2. Centre crack tension (CCT) specimen

1.2 Fatigue Crack Propagation Test

Fatigue crack propagation test was finished with constant-amplitude sine wave fatigue loadings, the frequency of 10 Hz and the stress ratio R of 0.1 on 2.5T MTS-858 electohydraulic servocontrolled fatigue testing machine. Crack length was observed by two JDX-B magnification microscopes with scale of 30X. Average crack length a_m is obtained by averaging the front-left side crack length a_1 and back-right side crack length a_2. The matrix of the test is shown in Table 1.

Table 1. Matrix of fatigue crack propagation test

Saw-cut length $2a_s$/mm	Stress level σ_{max}/MPa	Target average crack length a_m/mm
10	60	12，17，22
10	85	12，17，22
15	60	12，17，22

Crack opening contours are captured when a_m reaches nearly 12mm, 17mm and 22mm. Specific measurement method is: take pictures of crack area with a ruler after applying a tension loading which equal to the maximum fatigue loading, then measure the crack opening contour by using image measurement software, and finally obtained the crack opening contour, as shown in Fig. 3.

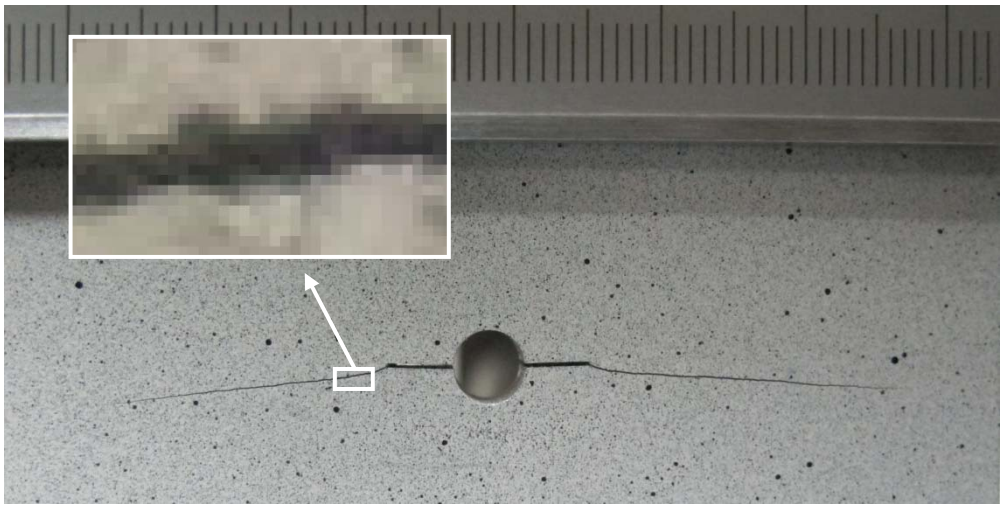

Figure 3. Image analysis measurement method for crack opening contour

To investigate delamination behavior, etch the specimen when a_m reaches nearly 12mm, 17mm and 22mm. Through image analysis measurement method, acquired delamination shape and size finally, as shown in Fig. 4.

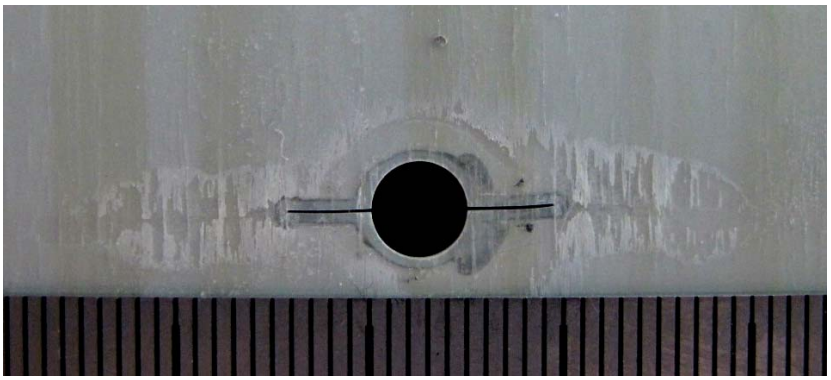

Figure 4. Image analysis measurement method for delamination shape and size after etching

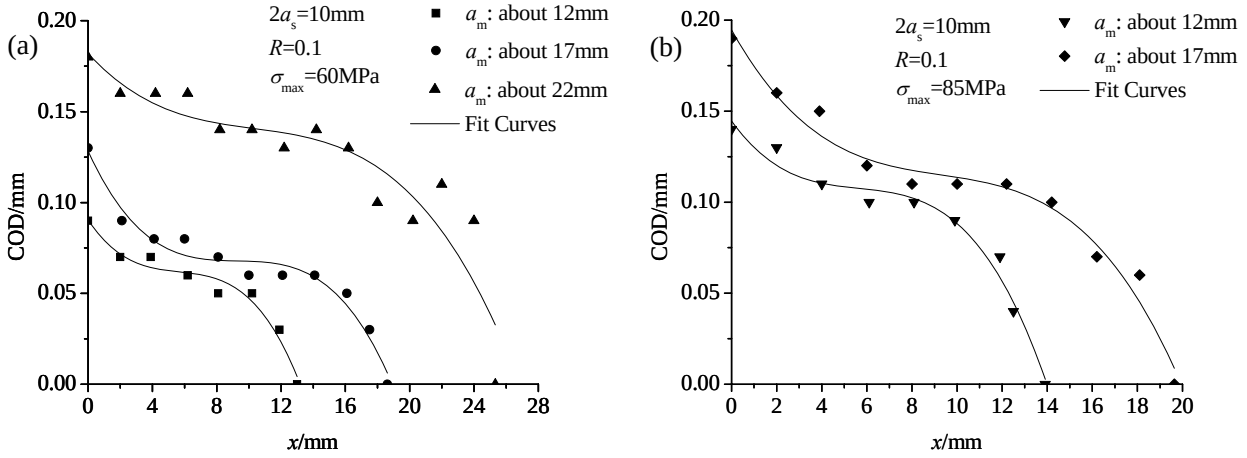
2. Results and Analysis

2.1. Crack opening contour

Experimental data and fit curves are shown in Fig. 5. The direction of axis *x* represents the direction of crack propagation and the zero point in axis *x* is the location of the saw-cut tip.



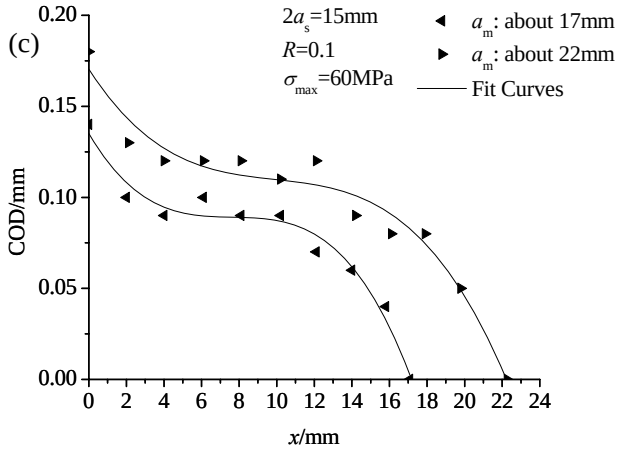


Figure 5. Variation of crack opening contour

As shown in Fig. 5, the crack opening contour can be described as: be maximum value near the tip of saw-cut, decline rapidly along the crack propagation direction, remain almost a constant value in the middle, and decrease to zero at the tip of the crack. Based on the distribution of data, it can be fitted to time by cubic polynomial equation perfectly.

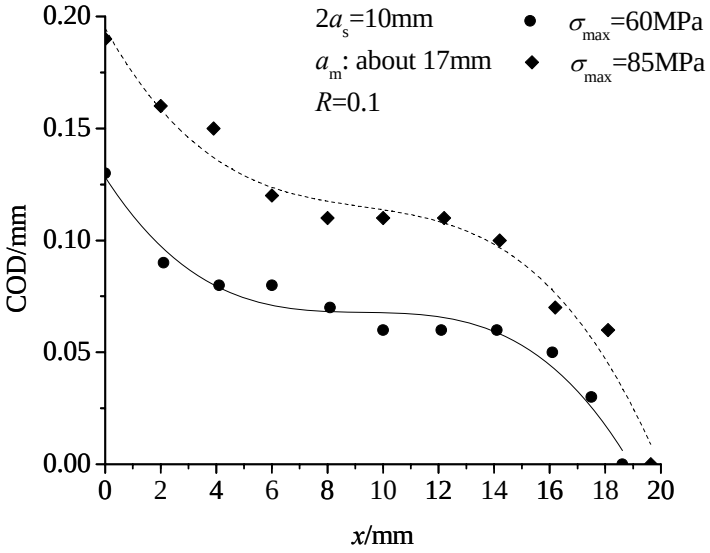

Figure 6. Influence of stress level on crack opening contour

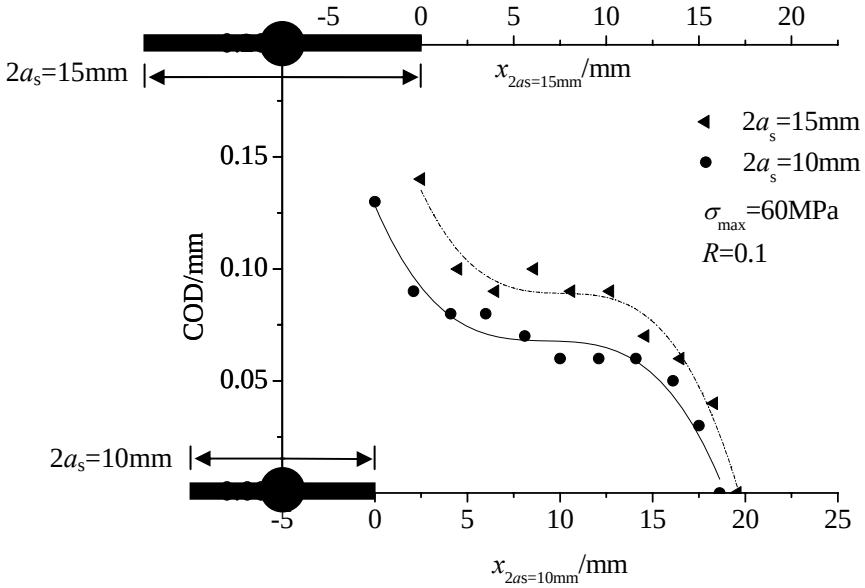

Figure 7. Influence of saw-cut length on crack opening contour

The crack opening contour for a nearly 17mm average crack length under two different stress level is shown in Fig. 6. It can be seen that crack opening contour increase significantly with a higher stress level.
On the other hand, Fig. 7 display the relationship between saw-cut length and crack opening contour. The crack opening contour in a larger 15mm saw-cut length is slightly larger.

2.2. Delamination shape and size

Past studies[2, 16] have described the crack length and delamination in each layer for AHL in detail, as shown in Fig. 8. The outer aluminium alloy sheet, adhesive film and inner aluminium alloy sheet own the same longer length crack without delamination inside. There is a large delamination size between inner aluminium alloy sheet and prepreg, and the sharp point of the delamination locate in the same place with the crack tip of inner aluminium alloy sheet. Crack in central aluminium alloy sheet is obviously shorter than other layers, meanwhile there is a smaller size delamination between prepreg and central aluminium alloy sheet.

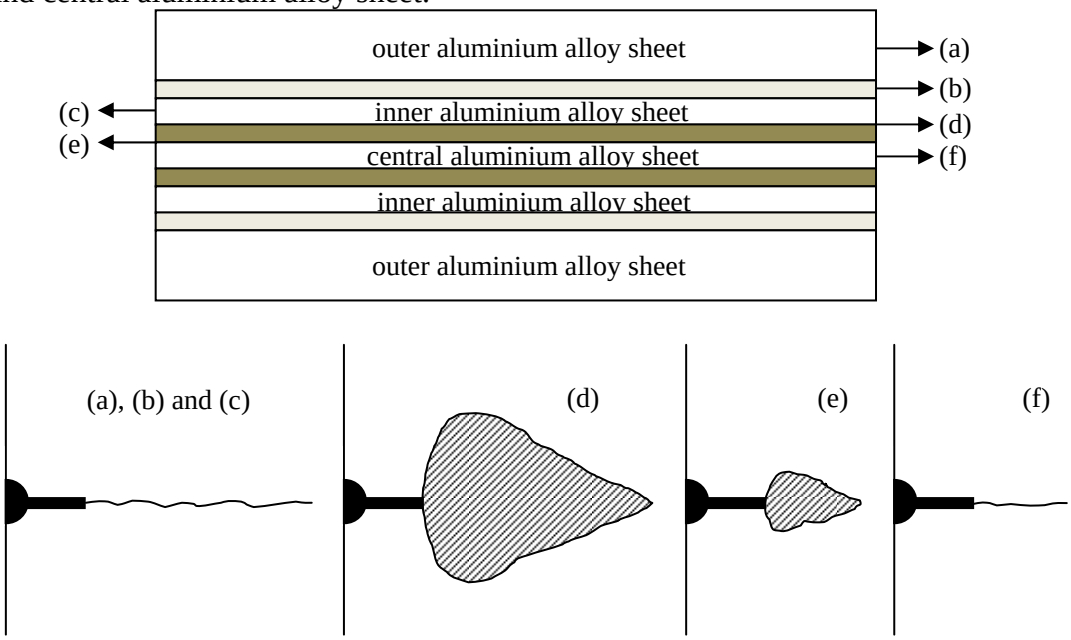

Figure 8. Crack and delamination in each layers

The delamination between inner aluminium alloy sheet and prepreg affect the fiber bridging effect markedly for its large scale, determine the fatigue crack propagation property of AHL, and thus is selected as the study object for delamination behavior.
The results are shown in Fig. 9(a-c). Similar with above, the direction of axis x represents the direction of crack propagation and the point in axis x=0 and axis y=0 is the location of the saw-cut tip.
Fig. 9(a-c) indicates the variation of delamination between inner aluminium alloy sheet and prepreg. With the increase of crack length, delamination grows larger while remaining a similar shape: the size close to zero in the crack tip, increase from crack tip to saw-cut tip, and decrease slightly near the saw-cut tip. Considering the symmetry of the delamination shape, delamination data were grouped and compared after adding together the data from two sides of crack. As shown in Fig. 10, data in axis d represent the width of the delamination shape in Fig. 9, that is $d=|y_1-y_2|$, in which y_1 and y_2 separately indicate the data of upper and lower delamination boundary.

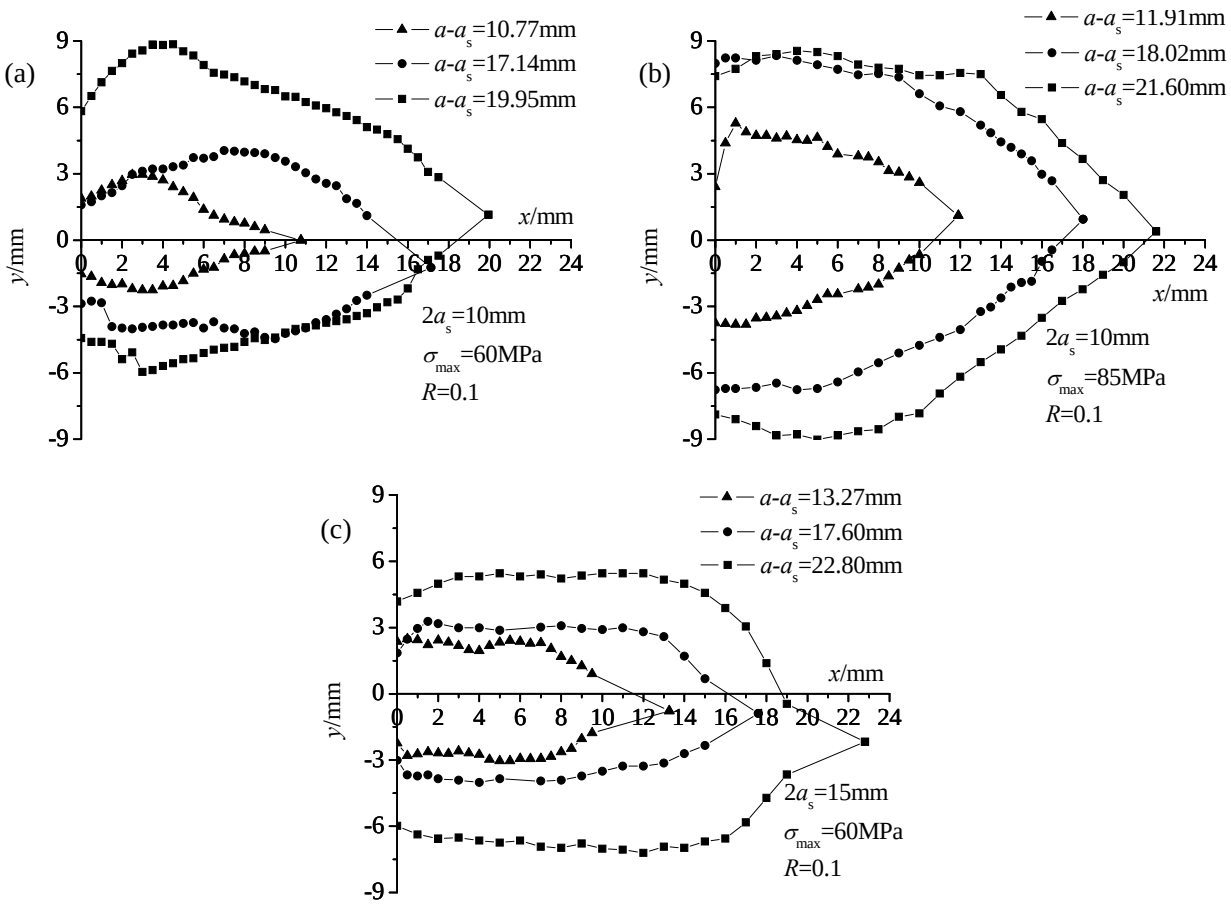

Figure 9. Variation of delamination between inner aluminium alloy sheet and prepreg

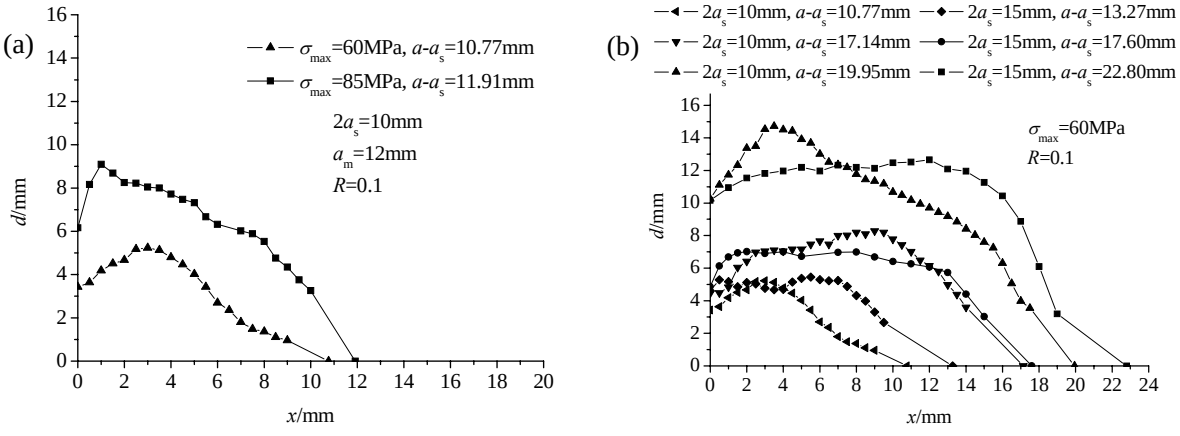

Figure 10. Influence of saw-cut length and stress level on delamination size

Delamination size in the higher stress level is clearly larger than it in lower stress level, as shown in Fig. 10(a). Stress level has a significant impact on delamination behavior. Previous work had shown that the bridging stress becomes too low in case the delamination growth is high, resulting in inefficient fiber bridging[15]. As a result, for AHL, in the condition of high stress level, the bridging effect drops so that the fatigue crack propagation property reduces.

However delamination size seems to be same with different saw-cut length, as shown in Fig. 10(b). Thus it can be seen that the influence of saw-cut length on delamination behavior for AHL is not distinct.

3. Conclusions and prospect

Based on the test data and analysis, it can be concluded as follows:
(1) The crack opening contour of AHL is typically regular, that is be the maximum value at the saw-cut tip, be zero at the crack tip, nearly remaining a constant value in the middle. And the data of crack opening contour is suitable for cubic polynomial fitting.
(2) The crack opening contour becomes larger as the stress level or saw-cut length rises when the other condition is the same.
(3) Delamination shape between inner aluminium alloy sheet and prepreg stays the same basically, that is be nearly zero at the crack tip, increase from crack tip to saw-cut tip, and decrease slightly near the saw-cut tip.
(4) The delamination size increases as the stress level rises when the other condition is the same. The influence of saw-cut length on delamination behavior is not distinct.
Because of the balance of bridging stress, crack opening contour and delamination, there is significance for the data of crack opening contour, delamination shape and size displayed in this research, which can support the creation and verification of fatigue crack propagation predict model for AHL.

Acknowledgements

Advanced hybrid laminates were prepared by Post Doctor Shigang Bai and Master Shiyu Wang in Harbin Institute of Technology. Specimen processing and fatigue crack propagation test were finished with great help of Engineer Shufen Li in Beijing Institute of Aeronautical Materials and Professor Liyang Xie, Professor Ruijin Zhang, Doctor Anshi Tong in Northeastern University (China). I would like to express my heartfelt gratitude to all the people mentioned above.

Abstract In this paper, the existence of crack closure and its sufficiency for crack growth prediction is investigated by multi-resolution in-situ optical microscopy experiment and SEM experiment. In in-situ optical microscopy testing, the digital image correlation analysis is used to measure the plastic zone size in front of the crack tip. In in-situ SEM testing, the crack tip opening displacement and the crack growth kinetics are investigated. Besides, crack closure behavior under constant loading with a single overload is studied in in-situ SEM test. This experimental methodology is applied to two different metallic materials (aluminum alloys and steels). Detailed imaging analysis and experimental results are presented and compared. It is found that first, there exists crack closure phenomena for aluminum alloys, but not for steels in our current researches; second, the crack closure will significantly change the crack tip plasticity behavior; third, the crack closure concept is able to account for crack growth kinetics uniquely for constant loading, but it is insufficient for constant loading with a single overload. Finally, the necessarily and the insufficiency of crack closure for crack growth prediction is discussed.

Keywords fatigue, crack closure, crack growth, plastic zone, overload

1. Introduction

In the past half century, many existing studies have been done on fatigue crack growth mechanism and prediction models. The most famous and successful model should be Paris' Law, which based on the applied stress intensity range [1]. However, Paris' model cannot be applied to loadings with different load ratio and modification is required. In 1970, Elber introduced a crack closure mechanism and modified the applied stress intensity factor range in order to characterize the effect of load ratio [2]. Since Elber's discovery provides a physical meaning to the modification, many researches have been done to get crack-opening load in theoretical method or experimental way. In 1978, Budiansky and Hutchinson provided an analytical estimation of crack opening load with the assumptions of long crack and small scale yielding according to the ideally plastic Dugdale-Barenblatt model [3]. In 1984, Newman analyzed the crack closure problems by developing a strip yield model, which employs a strip yield type plastic zone for leaving residually stretched material in the wake of the crack, causing plasticity-induced closure [4]. However, it is found that the measurement is difficult and the result depends on the measuring location and technique employed such as by traditional gauge and acoustic method [5]. Others methods like electrical potential method [6], ultrasonic method [7][8], and numerical method [9] are also used to measure crack opening load. These methods mentioned are indirectly way to observe crack closure and measure the crack opening loading, and it might be affected by many other factors, for example, it is found that commonly employed notch-mouth clip-gauge method is not sensitive enough to detect the closure of short cracks in regions of notch plasticity [10].

In this paper, in-situ testing and imaging analysis is used to directly observe the crack closure level and its relationship with crack tip behavior. Compare to the other indirect method, it is non-contact and can provide direct evidence about the crack closure at very different resolutions. Next, the proposed methodology is applied to two different metallic material systems and the existence of crack closure is investigated in detail. Following the testing under constant loading, a variable loading situation is tested to investigate crack closure effects on crack growth rate. In mechanics,

the crack closure behavior under overloading load is investigated in detail. Meanwhile, a statistical crack growth rate under constant loading and overloading load is compared. Finally, a discussion for the existence and insufficiency of crack closure for the fatigue crack growth analysis is given based on the current investigation.

2. In-situ optical microscopy study for crack closure

In in-situ optical microscopy test, a unit load cycle is divided into several steps and images are taken at each step. By digital image correlation analysis, then the strain distribution can be calculated. When the load is decreasing, the plastic zone is increasing due to the reversed plastic flow. However, if the crack is closed, the crack surfaces will contact and begin to undertake the reversed stress, thus the reversed plastic zone size will stop increasing. The reversed plastic zone size is a better indicator for crack closure than many other methods due to the advantages of non-contact and a stable precision inherited from digital image correlation method.

2.1. Experiment set-up and procedure

The experimental set-up for in-situ optical microscopy experiment is shown in Figure 1. It contains two parts: a palm-sized tensile stage and an optical microscope system. The tensile stage is fixed on the microscope and the cyclic loading is applied to the specimen. A Nikon metallurgical microscope is used to monitor the specimen surface and a high resolution imaging acquisition system is used to record images during the testing.

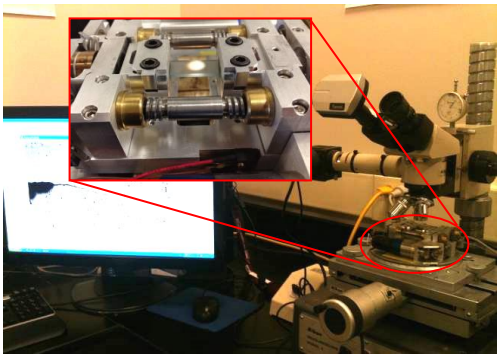

Figure 1. Experiment setup

The specimen is a ingle edge notched plate with width W = 8 mm, length L = 52 mm and thickness T = 0.86 mm. Due to the small thickness of specimens, it is assumed to be under the plane stress conditions for a relatively long crack. An edge notch of length 1mm is machined on the specimen. After machining, the specimens are pre-cracked until the initial crack reaches about 1 mm. The pre-cracking procedure follows the ASTM standard E647-08. Following this, both surfaces of the specimen are polished with the sandpaper whose average particle diameter is smaller than 10 um.

The experiment procedure contains four major steps.

Step 1: specimen manufacturing and pre-cracking. Single edge notched plate specimen is used for testing. After notching, the specimens are pre-cracked under a hydraulic tension machine INSTRON 1331 until the initial crack reaches about 1 mm. The pre-cracking procedure follows the ASTM standard E647-99;

Step 2: polish the specimen to form randomly distributed small dark regions on the smooth surface,

which is a requirement for digital image correlation (DIC) analysis. Both surfaces of the specimen should be polished with the sandpaper whose average particle diameter is smaller than 10 um. The final polishing is done using a vibration polishing machine with 1~3um polishing suspension;

Step 3: apply load on the specimen under the monitoring of a microscope, while image of the crack tip region is taken during the loading and unloading process. A unit load cycle is divided into several steps in the load profile. At each step, the image around the crack region is taken for strain calculation. The step load is set according to the precision requirement and computation resource limitation. An example profile is shown in Figure 2, which has about forty segments during the loading and unloading path.

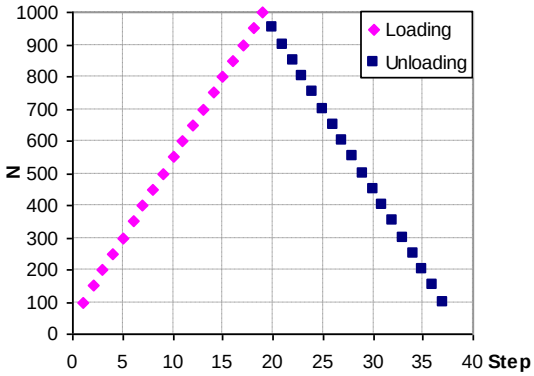

Figure 2. Load profile

Step 4, process the images by DIC software to get the strain field of the crack tip region and calculate the plastic zone using mechanical analysis. The plastic zone size is defined along the crack propagation direction and it can be measured directly from the processed image.

The theoretical reversed plastic zone under cyclic loading can be estimated by Eq. (1) without the consideration of crack closure [11]

$$\rho = \frac{1}{\pi}\left(\frac{\Delta K}{2\sigma_y}\right)^2, \tag{1}$$

where σ_y is the yielding strength and

$$\Delta K = F \cdot \Delta\sigma\sqrt{\pi a} = F \cdot (\sigma_{\max} - \sigma_{\min})\sqrt{\pi a} \tag{2}$$

where F is the geometry factor and

$$\mathrm{F} = 1.12 - 0.231\left(\frac{a}{W}\right) + 10.55\left(\frac{a}{W}\right)^2 - 21.72\left(\frac{a}{W}\right)^2 + 30.39\left(\frac{a}{W}\right)^3 \tag{3}$$

where a is the crack length.

2.2. Title and author information

With the above described experiment procedure, two sets of experiment are carried out to investigate the crack closure behavior under constant loading in Al 7075-T6 and Steel 4340 separately.

The chemical composition aluminum 7075-T6 is listed in Table 1. The aluminum is the balance in the total weight. The basic physical properties are listed in Table 2.

Following the above discussed general experiment methodology, the plastic zone size at each

loading step can be measured using the digital image correlation analysis. Three specimens have been tested and the reversed plastic zone size is shown in Figure 3. It can be found that there is a plat form when stress intensity factor (SIF) is less than about 3.5 MPa·m$^{0.5}$, which indicates the crack closes and the reversed stress is released by the surface contact.

Table 1. Chemical composition of Al 7075-T6 (weight, %)

Element	Zn	Mg	Cu	Fe	Si	Mn	Cr
Min	5.1	2.1	1.2	0	0	0	0.18
Max	6.1	2.9	2.0	0.5	0.4	0.3	0.28

Table 2. Basic mechanical properties of Al 7075-T6

Elastic Modulus /GPa	Yield Strength /MPa	Tensile Strength /MPa
71.7	502~516	573~582

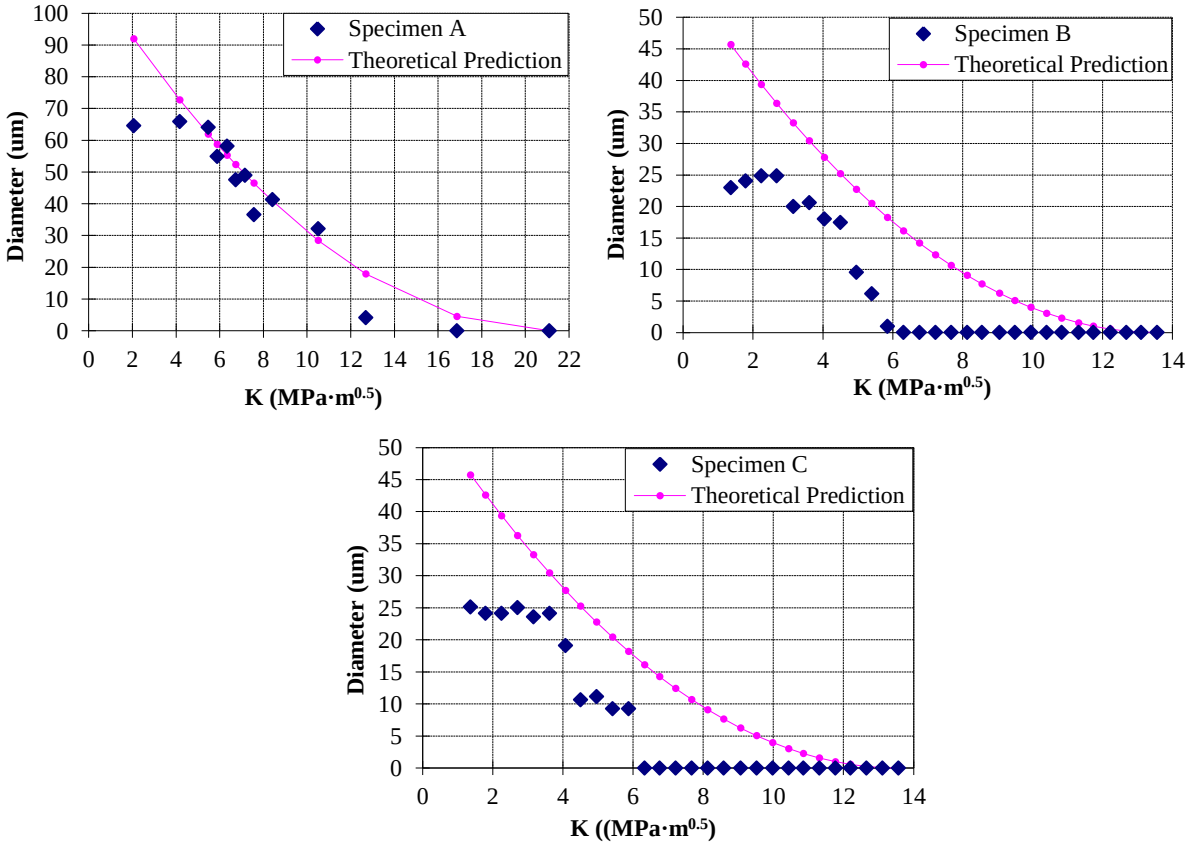

Figure 3. Plastic zone size of aluminum [12]

The same experiment is carried on steel 4340. AISI 4340 steel is a heat treatable, low alloy steel containing nickel, chromium and molybdenum. The chemical composition of this material and its basic physical properties are listed in Table 3 and 4.

Table 3. Chemical composition of AISI 4340 steel

Element	C	Cr	Mn	Mo	Ni	P	Si	S
Min	0.38	0.7	0.6	0.2	1.65	0	0.15	0
Max	0.43	0.9	0.8	0.3	2	0.035	0.3	0.04

Table 4. Basic physical properties of AISI 4340 steel

Elastic Modulus /GPa	Yield Strength /MPa	Tensile Strength /MPa
190~210	472.3	744.6

In the test, the load starts from 100 N to 1000 N at a step of 50 N. Result of the plastic zone size during the unloading process is obtained as shown in Figure 4. It is found that the reversed plastic zone size keeps increasing throughout the unloading process and these experiment data shows similar trends to the theory data without plastic closure phenomena. This is very different compared with the results of aluminum alloys and it indicates no crack closure for steel in these tests.

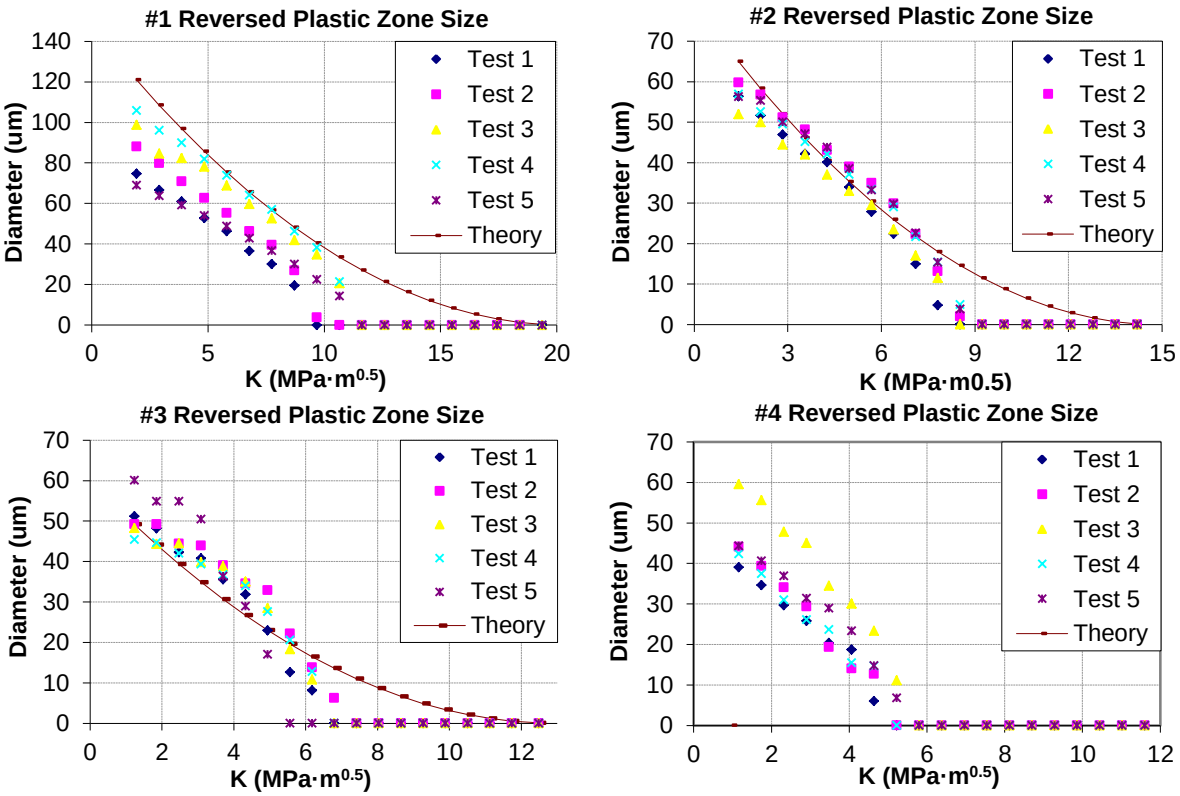

Figure 4. Plastic zone size of steel specimens

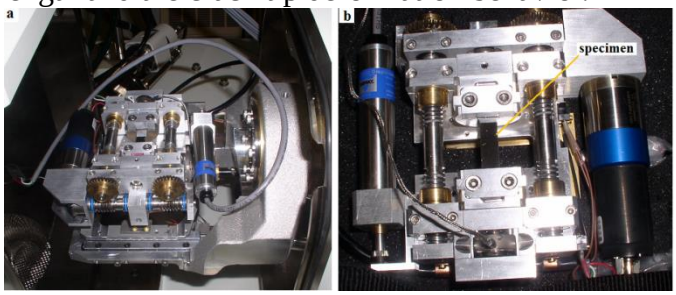
3. In-situ SEM study for crack closure

In order to verify the crack closure indications from optical microscope observation and get further information of the crack tip deformation behavior, in-situ SEM experiment is carried out on the two materials. Further, the behavior of crack closure under variable load is studied for the sufficiency of K_{eff} for crack growth prediction. In mechanics, crack closure behavior under a single overload is studied for the sufficiency of K_{eff} for crack propagation mechanics. In statistics, the crack growth rate under constant loading and overloading load is compared to show the sufficiency of K_{eff} for crack growth prediction. Detailed experimental procedure has been discussed in [13][14] and only a brief description of the experimental methodology is given below.

3.1. In-situ SEM study under constant amplitude loading

An in-situ SEM fatigue testing is performed to achieve the high resolution investigation for the hypothesis verification of crack growth kinetics and crack deformation in the vicinity of the crack tip. Compared with experiment under optical microscope, crack tip opening displacement (CTOD) is measured directly to find the crack is closed or not. Some details of the experimental set-up for the in-situ SEM experiment are shown in Figure 5. It consists of the tensile sub-stage and a field emission SEM (JEOL-7400F). The sub-stage is fixed in the SEM and the cyclic loading is applied during the experiment. Multiple resolution images are recorded during the testing for the

measurements of crack length and the crack tip deformation behavior.



a) loading stage installed in SEM; b) specimen installed in loading stage.
Figure 5. In-situ SEM fatigue testing setup

The specimen configuration and preparation are almost the same as that in optical microscope experiment. In this experiment, the final polishing is done by a vibration polishing machine with 1~3 um polishing suspension.

The specimen is undergoing cyclic loading and observed in-situ under SEM. In the following comparison for aluminum and steel, the stress ratio is 0.1. The measurements are usually taken after 50 to 100 cycles to ensure the crack growth is stable. During the testing, one loading cycle is divided into many steps, similar with the testing under optical microscopy. The applied loading increases/decreases at a very slow rate. CTOD is measured directly from the processed images. The CTOD is defined as the distance of crack surface at the place of crack tip in last cycle. With the same reference, the crack growth rate at each cycle could be measured, as shown in Figure 6.

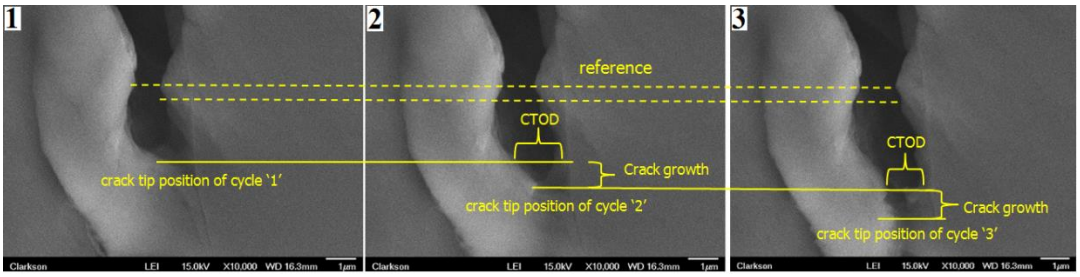


Figure 6. Images of crack tip position and CTOD under maximum loadings

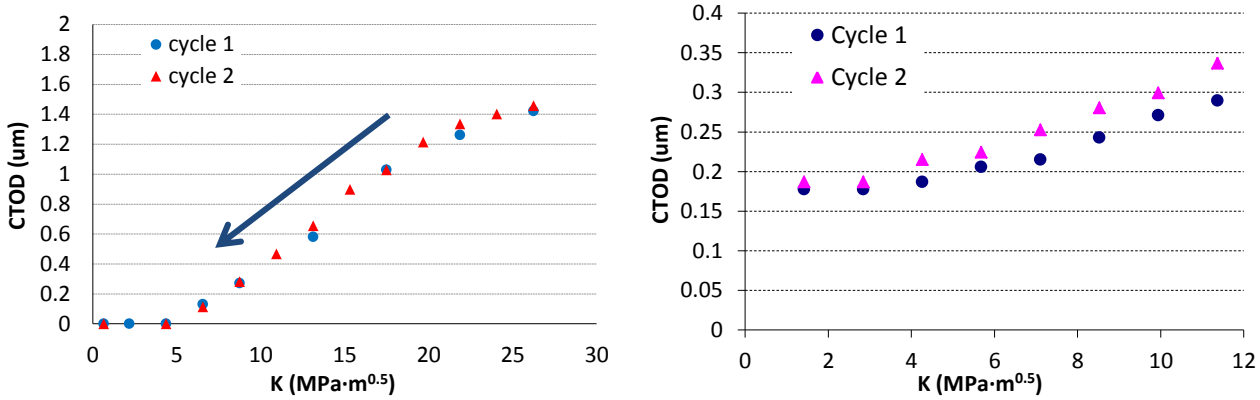
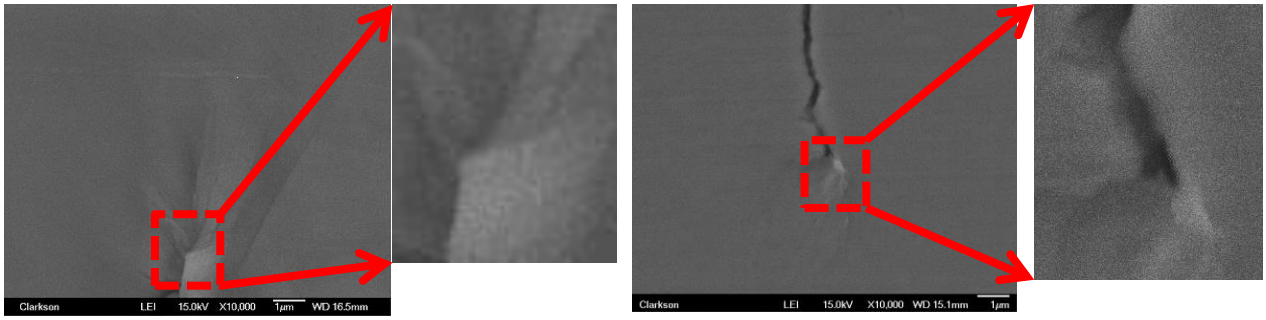
Using the measuring method, two sets of experiments on steel 4043 and aluminum 7075-T6 have been performed. The results are shown in Figure 7. It shows that CTOD reduces to zero when SIF is less than 5 MPa·m$^{0.5}$ for Al 7075-T6, while for steel 4340, CTOD is not zero under the minimum loading. The crack tip details are shown in Figure 8. It shows the crack closure in Al 7075-T6 clearly but the crack remains open for steel 4340.



(a) Al 7075-T6 (b) Steel 4340

Figure 7. CTOD during unloading process on Al 7075-T6 and steel 4340



(a) Al 7075-T6 (b) Steel 4340

Figure 8. Crack tip under minimum loading of Al 7075-T6 and steel 4340

This result is consistent to the experiment under optical microscope and they show that the existence of crack closure in Al 7075-T6, but it is not observed in steel 4340 at this stage.

3.2. In-situ SEM study under variable loading with single overload

As crack closure is observed both under optical microscope and SEM, its effects on crack growth rate is not negligible for fatigue crack growth prediction for some metallic materials, if it happens. However, it is not clear that the crack closure is the only/dominant mechanisms for aluminum materials, especially under different loading conditions. Thus, the crack closure effect on crack growth rate under variable loading is investigated and is shown below.

The procedure of SEM experiment under variable loading is the same with that under constant loading. The only difference is the loading profile. In this experiment, a cycle of over-load is inserted in a constant loading spectrum. The constant loading ranges from 10 to 30 MPa·$m^{0.5}$ and the overload ranges from 10 to 36 MPa·$m^{0.5}$. Thus the over load ratio is 1.2 as the ratio of two maximum load. A schematic plot is shown in Figure 9.

In order to observe and compare the effects of overload loading, four types of loading cycle are chosen for observations. The first type is the constant loading cycles before the over load (cycle **A** in Figure 9), which provides the baseline information of the crack propagation kinematics. The second and the third type are the overload cycle (B) and the cycle right after it (C). The last type is the cycle 5~20 cycles after the overload (D). In this study, two experiments data are obtained. In the first experiment, the background stress ratio is 0.33 and the overload ratio is 1.2. In the second experiment, the background stress ratio is 0.025 and the overload ratio is 1.1. In the following discussion, the result of the first experiment will be discussed in detail and the second one will be given as a comparison.

Following the experiment procedure and the loading profile, the details of crack growing before, during, and after overload under SEM is obtained and compared.

For all testing measurements, the crack opening stress intensity factor at each observing cycle are plotted in Figure 10. The X axis is cycle number and Y axis is the ratio of crack opening SIF over the maximum SIF (K_{open}/K_{max}). It is shown that during the constant loading in stage 1 (cycle A), K_{open}/K_{max} is 0.57. In the overload cycle (B) and right after the overload cycle (C), the crack opening slightly decreases and increases to about 75% after more than 10 cycles (D). Another experiment has been performed with stress ratio R=0.025, the maximum SIF of the constant loading is 26.26 MPa·$m^{0.5}$ and the overload ratio 1.1. Very similar result is observed as shown in Figure 11.

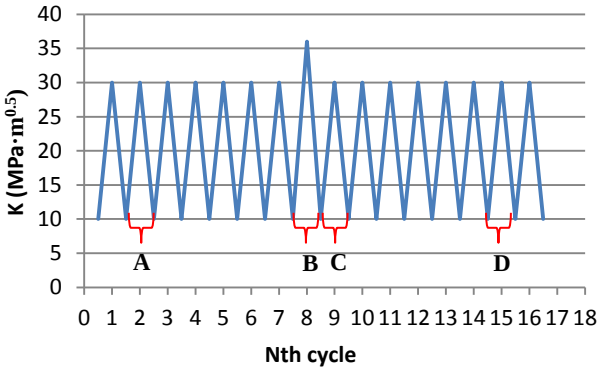


Figure 9. Schematic representation of single overload spectrum

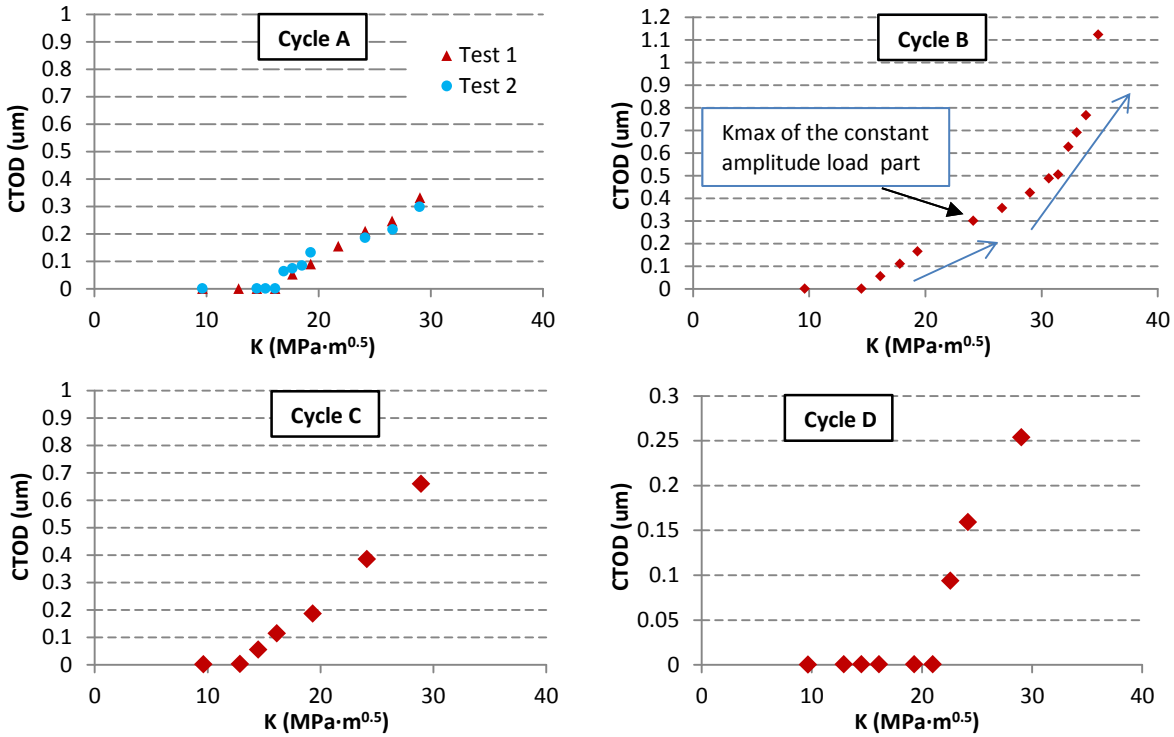

Figure 10. CTOD variation at each loading cycle in Figure 9

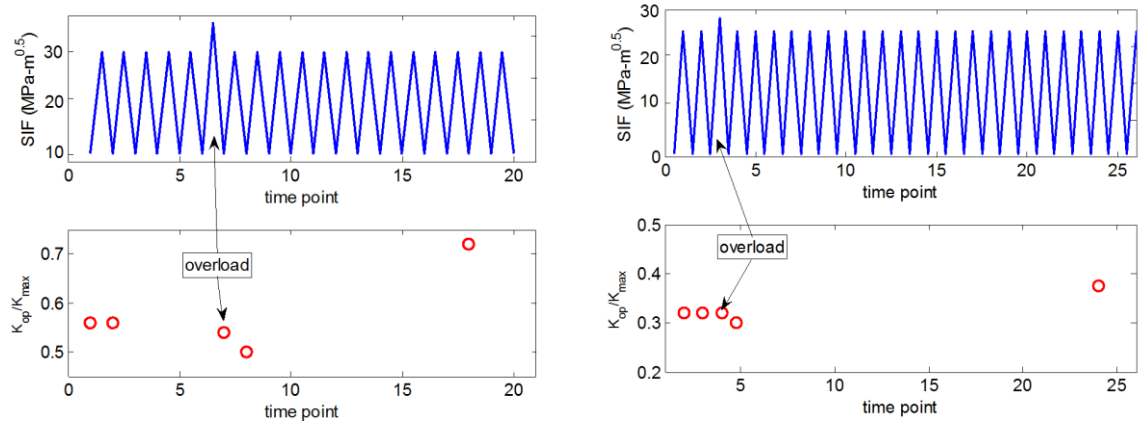


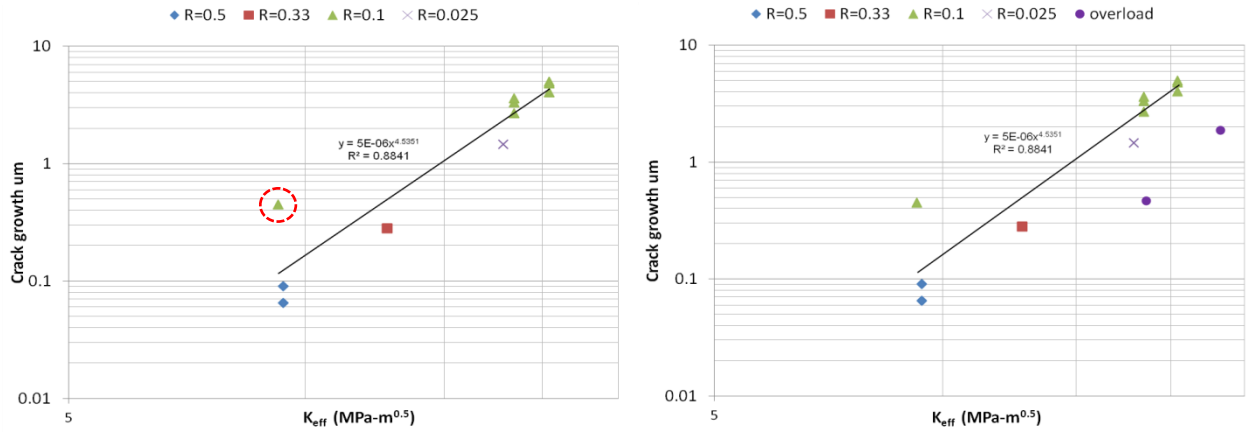
(a) R=0.33 (b) R=0.025

Figure 11. Illustration of the crack opening stress level variation

One important hypothesis in the classical crack closure theory is that the effective stress intensity

factor range (defined as the maximum SIF minus the opening SIF) can be used to uniquely correlate with crack growth rate under different loadings. However, this experiment shows that under single overload loading, crack opening SIF becomes variable and crack starts to kink and bifurcate. These mechanics cannot be explained only by the phenomena of crack closure.

Further, a statistical study of crack growth rate under constant load and overload lading is conducted to verify this hypothesis. Several experiments have been completed at stress ratio R=0.5, 0.33, 0.1 and 0.025, and the result of crack growth rate with the effective SIF is plotted in Figure 12. Figure 12 (a) shows the result under constant loading. It can be found that all the data shows a good linear relationship in log-log scale, except one data in red dashed circle. Figure 12(b) shows the data together with the single overload testing. It is observed that the two data points are not consistent with the linear trend from the constant amplitude loading data. This observation further indicates that other mechanism also contributes to the crack growth under single overload loading, such as crack branching and blunting as observed in the experiment.



(a) Constant load (b) Constant loading and overloading load

Figure 12. Crack growth rate with SIF under constant load and overloading load

3. Conclusions

In this paper, in-situ experiment at micrometer scale and nanometer scale has been introduced and the observation of crack closure behavior of steel 4340 and aluminum 7075-T6 under constant loading has been obtained. Besides, preliminary crack closure behavior under single overload on aluminum 7075-T6 is studied. Several conclusions can be made from the experiments as follows.

1. Crack closure is directly observed in Al 7075-T6 under both constant and variable loads, but it is not observed in steel 4340 under constant loading at stress ratio 0.1.

2. The crack closure can significantly change the plasticity distribution in front of the crack tip;

3. K_{eff} defined as the difference of K_{max} and K_{open} in the classical fracture theory correlates with the unique crack growth rate under constant loading, but it not enough for crack growth prediction under variable loading. Additional parameter for the mechanism is need for the prediction;

The proposed study focus on simple variable loadings and more complex loading conditions require additional study. The current imaging analysis is for surface measurements and 3D imaging technique will be very helpful for the investigation of subsurface behavior near a crack tip.

Abstract

This paper is concerned with the extension of a recently developed probabilistic framework based on Weibull's weakest link and extreme-value statistics to aero-engine materials like titanium alloy and nickel-base super alloys using simulation strategies that capture both the essence of notch root stress gradient and the complexity of realistic microstructures. In this paper, notch size effects and notch root inelastic behavior are combined with probability distributions of microscale stress-strain gradient and small crack initiation to inform minimum life design methods. A new approach which can be applied using crystal plasticity finite element or closed-form solution is also proposed as a more robust approach for determining fatigue notch factor than the existing classical methods. The fatigue notch factors predicted using the new framework are in good agreements with experimental results obtained from literature for notched titanium alloy specimens subjected to uniaxial cyclic loads with various stress ratio.

Keywords: probabilistic mesomechanics, weakest link, microstructure-sensitive, fatigue notch factor, fatigue indicator parameters.

1. Introduction

Titanium alloy is widely used in aero engine components. The fatigue resistance of aero-engine components made from this material can be drastically reduced by the presence of small notches on the components formed from the ingestion of foreign objects causing foreign object damage (FOD) [1 - 2]. To account for the effects of FOD on the fatigue strength of these materials, the damage are usually modeled as notches with a certain depth and notch root radius [1- 2]. The severity of these notches in materials is characterized by the elastic stress concentration factor, k_t which is the ratio of peak (maximum) local stress at the notch root to the remotely applied stress, *S* as shown in Figure 1.

$$k_t = \frac{\sigma_{peak}}{S} \tag{1}$$

k_t is dimensionless and a compilation of its values for different notch geometries and loading modes can be found in Peterson's book [3]. However, k_t under-estimate fatigue life and several arguments have been attributed to this observation. The fatigue life of notched component is not only dependent on the peak stress as predicted by k_t, but also on the average stress that acts over a finite damage process zone. Consequently, fatigue life prediction methods based on k_t typically do not consider stress gradients which have been shown to influence the fatigue life of complex notched components [4 - 5]. Thus, the actual reduction factor on long fatigue lives is typically represented by the concept of fatigue notch factor, otherwise known as the fatigue strength reduction factor, k_f.

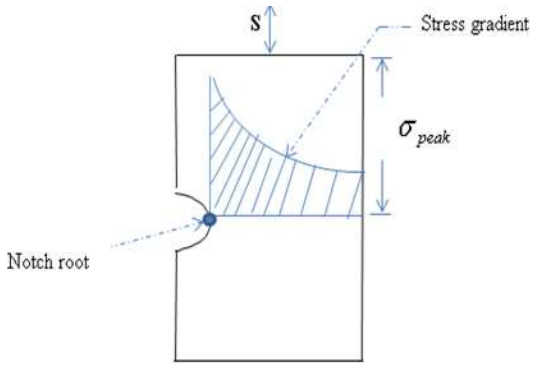

Figure 1. Stress distributions in a notched specimen

The fatigue notch factor, k_f, is determined at a given number of completely reversed cycles (typically 10^6 or 10^7) to crack initiation and is given as:

$$k_f = \frac{\sigma_f^{unnotched}}{\sigma_f^{notched}} \tag{2}$$

Where $\sigma_f^{unnotched}$ is the fatigue strength of the unnotched specimen and $\sigma_f^{notched}$ is the fatigue strength of the notched specimen. The difference between k_t and k_f for a given microstructure is typically represented by the notch sensitivity factor, q given as:

$$q = \frac{k_f - 1}{k_t - 1} \tag{3}$$

At $q = 0$, there is no notch sensitivity and at $q=1$ we have full notch sensitivity. i.e. full theoretical elastic concentration effect. Several empirical relations have been developed to estimate the fatigue notch factor of a material and its associated notch sensitivity index. These techniques include: the classical methods (Neubers [6 - 7], Peterson [3, 8] and Heywood [9]), stress field intensity method [10], and probabilistic method based on linear elastic fracture mechanics [11]. Detail review of these methods can be found in [12], each attempt to simplify the complex behavior of fatigue in notched components to a few geometric and characteristic material constants. However, these approaches suffer from some fundamental drawbacks. Among these drawbacks is that the fatigue notch factors are obtained through time consuming and costly experiments. Moreover, the relationship of microstructure to K_f, using these constants has proven difficult to establish. Recently, Owolabi et al. [14] have established a probabilistic framework based on weakest link theory and extreme-value statistics which incorporates information regarding the peak stress and stress gradient relative to microstructure length scales within a well defined fatigue damage process zone around the notch root. This paper combines the developed probabilistic framework with other existing probabilistic formulations that consider the size distribution and different competing damage mechanisms for aero-engine materials.

2. Material Systems

The alloy used for this study is a dual-phase titanium alloy, Ti-6Al-4V. Ti-Al alloys offer a range of properties such as high strength and fracture toughness at low temperatures to high strength and creep resistance at elevated temperatures. These wide ranges of properties have led to extensive use of Ti-Al

alloys in engineering applications from airframe components to compressor blades applications. The experimental data used in this work were obtained from Haritos et al [1], Lanning et al [13] and Naik et al. [15] on Ti-6Al-4V for various notch root geometries and stress ratios. The Ti-6Al-4V specimens used in these papers were obtained from forged bar, which were initially heat treated to 705^{o}C for 2 h, and then followed by static argon cooling to below 149^{0}C. The material was subsequently annealed in vacuum at 549^{0}C for 2 h. This is then followed by static argon cooling to below 149^{0}C. The microstructure of the resulting bar is as shown Figure 2.

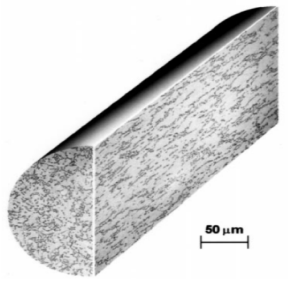

Figure 2. Ti-6Al-4V forged plate microstructure [1]

3.0. Crystal Plasticity model of Ti-6Al-4V

Crystal plasticity models are more suited for studying heterogeneity and interaction across grains in the notch root field as they relate grain scale stress to crystallographic slip response [16 - 18]. The use of crystal plasticity is thus relevant for the accurate prediction of the stress-strain field response at the notch root. The crystal plasticity model used in this work is based on 3D crystal plasticity models developed by Mayeur and McDowell (2007)[19]. Thus, only the summary of the crystal plasticity constitutive models is presented in this section.

The deformation in the material is based on a standard two term multiplicative decomposition of the deformation gradient into elastic and plastic parts, i.e.,

$$F=F^{e}F^{p} \tag{4}$$

Here, F is the total deformation gradient, F^{p} captures the dislocation glide through the lattice while F^{e} captures the rigid body rotation and elastic stretching of the lattice. The plastic velocity gradient $\hat{}L^{p}$ defined as the sum of the crystalline shear displacement rates over all slip systems k is given in the isoclinic, lattice invariant intermediate configuration as [20]:

$$\hat{L}^{p}=\dot{F}^{p}\cdot(F^{p})^{-1}=\sum_{k=1}^{N_{sys}}\dot{\gamma}^{k}(s_{0}^{k}\otimes n_{0}^{k}) \tag{5}$$

Here, γ^{k} is the slip system shearing rate, and S_0^{k} and n_0^{k} are fixed unit vectors in the slip direction and slip plane normal direction, respectively. The slip vectors S_0^{k} and n_0^{k} remain unchanged through deformation F^{p} from the reference to the intermediate configuration and maintain orthogonality through F^{e}. The relationship between the slip system shearing rate and the resolved shear stress of the k_{th} slip system is described by the power law flow rule given by McGinty [21] as:

$$\dot{\gamma}^{k}=\dot{\gamma}_{0}\left\langle\frac{\left|\tau^{k}-\chi^{k}\right|-\kappa^{k}}{D^{k}}\right\rangle^{M}\operatorname{sgn}(\tau^{k}-\chi^{k}) \tag{6}$$

Here, γ_0 is the reference shearing rate, M is the inverse strain-rate sensitivity exponent which controls the rate sensitivity of flow, τ^k is the resolved shear stress, χ^k is the back stress, κ^k is the length scale-dependent threshold stress and D^k is the drag stress. As developed by Zhang et al. [22], the drag stress is taken as a non-evolving constant, while the back stress evolves according to an Armstrong-Frederick direct hardening/dynamic recovery type of equation, i.e.,

$$\dot{\chi}^k = h\dot{\gamma}^k - h_D \chi^k \left|\dot{\gamma}^k\right| \tag{7}$$

With $\chi^k(0)=0$. The threshold stress is expressed as

$$\kappa^k = \frac{\kappa_y}{\sqrt{d^k}} + \kappa_s^k \tag{8}$$

3.1 Simulation of Notched Components

The crystal plasticity constitutive model was coded into ABAQUS 2006 UMAT, based on previous work by Zhang et al [22]; Mayeur and McDowell, 2007[19]. For textured Ti-6Al-4V alloy, some of the material parameters in the crystal plasticity are obtained from Bridier et al [23]. Finite element simulation was performed on three different geometries, meshed using 3D stress four-node linear tetrahedron element type (C3D4) and consisting of approximately 218940 elements to estimate the stress distribution and possible plastic straining that occur in the notched specimens. The dimensions of the specimens used and the different test cases are as given in Table 1. A diagram of the gage section of the specimen is provided in Figure 3.

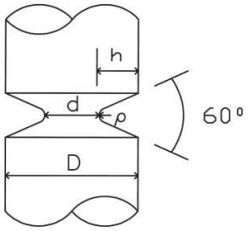

Figure 3. Gage section of the cylindrical specimen with a circumferential V-notch.[1]

To reduce computational time, the notched specimen geometries are decomposed into three different regions: an outermost region, far from the notch root, where isotropic linear elasticity is used; an intermediate transition region where macroscopic J_2 cyclic plasticity theory is used; and finally the notch root region where crystal plasticity theory is used. The element size at the crystal plasticity region was chosen to coincide with the average grain size of Ti-6Al-4V which is 45 μm. The domain decomposition is as shown in Figure 4. Also, One quarter of the cylindrical notched specimen was modeled because of the symmetry in loading and geometry of the specimen as shown in Figure 5.
The bottom of the notched specimen is encastre while symmetry boundary conditions are applied to the two planes of symmetry. The notched specimens were tested at four different load ratios; R=0.1, R=0.5 and R=-1. Average alternating HCF strength at 10^6 cycles, as determined by Naik et al [15] and as contained in Table 1 for different load ratios, are applied to the top of the specimen.

Table 1. The 7 different test cases

Test Case	K_t	Notch radius, **ρ** (mm)	Notch depth, h (mm)	R-ratio	Average alternating HCF strength at 10^6 cycles (MPa)
1	2.78	0.330	0.729	-1	173.6
2	2.78	0.330	0.729	0.1	158.9
3	2.78	0.330	0.729	0.5	104.6
4	2.78	0.203	0.254	0.10	167.2
5	2.78	0.203	0.254	0.50	105.2
6	2.78	0.127	0.127	0.10	144.7
7	2.78	0.127	0.127	0.50	111.0

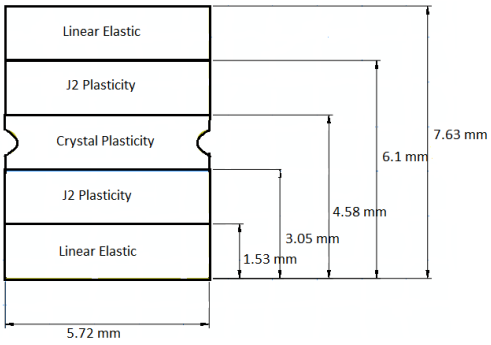

Figure 4. Domain decomposition of the cylindrical notched specimen geometry.

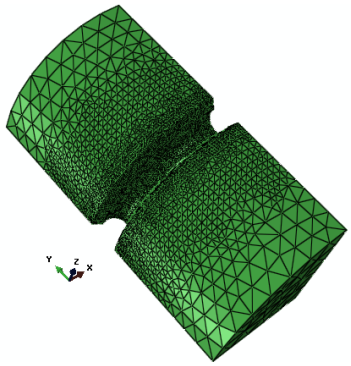

Figure 5 Finite element mesh for 0.33 mm notch root radius and K_t = 2.78 consisting of four-node linear tetrahedron element type (C3D4)

For a smooth specimen with defects having a fatigue damage process zone of volume V, the whole volume is divided into small volume elements, dV with probability of failure of a sufficiently small volume element given as:

$$dP = \lambda dV \tag{9}$$

Where here, λ is the critical defect density defined as the expected number of defects per unit volume of the smooth specimen. Using weakest link theory, the probability of survival of the entire volume is obtained from the probability of survival of all "m" number of sub-volumes i.e.

$$P_s = \prod_{i=1}^{m} (1 - dP_i) = \prod_{i=1}^{m} (1 - \lambda dV) \tag{10}$$

This equations assumes that the defects are randomly distributed within the volume and thus do not interact, which is only reasonable when considering the formation of a fatigue crack(s) in high cycle (HCF) and very high cycle fatigue (VHCF) regimes. Following the framework presented in [14], as the volume of each small element tends to zero, equation (10) can be transformed into

$$P_s = \exp\left(-\int_{V_d} \lambda dV \right) \tag{11}$$

Using the generalized extreme value distribution function, the distribution of defects, *a*, that are above the threshold, a_{th}, is modeled by a power law of the form

$$\lambda = \frac{1}{V_0}\left(1 + \xi\left(\frac{a - a_{th}}{a_0}\right)\right)^{-1/\varepsilon} \tag{12}$$

Where a_0 and ξ are the scale and shape parameters respectively. Substituting (12) into (11) yields

$$P_s = \exp\left\{-\frac{1}{V_0}\int_{V_d}\left(1+\xi\left(\frac{a-a_{th}}{a_0}\right)\right)^{-1/\varepsilon} dV\right\} \tag{13}$$

If $a_{th} = a_0^*\xi$, re-arranging equation (13) yields,

$$P_s = \exp\left\{-\frac{1}{V_0}\int\left(\frac{a}{a_0^*}\right)^{-1/\varepsilon} dV\right\} \tag{14}$$

Where a_0^* is regarded here as the mean defect size. Equation (14) is valid only if $\xi \neq 0$. The critical defect size is related to the microscopic stress (taking here as a random variable) through a power law relationship of the form

$$\sigma = \frac{A}{\sqrt[z]{a}} \tag{15}$$

where A and z are materials constants. Similarly, the stress amplitude, σ_0 corresponding to the mean defect size a_0^* can be taken as the fatigue limit of the reference volume V_o for 50% failure probability. The two parameters can also be related by a power law of the form:

$$\sigma_0 = \frac{A}{\sqrt[z]{a_0^*}} \tag{16}$$

Combining equations (15) and (16) we have

$$\frac{a}{a_0^*} = \left(\frac{\sigma_0}{\sigma_a}\right)^z \tag{17}$$

Substituting Equation (17) into Eq. (14) yields

$$P_s = \exp\left\{-\frac{1}{V_0}\int\left(\frac{\sigma}{\sigma_0}\right)^b dV\right\} \tag{18}$$

Where $b=z/\xi$. For $\xi>0$, b and σ_0 represents a 2-parameter Weibull shape and scale parameters. The cumulative probability of HCF failure of the component, specifically defined can be obtained from Eq. (18) as

$$P_f = 1-\exp\left\{-\frac{1}{V_0}\int\left(\frac{\sigma}{\sigma_0}\right)^b dV\right\} \tag{19}$$

To facilitate development of the expression for fatigue notch factor from Eq. (18), the concept of stress homogeneity factor that have been used is introduced here. Thus equation (18) can be re-written as,

$$P_f = 1-\exp\left\{-\frac{kV}{V_o}\left(\frac{\sigma_{\max}}{\sigma_0}\right)^b\right\} \tag{20}$$

where

$$k = \frac{1}{V}\int\left(\frac{\sigma}{\sigma_{\max}}\right)^b dV \tag{21}$$

is regarded as the stress homogeneity factor. Conventionally, the fatigue notch factor is the ratio of

unmatched to notched fatigue strength at the same probability of failure (usually 50%). Using equation 20, the probability of failure of unmatched specimen and a notched specimen will be the same when

$$\exp\left\{-\frac{k_s V_s}{V_o}\left(\frac{\sigma_{\max,s}}{\sigma_0}\right)^b\right\} = \exp\left\{-\frac{k_n V_n}{V_o}\left(\frac{\sigma_{\max,n}}{\sigma_0}\right)^b\right\} \tag{22}$$

where the subscripts *n* and *s* represent the respective value of the variable for notched and smooth (unmatched) specimens. The ratio of the smooth to notch fatigue driving force parameters (i.e., the stress amplitude) is used to define a new fatigue notch factor given as

$$k_f = \frac{\sigma_{\max,s}}{\sigma_{\max,n}} = \left(\frac{k_n}{k_s}\right)^{1/b}\left(\frac{V_n}{V_s}\right)^{1/b} \tag{23}$$

For smooth specimen that is loaded at a very low stress or strain amplitude in the HCF regime, the number of critically stressed grains (or elements) is very small. Thus for the life limiting case in which only one grain or element is critically stressed above the threshold, $V_s = V_e$ (i.e. volume of element or grain) and $K_s = 1$; thus Equation (23) becomes

$$k_f = \frac{\sigma_{\max,s}}{\sigma_{\max,n}} = (k_n)^{1/b}\left(\frac{V_n}{V_e}\right)^{1/b} = \left(\frac{1}{V}\int\left(\frac{\sigma}{\sigma_{\max,n}}\right)^b dV\right)^{1/b}\left(\frac{V_n}{V_e}\right)^{1/b} \tag{24}$$

However, if the materials contain some pores or inclusions, equation (23) must be used. It is important to state that Eqs. (23) and (24) can be used only if subsurface crack initiation is the failure process, if crack originates from the surface, then the volume parameter in this equation should be replace with the surface area.

5. Closed Form Solution for Fatigue Notch Factor

To resolve inelastic deformation at the scale of microstructure to facilitate next generation microstructure-sensitive notch root analyses inherently requires mesh refinement to the scale of microstructure, which is often several orders of magnitude finer than the scale of the component. Moreover, the kind of constitutive equations that must be used are often of advanced form and requiring rather sophisticated and time-consuming computational strategies to perform concurrent analyses at the component and notch root microstructure scales. Accordingly, direct application of multiscale finite element analysis is simply too computationally time consuming for practical microstructure-sensitive fatigue damage assessment of notched components under multiaxial loads. Thus, for practical engineering application, a more simplified and approximate model for fatigue notch factor is presented here based on closed form solution for stress distribution at the notch developed by Glinka using the Creager-Paris solutions of the stress field ahead of a crack. For a notch component with notch root radius ρ and stress concentration factor, k_t, the axial stress distribution along the notch root centre line is given as:

$$\sigma = \frac{1}{2}\left(\left(\frac{\rho}{x+\rho/2}\right)^{1/2} + \frac{1}{2}\left(\frac{\rho}{x+\rho/2}\right)^{3/2}\right)k_t S = \frac{1}{2}\left(\left(\frac{\rho}{x+\rho/2}\right)^{1/2} + \frac{1}{2}\left(\frac{\rho}{x+\rho/2}\right)^{3/2}\right)\sigma_{\max,n} \tag{25}$$

Finding the ratio of the stress amplitude to the maximum stress and substituting into equation (24) at x

= a_c (i.e., the critical distance) will allow the determination of an expression for the fatigue notch factor of the form

$$k_f = \left(\frac{1}{V} \int \left(\frac{1}{2} \left(\left(\frac{\rho}{a_c + \rho/2} \right)^{1/2} + \frac{1}{2} \left(\frac{\rho}{a_c + \rho/2} \right)^{3/2} \right) \right)^b dV \right)^{1/b} \left(\frac{V_n}{V_e} \right)^{1/b} \tag{26}$$

Assuming that the critical distance is constant for the notched component with a notch root radius ρ, Eq. (26) reduces to

$$k_f = \left(\frac{1}{2} \left(\left(\frac{\rho}{a_c + \rho/2} \right)^{1/2} + \frac{1}{2} \left(\frac{\rho}{a_c + \rho/2} \right)^{3/2} \right) \right) \left(\frac{V_n}{V_e} \right)^{1/b} \tag{27}$$

The above equation for k_f was derived using the fatigue damage process zone based on critical distance, probabilistic framework based on the weakest link, and the Glinka's closed form solution based on the notch root stress distribution. The expression in Eq. (25) has been shown to give a good prediction of the stress field for relatively blunt U-notches and be used over a distance of 3ρ from the notch root with an accuracy of approximately 7% [15].

6. Results and Discussion

The stress distribution obtained from the finite element analysis was used in determining the average k_f for the geometry using the proposed probabilistic framework based on Weibull's weakest link and extreme-value statistics. Also as a further validation of the proposed approach, the value of k_f was calculated using the closed form solution for fatigue notch factor in Eq. (27) and the result is compared to experimental results determined by R.A. Naik et al [15] as shown in Table 2. Both results are in agreement with the experimental results with minimal difference. The k_f determined using the Weibull's weakest link approach, when the loading ratio R =-1, is more accurate than for every other loading ratios tested.

Table 2. Comparison of measured and predicted K_f using FEM and closed form analysis

Test Case	K_t	Notch radius, **ρ** (mm)	Notch depth, h (mm)	R-ratio	Experimental average K_f	K_f using Weibull's weakest link	K_f using closed-form analysis
1	2.78	0.330	0.729	-1	2.79	2.73	2.66
2	2.78	0.330	0.729	0.1	1.80	1.89	1.88
3	2.78	0.330	0.729	0.5	1.75	1.82	1.84
4	2.78	0.203	0.254	0.1	1.71	1.86	1.80
5	2.78	0.203	0.254	0.5	1.74	1.83	1.83
6	2.78	0.127	0.127	0.1	1.98	2.05	2.01
7	2.78	0.127	0.127	0.5	1.65	1.72	1.77

Also, the radius of curvature at the notch root plays a vital role on the stress gradient at the notch. This effect is captured by the fatigue notch sensitivity factor q given in Equation 3. Figure 6 gives a plot of the notch sensitivity factor as a function of the notch root radius for the different load ratio. The

straight line plot represents the notch sensitivity factor calculated using the Neuber's formulation [7] given in Equation 28 where a_0 is a material constant taken to be 0.2 for Ti-6Al-4V [1]. The plot shows that the new approach and the closed-form solutions give more accurate result compared to the existing Neuber's formulation.

$$q = \frac{1}{1 + \sqrt{\frac{a_0}{\rho}}} \tag{28}$$

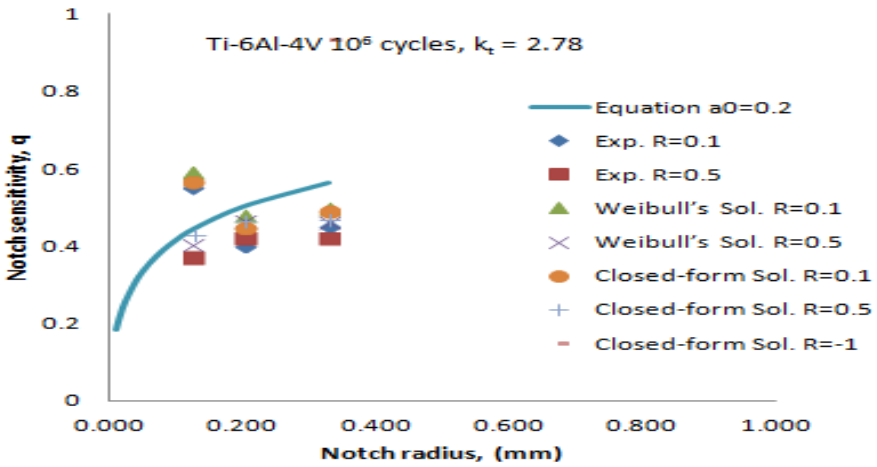

Figure 6. Notch sensitivity versus notch root radius for three notch sizes.

6. Conclusions

A probabilistic framework based on Weibull's weakest link extreme-value statistic that accounts for stress gradient at the notch root and the realistic microstructure of the material is presented. The fatigue notch factors, $k_{f,}$ estimated by this approach are compared with experimental k_f. The comparison shows that the proposed method accurately predicts the fatigue notch factor of Ti-6Al-4V for the different Load ratios applied to the specimen geometry analyzed. Also, k_f determined from a closed form solution of the proposed probabilistic approach validates the effectiveness of the proposed method. A plot of the notch sensitivity index against the notch root radius analyzed for the different load ratios as shown in Figure 6 shows that the proposed approach gives more accurate result compared to the existing Neuber's formulation.

A Prediction Model for Low Cycle Fatigue Crack Initiation under Axial Loading

Luoyang Ship Material Research Institute, Luoyang 471023, China

* Corresponding author: zhangyj309@163.com

Abstract: A prediction model for low cycle fatigue crack initiation was proposed, based on damage mechanics theory, which indicated the relation of equivalent value *d* of low cycle fatigue crack initiation to stress attenuation percentage $\triangle S/S$. Then, parameter *d* will be calculated if $\triangle S/S$ is given, and the corresponding cyclic life is initiation life of fatigue crack. To validate the model, a group of 10CrNiMo structural steel specimens with a round-section were tested through low cycle fatigue test controlled by constant strain under axial loading, and the results manifested that the model is dependable and applicable; and the error of *d* to really measured value is not more than 5.0%; when the total strain amplitude is 0.6%, *d* is close to 2.0mm and the initiation life is approximately 900 cycles, which is nearly 80% of the entire life.

Keywords: Low cycle fatigue, Crack initiation， Prediction model, Initiation life

1. Introduction

In engineering, a crack which can be observed through a microscope with a low magnification (10×～20×), usually was defined as crack initiation and its length is 0.13mm to 0.25mm [1,2]. In design, crack initiation was deemed as a range from 0.25mm to 2.5mm [3]. When a crack increases to a certain length such as 0.1mm, 0.5mm, or 1.0mm, relevant fatigue cycle is called initiation life of fatigue crack. In general, there are three methods to measure crack initiationi, replication technique, potential drop method and observation through a microscope with a long focal length. Basically, the three methods have a high precision, and can meet engineering requirements. But all of them are inconvenient in real application [4]. In the fields of crack initiation and life prediction, many scholars proposed several models based on different parameters, for examples, Manson-Coffin Model [5] beginning with macro-mechanics, Mesomechanics Model [6] to describe microcosmic dispersivity using macroscopic parameters, Probability Model [7] calculating crack initiation life taking microcrack bulk density as index and so on. Many problems appeared when above models applied in reality [8]. In this paper, a new prediction model for low cycle fatigue crack initiation was proposed, based on damage mechanics theory, by which equivalent value of crack initiation could be calculated in case of an assuming condition, and crack initiation life could be measured combining with some simple tests, which would provide some reference for engineering design.

2. A prediction model for low cycle fatigue crack initiation based on damage mechanics

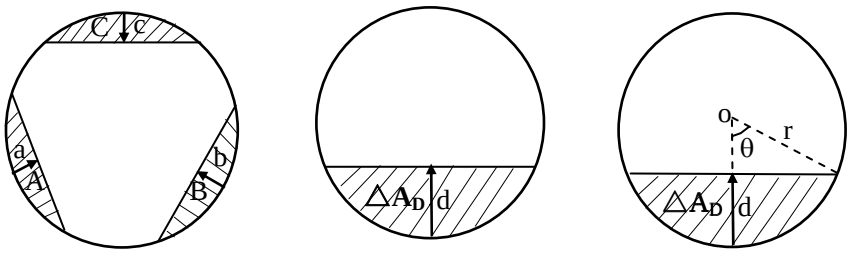
Damage mechanics is a subject studying evolution law of damage field of the deformable solid, including damage and its effect on mechanical properties of materials under action of outside factors such as load, changing temperature and corrosion and so on. Based on damage mechanics theory, a relation was deduced in literature [8] as follows:

$$\frac{\Delta A}{A}=\frac{\Delta S}{S} \tag{1}$$

where △A and △S were after damaged area, stress amplitude , accordingly.

Constant strain is admitted as control parameter generally, so low cycle fatigue is also called strain fatigue. Under cyclic action of constant strain, grains in material may come into microcracks because of repeated slips, which will damage the material. Simultaneously, effective area of the material will decrease gradually and capacity enduring the load may drop and nominal stress acted on the material will attenuate step by step. Supposing a crack or several cracks initiated, and damage effect produced by several cracks initiated in the same section or different sections is equivalent to one crack, then attenuation of the stress and the length of the crack should meet a certain mathematical relation. When cracks don't initiate, stress will keep constant; and cracks initiated and propagated to fracture the material, stress would drop to zero. That's to say, ratio of reduction of the specimen area perpendicular to the direction of the crack propagation to original specimen area should be equal to ratio of attenuation of the current stress to steady stress, that is Eq. (1). Reduction of the specimen area and length of the crack propagation should satisfy some mathematic relation, which would provide a basis of damage mechanics theory for setting up the expression of a equivalent value of crack initiation to stress attenuation. Attenuation of stress can be measured by a test, and the equivalent value of crack initiation be also obtained through the built expression, and corresponding cycle is called crack initiation life.

Literatures [9,10] indicated that several cracks initiated in the course of low cycle fatigue. It could be seen that several cracks sometimes initiated in the same section perpendicular to loading orientation, sometimes not from many tests. No matter one crack or several cracks initiated in the same section or not, damage effect should be deemed as that of one crack in one section. Figure 1 reveals above analysis. Parameters a, b and c are crack lengths located in one section or different sections, and parameters A, B and C are corresponding areas swept by above three cracks, see figure 1(1) for details. Damage effect produced by above three cracks or more equals to that by one crack *d,* with a corresponding swept area $\triangle A_{D,}$ see figure1(2). Figure1(3) shows the geometry relations of equivalent crack length *d,* its swept area $\triangle A_D$ and specimen radius *r,* and also is calculation model to predict crack initiation.



(1) (2) (3)

(1) Several cracks and corresponding swept areas (2) Equivalent to one crack and an area (3) Sketch of calculation model

Fig.1 Calculation model predicting crack initiation based on damage mechanics theory

From figure 1(3), some equations may be obtained:

$$\theta = \arccos\frac{r-d}{r} \tag{2}$$

$$\Delta A_D = r^2\theta - r(r-d)\sin\theta \tag{3}$$

$$d = r - \frac{r\theta - \pi\Delta A_D\theta}{\sin\theta} \tag{4}$$

From above analysis, ratio of reduction of the specimen area to original area $\Delta A_D/A_D$ should equal to ratio of attenuation of nominal stress to steady stress $\Delta S/S$, namely:

$$\frac{\Delta A_D}{A_D} = \frac{\Delta S}{S} \tag{5}$$

Based on above equations, when specimen radius r is determined (e.g. 5mm), the relation of equivalent length d of crack initiation and $\Delta S/S$ will be built. Through test data processed (see figure2), the following equation would be set up:

$$\frac{\Delta S}{S} = -0.1186d^3 + 1.7765d^2 + 4.1698d - 0.5006 \quad (R = 1) \tag{6}$$

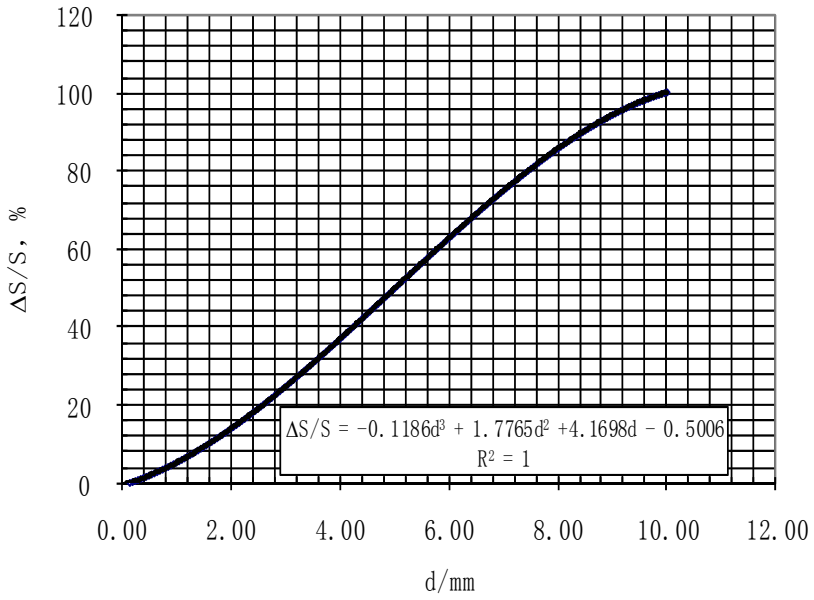


Fig.2 Relation curve and corresponding equation of △S/S-d

3. Correction for prediction model for low cycle fatigue crack initiation

Considering deviation of damage effect of one crack equivalent to several cracks in one section or several sections, damage coefficient λ (0～1) was introduced. Simultaneously, many factors including some measurement errors of attenuation of stress, areas swept by cracks and section distortion when specimen fractured and so on, which would directly influence calculation precision of equivalent crack length. Supposing calculating error is d_0 (a constant relevant to material), then expression (6) can be further amended:

$$\frac{\Delta S}{\lambda S} = -0.1186(d + d_0)^3 + 1.7765(d + d_0)^2 + 4.1698(d + d_0) - 0.5006 \quad (R = 1) \qquad (7)$$

From equation (7), we know, firstly, through a simple test, for each specimen, solve damage coefficient λ and material constant d_0, then, whatever equivalent length *d* of crack initiation is defined,

△S/S will be calculated .Vice versa, we can get *d* from the known ΔS/S and corresponding cycle is crack initiation life.

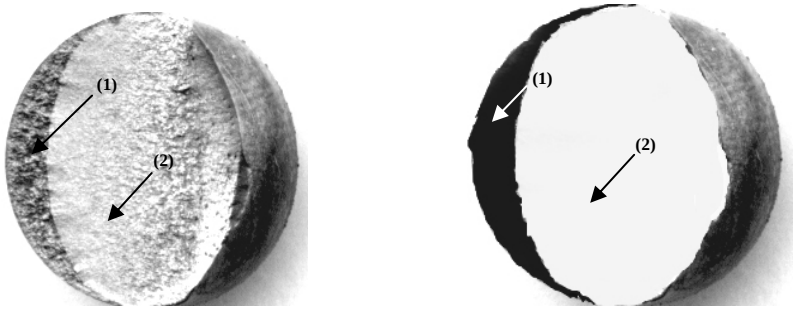
It could be seen from many tests, when ΔS/S reached 50% (corresponding equivalent crack length was 5mm), specimen fractured immediately. So, for formulas (6) and (7), the following boundary conditions will be satisfied: 0≤△S/S≤0.5, 0≤d≤r.

4. Verification of prediction model for low cycle fatigue crack initiation

In order to ensure correctness of the built prediction model, related test were carried out, with the following test conditions: four pieces used with series of number 1 to 4, constant strain amplitude 0.6%, test frequency 0.2Hz; when percentage of stress attenuation increased to 5.33%, 9.35%, 14.0%, 19.17% respectively (corresponding equivalent crack length was 1.00mm, 1.50mm, 2.00mm and 2.50mm accordingly), test ended. Afterwards, the tested specimens were heated about 30 minutes at a temperature from 300℃ to 400℃ and then fatigued again, and finally all specimens were fractured into two parts. Adopting PHOTOSHOP tool software, daubing fatigue crack propagation district black and re-fatigue and fractured distracts white, see figure 3(a) and (b).

Figure 3 showed that the specimen fracture appearance had different degree distortion, and measured area swept due to crack propagation was not uniform with the real area by reason of measurement error. So, it is necessary to correct the prediction model.

Percentage of black distract to the entire fractured area was measured by OLYCIAm3 Image Analysis System, and equivalent crack length was calculated per equation (7). Relative errors of real crack length to calculated crack length from prediction model, λ value of each specimen, and corrected value d_0 (difference between average of real equivalent crack length and that from prediction model) were listed in table1.



(a) before (magnification 5×) (b) after (magnification 5×)

(1) District of fatigue crack propagation (2) Districts of re-fatigue and fracture

Fig.3 Fracture appearance of the specimen processed before and after

Tab.1 Comparison of real value and calculated value from prediction model of equivalent length of crack initiation

Spec. No.	Specimen diameter /mm	ΔS/S /%	Damage coefficient λ	Measured $\Delta A_D/A_D$ /%	$\triangle A_D$ /mm^2	Calculated crack length /mm	Constant d_0/mm	Real crack length /mm	Corrected crack length /mm	Relative error /%
1	10.07	5.33	0.33	16.32	12.82	1.0	1.10	2.20	2.10	4.39
2	10.08	9.35	0.47	19.85	15.59	1.5		2.54	2.60	-2.46
3	10.07	14.00	0.53	26.56	20.86	2.0		3.15	3.10	1.61
4	10.10	19.17	0.57	33.545	26.35	2.5		3.74	3.60	3.72

Table 1 shows that parameter d_0 really is a constant. Although there is some difference between average of real equivalent crack length and that from prediction model, relative error is not more than 5.0%, which manifests that the prediction model is reliable and applicable.

5. Predetermination crack initiation life by means of the prediction model

Generally, for low cycle fatigue test using smooth specimen, specimen will fail quickly once crack initiates, due to larger stress and strain acted on the specimen. For most of metallic materials, crack initiation life will dominantly take up 80% or so of the entire life. It is very difficult to directly measure crack initiation life through normal low cycle fatigue tests using smooth specimen. In order to investigate applicability of the prediction model, relation of crack initiation life to entire life was studied below.

Simple-specimen-method was employed in order to avoid data distribution. Amount of cycle, corresponding to percentage of stress attenuation which relates to some equivalent crack length, is crack initiation life of the equivalent crack length. Different literatures defined different crack initiation, and it is difficult to determine one proper equivalent value for steel such as 10CrNiMo structural steel, which will rely on concrete test. In this paper, three of specimens were performed, with series of number 5 to 7, and percentage of stress attenuation was supposed to 0.65%, 2.0%, 5.33%, 9.35%, 14.0%, 19.17%, 20%, 30% and 50% from a low-level to a high-level, recording relevant repeated cycles. See figure 4 for final test results.

Curve of $\triangle$S/S-N in figure 4 indicates that with cycle increasing, percentage of stress attenuation is improved, and when the cycle is close to 800 to 1000 cycles, specimens fail quickly with a high speed. Based on above analysis, when repeated cycle attains to 800 to 1000 cycles, it is suitable taking corresponding equivalent crack length as crack initiation for 10CrNiMo steel. In the range from 800 to 1000 cycles, $\triangle$S/S of the three specimens are all 5.33% and corresponding equivalent length of crack initiation is 1.0mm. Considering of correctness of the prediction model, real crack initiation should be as 2.1mm. See table 2 for data analysis of three specimens.

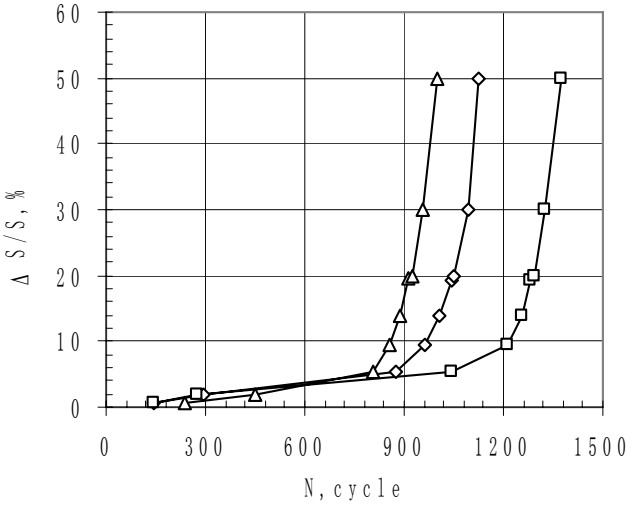


Fig.4 Relations of percentage of stress attenuation to cycle N

Table.2 Data of crack initiation and initiation life

Specimen No.	Percentage of stress attenuation ΔS/S， %	Crack initiation length a_0/mm	Crack initiation Life N_i	Entire life N	N_i/N /%
5	5.33	2.10	808	1003	80.6
6	5.33	2.10	876	1228	77.7
7	5.33	2.10	1044	1372	76.1
average	5.33	2.10	909	1168	78.1

Table 2 indicate that equivalent value of crack initiation of the structural steel 10CrNiMo is close to 2.0mm and initiation life is approximately 900 cycles, which is nearly 80% of the entire life.

6. Conclusions

(1)Any equivalent value of crack initiation, corresponding percentage of stress attenuation, can be calculated and crack initiation life be predetermined, according to prediction model for low cycle fatigue crack initiation proposed by damage mechanics theory, combining with some simple tests.

(2)Relative error between average of real equivalent crack length and that from prediction model is not more than 5.0%, which manifests that the prediction model is reliable and applicable.

(3) When the total strain amplitude is 0.6%, equivalent value of crack initiation of the structural steel 10CrNiMo is close to 2.0mm and initiation life is approximately 900 cycles, which is nearly 80% of the entire life, on the basis of prediction model and related tests, which will be referred to in engineering application and design.

Abstract A cyclic tension and alternating bending tests of 12Cr1MoV and 30CrMnSiNi2 steels specimens in as–supplied state and after surface nanostructuring by Zr^+ ion beam have been carried out. Distinctions in formation of strain induced relief, as well as the cracking pattern of modified surface layer are illustrated by methods of optical microscopy and interferential profilometry. Changes to occur in subsurface layer are characterized by means of nanoindentation and fractography (scanning electron microscopy) of fracture surfaces. The description of differences of deformation behavior is carried out with use of the multiple cracking concepts.

Keywords strength, nanostructuring, multiple cracking, deformation, fracture.

1. Introduction

The majority of products and machine parts during their exploitation experience the impact of variable loads, which can give rise to their fatigue fracture. In doing so regardless the long history of study the problem of fatigue fracture and approaches to increase fatigue durability are of substantial importance [1]. Surface modification is an effective way both to protect and to improve the mechanical properties of structural materials. On the other hand, under mechanical loading the distinction of elastic modules of a modified surface layer and adjacent bulk material causes the stress concentrators to occur, whose relaxation may give rise to localized development of plastic deformation or fracture [2]. Under cyclic loading such distinction of the properties brings to microcracking within strengthened surface layer, to act as structural micronotches. Therefore, the choice of modes and options for modifying the surface layer should be a compromise between strength/ductility of this layer and its thickness (this as well depends on several other factors, including adhesion etc.).

Ion implantation technique for a long time is widely used for industrial applications and is an extensively studied process. Recently, with the use of vacuum arc ion sources the modes of surface layer nanostructuring which allowed modifying surface layers with a thickness of some microns that is several times higher in contrast with ion implantation at conventionally used regimes were realized. Such nanostructured surface layers are not coatings yet, but no longer can be called ion-implanted ones [3]. Study of influence of such layers on fatigue life-time of structural steel specimens is of particular interest due to the possibility of simultaneously improvethe fatigue durability and wear resistance. To study the influence of surface layer nanostructuring of 12Cr1MoV and 30CrMnSiNi2 steels by Zr^+ ions on the fatigue durability increase is the purpose of this work.

2. Materials and research methods

Two types of steel were used in the current research for Zr+ ion beam surface modification: heat resistant ductile 12Cr1MoV steel intended for operation at high temperatures as well as 30CrMnSiNi2 high strength steel used for manufacturing of heavy-loaded machine parts [4]. The choice of 12Cr1MoVsteel for research was caused by the fact that the steel experiences no structural changes at the temperature at which the process of surface layer nanostructuring by ion beam is performed. Besides, the steel is quite ductile, so the study of processes of localized deformation and fracture under cyclic load provides much more evidence at lower rate of deformation processes.

High strength 30CrMnSiNi2 steel is used for manufacturing responsible and highly loaded parts that experience action of alternate loadings. Increasing of fatigue durability of this steel is a complex process since its low heat resistance and high level of alloying. Using the experience of 12Cr1MoV steel treatment new regimes for the surface nanostructuring were determined that make possible to slightly decrease mechanical properties while to enhance substantially fatigue durability.

Flat specimens of size 70×10×1 mm for 12Cr1MoVsteel and 70×8×1 mm for 30CrMnSiNi2 steel were made from a peace of a pipe by electro-spark cutting. For running fatigue tests the holes of 2 mm were drilled as a stress concentrator in the specimens at a distance of 50 mm from one of its edges. For static tension tests specimens in the shape of dog-bone with gauge length of 20×5×1 mm were also used, as well as ones with the stress concentrator (similar to the specimens for fatigue tests). The specimens were mechanically polished and divided into 2 groups: a) in initial state (without treatment) and b) specimens with a nanostructured surface layer by zirconium Zr^+ ion beam (after ion beam treatment). In the initial state steel 12Cr1MoV has the ferrite-pearlite structure with a characteristic grain size of 30 ÷ 50 μm.

Ion nanostructuring of surface layer of the steel specimens was carried out with a help of high current vacuum arc source of metal ions UVN-0.2 "Quant". Images of specimen's surface were obtained by means of optical microscopes Carl Zeiss Axiovert 25 CA and EPIQUANT, as well as scanning electron microscope Carl Zeiss EVO 50.Surface profilometry were performed with the help of Optical Interferometer of white light NewView 6200. X-ray phase analysis was conducted by X-ray difractometer DRON-7.

Tests on static tension were performed using electromechanical testing machine Instron 5582 while for the cyclic tension using servo hydraulic testing machine Biss UTM 150 were employed. Surface micrographs of specimen's were captured by Canon D550 digital photo camera during the process of fatigue tests. Nanohardness of specimens was measured by Nanotest (Micromaterials Ltd., UK).

2. The results of the experiments

2.1. Study of the modified surface layer of 12Cr1MoV steel

2.1.1. Electron-microscopy study

The structure of the surface layer of the steel in the initial state is represented by large ferrite grains >1 μm with inclusions of cementite (Fe_3C), whose average size makes 120 nm (fig. 1, a). Surface

layer structure after nanostructuring by the beam of Zr^+ ions is represented by phases of $FeZr_3$, $FeZr_2$, as well as ferrite grains. The average size of the grains in the surface layer is 100-150 nm (fig. 1, b-d).

2.1.2. Specimensnanoindentation

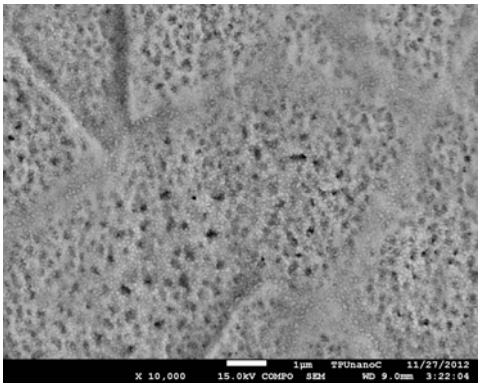
Strength properties of the specimens under study before and after the treatment were evaluated by nanoindentation to penetrate at the depth of 200 nm. It is revealed that due to nanostructuring the hardness of the surface layer increases approximately by 1.5 times. At the same time elastic modulus is reduced almost by 2 times.

2.1.3. X-raydiffraction

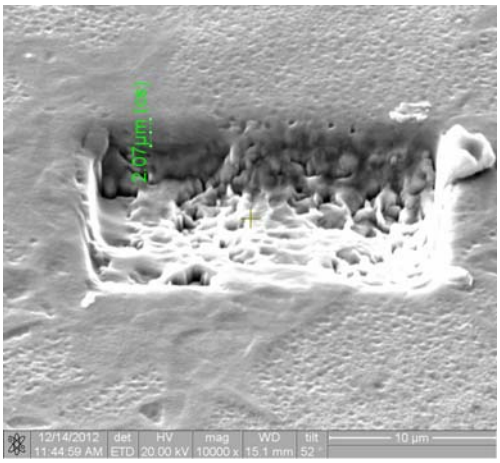
For specimens in the initial state structure is primarily represented by the α-Fe iron, whereas after nanostructuring the formation of intermetallic phases of the system Fe-Zr: $FeZr_2$ and $FeZr_3$, as well as the carbides ZrC into the subsurface layer takes place. Structural-phase micro-analysis of the specimen surface with nanostructured surface layer was performed. The data indicate that the overall content of zirconium in the subsurface layer of the specimen makes about 14.2 %.

2.2. Study of the modified surface layer of 30CrMnSiNi2 steel

Investigations of surface layer of 30CrMnSiNi2 steel specimens performed with the use of SEM have allowed to reveal nanosized particles in the modified layer (fig. 1,a). Average size of the particles made 80-10 nm. The particles are non-uniformly distributed over the specimen surface. The thickness of the modified surface layer was also estimated to show the depth of 2 μm (fig. 1,b). X-ray microanalysis has shown that iron in the layer has α-structure, while Zr-containing phases are as well revealed there.



a)



b)

Figure 1. SEM-micrographs of surface nanostructured specimen

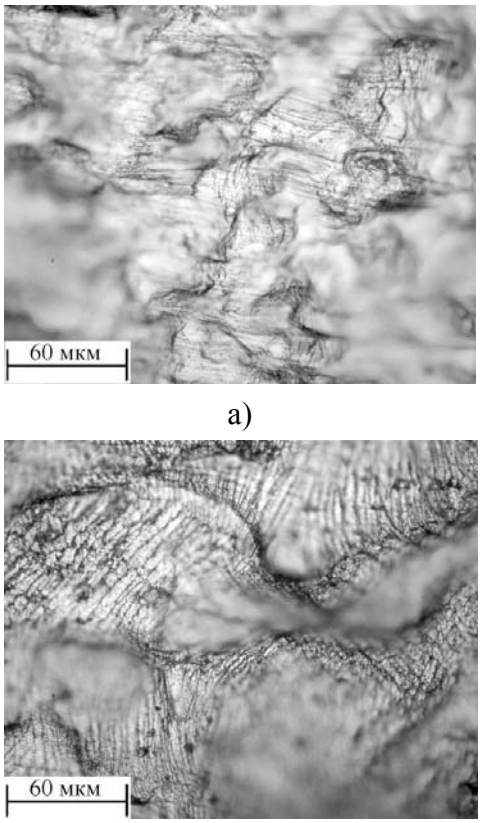
2.3. Static tension tests

2.3.1. Mechanical properties

During tensile tests the loading diagram of 12Cr1MoV steel for dog-bone shape specimens was registered. It was found that for untreated specimens the presence of sharp yield point (yield tooth) is evident like it takes place for low carbon steels. Yield point of such specimens makes $\sigma_{0.2}$= 270 ± 25 MPa, ultimate strength –σ_u= 494 ± 36 MPa and elongation – ε = 20 ± 3 % which is close by values to the reference book data for this steel [4]. After the surface nanostructuring the value of ultimate strength is increased up to σ_u = 570 ± 17 MPa while elongation becomes lower ε = 16 ± 0.7 %. In doing so, there is no formation of the yield plateau at the diagram of the processed specimens.

2.3.2. Optical microscopy

Microscopic investigations of specimens surface near the area of the main crack at a certain distance from the fracture edge were performed (fig. 2). It is found that the specimen without surface treatment has the pronounced grain strain induced relief (fig. 2, a). At the same time undermore detailed observationit is seen that the surface of the nanostructured layer has small microcracks characterized by variation in their orientation in the modified layer (fig. 2, b). Whether, presence of the nanostructured layer on the surface of 12Cr1MoV steel hinders the formation of the grain relief that results in lower surface roughness of such specimens. The fracture surface of specimens after treatment shows signs of ductile fracture except for surface layer where the fracture was brittle. It is obvious that the thickness of the layer is not strictly constant which is manifested in the form of varying width of subsurface layer characterized by brittle fracture.



a)

b)

Figure 2. Surface images of failured specimens at static tensile tests: a) specimen without treatment; b) after nanostructuring surface; a), b) optical images, axis of loading is oriented horizontally

2.4. Cycling tension tests

2.4.1. Low-cycle fatigue (LCF) 12Cr1MoV

Results of cyclic tension tests have shown that under LCF the number of cycles prior to the fracture of the specimens with nanostructured surface layer is increased by 3 times. In doing so, the time before main crack initiation is increased approximately by3 times. The graphs of dependence of the main crack length versusthe number of cycles were plotted. It is clear that for the treated specimen later origination and more slow development of the main crack in the specimen is characteristic feature as compared with oneswithout the treatment. For the latter the rate of crack growth makes 0.085 μm/cycle while for one with nanostructured surface layer it makes 0.023 μm/cycle which is lower by more than 3.5 times. Thus, a modified surface layer effectively hinders the fatigue crack origination. In doing so the number of cycles before the main crack appearance is enlarged by 3 times and reduces the rate of its growth.

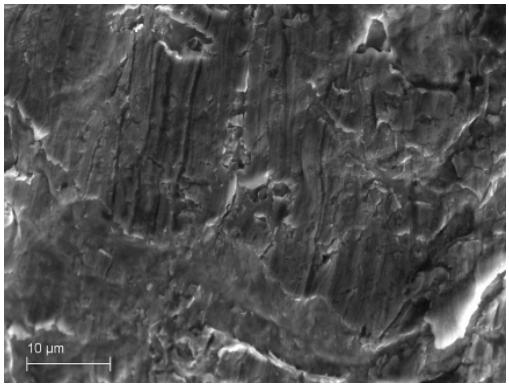
2.4.2. High-cycle fatigue (HCF) 12Cr1MoV

The results of tensile tests under HCF showed that the number of cycles prior to the fracture of specimens with nanostructured surface layer is increased by 2 times.The number of cycles before the crack nucleation is increased approximately by 2 times. Based on analysis of optical images the

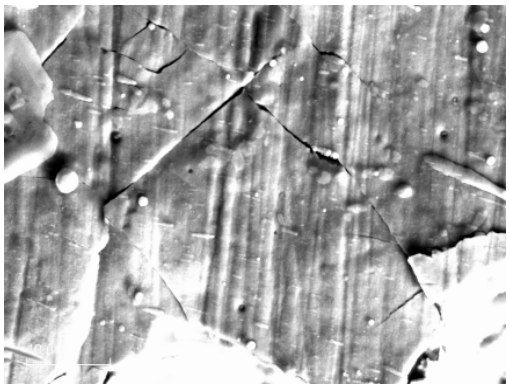
dependence the crack length on the normalized and the absolute number of tension cycles were calculated and plotted. Much like to the case of LCFat comparisonthe graphs of specimens without treatment and after the surface nanostructuring differences in time of the main crack origination, as well as the rate of its development becomes visible. Crack growth rate of the specimens without treatment made0.03 μm/cycle, while for one with the nanostructurized surface layer its rate is reduced by 2 times that can be estimated as 0.015 μm /cycle.

2.4.3. Fractography study of cyclically fractured specimens 12Cr1MoV

Micrographs of specimens fractured under cyclic tensile were obtained using scanning electron microscope at high magnification (fig. 3). Micrographs gained in fatigue crack growth region (fig. 3, b) also point to the brittle pattern of the nanostructured surface layer fracture being compared with untreated specimens (fig. 3, a). It is seen that the surface layer of the nanostructured specimen is damaged by multiple cracks that does not bring to noticeable deformation localization. According to the author's opinion, multiple cracking allows to redistribute efficiently the loading and minimize the effect of the powerful stress macroconcentrator operating in the vicinity of the main fatigue crack tip.



a)



b)

Figure 3. SEM micrographs for the area of fatigue crack growth found at the flat face failured at cyclic tension tests; (a) specimens without treatment; b) with nanostructured surface layer; axis of loading oriented vertically

2.4.4. High-cycle fatigue (HCF) 30CrMnSiNi2

The tests on cyclic tension of 30CrMnSiNi2 steel specimens have shown that surface nanostructuring by Zr^+ ions gives rise to double-or-triple time increase of fatigue durability. In doing so nucleation of fatigue crack in specimens with the surface modification happens later, while rate of its growth is noticeably slower in contrast with non-treated specimens.

2.5. Test on cyclic alternating bending

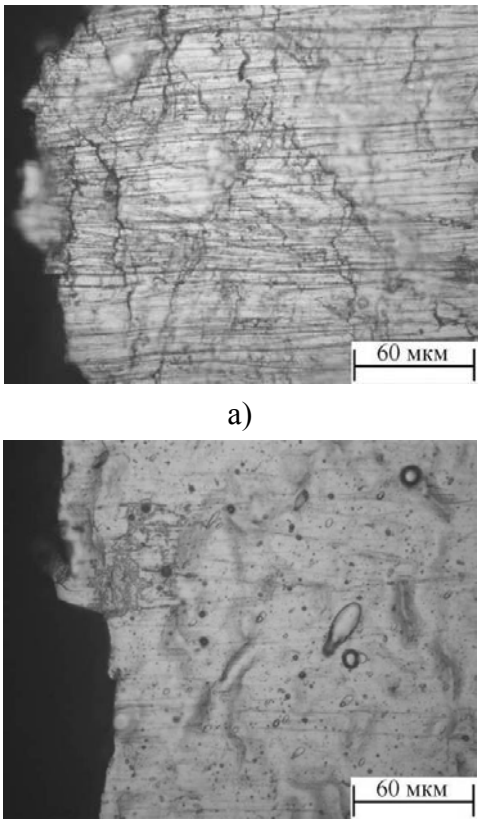
According to the testingdata the fatigue life-time of specimens under cyclic alternating bending is increased due to nanostructuring of a surface layer by~ 2 times. The series of optical images were used for plotting the graphs to characterize dependence the crack length versus the number of loading cycles. At cyclic bending the main crack originates nearly at the same time for both types of specimens but has significant differences in thepropagation rate. Crack growth rate forthe untreated specimen was 0.05 μm/cycle while for the specimen with modified surface layer it made 0.024 μm/cycle. Thus, it is shown that nanostructuring of surface layer by ion beam to slow the rate of fatiguecrack growth by about 2 times.

2.5.1. Optical observation of strain induced relief

Images of surfaces of both type specimens after the different number of cycles before fracture to cause distinction in the formation of strain induced relief are given in fig. 4. One can see formation of manifested thin folds (fig. 4,a) located close to the fracture area (region of maximum curvature) in the specimen without treatment which shows an intensive deformation development in this area. Most likely their presence contributes to a rapid propagation of fatigue crack in this specimen. Reason of formation of these folds is apparently related to the testing scheme that governs periodical application of tensile and compressive stresses. Mechanism of material deformation for this case is similar to the corrugation formation which is formed as a result of greater deformation in the subsurface layer. In the nanostructured layer the number of such folds is slightly visible and deformation relief is smoother and changeable more lightly (fig. 4, b).

The analysis of surface roughness of failured specimens in the fracture area was carried out with a help of optical interferential profilometer. According to obtained values of roughness parameter R_a the surface roughness of the specimen without treatment is more than 1.5 times higher in comparison with one for the specimen with nanostructured surface layer.

During the test, in the specimen without the treatment clearly pronounced microcracks are formed along the grain boundaries and the main crackis more clearly manifested and propagates just along the microcracks. The specimen after the treatment has the number and size of the microcracks noticeably smaller and the main crack develops to a less extent. More detailed view of the main crack for specimen without treatment testifies for the fact that it is developed intensively not only on the surface, but into the bulk of the specimen as well. The main crack in the nanostructured specimen is less pronounced that could indicate that it develops mainly in the modified surface layer which hinders its spreading into the bulk of the material. This may cause a reduction in growth rate atmain fatigue crack propagation.



a)

b)

Figure 4. Optical micrographs to illustrate strain induced reliefonthe surfaceofspecimens: a) without treatment; b) withnanostructured surface layer

3. Discussion of results

The first effect of the surface layer nanostructuring which is to be stressed is the noticeable increase of flowstress with a ratherlow decrease of ductility. Traditionally, ion beam treatment is accompanied by the formation of a layer with thickness up to 0.1 micron, whereas under the treatment used the thickness of modified layer is estimated as 2 μm (according to the data of optical profilometry of the cracked layer) up to 10 μm (according to data of the scanning electron microscopy at observation of the fracturesurface after fatigue fracture).In doing so, presence of multiple cracksin the modified layerin the vicinity of neck exerts no significant impact on the reduction of plasticity due to the small thickness of the modified layer,as well as realization of multiple cracking. As a result, none of the cracks becomes the main oneand plastic deformation of the composition is determined mostlyby the development of plastic flow in the ductile material of the substrate.

The following key result is associated with notable changein the character of the localized plastic deformation development in the subsurface.It is shown that the layer to have the 1.5 times increased hardness and thickness of several microns can significantly change the pattern of the deformation relief formed. At low strain of the substrate (for example, at static tension out the neck area) deformation relief on the surface almost is not formed while in the region of intensive development of plastic deformation the size of strain induced relief elements is noticeably bigger than that in specimens without the treatment. This result is consistent with data on the cyclic bending tests

where during the process of cyclic loading the modified layer behaves much like a thin polymeric film placed on the water surface which is manifested both in dumping the deformation development and remarkable smoothing reliefto form at the specimen's surface. The hindering formation of strain induced relief under tests by another scheme (cyclic tension) when the surface relief to a large extent determines the origin of the main crack brings to increasing by more than twice the time period prior to origin of fatigue crack in the case of the ion beam modification.

Of particular interest in the light of the results obtained is observed difference in the character of the fatigue fractureunder cyclic tension and bending. It should be reminded that in the first case the crack originwas fixed at cyclic deformation not less than 0.75 N_F (the total number of loading cycles). At the same time, under alternating bending tests the main crack is already initiated at cyclic load of 0.15-0.2 N_F which in absolute terms corresponds to the same number of bending cycles of the non-treated specimens and ones with modified surfacelayer. Thus, for the case of cyclic bending the main crack in the specimen without the treatment originated very early but the rate of its growth was rather low in contrast with one under cyclic tension tests. This result, in principle, can be quite simply interpreted, because under the cyclic bending a surface layer is subjected to the periodic effects of maximum tensile and compressive stresses. Therefore, presence of the nanostructured layer on the surface hinders noticeable delay the origination (but not propagation!) of the crack.

However, its subsequent growth is realized significantly slower that was interpreted a result of fewer microcracks arising along the grain boundaryin the specimen without treatment, while the nanostructured layer hinders the formation of microcracks and, consequently, the rate of the crack growth. Another factor that may have a significant impact on the character and the rate of the origination and propagation of the crack is its depth. Despite the fact that in the work direct measurements of the depth of a forming fatigue crack was not carried out but judging by the size of its opening the depth of a crack in a specimen of the initial state should be noticeably higher, which in it turn should bring to its more rapid growth.

In contrast, under cyclic tension test a crack is originated sufficiently later that could be associated with roughly equal distribution of stresses through the cross section. As a result, it is the deformation relief of surface that can be a key factor in terms of origin of the main crack. A visible hindering in its formation has led not only to a multiple increasing of fatigue life-time of nanostructured specimens but also significantly slower rate of the main crack propagation.

It is proved by the notable difference in the rate of its propagation which under LCF (when influence of processes of localized plastic deformation is dominant) amounted up to 3.5 times (nanostructured layer hinders the development of plastic deformation), while under HCF when crack growth is governed by dominant mechanisms of the brittle fracture, the difference in the rate of the crack growth made two times.

In conclusion, one should point the role of multiple cracking processes, especially under conditions of high ductility of the substrate. In our view, the greater contribution to improving fatigue durability is associated with suppression of plastic deformation processes by nanostructured layer of higher strength causing substantial delay of the moment of the fatigue crack initiation. Noticeably smaller contribution to increasing the fatigue life-time is associated with the processes of multiple cracking. At the same time, usingmaterials of higher strength in contrast with substrate, as well as greater thickness of a coating will result in its cracking with their fast coalescence into the main one

resulting in a substantial reduction of fatigue durability of "coating-substrate" compositions.The combination oflow thickness of themodified surface layer and the ratio of the elastic characteristics compared with more ductile substrate material with high plastic deformations (for instance, in the area of a neck, or plastic tension under cyclic bending) has led to a formation of the system of multiple crackswhose orientation is not always in line with the normal to the direction of the external load.This is a fact that allows us to discuss the thesis of multiple cracking as one of the ways to improve the fatigue durability of "coating-substrate" compositions.

4. Conclusion

A study of structure and deformation behavior under static and cyclic tension and alternating bending the specimens of heat resistant 12Cr1MoVsteel subjected to surface layer nanostructuring by zirconium ion beam was performed. It is shown that ultra-dispersed particles of zirconates with the size about 100-150 nm were formed as a result of such treatment in a subsurface layer with a thickness up to several microns. Increase of strength properties by 15 % and decrease elongation before fractureby ~ 19 % is fixed due to thistreatmentat the static tensile.

It is found that the formation of the nanostructured surface layer increases the fatigue durability by 2-3 times at cyclic tension tests. The authors associate this with the delay of time the main crack initiationdue tohindering in deformation relief formation which play the key role in propagation of a crack.

At cyclic alternating bending the main crack origination in specimens of both types happens at almost equal numbers of cycles that is associated with the periodic occurrence in the surface layer of tensile and compressive stresses. However, at a subsequent stage the growth rate of the main crack is differing approximatelyin 2 times because of the nanostructured surface layer hinders microcracks origin on the grain boundaries of the substrate. This result is consistent with data of distinction comparison for both fatigue crack growth rate at the cyclic tensile and bending. For the second case, the growth rate is several times less.

The influence of multiple cracking on improving fatigue durability of specimens under study is discussed. It is shown that in the area of the main crack (predominantly under cyclic tensile) the finite length microcracks whose orientation does not always coincide with the direction of normal to the axis of the applied load are formed. This fact may be the manifestation of the effect of channeling plastic shears in the substrate material.

Effects of Short-Time Duplex Heat Treatment on Microstructure and Fatigue Strength of Ti-6Al-4V Alloy

Satoshi Tanaka[1,*], Tatsuro Morita[1], Kosuke Shinoda[1]

Abstract This study was conducted to investigate the effects of short-time duplex heat treatment on the microstructure, mechanical properties and fatigue strength of α+β titanium alloy Ti-6Al-4V. The duplex heat treatment was composed of short-time solution treatment (1203 K, 60 s) and short-time aging (753-903 K, 40 s). The first heat treatment transformed a part of prior β phase to acicular α' martensite phase. The second heat treatment precipitated fine α phase in metastable β phase. These change in microstructure increased the hardness of prior β phase. At the same time, the tensile strength and fatigue strength greatly improved without reduction in ductility and their maximum improvement rates reached 29 % and 22 %, respectively.

Keywords Ti-6Al-4V Alloy, Short-Time Duplex Heat Treatment, Microstructure, Mechanical Properties, Fatigue Strength

1. Introduction

Ti-6Al-4V alloy is a typical α+β titanium alloy possessing high specific strength (tensile strength/density) and excellent corrosion resistance, and has been widely used in the aerospace industry. For example, this titanium alloy is used to fix CFRP components in the airplanes recently developed because of its high electric corrosion resistance as well as high specific strength [1]. Ti-6Al-4V alloy occupies more than 50 % of the titanium market in the USA [2]. Accordingly, further improvement in the strength of this titanium alloy will have a great impact.

The strength of Ti-6Al-4V alloy is improved by controlling microstructure through heat treatment. Conventional heat treatment for titanium alloys is solution treatment and aging [3, 4]; however, it needs relatively long hours. In the previous study, one of the authors showed short-time solution treatment (1173-1263 K, 60 s) improves the tensile and fatigue strengths of Ti-6Al-4V alloy. Moreover, the above heat treatment was combined with short-time aging (753-953 K, 40 s). This duplex heat treatment further improved the tensile strength without reduction in ductility [5-8].

Although fatigue strength of metals is usually related to tensile strength, the fatigue strength of Ti-6Al-4V alloy markedly depends on the microstructure [9]. For the newly developed heat treatment, therefore, a detailed study was needed to investigate its effect on the fatigue strength.

From the above back ground, this study comprehensively investigated the effects of the short-time duplex heat treatment on the microstructure, mechanical properties and fatigue strength of Ti-6Al-4V alloy. To accumulate data, we conducted the metallographic examinations such as the optical observation of microstructure, TEM (transmission electron microscopy) observation and electron diffraction. Furthermore, the hardness measurement, tensile test and fatigue test were performed.

2. Materials and Experimental Procedures

Table 1 shows the chemical composition of Ti-6Al-4V used in this study. The material was supplied as round bars (diameter: 14 mm) and machined to the three specimen shapes shown in Fig. 1. For the short-time solution treatment, the specimens were kept at 1203 K for 60 s and quenched.

Hereafter, this heat-treated material is called "STQ material". In the short-time aging, STQ material was kept at 753, 803, 853 and 903 K for 40 s and air-cooled. They are called "STA materials". For comparison, the untreated material was also prepared.

The test sections of the button specimens (Fig.1 (a)) were polished to mirror surfaces with emery papers and alumina powder. The button specimens were used in the observation of the microstructure and hardness measurement. The test sections of the tensile and fatigue specimens (Fig. 1 (b), (c)) were polished with emery papers and electro-polished to mirror surfaces.

For TEM observation, thin small disks (diameter: 3 mm, thickness: 50 μm) were prepared from STQ and STA materials. The observation regions were polished with alumina powder and finally thinned by ion milling. Electron diffraction patterns of STQ material were obtained at the same positions where the microstructure was observed.

In the hardness measurement, a super micro-Vickers hardness tester with a CCD camera was used. The average hardness was measured under the test force of 2.94 N, and the hardness of α phase and prior β phase was measured under the test force of 19.6 mN. The tensile test was conducted in air at room temperature. The plane-bending fatigue test was performed under the conditions of frequency of 33 Hz and stress ratio R=-1 in air at room temperature. After the fatigue test, crack initiation sites were observed on the fracture surfaces by SEM (scanning electron microscopy).

3. Results and Discussion

3.1. Microstructure

Figure 2 shows the microstructures of the untreated, STQ and STA materials, and Fig. 3 shows the microstructures of prior β phase observed by TEM. Figure 3 includes the electron diffraction profiles of STQ material. Figure 4 shows a schematic illustration to explain the change in microstructure with the duplex heat treatment.

In the untreated material (Fig. 2(a)), a lot of small dark points correspond to β phase, and the

other bright regions are equiaxed α phase. In STQ material (Fig. 2 (b)), isolated regions are α phase and the regions surrounding α phase are prior β phase. As seen in Fig. 2 (b), the volume fraction of prior β phase increased with STQ treatment [5]. At the same time, a part of prior β phase was transformed to acicular α' martensite (Fig. 3(a)); however, the result of the electron diffraction showed the existence of metastable β phase. This point is important to think about the ductility of STQ material because strain-induced transformation can arise in metastable β phase.

Although the volume fraction of prior β phase was unchanged with the subsequent short-time aging, the inside of prior β phase became dark with increasing the treatment temperature (Fig. 2 (c)). This change in etching degree meant that metastable β phase was decomposed into fine α phase and stable β phase.

The change in microstructure with the duplex treatment was summarized as follows (Fig. 4): the untreated material was composed of α phase and stable β phase. Since the volume fraction of prior β phase increased with the short-time solution treatment, concentration of vanadium which is a β stabilizer decreased in prior β phase. As a result, acicular α' phase was generated in prior β phase through quenching. The short-time aging decomposed a part of remained metastable β phase into fine α phase and stable β phase during. The decomposition was accelerated by increasing the aging temperature.

3.2. Hardness and mechanical properties

Figure 5 shows the changes in the average hardness, hardness of α phase and prior β phase with the duplex heat treatment. Figure 6 shows the changes in the mechanical properties.

As shown in Fig. 5, the hardness of prior β phase was significantly increased by STQ treatment due to the formation of α' phase, although the hardness of α phase was almost unchanged. As a result, the average hardness also increased. The subsequent short-time aging generated fine α phase, so that the hardness of prior β phase further increased and it reached the maximum value at 803 K.

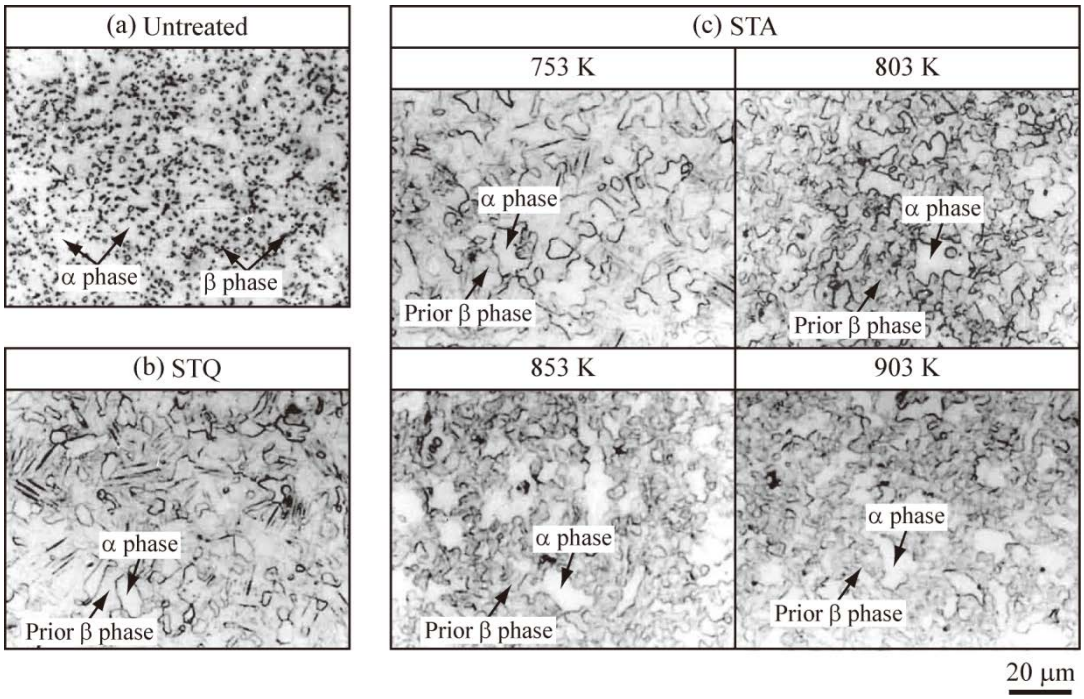

Figure 2 Microstructures optically observed after etching.

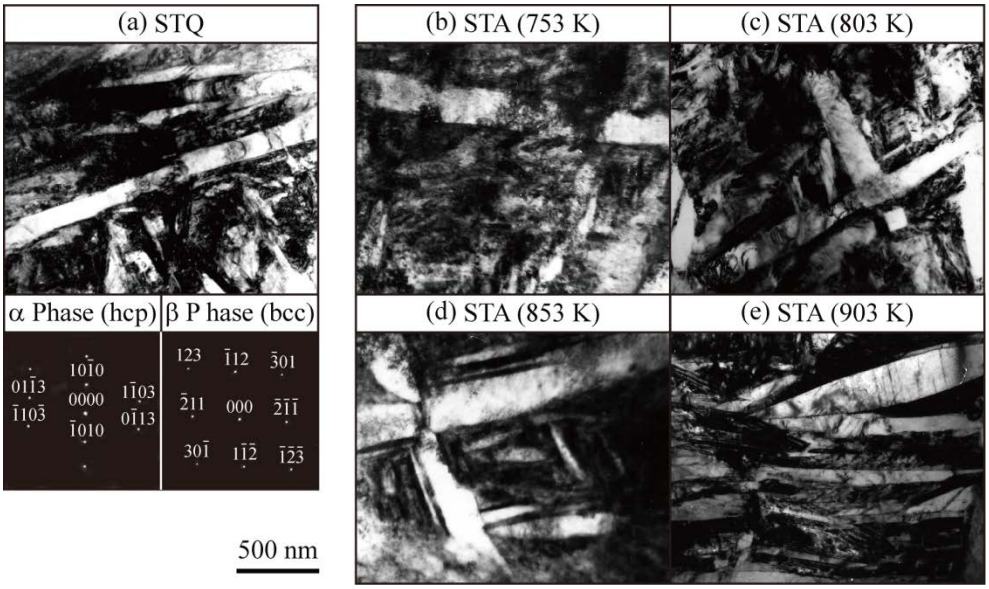

Figure 3 Microstructures of prior β phase observed by TEM and the electron diffraction patterns.

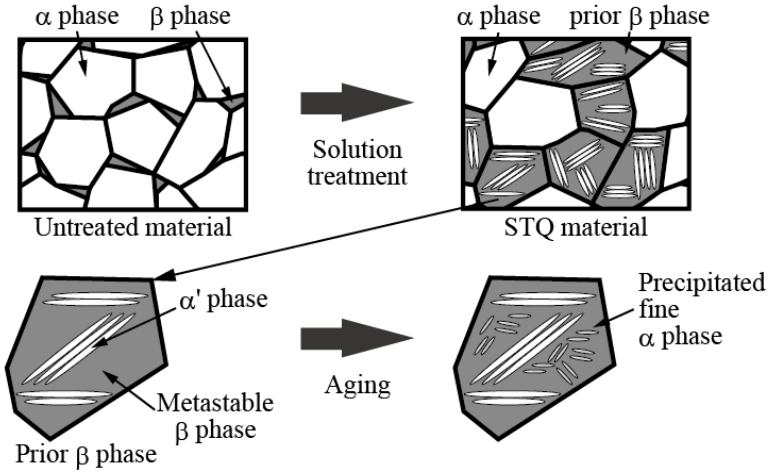

Figure 4 Schematic illustration to explain the change in microstructure with the duplex treatment.

If the aging temperature was increased beyond 803 K, the decomposition of prior β phase proceeded and the hardness showed a decline tendency.

The yield and tensile strengths obeyed the hardness of prior β phase (Fig. 6). Namely, the static strengths were improved by STQ treatment, and they were further increased by the subsequent short-time aging. The highest static strengths were achieved by STA treatment (aging temperature: 803 K), and their improvement rates were 46 % and 28 %, respectively.

The interesting point was found on the change in ductility. The reduction in area was increased by STQ treatment in spite of the great increase in the static strengths. This improvement will result from the strain-induced transformation of metastable β phase under tensile loading [3, 10]. Through the subsequent short-time aging, the ductility slightly decreased because a part of metastable β phase was decomposed. Nevertheless, the reduction in area was higher than that of the untreated material. As mentioned above, STA treatment greatly improved the static strengths without reduction in ductility.

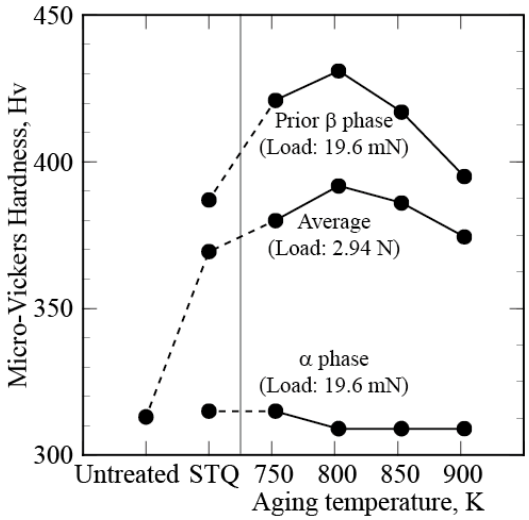

Figure 5 Changes in the average hardness, hardness of α phase and prior β phase with the duplex heat treatment.

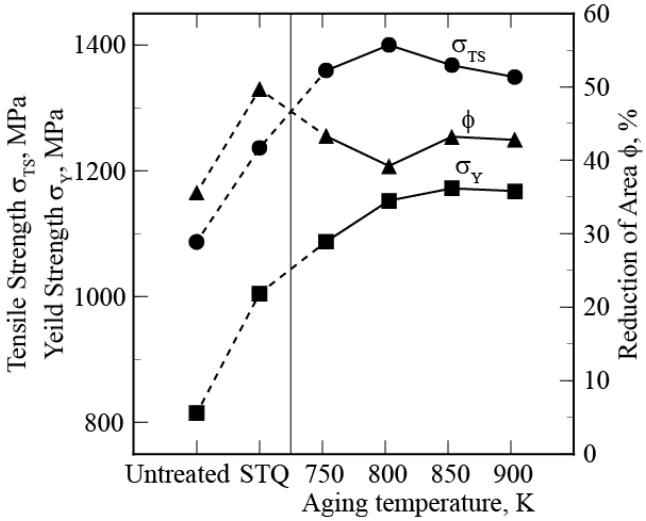

Figure 6 Changes in the mechanical properties with the duplex heat treatment.

3.3. Fatigue strength

Figure 7 shows the S-N curves of all materials, and Fig. 8 shows the change in the fatigue strength by STQ and STA treatments. Figure 8 includes the change in the ratio of the fatigue strength and the tensile strength, σ_W/σ_{TS}. Figure 9 shows the fatigue fracture surfaces of STQ material and STA material (aging temperature: 803 K).

The fatigue strength of Ti-6Al-4V alloy greatly increased with STQ treatment (Fig. 8). The maximum improvement in the fatigue strength was achieved by STA treatment (aging temperature: 803 K). As shown in Fig. 9, facets were observed at crack initiations sites of both materials, and their sizes were almost the same to α grain size. Moreover, no non-propagating crack was found on the test sections of the specimens which did not fracture until fatigue cycles of 10^7.

The above results meant that the fatigue strength was the maximum stress amplitude at which fatigue cracks did not initiate from α grain. The difference in the fatigue strength between STQ and STA materials resulted from the difference in the characteristics of prior β phase surrounding α phase. In the case of STA material, since the hardness of prior β phase was markedly higher than α phase, this region suppressed extension of slippages induced in α grain. In consequence, initiation of fatigue cracks was strongly restricted and the fatigue strength was improved.

On the other hand, STQ material also showed high fatigue strength although the hardness of prior β phase was lower than that in STA material. This will result from high ductility of prior β phase. That is, prior β phase in STQ material included much metastable β phase. Even if slippages in α phase generated a strain field in prior β phase, such strain field can be effectively cancelled through its strain-induced transformation. Consequently, the fatigue strength was improved by STQ treatment. As mentioned above, the improvement of the fatigue strength by the short-time treatments will be closely related to the two factors: the hardness of prior β phase and its ability for strain-induced transformation.

Finally, Fig. 10 summarized the tensile and fatigue strengths of the materials examined in this study. In addition, the figure includes the reference data [9]. As understood in this figure, STQ treatment effectively increased the fatigue strength although the improvement rate of the tensile

strength was relatively low; however, the subsequent short-time aging conducted at 803 K showed the great improvement of both strengths, and the reached level was markedly higher than the reference data.

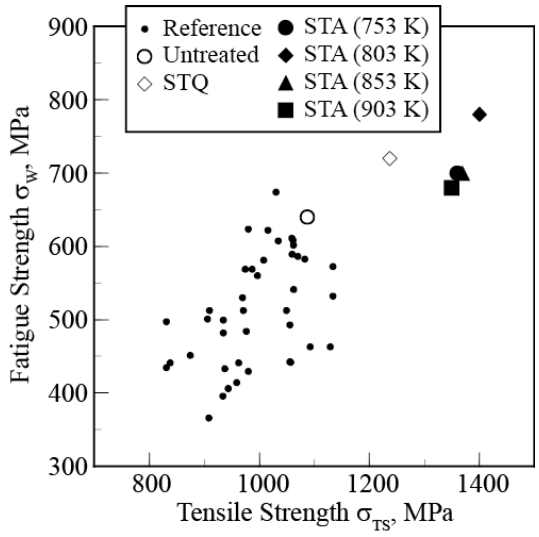

Figure 10 Changes in the tensile strength and the fatigue strength of Ti-6Al-4V alloy, including reference data [9].

4. Conclusions

(1) The short-time solution treatment transformed a part of prior β phase to acicular α' martensite phase. The subsequent short-time aging precipitated fine α phase in metastable β phase. These changes in microstructure increased the hardness of prior β phase.

(2) The short-time duplex heat treatment greatly increased the tensile strength and fatigue strength

of Ti-6Al 4V alloy without reduction in ductility. The most appropriate heat treatment was composed of STQ treatment at 1203 K for 60 s and short-time aging at 803 K for 40 s. Through this duplex heat treatment, the improvement rates of the tensile strength and fatigue strength reached 29 % and 22 %, respectively.

Abstract Due the fatigue life of aluminum alloys is strongly sensitive to the environmental effect in the most engineering applications, one of effectively improved methods on the strength and fatigue life of aluminum alloys is generally to take a coating process on the surface of these aluminum alloys. And the micro-arc oxidation ceramics coating method is not only to enhance the fatigue strength but also to avoid the environment corrosion. In this work, a dual-spindle rotating bending environment fatigue tests for two types aluminum alloys were carried out. The effects of differently relative humidity and oxidation ceramics coating types on fatigue life of aluminum alloys were discussed. These results indicated that the fatigue life (N_f>10^6) of 7074-T6 alloy began obviously to degrade when the relative humidity is over than 75% and there is a threshold. At the same time, the fatigue lives of 2024-T4 alloy by using the different oxidation ceramics coating treatments present the different changed tendencies. For example, the effect of micro-arc oxidation ceramics coating with sealing hole technology on fatigue life is positive and the effect of other two oxidation ceramics coating technologies on fatigue life is negative, such as micro-arc oxidation coating and hard oxidation coating.

Keywords Fatigue life, Aluminum alloy, Micro-arc oxidation technology, Coating layer, Relative humidity

1. Introduction

Aluminum alloys have been widely used for making structural parts in transport vehicles such as ships and aircraft for the purpose of reducing their weight. However, these structures are usually exposed to the natural environment throughout their lifetime. In these fields, very often the main requirements for the components include high-cycle fatigue (HCF) and corrosion resistance [1], especially the corrosion fatigue (CF) is defined as the sequential stages of aluminum alloys damage that develops during accumulated load cycling in an aggressive environment [2-4]. In addition, the effect of the relative humidity of over 60% on the HCF life of aluminum alloys can not be ignored. This is because the decrease in fatigue life was mainly the acceleration of crack growth caused by brittle fracture under rotating bending and the transition to shear mode crack accompanied with glide plane decohesion and void formation under ultrasonic loading respectively [5,6]. The first requirement is achieved usually by a proper material selection to enhance the fatigue resistance of aluminum alloy but not to avoid the higher cost. The second requirement for aluminum alloys is achieved by using corrosion resistance coatings [7,8]. Micro-arc oxidation ceramics process is a classical approach to enhance the fatigue properties [9] and to provide one of countermeasures against the fatigue corrosion damage of aluminum alloys. However, the enhanced behavior and effective mechanism to fatigue property of aluminum alloys exists still some arguments and/or there are not enough experimental evidences. In this work, we sum up the effect of the relative humidity on the fatigue life of aluminum alloys then investigate the effects of different micro-arc oxidation ceramics methods on the fatigue life of Al 2024-T4 alloy. The results indicated that the fatigue life (N_f>10^6) decreased obviously when the relative humidity scopes from 50% to 75% and the effect of micro-arc oxidation ceramics coating with sealing hole on the fatigue life of Al 2024-T4 alloy is

positive and the effect of other micro-arc oxidation ceramics coating technologies, such as micro-arc oxidation process and hard oxidation process, on the fatigue life of Al 2024-T4 alloy is negative.

2. Material and Experimental Procedure

Materials used were Al 2024-T4 alloy and Al 7074-T6 alloy. And the size and shape of the experimental specimens is shown in Figure. 1 including the morphology of specimen with the different micro-arc oxidation ceramics coating processes consisting of the different micro-arc oxidation ceramics coating technologies with sealing hole, micro-arc oxidation ceramics coating and hard oxidation ceramics coating surface technologies as shown in Fig. 1b. The oxidation ceramics coating layer of all experimental specimens by the different oxidation ceramics coating surface technologies has the approximate same ceramics coating layer thickness of about 0.15 mm. The center notch in these specimens was fabricated to control the stress concentration factor as about 1.08. The mechanical properties of aluminum alloys are presented in Table 1. All fatigue tests were performed by using the rotating bending machine including the addition relative humidity controlled device and 4-spindle loading device (by Yamamoto Metal Tech Co. LYD, Japan) as shown in Figure 2. The machine provides the cyclic loads at the frequency of 50 Hz and at the stress ratio of R=-1.

Table 1. Mechanical properties

	$\sigma_{0.2}$ (MPa)	σ_B (MPa)	E (GPa)	δ (%)
Al 2024-T4	325	470	70.0	20
Al 7075-T6	527	673	72.2	11

$\sigma_{0.2}$: 0.2% proof stress. σ_B: Tensile strength. E: Young's modulus. δ: Percentage elongation.

3. Results and discussion

3.1 Effect of the relative humidity on fatigue life of Al 7075-T6 alloy

Figure 3 illustrates the S-N curves under the different relative humidity scopes of Al 7075-T6 alloy. The high-cycle fatigue (HCF) behavior of Al 7075-T6 alloy indicated that the effect of the relative humidity on the fatigue life can not be ignored. Especially when the relative humidity is over than 75% and the fatigue cycles is over than 2×10^6, the effect of the relative humidity on fatigue life of aluminum alloy is very obvious. At the same time, there is a difference about the fatigue behavior in the two relative humidity states of both 75% and 100% (in water), in which with the increasing of relative humidity, the fatigue life of Al 7075-T6 alloy observably decreases no matter what is the relative humidity of over than 75% and the low- or high- cycle fatigue life of aluminum alloy. Of course, the difference of fatigue life is much obvious when the cycles are over than 10^6. However, the decreasing trend of fatigue life was restrained at lower relative humidity scopes from 75% to 50% and low-cycle or $N<10^6$. The effect of the relative humidity on the fatigue life of aluminum alloy can be even ignored. It has previously been reported that the influence mechanism was expressed by the different fatigue fracture models [5,10]. One of main reasons is because the shear stress action occupies more than part in fatigue fracture process although the applied stress is only a compressive and tensile stress at the surface damage point of specimen. The shear stress at the fatigue fracture surface might be caused by the coupling action both stress state and hydrogen or oxygen on the fatigue crack initiation and growth mechanism of aluminum alloys. Therefore, the fatigue crack growth driven force of Al 7075-T6 alloy comes from the interaction both shear and normal stresses. With the corrosion effect of hydrogen or oxygen increasing, the shear stress occupied the proportion to increase. However, the composite damage behavior of humidity effect needs to be carefully discussed in further.

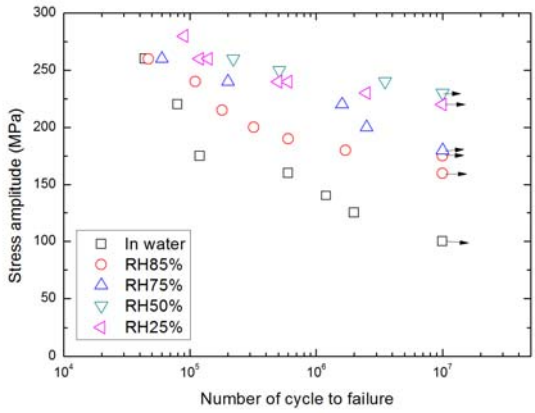

Figure 3 S-N curves under the different relative humidity scopes of Al 7075-T6 alloy

3.2 Effect of different micro-arc oxidation processes on fatigue life of Al 2024-T4 alloy

Considering the countermeasures against the effect of relative humidity on the fatigue life of aluminum alloy, the oxidation ceramics coating layer were carried out on the surface of Al 2024-T4 alloy specimens by using the micro-arc oxidation, micro-arc oxidation plus the sealing hole and hard oxidation technologies, respectively. All coating layers have an approximate same thickness of about 0.15 mm. in addition, to compare with the differently typical coating layer how to influence on the fatigue life of Al 2024-T4 alloy, the fatigue data without coating layer has been also plotted

in the S-N curves as shown in Figure 4. These experimental results indicated that the fatigue life (mark Δ) of Al 2024-T4 alloy is seriously injured with the hard oxidation ceramics coating layer, but the effect of micro-arc oxidation plus sealing hole method on the fatigue life of Al 2024-T4 alloy is positive. And the fatigue life (mark ○) of Al 2024-T4 alloy with the micro-arc oxidation ceramics coating layer is approximate same fatigue life (mark ■) of Al 2024-T4 alloy. By means of the fatigue data with and without oxidation ceramics coating layer of Al 2024-T4 alloy compared as shown in Figure 4, we clearly know that the coating layer is able to avoid the effect of humidity or corrosion on the fatigue strength of aluminum alloy but the different coating layer technologies cause the fatigue damage mechanism change of aluminum alloy. Therefore, we should pay close attention to the issue in future to optimize and improve the coating layer technology.

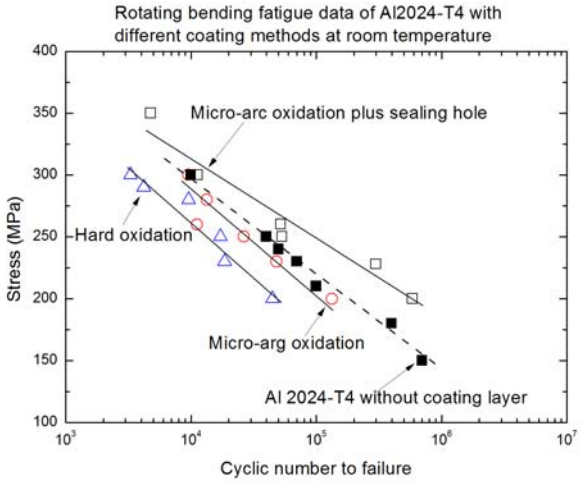

Figure 4 S-N curves under the different micro-arc oxidation processes of Al 2024-T4 alloy

(a) (b) (c)

Figure 5 Fatigue fracture surfaces for differently typical micro-arc oxidation processes of Al 2024-T4 alloy (a) micro-arc oxidation ceramics coating with sealing hole, (b) micro-arc oxidation ceramics coating, (c) hard oxidation ceramics coating.

Figure 5 illustrates the fracture appearances for the different oxidation ceramics coating layer technologies including (a) the micro-arc oxidation ceramics coating layer with sealing hole, (b) the micro-arc oxidation ceramics coating layer and (c) hard oxidation ceramics coating layer. All the applied stress amplitudes are 230 MPa, respectively. These fracture surfaces have much more different flat fracture surface such as the smooth area in the center or concave-convex surface in the marginal zone as shown in Figure 5a and 5b as well as 5c. This is a fact that the different flat fracture surface reflects the different fatigue crack propagation life. That is the fatigue crack propagation life for micro-arc oxidation ceramics coating layer with sealing hole is slower than that for micro-arc oxidation ceramics coating layer. This is because the center area and the fatigue crack propagation area in the marginal zone for the micro-arc oxidation coating ceramics layer with sealing hole are larger and relative smoother than that other two oxidation technologies. It means

that the surface quality in the oxidation ceramics coating layer processes plays an important part in fatigue damage of aluminum alloy. In additional, the fracture-resistant of the different fracture appearances is different under the different oxidation ceramics coating layer methods. The different oxidation ceramics coating layer methods cause unavoidably the different surface quality. The oxidation ceramics coating layer with sealing hole can much easily avoid the surface defects such as shrinkage cavity. And the shrinkage cavity causes unavoidably the stress concentration and fatigue life degradation of materials. At the same time, the residual stress affects on the fatigue life of Al 2024-T4 alloy to exist the different results in three oxidation ceramics coating processes.

4. Summary

Fatigue life of aluminum alloys may be either affected by relative higher humidity when the cycle is over than 2×10^6 or improved by the appropriate oxidation ceramics coating layer technology. For example, the effect of micro-arc oxidation with sealing hole process on the fatigue life of Al 2024-T4 alloy is positive and the effect of other micro-arc oxidation processes, such as micro-arc oxidation process and hard oxidation process, on the fatigue life of Al 2024-T4 alloy is negative. Therefore, the micro-arc oxidation ceramics coating layer with sealing hole technology is not only to enhance the fatigue strength but also to avoid the harmful or negative effect of the relative humidity on the fatigue life of Al 2024-T4 alloy.

Three-dimensional Fatigue Crack Growth Path Simulation under Non-proportional Mixed-mode Loading

Ying Yang[1,*], Michael Vormwald[1]

[1] Material Mechanics group, Technische Universität Darmstadt, Petersenstaße 12, 64287 Darmstadt (Germany)
* Corresponding author: yang@wm.tu-darmstadt.de

Abstract An algorithm based on linear elastic fracture mechanics (LEFM) for three-dimensional fatigue crack growth simulation under non-proportional mixed-mode loading is proposed in the present paper. Combined non-proportional cyclic tension and torsion loading with different phase angle and loading ratio M_T/F are considered. The maximum tangential stress (MTS) criterion is performed as the main theory to predict crack propagation direction. Under some specific loading cases, especially for high stress intensity factors, the crack growth direction needed to be modified in order to be in accordance with the experimental results. By analyzing the simulated crack growth paths, three distinct features are observed that are tension mode dominated crack paths, shear mode dominated crack paths and transitional crack paths. When crack growth changes from tension to shear mode, the latter is described by the maximum shear stress (MSS) criterion. A preliminary proposal is made to predict the transitional mode.

Keywords Linear elastic fracture mechanics, Non-proportional loading, Mixed mode, Transitional fracture

1. Introduction

Considering that a great amount of structures or components are subjected to mixed mode loading during the service time, research on material fracture under this kind of loading type has attracted more attention in recent years. Crack propagation direction is one of the major problems in this field. Since the maximum tangential stress criterion was first proposed by Erdogan and Sih [1], the minimum strain energy density criterion (S-Criterion), the maximum energy release rate criterion and maximum tangential strain criterion [2–4] and so on were suggested subsequently. All the mentioned criteria present similar crack propagation direction for proportional mixed mode loading, showing small deviation with the experiment results. The crack growth directions display a tension mode feature following the direction which minimizes the K_{II} values. However, large distinction between experimental crack propagation direction and the predicted crack kink angle were also observed for some materials. In these cases, the crack growth occurred in the plane that K_{II} values were maximum. As a result the maximum shear stress (MSS) criterion was proposed. Crack growth in shear mode was summarized in a literature review by H. W. Liu [5].

The criteria represented by MTS and MSS are deduced according to the stress field solution in the vicinity of crack tip on the basis of linear elastic fracture mechanics. Strictly speaking, these criteria are appropriate only in monotonic loading condition. Nevertheless, Highsmith et al. [6] pointed out that the criteria can be performed straightforward to fatigue crack growth under proportional mixed mode loading. Fatigue crack growth under non-proportional mixed mode loading is a more complex situation and there are insufficient experiments and hypotheses for application. Vormwald et al. [7] reviewed some research consequences in recent years. Six relevant factors which influence the crack growth behavior under non-proportional loading were denoted and an algorithm based on LEFM for three-dimensional fatigue crack growth simulation under non-proportional mixed-mode loading is proposed [8]. The emphasis in the present paper is focusing on the crack growth path behavior. A description of the algorithm is presented.

2. Application of the algorithm

The algorithm is applied to simulate the fatigue crack growth including path and propagation rate in a thin-walled, hollow cylindrical specimen (see Figure 1) with a notch. The corresponding experimental data were obtained by Brüning [9]. In the experiment two common used materials were tested, the aluminium alloy AlMg4.5Mn and steel S460N. The combined non-proportional cyclic tension and torsion loading with phase angles of 45° and 90° were applied to the specimens with an R ratio of -1. The results of 4 specimens marked as A7, A8, S7 and S13 could be used here for comparison purpose because the loading was relatively low to meet small scale yielding requirements.

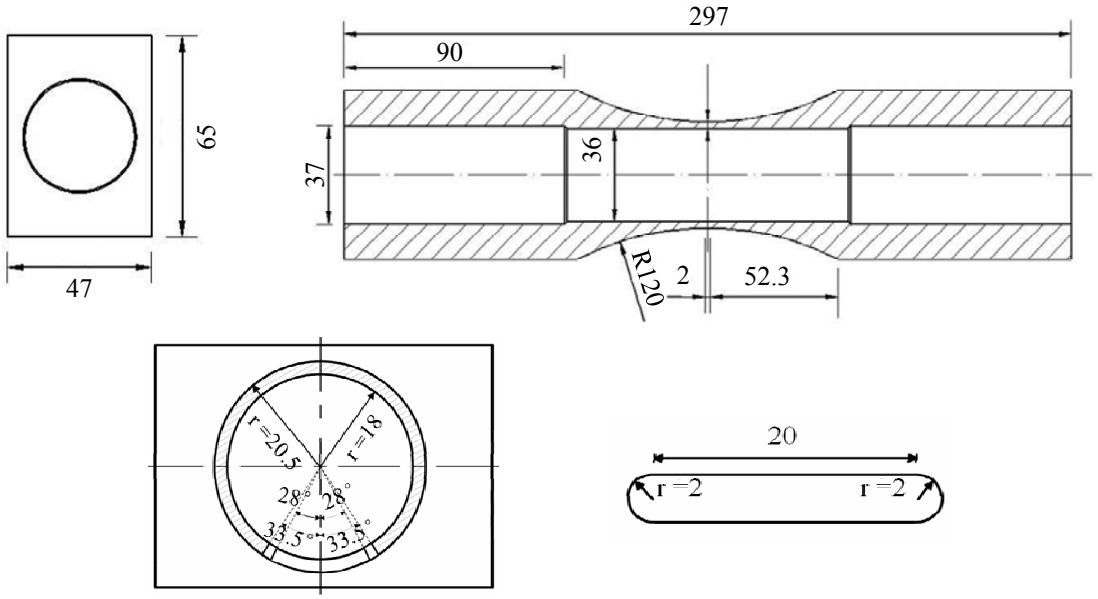

Figure 1. Specimen and notch geometry (dimensions in millimetres)

The algorithm consists of three main modules: (a) determination of the crack initiation position; (b) calculation of the maximum equivalent stress intensity factor K_{eq} in one loading cycle, which is taken as the crack driving force parameter; (c) crack growth process. Module (b) and (c) are repeated until the crack growth path can be presented clearly. Brief expression of each module is introduced in the following sections, more details can be found in reference [8].

2.1. Location of crack initiation

The crack initiation will occur in the notch root at the position where the locally uniaxial notch stress is maximum in one loading cycle. A 3-dimensional finite element model was created using ABAQUS software for stress analysis. Refined mesh was applied in the crack growth region as shown in Fig 2 (a). Along the notch root, there are four potential crack initiation sites numbered 1, 2, 3 and 4 clockwise, shown in Fig 2 (b). The analysis indicated that the maximum tangential stress in one loading cycle along the notch root on the inside edges is almost 2 times larger than the tangential stress on the outside edge, therefore a corner crack is considered to be a reasonable shape to initial crack simulation. As can be expected, the initial corner crack will propagate through the thickness of the notch and extend to the outside surface of the specimen in the crack growth process.

An incipient corner crack was inserted into the inside edge of the notch root where tangential stress is maximum by program Fracture Analysis Code 3D (FRANC3D). This program package is designed to simulate crack growth in engineering structures or components with arbitrary crack

geometry under different loading and boundary conditions. FRANC3D adaptively remeshes an existing finite element model with the inserted initial crack to generate a cracked model. Furthermore, FRANC3D is also used to calculate stress intensity factor (SIF) for an entire crack front.

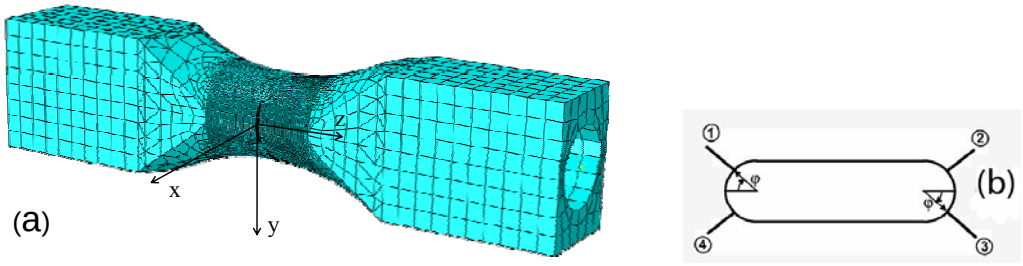

Figure 2. (a) Finite element model, (b) Crack initiation sites

2.2. Crack driving force calculation

In the present paper, mode I and mode II SIFs, K_{I} and K_{II} in one cycle under non-proportional tension combined with torsion loading are computed for the sake of obtaining the equivalent SIF, K_{eq}. Erdogan and Sih proposed that the equivalent stress intensity factor according to the maximum tangential stress criterion can be described by:

$$K_{eq}=\frac{1}{4}\left(3\cos\frac{\theta^{*}}{2}+\cos\frac{3\theta^{*}}{2}\right)K_{\mathrm{I}}-\frac{3}{4}\left(\sin\frac{\theta^{*}}{2}+\sin\frac{3\theta^{*}}{2}\right)K_{\mathrm{II}} \tag{1}$$

θ^{*} is a function of K_{I} and K_{II}, representing the direction where the tangential stress $\sigma_{\theta\theta}$ in the vicinity of the crack tip is maximum. And also the shear stress $\tau_{r\theta}$ vanishs along this direction on the basis of MTS criterion.

$$\theta^{*}=2\arctan\left(\frac{1}{4}\frac{K_{\mathrm{I}}}{K_{\mathrm{II}}}\pm\frac{1}{4}\sqrt{\left(\frac{K_{\mathrm{I}}}{K_{\mathrm{II}}}\right)^{2}+8}\right) \tag{2}$$

The stress intensity factors for mode I and mode II are calculated by FRANC3D software for tension F=1 and torsion M_{T} =1. The combined tension and torsion mixed mode stress intensity factors K_{I} and K_{II} are obtained from the superposition according to equation (3):

$$\begin{aligned}K_{\mathrm{I}}(\mathrm{t})&=K_{\mathrm{I},F}\cdot F(\mathrm{t})+K_{\mathrm{I},M}\cdot M_{T}(\mathrm{t})\\ K_{\mathrm{II}}(\mathrm{t})&=K_{\mathrm{II},F}\cdot F(\mathrm{t})+K_{\mathrm{II},M}\cdot M_{T}(\mathrm{t})\end{aligned} \tag{3}$$

The combined SIFs computed from equation (3) are inserted to equation (2) to find the angle θ^{*}, which is put into equation (1). The equivalent stress intensity factor K_{eq} is calculated for a full loading cycle. Among all the equivalent stress intensity factors, the peak value $K_{eq,\max}$ is taken as the crack driving force, which means the loads at this instant $t_{\max}$, $F(t_{\max})$ and $M_{\mathrm{T}}(t_{\max})$ are used for

crack propagation simulation.

2.3. Crack growth process

The load corresponding to the $K_{eq,\max}$, $F(t_{\max})$ and $M_T(t_{\max})$ are applied to the cracked finite element model. Stress analysis is carried out in ABAQUS. The SIF solutions for the cracks are again obtained from FRANC3D based on the stress analysis. Although the solutions for K_I, K_{II} and K_{eq} are already at hand for $t = t_{\max}$, the re-evaluation of this loading case combination can now be used to let the FRANC3D software create the crack propagation increment Δa. The ABAQUS/FRANC3D interface was implemented to perform the crack growth analysis. The finite element modeling and the stress analysis are performed in ABAQUS, FRANC3D is used to calculate crack growth parameters and updates the crack geometry and mesh. This process is continued until the crack has grown to a certain length.

As referred before, on one hand the MTS criterion is used as the rule for estimating crack propagation direction in most cases, on the other hand as will be shown later that under certain loading conditions, the simulated crack growth path deviated from the experimental crack path when the length of the crack is long enough. In order to investigate the crack growth path behavior under these complicated loading cases, a modification is essentially to keep the deviation between experimental results and simulation in an acceptable extent. Due to an extremely inadequate hypothesis about the criterion which is suitable for fatigue crack growth direction prediction under non-proportional mixed mode loading, the modification is implemented manually to adjust the position of newly generated crack front in order to make the simulated crack increment direction coincident with the experimental results. As a result, although the simulated crack growth path is not perfectly identical with the experimental data, a close match is enforced.

3. Results

3.1. AlMg4.5Mn specimens

In the experiment, specimen A7 (amplitude load values: F=8kN; M_T=96Nm) was tested under a non-proportional loading with an out of phase angle of 90°, while specimen A8 (amplitude load values: F=6.5kN; M_T=72Nm) was subjected a loading with a out of phase angle of 45°. The crack growth paths are shown in Figure 3. According to the stress analysis for the uncracked specimen, the local tangential stress along the notch root in site 1 and 3 are approximately 1.6 times larger than the stresses in site 2 and 4, therefore cracks should occur in site 1 and 3. Very curvilinear paths were displayed in specimen A7, furthermore in the experiment, crack branching appeared and then the crack growth path continues nearly perpendicularly to the previous propagation direction. The simulation algorithm at present does not contain a condition for crack branching, only the first curvilinear paths are presented. For specimen A8, the crack propagates along an angle of nearly 45° with the longitudinal axis. After the crack reaches a certain length, it has a tendency to turn into a plane, which is perpendicular to the longitudinal axis.

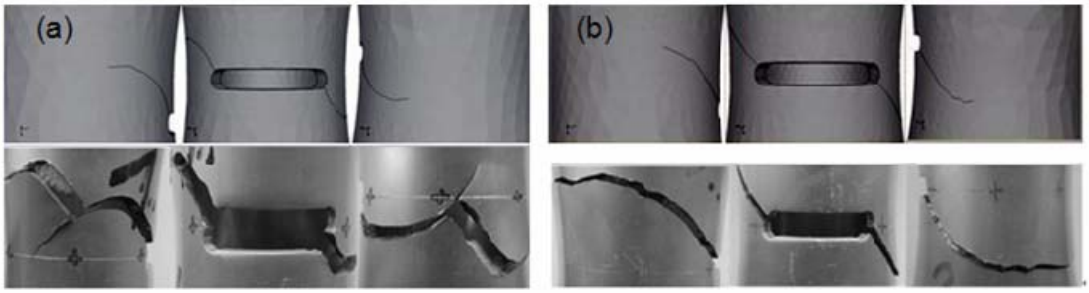

Figure 3. (a)A7 crack growth path, (b) A8 crack growth path [8]

3.2. S460N specimens

Specimen S7 (amplitude load values: F=27kN; M_T=408Nm) under the loading with a out of phase angle of 90° and the corresponding loading phase angle for specimen S13 (amplitude load values: F=22.5kN; M_T=272Nm) is 45°. 4 initial corner cracks are inserted into the notch root in specimen S7 because the maximum local tangential stresses are almost equal for sites 1-4. The crack propagation trend for specimen S13 is similar with specimen A8 as shown in Figure 4(b).

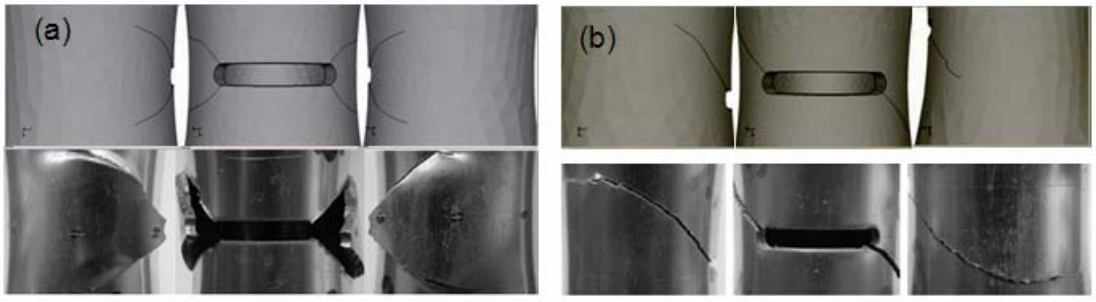

Figure 4. (a) S7 crack growth path, (b) S13 crack growth path [8]

Besides crack growth paths, the fatigue life for each specimen was also calculated based on Paris law. More details and the curves for crack length versus number of cycles are shown in reference [8].

4. Discussion

4.1. Crack propagation behavior of specimen A7

Crack paths are marked as ①, ②, ③ and ④ corresponding to the crack initiation sites as shown in Figure 2(b). The coordinate system is illustrated in Figure 2(a), the centre point of specimen is considered as the origin. The crack propagation trajectory (path ①) for specimen A7 is plotted in Figure 5(a). The solid line represents the simulated crack growth path in FRANC3D. The path labelled by squares is calculated based on the MTS criterion. It can be seen that when the crack reaches to a certain length (the length of this crack is from the notch root to point A), the crack growth path will deviate from the prediction of MTS criterion. From point A, MSS criterion predicted path is marked by triangle symbols. Obviously, the crack path starting from point A does

not follow the route estimated by either MTS criterion or MSS criterion. A path between the prediction of MTS and MSS criteria seems more reasonable compared with the experiment results. From point B, the simulated crack path seems to be controlled by MSS criterion, a negligible deviation can be found in Figure 5(a). In the contrary, large divergence is shown for the crack path estimated by MTS criterion. Based on the LEFM analysis, MTS criterion is valid in tension mode fracture and MSS criterion is used in shear mode problem, both of these two criteria are supported by a large quantity of corresponding experiments. The simulated crack path from point A to point B which keeps the same trend with the experimental result between tensile mode and shear mode is defined as the so called transition mode fracture [10]. Comparing to common investigated tension mode and shear mode, the transition mode is an occasional situation, appearing under very complex and dynamic loading, for instance for the present cyclic non-proportional mixed mode loading.

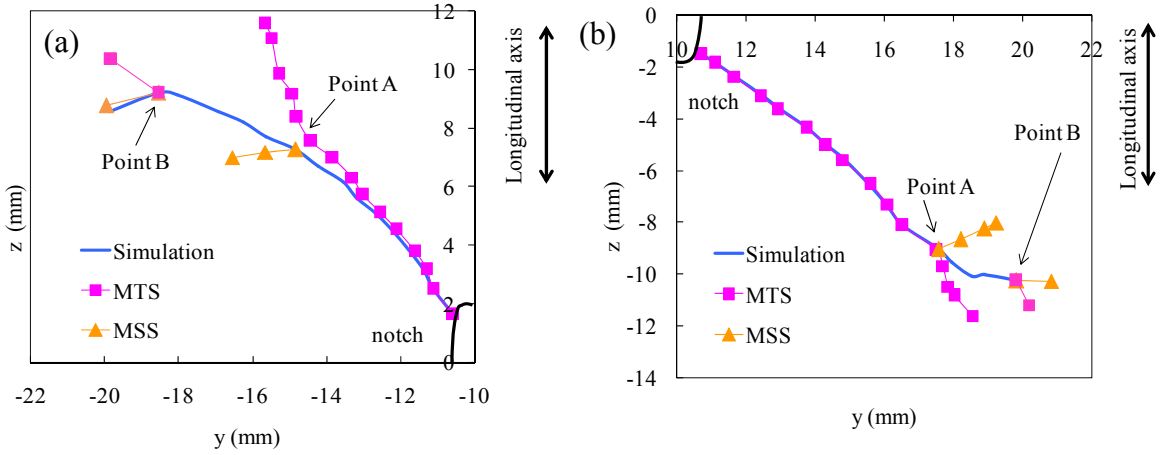

Figure 5. Crack growth path of (a) specimen A7, (b) specimen A8

4.2. Crack propagation behavior of specimen A8

Figure 5(b) shows the propagation crack path ③ for specimen A8. The symbols for different crack growth paths are defined as the same for specimen A7. The crack path starting from the notch root to point A complied perfectly with the prediction of MTS criterion. Beginning with point A, the crack path estimated by MTS criterion propagated almost along with the total previous crack path angle with no obvious transforming for the direction of crack extension. When the MSS criterion predicted crack growth path is contrasted with the MTS one from point A, the difference is very apparent as shown with the triangle diagram in Figure 5(b). The MSS path displayed a sharp deflection with the previous crack path direction and extended nearly in an opposite orientation, which is upward compared to the previous crack path. Obviously, these two crack growth paths do not conform to the experiment result. A path between the prediction of MTS criterion and MSS criterion gradually routed the crack to grow perpendicularly to the longitudinal axial. A transition fracture mode occurred in this specimen. As well as specimen A7, the transition fracture mode is followed by a shear fracture dominant crack path from point B. The MSS criterion predicted crack path could be considered to be perpendicular to the longitudinal axial of specimen. As can be seen from Figure 3(b), in the experiment once the crack changed propagating direction normal to the longitudinal axial, the coplanar shear crack growth is persistent until to the final fracture.

4.3. Crack propagation behavior of specimen S13 and S7

The crack growth path (path ①) for specimen S13 is plotted in Figure 6(a). An acceptable crack path compared with the experimental result from the notch root to point A was predicted by the MTS criterion. The transition fracture mode is expected following tension mode fracture. The simulated crack growth path for this specimen is not long enough to show a complete transition path. Nevertheless, it could be inferred that a shear mode fracture would occur as well as in specimen A8. The crack propagation path of specimen S13 is similar with specimen A8 (see Figure 3(b), Figure 4(b)), the final fracture is a coplanar crack extension perpendicular to the longitudinal axis which can be predicted by MSS criterion. Figure 6(b) illustrates one crack growth path (path ①) for specimen S7. It is found that the presented crack path has good agreement with the predicted crack path using MTS criterion. From the experimental result as shown in Figure 4(a), the crack growth paths did not deflect to the plane perpendicular to the longitudinal axis for coplanar shear crack extension, which means no shear mode fracture occurred in this specimen.

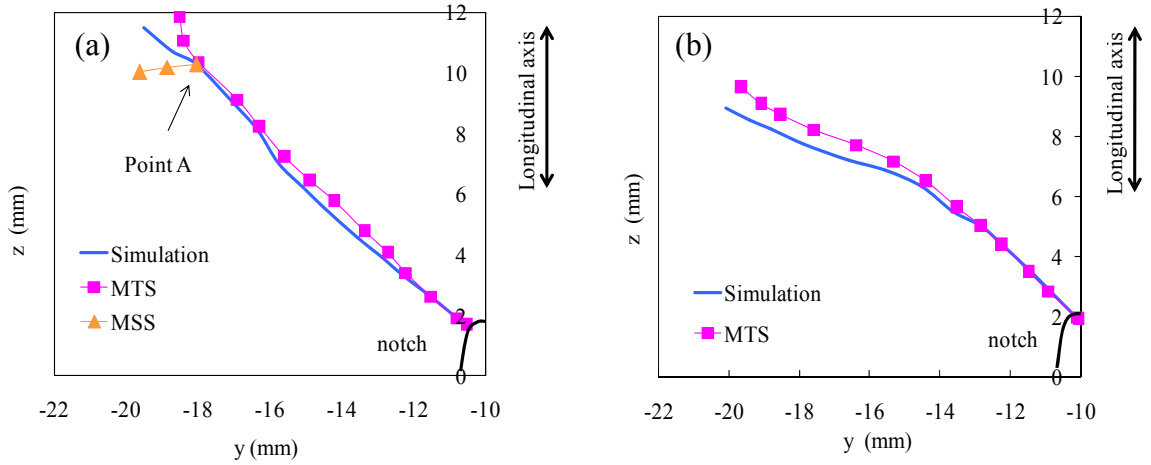

Figure 6. Crack growth path of (a) specimen S13, (b) specimen S7

4.4. Mode transition analysis

The tension mode and shear mode competition under non-proportional mixed mode loading reflects the variation of K_I and K_{II} values. Figure 7 illustrates the K_I and K_{II} values in one loading cycle under combined tension and torsion with a phase angle of 90°. The equivalent stress intensity factors K_{eq} reaches its peak values $K_{eq,\max}$ at time $t_{\max}$, which is taken as the crack growth driving force. The corresponding K_I, K_{II} components are marked as K^*_I and K^*_{II}. The K^*_{II} values of each crack propagation step for the four different specimens are shown in Figure 8 (①, ③ represent the corresponding crack paths) based on the calculation results from FRANC3D. The ordinate represents K^*_{II} values (absolute value), the abscissa represents the crack growth step. For all specimens the same tendency of increasing K^*_{II} with crack length is observed. From step 13 for specimen A7, step 15 for specimen A8 and S13, the transition mode started. It can be inferred that a threshold value $K^*_{II\ th}$ exists in the transition mode. If the mode II component of the maximum equivalent stress intensity factor $K_{eq,\max}$ in a loading cycle, K^*_{II}, is less than the threshold value,

tension mode dominated crack propagation prevails, if a threshold value is exceeded, transition mode dominated crack propagation is a reasonable crack growth pattern. The threshold $K^*_{\mathrm{II\ th}}$ is a function of several parameters, such as material property, the R ratio or the mode I threshold value and so on. Further research is needed to complete the concept.

$$K^*_{\mathrm{II}} > K^*_{\mathrm{II\ th}} \tag{4}$$

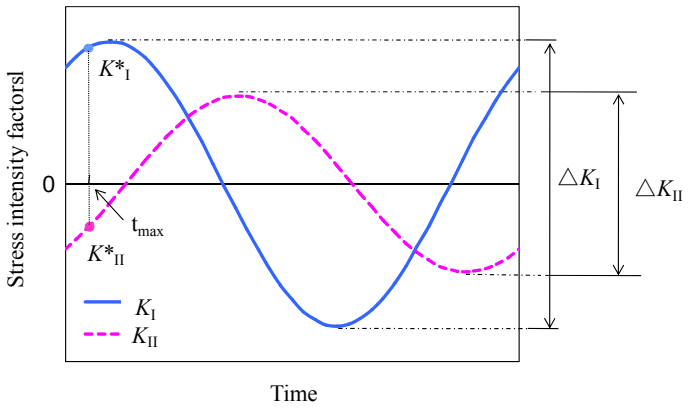

Figure 7. Variation of stress intensity factors

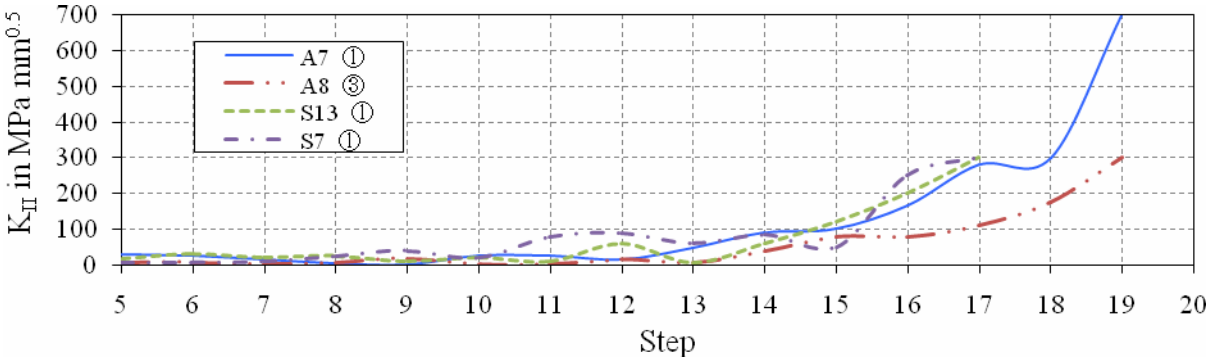

Figure 8. K^*_{II} values

Only for specimen S7 transition and shear modes did not appear. However, the K^*_{II} increased in the same way as for the other specimens. This implies that the crack growth path behaviour is not just controlled by K^*_{II}. Considering one loading cycle, the stress intensity range is defined as: (see Figure 7)

$$\triangle K_i = K_{i\ \max}(1\text{-}R) \quad (i\text{=I, II}) \tag{5}$$

The ratios of $\triangle K_{\mathrm{II}}$ to $\triangle K_{\mathrm{I}}$ in one loading cycle are shown in Figure 9. Similar with K^*_{II} versus crack growth step curve, an ascending tendency is revealed in the ratio of mode II range to mode I range especially for specimen A7 and A8. The transition mode started at step 13 for specimen A7 and at step 15 for specimen A8, the ratio of stress intensity range corresponding to these two steps are larger than 0.4, which could be considered as an assumed threshold value. Although the ratios from step 8 to 11 are also larger than 0.4 in specimen A7, the K^*_{II} values are too small to induce transition mode crack growth. In specimen A7 and A8 shear mode was subsequent from step 18,

step 19, the ratio values are larger than 1.3. It implies that transition mode is not a stable crack growth pattern; a critical ratio of stress intensity factor range is proposed between transition mode and shear mode. Once the proportion of $\triangle K_{II}$ in one loading cycle is large enough, shear mode crack growth occurred.

$$(\triangle K_{II}/\triangle K_I)_{th} < \triangle K_{II}/\triangle K_I < (\triangle K_{II}/\triangle K_I)_{cr} \tag{6}$$

The curves for specimen S13 and S7 are much smoother compared to the curve of A7 and A8. The different loading type may be a main reason to explain this phenomenon. Even so, it can be observed that from step 15 curve S13 increased persistently and the values are larger than 0.25. The curve of S7 does not show a rising trend but a relative downward tendency. It means that the mode I stress intensity range increased faster than the mode II range in this specimen. Transition and shear mode crack propagation is suppressed by this rapidly growing mode I component. The assumed transition mode threshold ratios for specimen A7 and A8, S13 are 0.6, 0.45 and 0.25 respectively. Beside the different material property, plasticity plays an important role in reducing the threshold value for specimen S13. Depending on the loading level, more plasticity compared to A7, A8 is displayed in specimen S13, accelerating the transformation of tension mode to transition mode or even to shear mode.

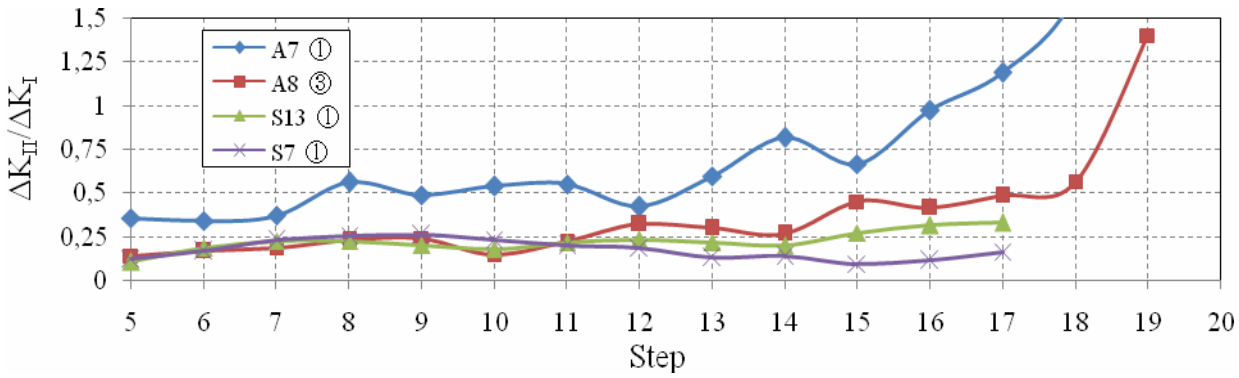

Figure 9. Ratio of stress intensity factors range

5. Conclusions

In the present paper, 3-dimensional crack growth simulation is implemented by using the LEFM-based algorithm. The simulation for two different materials AlMg4.5Mn, S460N, two phase angles 45° and 90°, different loading levels and M_T/F ratio have been presented. The M_T/F ratio has a great influence on the number of cracks, 4 cracks will occur when torsion loading M_T reaches a certain percentage of the total loading. The loading phase angle affects the crack growth path behaviour and also numbers of initiated cracks. Compared to the phase angle of 45°, specimens under out of phase loading with a phase angle of 90°, demonstrate more variations in crack initiation and crack growth path, depending on different load levels and M_T/F ratios.

Under non-proportional mixed mode loading, three distinct features of the crack growth path behaviour are observed which are tension mode, transition mode and shear mode. Based on the

analysis of specimen A7, A8 and S13, crack growth followed tension mode in most cases until the crack reaches a certain length corresponding to:
(1) The mode II component of the maximum equivalent $K_{eq,\max}$ in one loading cycle exceeds a threshold value and in the meantime;
(2) The ratio of mode II stress intensity factor range to mode I stress intensity factor range in one loading cycle is higher than a corresponding threshold value and;
(3) Shear mode crack growth occurs when the latter ratio exceeds a critical value.

Considering that no theoretical hypotheses can be applied to confirm the two threshold values to the transition mode at present, further research is needed to explain the crack growth path behavior under non-proportional loading cases. Further investigations especially in the field of micromechanics may provide more indications for this problem and improve the proposal of the present paper.

Abstract In this paper, fatigue crack growth of finite plate with hole under constant amplitude loading through compressive residual stress at notch of aluminum alloys was investigated. Residual stress fields were generated by plastic deformation using finite element method. Based on fatigue crack growth rates (FCGRs) experimental data without residual stress, fatigue life and FCGR were predicted using AFGROW code. It was shown that the fatigue crack growth was affected by level of residual stress at notch for different level of plastic deformation. In this investigation, the presence of compressive residual stresses increase the total fatigue life and reduces the FCGRs. In addition stress ratio effect on fatigue behavior was studied.

Keywords Fatigue crack, Compressive residual stress, Al-alloy, notch, stress ratio

1. Introduction

Fatigue crack growth behavior is a significant issue in the establishment of inspection and maintenance procedures in variety industries such as aerospace, automotive, oil industries, rail...etc. This behavior is divided in three stages [1]: fatigue crack initiation, stable crack propagation and unstable crack propagation. Generally, mechanical components and structures contain geometrical discontinuities and notches. Stress concentration will be produced in theses discontinuities as a result of external force and depend of notch radius. The stresses are generally higher than the nominal values, and if precautions (good quality of machining of notch, induction of residual stress …etc.) are not taken into account, notches could be sites of crack initiation. Residual fatigue life of materials and structures depends on several parameters. In stable stage, fatigue life is linked strongly geometrical, loading parameters and residual stress. However, the stresses resulting from applied service loading are not the only stresses of significance for fatigue. Many components also contain residual stresses that were established prior to placing the component into service and which remain in place during the service life. These residual stresses are static load and influence the mean or maximum value of the load in each fatigue cycle. The residual stresses present diverse origin and several shapes [2-11] namely shot-penning, expansion of hole, overloads, underload, pre-strain or pre-deformation, welding, machining process… The stress field is beneficial if the stress is in compressive state [12, 15]. Contrary to this, the fatigue crack is accelerated [16]. Pre-strain is a process when preload induced plastic deformation, induced intentionally or not and create a residual stress field. The level and nature of these residual stresses depend on the amplitude and direction of applied load.

In the investigation of Kamel et al. [17] effects of tensile and compressive residual stress in fracture mechanics specimens by the application of a mechanical pre-load were studied using ‘C’ shape specimen. Finite element analysis is performed to simulate the pre-loading and the subsequent fracture loading of the cracked specimen. Recently, effect of residual stress on the fatigue behavior

of 2024 Al-alloy was studied experimentally and numerically using FEM by Al-Khazraji et al. [18]. Effect of plastic predeformation by bending to create deep residual compressive stresses on the fatigue strength of steel specimens and compressor blades was studied by Ezhov and Sidyachenko [19]. It was found that plastic predeformation increases the fatigue strength by about 20%. In other work, effect of residual stress induced by plastic predeformation was investigated by Mokhdani [20] on API 5L pipeline steel and Benachour [21] and Jones [22] on 2024 T351 Al-alloy using Four bent specimen. It was found that the fatigue life was influenced by the plastic preload. An increasing in fatigue life was shown by increasing of the level of plastic preload. The fatigue crack growth rates at low stress intensity factor were decreased by the presence of compressive residual stress. In study conducted by Jones and Dunn [23], fatigue crack growth from a hole with residual stress introduced by tensile preload was predicted using linear elastic fracture mechanics and the principle of superposition. O'Dowd et al. [24] introduced residual stresses in compact tension (CT) specimen by mechanical compression. The level of the compressive load was determined by finite element method (FEM). The compressive residual stresses present a beneficial effect on fatigue lifetime. Additionally fatigue life and fatigue crack growth rate (FCGR) were affected by stress ratio. Many researchers [25-28] have studied effect of this parameter on some Al-alloy with and without residual stress.

The main aims of the present investigation is to studied effect of residual stress on fatigue life and fatigue crack growth around hole, determined by plastic preload in tension of samples using finite element method.

2. Finite element model and analysis procedure

2.1. Modeling

The FE model used in simulation of plastic preload (PP) was a plate assumed to be made from Al-alloy 2024 T351 and 6061 T6. The mechanical properties of the both materials are shown in Table 1. In order to analyze the respect of elasto-plastic behavior, a true stress–true strain curve as shown in Figure 1 was used as an input property of FE analysis. As shown in Figure. 2, the dimensions of the plate containing Ø 6 diameter holes and thickness (t) = 4 mm. I have varied the level of applied preload characterized by non dimensional ratio σ_p/σ_y, where σ_p is applied preload and σ_y is yield stress for specified material, in order to investigate the level of the residual stress variation on fatigue crack growth behavior. The finite element mesh is shown in Figure 3. Only four quart of the entire plate has been modeled considering of the symmetry. More finite elements than those in other regions are put closer to the boundary of holes. Since we are interested of the residual stress variation according to the X axis from hole edge to free surface, two-dimensional analysis has been carried out with uniform distributed plastic preload σ_p. The program used in the FE analysis was ANSYS, Ver. 11. The mesh element type was “PLANE183”.

Table 1. Mechanical properties for Al-alloys

Al-alloys	E (GPa)	σy (MPa)	UTS (MPa)	ν
2024 T351 [44]	74.08	363	477	0.33
6061 T6 [45]	69.04	252	360	

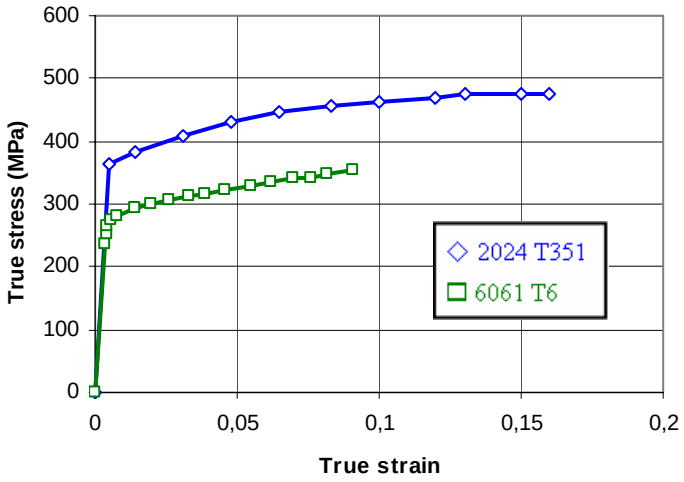

Figure 1. True stress–true strain curves of Al-alloy 6061-T6 and 2024 T351

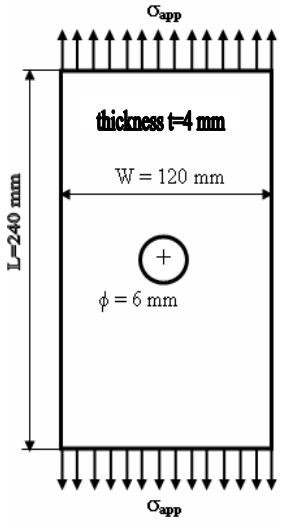

Figure 2. Analysis model

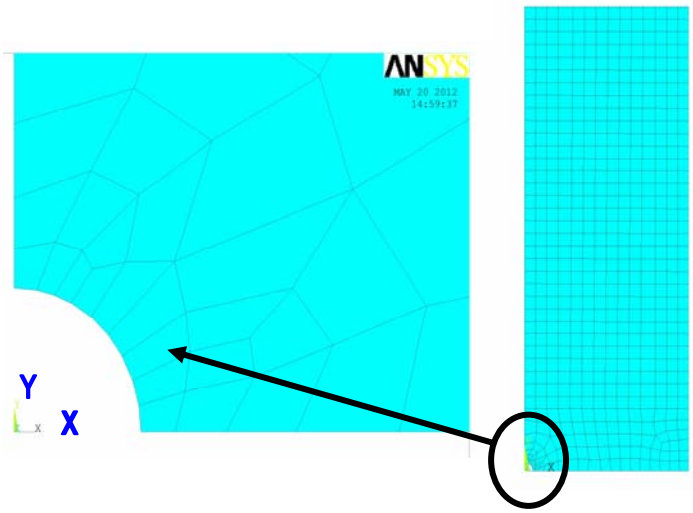

Figure 3. Quarter of finite element mesh with central hole

To generate a residual stress field, the applied load must exceed the elastic limit is to say that the force generated during the loading phase of plastic deformation where the isotropic plasticity model of Von Mises was used to account of the plasticity of material. The applied loading and unloading sequence (i.e. 2024 T351 Al-alloy) to generate residual stress by preload is shown in figure 4. The levels of preload is characterized by ratio σ_p/σ_y for both materials are shown in Table 2.

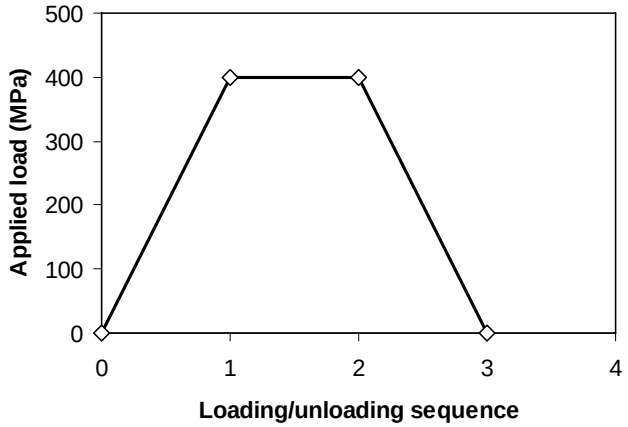

Figure 5. Loading sequence to generate residual stress

Table 2. Levels of preload for both materials

Al-Alloy	2024 T351	6061 T6
σp/σy	1.047	1.19
	1.102	1.23
	1.212	1.39
	1.350	

2.2. Generated residual stress

Under levels shown in Table 2, respective residual stress fields were generated. Figures 6 and 7 shown residual stress distribution around hole σ_{yy} for different applied preload for 2024 T351 and 6061 T6 Al-alloy respectively for specified levels. Interesting distributions of these residual stresses are along X-axis. X-axis is a planned path for crack propagation in mode I. Figure 8 shows variation of residual stress distribution σ_{yy} along X-axis for 2024 Al-alloy for different preload levels. It shows an increasing of compressive residual stress with increasing of preload levels at hole. was shown

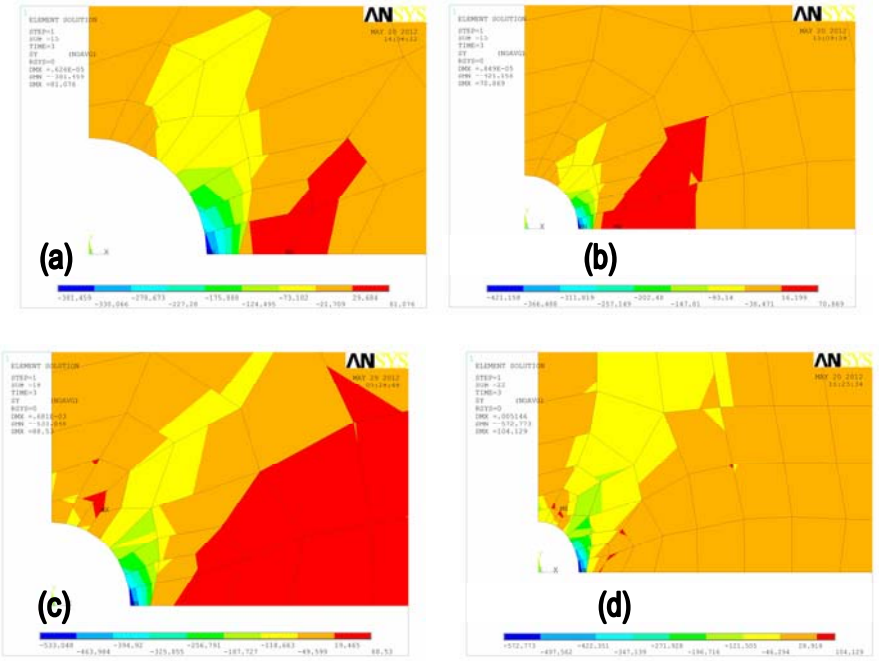

Figure 6. Stress contour for preload levels σ_p/σ_y for 2024 T351: (a) 1.047; (b) 1.102; (c) 1.212 (d) 1.350

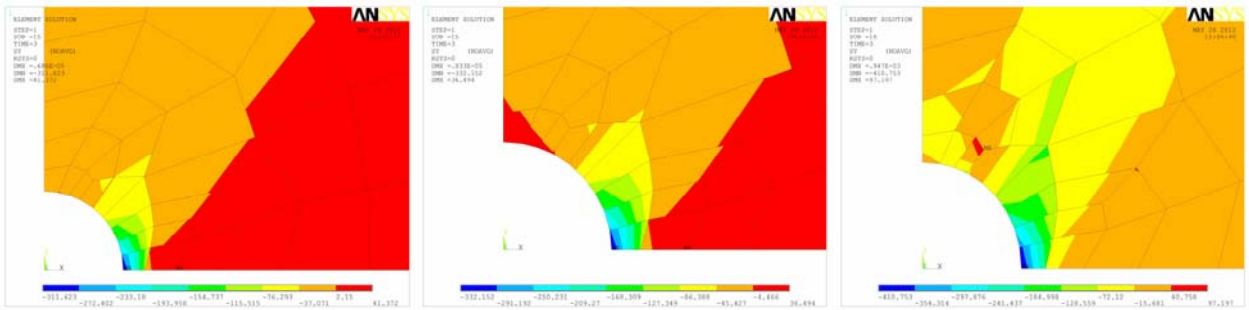

Figure 7. Stress contour for preload levels for 6061 T6 σ_p/σ_y: (a) 1.19 ; (b) 1.23 ; (c) 1.39

Figure 8 shows variation of residual stress distribution σ_{yy} along X-axis for 2024 Al-alloy at different preload levels. Residual stresses are in compression state up to a depth of 1.57 to 1.72 mm from the edge of the hole. It shows an increasing of compressive residual stress with increasing of preload levels at hole. Around distance of 4.5 mm, residual stresses become tensile stresses and difference is negligible. Distributions of residual stresses σ_{yy} along X-axis for 6061 T6 Al-alloy at specified preload levels, are shown in figure 9. No high difference of residual stress at edge of hole was shown. The residual stress in tension is maximal at 2 mm deep from the edge of the hole still; it is of the order of 30 MPa.

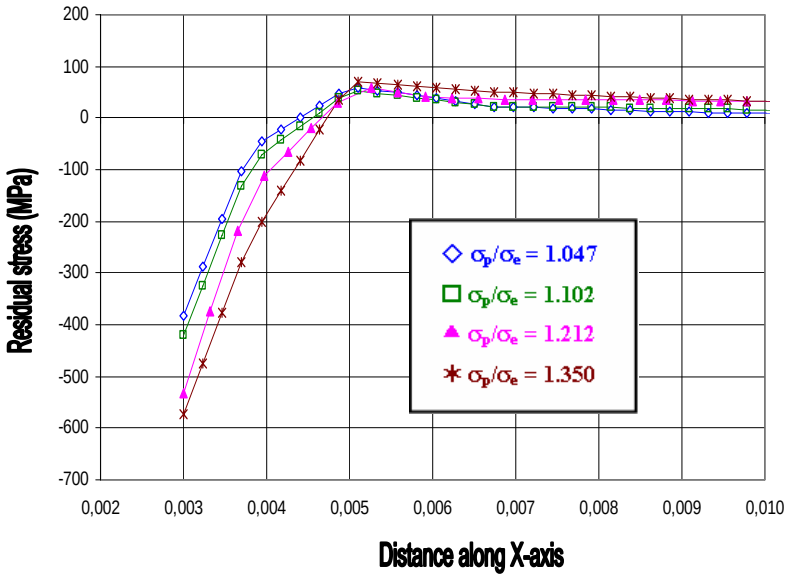

Figure 9. Residual stress along X-axis for 2024 T351 Al-alloy

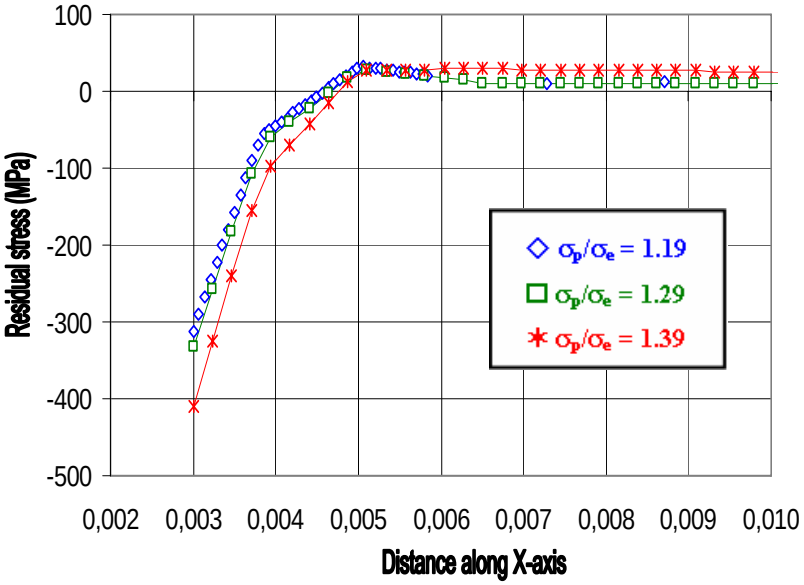

Figure 10. Residual stress along X-axis for 6061 T6 Al-alloy

3. Results and discussion

3.1. Fatigue crack growth modeling

The stress intensity factor for the studied specimen implemented in AFGROW code depends on several parameters and is given by Eq. 1.

$$\Delta K = \sigma\sqrt{\pi.a}.\beta\left(\frac{a}{r}\right) \tag{1}$$

where β is the geometry correction factor is expressed below (Eq. 2):

$$\beta\left(\frac{a}{r}\right) = 1 - 0.15\lambda + 3.46\lambda^2 - 4.47\lambda^3 + 3.52\lambda^4 \tag{2}$$

where: $\lambda = 1/(1 + (a/r))$

The interest model is NASGRO model when totality of fatigue crack growth curves is considered. Nasgro model are expressed bellow (Eq. 3):

$$\frac{da}{dN} = C\left[\left(\frac{1-f}{1-R}\right)\Delta K\right]^n \frac{\left(1 - \frac{\Delta K_{th}}{\Delta K}\right)^p}{\left(1 - \frac{K_{\max}}{K_{crit}}\right)^q} \tag{3}$$

f present the contribution of crack closure and the parameters C, n, p, q were determined experimentally and ΔK_{th} is the crack propagation threshold value of the stress–intensity factor range. For constant amplitude loading, the function f was determined by Newman [28] (see Eq. 4).

$$f = \frac{K_{op}}{K_{\max}} = \begin{cases} \text{Max}\left(R, A_0 + A_1 R + A_2 R^2 + A_3 R^3\right) & R \geqslant 0 \end{cases} \tag{4}$$

Crack growth parameters of Nasgro model for both materials are presented in Table 3.

Table 3. Parameters of Nasgro model for Al-alloys

Al-Alloy	ΔK_{tho} $MPa\sqrt{m}$	K_{IC} $MPa\sqrt{m}$	K_C $MPa\sqrt{m}$	n	p	q	C
2024 T351	2.857	37.36	74.72	3	0.5	1	1.707×10^{-10}
6061 T6	3.846	28.57	50.0	2.3	0.5	0.5	0.840×10^{-10}

3.2. Residual stress effect on fatigue crack growth

The variation of the fatigue crack growth rate (FCGR) as a function of the amplitude of the stress intensity factor ΔK through residual stresses fields obtained for different preload levels for 2024 T351 Al-alloy is shown in Figure 11. The result shows that FCGR depends on the magnitude of the compressive residual stresses developed at edge of hole.

We note that the FCGR increases while decreasing the preload level. At preloading level σ_p/σ_y equal 1.350, FCGR is about 1.6×10^{-9} m/cycle to crack initiation; against by a low level ie at σ_p/σ_y= 1.047, the FCGR is 1.75×10^{-7} m/cycle. This reduction is influenced by the decrease in residual stress intensity factor K_r whose variation is shown in Figure 12. Factor K_r past from -13.83 $MPa\sqrt{m}$ to -4.65 $MPa\sqrt{m}$. In absence of residual stress, FCGR is about 3.83×10^{-7} m/cycle.

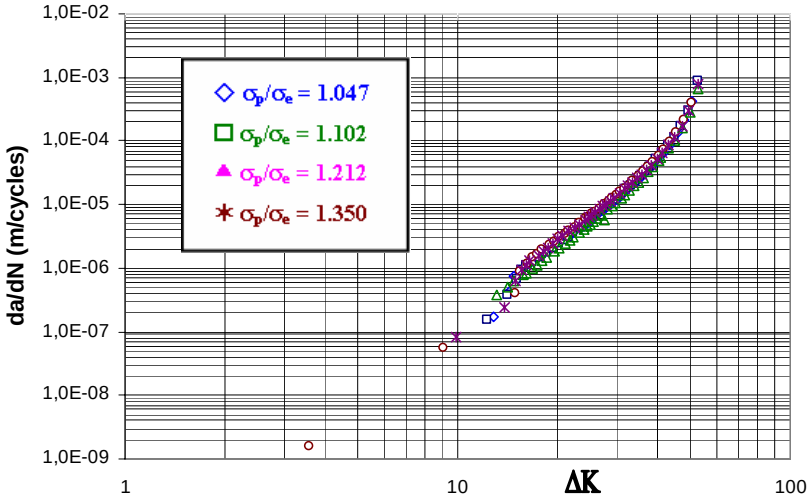

Figure 11. Preload levels effect on FCGR for 2024 T351 Al-alloy at R=0.25

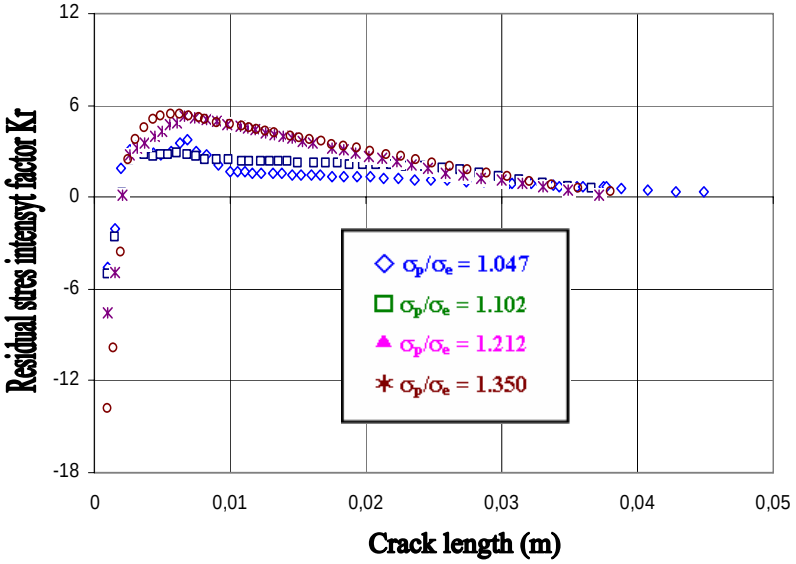

Figure 12. Variation of residual stress intensity factor Kr for preload levels of 2024 T351 Al-alloy

Residual stress effect on FCGR for 6061 Al-alloy is shown in figure 13. Their effect was significant at early cracking when residual stresses are is compressive state. Comparatively to state without residual stress, FCGR for level σ_p/σ_y equal to 1.19 was increased by 30%. For high preload level, σ_p/σ_y=1.37, FCGR was increased by 28.6%. The increasing of FCGR was linked to the decreasing of factor Kr when his variation was shown in figure 14. From 3.37 mm of crack length, residual stress intensity factor at σ_p/σ_y=1.37 is greatest to the other levels. This increasing was due to the presence of tensile residual stress at this area from 3.37 to 20 mm. The effect of residual stress was explained by the variation of stress ratio at any cycles for specified crack length.

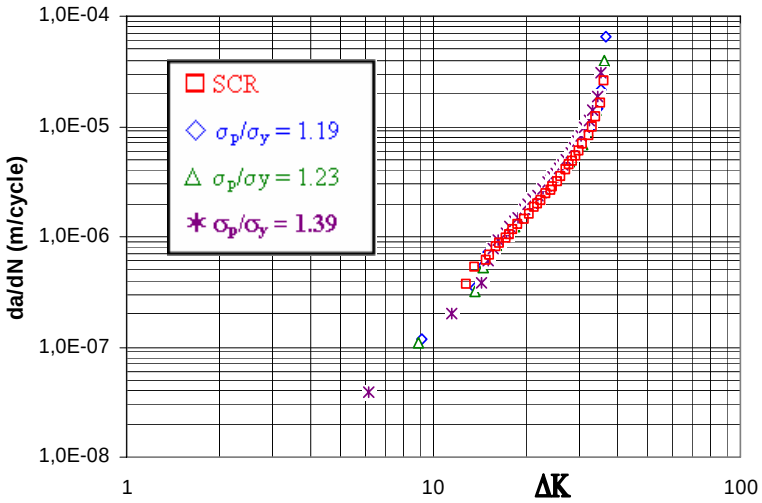

Figure 13. Preload levels effect on FCGR for 6061 T6 Al-alloy at R=0.25

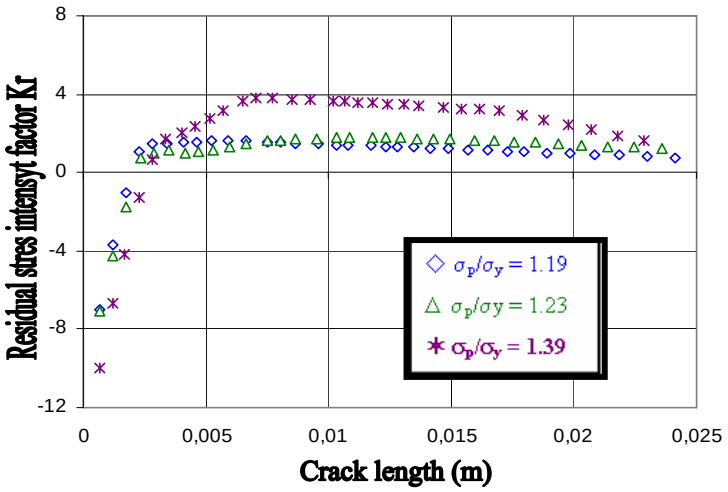

Figure 14. Variation of residual stress intensity factor Kr for preload levels of 6061 T6 Al-alloy

Abstract There are different documents and standards containing fatigue crack propagation limit or design curves and rules for the prediction of crack growth. The research work aimed to characterise the fatigue crack propagation resistance of different steels using limit curves, based on statistical analysis of test results and fatigue crack propagation law, and to determine fatigue crack propagation limit curves for different structural steels and wide-spreading high strength steels, and their welded joints, under mode I and mixed mode I + II loading conditions. Experiments were performed on different (high strength) steels and partially their welded joints. The specimens were cut parallel and perpendicular to the characteristic directions of the materials; therefore the specimens represent the different possible locations of cracks in the base materials and welded joints. Fatigue crack growth experiments were performed by *ΔK*-decreasing and constant load amplitude methods. The evaluation process consists of six steps and by means of the evaluated and selected values a simplified method can be proposed for determination of fatigue crack propagation limit curves. The determined limit curves represent a compromise of rational risk and acceptable safety.

Keywords fatigue crack growth, limit curve, high strength steel, engineering critical assessment

1. Introduction

Reliability of a structural element having crack or crack-like defect under cyclic loading conditions is determined by the geometrical features of the structural element and the flaws, the loading conditions, as well as the material resistance to fatigue crack propagation. There are different documents [1-3], standards and recommendations [4-6] containing fatigue crack propagation limit or design curves and rules for the prediction of crack growth [6, 7]. The background of the fatigue crack propagation limit curves and the calculations consist of two basic parts: statistical analysis of numerous experiments (fatigue crack propagation tests) and fatigue crack propagation law, frequently the Paris-Erdogan law [8],

$$\frac{da}{dN} = C\Delta K^n, \tag{1}$$

where *da/dN* is the fatigue crack growth rate, *ΔK* is the stress intensity factor range, furthermore *C* and *n* are material constants.

The research work aimed
- to characterise the fatigue crack propagation resistance of different steels using limit curves [9], [10], based on statistical analysis of test results and the Paris-Erdogan law;
- determination of limit curves for different structural steels and wide-spreading high strength steels [11], and their welded joints, under mode I (tension) and mixed mode I + II (tension and shear) loading conditions.

2. Examinations

2.1. Materials and welding characteristics

The most important characteristics of the investigated structural steels and high strength steels, and used welding technologies are summarized in Table 1.

Table 1. Main characteristics of the investigated materials and used welding technologies

Steel type	Grade/Mark	Welding method	Shielding gas	Filler material
micro-alloyed	37C	gas metal arc	100 CO_2	VIH-2
low-alloyed DP	DP-25156	–	–	–
micro-alloyed	E420C	gas metal arc	80 Ar + 20 CO_2	Union K56
high strength TRIP	TRIP-28670	–	–	–
high strength	X80TM	gas metal arc	82 Ar + 18 CO_2	X-90 IG
high strength	QStE690TM	–	–	–
high strength	S960QL	under development (see 5. Conclusions, too)		
high strength	XABO 1100	–	–	–

The measured mechanical properties (R_y, R_m, A_5) and the therefrom calculated values (R_y/R_m, R_m*A_5) of the investigated base materials and weld metals are summarized in Table 2.

Table 2. Mechanical properties and characteristic calculated values of the investigated materials

Grade/Mark	R_y [(1)] N/mm^2	R_m N/mm^2	R_y/R_m –	A_5 %	$R_m * A_5$ $N/mm^2 * \%$

(1) R_y means R_{eH} or $R_{p0,2}$.
(2) For these material A_{80} instead of A_5.
(3) For these material A_{97} instead of A_5.

Fig. 1 shows the ultimate tensile strength vs. elongation (fracture strain) diagram [12] and the location of the investigated base materials based on the data can be found in Table 2.

2.2. Fatigue crack growth examinations

Compact tension (*CT*), three point bending (*TPB*) and single edge notched tension (*SENT*) specimens were tested for base materials and welded joints, while for testing of weld metal *TPB* type specimens were used. *CT* and *TPB* type specimens were cut from the sheets parallel and perpendicular to the rolling direction, so the directions of fatigue crack propagation were the same. For testing of weld metals cracks, which propagate parallel or perpendicular to the axis of the joint were also distinguished. Compact tension shear (*CTS*) specimens were used for tests under mixed mode I + II loading condition. The specimens were cut parallel to the rolling direction; the ratio of the two loading modes (I and II) was varied using a special specimen holder [13], so the cracks were propagated in different angles according to the rolling direction.
Tests were carried out according to the ASTM prescription [14] by an universal electro-hydraulic MTS testing machine. Experiments were performed by ΔK-decreasing and constant load amplitude methods, at room temperature, in air, following sinusoidal loading wave form. Stress ratio was constant ($R = 0,1$), and the crack propagation was registered by compliance and/or optical method.

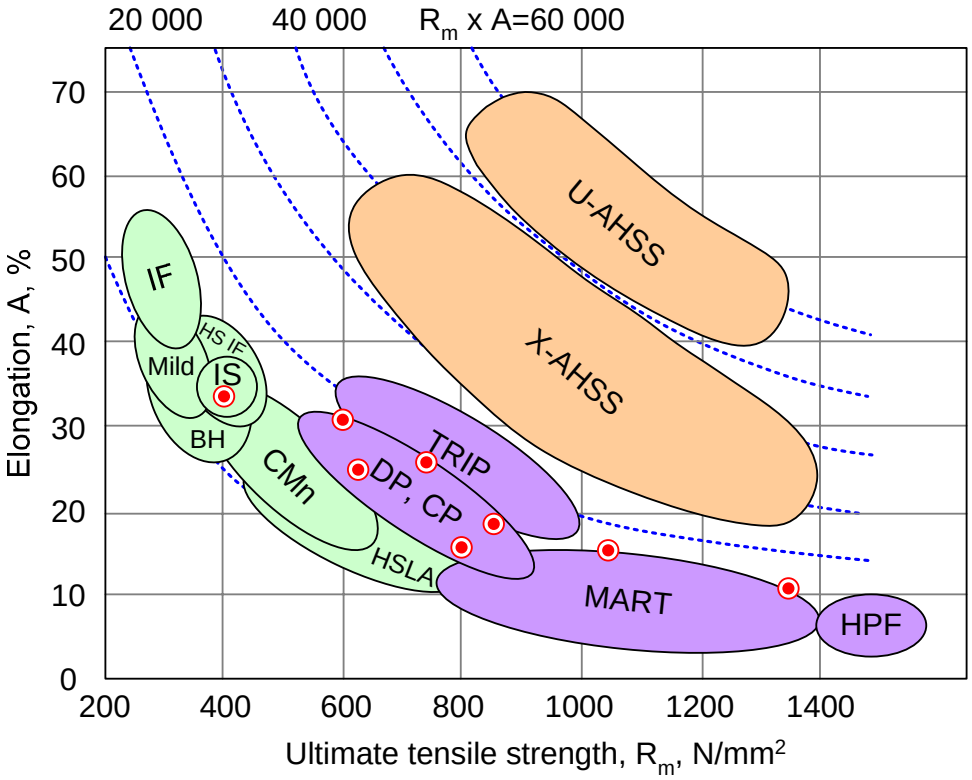

Figure 1. The investigated base materials in the ultimate tensile strength vs. elongation diagram

Fig. 2, Fig. 3 and Fig 4 show the calculated kinetic diagrams (fatigue crack propagation rate vs. stress intensity factor range curves) of tested DP-25156 and TRIP-28670 steels using *SENT* specimens, and S960QL steel using *TPB* specimens, respectively.

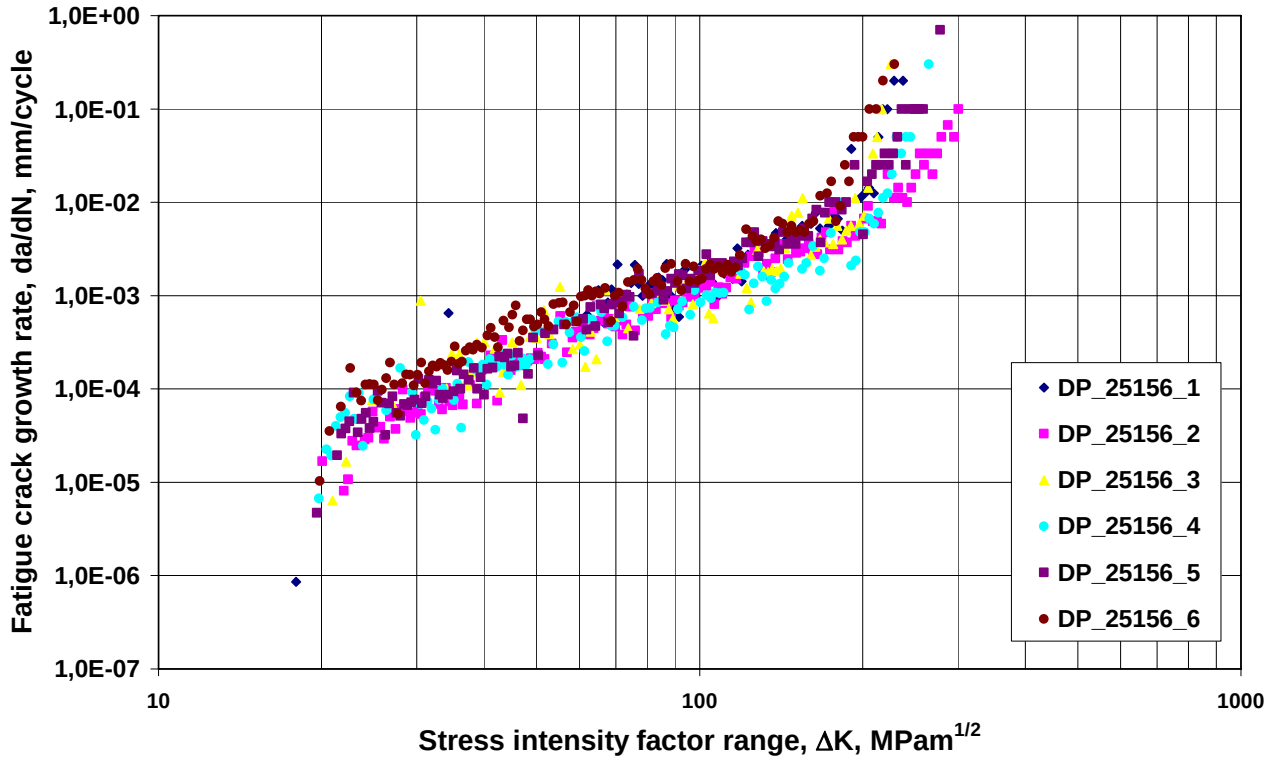

Figure 2. Kinetic diagrams of fatigue crack propagation from tested DP-25156 steel (*SENT* specimens)

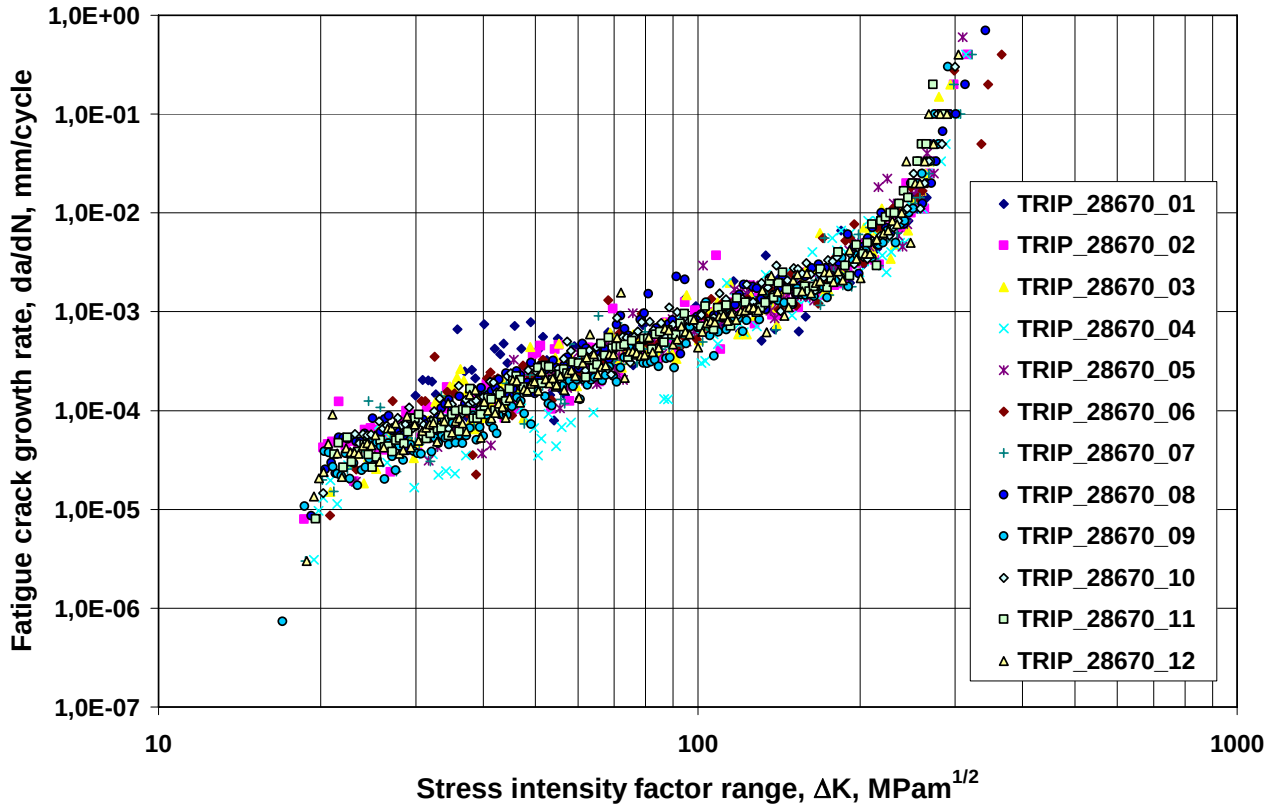

Figure 3. Kinetic diagrams of fatigue crack propagation from tested TRIP-28670 steel (*SENT* specimens)

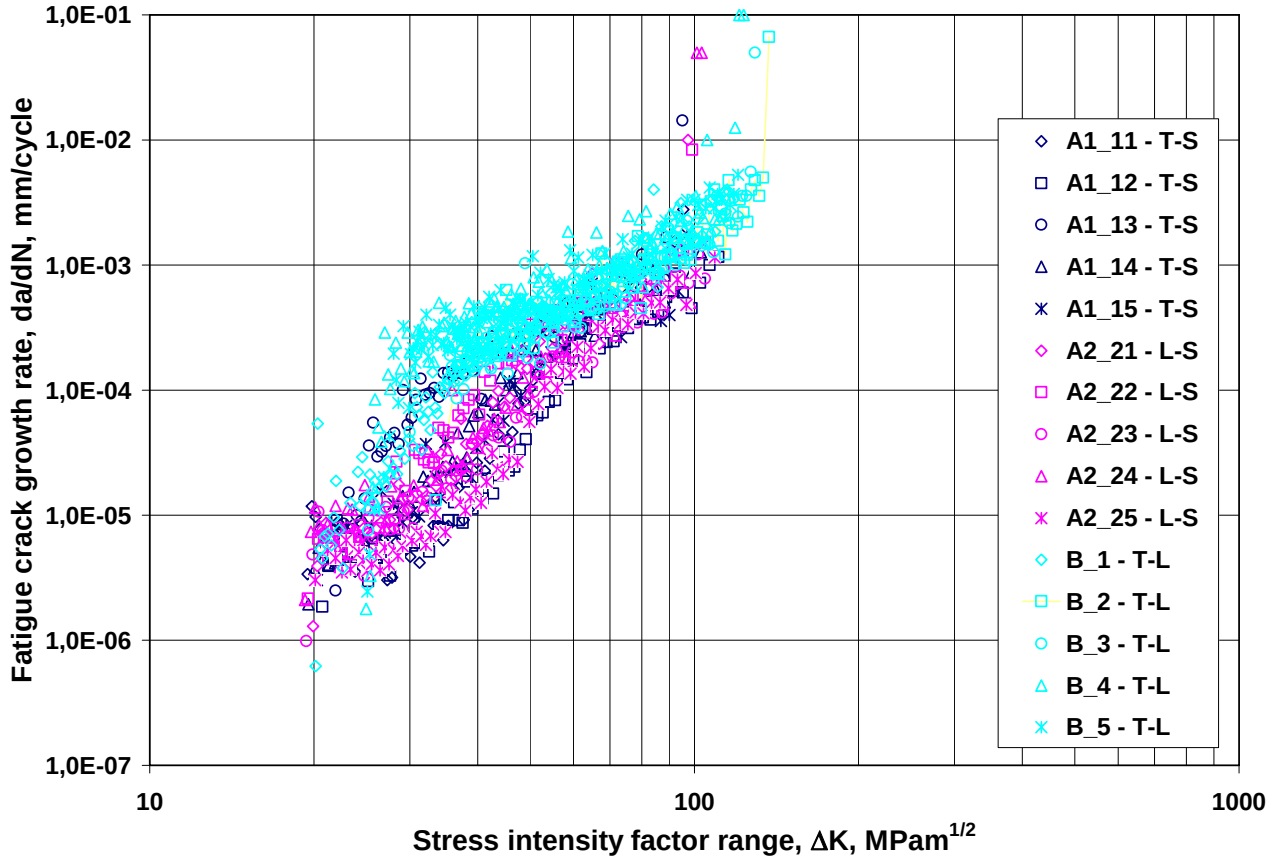

Figure 4. Kinetic diagrams of fatigue crack propagation from tested S690QL steel (*TPB* specimens)

3. Determination of fatigue design limit curves

The determination of the fatigue design limit curves consists of six steps.

First step: determination of measuring values. Values of threshold stress intensity factor range (ΔK_{th}) and two parameters of Paris-Erdogan law (C and n) were calculated according to ASTM prescriptions [14]. Fatigue crack propagation rate was determined by secant method or seven point incremental polynomial method. Values of fatigue fracture toughness (ΔK_{fc}) were calculated from crack size determined on the fracture surface of the specimens by the means of stereo-microscope.

Second step: sorting measured values into statistical samples. On the basis of calculated test results, mathematical-statistical samples were examined for each testing groups. As its method, Wilcoxon-probe was applied [15], furthermore statistical parameters (average, standard deviation and standard deviation coefficient) of the samples were calculated. Standard deviation coefficients (standard deviation/average) of the samples were generally less than *0,2*, which means reliable and reproducible testing and data processing methods. Table 3 summarizes the mathematical-statistical samples and their characteristics of experimental results on S690QL steel, as an example.

Table 3. Mathematical-statistical samples and their characteristics of experimental results on S690QL steel

Orientation	Element number of the sample	Parameter	Unit	Average	Standard deviation	Standard deviation coefficient
T-S	5	n	–	3,959	0,946	0,2390
L-S	5			3,735	0,273	0,0731
T-S and L-S	10			3,847	0,667	0,1734
T-L	5			2,441	0,615	0,2519
T-S	5	ΔK_{fc}	$MPam^{1/2}$	100,22	6,685	0,0667
L-S	5			102,68	4,574	0,0446
T-S and L-S	10			101,45	5,553	0,0547
L-T	5			125,11	8,385	0,0670

Third step: selection of the distribution function. Afterwards it was examined, what kind of distribution functions can be used for describing the samples. For this aim Shapiro-Wilk, Kolmogorov, Kolmogorov-Smirnov and χ^2 statistical probes were used at a level of significance $\varepsilon = 0,05$ [15-17]. It was concluded, that three parameter Weibull-distribution is the only function suitable for describing all the samples.

Fourth step: calculation of the parameters of the distribution functions. Parameters of three parameter Weibull-distribution function were calculated for all the samples:

$$F(x) = 1 - \exp\left[-\left(\frac{x - N_0}{\beta} \right)^{1/\alpha} \right] \tag{2}$$

where N_0 is the threshold parameter, α is the shape parameter and β is the scale parameter of the three parameter Weibull distribution function.

Fifth step: selection of the characteristic values of the distribution functions. Based on the calculated distribution functions, considering their influencing effect on life-time, characteristic values of ΔK_{th}, n and ΔK_{fc}, were selected. With the help of these values a reliable method can be proposed for determination of fatigue crack propagation limit curves:

– the threshold stress intensity factor range, ΔK_{th}, is that value which belongs to the *95 %*

probability of the Weibull-distribution function;
- the exponent of the Paris-Erdogan law, n, is that value belonging the *5 %* probability of Weibull-distribution function;
- the Paris-Erdogan constant, C, is calculated on the basis of the correlation between C and n;
- the critical value of the stress intensity factor range or fatigue fracture toughness, ΔK_{fc}, is that value which belongs to the *5 %* probability of the Weibull-distribution function.

Sixth step: calculation of the parameters of the fatigue crack propagation limit curves. Simplified method was used for the calculation of the design curves, based on simple crack growth law, using the above mentioned five steps. The details of the curves can be found in the Table 4. and on Fig. 5.

Table 4. Details of determined fatigue crack propagation limit curves (simple law)

Grade/Mark	ΔK_{th}	n	C	ΔK_{fc}
	$MPam^{1/2}$	$MPam^{1/2}$ and mm/cycle		$MPam^{1/2}$
37C base material	10,4	2,98	8,22E-09	53
37C welded joint	–[(1), (2)]	3,16	2,42E-09	70
DP-25156 base material	–	2,02	1,68E-07	95
E420C base material	8,0	2,26	9,78E-08	92
E420C welded joint	–[(1), (3)]	2,74	1,16E-08	101
TRIP-28670 base material	–	1,84	3,06E-07	250
X80TM base material	–	1,78	3,74E-07	129
X80TM welded joint	–[(1)]	1,86	3,13E-07	–
QStE690TM base material	–	1,82	3,27E-07	–
QStE690TM base material[(4), (5)]	–	2,15	1,09E-07	–
S960QL base material	–	1,80	3,50E-07	94
XABO 1100 base material	–	1,76	4,00E-07	104

(1) It can be derived from data concerning to the base metal after the evaluation of characteristic and assessment of magnitude of residual stresses.

(2) Average value of *16* tests under compressive residual stress: $\Delta K_{th} = 16{,}9\ MPam^{1/2}$.

(3) Average value of *4* tests under compressive residual stress: $\Delta K_{th} = 16{,}3\ MPam^{1/2}$.

(4) Under mixed mode I + II (tension and shear) loading condition.

(5) ΔK should be replaced by ΔK_{eff}.

4. Discussion

For the investigated steels and their welded joints both the tendency of threshold stress intensity factor range (ΔK_{th}) and the tendency of the Paris-Erdogan exponent (n) decrease with the increase of the strength of material; while the tendency of fatigue fracture toughness (ΔK_{fc}) has not unambiguous dependence on the strength of material.

For the investigated steels both the Paris-Erdogan exponent (n) and the fatigue fracture toughness (ΔK_{fc}) for welded joints are higher than those of base materials.

The proposed method is suitable for determination of fatigue crack propagation design curves under mixed mode I + II (tension and shear) loading condition, too. For this case stress intensity factor range (ΔK) should be replaced by effective stress intensity factor range (ΔK_{eff}).

The design curves of welded joints in the near threshold region are open. On the one hand, if the threshold stress intensity factor range value (ΔK_{th}) is not known, values can be found in the

literature (e.g. [18]) are usable. On the other hand, the threshold stress intensity factor range, ΔK_{th}, must be reduce by tensile residual stress field and may be increase by compressive residual stress field (e.g. welding residual stresses).

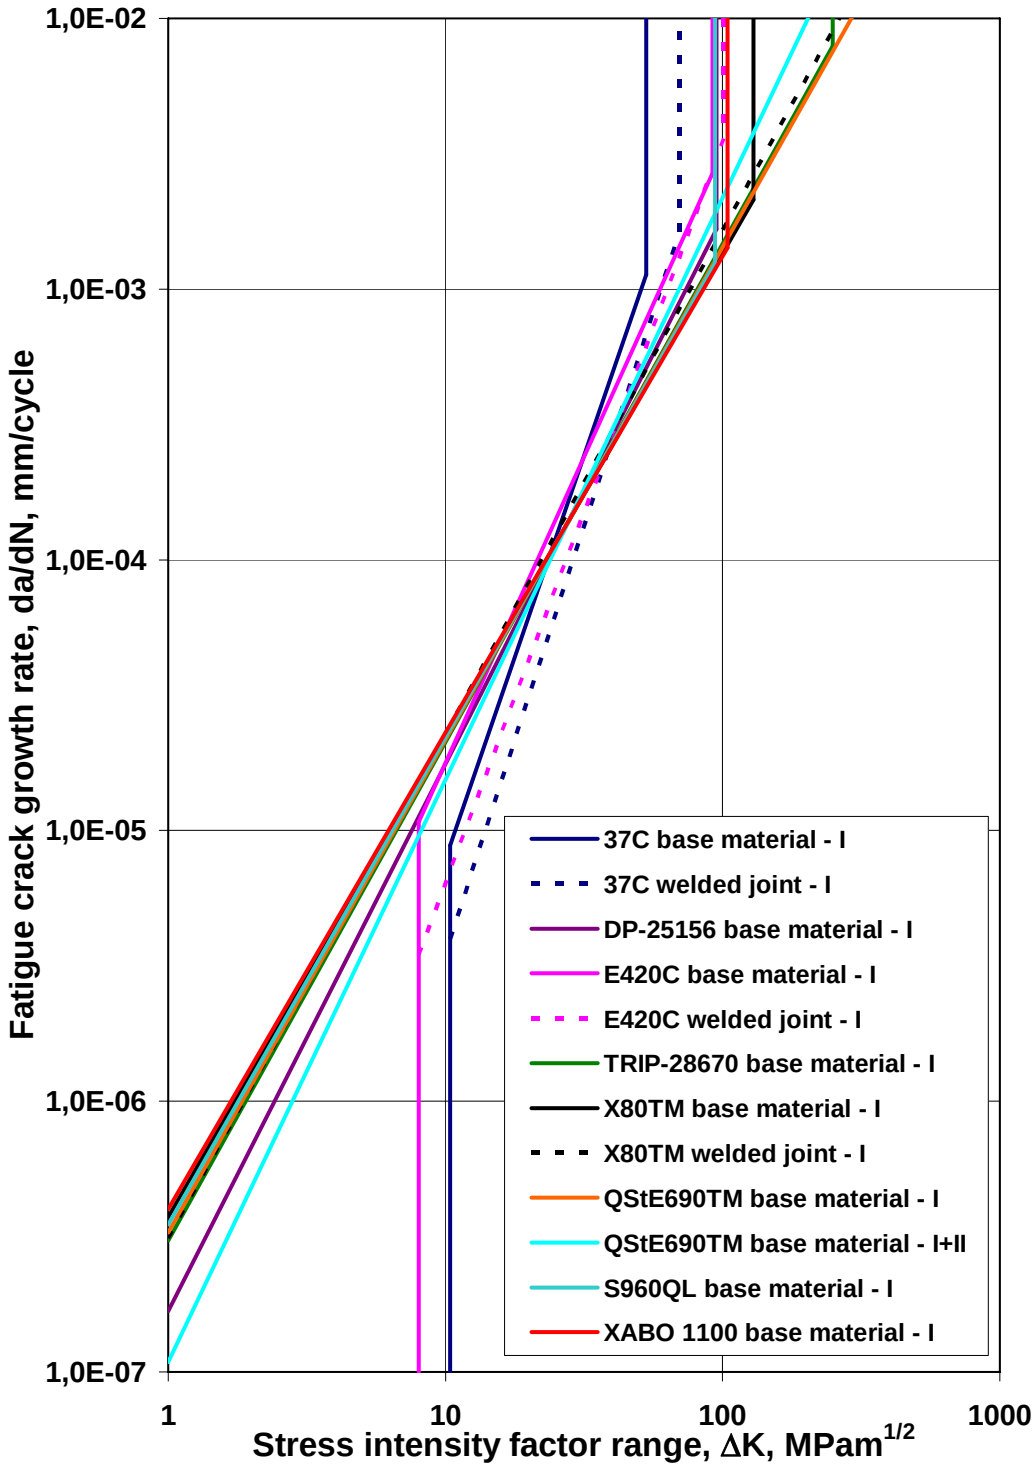

Figure 5. Fatigue design limit curves for the investigated steels, and their welded joints

The calculated fatigue crack propagation limit curves of base materials locate among the design curves determined by various procedures. Table 5. summarizes our measured average data and measured individual data can be found in the literature [19]. It can be concluded that our average values are in harmony with the individual values.

Table 5. Comparison of measured data with data from the literature

Grade/Mark	R_y	R_m	ΔK_{th}	n	ΔK_{fc}

5. Conclusions

Based on the results of our experimental tests, evaluated samples and data can be found in the literature the following conclusions can be drawn.

- The proposed method can be generally applied for determination of fatigue crack propagation limit curves for steels and high strength steels, and their welded joints under mode I (tension) and mixed mode I + II (tension and shear) loading conditions. Additional information of applications of the proposed method for metallic materials (e.g. pressure vessel steels, aluminium alloys, austempered ductile iron) and non-metallic materials (e.g. silicon nitride ceramics, polymers, reinforced polymer matrix composites) see in our earlier works in the literature [10, 21-23].
- The limit curves calculated by both methods represent a compromise of rational risk (not the most disadvantageous case is considered) and striving for safety (uncertainty is known).
- Based on the determined fatigue design limit curves integrity assessment calculations can be done for operating structural elements and structures having cracks or crack-like defects:
  - = determination of propagable an critical crack sizes;
  - = calculation of lifetime determined by the propagable crack size;
  - = calculations of remaining lifetime functions, influences on the lifetime values and lifetime function (parameter study);
  - = reliability of remaining lifetime estimation;
  - = calculation of damage parameter and damage function [24].
- The examinations of the welded joints should be continued. The welding technologies, the welding parameters and their influences should be investigated, on the basis of their influences on the properties and the adequacy of the welded joints [25, 26].

Abstract Coke drums are vertical pressure vessels used in the delayed coking process in petroleum refineries. Significant temperature variation during the delayed coking process causes damage in coke drums in the form of bulging and cracking. There were some studies on the fatigue life estimation for the coke drums, but most of them were based on strain-fatigue life curves at constant temperatures which do not consider simultaneous cyclic temperature and mechanical loading conditions. In this study, a thermal-mechanical material testing system is successfully designed and implemented. A selected set of base and clad materials of coke drums are investigated under isothermal cyclic loadings. In addition, a comparative study between isothermal and thermal mechanical fatigue lives of clad materials is conducted. Some of these fatigue tests are similar to the actual loading scenario experienced by the coke drums. The experimental findings lead to better understanding of the damage mechanisms occurring in coke drums and more accurate prediction of fatigue life of coke drum materials.

Keywords: Coke drums, Low cycle fatigue, Isothermal mechanical fatigue, Thermal mechanical fatigue

1. Introduction

Coke drums are vertical pressure vessels used in the delayed coking process in petroleum refineries and oil sands plants. They are normally constructed of carbon or low carbon alloy steels and internally clad with SA 240 Type 410S or Type 405 stainless steel to protect the coke drums from corrosion. They range in size from 4 to over 9 meters in diameter and 25 to over 40 meters in height. The maximum shell thickness varies from 14 to 42 millimeters. The maximum operating temperature ranges from 427 to 482°C [1].

First, heavy residual is imported into a coker heater and heated to approximately 482°C. Before direct the heavy oil into the coke drum, the drum is preheated by flowing vapour from the bottom of the drum to the top. (Temperature rises from approximate 150 °C to 360 °C). Then, the hot heavy oil is directed into the coke drum to begin the fill cycle. The fill cycle usually takes 14-18 hours. When the filling is completed, light hydrocarbon from the coke produced during the thermal cracking process is removed by steam stripping. (Temperature drops from 450 °C to 250 °C approximately) After that, high rate of quench water is injected into the coke drum cooling the vessel and possibly extracting the solid coke. After soaking, the solid coke is cut by applying the high-pressure water steams. After all the coke is removed from the drum, the coke drum is reheated and checked in order to prepare for a new operation cycle. [1]

The severe cyclic thermal-mechanical load makes coke drums susceptible to damage. It is also found that shell bulging is one of the causes contributing to cracking and failure in the vessel shell

of coke drums. There are studies on the fatigue life estimation for the coke drums [2-4], these are based on base metal under uniaxial isothermal fatigue lives which do not consider cyclic temperature conditions. Xia et al. [5, 6] conducted a finite element study on heat transfer and stress analysis of coke drum for a complete operating cycle. It is found that significant stress and strain values are observed at the clad of the coke drum, which can exceed the yield limit of the material. Therefore, the fatigue life evaluation of coke drum based only on base material is not sufficient. The more accurate evaluation of the fatigue life behavior should be carried out under loading conditions similar to the operational condition, such as under thermal-mechanical cyclic loading.

In this paper, a successfully-developed thermal-mechanical fatigue testing system is presented. A selected set of base and clad materials of coke drums are investigated under isothermal cyclic loadings. In addition, in addition, a comparative study between isothermal and thermal mechanical fatigue lives of clad materials is conducted.

2. Experimental Setup

In order to experimentally investigate fatigue life of coke drum materials under thermal-mechanical cyclic loading, a thermal-mechanical fatigue (TMF) testing system has been successfully installed in our lab. The system mainly consists of a closed-loop servo-controlled hydraulic MTS testing machine which is used as a principal loading frame, a heating device, a control system, and gripping fixtures.

2.1. Heating Device

The TMF testing involves a temperature cycling. Therefore, a relatively fast heating and cooling is essential for conducting a fatigue test. There are various techniques including induction, direct resistance, radiant, or forced air heating. By evaluating the scope of this research and the interested regime of fatigue life, an induction heating with power rated at 5 kW is selected as a effective heating source. The induction unit mainly consists of a power unit, a working coil, and a cooling system. By positioning the conductive material such as metal specimen inside the working coil, the specimen can be heated up at adjustable rate. Because the working coil provides an open environment, this approach also offer an opportunity to install active specimen cooling (for example, forced air) to achieve desired cooling rate.

One of the difficulties using this system is to minimize the dynamic thermal gradient along the axial-direction of the specimen. The configuration of working coil plays an important role affecting the thermal gradient along the axial direction. Variables such as number of coil turns and patterns can have significant effect on the thermal gradients. There are several researchers [7-10] investigated the effect of working coil configuration on the thermal gradient of the specimen. In reference [7] it was found that by using ten-turns one direction helical configuration of the working coil, the thermal gradient along the gauge length of a solid cylindrical specimen could be within ±10°C at 800°C. In reference [9] an investigation on the effect of working coil configuration on

solid flat specimen was carried out. It concludes that an elliptical coil with its centre axis perpendicular to the middle axis of the specimen gives a smallest thermal gradient on the solid flat specimen. In addition, it was recommended in [10] that a longitudinal opposite direction working coil is for better axial temperature gradients. An experimental investigation of effect of working coil configurations on thermal gradient along a flat specimen was first carried out, as shown in Fig. 3-3.

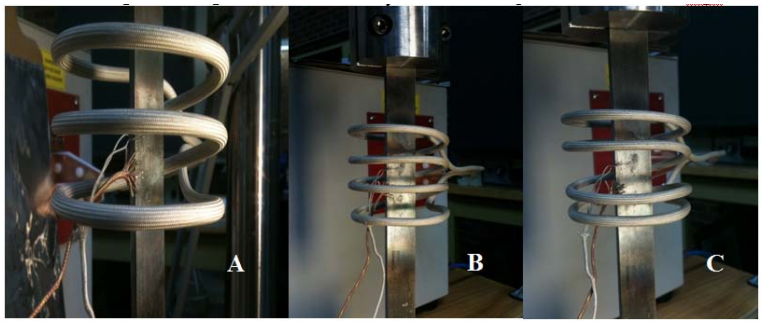

Figure 1 Configuration of working coil on flat specimen

Fig. 1 A-C shows the one direction longitudinal configuration with different turns. The temperature increases up to 500°C, and the dynamic temperature was recorded. The results shows that the working coil configuration C (4 turns with 25 mm gap in the middle) gives the minimal thermal gradients (10°C) at 500°C.

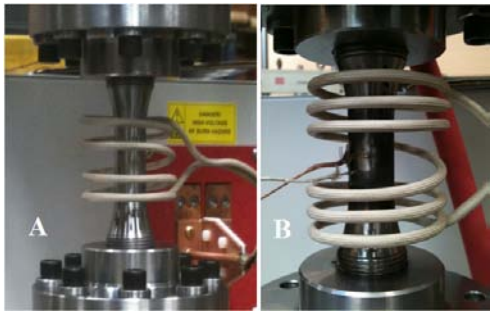

Figure 2 Configuration of working coil on thin-walled tubular specimen

Fig. 2 shows the two different working coil configurations on thin-walled tubular specimen. The temperature increases up to 500°C, and the dynamic temperatures were recorded. The results shows that the working coil configuration A (4 turns with gap in the middle) gives larger thermal gradients (50°C) at 500°C. If the number of turns increases to 6 with gap in the middle, the thermal gradients greatly reduced to 10°C at 500°C.

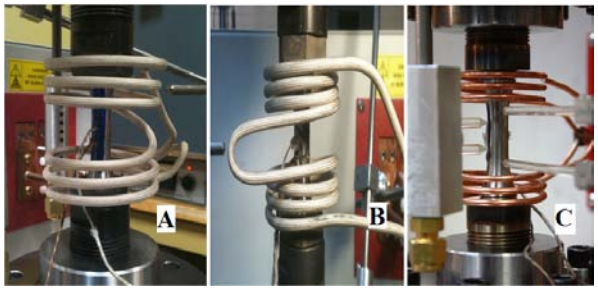

Figure 3 Configuration of working coil on cylindrical solid specimen

Figure 3 shows the three different working coil configurations on cylindrical solid specimen. The results showed that the working coil configuration A (6 turns with gap in the middle) gives larger thermal gradients (30~40°C) at 500°C. A configuration of longitudinal opposite-direction working coil (Fig. 3-5 B) was then tested, the result showed oppose thermal gradient (500°C in the center, 520~530°C at 12.7 mm away from the center). After several trial and error experimentations, the third configuration C was designed. Two separate working coils were attached on the power unit, and each with three turns. From the experimental result of this configuration, the dynamic thermal gradient almost disappears (within 5~10°C) along the axial direction at 500°C. Therefore, through this series of experimentations of working coil configuration, two separate working coil gives the minimal thermal gradient in axial direction.

2.2. Control System

To conduct in-phase strain-controlled TMF test, a program was written in the control system to accurately manage all the components. The dynamic temperature of the specimen is measured by the spot-welded thermocouple in the center of the gage length, and the temperature controller sends the measurement to the signal controller synchronistically. The signal controller send the commands to the heater and air jet during the heating and cooling phases, and it also controls the axial strain to feedback the hydraulic piston to apply the load. All the data is stored by the data acquisition on timed-basis. The strain is controlled by the dynamic temperature signal as shown in Fig. 4. The thermal cycling is carried out at beginning of each test, and thermal strains at T_{max} and T_{min} are recorded. The total strains at T_{max} and T_{min} are calculated:

$$\varepsilon_{Tot}^{T_{\max}} = \varepsilon_{Thermal}^{T_{\max}} + \varepsilon_{mech} \tag{1}$$

$$\varepsilon_{Tot}^{T_{\min}} = \varepsilon_{Thermal}^{T\min} + (-\varepsilon_{mech}) \tag{2}$$

A strain-temperature range ratio δ is defined as:

$$\delta = \frac{\Delta\varepsilon}{\Delta T} = \frac{\left(\varepsilon_{Tot}^{T_{\max}} - \varepsilon_{Tot}^{T_{\min}}\right)}{\left(T_{\max} - T_{\min}\right)} \tag{3}$$

both ε and T in voltages.

The ratio of input to output voltages of the gain amplifier and attenuator is then adjusted to the ratio of δ. The temperature cycling between T_{max} and T_{min} will also generate a voltage which is equal to total strain at the corresponding temperature. After the test, thermal strain is fitted as a function of temperature in a polynomial equation. The mechanical strain can be obtained by subtracting the thermal strain from the total strain.

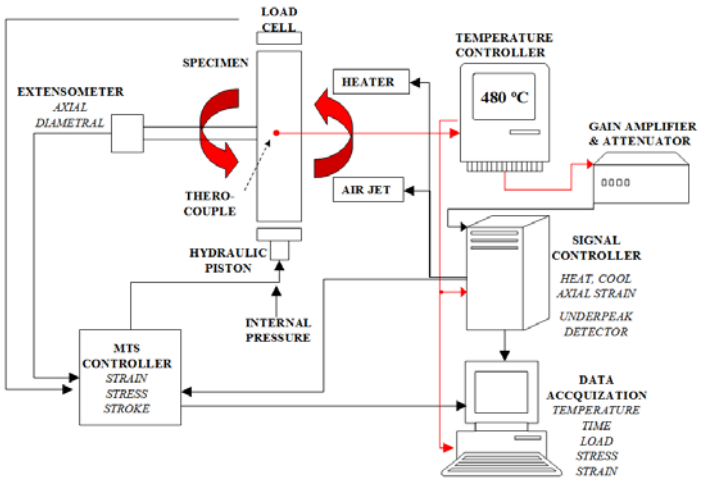

Figure 4 Demonstration of temperature-dependent strain-controlled mode

2.3. Strain Control and Measurement

A new strain control and measurement technique is introduced for high temperature fatigue testing. For high temperature strain-controlled fatigue tests, implementation of punching dimples or knife-edges within gauge length of specimen are common practices for mounting extensometers. Premature failure on the test section of the specimens were introduced at the punch dimple or knife-edge contact area by implementing these techniques as shown in Fig. 5 A and B, respectively.

Figure 5 Photos of premature failure caused by dimple and knife-edge

Alternatively, a pair of dimples is punched outside the gauge length of the specimen as shown in Fig. 6. The punched dimples are located on the thicker cross sections which are outside the effective gauge length of the test sections. Therefore, the premature failure will not be introduced by these dimples. However, since the controlled strain is from outside of gage length, a correlation between measured strain and strain within gauge length should be carefully calibrated and verified. The correlation coefficient is defined as (in this case):

$$C = \frac{\varepsilon_{0.6"}}{\varepsilon_{1"}} \tag{4}$$

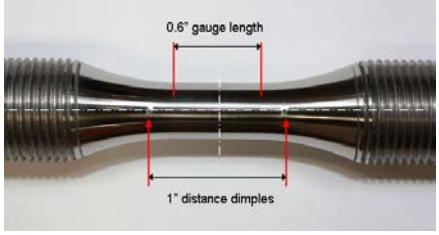

Figure 6 Picture of the specimen with dimples

Two approaches, analytical analysis and finite element analysis are implemented to establish the strain correlation at elevated temperature for each material. The results are then compared with the experiments to verify the established correlations at each temperature.

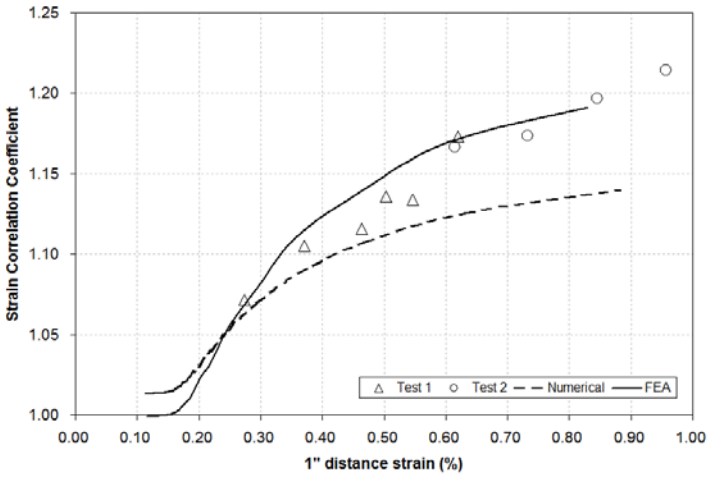

Figure 7 Comparison of room temperature correlation coefficients

The correlation coefficients between the experiment and the two analysis methods are shown in Fig. 7. It can be seen that the experimental points are mainly fallen in the range between the two correlation curves by the analytical and FEA methods. At higher strain range, those points are closer to the FEM correlation curve. However, the difference of the correlation coefficients predicted by the analytical and FE methods is about only 4% when the strain is up to 0.8%. Therefore, a mean curve of the two predictive curves is suggested to be used. In addition, the strain correlation technique can also be applied to thermal-mechanical fatigue tests.

2.4. Materials and Test program

Table 1 Tested coke drum materials

Name	Nominal Chemical Comp.	Plate
SA387 Gr. 22 CL2	2 ¼Cr-1 Mo	Base
SA 240 TP410S	13Cr	Clad

In this paper, low cycle fatigue tests conducted for the following materials: SA387 Gr. 22 CL2 and 410S. Uni-axial isothermal low cycle fatigue tests were carried out as benchmark tests. The tests are under strain-controlled condition at rate of 0.005/Sec. The tests were conducted at fully-reversed cyclic loading condition ($R=\varepsilon_{min}/\varepsilon_{max}$ = -1) at both 100 and 480°C. In addition, TMF tests were conducted on 410S. The tests are under temperature-dependent strain-controlled condition, and in-phase thermal-mechanical loading was applied.

3. Results

Isothermal fatigue lives of SA387 Gr.22 CL 2 at 100 and 480^{o}C are shown in Fig 8. From the results,

it is shown that as the temperature increases, the fatigue life decreases. One also see that the linear lines can fit the data points quite well, in addition the two fatigue lines at two different temperature are almost parallel to each other in the log-log scale graphs. Therefore, the isothermal fatigue data can be fit by the following equation:

$$\frac{\Delta\varepsilon}{2} = A(T)(N_f)^c \tag{5}$$

where $\Delta\varepsilon/2$ is the strain amplitude (mechanical strain), N_f is the number of cycle to failure, c is a constant and A is a temperature dependent constant,

where
$$A(T) = A_{T_{\max}} - \frac{(T_{\max} - T)(A_{T_{\max}} - A_{T_{\min}})}{(T_{\max} - T_{\min})} \tag{6}$$

T_{max} = 480°C and T_{min} =100°C in this case.

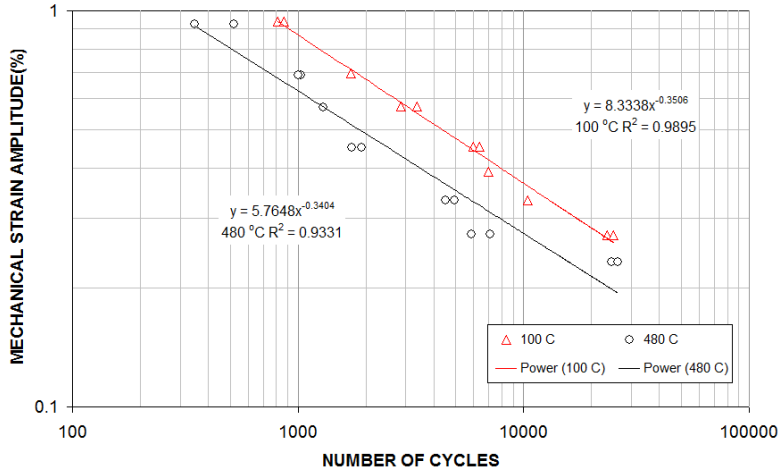

Figure 8 Isothermal fatigue Lives of SA387 GR.2 CL2 at 100 and 480°C

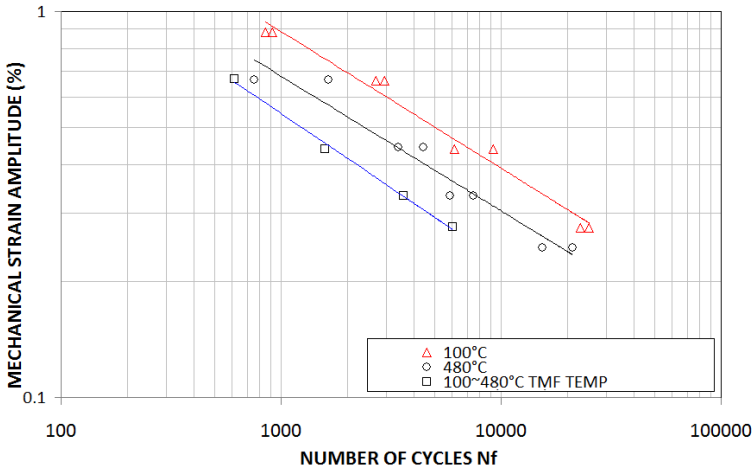

Figure 9 Isothermal and TM fatigue lives of 410S

Isothermal and thermal-mechanical fatigue lives of 410S are shown in Fig 9. From the results, it is shown the same trend as that of the isothermal fatigue tests for the material SA387 Gr. 22 CL2. Therefore the same form of the above equations (5) and (6) can be used to fit the fatigue life data

for the material 410S. In Fig. 9, four data points from the in-phase TMF tests with temperature cycling between 100 and 480°C are provided. It is found that the fatigue life of 410S under TMF loading is even shorter than the life at constant temperature of 480°C, though in the TMF loading the maximum temperature is 480°C. Due to the insufficient amount of data conducted, more data points are required to verify the trend of this observation.

4. Summary

In this paper, newly-developed thermal-mechanical fatigue testing system is presented. The developed system can successfully simulate in-phase thermal-mechanical loading which is similar to the loading experienced by the coke drums. Some key developments of this system are introduced such as heating device and control system. In addition, an alternative strain control and measurement technique was developed for both isothermal and TMF fatigue tests Furthermore, some preliminary fatigue tests results were presented. For isothermal fatigue tests, it is shown that as temperature increases, the fatigue lives of SA387 and 410S decrease significantly. Additionally, by comparing lives between isothermal and thermal-mechanical fatigue, it is found that the fatigue life of 410S under TMF loading is shorter than the life at 480°C. Therefore, it is inaccurate to estimate the service life of coke drums based on isothermal fatigue data. Due to the insufficient amount of experimental data, this trend need to be further verified and the mechanisms of this observation need to be explored. More tests are still carrying on in our lab. Based on the comprehensive experimental investigation, reasonable fatigue life models will be developed for the coke drum materials.

Application of a non local fatigue stress gradient- weigth function approach to predict the crack nucleation risk induced by Fretting Fatigue

Siegfried Fouvry*, Bruno Berthel

Abstract

Fretting-Fatigue problems are very complex to address due to the multiaxiality and the very sharp stress gradients imposed below the interfaces. Hence, multiaxail and non local fatigue approach must be considered. An experimental cylinder/plane fretting fatigue and plain fretting analysis a 35 Ni Cr Mo 16 low alloyed steel at 10^6 cycles has been performed to investigate the incipient crack nucleation response for various stress gradient conditions. Imposing elastic stress conditions, the Crossland's approach is applied to predict the crack nucleation risk. This analysis confirms that a local stress analysis at the "hot spot" stress located at surface trailing contact border is not suitable. The non local "critical distance" approach which considers the stress loading path at a fixed distance from the "hot spot" improves the prediction but still induce a large discrepancy. Finally, the best predictions are achieved using an alternative non local "weight function" approach where the crack nucleation risk computed at the "hot spot" is weighted by a function expressed as as a linear decreasing expression of the hydrostatic stress gradient operating around the "hot spot" location. The stability of this approach regarding the contact stress field resolution and related application for FEM application is discussed.

Keywords Fretting Fatigue crack nucleation, Stress gradient, Non local fatigue approach, Crossland

1. Introduction

Fretting is a small amplitude oscillatory movement, which may occur between contacting surfaces that are subjected to vibration or cyclic stress. Combined with cyclic bulk fatigue loading, the so-called fretting-fatigue loading can induce catastrophic cracking phenomena which critically reduce the endurance of assemblies [1]. Fretting Fatigue loading can be characterized by the superposition of a heterogeneous cyclic stress gradient related to the contact loading, and a quasi-homogeneous fatigue bulk loading (Fig. 1). The crack nucleation phenomenon is commonly addressed by transposing conventional multi-axial fatigue criteria [2] taking into account or not the stress gradient effects [3, 4]. Indeed, as illustrated in Figure 2, the fretting stressing conditions are characterized by very severe stress gradients which could be one order of magnitude higher than common notch fatigue stress configurations. Non local fatigue approaches are therefore required to predict the cracking risk. Stress averaging approaches [3, 5], or equivalent critical distance methods [4] which consist to consider the stress state at a "critical distance" from the stress "hot spot" are commonly applied to capture the stress gradient effect. However, these approaches, which consider a fixed length scale value are limited when large stress gradient fluctuations are operating. To palliate such limitation, an alternative strategy which consists to weight the prediction given at the "hot spot" location using a linear decreasing function expressed as a function of the gradient of the hydrostatic stress around the hot spot stress location is considered. Introduced by Papadopoulos [6], this approach was simplified by Amargier et al. to predict plain fretting crack nucleation conditions

[7]. The purpose of this research work is to extend this approach for partial slip fretting fatigue situations. This analysis also addresses the influence of the size domain over which the hydrostatic stress gradient is computed thus to establish the stability of this approach regarding the spatial contact stress resolution.

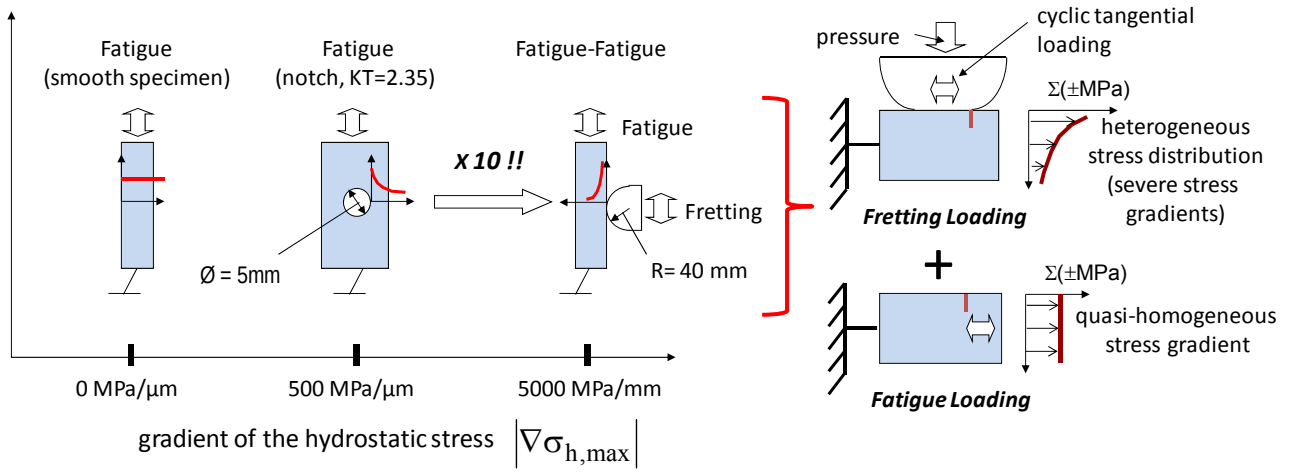

Figure 1. Illustration of the stress condition characterizing the fretting fatigue loading.

2. Materials and experimental procedure

2.1. Materials

The studied material is a tempered a 35 Ni Cr Mo 16 low alloyed steel displaying a tempered Martensitic structure. The original austenite grain size is about Ø =20 µm. The mechanical and fatigue properties of this steel, are summarized in the following table 1.

Table 1. Mechanical and fatigue properties of the studied 35 Ni Cr Mo 16 low alloyed steel.

E(MPa)	ν	$\sigma_{y0.2\%}$ (MPa)	σ_u (MPa)	σ_d (MPa)	τ_d (MPa)	ΔK_{th} (MPa$\sqrt{m}$)
205000	0.3	950	1130	575	386	3.2

E: Young's modulus; ν: Young's modulus, $\sigma_{y0.2\%}$: Yield stress (0.2%); σ_u: ultimate stress; σ_d : traction – compression fatigue limit ($R\sigma = \sigma min/\sigma max = -1$ for 10^7 cycles); τ_d : shear fatigue limite ($R\tau = -1$ for 10^7 cycles); ΔK_{th} : long crack threshold (R=-1).

Chromium 52100 steel was chosen for the cylindrical pads in order to maintain elastically similar conditions whilst simultaneously ensuring that cracks arose only in plane and fatigue 35NiCrMo16 specimens. Both plane and cylindrical pad surfaces were polished to achieved a small Ra=0.05 µm surface roughness.

2.2. Test conditions

As illustrated in Figure 3, two different test apparatuses were involved to quantify respectively the fretting and the fatigue influences in cracking processes.

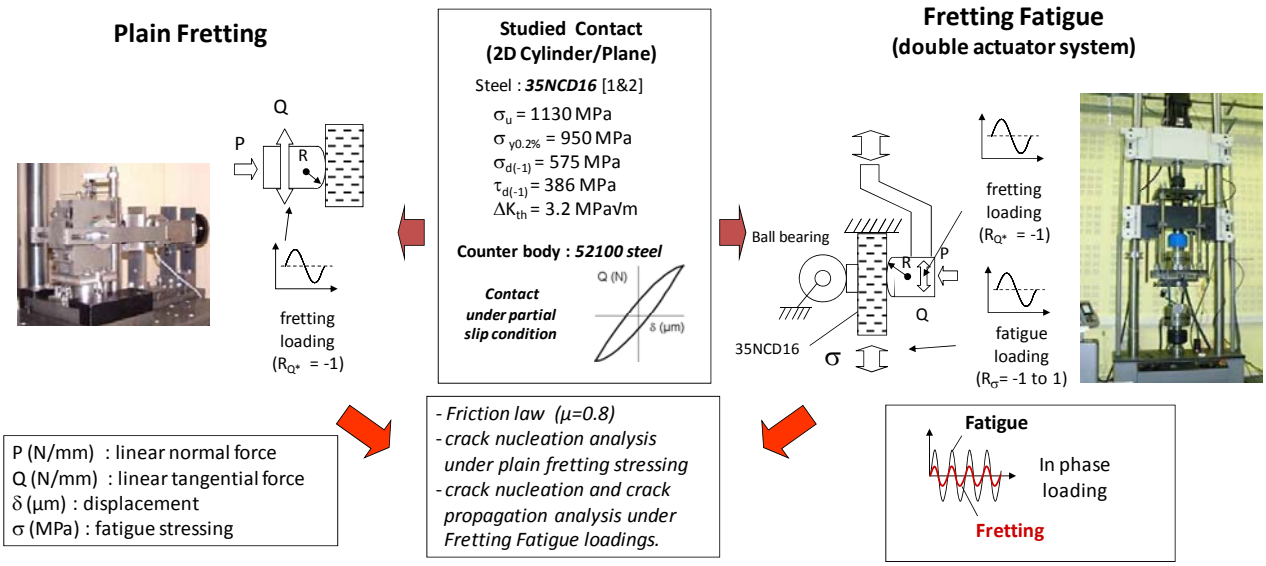

Figure 2. Illustration the experimental strategy based a combined plain fretting and fretting fatigue analysis involving similar contact configurations.

Plain Fretting tests were applied by imposing a nominally static normal force P, followed by a purely alternating cyclic displacement amplitude (δ*), so that an alternating cyclic tangential load Q was generated on the contact surface. During a test, P, Q and δ are recorded, from which the δ - Q fretting loop can be plotted. The studied plane specimen is not subjected to any fatigue stressing.
The fretting fatigue experiments were performed using a dual actuator device inspired by Fellows et al. [8]. This test system allows the separate application and control of fretting and fatigue loadings. Like for the plain fretting, the system is instrumented to measure the contact loading (P, Q*, δ*) but also the fatigue stressing (σ, $R_\sigma=\sigma_{min}/\sigma_{max}$).
In order to analysis both contact pressure, fatigue stress and stress gradient effects, various cylinder radius from R= 20 to 80 mm, Hertzian contact pressures from p_{max}=600 to 1000 MPa and fatigue stress conditions from σ_{max}= 0 and 400 MPa considering two stress ratio Rσ=0.1 and 1.0 were investigated. The details of the studied conditions are compiled in table 2. Note that the lateral width of the cylinder pads (W) was chosen to satisfy plain strain conditions.

3. Experimental results

3.1. Friction analysis

Because the partial contact stress field depends on the coefficient of friction, it is important to establish this value. H. Proudhon et al. show in [10] that the friction coefficient measured at the transition between partial and gross slip conditions (μ_t) may be used to provide a representative value of the friction under partial slip conditions (i.e. $\mu_{PS}=\mu_t$). Figure 3b compares the obtained μ_t

values as a function of the Hertzian contact radius for different contact pressures. A quasi constant evolution is observed which allows us to consider a constant friction value (i.e. $\mu=\mu_{PS}=\mu_t=0.8$).

3.2. Crack nucleation analysis

The cracking investigation consists in identifying the partial fretting loading (i.e. $Q^*<\mu P$) inducing

a threshold crack length after 10^6 cycles. The following methodology is applied: After each fretting test, the plane specimen is cut along the median axis of the fretting scar. Cross section observations are performed to determine the projected crack length (b_p) along the normal of the surface. The polishing process is then repeated twice so that the crack measurement is performed on 6 different planes located along the median axis of the fretting scar. From these six measurements, the maximum projected crack length (b_{pmax}) is determined. This crack analysis is generalized to various tangential force amplitudes in order to plot the evolution of b_{pmax} versus the applied tangential force amplitude (Fig. 3b). Finally, the threshold crack nucleation is determined by extrapolating the tangential force amplitude related to a b_{pth} = 10 µm projected crack length. This strategy was systematically applied for all the studied conditions. The corresponding Q^*_{CN} values are compiled in table 2. The expertise shows that the incipient crack nucleation is systematically observed at the trailing contact borders. Note that under established partial slip conditions, the surface wear is negligible and the contact geometry assumed unchanged during the fretting tests.

4. Contact stress analysis

4.1. Fretting Fatigue Stress field computation

The contact stress analysis of studied plain fretting and fretting fatigue experiments is performed by applying an analytical formulation which consists to combine the Mindlin's analytical description of partial slip contact (Fig. 4a) [9] with an adequate application of the McEven formalism's [9].

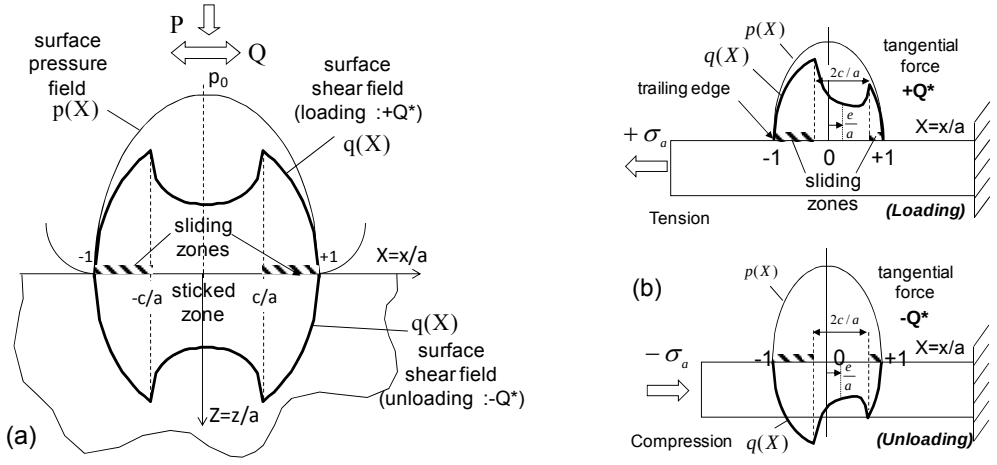

Figure 4. Pressure and Shear surface profiles under partial slip conditions a) plain fretting – b) fretting fatigue

The McEven formalism allows us to establish the stress state below the surface related to elliptical surface pressure or shear profiles. By summing the contribution of various elliptical shear distributions, the partial slip loading path can be determined. Note that the offset or eccentricity "e" of the stick zone, which induced by the fatigue strain deformation of the fatigue specimen, is considered by applying the Nowel's formalism [11] (Fig. 4b). This approach is justified if the

Hertzian hypotheses are satisfied which implies elastic stress conditions, smooth surfaces, plain strain hypothesis and thick enough specimen to satisfy the semi infinite contact configuration. The low surface roughness of specimens, the large lateral width of cylinder pads and the 10 mm specimen thicknesses support such hypothesis. Besides, a posteriori stress analysis shows that all the crack nucleation conditions correspond to elastic stress conditions ($\sigma_{VM}/\sigma_y < 1$). A major interest of this analytical stress description is the very fast computation of the cyclic stress path which allows an extensive non local multiaxial fatigue stress analysis.

4.2. Crossland's Multiaxial Fretting criterion

The stress loadings operating below the surface are multiaxial and therefore a multixial fatigue analysis is required. The Crossland's multiaxial fatigue approach [12], well adapted to describe the fatigue response of the studied alloy, is considered. The crack risk is expressed as a linear combination of the maximum amplitude of the second invariant of the stress deviator $\sqrt{J_{2,a}}$, and the maximum value of the hydrostatic pressure ($\sigma_{h,max}$) (Fig. 5a).

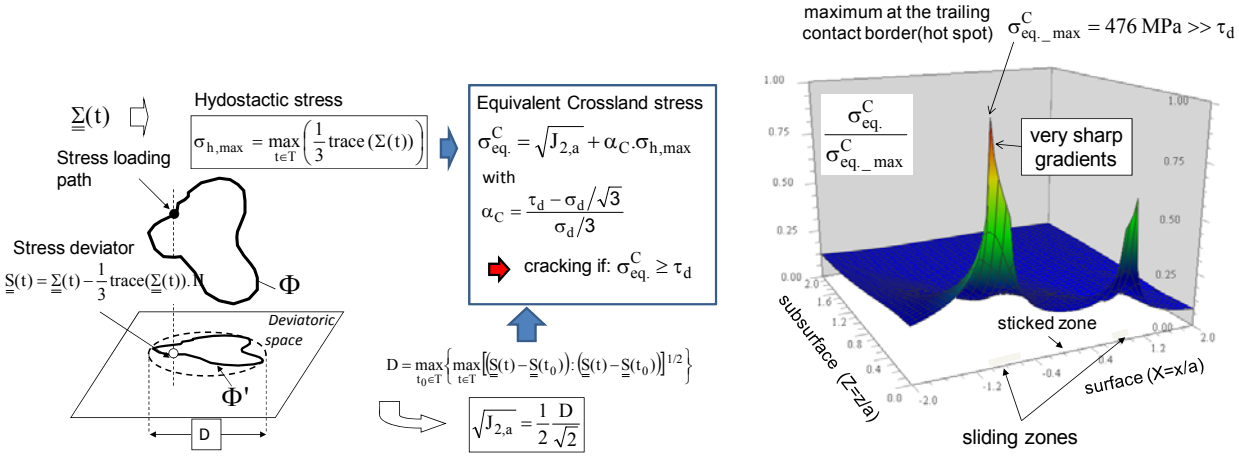

Figure 5. a) Illustration of the Crossland criterion – b) Crossland distribution of the FF2 condition (local stress analysis) (Table 2)

The crack nucleation condition is verify if the equivalent Crossland fatigue stress is becoming larger than the shear fatigue limit :

$$\sigma_{eq.}^{C} = \sqrt{J_{2,a}} + \alpha_C.\sigma_{h,max} \geq \tau_d \quad \text{with for the studied alloy} \quad \alpha_C = 0.28 \qquad (1)$$

Figure 5b shows the distribution of Crossland criterion computed for a representative Fretting Fatigue crack nucleation condition (i.e. FF2 test, Table 2) applying a local stress analysis. Confirming the experimental results, the maximum risk value is localized at the trailing contact border. The distribution shows very sharp gradients and a dissymmetry of the profile induced by stick zone offset generate by the fatigue mismatching strain deformation within the interface.

5. Comparison between experiments and fatigue modeling

5.1. Local « hot spot » fatigue analysis

The multaxial fatigue analysis is applied using a local stress description at the hot spot stress location (i.e. trailing contact border). The analysis is performed for each plain fretting and fretting fatigue crack nucleation conditions and reported in a $\sqrt{J_{2,a}}$ - $\sigma_{h,max}$ diagram (Fig. 6).

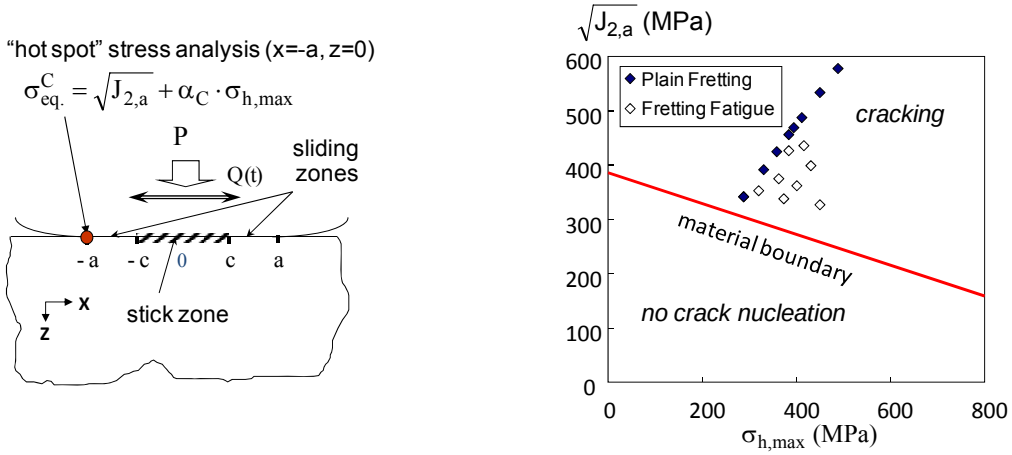

Figure 6. Local Crossland analysis at the "hot spot" trailing contact border.

As expected, the experimental data are highly dispersed and systematically above the material boundary. This local Crossland fatigue approach does not integrate the severe stress gradients operating next to the "hot spot" and therefore is not suitable to predict the fretting cracking risk. To quantify the stability of the prediction, the mean value and the square root variance of the equivalent Crossland stress obtained for the 16 test conditions are computed.

$$\overline{\sigma}_{eq.}^{C.} = \frac{1}{N}\sum_{i=1}^{N}\sigma_{eq.}^{C.}(i)\,,\quad \%E\overline{\sigma}_{eq.}^{C.} = \left(\frac{\overline{\sigma}_{eq.}^{C.} - \tau_d}{\tau_d}\right)x100\,,\quad V\sigma_{eq.}^{C.} = \sqrt{\frac{\sum_{i=1}^{N}\left(\sigma_{eq.}^{C.}(i) - \overline{\sigma}_{eq.}^{C.}\right)}{N-1}}\,,\quad \%V\overline{\sigma}_{eq.}^{C.} = \left(\frac{V\overline{\sigma}_{eq.}^{C.}}{\overline{\sigma}_{eq.}^{Cross.}}\right)x100 \qquad (2)$$

The $\%E\overline{\sigma}_{eq.}^{C}$ allows to estimate the global error of prediction versus the theoretical material prediction, whereas the $\%V\overline{\sigma}_{eq.}^{C}$ variable provides a relative estimation of the dispersion. For the given local fatigue description, we found $\%E\overline{\sigma}_{eq.}^{C}$ = +36 % and $\%V\overline{\sigma}_{eq.}^{C}$ = 16% which correspond to a critical overestimation and a high dispersion.

5.2. Non local « critical » distance fatigue approach

The critical distance method which consists to define the stress state at a certain distance below the contact "hot spot" (Fig. 7a) is applied. Using the Taylors's theory [13] which approximates the critical distance as the half value of the long crack propagation transition b_0, we deduced :

$$\lambda_T = \frac{b_0}{2} \approx \frac{1}{2\pi}\left(\frac{\Delta K_{th}}{\sigma_d}\right)^2 \approx 5\mu m \tag{3}$$

This strategy previously applied par Araujo et al. in [4] is now considered for the given Crossland's fatigue analysis (Fig. 7).

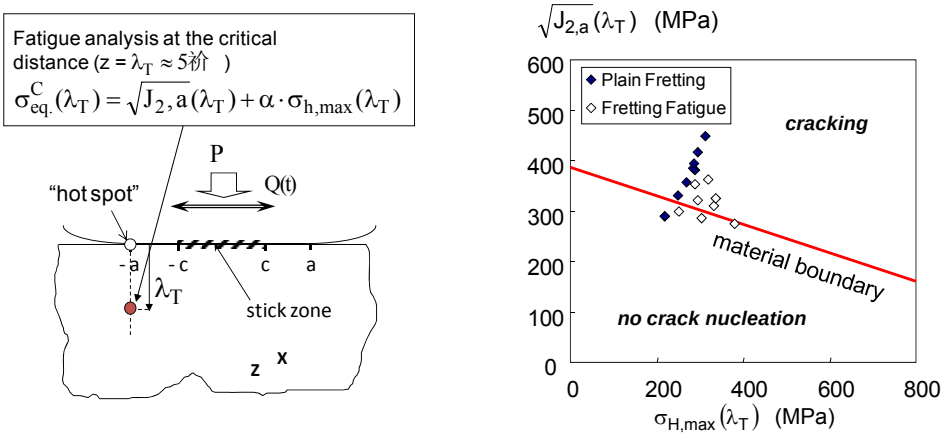

Figure 7: Critical distance approach assuming a constant length scale value ($\lambda_T = b_0/2 = 5\mu m$).

The experimental results are closer to the material boundary and the dispersion is reduced. The statistical analysis gives $\%E\overline{\sigma}^C_{eq.}(\lambda_T) = 11\%$ and $\%V\overline{\sigma}^C_{eq.}(\lambda_T) = 12\%$. The global predictions are less conservative but still dispersed. This suggests that the "critical distance" approach which consider a single "material" length scale parameter is not sufficient to fully capture the stress gradient for such very large stress gradient range.

5.3 Weigth function approach

An alternative non local approach which consists to consider the "hot spot" fatigue stress value weighted by a linear decreasing function (w) of the hydrostatic stress gradient surrounding the hot spot location is now considered [6, 7]:

$$\sigma^{C*}_{eq.} = \sigma^{C}_{eq.}.w\left(\left|\overline{\nabla}_\lambda(\sigma_{h\,max})\right|\right) \quad \text{where} \quad w = 1 - k.\left|\overline{\nabla}_\lambda(\sigma_{h\,max})\right| \tag{4}$$

With $\left|\overline{\nabla}_\lambda(\sigma_{h\,max})\right|$ the mean stress gradient of the hydrostatic stress over a cubic volume defined by the length scale λ. Hence for plain strain conditions it leads to

$$\left|\nabla(\sigma_{h,max}(x,z))\right| = \sqrt{\left(\frac{\partial\sigma_{h,max}}{\partial x}\right)^2 + \left(\frac{\partial\sigma_{h,max}}{\partial z}\right)^2} \tag{5}$$

which for the studied fretting conditions infers :

$$\left|\overline{\nabla}_\lambda(\sigma_{h\,max})\right| = \sqrt{\left(\frac{\sigma_{h,max}(-a,0) - \sigma_{h,max}(-a,\lambda)}{\lambda}\right)^2 + \left(\frac{\sigma_{h,max}(-a,0) - \sigma_{h,max}(-a+\lambda,0)}{\lambda}\right)^2} \tag{6}$$

The length scale λ is usually related to the grain size so that $\lambda = Ø/2 = 10\ \mu m$ which presently gives $k = 0.0142\ (MPa/\mu m)^{-1}$

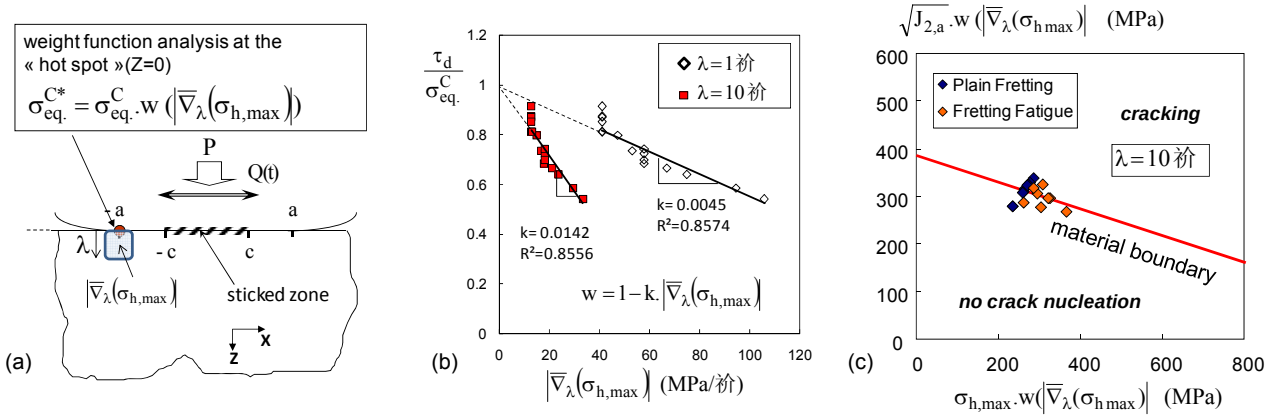

Figure 7: Weight function approach: a) illustration of the methodology- b) identification of the weight function – c) Application of the methodology (ℓ=Ø/2=10µm).

Using this weight function approach the predictions are highly improved. The statistical analysis gives $\%E\bar{\sigma}_{eq.}^{C*} = 1\%$ and $\%V\bar{\sigma}_{eq.}^{C*} = 6\%$. However, as shown in Fig. 7b, the "k" coefficient highly depends on the volume dimension over which the hydrostatic stress gradient is computed. The smaller the ℓ value, the higher the stress gradients, and smaller the k factor is. This suggests that the methodology must be calibrated keeping constant the ℓ dimension from the identification of the weight function to the structural fatigue analysis. By contrast, the R^2 coefficient is very stable which indirectly support the stability of this approach. Theses tendencies are confirmed by Figure 8, where using extensive computations, both "k and R^2" variables are plotted versus ℓ variable. The k variable can be expressed using a very simple power function at least for the studied cylinder/plane contact:

$$k = 5.10^{-3} \cdot \sqrt{\lambda} \tag{7}$$

Besides, the related R^2 coefficient remains unchanged around 0.85 whatever the ℓ value. Hence, it can be intuited that such approach could be transposed for any low spatial stress field resolution like observed in industrial FEM contact analysis. Fixing the ℓ variable equal for instance to the FEM contact mesh size and calibrating the related k weight function factor, very good prediction of the crack risk are expected.

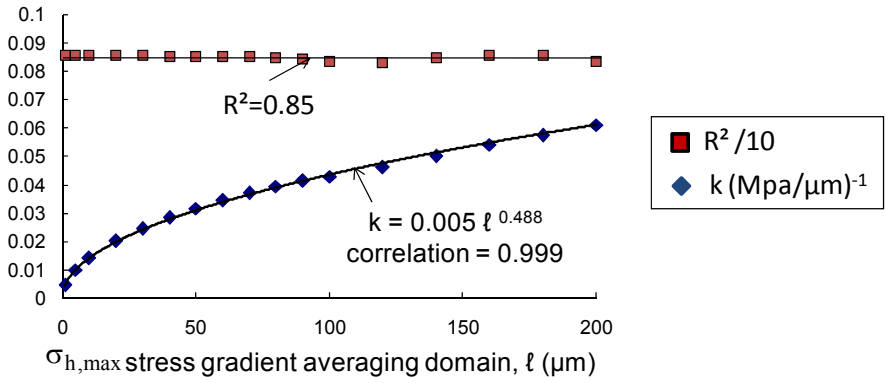

Figure 8: evolution of the k coefficient and related R^2 correlation factor as a function of the length scale ℓ.

5. Conclusion

A combined experimental and Crossland multiaxail fatigue approach is developed to rationalise the crack nucleation risk induced by plain fretting and fretting fatigue loadings. It shows that due to the very stress grading imposed by the contact stressing, a local “hot spot” fatigue stress analysis is not suitable. The application of the critical distance approach based on the Taylor’s formalism improves the prediction but still display high dispersion. Finally, the non local “weight function” approach provides very consistent and stable predictions. This analysis shows that the “k” factor defining weight function is highly dependent on the ℓ length scale variable over which the hydrostatic stress gradient is computed. We show a variation of the k factor versus the ℓ length variable. Finally, we confirm that the stability of this approach according that the related R^2 correlation factor remains high and constant (i.e. above 0.85) over the whole studied ℓ length (i.e. up to 200μm). This stability regarding the spatial stress resolution suggests that, this approach could efficiently be transposed in coarse industrial FEM contact meshing to achieve pertinent fretting cracking predictions.

Abstract Fatigue life computing methods are generally based on putting into equation the mechanical quantities calculated at the micro or meso scale, the relevance of these selected quantities being validated by the capacity of the models to reproduce experimental results at the macroscopic scale. Although the scaling of the damage mechanisms involved in fatigue crack initiation processes are relatively well identified (grain scale, slip bands), their explicit consideration in fatigue criteria is still not well-developed. Furthermore, the existing methods do not consider the microstructure-sensitivity. The aim of this paper is to present the computational strategies developed to account for the microstructure-sensitivity in the calculation of fatigue strength. This work is based on three parts: (1) the development of 3D microstructure modeling tools (2) the analysis of the dispersion induced by the microstructure heterogeneities on the critical fatigue damage indicators and (3) the development of a statistical approach which provides a framework for analyzing calculation results in the HCF (High Cycle Fatigue) regime.
In this context, a method based on the construction of statistical extreme value distributions from FEA calculation results was developed. The evolution of the scaling parameters of these distributions for different loading conditions is related to the effect of non-proportional loading and microstructure. A design method based on these extreme value statistics is presented to obtain a new mesoscopic criterion sensitive to microstructure parameters. Finally, surface effects are discussed.

Keywords HCF, crystal plasticity, extreme value probability, FE simulation.

1. Introduction

In literature, methods for determining the fatigue behavior based on multiscale modeling estimate that the fatigue strength of metals depends on the extreme value statistics of a single microstructure

attribute [1] (for example inclusion size). This is only valid when the considered element of microstructure is a representative volume element (RVE) with regards to fatigue. Although the definition of the RVE is possible for some deterministic behaviour aspects (such as elastoplastic behaviour), it is difficult to evaluate a RVE for the HCF strength which is macroscopically highly dispersed. Therefore the use of a single microstructure element (with a smaller volume than the RVE with regards to the fatigue behaviour but equal to the RVE size with regards to the elastoplastic behaviour) does not make it possible to take into account the contribution of the microstructure heterogeneities in the HCF response. To solve this issue, Liao [2] used the Monte Carlo method to build statistical volume element (SVE) of a microstructure with a random distribution of grain sizes and crystallographic orientations. Despite considering elastic behaviour of crystal only, Liao showed a good correlation between the results obtained by modeling the extreme value probability with a Fréchet distribution and experimental results. Recently, Przybyla et al. [3, 4] introduced a new framework taking into account the effects of neighborhood through the extreme values of the marked correlation functions to quantify the influence of microstructure on the fatigue limit and the contribution of interactions in the microstructure in the case of uniaxial loading. Przybyla used Gumbel distribution function to describe the extreme value probability of the studied parameters.

The purpose of this work is, first, to analyze the microstructure sensitivity (morphology and orientation) of the fatigue indicator parameter (FIP) corresponding to the adaptation of multiaxial fatigue strength criteria at the mesoscopic length scale. Then a statistical study is used to define new mesoscopic thresholds for the FIPs, different from the original thresholds of the macroscopic criteria. Finally, the capability of the macroscopic criteria to take into account the microstructure sensitivity will be discussed through a comparison between the thresholds determined by the statistical response of the microstructure at the grain scale (called mesoscopic) and the original macroscopic thresholds. Free surface effects are also discussed with the comparison between FIPs determined from different FE models: 2D, 3D and 3D taking into account the grain surface only.

2. Numerical model

2.1. Constitutive relations

The material parameters considered in this work are those of pure copper. This material has a face-centered cubic crystal structure with 12 slip systems (<111> {110}). The behaviour is modeled by cubic elasticity and crystal plasticity constitutive law. The crystal plasticity model used in this work is the one introduced by Meric and Cailletaud [5]. The cubic elasticity constants, the material parameters and the coefficients of the interaction matrix have been identified on a high purity copper by Gérard et al. [6].

2.2. Grain morphology and crystallographic texture

The simulations performed in this study were done using 3D semi-periodic microstructures (periodicity along X_1 and X_2 directions). The Voronoï polyhedra method was used to model the morphology of the grains. The initial domain (with dimensions x_1=1, x_2=1 and x_3=0.5) is filled by

randomly positioned and oriented germs so as to have a distance greater than or equal to 0.02 between two germs. The CAD model was discretized by around to 5.10^5 linear tetrahedral finite elements (figure 1-(b)). Computed microstructure contains 200 equiaxed grains (figure 1-(a)) with an average of 2500 finite elements per grain. In addition to loading, periodicity conditions were applied on the planes corresponding to X_1min, X_1max, X_2min and X_2max. To take into account the free surface effect, the symmetry conditions were applied on the face corresponding to X_3min. The grain number on the free surface (corresponding to X_3max) is about 50. Finally, the random selection of 200 crystal orientations was carried out in the Euler space defined by the three angles $(\varphi_1, \phi, \varphi_2)$ assuming cubic crystal symmetry and triclinic sample symmetry. Figure 1-(c) shows the {100} and {110} pole figures of these 200 orientations. Given the low number of orientations, this crystallographic aggregate can be considered as having no preferential orientations.

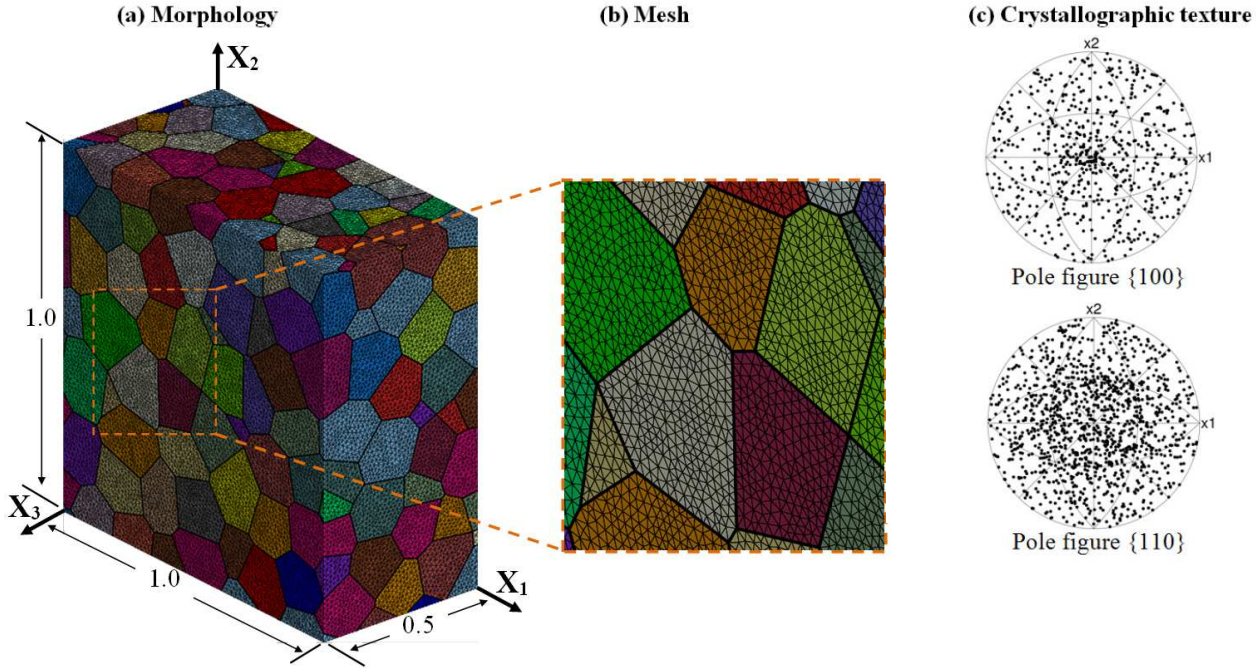

Figure 1. (a) Grain morphology, (b) Mesh and (c) {100} and {110} pole figures showing the selected crystallographic orientations

2.3. Fatigue loading conditions

Different loading conditions are investigated in this section: uniaxial loading, and tension /torsion loadings with different biaxiality ratios $k = \sigma_a / \tau_a$ and different phase shifts. The selected loading ratio is $R_\Sigma = \sigma_{a,\min} / \sigma_{a,\max} = -1$. The combined loading levels equivalent to the median fatigue limit at 10^7 cycles are determined using the Crossland criterion [9]. These load levels are given in Table1.

Table 1. Tension (σ_a) and torsion (τ_a) stress amplitude used for different load conditions

	loading	**Tension**	**Torsion**	**Combined loading** $\sigma_a[MPa]/\tau_a[MPa]$		
Phase shift	biaxiality	$k=0$	$k=\infty$	$k=0.5$	$k=1$	$k=2$
	$\varphi=0°$	56/0	0/36	43.5/22	30/30	17/34
	$\varphi=45°$			47/23	31/31	17/34.5
	$\varphi=90°$			56/28	34/34	17.5/35

3. Mesoscopic fatigue indicator parameters

The studied fatigue indicator parameters (FIPs) were selected from stress criteria widely used in the literature. The multiaxial HCF criteria considered here are Crossland [9], Matake [10] and Dang Van [11]. These fatigue criteria are generally defined in the context of continuum mechanics. In order to evaluate the fatigue criterion on each computed microstructures, the usual HCF criteria are projected on the slip systems of the crystals. This procedure is repeated for each crystal considering its local orientation (φ_1,ϕ,φ_2) and local stress state computed by FE for each loading case. For instance, the shear stress vector in a given plane is transformed into a resolved shear stress vector over a slip system. The rotation of the crystal in space (defined by the Euler angles (φ_1,ϕ,φ_2)) covers all the planes and directions of space, which enables to find the same critical planes and directions (planes and directions maximizing the criterion) than those obtained by the original criterion (with continuous formulation). Table 4 gives FIP expressions adapted to the crystal scale.

Table 2. Expression of Fatigue Indicator Parameters (FIPs) of the studied criteria

Criterion	I_i	α_i
Crossland	$I_c=\tau^s_{oct,a}+\alpha_c\sigma_{hyd,\max}\le\beta_c$	$\alpha_c=\dfrac{t_{-1}-\left(s_{-1}/\sqrt{3}\right)}{\left(s_{-1}/3\right)}$
Matake	$I_m=\max\limits_{s=1,12}(\tau^s_a)+\alpha_m\sigma_{s,\max}\le\beta_m$	$\alpha_c=2\dfrac{t_{-1}}{s_{-1}}-1$
Dang Van	$I_{dv}=\max\limits_{s=1,12}(\max\limits_t[\left\|\hat{\underline{\tau}}^s(s,t)\right\|+\alpha_{dv}\sigma_{hyd}(t)])\le\beta_{dv}$	$\alpha_{dv}=\dfrac{t_{-1}-\left(s_{-1}/2\right)}{\left(s_{-1}/3\right)}$

Finally, the parameters α_i and β_i describing the median macroscopic threshold of the considered criteria are identified from two median fatigue limits for 10^7 cycles of the considered material on smooth specimens under fully reversed loadings: tension ($s_{-1}=56\ MPa$) and torsion ($t_{-1}=36\ MPa$)

from the work of Lukas and Kunz [12]. The parameters β_i are identical for the three criteria ($\beta_c = \beta_m = \beta_{dv} = t_{-1}$). The expression of α_i are given in Table 2.

A comparison between the mesoscopic FIPs predictions and the macroscopic (original) criteria is shown in Figure 2. This comparison shows the existence of grains at the surface (highlighted in light blue) or in the bulk of the volume element from which the FIP exceeded the macroscopic threshold. The macroscopic threshold is not applicable at the grain scale. This is especially true for the Crossland criterion where most of the grains are above the threshold. For other criteria, only a small number of grains exceeded the macroscopic threshold. A statistical analysis of the microstructure-sensitivity of the different FIPs will be presented in the next section. This statistical analysis will determine a new mesoscopic threshold to take into account the microstructure heterogeneities.

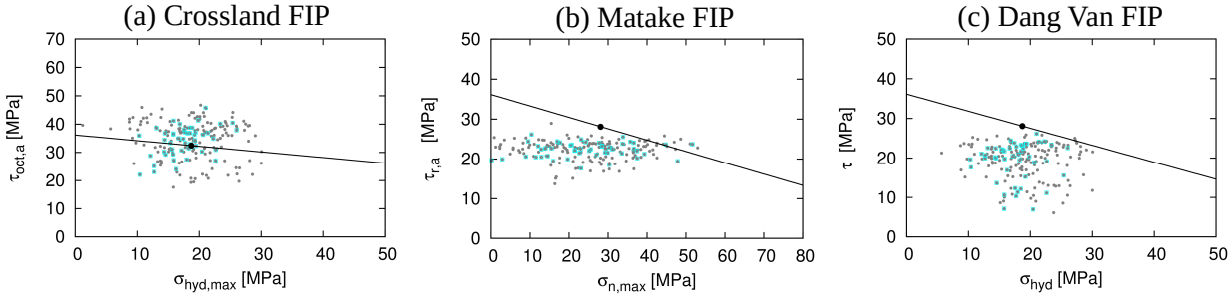

Figure 2. Locus of the 200 FIPs at the grain length scale (gray dots), and macroscopic criterion (black dot) in the case of tension loading ($R_\Sigma = -1$). The FIPs corresponding to the surface grains are highlighted (in light blue) and the black straight line is the experimental macroscopic threshold

4. Microstructure sensitivity

The HCF strength is related to the critical grain whose response leads to the maximum value of the FIP. These extreme values are located at the tails of the probability density functions of mesoscopic responses (see Figure 3) and are highly sensitive to the microstructure attributes. To study these critical grains, several statistical approaches are possible. The method selected for this work was based on the extreme value probability. This method involves the statistical analyze of the maximum values of the mesoscopic FIP, corresponding to the various studied volume element, by considering a single value for each aggregate.

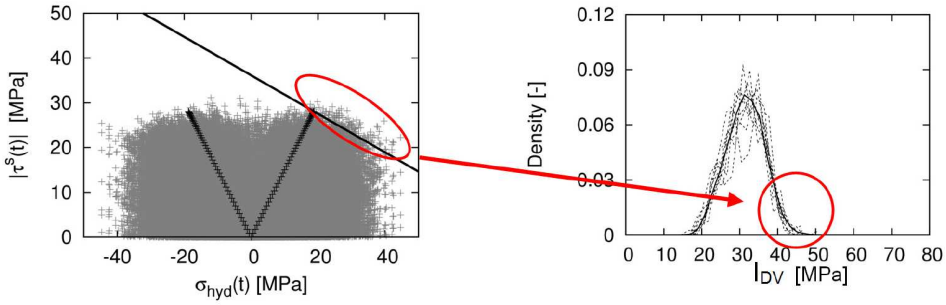

Figure 3. Localization of the extreme values in the tails of the Dang Van FIP distribution

The extreme value database was constructed by identifying the maximum value of FIP for each statistical volume element (SVE). The number of SVEs was between 25 and 35: they were obtained by the combination of 7 random morphologies (Figure 4-(a)) and 5 isotropic textures (Figure 4-(b)). This sample size is sufficient to determine the extreme values distribution function. Indeed Przybyla showed that from a number of SVEs greater than 20, the difference between the empirical distribution and the experimental sample becomes negligible [3, 4]. The maximum value of FIP has been determined on the one hand from the FIP concerning all the grains of the SVE and on the other hand by separating only the surface grains of the aggregate.

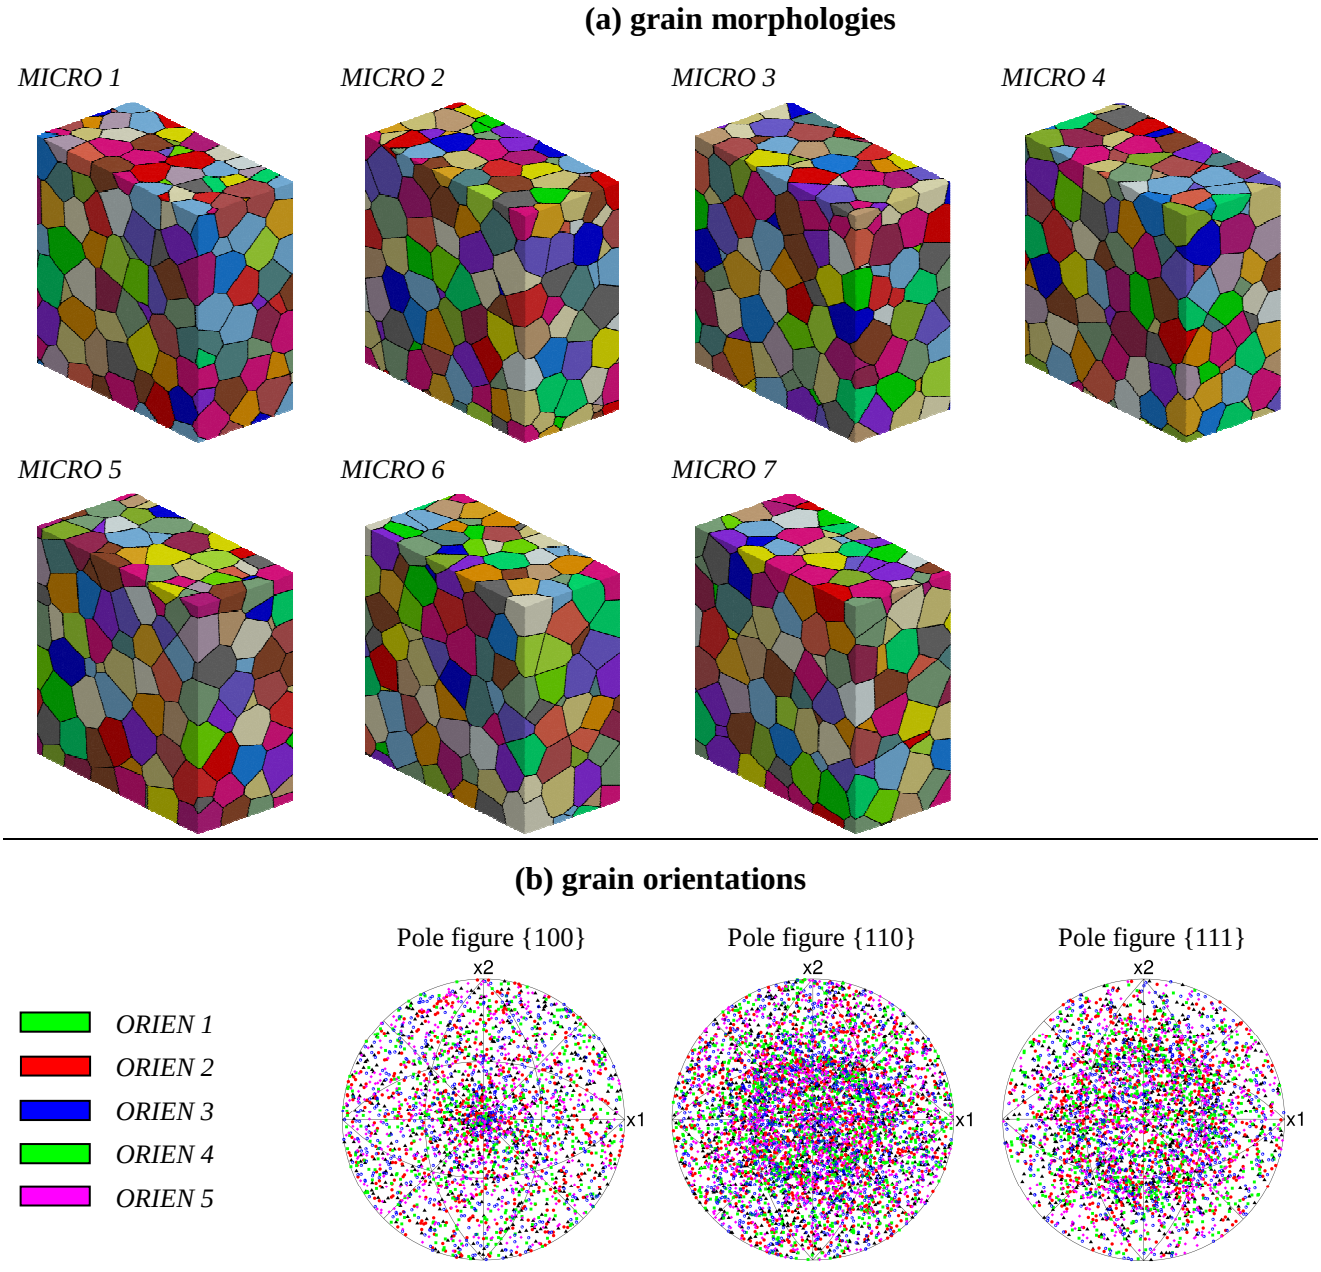

Figure 4. (a) random morphologies and (b) isotropic textures used to create the extreme values database

5. Generalized extreme values probability

Let us consider a random variable x with the distribution function $F_X(x)$. The n extreme realizations in n samples of the random variable can be defined as:

$$Y_n = \max(X_1, X_2, ..., X_n) \tag{1}$$

The distribution function of Y_n is defined as:

$$F_{Y_n}(y) \equiv P(Y_n \le y) = P(X_1 \le y, X_2 \le y, ..., X_n \le y) \tag{2}$$

According to the *Fisher-Tippet theorem*, if there exist two real normalizing sequences $(a_n)_{n\ge1}$, $(b_n)_{n\ge1}$ and a non-degenerated distribution (not reduced to a point) G so that:

$$P\left(\frac{Y_n - b_n}{a_n} \le x\right) = F^n(a_n x + b_n) \underset{n\to+\infty}{\longrightarrow} G(x) \tag{3}$$

G is necessarily one of the three types of distributions: Fréchet, Weibull or Gumbel.
Jenkinson [13] combined the three limit distributions in a single parametric form called Generalized Extreme Value (GEV) distribution depending on a single parameter ξ:

$$G_\xi(x) = \begin{cases} \exp\left(-(1+\xi x)^{-\frac{1}{\xi}}\right) & si\ \xi \ne 0, \forall x / 1+\xi x > 0 \\ \exp(-\exp(-x)) & si\ \xi = 0 \end{cases} \tag{4}$$

The ξ parameter is called extreme index. Its sign indicates the type of asymptotic distribution: Weibull ($\xi < 0$), Gumbel ($\xi = 0$) or Fréchet ($\xi > 0$). The variable $(Y_n - b_n)/a_n$ is called normalized maximum of the random variable x.The parameters a_n and b_n are also called shape factors of the distribution.

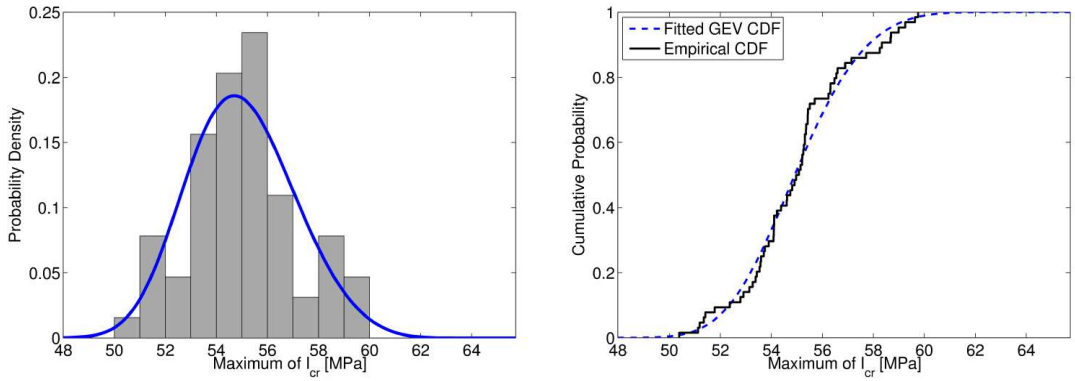

Figure 5. Probability density and cumulative probability determined using the maximum likelihood method from the extreme values of Crossland FIP for tensile loading ($R_\Sigma = -1$)

We are interested in the maximum values of different FIPs listed in Table 2. Scale factors (a_n and b_n) and extreme index ξ are determined using the maximum likelihood method with a confidence interval of 99%. Figure 5 shows a comparison between the determined distributions and the samples for the Crossland FIP. The identified GEV density function and distribution function showed a good correlation with the probability density and the cumulative probability determined from the extreme values of FIPs database.

6. Results and discussions

Figure 6 represents the mesoscopic thresholds (medians and also the values of 0.1 and 0.9 quantiles) for each loading condition. The mesoscopic thresholds are statistically determined from the FIPs at the grain scale considering the local stress state. This local stress state is computed by a finite element (FE) simulation. A comparison between the mesoscopic thresholds obtained by considering a 3D FE model (described above) and a 2D FE model [14] is presented in this figure.

The mesoscopic thresholds are normalized by the macroscopic threshold to analyze the effect of microstructure variability. Referring to figure 6, for all studied loading conditions and studied FIPs, the normalized mesoscopic thresholds were always larger than 1 in the case of the local stress state computed by 2D FE model [14]. When the local stress state is determined by a 3D model, the mesoscopic threshold determined from all grains decreases for Matake and Dang Van criteria, and increases slightly in the case of Crossland criterion. When considering all the grains (bulk + surface), this threshold is higher for Crossland criterion and is close to 1 for Matake criterion and especially for Dang Van criterion. The mesoscopic threshold determined by considering only the surface grains becomes lower than the macroscopic threshold for Dang Van criterion. This is not verified for the other two criteria. This comparison highlights the ability of the Dang Van criterion to reflect the microstructural heterogeneities compared to the two other criteria.

On the other hand, the mesoscopic thresholds, defined as the medians of the extreme value distribution of the studied FIPs depend on the loading case. This gap depends on the studied FIP: it is low in the case of the Crossland and Dang Van FIPs (Figure 6-(a) and (c)) and significant in the case of the Matake FIP (Figure 6-(b)). For this last FIP, the change in mesoscopic thresholds was observed especially for the biaxial loading with a phase shift of 90°.

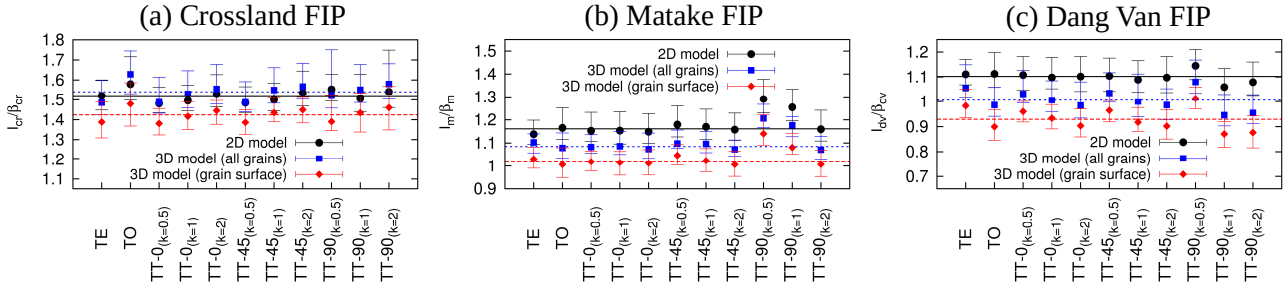

Figure 6. Evolution of the median (a probability of 0.50) of the extreme value distributions of (a) Crossland, (b) Matake and (c) Dang Van FIPs, as a function of loading conditions determined by 2D (in black), and 3D (in blue and red) FE model. The two limits of the interval correspond to a probability of 0.10 and 0.90.

Finally, the mesoscopic threshold, common to all the loading cases was determined as the average of the thresholds associated to each loading conditions. This mesoscopic average threshold is shown in Figure 6 by the dashed horizontal lines passing through all intervals bounded by the values of 0.1 and 0.9 quantiles in the case of Crossland and Van Dang FIPs. For Matake FIP, this was also true except for the case of biaxial loadings with a phase shift of 90° due to the reasons mentioned above.

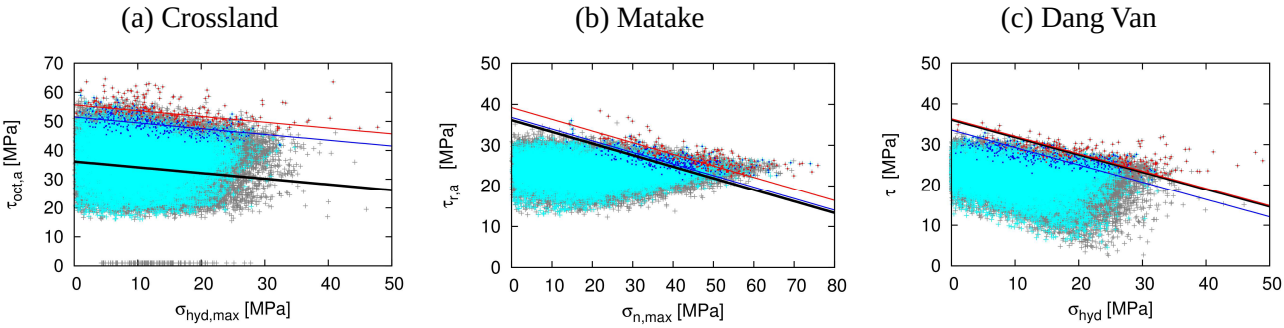

Figure 7. Predictions from (a) Crossland, (b) Matake and (c) Dang Van at the macroscopic length scale (black line) and the mesoscopic length scale considering all grains (gray dots) and surface grains (gray dots).

The mesoscopic threshold of different FIPs is the average (over the different loading conditions) of the medians of the extreme value distributions. Keeping the same value for the α_i parameter, the new criterion containing microstructural heterogeneities contribution at the mesoscopic length scale is plotted in Figure 7. This Figure illustrates for each criterion two mesoscopic thresholds : the first was determined from all the grains of the aggregate (red line) and the second was computed by considering only the surface grains. When the mesoscopic threshold is close to the macroscopic one (black line), the microstructure heterogeneities are taken into account by the original criterion. This is especially the case of Dang Van criterion, when the mesoscopic threshold determined for all the aggregate grains is equal to the macroscopic thresholds, and to a lesser extent the case of Matake criterion (Table 3). For the Crossland criterion, the distance between the two straight lines is important in the case of thresholds determined from all the grains and from the surface grains (table 3). This comparison shows that critical plane type approaches can capture the microstructure heterogeneity despite simplifying assumptions [11].

Table 3. Values of macroscopic thresholds and mesoscopic thresholds obtained by 2D and 3D FE modeling

Criterion	**Macroscopic Thresholds**	**Mesoscopic Thresholds**		
		2D model (all grains)	3D model (all grains)	3D model (surface grains)
Crossland	36.15	54.78	55.68	51.48
Matake	36.15	41.97	39.21	36.82
Dang Van	36.15	39.81	36.36	33.59

7. Conclusion

From polycrystalline modeling of pure copper coupled with a statistical study of the critical grains, we analyzed the mesoscopic responses of the multiaxial fatigue criteria, widely studied in the literature (Crossland, Matake and Dang Van). This statistical study allows us to introduce microstructural heterogeneities effect in the variability of the fatigue strength.

The comparison between the mesoscopic predictions of these criteria and the macroscopic (original) ones shows that they are not conservative at the grain scale. Indeed the identification of macroscopic parameters of these criteria does not take into account variations of the strain field at the microstructure scale. The proposed method, based on extreme value statistics, consists in readjusting these parameters on the most critical grain computed from FE calculations. These critical grains are located in the tails of the aggregate response distributions. The determination of the different distributions allowed us to define a new mesoscopic threshold for the studied criteria.

These thresholds are the average of the medians of the extreme value distributions related to the different loading conditions. These thresholds are different or similar to the macroscopic thresholds depending on the considered criterion. For Dang Van, the mesoscopic threshold is equal to the macroscopic value of the fatigue indicator parameter. At the opposite, for Crossland, the ratio between meso and macro thresholds is greater than 1.4. Matake criterion has a ratio of around 1.1.

Finally, except for the biaxial loading with a phase shift of 90° where FIP median values are very different from one criterion to another, the mesoscopic thresholds is almost the same for all the loading conditions. Thus, these new mesoscopic thresholds can therefore be determined by applying a single loading case.

Abstract

Grid-to-rod fretting failure due to fuel rod vibration remains as a significant cause of nuclear fuel failure in pressurized water reactors (PWRs). In order to carry out fretting fatigue tests to tube shaped specimens, a special designed apparatus was developed. The strain-life curve of the Zr-4 tube specimen under some given fretting contact pressure is obtained. It is found that the fatigue life of the Zr-4 tube under fretting contact conditions can be substantially lower than its life without fretting. The fretting wear scars and fatigue cracks were analyzed by microscope. The results show that the initial crack does not occur at the middle of the contact area where the wear depth reached the maximum, but at the edge of the initial contact area. where the amplitude of stress is confirmed to reach the maximum by FEM simulation. The position of crack nucleation can be predicted by half-length of the initial contact region and the slip displacement.

Keywords: Fretting fatigue test, Tube specimen, Nuclear fuel cladding tube, Fretting fatigue nucleation.

1. Introduction

Fretting is a special wear process that occurs at the contact area between two materials under loads and subject to minute relative motions by vibrations or some other forces. Fretting decreases the fatigue strength of materials operating under cycling stresses [1, 2]. The fretting fatigue phenomenon is very complex because there are too many factors that can affect the fretting behavior of materials [3]. A number of studies were taken to analyze the effects of various parameters on the fretting damage, such as the contact pressure [4-6], the amplitude of slip displacement [4], the coefficient of friction [5] and the nature of contact [7, 8]. For various materials, both experimental and numerical methods are taken to analyze the fretting damage [6, 9-11, 15]. Bridge-type fretting pads were used in many fretting fatigue experiments to produce contact in two places on each side of the specimen [6, 13, 14]. The pair of bridges and its load cell had to be hung on the specimen during the test by friction, thus a large clamping force and a flat contact were a must. Petiot [9] bolted one foot of the bridge to the end of the specimen and reduced the clamping force to a value of 100N. Similar apparatus were developed for the cases of point contact, such as cylinder-cross-cylinder and sphere-on-flat. The advantages of two arrangements of specimens and fretting bridges were discussed by Waterhouse [17].

Grid-to-rod fretting failure due to fuel rod vibration remains as a significant cause of nuclear fuel failure in pressurized water reactors (PWRs) [16]. The fuel rods are supported by the friction forces between the fuel rods and the springs or dimples of the grids in a fuel assembly as shown in Fig.1. When the reactor operates, the coolant flows through the surface of the fuel rods, and causes a flow-induced vibration (FIV) phenomenon, which is considered as the main driving force for fretting damage of the fuel rods. Fretting wear experiments of nuclear fuel cladding tubes were carried out by Kim [7] to study the effects of contact forces and slip displacements on fretting wear

under environment of air as well as water.

In this paper, both experimental and numerical researches are taken for fretting fatigue analysis on Zr-4 tube specimen. In section 2, fretting fatigue experiment device, design and results will be introduced. In section 3, a similar structure as experiment is analysis by FEM. Initial crack nucleation can be predicted.

2.1. Experiment Design

An experiment device is designed and added to a MTS fatigue testing machine, as shown in Fig. 2. It is assembled by several separated parts, and every part can be replaced for different experimental conditions. Compared with the bridge-type fretting apparatus, this kind of device is supported on the MTS machine directly but not hung on the specimen. A much smaller and stable contact force could be supplied. By using this device, fretting fatigue experiments can be made directly on tube specimens.

In our case, Zr-4 fuel rod cladding tubes (size Φ10mm×0.7mm×250mm) which are used in Chinese 300MWe reactors were tested as specimens. Its chemical composition is given in Table 1. As shown in Fig. 3, some necessary preventive measures were taken to make sure that there was no radial deformation neither any surface scars inside or outside the tube except the fretting point we expected. The contact force was set as 150N, and a constant amplitude displacement loading ($R_e=\varepsilon_{min}/\varepsilon_{max}$ =0.1) at a frequency of 10 Hz was applied. The contact geometry is a cylinder-cross-cylinder type. The pads are made of Cr12MoV Steel. The slip displacements (δ) between the pads and the specimen are determined by the imposed strain in specimen and the vertical motion of the pads during the tests measured by a dial indicator. For a maximum strain ε_{max} =0.4%, the slip displacement is 200 μm.

2.2. Experiment Results

Fig. 4 shows the fretting scars and cracks of two specimens for cases of maximum strain ε_{max}=0.6%. Ellipse fretting scars are made after 10^4 cycles. And the crack does not occur at the middle of the contact area where the wear depth reached the maximum, but at the edge of the initial contact area. Fig. 5 shows the comparison between fatigue S-N curve of the standard specimens and fretting fatigue S-N curve of the tube specimens. σ_{max} is the maximum engineering stress calculated by the measured force and the area of the section, σ_{min} is the minimum one, and $\Delta\sigma=\sigma_{max}-\sigma_{min}$ is the amplitude of the stress. N_f is the number of cycles when the specimen cracks. It is illustrated that the influence of fretting on the fatigue resistance occurs above 10^4 cycles and becomes stronger in higher cycle fatigue situation. The fretting decreases fatigue strength of material above 50% after 10^5 cycles. For cases of ε_{max}=0.4~0.8% (specimen no.6~15), the results are listed in Table 2. l_1 and l_2 is the length of the fretting scars on two sides of the specimen, and d_1 and d_2 are the corresponding distances from the crack to the middle of the fretting wear scar. The mean value of d equals 0.52834mm, and variance of d equals 0.0416mm^2.

14	2.2524	0.5993	2.1378	0.5708
15	2.3581	0.3850	2.2173	0.6122

3. FEM simulation

3.1 FEM model

Because of the symmetry of the structure, a quarter model of pad-on-tube structure is employed as shown in Fig. 6. The size of the tube is Φ10mm×0.7mm×100mm. Symmetrical boundary condition is applied on plane XoZ and XoY. Clamped boundary condition is applied on plane YoZ. P is the applied contact pressure on the back of the pad. Dload is the displacement load on the top end of the tube. Fig. 7 shows that the applied contact pressure keeps 7.5MPa during the displacement load

cycles and Dload with an range of 0.04~0.4mm is applied, which can make a similar fretting situation as the test (ε_{max} =0.4%, δ=200 μm, Re=0.1). Both tube and pad are considered as isotropic linear elastic material. The material parameters are listed in Table 3. Several cycles' loading is necessary because of plasticity.

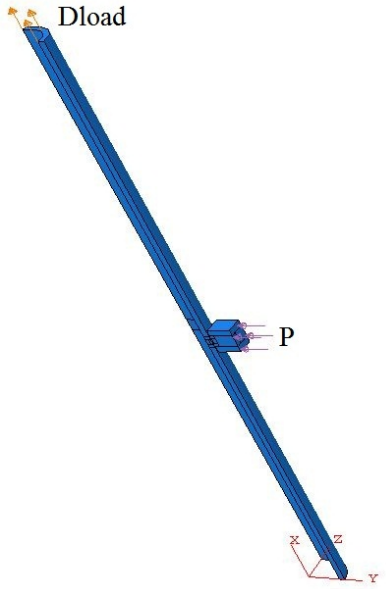

Figure 6. Quarter FEM model of pad-on-tube

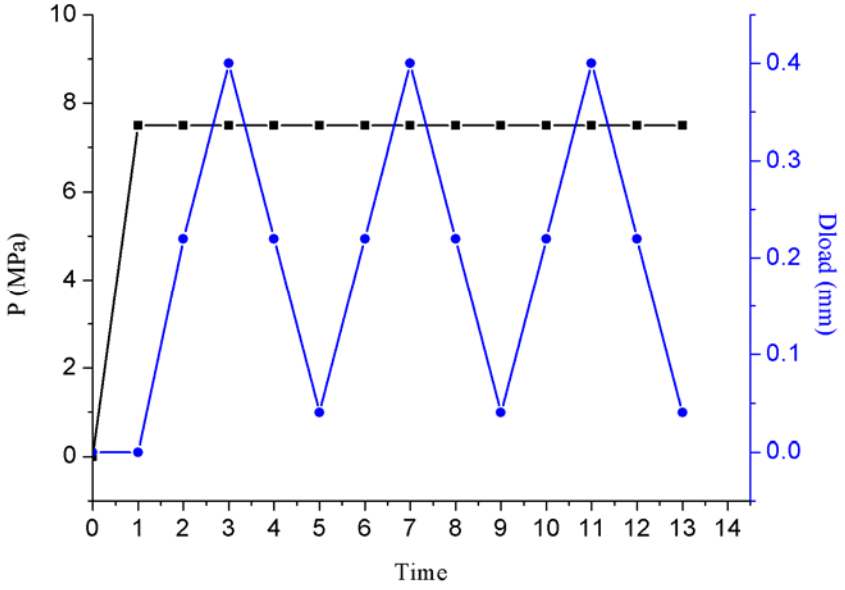

Figure 7. Applied contact pressure and displacement load

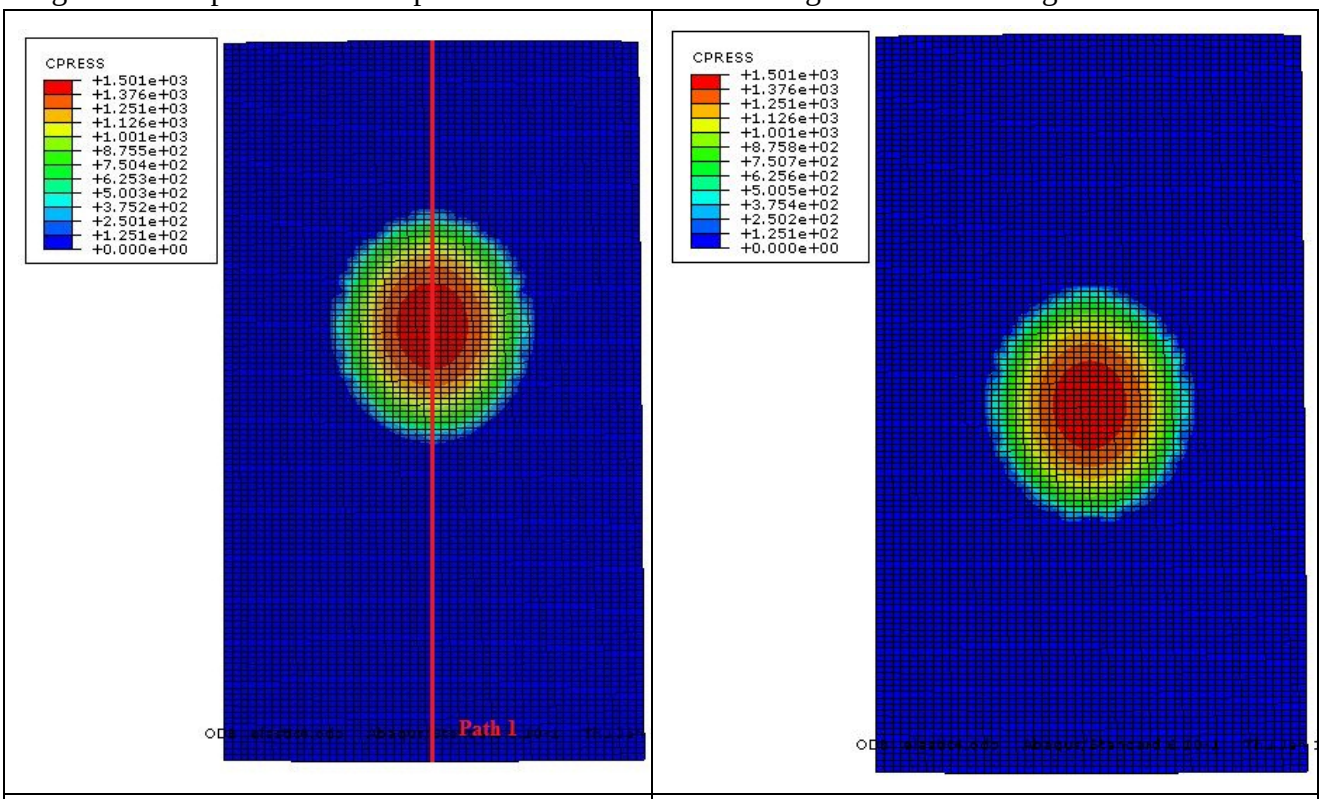
Table 3. Material Parameter

	Young's module	Passion's ratio
Tube	96GPa	0.43
Pad	206GPa	0.3

3.2 Simulation results

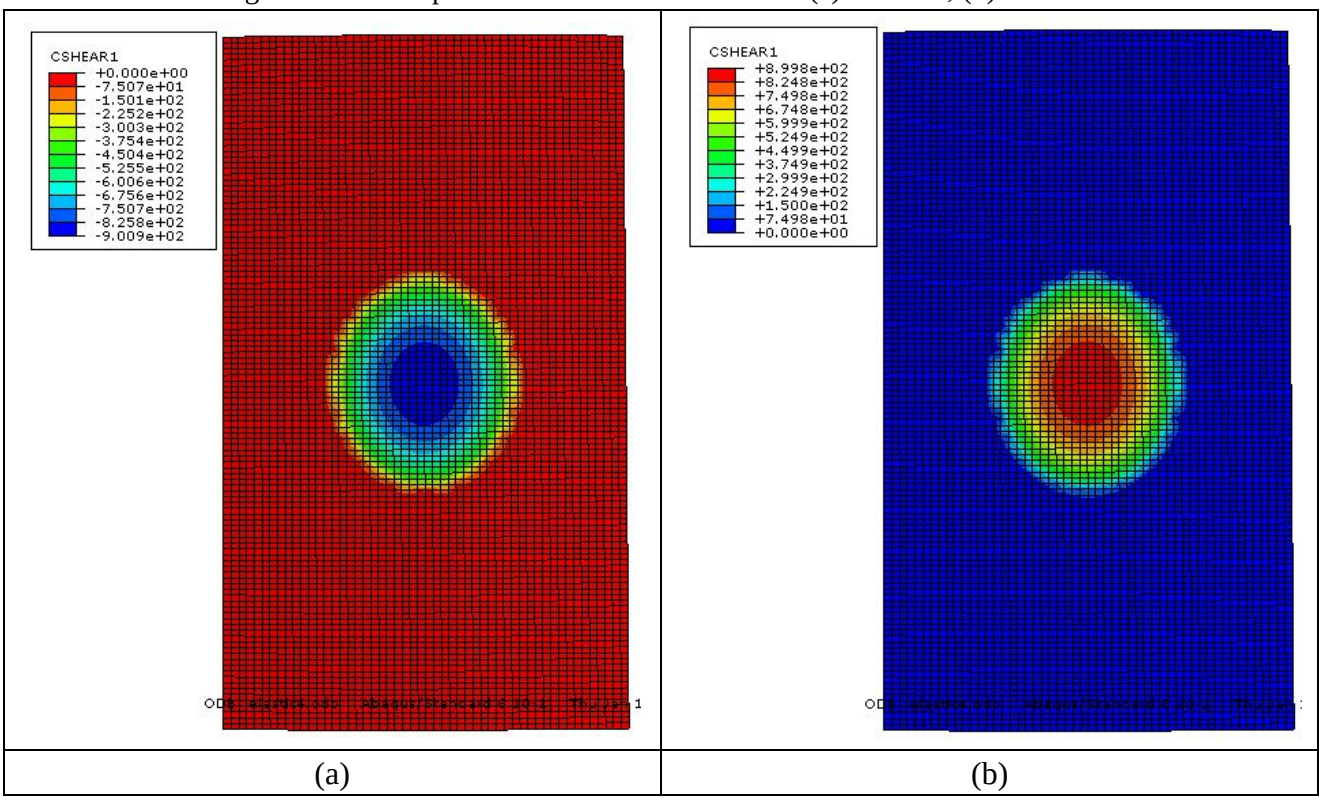
The contours of the contact pressure on the tube are plotted in Fig. 8 for different time steps. Fig. 8(a) shows that the initial contact region is an ellipse with a length of 600μm and a width of 480μm. Comparison of Fig. 8(a) and 8(b) shows that the contact region is moving with the increasing of the applied load. Fig. 9(a) and 9(b) shows the contact shear stress on the tube surface for the same Dload, but one is increasing and the other is decreasing. It is illustrated that the absolute value of the contact shear stress for the two cases are almost the same, but the directions of the friction force are the opposite. The contact pressures of path 1 for different times are shown in fig. 10. The contact region on the surface of the tube can be separated into two parts. One is always under the contact (noted as Region I in Fig. 10) and the other is scanned by the edge of the contact region during the cycles (noted as Region II in Fig. 10). The rest region of the tube surface is not under contact during the cycles (noted as Region III in Fig. 10). The separation of the contact surface is shown in fig. 11. σ_x is a periodic function with a same frequency of applied load. σ_x of three point from these three separated regions are shown in Fig.12. σ_x of point A keeps increasing in the loading process and decreasing in the unloading process. For the point B, the increasing of σ_x in the loading process is faster than in region I and reaches a maximum value when the edge of the contact region scans over it. And the decreasing of σ_x in unloading process is also faster than point A and reaches a minimum

value when the edge of the contact region scans over it again. For the point C, σ_x keeps negative during the loading and unloading process. Apparently, the amplitude of σ_x of the point B is much larger than the point A and the point C because of the scanning of the contact edge.



(a) (b)

Figure 8. Contact pressure on the tube surface for (a)time=1.0; (b)time=3.0



(a) (b)

Figure 9. Contact shear stress on the tube surface for (a) time=2.9; (b) time=3.1.

σ_{max} and σ_{min} are of path 1 are shown in Fig. 13, where

$$\sigma_{max}(x) = \max_t(\sigma_x(x,t)), \qquad \sigma_{min}(x) = \min_t(\sigma_x(x,t)), .$$

It is illustrated that the σ_{max} of nodes in region II are larger than the nodes in region I and region III. σ_{max} reaches a maximum value when the contact region moves to the red region in Fig. 11 because of the cumulated effect of contact shear stress and maximum applied load. $\Delta\sigma = \sigma_{max} - \sigma_{min}$ is shown in Fig. 14. It gives a different property with the stress amplitude of a standard specimen as shown in Fig 15. It may clarify that the crack does not occur at the middle of the contact area where the wear depth reached the maximum, but at the edge of the contact area.

4. Conclusion and discussions

(1) The fretting fatigue experiment taken on tube specimen gives a S-N curve of nuclear fuel cladding tube material. It is illustrated that the influence of the fretting on the fatigue resistance occurs above 10^4 cycles and becomes stronger in higher cycle fatigue situations. The fretting decreases fatigue strength of material above 50% after 10^5 cycles.

(2) The fretting fatigue experiment shows that crack does not occur at the middle of the contact area where the wear depth reached the maximum, but at the edge of the initial contact region. The mean value of distances from the crack to the middle of the fretting wear scar (d) equals 0.52834mm, and variance of d equals 0.0416mm^2.

(3) An FEM simulation is employed to analyze the crack nucleation on the tube surface. It is predicted that the region scanned by the edge of the contact region during the cycles will be the region of crack nucleation. The region II in Fig. 10 can be predicted by initial contact region and slip displacement. The distance from the crack to the middle of the fretting wear scar $d=a\pm\delta/2$, where a is the half-length of the initial contact region.

(4) Elastic materials are used in this simulation, which leads a smaller contact region and a larger contact stress. For the case in Section 3.1, a=0.455mm and δ=0.2mm if linear elastoplastic materials are employed in the simulation. This fits the tests of the specimen no.13~15 better.

Abstract Usually, the Wöhler field of a material is obtained from fatigue lifetime data resulting from testing specimens of reduced size in the laboratory. This basic information finds subsequent application in lifetime prediction of larger structural and mechanical components. Thus, an important question arises: how can the S-N field be transformed into an ideal one referred to a characteristic size (length, area or volume) subjected to a constant stress distribution in order to achieve a safe structural integrity design?
In this work, the influence of specimen geometry and variable stress state on the fatigue lifetime distribution for constant amplitude fatigue tests is investigated. An experimental program has been carried out with unnotched specimens of nominally the same material but differing in length, diameter, and shape.
The experimental data is fitted to a newly developed fatigue model, capable of describing the S-N-field in a probabilistic manner accounting for both the specimen geometry and the variable stress state of the specimens. As the estimated Wöhler field is referred to an elemental surface, loaded by a constant stress level $\Delta\sigma$, the extrapolation of the fatigue resistance to different specimen geometries is possible. Additionally, problems encountered due to scatter of the material properties are discussed.

Keywords SN curves, Size effect, Probabilistic modelling, Transferability, Specimen geometry

1. Introduction

It has been observed that fatigue lifetime depends on the size of the structural element, whereby larger specimens present lower fatigue lifetime than smaller ones when loaded by the same stress range. This so-called size effect stems from the higher probability of larger specimens to contain a critical crack, capable of initiating the fatigue process, compared to smaller specimens. Investigations on the size effect in fatigue have been done, amongst others, by Weibull [1] on ball bearing steel, by Picciotto [2] on yarn, by Köhler [3] on wires and flat specimens, by Fernández-Canteli et al. [4] on prestressing wires and by Shirani et al. [5] on wind turbine castings.
Understanding the size effect is crucial to extrapolate fatigue data from small specimens tested in the laboratory to real structures. Additionally, specimen geometries used in fatigue experiments sometimes present a cross-section with varying diameter along their lengths (see Fig. 2). The experimental results ($\Delta\sigma$ versus lifetime N) obtained from testing these specimens are usually evaluated considering the maximum nominal stress range $\Delta\sigma_0$ acting in the smallest cross section and the stress ratio $R=\sigma_{min}/\sigma_{max}$. While the stress ratio R is the same for all cross sections, $\Delta\sigma$ varies along the specimen length. Thus, even if a specimen is likely to fail in the section with the highest $\Delta\sigma$, the remaining sections with lower $\Delta\sigma$ influence the overall failure probability. That is why for a specimen as depicted in Fig. 2 it is statistically not correct to refer the results only to the surface or volume with the smallest radius (central section). Though there are models to account for the pure length effect, e.g. [6], the variable stress in the specimen is in general not accounted for.
The present investigation proposes a new model to evaluate fatigue test data considering both size effect and variable stress state of the test specimens. This allows, on one hand, a comparison of fatigue data obtained for different specimen sizes and, on the other hand, to establish a new method to extrapolate fatigue life results from laboratory tests to different specimen sizes and real structures. The applicability of the model is checked by evaluating three experimental fatigue data

sets corresponding to three specific specimen geometries of the same material: the aluminium alloy AlMgSi1-6082.

2. Model proposal

In this section a new method to evaluate fatigue data is presented which extends the applicability of the probabilistic fatigue model presented by Castillo and Fernández-Canteli [6] for a more general description of the fatigue behaviour considering specimen geometry, i.e. size effect and variable stress state.

2.1. Probabilistic model

The Weibull regression model described in [6] is based on physical and statistical assumptions. The compatibility condition between the probability distributions present in the Wöhler field, i.e. the probability distribution $P_f(\Delta\sigma|N)$ of $\Delta\sigma$ for constant N and the probability distribution $P_f(N|\Delta\sigma)$ of N for constant values of $\Delta\sigma$, plays an important role, manifesting that the values of the failure probability for every combination of $\Delta\sigma$ and N must be equal for $P_f(\Delta\sigma|N)$ and $P_f(N|\Delta\sigma)$. The model describes the Wöhler field in a probabilistic way by means of percentile curves, i.e. curves representing a constant failure probability, and computes the failure probability $P_f(N, \Delta\sigma)$ for a combination of stress range $\Delta\sigma$ and number of cycles N by

$$P_f(N,\Delta\sigma) = 1 - \exp\left[-\left(\frac{\left((\ln N - B)(\ln \Delta\sigma - C) - \lambda\right)}{\delta}\right)^{\beta}\right], \tag{1}$$

which corresponds to a three-parameter Weibull distribution of the variable $V = (\ln N - B)(\ln \Delta\sigma - C)$ with location parameter λ, shape parameter β, and scale parameter δ [7]. V represents a normalizing variable and could be interpreted as a damage parameter. B and C are the threshold parameters for lifetime and stress range, respectively. Fig. 1 gives an example of the model depicting the SN field on the left and the normalized variable on the right. A detailed description of the model can be found in [6].

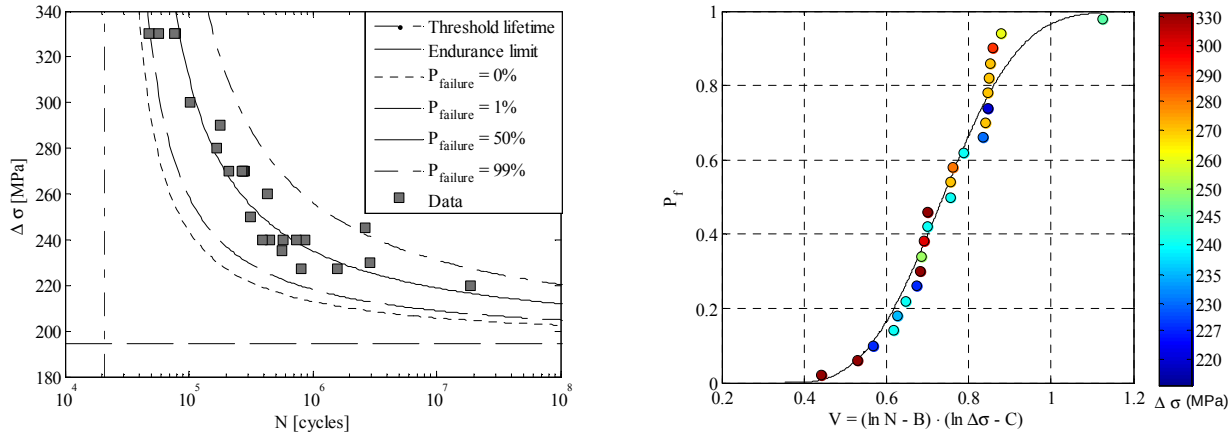

Figure 1. SN field and normalized variable V

2.2. Consideration of size effect and variable stress state

In principle the fatigue life depends not only on the material, the stress range, and the stress ratio, but also on the specimen length, as found for example in [4]. This means that the longer a specimen the higher the failure probability if the same stress range $\Delta\sigma$ is applied. This phenomenon, called statistical size effect, is due to the fact that a larger specimen is more likely to contain a large critical crack than a smaller specimen, cracks being considered to originate fatigue failure. Furthermore, specimen geometries used in fatigue experiments frequently present a cross-section with varying diameter along their lengths (see Fig. 2). The experimental results ($\Delta\sigma$ versus lifetime N) stemming from testing these specimens are usually evaluated considering only the maximum stress range $\Delta\sigma_0$, acting on the smallest cross section, and the stress ratio $R=\sigma_{min}/\sigma_{max}$. While the stress ratio R is the same for all cross sections, $\Delta\sigma$ is varying along the specimen length. To extrapolate from those test results to structural elements or specimens of different size it is advantageous to obtain a "normalized" Wöhler field. To accomplish this task a new method is developed, based on the following assumptions:

a) Fatigue failure initiates from surface flaws. Therefore the size effect is related to the stressed surface area, i.e. the larger the stressed surface the higher is the failure probability for the same combination of $\Delta\sigma$ and N.

b) Validity of statistical independence and weakest-link principal implying that the survival probability $P_{s,S}$ of a surface $S = n \cdot S_i$ composed of n surface elements of size S_i is given by the product of the individual survival probabilities P_{s,S_i} of the subelements each loaded by a stress range $\Delta\sigma_i$, i.e.

$$P_{s,S}(N,\Delta\sigma) = \prod_{i=1}^{n} P_{s,S_i}(N,\Delta\sigma_i). \tag{2}$$

Accordingly, if all surface elements have the same size S_i and are loaded by the same stress range $\Delta\sigma_i$ one gets

$$P_{s,S}(N,\Delta\sigma) = \left(P_{s,S_i}(N,\Delta\sigma_i)\right)^{S/S_i}. \tag{3}$$

c) For the moment, only the uni-axial load case is considered, so that Eq. (1) describes the failure probability $P_{f,\Delta S}$ for a uni-axially tensioned surface element ΔS.

With those assumptions and $P_{s,\Delta S} = 1 - P_{f,\Delta S}$ we can combine Eqs. (1) and (3) to obtain the survival probability for a uni-axially tensioned surface element of size $S_i = n_i \cdot \Delta S$ as

$$P_{s,S_i}(N,\Delta\sigma) = \left(1 - P_{f,\Delta S}(N,\Delta\sigma)\right)^{S_i/\Delta S} = \exp\left[-\frac{S_i}{\Delta S}\left(\frac{(\ln N - B)(\ln\Delta\sigma - C) - \lambda}{\delta}\right)^{\beta}\right] \tag{4}$$

Thus, for an arbitrary structure under fatigue load with tensioned surface $S = n \cdot S_i$ composed of n surface elements of size S_i, each loaded by a different stress level $\Delta\sigma_i$, combining Eqs. (2) and (4) one gets

$$P_f(N,\Delta\sigma_0) = 1 - \prod_{i=1}^{n} \exp\left[-\frac{S_i}{\Delta S}\left(\frac{(\ln N - B)(\ln \Delta\sigma_i - C) - \lambda}{\delta}\right)^{\beta}\right]$$
$$= 1 - \exp\left[-\sum_{i=1}^{n} \frac{S_i}{\Delta S}\left(\frac{(\ln N - B)(\ln \Delta\sigma_i - C) - \lambda}{\delta}\right)^{\beta}\right] \quad (5)$$

For a specimen with circular cross section and variable diameter $d(x)$ over its length, being d_0 the minimal diameter in the section loaded by the maximum stress level $\Delta\sigma_0$, the summation can be extended to an integral. With $S_i = \pi\, d(x)\, dx$, we get

$$P_f(N,\Delta\sigma_0) = 1 - \exp\left[-\frac{2\Pi}{\Delta S}\int_0^{UB}\left(\frac{(\ln N - B)\left(\ln\left(\Delta\sigma_0 \frac{d_0^2}{d(x)^2}\right) - C\right) - \lambda}{\delta}\right)^{\beta} d(x)dx\right]. \quad (6)$$

Due to symmetry, the integration is carried out over half the specimen length starting in the centre of the specimen, being the upper integration bound UB the x-coordinate, where $(\ln N - B)(\ln(\Delta\sigma(x)) - C) = \lambda$.

2.3. Effective surface area

For a specimen under variable stress state an effective specimen surface S_{eff} can be defined having the same failure probability as the whole specimen but subjected to a constant stress range $\Delta\sigma$. The normalizing variable for the nominal maximum stress $\Delta\sigma_0$ acting in the central section of the specimen with diameter d_0 is represented by $V_0 = (\ln N - B)(\ln \Delta\sigma_0 - C)$. For different specimen sections with diameter $d(x)$ we have $V(x) = (\ln N - B)(\ln(\Delta\sigma_0 \cdot d_0^2/d(x)^2) - C)$. An analytical expression for S_{eff} is obtained equating Eqs. (5) (with $S_i = S_{eff}$) and (6):

$$S_{eff} = \frac{2\,\Pi \int_0^{UB} (V(x) - \lambda)^{\beta} d(x)\mathrm{d}x}{(V_0 - \lambda)^{\beta}}. \quad (7)$$

As can be observed from Eq. (7) S_{eff} is independent of δ but depends on the parameters B, C, λ and β of the Weibull model and also on the number of cycles N and the stress range $\Delta\sigma$. For given values of N and $\Delta\sigma_0$ and known material parameters B, C, λ and β the effective surface and the failure probability can be computed. However, for a specific specimen S_{eff} cannot be calculated directly from the failure data, since the Weibull parameters are still unknown. Thus, an iterative process, as explained in [8], is used for the parameter estimation. Firstly, the n test data are fitted to the model given by Eq. (1), then the normalized values V_0 are assigned their accumulated failure probabilities by $P_f = (i - 0.3)/(n + 0.4)$. To refer the data to the surface element ΔS, those failure probabilities are shifted by using $P_{f,i,\Delta S} = 1 - \left(1 - P_{f,i,S_{eff}}\right)^{\Delta S/S_{eff,i}}$. The $V_{0,i}$ and their corresponding $P_{f,i,\Delta S}$ are fitted to a three-parameter Weibull distribution. The obtained values for λ and β are used to update the effective surface given by Eq. (7) in each iteration loop. Those steps are repeated until the Weibull parameters converge.

3. Material and experimental programme

To investigate the influence of the size effect and the variable stress state on the fatigue behaviour, specimens with different geometries have been tested until complete fracture at EMPA-Dübendorf (Swiss Federal Material Testing and Research Laboratories). All specimens whose dimensions are given in table 1 and refer to Fig. 2 have been machined by the same manufacturer from rods of the aluminium alloy AlMgSi1 6082-T6 with chemical composition given in table 2. The d3 and d8 specimens were machined from rods of diameter 25 mm and the d22 specimens from rods with diameter 45 mm. The corresponding yield and ultimate strengths are given in table 2 as the mean of three values obtained from static strength tests using normalized specimens.

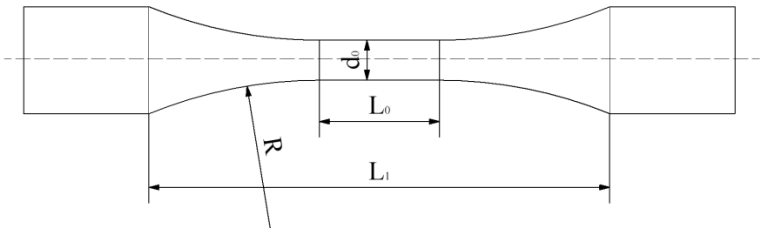

Figure 2. Specimen geometry

Table 1. Tested specimen geometries

Name	d_0 [mm]	L_0 [mm]	L_1 [mm]	R [mm]
d3	3	0	22.4	24
d8	8	24	88.6	90
d22	22	240	385.0	245

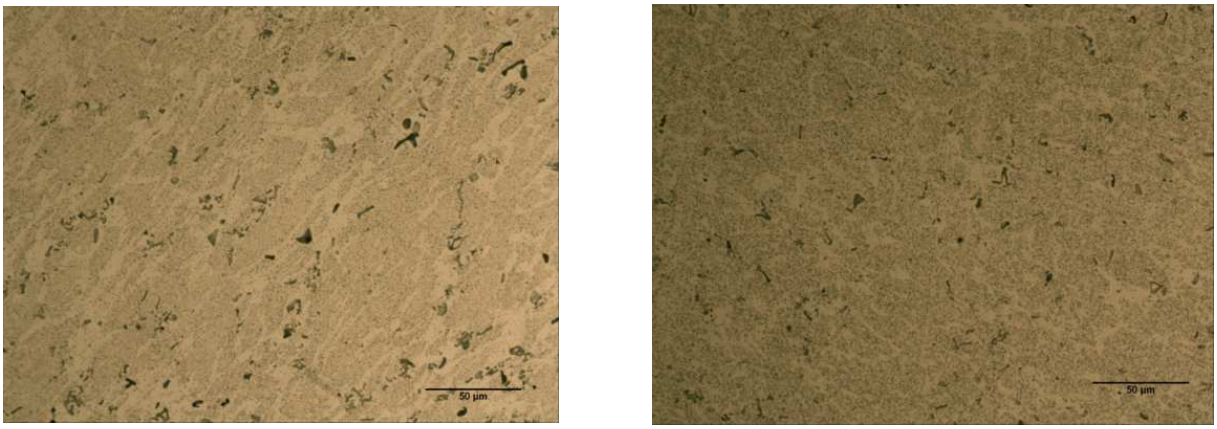
Table 2. Chemical composition and strength of AlMgSi1 6082-T6

d [mm]	Si [%]	Fe [%]	Cu [%]	Mn [%]	Mg [%]	Cr [%]	Zn [%]	Ti [%]	Pb [%]	R_m [MPa]	$R_{p0.2}$ [MPa]
25	1.002	0.499	0.091	0.749	0.831	0.032	0.186	0.063	0.026	410	402
45	0.850	0.280	0.060	0.430	0.710	0.050	0.050	0.030	N/A	369	350

Since the static strength of the specimens differs for the different rods, additionally micrographies were taken (one from each rod) as shown in Fig. 3. It can be observed that the microstructure happens to be quite similar for both samples, thus, justifying a direct comparison of the fatigue test data.

The constant amplitude fatigue tests were carried out in pure tension with a stress ratio R=0.1. For the tests of the d3 and d8 specimens resonance frequency machines (Rumul) equipped with 5 kN and 100 kN load cells, respectively, were used, whereas the d22 specimens were tested by a servo-hydraulic machine (Schenck) with 630 kN load cell. The forces were calculated taking into account the measured diameters in the central section of each specimen and the stress ranges $\Delta\sigma$, to be applied in this section. For all specimens the difference between measured and nominal diameter was less than 0.03 mm. The predominant role of the surface flaws has been corroborated by ocular

and microscopic inspection of the failure sites revealing that the practical totality of the fatigue failures started from the specimen surface. In the exceptional case that a failure could be identified to have its origin in a volume defect, it was not considered in the present analysis.



a) Rod d=25 mm (used for d3 and d8 specimens) b) Rod d=45 mm (used for d22 specimens)

Figure 3. Microstructure of AlMgSi1

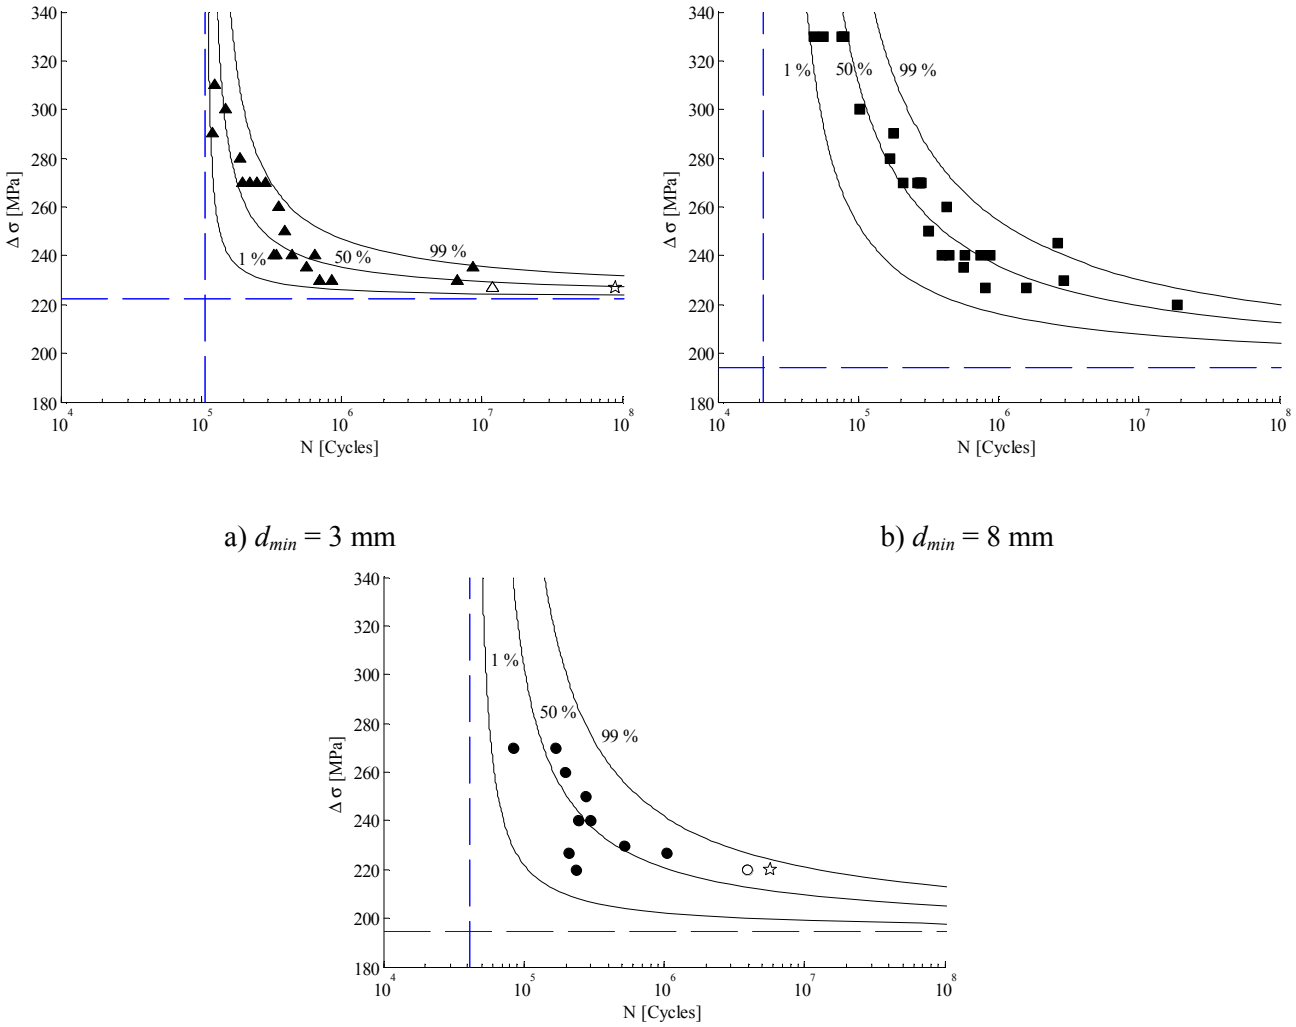
4. Results and model application

The experimental data sets for each specimen geometry were individually fitted to the model given by Eq. (6) of section 2.2. to obtain the parameters referred to ΔS=9 mm^2 as shown in table 3. The choice of ΔS is free, so that larger values of ΔS will only result in smaller values of δ, remaining the other parameters unchanged.

Table 3. Parameter estimates for each data set

d_{min} [mm]	ΔS [mm^2]	B	exp(B) [cycles]	C	exp(C) [MPa]	λ	β	δ
3	9	11.57	105873	5.40	221	0.01	2.42	0.16
8	9	9.95	20952	5.27	194	0.21	4.31	1.65
22	9	10.63	41357	5.27	194	0.00	3.41	4.09

The fatigue test data and their corresponding Wöhler fields are represented in Fig. 4 for the specimen geometries d3, d8, and d22. The percentiles are computed replacing into Eq. (6) the parameter estimates referred to the area ΔS given in table 3 and the specimen geometries of table 1.
In a second step, the SN fields for the d3 and d22 specimens are predicted based on the parameter estimates, found by fitting the data of another specimen geometry, by substituting the corresponding radii and lengths in Eq. (2). Figs. 5a and b show the Wöhler fields for the d3 and d22 specimens using the parameter estimates obtained by fitting the d8 data. The extrapolations from the d3 to the d22 specimen and from the d22 to the d3 specimen are given in Figs. 5c and d, respectively.



a) d_{min} = 3 mm

b) d_{min} = 8 mm

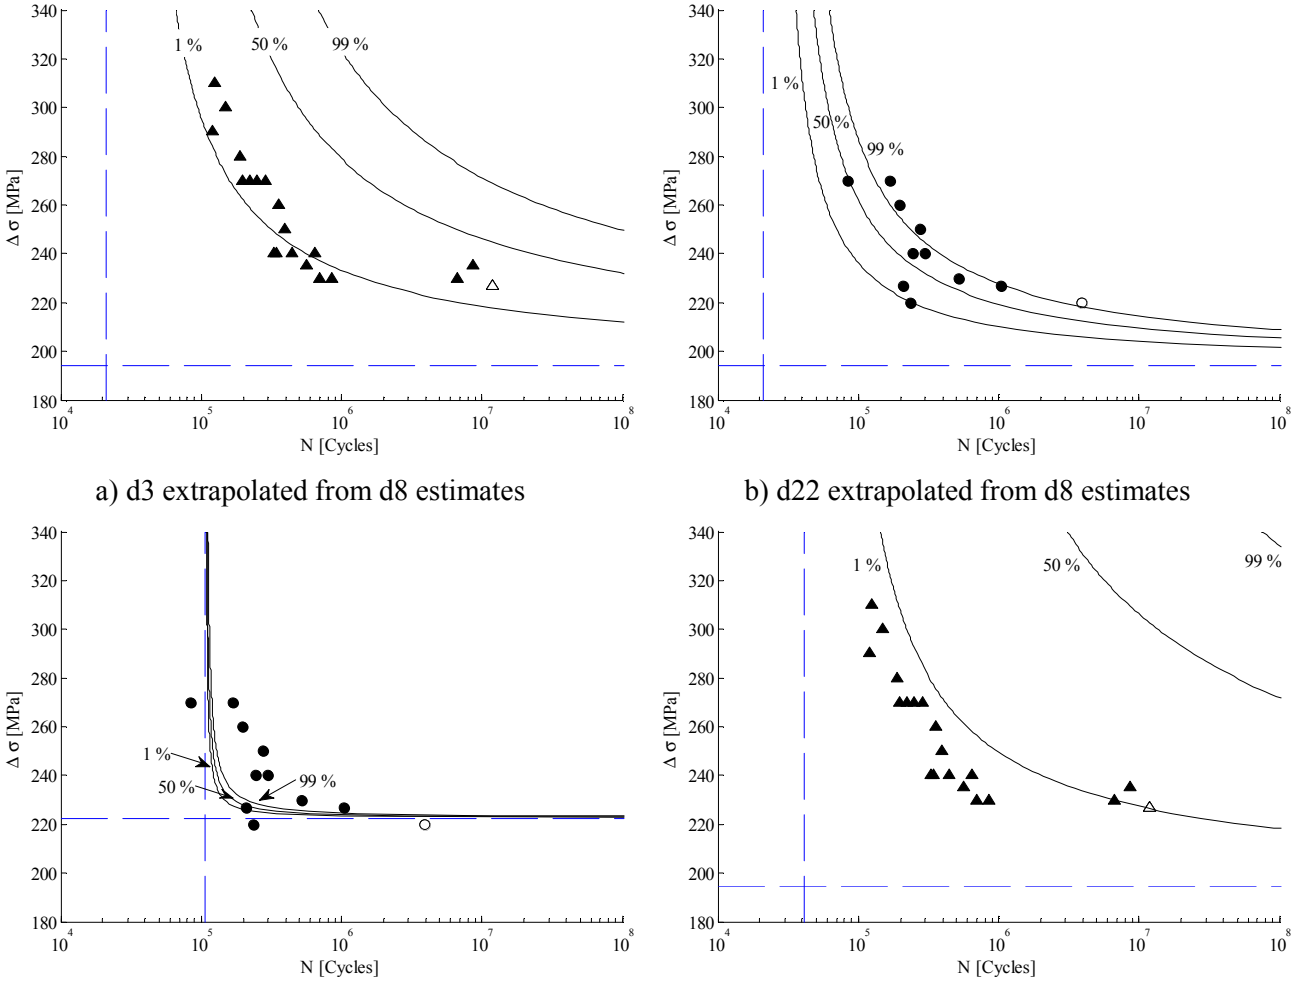
c) d_{min} = 22 mm

Figure 4. AlMgSi1 fatigue data and percentile curves for 1, 50 and 99 % failure probability

5. Discussion

As can be observed in Fig.4, the percentile curves for all three specimen geometries provided by the model describe the fatigue data well, both in terms of median curve and data scatter. As the estimated parameters for each data set are referred to the same surface area ΔS, they should coincide for all three data sets. Nevertheless, as can be seen in table 3, this is only the case for the threshold parameter C for the d8 and d22 specimens. According to the model, a comparison of the Weibull parameters λ, β and δ requires the parameters B and C to be coincident to compute the normalized variable V.

The extrapolation from the d8 estimates to the d3 Wöhler field overestimates both the median curve of fatigue life for constant stress levels and the data scatter. A possible reason could be that for such small specimens statistical independence, as is an assumption of the model, is not fulfilled in this case. As reference for other practical cases, in [6] it was also observed that the fatigue behaviour of the shortest prestressing wires could not be described based on the estimates for the longer wires. Therefore, the statistical dependence [9] based on considerations related to the defects from which fatigue initiation arises together with experimental work should be further investigated in order to



a) d3 extrapolated from d8 estimates

b) d22 extrapolated from d8 estimates

c) d22 extrapolated from d3 estimates

d) d3 extrapolated from d22 estimates

Figure 5. Extrapolation to different specimen geometries (1, 5 and 99 % percentile curves)

improve the model. Different surface quality can also be excluded, as all specimens were machined in the same workshop, therefore supposedly having undergone the same surface treatment. In particular, both the d3 and d8 specimens were fabricated from 25 mm diameter rods. Although, this implies that the surface of the d3 specimens is closer to the centre of the rods than the surface of the d8 specimens and possibly having experienced both different cooling rates, the difference is negligible bearing in mind the original rod diameter.

One could also question the existence of a size effect. Though this assumption might be true for the d3 and d8 specimens, it is obvious from Fig. 6 that the d22 specimens have lower lifetimes than the d3 and d8 specimens for the same stress ranges. Nevertheless, in the region of low stress ranges, the d3 specimens tend to present higher fatigue lifetimes than the d8 specimens.

On the other hand, the prediction for the d22 specimens based on the d8 estimates (Fig. 5b) is quite good lying almost all failure data for the d22 specimens between the 1 and 99 % - percentiles. However, a tendency to underestimate the fatigue strength is noticeable since by the extrapolation the data with highest lifetime are assigned to failure probabilities higher than 99 %.

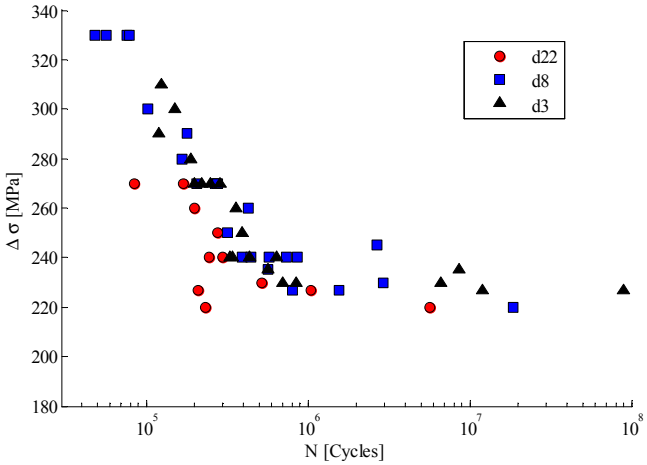


Figure 6. AlMgSi1 fatigue data for the tested specimen geometries

The extrapolation to the d22 specimen geometry based on the d3 estimates (Fig. 5c) leads to an underestimation of the data scatter and of the median curve. In this context, it has to be noted that the threshold parameters for the d3 data set were estimated in higher values than those for the d8 and d22 data sets. In fact, the threshold stress exp(C) for the d3 specimens results in 221 MPa which represents a higher value than the lowest stress range in the fatigue results for the d8 and d22 specimens equal to 220 MPa. Therefore, failure data lying below the threshold stress of the estimated model cannot be represented by the model. In contrast, the prediction of the SN field for the d3 geometry based on the d22 estimates (Fig. 5d) results in a noticeable overestimation of mean curve and data scatter.

6. Conclusions

A new model for the evaluation of fatigue test results under simultaneous consideration of size effect and variable stress state along the specimens is presented. The model, describing the SN field by means of percentiles, has been applied to three sets of fatigue data for AlMgSi1, each set obtained on specimens with different size. The estimated SN fields fit the experimental data well. As the parameters of the fatigue model are referred to a uni-axially and uniformly tensioned surface element, extrapolation to different specimen geometries can be performed. However, extrapolation to different specimen geometries is only satisfactory from the d8 to the d22 specimens. For the other presented cases, an extrapolation of the model from larger to smaller specimens overestimates the lifetimes of the smaller specimens and vice versa, an extrapolation from smaller to larger specimens tends to underestimate the fatigue behaviour. Thus, further research will be undertaken to get a deeper understanding of the size effect, and the role played by the defect distribution and the statistical independence assumption in order to improve the model.

Abstract
In this study, crack propagation tests were conducted to clarify property for the fatigue crack propagation of Friction Stir Welded (FSW) 2024-T3 aluminum alloy. FSW panel has residual stress around weld line and the longitude residual stress is higher around it. The peak tensile residual stress is about 180 MPa in this case. To understand fatigue crack growth property on FSW panel, crack opening stress measurement of the base material and FSW joint using an extensometer with the modified tool is also conducted during the crack growth test. The modified tool is jig to mount the extensometer to the specimen with magnets. The test results indicate that the accuracy of crack opening stress measurement is improved. In addition, the crack growth acceleration and decelerate around the FSW line under the low applied stress range (25 MPa) is bigger than that under high applied stress range (50 MPa). This means the effect of residual stress under low stress range is relatively larger than that under high stress range.

Keywords: Friction Stir Welding, Fatigue Crack Growth Propagation, Residual Stress, Crack Opening Stress

1. Introduction

Friction stir welding (FSW) is one of recently developed welding process[1] as shown in figure 1. It has the capability of welding high strength Aluminum alloys of 2xxx and 7xxx type which are difficult to weld by conventional welding. FSW has applied many structures such as trains, rockets and ships. From point of reducing production cost and structural weight, FSW is expected to be applied to commercial aircraft primary structures as an alternative to riveted joints. FSW was firstly used on a normal category aircraft “Eclipse 500” by Eclipse Aviation in 2006. However, the safety factor of FSW joint is estimated high in this aircraft. So far the study of FSW has been not sufficient to meet a damage tolerance. The Federal Aviation Regulations (FARs) on damage tolerance and fatigue evaluations of aircraft structures require understanding of the locations of fracture origin and the fatigue crack propagation property of the materials for aircrafts. To apply the structures jointed by FSW on aircrafts, the investigation of relationship between fatigue crack propagation property and residual stress on FSW panel is particularly significant. In case of FSW, the fatigue crack propagation rate is accelerated by the tensile residual stress around weld line as a result of non-uniform deformation caused by welding heat. Therefore, the explanation is required to determine an effect of residual stress on the crack propagation in the FSW panel. The aim of this study is to accurately evaluate the crack growth rate on FSW panel. The significance of this study is to focus on the crack opening stress to predict crack growth rate on FSW panel.
Our final goal of this research is to accurately predict the crack growth rate using FEM analysis. To achieve this goal, we have conducted the crack growth test[2-5]. In this paper we report the crack growth test results of the FSW panel with different applied stress and crack opening stress of the base material and FSW joint using an extensometer with the modified tool.

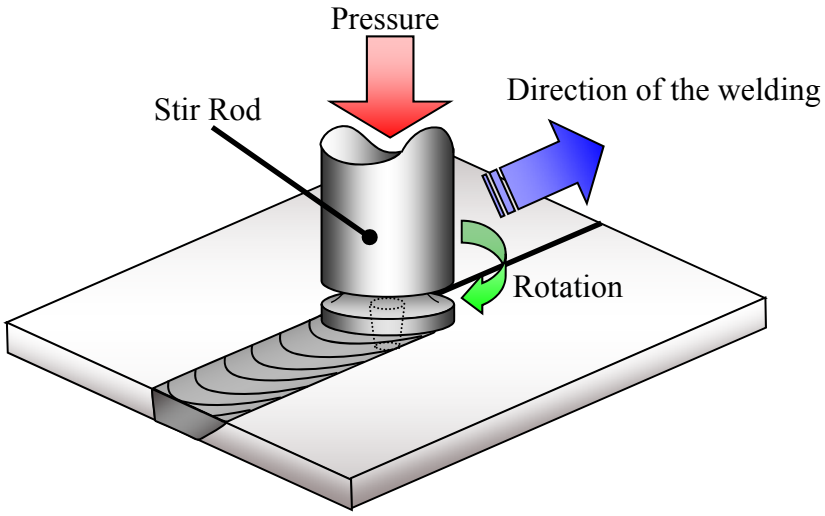

Figure 1. Schematic scheme of Friction Stir Welding

2. Material, specimen and method

The crack propagation tests were conducted, in accordance to the procedure in ASTM E647-08[6] standard test method. Sheet of 2024-T3 with a thickness of 2 mm were joined by FSW to form a butt joint. It is fabricated by Japanese aircraft manufacturer. The situations of Base metal panels and FSW panels are shown as Figure 2. Table 1 shows the list of specimens. All specimens have a center hole and notches as the initial flaw. All FSW panels have been welded by same welding procedures. So the level of residual stress is presumed to become same as each FSW panels. Figure 3 shows the result of measuring the residual stress in the vicinity of the weld line.

The crack growth test is subject to cyclic load with stress range: $\Delta\sigma$ = 25, 50, 75 MPa, stress ratio: R = 0.1 and load frequency: f = 5 Hz. The crack length was measured using a CCD camera. And we have installed the extensometer on specimens to measure crack opening displacement in order to evaluate the crack opening stress based on the compliance method which is improved by Chung et. al.[7]. In this test, the displacement above and below the hole was measured by an extensometer; the crack opening stress was determined on the basis of the change in the compliance of the specimen. We had installed the extensometer with bolts. In this study, the extensometer has been installed with modified tools. The modified tool is jig to mount the extensometer to the specimen with magnets.

Table 1. The list of specimens

No.	Base metal or FSW panel	Specimen size	stress range Δσ MPa
1	Base metal	Large size	50
2		Small size	25
3	FSW panel	Large size	75
4		Large size	50
5		Small size	25

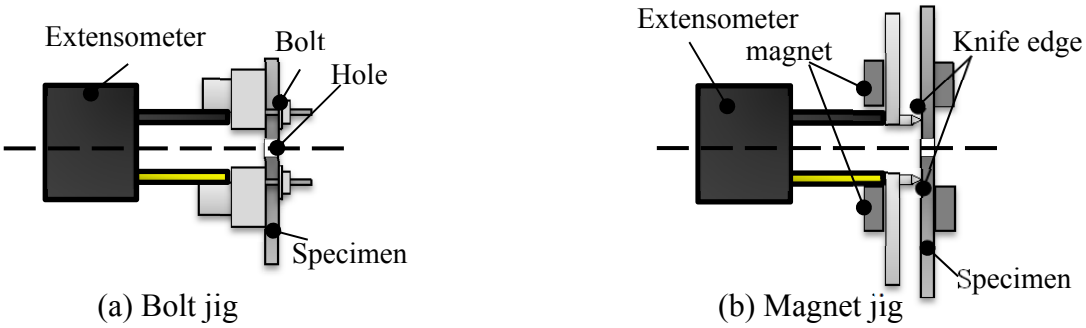
3. Result and discussion

3.1. Improvement of the jig

We need to mount an extensometer on specimens when we measure the crack opening stress. In case of $\Delta\sigma$ = 50 and 75 MPa, the extensometer was installed on specimen with bolt jig as shown in Figure 3(a) and measure the crack opening displacement. However, if tightening torque of bolts is not appropriate, the extensometer is not fixed on specimen and it is drifted. Therefore, we improved jig to mount the extensometer to the specimen tightly with magnets as shown in Figure 3(b).
To verify that the magnet jig can measure the crack opening stress, we measured the crack opening stress of base metal and compare the result of both jigs. In this study, we decided that crack is opening completely when the relative compliance offset become 5 %. This method is based on Chung's research[7]. In case of using bolt jig, the result of relative compliance offset is unstable and become greater than 5 % when the crack tip is not opening. So judgment of crack opening had been difficult. In case of using magnet jig, the relative compliance offset is stable and become less than 5 % when the crack tip is not opening. Therefore, the accuracy of crack opening stress measurement is improved by the magnet jig.



(a) Bolt jig (b) Magnet jig

Figure 3. Installing extensometer

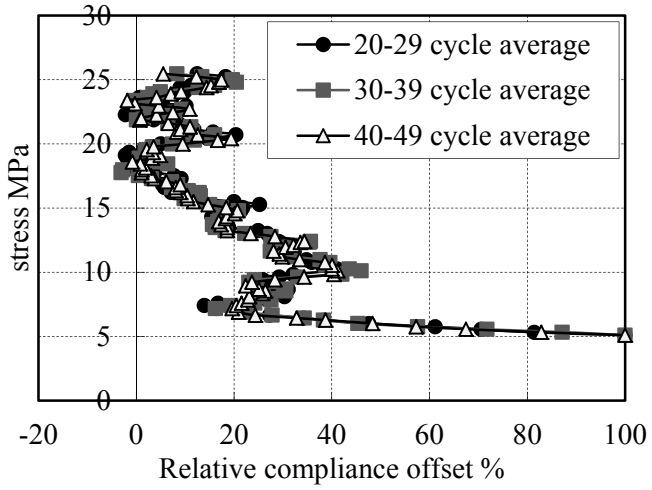


Figure 4. Determination of crack opening stress (bolt, a = 25.93 mm)

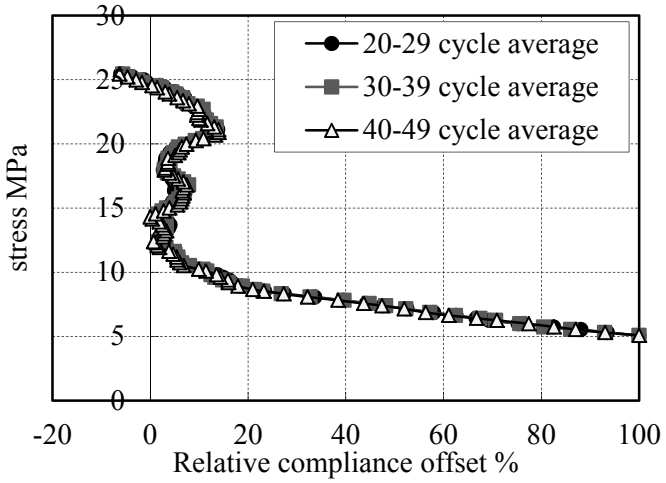

Figure 5. Determination of crack opening stress (magnet, a = 25.93 mm)

3.2. The result of crack opening stress measurement

The effective stress range, $\Delta\sigma_{eff}$, which is calculated using the maximum stress, σ_{max}, has one to one correlation to the crack growth rate. Here, $\Delta\sigma_{eff}$ is calculated by the following equation 1.

$$\Delta\sigma_{eff} = \sigma_{max} - \sigma_{op} \tag{1}$$

Elber[8] shows in full detail that The rate of crack propagation can be evaluated uniformly by using the effective stress range.

So the crack growth rate can be predicted by crack opening stress. To use the effective stress range, we have to accurately measure the crack opening stress of FSW panel.

There are some studies calculating crack opening stress of base metal by using empirical equations. Some of them, we have used empirical equations for 2024-T3 proposed by schijive[9] as eq. 2 and eq. 3.

$$U = 0.55 + 0.3R + 0.1R^2, \tag{2}$$

$$\therefore \sigma_{op} = \sigma_{max} - \left(0.55 + 0.3R + 0.1R^2\right)\Delta\sigma. \tag{3}$$

Figure 6 shows the result of crack opening stress measurement in each crack length. In addition, the calculated values obtained by the Schijive's equation and the experimental result of base metal ($\Delta\sigma$ = 75 MPa) are shown together.

In case of $\Delta\sigma$=75 MPa, the unti-buckling pate which suppress the out of plane deformation was used and measured with bolt jig. However, in case of $\Delta\sigma$ = 25 MPa, the unti-buckling plate was not used and measured with magnet jig. Therefore, the width of the variability of the measurement results is reduced by about 58%. Moreover, the result of measurement is same as the calculated values obtained by Schijive equation. For that reason, the validity of this measurement was confirmed and the test results indicate that the accuracy of crack opening stress measurement is improved.

Next, focus on the result of FSW panel as shown part A in figure 6. After crack tip invasion into weld line, crack opening stress is reduced substantially. Then, crack opening stress is asymptotic to the result of base metal as go away from weld line. From this result, the effect of residual stress is reduced when a position of crack tip is taken enough away from the weld line.

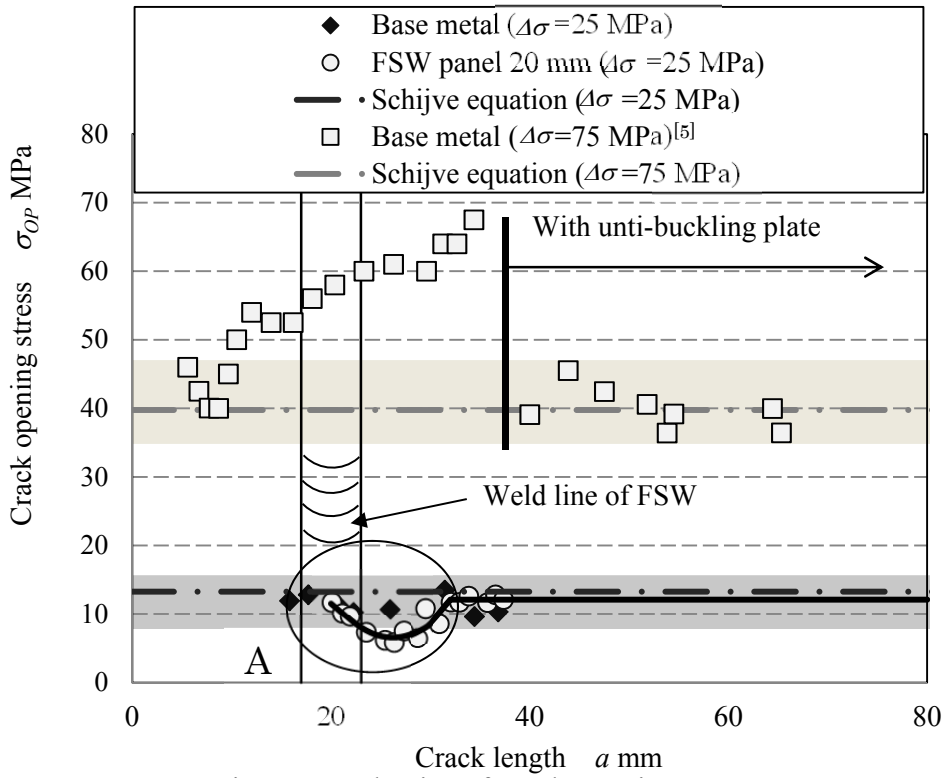

Figure 6. Behavior of crack opening stress

3.3. Effect of residual stress on crack propagation rate

We conducted crack growth tests with three types of external load conditions; $\Delta\sigma$ = 25, 50, 75 MPa. First, The results of $\Delta\sigma$ = 50, 75 MPa are shown in Figure 8. The stress intensity factor range is calculated by equation 4.

$$\Delta K = \Delta\sigma\sqrt{\pi a}\cdot F(a) \tag{4}$$

Here, F(a) is a correction factor. The reason why the position of weld line of FSW is different is because these two tests are different in stress range $\Delta\sigma$.

The maximum of the acceleration ratio of the crack growth rate for the FSW panel against the base material is 1 to 2 mm far away from the weld line after crack tip passes it. In case of $\Delta\sigma$ = 50 MPa, the acceleration ratio is 2.1, and $\Delta\sigma$ = 75 MPa the ratio is 2.3. The residual stress influences the crack growth rate. The FSW panels have the same level of residual stress distribution. So in case of external stress is high, the effect of residual stress is expected relatively low. This means the acceleration of crack growth rate for that situation is also low. However in this experiment, the difference on the acceleration ratio for crack growth rate is almost same at this two stress level; $\Delta\sigma$ = 50, 75 MPa.

The result of $\Delta\sigma$ = 25 MPa is shown in Figure 9. From the figure, it is observed that the crack propagation rate is decelerated by the compressive residual stress when the crack tip is located before the weld line. After the crack tip had moves on the weld line, the crack propagation rate is accelerated by the tensile residual stress. Finally, when the crack tip is located after the weld line, the crack growth rate is gradually approached to that of the base metal. In case of $\Delta\sigma$ = 25 MPa, the acceleration ratio of the crack growth rate for the FSW panel against the base material is 3.7.

The acceleration ratio of each stress range is shown in Figure 10. In summary, the crack propagation rate is affected by the residual stress and stress range $\Delta\sigma$. All FSW panel using in this study is made

under the same FSW condition. Therefore, residual stress of all specimens is identical. So, in the case of $\Delta\sigma$ = 25 MPa, the effect of residual stress is relatively high. This means the acceleration and deceleration of crack growth rate for that situation is also high.

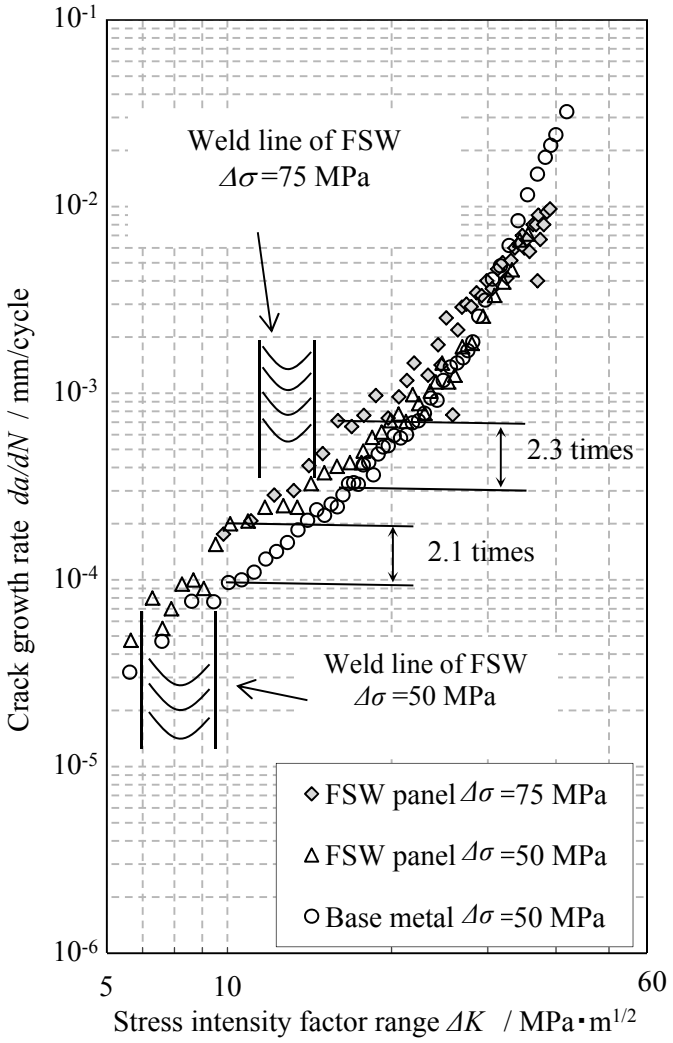

Figure 8. da/dN-ΔK curves for different external stress

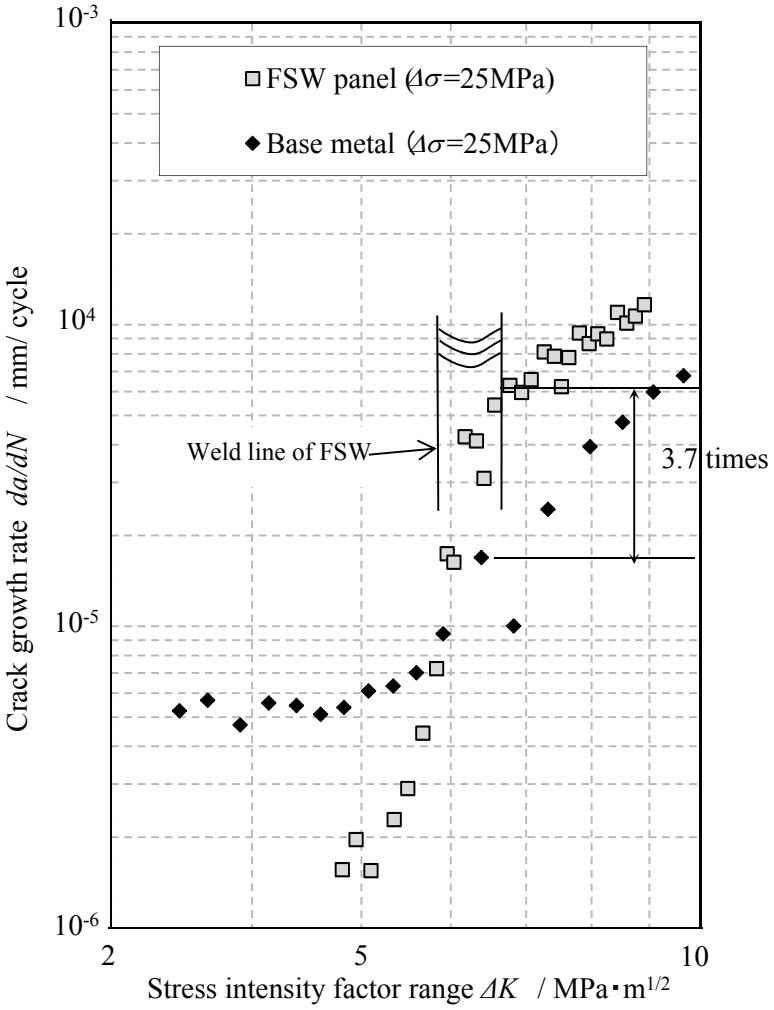

Figure 9. da/dN-ΔK curves ($\Delta\sigma$ = 25 MPa)

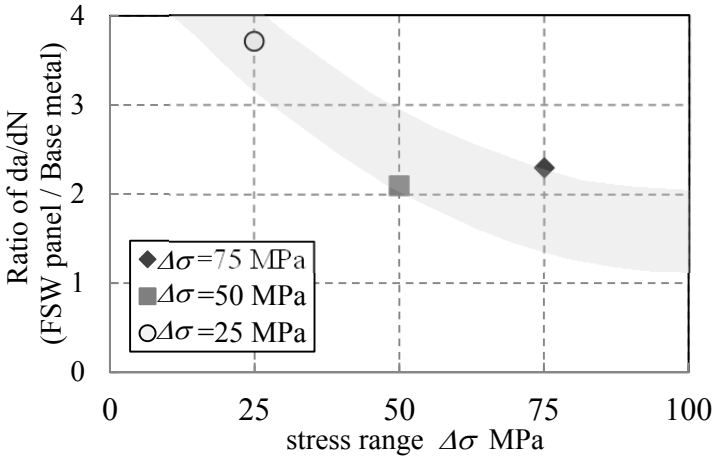

Figure 10. Comparison of fatigue crack growth rate

4. Conclusions

Fatigue crack growth test were conducted in order to evaluate the effect of residual stress field on crack growth propagation. The results are as follows:

(1) The extensometer can be installed tightly on the specimen by using the modified jig with magnet. The test results indicate that the accuracy of crack opening stress measurement is improved.
(2) Stress ranges between 50 MPa and 75 MPa does not clearly affect the acceleration ratio for crack growth rate against the base material. On the other hand, in the case of $\Delta\sigma$ = 25 MPa, the effect of residual stress on the acceleration ratio for crack growth rate against the base material is relatively high. This means the acceleration and deceleration of crack growth rate for that situation is also high. In this test, the acceleration ratio of the crack growth rate for the FSW panel against the base material is 3.7.

Abstract In order to investigate the fatigue characteristics of metallic materials experimentally, a long period of time is required to get sufficient number of S-N data. In recent years, in order to overcome this difficulty, multi-type rotating bending fatigue testing machine whose name is GIGA QUAD have been developed by Yamamoto Metal Technos Co., Ltd., in which four specimens can be tested simultaneously.
In this time, some additional new functions have been developed as follows;
(1) 'high and low temperature environmental testing unit' whose target temperature is in a range of 600℃ and -150deg.C, (2) 'constant temperature/humid environmental testing unit' combined with the conventional corrosive cell, (3) ‘fracture alarm unit’, and (4) ‘2-step variable loading unit’.
By combining these new functions with the machine of GIGA QUAD, one can perform the fatigue tests efficiently corresponding to the respective requirements for researchers in both of academic and industrial sectors.
Keywords High temperature environmental testing unit, Low temperature environmental testing unit, Constant temperature/humid environmental testing unit, Fracture alarm unit, 2-step variable loading unit

1. Introduction

One of difficulties in fatigue tests for structural materials is to take a long time to perform the fatigue test. Fatigue tests are usually conducted toward the loading cycles of $N=10^7$, but the fatigue property in gigacycle regime is also focused as an important subject in recent years[1]-[8]. In such a long life region, a tremendous long period is required to perform fatigue tests. If the fatigue test is performed at the loading frequency of 50Hz, it takes more than 200 days to reach 10^9 cycles of the load application. It means that it takes very long term for us to obtain one S-N curve.
In addition, since the fatigue life of any metallic material has a distinct scatter, sufficient number of specimens should be tested to obtain the reliable fatigue property. An example of such fatigue test data for a bearing steel in very high cycle regime are shown in Figure 1 as an S-N diagram[5]. Type I indicates the conventional bearing steel, whereas Type II indicates the high purity bearing steel.

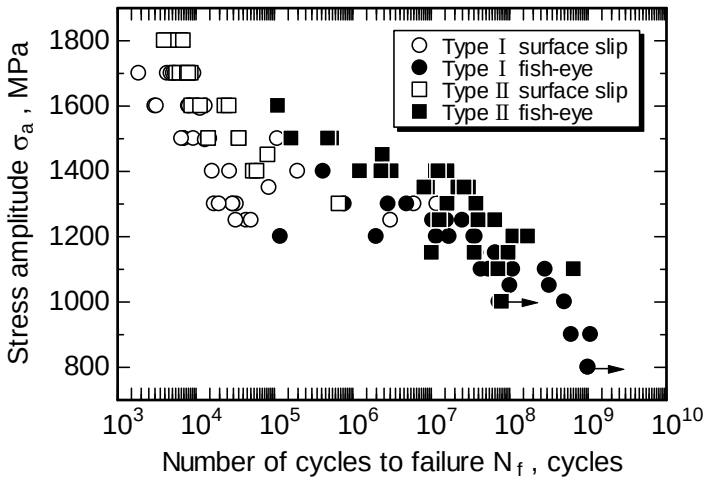

Figure 1. Typical example of fatigue test data for bearing steel in very high cycle regime

Open marks indicate the data in the surface initiated fracture, while solid marks give those data in the interior inclusion initiated fracture. In order to complete a series of fatigue tests to obtain all the data in Fig.1, it takes several years for one kind of metallic material. This circumstance introduces a serious difficulty to every researcher in the area of "*Metal Fatigue*" from technological and economical backgrounds.

If the high loading frequency such as ultrasonic fatigue test was accepted to save the testing time, temperature raising of the specimen due to the internal friction would take place and some cooling system or intermittent loading system should be furnished to examine the original fatigue property[9-12]. Thus, the acceleration fatigue test by ultrasonic technology would cause new difficult subjects as the fatigue testing method to obtain the fatigue property at the usual frequency.

In order to overcome these difficulties, authors have developed special types of fatigue testing machines in rotating bending, in which four specimens can be tested simultaneously[13,14]. Thus a series of fatigue tests even in gigacycle regime can be carried out within a reasonable time period. Based on this advantageous performance, the name of "GIGA QUAD" was accepted for this new machine. By using this machine of GIGA QUAD, fatigue tests can be performed much quickly comparing with the conventional testing machines, even if it is used with various environment options. Accordingly, this machine is useful to file up a number of fatigue test data in gigacycle regime for various kinds of metallic materials, and such databases can provide the fundamental design data for mechanical structures in the wide variety of the engineering application.

2. DUAL-SPINDLE ROTATING BENDING FATIGUE TESTING MACHINE

This machine has two spindles and two specimens can be mounted at both ends of each spindle as indicated in Fig.2 and Fig.3. Each spindle is driven by an electric motor via a V belt and the number of revolution is counted by means of photo-sensor. Thus, this machine can perform fatigue tests for 4 specimens simultaneously. In order to apply the testing load, the corresponding weight is suspended through a helical spring attached to the outer bearing block. The rotating speed of the spindle, that is, the testing speed is 3,150rpm (52.5Hz)

GIGA QUAD has two types of 'YRB200' and 'YRB200L' according to the loading capacity (Maximum load). The maximum load of YRB200 is 20kg, whereas the load of YRB200L is 80kg.

Table 1. Specification of the Device

	YRB200	YRB200L
Motor	0.2kw-4P	0.4kw-4p
Capacitance	380V	380V
Collet Chuck	φ2.5～13	φ2.5～20
Max Load	20kg x 4	80kg x 4
Spindle Speed	3,150rpm	3,150rpm
Weight	140kg	170kg
Size	470x400x1050	800x660x1100
Spindle Number	2	2

Figure 2. GIGA QUAD YRB200

Figure 3. GIGA QUAD YRB200L

Hourglass type of specimen as shown in Fig.4 is accepted as a formal test piece. Diameter of the critical section 'φβ' is designed as to give the reasonable stress level for the each material, while the diameter of the specimen grip 'φγ' may be decided by user freely. Collet chucks with different diameters such as 6mm, 8mm and 10mm are prepared in advance. Among them, the user can choose the most preferable collet chuck depending on the individual circumstance for the testing material.

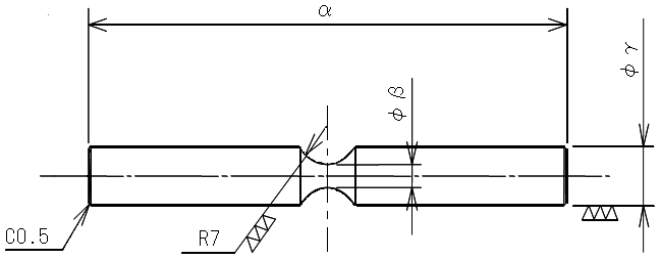

Figure 4. The shape and dimensions of the specimen

3. Support for environmental testing

3.1. High temperature environmental testing unit

In order to perform the rotating bending fatigue test at high temperature, a special chamber and a

temperature controlling system have been developed.
By using such an unit, one can carry out the fatigue test within a temperature range of room temperature (RT) to 600deg.C. Accuracy of the temperature controlling is within ±2deg.C. As fatigue test data are distinctly affected by the testing temperature, it is important to perform the fatigue tests at the accurate temperature. In such a case, this unit is useful to obtain the correct S-N property of the material at the definite temperature.

Specification
Temperature controlling range: room temperature to 600deg.C
Size of control panel box: 170mm x 220mm x 280mm
Specimen type : our standard specimen (φ10)
Power: AC100V 1set

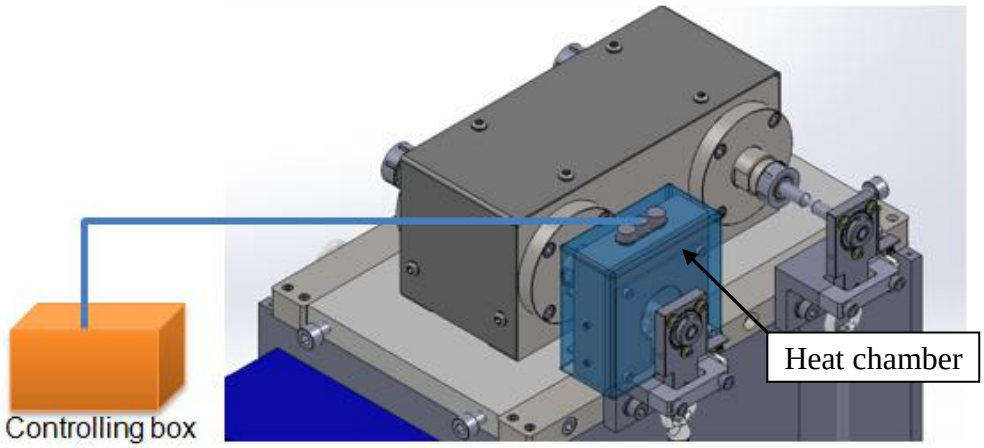

Figure 5. High temperature environmental testing unit

3.2. Low temperature environmental testing unit

A special unit to spray liquid nitrogen into the chamber has been developed to conduct the rotating bending fatigue test at low temperature environment.
By using this unit, one can carry out the fatigue test within the temperature range of RT to -150deg.C with the accuracy of ±2deg.C.

Specification
Temperature controlling range : -150 deg.C to room temperature
Size of control panel box : 170mm x 220mm x 280mm
Specimen type : our standard specimen (φ10)

3.3. Constant temperature/humid environmental testing unit

A special unit to control the temperature and humidity inside the chamber has been developed to perform the rotating bending fatigue test under such a corrosive environment.
In the case of corrosive environment, the control of temperature and humidity is the most important requirement to obtain reliable experimental data.

By means of this unit, a variety of environment varying cycles such as dried and humid environment after dropping the corrosive solution can be created easily.

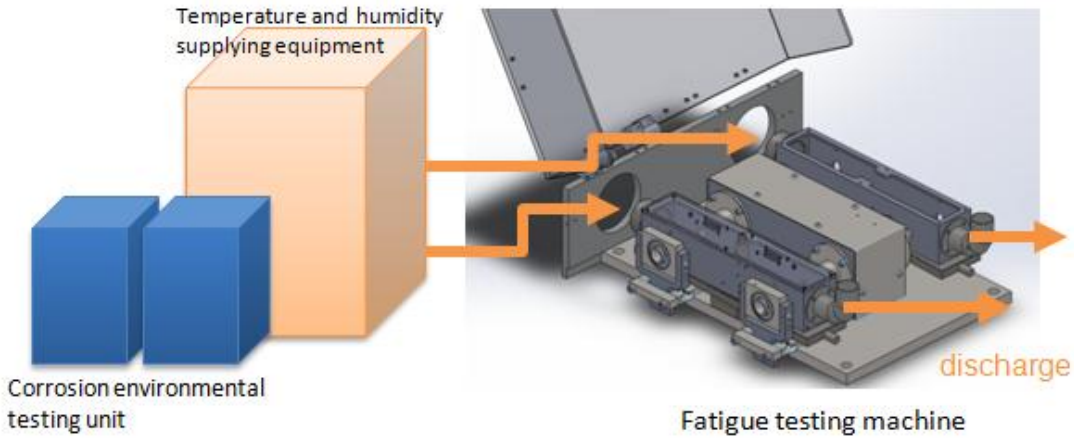

Figure 6. High temperature environmental testing unit

3.4. 2-step variable loading unit

A special loading unit has been developed to perform the rotating bending fatigue test under the condition of 2-step variable loading. Stress applied to the specimen is provided by suspending the appropriate weight in the structure of the machine. In this unit, 2-step loading is applied by lifting a part of weight with air cylinder periodically in testing. By setting any value of the weight and the lifting period, one can perform fatigue tests in a wide variety of the testing environments close to real machines in the practical use.

3.5. Fracture alarm unit

A fracture alarm unit which can detect fracture of specimen and inform the fracture to researchers via e-mail has been developed. In the case of fatigue test to obtain the S-N property, the test is repeatedly conducted by using a lot of specimens. In some cases, stress is changed with a definite time span in order to simulate the actual service loading. Since the fatigue life of each specimen has a distinct scatter, it is impossible to know the fatigue life exactly before the fatigue test. Due to this difficulty, every researcher has to come to the testing machine to confirm whether the specimen has failed or not.

If the person does not notice the fracture of the specimen, he/she wastes much time to find the fatigue failure even though the number of cycles to failure is recorded. In order to prevent such a time consumption, this unit was originally developed here.

Adopting this unit, the researcher can get the prompt information on the failure immediately after the specimen has failed. Thus, the next fatigue test can be started soon and the above time consumption can be effectively solved. In addition to this advantage, researchers' mental stress to check the fatigue failure can be also reduced.

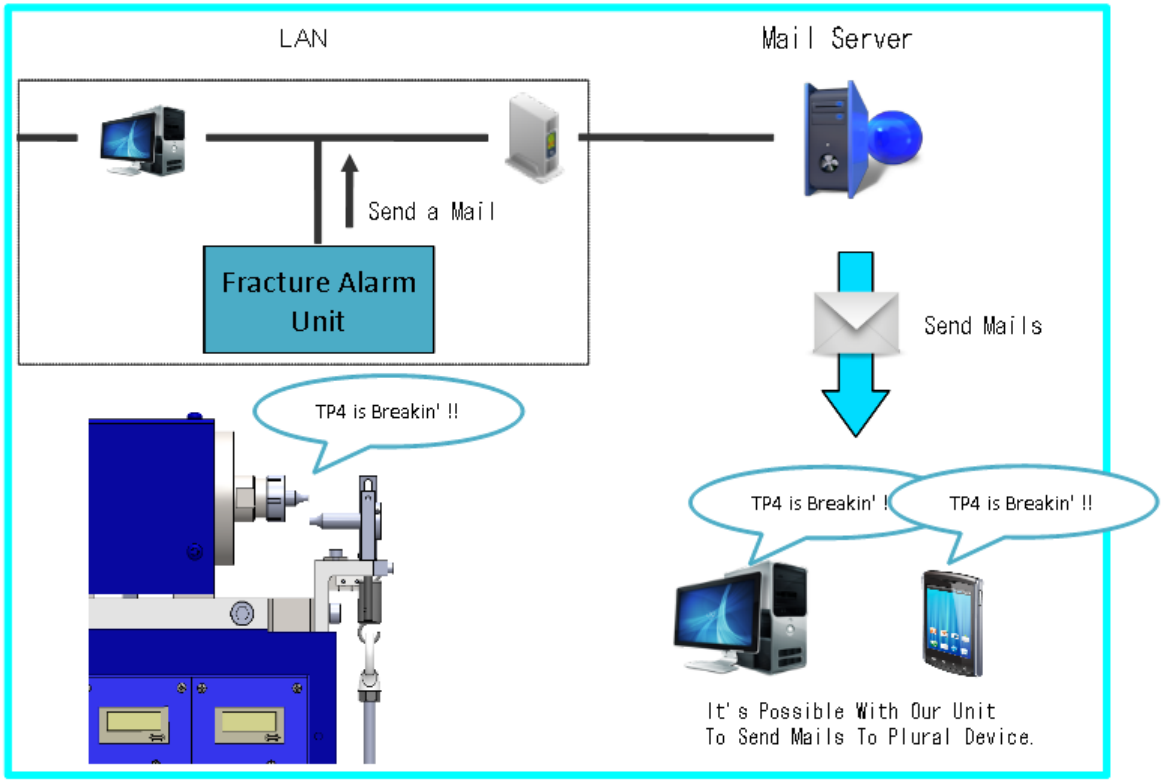

Figure 7. Fracture alarm unit

4. CONCLUDING REMARKS

Conventional fatigue tests take a long time more than 200days to reach $N=10^9$, and a number of fatigue test data are required as the fundamental data in the mechanical design. In order to solve such difficulties, the high performance fatigue testing machine in rotating bending "GIGA QUAD" has been developed in this work.

Based on a lot of experimental results, the fundamental performance of this testing machine was confirmed. Actually these machines are already being used at many laboratories in universities and industries. Thus, conventional customers and new customers have informed that this testing machine is successfully used to obtain a number of fatigue data within a reasonable short period.

Abstract A multiple temporal scale computational approach for assessing the fatigue life of engineering materials and components is presented. This full-scale simulation approach is developed in light of the challenges in employing the traditional computational method based on Finite Element Method (FEM)) and semi-discrete schemes for fatigue design and analysis. Simulating loading conditions with cycles on the order of hundreds of thousands and beyond is generally an impractical task for FEM even with the high-performance computing platform. Two critical aspects are addressed, i.e., the multiple time scales associated with the fatigue loading condition and the fatigue initiation/growth representations. Detailed implementation of integrating a multiscale space-time representation with a robust material model for the fatigue failure is outlined and demonstrated in the context of a common choice of industrial metal.

Keywords Space-time FEM, High Cycle Fatigue, Multi-temporal Scale Method, Enrichment

1. Introduction

In fatigue-based design of mechanical components and structures, safe-life and damage-tolerance approaches have been widely employed in practice. In safe-life approach, stress or strain are related to the number of cycles to failure under fatigue loading. Empirical curves developed from such a kind of relation are utilized to predict the life or acceptable level of fatigue load. Damage-tolerance approach based itself on the fracture mechanics concepts established by Griffith [1] and Irwin [2]. Using these concepts, Paris [3] proposed the relationship between the rate of crack growth and the range of applied stress intensity factor, which is used to predict the fatigue crack growth under cyclic loading history. While both methodologies have been widely used by the industry, they have significant limitations due to the empirical nature of the method. In addition, there can be significant scatterings in the fatigue test, which makes the curve-fitting unreliable. Further, the extrapolation of constant amplitude (CA) test data to predict life under variable amplitude (VA) and random loading conditions is a challenging task [4].

Motivated by these limitations, a multiple temporal scale computational approach is developed to assess the fatigue life of structural components. Examples include columns, beams, plates, and shells that are extensively used in assembly of mechanical components. This full-scale simulation approach is established in light of the challenges in employing the traditional computational method based on Finite Element Method (FEM) and semi-discrete schemes for fatigue design and analysis. Semi-discrete schemes such as the popular central difference or Newmark-β methods are known to suffer from either the time-step constraints or lack of convergence due to the oscillatory nature of the fatigue loading condition. As such, simulating loading conditions with cycles on the order of hundreds of thousands and beyond is generally an impractical task for FEM even with the high-performance computing platform. On the other hand, there is a great demand for such a computational capability as factors such as stress history and triaxiality, nonlinear coupling among the loads, complex geometry are known to critically influence the fatigue failure and generally not

fully accounted for in the empirical design approaches that are in practice today.

More specifically, an enriched space-time finite element method (XTFEM) based on the time discontinuous Galerkin formulation is developed to handle the multiple temporal scales in fatigue problems. XTFEM is coupled with the two-scale continuum damage mechanics model for evaluating fatigue damage accumulation, with a damage model governing the fatigue crack-initiation and propagation as the simulation progresses. High Cycle Fatigue (HCF) simulations are performed using the developed methodology on a notched specimen of AISI 304L steel to predict total fatigue life under cyclic conditions.

2. Technical Approach

2.1 A Computational Framework of Enriched Space-time FEM

As the name suggests, space-time method introduces discretization both in the spatial and time domains. The main advantage of the space-time method over the semi-discrete scheme based methods is reflected in the ability to introduce approximations in the temporal domain. Space-time methods are also known for their capability of reducing artificially oscillations and handling loads with sharp gradients. These features of space-time method make it an attractive platform for fast and accurate simulation of the fatigue loading. In the semi-discrete scheme, approximations are established in space **x** for each time instance *t*. In the space-time formulation, the approximations are built simultaneously with both space **x** and time *t*. If finite element method is used, we have the following approximation in the space/time description for a general three-dimensional case

$$\mathbf{u}(\mathbf{x},t)=\sum_{I} N_{\mathbf{I}}(\mathbf{x},t)\mathbf{d}_{\mathbf{I}} \tag{1}$$

in which $N_I(\mathbf{x},t)$ is the finite element shape functions at nodes indexed by I and $\mathbf{d}_I$ is the corresponding nodal displacement vector. Note that although N_I and $\mathbf{d}_I$ look similar to the ones in the semi-discrete scheme, they are defined on a space/time grid as opposed to space only.

To describe our approach what is also known as the time discontinuous Galerkin method (TDG) [5], the 2D space/time grid plotted in Figure 1 will be used as a reference. We consider a space/time domain Q, which is the Cartesian product of space domain Ω and time duration $(0,\mathrm{T})$, i.e., $Q=\Omega\times(0,\mathrm{T})$.

As can be seen from Figure 1, the time domain is subdivided into time slabs with the n-th time slab given as $Q_n=\Omega\times(t_{n-1},t_n)$. In the current method, we will restrict the presence of discontinuities to the mechanical field only. We define a jump operator $[\ ]$, given as

$$[w(t)]=w(t^+)-w(t^-) \ \text{ and } \ [w(\mathbf{x})]=w(\mathbf{x}^+)-w(\mathbf{x}^-) \tag{2}$$

with $w(t^\pm)=w(t\pm\varepsilon)$, $w(\mathbf{x}^\pm)=w(\mathbf{x}\pm\varepsilon\mathbf{n})$, ε represents infinitesimal perturbation, **n** is the

normal to the surface of discontinuity.

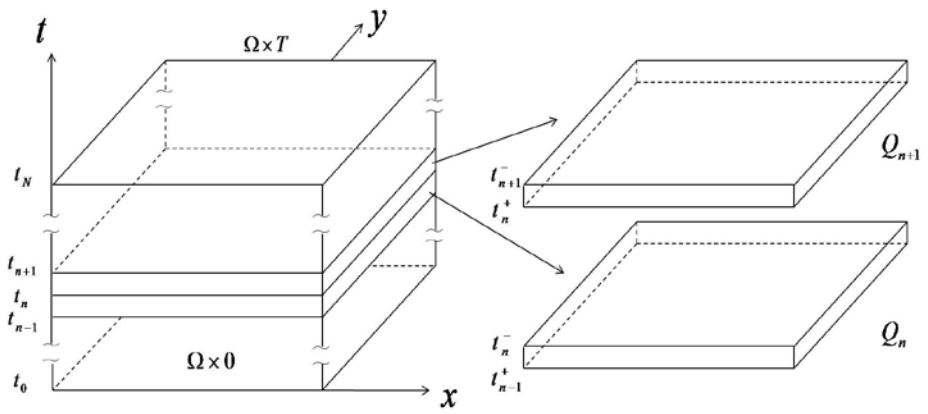

Figure 1: Illustration of TDG discretization of space-time finite elements.

By applying the variational principle to the governing equations of momentum within each time slab, we develop the so-called weak form that serves as the basis for computational implementation. For the the *n*-th time slab, we have the following bilinear form:

$$B_{DG}\left(\mathbf{w}^h,\mathbf{u}^h\right)_n = L_{DG}\left(\mathbf{w}^h\right)_n \tag{3}$$

with

$$B_{DG}\left(\mathbf{w}^h,\mathbf{u}^h\right)_n = \int_Q \dot{\mathbf{w}}^h\cdot\rho\ddot{\mathbf{u}}^h dQ_n + \int_Q \nabla\dot{\mathbf{w}}^h\cdot\boldsymbol{\sigma}\left(\nabla\mathbf{u}^h\right)dQ_n + \int_\Omega \dot{\mathbf{w}}^h\left(t_{n-1}^+\right)\cdot\rho\dot{\mathbf{u}}^h\left(t_{n-1}^+\right)d\Omega + \int_\Omega \nabla\mathbf{w}^h\left(t_{n-1}^+\right)\cdot\boldsymbol{\sigma}\left(\nabla\mathbf{u}^h\left(t_{n-1}^+\right)\right)d\Omega$$

$$L_{DG}\left(\mathbf{w}^h\right)_n = \int_Q \dot{\mathbf{w}}^h\cdot\rho\,\mathrm{b}dQ_n + \int_\gamma \dot{\mathbf{w}}^h\cdot\mathrm{t}d\left(\gamma_t\right)_n + \int_\Omega \dot{\mathbf{w}}^h\left(t_{n-1}^+\right)\cdot\rho\dot{\mathbf{u}}^h\left(t_{n-1}^-\right)d\Omega + \int_\Omega \nabla\mathbf{w}^h\left(t_{n-1}^+\right)\cdot\boldsymbol{\sigma}\left(\nabla\mathbf{u}^h\left(t_{n-1}^-\right)\right)d\Omega + \int_\gamma \dot{\mathbf{w}}^h\cdot\left[\mathrm{n}\cdot\boldsymbol{\sigma}\right]d\left(\gamma_i\right)_n \tag{4-5}$$

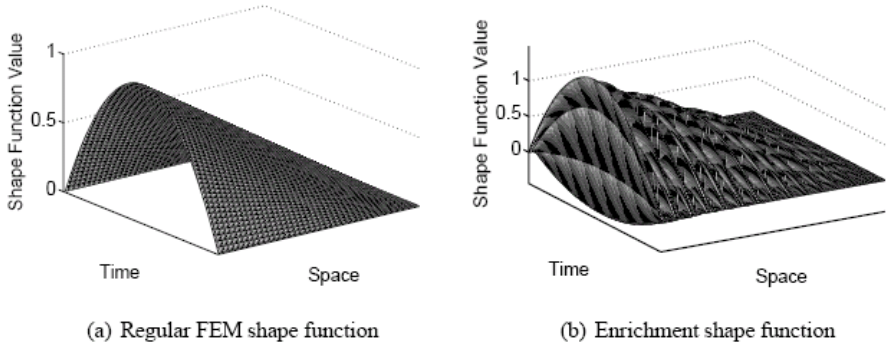
in which $\mathbf{u}^h$ and $\mathbf{w}^h$ are respectively the trial and test function for displacement. In Eqs.(4) and (5), the combination of the first two terms represents the momentum balance and traction boundary conditions. The 3rd and 4th terms in Eqs.(4) and (5) combined gives the continuity conditions between the time slabs. The last term in Eq.(5) is due to internal discontinuity.

In addressing the multiple temporal scales, we propose that the space-time approximation from Eq.(1) can be further improved by introducing enrichment [6-8]. In the enrichment formulation, the displacement field is approximated as

$$\mathbf{u}^h\left(\mathbf{x},t\right) = \sum_{I\in\bar{N}} N_I\left(\mathbf{x},t\right)\mathbf{d}_I + \sum_{J\in\bar{N}} N_J\left(\mathbf{x},t\right)\left(\phi\left(\mathbf{x},t\right)-\phi\left(\mathbf{x}_J,t_J\right)\right)\mathbf{a}_J \tag{6}$$

in which $N_I\left(\mathbf{x},t\right)$ is the regular space/time finite element shape functions, $\phi\left(\mathbf{x},t\right)$ is the called an enrichment function and is selected based on the physics of the problem. Correspondingly, $\mathbf{d}_I$ is the nodal displacement, and $\mathbf{a}_J$ is the enriched degree of freedom. The multiscale

decomposition in Eq.(6) can be further written in direct notation, i.e., $\mathbf{u}^h(\mathbf{x},t) = \mathbf{N}\mathbf{u} = \bar{\mathbf{N}}\mathbf{d} + \tilde{\mathbf{N}}\mathbf{a}$ where $\bar{\mathbf{N}}$ is the FEM shape function matrix and $\tilde{\mathbf{N}}$ is the enrichment shape function matrix. $\mathbf{N} = \left[\bar{\mathbf{N}}, \tilde{\mathbf{N}}\right]$ and $\mathbf{u} = [\mathbf{d}, \mathbf{a}]^T$ with $\mathbf{d}$ the nodal displacement vector and $\mathbf{a}$ the vector for the enriched degree of freedom. Note that the way that the enrichment function $\phi(\mathbf{x},t)$ being built in Eq.(6) is an equivalent statement of the "partition-of-unity" concept. It ensures the consistency of the approximation. An example of regular and enrichment space-time shape functions is shown in Figure 2. In this case, we have used a fine scale harmonic function for $\phi(\mathbf{x},t)$ with a temporal scale that is smaller than the temporal element size of the regular space-time FEM.



(a) Regular FEM shape function (b) Enrichment shape function

Figure 2: Examples of regular and enrichment shape functions.

We have employed *harmonic* enrichment function considering the fine scale harmonic components of the loading and the solution (displacement) in the case of HCF. i.e., $\phi(\mathbf{x},t) = \sum_k \sin(\omega_k t)$ in which ω_k represents the *k*-th characteristic frequency. Complete spatial domain will be enriched with the time enrichment function as the whole structure is subjected to fatigue loads. With the addition of the enrichment, the final discretized equation is in the form of

$$\begin{bmatrix} \mathbf{K}_{rr} & \mathbf{K}_{re} \\ \mathbf{K}_{er} & \mathbf{K}_{ee} \end{bmatrix} \begin{Bmatrix} \mathbf{d} \\ \mathbf{a} \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_r \\ \mathbf{F}_e \end{Bmatrix} \tag{7}$$

with subscripts "r" and "e" representing the contribution from the regular and enrichment components, respectively.

2.2 Modeling of Material Failure under Cyclic Loading

Modeling damage under fatigue loading is challenging due to the strong coupling to the loading path. Many techniques have been developed, including fracture mechanics, porous plasticity and continuum damage mechanics (CDM). In HCF, we introduce the two-scale CDM approach proposed by Lemaitre et al. [9] and Desmorat et al. [10]. This approach assumes that material behavior at mesoscale is elastic and damage can be treated as quasi-brittle in HCF. This quasi-brittle damage is modeled by introducing damage variables that represent the microcracks and microvoid

due to HCF at microscale. These microdefects cause the plasticity at microscale but the mesoscale behavior remains elastic. In light of the the basic features of HCF, a two-scale damage model is developed. A schematic of the model is shown in Figure 3. All the quantities with subscript μ are defined at the microscale.

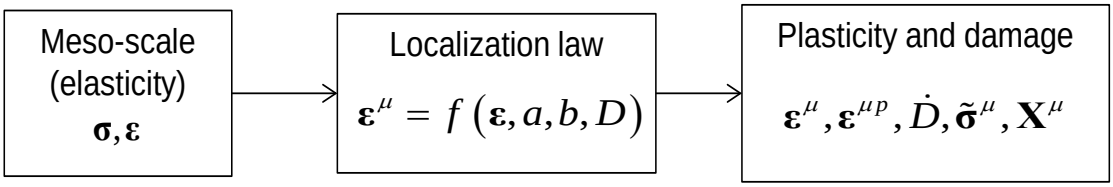


Figure 3: A schematic for the two-scale damage model.

The development of the model can be described by three steps. First of all, stress-strain $\left(\boldsymbol{\sigma}-\boldsymbol{\varepsilon}\right)$ data at mesoscale can be obtained using the elastic material properties such as Young's modulus and Poisson's ratio $\left(E,\nu\right)$. Secondly, the scale transition from the meso to micro will be described by a localization law based on the modified Eshelby-Kroner law. Localization law relates the microscale strain $\boldsymbol{\varepsilon}^{\mu}$ to the mesoscale strain $\boldsymbol{\varepsilon}$ through material parameters *a*, *b* and damage *D* given in the second box in Figure 3. Here *a*, *b* are functions of ν based on Eshelby's inclusion theory. Finally we will formulate a plasticity-damage model at the microscale as shown in the third box of Figure 3. The key component of this model is the damage evolution law, which assumes that the damage rate is proportional to the effective plastic strain rate $\dot{p}^{\mu}$, given as

$$\dot{D} = \left(\frac{Y^{\mu}}{S}\right)^{s} \dot{p}^{\mu} \quad \text{if } \dot{p}^{\mu} \geq \dot{p}_{D}^{\mu} \text{ or } w_s \geq w_d \tag{8}$$

Here s, S are the material parameters to be calibrated from available experimental data on fatigue, Y^{μ} is the damage energy release rate and w_s is the stored energy in the material, w_d is the damage threshold energy, $\dot{p}_{D}^{\mu}$ is the threshold effective plastic strain. Threshold values act as a barrier for damage initiation. Once these conditions are met, damage accumulation begins. Threshold values depend on the material and the type of loading condition. The major advantage of employing Eq.(8) is from the fact that fatigue failure is regarded as a function of increment in strain or stress as opposed to function of the load cycles.

A constitutive solver has been developed for the two-scale damage model outlined here and integrated with the space-time FEM framework. The specific algorithm will be similar to that of a standard rate-dependent plasticity-damage model. A mixed explicit-implicit scheme has been implemented.

3. Numerical Example

The developed methodology is applied to the simulation of fatigue response of a single notched rectangular steel plate subjected to cyclic load. The geometry and boundary condition are shown in Figure 4. A fully reversed fatigue load at $\omega = 20Hz$ is applied to the top face of the plate in a form of uniformly distributed pressure of 70 MPa while the bottom surface is fixed, which replicates the loading conditions during the actual fatigue test where the bottom surface is clamped in grips and top surface is subjected to push-pull loading. The plate thickness is taken as $2mm$. The problem is modeled as plane stress problem. Motivation behind this problem is to simulate the complete fatigue loading history using the presented formulation, calculate damage at gauss points during the simulation, and predict the fatigue crack initiation and propagation. Mode I crack growth is expected in this loading situation.

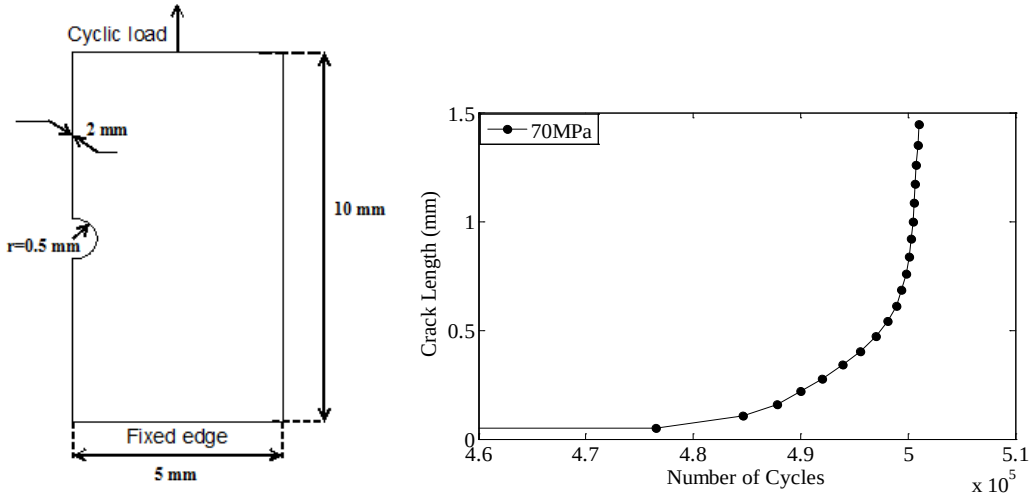

Figure 4: (a) Configuration of the fatigue simulation of a single notched plate. (b) Crack growth vs. number of cycles for the case of completely reversed load of 70 MPa

The space-time discretization employs a multiplicative form of the shape function so that the spatial discretization is independent of the temporal discretization. Advantage of this treatment is that the existing meshing scheme widely used in the case conventional FEM can be directly adopted. In the present case, the plate is discretized by quadrilateral mesh with non-uniform mesh density. Fine mesh is prescribed close to the notch in order to capture crack initiation and growth. In the temporal dimension, quadratic shape function is employed for each space-time slab. The regular space-time shape functions are enriched with a harmonic function with frequency of $20\,Hz$. With the two-scale damage model introduced here, crack initiation and propagation are governed by the evolution of the damage. Numerically, once the damage-based the crack criteria is met, the corresponding space element is eliminated. The material parameters chosen correspond to 304L steel and are based on the earlier work by Lemaitre and Desmorat [9-12]. Detailed implementations of the model is documented in an upcoming paper [13] and will not be presented here due to page limitation.

Crack growth as a function of the load cycles predicted by the simulation is shown in Figure 4. It is worth noting that up to half-million load cycles are successfully simulated with the proposed numerical approach. In addition, the nature of the crack growth data is similar to that obtained from the experiments. This suggests that, with the calibrated material model accurate fatigue simulation for the HCF loading can be performed using the methodology outlined in this paper.

4. Conclusions

In summary, the proposed multiscale space-time formulation with harmonic enrichment function successfully simulates the practical fatigue loading histories. To capture the fatigue crack initiation and propagation, a two-scale damage model algorithm is implemented. Damage model algorithm is integrated with the multiscale space-time FEM formulation. Standard techniques of *element deletion* are used to predict the fatigue crack initiation and propagation. HCF simulations are performed on the notched plate without any *ad hoc* procedure to predict the total fatigue life. Based on the simulations, crack length verses number of cycles curve is generated. The trend of the results is similar to what is observed in the experiments. Mode I crack growth is successfully using XTFEM. Future plan is to verify the predictions by comparing with either literature data or analytical model (e.g., Paris law crack growth predictions). In addition, different fatigue-based material model can be integrated with the framework presented.

Abstract The finite element model of straight attachment lug subjected to axial or oblique loading is built by using finite element software, a cosine pin-bearing pressure distribution is applied on the pin-hole squeeze surface as a boundary condition. The stress intensity factor (SIF) expressions for single through-the-thickness crack in straight attachment lug that subjected to axial or oblique pin-load less than 45 degrees are determined and validated. The fatigue crack growth rate da/dN and the stress intensity factor range ΔK are obtained by using the fatigue crack growth test data and the SIF expressions. The fatigue crack growth model of the typical straight lugs is established by using the Paris law, offering an analytical as well as experimental method for assessing and designing damage tolerant attachment lugs.

Keywords attachment lug, finite element method, fatigue crack growth, stress intensity factor, the Paris law

1. Introduction

Attachment lugs are one of the most fatigue-and fracture-critical components in modern engineering structures[1]. In aircraft structures, lug-type joints are frequently used to connect major structural components or in linkage structure, theirs failure can result in disastrous accidents. In the study of fatigue crack growth and fracture behavior of attachment lugs, an accurate calculation of the stress intensity factor is essential. There are a number of different methods for determining SIF, K, for crack in aircraft attachment lug.

Over the years, several extensive studies have been made on lug fatigue performance, involving both experimental and analytical means. Liu and Kan[2] and Kirkby and Rooke[3] used the simple compounded solution method which involves superimposing known solutions, such as in Reference [4] to estimate the stress intensity factors. Schijve and Hoeymakers[5] and Wanhill[6] derived empirical K-solutions from the growth rate data for through cracks under constant amplitude loading using a backtracking method such as that proposed by James and Anderson[7]. Pian, et al[8], used the hybrid finite element method to compute the K-values for cracks oriented in various angles from the axial direction of straight lugs. Aberson and Anderson[9] used a special crack-tip singularity element to compute the stress intensity factors for a crack in a nonsymmetrical aircraft lug of an engine pylon. Impellizzeri and Rich[10] modified the exact weight function derived by Bueckner[11], for an edge crack in a semi-infinite plate, to include a series of geometry correction factors. Then they computed the K-values using the weight function method. However, at the aspect of damage tolerance design and analysis, only the situation of straight lug subjected to axial pin loading can be solved. For the straight lug and symmetric tapered lug, which are subjected to axial, oblique and transverse pin loadings, there is a lack of methods for ascertaining the crack propagation characteristics and residual strength. So, it is important to develop analytical as well as experimental procedures for assessing and designing damage tolerant attachment lugs to ensure the operational safety of aircraft[12], and to calculate the stress intensity factors (SIFs) in different geometric parameters and load conditions.

Most of the researches made the assumption that the assumed or computed pin-bearing pressure distribution for an uncracked case remains unchanged even after the crack has initiated and propagated. Based on the parametric study conducted in Reference [8], it was found that, for any given crack length, the difference in the SIF computed using the uniform and cosine pin-bearing pressure distributions was as much as 30 percent. Therefore, it is salient that the correct representation of the pin-bearing pressure distribution during the crack growth process is essential to the calculation of accurate stress intensity factors.

This paper presents a systemic study of the 30CrMnSiA straight attachment lug's fatigue crack growth behavior using the finite element software ANSYS. The finite element model of the lug is established

and the effect of geometric parameters on SIF is calculated and analyzed by the finite element method (FEM) with linear elastic assumptions, as in essence, the fatigue crack growth is brittle and it is often based on Linear Elastic Fracture Mechanics (LEFM) assumption[13]. The fatigue crack growth test and residual strength test are carried out by the material test system MTS-810, the test data validate the finite element analysis and are used to determine the constants C&m of the Paris Law. The fatigue crack growth model of the typical straight lugs is established, offering an analytical as well as experimental method for assessing and designing damage tolerant attachment lugs.

2. Finite Element Modeling and Analyzing

2.1. Finite element modeling and meshing

Figure 1 shows the size of the straight lug discussed in this paper, millimeter is used as the length unit. The length of the single through-the-thickness crack is *a*. The model is meshed with PLANE 183 triangular element, the real constant for "plane stress with thickness" is set to 6.7. The elastic modulus is 200Gpa and the Poisson ratio is 0.3. The node at the crack tip is defined as a singular point and there are 12 triangular elements around it. The radius of the 1st row of elements is *a*/10. The global elements edge length is set to 2. Figure 2 & Figure 3 show the mesh result.

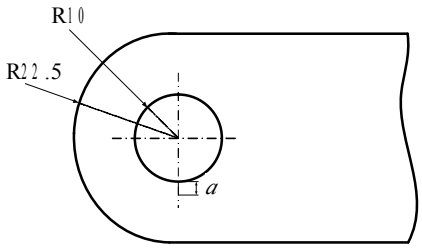

Figure 1. Size of the straight lug

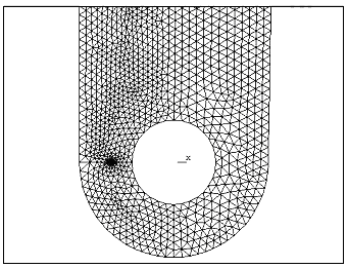

Figure 2. Mesh of the straight lug

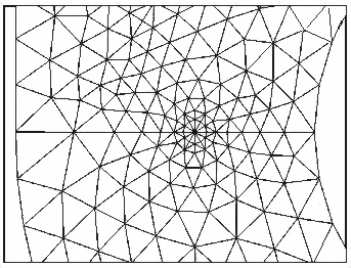

Figure 3. Mesh of the crack tip

2.2. Setting boundary conditions and applying cosine distributed load

Pin load is transferred by squeezing between the lug and the pin matched. Load and stress are supposed to keep unchangeable along the thickness of the hole. The pressure distributed on the squeeze surface follows the cosine distribution law, and the radial load P_i at the point i on the squeeze surface is equal to $P_0 \cos\gamma_i$ [14], as shown in Figure 4.

The x and y axis components of the load P_i are as follows.

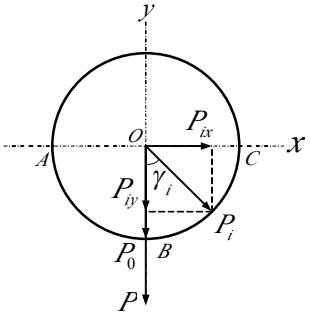
$$P_{ix} = P_i \sin\gamma_i \,, \tag{1}$$

$$P_{iy} = P_i \cos\gamma_i \,. \tag{2}$$

The resultant force along y axis is shown as follow.

$$P = \sum P_{iy} = \sum P_i \cos\gamma_i = \sum P_0 \cos^2\gamma_i \,. \tag{3}$$

The cosine distributed nodal force is applied on the nodes on the surface ABC. All the nodes on the symmetry plane of the lug are selected and the displacement values are set to zero. Figure 5 shows the boundary conditions.



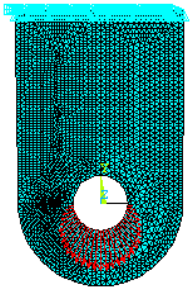


Figure 4. Pin-loading on the squeeze surface

Figure 5. Boundary conditions

2.3. Results analysis

Figure 6 and Figure7 respectively show the Von Mises stress distribution around the lug's hole and the crack tip.

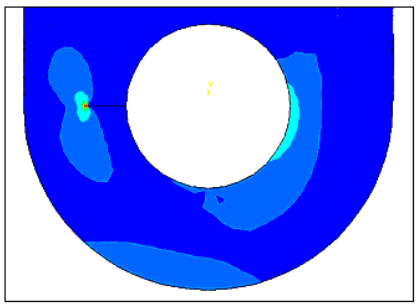

Figure 6. Stress distribution around the lug's hole

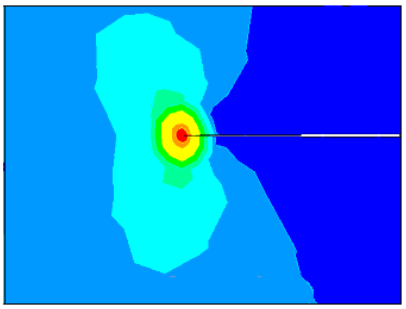

Figure 7. Stress distribution around the crack tip

SIFs of cracks with different lengths are calculated by three methods. Case 1 uses the equation that is used for estimating the straight lugs' critical load in [15] (see formula (4)) to calculate the SIFs. Case 2 uses the configuration factor J_{41L} in [15] (see Figure 8) to get the SIFs' values. This paper calculates the SIFs by finite element method, and the results are shown as case 3 in Figure 9 to compare with the other two cases.

In reference [15] (page 270), it is indicated that the critical load $[P]_c$ of the attachment lug subjected to axial pin-load is

$$[P]_C = \frac{2R_2 tK_C}{\beta\sqrt{\pi a}}. \tag{4}$$

Where

$$\beta = \left(\frac{2W}{1.971D}\beta_1 + \frac{1}{2}\beta_2\right)\cdot\beta_{fw}, \tag{5}$$

$$\beta_1 = \frac{0.31711}{\left(0.3857 + \frac{a}{R_1}\right)^{1.33734}}, \tag{6}$$

$$\beta_2 = \frac{0.8734}{0.3246 + \frac{a}{R_1}} + 0.6762, \tag{7}$$

$$\beta_{fw} = \sqrt{\sec\left(\frac{\pi}{2}\cdot\frac{2R_1 + a}{2R_2 - a}\right)}. \tag{8}$$

In reference [15] (page 139), the SIF of attachment lug subjected to axial pin-load is equal to

$$K = J_{41Z}\cdot\sigma\cdot\sqrt{\pi a}. \tag{9}$$

where the configuration factor J_{41L} can be determined by using Figure 8.

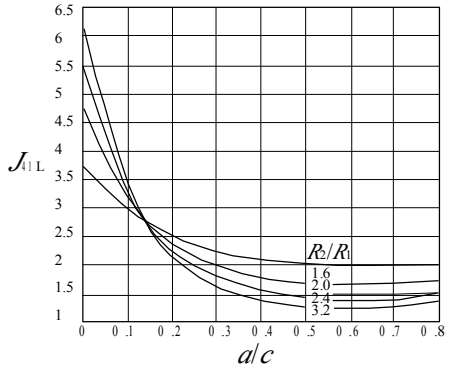

Figure 8. The configuration factor J_{41L} curves

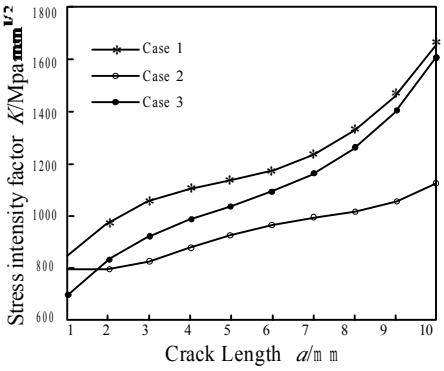

Figure 9. Comparison of the stress intensity factors

3. Calculation of the SIF equations

The geometric parameters of the lug are wrote to the APDL program text file and executed by ANSYS to solve the SIFs automatically and efficiently. The case of the straight attachment lug subjected to axial pin-load is taken as an example for illustrating the approach. Figure 10 shows the parameterized geometry of the lug.

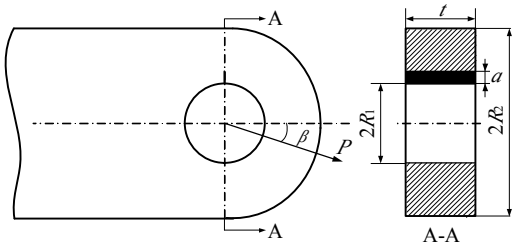

Figure 10. Geometry of the straight attachment lug

The influence law of the dimensionless crack length (a/R_1), the ratio of outer radius to inside radius (R_2/R_1) and the inside radius (R_1) on the SIF are studied, and then, the equation (4) is modified to fit the SIF equation for the straight attachment lug with a single through-the-thickness crack.

Table 1 shows the solving idea. K, K_1, K_2, K_3 stand for the SIFs calculated by equation (4) and represent the values that need to be modified by the influence law of a/R_1, R_2/R_1 and R_1 respectively. K' stands for the SIF calculated by ANSYS as the reference exact value for modifying K_1, K_2, K_3.

Table 1. Solving the SIF equation of the straight lug subjected to axial pin-load

Variate	Invariants	K	K'	$(K')_i/K_i$	Calculating process
$(a/R_1)_1$	R_2/R_1, R_1	$(K_1)_1$	$(K')_1$	$(K')_1/(K_1)_1$	$(a/R_1)_i$ is set as the variate, while $(K')_i/(K_1)_i$ as the dependent variable, function $g(a/R_1)$ can be fitted as below.
⋮	⋮	⋮	⋮	⋮	
$(a/R_1)_n$	R_2/R_1, R_1	$(K_1)_n$	$(K')_n$	$(K')_n/(K_1)_n$	$K_2=K_1\cdot g(a/R_1)$ (10)
$(R_2/R_1)_1$	a/R_1, R_1	$(K_2)_1$	$(K')_1$	$(K')_1/(K_2)_1$	$(R_2/R_1)_i$ is set as the variate, while $(K')_i/(K_2)_i$ as the dependent variable, function $f(R_2/R_1)$ can be fitted as below.
⋮	⋮	⋮	⋮	⋮	
$(R_2/R_1)_n$	a/R_1, R_1	$(K_2)_n$	$(K')_n$	$(K')_n/(K_2)_n$	$K_3=K_2\cdot f(R_2/R_1)= K_1\cdot g(a/R_1)\ f(R_2/R_1)$ (11)
$(R_1)_1$	a/R_1, R_2/R_1	$(K_3)_1$	$(K')_1$	$(K')_1/(K_3)_1$	$(R_1)_i$ is set as the variate, while $(K')_i/(K_3)_i$ as the dependent variable, function $h(R_1)$ can be fitted.
⋮	⋮	⋮	⋮	⋮	Finally the straight attachment lug's SIF equation can be obtained as below.
$(R_1)_n$	a/R_1, R_2/R_1	$(K_3)_n$	$(K')_n$	$(K')_n/(K_3)_n$	$K=K_3\cdot h(R_1)=K_1g(a/R_1)\cdot f(R_2/R_1)\cdot h(R_1)$ $=K_1\mathrm{F}(a/R_1,R_2/R_1, R_1)$ (12)

The value of a/R_1 is increased from 0.1 to 1.6 by 0.1 while the others are fixed, K_1 can be modified as $K_2=K_1*g(a/R_1)$, where

$$g(a/R_1)=-0.1285*(a/R_1)^2+0.3059*(a/R_1)+0.8228 \tag{13}$$

The value of R_2/R_1 is increased from 1.5 to 3 by 0.1 while the others are fixed, K_2 can be modified as $K_3=K_2*f(R_2/R_1)$, where

$$f(R_2/R_1)=-0.1654*(R_2/R_1)^4+1.6326*(R_2/R_1)^3-6.0293*(R_2/R_1)^2+9.9046*(R_2/R_1)-5.1399 \tag{14}$$

The value of R_1 is increased from 5 to 20 by 1 while the others are fixed, the function $h(R_1)$ can be obtained as $h(R_1)= 0.99$, it is obvious that the effect of R_1 on SIF is less than the other parameters. Finally we can obtain the modified straight attachment lug's SIF equation as $K=K_3*h(R_1)$, the SIF equation of straight lug (Figure 10) is obtained as blows.

$$K = F\cdot\sigma\cdot\sqrt{\pi\cdot a}. \tag{15}$$

Where

$$\sigma = \frac{P}{2ct}, \tag{16}$$

$$c = R_2 - R_1, \tag{17}$$

$$F = f_{ar}\cdot f_{fw}\cdot f_r, \tag{18}$$

$$f_{ar} = \frac{1.98R_2}{1.971R_1}\cdot\frac{0.31711}{\left(0.3857+\frac{a}{R_1}\right)^{1.33734}}+\frac{1}{2}\cdot\left(0.8734/\left(0.3246+a/R\right)+0.6762\right), \tag{19}$$

$$f_{fw} = \sqrt{\sec\left(\frac{\pi}{2}\cdot\frac{2R_1+a}{2R_2-a}\right)}, \tag{20}$$

$$f_r = \left(-0.1654\cdot\left(\frac{R_2}{R_1}\right)^4+1.6326\cdot\left(\frac{R_2}{R_1}\right)^3-6.0293\cdot\left(\frac{R_2}{R_1}\right)^2+9.9046\cdot\left(\frac{R_2}{R_1}\right)-5.1399\right)\cdot \tag{21}$$

Scope of application：

$$0.1\le\frac{a}{R_1}\le 1.6,\quad 1.5\le\frac{R_2}{R_1}\le 3,\quad 5\le R_1\le 20.$$

In the same way, considering the load degrees β additionally, the SIF equation of the straight attachment lugs subjected to oblique pin-load less than 45 degrees can be obtained as below.

$$K = F\cdot\sigma\cdot\sqrt{\pi\cdot a} \tag{22}$$

where

$$\sigma = \frac{P}{2ct}, \tag{23}$$

$$c = R_2 - R_1, \tag{24}$$

$$F = f_\beta\cdot f_{ar}\cdot f'_{ar}\cdot f_{fw}\cdot f_{rr}, \tag{25}$$

$$f_\beta = -3.7107\times10^{-6}\cdot\beta^3+8.4026\times10^{-5}\cdot\beta^2+0.0092469\cdot\beta+1.05, \tag{26}$$

$$f_{ar} = \frac{1.98R_2}{1.971r_1}\cdot\frac{0.31711}{\left(0.3857+a/R_1\right)^{1.33734}}+\frac{1}{2}\cdot\left(0.8734/(0.3246+a/R_1)+0.6762\right), \tag{27}$$

$$f'_{ar} = -0.063305\cdot\left(\frac{a}{R_1}\right)^2+0.067224\cdot\frac{a}{R_1}+0.94853, \tag{28}$$

$$f_{fw}=\sqrt{\sec\left(\frac{\pi}{2}\cdot\frac{2R_1+a}{2R_2-a}\right)}\ , \tag{29}$$

$$f_{rr}=\left(-0.1654\left(\frac{R_2}{R_1}\right)^4+1.6326\left(\frac{R_2}{R_1}\right)^3-6.0293\left(\frac{R_2}{R_1}\right)^2+9.9046\left(\frac{R_2}{R_1}\right)-5.1399\right)\cdot \tag{30}$$

Scope of application：

$$5°\le\beta\le45°,\ \ 0.1\le\frac{a}{R_1}\le1.6,\ \ 1.5\le\frac{R_2}{R_1}\le3,\ \ 5\le R_1\le20\ .$$

4. Fatigue crack growth test and residual strength test

4.1 Test pieces

Figure 11 shows the dimensional drawing of the straight attachment lug piece. There is a small slot made by electrical discharge machine (EDM) besides the lug hole with an angle of θ=90° or θ=60°. The slot length a_0 is approximately equal to 1mm. The lugs pieces subjected to axial (θ=90°) or 30 degrees oblique (θ=60°) pin-load are all made of 30CrMnSiA material, 4 pieces for each case.

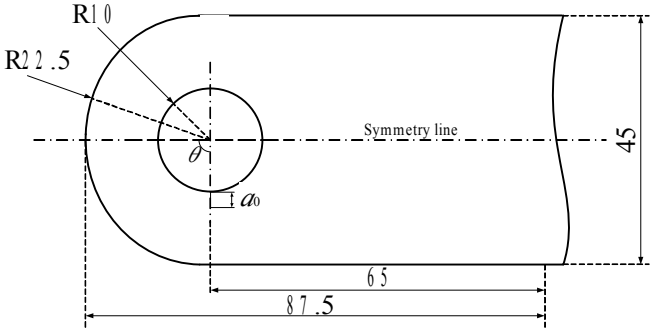

Figure 11. Geometry of the test piece

4.2 Test equipments and loading requirement

The tests are carried out on the material test system MTS-810 (load relative error <±2%) with a constant amplitude loading spectrum of sine waveform. The length of the crack is observed and measured by JXD-250mm scale microscope with a precision of 0.01mm.

Surface around test piece's wire-cutting slot tip is polished by a sand paper along the direction perpendicular to the slot direction. Peak load P_{pp} in the crack growth preparation test is 13.85KN, valley load P_{pv} is 0.83KN, R=0.06, load frequency is 5Hz. A crack with a length of 0.314mm was observed when fatigue cycle reaches about 15000, and grows to 0.612mm when 21000 cycles. The a-N data shows that the crack is growing steadily under the peak load of the fatigue crack growth test P_p=20.77KN and the valley load P_v=1.246KN.

Table 2 shows values of the test load.

Table 2. The test load values

Case	P_{pp}/(KN)	P_{pv}/ (KN)	P_p/(KN)	P_v/(KN)
θ=90°	13.85	0.83	20.77	1.25
θ=60°	13.85	0.83	20.77	1.25

4.3 Fatigue crack growth test

Figure 14 & Figure 15 show the experimental scene.

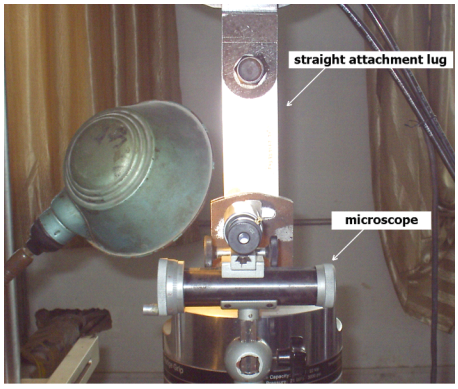

Figure 14. Experimental field of the case of θ=90°

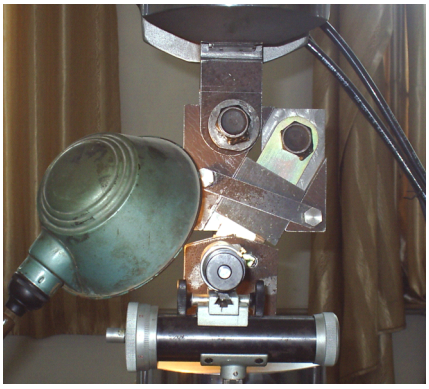

Figure 15. Experimental field of the case of θ=60°

The micro objective is aimed at the wire-cutting slot tip for detecting the fatigue crack in time. The frequency is changed to 1Hz every other 1000~2000 cycles in order to observe the crack length and record the *a*-*N* data.

4.5 Residual strength test

After obtaining enough *a*-*N* data, the test pieces with different residual fatigue crack lengths are loaded with a sustained increasing load till the test pieces fracture, the corresponding residual strength data are recorded in Table 3 & Table 4.

Table 3. The residual strength test results of the lugs subjected to axial pin-load

test piece num.	No.1	No.2	No.3	No.4
crack length *a*/(mm)	7.109	8.127	8.972	10.115
residual strength *P*/(KN)	91.456	83.242	78.051	72.947

Table 4. The residual strength test results of the lugs subjected to 30 degrees oblique pin-load

test piece num.	No.1	No.2	No.3	No.4
crack length *a*/(mm)	10.58	10.99	11.45	9.98
residual strength *P*/(KN)	58.54	42.38	40.24	58.8

The data of crack length *a* and corresponding residual strength *P* in Table 4 & Table 5 are used to substitute the *a*&*P* in formula (15) and formula(22) to calculate the SIFs. The SIFs of the axial pin-load case are: 164.30, 162.47, 166.37, 184.04, while the other case's SIFs are: 214.91, 162.08, 171.77, 179.69, the unit is $MPa\cdot\sqrt{m}$. As the fracture toughness of the material 30CrMnSiA with thickness 6.7mm is around 180 $MPa\cdot\sqrt{m}$ [16], it shows the SIFs calculated by formula (15) and formulas (22) are consistent with the true values.

5. Establishment of the fatigue crack growth model

The fatigue crack growth data are fitted by using least square method, the curves are shown in Figure16 and Figure 17.

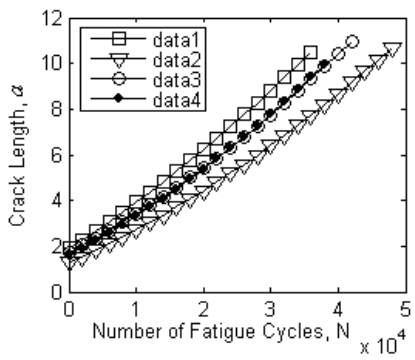

Figure 16. *a*-*N* curves of the case of axial pin-load

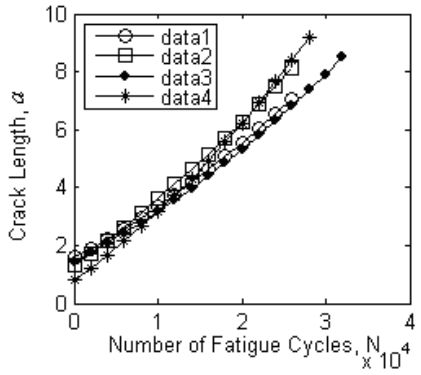

Figure 17. *a*-*N* curves of the case of 30° pin-load

The *a*-*N* data are calculated by the seven points incremental polynomial method[16]. The SIF range value ΔK and da/dN can be obtained by the fitted crack length value a^*. Table 5 shows the data processing of the test piece No.1.

Table 5. Data processing of the test piece No.1

N/(cycle)	a /(mm)	a^*/(mm)	da/dN	ΔK/(MPa·m$^{1/2}$)	lg(da/dN)	$lg(\Delta K)$
0	1.539					
2000	1.967					
4000	2.276					
6000	2.506	2.579	1.79E-7	26.556	1.424	-6.746
8000	2.958	2.927	1.85E-7	27.292	1.436	-6.732
10000	3.307	3.316	2.01E-7	28.026	1.447	-6.697
12000	3.767	3.752	2.14E-7	28.781	1.459	-6.669
14000	4.159	4.186	2.16E-7	29.497	1.469	-6.665
16000	4.652	4.629	2.24E-7	30.218	1.480	-6.649
18000	5.091	5.074	2.31E-7	30.956	1.490	-6.636
20000	5.503	5.543	2.43E-7	31.771	1.502	-6.614
21800	5.981	5.976	2.47E-7	32.577	1.512	-6.608
23000	6.291	6.278	2.59E-7	33.180	1.520	-6.585
24000	6.578					
25000	6.756					
26000	7.109					

The da/dN data of the other three test pieces can be obtained by the same method. The data points of region II are fitted by the least square method to get the lg(da/dN)~lg(ΔK) curve. Figure18 shows the fitted line of the data points.

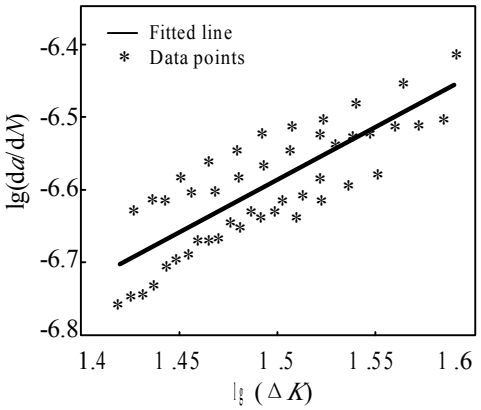

Figure 18. lg(da/dN)~lg(ΔK) curve of the axial pin-load case

The equation of the line is shown as below.

$$\lg(da/dN) = 1.4231 \cdot \lg(\Delta K) - 8.7221. \tag{31}$$

The Paris equation is

$$da/dN = C(\Delta K)^m. \tag{32}$$

In order to get the values of C and m, the paper takes the logarithm on both sides of the equation (32).

$$\lg(da/dN) = m \cdot \lg(\Delta K) + \lg C. \tag{33}$$

The values of the Paris constants C and m are obtained by comparing the equation (31) with (33).

C=1.896E-09, m=1.4231.

The lg(da/dN)~lg(ΔK) curve of region II of the lugs subjected to 30 degrees oblique pin-load can be got by the same method. Figure 19 shows the lg(da/dN)~lg(ΔK) curve.

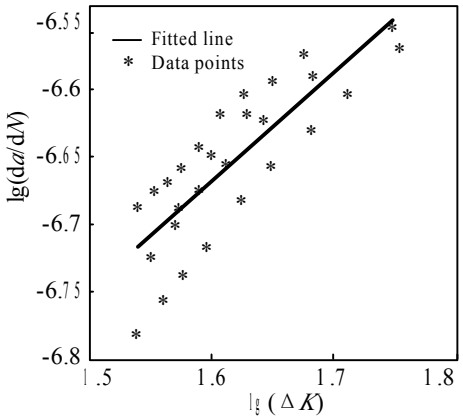

Figure 19. lg(da/dN)~lg(ΔK) curve of the 30 degrees oblique pin-load case

The equation of the line and the values of the Paris constants C and m are shown as below.

$$\lg(da/dN) = 0.7649 \cdot \lg(\Delta K) - 7.8902 \tag{34}$$

C=1.2877E-08, m=0.7649.

6. Conclusions

Analytical and experimental investigations for fatigue crack growth behavior of 30CrMnSiA straight attachment lugs were performed. From this investigation followings are concluded.

1. The boundary conditions of the finite element model is consistent with the true condition, cosine distributing load is the key of ensuring precision of FEM analysis.
2. The expressions of the SIFs of straight lugs subjected to axial or less than 45 degrees oblique pin-load are determined and validated. Based on this, the stress intensity factor range (ΔK) can be calculated.
3. The fatigue crack growth model of the typical straight lugs is established, offering an analytical as well as experimental method for assessing and designing damage tolerant attachment lugs in engineering.

Abstract It is a new and valuable research that studying the influence of heat treatments on fatigue performance of materials by the infrared thermographgic method. Based on three theoretical models of fatigue indicators, this paper studied mechanical properties of the virgin and heat-treated FV520B steels. With the three indicators and the energy theory, comparison analysis of macro-phenomenon and microstructure evolution during fatigue of the two type specimens was performed. Using the intrinsic dissipation, fatigue limits were fast determined. Influence of heat treatments on mechanical properties and fatigue life was discussed. The research shows that the accuracy of the lock-in thermography could satisfy the needs of engineering design.

Keywords Infrared thermographic method, Fatigue indicator, Heat treatment, Energy Approach

1. Introduction

Fatigue design requires statistical processing of numerous tests. However, the traditional evaluation methods are often difficult to be performed for their time-consuming and expensive costing[1,2]. The infrared thermographic method was first proposed by Risitano et al. [3] by using the surface temperature increments as the major fatigue indicator. The infrared thermographic method, based on the analysis of the heat during a loading fatigue test, was developed over the last 30 years. Fargione et al. [4] obtained the connection between the quantity of heat dissipated in taking a given element to failure based on the physical hypothesis, which the failure of materials through fatigue occurs when the energy of plastic deformation reaches a constant limiting value, and the fatigue limit by applying fatigue tests.

Suitable heat treatments can improve the static tensile strength and fatigue resistance of materials [5,6]. Now it is still a new task to investigate effect of heat treatments on fatigue behavior of materials using the infrared thermographic method. The purpose of this paper is to study the relationship between the internal microstructure and mechanical properties using different fatigue indicators. FV520B steel is a kind of martensite steel developed by Firth-Vickers Materials Lab in British. The steel is widely used in aerospace engineering and medical instruments, etc. due to its high strength, corrosion resistance and weldability [5,7]. However, heat treatments, used in practical engineerings, play an important role in determining the internal microstructure which governs mechanical responses of FV520B. Therefore, it is necessary to investigate the correlation between heat treatments and mechanical behavior useful for directing the mechanical design.

In the present paper, the infrared thermographic method was employed to explore influence of different heat treatments on FV520B steel. Fatigue limits of two type steels were determined by the intrinsic dissipation. The internal microstructural changes were studied to understand the fatigue process.

2. Theoretical models of fatigue damage indicators

Relative temperature increment. Fatigue damage is known as energy dissipation accompanied by temperature changing. The temperature linked with energy dissipation enables us to understand the energy transformation, toughness reduction and damping vibration of materials. Therefore, the fatigue process can be qualitatively evaluated using the relative temperature increment.

During fatigue tests, to avoid any possible errors induced by the environmental perturbation and the experimental system sensitivity, the relative temperature increment ΔT on the hot-spot zone of the specimen surface is used to describe fatigue damage status:

$$\Delta T = T_m - T_0 \tag{1}$$

where T_m is the average temperature on the zone; and T_0 is the initial temperature.

Standard deviation of stress. Microcracks often initiate from local points due to the stress concentration. The fatigue damage distribution is not uniform when a material suffers from cyclic loading. The distribution of the local stress can be described by the standard deviation. The stress state on the hot-spot zone, due to the local high stress, enables us to qualitatively identify the critical location responsible for the final fracture. Accordingly, the economic losses caused by the sudden fatigue fracture might be greatly decreased by analyzing this damage indicator.

The stress level used here is the thermoelastic stress calculated by the equation below:

$$\Delta T = -\frac{\alpha}{\rho C_p} \cdot T \cdot \Delta\sigma \tag{2}$$

where α is the coefficient of linear expansion; C_p is the specific heat capacity; ρ is the material density; T is the absolute temperature; Δσ is the change in the sum of principal stresses; and ΔT is the change in temperature.

The stress pattern can be visibly obtained using the infrared camera, and each pixel stands for a point in the selected zone Ω. Thus, the standard deviation of the stress can be written as:

$$\sigma_{SDS} = \sqrt{\frac{1}{N}\sum_{x,y\in\Omega}(\sigma(x,y)-\sigma_m)^2} \tag{3}$$

Where σ_m denotes the average stress in the zone Ω; σ(x, y) denotes the stress value at the point (x, y); and N denotes all the points in the zone Ω.

Intrinsic dissipation. Based on the small perturbation hypotheses, fatigue test is considered as a quasi-static dissipation process. The local coupled thermomechanical equation is derived [8]:

$$\rho C_p \dot{T} - k\nabla^2 T = (\sigma - \rho\frac{\partial\psi}{\partial\varepsilon}) : \dot{\varepsilon} - \rho\frac{\partial\psi}{\partial\alpha}\cdot\dot{\alpha} + \rho T\frac{\partial^2\psi}{\partial T\partial\varepsilon} : \dot{\varepsilon} + \rho T\frac{\partial^2\psi}{\partial T\partial\alpha} : \dot{\alpha} + \gamma^e \tag{4}$$

where k is the heat conduction coefficient; σ denotes the stress tensor; ψ is Helmholtz free energy; ε is the strain tensor; α is internal variables; and γ^e is the external heat resource.

The intrinsic dissipation is defined as:

$$d = (\sigma - \rho\frac{\partial\psi}{\partial\varepsilon}) : \dot{\varepsilon} - \rho\frac{\partial\psi}{\partial\alpha}\cdot\dot{\alpha} \tag{5}$$

In fact, the intrinsic dissipation describes the dissipated energy due to inelastic effects, and it is an important part of the non-linear energy dissipation for materials and components subjected to fatigue loading. The infrared thermographic method can be used to quantitatively evaluate fatigue

damage status, and accordingly the fatigue limit can be fast determined.

3. Experiment investigations

Material and specimen. The studied material is FV520B [7]. Its mechanical properties are greatly affected by heat treatments. Thus, two type specimens (Figure 1. Size of the specimen) were machined from two plates. One plate was just annealed (type A), and the other was treated with treatments in Ref.[9] (type B).

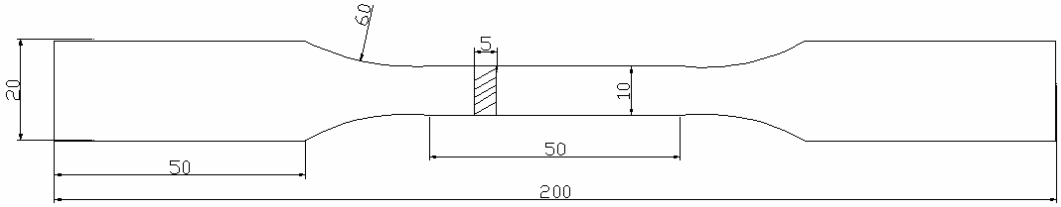

Figure 1. Size of the specimen (unit: mm)

Experimental procedures. Fatigue tests were carried out at room temperature without disturbance of the external heat resource. The testing system is composed of MTS810 system, infrared camera, lock-in module, computers and corresponding softwares [9].

Before tests, all the specimens were polished with fine grit papers, and then painted the specimens black to improve the heat radiation. The stress ratio is set as R=-1 with a frequency of 20Hz. The stepwise loading procedure was applied to the same specimen. To avoid fatigue damage accumulation, the stress was applied from 100MPa with steps of 50MPa until fracture. The thermal images on the hot-spot zone were recorded by the infrared camera to perform the subsequent data analysis.

3. Results and discussion

Qualitative identification of the fatigue damage. Temperature evolution is mainly attributed to the thermoelastic effect, plastic effect and heat conduction. The fluctuating temperature is due to the thermoelastic effect. The temperature amplitudes increase with the increasing cyclic loading. However, the thermoelastic effect has no contribution to the average temperature [8]. Figure.2 exhibits the relative temperature evolution of the two type specimens, showing the almost same trend.

The elastic stress controls mechanical responses of tested specimens when the stress is less than 300MPa. At this term, the specimen mainly takes place elastic deformation, and the temperature increment are mainly induced by non-plastic effects, i.e. viscosity effect etc. If the stress is higher than the fatigue limit, microcracks will initiate from the specimen boundaries, such as: the corner and the free surface. They initiate along the axial direction of 45^{o}, and then coalesce to form a main crack. The main crack propagates perpendicular to the principal stress direction. The plastic strain energy accumulates with the fatigue evolution. Most of the mechanical energy is dissipated as heat energy heating up the specimen. There are，however, still some different between the two type steels. The temperature increment of the type B is generally less than that of the type A. That is attributed to the slow evolution of internal microstructures of the type B, indicating its better fatigue resistance.

As a consequence, heat treatments [9,10] improve the microstructure of the type B (such as dislocation distribution and defect density, etc.), and accordingly enhance its mechanical properties. Figure.3 presents variations of the stress standard deviation of the two type steels. There is no obvious plastic deformation when the applied stress is lower. Accordingly the standard deviation is relatively small. If the stress is higher than the fatigue limit, it sets to increase sharply in the local zone due to stress concentration. The break point indicates that the mechanisms related to fatigue failure have changed into plastic effect. Local stress concentration, due to pores and impurities, governs the stress distribution. The damage status can be qualitatively identified by the standard deviation to avoid the sudden fracture. From Figure.3, the standard deviation of the type B is small relative to the type A since the grain refinement due to heat treatments improves the arrangement of the internal microstructure, which makes the type B take on better fatigue resistance.

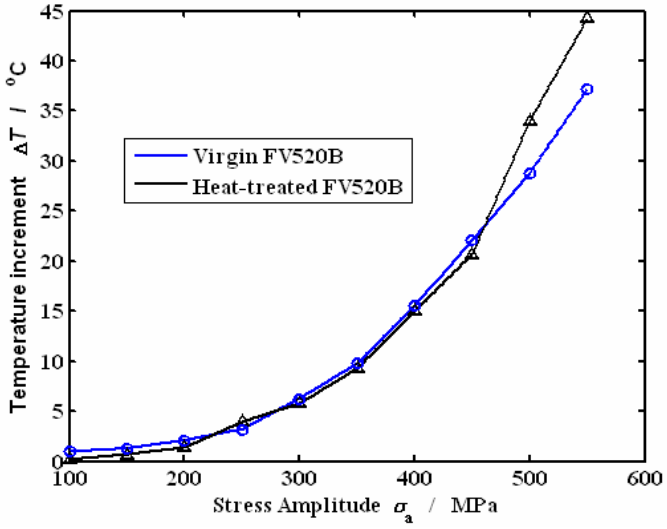

Figure.2 Relative temperature increment

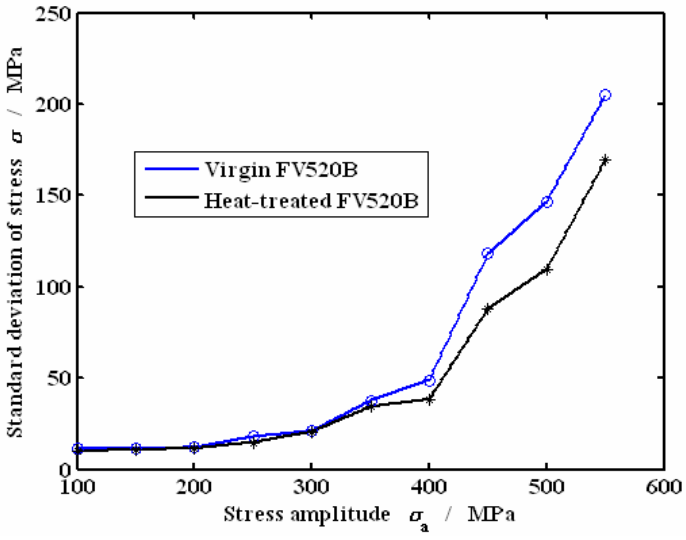

Figure.3 Standard deviation of stress

Fatigue limit evaluation. From Figure.2 and 3, the fatigue limit of the type B should be higher than that of the type A. In this part, the intrinsic dissipation shown in Figure.4 was utilised to get their fatigue limits. The break points are in the range of 250MPa~350MPa. The intersection of the two straight lines denotes the corresponding fatigue limit [11]. Thus the fatigue limit of the type A is

291MPa, and 319MPa for the type B. Fortunately, using the traditional method, the fatigue limits of the type A and B are 274MPa and 310MPa, respectively. The low values of errors, 6.2% and 2.9%, confirm the reliability of the infrared thermographic method in predicting fatigue parameters of materials with different heat treatments. To verify that the fatigue limit of the type B is higher, two fatigue tests, with the same cyclic stress 400MPa, were carried out to compare their fatigue life. The life of the type A is 141606 cycles, and 300748 cycles for the type B, confirming our results.

It is different for the variation of energy accumulation and heat dissipation during different fatigue process. The above fatigue tests can be divided into three phases. At lower stress, i.e. 100MPa~300Mpa, the temperature increases slowly, and the intrinsic dissipation is practically null. The internal microstrucutre evolution is reversible under the elastic stress. However, when the stress is close to the fatigue limit, the local stress may be beyond the yield limit due to the stress concentration in micro-scale. Consequently, the slip band begins to form, and numerous microcracks initiate here. Fatigue damage sets to accumulate continuously. If the stress is higher than 450MPa, all the three damage indicators, related to the final failure, increase drastically.

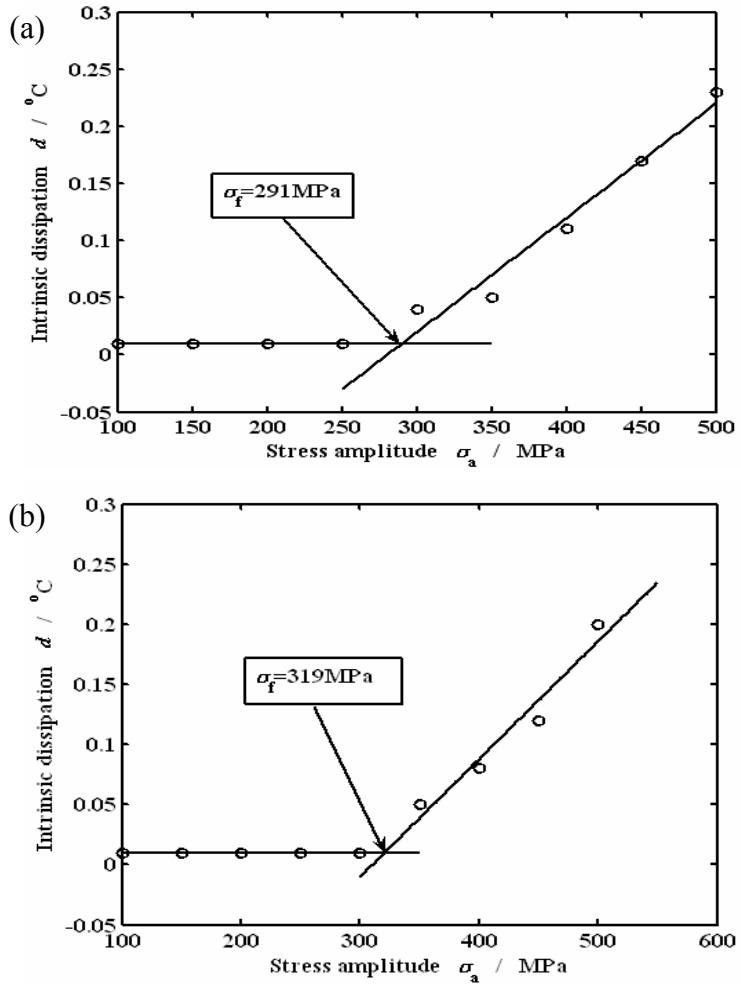

Figure. 4 Fatigue limit by the infrared thermographic method: (a) the type A; (b) the type B

4. Conclusions

[1] The infrared thermographic method enables us to qualitatively and quantitatively evaluate fatigue behavior of materials with different heat treatments.

[2] All the three fatigue damage indicators can describe the fatigue damage process. The macro-phenomenon and internal microstructure evolution are associated by the energy theory.
[3] The low errors of the predicted fatigue limits demonstrate the reliability of the infrared thermographic method in predicting fatigue parameters of materials and components.
[4] It is a fast and accurate technique for fatigue evaluation using various damage indicators resorting to the infrared technique. Consequently, the method may be used to identify the fatigue damage status of structures in service in the future.

Abstract The aim of this paper is to calculate how the surface crack front and the dimensionless compliance evolve in cracked cylindrical bars subjected to cyclic tension or bending with different initial crack geometries (crack depths and aspect ratios). To this end, a computer application (in the Java programming language) that calculates the crack front's geometric evolution and the dimensionless compliance was made by discretizing the crack front (characterized with elliptical shape) and assuming that every point advances perpendicularly to the crack front according to the Paris law, and using a three-parameter stress intensity factor (SIF). The results show that in fatigue crack propagation, relative crack depth influences more on dimensionless compliance than the aspect ratio, because the crack front tends to converge when the crack propagates from different initial geometries, the compliance showing greater values for tension than for bending. Furthermore, during fatigue crack growth, materials with higher values of the exponent of the Paris law produce slightly greater dimensionless compliance and a better convergence between the results for straight-fronted and circular initial cracks.

Keywords Numerical modelling, Cracked round bar, Fatigue crack growth, Dimensionless compliance

1. Introduction

The problem of fatigue crack propagation in round bars is of great interest in fracture mechanics, applied to linear structural elements. These components, usually subjected to oscillating load, may fracture after surface fatigue crack growth, frequently with semi-elliptical flaws contained in a plane perpendicular to the loading axis.

Several criteria have been stated in the past to characterize fatigue crack growth in these geometries, e.g., prediction of the 90º intersecting angle of the crack with the surface or the iso-K criterion along the crack front [1]. The most used are those based on the Paris-Erdogan law [2-7], requiring the knowledge of the dimensionless stress intensity factor (SIF), Y, along the crack front in the round cracked bar. It has been deducted by several authors following different procedures: compliance methods, finite element analysis, boundary integral equation methods, experimental techniques, etc. [1, 8-11].

Dimensionless compliance in round cracked bars under tension or bending depends on the crack geometry. If the crack is characterized by an elliptical shape, there are two factors exerting influence: the relative crack depth (crack depth divided by the diameter), which causes an increase of its value, and the aspect ratio (ratio of the crack depth to the other semiaxis of the ellipse), which causes a decrease of its value [3, 12]. Thus, there is a relation between the change in compliance during fatigue crack growth and the crack geometry evolution, depending on the specimen material, the initial crack geometry and the type of applied load [11, 13].

The aim of the present paper is the numerical modelling of crack front evolution for semielliptical surface cracks (under the hypothesis that every point at the crack front advances according to a Paris-Erdogan law), as well as analyzing how dimensionless compliance evolves during fatigue of round bars of different materials (Paris coefficient m of 2, 3 and 4), with different initial crack geometries (circular and quasi-straight, both crack shapes linked with initial relative depth $(a/D)_0$ of 0.1, 0.3 and 0.5) and applying tensile load or bending moment.

2. Numerical Modelling

A computer program in the Java programming language was developed to determine the geometrical evolution of the crack front according to the Paris law, for a transverse surface crack in a cylindrical geometry subjected to tensile loading or bending fatigue moment (Fig. 1). This would be the basis to determine the change taking place in the dimensionless compliance of the round bar during the fatigue crack propagation process.

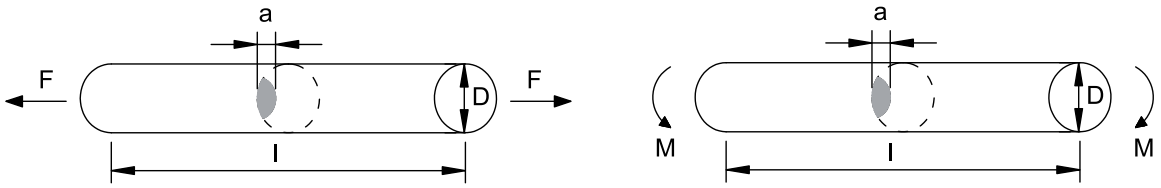

Figure 1. Cracked bar under tension loading (left) and bending moment (right)

2.1. Aspect Ratio

The basic hypothesis of the modelling consisted of assuming that the crack front can be modelled as an ellipse with centre on the bar surface [13] and the fatigue propagation takes place in a direction perpendicular to this crack front, following a Paris Erdogan law [14],

$$\frac{\mathrm{d}a}{\mathrm{d}N} = C\Delta K^{\mathrm{m}} \tag{1}$$

Every elliptical arc of the crack front was divided in z segments with exactly the same length using the Simpson's rule in order to discretize the front. The point on the round bar surface was not taken into account, since it presents some difficulties regarding the computation of the dimensionless SIF (there is a plane stress state on the crack surface).

After that, every single point was shifted according to the Paris-Erdogan law perpendicular to the front and so as to keep constant the maximum crack depth increment, $\Delta a(\max) \equiv \max \Delta a_{\mathrm{i}}$, all over the process [7]. The advance of every front point, Δa_{i}, can be obtained from the maximum crack increment and the ratio of the SIF at that point to the maximum SIF over the crack front,

$$\Delta a_{\mathrm{i}} = \Delta a(\max)\left[\frac{Y_{\mathrm{i}}}{Y(\max)}\right]^{\mathrm{m}} \tag{2}$$

The newly obtained points, fitted by the least squares method, generate a new ellipse with which the process is repeated iteratively until the desired crack depth is reached. Due to the existing symmetry, only half of the problem was used for the computations.

2.2. Dimensionless SIF

The dimensionless SIF, Y, depends on three-parameters for the crack modelled as an ellipse with centre on the round bar surface and its value depends on the crack geometry (depth and aspect ratio) and on the point on the front where it is calculated. The dimensionless SIF used in the computations is that proposed by Shin and Cai [11] obtained by the finite element method and the virtual crack extension technique, whose value is function of the relative crack depth a/D, the crack aspect ratio a/b, and the position of the point considered on its front x/h (Fig. 2).

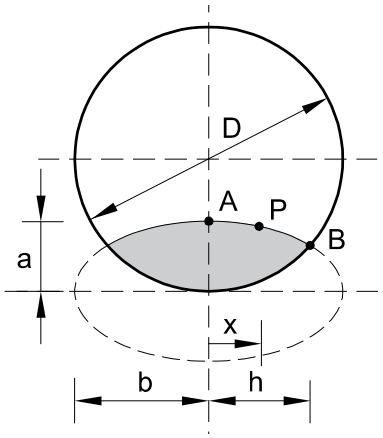

Figure 2. Elliptical crack model used by Shin and Cai [6]

The fitting of the results provides a three-parametrical expression which is defined as a function of the coefficients M_{ijk} for tension with free sample ends [11], i.e., unrestrained bending during tension,

$$Y = \sum_{i=0}^{2}\sum_{j=0}^{7}\sum_{k=0}^{2} M_{ijk}\left(\frac{a}{b}\right)^{i}\left(\frac{a}{D}\right)^{j}\left(\frac{x}{h}\right)^{k} \tag{3}$$

and the coefficients N_{ijk} for bending [11],

$$Y = \sum_{i=0}^{2}\sum_{j=0}^{6}\sum_{k=0}^{2} N_{ijk}\left(\frac{a}{b}\right)^{i}\left(\frac{a}{D}\right)^{j}\left(\frac{x}{h}\right)^{k} \tag{4}$$

2.3. Dimensionless Compliance

Experimentally the geometrical evolution of the crack front in a cylindrical bar can be observed *post mortem* (once fractured) and there are several techniques to mark the front according to the material studied. It is possible to relate the crack front geometry with compliance, one of the few characteristics which can be measured during the crack propagation [15].

If tensile load is applied, it is obtained that the local displacement u is related to the applied force F through compliance as follows:

$$u = \lambda F \tag{5}$$

If bending is applied, in this case the angle φ is related to the applied moment M through compliance as follows:

$$\varphi = \lambda M \tag{6}$$

The strain energy U can be expressed taking into account the equivalence between the energy release rate G and the stress intensity factor in plane strain K,

$$\mathrm{d}U = G\mathrm{d}A = \frac{K^2(1-\nu^2)}{E}\mathrm{d}A \tag{7}$$

where ν is the Poisson coefficient and dA the differential of the cracked area.

On the other hand, the strain energy for a cracked bar subjected to tensile load is, introducing the value du from eq. (5),

$$\mathrm{d}U = \frac{1}{2}F\mathrm{d}u = \frac{1}{2}F^2\mathrm{d}\lambda \tag{8}$$

and the strain energy for a cracked bar subjected to bending is, introducing the value du from the eq. (6),

$$\mathrm{d}U = \frac{1}{2} M \mathrm{d}\varphi = \frac{1}{2} M^2 \mathrm{d}\lambda \tag{9}$$

The SIF in plane strain for the geometry of the study can be obtained as follows:

$$K = Y\sigma\sqrt{\pi a} \tag{10}$$

where the stress σ for axial tension is calculated as:

$$\sigma = \frac{4F}{\pi D^2} \tag{11}$$

and the maximum stress σ for bending is calculated as:

$$\sigma = \frac{32M}{\pi D^3} \tag{12}$$

If equations for strain energy are made equal and introducing values K and σ, the isolated compliance is obtained for tension loading:

$$\lambda = \frac{32\left(1-\nu^2\right)}{\pi D^4 E} \int_0^a Y^2 a \mathrm{d}A \tag{13}$$

and for bending moment,

$$\lambda = \frac{2048\left(1-\nu^2\right)}{\pi D^6 E} \int_0^a Y^2 a \mathrm{d}A \tag{14}$$

Solving the integral which appears in eqs. (13) and (14) is not trivial. In order to achieve that, the Cartesian coordinates (x, y) were change into parametrical coordinates (a, θ), relating themselves through the expressions:

$$x = b\cos\theta \tag{15}$$

$$y = a\sin\theta \tag{16}$$

where the correspondence between angles δ and θ, deducted from Fig. 3, is as follows,

$$\tan\delta = \frac{y}{x} = \frac{a}{b}\tan\theta \tag{17}$$

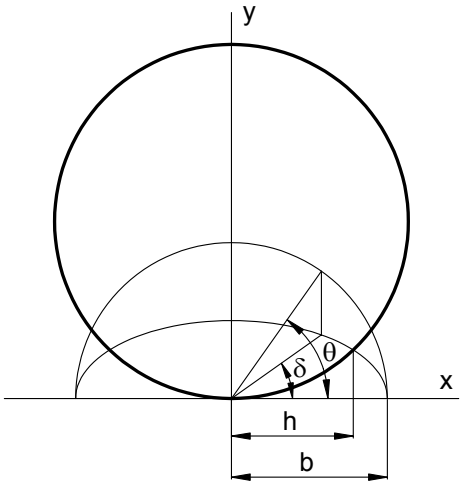

Figure 3. Relationship between δ and θ angles

The differential of the ellipse area modelling the crack advance is:

$$\mathrm{d}A = \mathrm{d}x \wedge \mathrm{d}y \tag{18}$$

differentiating the coordinates (x, y) according to the new coordinates (a, θ),

$$\mathrm{d}x = b'(a)\cos\theta\,\mathrm{d}a - b\sin\theta\,\mathrm{d}\theta \tag{19}$$

$$\mathrm{d}y = \sin\theta\,\mathrm{d}a + a\cos\theta\,\mathrm{d}\theta \tag{20}$$

and substituting these expressions on the eq. (18), it is obtained:

$$\mathrm{d}A = \left(ab'(a)\cos^2\theta + b\sin^2\theta\right)\mathrm{d}a \wedge \mathrm{d}\theta \tag{21}$$

The problem that arises in calculating eq. (21) can be found in the previous knowledge of the variation of the parameter b with the crack depth a. The definition of the derivative at a point can be used to this purpose,

$$b'(a) \approx \frac{b(a+\Delta a) - b(a)}{\Delta a} \tag{22}$$

Introducing eq. (21) in eq. (13), that allows the computation of the compliance in a cracked round bar subjected to axial tensile loading, it is obtained:

$$\lambda = \frac{64\left(1-\nu^2\right)}{\pi D^4 E}\int_0^a \int_{\arccos\frac{h}{b}}^{\pi/2} Y^2 a\left(ab'(a)\cos^2\theta + b\sin^2\theta\right)\mathrm{d}\theta\,\mathrm{d}a \tag{23}$$

Introducing eq. (21) in eq. (14), which allows calculating compliance in a cracked round bar subjected to bending loading, it is obtained:

$$\lambda = \frac{4096\left(1-\nu^2\right)}{\pi D^3 E}\int_0^a \int_{\arccos\frac{h}{b}}^{\pi/2} Y^2 a\left(ab'(a)\cos^2\theta + b\sin^2\theta\right)\mathrm{d}\theta\,\mathrm{d}a \tag{24}$$

where f is defined as the dimensionless compliance due to tensile or bending load:

$$f = \int_0^a \int_{\arccos\frac{h}{b}}^{\pi/2} Y^2 \frac{a}{D^3}\left(ab'(a)\cos^2\theta + b\sin^2\theta\right)\mathrm{d}\theta\,\mathrm{d}a \tag{25}$$

The dimensionless compliance value can be calculated incrementally with the crack growth, where the integral,

$$f = \sum_i \int_{a_i}^{a_{i+1}} \int_{\arccos\frac{h}{b}}^{\pi/2} R\,\mathrm{d}\theta\,\mathrm{d}a \tag{26}$$

it is solved using the trapezoidal rule (where R is the corresponding expression according to eq. (25)), following the scheme on Fig. 4, dividing every crack increment in eight parts for half of the problem, so they correspond with the coordinate's isolines (a, θ).

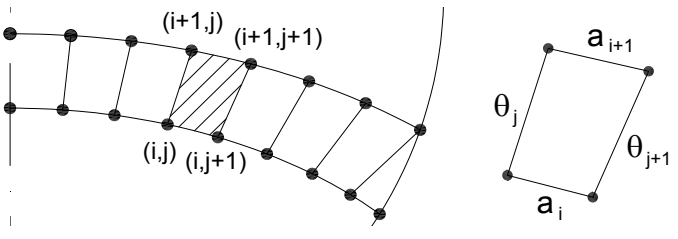

Figure 4. Divisions with the isolines used in the trapezoidal rule

The compliance increment in every crack advance is calculated using the following expression,

$$f = \sum_{i} \left(a_{i+1} - a_{i} \right) \left(\sum_{j=0}^{7} \left(\theta_{j+1} - \theta_{j} \right) \frac{\left(R(i,j) + R(i,j+1) + R(i+1,j) + R(i+1,j+1) \right)}{4} + \right.$$
$$\left. + \frac{\left(\theta_{8} - \theta_{7} \right)}{2} \frac{\left(R(i,7) + R(i+1,7) + R(i,8) \right)}{3} \right) \tag{27}$$

In order to obtain the dimensionless compliance of the initial crack, the process is similar to that just described, but easier, because it considers that every previous crack front has the same aspect ratio as the initial one. Furthermore, cracks smaller than the minimum ones used by Shin and Cai (a/D=0.067) were not taken into account in the compliance calculation.

3. Numerical Results and Discussion

3.1. Fatigue Cracking Paths

The study of the convergence was performed to obtain the number of segments in which each ellipse is divided, z=14, and the value of the maximum crack increase, $\Delta a(\max)=D/1000$. The geometrical evolution of the crack front, characterized as part of the ellipse, was determined for every relative crack depth, a/D, through the aspect ratio, a/b, for materials with Paris exponent m=2, 3 and 4, starting from different initial crack geometries (corresponding to the beginning of each curve, i.e., the point of minimum crack depth a/D) under tension loading and bending moment (Figs. 5 to 7).

Under fatigue loading, different initial crack configurations tend to a preferential path (in a plot a/b-a/D), the convergence (proximity between the curves representing the crack advance from different initial crack shapes) being faster for higher values of the m coefficient of the Paris law and greater for the bending loading than for the tensile loading. When subjected to bending, growth curves generally present lower values for the a/b parameter than under tension, with the exception of the deepest cracks growing from an initial crack aspect ratio $(a/b)_0 \cong 0$. If the initial crack is circular (i.e., $(a/b)_0=1$), the aspect ratio a/b diminishes with the crack growth, whereas when the initial crack is quasi-straight (i.e., $(a/b)_0 \cong 0$), the aspect ratio a/b increases at the beginning and decreases later (with the exception of initially deep cracks with $(a/D)_0 \cong 0.5$, where the aspect ratio a/b always increases), cf. Figs. 5 to 7.

It is observed that results depend on the exponent of the Paris law (Paris coefficients), so that for m=2 and m=3 the crack fronts are more distant between them than for m=3 and m=4, where the m=3 front is between m=2 and m=4. In the case of growth from *circular initial cracks* (i.e., $(a/b)_0=1$), the maximum discrepancy with regard to the crack fronts appears for intermediate cracks (a/D~0.5), a/b being lower for higher values of m-exponent in the Paris law.

In the case of growth from *quasi-straight initial cracks* (i.e., $(a/b)_0 \cong 0$), the maximum discrepancy in the matter of the crack fronts appears for short ($(a/b)_0$~0.3) and long ($(a/b)_0$~0.7) cracks, whereas for intermediate ($(a/b)_0$~0.5) cracks the results for different Paris coefficient m almost match. For short cracks a/b is higher for greater m; whereas for long cracks a/b is higher for lower values of m (again with the exception of initially deep cracks with $(a/D)_0 \cong 0.5$).

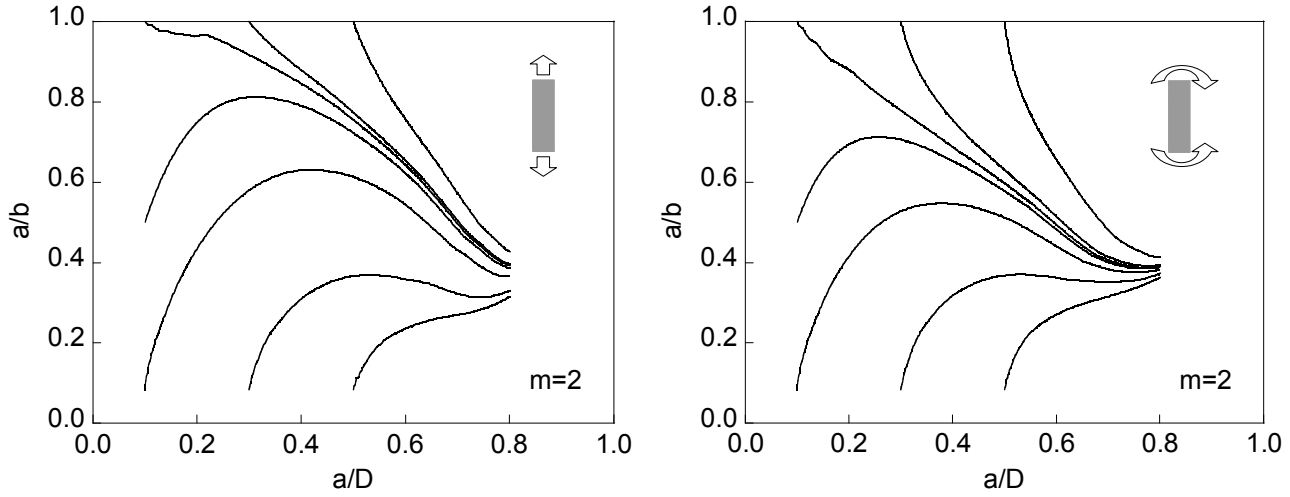

Figure 5. Evolution of the aspect ratio a/b with crack growth (represented by the relative crack depth a/D) for m=2, starting from different initial crack geometries under tension loading (left) and bending moment (right)

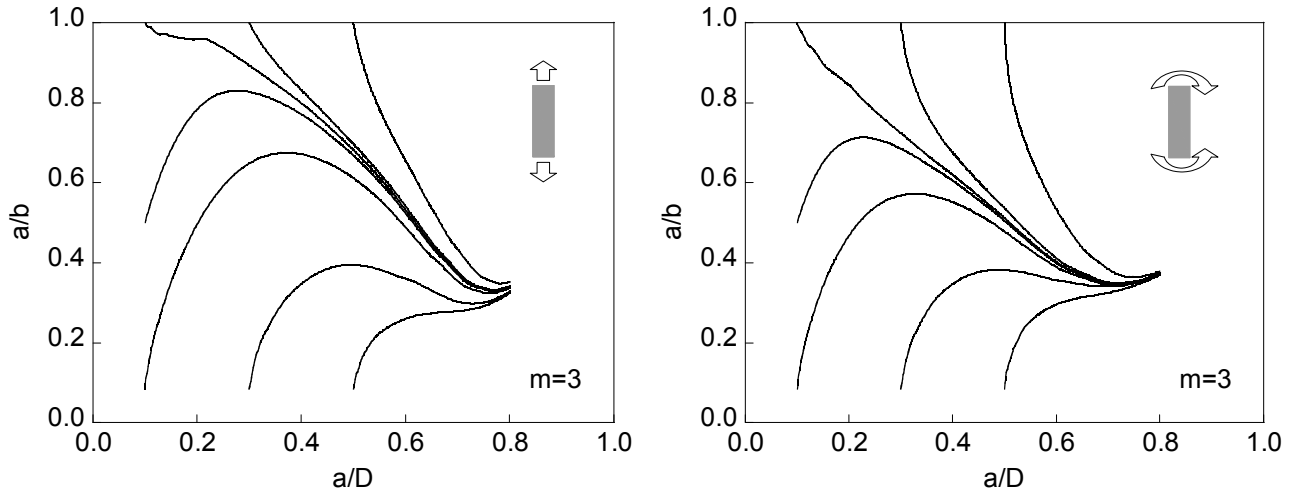

Figure 6. Evolution of the aspect ratio a/b with crack growth (represented by the relative crack depth a/D) for m=3, starting from different initial crack geometries under tension loading (left) and bending moment (right)

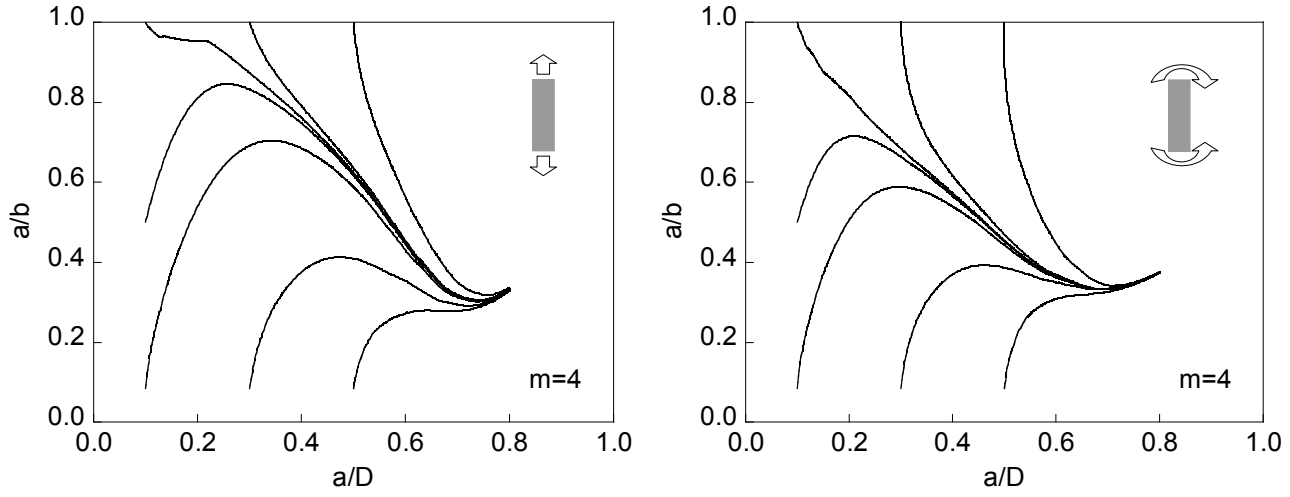

Figure 7. Evolution of the aspect ratio a/b with crack growth (represented by the relative crack depth a/D) for m=4, starting from different initial crack geometries under tension loading (left) and bending moment (right)

3.2. Dimensionless Compliance

The evolution of the dimensionless compliance f during fatigue crack propagation is shown in Figs. 8 to 10, for different initial crack depths ($(a/D)_0$={0.1, 0.3, 0.5}), initial crack aspect ratios $(a/b)_0$=0.08 (quasi-straight front) and $(a/b)_0$=1.00 (circular front), and different loading conditions (tension under free ends and bending).

In cracked cylindrical bars, dimensionless compliance f depends on the loading conditions, on the relative crack depth a/D and on the crack aspect ratio a/b. During fatigue crack growth starting from different initial crack geometries, it is observed how the dimensionless compliance f increases with the relative crack depth a/D and how the influence of the crack aspect ratio a/b is lower as the crack grows, due to the marked geometrical convergence taking place for the deepest cracks, in which the compliance reaches the highest values. The dimensionless compliance f for initially quasi-straight cracks is approximately twice than that for initially circular crack, both being really small at the beginning (initial cracks) and increasing clearly and approaching between them under fatigue.

The dimensionless compliance f in the cracked bars is higher under tensile loading (with free ends) than under bending moment, the ratio being as high as five for the deepest cracks of the present analysis (a/D=0.7). The f-a/D plots starting from an initially circular crack front $(a/b)_0$=1 and from an initially quasi-straight crack front $(a/b)_0$=0.08 are closer when (i) the applied load is bending instead of tension, (ii) the exponent m of the Paris law is higher, (iii) the initial crack depth $(a/D)_0$ is lower. Furthermore, during fatigue crack growth, materials with higher values of the Paris parameter m produce slightly greater dimensionless compliance.

4. Conclusions

According to the Paris-Erdogan law, in fatigue propagation the different initial crack geometries tend to a unique path on the a/b *vs*. a/D plot, this convergence (proximity between the curves representing the crack advance from different initial crack shapes) being faster for higher coefficients m of Paris and quicker for bending moment than for tensile loading.

With quasi-circular initial geometries (i.e., $(a/b)_0$=1), the crack aspect ratio a/b always diminishes with the crack growth, whereas when the initial crack is quasi-straight (i.e., $(a/b)_0$=0.08), the aspect ratio a/b increases at the beginning and decreases at the end (with the exception of initially deep crack with $(a/D)_0 \cong 0.5$).

In fatigue crack propagation, relative crack depth a/D influences more on dimensionless compliance f than the aspect ratio a/b, because the crack fronts tend to converge as the cracks propagate from different initial geometries, the convergence being quicker for initially short cracks than initially long cracks.

The f-a/D plots starting from an initially circular crack front $(a/b)_0$=1 and from an initially quasi-straight crack front $(a/b)_0$=0.08 are closer when the applied load is bending, the exponent m of the Paris law is higher or the initial crack depth $(a/D)_0$ is lower. Materials with higher values of the Paris parameter m produce slightly greater dimensionless compliance during fatigue crack growth.

The greater the m coefficient of the Paris law, the greater the convergence of the different initial crack conditions: geometry of the crack front (a/b) and dimensionless compliance f. The difference between the results for the different values of m is always bigger between m=2 and m=3 than between m=3 and m=4, which implies that, as this parameter increases, there is less dependence of results on it.

Abstract In this paper, tensile fatigue tests were performed under load control, with constant stress amplitude, on pearlitic steel wires with different cold drawing degree, from the hot rolled bar (not cold drawn at all) to the commercial prestressing steel wire (which has undergone seven cold drawing steps and a stress relieving treatment). Results show that fatigue cracks in pearlitic steels initiate at the wire surface starting from small defects, whose size decreases with the drawing process, as the cross sectional area of the wire does. Some of these defects appear during the drawing process itself. Fatigue cracks created from defects (initiation phase) exhibit a fractographic appearance consisting of ductile microtearing events which can be classified as tearing topography surface or TTS. Such microtearings are more planar in the initiation period than in the propagation phase and exhibit a spacing remarkably lower in the pretressing steel wire than in the hot rolled bar, so that their size decreases with cold drawing as the steel microstructure does.

Keywords Pearlitic steel, Cold drawn steel wire, Initiation of fatigue cracks, Surface defects

1. Introduction

Fatigue life of steel wires depends on their surface state and the existence of defects (such as microcracks, inclusions, etc.) present in the material. In wires made of eutectoid cold drawn steel, the fatigue process initiates in surface defects [1-3], broken martensite layers (due to a overheating during the wire drawing process), longitudinal groves and holes mainly caused by surface inclusions [1]. Many times surface defects are caused by the drawing process itself [4].

Surface defects present in the material before wire drawing can be eliminated by such a mechanical treatment. A scratch on the wire surface can be removed by repeated drawing; however, the flaw remains inside the wire because of the development of an overlap, and it is thus difficult to completely remove the flaw [5]. In corrosion-fatigue the aggressive environment can blunt the surface defects due to material dissolution, increasing the number of cycles required to initiate cracking [6].

The main cause of failure in steel wires is the presence of non-metallic inclusions during wire drawing or service [7]. The existence of non-metallic inclusions in cold drawn pearlitic steel affects its fatigue properties [8] by modifying the local stress state surrounding the inclusions, depending on the size, localization, composition and geometry of the inclusion [9].

This paper studies the defects able to initiate the fatigue phenomenon in pearlitic steel applied in two forms —i.e., as a hot rolled bar and as a commercial prestressing steel wire— by analyzing the effects of cold drawing on such defects and the microstructural arrangement and how these changes affect the fatigue performance of prestressing steel.

2. Experimental Procedure

2.1. Material

The material used was eutectoid pearlitic steel (chemical composition 0.789% C, 0.681% Mn, 0.210% Si, 0.010% P, 0.218% Cr, 0.061% V). It was studied in two forms: firstly, as a hot rolled bar

(non cold drawn at all) and, secondly, as a commercial prestressing steel wire which has undergone seven cold drawing steps up to reaching a cumulative plastic strain ε^P=1.6 and a posterior stress-relieving treatment to eliminate, or at least diminish, residual stresses. Steel was supplied in form of wires with circular section, the diameter ranging respectively between 11 and 5 mm for the hot rolled bar and the prestressing steel wire.

Cold drawing produces a clear improvement of conventional mechanical properties (Table 1) obtained from a standard tension test: both the yield strength (σ_Y) and the ultimate tensile strength (UTS, σ_R) increase with cold drawing, while the Young's modulus (E) remains constant and the strain at UTS (ε_R) decreases with it.

Table 1. Mechanical properties of the material in both conditions, i.e. as a hot rolled bar and as a prestressing steel (cold drawn) wire

Steel	E (GPa)	σ_Y (MPa)	σ_R (MPa)	ε_R
Hot rolled bar	202	700	1220	0.078
Prestressing steel wire	209	1480	1820	0.060

Cold drawing also improves the fatigue and fracture behaviour of eutectoid steel. The fracture toughness K_{IC} was obtained by means of fracture test on precracked wires under tensile loading, as described in [10]. The K_{IC} value increases from 53 MPa·m$^{1/2}$ in the hot rolled bar to 137 MPa·m$^{1/2}$ (for θ=0º, fracture toughness in the transverse direction) in the prestressing steel wire, where cold drawing also induces an important strength anisotropy with a directional fracture toughness whose value is dependent on the particular axis of analysis. Values C and m (constants of the Paris law) were obtained by means of tensile fatigue tests, as explained in ref. [11]. The m coefficient in the Paris law (slope of the line) is the same for the two steels and rounds the value 3, whereas the C parameter decreases with cold drawing, changing form $5.3\cdot10^{-12}$ in the hot rolled bar to $4.1\cdot10^{-12}$ in the cold drawn wire (units for C and m are the adequate to measure da/dN in m/cycle and ΔK in MPa·m$^{1/2}$).

2.2. Test Procedure

Wöhler fatigue tests were performed under tensile load control with constant $\Delta\sigma$, sinusoidal wave shape, frequency of 10 Hz, R-ratio R=0 and a maximum stress lower than the yield stress σ_Y (some S-N tests were performed under a stress range of about half the yield strength). The specimens were in the form of 30 cm long bars of circular cross section and the same diameter as the supplied wires. A total number of 20 tests were performed. Fracture surfaces were analyzed by scanning electron microscopy (SEM).

3. Experimental Results

3.1. Microstructure

Figs. 1 and 2 show the microstructure of both steel forms, hot rolled bar and prestressing steel wire, in both transverse and longitudinal section, where the horizontal side of the micrograph corresponds to the radial direction and the vertical side is associated with the axial direction in the longitudinal cut and with the circumferential one in the transverse cut.

Cold drawing produces important microstructural changes in the pearlitic steel [12, 13] in the form of slenderizing of pearlitic colonies, decreases of interlamellar spacing of pearlite and progressive orientation with cold drawing of both colonies and lamellae. Thus, the transverse section (Fig. 1) shows that the lamellae evolve towards a structure with increased packing closeness while at the same time adopting a curved appearance (*curling* phenomenon) from the very beginning of the cold drawing

process (very common when drawing metals with bcc structure). With regard to the longitudinal section (Fig. 2), both decrease of interlamellar spacing and lamellar orientation in axial direction are observed.

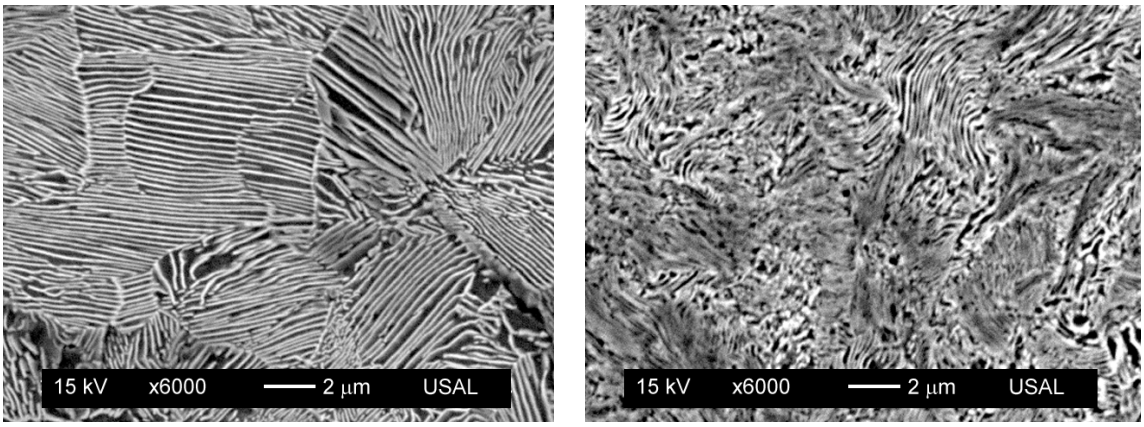

Figure 1. Microstructure in the transverse section: hot rolled bar (left) and prestressing steel wire (right)

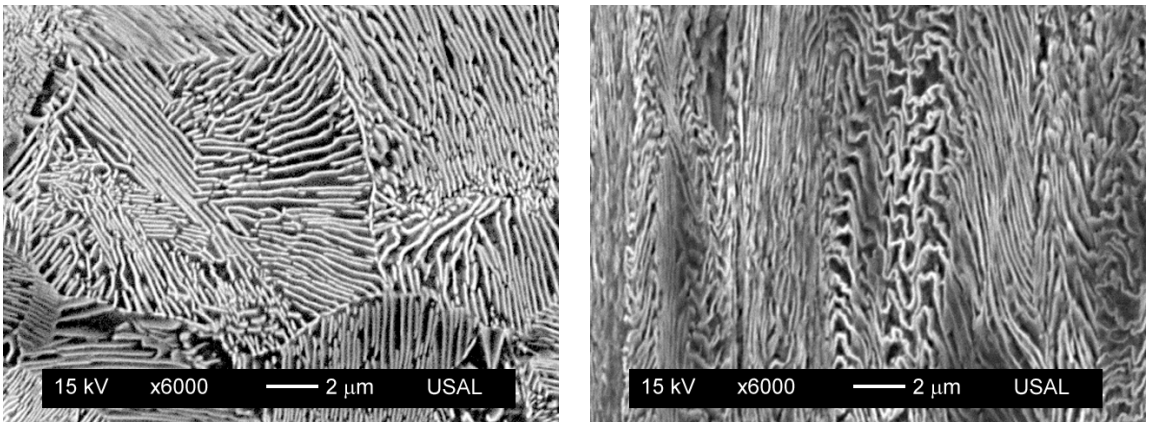

Figure 2. Microstructure in the longitudinal section: hot rolled bar (left) and prestressing steel wire (right). In both micrographs the vertical side is associated with the wire axis or cold drawing direction

3.2. Initiation of Fatigue Cracks from Surface Defects

The surface quality of both commercial products, hot rolled bar and prestressing steel wire, is very different (Fig. 3). While in the first (which comes from a hot rolling process) some material losses and irregularities can be observed on its uneven surface, in the prestressing steel wire (heavily drawn) longitudinal grooves are observed (typical surface features in drawn steel wires [1]), the roughness being higher in the hot rolled bar than in the prestressing steel wire. The defects (pre-existent in the hot rolled bar) change the geometry with the drawing process, their depth decreasing up to the total disappearing in some cases [5]. In addition, the analyzed material (in the two forms as a hot rolled bar or a prestressing steel wire) has frequent inclusions (sulphides, oxides, silicates…), some of which can be found on the wire surface, provoking voids on the material (Fig. 4).

Results show that fatigue cracks in pearlitic steels begin at the wire's surface starting from some of these small defects (Fig. 5). The defect size decreases with the drawing process, as the cross sectional of the wire does. In the hot rolled bar the fatigue initiators are mainly the surface defects with small aspect ratio (material losses at the peripheral zones) while in the prestressing steel wire such initiators are principally the voids created by, probably, the existence of particles near the wire surface (cf. Fig. 5). Depth of maximum surface defects is about 120 μm in the hot rolled bar and about 25 μm in the cold drawn wire. Initiation of fatigue cracks from surface defects is due to the fact that the latter act as stress concentrators.

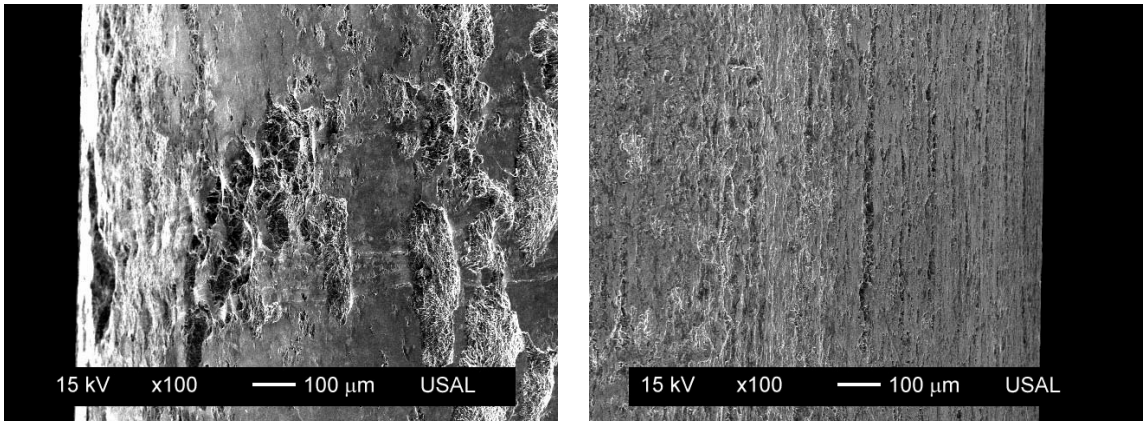

Figure 3. Surface of the material in the two forms: hot rolled bar (left) and prestressing steel wire (right). In both pictures the vertical side is aligned with the wire axis or cold drawing direction

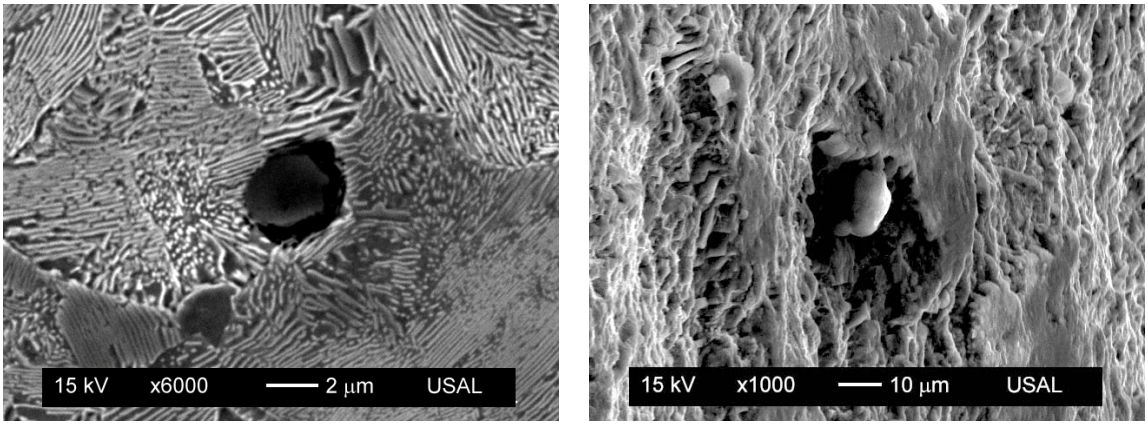

Figure. 4. Inclusions in hot rolled bar: inside the wire (left) and on the wire surface (right). In both pictures the vertical side is aligned with the wire axis or cold drawing direction

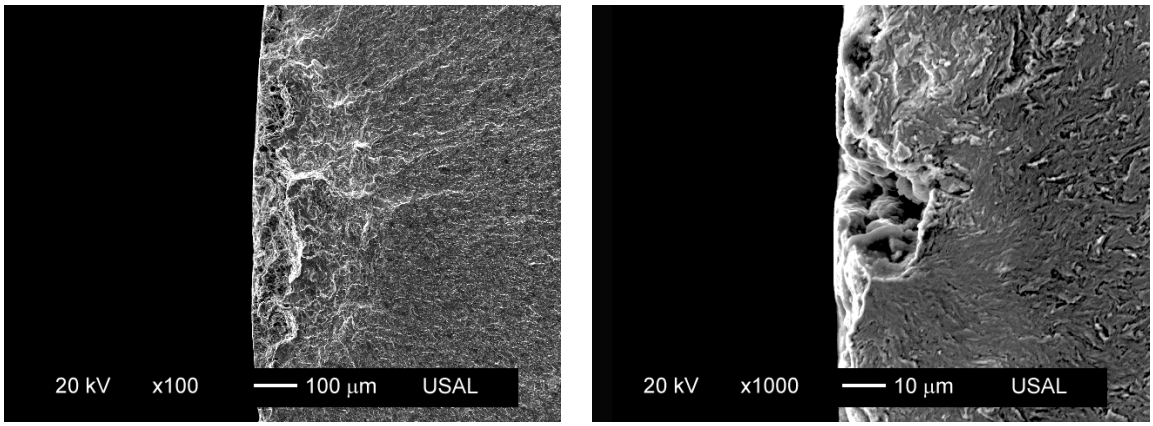

Figure. 5. Initiation of fatigue crack growth from a surface defect: hot rolled bar (left) and prestressing steel wire (right). Both images represent the transverse fatigue fracture surface (circular section perpendicular to the wire axis or cold drawing direction) and crack growth direction takes place from left to right in the fractographs

With regard to fatigue crack initiation from the surface defects in the material supplied as a hot rolled bar and a prestressing steel wire, Fig. 6 shows the same information as Fig. 5 but includes arrows to identify the fatigue crack growth from the aforesaid defect. It is seen that the defect appearance is different in the two material forms. In the hot rolled bar the surface defect looks like an extremely shallow flaw with an approximate aspect ratio of 0.2 whereas the prestressing steel wire such a defect looks like a relatively small circumferential flaw with an approximate aspect ratio equal to the unity. In the matter of the initiation of fatigue crack growth, it is important to say

that, apparently, there is no single initiation point over the defect boundary, but instead of it a line (i.e. a set of points can be viewed) defining the emerging fatigue crack front at the early stages of cracking and diverging fatigue propagation lines emanating from the defect: lack of material previously lost during the manufacturing process in the case of the hot rolled bar and voids created by a previous inclusion in the prestressing steel wire.

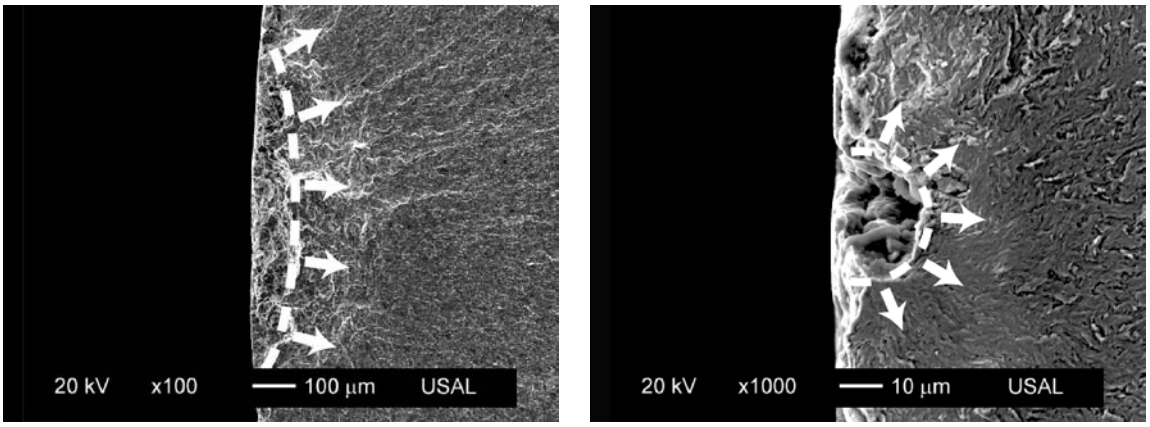

Figure 6. Initiation of fatigue crack growth from a surface defect: hot rolled bar (left) and prestressing steel wire (right), including arrows to identify the fatigue crack growth from defect

In high strength eutectoid steels fatigue crack growth can start from defects caused by the drawing process itself. Fig. 7 shows a surface defect possibly generated by a hard particle in the wire surface during the drawing process, because a longitudinal track, aligned in the drawing direction, appears in the wire surface. A sort of plastic deformation can be observed surrounding the hole (Fig. 7; left) with a very regular geometry. Fig. 7 also includes a magnification (right) of the surface defect (and consequent fatigue crack growth) viewed from different angle, showing the longitudinal scratching marks, an evidences of the pre-damage created by an inclusion (hard particle) during the plastic straining as a consequence of the manufacturing process by cold drawn.

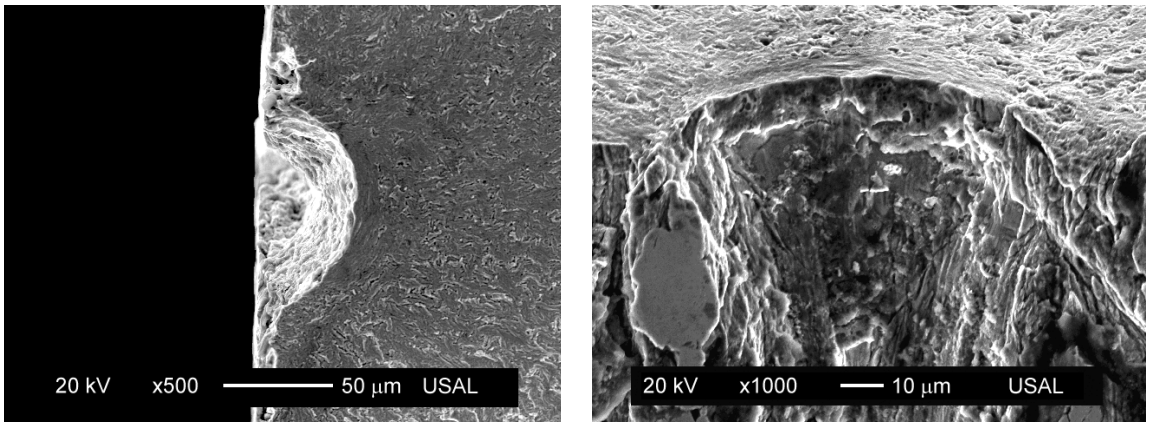

Figure 7. Surface defect caused by cold drawing producing transverse cracking in the prestressing steel wire (left) and magnification of the surface defect (and consequent fatigue crack growth) viewed from different angle (right)

Fatigue cracks created from defects exhibit a fractographic appearance consisting of ductile microtearing events (Fig. 8), which can be classified as *tearing topography surface* or TTS [14]. Such microtearings are less rough in the initiation period (Fig. 8) than in the propagation phase (Fig. 9) and exhibit a spacing remarkably lower in the prestressing steel wire than in the hot rolled bar, so that their size decreases with cold drawing as the steel microstructure does, and a sort of materials science relationship appears between microstructural unit size and fatigue microfracture event. The aforesaid TTS microfracture mode has been associated with hydrogen embrittlement in

pearlitic steel [15] and it can be considered a slow propagation mode in hydrogen-assisted fracture processes linked with subcritical cracking at one micrometer per second or less [16].

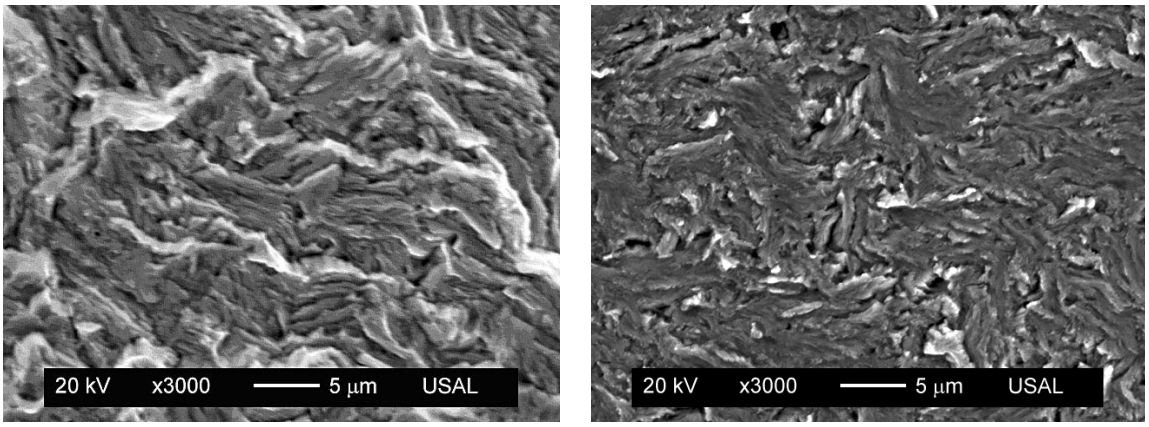

Figure 8. Fractograph corresponding to fatigue initiation phase: hot rolled bar (left) and prestressing steel wire (right). In both images the fatigue crack growth direction is from left to right

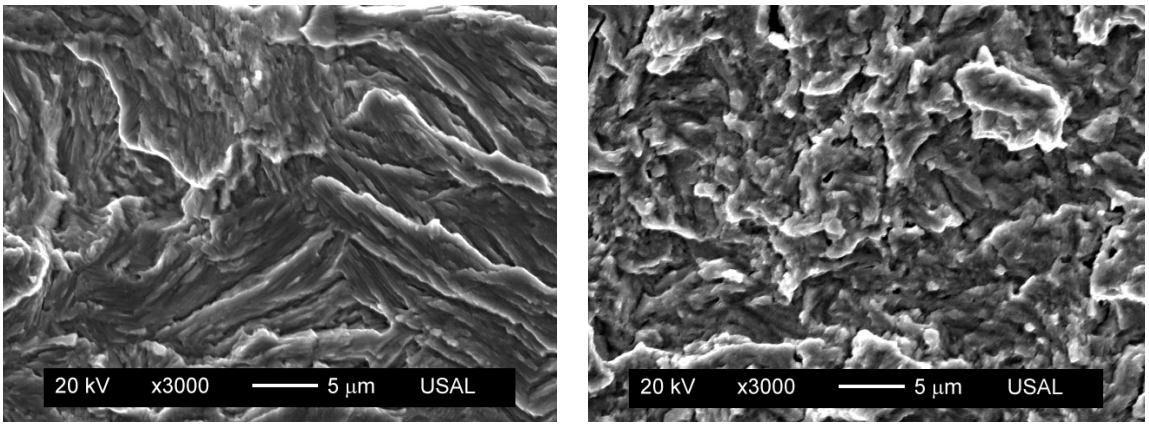

Figure 9. Fractograph corresponding to fatigue propagation phase: hot rolled bar (left) and prestressing steel wire (right). In both images the fatigue crack growth direction is from left to right

4. Simulations

In the Whöler tests, a smooth specimen (samples of the as-supplied wire) was subjected to fatigue loading under constant amplitude, stress level of about half of the yield strength ($\Delta\sigma=\sigma_Y/2$), up to fracture due to initiation and propagation of a fatigue crack reaching its critical value (Fig. 10).

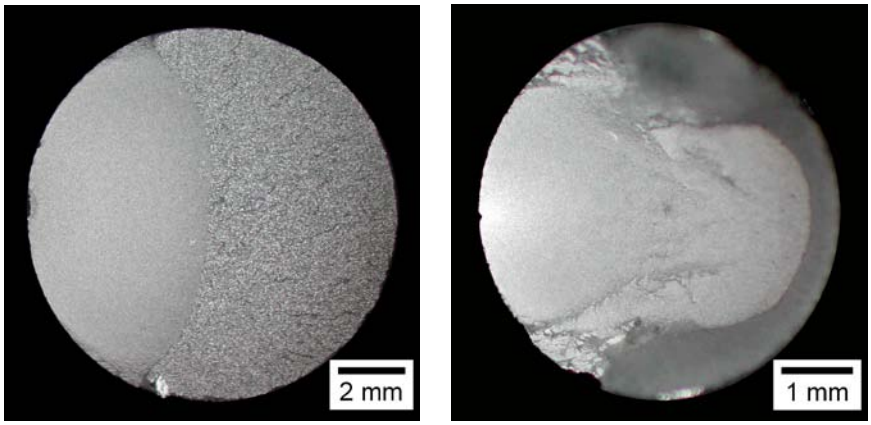

Figure 10. Fracture surface in the specimens after the Whöler tests: hot rolled bar (left) and prestressing steel wire (right). In both images the fatigue crack growth direction is from left to right

Fatigue life N_f was experimentally obtained by means of Whöler tests. The experimental results corresponding to prestressing steel are similar as those previously obtained by Beretta and co-workers [3, 4]. In addition, a numerical estimation was made of the number of cycles needed for crack propagation N_p, on the basis of a simple model previously used by other authors in the scientific literature [17, 18], considering that it follows the Paris law [19],

$$\frac{da}{dN} = C\Delta K^m \tag{1}$$

and the stress intensity range ΔK is given by,

$$\Delta K = Y\Delta\sigma\sqrt{\pi a} \tag{2}$$

where Y is the dimensionless stress intensity factor (SIF).

The number of cycles for propagation was calculated by following expression derived from the Paris law,

$$N_p = \frac{1}{C\Delta\sigma^m \pi^{m/2}} \int_{a_0}^{a_C} \frac{da}{Y^m a^{m/2}} \tag{3}$$

where a_0 and a_C are respectively the initial and the final crack sizes, the first associated with the fatigue threshold [2] and the latter with the critical instant of failure ($K_{Imax}=K_{IC}$, according to the local fracture criterion) and the path followed by the crack during propagation is that plotted in Fig. 11. During its growth, the fatigue crack exhibits an elliptical shape in the Paris regime.

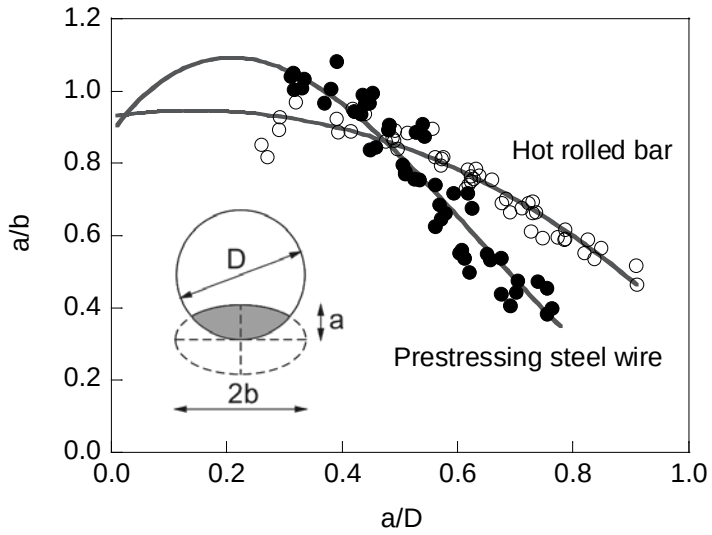

Figure 11. Geometrical changes in the crack front during fatigue crack propagation

The crack front was characterized as an ellipse with semiaxes a (crack depth) and b, its centre been at the wire surface. On the basis of the experimental tests [11] and extrapolating for small crack sizes where the crack front exhibits a quasi-circular appearance (Fig. 12), a relationship was obtained between the relative crack depth (crack depth divided by the diameter, a/D) and the aspect ratio (ratio between the semiaxes of the ellipse, a/b), Fig. 11.

The size effect appearing in the steel samples was taken into account during the propagation phase because it changes the geometric evolution during fatigue. In a previous research work, Shin and Cai [20] observed how when the sample diameter decreases, the fatigue crack growth rate (FCGR) changes at the crack surface when compared with the same value at the crack centre, whereas for higher diameters the FCGR (represented by the Paris law) is the same at the centre and the surface. The aforesaid size effect affects how the crack front evolves (and thus the crack aspect ratio).

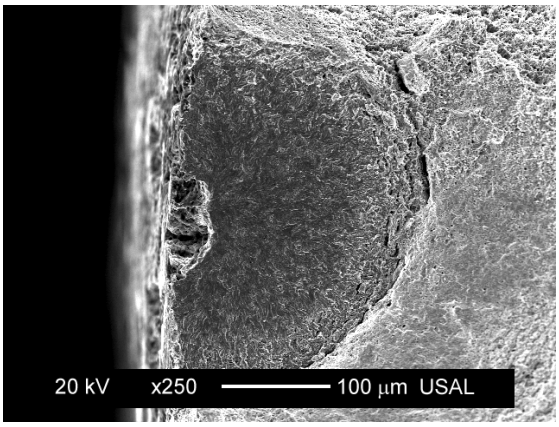

Figure 12. Short crack emanating from a surface defect in the form of void created by a previous inclusion in cold drawn steel. Fatigue crack propagation from left (surface defect) to right

The dimensionless SIF Y employed is that calculated by Astiz [21], for the central point of the crack front by using the finite element method, which depends on the relative crack depth a/D and the aspect ratio a/b through the coefficients C_{ij} (Table 2),

$$Y = \sum_{\substack{i=0 \\ i\neq 1}}^{4} \sum_{j=0}^{3} C_{ij} \left(\frac{a}{D}\right)^{i} \left(\frac{a}{b}\right)^{j} \tag{4}$$

Table 2. Coefficients C_{ij} of Eq. (4) taken from ref. [21]

i	*j=0*	*j=1*	*j=2*	*j=3*
0	1.118	-0.171	-0.339	0.130
2	1.405	5.902	-9.057	3.032
3	3.891	-20.370	23.217	-7.555
4	8.328	21.895	-36.992	12.676

Solution of equation (3) was obtained in incremental form, the convergence being guaranteed by the adequate choice of the crack increment Δa (sufficiently low).

The number of cycles associated with crack initiation N_i can also be estimated as follows [17, 18],

$$N_i = N_f - N_p \tag{5}$$

where the common definition of initiation in reality pertains to both nucleation and propagation of microcracks [22].

Table 3 shows the fatigue life N_f experimentally obtained for a stress range about half of the yield strength of each material. In both the hot rolled bar and the cold drawn wire the life is around 300000 cycles, which indicates that the cold drawing process improves the fatigue performance in a similar way that the increase of material strength. In addition, the main part of the fatigue life (measured as number of cycles) is associated with the propagation phase in the hot rolled bar and with the initiation phase in the cold drawn wire.

Table 3. Fatigue life N_f (experimental, average of five tests), number of cycles for propagation N_p (obtained by simulations) and number of cycles for initiation N_i ($N_i = N_f - N_p$)

Steel	$\Delta\sigma$ (MPa)	N_f (cycles)	N_p (cycles)	N_i (cycles)
Hot rolled bar	347	308200	253700	54500
Prestressing steel wire	790	312910	57655	255255

The prestressing steel wire exhibits a Paris curve below that of the hot rolled bar (lower parameter *C*) [11], thus producing a retardation in fatigue crack propagation with the cold drawing process. In addition the fracture toughness is also higher in the cold drawn wire than in the hot rolled bar [23]. This indicates that cold drawing is beneficial since it improves both the fatigue and the fracture performance by dropping the Paris law [11] and elevating the fracture toughness [10], a clear implication for structural engineers. Moreover, the prestressing steel wire is again the best option on the basis of a clear reduction of the size of the surface defects (acting as crack initiators) and the microstructural changes induced by the drawing process (e.g., orientation of the cementite layers acting as barriers to dislocational movement). Both characteristics, small surface defects and special microstructural arrangement, contribute to a delay of the initiation of fatigue crack growth.

5. Conclusions

The following conclusions may be drawn from the experimental results of fatigue crack growth from surface defects in pearlitic steel:

(i) Fatigue cracks in pearlitic steels are initiated at the wire surface starting from small defects. In the hot rolled bar the fatigue initiators are mainly the surface defects (material losses) while in the prestressing steel wire such initiators are principally the voids created by the existence of particles near the wire's surface.

(ii) Fatigue cracks created from defects exhibit a fractographic appearance consisting of ductile microtearing events which can be classified as *tearing topography surface* or TTS, and exhibit a spacing remarkably lower in the prestressing steel wire than in the hot rolled bar.

(iii) The number of cycles necessary for fatigue crack initiation in the prestressing steel wire is quite higher than that of the hot rolled bar (for $\Delta\sigma=\sigma_Y/2$) and thus changes in surface defects and microstructural arrangement produced by the drawing process considerably improves its fatigue performance.

Abstract Impact fatigue damage is the main factor which influenced the life of a wind tunnel balance. It is necessary to predict impact fatigue life of a balance especially in the key points of a balance after static analysis. It is unpractical to implement the impact fatigue experiment in the laboratory while wind tunnel balance is a special transducer which would not be manufactured in batches. Generally, balance designers didn't do this analysis for its special use. In fact, accidents of this sort which is in the testing are happening with increasing frequency. This paper provided a method to predict impact fatigue life of a balance which based on the finite element analysis. We used finite element analysis tools to modeling the wind tunnel balance, and then we meshed the whole model as fine as possible. After that, stress of the wind tunnel balance under static loading was figured out, as well as the key points of the balance. The fatigue analysis tools were used to estimate the stress of the balance which was bearing the impact loading. These analysis results would much valuable to the wind tunnel testing.
Keywords wind tunnel balance, fatigue damage, finite element analysis

1. Introduction

Wind tunnel balance is used in the wind tunnel widely by the enlargement of the wind tunnel testing, thus the performance of the balance is more attractive to the researchers. These researchers focused on the failure and accident of the wind tunnel balance, because they doubt that the fatigue of the balance is the main factor of these accidents. But what is the fatigue? Maybe this is the first thing which the wind tunnel balance researchers want to know eagerly. Here quote a definition of ASTM E206-72: The process of progressive localized permanent structural change occurring in a material subjected to conditions which produce fluctuating stresses and strains at some point or points and which may culminate in crack or complete fracture after a sufficient number of fluctuations. The actual mechanization of the material fatigue and its scientific describe are not reported at present. Analysis method of fatigue life prediction is the main aspect of fatigue, and this content was concluded throughout of the history of fatigue. For the cost of the fatigue testing is so large that most researchers tend to using finite element analysis to acquire the data of the material which they concerned. Finite element analysis is the most important method for the researcher to develop a new balance for the wind tunnel balance is special research equipment which is unpractical to proceed the fatigue testing.

The purpose of a wind tunnel balance is to measure the aerodynamic forces and moments, which load a model during wind tunnel tests. The balance measures the aerodynamic forces and moments by the wheatstone bridge which consist of strain gauges adhere to the sensitive elements. The sensitive elements suffered pull、torsion、torsion and bend，and even the combination of them. A slot partition a balance into two parts, the axial force elements combined these as a parallelogram. The forces and moments will transfer from model to the balance. The balance used in the airplane was show in figure1.

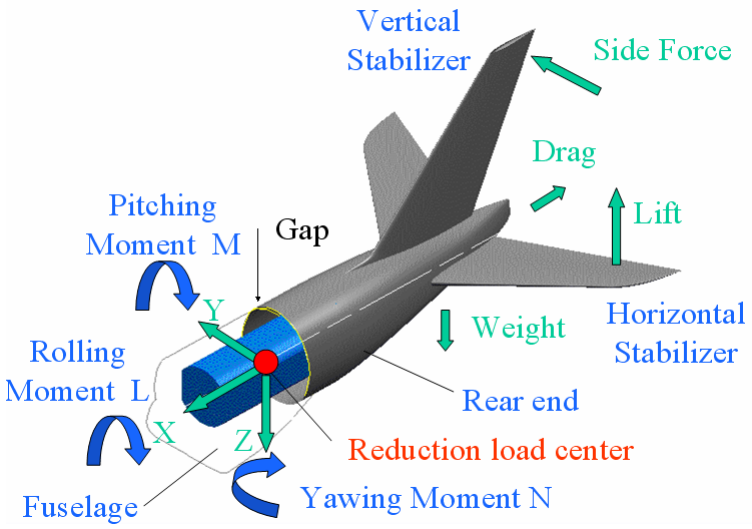

Figure 1. sketch of the six components of wind tunnel balance

Wind tunnel balance is special testing equipment for the wind tunnel testing. They are many rigorous procedures before and after the manufacture of a wind tunnel balance to ensure the balance to be qualified testing equipment. Wind tunnel balance flourishing many years accompany with the new structure and new application domain while the fatigue performance of the balance was ignored by most wind tunnel balance researchers. But this is a question which we could not inevitable, and this is the purpose of this paper also.

2. Fatigue Life Prediction of wind tunnel balance

Fatigue Life Prediction of wind tunnel balance is the responsibility of every balance researcher as other engineering's. Balance users would utilize balance reasonably after fatigue life prediction, and exception handles would also more easier.

Supersonic wind tunnel balance usually bear impact load and steady load and even other complexity situations. Sensitivity of the wind tunnel balance is so excellent that even any relative collection data of the balance would show the trouble of the balance. All of these factors complexes the designing of a wind tunnel balance. Utilizing analysis method to replace the testing method is the goal of the finite element analysis for the balance, and this will decrease the workload and cut down the cost. Utilizing analysis method would get the accurate fatigue life data for the ability of complex geometry processing and anomalous load curse.

Fatigue Life Prediction of wind tunnel balance included several steps. Firstly, we analysis the static stress of the wind tunnel balance, we obtained the dangerous sections or key points of the balance. After that, we take the process of the fatigue analysis until acquire the fatigue life data.

2.1. static stress analysis

The first step of the fatigue life prediction is the static stress analyses, which will also the very important step in the whole curse. Static stress analyzes means that we load the balance by every possible load or rated load. The purpose of static stress analyzes is obtain the dangerous sections by various loading condition. The results of this analysis would play important role to the designing of a wind tunnel balance.

Static stress analyses include several steps: modeling the balance; meshing, loading and solving the problem.

2.2. fatigue analysis

Fatigue analysis should according to the actual working condition, which means every balance designer should find out the actual load curve of the balance. It is useful to predict the true life of a balance by analysis the balance in a real loading condition and real working frequency.

It is more suitable to use the Miner assumption when the curse contains various fatigue stress breadth. Miner on the assumption that: if the cycle stress were a serials breadth denote as S1,S2,S3,….and corresponding destroy life of this material were Nf1,Nf2,Nf3,… then, the life of every stress breadth will be express as the quotient of the actual cycles Ni and life Nfi. We can assumption that the damage cumulate as above method, see Eq. (1)

$$\frac{N_1}{N_{f1}}+\frac{N_2}{N_{f2}}+\frac{N_3}{N_{f3}}...+\frac{N_i}{N_{fi}}=1, \qquad (1)$$

Life will come to the end while the cycles up to the failure times Nfi under a specified stress breadth.

It has many reproaches when we regard the Miner assumption as a effectively designing rule for the testing results are very decentralization. It is widely used in many fields for its simpleness and other strongpoint.

2.3. process of fatigue life prediction

The process of fatigue life prediction listed as follows:

(1) create the frame of fatigue life prediction, define the characteristic of material, set up the parameter of analysis；
(2) define the mode of contact;
(3) using solution combination or specify special stress curve。
(4) solve this problem；

3. example of the fatigue Life Prediction of wind tunnel balance

This section analysis the fatigue life of the B630Q wind tunnel balance which was used in the supersonic wind tunnel.

B630Q wind tunnel balance is a usual balance used for the force and moment measurement. The rated load of this balance listed in the table 1.

Table 1. rated load of B630Q

	My （N.M）	Z （N）	Mz （N.M）	Y （N）	Mx（N.M）	Q（N）
Rated load	50	600	100	2000	30	600

B630Q wind tunnel balance connected with the model by a structure which looked like a cone, which means the contact region is a cone. The finite element model which contains the load equipment showed in the figure 2.

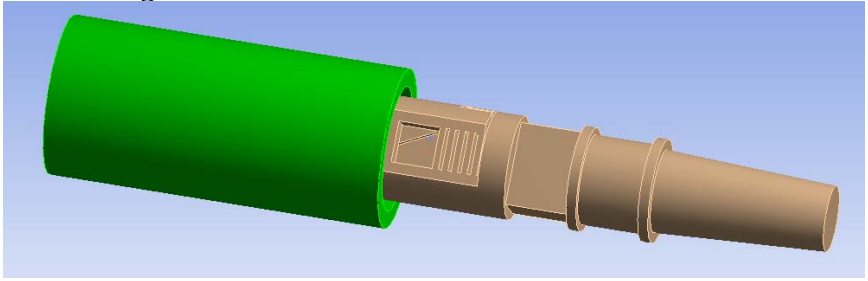

Figure 2. finite element analysis model

3.1. static stress analysis of B630Q balance

This paper analyzed the B630Q wind tunnel balance by finite element analysis. We modeled the balance after the theoretic analysis of this balance. After that, meshing the model was conducted by the software. We can conclude from the meshing contour that the compute node is 172545 and the number of element is 105639. Meshing results of B630Q balanc was showed in figure3. Figure4 showed the contact region of the balance and loading equipment.

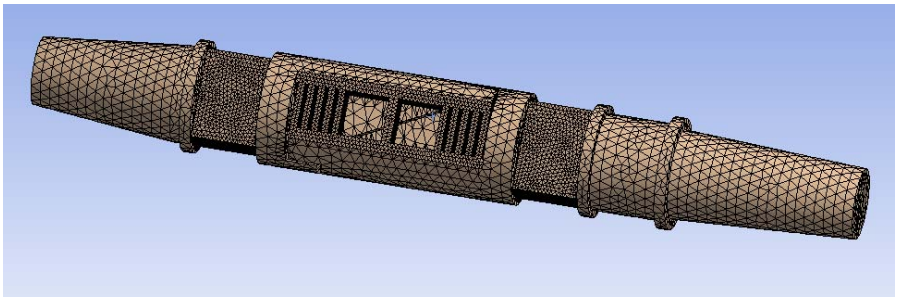

Figure 3. meshing results of the balance

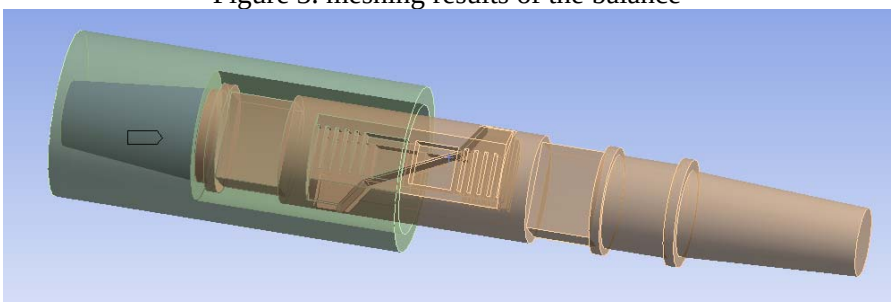

Figure 4. Contact Region

The processing was conducted after the process of meshing the model was completed. The static stress contour and dangerous sections were obtained after six component's load was imposed on the balance and also the integrative load. Figure 5 showed the stress contour of that the six component rated load was loaded integrative. We can conclude that the maximum stress was only 410.7MPa which was lower than the tensile ultimate strength and the location was lie on the root of the supporting beam. Figure 6 showed the each life contour of six components's loading. These figures informed that the dangerous sections were in the root of the supporting beam and the root of the axial force element indeed.

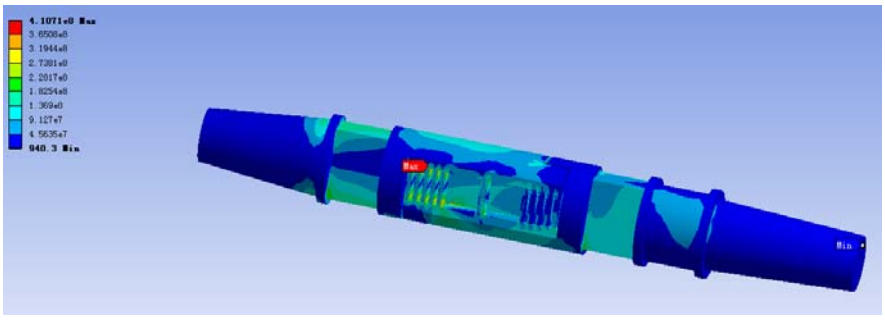

Figure5. Contour of stress

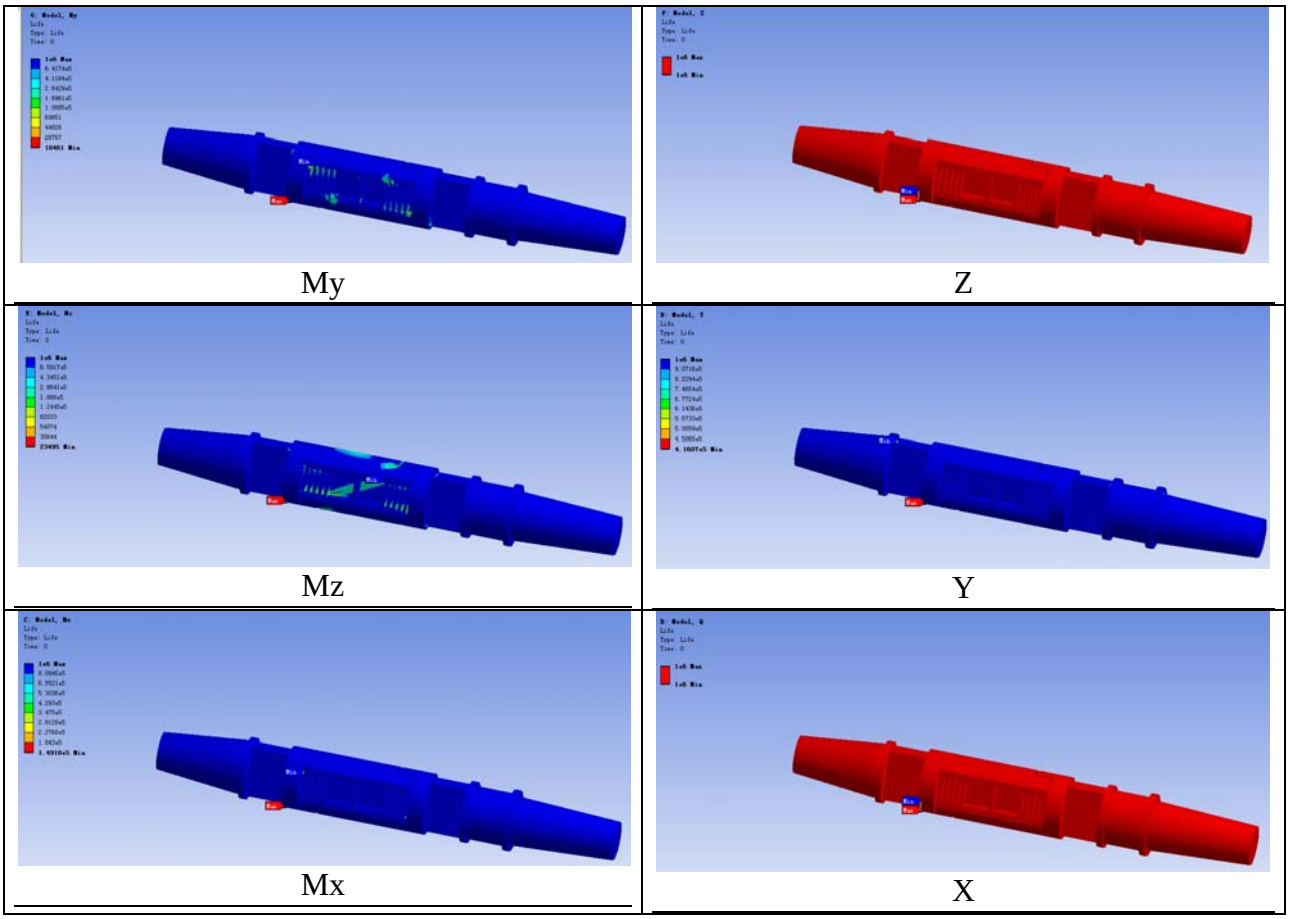

Figure6. Life contour of six component load alone

3.2. fatigue Life Prediction of B630Q balance

We defined the characteristic of the material which was used to manufacture balance. The material was used the structural steel. Detailed parameter were showed subsequently， Poisson's Ratio is 0.3,Young's Modulus is 2.0e+011Pa.Tensile Yield Strength is 2.5e+008 Pa, Compressive Yield Strength is 2.5e+008 Pa. Tensile Ultimate Strength is 4.6e+008 Pa, N-S curve showed in the figure 7.

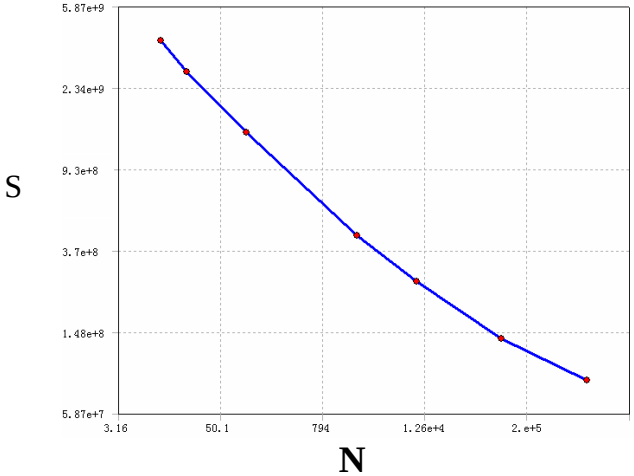

Figure7. N-S curve of structural steel

First, we used history data to simulate the balance. For simplification, the fatigue life prediction curse concerned on the impact on the balance while the wind tunnel startup and steady flow after that and the course of shut down the wind tunnel. We defined the load curve after colligate the

above situation. The load curve was showed in figure8.

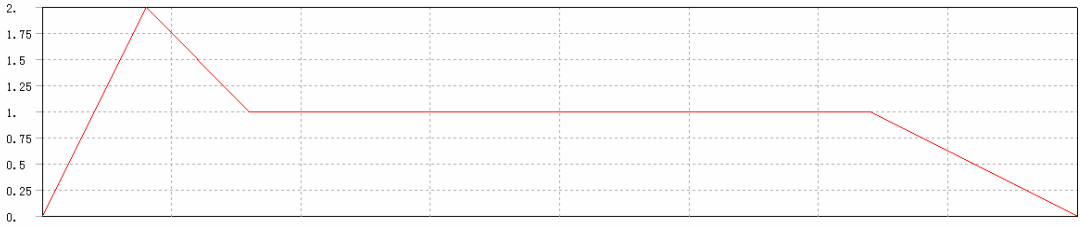

Figure8. load curve of the B630Q balance

Life contour of balance B636Q bearing the combination load was showed in figure 9. We can conclude that the minimum life of balance is 2616 cycles, and the dangerous section was in the root of the supporting beam.

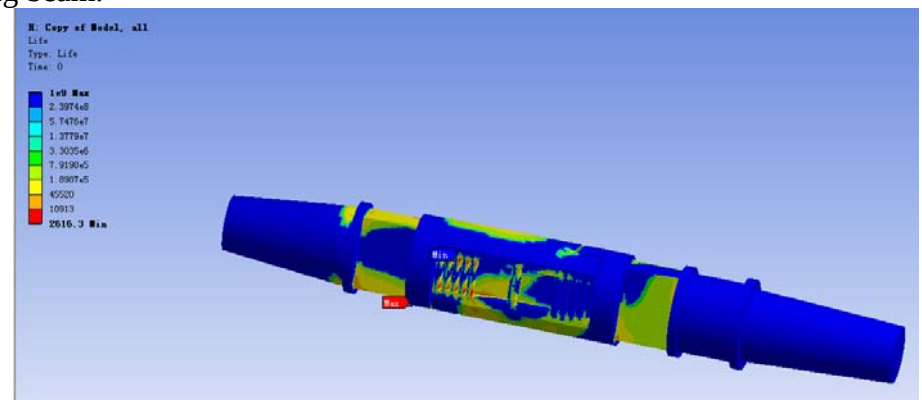

Figure9 Life contour of balance B630Q bearing the combination load

Second, we used solution combination methods to solve this problem. We combined the lift force、pitching moment and axial force according the actual using setting.Life contour of balance B630Q subjected the combination load was showed in figure 10. We can conclude that the minimum life of balance is 15388 cycles, and the dangerous section was not in the root of the axial force element but in the root of the rectangular section. These results maybe arise from the actual load curve didn't contain the side force and yawing moment.

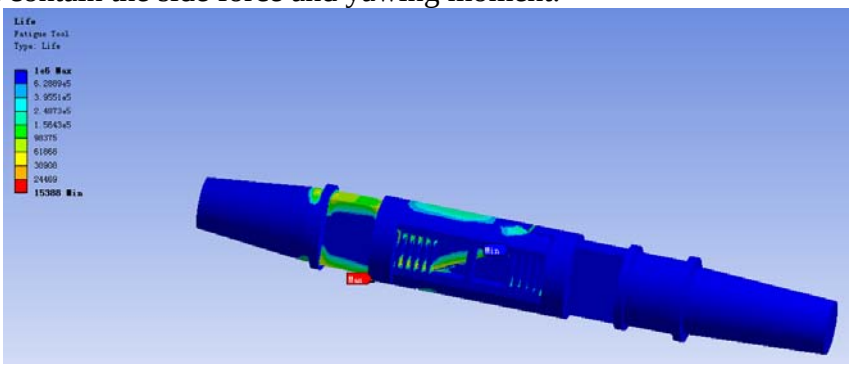

Figure10 Life contour of balance B630Q bearing the combination load

4. conclusions

This paper developed a method to predict the fatigue life of a wind tunnel balance, which was verified by a B630Q balance.

Abstract: According to the fatigue crack extension theory of the fracture mechanics, this paper analysis the relationship between the property of the high-strength bolts and the connection surface friction coefficient, as well as the relationship between the property of the high-strength bolts and temperature. The fatigue life and fatigue damage degree under different anti-friction coefficient and different temperature are calculated by high-strength bolt three-dimension FEM model. After recycling for the same times, the fatigue life will decrease with the increase of the anti-fiction coefficient as well as the temperature. The bigger the anti-friction coefficient is, the more serious the fatigue damage is. The higher the temperature is, the more serious the fatigue damage degree is. With the increase of the anti-friction coefficient, the structure safety factor will decrease, for the increased anti-friction coefficient makes the connection surface geometric discontinuities degree become serious, then the crack extension rate will be faster. With the increase of the temperature, the structure safety factor will also decrease. The conclusions can be used as a reference for the afterwards fatigue design about such components.

Keywords: Fatigue Life, Fatigue Damage, Safe factor, Fracture mechanics

1. Introduction

Because of convenient installation, high-strength material of steel bridge, it was adapted by engineer, as the main form of the structure of large- span bridge design. Factory welding and construction site bolt connection as the general connection between Steel components. As welding connection mode restrictions by welding process and construction environmental, it was difficult to ensure the construction quality when the construction site in the way. So components on site installation connected often use high strength bolt connection. Because bridge often bears car live load function etc, as a result the bridge always under repeated load, will eventually cause fatigue damage of steel bridge. Now a lot of research on the fatigue of the connection method for welding, but for the high strength bolts of fatigue performance opposite less, but bolt-connection structure also had fatigue problems. In this article we use three dimension finite element model of double plate joints connected by high strength friction type bolt, and analysis the node fatigue performance under different temperature and different interface handle methods.

2 Fatigue crack expansion and estimate fatigue life of structure

Fatigue phenomenon produced when the cyclic stress impact on the structure, caused by the subtle crack and steady state expansion, most components considered having the internal defects, having the propagation of the crack which eventually leads to fatigue damage. The maximum stress reached probably in t elastic deformation range in the entire stress object, so effective prediction of fatigue life is the key to guarantee the safety of component. Fracture mechanics applied to solve the problem of the fatigue crack propagation law made well. Etc of variable load in the fatigue crack propagation characteristics can be made by Pairs formula says:

$$\frac{da}{dN} = A \bullet (\Delta K)^n \qquad (\ )$$

a—Crack length,N—Cycle, ΔK —Stress intensity factor range, A, n material constants

From the formula, we can see the fatigue crack growth rate has a close relationship with the stress intensity factor of the materials. Stress intensity factor can be used to characterize crack toughness of the materials that the ability of gap materials to bear loads and plastic deformation under slow loading and linear elastic properties. Generally the critical stress intensity factor (K_C) is used to describe it. Generally speaking, the structure crack toughness, especially steel, increased with temperature, the destroyed stress intensity factor will increase the range and will increase the crack growth rate.

Another factor of fatigue crack propagation is stress concentration .The influence of the geometric not continuity will increase the nominal stress value of bearing structure parts. For fatigue crack with stress concentration expansion laws can be shown as (2) formula express:

$$\frac{da}{dN} = A \bullet (\Delta K_{eff})^n \qquad (2)$$

In the formula： A ， n ——material constant, $\Delta K_{eff} \propto K_t(a)\Delta\sigma\sqrt{a}$, $\Delta\sigma$ —Nominal stress range, a ——Crack length, $K_t(a)$ ——The stress concentration factor.

The strength problem of engineering structure , often need to estimation fatigue life of the dangerous parts in the structure. If knowing the material fatigue performance data, fatigue load spectrum, in principle we can estimation life by cumulative damage theory.

In this article, the circulation of the cumulative damage as circulation method, namely to crack length as the measure of the damage, the initial damage is described by initial crack length, the critical damage is described by critical crack length,the cumulative damage produced by each load cycles is described wit the crack propagation incremental produced by one load cycles. So damage accumulation formula can express into (3) type:

$$a_c = a_0 + \sum_{i=1}^{N_c} \Delta a_i = a_0 + \sum_{i=1}^{N_c} \Delta\left(\frac{da}{dN}\right)_i \qquad (3)$$

a_c—Critical crack length, a_0—Initial crack length, Δa_i—Crack propagation incremental, i — Cycle time, N_c — Cycle times reached the critical crack length.

Through the cycle by the expression of the total circulation damage theory we can see, the fatigue life of the component has a close relationship to the crack growth rate In practical engineering, the maximum length of fatigue crack propagation general is considered to be certain value, we usually think the maximum length of bolt connection is the pure distance between two bolt hole. So the crack's growth rate directly affects the fatigue life of components.

3 The finite element analysis

3.1 Calculation model size and material parameters

In this paper the calculation model is a double board lap connected by high strength bolt with tension load impacting on the axis of it. The joints has a top and a bottom board and one middle connection plate And thickness of joining board is 12 mm &Q345q steel, the connecting slab is 24 mm. the magnitude of bolt is 10.9 specification.&M20. Friction type aperture of the high strength bolts is 1.5~2mm more than bolt stem nominal diameter .During the calculation process bolt aperture takes 22 mm. In the process of computation, steel plate and bolts are assumed for isotropic elastic material, characteristic parameters of material see table 1. For material fatigue properties, there are many scientific research data as a reference, material fatigue properties in this paper using literature [5], [6] research data.

Table 1 Material parameter table

Member	$E(Ngmm^{-2})$	$\rho(kggn^{-3})$	μ	$f_y(Ngmm^{-2})$	$\alpha(^{o}C^{-1})$
Gusset plate	201	7850	0.3	420	1.4e-7
Connected plate	201	7850	0.3	420	1.4e-7
High-strength bolts	206	7850	0.3	942	1.4e-7

3.2 Unit selection and boundary conditions

Because screw, nut, washer are the same material, in order to reduce the contact surface analysis and unit number to increase the simulation efficiency ,the bolt model ignored the contact among screw, nut and washer ,built whole bolt. This paper we simulated high strength bolt and ignored the impact of tightening the nut on the bolt lever torque. The cell division of the finite element model is shown in Figure 1. The model is divided into seven entities part by regular hexahedron unit . the Meshing number is 1333 unit. Bolts and nuts adopted bound connection contact , reaction in the form of a confrontation between two binding contact area designated as the two roles are equal and opposing. Nut with connecting plate and connected to the backplane, connected to the base plate and connecting plate using frictional contact, this contact before the relative sliding can assume a certain level of shear stress in the two contact surfaces. Freedom at one end of the adapter plate, the intermediate connecting both DON stress is applied at one end of the freedom of the upper and lower splicing plates fixed constraints. The simulation consider different temperatures, temperature load is applied at the same time.

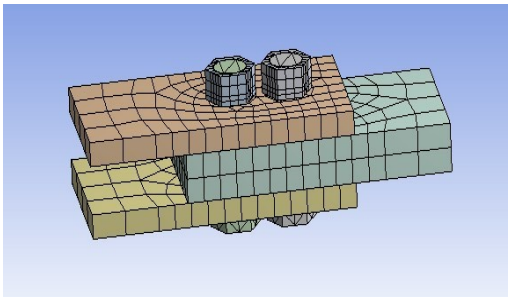

Fig 1 3D Single lap connecting slab model finite element grid partition

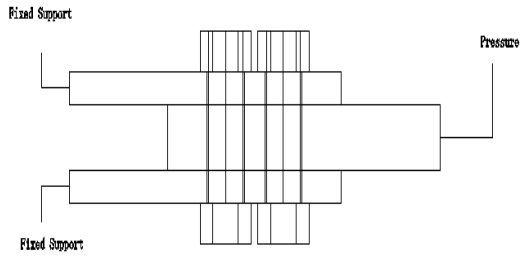

Fig 2 Boundary condition and the load

Different friction coefficients were chosen 0.35,0.40,0.55, many studies were studied for the effects of temperature, this taking into account the temperature difference between the bridge actual working environment, respectively, of -45 a working temperature of -25, 0, 25, 45, etc., fatigue performance simulation.

4 Results analysis

This paper the finite element model of the design life of the times, a major concern under constant stress amplitude fatigue damage D (design life and the useful life of the ratio), the expression can be expressed as (4). Safety factor S (in a given design life, the failure probability), the fatigue life of F (member fatigue failure when the number of load cycles).

$$D = \frac{L_A}{L_D} \qquad (4)$$

D —Fatigue damage, L_D —Fatigue design life, L_A —Available fatigue life.

As can be seen from Figure 3 to 5 leads to the difference in coefficient of the contact surface of the anti-friction, after the same number of times in the cycle as the anti-friction coefficient increases effective fatigue life is gradually reduced, resulting in increased fatigue damage due to the contact surface of the processing in different ways, The safety factor is gradually reduced.

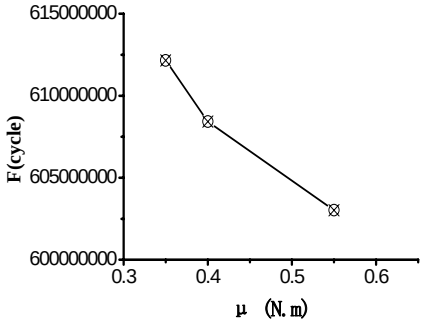

Fig 3 Fatigue life under different friction factor

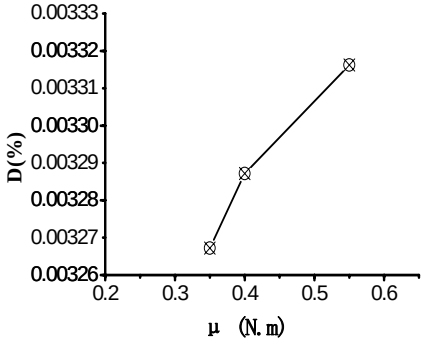

Fig 4 Fatigue damage under different friction coefficient

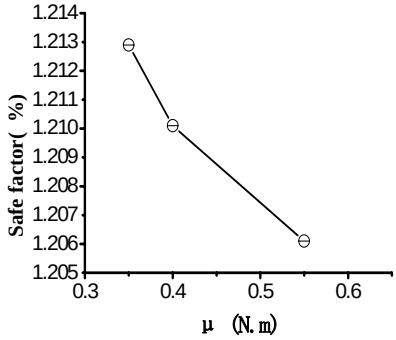

Fig 5 Safe factor with different friction factor

The different friction coefficients reflect the different processing side, the increase in friction coefficient can effectively reduce the relative slippage between the connecting plate, but so that the contact surface between the geometric discontinuity degree increases, resulting in a discontinuous area near the nominal stress value increases, The fatigue crack growth faster, reduce the safety factor of the structure[9].

As can be seen from Figure 6 to 8 with the temperature increasing the effective life of the same times in the cycle after the fatigue decreased, resulting in increase in the fatigue damage in the function of temperature, the safety factor of the structure decreases.

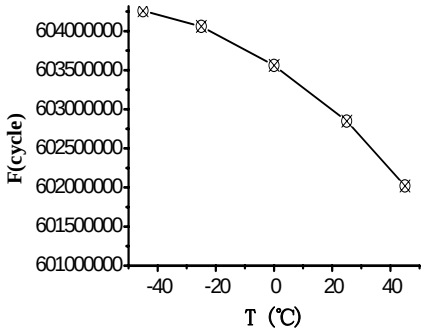

Fig 6 Fatigue life under different temperature

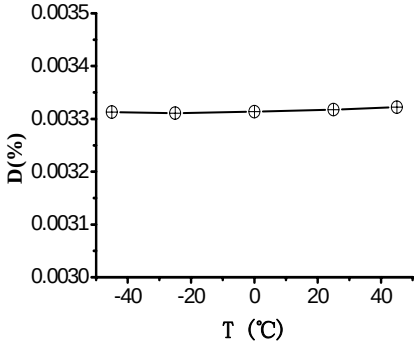

Fig 7 Fatigue damage under different temperature

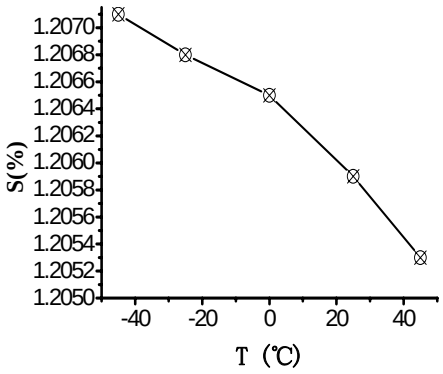

Fig 8 Safe factor with different temperature

5 Conclusion

By the theoretical analysis and finite element analysis, we can get about fatigue life and fatigue damage as well as the structure of the safety factor, the following conclusions:

(1) the effective life of the cycle the same number of times of fatigue due to the approach, in the contact surface between the structure of the different working environment varies, the contact surface more rough lower fatigue life, the lower the higher the fatigue life of the temperature of the working environment.

(2) of the contact surface of the node using a different approach and structure in a different working environment showed a different degree of damage. Contact surface more rough structure of fatigue damage is more severe, and the greater the higher the temperature of the work environment the structure of the fatigue damage.

(3) The different treatment of the contact surface causes the contact surface of the geometric discontinuity degree is increased, resulting in crack growth rate is accelerated to the structure of the lower safety coefficient; increase the safety of the structure with the elevated temperature of the fatigue crack growth rate coefficient is reduced.

Elastodynamic analysis of a finite crack at an arbitrary angle in the functionally graded material under in-plane impact loading

Sheng-Hu Ding*, Xing Li
School of Mathematics and Computer Science, Ningxia University, Yinchuan, 750021, China
*Corresponding author:Email:dshsjtu2009@163.com

Abstract The plane problem for a infinite functionally graded material containing a finite crack subjected to the dynamic impact loads is investigated. The crack arbitrarily oriented with respect to the direction of property gradient is considered. Based on the use of Laplace and Fourier integral transforms, formulation of the transient crack problem is reduced to solving a system of Cauchy-type singular integral equation in the Laplace transform domain. The crack-tip response in the physical domain is recovered via the inverse Laplace transform and the values of dynamic stress intensity factors are obtained as a function of time. The effects come from the crack orientation and the nonhomogeneous material parameter on the dynamic stress intensity factors are discussed graphically.

Keywords Functionally graded material, Arbitrarily oriented crack, Singular integral equations, Dynamic stress intensity factors

1. Introduction

With the application of functionally gradient materials in engineering, most of the current researches [1-5] on the fracture analysis of the FGMs interface have been devoted to the FGMs interlayer and the interface between the functionally graded material (FGM) coating and the homogeneous substrate. However, to date, only a few articles were devoted to the dynamic fracture mechanics of FGMs. Among these limited work, Atkinson [6] first studied the crack propagation in media with spatially varying elastic properties. Li and Wen [7] investigated the dynamic stress intensity factor of a cylindrical interface crack located between two coaxial dissimilar homogeneous cylinders that are bonded with a functionally graded interlayer and subjected to a torsional impact loading. The transient response of a functionally graded coating-substrate system with an internal or edge crack perpendicular to the interface [8] has been studied under an in-plane impact load. Recently, the dynamic fracture problem of the weak-discontinuous interface between a FGM coating and a FGM substrate have been studied by Li and his coauthors [9]. Ding and Li [10] studied the dynamic stress intensity factor of collinear crack-tip fields in bonded functionally graded finite strips.

For the arbitrarily oriented crack, Bogy [11] studied the problem of an arbitrarily oriented crack terminated at the bonded interface. For FGMs, till 1994 when Konda and Erdogan [12] considered the mixed mode crack problem in a nonhomogeneous elastic medium. Under the condition of antiplane shear impact, the corresponding dynamic stress intensity factors for a crack in a homogeneous material when a graded stip between dissimilar half-planes was evaluated by Choi [13].

The objective of the present paper is to provide a theoretical analysis of the dynamic behavior of a finite crack in the functionally graded material subjected to in-plane impact loading. To solve the proposed crack problem, the Fourier integral transform method is employed together with Laplace transform, leading to the derivation of a singular integral equation with a generalized Cauchy kernel. It is a simple and convenient method for solving this problem. In the numerical results, the values of mixed-mode stress intensity factors (SIFs) are provided as a function of crack orientation angle. The effects come from the crack orientation and the nonhomogeneous material parameter on the dynamic stress intensity factors (DSIFs) are discussed graphically.

2. Formulation of the problem

As shown in Fig.1, consider the plane problem of an arbitrarily oriented crack located in a functionally graded material. Two rectangular Cartesian coordinate systems, (x, y, z) and (x_1, y_1, z_1), are defined to describe the direction of the material gradient and crack orientation, respectively. The system (x_1, y_1, z_1) is obtained by rotating counterclockwise to the system (x, y, z) with angle θ .The crack is assumed to occupy the region $a \le x_1 \le b$, $y_1 = 0$, $|z_1| < \infty$. The shear modulus μ and mass density ρ in (x_1, y_1, z_1) and (x, y, z) coordinate can be written, respectively, as follows [12]

$$\mu(x_1, y_1) = \mu_0 \exp(\beta_1 x_1 + \beta_2 y_1), \quad \rho(x_1, y_1) = \rho_0 \exp(\beta_1 x_1 + \beta_2 y_1), \tag{1}$$

$$\mu(y) = \mu_0 \exp(\beta y), \quad \rho(y) = \rho_0 \exp(\beta y), \tag{2}$$

where β, μ_0 and ρ_0 are material constants, and $\beta_1 = \beta \sin(\theta), \beta_2 = \beta \cos(\theta)$.

The mixed boundary value problem shown in Fig.1 will be solved under the following conditions

$$\sigma_{y_1 y_1}(x_1, 0^+, t) = \sigma_{y_1 y_1}(x_1, 0^-, t), \quad \sigma_{x_1 y_1}(x_1, 0^+, t) = \sigma_{x_1 y_1}(x_1, 0^-, t), \quad -\infty < x_1 < \infty, \tag{3}$$

$$u(x_1, 0^+, t) = u(x_1, 0^-, t), \quad v(x_1, 0^+, t) = v(x_1, 0^-, t), \quad x_1 < a, \quad \text{or} \quad x_1 > b, \tag{4}$$

$$\sigma_{y_1 y_1}(x_1, 0^+, t) = \sigma_1 H(t), \quad a < x_1 < b, \tag{5}$$

$$\sigma_{x_1 y_1}(x_1, 0^+, t) = \sigma_2 H(t), \quad a < x_1 < b, \tag{6}$$

where $\sigma_1 H(t)$ and $\sigma_2 H(t)$ are the negative of dynamic normal stress and shear stress at the crack plane under external loading in an uncracked specimen. $H(t)$ is the Heaviside function of time t. When $t < 0$, $H(t) = 0$, and when $t \ge 0$, $H(t) = 1$.

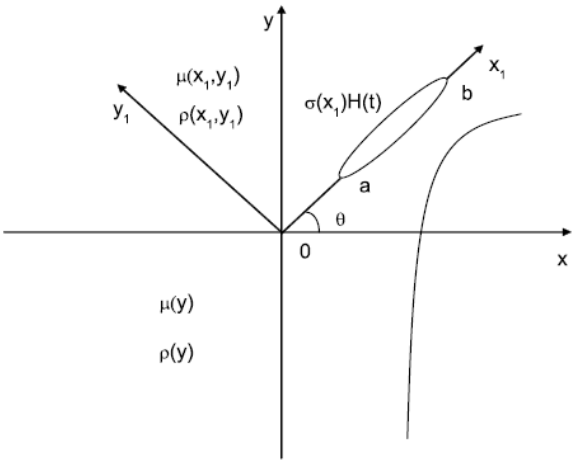

Figure 1. Geometry of the functionally graded material with an arbitrarily oriented crack

3. Method of solutions

The general expressions for displacements components can be written as

$$\hat{u}(x_1, y_1^+, p) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\left[G_1(\xi, p)C_1(\xi, p)e^{\lambda_1(\xi,p)y_1} + G_2(\xi, p)C_2(\xi, p)e^{\lambda_2(\xi,p)y_1}\right]e^{i\xi x_1}\mathrm{d}\xi,$$
$$\hat{v}(x_1, y_1^+, p) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\left[C_1(\xi, p)e^{\lambda_1(\xi,p)y_1} + C_2(\xi, p)e^{\lambda_2(\xi,p)y_1}\right]e^{i\xi x_1}\mathrm{d}\xi, \tag{7}$$

$$\hat{u}(x_1, y_1^-, p) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\left[G_3(\xi, p)C_3(\xi, p)e^{\lambda_3(\xi,p)y_1} + G_4(\xi, p)C_4(\xi, p)e^{\lambda_4(\xi,p)y_1}\right]e^{i\xi x_1}\mathrm{d}\xi,$$
$$\hat{v}(x_1, y_1^-, p) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\left[C_3(\xi, p)e^{\lambda_3(\xi,p)y_1} + C_4(\xi, p)e^{\lambda_4(\xi,p)y_1}\right]e^{i\xi x_1}\mathrm{d}\xi, \tag{8}$$

where $C_j(\xi, p)(j = 1-4)$ are unknown functions, and $\lambda_j(\xi, p)(j = 1-4)$ are the roots of the characteristic equation

$$\lambda^4 + \Omega_1\lambda^3 + \Omega_2\lambda^2 + \Omega_3\lambda + \Omega_4 = 0, \tag{9}$$

where

$$\Omega_1 = 2\beta_2, \quad \Omega_2 = -2\xi^2 + 2i\xi\beta_1 + {\beta_2}^2 + \frac{(\kappa-3){\beta_1}^2}{1+\kappa} - 2\frac{\kappa\rho_0 p^2}{(1+\kappa)\mu_0}, \tag{10}$$

$$\Omega_3 = -2\xi^2\beta_2 + \frac{8i\beta_2\beta_1\xi}{1+\kappa} - 2\frac{\beta_2\kappa\rho_0 p^2}{\mu_0(1+\kappa)}, \tag{11}$$

$$\Omega_4 = \xi^4 - 2i\xi^3\beta_1 - \xi^2{\beta_1}^2 + \frac{(3-\kappa){\beta_2}^2\xi^2}{1+\kappa} + 2\frac{\kappa\rho_0 p^2\xi^2}{\mu_0(1+\kappa)} - \frac{2i\beta_1\rho_0 p^2\kappa\xi}{\mu_0(1+\kappa)} + \frac{-{\rho_0}^2 p^4 + {\rho_0}^2 p^4\kappa}{(1+\kappa){\mu_0}^2}. \tag{12}$$

Here, $G_j(\xi, p)(j = 1-4)$ can be expressed as

$$G_j(\xi, p) = -\frac{[2i\xi + \beta_1(3-\kappa)]\lambda_j + i\xi\beta_2(\kappa-1)}{(\kappa-1)\lambda_j^2 + \beta_2(\kappa-1)\lambda_j + (i\xi\beta_1 - \xi^2)(\kappa+1) - \rho_0(\kappa-1)p^2/\mu_0}. \tag{13}$$

4. Singular integral equation

Now, we define the following new unknown functions

$$\hat{g}_1(x_1, p) = \frac{\partial}{\partial x_1}[\hat{u}(x_1, 0^+, p) - \hat{u}(x_1, 0^-, p)], \quad a < x_1 < b,$$
$$\hat{g}_2(x_1, p) = \frac{\partial}{\partial x_1}[\hat{v}(x_1, 0^+, p) - \hat{v}(x_1, 0^-, p)], \quad a < x_1 < b. \tag{14}$$

From (3-6), we obtain

$$\int_a^b \frac{\hat{g}_2(t, p)}{t - x_1}\mathrm{d}t + \int_a^b K_{11}(x_1, t, p)\hat{g}_1(t, p)\,\mathrm{d}t + \int_a^b K_{12}(x_1, t, p)\hat{g}_2(t, p)\,\mathrm{d}t = \frac{(\kappa+1)\sigma_1}{2\mu_0 p e^{\beta_1 x_1}},$$
$$\int_a^b \frac{\hat{g}_1(t, p)}{t - x_1}\mathrm{d}t + \int_a^b K_{21}(x_1, t, p)\hat{g}_1(t, p)\,\mathrm{d}t + \int_a^b K_{22}(x_1, t, p)\hat{g}_2(t, p)\,\mathrm{d}t = \frac{(\kappa+1)\sigma_2}{2\mu_0 p e^{\beta_1 x_1}}, \tag{15}$$

where

$$K_{11}(x_1, t, p) = \frac{\kappa+1}{4(\kappa-1)}\left\{\int_0^A (k_{11} + k_{11c})\cos[\xi(t - x_1)]d\xi + \int_A^\infty (k_{11} + k_{11c} - \frac{2(\kappa-1)\beta_2}{\xi(1+\kappa)})\cos[\xi(t - x_1)]d\xi\right.$$
$$\left. + \int_A^\infty \frac{2(\kappa-1)\beta_2}{\xi(1+\kappa)}\cos[\xi(t - x_1)]d\xi - \int_0^\infty (k_{11} - k_{11c})i\sin[\xi(t - x_1)]d\xi\right\}, \tag{16}$$

$$K_{12}(x_1,t,p)=\frac{\kappa+1}{4(\kappa-1)}\Big\{\int_0^A(k_{12}+k_{12c})\cos[\xi(t-x_1)]d\xi+\int_A^\infty(k_{12}+k_{12c}-\frac{2(\kappa-1)\beta_1}{\xi(1+\kappa)})\cos[\xi(t-x_1)]d\xi$$
$$+\int_A^\infty\frac{2(\kappa-1)\beta_1}{\xi(1+\kappa)}\cos[\xi(t-x_1)]d\xi-\int_0^\infty(k_{12}-k_{12c}-\frac{4i(\kappa-1)}{\kappa+1})i\sin[\xi(t-x_1)]d\xi\Big\},\tag{17}$$

$$K_{21}(x_1,t,p)=\frac{\kappa+1}{4}\Big\{\int_0^A(k_{21}+k_{21c})\cos[\xi(t-x_1)]d\xi+\int_A^\infty(k_{21}+k_{21c}-\frac{2\beta_1}{\xi(1+\kappa)})\cos[\xi(t-x_1)]d\xi$$
$$+\int_A^\infty\frac{2\beta_1}{\xi(1+\kappa)}\cos[\xi(t-x_1)]d\xi-\int_0^\infty(k_{21}-k_{21c}-\frac{4i)}{\kappa+1})i\sin[\xi(t-x_1)]d\xi\Big\},\tag{18}$$

$$K_{22}(x_1,t,p)=\frac{\kappa+1}{4}\Big\{\int_0^A(k_{22}+k_{22c})\cos[\xi(t-x_1)]d\xi+\int_A^\infty(k_{22}+k_{22c}+\frac{2\beta_2}{\xi(1+\kappa)})\cos[\xi(t-x_1)]d\xi$$
$$-\int_A^\infty\frac{2\beta_2}{\xi(1+\kappa)}\cos[\xi(t-x_1)]d\xi-\int_0^\infty(k_{22}-k_{22c})i\sin[\xi(t-x_1)]d\xi\Big\},\tag{19}$$

$$k_{11}=\frac{i}{\xi}\frac{E_1J_4-E_2J_3}{J_3J_2-J_1J_4},\quad k_{12}=\frac{i}{\xi}\frac{E_2J_1-E_1J_2}{J_3J_2-J_1J_4},\tag{20}$$

$$k_{21}=\frac{i}{\xi}\frac{F_1J_4-F_2J_3}{J_3J_2-J_1J_4},\quad k_{22}=\frac{i}{\xi}\frac{F_2J_1-F_1J_2}{J_3J_2-J_1J_4},\tag{21}$$

$$J_1=G_1+\frac{G_3\left(E_4F_1-E_1F_4\right)}{E_3F_4-F_3E_4}-\frac{G_4\left(E_3F_1-F_3E_1\right)}{E_3F_4-F_3E_4},\tag{22}$$

$$J_2=G_2-\frac{G_4\left(E_3F_2-F_3E_2\right)}{E_3F_4-F_3E_4}+\frac{G_3\left(E_4F_2-E_2F_4\right)}{E_3F_4-F_3E_4},\tag{23}$$

$$J_3=1+\frac{E_4F_1-E_1F_4}{E_3F_4-F_3E_4}-\frac{E_3F_1-F_3E_1}{E_3F_4-F_3E_4},\tag{24}$$

$$J_4=1+\frac{E_4F_2-E_2F_4}{E_3F_4-F_3E_4}-\frac{E_3F_2-F_3E_2}{E_3F_4-F_3E_4}.\tag{25}$$

and $k_{ijc}(i,j=1,2)$ are the complex conjugates of k_{ij}.

The solutions of the singular integral equations Eq.(15) are [14]

$$\hat{g}_1(u,p)=G_1(u,p)/\sqrt{1-u^2},\quad \hat{g}_2(u,p)=G_2(u,p)/\sqrt{1-u^2}.\tag{26}$$

The stress intensity factors in Laplace domain can be defined as

$$\hat{K}_I(a,p)=\lim_{x_1\to a}\sqrt{2(a-x_1)}\sigma_{y_1y_1}(x_1,0)=\frac{2\mu_0e^{\beta_1a}}{\kappa+1}\sqrt{(b-a)/2}G_2(-1,p),\tag{27}$$

$$\hat{K}_I(b,p)=\lim_{x_1\to b}\sqrt{2(x_1-b)}\sigma_{y_1y_1}(x_1,0)=-\frac{2\mu_0e^{\beta_1b}}{\kappa+1}\sqrt{(b-a)/2}G_2(1,p),\tag{28}$$

$$\hat{K}_{II}(a,p)=\lim_{x_1\to a}\sqrt{2(a-x_1)}\sigma_{x_1y_1}(x_1,0)=\frac{2\mu_0e^{\beta_1a}}{\kappa+1}\sqrt{(b-a)/2}G_1(-1,p),\tag{29}$$

$$\hat{K}_{II}(b,p)=\lim_{x_1\to b}\sqrt{2(x_1-b)}\sigma_{x_1y_1}(x_1,0)=-\frac{2\mu_0e^{\beta_1b}}{\kappa+1}\sqrt{(b-a)/2}G_1(1,p).\tag{30}$$

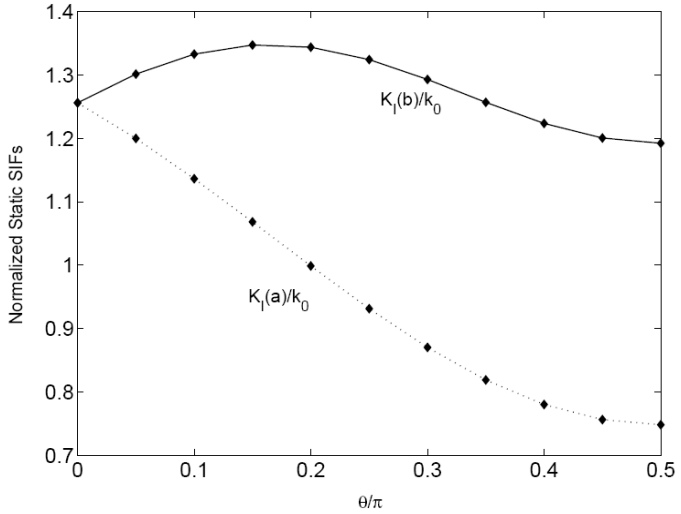

Figure 2. The variation of static SIFs with crack orientation angle θ under crack surface pressure ($\beta a_0 = 1.0$)

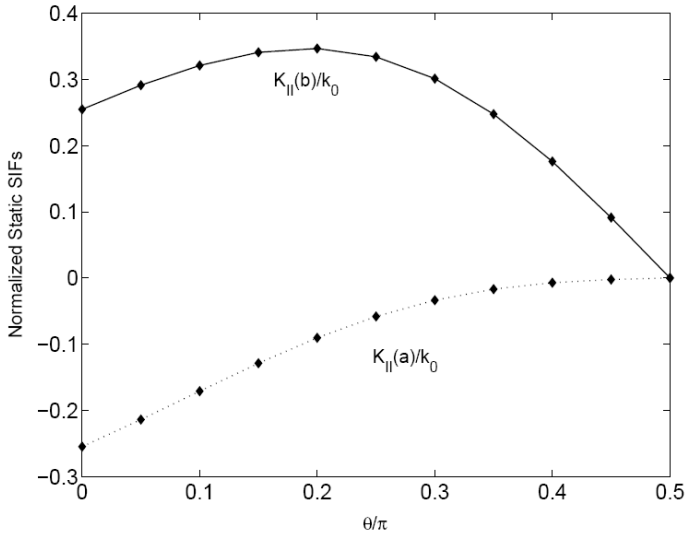

Figure 3. The variation of static SIFs with crack orientation angle θ under crack surface pressure ($\beta a_0 = 1.0$)

The stress intensity factor in the time domain can be obtained from Eqs.(27-30) by using Laplace numerical inversion by Miller and Guy [15].

5. Numerical results and discussion

The following analysis will be conducted under the plane strain state. The surface of the crack loaded by $\sigma_{10}H(t)$ and $\sigma_{20}H(t)$ respectively, where σ_{10} and σ_{20} are constant tractions. Poisson's ratio is taken as $\nu = 0.3$. The dynamic stress intensity factors are normalized by $k_0 = \sigma_{10}\sqrt{a_0}$ and $k = \sigma_{20}\sqrt{a_0}$ for different loads respectively, where $a_0 = (b-a)/2$. $c_2 = \sqrt{\mu_0 / \rho_0}$ is the shear wave velocity, $c_2 t / a_0$ is the non-dimensional time.

Before the analysis, the validity of the analytical solution must be verified. First, we restrict our attention to the crack problem in FGM under static loading. The corresponding static problem was

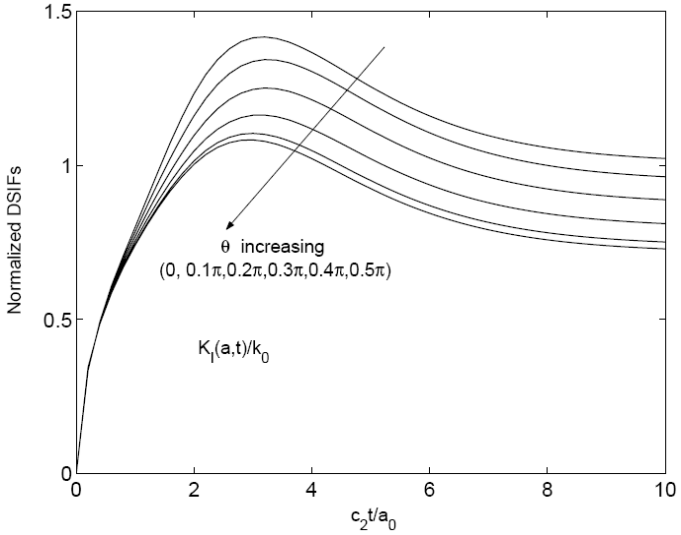

Figure 4. The variation of DSIFs with crack orientation angle θ under crack surface pressure ($\beta a_0 = 0.5$)

studied in [12]. Figs. 2-3 show the variations of the normalized SIFs with the angle θ under the uniform normal traction. These results are very similar to Konda's results [12].

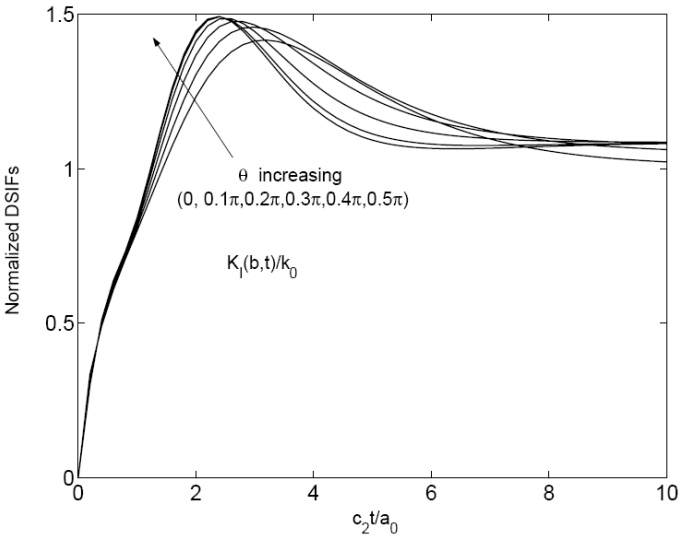

Figure 5. The variation of DSIFs with crack orientation angle θ under crack surface pressure ($\beta a_0 = 0.5$)

Figs.4-5 show the influence of θ on the DSIFs. It can be found that the peak value of $K_I(a,t)/k_0$ decreases with an increase of θ regardless of the value of βa_0. For $\beta a_0 = 0.5$, the peak value of $K_I(b,t)/k_0$ increases with the increasing of θ. And meanwhile, the emergence of time for the DSIFs gradually delays with the decreasing of θ.

Figs.6-7 depict the variations of the normalized mode II DSIFs with the crack direction angle under

uniform shear stress when $\beta a_0 = 0.5$. It can be found that the normalized DSIFs increases quickly with time up to the peak, and then the oscillations gradually decay until corresponding steady-state value. The peak time of DSIFs appears more or less for $c_2 t / a_{01} = 1.5$, and then exhibit a slight oscillation after reaching a peak. The peak values of $K_{II}(a,t)/k_0$ and $K_{II}(b,t)/k_0$ increase or decrease with an decrease of θ regardless of the value of βa_0.

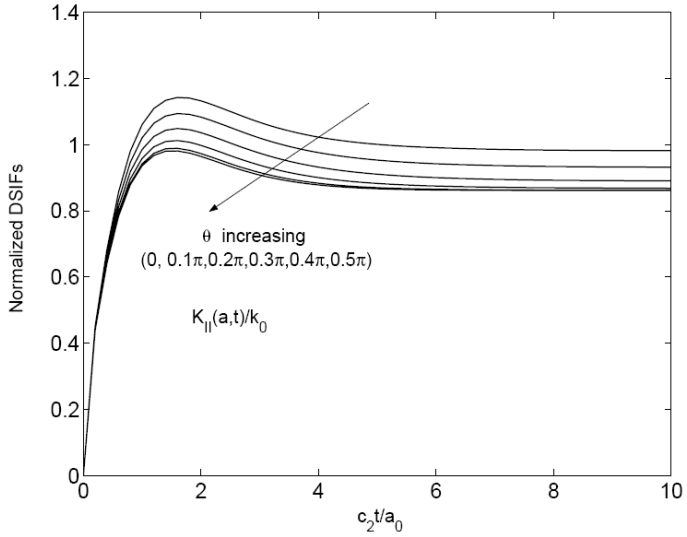

Figure 6. The influence of crack orientation angle θ on the DSIFs under crack surface shear ($\beta a_0 = 0.5$)

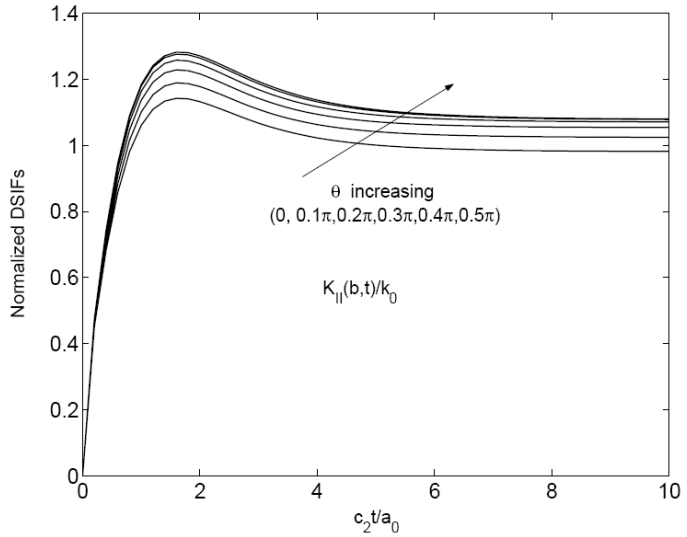

Figure 7. The influence of crack orientation angle θ on the DSIFs under crack surface shear ($\beta a_0 = 0.5$)

Based on the premise that the peak dynamic stress intensity factors may induce brittle fracture, such peaks are plotted in the sequel as a function of the crack orientation angle θ in Figs. 8-9. For $\beta a_0 = 0.5$, as shown in Fig.8, the peak value of the mode I DSIFs in crack tip a increases with an decrease of θ, while the peak value of the mode I DSIFs in crack tip b increases with an increase of θ. For $\beta a_0 = 1.0$ or 1.5, the peak value of the mode I DSIFs in crack tip b increases with θ, going through the maxima at some angle, and then begin to decrease at the enlarged crack obliquity,

e.g., $\theta = 0.1\pi$ or 0.15π. The peak value of the mode I DSIFs in crack tip a decreases with an increase of θ. Of interest in the figure is that for the crack angle more than 0.4π, the variation of θ appears to hardly affect the peak stress intensification at the crack tips. From Fig.9, it can be seen that the peak values of crack tips a and b decrease or increase with an increase of θ.

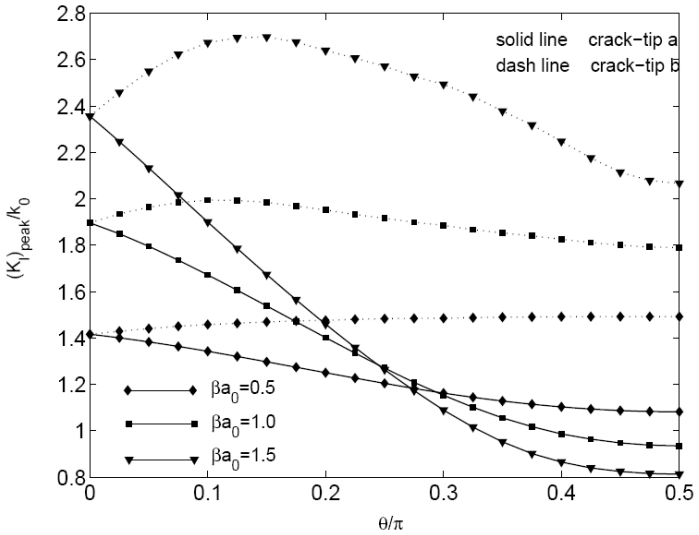

Figure 8. The influence of crack orientation angle θ on the peak values of the DSIFs under crack surface pressure

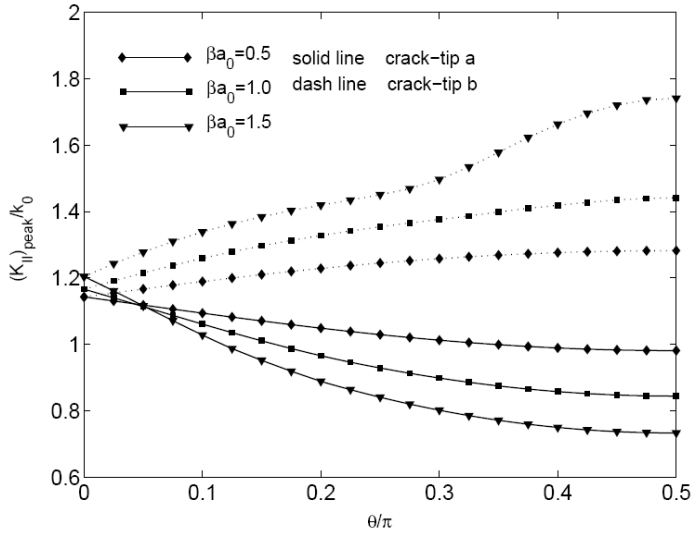

Figure 9. The influence of crack orientation angle θ on the peak values of the DSIFs under crack surface shear

6. Conclusion

The elastodynamic response of an arbitrarily oriented crack in functionally graded materials has been investigated with the aid of the basic plane elasticity equations. The mixed-mode DSIFs evaluated for an arbitrarily oriented crack were shown to be strongly affected by the geometric and loading configuration of the media in conjunction with the material gradations in the

nonhomogeneous constituent. The integral transform techniques were employed in conjunction with the coordinate transformations of relevant field variables and a resulting Cauchy-type singular integral equation was solved in the Laplace transform domain. Following the inversion of the Laplace transforms, the evolution of the dynamic mixed-mode DSIFs stress intensity factors with time was evaluated.

ABSTRACT: Present work examines theoretically the relationship between micro-cracks and failure criteria for fracture modes I and II in coating films. TiN films deposited by magnetron sputtering on substrates of steel or aluminum, with homogeneous (HMG) or functionally graded (FGM) structure were considered. The stress field in the film and substrate was generated from the Hertzian normal pressure and tangential force due to the friction from loading displacement at constant sliding velocity on the film surface. At the interface of the film and substrate, there are substantial differences among material properties. These differences, together with the film deposition conditions, can induce the formation of imperfections in the film condensation front, thus, becoming a region of potential micro-cracks formation. Stress-intensity factors at crack tip and a fracture criterion for combined rupture modes I and II in function of TiN film thickness, structure type (FGM x HMG), friction coefficient μ and substrate, were analyzed. A variance study by ANOVA has indicated that for both fracture failure mode I and II, the material factors, substrate and film structure, have higher significance than other factors analyzed. Film thickness is a significant factor, but not at the same level as material factors. Aluminium substrate with HMG coating has a higher risk level than steel substrate. FGM films reduce drastically the fracture failure risk mode I and II, when compared with HMG films,for both substrate. On FGM films, and HMG thin films over steel substrate, the mode II is more importante than the mode I, although the values are not high. For other cases, the mode I is more significative. The friction, altough is a important fator, has not the same significance level when compared with the others investigated.

Key-words: FGM, micro-cracks, TiN film, fracture criterion, combined fracture mode I and II.

1. Introduction

The use of coating films is based on the idea to combine materials with different properties, in order to obtain the benefit of both constituents. However, such differences lead to a non-continuous mechanical behavior at the interface film and substrate. To reduce this functional discontinuity, materials were developed whose properties vary gradually through the thickness direction and are called Functionally Gradade Materials (FGM). One consequence of this properties discontinuity is delamination of the film at the interface with the substrate due to load applications. This behavior depends on load factors, geometry, surface roughness and material of the film and substrate. The variation of the properties in films FGM can follow linear or exponential laws, making the transition smoother interface than the homogeneous films. Several works have been presented in this area. Shodja [1] presented a study with analytical solutions for the temperature field and stress of a tribological pair under thermomechanical loading. Odorczyk [2] presented a study with numerical solutions for the same case. The tribological pair study consists of a displacement normal force over the surface of a TiN film HMG or FGM deposited on a steel or aluminum substrate. The stress intensity factors KI and KII were analyzed in relation to the main normal and shear stresses at the interface. By analysis of variance, it was evaluated the significance of the factors friction, thickness, substrate material and film strucutre on a mixed KI/KIc and KII/KIIc criteria.

2. Methods

Titanium Nitride (TiN) is typically used in coating films due to their high elastic modulus E, low thermal conductivity *k* and low coefficient of thermal expansion α compared to steel or aluminum substrates. A normal force is applied in the form of Hertzian pressure that combined with the friction and displacement between the surfaces, generates a normal and a tangential mechanical and thermal loading, shown in Fig 1.

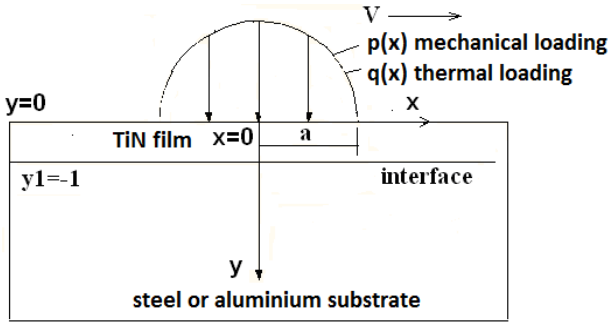

Figure 1. Tribological pair under thermomechanical loading.

The film coating was considered isotropic, following the laws of functional gradation according to Eqs (1) and (2)

$$P_c(y_c) = P_0 e^{\beta y^M} \tag{1}$$

$$\beta = \frac{1}{y_s^M} \ln \frac{k_s}{k_0} \tag{2}$$

where P is the property studied (α, k E), the index M = 0 is for HMG and M = 1 for FGM film structure, the subscripts s, c and 0 respectively identify the values at the interface between the film and the substrate, within the film and at the surface of the coating film and y is the direction across the film. The properties of the substrates, Poisson's ratio and the thermal diffusivity of the film coating were considered constant. It is assumed that the substrate is an elastic solid homogeneous, isotropic and dimensions enough large to be considered as infinite. The normal and tangential Hertzian pressure due to mechanical loading and the friction between the sliding surfaces generates normal and shear stress and heat. The normal pressure loads p(x), shear $p_{tan}(x)$ and heat flux are defined by Eqs (3) to (5)

$$p(x) = p_0 \sqrt{(1-x^2)} H(1-|x|) \tag{3}$$

$$p_{tan}(x) = p(x)\mu \tag{4}$$

$$q_p(x) = p(x)v\mu \tag{5}$$

where p_0 is the load at x = 0, H is the Heaviside function, μ is the film friction coefficient, q_p is the heat flux generated at the film surface and v is the load displacement velocity on x direction.
The flexural tensile and shear stress at film and substrate interface, responsible for failure adhesion, are defined by Eqs (6) and (7)

$$\tau_{xy(adim)} = \frac{\tau_{xy(max)}}{p_0} \tag{6}$$

$$\sigma_{xx(adim)} = \frac{\sigma_{xx(max)}}{p_0} \tag{7}$$

where $\tau_{xy(adim)}$ is the maximum shear stress normalized, $\tau_{xy(max)}$ is the maximum shear stress, $\sigma_{xx(adim)}$ is the maximum flexural stress normalized, $\sigma_{xx(max)}$ is the maximum normal stress, all at the interface. The stresses do not occur at the same point at the interface.

A variance study ANOVA presented by Odorczyk [4] indicated film thickness, friction coefficient and its interaction are factors of high significance for shear stresses. For tensile flexural stresses, material of substrate, thickness and structure and its interactions are highly significant. The velocity is not significant for both stress cases.

From the stresses calculated in Eqs.(6) and (7), were calculated the principal stresses, tensile flexural and shear for the same points. With the principal stresses, assuming the greatest stress state at the interface, were calculated values for stress intensity factors KI and KII for brittle fracture failure modes I and II.

Considering that a crack can propagate in any direction, the KI and KII parameters for the principal stress directions were investigated. It was considered a crack length of about 0.4 film thickness. The stress intensity factors KI and KII were obtained by Eq. (8)

$$\begin{Bmatrix} K_I \\ K_{II} \end{Bmatrix} = \begin{Bmatrix} \sigma \\ \tau \end{Bmatrix} \sqrt{\pi a_t} \tag{8}$$

It was adopted a mixed fracture criterion [6] considering KI and KII according to Eqs (9) and (10)

$$\left(\frac{K_I}{K_{IC}}\right)^m + \lambda \left(\frac{K_{II}}{K_{IC}}\right)^n = 1 \tag{9}$$

$$\lambda = \left(\frac{K_{IC}}{K_{IIC}}\right)^n \tag{10}$$

assuming m = n = 2.

Also, it were considered the values of fracture toughness KIc = 1 and KIIc = 2, since the present study investigates just the competition between modes of fracture I and II.

It were obtained KI and KII values for combinations of thickness, μ, type of substrate (steel and aluminum), and TiN film structure FGM x MGF. A variance study ANOVA was performed to investigate the influence of the parameters mentioned on the mixed fracture criteria shown in Eq. (9), to the main directions normal and shear. The experiment structure is shown in Table (1).

Table 1. Influence of parameters on KI/KIc and KII/KIIc.

Figure 3. ANOVA results for KII/KIIc

The results on Fig.(2) and (3) shows that the film structure (FGM x HMG) and his interactions, followed by the substrate material, are the most important factors to prevent fracture failure, on mode I and II. The film thickness is a significant factor, but lower (about 10 times) than the material factors significance. The friction is not significant for mode I and II. On Fig. (4), it is possible to compare the significance of the factors and their interactions.

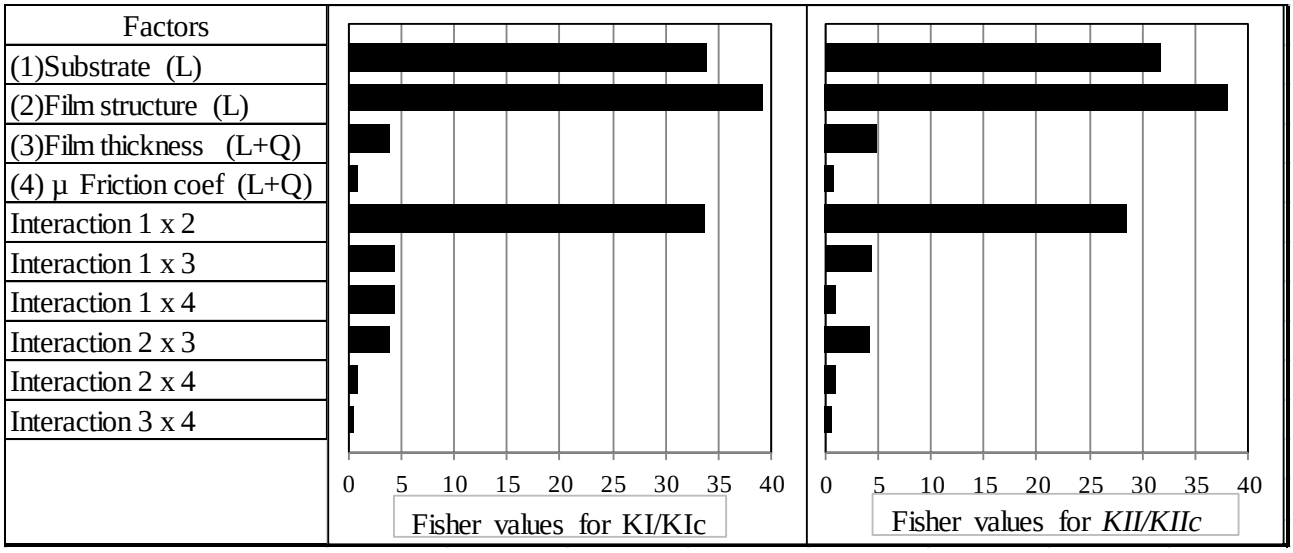

Figura 4. Fisher distribution values of influence factors on KI/KIc and KII/KIIc modes.

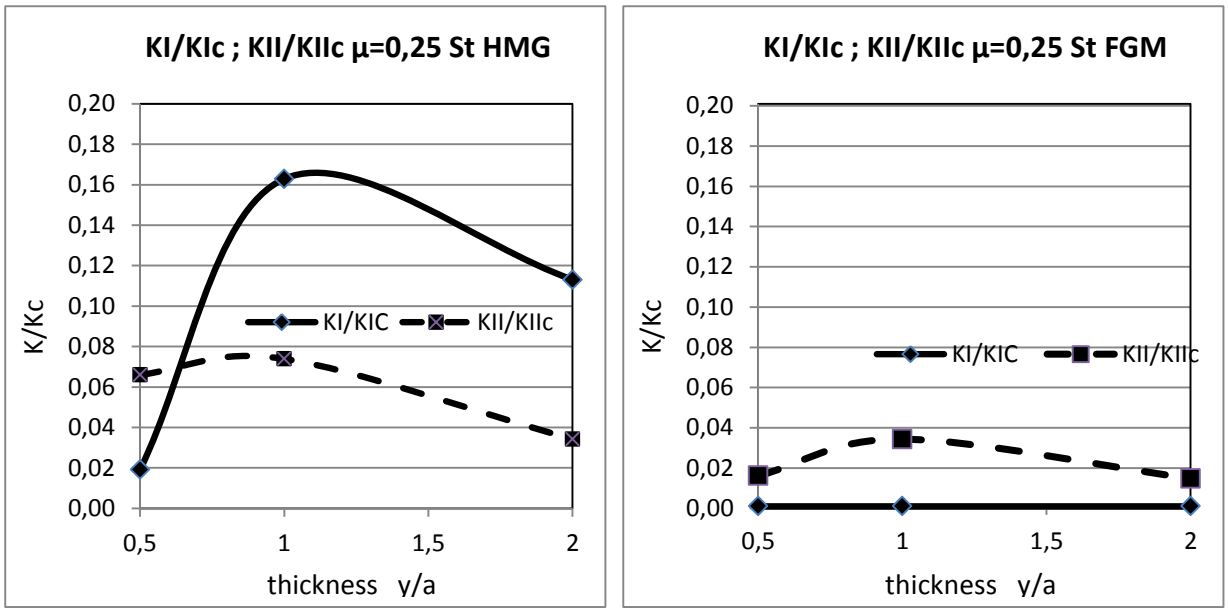
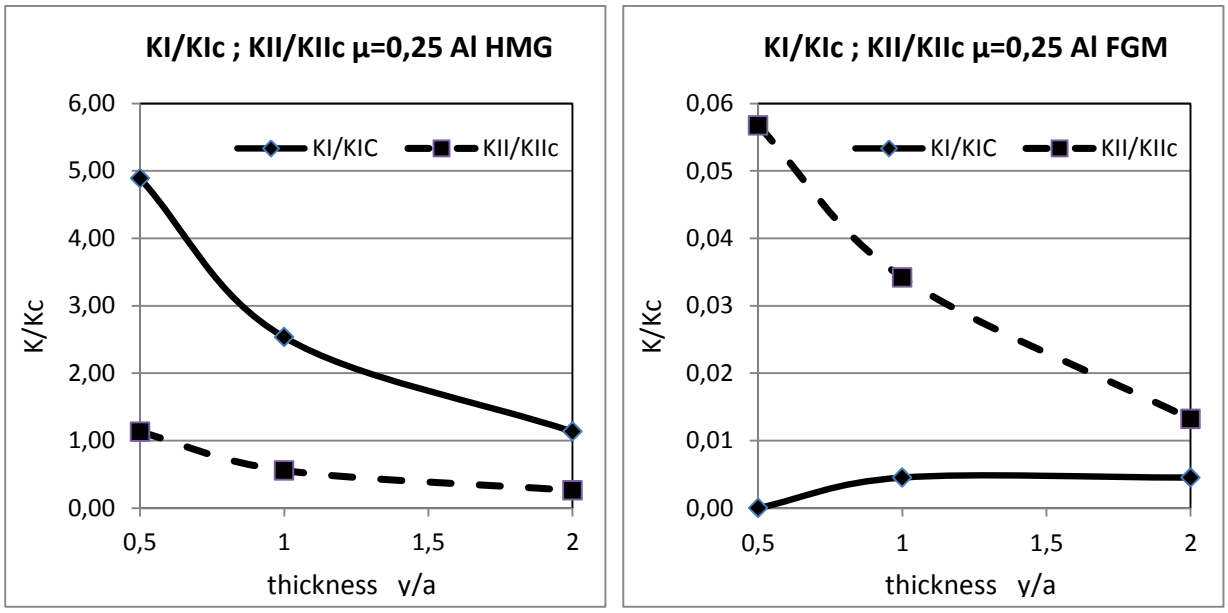
The results of KI/KIc and KII/KIIc obtained by Eq.(9) corresponding to the principal directions, for μ=0.25, for film thickness thin, medium, large, for TiN film FGM and HMG over steel and aluminium substrate, are shown in Fig. (5a), (5b), (6a), (6b).



(a) (b)

Figure 5. KI/KIc and KII/KIIc for μ=0.25 Steel, (a) TiN HMG, (b) TiN FGM.

In Fig. (5) is possible to see that for TiN film HMG over steel substrate, the fracture mode I is more important than the mode II, except for thin films, although these values for thin films are not high when compared with other film thickness. For TiN film FGM over steel substrate, the mode of fracture II is more important than the mode I for all thickness, although the values are not high when compared with TiN HMG steel cases.



(a) (b)

Figure 6. KI/KIc and KII/KIIc for μ=0.25 and aluminium: (a) TiN HMG, (b) TiN FGM.

In Fig. (6) is possible to see that for TiN film HMG over aluminium substrate, the fracture mode I is more importante than the mode II and the values are significativelly higher compared with TiN steel cases. For TiN film FGM over aluminium substrate, the mode of fracture II is more important than the mode I, although the values are not high compared with TiN HMG Al and similar to TiN FGM steel cases.

4. Conclusions

From the theoretical analysis using ANOVA variance study to investigate the influence of factors such as friction, thickness, substrate material and film structure and the relationship between micro-cracks and failure criteria for fracture modes I and II in coating films, the following conclusions can be drawn.

For both fracture failure modes I and II, the material factors, substrate and film structure, have higher significance than other factors analyzed. Film thickness is a significant factor, but not at the same level as material factors. Aluminium substrate with homogeneous structure, HMG, coating has a higher risk level than steel substrate. The functionally graded structure, FGM, films reduce drastically the fracture failure risk mode I and II, when compared with HMG films, for both substrate. On FGM films, and HMG thin films over steel substrate, the mode II is more important than the mode I, although the values are not high. For other cases, the mode I is more significant. The friction, altough is an important factor, has not the same significance level when compared with the others investigated.

Abstract This work investigates the effects of cooling rate on the thermal fracture behavior of a functionally graded plate (FGM plate) with a periodic array of parallel edge cracks of alternating lengths. The thermal properties of the FGM are assumed to be continuous and piecewise differentiable functions of the coordinate in the plate thickness direction. A linear ramp function describes the rate of boundary temperature variation at the surfaces of the FGM plate. The integral equation method is used to analyze the thermal stress intensity factors (TSIFs) at the crack tips. The asymptotic solutions of TSIF are obtained using a closed form, short time solution of temperature field in the FGM plate. The effects of cooling rate and crack length ratio on the TSIF are examined using an Al_2O_3/Si_3N_4 FGM. Numerical results show that for given material gradation profile and crack morphology parameters, a lower cooling rate leads to a lower peak TSIF. For a given cooling rate, an appropriate material gradation profile reduces peak TSIFs. Finally, the variations of the TISF for the long and short cracks with the cooling rate and crack length ratio exhibit a complex pattern due to the interactions between the long and short cracks.

Keywords functionally graded material, heat conduction, cooling rate, thermal stress intensity factor, periodic cracks

1. Introduction

Functionally graded ceramics suffer multiple surface cracking when subjected to thermal shocks [1, 2]. These surface cracks greatly influence the thermal fracture behavior of the materials. FGMs with multiple surface cracks under thermal loading were considered by Rangaraj and Kokini [3], Han and Wang [4], and Jin and Feng [5]. Jin and Feng [6] further investigated thermal shock residual strength of an FGM with multiple surface cracks. The existing analytical and computational studies on multiple surface cracking in FGMs have assumed that the cracks have equal length. However, FGMs when subjected to thermal shocks may develop multiple cracks of unequal lengths as in the case of monolithic ceramics. An improved model is a periodic array of parallel cracks with alternating lengths. For monolithic ceramics, Nemat-Nasser et al. [7] considered a periodic array of parallel cracks with alternating lengths in a half plane and studied the stability problem of crack growth. Using a boundary element method and an energy release fracture criterion, Bahr et al. [8] studied the same crack geometry in a plate of finite thickness. Jin and Feng [9] considered an array of parallel edge cracks with alternating lengths in an elastic strip subjected to a thermal shock and presented detailed results on the effects of crack length ratio and crack spacing on the thermal stress intensity factors (TSIFs). For functionally graded ceramics, Feng and Jin [10, 11] investigated the effects of crack length ratio on the TSIFs at the tips of long and short cracks and thermal shock residual strength using a singular integral equation technique.

All of the analytical studies above assume that the FGM specimens are subjected to a sudden cooling condition at their surfaces, i.e., the boundary temperature immediately attains the ambient temperature. In practical applications, however, the cooling rates on the material surfaces are finite.

The objective of this work is to investigate the effects of cooling rate on the TSIFs for an array of parallel edge cracks with alternating lengths in a functionally graded ceramic plate. A linear ramp function is used to describe the rate of boundary temperature variations at the surfaces of the FGM plate. The remainder of the paper is organized as follows. Section 2 reviews a closed-form, asymptotic solution of temperature field for short times and the thermal stresses in the periodically cracked FGM plate. Section 3 describes an integral equation method to obtain the TSIFs at the tips of long and short cracks. Section 4 presents numerical results of TSIFs for an Al_2O_3/Si_3N_4 FGM. Section 5 provides concluding remarks.

2. Temperature and Thermal Stress Fields

This section reviews the temperature and thermal stress solutions for a long FGM plate with an array of parallel edge cracks with alternating lengths as shown in Fig. 1, where a_1 is the length of the long cracks, a_2 is the length of the short cracks, h is the crack spacing, and b is the plate thickness. The thermal properties of the FGM plate are arbitrarily graded in the thickness direction (x-direction). Initially the temperature of the plate is a constant T_0 which can be assumed to be zero without loss of generality. The temperature then gradually changes to $-T_a$ and $-T_b$ at the surfaces $x = 0$ and $x = b$ of the plate, respectively. We use a linear ramp function to describe the variations of the boundary temperatures. The initial and boundary conditions for the heat conduction problem are thus

$$T(x,0) = 0, \qquad 0 \le x \le b, \tag{1}$$

$$T(0,t) = \begin{cases} -T_a\left(t/t_a\right), & 0 \le t \le t_a \\ -T_a, & t > t_a \end{cases}, \tag{2a}$$

$$T(b,t) = \begin{cases} -T_b\left(t/t_b\right), & 0 \le t \le t_b \\ -T_b, & t > t_b \end{cases}, \tag{2b}$$

where $T = T(x, t)$ is the temperature, t is time, and t_a and t_b are two temporal parameters describing the rates of temperature variation (cooling/heating rates) at the plate surfaces. The one-dimensional heat conduction in the plate is governed by the following basic equation

$$\frac{\partial}{\partial x}\left[k(x)\frac{\partial T}{\partial x}\right] = \rho(x)c(x)\frac{\partial T}{\partial t}, \tag{3}$$

where $k(x)$ is the thermal conductivity, $\rho(x)$ the mass density, and $c(x)$ the specific heat.

Jin [12] obtained a closed form solution of the temperature field for short times in the FGM plate with continuous and piecewise differentiable properties as follows

$$\frac{T(x,\tau)}{T_a} = T^{(1)}(x,\tau) + \left(\frac{T_b}{T_a}\right) T^{(2)}(x,\tau), \tag{4}$$

where $T^{(1)}(x,\tau)$ and $T^{(2)}(x,\tau)$ are given by

$$\begin{aligned} T^{(1)}(x,\tau) = &-\frac{1}{\tau_a}\left[\frac{\rho_0 c_0 k_0}{\rho(x)c(x)k(x)}\right]^{1/4} \\ &\times\left\{\left[\tau + \frac{1}{2}\Omega_1^2(x)\right] erfc\left(\frac{\Omega_1(x)}{2\sqrt{\tau}}\right) - \frac{\Omega_1(x)}{\sqrt{\pi}}\sqrt{\tau}\exp\left[-\frac{\Omega_1^2(x)}{4\tau}\right]\right\}, \quad \tau \le \tau_a, \end{aligned} \tag{5a}$$

$$T^{(1)}(x,\tau)=-\frac{1}{\tau_a}\left[\frac{\rho_0 c_0 k_0}{\rho(x)c(x)k(x)}\right]^{1/4}\left\{\left[\tau+\frac{1}{2}\Omega_1^2(x)\right]erfc\left(\frac{\Omega_1(x)}{2\sqrt{\tau}}\right)-\frac{\Omega_1(x)}{\sqrt{\pi}}\sqrt{\tau}\exp\left[-\frac{\Omega_1^2(x)}{4\tau}\right]\right.$$
$$\left.-\left[\tau-\tau_a+\frac{1}{2}\Omega_1^2(x)\right]erfc\left(\frac{\Omega_1(x)}{2\sqrt{\tau-\tau_a}}\right)+\frac{\Omega_1(x)}{\sqrt{\pi}}\sqrt{\tau-\tau_a}\exp\left[-\frac{\Omega_1^2(x)}{4(\tau-\tau_a)}\right]\right\},\quad \tau>\tau_a, \tag{5b}$$

and

$$T^{(2)}(x,\tau)=-\frac{1}{\tau_b}\left[\frac{\rho(b)c(b)k(b)}{\rho(x)c(x)k(x)}\right]^{1/4}$$
$$\times\left\{\left[\tau+\frac{1}{2}\Omega_2^2(x)\right]erfc\left(\frac{\Omega_2(x)}{2\sqrt{\tau}}\right)-\frac{\Omega_2(x)}{\sqrt{\pi}}\sqrt{\tau}\exp\left[-\frac{\Omega_2^2(x)}{4\tau}\right]\right\},\quad \tau\le\tau_b, \tag{6a}$$

$$T^{(2)}(x,\tau)=-\frac{1}{\tau_b}\left[\frac{\rho(b)c(b)k(b)}{\rho(x)c(x)k(x)}\right]^{1/4}\left\{\left[\tau+\frac{1}{2}\Omega_2(x)\right]erfc\left(\frac{\Omega_2(x)}{2\sqrt{\tau}}\right)-\frac{\Omega_2(x)}{\sqrt{\pi}}\sqrt{\tau}\exp\left[-\frac{\Omega_2^2(x)}{4\tau}\right]\right.$$
$$\left.-\left[\tau-\tau_b+\frac{1}{2}\Omega_2^2(x)\right]erfc\left(\frac{\Omega_2(x)}{2\sqrt{\tau-\tau_b}}\right)+\frac{\Omega_2(x)}{\sqrt{\pi}}\sqrt{\tau-\tau_b}\exp\left[-\frac{\Omega_2^2(x)}{4(\tau-\tau_b)}\right]\right\},\quad \tau>\tau_b, \tag{6b}$$

respectively, and τ, τ_a and τ_b are the nondimensional times defined by

$$\tau=t\kappa_0/b^2,\qquad \tau_a=t_a\kappa_0/b^2,\qquad \tau_b=t_b\kappa_0/b^2, \tag{7}$$

in which $\kappa_0=\kappa(0)$ and $\kappa(x)=k/(\rho c)$ is the thermal diffusivity. In Eqs. (5) and (6), *erfc*( ) is the complementary error function and $\Omega_1(x)$ and $\Omega_2(x)$ are defined by

$$\Omega_1(x)=\frac{1}{b}\int_0^x\sqrt{\frac{\kappa_0}{\kappa(x')}}\,dx',\qquad \Omega_2(x)=\frac{1}{b}\int_x^b\sqrt{\frac{\kappa_0}{\kappa(x')}}\,dx'. \tag{8}$$

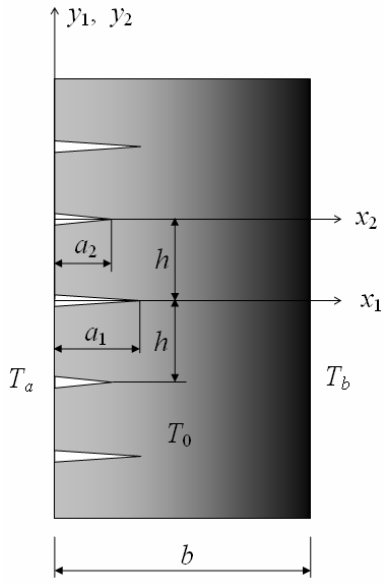

Figure 1. An FGM plate containing an array of periodic edge cracks with alternating lengths subjected to a thermal shock

The above temperature filed induces thermal stresses in both longitudinal (perpendicular to the crack direction) and transverse (perpendicular to the *x*-*y* plane) directions in the FGM plate. The

growth of the periodic edge cracks, however, is caused by the longitudinal stress which has the following form when the cracks have not been considered

$$\sigma_{yy}^{T}(x,\tau)=-\frac{E\alpha\theta(x,\tau)}{1-\nu}+\frac{E}{1-\nu}\left[\left(4-6\frac{x}{b}\right)\frac{1}{b}\int_0^b\alpha\theta(x,\tau)dx-\left(6-12\frac{x}{b}\right)\frac{1}{b^2}\int_0^b\alpha x\theta(x,\tau)dx\right], \quad (9)$$

where $\theta(x,\tau) = T(x,\tau)-T_0$, E is Young's modulus, ν is Poisson's ratio, and $\alpha = \alpha(x)$ is the coefficient of thermal expansion. Here we assume that the FGM plate is thermally nonhomogeneous but elastically homogeneous, i.e., the Young's modulus and Poisson's ratio are constant. While this assumption imposes limitations on the application of the present model, there exist some FGM systems for which the Young's modulus remains approximately constant. Examples include TiC/SiC, $MoSi_2/Al_2O_3$, Al_2O_3/Si_3N_4, and ZrO_2/Nickel FGM systems.

3. Thermal Stress Intensity Factors

This section uses the asymptotic temperature solution (4) – (6) to calculate the thermal stress intensity factor (TSIFs) at the tips of long and short crack in an elastically homogeneous but thermally graded FGM plate (see Fig. 1). The integral equation method is employed and the singular integral equations of the crack problem are given as follows

$$\int_{-1}^{1}\left[\frac{1}{s_1-r_1}+\frac{a_1}{2}k_{11}(r_1,s_1)\right]f_1(s_1)ds_1+\int_{-1}^{1}\frac{a_2}{2}k_{12}(r_2,s_2)\,f_2(s_2)ds_2 = -\frac{2\pi(1-\nu^2)}{E}\sigma_{yy}^{T}(r_1,t), \qquad -1\le r_1\le 1, \quad (10a)$$

$$\int_{-1}^{1}\left[\frac{1}{s_2-r_2}+\frac{a_2}{2}k_{22}(r_2,s_2)\right]f_2(s_2)ds_2+\int_{-1}^{1}\frac{a_1}{2}k_{21}(r_1,s_1)\,f_1(s_1)ds_1 = -\frac{2\pi(1-\nu^2)}{E}\sigma_{yy}^{T}(r_2,t), \qquad -1\le r_2\le 1, \quad (10b)$$

where the basic unknown variables $f_1(x_1)$ and $f_2(x_2)$ are defined by

$$f_1(x_1)=\frac{\partial v^{(1)}(x_1,0^+)}{\partial x_1}, \quad f_2(x_2)=\frac{\partial v^{(2)}(x_2,0^+)}{\partial x_2}, \quad (11)$$

with $v^{(1)}(x_1, y_1)$ and $v^{(2)}(x_2, y_2)$ being the displacements in the y-direction, x_1, y_1, x_2 and y_2 are coordinates defined by

$$x_1 = x, \quad y_1 = y, \qquad x_2 = x, \quad y_2 = y - h. \quad (12)$$

r_1, s_1, r_2, and s_2 are the normalized coordinates

$$x_1=\frac{a_1}{2}(1+r_1), \quad x_1'=\frac{a_1}{2}(1+s_1), \qquad x_2=\frac{a_2}{2}(1+r_2), \quad x_2'=\frac{a_2}{2}(1+s_2). \quad (13)$$

k_{11}, k_{12}, k_{21} and k_{22} are known kernels given by Feng and Jin[10], and σ_{yy}^{T} is given in Eq. (9).

According to the singular integral equation theory [13], the solutions of Eq. (7) have the following form

$$f_1(r_1)=\frac{F_1(r_1)}{\sqrt{1-r_1}},\qquad f_2(r_2)=\frac{F_2(r_2)}{\sqrt{1-r_2}}, \tag{14}$$

where $F_1(r_1)$ and $F_2(r_2)$ are continuous and bounded functions. Once the solutions of the above integral equations are obtained, the TSIFs at the periodic crack tips can be computed from

$$\begin{aligned} K_I^{(1)*}&=\frac{(1-\nu)K_I^{(1)}}{E\alpha_0\Delta T\sqrt{\pi\, b}}=-\frac{1}{2}\sqrt{\frac{a_1}{b}}F_1(1),\\ K_I^{(2)*}&=\frac{(1-\nu)K_I^{(2)}}{E\alpha_0\Delta T\sqrt{\pi\, b}}=-\frac{1}{2}\sqrt{\frac{a_2}{b}}F_2(1), \end{aligned} \tag{15}$$

where $K_I^{(1)}$ and $K_I^{(2)}$ denote the TSIFs at the tips of the long and short cracks, respectively, $K_I^{(1)*}$ and $K_I^{(2)*}$ are the corresponding nondimensional TSIFs, $\Delta T = T_a$, and α_0 is the coefficient of thermal expansion at $x = 0$. In Eq. (15), $F_1(1)$ and $F_2(1)$ have been normalized by $(1+\nu)\alpha_0\Delta T$.

4. Numerical Results and Discussion

In the numerical examples, we use a graded system of alumina/silicon nitride (Al_2O_3/Si_3N_4) FGM for cutting tools applications to examine the effects of cooling rate on the TSIFs. The FGM is assumed to be a two-phase composite material with graded volume fractions of its constituent phases. The volume fraction of Si_3N_4 is assumed to follow a simple power function

$$V(x)=(x/b)^p, \tag{16}$$

where p is the exponent determining the volume fraction profile. The material properties of the FGM are calculated using conventional micromechanics models [14] and the properties of Al_2O_3 and Si_3N_4 are given in Table 1 [15]. In the numerical calculations, we only consider the loading case of $T_b = 0$ (the initial temperature), which means that only the cracked surface $x = 0$ of the FGM plate is subjected to a temperature drop.

Fig. 2a shows the normalized TSIF $K_I^{(1)*}$ at the tips of the long cracks versus nondimensional time τ for various values of the cooling rate parameter τ_a. The crack spacing is $h/b = 1$, the length of the long cracks is $a_1/b = 0.1$, the crack length ratio is $a_2/a_1 = 0.2$, and the material gradation profile index is $p = 0.5$. The TSIF under the sudden cooling condition ($\tau_a = 0$, and hence infinite cooling rate) is also included. For a given cooling rate (T_a/τ_a), the TSIF initially increases with time, rapidly reaches the peak value and then decreases with time. The peak TSIF decreases dramatically with a decrease in the cooling rate (increasing τ_a). Moreover, the time at which the TSIF reaches its peak increases with a decrease in the cooling rate.

Fig. 2b shows the normalized TSIF $K_I^{(2)*}$ at the tips of the short cracks versus nondimensional time τ. All the geometrical and material gradation parameters are the same as those in Fig. 2a. The TSIF versus time response exhibits similar trend to that at the tips of the long cracks shown in Fig. 2a. Comparing the results in Figs. 2a and 2b, we can see that the peak TSIF at the short crack tip under the sudden cooling condition is about the same as the corresponding value for the long cracks. The peak TSIFs under finite cooling rates (nonzero τ_a), however, are significantly lower than the

corresponding values at the tips of the long cracks.

Table 1. Material properties of Al_2O_3 and Si_3N_4

	Young's modulus (GPa)	Poisson's ratio	CTE (10^{-6}/K)	Thermal conduc-tivity (W/m-K)	Mass density (g/cm^3)	Specific heat (J/g-K)	Fracture toughness (MPa-m$^{1/2}$)
Al_2O_3	320	0.25	8.0	20	3.8	0.9	4
Si_3N_4	320	0.25	3.0	35	3.2	0.7	5

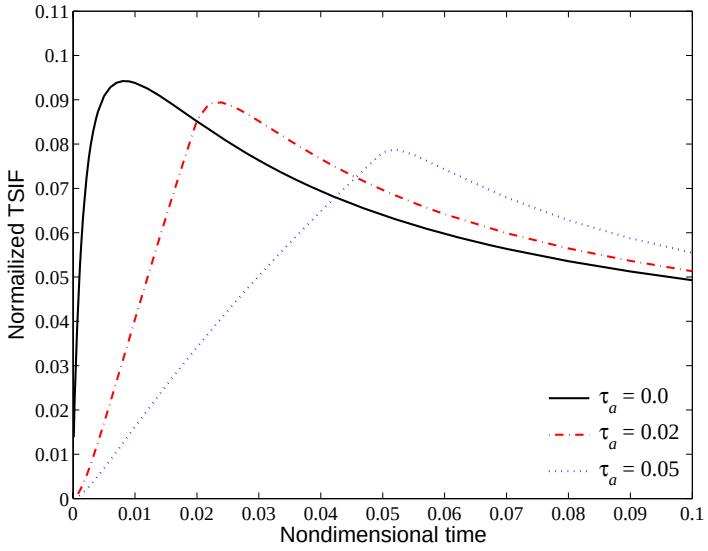

Figure 2a: Normalized TSIF versus nondimensional time at the tips of the long cracks (a_1/b = 0.1, a_2/a_1 = 0.2, h/b = 1.0, p = 0.5)

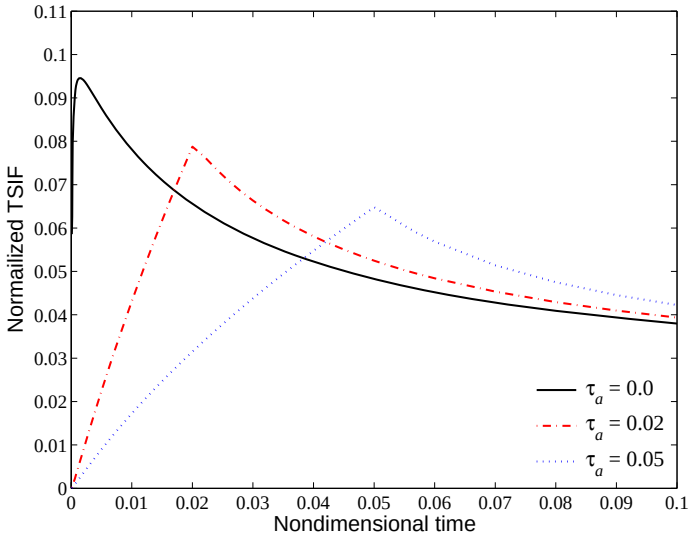

Figure 2b: Normalized TSIF versus nondimensional time at the tips of the short cracks (a_1/b = 0.1, a_2/a_1 = 0.2, h/b = 1.0, p = 0.5)

Figs. 3a and 3b show the normalized TSIFs at the tips of the long and short cracks, respectively, versus nondimensional time τ for a different crack length ratio a_2/a_1 of 0.6. All other parameters are the same as those in Fig. 2. It is seen that the trend of the TSIF versus time is similar to the case of a_2/a_1 = 0.2 shown in Figs. 2a and 2b. The peak TSIFs for the long cracks now are lower than those for a_2/a_1 = 0.2. However, the peak TSIFs for the short cracks are higher than those for a_2/a_1 = 0.2. The decreased peak TISF for the long cracks and the increased peak TSIFs for the short cracks are the results of enhanced interaction between the long and short cracks as the difference in the crack lengths is now smaller.

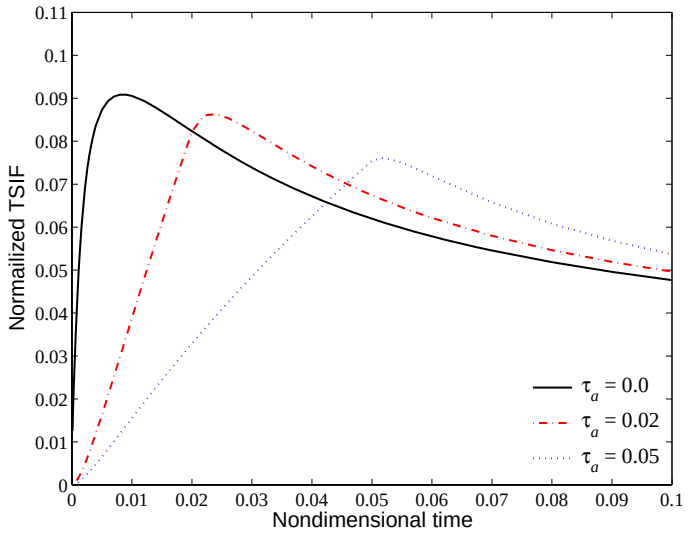

Figure 3a: Normalized TSIF versus nondimensional time at the tips of the long cracks (a_1/b = 0.1, a_2/a_1 = 0.6, h/b = 1.0, p = 0.5)

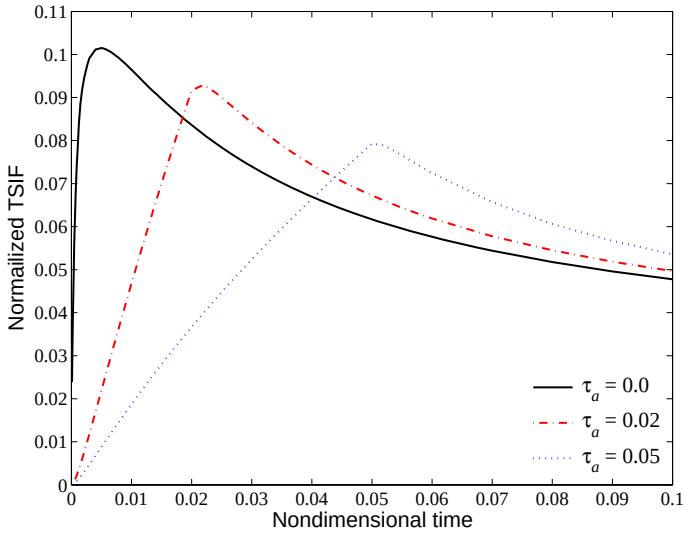

Figure 3b: Normalized TSIF versus nondimensional time at the tips of the short cracks (a_1/b = 0.1, a_2/a_1 = 0.6, h/b = 1.0, p = 0.5)

5. Concluding Remarks

This work is focused on the effects of cooling rate on the thermal stress intensity factors (TSIFs) at the tips of parallel edge cracks of alternating lengths in an FGM plate. The cooling rates at the surfaces of the FGM plate are described by a linear ramp function. The TSIFs are obtained using a closed-form, short-time temperature solution and an integral equation method. Numerical results for an Al_2O_3/Si_3N_4 FGM system show that the peak TSIFs at the tips of both long and short cracks decrease with a decrease in cooling rate. The variations of the peak TISF for the long and short cracks with the cooling rate and crack length ratio exhibit a complex pattern due to the interactions between the long and short cracks.

The Higher Order Crack Tip Fields for FGMs Spherical Shell with Reissner's Effect

Yao Dai[1], Xiao Chong[1,*], Lei Zhang[1]

[1] The department of mechanical engineering, the academy of armored force engineering, Beijing, 100072, China
* chongxiao2005@163.com

Abstract Based on the theory of shells considering the transverse shear deformation or Reissner's effect, the crack tip fields are investigated for a cracked spherical shell made of isotropic functionally graded materials (FGMs). The elastic modulus and Poisson's ratio of the FGMs are assumed to be the linear function of x and a constant, respectively. The governing equations, i.e. the system of the tenth order partial differential equations with variable coefficients are first derived. Then, the eigen-expansion method is employed to the system, and the higher order crack tip fields of the cracked spherical shell are obtained. As the in-homogeneity parameter approaches to zero, the solutions degenerate to the corresponding fields of isotropic homogeneous spherical shell with Reissner's effect.

Keywords crack tip fields, Reissner's effect, spherical shell, FGMs

1. Introduction

As the gradient can be tailored to meet specific needs and the macroscopic interfaces of traditional composites are eliminated, the functionally graded materials have been widely applied in engineering. However, due to the limitations of the manufacture technology, a large number of micro-cracks cannot be avoided in functionally graded plates and shells, which would seriously endanger the security of these structures. Therefore, the fracture analysis for functionally graded shells is necessary.

It is well known that Kirchhoff classical theory does not consider the transverse shear deformation and has some limitations in the fracture analysis [1], so Reissner's theory [2] is often adopted.

Considering the effect of transverse shear, F.Delale[3] investigated the problem for spherical cap containing a through crack. For the plates and shells of homogeneous materials, the higher order crack tip fields are obtained based on Reissner's theory by Liu Chuntu[4]. The corresponding field for FGMs shell has been given only for which the material gradient is along thickness direction [5]. In this paper, the crack tip fields are studied for functionally graded spherical shell with Reissner's effect by the eigen-expansion method.

2. Basic equations

The effect of Poisson's ratio on stress intensity factor (SIF) is far less than that of elastic modules [6]. Therefore, Poisson's ratio is assumed as a constant, and the elastic modules is assumed as the linear function of spatial coordinates x as

$$E = E(x) = E_0(1+\beta x), \quad \mu = const \tag{1}$$

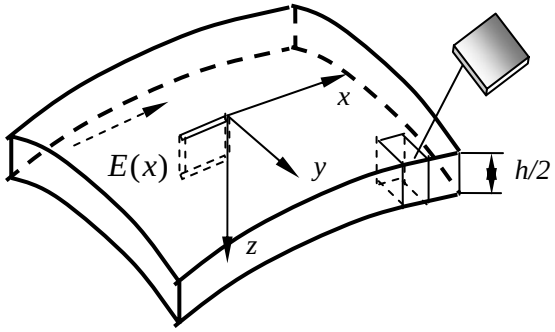

Fig.1 The functionally graded spherical shell

where, E_0 is elastic modulus at $x=0$, β is non-homogeneous coefficients. *Z*–axis is along the thickness direction, the radius is *R* and the thickness is *h* as shown in Fig.1.

The basic equations for Reissner's spherical shell are

$$\begin{cases} \beta(\mu\dfrac{\partial\varphi_y}{\partial y}+\dfrac{\partial\varphi_x}{\partial x})h^3+(1+\beta x)(\mu\dfrac{\partial^2\varphi_y}{\partial x\partial y}+\dfrac{\partial^2\varphi_x}{\partial x^2})h^3-\dfrac{1}{2}(1+\beta x)(\mu-1)(\dfrac{\partial^2\varphi_x}{\partial y^2}+\dfrac{\partial^2\varphi_y}{\partial x\partial y})h^3 \\ -5(1+\beta x)(\mu-1)h(\dfrac{\partial w}{\partial x}-\varphi_x)=0 \\ -\dfrac{1}{2}\beta(\mu-1)(\dfrac{\partial\varphi_x}{\partial y}+\dfrac{\partial\varphi_y}{\partial x})h^3-\dfrac{1}{2}(1+\beta x)(\mu-1)(\dfrac{\partial^2\varphi_x}{\partial x\partial y}+\dfrac{\partial^2\varphi_y}{\partial x^2})h^3+(1+\beta x)(\mu\dfrac{\partial^2\varphi_x}{\partial x\partial y} \\ +\dfrac{\partial^2\varphi_y}{\partial y^2})h^3-5(1+\beta x)(\mu-1)h(\dfrac{\partial w}{\partial y}-\varphi_y)=0 \\ 5hE_0(1+\beta x)(\nabla^2 w-\dfrac{\partial\varphi_x}{\partial x}-\dfrac{\partial\varphi_y}{\partial y})+12\kappa(1+\mu)\nabla^2\psi+5E_0\beta h(\dfrac{\partial w}{\partial x}-\varphi_x)=0 \\ (1+\beta x)^2\nabla^4\psi+\kappa E_0 h(1+\beta x)^3\nabla^2 w-2\beta(1+\beta x)\dfrac{\partial(\nabla^2\psi)}{\partial x}-2\beta^2\mu\dfrac{\partial^2\psi}{\partial y^2}+2\beta^2\dfrac{\partial^2\psi}{\partial x^2}=0 \end{cases} \tag{2}$$

where, φ_x, φ_y are the angle displacement, w is the deflection, κ is the curvature, ψ is the stress function.

3. The boundary conditions

As the crack surface is free, the boundary conditions are

$$\begin{cases} M_y=0,\ M_{xy}=0,\ Q_y=0 \\ N_y=0,\ N_{xy}=0 \end{cases} \tag{3}$$

Further, they can be expressed as

$$\begin{cases} \mu\dfrac{\partial\varphi_x}{\partial x}+\dfrac{\partial\varphi_y}{\partial y}=0, & \dfrac{\partial\varphi_x}{\partial y}+\dfrac{\partial\varphi_y}{\partial x}=0 \\ \dfrac{\partial w}{\partial y}-\varphi_y=0, & \dfrac{\partial^2\psi}{\partial x^2}=0, \quad \dfrac{\partial^2\psi}{\partial x\partial y}=0 \end{cases} \tag{4}$$

The crack tip stress field would be equipped with the same square root singularity as that of homogeneous materials when the material properties of different composite materials at the interfaces are continuous [7,8]. Therefore, the generalized displacements $\varphi_r, \varphi_\theta, w$ and the stress function ψ can be expressed as follows [9]

$$\varphi_x=\sum_{i=1}^{\infty}\varphi_{xi}(\theta)r^{i/2},\ \varphi_y=\sum_{i=1}^{\infty}\varphi_{yi}(\theta)r^{i/2},\ w=\sum_{i=1}^{\infty}w_i(\theta)r^{i/2},\ \psi=\sum_{i=1}^{\infty}\psi_i(\theta)r^{1+i/2} \tag{5}$$

where, $\varphi_{xi}(\theta)$、$\varphi_{yi}(\theta)$、$w_i(\theta)$ are the eigen-functions of the generalized displacement components, $\psi_i(\theta)$ are the eigen-functions of the stress function.

Substituting Eq. (5) into Eq. (4) and considering the linear independence of $r^{-3/2}$, r^{-1}, $r^{-1/2}$,…, $r^{i/2-2}$,…, the boundary conditions are

$$\begin{cases} i\mu\cos\theta\varphi_{xi}(\theta)-2\mu\sin\theta\varphi'_{xi}(\theta)+i\sin\theta\varphi_{yi}(\theta)+2\cos\theta\varphi'_{yi}(\theta)=0 \\ i\sin\theta\varphi_{xi}(\theta)+2\cos\theta\varphi'_{xi}(\theta)+i\cos\theta\varphi_{yi}(\theta)-2\sin\theta\varphi'_{yi}(\theta)=0 \\ \begin{cases} i\sin\theta w_{i+2}(\theta)+2\cos\theta w'_{i+2}(\theta)-2\varphi_{yi}(\theta)=0, & i=1,2,3,\mathrm{L} \\ i\sin\theta w_{i+2}(\theta)+2\cos\theta w'_{i+2}(\theta)=0, & i=1,2. \end{cases} \\ 4\psi''_i(\theta)\sin^2\theta-2i\psi'_i(\theta)\sin 2\theta+\psi_i(\theta)(i^2\cos^2\theta+4\sin^2\theta+2i)=0 \\ -4\psi''_i(\theta)\sin 2\theta+4i\psi'_i(\theta)\cos 2\theta+\psi_i(\theta)\sin 2\theta(i^2-4)=0 \end{cases} \tag{6}$$

where, $(\ )'=d(\ )/d\theta$, $(\ )''=d^2(\ )/d\theta^2$.

4. The higher order crack-tip field

Substituting Eq. (5) into Eq. (2) and Eq. (6) and utilizing the linear independence of $r^{-3/2}$, r^{-1}, $r^{-1/2}$,…, $r^{i/2-2}$,…, the system of ordinary differential equations are obtained. Solving the system, we can obtain the results

$$
\begin{cases}
\varphi_{x1}(\theta)=C_{11}\sin\dfrac{\theta}{2}+C_{12}\cos\dfrac{\theta}{2}+C_{13}\sin\dfrac{3\theta}{2}+C_{14}\cos\dfrac{3\theta}{2} \\

\qquad +(20hE_0B_{32} + 20hE_0\mu B_{32})\sin\dfrac{3\theta}{2} + (20hE_0B_{31} + 20hE_0\mu B_{31})\cos\dfrac{3\theta}{2}] \\
w_4(\theta) = B_{42}\sin 2\theta + B_{41}\cos 2\theta + \dfrac{5hE_0(C_{21} + C_{24} - \beta B_{22}) - 48A_{21}(\mu+1)\kappa}{2E_0h} \\
\qquad \text{.....}
\end{cases}
\tag{10}
$$

where: A_{ij} , B_{ij} , C_{ij} are the undetermined coefficients.

Substituting Eq. (7)-(10) into Eq.(5), the generalized displacement fields of FGMs spherical shell are obtained.

5. Conclusion

For a functionally graded spherical shell with Reissner effect, the higher order crack tip fields which are similar to the Williams' solutions of crack problems in homogenous materials are obtained. As the in-homogeneity parameter $\beta \to 0$, the solutions degenerate to the corresponding fields of isotropic homogeneous spherical shell with Reissner's effect. Obviously, these results provide the theoretical basis for experimental investigation and engineering application.

Abstract

This article focused on three-dimensional analyses of a functionally graded material plate which contains a semi-elliptical surface crack and subjected to transient thermal loading. Strain singularity around the crack front is simulated using collapsed 20 – node quarter – point brick elements. Three –dimensional displacement correlation technique is utilized to extract the mixed mode stress intensity factors around the crack front for different inclination angles of the semi-elliptic surface crack. Comparisons between current results and those from analytical and other numerical methods yield good agreement. Thus, it is concluded that the applied three-dimensional enriched finite elements are capable of accurately computing mixed-mode fracture parameters for cracks in FGMs.

Keywords: FGM, semi–elliptical inclined surface crack, displacement correlation technique, mixed modes stress intensity factors, finite element method

1. Introduction

Numerical simulations of crack initiation, propagation and branching are a computationally intensive process. Traditional finite element packages simulate the crack propagation problem either by using singularity elements or by using line spring elements with built-in fracture criteria. Recently, a popular method to do this task is the cohesive surface modeling of the fracture zone. Following the work of Baren blatt[2], Dugdale [3] ,and Willis [4], many researchers have addressed the issue to this approach. Nee-dleman[5] provided a framework for these parathion process starting from initial de-bonding in the cohesive zone. Larsson [6] used this approach to simulate crack growth in brittle materials, while Xia and Shih[7] simulated fracture inductile material sunder static loading. Camacho and Ortiz[8] have used cohesive surface modeling to study material fragmentation, while Xu and Needleman[9] used it to study dynamic crack tip in stabilities by allowing cracks to formal on element boundaries. The method by Xu and Needleman involves introducing special boundary elements between regular elements, where the boundary Elements obey a cohesive law. Three factors influence the cohesive law behavior, namely the cohesive Strength, the critical separation at cohesive strength and the fracture energy in the separation process. These Models obviate the need for a separate external fracture criterion in fracture simulations. The effects of Plasticity inside volumetric elements have been investigated using the embedded-process-zone cohesive Fracture model by Tvergaard and Hucthinson[10,11]. Gullerud and Dodds [12] have used 3-D cohesive Elements for modeling ductile crack growth. More recently Foulketal.[13] presented a procedure for Implementing the cohesive zone modeling a 3-D finite

element framework where zones of cracking are Known a-priori and cohesive zone elements are placed along these element boundaries.
Gao [14,15] proposed that materials undergoing brittle fracture have large non-linear elastic deformations and that a hyper elastic description of the crack tip behavior provides a better explanation of dynamic Crack tip in stabilities. Gao and Klein[16] developed a method, called the virtual internal bond(VIB)model ,In which a cohesive type law is directly incorporated in to the constitutive model. This is done by treating the Body as a collection of randomly distributed material points inter connected by a network of cohesive bonds.
The Cauchy–Bornrule of crystal elasticity is used to derive the overall constitutive relations. This is done by equating the strain energy of the bonds to the potential energy stored in the continuum due to applied loads and deformations. As this is implemented in a hyper elastic frame work deformation continuum mechanics, the Green–Lagrange strain tensor can be evaluated from deformation gradient, and the second Piola–Kirchoff stress tensor can be computed from the potential energy expression. The main advantage of this method is that, as in the cohesive boundary element approach [9], no separate fracture criterion is needed. Furthermore, the cohesive law is now embedded directly into the constitutive equations, thus no special boundary elements between regular elements are needed.
This study implements a finite element model to study the thermal fracture behavior of functionally graded materials. Stress intensity factors (SIF) are evaluated using a thermo mechanics and fracture mechanics approach. The results show that the components gradation of the FGM composites has significant influence on the specimens' thermal behavior.

2. Thermo-mechanical finite element modeling of FGM

A problem which is encountered in three-dimensional finite element analyses is the large number of elements and as a result, a remarkable and time consuming computation. Also, because of very rapid changes in the geometrical parameters around the crack front region, mesh generation of this region must be done with a great care. This may lead to increase the run time which makes it difficult to reach valid results and conclusion [17].
The main objective of this study is to model and analyze a three dimensional inclined semi-elliptic surface crack in a plate made of Functionally Graded Material (FGM). FGM is 100% zirconia-yttria (ZrO2-8wt%-Y2O3) at x=0 and 100% nickel-chromium–aluminum– zirconium (NiCrAlY) at x= t. The thermo mechanical properties of the FGM structure are assigned according to variation function by using the centroid of each finite element. This procedure is developed by utilizing ANSYS codes. A unique material property is assigned to each element with the help of this method.
In this study three different ratio regarding to modulus of elasticity (E) are considered as E2/E1= 20, E2/E1= 0.05 and homogeneous material case.E1and E2 are the values of the elastic module at x= 0 and x=t, respectively. Except elastic module a total of five material parameters are required to be known in order to carry out the transient thermal fracture analysis. These parameters are Poisson's ratio υ, thermal expansion coefficient αt, thermal conductivity k and density multiplied by specific heat (ρc_t). (ρc_t) can be evaluated using the relationship $D = {}^{k}/_{\rho c_t}$ where D is the thermal diffusivity.

$$E(x) = Ee^{\beta x} \quad 0 < x < t \qquad \textit{(Eq. 1)}$$
$$v(x) = ve^{\beta x} \quad 0 < x < t \qquad \text{(Eq. 2)}$$
$$\alpha(x) = \alpha e^{\beta x} \quad 0 < x < t \qquad \textit{(Eq. 3)}$$
$$k(x) = ke^{\beta x} \quad 0 < x < t \qquad \text{(Eq. 4)}$$
$$\rho c_t(x) = \rho c_t e^{\beta x} \quad 0 < x < t \qquad \text{(Eq. 5)}$$

β is material constant and

$$\beta = {}^{1}/_{t}\, Ln\left({}^{E_2}/_{E_1}\right) \qquad \text{(Eq. 6)}$$

Table 1

Table 1

Material	Modulus Of Elasticity (GPa)	Poisson's ratio	Coefficient of thermal expansion ($^{\circ}C^{-1}$)	Coefficient of thermal conductivity (W/mK)	thermal diffusivity (m^2/s)
Substrate (Ni)	175.8	0.25	13.91×10^{-6}	7	2×10^{-6}
Bond Coat (NiCrAIY)	137.9	0.27	15.16×10^{-6}	25	8×10^{-6}
Zirconia-Yttria	27.6	0.25	13.91×10^{-6}	1	5×10^{-6}

In this paper combined thermal-structural analysis is studied. In the thermal analysis, first transient heat conduction in the FGM structure is conducted and consequently temperature distribution within the structure is computed. Afterwards, this temperature distribution is utilized as an input for the structural problem. While performing the analyses, it is assumed that the crack surfaces are completely insulated and the medium is free of any mechanical constraints. Furthermore, coupling of the thermal and structural problems are assumed to be through the calculated temperature distribution only since the inertia effects are not taken into account. During the solution, minimum and maximum time step sizes are entered. In order to overcome oscillations in the distribution of temperature, minimum time step size is taken to be very small and maximum time step size is chosen as not to be very large. By imposing temperature of the environment and applying free and forced convection coefficients on related surfaces of the FGM structure in time steps the problem is solved and calculated at each node. Then after computing the mixed mode stress intensity factors at the crack front nodes by utilizing the displacement correlation technique, the procedure of solving is repeated for each required time until the end time is reached.

3. The Displacement Correlation Technique (DCT)

Since the problem considered in this study is related to the inclined cracks (unsymmetrical), a complete crack model is needed to calculate the stress intensity factors. The figure below shows the full model which is to be used for mode I stress intensity factor calculation of an inclined crack.

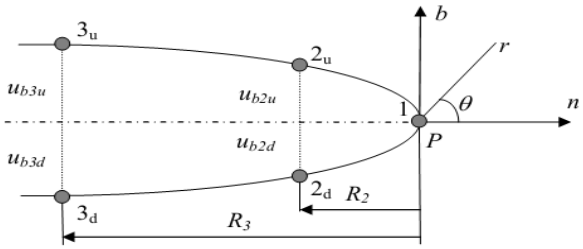

Fig 1- Deformed shape of the crack surface (non-symmetric)

The displacement component, which is required to calculate KI, at point P on the crack front can be expressed as

$$u_{\Delta}(r,\theta)=\left(\frac{1+\nu}{E}\right)\sqrt{\frac{2r}{\Pi}}\left\{k_{\imath}(s)\sin\left(\frac{\theta}{2}\right)\left[2(1-\nu)-\cos^2\left(\frac{\theta}{2}\right)\right]\right.$$

$$\left.-k_{\imath\imath}(S)\cos\left(\frac{\theta}{2}\right)\left[(1-2\nu)-\sin^2\left(\frac{\theta}{2}\right)\right]\right\} \qquad \text{(Eq. 1)}$$

$u_{\Delta}(r,\Pi)$is calculated by using equation (4.1). For the non-symmetric crack model, $u_{\Delta}(r,-\Pi)$ is also required. Thus, substituting $\theta=-\Pi$ into equation:

$$u_{\Delta}(r,-\Pi)=-\left(\tfrac{1+\nu}{E}\right)\sqrt{\tfrac{2r}{\Pi}}k_1 2(1-\nu) \qquad \text{(Eq. 2)}$$

Kı can be obtained as

$$k_1=\frac{\sqrt{2\Pi}\cdot E}{8(1-\nu^2)}\cdot\left[\lim_{r\to 0}\left\{\frac{u_{\Delta}(r,\Pi)-u_{\Delta}(r,-\Pi)}{\sqrt{r}}\right\}\right] \qquad \text{(Eq. 3)}$$

At the crach tip (i.e. $r\to 0$) , $\lim_{r\to 0}\left\{\frac{u_{\Delta}(r,\Pi)-u_{\Delta}(r,-\Pi)}{\sqrt{r}}\right\}=X$.Hence, equation

$$k_1=\frac{\sqrt{2\Pi}\cdot E}{8(1-\nu^2)}\cdot X \qquad \text{(Eq. 4)}$$

$$x=\frac{R_3^{3/2}(u_{\Delta\,2,0}-u_{\Delta\,2,3})-R_2^{3/2}(u_{\Delta\,3,0}-u_{\Delta\,3,3})}{\sqrt{R_2}\sqrt{R_3}(R_3-R_2)} \qquad \text{(Eq. 5)}$$

For r=R_2 → $\frac{u_{\Delta}(R_2,\Pi)-u_{\Delta}(R_2,-\Pi)}{\sqrt{R_2}}=\frac{u_{\Delta\,2,0}-u_{\Delta\,2,3}}{\sqrt{R_2}}=x+YR_2$

And

For r=R_3 → $\frac{u_{\Delta}(R_3,\Pi)-u_{\Delta}(R_3,-\Pi)}{\sqrt{R_3}}=\frac{u_{\Delta\,3,0}-u_{\Delta\,3,0}}{\sqrt{R_3}}=x+YR_3$

$$k_{\imath\imath}=\frac{\sqrt{2\Pi}\cdot E}{8(1-\nu^2)}\cdot\left[\lim_{r\to 0}\left\{\frac{u_0(r,\Pi)-u_0(r,-\Pi)}{\sqrt{r}}\right\}\right] \qquad \text{(Eq. 6)}$$

For r=R_2 → $\frac{u_0(R_2,\Pi)-u_0(R_2,-\Pi)}{\sqrt{R_2}}=\frac{u_{0\,2,0}-u_{0\,2,3}}{\sqrt{R_2}}=x+YR_2$

And

For r=R_3 → $\frac{u_0(R_3,\Pi)-u_0(R_3,-\Pi)}{\sqrt{R_3}}=\frac{u_{0\,3,0}-u_{0\,3,3}}{\sqrt{R_3}}=x+YR_3$

$$x = \frac{R_3^{3/2}(u_{0\,2,0}-u_{0\,2,3})-R_2^{3/2}(u_{0\,3,0}-u_{0\,3,3})}{\sqrt{R_2}\sqrt{R_3}(R_3-R_2)} \quad \text{(Eq. 7)}$$

$$k_{II} = \frac{\sqrt{2\Pi}\cdot E}{8(1-\nu^2)} \cdot X \quad \text{(Eq. 8)}$$

KIII can be calculated by the tangential displacement component at point P on the crack front. The tangential displacement component at this point is

$$u_c(r,\theta) = 2\left(\frac{1+\nu}{E}\right)\sqrt{\frac{2r}{\Pi}}k_m(s)\sin\left(\frac{\theta}{2}\right) \quad \text{(Eq. 9)}$$

For r=R_2 → $\frac{u_c(R_2,\Pi)-u_c(R_2,-\Pi)}{\sqrt{R_2}} = \frac{u_{c\,2,0}-u_{c\,2,3}}{\sqrt{R_2}} = x + YR_2$

And

For r=R_3 → $\frac{u_c(R_3,\Pi)-u_c(R_3,-\Pi)}{\sqrt{R_3}} = \frac{u_{c\,3,0}-u_{c\,3,3}}{\sqrt{R_3}} = x + YR_3$

$$x = \frac{R_3^{3/2}(u_{c\,2,0}-u_{c\,2,3})-R_2^{3/2}(u_{c\,3,0}-u_{c\,3,3})}{\sqrt{R_2}\sqrt{R_3}(R_3-R_2)} \quad \text{(Eq. 10)}$$

$$k_{III} = \frac{\sqrt{2\Pi}\cdot E}{8(1-\nu^2)} \cdot X \quad \text{(Eq. 11)}$$

$$\mu = \frac{E}{2(1+\nu)} \quad \text{(Eq. 12)}$$

Therefore, the total strain energy release rate under mixed mode loading is

$$G_T = G_1 + G_{II} + G_{III} = \frac{(1-\nu^2)}{E}\left\{k_1^2 + k_{II}^2 + \frac{k_{III}^2}{1-\nu}\right\} \quad \text{(Eq. 13)}$$

After the accuracy of the finite element model is checked out, the same model is used for the analyses of semi-elliptic inclined surface crack embedded in the FGM coating of composite structure. The finite element analyses of FGM coating- bond coat-substrate structure are carried out and the numerical results are calculated for various inclinations of three dimensional semi-elliptic surface crack, coating types, crack front angles and relative dimension of the crack with respect to FGM coating thickness.

4. Numerical results

There is a semi-elliptic inclined surface crack which has a length of 2c and a depth of a. The semi-elliptic crack has an inclination angle α, on the surface of the FGM at x=0. In the numerical analysis conducted, crack depth/ FGM thickness $^a/_t$ ratios and aspect ratio are used. These are as follows:

$$^a/_t = 0.2 \; and \; ^a/_c = {}^1/_2 \quad \text{(Eq. 14)}$$

In this analysis, the stress intensity factors are normalized by,

$$k_R = \sigma_0\sqrt{\frac{\Pi a}{Q}} \quad \text{(Eq. 15)}$$

Q is defined by,

$$Q = \begin{cases} 1 + 1.464(a\ /\ c)^{1.65} & \text{if } (\frac{a}{c}) \le 1 \\ 1 + 1 \cdot 464(c\ /\ a)^{1.65} & \text{if}(\frac{a}{c}) > 1 \end{cases} \qquad \text{(Eq. 16)}$$

The schematic of the crack front can be seen at Figure 2. The validation of the model is done by modeling and analyzing the plate, which contains a semi-elliptic inclined surface crack, with finite dimensions subjected to uniform tension (figures 3 and 4). As it can be seen from these figures, the results of this study are plotted for $\alpha = 0\ and\ \alpha = 30$. it can be said that the obtained results are in good agreement with that of Ayhan et al. [11]

Transient Thermal Loading

The boundary conditions for this loading case are depicted in Figure 5.

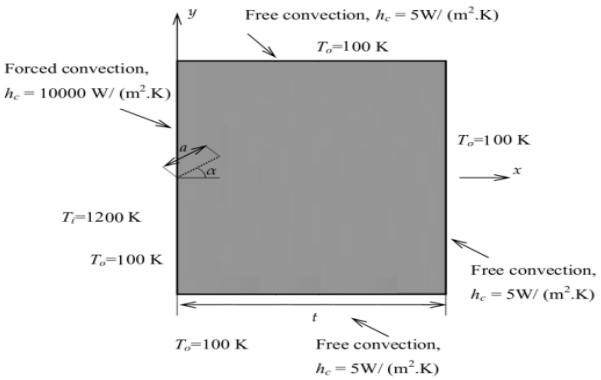

Fig 5- Thermal boundary conditions for the FGM coating, bond coat and substrate structure

It is assumed that the composite medium is initially stress-free at a high processing temperature of T_i = 1200 K. Then, the other face of solid is left in an environment which has a temperature of T_o = 100 K. The boundary conditions for this loading case are depicted in Figure 5. The thermo mechanical parameters used in the transient thermal analyses are described before. For the transient thermal analyses, inclination angles of 45^osemi-elliptic surface crack are considered. It is seen that the normalized stress intensity factors rates go through a maximum in a short time period and then starts to decrease (Figures 6, 7 and 8) for different ratio of E_2/E_1. Figures 9 show the distribution of energy release around the crack front.

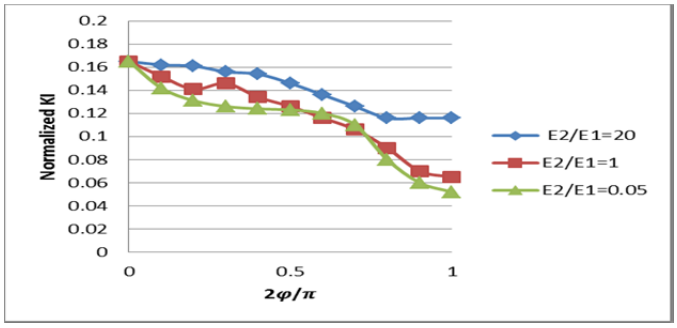

Fig 6- Distribution of normalized mode I stress intensity factors around crack front

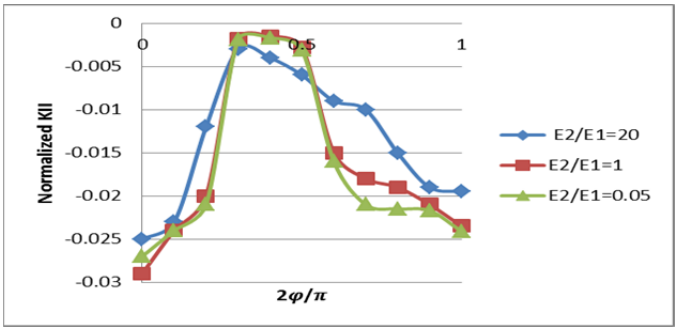

Fig 7- Distribution of normalized mode II stress intensity factors around crack front

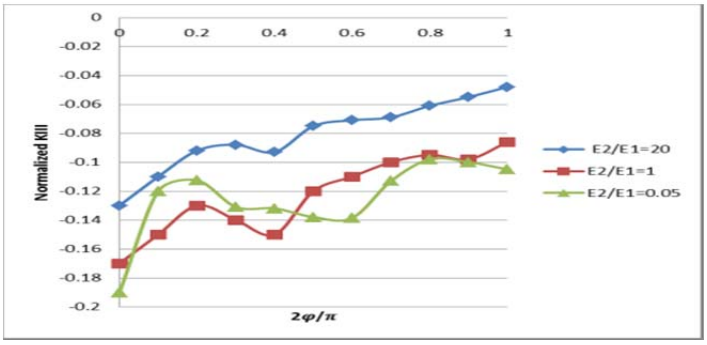

Fig 8- Distribution of normalized mode III stress intensity factors around crack front

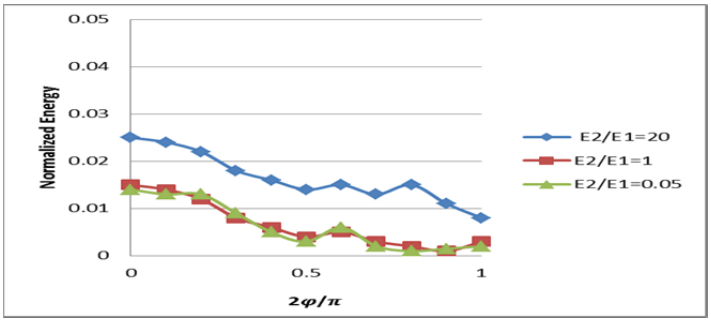

Fig 9- Distribution of normalized energy release rates around crack front

Figures 10 shows the distribution of temperature around the crack front at the time maximum values of normalized SIFs and energy release rates are reached.

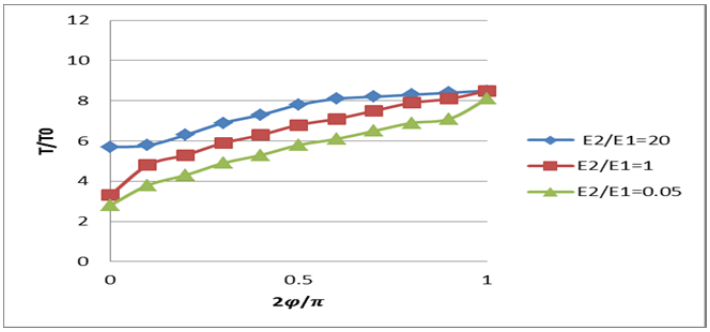

Fig 10- Distribution of temperature around crack front

In this study, an inclined semi-elliptical surface crack in an FGM structure is modeled in three dimension and fracture analyses are carried out by implementing finite element technique. For the model generations and finite element analyses, the multi-purpose finite element code ANSYS is used. The behavior of three dimensional inclined semi-elliptical surface cracks is examined under transient thermal loading for different ratios of material gradient. The mixed mode stress intensity factors and energy release rates around the crack front are calculated by utilizing displacement correlation technique.In order to verify the model and technique utilized in FGM structure, first of all, a plate and a semi-infinite solid with homogeneous material properties are modeled and analyzed under uniform tension. Then, the results obtained are compared to those given by Ayhan et al. [1 1]. It is observed that the figures generated for comparisons are in good agreement and therefore, it is concluded that this model can also be used for the finite element

analyses of the composite medium. The transient thermal analyses of the FGM structure are carried out for three different material gradients. It is assumed that the composite medium is initially at a high processing temperature. Then, this structure is left in an environment which is at a low temperature. Due to the high temperature difference, thermal stresses are induced at the composite structure containing an inclined semi-elliptical surface crack. Mixed mode SIFs and energy release rates are calculated along the crack front. It is observed that as the inclination angle increases, the normalized modes stress intensity factors decrease. The normalized energy release rates also decrease as the inclination angle increases. It is seen that for all inclination angles the normalized temperature increases as the crack front angle increases. It is could be concluded that material gradation has considerable effect on mode-II and mode-III stress intensity factors also. Thus, it is concluded that the 3D elements can be applied to calculate mixed-mode cracks in FGMs accurately and efficiently without needing special meshes near the crack front and detailed post-processing of the finite element solution.

Abstract The thermal effect of mode III crack in a functionally graded strip under the electric shock is investigated. This fracture analysis can be expressed through the superposition of two problem solutions. The first solution is the dynamic behaviors of a functionally graded piezoelectric material with central crack subjected to the electric shock. The second solution means the temperature field by calculating the power of point heat source around the crack tip. Based on the Laplace transform and Fourier transform technique, this mixed boundary value problems is reduced to a Cauchy singular integral equation, which is solved numerically by the Cauchy-Chebyshev quadrature technique. Numerical results are presented to show the effects of geometrical of crack and graded quantities of material on the stress intensity factors.

Keywords Anti-plane crack, Functionally graded piezoelectric materials, Electric shock, Thermal effect

1. Introduction

Piezoelectric materials (PMs) have been widely used as a smart material in electromechanical devices due to the demand of transform from mechanical to electrical loadings, and vice versa. To improve the reliability and durability problems arising largely from high residual and thermal stress, poor interfacial bonding strength, the functionally graded piezoelectric materials (FGPMs) as a new class of advanced composites have been developed.

Recently, some researchers start to investigate the fracture behavior in FGPMs. Wang and Node [1] firstly studied the thermo-piezoelectric fracture problem of a functionally graded piezoelectric layer bonded to a metal. They obtained the thermal flow, stress and electric displacement intensity factors and predict the direction of crack extension by using the energy density theory. Wang considered the mode III crack problem in FGPM, where the material properties are assumed in a class of functional form such that an analytic solution is possible. Recently, Li and Lee [2] investigated the fracture behavior of a weak discontinuous interface between two piezoelectric strips under electro-mechanical loads by using the methods of Fourier integral transform and Cauchy singular integral equation. Ding and Li [3] studied the problem of periodic interface cracks in a functionally graded coating-substrate structure. Recently, based on the methods of variable separation and singular integral equation, Ref. [4] investigated the arc-shaped interfacial cracking problem in a hollow cylinder that consists of an inner orthotropic dielectric layer and an outer functionally graded piezoelectric layer.

Although a variety of challenging issues related to certain crack problems in the functionally graded piezoelectric materials have been addressed, one of the remaining problems that need to fully understand is that FGPMs belongs to the dielectric material. Research of Bilyk et al [5] revealed that applying high current on the conductor, the temperature of conductor is lager than the temperature just under force load. To the authors' knowledge, few papers considered the solution for the problem of the heating effect of the crack tip in FGPM under electric shock. Then, this paper discusses the heating effect of the crack tip on piezoelectric medium under the high electric shock load.

2 Formulation of the problem

2.1 Theoretical model

The thermal effect of mode III crack in a functionally graded strip under the electric shock is investigated. This fracture analysis can be expressed through the superposition of two problem solutions. The first solution refers to the dynamic behaviors of a functionally graded piezoelectric material with central crack subjected to the electric shock. The second solution means the temperature field by calculating the power of point heat source around the crack tip. Illustrated in Fig.1 is the fracture model of a functionally graded piezoelectric strip which is assumed to contain a center crack. The crack of length and the thickness of strip are defined as $2c$ and $2h$. In addition, the rectangular coordinate system is established as fig 1. Since the poling directions of piezoelectric materials are orientated along z-axis, the antiplane mechanical field and inplane electric field are coupled. Here, the fundamental solution of crack under a pair of the equivalent electric shock $-D_0H(t)$ and shear traction $-\tau_0H(t)$ acting on the crack surface is considered. $H(t)$ is Heaviside function, and τ_0, D_0 are the range of the impact load of force field and electric field.

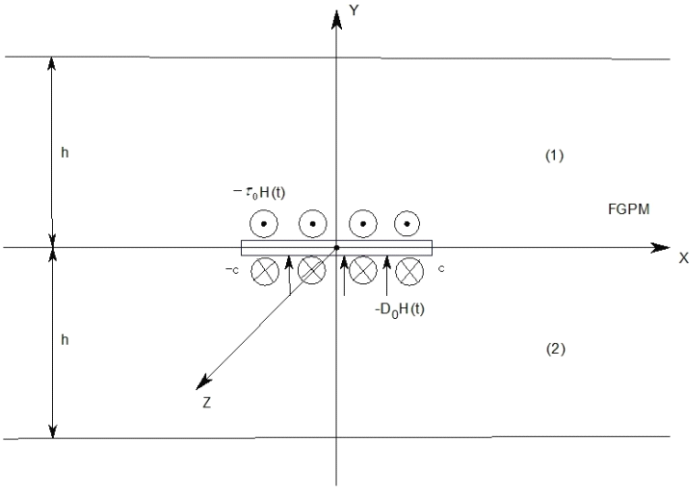

Figure 1. Functionally graded piezoelectric strip with central crack subjected to the electric shock

In fracture analysis of functionally graded piezoelectric strip, for the convenience of employing some standard methods such as Fourier transforms and integral equations, material properties are always assumed to be continuous functions of spatial coordinates, among which the most widely used one is exponential function [4]. Therefore, like many previous literatures, the properties of the functionally graded piezoelectric strip are assumed in power forms along y axis as follows:

$$c_{44} = c_0 e^{\beta y}, \quad e_{15} = e_0 e^{\beta y}, \quad \kappa_{11} = \kappa_0 e^{\beta y}, \quad \rho = \rho_0 e^{\beta y} \tag{1}$$

where $c_0, e_0, \kappa_0, \rho_0$ are the coefficient of the functionally graded strip at $y=0$, such as shear modulus, piezoelectric coefficient, dielectric permittivity and density permeability, respectively. β is the non-homogeneity parameters controlling the material coefficient in the graded layer.

2.2 Governing equations

Firstly, without considering the related effect of temperature field, a theoretical model is developed for the dynamic fracture analysis of a functionally graded piezoelectric material of a finite dimension with central crack subjected to the electric shock. Under axial shear deformation, the constitutive relations can be expressed in terms of polar coordinate system in the form

$$\sigma_{xz} = c_{44}(y)\frac{\partial \omega}{\partial x} + e_{15}(y)\frac{\partial \phi}{\partial x}, \sigma_{yz} = c_{44}(y)\frac{\partial \omega}{\partial y} + e_{15}(y)\frac{\partial \phi}{\partial y}$$
$$D_x = e_{15}(y)\frac{\partial \omega}{\partial x} - \kappa_{11}(y)\frac{\partial \phi}{\partial x}, D_y = e_{15}(y)\frac{\partial \omega}{\partial y} - \kappa_{11}(y)\frac{\partial \phi}{\partial y} \quad (2)$$

where ϕ and w denote the electric potential and anti-plane mechanical displacement, D and σ are the electric displacement and anti-plane stresses, respectively.
The geometric equation can be written as

$$2\varepsilon_{xz} = \frac{\partial \omega}{\partial x}, \quad 2\varepsilon_{yz} = \frac{\partial \omega}{\partial y}, \quad E_x = -\frac{\partial \phi}{\partial x}, \quad E_y = -\frac{\partial \phi}{\partial y}, \quad E_z = -\frac{\partial \phi}{\partial z} \quad (3)$$

Under the static condition, when body forces and body charges are omitted, the stress, electric displacement should satisfy the following equations

$$\frac{\partial \sigma_{xz}}{\partial x} + \frac{\partial \sigma_{yz}}{\partial y} = \rho \frac{\partial^2 \omega}{\partial t^2}, \quad \frac{\partial D_x}{\partial x} + \frac{\partial D_y}{\partial y} = 0 \quad (4)$$

Introduce an auxiliary function by

$$\psi = \phi - \frac{e_0}{\kappa_0}\omega \quad (5)$$

Substituting Eqs. (1-3) into Eq. (4) yields the decoupled governing equations in the piezoelectric strip

$$\nabla^2 \omega + \beta \frac{\partial \omega}{\partial y} = s_0 \frac{\partial^2 \omega}{\partial t^2}, \nabla^2 \psi + \beta \frac{\partial \psi}{\partial y} = 0 \quad (6)$$

where

$$s_0 = \rho_0 / (c_0 + \frac{e_0^{\ 2}}{\kappa_0}) \quad (7)$$

2.3 Boundary conditions

The upper region $y \in [0, h]$ and lower region $y \in [-h, 0]$ is symmetric with respect to the x axis. Therefore, in the following we confine our attention to the upper region $y \in [0, h]$. Then, based on the symmetry, the corresponding boundary conditions are imposed

$$\omega(x,0,t) = 0, \quad \phi(x,0,t) = 0 \ (|x| > c) \quad (8)$$

Here, the fundamental solution of crack under a pair of the equivalent electric shock $-D_0 H(t)$ and shear traction $-\tau_0 H(t)$ acting on the crack surface is considered. The corresponding mechanical boundary conditions on the crack surface are imposed

$$\sigma_{yz}(x,0,t) = -\tau_0 H(t), \quad D_y(x,0,t) = -D_0 H(t) \ (-c < x < c) \quad (9)$$

Assume that the upper surface $y = h$ is free of loading. Therefore, the electric displacement and anti-plane stresses on the upper surface is taken as zero,

$$\sigma_{yz}(x,h,t) = 0, \quad D_y(x,h,t) = 0 \ (-\infty < x < +\infty) \quad (10)$$

3. Solution

3.1 Basic solution expression

Using the Laplace transform and Fourier transform technique, ones can transform Eqs. (6) into a system of decoupled differential equations

$$(-s^2)F(s,y,p)+\frac{\partial^2}{\partial y^2}F(s,y,p)+\beta\frac{\partial}{\partial y}F(s,y,p)=s_0p^2F(s,y,p) \tag{11}$$

$$(-s^2)G(s,y,p)+\frac{\partial^2}{\partial y^2}G(s,y,p)+\beta\frac{\partial}{\partial y}G(s,y,p)=0 \tag{12}$$

where

$$\psi^*(x,y,p)=\int_0^{+\infty}\psi(x,y,t)e^{-pt}dt,\psi(x,y,t)=\int_{Br}\psi^*(x,y,p)e^{pt}dp \tag{13}$$

$$\omega^*(x,y,p)=\int_0^{+\infty}\omega(x,y,t)e^{-pt}dt,\omega(x,y,t)=\frac{1}{2\pi i}\int_{Br}\omega^*(x,y,p)e^{pt}dp \tag{14}$$

$$\omega^*(x,y,p)=\frac{1}{2\pi}\int_{-\infty}^{+\infty}F(s,y,p)e^{-isx}ds,F(s,y,p)=\int_{-\infty}^{+\infty}\omega^*(x,y,p)e^{isx}dx \tag{15}$$

$$\psi^*(x,y,p)=\frac{1}{2\pi}\int_{-\infty}^{+\infty}G(s,y,p)e^{-isx}ds,G(s,y,p)=\int_{-\infty}^{+\infty}\psi^*(x,y,p)e^{isx}dx \tag{16}$$

where $\omega^*(x,y,p),\psi^*(x,y,p)$ are the Laplace transform of $\omega(x,y,t),\psi(x,y,t)$, Br means path integral Bromwich formulation. And $F(s,y,p),G(s,y,p)$ are the Fourier transform of $\omega^*(x,y,p),\psi^*(x,y,p)$.

Afterwards, solving Eqs. (11-12), one can finally express the mechanical displacement, electric potential of the strip in the Laplace domains below

$$\omega^*(x,y,p)=\frac{1}{2\pi}\int_{-\infty}^{+\infty}[A_1(s,p)e^{t_1y}+A_2(s,p)e^{t_2y}]e^{-isx}dx \tag{17}$$

$$\psi^*(x,y,p)=\frac{1}{2\pi}\int_{-\infty}^{+\infty}[A_3(s,p)e^{t_3y}+A_4(s,p)e^{t_4y}]e^{-isx}dx \tag{18}$$

$$\begin{aligned}\phi^*(x,y,p)=&\frac{1}{2\pi}\int_{-\infty}^{+\infty}\frac{e_0}{\kappa_0}[A_1(s,p)e^{t_1y}+A_2(s,p)e^{t_2y}]e^{-isx}dx\\&+\frac{1}{2\pi}\int_{-\infty}^{+\infty}[A_3(s,p)e^{t_3y}+A_4(s,p)e^{t_4y}]e^{-isx}dx\end{aligned} \tag{19}$$

There are four unknown functions $A_i(s,p),i=1,2,3,4$ which can be solved by considering the boundary conditions and continuity conditions which are formulated by Eqs. (8-10).

$$t_1=-\frac{\beta}{2}+\sqrt{(\frac{\beta}{2})^2+s^2+s_0p^2},t_2=-\frac{\beta}{2}-\sqrt{(\frac{\beta}{2})^2+s^2+s_0p^2},t_3=-\frac{\beta}{2}+\sqrt{(\frac{\beta}{2})^2+s^2},t_4=-\frac{\beta}{2}+\sqrt{(\frac{\beta}{2})^2+s^2} \tag{20}$$

3.2 Transformation to singular integral equation

In order to derive the singular integral equation, two dislocation density functions are introduced as

$$f^*(x,p)=\begin{cases}\dfrac{\partial\omega^*(x,0,p)}{\partial x} & |x|\le c\\ 0 & |x|>c\end{cases} \tag{21}$$

$$g^*(x,p)=\begin{cases}\dfrac{\partial\phi^*(x,0,p)}{\partial x} & |x|\le c\\ 0 & |x|>c\end{cases} \tag{22}$$

Substituting Eqs. (17-19) into Eq. (8), and considering Eqs. (21-22), one can obtain the following relation

$$A_1(s,p)+A_2(s,p)=\frac{1}{-is}\int_{-c}^{c}f^*(t,p)e^{ist}dt \tag{23}$$

$$A_3(s,p)+A_4(s,p)=(-\frac{e_0}{\kappa_0})\cdot(\frac{1}{-is}\int_{-c}^{c}f^*(t,p)e^{ist}dt)+\frac{1}{-is}\int_{-c}^{c}g^*(t,p)e^{ist}dt \tag{24}$$

Substituting Eqs. (2) (17-19) into Eq. (10), it yields

$$(c_0+\frac{e_0^{\ 2}}{\kappa_0})e^{\beta h}[t_1A_1(s,p)e^{t_1h}+t_2A_2(s,p)e^{t_2h}]+e_0e^{\beta h}[t_3A_3(s,p)e^{t_3h}+t_4A_4(s,p)e^{t_4h}]=0 \tag{25}$$

$$2e_0e^{\beta h}[t_1A_1(s,p)e^{t_1h}+t_2A_2(s,p)e^{t_2h}]+\kappa_0e^{\beta h}[t_3A_3(s,p)e^{t_3h}+t_4A_4(s,p)e^{t_4h}]=0 \tag{26}$$

One can finally obtain the following relations form Eqs. (23-26)

$$A_1=\frac{-t_2e^{t_2h}}{t_1e^{t_1h}-t_2e^{t_2h}}f,\quad A_2=\frac{t_1e^{t_1h}}{t_1e^{t_1h}-t_2e^{t_2h}}f \tag{27}$$

$$A_3=\frac{-t_4e^{t_4h}}{t_3e^{t_3h}-t_4e^{t_4h}}(-\frac{e_0}{\kappa_0}f+g),\quad A_4=\frac{t_3e^{t_3h}}{t_3e^{t_3h}-t_4e^{t_4h}}(-\frac{e_0}{\kappa_0}f+g) \tag{28}$$

where

$$f=\frac{1}{-is}\int_{-c}^{c}f^*(t,p)e^{ist}dt,\quad g=\frac{1}{-is}\int_{-c}^{c}g^*(t,p)e^{ist}dt \tag{29}$$

Then, substituting Eqs. (2) (27-29) into Eqs. (2), the basic solution expression of the electric displacement and anti-plane stresses is obtained. And then, substituting the electric displacement and stress component into Eq. (8), one arrives at an integral equation in the form [6]

$$\frac{1}{\pi}\int_{-c}^{c}\frac{f^*(t,p)}{t-x}dt+\frac{e_0}{\pi}\int_{-c}^{c}\frac{g^*(t,p)}{t-x}dt+\frac{1}{\pi}\int_{-c}^{c}K_{11}(x,t,p)f^*(t,p)dt$$
$$-\frac{e_0}{\pi}\int_{-c}^{c}K_{12}(x,t,p)g^*(t,p)dt=-\frac{\tau_0}{p} \tag{30}$$

$$-\frac{e_0}{\pi}\int_{-c}^{c}\frac{f^*(t,p)}{t-x}dt+\frac{\kappa_0}{\pi}\int_{-c}^{c}\frac{g^*(t,p)}{t-x}dt-\frac{e_0}{\pi}\int_{-c}^{c}K_{21}(x,t,p)f^*(t,p)dt$$
$$+\frac{\kappa_0}{\pi}\int_{-c}^{c}K_{22}(x,t,p)g^*(t,p)dt=-\frac{D_0}{p} \tag{31}$$

where

$$K_{11}=\int_0^{+\infty}[U_1(s,p)-1]\sin s(t-x)ds,\quad K_{12}=\int_0^{+\infty}[U_2(s,p)+1]\sin s(t-x)ds,$$
$$K_{21}=K_{22}=\int_0^{+\infty}[U_2(s,p)-1]\sin s(t-x)ds \tag{32}$$

$$U_1=\frac{1}{s}[\frac{e_0^{\ 2}}{\kappa_0}\cdot\frac{t_3t_4e^{t_3h}-t_3t_4e^{t_4h}}{t_3e^{t_3h}-t_4e^{t_4h}}-(c_0+\frac{e_0^{\ 2}}{\kappa_0})\cdot\frac{t_1t_2e^{t_1h}-t_1t_2e^{t_2h}}{t_1e^{t_1h}-t_2e^{t_2h}}],\ U_2=\frac{1}{s}\cdot\frac{t_3t_4e^{t_3h}-t_3t_4e^{t_4h}}{t_3e^{t_3h}-t_4e^{t_4h}} \tag{33}$$

Because of the symmetry of fracture analysis, the dislocation density function $F(u,p),(u,p)$ must be an odd function of u. Then, it is automatically satisfied

$$f^*(0,p)=0,g^*(0,p)=0 \tag{34}$$

3.3 Numerical solution

Introducing $t=uc,x=rc$, $f^*(t,p)=F(u,p),g^*(t,p)=G(u,p)$, $K_{ij}(x,t,p)=K_{ij}^{\ *}(u,r,p)(i,j=1,2)$, Eqs. (30-31) and (34) can be transformed into the standard form of the first kind Cauchy singular integral equations as

$$\frac{1}{\pi}\int_{-1}^{1}\frac{F(u,p)}{u-r}du+\frac{e_0}{\pi}\int_{-1}^{1}\frac{G(u,p)}{u-r}du+\frac{c}{\pi}\int_{-1}^{1}K_{11}^{*}(r,u,p)\cdot F(u,p)du$$

$$-\frac{e_0 c}{\pi}\int_{-1}^{1}K_{12}^{*}(r,u,p)G(u,p)du=-\frac{\tau_0}{p} \tag{35}$$

$$-\frac{e_0}{\pi}\int_{-1}^{1}\frac{F(u,p)}{u-r}du+\frac{\kappa_0}{\pi}\int_{-1}^{1}\frac{G(u,p)}{u-r}du-\frac{e_0 c}{\pi}\int_{-1}^{1}K_{21}^{*}(r,u,p)\cdot F(u,p)du$$
$$+\frac{\kappa_0 c}{\pi}\int_{-1}^{1}K_{22}^{*}(r,u,p)G(u,p)du=-\frac{D_0}{p} \tag{36}$$

$$F(0,p)=0\,,\ G(0,p)=0 \tag{37}$$

According to the theory of singular integral equation, the solution of $F(u,p)$ 和 $G(u,p)$ may be expressed as [6]

$$f^{*}(t,p)=F(u,p)=\frac{R(u,p)}{\sqrt{1-u^2}}\,,\quad R(u,p)=\sum_{n=0}^{\infty}C_n T_n(u,p) \tag{38}$$

$$g^{*}(t,p)=G(u,p)=\frac{S(u,p)}{\sqrt{1-u^2}}\,,\quad S(u,p)=\sum_{n=0}^{\infty}D_n T_n(u,p) \tag{39}$$

Based on the Cauchy-Chebyshev collocation method, Eqs. (35-37) are reduced into a system of algebraic equations [6]

$$\sum_{l=1}^{N}\left[\frac{1}{u_l-r_m}+cK_{11}^{*}(r_m,u_l,p)\right]\frac{R(u_l,p)}{N}+\sum_{l=1}^{N}\left[\frac{e_0}{u_l-r_m}+e_0 cK_{12}^{*}(r_m,u_l,p)\right]\frac{S(u_l,p)}{N}=-\frac{\tau_0}{p} \tag{40}$$

$$\sum_{l=1}^{N}\left[-\frac{e_0}{u_l-r_m}+e_0 cK_{21}^{*}(r_m,u_l,p)\right]\frac{R(u_l,p)}{N}+\sum_{l=1}^{N}\left[\frac{\kappa_0}{u_l-r_m}+\kappa_0 cK_{22}^{*}(r_m,u_l,p)\right]\frac{S(u_l,p)}{N}=-\frac{D_0}{p} \tag{41}$$

$$\sum_{l=1}^{N}\frac{R(u_l,p)}{N}=0\,,\sum_{l=1}^{N}\frac{S(u_l,p)}{N}=0 \tag{42}$$

where

$$u_l=\cos\left(\frac{2l-1}{2N}\pi\right)\ (l=1,2,\cdots,N)\,,\ r_m=\cos\left(\frac{m}{N}\pi\right)\ (m=1,2,\cdots,N-1) \tag{43}$$

Solving Eqs. (40-41) and taking (42) into account, the numerical values of the function $R(u_l,p)$ and $S(u_l,p)$ can be obtained. Furthermore, the values of the function $F(u,p)$ and $G(u,p)$ can be obtained numerically. Thus, after obtaining the solutions $f\,,g$ from the Eqs. (19), we may obtain the four unknown functions $A_i(s,p),i=1,2,3,4$ from Eqs. (27-28), furthermore, the mechanical displacement, electric potential of the strip in the Laplace domains will be obtained from Eqs. (17-19).

3.4 Temperature field of the crack tip

Research of Bilyk et al [5] revealed that applying high current on the conductor, the temperature of conductor is lager than the temperature just under force load. Then, this paper discusses the heating effect of the crack tip on piezoelectric medium under the high electric shock load. Secondly, within supposing that it is a heat insulation process in a short time, and thermal field and electromechanical filed is decoupled, the thermal effect is calculated. according to ref. [5] which shows that electromagnetic field diffusion time scale is far less than the heat conduction time scale under action current load, the this process can be approximated as adiabatic process, so this assumption is established.

In accordance with the above assumptions, under the adiabatic conditions, the first approximation of heat conduction equation of the piezoelectric materials is

$$p = c_0 \frac{\partial T}{\partial t} \tag{44}$$

where c_0 denotes specific heat capacity.

For there is no external heat source, according to the ref. [7] of the electric shock which can retard effectively crack propagation, the heat source power can be introduced to the function of equivalent external point heat source

$$p = E \cdot J \tag{45}$$

where J denotes the electric current density vector field of the dielectric materials.

Current density vector of the dielectric material can be expressed as

$$J = \frac{\partial D}{\partial t} \tag{46}$$

Functionally graded piezoelectric material belongs to the dielectric material. Similarly, introducing power of heat source, temperature field of piezoelectric medium is obtained from the time integration of expression which can be obtained by substituting (45-46) into expressions of (44),

$$T(x,y,t) = \frac{1}{c_0}\int_0^t E(x,y,\tau)\frac{\partial D(x,y,\tau)}{\partial \tau}d\tau \tag{48}$$

For the geometric Eq. (3), constitutive Eq. (2) and fundamental solution (17-19), we get

$$\begin{aligned} E_x^*(x,y,p) = {} & \frac{1}{2\pi}\int_{-\infty}^{+\infty} is\cdot\frac{e_0}{\kappa_0}[A_1(s,p)e^{t_1 y} + A_2(s,p)e^{t_2 y}]e^{-isx}ds \\ & + \frac{1}{2\pi}\int_{-\infty}^{+\infty} is\cdot[A_3(s,p)e^{t_3 y} + A_4(s,p)e^{t_4 y}]e^{-isx}ds \end{aligned} \tag{49}$$

$$\begin{aligned} E_y^*(x,y,p) = {} & -\frac{1}{2\pi}\int_{-\infty}^{+\infty}\frac{e_0}{\kappa_0}[t_1 A_1(s,p)e^{t_1 y} + t_2 A_2(s,p)e^{t_2 y}]e^{-isx}ds \\ & - \frac{1}{2\pi}\int_{-\infty}^{+\infty}[t_3 A_3(s,p)e^{t_3 y} + t_4 A_4(s,p)e^{t_4 y}]e^{-isx}ds \end{aligned} \tag{50}$$

$$\begin{aligned} D_x^*(x,y,p) = {} & (e_{15} - \kappa_{11}\cdot\frac{e_0}{\kappa_0})\frac{1}{2\pi}\int_{-\infty}^{+\infty}(-is)\cdot[A_1(s,p)e^{t_1 y} + A_2(s,p)e^{t_2 y}]e^{-isx}ds \\ & - \kappa_{11}\cdot\frac{1}{2\pi}\int_{-\infty}^{+\infty}(-is)\cdot[A_3(s,p)e^{t_3 y} + A_4(s,p)e^{t_4 y}]e^{-isx}ds \end{aligned} \tag{51}$$

$$\begin{aligned} D_y^*(x,y,p) = {} & (e_{15} - \kappa_{11}\cdot\frac{e_0}{\kappa_0})\frac{1}{2\pi}\int_{-\infty}^{+\infty}[t_1 A_1(s,p)e^{t_1 y} + t_2 A_2(s,p)e^{t_2 y}]e^{-isx}ds \\ & - \kappa_{11}\cdot\frac{1}{2\pi}\int_{-\infty}^{+\infty}[t_3 A_3(s,p)e^{t_3 y} + t_4 A_4(s,p)e^{t_4 y}]e^{-isx}ds \end{aligned} \tag{52}$$

Furthermore, the solution of electric field strength and electric displacement intensity in the Laplace transform domain is

$$E_x^*(x,y,p) = c[\sum_{l=1}^{N} K_{ex1}(u_l,x,y,p)\frac{R(u_l,p)}{N} + \sum_{l=1}^{N} K_{ex2}(u_l,x,y,p)\frac{S(u_l,p)}{N}] \tag{53}$$

$$E_y^*(x,y,p) = c[\sum_{l=1}^{N} K_{ey1}(u_l,x,y,p)\frac{R(u_l,p)}{N} + \sum_{l=1}^{N} K_{ey2}(u_l,x,y,p)\frac{S(u_l,p)}{N}] \tag{54}$$

$$D_x^*(x,y,p) = c[\sum_{l=1}^{N} K_{dx1}(u_l,x,y,p)\frac{R(u_l,p)}{N} + \sum_{l=1}^{N} K_{dx2}(u_l,x,y,p)\frac{S(u_l,p)}{N}] \tag{55}$$

$$D_y^*(x,y,p)=c[\sum_{l=1}^{N}K_{dy1}(u_l,x,y,p)\frac{R(u_l,p)}{N}+\sum_{l=1}^{N}K_{dy2}(u_l,x,y,p)\frac{S(u_l,p)}{N}] \tag{56}$$

where

$$K_{ex1}(u,x,y,p)=\int_0^{+\infty}\frac{e_0}{\kappa_0}[\frac{t_2e^{t_2h+t_1y}-t_1e^{t_1h+t_2y}}{t_1e^{t_1h}-t_2e^{t_2h}}+\frac{t_3e^{t_3h+t_4y}-t_4e^{t_4h+t_3y}}{t_3e^{t_3h}-t_4e^{t_4h}}]\cos[s(cu-x)]ds \tag{57}$$

$$K_{ex2}(u,x,y,p)=\int_0^{+\infty}\frac{t_4e^{t_4h+t_3y}-t_3e^{t_3h+t_4y}}{t_3e^{t_3h}-t_4e^{t_4h}}\cos[s(cu-x)]ds \tag{58}$$

$$K_{ey1}(u,x,y,p)=\int_0^{+\infty}\frac{e_0}{\kappa_0}[\frac{t_1t_2e^{t_1h+t_2y}-t_1t_2e^{t_2h+t_1y}}{t_1e^{t_1h}-t_2e^{t_2h}}+\frac{t_3t_4e^{t_4h+t_3y}-t_3t_4e^{t_3h+t_4y}}{t_3e^{t_3h}-t_4e^{t_4h}}]\sin[s(cu-x)]ds \tag{59}$$

$$K_{ey2}(u,x,y,p)=\int_0^{+\infty}\frac{t_3t_4e^{t_3h+t_4y}-t_3t_4e^{t_4h+t_3y}}{t_3e^{t_3h}-t_4e^{t_4h}}\sin[s(cu-x)]ds \tag{60}$$

$$K_{dx1}(u,x,y,p)=\int_0^{+\infty}(e_{15}-\kappa_{11}\frac{e_0}{\kappa_0})\frac{t_1e^{t_1h+t_2y}-t_2e^{t_2h+t_1y}}{t_1e^{t_1h}-t_2e^{t_2h}}+\kappa_{11}[\frac{t_3e^{t_3h+t_4y}-t_4e^{t_4h+t_3y}}{t_3e^{t_3h}-t_4e^{t_4h}}]\cos[s(cu-x)]ds \tag{61}$$

$$K_{dx2}(u,x,y,p)=\int_0^{+\infty}\kappa_{11}\frac{t_4e^{t_4h+t_3y}-t_3e^{t_3h+t_4y}}{t_3e^{t_3h}-t_4e^{t_4h}}\cos[s(cu-x)]ds \tag{62}$$

$$K_{dx1}(u,x,y,p)=\int_0^{+\infty}(e_{15}-\kappa_{11}\frac{e_0}{\kappa_0})\frac{t_1t_2e^{t_2h+t_1y}-t_1t_2e^{t_1h+t_2y}}{t_1e^{t_1h}-t_2e^{t_2h}}-\kappa_{11}[\frac{t_3t_4e^{t_3h+t_4y}-t_3t_4e^{t_4h+t_3y}}{t_3e^{t_3h}-t_4e^{t_4h}}]\sin[s(cu-x)]ds \tag{63}$$

$$K_{dx2}(u,x,y,p)=\int_0^{+\infty}-\kappa_{11}\frac{t_3t_4e^{t_4h+t_3y}-t_3t_4e^{t_3h+t_4y}}{t_3e^{t_3h}-t_4e^{t_4h}}\sin[s(cu-x)]ds \tag{64}$$

The solution of electric field strength and electric displacement intensity in the time domain are calculated by Laplace numerical inversion method. Furthermore using Eq. (48), the temperature field of the crack tip is obtained.

4. Numerical Examples and discussions

In the numerical computation, the functionally graded piezoelectric strip layer is assumed to be a non-homogeneous $BaTiO_3$ composite and the material constants of $y=0$ are

$$c_{44}=44Gpa,\quad e_{15}=11.4C/m^2,\quad \kappa_{11}=128.3\times10^{10}C/Vm,\quad \rho=5700Kg/m^3 \tag{65}$$

Here, the fundamental solution of crack under a pair of the equivalent electric shock $-D_0H(t)$ acting on the crack surface is considered strongly, so it assume that $\tau_0=0$.

Fig. 2 show the the temperature field around the crack tip versus the value of time. It is indicated that the effect of time on the temperature field is simple, i.e., when $c/h=1/2,1/3,1/4$ are specified, the temperature field increases drastically as time increases from 0 to 3. However, when time is larger than 3, the temperature field gradually decrease with time, finally, stabilized. It is also observed that the temperature field increases with the c/h increasing.

Fig. 3 depict the variation of the the temperature field around the crack tip versus the non-homogeneity parameter β. When time is small (t<2), the temperature field decreases as β increases; but when time is larger than 2, the temperature field increases drastically as β increases. Meanwhile, it is obviously indicated that when time is larger (t>2), the effect is larger than that when time is small (t<2). The above results show that the crack tip will cause high temperature change under high electric shock load. In this case, the crack tip temperature effect cannot be ignored

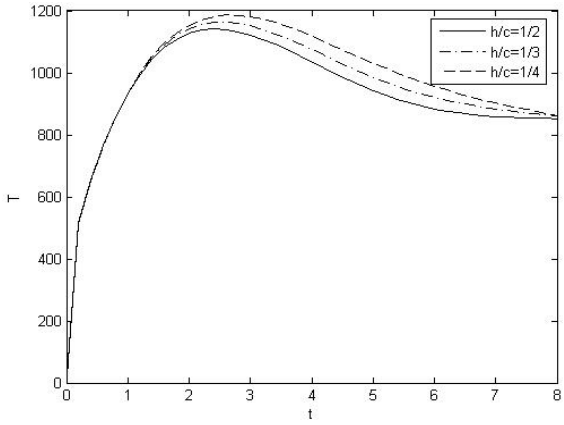

Figure 2. The temperature field around the crack tip versus time（$\beta = 0.5$ $\tau_0 = 0$， $D_0 = 5\times10^4$）

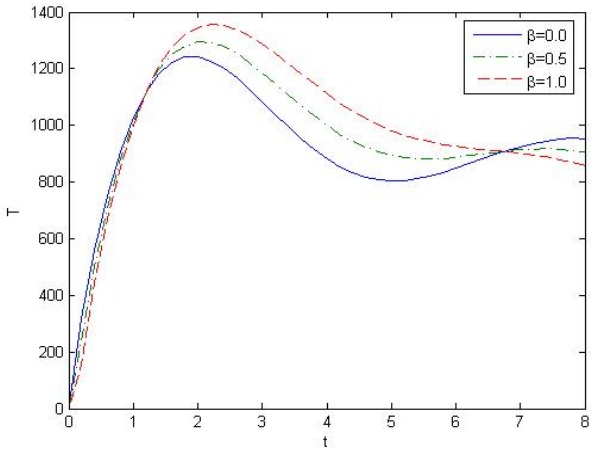

Figure 3. The temperature field around the crack tip versus parameter β （$h = 0.5c$，$\tau_0 = 0$，$D_0 = 5\times10^4$）

5. Conclusions

Research of Bilyk et al [5] revealed that applying high current on the conductor, the temperature of conductor is lager than the temperature just under force load. Then, this paper discusses the heating effect of the crack tip on piezoelectric medium under the high electric shock load. The thermal effect of a mode III crack in a functionally graded strip under the electric shock is investigated. This fracture analysis can be expressed through the superposition of two problems. The first problem refers to the dynamic behaviors of a functionally graded piezoelectric strip with central crack subjected to the electric shock. The second problem means the temperature field by calculating the power of point heat source around the crack tip.

Firstly, without considering the related effect of temperature field, a theoretical model is developed for the dynamic fracture analysis of a functionally graded piezoelectric strip of a finite dimension with central crack subjected to the electric shock. The Laplace transformation and the Fourier transforms are applied to make the transient problem tractable, and singular integral equations is derived with the dislocation density functions of crack as the unknown functions. In particular, the closed-form expressions for the electric field intensity and electric displacements intensity in terms of fundamental functions are derived, which provide a scientific basis for the interpretation of the thermal effect. Secondly, within supposing that it is a heat insulation process in a short time, the thermal effect is calculated. For this problem, thermal field and electromechanical filed is decoupled. So the heat conduction equation contains no electromechanical quantity. Based on that the

temperature of conductors increases when high voltage is applied and that the electric field intensity and electric displacements intensity is obtained in the first solution. The power of point heat source of functionally graded piezoelectric strip is deduced. Therefore, from the time integration of power equations of point heat source, the temperature field around the crack tip is calculated.
It is worth noting that the problem of a cracked functionally graded piezoelectric strip under electric shock is a mix mode crack problem. The first problem is an electromechanical coupling problem. And the second problem is the temperature field around the crack tip, which is the basis problem of mode I or II heat crack analysis.

Abstract
An experimental approach is presented for characterizing the fatigue behavior of a functionally graded flange shaft. Micro-specimens are defined based on the inhomogeneous phase distribution and microstructure of the flange. Subsequently the experimental setup is described for the investigation of the phase dependent fatigue behavior, and some results are presented. It was found that there is a significant amount of crack retardation in the transition zone in the flange which is located between the soft ferritic phase and the hard martensitic phase. This is verified using a two-sided observation of the propagating crack with two travelling microscopes.
Keywords Graded material, crack growth, fatigue, edge crack

1. Introduction

Functionally graded steel components can play a key-role in the on-going challenges about increase of productivity and saving of resources as they can be tailor-made to the specific requirements in a given application case. However, standard testing and design procedures based on results obtained with homogenous materials may not be sufficient to ensure reliable operation of such components as the interaction of the different regions in the graded component can induce additional damage mechanisms. This is especially true for microstructure-based failure processes such as fatigue failure.

A simple example for a functional gradation is the surface hardening process of a steel component in order to achieve a soft, ductile core and a hard, wear resistant surface. The fatigue behavior of case or surface hardened steel component has investigated (e.g. [1, 2]) recently, and it was found that the failure behavior could not be predicted by just superimposing the results obtained with the constituents in standard tests.

Another, more complex way to produce a functionally graded component is an integrated thermo-mechanical treatment on a steel shaft to form a flange shaft. [3] Such a flange shaft is characterized by a defined local distribution of at least three phases – the soft ferritic-pearlitic base material in an untreated and a deformed state, a hard martensitic phase and a small, mainly bainitic transition zone in between. Under fatigue loading, crack may initiate in the soft phase and propagate towards the hard phase leading to catastrophic failure. In this case, crack initiation and propagation depends not only on the fatigue properties of each phase, but also on their spatial distribution. Obviously, conventional fatigue testing with homogenous specimens will not capture these specific features of the damage accumulation process in a graded component, and may therefore lead to erroneous results. Instead, specimens have to be defined which can directly be cut from the component and contain the phases of interest together with the component specific grading [4, 5].

This paper deals with obtaining valid crack growth data in the flange-shaft mentioned above [3].

The material and the microstructure obtained by the thermo-mechanical forming process are described in the first section. Then the experimental set-up is described which has been developed for obtaining microstructure-dependent crack growth rates. Finally the experimental results are compared with findings of a FE simulation.

2. Material and graded microstructure

The tested material is a low-alloy steel in tempered condition (German designation 51CrV4) with the chemical composition given in Table 1. It has a ferritic-perlitic microstructure and a yield strength of 520 MPa.

Table 1. Chemical composition of 51CrV4

Element	C	Si	Mn	Cr	V	P	S
Weight %	0,47-0,55	≤0,40	0,70-1,10	0,90-1,20	0,10-0,25	≤0,035	≤0,035

An integrated thermo-mechanical forming process, as shown in Fig. 1, was applied to a shaft resulting in a flange shaft with a graded microstructure [3]. First the shaft was heated up above austenitization temperature by induction heating and then put into the molding press to form the flange, which lead to a local martensitic transformation of the original ferritic-perlitic phase.

Figure 1: Integrated thermo-mechanical forming process of the flange shaft [6]

Due to the high natural strain during the forming process a fine grained microstructure is formed, which contains dispersed small defects like inclusions and carbides. The resulting phase distribution is given in the etched micrograph in Fig. 2. It is characterized by the ferritic-perlitic base cold-worked material (grey) in a in the core of the flange shaft and a martensitic phase (dark) at the outside of the flange. The phases are linked by a transition zone (white) of varying width and material properties. For an unambiguously phase identification micro-hardness measurements are used. As shown in Fig. 3, the martensite possesses hardness values above 650 HV (Pos. 1), the transition zone about 450 HV (Pos. 2) and the deformed base material has hardness values below 300 HV (Pos. 1).

Figure 2. Micrograph of the flange shaft, etched

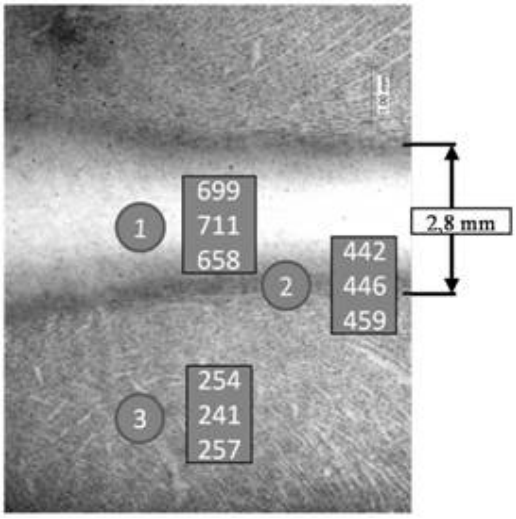

Figure 3. Vickers hardness of the different phases

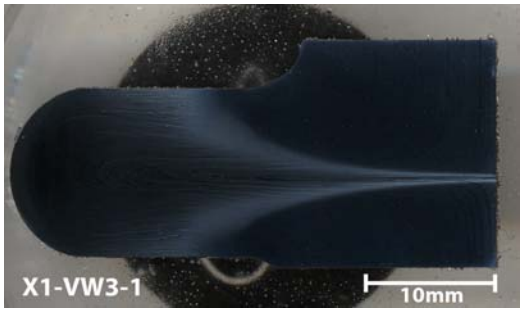
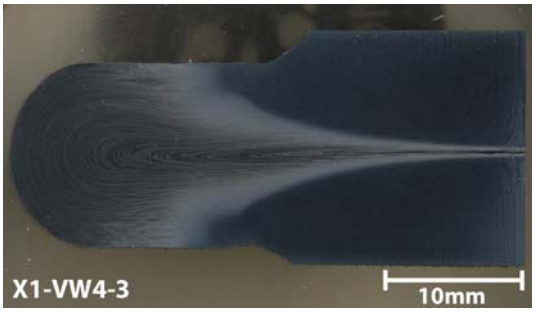
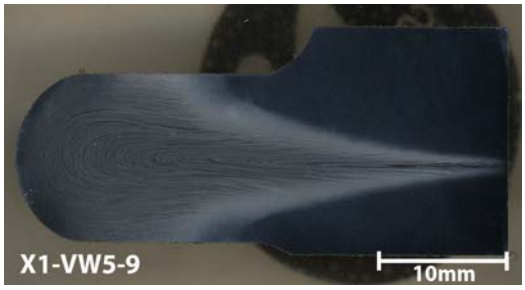
In order to optimize the local phase distribution and its properties in the flange shaft several pre-heating strategies were developed. Beside the standard flange shaft having room temperature at the start of the forming process four pre-heating temperatures were used for the flange. Therefore the flanges were heated up to 300, 400, 500 or 600°C in a convection oven. Then the local induction heating above the austenitization temperature was carried out before forming. The corresponding phase distribution in the flange shaft for each pre-heating temperature is given in Fig. 4 a-d).



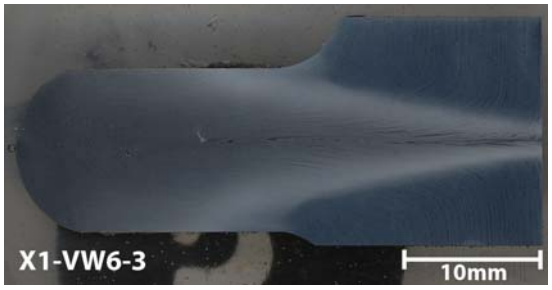
a) pre-heating temperature 300°C



b) pre-heating temperature 400°C



c) pre-heating temperature 500°C

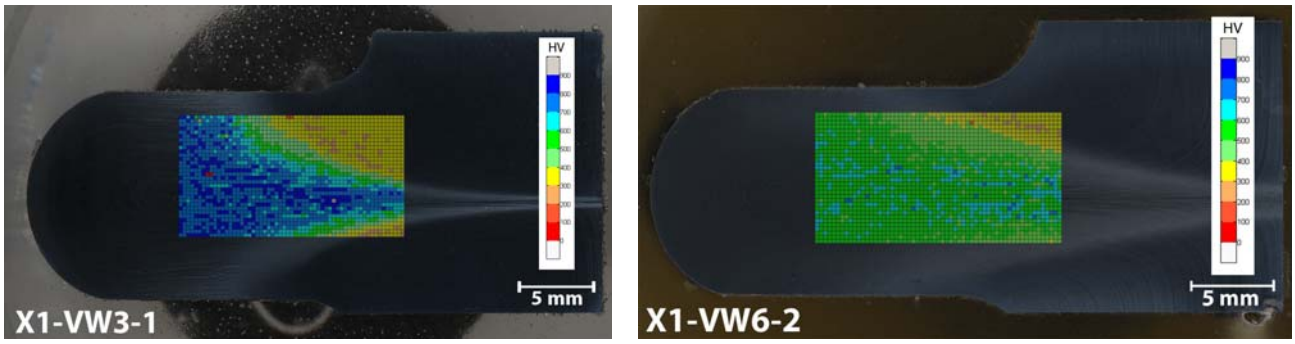


d) pre-heating temperature 600°C

Figure 4. Micrographs of the flange shafts with various pre-heating temperatures, etched

The etched micrographs of the flange shafts, given in Fig. 4 a)-d), reveal that an increasing pre-heating temperature leads to an increasing amount of the transformed phase at the outer part of the flange. The width of the transition zone (white area) increases as well. A second observation of

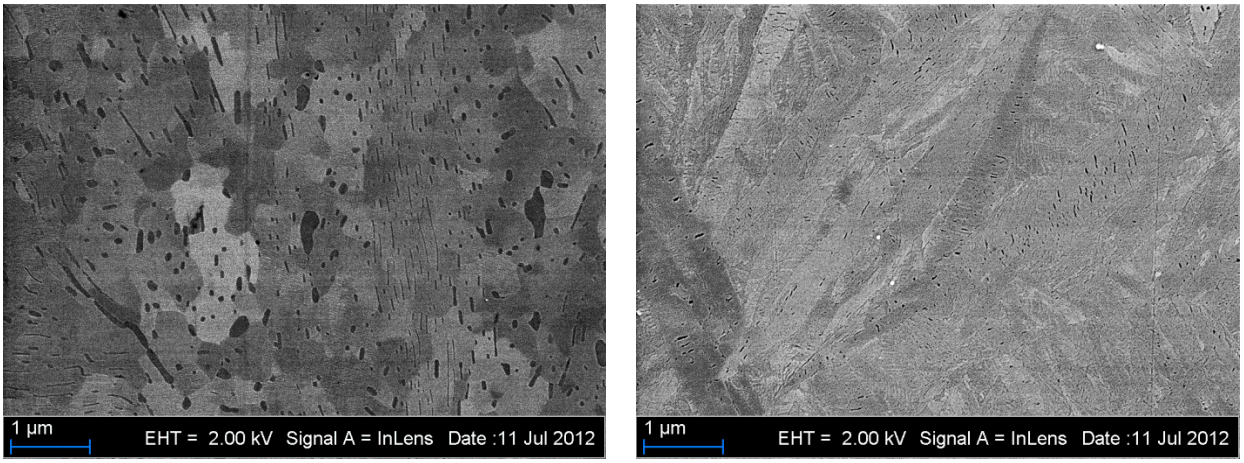
the micrographs is that the etched micrograph becomes brighter in the transformed phase with an increasing pre-heating temperature. This indicates an increasing amount of bainite in the martensitic zone caused by a lower cooling rate during the phase transformation. Verification of this observation can be given by a micro-hardness indentation only, which is shown in Fig. 5 a-b).



a) pre-heating temperature 300°C b) pre-heating temperature 600°C

Figure 5. Micro hardness indentations on 300°C and 600°C pre-heated flange shafts

Pre-heating the flange shaft with a temperature of 600°C decreases the hardness gradient in the flange as expected. As presented in Fig. 5 b), the difference in the Vickers hardness between transition zone and the martensitic zone becomes marginal compared to a 300°C pre-heated flange shaft, given in Fig. 5 a).



c) deformed base material b) martensite

Figure 6. SEM-images from the microstructure of a 500°C pre-heated flange-shaft

Due to the high degree of deformation combined with the high temperature during the forming process a very fine grained and complex microstructure exists in the flange shaft. SEM micrographs show that the grain size is of the order of 1 micron, see Fig. 6 for a 500°C pre-heated flange shaft. The deformed base material, shown in Fig. 6 a), still has its ferritic-pearlitic microstructure, but the original lamellar structure of the pearlite is mainly destroyed. The former cementite lamellae now mostly have a globular shape while the remaining ones are highly deformed. The martensite, shown in Fig. 6 b), is characterized by small carbides in the martensitic needles. It has been observed, that with an increasing pre-heating temperature the amount of carbides increases as well. This observation may support the assumption of a hardness decreasing tempering effect which is caused by significantly slower cooling rate after the phase transformation [7].

Both the increase of the transition zone width and the decrease of the hardness in the transformed phase are desired effects of the pre-heating strategy, but will lead to a variation in the fatigue behavior of the flange shaft. So, a comparison of the fatigue crack propagation in the flange shafts for all four pre-heating temperatures is necessary.

3. Experimental set-up

For analyzing the fatigue behavior of the transition zone micro-specimens were cut out from the flange using high precision spark erosion. A dog-bone shaped micro-specimen (32.5 mm long and about 2.4 mm thick), shown in Fig. 8, was developed with the purpose of performing microstructure specific fatigue tests. As shown in Fig. 8, the center of the specimen consists of martensite (dark) while the white areas mark the transition zone and the deformed base material is in grey again. The preparation of the specimens consisted of mechanical polishing and mechanical-chemical polishing with OPS in the final step.

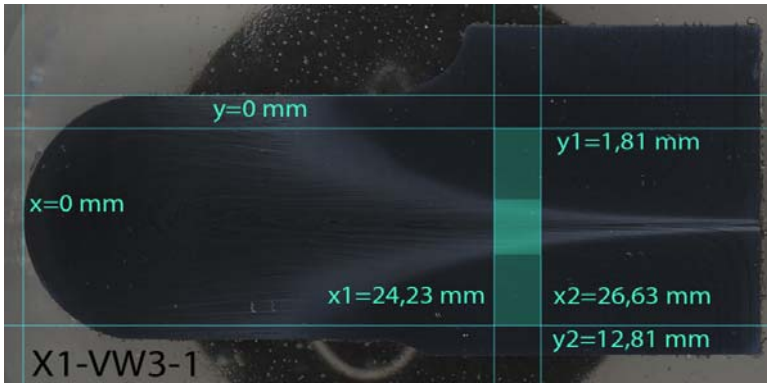


Figure 7. Micrograph taken from a flange shaft to determine the exact specimen position, etched

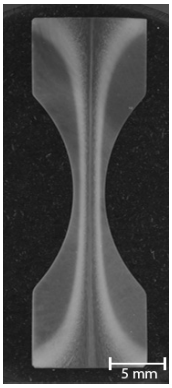

Figure 8. Micro specimen, etched

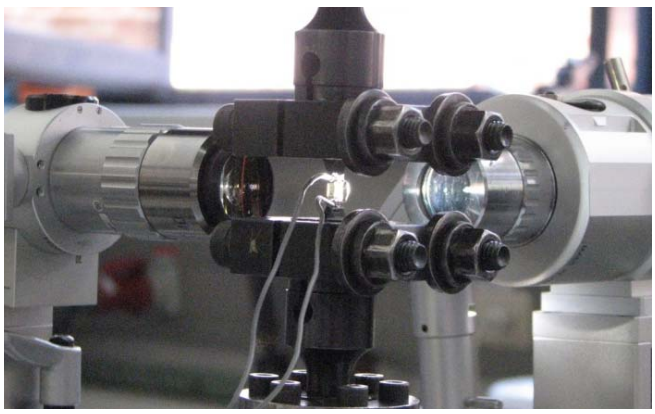

Figure 9. Experimental setup with two long distances microscopes in front of the micro-specimen

All fatigue tests were carried out as uniaxial tests at room temperature on a servo-hydraulic testing machine. The stress ratio was set to R = -1 (i.e. fully reversed) with 500 MPa were chosen as load amplitude. Tests with smooth specimens were monitored using one travelling long distance

microscope, whereas two long distance microscopes sitting on motorized three-axis stages were mounted on the rig of the fatigue testing machine to observe the fatigue crack growth at the edge-notched micro-specimen in horizontal and vertical direction, as shown in Fig. 9.
The test procedure itself starts with a scan of the unloaded surface of the micro-specimen. Then the micro-specimen is subjected to fatigue loading with a pre-defined number of load cycles and the surface is scanned again. Repeating this procedure allows monitoring the damage accumulation process on the surface of the micro-specimen and determining the local crack growth rates.

4. Results

Under fatigue loading, microcracks were initiated at inclusions in the base material on the surface of smooth specimens. However, these cracks showed only limited crack extension and never caused failure. Instead, one or two edge cracks were initiated in the vicinity of the notch root. A typical example is shown in Figure 10. It can be seen that the crack paths are fairly rough in spite of the fine microstructure and that the averaged crack line is not exactly perpendicular to the loading direction. These effects can be attributed to texture effects in the deformed base material. First of all, the rods used in the forming process possessed a rather pronounced manufacturing texture and showed lines of enhanced chromium content (dark lines in the shaft in Figure 2). These lines are still visible in the flange after the thermo-mechanical forming process. SEM analyses indicated that crack kinking can also be correlated with local bands of pearlite which survived the forming process. Moreover, there are regions in which the grains in the deformed base material are strongly correlated in their crystallographic orientations (e.g. areas highlighted with white dashed lines Figure 11), i.e. the grain structure shown in Figure 6 is replaced by set of subgrains separated by low angle boundaries. A crack passing through such an area is deviated from its original path due to the local anisotropy of the microstructure (yellow dashed line in Figure 11).
The growth rate of crack #1 is depicted in Figure 12. Apparently, the crack was slowed down after it had reached a length of about 1mm, and picked up considerable speed at about 1.3mm. Comparison with Figure 10 indicates that these changes in the crack growth rate may be related to the graded microstructure. This conjecture was verified using micro-hardness indentation along the crack faces as shown in Figure 13. Figure 12 indicates that there is a clear correlation between an increase in the hardness (corresponding to the transition region) and a decrease in the crack growth rate, and that the sudden rise in the crack growth rate occurs at the maximum of the hardness curve (martensite).

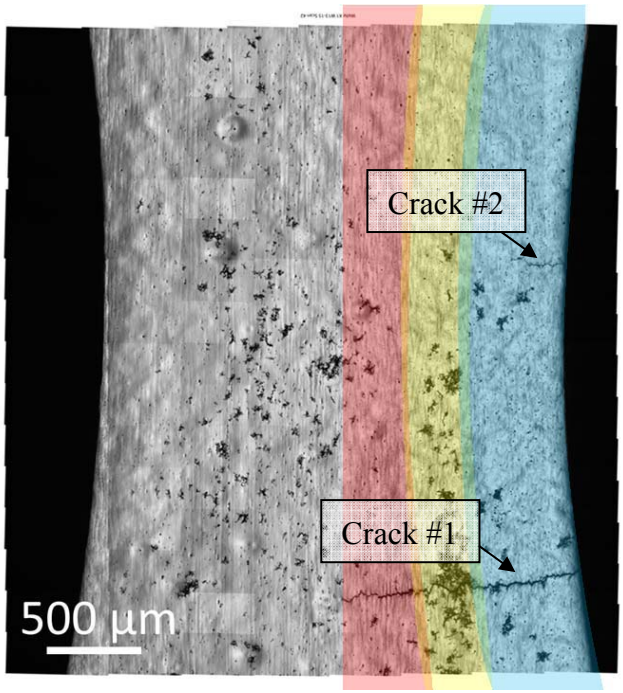

Figure 10. Typical crack paths on the surface of a micro-specimen; phase boundaries are indicated in color

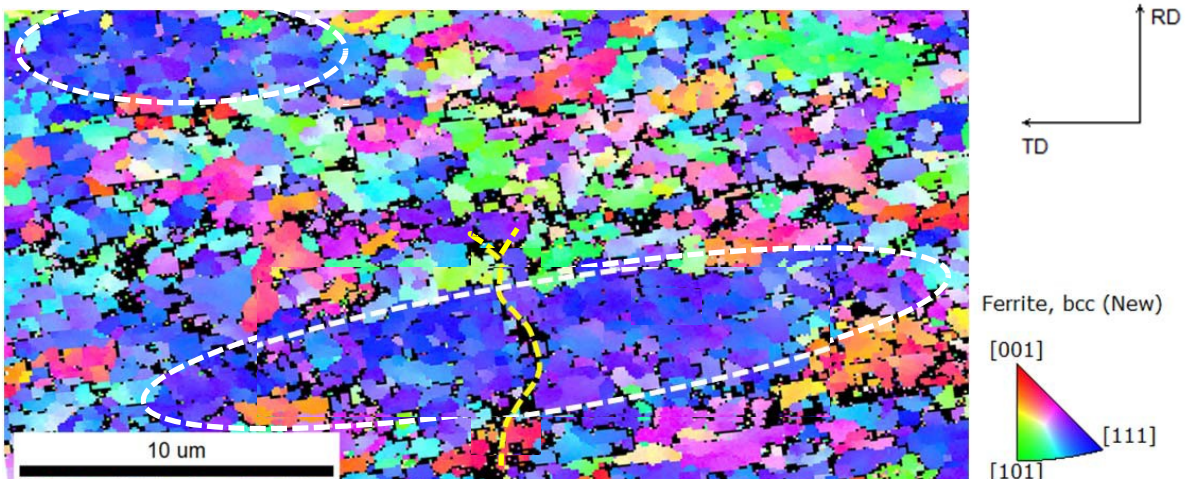

Figure 11. Interaction of crack with areas of local anisotropy

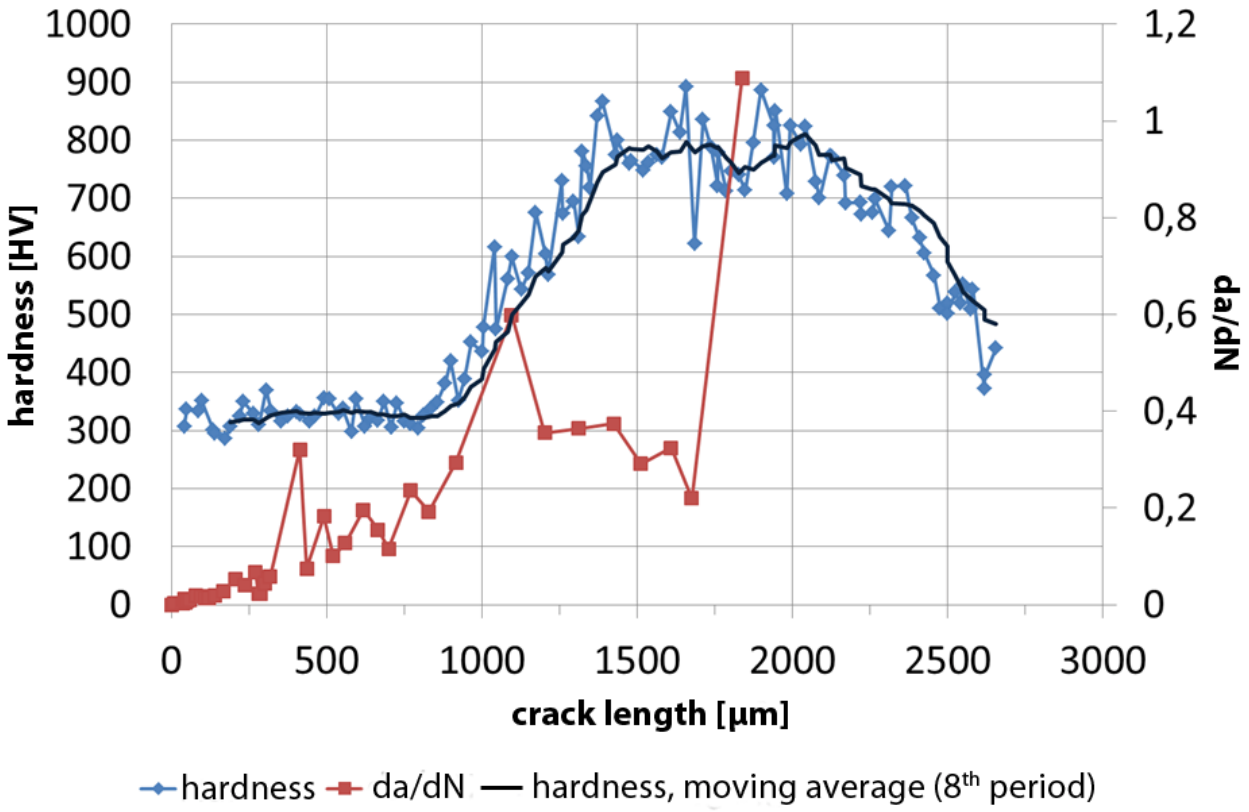

Figure 12. Microstructure dependent growth rate of crack #1

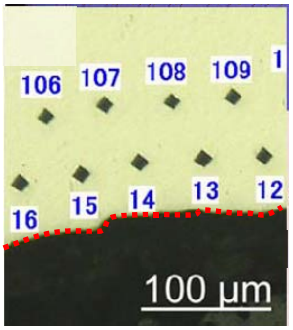

Figure 13. Micro-hardness indentations along section of crack face (dotted red line)

Even though the correlation between the distribution of the phases in the specimen and the acceleration and deceleration of the crack extension process is quite good, it has to be kept in mind that extension of an edge crack is a three-dimensional process, and that conclusions based only on surface observation may be misleading. Therefore a micro-specimen was prepared with an artificial edge notch, and the crack extension from the notch was monitored using the experimental set-up with two travelling microscopes as shown in Figure 9. The initial scans were made in the unloaded state and are given in Fig. 14 a) for the side view (vertical direction) of the micro-specimen and in Fig. 14 b) for the front view (horizontal direction). The fatigue crack initiated at the notch as expected and propagated in both directions. After a total of 45.000 load cycles, which represents approx. 96 % of the lifetime, the fatigue crack has reached a length of 1693.75 µm in the vertical direction (see Fig. 14 c)) and 1002.62 µm in the horizontal direction (see Fig. 14 d)). It seems that

the fatigue crack extends more rapidly in the vertical direction than in the horizontal direction. This effect may be related to an inhomogeneous phase distribution in the specimen. This will be clarified by a phase analysis of the fracture surface which is under way.

5. Summary and outlook

The fatigue damage accumulation process in a flange shaft made by a thermo-mechanical forming is dominated by single cracks which are initiated in the soft ferritic phase. Even though in those cases where these cracks are very small they do not propagate as microscopically small cracks as the microstructure is greatly refined due to the forming process with grain sizes of the order of 1 micron or even less. However there is a strong influence of the texture of the material on the crack path leading to pronounced deviations from straightforward mode-I crack propagation. A significant retardation in the crack growth rate was observed when the crack crosses the transition zone between the ferritic and the martensitic phases. This effect will be studied by using different

pre-heating strategies which greatly influence the phase distribution in the flange shaft.

Abstract

This ~~work~~ paper considers the problem of a partially permeable mixed-mode crack embedded in a graded magneto electro elastic layer subjected to magneto electro mechanical loads. The medium is graded in the direction orthogonal to the crack plane and is modeled as a non homogeneous medium with anisotropic constitutive laws. Using Fourier transform, the resulting magneto electro elasticity equations are converted analytically into singular integral equations which are then solved numerically to yield the crack-tip mode I and II stress, electric displacement and magnetic induction intensity factors. The main objective of this work is to study the influence of material non homogeneity, crack position and magneto electric permeabilities on the fields' intensity factors for the purpose of gaining better understanding on the behavior of fractured graded magneto electro elastic layers. Results showed that fields' intensity factors increase with nonhomogeneity, and decrease with magnetic and electric permeabilities, and as the crack become closer to the layer's center.

Introduction

Smart structures possessing the ability of magneto electro mechanical energy conversion have found increasing application in several engineering fields such as magnetic field probes, electric packaging, acoustic, hydrophones, medical ultrasonic imaging, microwave electronics, optoelectronics, electronic instrumentation, transducers, sensors and actuators. Research has focused on the use of Functionally Graded Magneto Electro Elastic Materials (FGMEEM) in smart structures to improve their performance. But, the manufacturing of FGMEEMs may lead to cracks that can eventually propagate and cause premature failure. Therefore, it is of a great importance to study the fracture behavior of magneto electro elastic composites.

A number of authors considered FGMEEM crack problems. Ma et al (2007) studied the mode III crack problem in a functionally graded magneto electro elastic strip accounting for ideal crack surface magneto electric permeability. Ma et al (2009) considered the problem of a surface crack in a functionally graded magneto electro elastic coating homogeneous elastic substrate subjected to anti-plane mechanical and in plane magneto electrical loading for the ideal crack surface magneto electric permeability. Zhou et al (2004) examined the problem of two parallel symmetric permeable cracks in functionally graded materials under anti-plane shear loading. Feng et al (2007) analyzed the dynamic behavior of magneto electrically impermeable cracks in functionally graded magneto electro elastic plates. Feng et al (2006) studied the dynamic problem of a crack embedded in a graded magneto electro elastic strip assuming ideal crack surface permeability. Jun (2007) examined the scattering of harmonic anti-plane shear stress waves by a crack in functionally graded magneto electro elastic materials assuming purely permeable crack surfaces. Zhou et al (2008) solved the mode I crack problem in a FGMEEM infinite medium assuming air permeability within the crack. Li et al (2008) considered the anti-plane problem of a permeable crack intersecting the interface between two FGMEEM layers. Li et al (2008) analyzed the anti-plane problem of a crack in the interface of tow symmetrically bonded FGMEEM assuming a linear variation of the magneto electromechanical properties. Guo et al (2009) solved the anti-plane problem of a crack in bonded FGMEEM strip sandwiched between two functionally graded strips assuming ideal magneto electrical permeability on the crack faces. Rekik et al (2012) considered the problem of magneto electrically impermeable crack embedded in a graded infinite medium subjected to magneto electro mechanical loading.

The present work consists of studying the plane problem of a partially magneto electrically permeable crack embedded in a graded magneto electro elastic layer. The applied magneto electro mechanical loading will give rise to coupled fields intensity factors; namely, mode I and II stress, electric

displacement and magnetic induction intensity factors denoted respectively k_1, k_2, k_D and k_B. To the best of the authors' knowledge, this problem was not considered in the open literature to-date.

Problem description and formulation

As shown in Figure 1, the problem under consideration consists of a functionally graded magneto electro elastic layer containing an embedded crack of length *2a* along the *x*-axis. The crack surfaces are assumed to be partial magneto electrically permeable using the magnetic and electric permeability parameters k_m and k_e varying in between 0 and 1 representing the cases of completely impermeable and completely permeable crack surfaces, respectively. Consequently, crack faces are subjected to mechanical tangential and normal tractions $\omega_1(x)$ and $\omega_2(x)$, electric displacement $(1-k_e)E(x)$, and magnetic induction $(1-k_m)B(x)$. The graded layer is modeled as a nonhomogeneous elastic medium with magneto electromechanical properties varying in the depth direction (y-coordinate) as follows:

$$\left(c_{11}, c_{13}, c_{33}, c_{44}\right) = \left(c_{110}, c_{130}, c_{330}, c_{440}\right) \mathrm{e}^{\beta y}, \quad \left(e_{15}, e_{31}, e_{33}\right) = \left(e_{150}, e_{310}, e_{330}\right) \mathrm{e}^{\beta y}, \quad \forall y, \qquad (1a,b)$$

$$\left(f_{15}, f_{31}, f_{33}\right) = \left(f_{150}, f_{310}, f_{330}\right) \mathrm{e}^{\beta y}, \quad \left(\varepsilon_{11}, \varepsilon_{33}\right) = \left(\varepsilon_{110}, \varepsilon_{330}\right) \mathrm{e}^{\beta y}, \quad \forall y, \qquad (1c,d)$$

$$\left(g_{11}, g_{33}\right) = \left(g_{110}, g_{330}\right) \mathrm{e}^{\beta y}, \quad \left(\mu_{11}, \mu_{33}\right) = \left(\mu_{110}, \mu_{330}\right) \mathrm{e}^{\beta y}, \quad \forall y. \qquad (1e,f)$$

where $c_{ij0}, e_{ij0}, f_{ij0}, \varepsilon_{ij0}, g_{ij0}, \mu_{ij0}$ are the value of the magneto electromechanical coefficient in the FGMEEM layer along the axis $y = 0$ and β is the nonhomogeneity parameter controlling the variation of these coefficient in the graded layer.

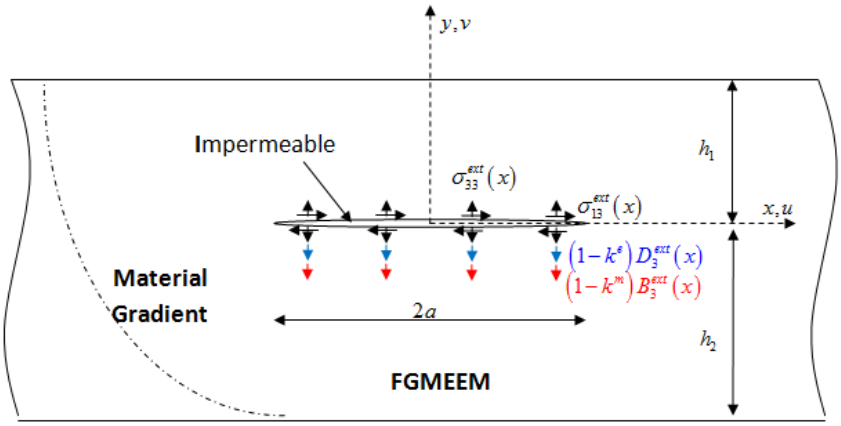

Figure 1. Geometry and loading of the crack problem

Neglecting body forces and local electric charge, assuming small deformations and considering linear constitutive laws, the basic equations consisting of equilibrium equations and Gauss's laws for electricity and magnetism can be combined, resulting in the following governing magneto electro elasticity equations:

$$c_{11}\frac{\partial^2 u}{\partial x^2} + c_{33}\left(\frac{\partial^2 u}{\partial y^2} + \beta\frac{\partial u}{\partial y}\right) + c_{12}\frac{\partial^2 v}{\partial x \partial y} + c_{33}\left(\frac{\partial^2 v}{\partial x \partial y} + \beta\frac{\partial v}{\partial x}\right) + e_{21}\frac{\partial^2 \phi}{\partial x \partial y} + e_{13}\left(\frac{\partial^2 \phi}{\partial x \partial y} + \beta\frac{\partial \phi}{\partial x}\right) + f_{21}\frac{\partial^2 \psi}{\partial x \partial y} + f_{13}\left(\frac{\partial^2 \psi}{\partial x \partial y} + \beta\frac{\partial \psi}{\partial x}\right) = 0, \qquad (2a)$$

$$c_{33}\frac{\partial^2 u}{\partial x \partial y} + c_{12}\left(\frac{\partial^2 u}{\partial x \partial y} + \beta\frac{\partial u}{\partial x}\right) + c_{33}\frac{\partial^2 v}{\partial x^2} + c_{22}\left(\frac{\partial^2 v}{\partial y^2} + \beta\frac{\partial v}{\partial y}\right) + e_{13}\frac{\partial^2 \phi}{\partial x^2} + e_{22}\left(\frac{\partial^2 \phi}{\partial y^2} + \beta\frac{\partial \phi}{\partial y}\right) + f_{13}\frac{\partial^2 \psi}{\partial x^2} + f_{22}\left(\frac{\partial^2 \psi}{\partial y^2} + \beta\frac{\partial \psi}{\partial y}\right) = 0, \qquad (2b)$$

$$e_{13}\frac{\partial^2 u}{\partial x \partial y} + e_{21}\left(\frac{\partial^2 u}{\partial x \partial y} + \beta\frac{\partial u}{\partial x}\right) + e_{13}\frac{\partial^2 v}{\partial x^2} + e_{22}\left(\frac{\partial^2 v}{\partial y^2} + \beta\frac{\partial v}{\partial y}\right) - \varepsilon_{11}\frac{\partial^2 \phi}{\partial x^2} - \varepsilon_{22}\left(\frac{\partial^2 \phi}{\partial y^2} + \beta\frac{\partial \phi}{\partial y}\right) - g_{11}\frac{\partial^2 \psi}{\partial x^2} - g_{22}\left(\frac{\partial^2 \psi}{\partial y^2} + \beta\frac{\partial \psi}{\partial y}\right) = 0, \qquad (2c)$$

$$f_{13}\frac{\partial^2 u}{\partial x\partial y}+f_{21}\left(\frac{\partial^2 u}{\partial x\partial y}+\beta\frac{\partial u}{\partial x}\right)+f_{13}\frac{\partial^2 v}{\partial x^2}+f_{22}\left(\frac{\partial^2 v}{\partial y^2}+\beta\frac{\partial v}{\partial y}\right)-g_{11}\frac{\partial^2\phi}{\partial x^2}-g_{22}\left(\frac{\partial^2\phi}{\partial y^2}+\beta\frac{\partial\phi}{\partial y}\right)-\mu_{11}\frac{\partial^2\psi}{\partial x^2}-\mu_{22}\left(\frac{\partial^2\psi}{\partial y^2}+\beta\frac{\partial\psi}{\partial y}\right)=0, \qquad (2d)$$

where u and v are, respectively, the x and y components of the mechanical displacement vector, ϕ and ψ are, respectively, the electric and magnetic potentials.

The above magneto electro elasticity equations are subjected to the following boundary conditions:

$$\sigma_{13}\left(x,0^+\right)=\sigma_{13}^{ext}\left(x\right), \qquad \sigma_{33}\left(x,0^+\right)=\sigma_{33}^{ext}\left(x\right), \qquad \left|x\right|\le a, \qquad (3a,b)$$

$$D_3\left(x,0^+\right)=\left(1-k^e\right)D_3^{ext}\left(x\right), \qquad B_3\left(x,0^+\right)=\left(1-k^m\right)B_3^{ext}\left(x\right), \qquad \left|x\right|\le a, \qquad (3c,d)$$

$$\sigma_{13}\left(x,0^+\right)=\sigma_{13}\left(x,0^-\right), \qquad \sigma_{33}\left(x,0^+\right)=\sigma_{33}\left(x,0^-\right), \qquad \forall x, \qquad (4a,b)$$

$$D_3\left(x,0^+\right)=D_3\left(x,0^-\right), \qquad B_3\left(x,0^+\right)=B_3\left(x,0^-\right), \qquad \forall x, \qquad (4c,d)$$

$$u\left(x,0^+\right)=u\left(x,0^-\right), \qquad v\left(x,0^+\right)=v\left(x,0^-\right), \qquad \left|x\right|\ge a, \qquad (5a,b)$$

$$\phi\left(x,0^+\right)=\phi\left(x,0^-\right), \qquad \psi\left(x,0^+\right)=\psi\left(x,0^-\right), \qquad \left|x\right|\ge a, \qquad (5c,d)$$

$$\sigma_{13}\left(x,h_1\right)=0, \qquad \sigma_{33}\left(x,h_1\right)=0, \qquad \forall x, \qquad (6a,b)$$

$$D_3\left(x,h_1\right)=0, \qquad B_3\left(x,h_1\right)=0, \qquad \forall x, \qquad (6c,d)$$

$$\sigma_{13}\left(x,-h_2\right)=0, \qquad \sigma_{33}\left(x,-h_2\right)=0, \qquad \forall x, \qquad (7a,b)$$

$$D_3\left(x,-h_2\right)=0, \qquad B_3\left(x,-h_2\right)=0, \qquad \forall x, \qquad (7c,d)$$

Eqs. (3a-d) describe the applied magneto electro mechanical loadings on the crack faces. Eqs. (4a-d) represent the continuity of stresses, electric displacement and magnetic fields along the crack plane. Eqs. (5a-d) describe the continuity of the mechanical displacement and the magnetic and electric potentials outside the crack. Eqs. (6a-d) and (7a-d) represent the free layer' surfaces boundary conditions.

Singular integral equations and their solutions

The magneto electro elasticity equations (2a-d) are solved using Fourier transform to yield the mechanical displacement and electric and magnetic potentials in the composite medium. The density functions which represent the discontinuity of the mechanical displacement, electric and magnetic fields across the crack are now introduced

$$\varphi_1\left(x\right)=\frac{\partial\left(u^+-u^-\right)}{\partial x}, \qquad \varphi_2\left(x\right)=\frac{\partial\left(v^+-v^-\right)}{\partial x}, \qquad (8a,b)$$

$$\varphi_3\left(x\right)=\frac{\partial\left(\phi^+-\phi^-\right)}{\partial x}, \qquad \varphi_4\left(x\right)=\frac{\partial\left(\psi^+-\psi^-\right)}{\partial x}. \qquad (8c,d)$$

Applying the boundary conditions and after a lengthy analysis, we obtain four coupled singular integral equations in which the unknowns are the density functions $\varphi_1,\varphi_2,\varphi_3$ and φ_4. After extracting the Cauchy and logarithmic singularities from the kernels, the four equations take the following form:

$$\frac{k_{11}^0}{\pi}\int_{-a}^{a}\frac{1}{t-x}\omega_u\left(t\right)dt+\frac{1}{\pi}\int_{-a}^{a}k_{11}\left(t,x\right)\omega_u\left(t\right)dt-\frac{k_{12}^1}{\pi}\int_{-a}^{a}\beta\ln\left|t-x\right|\omega_v\left(t\right)dt+$$
$$\frac{1}{\pi}\int_{-a}^{a}k_{12}\left(t,x\right)\omega_v\left(t\right)dt-\frac{k_{13}^1}{\pi}\int_{-a}^{a}\beta\ln\left|t-x\right|\omega_\phi\left(t\right)dt+\frac{1}{\pi}\int_{-a}^{a}k_{13}\left(t,x\right)\omega_\phi\left(t\right)dt-$$
$$\frac{k_{14}^1}{\pi}\int_{-a}^{a}\beta\ln\left|t-x\right|\omega_\psi\left(t\right)dt+\frac{1}{\pi}\int_{-a}^{a}k_{14}\left(t,x\right)\omega_\psi\left(t\right)dt=\sigma_{13}^{ext}\left(x\right), \qquad \left|x\right|\le a, \qquad (9a)$$

$$-\frac{k_{21}^{1}}{\pi}\int_{-a}^{a}\beta\ln|t-x|\,\omega_u(t)\,dt+\frac{1}{\pi}\int_{-a}^{a}k_{21}(t,x)\,\omega_u(t)\,dt+\frac{k_{22}^{0}}{\pi}\int_{-a}^{a}\frac{1}{t-x}\omega_v(t)\,dt+$$
$$\frac{1}{\pi}\int_{-a}^{a}k_{22}(t,x)\,\omega_v(t)\,dt+\frac{k_{23}^{0}}{\pi}\int_{-a}^{a}\frac{1}{t-x}\omega_\phi(t)\,dt+\frac{1}{\pi}\int_{-a}^{a}k_{23}(t,x)\,\omega_\phi(t)\,dt+$$
$$\frac{k_{24}^{0}}{\pi}\int_{-a}^{a}\frac{1}{t-x}\omega_\psi(t)\,dt+\frac{1}{\pi}\int_{-a}^{a}k_{24}(t,x)\,\omega_\psi(t)\,dt=\sigma_{33}^{ext}(x),\qquad |x|\le a, \tag{9b}$$

$$-\frac{k_{31}^{1}}{\pi}\int_{-a}^{a}\beta\ln|t-x|\,\omega_u(t)\,dt+\frac{1}{\pi}\int_{-a}^{a}k_{31}(t,x)\,\omega_u(t)\,dt+\frac{k_{32}^{0}}{\pi}\int_{-a}^{a}\frac{1}{t-x}\omega_v(t)\,dt+$$
$$\frac{1}{\pi}\int_{-a}^{a}k_{32}(t,x)\,\omega_v(t)\,dt+\frac{k_{33}^{0}}{\pi}\int_{-a}^{a}\frac{1}{t-x}\omega_\phi(t)\,dt+\frac{1}{\pi}\int_{-a}^{a}k_{33}(t,x)\,\omega_\phi(t)\,dt+$$
$$\frac{k_{34}^{0}}{\pi}\int_{-a}^{a}\frac{1}{t-x}\omega_\psi(t)\,dt+\frac{1}{\pi}\int_{-a}^{a}k_{34}(t,x)\,\omega_\psi(t)\,dt=\left(1-k^{e}\right)D_3^{ext}(x),\qquad |x|\le a, \tag{9c}$$

$$-\frac{k_{41}^{1}}{\pi}\int_{-a}^{a}\beta\ln|t-x|\,\omega_u(t)\,dt+\frac{1}{\pi}\int_{-a}^{a}k_{41}(t,x)\,\omega_u(t)\,dt+\frac{k_{42}^{0}}{\pi}\int_{-a}^{a}\frac{1}{t-x}\omega_v(t)\,dt+$$
$$\frac{1}{\pi}\int_{-a}^{a}k_{42}(t,x)\,\omega_v(t)\,dt+\frac{k_{43}^{0}}{\pi}\int_{-a}^{a}\frac{1}{t-x}\omega_\phi(t)\,dt+\frac{1}{\pi}\int_{-a}^{a}k_{43}(t,x)\,\omega_\phi(t)\,dt+$$
$$\frac{k_{44}^{0}}{\pi}\int_{-a}^{a}\frac{1}{t-x}\omega_\psi(t)\,dt+\frac{1}{\pi}\int_{-a}^{a}k_{44}(t,x)\,\omega_\psi(t)\,dt=\left(1-k^{m}\right)B_3^{ext}(x),\qquad |x|\le a, \tag{9d}$$

where the functions $k_{ij}(t,x)$, where $i,j=1...4$, are known continuous and bounded kernels that depend on the nonhomogeneity parameter β.

The solution of (9a-d) subject to the single-valuedness conditions may be expressed as $\varphi_i(t)=w(t)\vartheta_i(t)$, $(i=1..4)$. In this solution, $w(t)=1/\sqrt{1-t^2}$ is the weight function which is obtained from the nature of the singularity at the crack tips and which is associated with the Chebyshev polynomial of the first kind $T_n(t)=\cos(n\arccos(t))$. The functions $\vartheta_i(t)$, $(i=1..4)$ are continuous and bounded functions in the interval $[-1,1]$ which may be expressed as truncated series of Chebyshev polynomial of the first kind. Using a suitable collocation method, a linear algebraic system of the unknown coefficients of the density functions is obtained. As a result, the stress intensity factors, the electric displacement intensity factor and the magnetic induction intensity factor can be expressed as:

$$k_1(1)=-\sum_{n=1}^{N}\left(k_{22}^{0}\tilde{b}_n+k_{23}^{0}\tilde{c}_n+k_{24}^{0}\tilde{d}_n\right),\qquad k_1(-1)=-\sum_{n=1}^{N}(-1)^n\left(k_{22}^{0}\tilde{b}_n+k_{23}^{0}\tilde{c}_n+k_{24}^{0}\tilde{d}_n\right), \tag{10a,b}$$

$$k_2(1)=-k_{11}^{0}\sum_{n=1}^{N}\tilde{a}_n,\qquad k_2(-1)=-k_{11}^{0}\sum_{n=1}^{N}(-1)^n\tilde{a}_n, \tag{10c,d}$$

$$k_D(-1)=-\sum_{n=1}^{N}\left(k_{32}^{0}\tilde{b}_n+k_{33}^{0}\tilde{c}_n+k_{34}^{0}\tilde{d}_n\right),\qquad k_D(-1)=-\sum_{n=1}^{N}(-1)^n\left(k_{32}^{0}\tilde{b}_n+k_{33}^{0}\tilde{c}_n+k_{34}^{0}\tilde{d}_n\right), \tag{10e,f}$$

$$k_B(-1)=-\sum_{n=1}^{N}\left(k_{42}^{0}\tilde{b}_n+k_{43}^{0}\tilde{c}_n+k_{44}^{0}\tilde{d}_n\right),\qquad k_B(-1)=-\sum_{n=1}^{N}(-1)^n\left(k_{42}^{0}\tilde{b}_n+k_{43}^{0}\tilde{c}_n+k_{44}^{0}\tilde{d}_n\right). \tag{10g,h}$$

Results and discussion

The formulation using singular integral equations to determine the stress intensity factors of cracked functionally graded magneto electro elastic materials was established. For validation, the results for the case of a sufficiently thick layer, were compared to those of infinite medium (Rekik et al 2012) and a good agreement was obtained (Fig. 2).

Then, a number of simulations, for different magneto electro mechanical load cases, were performed by varying the nonhomogeneity parameter, crack position, crack length and permeability parameters. The considered material is a bimorph composed of the Barium Titanium Oxide, BaTiO3 and the Cobalt Iron Oxide, CoFe2O4.

Fig. 3 illustrates the effect of varying the nonhomogeneity parameter βa on the fields' intensity factors for normal tractions, tangential tractions, magnetic and electric loadings in case of a central crack as large as the layer thickness and electromagnetic permeability of 25%. For each loading case, the corresponding field''s intensity factors showss lower sensibility to material's nonhomogeneity while remaining fields' intensity factors increase ~~monotonously~~monotonically.

Fig. 4 illustrates the effect of varying the crack position on the fields' intensity factors for the same loading cases in the case of a crack as large as the layer thickness and electromagnetic permeability of 25%. In case of normal traction, electric or magnetic loadings, k_1, k_B and k_D show parabolic variation with crack position while k_2 varies oddly. Similarly, in case of tangential traction loading, k_2 varies ~~parbolically~~parabolically while the k_1, k_B and k_D vary oddly.

Fig. 5 illustrates the effect of varying magneto electric permeabilities parameter in case of a central crack as large as the layer thickness. Fields' intensity factors vary linearly with increasing impermeability.

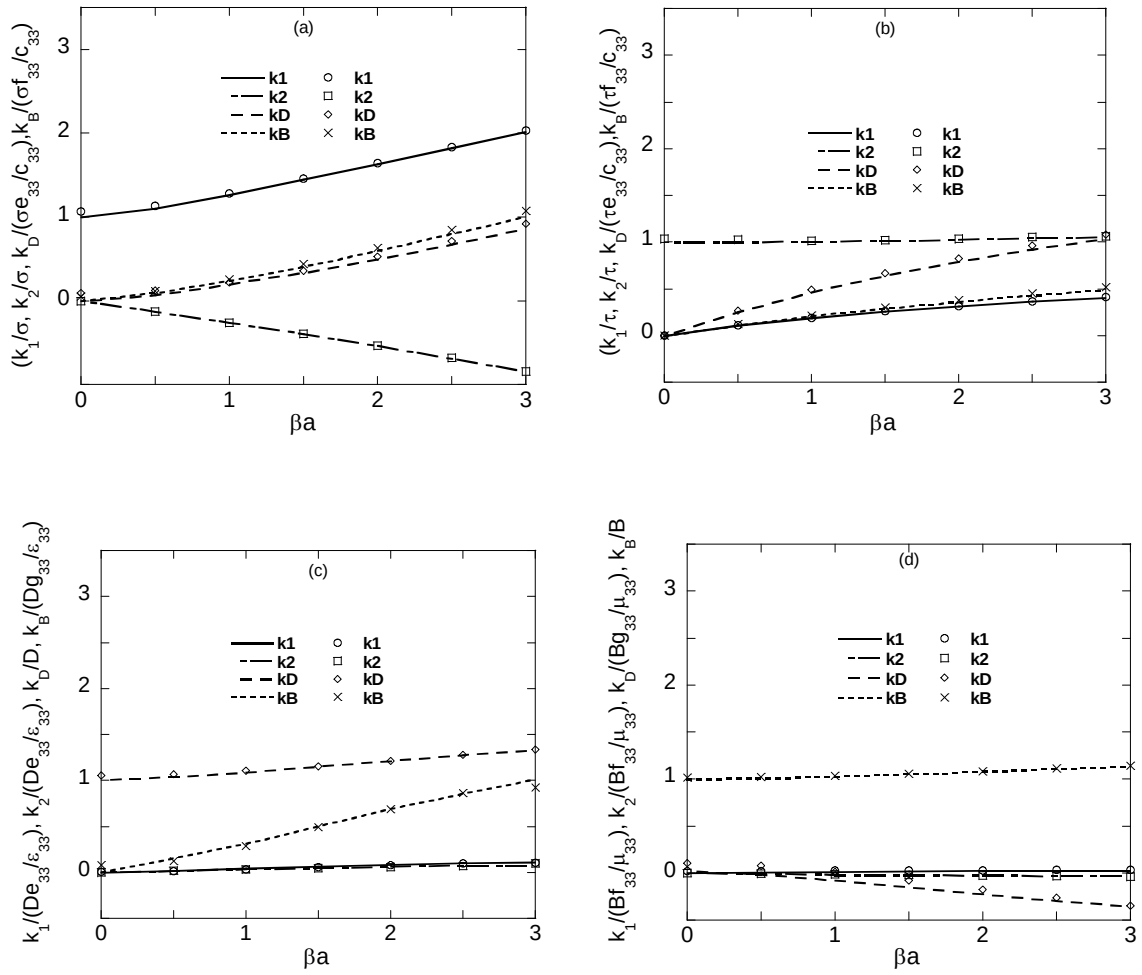

Figure 2: Comparison of normalized fields' intensity factors (markers) with those published by Rekik et al (2012) (continuous lines) for the case of a central crack, magneto electrically impermeable, embedded in an FGMEEM layer four times as thick as the crack length, subjected to uniform normal tractions (a), tangential tractions (b), electric displacement (c), and magnetic induction (d)

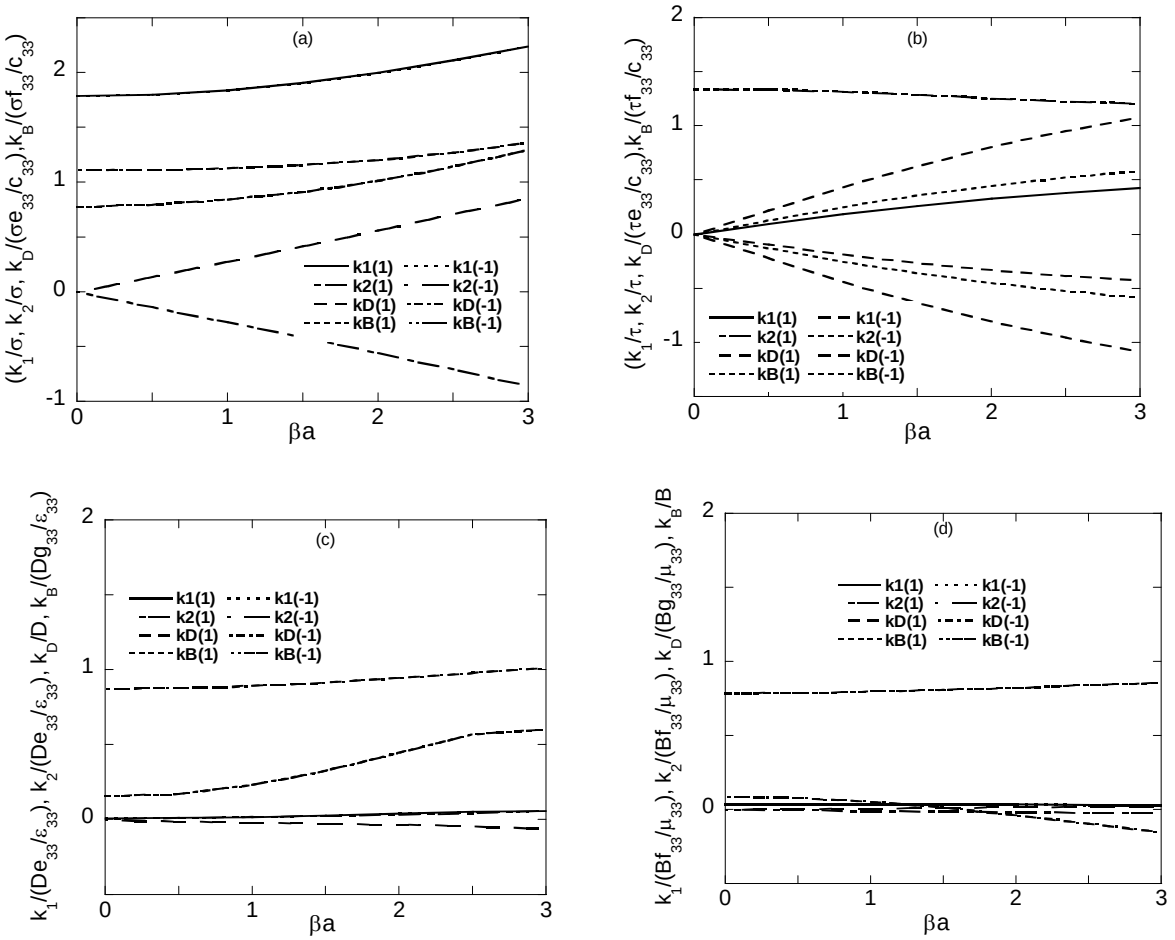

Figure 3: Effect of the non homogeneity parameter βa on the normalized fields' intensity factors under constant normal (a) and tangential (b) crack surface tractions in addition to constant electric displacement (c) and magnetic induction (d) in the case of central crack with $h_1 = h_2 = a$, and $k^e = k^m = 0.25$.

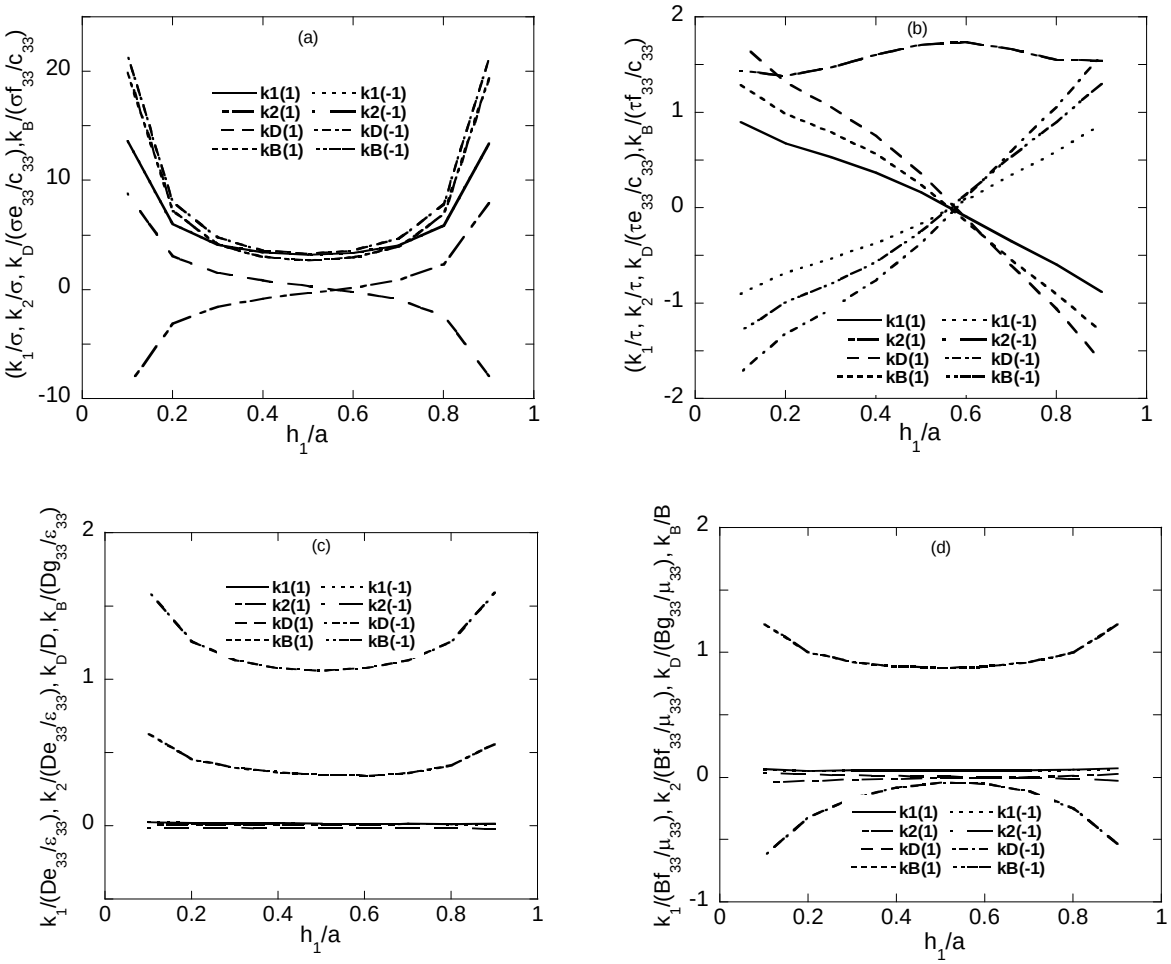

Figure 4: Effect of the crack position on the normalized fields' intensity factors under constant normal (a) and tangential (b) crack surface tractions in addition to constant electric displacement (c) and magnetic induction (d) in the case of $\left(h_1+h_2\right)=a$, $\beta a=1$ and $k^e=k^m=0.25$.

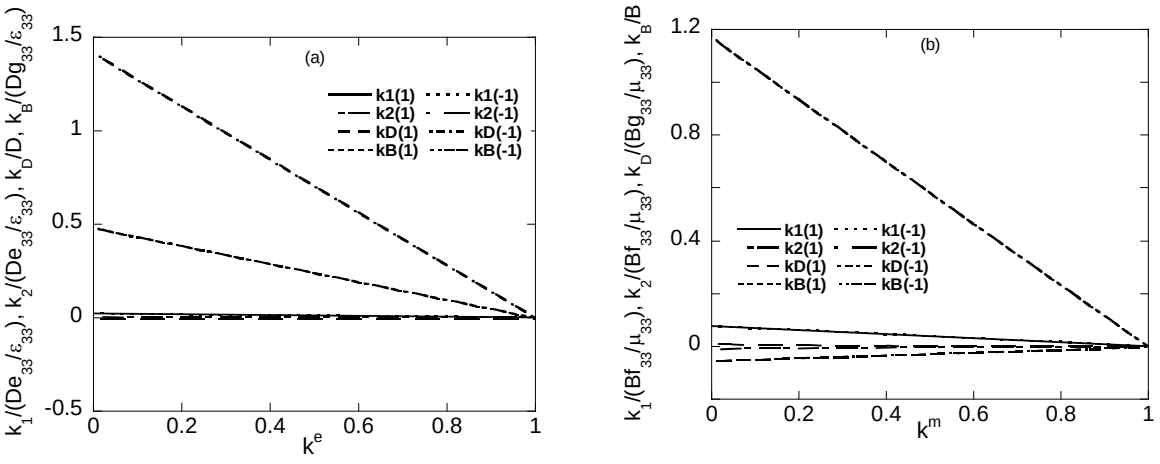

Figure 5: Effect of the magneto electric partial permeability parameters on the normalized fields' intensity factors under constant electric displacement (a) and magnetic induction (b) loadings in the case of central crack, $h = a$ and $\beta a = 1$.

Abstract The present work develops a multi-physics model to investigate subcritical propagation of initially oil-filled, sub-horizontal collinear microcracks driven by the excess pressure induced during the conversion of oil to gas in a petroleum source rock under continuous burial. The crack propagation distance, propagation duration, crack coalescence and overpressure in the crack are determined using a finite difference scheme that couples linear elastic fracture mechanics, oil-gas transformation kinetics and an equation of state for the gas. The numerical results for a source rock with typical properties show that when the crack spacing is greater than $b/a_0 = 3$ (where a_0 is the half crack length and b the half distance between crack centers) the cracks do not coalesce and the duration of gas-driven crack propagation is governed by the transformation kinetics because the subcritical crack propagation rate is much faster than the oil-gas conversion rate. The collinear cracks coalesce for smaller crack spacing and the crack propagation duration may be reduced significantly due to crack interactions. The multi-physics model developed in this work together with our previous model for crack propagation during conversion of solid kerogen to oil indicates that microcracks resulting from buildup of excess fluid pressure during hydrocarbon generation may serve as an effective pathway for primary petroleum migration.

Keywords: Collinear cracks, Migration, Oil-gas conversion, Overpressure, Subcritical growth

1. Introduction

Overpressures widely observed in the deep part of sedimentary basins coincident with primary zones of gas generation are commonly attributed to thermal cracking of kerogen to oil/gas and oil to gas. Microfractures are a common feature of petroleum source rocks in these basins interpreted to serve as migration conduits for oil and gas [1]. Understanding the dominant mechanisms responsible for the microfracture initiation and development in petroleum source rocks at great depth is crucial for hydrocarbon exploration and safe drilling.

Fine grained source rocks like shales rich in kerogen undergo progressive burial, which leads to an increase in bulk density and loss of porosity. With increasing depth of burial, there is also a marked decrease in permeability. As temperatures and pressures increases, kerogen breaks down to release oil when it becomes mature. Conversion of kerogen to oil results in significant volume increase due to the density difference between the precursors and the products. Meanwhile, part of the overburden load will be transferred to the newly generated oil. As a natural result, overpressure is generated [2, 3]. Clay-sized minerals within source rocks functioning as effective seals enable local overpressure build-up [1]. When the overpressure exceeds the mechanical strength of the source rocks, microfractures around kerogen particles are initiated, thus creating a migration pathway for oil [4, 5].

As burial proceeds, temperatures continue to increase. When the gas window is reached, oil retained in the microfractures will be subjected to thermal cracking to form gas, which consists predominantly of methane [2-3]. The volume increase associated with transformation of oil to gas is more appreciable. According to Barker [6], less than two percent of oil conversion to gas would

readily create overpressure in excess of lithostatic pressure and cause microfracturing in an effectively sealed reservoir. As a result, microfractures driven by the overpressure may grow and coalesce to form interconnected fracture networks, which may facilitate further migration of hydrocarbons [2, 7].

Convincing evidence from field observations has been presented to support the concept that microfractures induced by overpressure from hydrocarbon generation serve as migration conduits for hydrocarbons. Examples include the Bakken shale in Williston Basin [8], La Luna source rocks in the Maracaibo Basin [9], Woodford Formation in Oklahoma and Arkansas [10], fractured source rocks from the Oligocene Frio Formation, Texas [11], mature shales in the Hils area in Germany [12] and Alberta Basin in Canada [13]. Detailed observations by Lash and Engelder [14] showed that layer parallel microcracks filled with bitumen in organic-rich Dunkirk shale of Catskill delta, New York resulted from hydrocarbon generation. Common features of these microfractures in overpressured source rocks are summarized as follows: (1) the microcracks are of opening mode, i.e. mode I; (2) the preferred orientation of microfractures is parallel or sub-parallel to bedding plane; (3) most microcracks contain bitumen or calcite, showing the characteristic of petroleum generation; and (4) microfractures are found in organic-rich source rocks at high maturity level.

More recently, Jin et al. [4] developed a model of primary migration of oil by collinear microcrack coalescing during the main stage of oil generation and found that microfractures propagate subcritically since excess pressure resulted from kerogen conversion to oil is not high enough to drive critical crack growth. In the present paper we extend our previous work to investigate subcritical growth of a series of periodically spaced subhorizontal collinear microfractures driven by excess fluid pressure due to thermal cracking of oil to gas. As a special case, the propagation of a single crack is also studied. We focus on the effects of gas compressibility and crack spacing on the crack propagation behavior including crack propagation distance and duration, as well as excess pressure evolution.

2. Formulation of theoretical model of crack propagation during gas generation

2.1. Thermal cracking of oil to gas

Transformation of oil to gas satisfies the following first order differential equation [15]

$$\frac{dM}{dt} = -BM \exp\left[-\frac{E_A}{RT(t)}\right] \tag{1}$$

where M is the mass of convertible oil at time t, B is a pre-exponential constant, E_A is the activation energy of the transformation, R is the universal gas constant, and T is the absolute temperature. We assume a constant burial rate S and a constant geothermal gradient G so that the depth of burial z and time-varying temperature T can be written as

$$z(t) = H_0 + St\,, \quad T(t) = T_0 + G(z - H_0) = T_0 + GSt \tag{2}$$

where H_0 is the initial burial depth at which the oil-filled cracks are located, T_0 is the corresponding temperature at H_0. By integrating Eq. (1) with Eq. (2) and using mass conservation, Fan et al. [7] obtained the volumes of oil and gas at time t as follows

$$V_{oil}^t = M_0 \exp\left[-\Phi(t)\right]/\rho_{oil}\,, \quad V_{gas}^t = M_0\left\{1 - \exp\left[-\Phi(t)\right]\right\}/\rho_{gas} \tag{3}$$

where M_0 is the initial mass of oil, ρ_{oil} is the density of oil, ρ_{gas} is the gas density which is a function of pressure and temperature determined by the equation of state (EOS), and $\Phi(t)$ is given by

$$\Phi(t)=\frac{B(T_0+GSt)}{GS}\exp\left[-\frac{E_A}{R(T_0+GSt)}\right]-\frac{BT_0}{GS}\exp\left(-\frac{E_A}{RT_0}\right)+\frac{BE_A}{RGS}\left[E_i\left(-\frac{E_A}{R(T_0+GSt)}\right)-E_i\left(-\frac{E_A}{RT_0}\right)\right] \tag{4}$$

in which $E_i(\ )$ is the exponential integral defined by

$$E_i(x)=\int_{-\infty}^{x}\frac{e^{x'}}{x'}dx' \tag{5}$$

2.2. An equation of state (EOS) for gas

To account for the compressibility of gas under subsurface conditions, we adopt an EOS for methane developed by Duan et al. [16], since natural gas consists primarily of methane. The EOS, which is capable to describe the behavior of methane with high accuracy over wide temperature and pressure range (0 - 1000 ^{o}C and 0 - 800 MPa, respectively), takes the form

$$\frac{P_rV_r}{T_r}=1+\frac{C_1}{V_r}+\frac{C_2}{V_r^2}+\frac{C_3}{V_r^4}+\frac{C_4}{V_r^5}+\frac{C_5}{V_r^2}\left(\beta+\frac{\gamma}{V_r^2}\right)\exp\left(-\frac{\gamma}{V_r^2}\right) \tag{6}$$

where $P_r=P/P_c$, $T_r=T/T_c$, $V_r=V/V_c$, P and T are the pressure and temperature of the gas, respectively, $V = m/\rho_{\text{gas}}$ is the molar volume with m denoting the molar mass, T_c is the critical temperature above which methane can not be liquefied regardless of the pressure applied, P_c is the critical pressure required to liquefy methane at the critical temperature T_c, $V_c = RT_c/P_c$, and

$$C_1=a_1+\frac{a_2}{T_r^2}+\frac{a_3}{T_r^3}\quad C_2=a_4+\frac{a_5}{T_r^2}+\frac{a_6}{T_r^3},\ C_3=a_7+\frac{a_8}{T_r^2}+\frac{a_9}{T_r^3},\ C_4=a_{10}+\frac{a_{11}}{T_r^2}+\frac{a_{12}}{T_r^3},\ C_5=\frac{\alpha}{T_r^3} \tag{7}$$

The EOS contains 15 material constants: a_i (i = 1, 2… 12), α, β and γ， which can be found in [16].

From Eq. (6) we can express gas pressure in terms of gas density and temperature as follows

$$P=P(\rho_{gas})=\frac{P_cT_rV_c\rho_{gas}}{m}\left[1+\frac{BV_c\rho_{gas}}{m}+\frac{CV_c^2\rho_{gas}^2}{m^2}+\frac{DV_c^4\rho_{gas}^4}{m^4}+\frac{EV_c^5\rho_{gas}^5}{m^5}+\frac{FV_c^2\rho_{gas}^2}{m^2}\left(\beta+\frac{\gamma V_c^2\rho_{gas}^2}{m^2}\right)\exp\left(-\frac{\gamma V_c^2\rho_{gas}^2}{m^2}\right)\right] \tag{8}$$

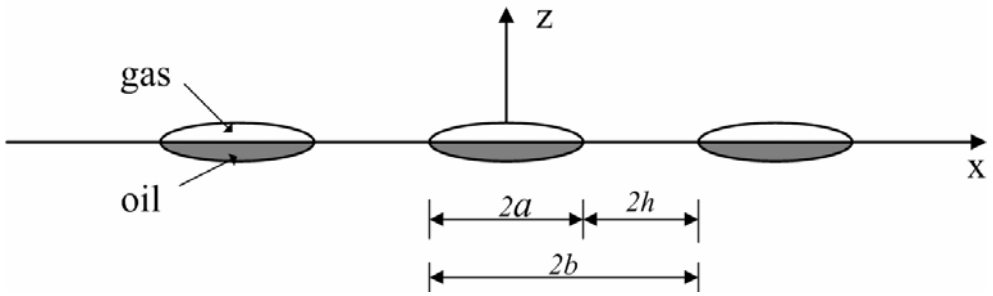

Figure 1. Subhorizontal periodically spaced collinear microcracks filled by oil and gas

2.3. Fracture mechanics model

Consider a row of periodic collinear microcracks initially filled by oil within a source rock under continuous burial as shown in Figure 1, where $2a = 2a\ (t)$ denotes the crack length at time t and

$2h$ is the crack spacing. Initially the crack is subjected to uniform oil pressure on the crack surface. The initial excess pressure is denoted by Δp_0 which is the oil pressure beyond the overburden pressure. The excess pressure increases as oil to gas conversion proceeds. At time t, the excess pressure can be obtained as follows

$$\Delta p = P(\rho_{gas}) - \rho_s g z = P(\rho_{gas}) - \rho_s g\left(H_0 + St\right) \tag{9}$$

where ρ_s is the average sediment density, g = 9.8 m/s^2 is gravitational acceleration, and $P(\rho_{gas})$ is the gas pressure given by Eq. (8).

The stress intensity factor (SIF) at the crack tips is given by

$$K_I = \Delta p\sqrt{2b\tan\left(\frac{\pi a}{2b}\right)} \tag{10}$$

where $b = a + h$. The volume per unit thickness in the y direction of the crack is

$$V_{crack}^{t} = \frac{16b^2\Delta p\left(1-\nu^2\right)}{\pi E}\ln\left[\sec\left(\frac{\pi a}{2b}\right)\right] \tag{11}$$

where E and ν are Young's modulus and Poisson's ratio of the source rock, respectively. Since the crack is fully saturated with oil and gas, the volume of the crack must equal the sum of oil and gas volumes, that is,

$$V_{oil}^{t} + V_{gas}^{t} = V_{crack}^{t} \tag{12}$$

From Eq. (11), we can get the initial mass of oil within the crack

$$M_0 = \frac{16b^2\rho_{oil}\Delta p_0\left(1-\nu^2\right)}{\pi E}\ln\left[\sec\left(\frac{\pi a_0}{2b}\right)\right] \tag{13}$$

where a_0 is the half initial crack length. Clearly the SIF increases with the increasing excess pressure.

Subcritical crack propagation will be initiated once the SIF reaches a threshold value K_{Ith}, but less than the rock fracture toughness K_{Ic}. Generally, the subcritical crack growth can be described by the Charles power law [17]

$$v = \frac{da}{dt} = A\left[K_I(a)\right]^n \tag{14}$$

where ν is the subcritical propagation velocity, n is the subcritical crack growth index and A is a material constant. It follows from Eq. (10) that the excess fluid pressure corresponding to the onset of subcritical crack growth is

$$\Delta p_{th} = K_{\mathrm{I}th} / \sqrt{2b\tan\left(\frac{\pi a_0}{2b}\right)} \tag{15}$$

The corresponding crack volume is

$$V_{crack}^{0} = \frac{16b^2\left(1-\nu^2\right)K_{\mathrm{I}th}}{\pi E\sqrt{2b\tan\left(\frac{\pi a_0}{2b}\right)}}\ln\left[\sec\left(\frac{\pi a_0}{2b}\right)\right] \tag{16}$$

The time needed for the excess pressure to reach Δp_{th} from the start of oil-gas transformation, denoted by t_0, can be determined by solving the following two equations

$$P\left(\rho_{gas}^{th}\right) - \rho_s g(H_0 + St_0) = K_{\mathrm{I}th} / \sqrt{2b\tan\left(\frac{\pi a_0}{2b}\right)} \tag{17}$$

$$\frac{M_0\left\{1-\exp\left[-\Phi\left(t_0\right)\right]\right\}}{\rho_{gas}^{th}}+\frac{M_0\exp\left[-\Phi\left(t_0\right)\right]}{\rho_{oil}}=\frac{16b^2\left(1-\nu^2\right)\Delta p_{th}}{\pi E}\ln\left[\sec\left(\frac{\pi a_0}{2b}\right)\right] \tag{18}$$

where ρ_{gas}^{th} is the corresponding gas density at time t_0.

2.4. Simulation of subcritical crack propagation and coalescence using finite difference

A finite difference formulation is used to study the coupling between gas generation from oil degradation and gas expulsion through microfracture propagation and coalescence. Consider the microcrack propagation from time t_0 to current time t. We subdivide the time domain into N intervals to construct a mesh of equally-spaced grids: $t_0, t_1,\ldots, t_{N-1}, t_N$ with $t_N=t$. The following notations are adopted. $a_i=a(t_i)$ and $\rho_{gas}^i=\rho_{gas}(t_i)$ represent the half crack length and the corresponding gas density at time step t_i , respectively. Replace the derivative in Eq. (14) by a forward difference approximation at time t_i, then we obtain the following expression for the half crack length at t_{i+1}

$$a_{i+1}=a_i+A[P(\rho_{gas}^i)-\rho_s g\left(H_0+St_i\right)]^n(2b)^{n/2}\left[\tan\left(\frac{\pi a_i}{2b}\right)\right]^{n/2}(t_{i+1}-t_i) \tag{19}$$

Neglecting the mutual solubility of gas and oil, we obtain the oil and gas volumes at t_{i+1} as follows

$$V_{oil}^{i+1}=\frac{M_0\exp\left[-\Phi\left(t_{i+1}\right)\right]}{\rho_{oil}},\qquad V_{gas}^{i+1}=\frac{M_0\left\{1-\exp\left[-\Phi\left(t_{i+1}\right)\right]\right\}}{\rho_{gas}^{i+1}} \tag{20}$$

where ρ_{gas}^{i+1} is the gas density at time step t_{i+1}. The volume of the crack at t_{i+1} is by Eq. (11) applied at step t_{i+1}.

The requirement that crack volume must be equal to the sum of oil and gas volumes yields the excess pressure Δp_{i+1} at t_{i+1},

$$\Delta p_{i+1}=M_0\left[\frac{\exp\left[-\Phi\left(t_{i+1}\right)\right]}{\rho_{oil}}+\frac{\left\{1-\exp\left[-\Phi\left(t_{i+1}\right)\right]\right\}}{\rho_{gas}^{i+1}}\right]\Bigg/\left\{\frac{16b^2\left(1-\nu^2\right)}{\pi E}\ln\left[\sec\left(\frac{\pi a_{i+1}}{2b}\right)\right]\right\} \tag{21}$$

Note that $\Delta p_{i+1}=P(\rho_{gas}^{i+1})-\rho_s g\left(H_0+St_{i+1}\right)$, and then we can solve this equation for the unknown gas density ρ_{gas}^{i+1}. Consequently the excess pressure Δp_{i+1} at t_{i+1} can be obtained using Eq. (21). To drive the crack growth subcritically, Δp_{i+1} must satisfy the following condition

$$\Delta p_{i+1}\geq K_{1th}/\sqrt{2b\tan\left(\frac{\pi a_{i+1}}{2b}\right)} \tag{22}$$

Otherwise, we need to adjust time t_{i+1} by solving Eq. (17) and (18) with a_0, t_0 and ρ_{gas}^{th} replaced by a_{i+1}, t_{i+1} and ρ_{gas}^{i+1}, respectively.

3. Numerical Results and Discussions

This section presents numerical examples to illustrate effects of initial burial depth and crack spacing on the excess pressure evolution with time and crack propagation distance for a single crack, and propagation and coalescence of collinear cracks. Since shales are major source rocks for oil and natural gas, in our simulation we study shales for illustration purpose. Typically thermal cracking of oil is initiated at temperatures of 120-160 ^oC, and ultimate conversion to methane may occur at

temperatures in excess of 200 ^{o}C, at depth of burial ranging between 3000m and 7000m [19]. We examine the sensitivity of crack propagation to variations of initial depth of burial in the range of 3500-5000m. The initial temperature is assumed as T_0 = 150 ^{o}C. We also assume that $\Delta p_0 = \Delta p_{th}$ and the stress intensity factor equals the threshold value K_{Ith} due to the excess oil pressure at the initial state. Other physical and geometrical parameters used in our simulation are summarized in Table 1[14, 16-19].

Table 1 Physical and geometrical parameters used in the numerical simulation

Symbols	Definition	Value(unit)
Rock Matrix		
E	Young's modulus	2.0 GPa
ν	Poison's ratio	0.4
ρ_s	Average sediment density	2350 kg/m^3
K_{Ith}	Threshold stress intensity factor	0.06 MPa-m$^{1/2}$
A	Subcritical crack growth constant	10^7 m/s/(MPa-m$^{1/2}$)^{10}
n	Subcritical crack growth index	10
a_0	Initial half crack length	50 μm
H_0	Initial depth of burial	4000 m
T_0	Initial temperature	150 ^{o}C
G	Geothermal gradient	30 ^{o}C/km
S	Burial rate	0.1 km/M.y.
Oil		
ρ_{oil}	Oil density	850 kg/m^3
Methane		
m	Molar mass	16 g/mol
T_c	Critical temperature	191.1 K
P_c	Critical pressure	4.64 MPa
Kinetics		
B	Pre-exponential constant	1.744×10^{13} sec^{-1}
E_A	Activation energy	217.6 kJ/mol
R	Universal gas constant	8.314 J/mole/K

3.1 Single crack case

When $b/a_0 \rightarrow \infty$ the crack interaction disappears and the problem reduces to the single crack case. Figures 2 shows crack propagation distance versus time corresponding to three different values of H_0 for a single crack. The corresponding excess pressure profiles are shown in Figure 3. Similar to the kerogen conversion to oil case [4], subcritical crack propagation rate is much faster than the oil-gas conversion rate, so the crack propagation duration is governed by the oil-gas transformation kinetics. The excess pressure decreases monotonically as crack propagation distance increases with time, which is indicated by Eq. (10). It is seen from Figure 2 that the final crack length increases with decreasing initial depth of burial. It can be explained by considering the gas compressibility in Eq. (8). Gas density increases monotonically with increasing depth of burial, so the density difference between the transformation precursor and end product becomes smaller. Therefore, the crack propagation distance becomes smaller at greater depth of burial. From Figure 3 we can see that at a given time, the excess pressure within the crack is lower at a shallower depth of burial because longer cracks require smaller overpressure to grow as suggested by Eq. (10).

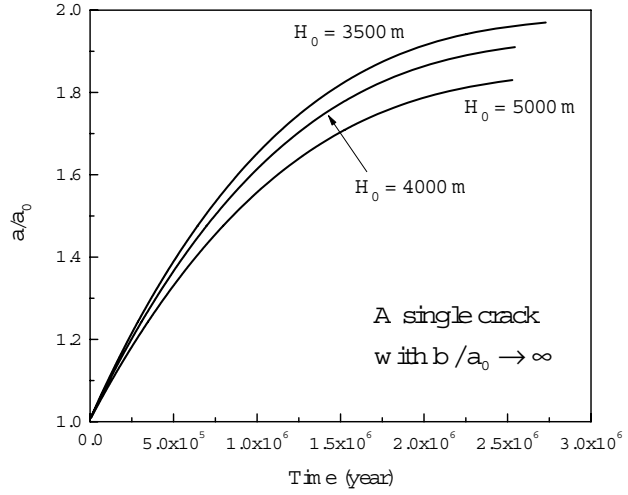

Figure 2. Crack propagation distance versus time for a single crack corresponding to different initial depths of burial

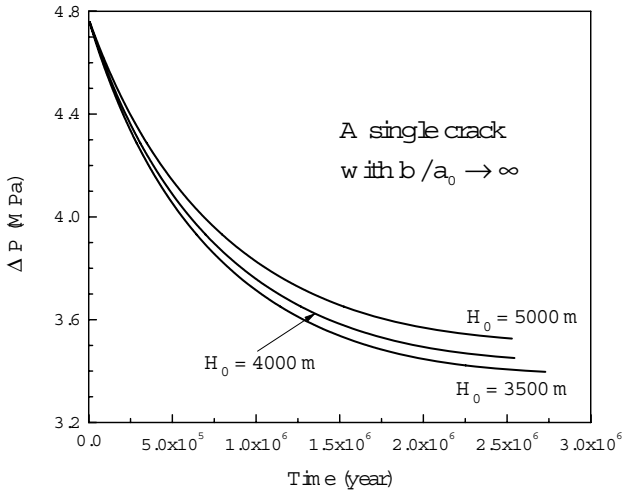

Figure 3. Excess pressure evolution over time for a single crack corresponding to different initial depths of burial

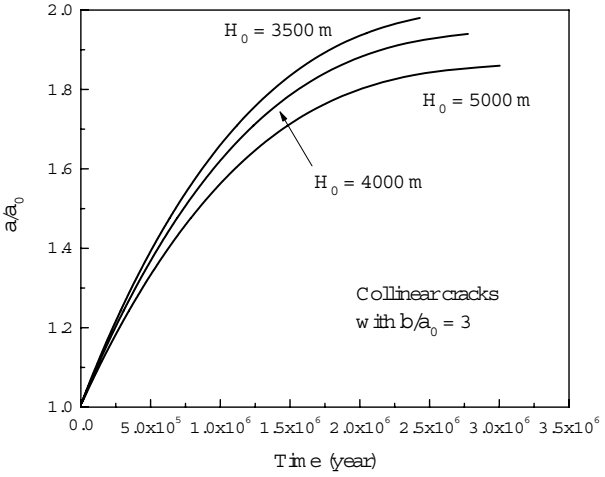

Figure 4. Effect of initial depth of burial on the crack propagation distance for collinear cracks with initial crack spacing $b/a_0 = 3$

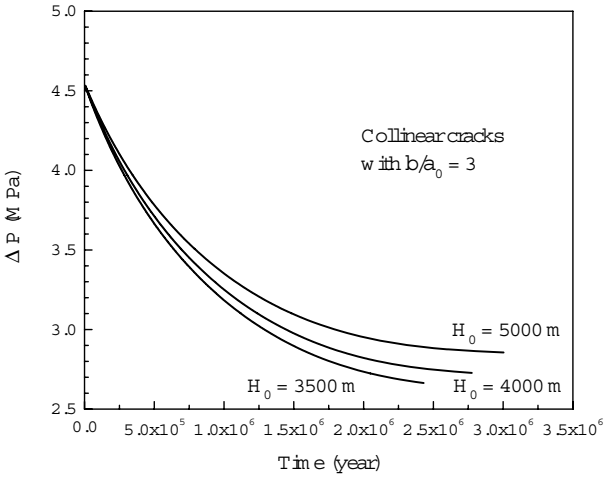

Figure 5. Effect of initial depth of burial on the excess pressure for collinear cracks with initial crack spacing $b/a_0 = 3$

3.2 Collinear cracks case

The effects of initial burial depth on crack propagation distance and excess pressure evolution for b/a_0=3 are shown in Figures 4 and 5, respectively. The general trends in the variation of crack propagation distance and excess pressure with time corresponding to different H_0 are quite similar to those observed in Figures 2 and 3, respectively. A particularly noteworthy feature is sharp differences on the crack propagation duration between a single crack and collinear cracks at shallow burial depth. For example, Figure 2 shows that it takes about 2.74 million years for the single crack to grow to 1.97 times its original length when all the oil within the crack converts to gas completely. For collinear cracks, it takes about 2.42 million years to grow to 1.98 times its original length and the microcracks are almost to coalesces (b/a_0=3 and h/a_0=2) to form macroscopic cracks. The

marked decrease in crack propagation duration is due to rapid acceleration of crack growth associated with drastic increase in stress intensity factor as crack spacing decreases.

We also examine the sensitivity of crack propagation distance and excess pressure to the changes of crack spacing, as shown in Figures 6 and 7, respectively. Our numerical calculation shows that when $b/a_0 > 3$, no crack coalescence is found for typical burial depth in the range of 3000-7000m where thermal cracking of oil to gas occurs. For $b/a_0 = 2.0$, the excess pressure decreases with time and drops sharply when the cracks are about to coalesce. Due to crack interaction, the threshold excess pressure to initiate subcritical crack growth increases with increasing crack spacing. The crack propagation reduces significantly for smaller crack spacing. For example, the crack propagation duration is about 3.39 million years for $b/a_0=5$. It reduces to about 1.09 million years when $b/a_0=2$.

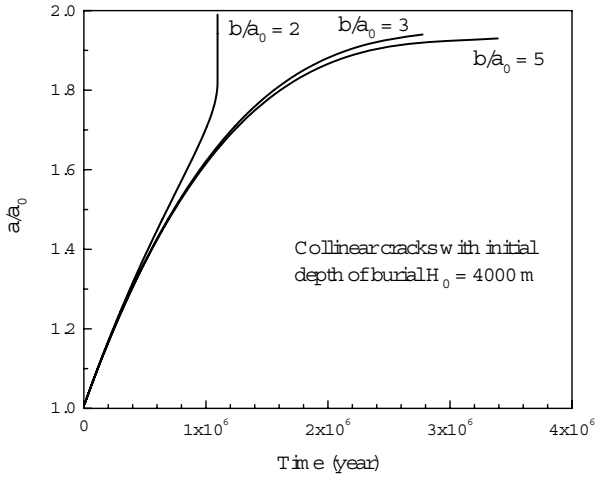

Figure 6. Effect of crack spacing on the crack propagation distance for collinear cracks with initial depth of burial $H_0 = 4000$ m

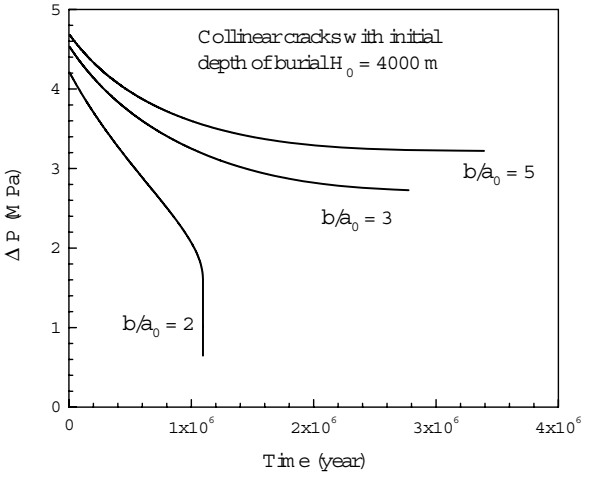

Figure 7. Effect of crack spacing on the crack propagation distance for collinear cracks with initial depth of burial $H_0 = 4000$ m

Concluding Remarks

To address the coupling between gas generation and expulsion, we develop a theoretical model to study the gas migration through propagation and coalescence of collinear microfractures initially filled by oil incorporating fracture mechanics of source rocks, geochemistry of thermal cracking of oil to gas, and an equation of state for gas. Based on our numerical simulation, the following conclusions can be reached, which may provide some insight into gas migration process.

(1) Gas expulsion through self-propagating microfractures is an effective mechanism for primary migration within well-sealed source rocks and excess pressure caused by thermal cracking of oil to gas serves as driving force for microfracture propagation.

(2) Increasing depth of burial leads to decreasing crack propagation distance due to gas compressibility. Therefore cracks at shallower depth are more likely to form interconnected fracture network.

(3) Crack spacing has a significant effect on crack propagation duration for collinear cracks with smaller crack spacing leading to shorter crack propagation duration.

On Incorrectness in Elastic Rebound Theory for Cause of Earthquakes

Zhong-qi Quentin Yue[1,*]

[1] Department of Civil Engineering, The University of Hong Kong, Hong Kong, China
* Corresponding author: yueqzq@hku.hk

Abstract The elastic rebound theory was developed 100 years ago from the observations of co-seismic surface ruptures induced by the 1906 California Earthquake. It is only partially correct because it associates earthquakes with geological faults. However, it is inconsistent and even violates many other phenomena that were present before, during and after earthquakes. Numerous failures have been encountered and experienced in the tremendous efforts using the elastic rebound theory in the prediction of earthquakes over the past 100 years. Many current seismo-geologist and seismologists have lost their original goals to predict earthquakes and turned to believe that earthquakes are unpredictable with present techniques. All these problems are due to the fact that the incorrect elastic rebound theory for cause of earthquakes was used in the investigation and prediction of earthquakes. The paper also shows that the energy released during earthquake is not the elastic stress and strain energy accumulated in brittle crustal rock solids during relative movements of tectonic plates. The released energy is the volumetric expansion energy of highly compressed and dense natural gas rapidly escaped from its deep crustal traps via fault channels. This gas hypothesis for the cause of earthquakes would make earthquake predicable in the near future.

Keywords Earthquake, Energy, Fault, Heat, Natural Gas

1. Introduction

Earthquake occurs every day. Seismologists have developed and used seismometers to report the locations and magnitudes of earthquakes within minutes of their occurrence. But, they cannot predict earthquakes. Earthquake prediction is to predict where and when the next damaging earthquake will occur and what will be its magnitude. For last hundred and thousand years, earthquakes have frequently hit us without notice and wreaked terrible disasters and numerous fatalities. In addition, there were many false prediction cases and only a few successful prediction cases. Due to numerous failure cases, seismologists have reached a consensus that the next strong earthquake can NOT be predicted.

For example, Chen and Wang [1] wrote, “Few seismologists believe that it is presently possible or forever impossible to predict an earthquake with the time, location, and size specified accurately enough to guide plans for evacuation. Regardless of its scientific merit and future development, governments of most industrial countries consider earthquake prediction to be presently impractical.” Hough [2] also wrote, “Are earthquake predicable? The title of this book implies an answer and suggests a paradox. We cannot say it will always be the case, but, given the state of earthquake science at the present time, earthquakes are unpredictable.” Therefore, the following issue must be asked and addressed: Why are the next damaging earthquakes unpredictable?

In this paper, the author tries to point out the core reason for this earthquake unpredictability issue. The core reason is the inadequacy of the existing theory in explaining the cause of earthquakes. It is the elastic rebound theory developed one hundred years ago in 1910 [3, 4]. It has been regarded as “one of the most fundamental tenets of earthquake science” [2]. The prediction efforts over the last one hundred years have been based on the incorrect cause theory of tectonic earthquakes. Hence, a majority of their results have been unsatisfactory. Furthermore, the theory of plate tectonics, developed in later 1950s and early 1960s, used this elastic rebound theory as one of the foundations. On the other hand, the plate tectonic theory gives the reasons why and how the elastic stress can be built up in crustal fault rocks for cause of earthquakes associated with the elastic rebound theory [5].

The plate tectonic theory has become the dominant theory for the Earth system in geosciences including seismogeology and seismology. Consequently, the belief and/or consensus that earthquakes are unpredictable have become much widely acceptance in recent 40 years.

In the ensuing, the author will give a brief account of the elastic rebound theory, and then show its incorrectness. At the end, the author will put forward his gas hypothesis to explain the cause of earthquakes [6-10].

2. The Elastic Rebound Theory

2.1. The origin

The 1906 California Earthquake was investigated by the State Earthquake Investigation Commission. The two reports [3, 4] are the first comprehensive and systematical documentations of damage earthquakes in modern science. In particular, co-seismic surface ruptures were frequently observed along the northern segment of San Andreas Fault and evidenced the fault motion of right-lateral strike-slip (horizontal motion), as shown by the red arrows in Figure 1. Accordingly to plate tectonics, this fault forms the tectonic boundary between the Pacific Plate and the North American Plate.

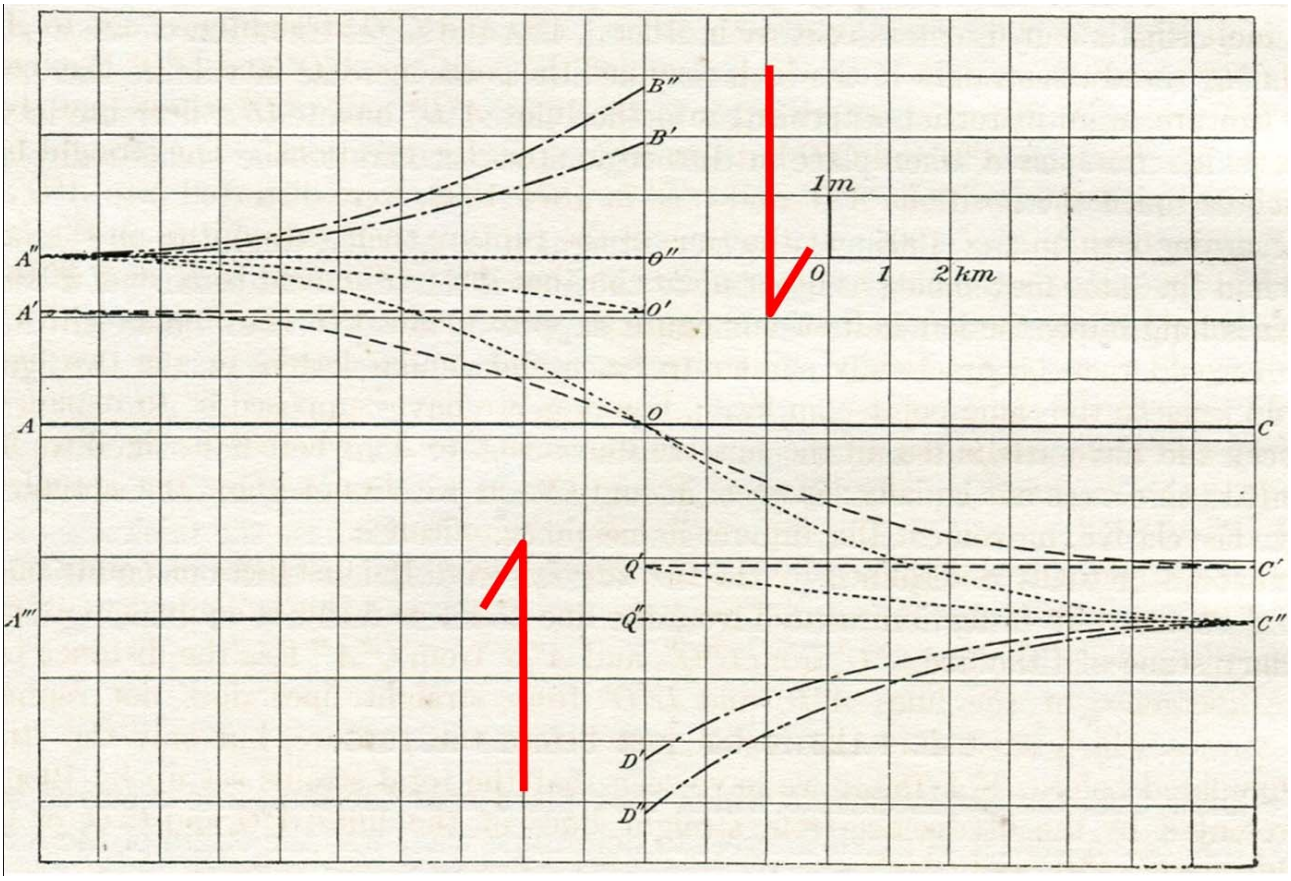

Figure 1. Illustration for elastic rebound for the cause of the 1906 California earthquake [4]

The ruptured fault traversed a part of the region where accurate ground topography surveys were made by the U. S. Coast and Geodetic Survey at various times before and after the earthquake [3, 4]. A summary of the survey results on ground plane is given in Figure 1. The central line passing through the points B'', B', O'', O', O, Q', Q'', D' and D'' is the fault line. The side with the

points A'', A', A, and A''' is the Pacific Plate on the west. The side with the points C, C', and C'' is the North American Plate on the east. It was pictured the displacements and the strains experienced at the region before, during and after the earthquake as follows [4].

"Let AOC be a straight line at some early data when the region was unstrained. By 1874-1892, A had been moved to A' and C to C', and AOC had been distorted into $A'OC'$; By the beginning of 1906, A had been further displaced to A'' and C to C'', then the sum of the distances AA'' and CC'' being about 6 meters; and AOC had been distorted into $A''OC''$."

"When the rupture came, the opposite sides of the fault slipt about 6 meters past each other; $A''O$ and $C''O$ straightened out to $A''O''$ and $C''O''$; and the straight lines which occupied the positions $A''O''$ and $C''Q''$ just before the rupture, were distorted afterwards into the lines $A''B''$ and $C''D''$, these lines being exactly like the lines $A''O$ and $C''O$ but turned in opposite directions."

"The straight lines, which occupied the positions $A'O'$ and $C'Q'$ in 1874-1892, were distorted into $A''O'$ and $C''Q'$ in the beginning of 1906; at the time of the rupture their extremities on the fault-line had the same movements as other points on that line; O' moved to B' and Q' moved to D'."

Subsequently, the elastic rebound theory for the cause of earthquake was developed, established and used by many others. It has been the main stream theory for the past one hundred years.

2.2. Brief description

Correspondingly, the existing elastic rebound theory in association with the plate tectonics for the cause of tectonic earthquakes can be briefly described below. The Earth's crust can be divided into a number of large and/or small tectonic plates. There edges are deep faults. The slow motion of convection currents in the plastic hot material of the mantle drives, pushes and pulls the plates. The tectonic plates can have relative motions in the order of several cm per year. Deep faults with brittle and locked zones can be present in the crust rocks. As the plates move slowly, their fault edges can stay locked, the surrounding crustal rocks can gradually deform for a long time. The elastic stress-strain energy can be built up and stored in rock masses. When the stress on the locked fault zone exceeds its breaking strength, a sudden rupture of the brittle fault part would occur, which causes an earthquake. Its side rocks can abruptly slip into new positions. Such sudden rupture can occur along pre-existing faults or newly formed faults. The larger the earthquake magnitude, the larger the ruptured fault length and the larger the slip offset. They take place at either tectonic plate boundaries or inside plates. So, there are interplate and intraplate earthquakes. The sudden rupture can occur along pre-existing faults or newly formed faults.

2.3. Work and energy

The work (W) done at the time of rupture was given by the following equation [4]:

$$W = \frac{1}{2} FDA, \tag{1}$$

where F is the force per unit area of the fault-plane, A the area of the fault plane and D the slip.

For the 1906 California earthquake, the fault depth was 25 km, the length 435 km, the average shift 4 meters, and the force 1×10^8 dynes per square centimeter. The work was estimated 1.75×10^{24} ergs (or 1.75×10^{17} joules). "This energy was stored up in the rock as potential energy of elastic strain

immediately before the rupture; when the rupture occurred, it was transformed into the kinetic energy of the moving mass, into heat and into energy of vibrations; the first was soon changed into the other two. When we consider the enormous amount of potential energy suddenly set free, we are not surprised, that, in spite of the large quantity of heat which must have been developt on the fault-plane, an amount was transferred into elastic vibrations large enough to accomplish the great damage resulting from the earthquake and to shake the whole world so that seismographs, almost at the antipodes, recorded the shock."[4]

Modern seismology has adopted the fault rupture and/or slip model in the quantitative analysis of seismic waves [5]. A quantitative measure of the size and strength of a seismic shear source is the scalar seismic moment M_0 with the unit Nm (or Joule). M_0 is a measure of the irreversible inelastic deformation in the rupture area and can be expressed as follows [5]:

$$M_0 = \mu \overline{D} A, \tag{2}$$

where μ the rigidity or shear modulus of the rock mass, $\overline{D}$ the average final displacement after the rupture, A the surface area of the rupture. M_0 has the following relations with the surface-wave magnitude scale M_S (or the moment magnitude M_W) and the radiated seismic strain energy E_S (Joule):

$$\log M_0 = 1.5M_S + 9.1, \tag{3}$$

$$\log E_S = 4.8 + 1.5M_S \tag{4}$$

Furthermore, the total energy release E_T can be expressed by:

$$E_T = E_S + E_f, \tag{5}$$

where E_f is the friction energy to power the growth of the earthquake fracture ($E_{fracture}$) and the production of heat (E_{heat}).

The ratio E_S/E_T (i.e., the seismic efficiency) is perhaps only about 0.01 to 0.1, depending both on the stress drop during the rupture as well as on the total stress in the source region. In other words, only a small fraction of E_T goes into producing seismic waves. For instance, the 2011 off the Pacific Coast of Tohoku Earthquake may have $M_W = 9.0$, Mo = 4.5×10^{22} Nm, and $E_S = 2.0\times10^{18}$ Joule. The 2001 Kunlun Pass W. Earthquake may have $M_S = 8.1$, Mo = 1.8×10^{21} Nm, and $E_S = 8.9\times10^{16}$ Joule.

3. Observations and Comments

Based on the above brief, the existing elastic rebound theory for the cause of earthquakes looks quite simple and straightforward. Accordingly, the classical theories of elasticity, elastodynamics, fracture mechanics and plasticity have been extensively applied to mechanically examine the mechanism of earthquakes and to quantitatively predict the earthquakes since the crustal rocks and soils can be considered as solid materials [5, 11, 12]. Furthermore, the monitoring, testing and modeling techniques and methods have been rapidly developed and used. A huge amount of accurate data such as GPS, satellite images and seismographs have been monitored and measured for the movement of tectonic plates and faults.

Hence, if the elastic rebound theory had been correct or along the right track, the movement and deformation of the massive solid rocks and soils associated with the tectonic plates and faults would have had many regularities and phenomena following the guidance of the classical theories of solid mechanics. The earthquake unpredictable statement would not have become a mainstream consensus in modern seismology and seismo-geology. However, many devastating damage earthquakes still occurred suddenly without pre-warning or pre-notice by human beings. Recent examples are the 2008 Wenchuan Earthquake [1] and the 2011 off the Pacific Coast of Tohoku Earthquake [13-15].

The author has actively participated in the field investigation of the Wenchuan Earthquake of May 12, 2008. He has found many natural phenomena that happened before, during and after Wenchuan Earthquake. These phenomena cannot be logically and consistently explained with the existing elastic rebound theory in association with the plate tectonics. Mostly importantly, the elastic rebound theory violates many phenomena. He has further actively investigated many other earthquakes including the 1976 Tangshan Earthquake, the 2001 Kunlun Pass W. Earthquake and the 2011 off the Pacific Coast of Tohoku Earthquake. The same observations can be made. The existing elastic rebound theory cannot describe many earthquake phenomena and sometimes violates the phenomena [6-10].

As discussed in Section 2, the elastic rebound theory claims that a large amount of heat must be developed on the rupture-plane [4]. The friction energy to power the growth of the earthquake fracture and the production of heat is about 90% to 99% of the total energy release during earthquake [5]. The rupture speed is very fast and can be 2 to 3 km/s over hundred kilometers crustal rock faults according to analysis of seismograph records. Accordingly, the heat must cause some substantial increases in temperatures of the ruptured rocks and soils and the ground air at epicenters. However, field observations did not show any expected increase in temperatures of the ground rocks, soils and air. For example, Rice [16] stated the observations of “low heat outflow from major faults and a scarcity of glass (pseudotachylyte) that would be left from rapid recooling of silicate melts”. The author has further found that temperatures of the ground rocks, soils and air can suddenly drop during and immediately after ground shocking. An example is given below to show the inconsistency between the observed phenomena and the elastic rebound theory.

4. The 2001 Kunlun Pass W. Earthquake

4.1. Brief description

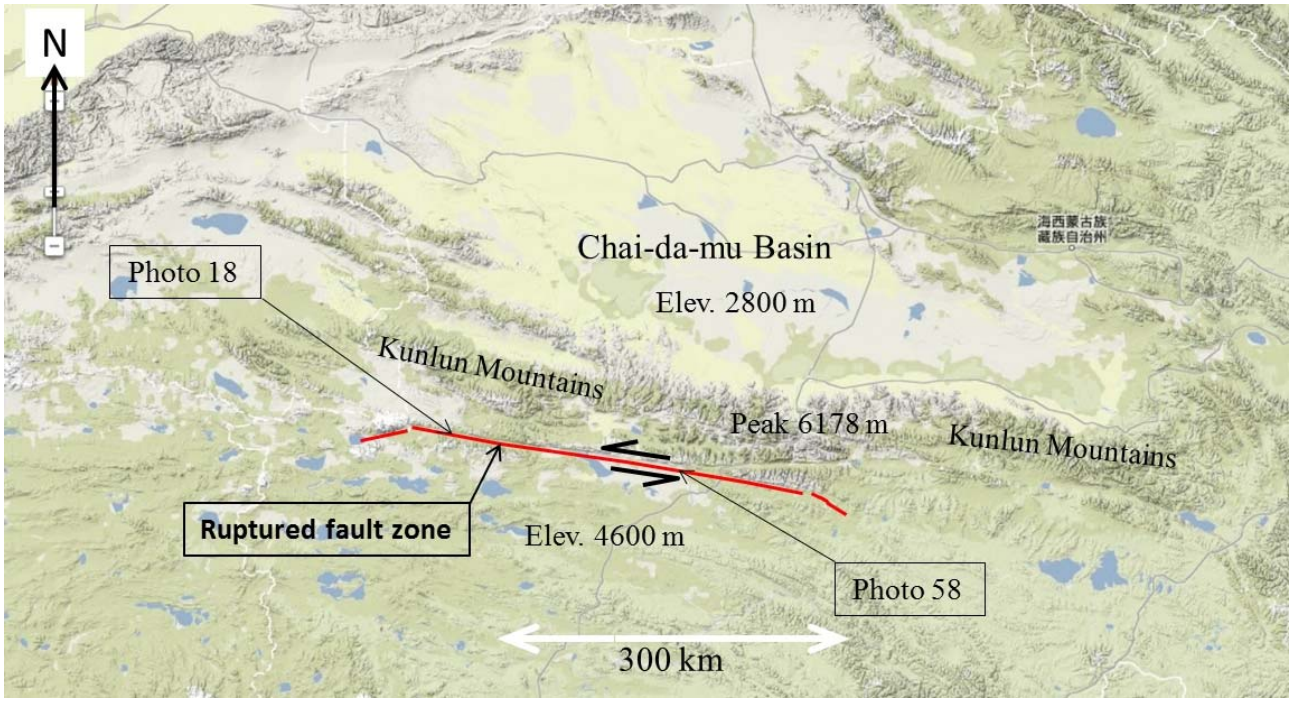

Figure 2. Google topography based seismic rupture zone for 2001 Kunlun Pass W. Earthquake

The Kunlun Pass W. Earthquake of magnitude 8.1 suddenly occurred along the western segment of

the Kunlun Mountain Fault at 17 hours and 26 minutes and 14.7 seconds (Beijing time) in the afternoon of November 14, 2011. The epicenter was at (35.6°N, 94.1°E). The focal depth was 15 km. The total duration was about 120 seconds. It released a huge amount of energy and made the grand Kunlun Mountains rupturing and slipping. The released radiated seismic strain energy E_S might be 8.9×10^{16} Joule. It resulted in a surface rupture zone in the south slope of Kunlun Mountains. The seismic surface rupture zone was 426 km in total length and several hundred meters in width (as shown in Figure 2).

On November 16, 2001, a group of scientists from China Seismological Bureau went to the epicenter area for seismological and damage investigation. They observed that the ground deformation and destruction were serious and great in scale. Their widths varied from several tens meters to several thousand meters along the 426 km long surface rupture zone. The maximum left-lateral displacement was 6 to 7 m.

4.2. Ruptured permafrost soils and ice

The Kunlun Mountain is part of the Qinghai-Tibet Plateau, a region of the largest-scale tectonic uplift. The ground elevations along the seismic surface rupture zone were about 4600 m to 5000 m above the sea level. The grounds that were ruptured by the seismic fault movement were dominantly permafrost grounds. Ice layers covered on the rivers were also ruptured. Album showing the seismic surface ruptures and destruction was published by China Seismological Bureau [17]. It contains 140 colored photographs showing the seismic rupture zone from the west to the east. Two photographs 18 and 58 from the Album [17] are represented in Figures 3 and 4, respectively. Their locations are identified in Figure 2.

Figure 3. A tent-shaped mole track typical of the frozen soil layer with a height of 2 m, north of Wuxue Peak (after photograph 18 of [17])

From the site photograph 18 in Figure 3, it can be evidently observed that the frozen soil layer was largely uplifted, bended and then cracked in tension and shear. The broken frozen soil layer was relatively rigid. Their fractured sides and edges were fresh, sharp and angular. There were no signs

of melting, thawing, plastic flow, muds, and/or re-freezing. In other words, the seriously broken frozen soil layer maintained its frozen state during and a few days after the ground rupture and shock.

From the site photograph 58 in Figure 4, it can be evidently observed that the frozen soil layer and the ice cover in a gully were largely uplifted, bended and then dislocated in tension and shear. The broken ice plates had fresh, sharp and angular sides and edges. There were no signs of melting, thawing, plastic flow, muds, and/or refreezing in the gully ice plates and frozen soils. In other words, the seriously broken frozen soils and ice plates maintained their frozen states during and a few days after the ground rupture and shock.

Figure 4. The ice in a gully was displaced 1.4 m in left-lateral sense 25 km east of Kusai Lake (after photograph 58 of [17])

The above no melting and thawing phenomena in the broken and deformed permafrost soils and ice covers are typical and can be observed in almost all the 140 photographs collected in the Album [4]. Chen et al. [18] also observed that the earthquake ruptures in frozen soils mainly showed brittle deformation, were composed of shear fractures, tension fracture and seismic ridges.

4.3. Energy analysis for melting frozen soils

Xu and Chen [19] carried out a temporal and spatial rupture process analysis of the earthquake by back-calculating the high signal-to-noise-ratio P-waveform data of vertical components of 20 stations with epicentral distances less than 900 km. Their back-calculated results showed that the earthquake had three sub-rupture events forming 220 km, 120 km and 270 km long fault ruptures. The six rupture speeds were 2.2 km/s to 5.8 km/s.

Secondly, according to fracture mechanics, the energy required for the growth of the earthquake fracture ($E_{fracture}$) in the rocks and soils may be estimated with the following equation.

$$E_{fracture} = \frac{AK_c^2}{E}, \quad (6)$$

where A is the total fractured area along the fault plane (m^2), K_c is the rock fracture toughness with the unit MPa $m^{1/2}$, and E is the rock elastic modulus (MPa). If E = 20,000 MPa, K_c = 1 MPa $m^{1/2}$, and A = 6.39 ×10^9 m^2 (=426 km × 15 km), then, $E_{fracture}$ = 3.2 ×10^{11} Joule. So, $E_{fracture}$ (3.2 ×10^{11} Joule) is far less than the E_S (8.9×10^{16} Joule).

Thirdly, the specific heat capacity c_p^{frozen} for completely frozen soil can be determined with the following equation:

$$c_p^{frozen} = \frac{c_p^{soil} + w_0 c_p^{ice}}{1 + w_0}, \quad (7)$$

where c_p^{soil} is the specific heat capacity for soil and is equal to 800 Joule/(kg °C), c_p^{ice} is the specific heat capacity for ice and is equal to 2060 Joule/(kg °C), and w_0 is the water (ice) content in the complete frozen soil. Normally, c_p^{frozen} is between 800 and 2060 Joule/(kg °C). The temperature increase ΔT of the frozen soil has the following relation with its mass M_{soil} and the heat increase ΔQ:

$$\Delta T = \frac{\Delta Q}{c_p^{frozen} M_{soil}}, \quad (8)$$

Assuming, w_0 is 15% and its degree of saturation 100%, then c_p^{frozen} 964 Joule/(kg °C) and the unit weight of the frozen soil is about 2209 kg/m^3. Assuming, for a total frozen soil along the ruptured zone, its thickness is 20 m, its length 426 km and its width 100 m. Its total mass is 1.9×10^{12} kg. It might have the temperature from –1°C to –20°C. The heats for the total frozen soil temperature increases 1°C and 20°C are 1.8×10^{15} Joules and 3.6×10^{16} Joules, respectively. The frozen soil has a total of 2.4×10^{11} kg ice. As the latent heat of ice is 3.34×10^5 Joule/kg, the total latent heat required for melting all the ice at 0°C in all the permafrost soil into liquid water is 8.2×10^{16} Joules.

As a result, the total heat required for melting all the frozen soil is between 8.3×10^{16} Joules and 11.8×10^{16}, which is similar to the released radiated seismic strain energy E_S 8.9×10^{16} Joule. Furthermore, if E_S is perhaps only about 0.01 to 0.1 of the total released energy E_T [5], there would be enough heat energy to melt and thaw the entire frozen soils along the surface ruptured zone. But, no melting or thawing phenomena were observed in the 140 site photographs [17]. The theoretical results and field observations can demonstrate that the elastic rebound theory is incorrect.

5. The Gas Cause of Earthquakes

A further question may be asked: what type of loading can rapidly crack the crustal fault for tens to hundreds km long and tens km deep, generates the strong seismic waves, but does not produce heat? One most possible and feasibility loading is the rapid expansion and migration of highly compressed natural gas from deep crustal traps via tectonic fault channel. This is the internal loading associated with the gas hypothesis for cause of earthquakes [6-10]. The hypothesis can be briefly described below.

An earth quaking is an adiabatic process of interaction between rapid upward expansion and migration of compressed natural gas and its surrounding crustal rocks and ground soils. The natural gas is produced in core and/or mantle and gradually accumulated in the traps below crustal fault rocks. It escapes from its traps in deep fault zones of the lower crustal rocks. Because of the

extremely high pressure drops in front of the moving gas mass, the gas migration speed in the fault zone can be several km/s. The interaction is instantaneous and flashing. It can be complete within few to tens and to hundreds seconds. The gas expansion and migration are confined and constrained by the inward gravity, the tectonic stresses and the rigidness and strengths of the crustal rocks. The energy of earth quaking is mainly the physical expansion energy of the highly compressed methane gas. The gas expansion is a cooling process, which reduces the temperatures of ground rocks and soils and air during and immediately after the shock. All the earthquake phenomena can be logically and consistently explained and predicted with the gas hypothesis. Specially, the broken permafrost soils and ices along the 426 km long surface rupture zone in south slope of Kunlun Mountains could keep sharp, angular and fresh immediately after the earthquake on November 14, 2001.

6. Concluding Remarks

The author would like to recall the four rules of reasoning in philosophical inquiries of nature summarized by Sir Isaac Newton about 300 years ago [20].

- RULE I. *We are to admit no more causes of natural things than such as are both true and sufficient to explain their appearances*.
- RULE II. *Therefore to the same natural effects we must, as far as possible, assign the same causes*.
- RULE III. *The qualities of bodies, which admit neither intensification nor remission of degrees, and which are found to belong to all bodies within the reach of our experiments, are to be esteemed the universal qualities of all bodies whatsoever*.
- RULE IV. *In experimental philosophy we are to look, upon propositions inferred by general induction from phenomena as accurately or very nearly true, notwithstanding any contrary hypotheses that may be imagined, till such time as other phenomena occur, by which they may either be made more accurate, or liable to exceptions*.

We may have to follow these four rules in our scientific inquiry of the nature of earthquakes. The elastic rebound theory was developed one hundreds year ago from the observations of co-seismic surface ruptures induced by the 1906 California Earthquake. It is only partially correct because it associates earthquakes with faults. It is inconsistent and even violates many other phenomena that were present before, during and after earthquakes.

Numerous failures have been encountered and experienced in our tremendous efforts using the elastic rebound theory in the prediction of earthquakes. Many current seismo-geologist and seismologists have lost their original goals to predict earthquakes and turned to believe that earthquakes are unpredictable with the present techniques. All these problems are due to the fact that the incorrect elastic rebound theory for the cause of earthquakes was used in the investigation and prediction of earthquakes.

It is evident that the energy released during earthquake is not the elastic stress and strain energy accumulated in brittle crustal rock solids during relative movements of tectonic plates. The released energy is the volumetric expansion energy of highly compressed and dense natural (methane) gas. The gas rapidly escaped from its deep crustal traps and was migrating via deep faults into shallow grounds and the sky. The author trusts that this gas hypothesis for the cause of earthquakes would make earthquake predicable in the near future.

Acknowledgements

The author would like to thank many friends and colleagues for their invaluable advices, assistances, discussions, information, data and supports during his independent investigations of the nature of

earthquakes and the Earth system.

Effects of a newly incorporated with a stress-weakening term in a revised RSF on earthquake nucleation

Abstract Quasi-static nucleation on a frictional fault embedded in an elastic medium is known to be sensitive to the frictional properties. Earlier works have employed 'aging' and 'slip' versions of rate- and state-dependent friction (RSF) law, but some clear flaws have been known; the aging law wrongly predicted linearly increasing slip-weakening distance with the amount of strength reduction, whereas the slip law could not reproduce observed time-dependent healing at very low velocities. Recently Nagata et al. [1] proposed a revised version of RSF by incorporating a stress-weakening effect newly found in laboratory experiments and by correcting the frictional parameters '*a*' and '*b*' largely, where '*a*' and '*b*' are the coefficients of RSF. It seems to be free from the previously known flaws and we here reexamined nucleation by using the revised RSF. From numerical simulations, two major differences were found. 1) For weakly velocity-weakening range of $0.85<a/b<1$, nucleation has characteristics of both unidirectional slip-pulse regime found in the slip law case and crack-like expansion regime in the aging law case. 2) Fixed-length patch regime occurs over a wider condition of a/b up to 0.85 in contrast with the previously reported range of $a/b<0.5$ implying strongly velocity-weakening faults.

Keywords Nucleation, Earthquake, Fault, Rate and State Friction

1. Introduction

On the basis of laboratory rock friction experiments the rate- and state-dependent friction law (RSF) was introduced [2]. It has been widely used in modeling of earthquake occurrence and successfully explained the mechanics of seismic cycles [3], aftershock activities [4] and many others. In the present paper, we focus on the modeling of earthquake nucleation by careful attention to the RSF formulae.

Quasi-static nucleation on a frictional fault buried in an elastic continuum is known to be sensitive to the frictional properties. Earlier works studied spontaneous nucleation under slow tectonic loading using 'aging' and 'slip' versions of rate- and state-dependent friction (RSF) law [5-7]. For strongly velocity-weakening faults characterized by $a/b<0.5$ ('*a*' and '*b*' are the coefficients of RSF), nucleation occurs in a 'fixed-length patch' regime, where regions of quasi-static slip remains relatively small. For weakly velocity-weakening faults ($0.5<a/b<1$), nucleation must propagate spatially (Fig. 1). Propagation occurs in a form of an expanding crack in the aging law case and in a form of a migrating slip pulse in the slip law case.

Both versions of RSF were proposed as descriptions of laboratory friction experiments, but some clear flaws are known; aging law's slip-weakening distance increases linearly with the amount of strength reduction, while slip law does not reproduce time-dependent healing at very low velocities. Recently Nagata et al. [1] proposed a revised version of RSF by incorporating a stress-dependent term with a coefficient '*c*' and by correcting the RSF parameters '*a*' and '*b*' largely. This new version of RSF seems to be free from the previously known flaws and is here employed to reexamine nucleation.

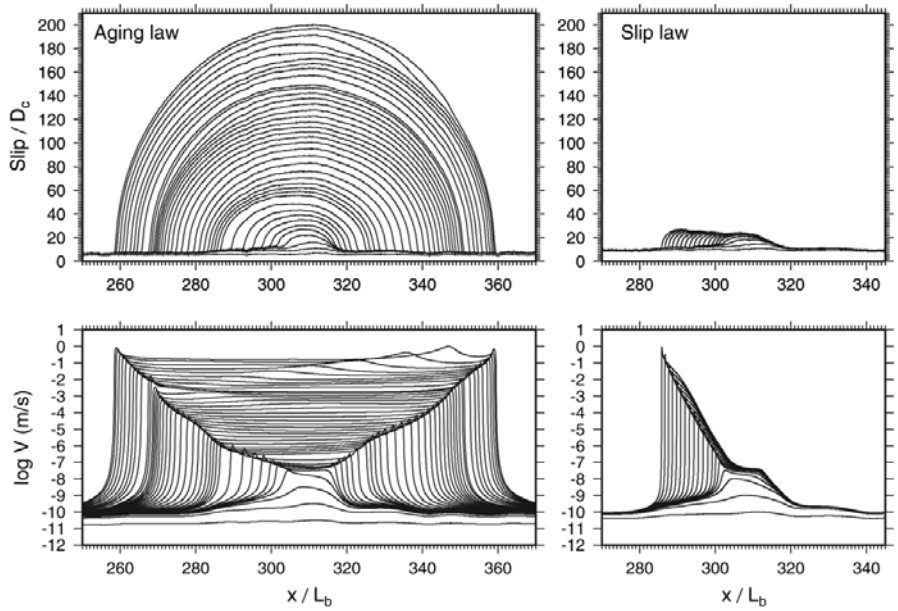

Figure 1. Snapshots of normalized slip (top panels) and slip rate (bottom) for two simulations identical in all respects except that the left panels use the aging law and the right panels the slip law. *a/b*=0.95, $D_c = 0.4 \times 10^{-3}\,\mathrm{m}$, $V_0 = 10^{-9}\,\mathrm{m/s}$, $\tau_r = 10^{-2}\,\mathrm{Pa/s}$, the normalizing length scale $L_b \equiv \mu_* D_c/(b\sigma) = 4.6\mathrm{m}$. From figure 2 of Ampuero and Rubin [7] (in the present paper, the notation D_c is replaced by L).

1-1. Existing and revised RSFs

RSF consists of two equations bearing logically separate roles [8]. One is the constitutive law, which describes the relationship between applied shear stress τ and slip rate V as

$$V = V\exp\left(\frac{\tau-\Phi}{a\sigma}\right), \text{ or } \tau = \Phi + a\ln\left(\frac{V}{V_*}\right), \tag{1}$$

where Φ is the state variable specifying the internal physical state of the interface, which may reflect the real contact area [9], a is called direct effect coefficient and play an important role in the constitutive law for which the physical mechanism has been attributed to thermally activated creep [8,10], σ is a normal stress and V_* is a reference velocity. Another equation is the evolution law, which phenomenologically describes variations of the state Φ. Two empirical evolution equations for the evolution of Φ, first formalized by Ruina [11], are common use. These are

$$\frac{d\Phi}{dt} = \frac{b\sigma}{L}V_*\exp\left(-\frac{\Phi-\Phi_*}{b\sigma}\right) - \frac{b\sigma}{L}V \quad \text{(Aging law)}, \tag{2}$$

$$\frac{d\Phi}{dt} = -\frac{V}{L}\left(\Phi - \Phi_* - b\sigma\ln\left(\frac{V}{V_*}\right)\right) \quad \text{(Slip law)}\,, \tag{3}$$

where b is a RSF parameter relating change in state, L is a length scale related with slip, Φ_* is a reference state. The first and second terms of eq. (2) represent logarithmic time-dependent healing and linear slip weakening with a constant rate b/L per unit slip, while eq. (3) represents exponential slip weakening with a fixed distance L [8]. The aging law has trouble in reproducing a symmetric exponential change of friction over a fixed slip distance subsequent to stepwise velocity jumps to opposite signs observed in velocity-step tests (Fig. 2a) though it explains time-dependent healing in hold-slide tests very well as observed [8,11]. The slip law does explain the slip weakening (Fig. 2b), but has a well-known difficulty in reproducing time healing at low slip rate [12-13].

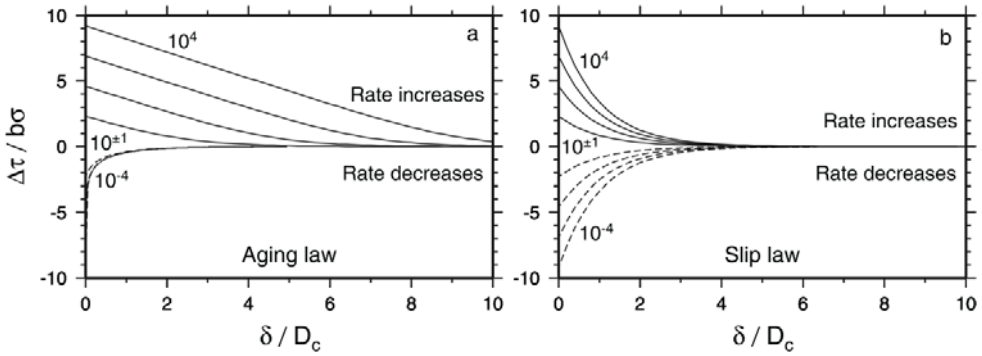

Figure 2. Plots of normalized stress as a function of normalized slip, for step velocity increases (solid lines) and decrease (dashed lines) of 1-4 orders of magnitude, for (a) the aging law and (b) the slip law. Stresses are relative to the future steady state value. For the aging law the curves for step decreases of 2-4 orders of magnitude appear indistinguishable, but they intersect the vertical axis at the same values of $\Delta\tau$ as the slip law. From figure 3 of Ampuero and Rubin [7] (in the present paper, the notation D_c is replaced by L).

Recently Nagata et al. [1] proposed a revised RSF, using new rigorous methods of laboratory data analysis. Firstly, the direct effect coefficient a was constrained to be 0.05, about five times larger than previously believed. The difference came from their new method to constrain a without using any evolution laws, contrasting to conventional methods where the state change from imperfection of real-world 'step' tests was inferred by assuming 'flawed' evolution law. This large a immediately led to similarly large $b \sim 0.05$ because $(b-a) \sim 0$ was reliably constrained from velocity dependence of steady-state friction without any evolution laws. Secondly, a strong linear negative dependence of $d\Phi/dt$ on $d\tau/dt$ was newly found from the misprediction analysis of Φ between the observed $\Phi(=\tau - a\ln(V/V_*))$ and the predicted Φ by using eq. (2). The shear-stress weakening effect was incorporated as

$$\frac{d\Phi}{dt} = \frac{b\sigma}{L} V_* \exp\left(-\frac{\Phi - \Phi_*}{b\sigma}\right) - \frac{b\sigma}{L} V - c\frac{d\tau}{dt} \quad , \tag{4}$$

where c is the stress weakening parameter. The term $-cd\tau/dt$ works to resolve the artifact of varying slip-weakening distance in the aging law as clearly seen in Fig. 3; when c=0, eq. (4) coincides with eq. (2) and the artifact remains unsolved, but with increasing c, the symmetric response in opposite sign of velocity-step tests was attained and the prediction curves became more symmetric like the slip law, keeping with the time-dependent healing term [14]. From the above misprediction analysis, the best-fit value of c was determined about 2.0. Nagata et al. [1] confirmed that the revised RSF could correctly reproduce both hold-slide and velocity-step tests with the same values of frictional parameters, which had never been attained in the existing RSFs. Very recently the revised RSF was employed to simulate earthquake cycle [15] and aftershock triggering [16].

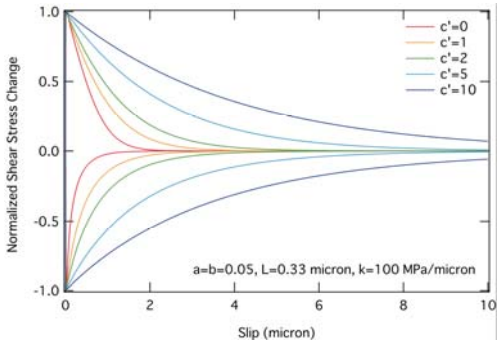

Figure 3. Normalized change of shear stress in velocity step-up and step-down tests predicted for different c. Slip rate is increased or decreased tenfold. From figure 5.21 of Nagata [14].

1-2. Nucleation regimes and lengths

We here briefly summarize nucleation regimes and their lengths in the previous studies [5-7] examined both numerically and analytically.

For strongly velocity-weakening faults characterized by $a/b<0.5$, nucleation occurs in a 'fixed-length patch' regime, where regions of quasi-static slip remains relatively small. In the patch regime, the state along patch kept well above steady state with insignificant healing. With a no-healing approximation, Rubin and Ampuero [6] analytically estimated the patch half-length as

$$L_\nu = 1.3774 L_b \qquad (L_b \equiv \frac{\mu_* L}{b\sigma}), \tag{5}$$

where $\mu_* = \mu/(1-\nu)$ is the stiffness of a medium for edge dislocation, μ is the rigidity, and ν is the Poisson's ratio. For the slip law, the patch length is slightly smaller than L_ν [7].

For weakly velocity-weakening faults ($0.5<a/b<1$), nucleation must propagate spatially. Propagation occurs in a form of an expanding crack ('crack-like expansion' regime) in the aging-law case (Fig. 1a) and in a form of a migrating slip pulse ('unidirectional slip-pulse' regime) in the slip-law case (Fig. 1b). In the crack regime, the state along expanding portion instead kept steady state for increasing slip, that is, healing effect was not negligible. The nucleation half-length was estimated with a steady-state approximation as

$$L_\infty = \left(\frac{b}{b-a}\right)^2 \frac{L_b}{\pi} \qquad (b-a>0). \tag{6}$$

Ampuero and Rubin [7] attributed the crack-like expansion to the slip-weakening curves predicted with the aging law in response to velocity step ΔV (Fig. 2a), which would be experienced at the expanding nucleation front where the concentrated stress yields with a sudden jump in the slip rate. In their analysis, nucleation zone was proven to be approximated by a crack; stress uniformly drops by $\Delta\tau$ on the crack and locally concentrates at the tips by peak-to-residual stress drop $\Delta\tau_{p\text{-}r}$. Fracture mechanics tells us the energy release rate G in terms of the crack length l and fracture energy G_c at the crack tip, which were then connected to slip rate V on RSF faults as

$$G = \frac{\pi}{2}\frac{l}{\mu_*}(\Delta\tau)^2 \propto (\ln V)^2 \qquad (\Delta\tau \sim \sigma(b-a)\ln(V/V') - b\varepsilon) \tag{7}$$

$$G_c = \frac{\Delta\tau_{p-r}\delta_c}{2} = \frac{L}{2b\sigma}(\Delta\tau_{p-r})^2 \propto (\ln V)^2 \qquad (\Delta\tau_{p-r} \sim b\sigma\ln(V/V'') - \varepsilon) \tag{8}$$

where V' and V'' are nearly constant slip rates, δ_c is the effective slip-weakening distance following the linear slip-weakening rate *(b/L)*, and $\varepsilon \sim 0$. Setting $G = G_c$ and solving for the instantaneous nucleation length l lead to

$$l = \frac{L_b}{\pi}\left(\frac{\Delta\tau_{p-r}}{\Delta\tau}\right)^2 = l(V). \tag{9}$$

At every moment in accelerating V, the energy balance $G=G_c$ is satisfied; this is why the nucleation can be the crack-like expansion. By considering the ratio $\Delta\tau_{p\text{-}r}/\Delta\tau$ approaching *b/(b-a)* in the limit of large slip rate V, the nucleation size L_∞ in eq. (6) was derived. However, the prediction curves with increasing slip-weakening distances are an artifact due to the linear slip-weakening rate and contradict with laboratory experiments [8].

On the contrary, following the slip-weakening curves of the slip law (Fig. 2b), the fracture energy becomes $G_c \propto (\Delta\tau_{p-r})^1 \propto (\ln V)^1$ due to the constant slip-weakening distance, keeping $G \propto (\ln V)^2$ remain the same extent. The energy balance suggests that the accelerating V is incompatible with the crack-like expansion of the nucleation zone and numerical simulation demonstrated that the nucleation instead takes the form of unidirectional slip pulse (Fig. 1b). It must be noted that the nucleation was, however, wrongly predicted at the very beginning where the slip rate was very low and healing should have dominated. A genuine regime following laboratory experiments should be investigated by using the revised RSF.

2. Simulation method and choice of parameters

Following Dieterich [5], quasi-static nucleation is modeled here by adopting the revised RSF. A fault is divided by n equally spaced segment with a length Δs and loaded by a constant stressing rate τ_r:

$$\tau_i = \tau_i^0 + \tau_r t + \Delta\tau_i \quad (i = 1, 2, \quad , n), \tag{5}$$

where τ_i is the shear stress, τ_i^0 is the initial stress, $\Delta\tau_i (= \Sigma S_{ij}\delta_j)$ is the change of stress resulting from the slip δ_j over the fault, and S_{ij} is stress kernel obtained from elastic dislocation solution [5]. By equating eq. (5) with eq. (1) and by substituting the revised law of eq. (4) to eliminate Φ, we obtain a couple of nondimensional differential equations:

$$d\tau_i'/dt' = \tau_r' + S_{ij}' V_j' \tag{1.1}$$

$$d\left(\ln V_i'\right)/dt' = \left(a/b\right)^{-1}\left\{(1+c)d\tau_i'/dt' - \exp[-(\tau_i' - (a/b)\ln V_i')] + V_i'\right\} \tag{1.2}$$

where $\tau_i' = (\tau_i - \tau_*)/(b\sigma)$, $V_i' = V_i/V_*$, $t' = t/(L/V_*)$, $\tau_r' = \tau_r/(b\sigma/(L/V_*))$, $S_{ij}' = S_{ij}/(b\sigma)$ and frictional parameters (a,b,c,L) are assumed the same at all points on the fault. A factor (1+c) is newly appeared by the shear-stress dependent term. Nagata et al. [1] obtained a best fit parameter set (a,b,c,L)=(0.051, 0.0565, 2.0, 0.33micron) and this is the only set ever constrained by laboratory experiments. It leads to a/b=0.90 and (1+c)=3.0 in simulating nucleation.

In our controlled numerical experiments, c is chosen for a tuning parameter: no stress weakening c=0.0 is for the aging law, the optimum c=2.0 for the revised law, and an excessed c=4.0 for comparison. a/b is chosen as 0.95, 0.90, 0.85, 0.80, 0.75, implying that smaller a/b corresponds to stronger velocity weakening. Except for a/b and c, all simulations are identical in all respects. Fault discretization is done with n=2400 and $\Delta s = L_b/10$, small enough to resolve nucleation length. Initial velocity is assumed to be uniformly distributed $V_i'^0 = 1.0 (= V_*')$ and initial stress $\tau_i'^0$ is assumed to be randomly distributed between [-1,0] in order to start nucleation from below-steady state where the time-healing term dominates the slip-weakening term. $\tau_r' = 0.1$ and $\mu_*' = 11.56 \times 10^3$ are chosen the same as in Ampuero and Rubin [7]. If $V_* = 10^{-9}$m/s is taken, our simulation results are directly comparable with Fig. 1. Time integration is numerically done by using the Runge-Kutta method until $V_{\max}' = 10^9$.

3. Result

We conducted nucleation simulations with the total 15 sets of the revised RSF parameters (*a/b*, *c*) and found systematic changes in the results. Figure 4 shows the results with variation of *c*=0.0, 2.0, 4.0 under a fixed *a/b*=0.95, the snap shots of slip and slip rate evolution. When *c*=0.0 (the aging law) was adopted, a crack-like expansion occurred similar to Fig. 1a. Contrasting to this, when *c*=2.0, 4.0 were adopted, the crack-like propagation was completely disappeared. A narrow zone of peak slip velocity appears at the edge of the nucleation front propagating outwards like in the slip-law case, but the wide (and growing) region behind the front remains slipping at a velocity more than the 1/3 of the peak velocity, resulting in a slip distribution similar to that of an expanding crack as in the aging law case. Namely, the nucleation regime with the revised RSF was found to have both pulse feature in the spatial propagation and the crack feature in the slip rate distribution. The result may be understandable by comparing the revised law and the slip law. The revised law, as in the slip law favoring pulse, yields a slip-weakening distance nearly independent of the amount of strength reduction (Fig. 3), but it differs from the slip law in that it involves a time-dependent healing term, which should contribute significantly where the slip is proceeding near steady state. Crack-like extension would be no longer incompatible with the energy balance for instantaneous nucleation length *l* as pointed out in the section 1.2.

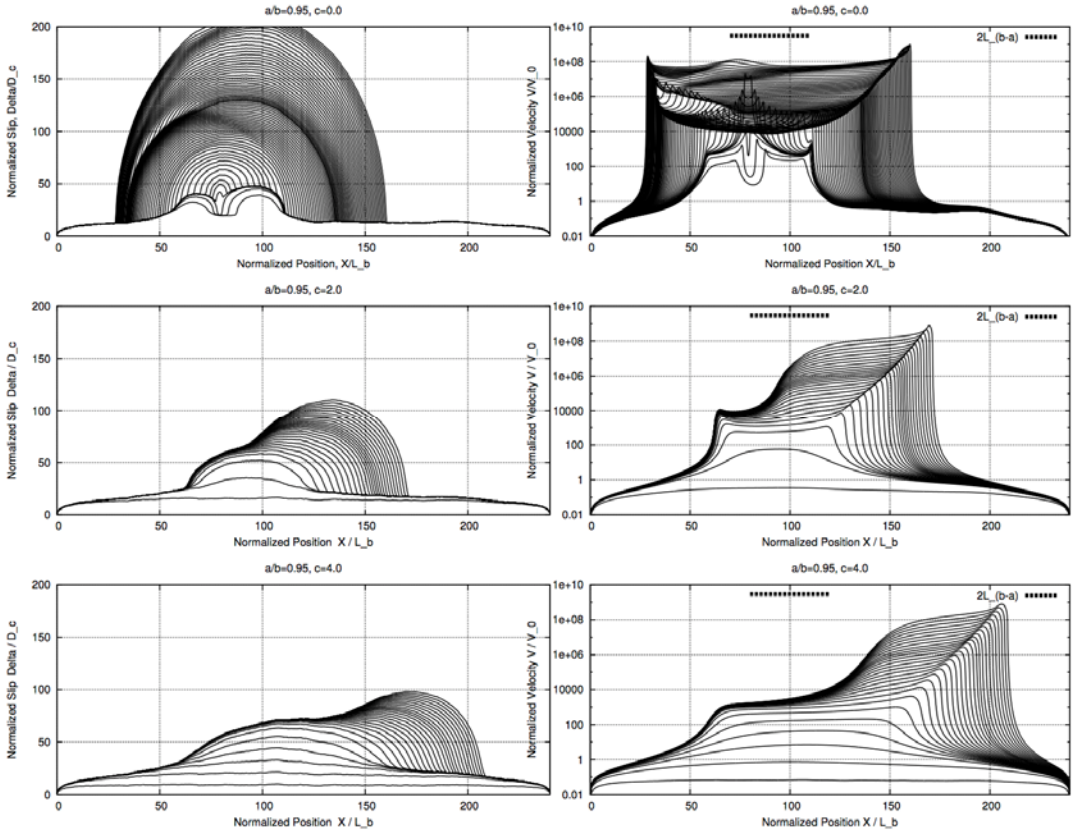

Figure 4. Snapshots of normalized slip (left panels) and slip rate (right panels) simulated by using the revised RSF for *a/b*=0.95 with three variations in the *c* parameter: (top) case with *c*=0.0, (middle) case with *c*=2.0, and (bottom) case with *c*=4.0.

Figure 5 shows the results with variation of *a/b*=0.90, 0.85, 0.80, 0.75 under fixed *c*=2.0 (the optimum) and *c*=4.0. Only snap shots of the slip rate are shown for brevity. For both *c*, transition from a pulse regime to a patch regime was observed as *a/b* was decreased. The transition was around *a/b*=0.80 for *c*=2.0 and *a/b*=0.85 for *c*=4.0, which are much larger than *a/b*=0.5 in the previous studies as schematically summarized in Fig. 6. The condition for the patch regime widens

as we increase a stress-weakening parameter *c*. As to the patch length with the revised RSF, it is obviously larger than the theoretical length $2L_\nu$ with the aging law in eq. (5) that is just a few digits $(\sim 2.7L_b)$ in the normalized position in Fig. 5. The newly incorporated stress dependent term brought significant effects on the fixed-length path regime: the wider *a/b* range and the larger patch length. As to these results, a clear explanation has not been come up with.

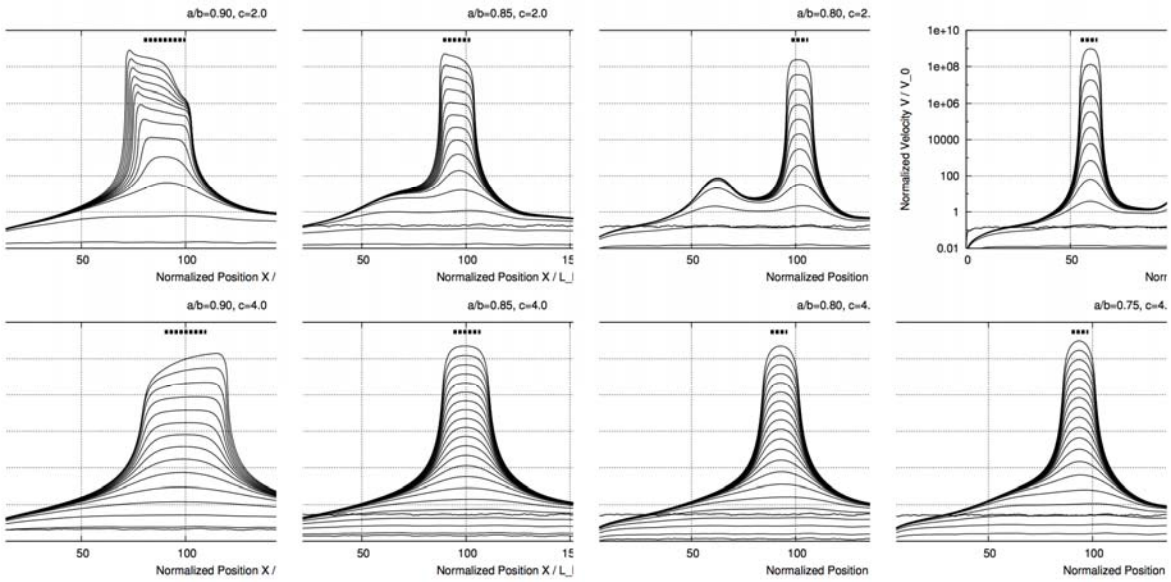

Figure 5. Snapshots of slip rate simulated with the revised RSF: (upper panels) cases with *c*=2.0, and (lower) cases with *c*=4.0 (from left to right: *a/b*=0.90, 0.85, 0.80, 0.75). All the vertical axes are in the same scale. A length scale $2L_{b\text{-}a}$ is plotted for reference by thick dashed line.

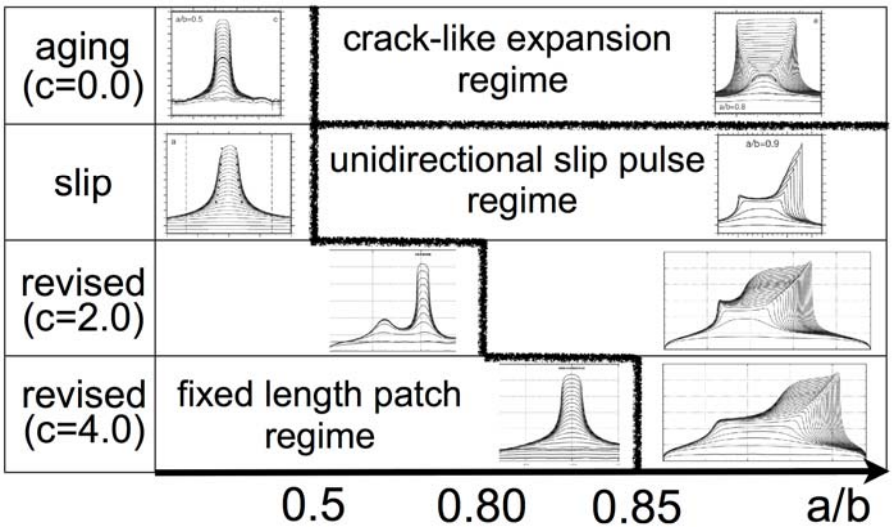

Figure 6. Nucleation regimes in 2-D simulation of quasi-static nucleation on RSF faults. The nucleation icons are from figure 1 of Rubin and Ampuero [6] in the aging law and figures 5 and 7 of Ampuero and Rubin [7] in the slip law.

4. Discussion

The simulated nucleation length was compared with the theoretically predicted value $2L_\nu$ and was

found to be larger than $2L_v$. Seeking for a characteristic patch length with the revised RSF, we then compare it with another length scale

$$L_{b-a} \equiv \frac{\mu_* L}{(b-a)\sigma}, \tag{6}$$

where L_{b-a} is a characteristic nucleation length based on long-tem stick-slip instability [6]. $2L_{b-a}$ is plotted for reference by thick dashed line in Fig. 5. It seems to show a better agreement than $2L_v$ and may be a possible reference length at the moment. It is a tentative scale as a matter of course and future analytic work will be absolutely necessary to quantify the nucleation patch length explicitly including *c* parameter [17].

4. Conclusion

Nucleation on frictional faults was reexamined by using the revised RSF which seems to be free from previously known flaws. Our simulation results with systematic changes in the frictional parameter sets (*a/b*,*c*) comprehensively disclosed two major differences. 1) For weakly velocity-weakening range of $0.85<a/b<1$, nucleation had characteristics of both unidirectional slip-pulse regime found in the slip law case and crack-like expansion regime in the aging law case. 2) Fixed-length patch regime occurred over a wider condition of *a/b* up to 0.85 in contrast with the previously reported range of $a/b<0.5$ implying strongly velocity-weakening faults, and its patch length was larger than that predicted by the aging law.

Abstract The theory of poromechanics is widely used to examine problems in the environmental geosciences. In classical poromechanics, the material parameters such as the elastic stiffness or the permeability are assumed to remain constant. The porous fabric can, however, experience micromechanical processes that can lead to alterations in the stiffness and fluid transport characteristics. Experiments on rocks indicate permeability increases even at deviatoric stress states well below peak stress levels, which can contribute to errors in predicting the progress of transient phenomena. This paper presents a multi-scale approach for investigating permeability evolution in a heterogeneous geomaterial. The complex microstructure of geomaterials is modelled using a level set-based extended finite element description (XFEM) that allows uncoupling the meshing operations from the presence of the fine scale material interfaces. A dedicated tool for the generation of representative volume elements based on similar concepts is exploited. Fine scale plastic constitutive laws are used to model the progressive mechanical degradation under stress. The local (fine-scale) permeability evolution can then be coupled to the local plastic dissipation quantities. These fine-scale developments are combined with a versatile computational homogenization technique to upscale mechanical and transport properties corresponding to heterogeneous microstructures. Using this procedure, the effect of progressive degradation on the averaged permeability properties of geomaterials is investigated. These procedures are illustrated by estimating the variation of permeability with the confining pressures and deviatoric stresses applied in triaxial testing.

Keywords Mechanical Degradation, Degradation-induced permeability, Level Set functions, XFEM modelling

1. Introduction

Heterogeneous geomaterials possess complex microstructures. The computational homogenisation of such microstructures requires specific tools to take this complexity into account, both from the point of view of the availability of representative volume elements, and from the point of view of the discretisation technique. This paper presents a level set-based extended finite element description (XFEM), that allows uncoupling the meshing operations from the modelling of the fine scale material interfaces. A dedicated tool for the generation of representative volume elements based on similar concepts is also exploited. Fine-scale plastic constitutive laws are used to model the progressive mechanical degradation under stress. The local (fine-scale) permeability evolution is assumed to be coupled to the local plastic dissipation. Using this procedure, the effect of progressive degradation on the averaged permeability properties of geomaterials is investigated. These procedures are illustrated by estimating the alteration of permeability with the confining pressures and deviatoric stresses applied in triaxial testing.

2. Computational homogenisation of mechanical and transport properties

The upscaling framework described in detail in [1] can be used to extract the homogenised behaviour of a heterogeneous material, starting from its microstructure. The essential features of this approach are summarized below. For completeness, a detailed derivation of the averaging relationships can be found in [1] and references therein.

2.1. Averaged mechanical response of a RVE

The averaged mechanical properties of a heterogeneous material can be deduced by loading a RVE containing the main microstructural features of the material, and solving the corresponding equilibrium problem. When a macroscopic strain $\mathbf{E}$ is applied to a RVE, the displacement of a point inside the RVE is given by

$$\vec{u}(\vec{x}) = E.\vec{x} + \vec{u}_f(\vec{x}) \tag{1}$$

where $\vec{x}$ is the position vector within the RVE and $\vec{u}_f$ is a fluctuation field caused by the heterogeneity of the material. Assuming that the macroscopic strain is the volume average of the fine-scale strain field ε resulting from the above equation, and accounting for a periodic fluctuation, the Hill-Mandel condition (energy equivalence between the fine-scale and macroscopic descriptions)

$$\Sigma : \delta E = \frac{1}{V}\int_V \sigma : \delta\varepsilon \, dV \tag{2}$$

implies that the macroscopic stress tensor is obtained as the volume average of the microstructural stress tensor. Considering the periodicity of the fluctuation field, the macroscopic stress tensor can next be identified based on the cell tying forces at nodes controlling the macroscopic loading as

$$\Sigma = \frac{1}{V}\int_V \sigma \, dV = \frac{1}{V}\sum_{a=1}^{4} \vec{f}^{(a)}\vec{x}^{(a)} \tag{3}$$

where the summation spans the nodes controlling the RVE loading. Any type of material behaviour can be postulated at the fine scale, and the periodicity of the microfluctuation field can be enforced by homogeneous linear connections between corresponding faces. In a three-dimensional body, four controlling points (denoted 1 to 4 in Fig. 1a) are used to apply the macroscopic stress or deformation modes of the boundary of the RVE, provided identical meshes are used on the opposite faces of the RVE.

The RVE equilibrium problem under the macroscopic stress loading is then solved by imposing forces $\vec{f}^{(a)}$ at the controlling points, which represent the action of the neighboring continuum on the RVE. The displacements of the controlling points, energetically conjugated to the imposed controlling forces, can be used to extract the macroscopic strain.

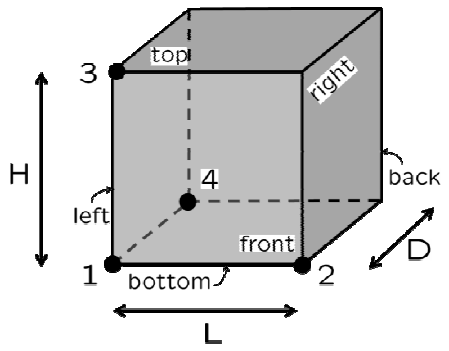

Figure 1. Control points for macroscopic quantities control on a RVE for upscaling principles

2.2. Averaged permeability of a RVE

The homogenised permeability for a given local permeability distribution within the RVE can be evaluated using an upscaling scheme similar to the one developed for heat conduction in [2]. For fluid flow, the mass conservation equation at the scale of the components has to be solved. Expressing the fine scale flux is expressed in terms of the local permeability distribution $K_m(\vec{x})$ and with a fluid of dynamic viscosity μ, mass conservation reads

$$\vec{\nabla}_m \left(-\frac{K_m(\vec{x})}{\mu} \vec{\nabla}_m p_m \right) = 0 \tag{4}$$

A periodic fluctuation $p_f(\vec{x})$ of the pressure field is assumed [1,2] to describe the pressure variation inside the RVE according to

$$p_m(\vec{x}) = p_m^k + \vec{\nabla}_M p_M . \left(\vec{x} - \vec{x}^k \right) + p_m(\vec{x}) \tag{5}$$

where $\vec{\nabla}_M p_M$ is the macroscopic pressure gradient to be applied in an average sense on the RVE, and where p_m^k is the pressure of an arbitrary point in the RVE. An averaging relation for the pressure gradient is required as

$$\vec{\nabla}_M p_M = \frac{1}{V} \int_V \vec{\nabla}_m p_m dV \tag{6}$$

Assuming the periodicity of the pressure field fluctuation and using the Green-Gauss theorem, the average of the fine-scale pressure gradient can be expressed as

$$\frac{1}{V} \int_V \vec{\nabla}_m p_m dV = \vec{\nabla}_M p_M + \frac{1}{V} \oint p_f \vec{n} \, dS \tag{7}$$

With the periodicity of $p_f(\vec{x})$, the last integral of this relationship vanishes and the relationship prescribing the consistency between the macroscopic and fine scale pressure gradients is satisfied. In a computational treatment, the periodicity constraint on the pressure fluctuation field requires that relationships of the form

$$p_m^S - p_m^M = \vec{\nabla}_M p_M . (\vec{x}^S - \vec{x}^M) \tag{8}$$

be satisfied between the master M and slave S nodes of opposite faces of the RVE. An additional averaging relationship is used to impose consistency between scales of the product of the pressure gradient by the flux

$$\vec{\nabla}_M p_M . \vec{q}_M = \frac{1}{V} \int_V \vec{\nabla}_m p_m . \vec{q}_m \, dV \tag{9}$$

Combining the pressure gradient averaging with this relationship, it can be shown that the macroscopic flux is automatically obtained as the RVE average of the fine-scale fluxes [2]

$$\vec{q}_M = \frac{1}{V} \int_V \vec{q}_m \, dV \tag{10}$$

Details of the derivation of this last averaging relationship can be found in [1]. The constraints on the pressures at the boundary can be enforced using control nodes to apply the macroscopic pressure gradients to the RVE. The averaged permeability tensor of the RVE can be identified from the link between the applied macroscopic pressure gradient and the fluxes developing as a reaction

to them. At equilibrium, the discretized system of equations for the transport problem can be condensed at the control nodes

$$q_{m_n}^{(a)} = \sum_{b=1}^{4} k_{disc}^{(ab)} \left(\nabla_j p \; x_j\right)^{(b)} \tag{11}$$

where $k_{disc}^{(ab)}$ results from the condensation of the entire RVE stiffness values. Using periodicity, the averaged flux is obtained from the 'reaction' fluxes at the controlling nodes as

$$q_{M_i} = \frac{1}{V} \oint_S q_{m_n} x_i dS = \frac{1}{V} \sum_{a=1}^{a=4} q_{m_n}^{(a)} x_i^{(a)} \tag{12}$$

Upon substitution of the two previous relationships, one identifies the (averaged) permeability as

$$K_{M_{ij}} = \frac{\mu}{V} \sum_{a=1}^{a=4} \sum_{b=1}^{b=4} x_i^{(a)} k_{disc}^{(ab)} x_j^{(b)} \tag{13}$$

As in the mechanical case, any modelling choice (constitutive laws, discretisation technique) can be adopted for the fine-scale modelling.

3. Representative volume element generation

The RVE generator tool is mainly designed based on distance fields and level set functions as presented in [3] for 2D RVEs, and extended in [4] for 3D simulations. A random distribution of inclusions is first generated, which is subsequently morphed to produce a grain-like structure.

3.1. Inclusion packing

The inclusion packing is the first step of the RVE generation method that gives the basis for the microstructural spatial arrangement. It allows incorporating prescribed volume fractions and/or grain size distributions as input parameters. The geometry used for the shape of inclusions is arbitrary and can be randomly generated through a parameterization, or explicitly defined from existing data (e.g. in order to use data from Computed X-Ray Tomography).

The problem of filling a container with a given volume fraction of inclusions while respecting prescribed size distributions and grain shapes is achieved here using a sequential addition of inclusions, improved by the use of distance fields. In the classical RSA algorithm, each loop generates randomly a trial position in the RVE for the next inclusion to be added. This inclusion is then verified to ensure no interpenetration with previously added inclusions when placed at the trial position, in which case it is rejected and another trial position is generated. Costly computational operations (overlap and distance evaluation) are required at each trial, but few trials lead to a successful inclusion addition, especially when dense packing must be reached.
This original sequential addition methodology can be dramatically improved using distance fields. Instead of a purely random trial position, a set of discrete positions satisfying a priori the non-overlapping and neighboring distance conditions is used to select new inclusion locations. This set is built using the nearest neighbor distance function $LS_1(x)$ (see Fig. 2a) which is maintained on a structured grid of points x_n at each inclusion addition. The radius *r* of the smallest enclosing circle (or sphere) of the new inclusion is used as an indicator of its size.

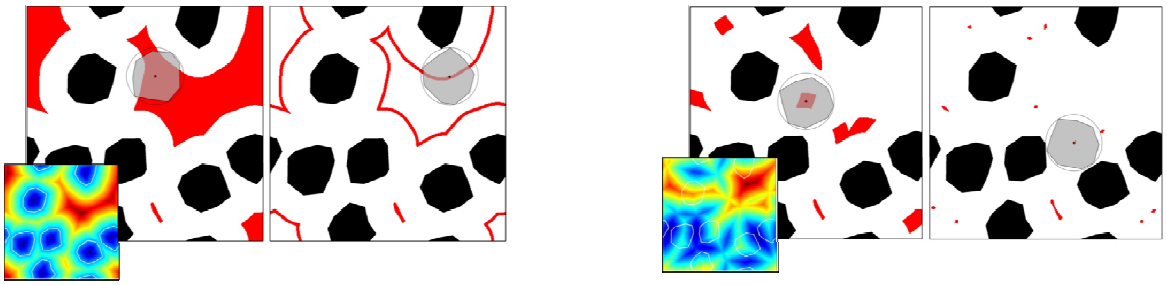
The positions on the grid leading to overlap with existing inclusions can be excluded for the random inclusion positions by allowing selection only among the points satisfying the condition (Fig.2a)

$$LS_1(x_n) > r \tag{14}$$

This allows the addition of a new inclusion at each trial, and the generation cost is therefore not linked to any probability relative to the actual density, but rather to the number of added inclusions. Additional neighboring distance conditions can be enforced using $LS_1(x)$ such as for instance

$$nn_{min} + r < LS_1(x_n) < nn_{max} + r \tag{15}$$

where $nn_{min}$and $nn_{max}$are the minimum and maximum distance imposed from the first neighbor of the added inclusion (Fig. 2a). To increase packing density, the spatial organization has to be optimized by minimizing the distances of the added inclusion to its second nearest neighbor in 2D and its third nearest neighbors in 3D. The corresponding distance functions $LS_2(x_n)$ and $LS_3(x_n)$ are used for this purpose with the same type of condition (Fig. 2b).



(a) (b)

Figure 2. (a) Non-overlap and first neighbor distance criteria to restrict the random position of the new inclusion to be added (the function $LS_1(\mathbf{x})$ is represented in the insert), (b) First and second neighbor distance criteria to optimize spatial organization to obtain dense packings (the function $LS_2(x_n)$ is represented in the insert)

3.2. Inclusion morphing

Marginal corrections required to adjust the inclusion volume fraction or shapes and more substantial modifications allowing to produce polycrystalline or cellular microstructures motivate the development of a tool enabling the morphing of inclusions once their population is entirely generated by sequential addition. At this stage, the inclusions neighborhood is completely determined and can be used to modify their shape according to inter-inclusion distance rules. A complete expansion of inclusions until vanishing the inter-grain joint thickness allows forming polycrystal-like microstructures.

The morphing technique is strongly based on level set functions. The $LS_1(x_n)$ and $LS_2(x_n)$ functions built during the sequential addition process are used to construct a function $O(x_n)$ that can be contoured to extract updated shapes of the inclusions. The case of complete expansion of inclusions to form a polycrystal morphology is used here to illustrate the methodology. The function

$$O(x_n) = LS_1(x_n) - LS_2(x_n) \tag{16}$$

vanishes at points of equal distance between two nearest inclusions and is negative elsewhere. The zero level set of this function thus determines a Voronoï-like diagram, each cell enclosing an inclusion and points closer to it than to other inclusions. If the initial inclusion distribution is a

dense arrangement of mono-sized spheres, the produced grains are convex and the result is exactly a Voronoï diagram (see Fig. 3a). The use of multi-sized arbitrary shaped polyhedra leads to disordered microstructures (see Fig. 3b). A constant thickness w joint between the grains can be obtained by considering the function $O(x_n) = LS_1(x_n) - LS_2(x_n) + w$.

4. LS-XFEM discretisation for material heterogeneities

The complexity of generating finite element meshes for the generated RVEs motivates the use of an alternative discretisation method. The eXtended Finite Element Method [5], that does not require meshes conforming with the material boundaries, is therefore used. In addition to be defined as an extension of the standard finite element scheme, this method uses the level set formalism to describe the RVE geometry, which allows its seamless integration with the RVE generator.

(a) (b)

Figure 3. (a) convex Voronoï-like cells produced by a circle packing, (b) disordered cells produced by an arbitrary shaped multi-sized inclusion packing

The principle of XFEM is to use a non conforming regular mesh with additional degrees of freedom related to additional shape functions (denoted the enrichment) introducing the strain jumps induced by material heterogeneities. This treatment, concentrated on finite elements intersected by a material interface (e.g. inclusion/matrix boundary), uses signed distance functions to construct the enrichment and to subdivide elements by material at the stiffness integration stage. The interpolation of each displacement field components therefore reads

$$u_{XFEM}(x) = \sum_i N_i(x)\, d_i + \sum_j N_j(x)\, \Psi(x)\, a_j \tag{17}$$

where the first term represents the usual finite element polynomial interpolation containing the standard shape functions as a partition of unity. The second term introduces the XFEM enrichment with a_j the additional unknowns and $\Psi(x)$ the enrichment functions. For heterogeneous materials, the LS_1 level set (distance) function was shown to introduce the required strain jump at the material boundary. This principle is illustrated in Fig. 4 for the 1D case.
Likewise, the pressure field within the heterogeneous microstructure can be described using a similar principle.

$$p_{XFEM}(x) = \sum_i N_i(x)\, p_i + \sum_j N_j(x)\, \Psi(x)\, d_j \tag{18}$$

The XFEM methodology was implemented in a 3D setting, and was coupled with periodic homogenization. The result of the mechanical loading of a RVE can subsequently be used in the

fluid transport simulation, thereby enabling a one-way coupling between the local mechanical degradation of the material and its local permeability.

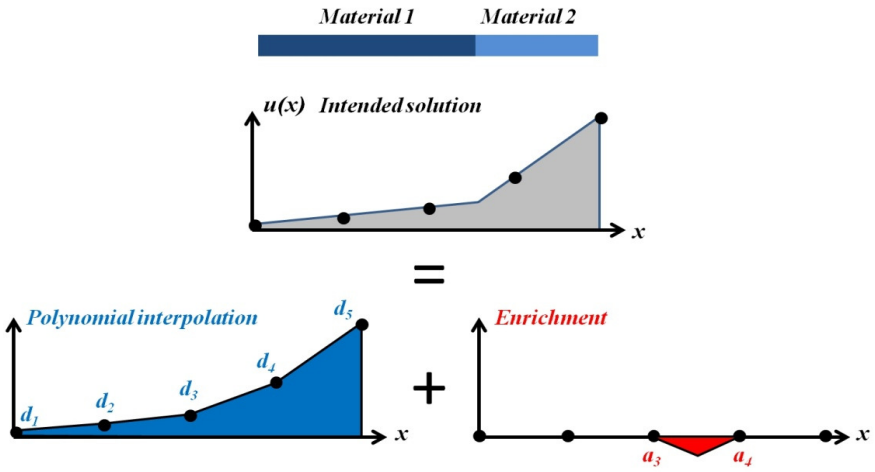


Figure 4. Principle of XFEM enrichment by level set function

5. Application to rock-type materials

The concepts presented previously are now illustrated using two RVEs generated with the tools described in Section 3 and in [4]. The first RVE used for fluid transport homogenisation is produced starting from an initial distribution of elongated inclusions that are subsequently morphed into grains separated by joints. Considering the aspect ratio of the grains, if different permeability properties of the constituents are selected, the resulting average permeability should be anisotropic, as will be illustrated in Section 5.1. The second RVE contains grains without any preferential orientation. The evolving macroscopic permeability resulting from the local plasticity-induced permeability evolution in the joints is analysed in Section 5.2.

5.1. Averaged anisotropic permeability properties

As a first illustration of the proposed level set based homogenisation of heterogeneous materials, the permeability of a anisotropic grain-based material is considered. An anisotropic RVE is generated with a 69% volume fraction of grains (Fig. 5). A grain permeability $k_{grains} = 10^{-13}m^2$ is used, while the joints are assumed 10 times more permeable ($k_{joints} = 10^{-12}m^2$). Since the inclusions are parallel and elongated along the vertical direction, the macroscopic averaged vertical permeability should be higher than for the transverse directions. This is indeed the case as the obtained permeability properties read

$$k_{vertical} = 3\ 10^{-13}m^2 \text{ and } k_{horizontal} = 2{,}3\ 10^{-13}m^2$$

This is further illustrated in Fig. 5 where the fluid flow is illustrated for a unit pressure gradient along the horizontal and vertical directions. As can be seen the preferential orientation of the inclusions clearly favors the fluid flow along the vertical direction, leading to a higher vertical permeability.

5.2. Plasticity-induced permeability evolution in a triaxial test

The coupling between the local mechanical degradation and the fluid transport properties is

illustrated based on a RVE made of grains and large joints with a grain volume fraction of 58%, and subjected to triaxial loading. The RVE is assumed to have dimensions of 10 mm along each direction.

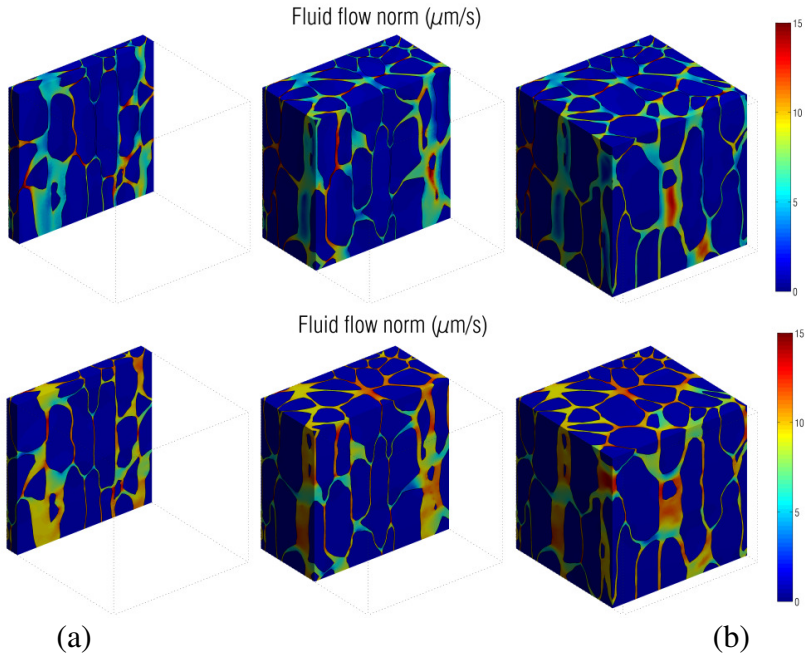

Figure 5. Norm of flow vector for (top) horizontal pressure gradient and (bottom) vertical pressure gradient in anisotropic medium

The grains do not present any preferential orientation as illustrated in Fig. 7. They are assumed purely elastic, whereas a plastic behaviour is assumed in the joints (${}^4H$ is the 4th order elasticity tensor)

$$\sigma = {}^4H : \left(\varepsilon - \varepsilon^{pl}\right) \tag{19}$$

with a Drucker-Prager criterion and an associated flow rule

$$f(p,q) = q - Ap - s(\kappa) \qquad \text{and} \qquad d\varepsilon^{pl} = d\kappa \frac{\partial f}{\partial \sigma} \tag{20}$$

with

$$p = \frac{I_1}{3}$$
$$q = \sqrt{3J_2}$$

where I_1 and J_2 are respectively the first invariant of the stress tensor and the second invariant of the stress deviator. The initial A and s can be expressed as a function of the cohesion c and of the friction angle φ of the material as

$$s = \frac{6c\cos\varphi}{3-\sin\varphi}, \qquad A = \frac{6\sin\varphi}{3-\sin\varphi} \tag{21}$$

To avoid numerical difficulties often met with perfect plasticity, a linear evolution of the yield limit with the plastic strain is introduced through

$$s = s_0 + s_1\kappa \tag{22}$$

Assuming a dilatant behaviour of the joints as defined by an associated plastic flow rule, the volumetric plastic strain increases during the deviatoric loading phase. This increase is used to update the local permeability in plastified joints according to

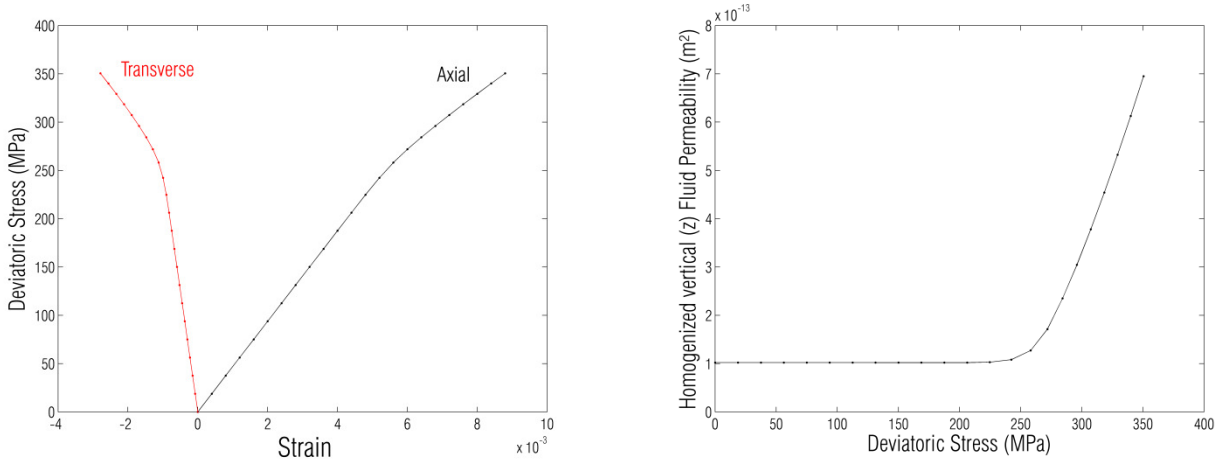
$$k = k_0\left(1 + B\varepsilon_{vol}^{pl}\right) \tag{23}$$

The set of parameters used in the computations is defined in Table 1. The applied loading follows a typical triaxial test with a strong confinement. A confinement of 100 MPa is first applied in all directions, followed by an increased of the axial stress, the other stress components remaining fixed. This high confining stress is used to avoid any convergence problem in the mechanical problem, and to keep the local strain distribution consistent with a small strain description.

Table 1. Material parameters used in mechanical and fluid transport homogenisation

Material	E	ν	c	φ	s_1	k_0	B
	GPa		MPa	°	GPa	(m²)	
Grains	60	0.1	-	-	-	10^{-13}	0
Joints	30	0.3	40	17	1	10^{-13}	5.10^4

Based on these material and loading parameters, the simulation of the triaxial test is performed. Fluid transport homogenisation is then performed for the mechanical degradation states of the RVE corresponding to successive deviatoric stress levels. The mechanical response of the RVE is depicted in Fig. 6a.



(a) (b)

Figure 6. Homogenised response of the RVE: (a) Mechanical response under triaxial conditions depicting the average deviatoric stress applied as a function of the axial and transverse strains, (b) Axial permeability evolution as a function of the applied deviatoric stress

The corresponding vertical averaged permeability evolution as a function of the deviatoric stress is depicted in Fig. 6b. A permeability increase of almost one order of magnitude is obtained based on the chosen value of the parameter B for the strong confinement applied (100 MPa). The volumetric strain distribution, that directly controls the local permeability evolution inside the RVE, is depicted in Fig. 7. As can be noted from these plots, local permeability can be magnified by a factor up to 500 at a macroscopic deviatoric stress of 350 MPa. The averaged permeability increase for the RVE however remains more restricted as a result of the absence of continuous pathways with high local permeability values inside the microstructure.

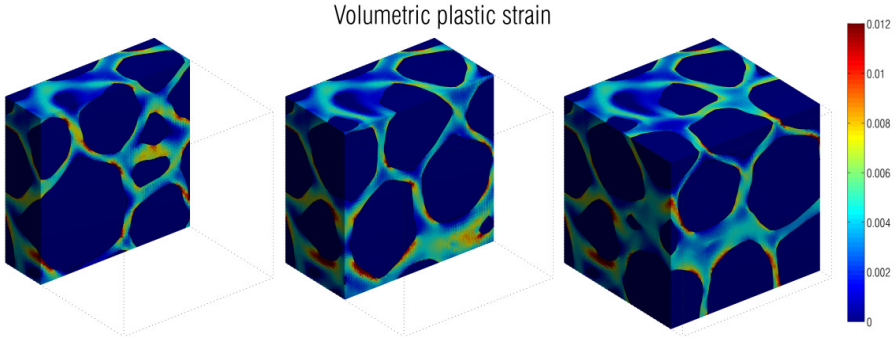


Figure 7. Local volumetric strain distribution inside the RVE at a deviatoric stress of 350 MPa

6. Concluding remarks

Based on the results presented, XFEM discretisation techniques can be efficiently combined with the proposed RVE generation approach to investigate the permeability and mechanical properties of heterogeneous geomaterials. From a fluid transport perspective, this modelling tool could be used in order to identify microstructural features responsible for average (fixed) permeability properties of rocks, in combination with kridging type approaches combined with surface permeability experimental tests [6].

With respect to stress induced permeability evolution, a moderate increase of permeability was obtained as a result of local plastic degradation. Complementary investigations should be performed to analyse the confinement dependency of the permeability evolution, as well as to compare quantitatively such computational results with experimental data. Further developments could incorporate cracking in addition to the plastic dissipation mechanisms contributing to the local permeability evolutions, as well as more advanced plasticity formulations.

Abstract
The paper presents an evaluation of the factors influencing fracture initiation at the boundary of a rigid test plate that are used to estimate the in-situ deformability characteristics of a geologic medium. The paper outlines the techniques that are used to perform in situ plate load tests and focuses on the problem of boundary fracture generation at the edges of the geologic medium. If the mechanical behaviour of the rock mass can be assumed to display brittle elastic behaviour, computational methods based on boundary element techniques can be used to examine the mode of crack extension within the elastic geomaterial. The process of fracture generation can influence the extent of the region being evaluated and, more importantly, this can adversely affect the theoretical relationships for the interpretation of test plate data. In most instances the boundary crack may not be visible; this is especially true if the plate load test is conducted with some nominal embedment. This paper discusses issues associated with the interpretation of plate load tests conducted as a validation of experimental data determined from plate load tests. The methodology for the correct interpretation of plate load tests conducted on brittle elastic materials requires knowledge of additional parameters governing the mechanical behaviour of the rock; this involves laboratory evaluation of fracture toughness data. The paper presents results concerning the influence of axisymmetric boundary fractures on the estimated deformability characteristics of the rock mass.

Keywords plate load tests, brittle edge fracture, boundary elements, interpretation of fields tests

1. Introduction

The evaluation of the effective geomechanical characteristics of complex and heterogeneous geological materials is best accomplished through static load tests that are conducted in-situ. A technique that has been used extensively in this connection is the plate loading test where a plate of known dimensions and flexural rigidity is maintained in contact with the surface of the geological medium under examination and is then subjected to an axial loading [1,2]. As the elastic stiffness of the geomaterial increases large loads are required to attain measurable test plate deflections. When plate load tests are conducted in galleries and adits, the loads needed to indent the test plate can be achieved through reaction against the walls of the gallery or enclosure. When plate load tests are performed on large open surfaces this facility is not available and recourse must be made to provide the test loads through a self stressing reaction system. The method of cable jacking introduces the reactive loads through an anchor region located in the medium that is being tested. The method was first proposed by Zienkiewicz and Stagg [3] and presents a simpler test configuration than that involving anchor piles and a bracing frame to accommodate the remoteness of the anchoring loads from the plate location. The influence of the anchor load on the resulting net settlement of the test plate was first examined by Selvadurai [4], who examined the problem of the interaction between a smoothly indenting plate and a Mindlin force [5] located at a finite depth from test plate. The analysis was subsequently extended to cover distributed anchor loads [6], transverse isotropy of the rock mass [7], flexibility of the test plate [8-11] and creep effects of the geologic medium [12].
In this paper we examine the problem of crack extension in a brittle elastic geologic medium during the indentation of the brittle elastic half-space by a cylindrical punch with a smooth flat contact surface. The paper discusses a procedure for locating the point of nucleation of the crack within the brittle elastic solid and employs a boundary element technique to locate the progress of crack evolution as the force on the loading device is increased [13]. The numerical results illustrate how the extent of crack development influences the load vs. displacement relationship for the rigid test plate. The development of boundary fracture is characteristic of any indentation problem involving brittle elastic materials and sharp-edged indenters. Results are developed for geomechanical investigations that are carried out both at the surface of a geomaterial and at depth. The work can also be extended to include flexibility of the plate that is applying the indentation loads.

2. Theoretical Results-Indentation

The theoretical concepts that are used in the interpretation of plate loading tests conducted on brittle elastic geologic media are invariably based on the validity of the theory of elasticity. The analysis is frequently restricted to assumptions of isotropy of the rock mass, While this is considered to be a limitation for in situ testing, the characterization of elastic materials that are generally anisotropic (with 21 independent elastic constants), orthotropic (with 9 independent elastic constants), or transversely isotropic (with 5 independent elastic constants) [14, 15] is regarded as a difficult exercise even under highly controlled laboratory conditions [16]. The best that can be accomplished in an in situ plate loading test is to arrive at an effective deformability modulus of the region in which the plate load test is conducted. The simplest idealization that permits the use of an effective property is the assumption of isotropy of the tested region. It is relatively clear that if the geologic medium possesses dominant stratification then the deformability should be interpreted appropriately. The theoretical concepts can also be extended to include both transverse isotropy of the rock mass and elastic inhomogeneity of the geologic medium [17-20]; however, the inverse analysis for the elasticity parameter identification in these situations cannot be conducted using only the results of plate load tests. Even with the restrictions of isotropic and homogeneous behaviour of the rock mass, the results of a plate load test can only provide an overall estimate for the deformability of the rock mass that can include both the elastic constants encountered in the isotropic elastic model. The theoretical analysis of the plate load test involving no reactive anchor forces can be conducted by formulating the mixed boundary value problem of the indentation of an isotropic elastic halfspace by a rigid test plate. In order to formulate the mathematical problem, it is also necessary to identify the contact conditions that can be present at the interface between the test plate and the geomaterial. This largely depends on the condition of the test plate and the procedures used to either make the interface completely smooth or completely frictional, which will inhibit relative slip between the plate and the geomaterial. Finally, the extent of the geomaterial region that is tested is assumed to be large in comparison to the dimensions of the plate, enabling the region to be approximated by an elastic halfspace region. Reviews of contact problems of special interest to in situ plate loading tests are given in [21-25]. The axisymmetric mixed boundary value problem associated with the smooth indentation of a halfspace by a rigid circular test plate (Figure 1) is described by the boundary conditions

$$u_z(r,0)=\Delta, \quad \forall r\in(0,a); \quad \sigma_{zz}(r,0)=0, \quad \forall r\in[a,\infty); \quad \sigma_{rz}(r,0)=0, \quad \forall r\in(0,\infty) \tag{1}$$

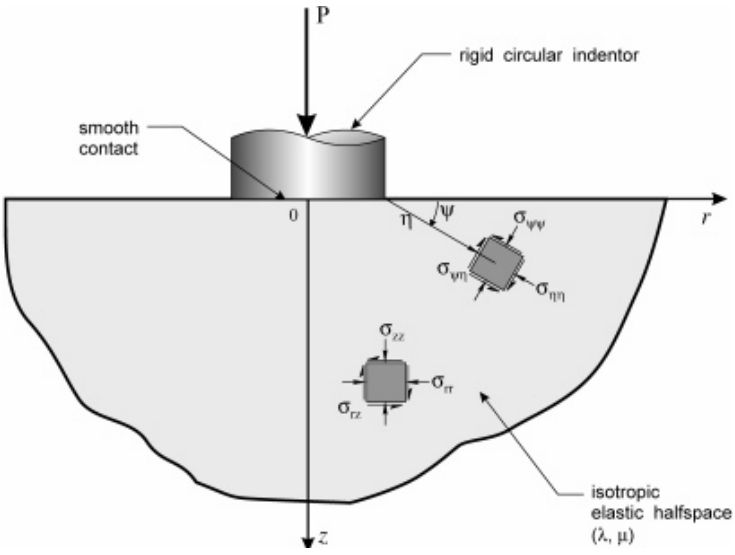

Figure 1. The classical indentation problem for a geomaterial halfspace.

where $\mathbf{u}(=(u_r,0,u_z))$ and $\boldsymbol{\sigma}$ are, respectively, the axisymmetric versions of the displacement vector and the stress tensor referred to the cylindrical polar coordinate system (r,θ,z) and Δ is the displacement of the test plate. In addition, the regularity conditions require that $\mathbf{u}$ and $\boldsymbol{\sigma}$ reduce to zero as either r or $z\to\infty$. The mixed boundary value problem in elasticity defined by the set of equations (1) is a classical problem solved by Boussinesq [26] employing results of potential theory and by Harding and Sneddon [27] using the theory of dual integral equations. Details of the methods of solution are also given in [21-25] and [28, 29]. The result of interest to geomechanics is the relationship between the indentation displacement (Δ) and the corresponding axial load (P) required to achieve the indentation. This can be obtained in exact closed form as

$$\Delta=\frac{P(1-\nu)}{4\mu a} \tag{2}$$

where μ and ν are, respectively, the linear elastic shear modulus and Poisson's ratio of the geomaterial. As is evident from (2), the classical analysis of the plate load test provides only an estimate of $\mu/(1-\nu)$ and additional information is needed to determine the parameters separately. When the plate adheres to the surface of the geomaterial, the resulting boundary value problem is described by the following boundary conditions:

$$\begin{aligned} &u_z(r,0)=\Delta,\ \forall r\in(0,a)\ ;\quad \sigma_{zz}(r,0)=0,\quad \forall r\in[a,\infty);\\ &u_r(r,0)=0,\ \forall r\in(0,a)\ ;\quad \sigma_{rz}(r,0)=0,\quad \forall r\in(a,\infty) \end{aligned} \tag{3}$$

This mixed boundary value problem can be examined by appeal to the theory of integral equations where the problem can be reduced to the solution of the Hilbert problem involving singular integral equations. The elasticity problem of adhesive contact between a plate and an elastic halfspace region was examined by Mossakovskii [30] and Ufliand [31] and the exact closed form result is given by

$$\Delta=\frac{P(1-2\nu)}{4\mu a\ln(3-4\nu)} \tag{4}$$

The Hilbert problem approach accounts for the oscillatory form of the stress singularity at the boundary of the rigid plate. Selvadurai [32] also examined the mixed boundary value problem defined by (3) but by replacing the oscillatory form of the stress singularity by a regular $(a^2-r^2)^{-1/2}$ type singularity, thus reducing the problem to the solution of a Fredholm integral equation of the second-kind. It was shown that the difference between the exact result based on the Hilbert problem formulation and the Fredholm integral equation formulation is less than 0.5% when $\nu=0$ and the results converge when $\nu=1/2$. A further classical development is to consider that the entire surface of the halfspace is composed of an inextensible membrane, in which case the bonded boundary condition is automatically satisfied in the indentation zone and the shear tractions are non zero beyond the indented zone. The load-displacement relationship of the indenter can be obtained from the result for the problem of a rigid disc embedded in an elastic infinite space [33, 34]: i.e.

$$\Delta=\frac{P(3-4\nu)}{16\mu a(1-\nu)} \tag{5}$$

It should be noted that in the limit of material incompressibility, (2) and (4) reduce to the same result. The analysis can be extended to include Coulomb friction at the contact zone [35] and the influence of depth of embedment of the test plate [36, 37].

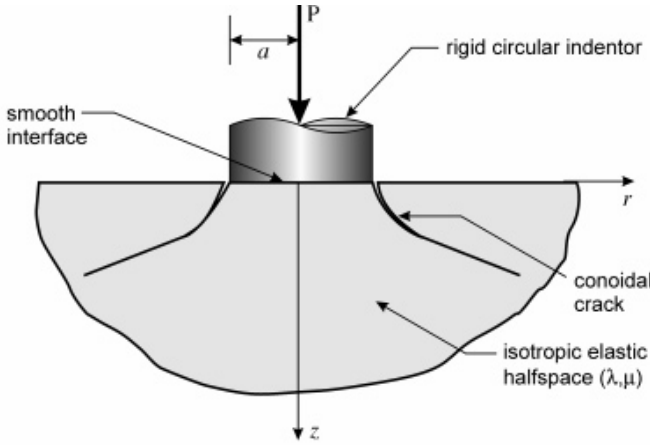

Figure 2. Conoidal boundary fractures emanating from the edge of the indented region.

3. Computational Results-Indentation Fracture

The region at the outer boundary of the test plate is subjected to singular stress fields due to the mixed boundary conditions imposed by the indentation. It can be shown that even when indentation is made by flexible flat test plates, the edges of the indented geomaterial will experience stress concentrations that are singular. The boundary of the indenter is therefore a location where indentation fracture can initiate. The objective of this paper is to demonstrate the influences of fracture development on the load displacement relationship for a rigid test plate. We consider the axisymmetric indentation of the surface of an isotropic elastic half-space region by a smooth flat rigid indenter of radius *a* (Figure 2). The process of crack initiation and crack extension is most conveniently handled using a computational approach that can model the quasi-static crack extension process. The analysis of crack extension during indentation can be performed via a variety of computational schemes. These can include either finite element methods or boundary integral equation methods or combinations of these. The application of finite element techniques to fracture extension is well established; it requires the specification of criteria both for the initiation of crack extension and for the location of the orientation of the crack path. These relationships applicable to brittle elastic fracture initiation and extension are available in the literature on fracture mechanics [38]. In modelling crack extension via the finite element method, re-meshing is an important feature that ensures accuracy of both the local and global stress fields. Adaptive re-meshing techniques have been used quite effectively to examine crack extension in brittle geomaterials such as concrete and rock [39]. An alternative to re-meshing involves extensive graded mesh refinement in the vicinity of the singular crack tip element and allows crack extension to take place at element boundaries. Alternative schemes, such as the boundary element method, provide greater flexibility when examining the crack extension process. The primary advantage of integral equation-based concepts such as the boundary element method or the displacement discontinuity method is that the domain rearrangement resulting from the crack extension process requires only an incremental change in the boundary element mesh or along the displacement discontinuity line of the crack extension. We shall illustrate here the application of the boundary element scheme to examine the process of quasi-static conoidal crack extension in the geomaterial originating at the boundary indenter. The application of boundary element schemes to problems in fracture mechanics originated with the work of Cruse and Wilson [40] and has been extended by a number investigators [41-43] to include a variety of problems including cracks with frictional interfaces. The review [44] gives a comprehensive survey of research related to boundary element formulations in fracture mechanics. Further details of the application of boundary element techniques to crack indentation problems are given in [13] and summarized here for completeness.

3.1. Governing Equations

We examine the class of axisymmetric problems where fracture extension in brittle elastic media satisfies Hooke's Law and the corresponding Navier equations: i.e.

$$\sigma_{ij} = \lambda\varepsilon_{kk}\delta_{ij} + 2\mu\varepsilon_{ij} \quad ; \quad \mu\nabla^2 u_i + (\lambda+\mu)u_{k,ki} = 0 \tag{6}$$

and λ and μ are Lamé's constants and ∇^2 is Laplace's operator. The boundary integral equation governing axisymmetric deformations of the geomaterial region can be written as

$$c_{lk}u_k + \int_\Gamma \left\{ P^*_{lk}u_k + u^*_{lk}P_k \right\} \frac{r}{r_i} d\Gamma = 0 \tag{7}$$

where Γ is the boundary of the domain; u_k and P_k are, respectively, the displacements and tractions on Γ and u^*_{ik} and P^*_{ik} are the fundamental solutions [45,46]. In (7), c_{lk} is a constant, which can take values of either zero (within the domain), $\delta_{ij}/2$ (if the point is located at a smooth boundary) or is a function of the discontinuity at a corner and of Poisson's ratio. For axial symmetry, the displacement fundamental solutions take the forms

$$u^*_{rr} = C_1 \left\{ \frac{4(1-\nu)(\rho^2+\overline{z}^2)-\rho^2}{2r\overline{R}} \right\} K(\overline{m}) - \left\{ \frac{(7-8\nu)\overline{R}}{4r} - \frac{(e^4-\overline{z}^4)}{r\overline{R}^3 m_1} \right\} E(\overline{m}) \tag{8}$$

$$u^*_{rz} = C_1\overline{z} \left\{ \frac{(e^2+\overline{z}^2)}{2\overline{R}^3 m_1} E(\overline{m}) - \frac{1}{2\overline{R}} K(\overline{m}) \right\} \tag{9}$$

…etc., where

$$\begin{aligned} &\overline{z} = (z - z_i); \quad \overline{r} = (r + r_i); \quad \rho^2 = (r^2 + r_i^2); \quad m_1 = 1 - \overline{m} \\ &e^2 = (r^2 - r_i^2); \quad \overline{R}^2 = \overline{r}^2 + \overline{z}^2; \quad \overline{m} = \frac{4rr_i}{\overline{R}^2}; \quad C_1 = \frac{1}{4\pi\mu(1-\nu)} \end{aligned} \tag{10}$$

and $K(\overline{m})$ and $E(\overline{m})$ are complete elliptic integrals of the first and second-kind and (r, z) and (r_i, z_i) correspond to the coordinates of the field and source points respectively. The relevant fundamental solutions for P^*_{lk} can be obtained by manipulating results of the types (8) and (9). Upon discretization of the boundary Γ, the integral equation can be expressed in the form of a boundary element matrix equation

$$[\mathbf{D}]\{\mathbf{U}\} = [\mathbf{T}]\{\mathbf{P}\} \tag{11}$$

where $[\mathbf{D}]$ and $[\mathbf{T}]$ are obtained, respectively, by integration of the displacement and traction fundamental solutions. When considering the discretization of the boundary Γ of the domain, quadratic elements can be employed quite effectively; the variations of the displacements and tractions within an element can be described by

$$\left.\begin{matrix} u_i \\ P_i \end{matrix}\right\} = \sum_{n=0}^{3} a_n \zeta^n \tag{12}$$

where ζ is the local coordinate.. Then modeling cracks that occur at the boundaries or within the interior of the elastic geomaterial, it is necessary to modify (12) to take into consideration the $1/\sqrt{\zeta}$ type locally two-dimensional stress singularity at the crack tip. In contrast to finite element approaches that use quarter-point elements, here we utilize the singular traction quarter-point boundary elements [40] where the tractions can be expressed in the form

$$P_i = \frac{c_0}{\sqrt{r}} + c_1 + c_2\sqrt{r} \tag{13}$$

where $c_i (i = 0,1,2)$ are constants. The Mode I and Mode II stress intensity factors that will be used in the estimation of crack growth can be determined by applying a displacement correlation technique, which makes use of the nodal displacement at four locations A, B, E and D and the crack tip (Figure 3).

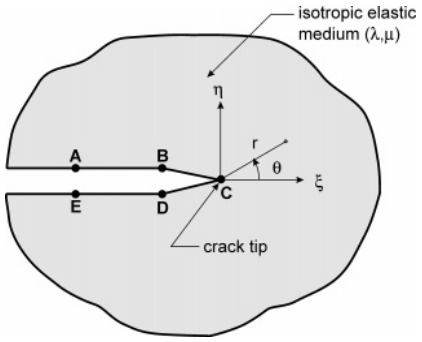

Figure 3. The crack tip geometry and the node locations.

The stress intensity factors are given by

$$\left.\begin{matrix} K_{\mathrm{I}} \\ K_{\mathrm{II}} \end{matrix}\right\} = \frac{\mu}{(k+1)}\sqrt{\frac{2\pi}{l_0}} \left\{\begin{matrix} 4[u_\eta(B) - u_\eta(D)] + [u_\eta(E) - u_\eta(A)] \\ 4[u_\xi(B) - u_\xi(D)] + [u_\xi(E) - u_\xi(A)] \end{matrix}\right. \tag{14}$$

where $k = (3 - 4\nu)$ and l_0 is the length of the crack tip element ξ and η are the local coordinates at the crack tip.

3.2. Modelling of Crack Extension

The boundary element approach can be used to examine the crack extension during indentation. The stress state necessary to initiate crack nucleation can be obtained by using integral results for the stress state associated with the mixed boundary value problem defined by (1). The results presented by Harding and Sneddon [27] can be used for this purpose. The axisymmetric stress state is

$$\begin{aligned}
\sigma_{zz}(r,z) &= -\frac{4\mu\Delta}{\pi a}\left(\frac{\lambda+\mu}{\lambda+2\mu}\right)\left\{J_1^0 + \xi J_2^0\right\} \\
\sigma_{\theta\theta}(r,z) &= -\frac{4\lambda\mu\Delta}{\pi a(\lambda+2\mu)}\left\{J_1^0\right\} - \frac{4\mu^2\Delta}{\rho(\lambda+2\mu)}\left\{J_0^1 - \frac{(\lambda+\mu)}{\mu}J_1^1\right\} \\
\sigma_{rz}(r,z) &= -\frac{4\mu\Delta}{\pi a}\left(\frac{\lambda+\mu}{\lambda+2\mu}\right)\xi J_2^1
\end{aligned} \tag{15}$$

etc…., where

$$\begin{aligned}
J_n^m &= \int_0^\infty p^{(n-1)}\sin(p)e^{-p\xi}J_m(\rho p)\,dp \\
r^2 &= 1+\xi^2; \quad \tan\theta = \xi^{-1}; \quad R^2 = (\rho^2 + \xi^2 - 1)^2 + 4\xi^2 \\
\tan\phi &= \frac{2\xi}{(\rho^2 + \xi^2 - 1)}
\end{aligned} \tag{16}$$

$J_m(x)$ is the Bessel function of the first kind of order m and the dimensionless coordinates are $\rho = r/a$ and $\xi = z/a$. The maximum local tensile stress within the elastic geomaterial, in the

vicinity of the boundary of the indenter (Figure 1) can be obtained through a computer based search technique. The location of the point of maximum tensile stress will be characterized by the local coordinates η_0 and ψ_0 and will depend only on Poisson's ratio. This technique allows the location of the orientation and length of a starter crack and the boundary element meshing is structured to accommodate this starter crack and a semi-infinite domain (Figure 4).

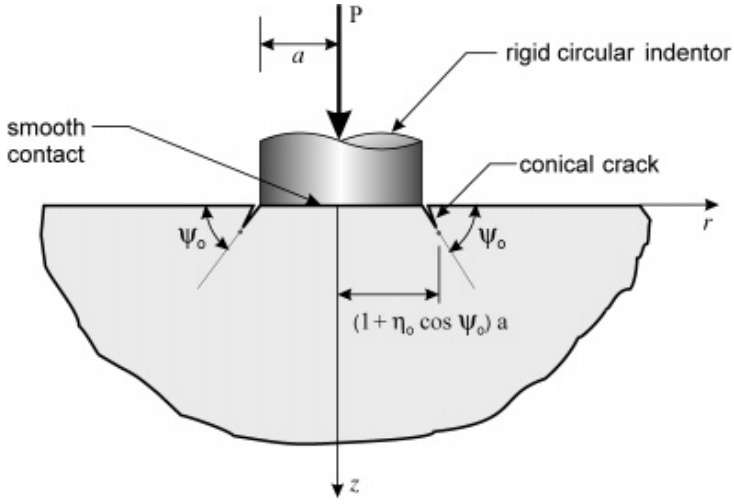

Figure 4.The location and orientation of starter crack.

3.2. Onset and Orientation of Crack Extension

The onset of crack extension can be based on a number of criteria applicable to brittle geomaterials. An elementary criterion for onset of crack extension is the attainment of a critical value of the Mode I stress intensity factor; i.e.

$$K_{\mathrm{I}} = K_{\mathrm{IC}} \tag{17}$$

The orientation of crack extension has to take into account the influence of both stress intensity factors. The criterion used is that proposed by Erdogan and Sih [47]. The maximum stress criterion assumes that the crack will extend in the plane that is normal to the maximum stress $\sigma_{\psi\psi}$ shown in Figure 4b and according to

$$K_{\mathrm{I}} \sin\psi + K_{\mathrm{II}}(3\cos\psi - 1) = 0 \tag{18}$$

Other criteria, such as crack extension along paths where $K_{\mathrm{II}} = 0$, are possible [48] but in this study the criterion (18) is used.

4. Numerical Results

The objective of the study is to examine the extent to which the load displacement of the rigid indenter is influenced by the development of boundary fracture. The results can be presented in relation to a load-displacement relationship for the rigid indenter, taking into account the parameters that control the crack initiation and extension process described previously and documented in detail in [13]. Figure 5a illustrates the results for the load-displacement relationship for the case where the orientation of the starter crack is determined from procedures outlined in Section 3.2. Figure 5b illustrates similar results derived by assuming a priori that the starter crack is oriented normal to the boundary of the indented surface. Results for the load-displacement relationships for

the uncracked situations are also presented for purposes of comparison. In both instances, cracking of the halfspace region will lead to a reduction in the elastic stiffness of the rigid indenter.

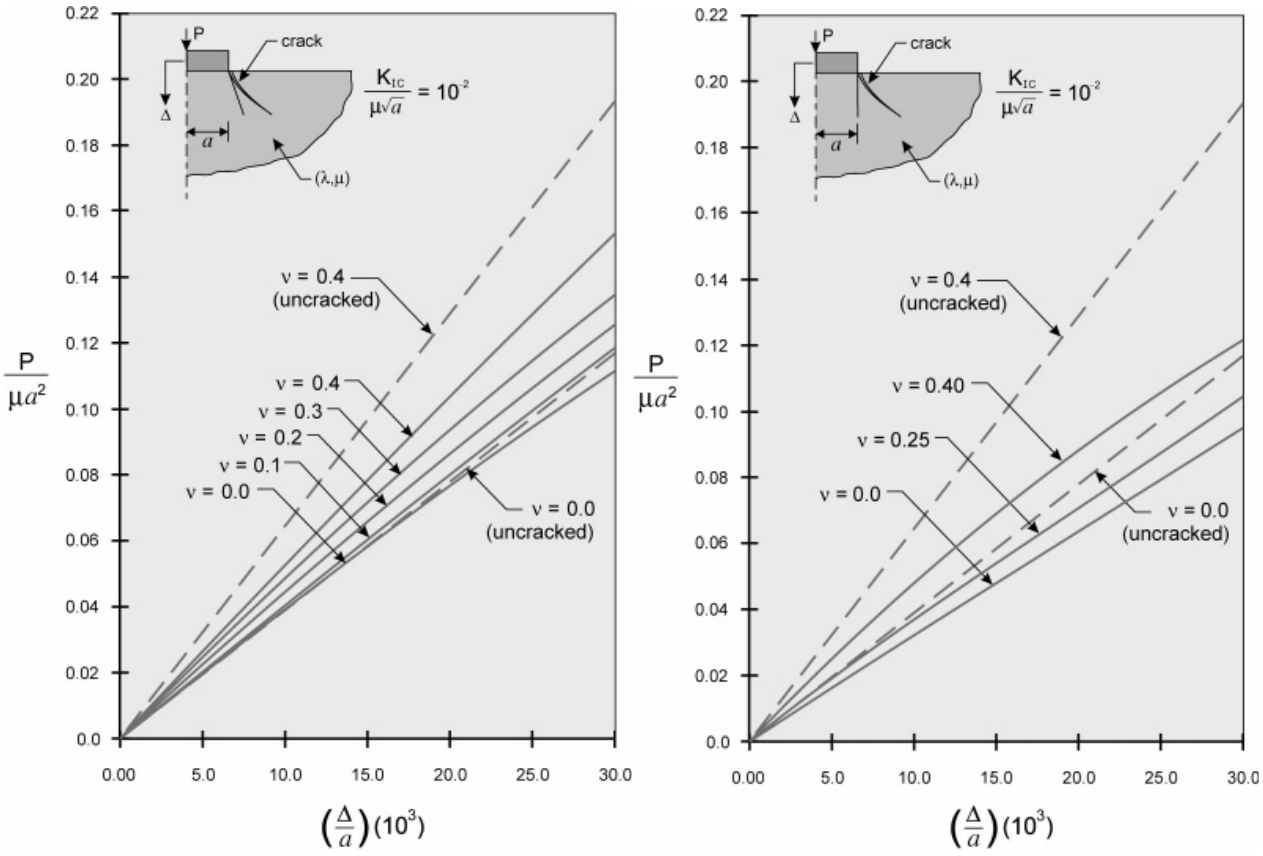

Figure 5. Influence of geomaterial cracking on the stiffness of the rigid indenter

5. Concluding Remarks

The objective of the study is to examine the extent to which the load displacement of the rigid indenter is influenced by indentation fracture that can occur beneath the surface of the region that is being indented. In a geomechanics context, indention testing is carried out in order to determine the in situ properties of the geomaterial. Studies of this type serve two purposes; first it will alert the user to the stress levels that can lead to the development of cracking in the indented region. Modern acoustic emissions monitoring could be used to supplement the experiments. Secondly, if fractures occur it will influence the interpretation of the in situ deformability characteristics of the geomaterial region. The boundary cracking will generally lead to a lower estimate of the in situ modulus. The methodology described here is not without constraints, the most important of which is the assumption that some estimates can be made of the fracture toughness of the geomaterial as interpreted through the critical Mode I stress intensity factor. This pre-supposes that this parameter can be estimated from either laboratory tests or preferably in situ fracture tests conducted by flat jack expansion testing of surface slots cut into the rock surface.

Abstract: Co-seismic earthquake faults can be treated as cracks of fracture theory in the framework of continuum mechanics. It is well known that the instability of the faults leads to earthquakes, and the relevant problem can be explored through the fracture theory. There are many factors influencing the instability such as tectonic stresses, geology structure and so on. In this work, we discuss the effects of geometry, interaction between faults and the speed of nucleation and co-seismic process. For single fault, the closed formulations of fracture theory is simpler; for two collinear faults, the analytic solution is available; while for two parallel faults the semi-analysis is approximate with finite element/boundary element method. The theoretical prediction is compared with the observation data of Xingtai earthquake 1966, Hejian earthquake 1967, Tangshan-Luanxian earthquake 1976 and Wenchuan earthquake 2008.

Keywords Fault, Strong Earthquake, Block and Plate, Instability, Fracture theory

1. Introduction

In China, some strong earthquakes happened in plate rather than in boundary between plates. These strong earthquakes are called in plate strong earthquake, or land strong earthquakes. The typical examples are the Ms7.3 Xingtai earthquake on March 8, 1966, the Ms7.8 Tangshan earthquake on July 28, 1976, the Ms8.0 Wenchuang earthquake on May 8, 2008, etc., which resulted in serious destroy and killed a lot of people.

Why did the strong earthquakes happen in plate? To explain the phenomenon, geologists, geophysicists and seismologists in China put forward the block hypothesis of the land strong earthquakes [1-5]. They observed that these earthquakes appeared in the boundaries between blocks. In China land the blocks are very developed, some blocks have quite big sizes though they are smaller compared with plates. For example, the Wenchuang earthquake is in Wenchuang-Beichuang fault, which is located in the boundary between the Tibet Block and the South China Block that have huge sizes. The land strong earthquake presents some natures themselves different from those of earthquakes in boundary between plates.

In this work, we focus on the block characters and apply fracture theory doing some analysis, and preliminarily explain phenomena concerning Xingtai Earthquake, Tangshan earthquake and Wenchuang earthquake those happening in China land.

2. Physics modeling

The land strong earthquakes occurred along some faults in the boundary between blocks, a crack

model concerning fault instability has been developing since the 1970s and numerous work has been done since then, e.g. refs. [1-6]. Thus studies may be beneficial for investigating the land strong earthquakes in China. Due to the dependence of the earthquakes with blocks, the complex system consisting of blocks and faults are studied. For this system a characteristic size is needed. For this purpose we consider the model shown in Fig.1. The configuration concerning a strike slip fault is only an example, if the applied shear stress in plane instead by a shear stress out of plane, then it represents an inverse fault. The boundary between blocks is a transitional region with thickness *2H*, and the fault with length *a*, we takes *a/H* as a characteristic size of the complex system. The tip of the fault is often the earthquake source, it has some intra-structures, one among them is the so-called the slip weakening zone (or breakdown zone), which can be described by a size *R*, so that have another characteristic size *R/H*.

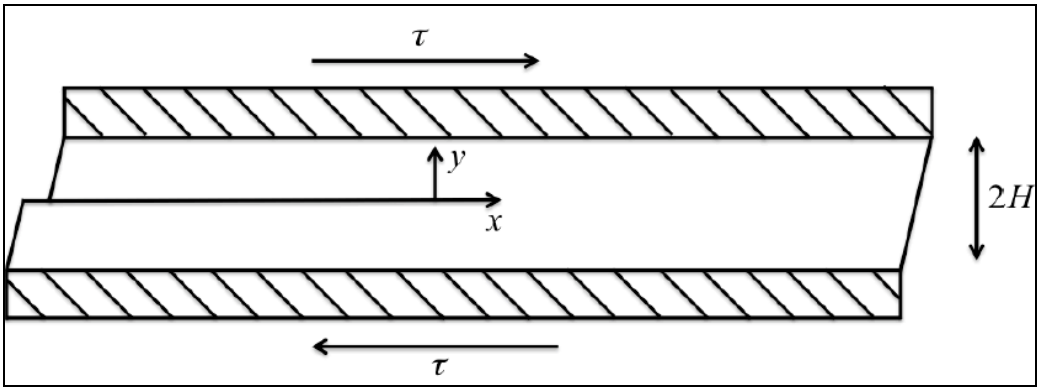

Fig. 1. The cracked strip model on fault

The tectonic shear stress τ acting at the external boundary of the body is removed, whereas the two faces of the fault are subjected to the stress τ over the length an extending back from the fault tip; the quantity a may simulate a finite fault. The fact that tectonic stress acts at fault plan has been proved by quite a lot of geological and geophysical observations, which comes from the interaction between blocks. Because of the roughness of rock materials, there is the frictional stress τ_f at the fault plane, so that the total stress applied at the fault faces should be $(\tau-\tau_f)$.

There is a breakdown zone with length *R* near the fault tip mentioned above, whose magnitude is unknown so far, whereas it will be determined in the successive analysis. At the break down zone another stress drop $(\tau_b-\tau_f)$ acts as well, in which τ_b denoting the breakdown limit of the rock material, should be a material constant. The introduction of the breakdown zone is consistent with the slip-weakening model adopted in the above-mentioned references, or say, it is a concrete application of the slip-weakening model. Fig. 2 shows the model schematically. According to the terminology of the fracture theory, $(\tau_b-\tau_f)$ is also named the cohesive stress.

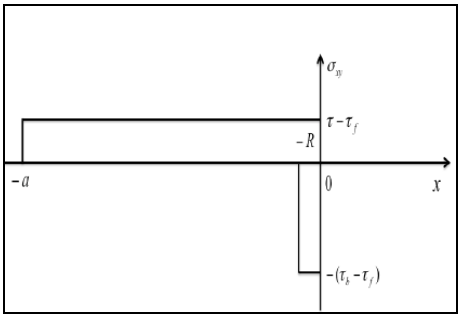

Fig.2 Breakdown zone and the stress distribution in the neighborhood of the fault tip

Reference [6] used this model, but the analysis there is preliminary only for the static case. The present analysis develops the study of Ref [6] in a quite wide range, i.e. it not only studies the static problem, but also the dynamic problem.

2.1 Fault extension initiation

The initiation of fault extension is a static problem. Assume that the fault body is anisotropic homogeneous elastic body. We define Airy stress function as $U(x, y)$, and then the strike slip process of the fault is governed by equation

$$\nabla^2\nabla^2 U = 0 \tag{1}$$

where $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$ denotes the two-dimensional Laplace operator, and the stress component, σ_{ij} , can be written as

$$\sigma_{xx} = \frac{\partial^2 U}{\partial^2 y^2} \quad \sigma_{yy} = \frac{\partial^2 U}{\partial^2 x^2} \quad \sigma_{xy} = \frac{\partial^2 U}{\partial^2 xy} \tag{2}$$

The problem of inverse fault is governed by

$$\nabla^2 u_z = 0 \tag{3}$$

The problem of the fault extension initiation induced by stress drop ($\tau_b - \tau_f$) (the tectonic stress) is described by the following boundary condition:

$$\left.\begin{aligned} &y = \pm H, -\infty < x < \infty : \sigma_{yy} = \sigma_{xy} = 0, \\ &y = \pm\infty, -H < x < H : \sigma_{xx} = \sigma_{xy} = 0, \\ &y = \pm 0, -\infty < x < a : \sigma_{yy} = \sigma_{xy} = 0, \\ &y = \pm 0, -a < x < 0 : \sigma_{yy} = 0, \sigma_{xy} = -\left(\tau - \tau_f\right) \end{aligned}\right\} \tag{4}$$

The most effective tool for solving boundary value problem (1), (4) is complex analysis, i.e., take the solution

$$U(x, y) = Re\left[\bar{z}\phi_1(z) + \int \psi_1(z)dz\right] \tag{5}$$

where $\phi_1(z)$ and $\psi_1(z)$ represents any analytic functions of complex variable $z = x + iy, i = \sqrt{-1}$. The author suggested a conformal mapping approach to solve the boundary value problem (4) of eq. (1),

i.e. by taking the function

$$z=\omega(\zeta)=\frac{H}{\pi}\ln\left[1+\left(\frac{1+\zeta}{1-\zeta}\right)^2\right] \tag{6}$$

and mapping the region of the physical plane (z=x+iy plane) onto the interior of the unit circle γ in the $\zeta(=\zeta+\mathrm{i}\eta)$ plane, the solution in closed form is found[9-11]

$$\phi'(\xi)=\frac{Hp}{2\pi^2 i}\left\{\frac{1}{1\text{-}\xi}\ln(\sigma-1)\text{-}\frac{1+\xi}{(1\text{-}\xi)(1+\xi^2)}\ln(\sigma-\xi)\ -\frac{\xi}{2(1+\xi^2)}\ln(1+\sigma^2)+\frac{i}{2(1+\xi^2)}\ln\left(\frac{\sigma-i}{\sigma+i}\right)\right\}_{\sigma_{-a}}^{\overline{\sigma_{-a}}} \tag{7}$$

in which

$$\left.\begin{aligned}\sigma_{-a}&=\frac{-e^{\pi a/H}+2i\sqrt{1-e^{-\pi a/H}}}{2-e^{-\pi a/H}}\\ \overline{\sigma_{-a}}&=\frac{-e^{\pi a/H}-2i\sqrt{1-e^{-\pi a/H}}}{2-e^{-\pi a/H}}\end{aligned}\right\} \tag{8}$$

and

$$\phi(\zeta)=\phi_1(z)=\phi_1[\omega(\zeta)],\psi(\zeta)=\psi_1(z)=\psi_1[\omega(\zeta)] \tag{9}$$

The corresponding stress intensity factor is determined as

$$K_{\tau-\tau_f}^{static}=\frac{\sqrt{2}(\tau-\tau_f)\sqrt{H}}{2\pi}\ln\left(\frac{2\exp(\pi a/H)-1+2\exp(\pi a/H)\sqrt{1-\exp(-\pi a/H)}}{2\exp(\pi a/H)-1-2\exp(\pi a/H)\sqrt{1-\exp(-\pi a/H)}}\right) \tag{10}$$

The initiation of fault growth induced by stress drop (τ_b - τ_f) (the cohesive stress) is interpreted by the boundary condition as follows:

$$\left.\begin{aligned}&y=\pm H,-\infty<x<\infty:\sigma_{yy}=\sigma_{xy}=0,\\ &y=\pm\infty,-H<x<H:\sigma_{xx}=\sigma_{xy}=0,\\ &y=\pm 0,-\infty<x<-R:\sigma_{yy}=\sigma_{xy}=0,\\ &y=\pm 0,-R<x<0:\sigma_{yy}=0,\sigma_{xy}=\tau_B-\tau_f\end{aligned}\right\} \tag{11}$$

Boundary value problem (11) of eq. (1) can be solved similarly as above. And the corresponding stress intensity factor is determined as

$$K_{\tau_b-\tau_f}^{static}=-\frac{\sqrt{2}(\tau_b-\tau_f)\sqrt{H}}{2\pi}\ln\left(\frac{2\exp(\pi a/H)-1+2\exp(\pi a/H)\sqrt{1-\exp(-\pi a/H)}}{2\exp(\pi a/H)-1-2\exp(\pi a/H)\sqrt{1-\exp(-\pi a/H)}}\right) \tag{12}$$

Because the stresses over the breakdown zone are refer to (11), it means that there is no stress singularity at the fault tip, i.e. the total stress intensity factor must vanish:

$$K_{\text{total}}^{\text{static}}=K_{\tau-\tau_f}^{\text{static}}+K_{\tau_b-\tau_f}^{\text{static}}=0 \tag{13}$$

Substituting (5) and (12) into (13) determines the size R of the breakdown zone. Actually, $R/a\ll 1$; this and (13) offer a very simple expression for R. For explicitly, we here

denote it by R^{static}, i.e.

$$R^{\text{static}} = \frac{\pi}{8}\left(\frac{K_{\tau-\tau_f}{}^{\text{static}}}{\tau_b - \tau_f}\right) \tag{14}$$

where $K_{\tau-\tau_f}^{\text{static}}$ is given by (11). At the end of the breakdown zone, i.e. at y=0, x=-R, the slip of the fault is

$$u_x(-R,+0) - u_x(-R,-0) \equiv \delta^{\text{static}} = \frac{\left(K_{\tau-\tau_f}^{\text{static}}\right)}{E'(\tau_b - \tau_f)} \tag{15}$$

in which

$$E' = \begin{cases} E & (\text{plane stress state}) \\ E/(1-\nu^2) & (\text{plane strain state}) \end{cases} \tag{16}$$

E and v represent Young's modulus and Poisson's ratio of the rock material, respectively. The physical quantity (15) may be taken as a control parameter in checking the fault instability. According to the fracture theory, there is a critical value of δ^{static} denoted by $\delta_{\text{c}}^{\text{static}}$, which should be a material constant, while

$$\delta^{\text{static}} = \delta_{\text{c}}^{\text{static}} \tag{17}$$

It can be considered as a criterion for judging the instability. By the criterion one can determine the critical shear stress τ_{c} of the initiation of fault growth. Inserting (11) into (15) and then into (17) yields

$$\tau_{\text{c}} - \tau_{\text{f}} = \frac{2\pi}{\sqrt{2H}}\sqrt{E'(\tau_b - \tau_{\text{f}})\delta^{\text{static}}} \Big/ \ln\left(\frac{2\exp(\pi a/H) - 1 + 2\exp(\pi a/H)\sqrt{1-\exp(-\pi a/H)}}{2\exp(\pi a/H) - 1 - 2\exp(\pi a/H)\sqrt{1-\exp(-\pi a/H)}}\right) \tag{18}$$

The initiation will occur as $\tau > \tau_b$. At H/a $\to\infty$, it follows from (10) that

$$(K_{\tau-\tau_f}{}^{\text{static}})_{H/a\to\infty} = (\tau_b - \tau_f)\sqrt{8a/\pi} \tag{19}$$

Which is identical with the well-known exact solution[12,13]. In this way, as H/a $\to$0, it follows from (10) that

$$(K_{\tau-\tau_f}{}^{\text{static}})_{H/a\to 0} = \sqrt{2}(\tau_b - \tau_f)a/\sqrt{H} \tag{20}$$

This is a completely new result. Ref. [6] shows that one can find a similar result by using J-integral, in which it contains an unknown constant which could not be determined by the method itself. According to formula (10) the constant=$\sqrt{2}$. Formulae (19) and (20) give an examination of the correctness of the above derivation.

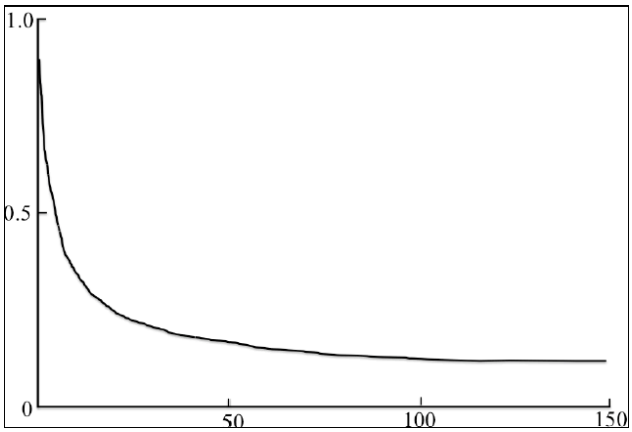

Fig.3.The effect of size of fault and the low-stress drop

Substituting (19) into the left-hand side of (17) determines the critical shear stress corresponding to the infinite fault body, and marked by $(\tau_c - \tau_f)_{H/a\to\infty}$, the ratio $(\tau_c - \tau_f)/(\tau_c - \tau_f)_{H/a\to\infty}$ is the normalized critical shear stress, the variation of which versus the characteristic size *a/H* of fault body describes the effect of fault body size on the fault instability, as description in Fig. 3. This result is identical with that obtained in ref. [2], and gives a quantitative description of the low-stress drop observed in earthquake source.

2.2 Fast propagation of fault

After the initiation of fault growth, it may experience a stable but further unstable growth, or it may become unstable growth directly after the initiation. Before and after the unstable propagation, there is another possibility that the propagation is arrested. Since the velocity of the unstable growth may reach the order of magnitude of elastic wave velocity, it may lead to an earthquake. We here discuss the case in which earthquake rather than arrest may be caused.

As pointed out just now, the state corresponding to the fast fault propagation is quite different from that corresponding to static case. It is necessary to carry out a fully dynamic analysis, which is governed by the following equations:

$$\nabla^2\phi = \frac{1}{c_1^2}\frac{\partial^2\phi}{\partial t^2}, \nabla^2\psi = \frac{1}{c_2^2}\frac{\partial^2\psi}{\partial t^2} \tag{21}$$

for strike slip fault; while for inverse fault

$$\nabla^2 u_z = \frac{1}{c_2^2}\frac{\partial^2 u_z}{\partial t^2} \tag{22}$$

where c_1 and c_2 represent the speeds of longitudinal and transverse waves, respectively. The dynamics analysis reveals the low stress drop effect again.

3. Interaction between co-linear faults

The principle discussed in the previous section can be used to the interaction between co-linear faults. The Ms7.2 Xingtai earthquake happened on March 8, 1966 in North China Block, immediately after the event, Prof. Li Shi-Guang, pointed out the earthquake transmission was going

along the north-east direction [5] ， and the fact of the happening of Ms6.3 Hejian earthquake on March 2, 1967 proved the prediction of Prof. Li Shi-Guang. This shows the interaction between earthquake faults.

3.1 The static fracture analysis

We take the physical model for the interaction between co-linear faults shown in Fig.4

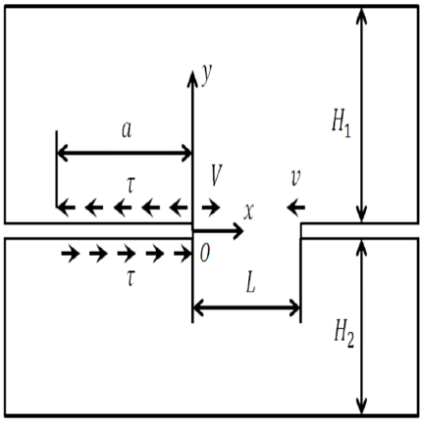

Fig.4 Model for co-linear faults in North China Block

The static fracture analysis on the interaction between co-linear strike slip faults can be based on the equation (1) and (2), but the boundary conditions are given as follows

$$\left.\begin{aligned} &y = H_1, -H_2, -\infty < x < +\infty : \sigma_{yy} = \sigma_{xy} = 0 \\ &y = 0, -a < x < 0 : \sigma_{yy} = 0\ ,\ \sigma_{xy} = -\tau \\ &x < -a : \sigma_{yy} = 0\ ,\ \sigma_{xy} = 0 \\ &x > L : \sigma_{yy} = 0\ , \sigma_{xy} = 0 \\ &H_1 > y > -H_2\ ,\ x = \pm\infty : \sigma_{xx} = 0\ , \sigma_{xy} = 0 \end{aligned}\right\} \tag{23}$$

The complex analysis is still effective for the present problem, but we should use the following conformal mapping

$$U(x,y) = Re\left[\overline{z}\phi_1(z) + \int \psi_1(z)dz\right] \tag{24}$$

$$z = \omega(\zeta) = \frac{H}{\pi}\ln\frac{1+\alpha\left(\dfrac{1-\zeta}{1+\zeta}\right)^2}{1+\gamma\alpha\left(\dfrac{1-\zeta}{1+\zeta}\right)^2} \tag{25}$$

$$\zeta = \xi + i\eta \qquad \alpha = \frac{1-e^{-\pi a/H}}{1-e^{-\pi(a+L)/H}} \qquad \gamma = e^{-\pi L/H} \tag{26}$$

and find the solution

$$\phi'(\zeta) = \frac{2\tau H}{\pi^2}\left[\frac{\sqrt{\gamma\alpha}M}{(1+\zeta)^2+\gamma\alpha(1-\zeta)^2} - \frac{\sqrt{\alpha}A}{(1+\zeta)^2+\alpha(1-\zeta)^2}\right] - \frac{2\tau H}{\pi^2}\frac{i\alpha(1-\gamma)(1-\zeta^2)}{[(1+\zeta)^2+\gamma\alpha(1-\zeta)^2][(1+\zeta)^2+\alpha(1-\zeta)^2]} \times \ln\frac{i-\zeta}{1-i\zeta} \tag{27}$$

where

$$\phi(\zeta)=\phi_1(z)=\phi_1[\omega(\zeta)],\psi(\zeta)=\psi_1(z)=\psi_1[\omega(\zeta)] \tag{28}$$

and

$$A=\ln(1+\sqrt{\alpha})/(1-\sqrt{\alpha}) \qquad M=\ln[1+\sqrt{\gamma\alpha}/(1-\sqrt{\gamma\alpha})] \tag{29}$$

so that

$$K\equiv K_{\mathrm{I}}-iK_{\mathrm{II}}=\lim_{\zeta\to\zeta_1}2\sqrt{\pi}\frac{\phi'(\zeta)}{\sqrt{\omega''(\zeta)}} \tag{30}$$

$$\zeta=\omega^{-1}(z)=\left[\sqrt{\alpha}-\sqrt{\frac{e^{\pi z/H}-1}{1-\gamma e^{\pi z/H}}}\right]/\left[\sqrt{\alpha}+\sqrt{\frac{e^{\pi z/H}-1}{1-\gamma e^{\pi z/H}}}\right] \tag{31}$$

$$K_{\mathrm{II}}^{(0,0)}=\frac{\sqrt{2H}\tau}{\pi\sqrt{1-\gamma}}[\ln\frac{1+\sqrt{\alpha}}{1-\sqrt{\alpha}}-\sqrt{\gamma}\ln\frac{1+\sqrt{\gamma\alpha}}{1-\sqrt{\gamma\alpha}}] \tag{32}$$

$$K_{\mathrm{II}}^{(\mathrm{L},0)}=\frac{\sqrt{2H}\tau}{\pi\sqrt{1-\gamma}}[\sqrt{\gamma}\ln\frac{1+\sqrt{\alpha}}{1-\sqrt{\alpha}}-\ln\frac{1+\sqrt{\gamma\alpha}}{1-\sqrt{\gamma\alpha}}] \tag{33}$$

The fracture criterion

$$K_{\mathrm{II}}^{(\mathrm{L},0)}=K_{\mathrm{IIC}} \tag{34}$$

Is used, in which $K_{\mathrm{IIC}}\approx K_{\mathrm{IC}}=2.81MPa\bullet m^{1/2}$

3.1.1 Earthquake example 1: *Interaction between Xingtai fault and Hejian fault*

The Xingtai fault and Hejian fault with $a=55km, L\approx 400km, H\approx 300km$ and Ms7.1 Xingtai earthquake in N37.5^0, E115.1^0 happened on March 8, 1966 with the stress drop $\tau=42$ bar. Substituting $a=55km, L\approx 400km, H\approx 300km$ into (34) can determine the critic stress τ_c which is $\tau_c=3.4$ bar. Because $\tau_c=3.4\,\mathrm{bar}\le\tau=42$ bar, this means the Xingtai earthquake can induce the Hejian fault to occur earthquake. In fact, the Ms 6.3Hejian earthquake happened on March 2, 1967.

3.1.2 Earthquake example 2: *Interaction between Tangshan fault and Luanxian fault*

The Tangshan fault and Luanxian fault with $a=115km, L\approx 10km, H\approx 150km$ and Ms 7.8 Tangshan earthquake in N38.5^0, E118.7^0 happened on July 28, 1976 with the stress drop $\tau=8$ bar. Substituting $a=115km, L\approx 10km, H\approx 150km$ into (25) can determine the critic stress τ_c that is $\tau_c=0.35$ bar. Because $\tau_c=0.35\,\mathrm{bar}\le\tau=8$ bar, this means the Tangshan earthquake can induce the Luanxian fault to occur earthquake. In fact, the Ms7.1 Luanxian earthquake happened on July 29, 1976 (only 15 hours after the main shock of Tangshan earthquake).

3.2 The dynamic fracture analysis

The dynamic fracture analysis is also carried out in which the wave equations (21~22) are used, and the initial and boundary value conditions are as follows

$$t=0: u_x=u_y=0\ ,\ \frac{\partial u_x}{\partial t}=\frac{\partial u_y}{\partial t}=0 \tag{35}$$

$$\left.\begin{array}{l}\sqrt{x^2+y^2}\to\infty:\sigma_{ij}=0\\ y=0\ ,-\infty<x<-a:\sigma_{yy}=\sigma_{xy}=0\\ -a<x<0:\sigma_{xy}=-\tau\ ,\sigma_{yy}=0\\ L<x<+\infty:\sigma_{yy}=\sigma_{xy}=0\\ -H_2<x<H_1:x=\pm\infty:\sigma_{xx}=\sigma_{xy}=0\end{array}\right\} \tag{36}$$

We developed a complex analysis method, in which the approximate conformal mapping

$$z_1/\alpha_1\ ,z_2/\alpha_2=\omega(\zeta)=\frac{H}{\pi}\ln\frac{1+\alpha\left(\dfrac{1-\zeta}{1+\zeta}\right)^2}{1+\gamma\alpha\left(\dfrac{1-\zeta}{1+\zeta}\right)^2} \tag{37}$$

Which is used with parameters $\alpha=\dfrac{1-e^{-\pi a/H}}{1-e^{-\pi(a+L)/H}}$, $\gamma=e^{-\pi L/H}$ and determine the approximate dynamic stress intensity factors $\alpha=\dfrac{1-e^{-\pi a/H}}{1-e^{-\pi(a+L)/H}}$, $\gamma=e^{-\pi L/H}$

$$\left.\begin{array}{l}K_{\mathrm{II}}^{(0,0)}(t)=\dfrac{\sqrt{2H}\tau}{\pi\sqrt{1-\Gamma}}[\ln\dfrac{1+\sqrt{A}}{1-\sqrt{A}}-\sqrt{\Gamma}\ln\dfrac{1+\sqrt{\Gamma A}}{1-\sqrt{\Gamma A}}]\\ K_{\mathrm{II}}^{(\mathrm{L},0)}(t)=\dfrac{\sqrt{2H}\tau}{\pi\sqrt{1-\Gamma}}[\sqrt{\Gamma}\ln\dfrac{1+\sqrt{A}}{1-\sqrt{A}}-\ln\dfrac{1+\sqrt{\Gamma A}}{1-\sqrt{\Gamma A}}]\end{array}\right\} \tag{38}$$

With $A=\dfrac{1-e^{-\pi a/\alpha_1 H}}{1-e^{-\pi(a+L)/\alpha_1 H}}$, $\Gamma=e^{-\pi L/\alpha_1 H}$, $\alpha_1=\sqrt{1-V^2/c_1^2}$, in which V is the fault propagating speed, and c_1 the longitudinal wave speed. We use the fracture criterion for fault propagation

$$K_{\mathrm{II}}^{(\mathrm{L},0)}(t)=K_{\mathrm{IIC}} \tag{39}$$

and $K_{\mathrm{IIC}}\approx K_{\mathrm{IC}}=2.81MPa\bullet\ m^{-1/2}$.

3.2.1 Earthquake example 1 *Interaction between Xingtai fault and Hejian fault*

The Xingtai fault and Hejian fault with *a=55km/s, L≈400km/s, H≈300km* and 1966 Ms 7.1 Xingtai earthquake (N37.5°, E115.1°) with the stress drop $\tau=42$ bar and $c_1=6\mathrm{km/s}$ $V=3$ km/s. Substituting the earthquake geometry parameters and $c_1=6\mathrm{km/s}$ $V=3$ km/s into (39) can determine the critic stress τ_c which can induce the Hejian earthquake is $\tau_c^{dyn}=0.39$ bar。Because $\tau_c^{dyn}=0.39\,\mathrm{bar}\le\tau=42$ bar, this means the Xingtai earthquake can induce the Hejian fault to occur earthquake. In fact, the Ms 6.3Hejian earthquake happened on March 2,1967.

3.2.2 Earthquake example 2 Interaction between Tangshan fault and Luanxian fault

The Tangshan fault and Luanxian fault with *a=111km/s, L≈115km/s, H≈150km* and 1976 Ms7.8 Tangshan earthquake (N38.5°, E118.7°) with the stress drop $\tau=8$ bar, and c_1*=6km/*s,$V=2.7$ km/s.

Substituting the earthquake fault geometry parameters and $c_1 = 3\text{km/s}$, $V = 2.7$ km/s into (39) can determine the critic stress τ_c which can induce the Luanxian earthquake is $\tau_c = 0.024$ bar. Because $\tau_c = 0.024\,\text{bar} \le \tau = 8$ bar, this means the Tangshan earthquake can induce the Luanxian fault to occur earthquake. In fact, the Ms7.1 Luanxian earthquake happened on July 29, 1976 (only 15 hours after the main shock of Tangshan earthquake).

4. Interaction between parallel faults

The zone of 2008 Ms8.0 Wenchuan earthquake and the simplified mathematical model are shown in Fig.5.The zone is located in the Longmenshan earthquake region that is the boundary between Tibet Block and South China Block. The line AB in Fig 5 represents Maoxian fault, which does not appear earthquake during the Wenchuan earthquake event 0f 2008, and can be treated as a free boundary. The line $\mathrm{A_2B_2}$ represents the main shock fault, the Yingxiu-Beichuan fault, the epicenter is the Yingxiu Town, and line $\mathrm{A_1B_1}$ the Pengxian-Guangxian fault, where the strong earthquake happened induced by the main shock, and line CD the boundary of South China Block, which can be seen as a fixed boundary. The main shock and induced shock are mainly the inverse motion rather than strike slip motion. This complicated configuration is not available for analytic solving. We have done the numerical analysis by finite element for initiation of fault growth only; the fast fault propagation has not been completed yet. At meantime, for the main shock fault (fault $\mathrm{A_2B_2}$) an approximate solution is given as below

$$K^{static}_{\tau-\tau_f}\Big|_{yingxiu} = \frac{\sqrt{2}\left(\tau_1-\tau_f\right)\sqrt{H_0}}{2\pi}\ln\left(\frac{2\exp(\pi a_{20}/H_0)-1+2\exp(\pi a_{20}/H_0)\sqrt{1-\exp(-\pi a_{20}/H_0)}}{2\exp(\pi a_{20}/H_0)-1-2\exp(\pi a_{20}/H_0)\sqrt{1-\exp(-\pi a_{20}/H_0)}}\right) \tag{40}$$

The analytic solution for fault $\mathrm{A_1B_1}$ in general cannot be obtained, we introduce an approximate formula [11]

$$K^{static}_{\tau-\tau_f}\Big|_{pengxian} = \frac{2\left(\tau_1-\tau_f\right)}{\pi}\sqrt{H_0\tanh\frac{\pi a_{20}}{H_0}}\arcsin\left(\frac{\sinh\frac{\pi(a_2-a_{20})}{H_0}}{\sinh\frac{\pi a_{20}}{H_0}}\right) \tag{41}$$

For the dynamic analytic solution cannot be obtained even if for approximate study. The comparison between numerical and approximate analytic solutions, we find that

$$\frac{K^{static}_{\tau-\tau_f}\Big|_{yingxiu}}{K^{static}_{\tau-\tau_f}\Big|_{pengxian}} \approx 3.0 \sim 8.0 \tag{42}$$

This means the accuracy of the approximate analytic solution and numerical solution is in the same order of magnitude. This also shows the main shock induces the shock of Pengxian-Guanxian. The shock is propagates in elastic wave speed, after happening of the main shock, the induced shock occurred immediately, because the distance between the two faults is only 10 to 20 kilometers.

5. Conclusion and discussion

The block hypothesis on the strong earthquake in plate in China land is explained with fracture theory, the single fault analysis explained the low stress drop phenomena, in the co-linear faults analysis the theoretical prediction is in good agreement to the observation results for Xingtai-Hejianfault interaction and Tangshan-Luanxia fault interaction. However the analysis on parallel faults is as just a preliminary work, which must be down the further analysis.

Abstract Unlike strike-slip earthquakes, the physical properties of shallow dip-slip quakes remain unexplored because of the insufficient number of near-field seismological recordings and analytical difficulties at the tip of a surface-breaking fault. Here, based on the finite difference technique and dynamic photoelasticity in conjunction with high speed digital cinematography, we numerically and experimentally simulate the source dynamics of dip-slip faulting. Our two-dimensional model may contain a flat fault plane (interface) dipping either vertically or at some angle in a monolithic linear elastic medium. We record the evolution of wave field related to the crack-like rupture along this fault. The observations suggest if the fault rupture, initiated at some depth, arrests just below or reaches the free surface, four Rayleigh-type waves are generated: two propagating along the free surface into the opposite directions to the far field, the other two moving back along the fractured interface downwards into depth. These downward interface waves may largely control the stopping phase of the dynamic rupture. In the case of an inclined fault plane, the interface and Rayleigh waves interact with each other and a shear wave carrying concentrated kinematic energy (corner wave) is induced to generate enormously strong particle motions in the hanging wall.

Keywords Earthquake dynamics, Earthquake ground motions, Fracture dynamics, Experimental mechanics, Computational seismology

1. Introduction

After the reasonable agreement between the theoretical and observational near-field seismograms related to the 1966 strike-slip Parkfield, California, earthquake [1], the techniques to evaluate the near-field generated by strike-slip faulting have become remarkably refined. At present it is common to invert seismological recordings for estimating fault slip distribution, rupture history and their effects for large, shallow strike-slip earthquakes [1–4]. However, the situation is different for shallow dip-slip earthquakes since only few seismic events of this type have been well recorded in the near-field and the mechanical characteristics have not been fully clarified owing to analytical difficulties at the tip of a surface-breaking fault [4–15]. Hazard risk due to such dip-slip earthquakes may be higher in the tectonically compressive regions like Los Angeles, Japan and Taiwan, Central and South America, and in extensional regimes such as the Mediterranean and the Great Basin of Nevada, Utah, and Idaho [5], and an extensive effort has been made to model dip-slip events and the strong motion (particle motion) generated by them [4–15]. Earlier study of shallow dip-slip faulting is based on kinematical models, using the Cagniard-de Hoop [12] or a numerical spectral method [13]. But the analysis becomes very sophisticated and often it does not work correctly, because of analytical singularities, when the fault rupture reaches the free surface. Nevertheless, the previous works posed questions regarding the effect of the free surface near the shallow dipping fault, which require careful study [4].

One noteworthy observation in shallow dip-slip earthquakes is the asymmetric ground motion in the vicinity of the fault: Generally, strong motion is much larger in the hanging wall than in the footwall. For example, the 1971 San Fernando and the 1994 Northridge earthquakes caused systematically severer damage or larger ground motion on the hanging wall [5]. The more recent earthquakes, the 1999 Chi-Chi in Taiwan [6, 7] and the 2004 Niigata-ken Chuetsu [16] and 2008 Iwate-Miyagi Inland [17] in Japan, seem to support this viewpoint. This observed effect is considered to be caused by the strong disturbance in the proximity of the propagating rupture front (rupture front wave) [4], the trapped wave in the hanging wall [5], or the asymmetric mass distributions on each wall and the

normal stress acting perpendicular to the fault surface [5, 7–9]. However, the dynamic properties of shallow dip-slip faulting are not fully understood yet.

Here, in order to give a possible physical explanation of the abovementioned observation, we numerically and experimentally study rupture (fracture) dynamics of a dip-slip fault (interface) situated in a two-dimensional, monolithic linear elastic medium. We employ the finite difference technique for numerical simulations on a PC basis, and in a series of experiments, we initiate rupture in the birefringent linear elastic material using a Q-switched Nd:YAG laser system or a projectile launched by a gun. We record the time-dependent evolution of the wave field induced by the crack-like rupture along the fault, and also monitor the particle motions on the free surface of the model.

2. Geometry and setting

Our model contains a fault plane dipping either 90° (vertical) or 45° (nonvertical case) (Fig. 1) and in each case, the initial static shear stresses acting on the fault plane are set to be equal: For the vertical case (Fig. 1a), remote shear loading which increases linearly with depth is assigned; In the nonvertical case (Fig. 1b), compressive normal stress increasing with depth is given so that linearly increasing static shear stress acts on the fault plane (Fig. 1b). Using the finite difference technique [18], we study the seismic wave field (isochromatic fringe patterns) produced by rupture of this straight fault and try to gain insight into the free surface effect on dip-slip faulting.

As we consider the problem in the framework of linear elasticity, we may assume, without loss of generality, the longitudinal (P) wave speed c_P in the medium is 1. If Poisson's ratio is 0.25, then the shear (S) wave speed c_S becomes $1/\sqrt{3}$ (~ 0.58) and the Rayleigh (R) wave speed c_R is about 0.53. We use the orthogonal 201 times 201 grid points and calculate displacements at each grid point with the second order accuracy. The uniform spacing between each orthogonal grid is 0.05, and the time step is also constant to be 0.025. We further assume the energy absorbing boundary conditions to the outer boundaries except for the upper free surface where the vertical normal and the tangential shear stresses are always zero.

We simulate three different situations: finite fault that ruptures only at depth (Fig. 2); fault rupture (interface crack) starting at depth and arrested well below the free surface (Fig. 3); and fault rupture initiated at depth and reaching the free surface (Fig. 4). By showing the time-dependent dynamic (maximum in-plane shear) stress field, we suggest that the magnitudes of the stresses induced in the

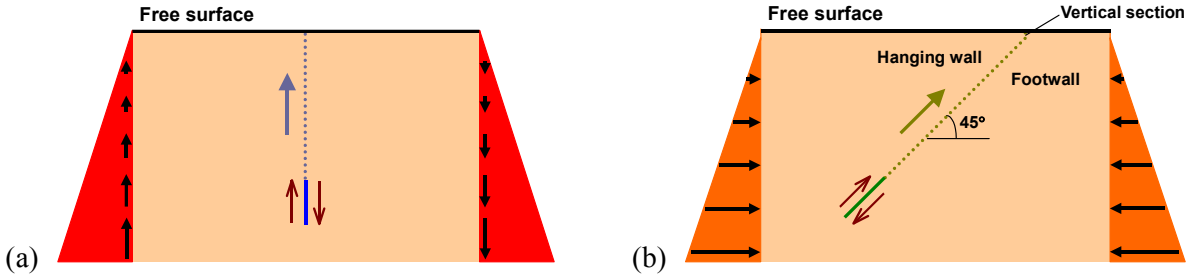

Figure 1. Schematic diagram of the geometry of the dip-slip fault model. For both (a) vertical and (b) nonvertical (45° dipping) situations, we assume a monolithic, linear elastic medium. The fault rupture (interface crack) starts at the bottom and in later simulations it propagates towards the free surface. While the geometrical symmetry is preserved in (a), the symmetry between the free surface and the two sides of the fault (hanging wall and footwall) is broken in (b).

hanging wall and in the footwall may become completely dissimilar for the three cases. Note, in all numerical simulations, we assume crack-like rupture, i.e., once a fault segment is ruptured, the accumulated static shear stress on that segment is released and that section of the fault remains broken without being healed. As shown in Fig. 1, fault slip (displacement discontinuity) is oriented so that the fault behaves as a thrust one, but the results shown below are valid also for normal dip-slip faulting. In the following, snapshots of the isochromatic fringe patterns, i.e., contours of the (dynamic) maximum in-plane shear stress (τ_{max}), are exhibited where the fringe order is proportional to τ_{max} (≥ 0) and all types of elastic waves may be displayed.

3. Numerical case studies

3.1. Finite fault buried at depth

Figure 2 shows the dynamic rupture-induced stress field for the case of a finite dip-slip fault located at depth (length $L = 0.05$, depth $h = 2$ and $L = 0.05\sqrt{2}$, $h = \sqrt{2}$ for the vertical and nonvertical cases, respectively). This problem is rather classical in seismology: The entire (short) fault segment breaks instantaneously at time $t = 0$ to radiate body waves. At time $t = 1.5$, we recognize weak shear waves radiated from the hypocenter (identified as S in the figure). In the geometrically symmetrical case (Fig. 2a), at $t = 3.9$, clear but weak surface reflected *SS* wave and two Rayleigh surface pulses (R) are visible. We also find weak *PS* waves, the *P* waves diffracted by the free surface and converted into *S* waves, but the *P* wave front propagating from the hypocenter is invisibly weak. These *PS* waves interact with the outgoing *S* waves, but their effects seem, again, negligible. At later stages ($t = 6.3$ and 8.7), both surface pulses *R* follow the *S* waves and propagate into the far-field (without decay in these two-dimensional simulations), but the reflected shear wave *SS* attenuates upon propagation and its interaction with the seismic source (hypocenter), now showing static stress singularities, is very small. Similar discussion holds in the asymmetrical case (Fig. 2b) except that here Rayleigh pulse (R_h) and shear wave (S_h) in the hanging wall are stronger than those (R_f and S_f) in the footwall. It is important to note that in seismology an approximate (kinematic) approach, stacking the finite fault segments and rupturing these segments sequentially, is usually employed to inversely obtain a progressive fault rupture related to an earthquake (seismograms). However, from dynamics point of view this approach may not be valid because, as we see below, the wave field generated in the finite fault segments approach (Fig. 2) has a characteristic radiation pattern very different from the one associated with the continuously rupturing fault (Figs. 3 and 4). This situation is akin to blasting simulations of a progressively detonating column charge: The characteristic dynamic wave patterns in the approximate approach that is based on stacking spherical charges and detonating these charges sequentially are very dissimilar compared with the radiation patterns of continuously exploding charge [19, 20].

3.2. Fault rupture starting at depth and arresting well below the free surface

In Fig. 3, the fault rupture is initiated at depth ($h = 2$ and $\sqrt{2}$ for Figs. 3a and 3b, respectively), propagated upwards but suddenly arrested well below the free surface. At time $t = 0$, fracture starts moving along the prescribed fault plane with a constant speed c, and after a certain time $t = L/V$ it arrests, leaving a final rupture zone of length $L = 1$. For this crack-like fault model, we assume the constant rupture speed is in the subsonic range, 0.4 c_P (~ 0.7 c_S; smaller than the Rayleigh wave speed c_R). The noteworthy phenomenon observed here is the strong rupture front wave ($t = 1.5$). In the vertical case (Fig. 3a), the problem is still geometrically symmetrical and the induced particle motions are symmetrical with respect to the rupturing fault plane: Upon arrest, a relatively strong shear wave (S_1) is radiated from the upper tip of the ruptured fault plane (interface) ($t = 3.9$) and

interacts with the free surface. The reflected shear wave (SS) and another shear (S_2) wave generated by the stopping phase of the rupture process interact with the ruptured interface but their influence on the interface seems relatively small. Rayleigh pulses propagating along the free surface are much stronger than those in Fig. 2a. When the fault plane is nonvertical (Fig. 3b), the geometrical symmetry is totally broken: The induced stress is much larger in the footwall than in the hanging wall, with a much stronger shear S_f wave recognizable in the footwall. It is contrary to the previous and the following observations (Figs. 2b and 4b) where the dynamic disturbances are stronger in the hanging wall than in the footwall, and it may be due to the strong rupture front wave that is diffracted at the upper tip of the ruptured interface and flows into the footwall across the unbroken (extended) section of the fault plane.

3.3. Fault rupture approaching the free surface from bottom

The wave field where the fault breaks the free surface is shown in Fig. 4. As in the previous case (Fig. 3), the crack-like rupture, starting at $t = 0$, propagates along the fault plane with a constant speed $c = 0.4\ c_P$ for a length $L = 2$ until it surfaces. In both vertical and nonvertical cases, when the rupture front approaches the free surface, four Rayleigh-type pulses are generated: two propagating along the free surface into the opposite directions to the far-field (labeled as R or R_h, R_f), the other two moving back along the ruptured interface downwards into depth (I). This downward surface-type pulse can be observed also in the numerical simulations of borehole blasting in a rock mass where the explosive charge is detonated at the bottom and a detonation front moves along an explosive column toward the free surface (bottom-to-top blasting); Rayleigh pulses are generated when the detonation front reaches the surface and they may move downwards along the explosive column [19, 20]. If the fault is vertical and geometrically symmetrical (Fig. 4a), the downward interface pulses may largely control the stopping phase of the dynamic rupture on the fault. If the fault is nonvertical and asymmetrical (Fig. 4b), the downward interface pulse and the outward-moving surface pulse (R_h) interact with each other to induce a specific shear wave, corner wave (C), in the hanging wall. This corner wave carries concentrated wave energy and generates strong particle motions in the hanging wall. In the footwall, on the contrary, the weaker surface pulse (R_f) dominates the ground (free surface) motion and the interaction of this surface pulse with the interface pulse moving in the opposite direction (I) is also small. Thus, the asymmetric ground motion, abovementioned and often observed in shallow dip-slip earthquakes, may be caused. The *P* and *S* waves generated in the footwall upon fault surfacing (P_f, S_f) is also relatively strong, but they are much weaker than the corner wave in the hanging wall. The generation of the interface pulse and the corner wave has not been well recognized so far, partly because these waves may not be expected for a fault fracturing only at depth (Figs. 2 and 3), but we should note that similar rupture pattern (downwards rupture after initial upward one) has been reported for the rupture development related to the 2011 off the Pacific coast of Tohoku, Japan, earthquake [21]. In the simulation of the surfacing nonvertical fault, the shallowest part (length 0.15, i.e., three times the grid spacing; see Fig. 1b) is assumed vertical so that we can numerically treat the corner effect appropriately in the framework of the finite difference method: This geometry is selected so as to avoid the problems related to analytical singularities. However, further computations may indicate that qualitatively same phenomena can be observed without this short vertical section, i.e., even when the nonvertical fault rupture stops just below the free surface (at a very shallow depth of 0.15). However, the amplitudes of the induced surface, interface pulses and the corner waves become smaller.

Figure 2 (continued). Snapshots of the dynamic stress field (isochromatic fringe patterns) associated with the rupture of the (a) vertical and (b) nonvertical finite dip-slip seismic sources at depth. The fringe order is proportional to the magnitude of the maximum in-plane shear stress (τ_{max}). Rupture is initiated at time $t = 0$. Weak Rayleigh surface pulses as well as the waves reflected at the free surface can be recognized.

4. Preliminary experimental results

Next, in order to try to confirm the numerical results, we perform laboratory photoelastic fracture experiments using a birefringent linear elastic material as well as a Q-switched Nd:YAG laser system or a projectile launched by a gun. We prepare a pre-cut interface in a polyurethane plate (50 mm × 25 mm × 12 mm), which is essentially under no static stresses. Dynamic fracture may be induced upon initiation of irradiation of laser pulses or incidence of a projectile (at a speed of 55.5 m/s) and propagated along the interface that is vertical or inclined at an angle of 45 degrees. We record the development of dynamic wave field with a high speed digital video camera system at a frame rate of 100,000 fps (e.g., Fig. 5 for incidence of a projectile), and at the same time, we monitor the particle motions on the free surface using a laser displacement meter (at positions 6 mm away from the surface-breaking point). The observations show that the experimental dynamic isochromatic fringe patterns are similar to the wave patterns generated by the numerical simulations, and if the inclined fault rupture reaches the free surface, the maximum vertical surface displacement on the hanging wall is about 4.6 times as large as that on the footwall (Fig. 6). On the contrary, as is expected from Fig. 3, when the fracture of the interface is arrested well below the free surface (arrested depth equal to a half of the plate height), the vertical motion on the footwall becomes about 1.2 times as large as that on the hanging wall.

5. Conclusions

We have studied the dynamic model of the seismic wave field radiated by rupture of a dip-slip fault located near Earth's free surface. The results of the numerical simulations and preliminary experiments suggest that the dynamic stresses and surface particle motions in the hanging wall, induced by nonvertical dip-slip faulting, may become larger or smaller than those in the footwall, depending on the depth of the arresting point of the fault rupture. We have also indicated that if the fault rupture starting at some depth approaches the free surface, four Rayleigh-type pulses (waves) may be produced: two moving along the free surface and the other two propagating back downwards along the ruptured interface. The downward interface pulses may considerably affect the stopping phase of the dynamic fracture process, and indeed, they might have governed the seismic rupture associated with the 2011 off the Pacific coast of Tohoku earthquake in Japan. If the fault plane is inclined, the interface pulse may interact with the Rayleigh pulse to generate a strong corner shear wave in the hanging wall. In the footwall, the interaction between the Rayleigh and interface waves is much smaller and the ground (free surface) motion is dominated simply by a weaker Rayleigh wave propagating along the free surface. The existence of downward interface waves and corner wave, which is not expected from a conventional seismological analyses where a fault ruptures only at depth, may play a crucial role in understanding the effect of the geometrical asymmetry on the strong motion induced by shallow dip-slip faulting. As stated above, the seismological recordings of recent earthquakes seem to support this idea, and there is certainly a need for careful consideration of dynamic fracture process along a shallow dip-slip fault plane. Although the model employed here is simple, they may provide a dynamic physical explanation of the observations associated with shallow dip-slip earthquakes.

Figure 3 (continued). The τ_{max} stress field induced by the (a) vertical and (b) nonvertical crack-like dip-slip faulting. Rupture starts at depth at time $t = 0$ and moves upward at a constant speed to suddenly arrest well below the free surface. The rupture propagation speed is assumed to be below the Rayleigh wave speed. In both cases, the rupture front wave, a strong disturbance in the proximity of the propagating rupture front, can be identified. In (b), the amplitude of the shear wave is larger in the footwall than in the hanging wall, because much of the energy carried by the rupture front wave in the hanging wall is diffracted at the tip of the broken fault segment and flows into the footwall.

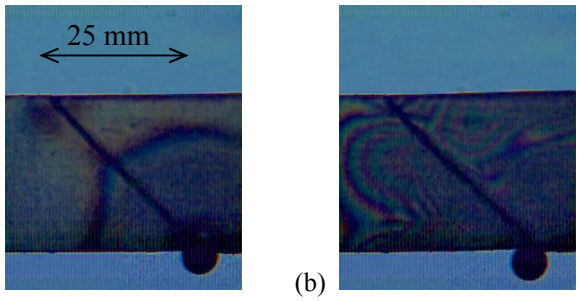
Figure 4 (continued). The sequence of snapshots of the τ_{max} stress field induced by the (a) vertical and (b) nonvertical dip-slip faulting. As in Fig. 3, the rupture, initiated at depth at $t = 0$, propagates upwards but now it breaks the free surface. In (a), upon fault surfacing, four surface-types waves are generated: The Rayleigh pulses (waves) (marked as R) move along the free surface into the far-field and the interface pulses (I) propagate downwards along the ruptured fault surfaces. At a later stage ($t = 8.7$), the interface pulses merge into a shear wave. In (b), the wave energy trapped in the hanging wall is identifiable as a Rayleigh pulse R_h and the corner wave C. Strong dynamic disturbance may be found in the hanging wall behind the corner wave while in the footwall the induced stresses are relatively small.



(a) (b)

Figure 5. The experimentally obtained snapshots of isochromatic fringe patterns showing the typical dynamic wave field induced by fracture of an interface inclined at an angle of 45 degrees to the free surface. The photographs are taken at (a) 40 and (b) 280 μs after the incidence of the projectile, respectively.

Abstract A sensitive identification method for fracture damage identification of pile was established using the rate of change of natural frequency, element modal strain energy method and fracture mechanics theory. According to the structural vibration equation of damaged pile, a structural damage identification equation was deduced which containing modal damage sensitivity factor, fracture injury factor of pile and element modal strain energy change ratio. Sensitive damage identification modals were selected applying modal damage sensitivity factor, then damage warning indicators of pile were established according to the strain energy changes ratio, and the fracture damage location identification of pile was implemented using wavelet analysis techniques. On the basis of the damage location identification, the pile fracture damage size was identified using structural damage identification equation. Pile damages of Wenzhou City Stadium were identified applying the proposed method. The comparation of the results using proposed method and low strain test results verified the correctness and practicability of the proposed method. This study provided a new and efficient method for structural damage identification for pile.

Keywords sensitive modals; element modal strain energy method; Fracture damage identification of pile; low strain test

1. Introduction

In service process, pile foundation's quality is influenced by factors related to the conditions of geotechnical engineering, structural design, construction quality, and the external environment, it is difficulty to found quality problems and hard to deal with the accident. For pile foundation, the characteristics of hidden and complexity, the limitations of the existing identification methods, and some other uncertainty factors make its damage detected in both theory and practice to face many problems[1-4]. How to early detect the crack damage of the pile foundation and how to develop the relevant prevention measures become a challenging topics for the structural health evaluators.

A variety of pile detection technology at home and abroad have been developed to solve the pile quality problems in the construction. Chen studied the application of core drilling method for testing the damage of piles[5], but the core drilling method can not accurately judge the fracture and the development of piles foundation in service. Xiao studied the application of ultrasonic transmission method for the pile foundation defect detection[6]. Liu et al. [7]applied the low strain method to detect the defects of piles. Wu et al.[8] proposed a approach of foundation piles test which combines application of core drilling method , ultrasonic transmission method and low strain integrity testing. Actually the results demonstrated the reliability of the technical advantages and the measures. The above studies are directed in the pile foundation detection of bridges or buildings under construction. Pile foundation construction of bridges or buildings, when the need to determine its integrity, due to the limitations of the superstructure, the usual pile testing methods are not fully applicable.

Johnson et al. [9] and Luo et al.[10]gradually proposed the low strain dual velocity method, super shock, equality seismic detection methods to detect damage of the pile foundation in service. In 1995, Japanese scientists explore the application hole camera technology roughly detect the foundation piles cracking and damage after southern Hyogo earthquake, but they did not achieve good results for various reasons[11]. Yuan et al. [12] determined the integrity of the bridge piles in service, applying combined horizontal impact load displacement signal collected under static

loading. Qi proposed the application of full-bore wall imaging technology to detect damage of the pile foundation in service, and achieved very good detection accuracy[13]. But the piles will produce some damage when the cores of piles are drilling. In order to weaken the flat-slab superstructure on the foundation pile test signal, Zhang et al. [14] used wavelet analysis method to eliminate the interference signal, and the applied wavelet analysis technology to detect the high-pile integrity.

In summary, scientists at home and abroad have done a series of studies on the pile injury, and they have achieved a certain amount of research. However, the in-service structure damage identification of pile foundation is only in the exploratory stage, a lot of work needs to be further in-depth research if the methods would be used in engineering practice. Especially for the small initial crack damage detection of pile foundation, it need more theoretically further analysis and further explore in practice. This article established a recognition method of small injury on the pile positioning and degree. The method take full use the advantage of the natural frequency on the integrity of the damage to determine, the sensitivity of the element modal strain energy method on small injuries, the efficient local analysis capabilities of time domain wavelet analysis. Finally, the engineering application examples are used to verify the accuracy and efficiency of the damage identification method for the piles in service.

2. Basic theory

2.1. Structural vibration eigenvalue equation with fracture damage

The general performance of the structure fracture damage is that the local stiffness of the structure reduced, and it has nothing to do with the quality of the structure. Therefore, according to the perturbation theory, the structural vibration injury eigenvalue equation is as follows[15]:

$$[(K+\Delta K)-(\lambda_i+\Delta\lambda_i)M)](\phi_i+\Delta\phi_i)=0 \tag{1}$$

Where,
$$\Delta K=\sum_{j=1}^{n}\Delta K_j=-\sum_{j=1}^{n}\alpha_j K_j \quad (0\le\alpha_j\le 1) \tag{2}$$

$$\Delta\lambda_i=\Delta\omega_i^2=\phi_i^T\Delta K\phi_i \tag{3}$$

M, K represent the mass matrix and stiffness matrix of the structure respectively; ϕ_i represents the i^{th} order modal vector of the structure; λ_i represents the eigenvalue of i^{th} modal of the vibration system, $\lambda_i=\omega_i^2=(2\pi f)^2$; ΔK represents Changes of structural stiffness; α_j represents j^{th} element damage factor of the structure; K_j represents structural stiffness matrix of the j^{th} element before damage; n represents the total number of elements of the structure.

Expand the Eq.(1) and finish structural vibration eigenvalue equation, the Eq.(1) of the structure can be expressed as:

$$\phi_i^T\Delta K\phi_i+\delta_i\phi_i^T K\phi_i+\phi_i^T\Delta K\Delta\phi_i+\delta_i\phi_i^T K\Delta\phi_i=0 \tag{4}$$

Where, $\delta_i=-\Delta\lambda_i/\lambda_i$ is structure Eigenvalue change rate, it is used to determine sensitivity of the i^{th} modal structural damage detection for the structure; therefore, it is called modal damage sensitivity factor.

2.2. Structural damage identification equation

According to the principle of energy balance, cracks release of elastic strain energy into plastic strain energy and surface energy when the pile cracks, thus contributing to the crack propagation, eventually lead to structural strain can be reduced. Based on this, the Eq. (4) can be expressed in the form of the strain energy. For piles structures, define the i^{th} modal j^{th} element strain energy as:

$$MSE_{ij} = \phi_i^T K_j \phi_i \tag{5}$$

$$MSE_{ij}^d = (\phi_i^d)^T K_j^d \phi_i^d = (1-\alpha_j)(\phi_i^d)^T K_j \phi_i^d \tag{6}$$

Where, the superscript "d" represents the damaged structure.
According to the above formulas we can get:

$$\phi_i^T K \phi_i = \sum_{j=1}^{n} \phi_i^T K_j \phi_i = \sum_{j=1}^{n} MSE_{ij} = MSE_i \tag{7}$$

$$\phi_i^T \Delta K \phi_i = \sum_{j=1}^{n} \phi_i^T \Delta K_j \phi_i = -\sum_{j=1}^{n} \alpha_j \phi_i^T K_j \phi_i = -\sum_{j=1}^{n} \alpha_j MSE_{ij} \tag{8}$$

Ignore second-order or more high-end items, we can get:

$$\phi_i^T K \Delta\phi_i = \sum_{j=1}^{n} \phi_i^T K_j \Delta\phi_i = \sum_{j=1}^{n} [(\phi_i^d)^T K_j \phi_i^d - \phi_i^T K_j \phi_i + (\phi_i^d)^T \Delta K_j \phi_i^d] \tag{9}$$
$$= \sum_{j=1}^{n} [(1-\alpha_j)(\phi_i^d)^T K_j \phi_i^d - \phi_i^T K_j \phi_i] = \sum_{j=1}^{n} (MSE_{ij}^d - MSE_{ij})$$

$$\phi_i^T \Delta K \Delta\phi_i = \sum_{j=1}^{n} \phi_i^T \Delta K_j \Delta\phi_i = -\sum_{j=1}^{n} \alpha_j \phi_i^T K_j \Delta\phi_i = -\sum_{j=1}^{n} \alpha_j (MSE_{ij}^d - MSE_j) \tag{10}$$

Eq.(7), Eq. (8), Eq. (9) and Eq. (10) substituted into Eq. (4), Eq. (4) can be expressed as:

$$\delta_i \cdot MSE_i^d = \sum_{j=1}^{n} (\alpha_j \cdot MSE_{ij}^d) \tag{11}$$

Where, $MSE_i^d = \sum_{j=1}^{n} MSE_{ij}^d$, the total strain energy of the i^{th} modal of Injury structure.

The formula (11) is structural damage identification equation, which is composed by modal damage sensitivity factor, modal strain energy of injury structure and the element damage factor.The strain energy is more sensitive to the small damage of the structure[16], Measuring modal the damage sensitivity factor is relatively easy, and it has a high measuring accuracy[17]. So the Eq.(11) can be used to identify small damage of the pile structure with higher accuracy.

δ_i is the indicator used to determine the modal sensitivity of structural damage, the value of δ_i is the larger, the modal damage identification of structural damage is the more sensitive, or vice versa. Therefore, according to the modal damage sensitivity factor δ_i, we can select the mode used for structural damage identification. Practical application is setting a threshold based on the environment and damage of the structure, it is the efficient mode when the threshold value greater than the set threshold value.

2.3. Element modal strain energy calculation

For the pile structure, in the case of element is sufficiently small, element modal strain energy can be represented by the formula as follow:

$$MSE_{ij} = \phi_i^T K_j \phi_i = \frac{1}{2}\int_{b_j}^{b_{j+1}} (EI)_j (\frac{\partial^2 \phi_i}{\partial z^2})^2 dz \quad (15)$$

$$MSE_{ij}^d = (1-\alpha_j)(\phi_i^d)^T K_j \phi_i^d = \frac{1}{2}\int_{b_j}^{b_{j+1}} (EI)_j^d (\frac{\partial^2 \phi_i^d}{\partial z^2})^2 dz \quad (16)$$

$(EI)_j$ and $(EI)_j^d$ represent the structural flexural rigidity of j^{th} element before and after damage respectively. b_j and b_{j+1} represent z coordinates of node j and node $j+1$ respectively.

The bending stiffness $(EI)_j^d$ of structure with damage is unknown for experimental modal analysis, it can be substituted by bending stiffness before injury ($(EI)_j$)in the case of small injuries. Consider the selected elements is relatively small, the bending stiffness $(EI)_j$ of the j^{th} element can be approximated as a constant, it can be mentioned the integral sign. Eq. (15) and (16) can be rewritten as:

$$MSE_{ij} = \frac{1}{2}(EI)_j \int_{b_j}^{b_{j+1}} (\frac{\partial^2 \phi_i}{\partial z^2})^2 dz \quad (17)$$

$$MSE_{ij}^d = \frac{1}{2}(EI)_j \int_{b_j}^{b_{j+1}} (\frac{\partial^2 \phi_i^d}{\partial z^2})^2 dz \quad (18)$$

$(\frac{\partial^2 \phi_i}{\partial z^2})^2$ in Eq. (17) can be instead by the mean value of $(\phi_{ij}^{''})^2$ and $(\phi_{i(j+1)}^{''})^2$, so Eq.(17) can be expressed as:

$$MSE_{ij} = \frac{1}{4}(EI)_j [(\phi_{ij}^{''})^2 + (\phi_{i(j+1)}^{''})^2](b_j + b_{j+1}) \quad (19)$$

Similarly, the equation (18) can be rewritten as:

$$MSE_{ij}^d = \frac{1}{4}(EI)_j \{[(\phi_{ij}^d)'']^2 + [(\phi_{i(j+1)}^d)'']^2\}(b_j + b_{j+1}) \quad (20)$$

Where, $(\phi_{ij}^{''})^2$、$(\phi_{i(j+1)}^{''})^2$、$[(\phi_{ij}^d)'']^2$ and $[(\phi_{i(j+1)}^d)'']^2$ can be got by measuring displacement mode shapes.

2.4.Damage location determination

The original signal of injury can be got by the difference of element modal strain energy of the before and after damage:

$$f_j(z) = MSE_{ij}^d - MSE_{ij} \quad (21)$$

Fitting signal $f_j(z)$ using cubic spline interpolation, the signal are transformed by wavelet function, we get the transform coefficients which can be used to detect the damage location.

$$DI_{ij} = C(a,b)_{i,j} \quad (22)$$

$C(a,b)_{i,j}$ represents the j^{th} element transform coefficient, DI_{ij} represent element injury positioning indicators. So index DI_{ij} can be used to determine the damage element, if the index DI_{ij} is a large value, we can judge the j^{th} element occur injury.

In order to reduce the impact of random noise from the test mode shapes , multi-order efficient modality are used to diagnose structural damage location:

$$DI_j = \frac{1}{N}\sum_m DI_{ij} \qquad (23)$$

Where, N is the efficient modal number of selection. A given threshold value of DI_j to determine whether the structure has occurred injury can be applied in practical applications.

2.5.Degree of damage calculation

After the injury element is determined, the formula (11) can be used to calculated the degree of element damage. The element damage factor α_j can be used to represent the degree of damage. If there is only one location injury, assuming k element injury, then $\alpha_j = 0(j \neq k)$, only $\alpha_k \neq 0$. The Eq.(11) can be expressed:

$$\alpha_k = \frac{\delta_i \cdot MSE_i^d}{MSE_{ik}^d} \qquad \textbf{(24)}$$

If there are multiple locations injury, assuming m element（k_1、k_2、$\cdots k_m$） injury $(m \le n)$, then need m efficient mode（q_1、q_2、$\cdots q_m$）to be calculated. m equations can solve the corresponding damage factor α. The equations are as follows:

$$\overline{\delta} \cdot MSED = \overline{\alpha} \cdot MSEDD \qquad (25)$$

Where,

$$\overline{\delta} = \begin{bmatrix} \delta_{q_1} & \delta_{q_2} & \delta_{q_3} & \ldots & \delta_{q_m} \end{bmatrix}$$

$$MSED = \begin{bmatrix} MSE_{q_1}^d \\ MSE_{q_2}^d \\ MSE_{q_3}^d \\ \ldots \\ MSE_{q_m}^d \end{bmatrix}$$

$$\overline{\alpha} = \begin{bmatrix} \alpha_{k_1} & \alpha_{k_2} & \alpha_{k_3} & \ldots & \alpha_{k_m} \end{bmatrix}$$

$$MSEDD = \begin{bmatrix} MSE_{q_1k_1} & MSE_{q_2k_1} & MSE_{q_3k_1} & \ldots & MSE_{q_mk_1} \\ MSE_{q_1k_2} & MSE_{q_2k_2} & MSE_{q_3k_2} & \ldots & MSE_{q_mk_2} \\ MSE_{q_1k_3} & MSE_{q_2k_3} & MSE_{q_3k_3} & \ldots & MSE_{q_mk_3} \\ \ldots & \ldots & \ldots & \ldots & \ldots \\ MSE_{q_1k_m} & MSE_{q_2k_m} & MSE_{q_3k_m} & \ldots & MSE_{q_mk_m} \end{bmatrix}$$

If $p < m$, extended modal can be applied to the calculation.

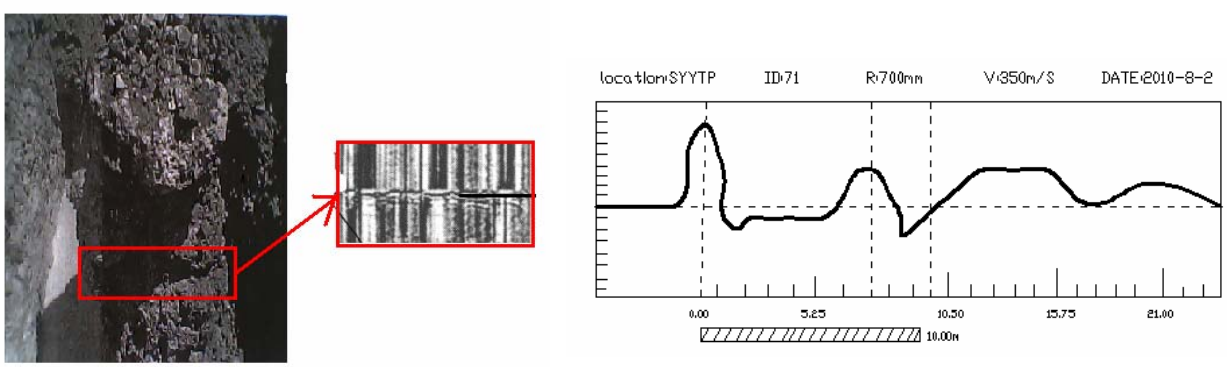
3. Instance of verification

3.1. Project overview

Artificial hollowed piles are used to pile foundation of Ouhai Sports Center Stadium. Effective pile length is 4.00m ~ 30m, pile diameter is 600mm ~ 1000mm, the pile concrete is C25. The project total pile is 129, according to the verify results of low strain detection and excavation, 9.6% of the damage occurred at 7.4m from the top of the pile of NO.71 piles. No. 71 piles pile length is 21m, diameter is 1m. Real damage of No.71 pile is shown in Fig.1.

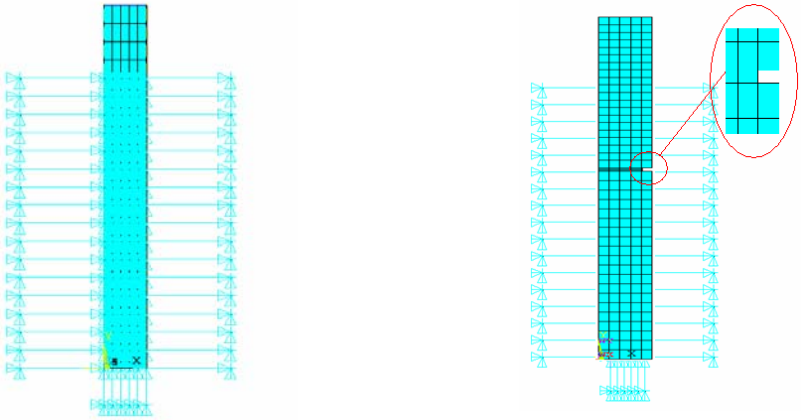
3.2.Finite Element Modeling

Applying of finite element software ANSYS, according to the design drawings, we establish finite element model of the role of interaction between pile and soil for NO.71 pile (Fig.2(a)). According to actual damage on the No. 71 pile, pile model with cracks was established at 7.4 meters from the top of the pile. Crack depth is 9.6% of the diameter of pile foundation (Fig.2(b)). The element type of pile foundation model is SOLID45. Pile-soil interaction applies the nonlinearity the spring element COMBIN139 to simulate. In order to establish the finite element computation model which are in line with the environment of the actual engineering, model updating technology based on the measured data was used to improve the finite element model.



（a）Site excavation detection　　（b）Detection of low strain

Figure 1 The actual damage location of No. 71 piles



（a）Before damage　　（b）After damage

Figure 2 Finite element model of pile-soil interaction

3.3.Efficient mode selection

The rate of change of the natural frequencies before and after the injury is shown in Fig. 3, efficient frequency threshold is set as $\delta_i \geq 0.4\%$. As Fig. 3 shows, the damage determination efficient modes are mode 1 and mode 4.

3.4. Damage location identification

Information function is established using the changes of element strain energy before and after injury, wavelet transform is used to determine the parameters (DI) for the location of damage. DI_j of efficient modal shown in Fig. 4. By setting the threshold （ $DI > 2$ ）, we can clearly determine that the element 55 to 59 crack damage occurs. This is is very consistent with the actual damage location. Results of location damage identification shown as table 1. Identification error is 3%, it proved that the method of damage location identification has a higher accuracy.

3.5. Identification of injury severity

Element damage factor is calculated applying Eq.25, the results of calculation shown as table 1. As shown in Table 1, actual injury and calculation of injury is very close. Identification error is 6.2%, it proved that the method of damage severity identification has a higher accuracy.

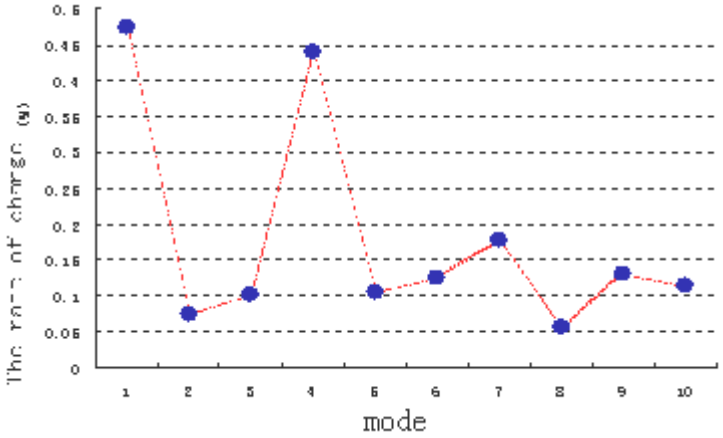


Figure 3 The rate of change of the natural frequency

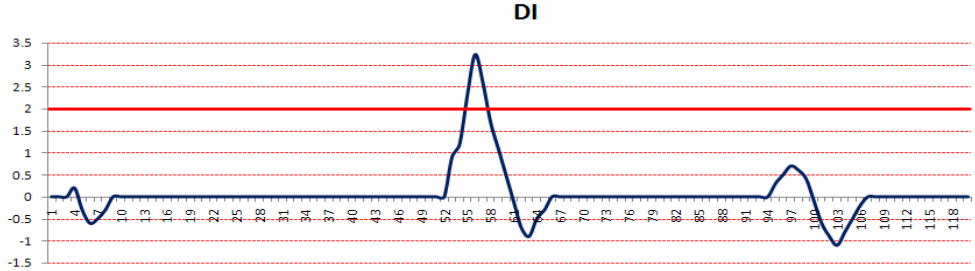

Figure 4　DI value for each element applying of efficient modal

Table 1 Results of damage identification

	Actual injury	Low strain method/error	New method/error
damage location	7.4m	6.71m/9.3%	7.08m/4.3%
damage severity	9.6%	Small damage	10.2%/6.2%

4 Conclusion

This paper selected efficient modal for damage identification applying the change rate of eigenvalues firstly, then established the small injury accurate recognition method based on the application of sensitivity of element modal strain energy to small structural injury and efficient local analysis capabilities of wavelet analysis. The efficiency and accuracy of the proposed method is verified by small cracks damage identification of the pile of Ouhai Sports Center. The concrete conclusions are as follows:

(1) Fracture identification method proposed in this paper for the pile foundation can effectively identify the fracture damage location of the hidden structures in service, this method has a high recognition accuracy.

(2) Fracture identification method proposed in this paper for the pile foundation can effectively identify the fracture damage severity of the hidden structures in service; it is able to quantify the degree of damage; it provides an important reference for the pile foundation fracture injury assessment.

(3) The method presented in this paper provides a new approach to concealed structure damage identification.

Abstract The local flexibility introduced by cracks changes the vibration behaviour of the structure and by examining this change, crack severity can be identified. This paper presents the natural frequencies of symmetric, in-plane free-vibrations of Timoshenko portal frame with and without open crack for different boundary conditions. Cracked segment is modelled as two segments connected by a massless torsional spring. Considering appropriate compatibility requirements at the crack section in any one of segments and at the junction of two segments, the characteristic equations are established for corresponding boundary conditions and solved for natural frequencies by numerically. Crack location ranging from 20% to 70% of length of segment and crack size ranging from 20% to 60% of depth have been considered. Results obtained analytically are compared numerically using standard commercially available finite element software. The frame has been modelled by using quadratic quadrilateral shell elements and quarter-point singular elements are employed around the crack-tip. It is observed that as expected, with increase in crack depth the change in frequencies of the frame with and without crack increases. The maximum difference between the analytical and numerical results is 7.09% for all the cases considered, which proves usefulness of the data.

Keywords Timoshenko Portal Frame, Open Crack, Massless Torsional Spring, In-plane Free Vibration, FEM

1. Introduction

The problem of Timoshenko portal frames with defect is of importance in many fields of engineering. Defects are almost unavoidable in such frames and their existences will decrease stiffness, strength and safety. Although, a number of accurate, effective and reliable on-line damage detection methods based on either X-ray, ultrasonic tests etc., are available, their adoption require scanning of the whole length of frame. This process is a very time consuming, labour-intensive and expensive. In view of these limitations there is a need to develop Non-Destructive Testing methods which can detect damages in a component from the measurement of vibration responses, which may be collected from at a single point, or at the most, a few points, on the component.

The most significant vibration parameter applied in damage identification methods is change in natural frequencies of vibrations of structures caused by the crack. Hence, it may be possible to predict the presence of a crack from the measurements of natural frequencies of the damaged component. A wide variety of beam structures modelled by Euler-Bernoulli or Timoshenko beam theory have been considered for crack detection by representing the crack with massless torsional spring[1-9] etc. Experimental results, though not very exhaustive, are also reported.

Most of the studies on frames consider them to be free from defects [10-16]. A few investigators have reported inverse problem of determination of crack details from the natural frequencies or mode shapes (e.g.,[17-19]) for frame modelled by Euler-Bernoulli beam theory. Frames modelled by Timoshenko beam theory with crack have not yet been studied. This paper presents, a method of solving a forward problem i.e., determination of natural frequencies knowing the crack details of symmetric, in-plane vibrations of Timoshenko portal frame with crack. Associated cracked segment in the portal frame is modelled as two segments connected by a massless torsional spring. The characteristic equations are established using boundary conditions, compatibility conditions at

junctions of two segments and continuity conditions at the crack location. These characteristic equations are used to compute the natural frequencies of Timoshenko portal frame by numerically. Finally, these computed natural frequencies are compared with that of natural frequencies obtained from finite element method for fixed-hinged, hinged-hinged and fixed-fixed end conditions.

2. Theoretical formulation

For in-plane free vibration analysis of Portal frame without and with crack, initially a beam with crack has been studied and natural frequencies have been compared with available literature. For the In-plane free vibration analysis of portal frame, transverse and longitudinal motions of each member are taken into consideration. In analytical modelling of frame, Timoshenko beam theory approach is used for analysis of transverse vibration, while axial vibration of rod is considered for analysis of longitudinal vibration of each member.

A portal frame containing a part through-the-thickness edge crack undergoing free transverse vibration, gives rise to a deformation pattern corresponding to natural frequencies. This in turn will change the slope-mode shape, curvature mode shape, etc. The forward problem of determination of natural frequencies knowing the crack details for fixed-hinged, hinged-hinged and fixed-fixed end conditions have been examined. Accuracy obtainable in connection with natural frequencies is compared numerically using commercially available FE tool for different boundary conditions.

2.1. Formulation for portal frame without crack

For a free, in-plane, symmetric transverse and axial motions of each segments in portal frame without any crack is modelled by using Timoshenko beam theory i.e., taking the effects of shear deformation and rotational inertia. Neglecting damping effect, the mode shape equations of each segments are governed by (Fig. 1)[11]

Transverse motion:

$$v_i''''(\eta_i) + (\sigma+\tau)\, v_i''(\eta_i) - (\alpha - \sigma\tau) v_i(\eta_i) = 0, \qquad 0 < \eta_i < \beta_i \quad \text{for } i = 1,2,3 \tag{1}$$

Slope due to bending:

$$\phi_i''''(\eta_i) + (\sigma+\tau)\, \phi_i''(\eta_i) - (\alpha - \sigma\tau) \phi_i(\eta_i) = 0, \qquad 0 < \eta_i < \beta_i \quad \text{for } i = 1,2,3 \tag{2}$$

Longitudinal motion:

$$u_i''(\eta_i) + \gamma^2\, v_i(\eta_i) = 0, \qquad 0 < \eta_i < \beta_i \quad \text{for } i = 1,2,3 \tag{3}$$

where v_i is transverse displacement, u_i is axial displacement, ϕ_i is the rotation due to bending of the segments, these are function of non-dimensional position, η_i along the length of segment in a particular mode for the segment i, a prime indicates differentiation with respect to η_i and additional parameters given by

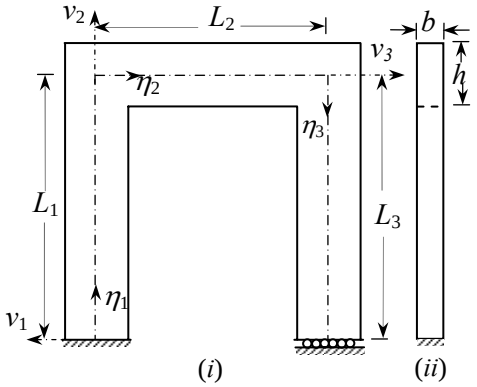

Figure 1. Schematic of Timoshenko portal frame: (*i*) front view and (*ii*) side view.

$$\sigma=\frac{\rho L^2\omega^2}{E},\ \tau=\frac{\rho L^2\omega^2}{\kappa G},\ \alpha=\frac{\rho L^4\omega^2 A}{EI},\ \gamma^2=\frac{\rho L^2\omega^2}{E},\ \beta_i=\frac{L_i}{L},\ L=L_1+L_2+L_3 \tag{4}$$

E is modulus of elasticity, I is second moment of inertia, A is cross sectional area, G is shear modulus, ρ is density of material, κ is Timoshenko's shear coefficient and its value is 5/6 for rectangular cross-section, L is total length of portal frame.

The solutions of Eq. (1-3) are given by

$$v_i(\eta_i)=A_i\cosh\lambda_1\eta_i+B_i\sinh\lambda_1\eta_i+C_i\cos\lambda_2\eta_i+D_i\sin\lambda_2\eta_i,\quad 0<\eta_i<\beta_i\quad \text{for } i=1,2,3 \tag{5}$$

$$\phi_i(\eta_i)=q_1A_i\sinh\lambda_1\eta_i+q_1B_i\cosh\lambda_1\eta_i+q_2C_i\sin\lambda_2\eta_i-q_2D_i\cos\lambda_2\eta_i,\quad 0<\eta_i<\beta_i\quad \text{for } i=1,2,3 \tag{6}$$

$$u_i(\eta_i)=E_i\sin\gamma\eta_i+F_i\cos\gamma\eta_i,\qquad 0<\eta_i<\beta_i\quad \text{for } i=1,2,3 \tag{7}$$

where $\lambda_1=\sqrt{\sqrt{\left(\frac{\sigma-\tau}{2}\right)^2+\alpha}-\frac{\sigma+\tau}{2}}$, $\lambda_2=\sqrt{\sqrt{\left(\frac{\sigma-\tau}{2}\right)^2+\alpha}+\frac{\sigma+\tau}{2}}$, $\lambda_3=\sqrt{\frac{\rho L^2\omega^2}{\kappa G}}$, $q_1=\frac{\lambda_1^2+\lambda_3^2}{\lambda_1}$, $q_2=\frac{\lambda_3^2-\lambda_2^2}{\lambda_2}$,

A_i, B_i, C_i, D_i, E_i and F_i are arbitrary constants evaluated from the boundary conditions.
The boundary and compatibility conditions for a fixed-hinged frame (Fig. 1) are as follows.

$$\left.\begin{aligned}&\text{at}\quad \eta_1=0;\qquad v_1(0)=0,\quad \phi_1(0)=0,\quad u_1(0)=0\\&\text{at}\quad \eta_3=\beta_3;\qquad v_3(\beta_3)=0,\quad \phi_3'(\beta_3)=0,\quad u_3(\beta_3)=0\end{aligned}\right\} \tag{8}$$

$$\left.\begin{aligned}&\text{at}\quad \eta_1=\beta_1,\quad \eta_2=0;\quad v_2(0)=u_1(\beta_1),\quad -v_1(\beta_1)=u_2(0),\quad v_2'(0)=v_1'(\beta_1),\quad \phi_2'(0)=\phi_1'(\beta_1)\\&\qquad\qquad \kappa G\left[v_2'(0)-\phi_2(0)\right]=Eu_1'(\beta_1),\quad \kappa G\left[v_1'(\beta_1)-\phi_1(\beta_1)\right]=-Eu_2'(0)\end{aligned}\right\} \tag{9}$$

$$\left.\begin{aligned}&\text{at}\quad \eta_2=\beta_2,\quad \eta_3=0;\quad v_3(0)=u_2(\beta_2),\quad -v_2(\beta_2)=u_3(0),\quad v_3'(0)=v_2'(\beta_2),\quad \phi_3'(0)=\phi_2'(\beta_2)\\&\qquad\qquad \kappa G\left[v_3'(0)-\phi_3(0)\right]=Eu_2'(\beta_2),\quad \kappa G\left[v_2'(\beta_2)-\phi_2(\beta_2)\right]=-Eu_3'(0)\end{aligned}\right\} \tag{10}$$

By substituting Eqs. (5-7) in to Eqs. (8-10) results in following 18 homogeneous equations.

$$A_1+C_1=0 \tag{11}$$

$$q_1B_1-q_2D_1=0 \tag{12}$$

$$F_1=0 \tag{13}$$

$$A_3\cosh\lambda_1\beta_3+B_3\sinh\lambda_1\beta_3+C_3\cos\lambda_2\beta_3+D_3\sin\lambda_2\beta_3=0 \tag{14}$$

$$A_3\lambda_1q_1\cosh\lambda_1\beta_3+B_3\lambda_1q_1\sinh\lambda_1\beta_3+C_3\lambda_2q_2\cos\lambda_2\beta_3+D_3\lambda_2q_2\sin\lambda_2\beta_3=0 \tag{15}$$

$$E_3\sin\gamma\beta_3+F_3\cos\gamma\beta_3=0 \tag{16}$$

$$E_1\sin\gamma\beta_1+F_1\cos\gamma\beta_1-A_2-C_2=0 \tag{17}$$

$$A_1\cosh\lambda_1\beta_1+B_1\sinh\lambda_1\beta_1+C_1\cos\lambda_2\beta_1+D_1\sin\lambda_2\beta_1+F_2=0 \tag{18}$$

$$A_1\lambda_1\sinh\lambda_1\beta_1+B_1\lambda_1\cosh\lambda_1\beta_1-C_1\lambda_2\sin\lambda_2\beta_1+D_1\lambda_2\cos\lambda_2\beta_1-\lambda_1B_2-\lambda_2D_2=0 \tag{19}$$

$$A_1\lambda_1q_1\cosh\lambda_1\beta_1+B_1\lambda_1q_1\sinh\lambda_1\beta_1+C_1\lambda_2q_2\cos\lambda_2\beta_1+D_1\lambda_2q_2\sin\lambda_2\beta_1-\lambda_1q_1A_2-\lambda_2q_2C_2=0 \tag{20}$$

$$\gamma E\left(E_1\cos\gamma\beta_1-F_1\sin\gamma\beta_1\right)-\kappa G\left[B_2\left(\lambda_1-q_1\right)+D_2\left(\lambda_2+q_2\right)\right]=0 \tag{21}$$

$$\kappa G\left[A_1\left(\lambda_1-q_1\right)\sinh\lambda_1\beta_1+B_1\left(\lambda_1-q_1\right)\cosh\lambda_1\beta_1-C_1\left(\lambda_2+q_2\right)\sin\lambda_2\beta_1+D_1\left(\lambda_2+q_2\right)\cos\lambda_2\beta_1\right]+E\gamma E_2=0 \tag{22}$$

$$E_2\sin\gamma\beta_2+F_2\cos\gamma\beta_2-A_3-C_3=0 \tag{23}$$

$$A_2\cosh\lambda_1\beta_2+B_2\sinh\lambda_1\beta_2+C_2\cos\lambda_2\beta_2+D_2\sin\lambda_2\beta_2+F_3=0 \tag{24}$$

$$A_2\lambda_1\sinh\lambda_1\beta_2+B_2\lambda_1\cosh\lambda_1\beta_2-C_2\lambda_2\sin\lambda_2\beta_2+D_2\lambda_2\cos\lambda_2\beta_2-\lambda_1B_3-\lambda_2D_3=0 \tag{25}$$

$$A_2\lambda_1q_1\cosh\lambda_1\beta_2+B_2\lambda_1q_1\sinh\lambda_1\beta_2+C_2\lambda_2q_2\cos\lambda_2\beta_2+D_2\lambda_2q_2\sin\lambda_2\beta_2-\lambda_1q_1A_3-\lambda_2q_2C_3=0 \tag{26}$$

$$\gamma E\left(E_2\cos\gamma\beta_2-F_2\sin\gamma\beta_2\right)-\kappa G\left[B_3\left(\lambda_1-q_1\right)+D_3\left(\lambda_2+q_2\right)\right]=0 \tag{27}$$

$$\kappa G\left[A_2\left(\lambda_1-q_1\right)\sinh\lambda_1\beta_2+B_2\left(\lambda_1-q_1\right)\cosh\lambda_1\beta_2-C_2\left(\lambda_2+q_2\right)\sin\lambda_2\beta_2+D_2\left(\lambda_2+q_2\right)\cos\lambda_2\beta_2\right]+E\gamma E_3=0 \tag{28}$$

These can be expressed conveniently in the following form.

$$\left[\Delta(\omega)\right]_{18\times18}\left\{C\right\}_{18\times1}=\left\{0\right\}_{18\times1} \tag{29}$$

where $\{C\}=\{A_1,B_1\ldots F_3\}^T$ are unknown arbitrary constants.

For non-trivial solution,

$$\left|\Delta(\omega)\right| = 0 \tag{30}$$

which gives the characteristic equations. Solving this equation numerically, the natural frequencies of portal frame without crack are obtained.

2.2. Formulation for portal frame with crack located in left vertical segment

One of the convenient methods of modelling the vibration of a beam segment with a crack is to split the segment into two around the crack section and connect them by massless spring element, whose flexibility is given by a matrix of size 6×6 [20,21]. When the various modes of vibration become uncoupled, the size of the flexibility matrix reduces. Particularly, for a pure transverse vibration the matrix is of size 1×1. That is, there is only one spring element, which is a torsional spring. A typical representation of a portal frame with a crack located in left vertical segment is shown in Fig. 2. The governing mode shape equations of each segment are of the form:

$$v_i''''(\eta_i) + (\sigma+\tau)\, v_i''(\eta_i) - (\alpha - \sigma\tau) v_i(\eta_i) = 0, \qquad 0 < \eta_i < \beta_i \quad \text{for } i = 1,2,3,4 \tag{31}$$

$$\phi_i''''(\eta_i) + (\sigma+\tau)\, \phi_i''(\eta_i) - (\alpha - \sigma\tau) \phi_i(\eta_i) = 0, \qquad 0 < \eta_i < \beta_i \quad \text{for } i = 1,2,3,4 \tag{32}$$

$$u_i''(\eta_i) + \gamma^2\, v_i(\eta_i) = 0, \qquad 0 < \eta_i < \beta_i \quad \text{for } i = 1,2,3,4 \tag{33}$$

where values of β_i are as follows.

$$\beta_1 = \delta L_1/L,\ \beta_2 = (1-\delta) L_2/L,\ \beta_3 = L_3/L,\ \beta_4 = L_4/L \text{ and crack location, } 0 \le \delta \le 1 \tag{34}$$

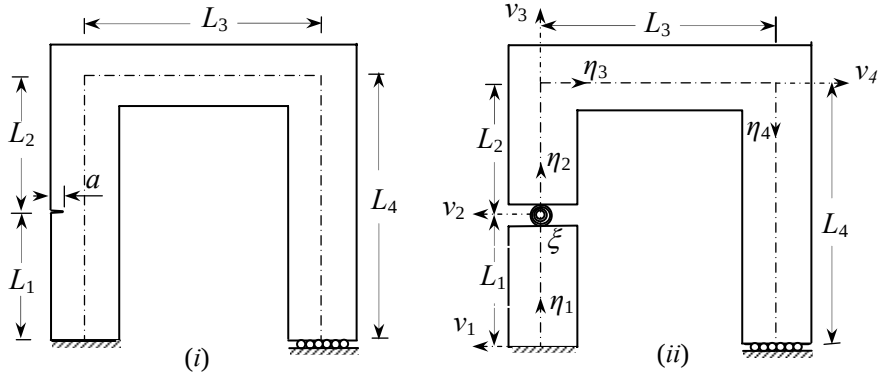

Figure 2. (*i*) Schematic of Timoshenko portal frame with crack in left vertical segment and (*ii*) Representation by rotational spring.

The general solutions of Eq. (31-33) are of the form Eqs. (5-7). Boundary and compatibility conditions at the junctions are as follows.

$$\left.\begin{array}{ll} \text{at} \quad \eta_1 = 0; & v_1(0) = 0, \quad \phi_1(0) = 0, \quad u_1(0) = 0 \\ \text{at} \quad \eta_4 = \beta_4; & v_4(\beta_4) = 0, \quad \phi_4'(\beta_4) = 0, \quad u_4(\beta_4) = 0 \end{array}\right\} \tag{35}$$

$$\left.\begin{array}{l} \text{at} \quad \eta_2 = \beta_2, \quad \eta_3 = 0; \quad v_3(0) = u_2(\beta_2), \quad -v_2(\beta_2) = u_3(0), \quad v_3'(0) = v_2'(\beta_2), \quad \phi_3'(0) = \phi_2'(\beta_2) \\ \qquad\qquad \kappa G\left[v_3'(0) - \phi_3(0)\right] = E u_2'(\beta_2), \quad \kappa G\left[v_2'(\beta_2) - \phi_2(\beta_2)\right] = -E u_3'(0) \end{array}\right\} \tag{36}$$

$$\left.\begin{array}{l} \text{at} \quad \eta_3 = \beta_3, \quad \eta_4 = 0; \quad v_4(0) = u_3(\beta_3), \quad -v_3(\beta_3) = u_4(0), \quad v_4'(0) = v_3'(\beta_3), \quad \phi_4'(0) = \phi_3'(\beta_3) \\ \qquad\qquad \kappa G\left[v_4'(0) - \phi_4(0)\right] = E u_3'(\beta_3), \quad \kappa G\left[v_3'(\beta_3) - \phi_2(\beta_3)\right] = -E u_4'(0) \end{array}\right\} \tag{37}$$

The compatibility conditions at crack location are given by

$$\left.\begin{array}{l} \text{at} \quad \eta_1 = \beta_1, \quad \eta_2 = 0; \quad v_2(0) = v_1(\beta_1),\ \phi_2'(0) = \phi_1'(\beta_1),\ v_2'(0) - \phi_2(0) = v_1'(\beta_1) - \phi_1(\beta_1), \\ \qquad\qquad v_2'(0) - v_1'(\beta_1) = \xi \phi_1'(\beta_1),\ u_2(0) = u_1(\beta_1),\ u_2'(0) = u_1'(\beta_1) \end{array}\right\} \tag{38}$$

where ξ is the non-dimensional flexibility of the torsional spring representing the crack and the relation through crack size can be written in the following form[6]:

$$\xi = 6\pi\, r^2 \frac{h}{L} f \tag{39}$$

where r is crack size a to segment depth h ratio and f is crack geometry parameter defined by

$$f(r) = 0.6384 - 1.035r + 3.7201r^2 - 5.1773r^3 + 7.533r^4 - 7.332r^5 + 2.4909r^6 \tag{40}$$

By inserting general solutions of type (5-7) into Eqs. (35-38) results in following 24 homogeneous equations.

$$A_1 + C_1 = 0 \tag{41}$$
$$q_1 B_1 - q_2 D_1 = 0 \tag{42}$$
$$F_1 = 0 \tag{43}$$
$$A_4 \cosh\lambda_1\beta_4 + B_4 \sinh\lambda_1\beta_4 + C_4 \cos\lambda_2\beta_4 + D_4 \sin\lambda_2\beta_4 = 0 \tag{44}$$
$$A_4\lambda_1 q_1 \cosh\lambda_1\beta_4 + B_4\lambda_1 q_1 \sinh\lambda_1\beta_4 + C_4\lambda_2 q_2 \cos\lambda_2\beta_4 + D_4\lambda_2 q_2 \sin\lambda_2\beta_4 = 0 \tag{45}$$
$$E_4 \sin\gamma\beta_4 + F_4 \cos\gamma\beta_4 = 0 \tag{46}$$
$$A_1 \cosh\lambda_1\beta_1 + B_1 \sinh\lambda_1\beta_1 + C_1 \cos\lambda_2\beta_1 + D_1 \sin\lambda_2\beta_1 - A_2 - C_2 = 0 \tag{47}$$
$$A_1\lambda_1 q_1 \cosh\lambda_1\beta_1 + B_1\lambda_1 q_1 \sinh\lambda_1\beta_1 + C_1\lambda_2 q_2 \cos\lambda_2\beta_1 + D_1\lambda_2 q_2 \sin\lambda_2\beta_1 - \lambda_1 q_1 A_2 - \lambda_2 q_2 C_2 = 0 \tag{48}$$
$$A_1(\lambda_1 - q_1)\sinh\lambda_1\beta_1 + B_1(\lambda_1 - q_1)\cosh\lambda_1\beta_1 - C_1(\lambda_2 + q_2)\sin\lambda_2\beta_1 + D_1(\lambda_2 + q_2)\cos\lambda_2\beta_1 - B_2(\lambda_1 - q_1) - D_2(\lambda_2 + q_2) = 0 \tag{49}$$
$$\left.\begin{aligned} &A_1(\lambda_1 \sinh\lambda_1\beta_1 + \xi\lambda_1 q_1 \cosh\lambda_1\beta_1) + B_1(\lambda_1 \cosh\lambda_1\beta_1 + \xi\lambda_1 q_1 \sinh\lambda_1\beta_1) \\ &+ C_1(\xi\lambda_2 q_2 \cos\lambda_2\beta_1 - \lambda_2 \sin\lambda_2\beta_1) + D_1(\lambda_2 \cos\lambda_2\beta_1 + \xi\lambda_2 q_2 \sin\lambda_2\beta_1) - B_2\lambda_1 - D_2\lambda_2 = 0 \end{aligned}\right\} \tag{50}$$
$$E_1 \sin\gamma\beta_1 + F_1 \cos\gamma\beta_1 - F_2 = 0 \tag{51}$$
$$E_1 \cos\gamma\beta_1 - F_1 \sin\gamma\beta_1 - E_2 = 0 \tag{52}$$
$$E_2 \sin\gamma\beta_2 + F_2 \cos\gamma\beta_2 - A_3 - C_3 = 0 \tag{53}$$
$$A_2 \cosh\lambda_1\beta_2 + B_2 \sinh\lambda_1\beta_2 + C_2 \cos\lambda_2\beta_2 + D_2 \sin\lambda_2\beta_2 + F_3 = 0 \tag{54}$$
$$A_2\lambda_1 \sinh\lambda_1\beta_2 + B_2\lambda_1 \cosh\lambda_1\beta_2 - C_2\lambda_2 \sin\lambda_2\beta_2 + D_2\lambda_2 \cos\lambda_2\beta_2 - \lambda_1 B_3 - \lambda_2 D_3 = 0 \tag{55}$$
$$A_2\lambda_1 q_1 \cosh\lambda_1\beta_2 + B_2\lambda_1 q_1 \sinh\lambda_1\beta_2 + C_2\lambda_2 q_2 \cos\lambda_2\beta_2 + D_2\lambda_2 q_2 \sin\lambda_2\beta_2 - \lambda_1 q_1 A_3 - \lambda_2 q_2 C_3 = 0 \tag{56}$$
$$\gamma E(E_2 \cos\gamma\beta_2 - F_2 \sin\gamma\beta_2) - \kappa G[B_3(\lambda_1 - q_1) + D_3(\lambda_2 + q_2)] = 0 \tag{57}$$
$$\kappa G[A_2(\lambda_1 - q_1)\sinh\lambda_1\beta_2 + B_2(\lambda_1 - q_1)\cosh\lambda_1\beta_2 - C_2(\lambda_2 + q_2)\sin\lambda_2\beta_2 + D_2(\lambda_2 + q_2)\cos\lambda_2\beta_2] + E\gamma E_3 = 0 \tag{58}$$
$$E_3 \sin\gamma\beta_3 + F_3 \cos\gamma\beta_3 - A_4 - C_4 = 0 \tag{59}$$
$$A_3 \cosh\lambda_1\beta_3 + B_3 \sinh\lambda_1\beta_3 + C_3 \cos\lambda_2\beta_3 + D_3 \sin\lambda_2\beta_3 + F_4 = 0 \tag{60}$$
$$A_3\lambda_1 \sinh\lambda_1\beta_3 + B_3\lambda_1 \cosh\lambda_1\beta_3 - C_3\lambda_2 \sin\lambda_2\beta_3 + D_3\lambda_2 \cos\lambda_2\beta_3 - \lambda_1 B_4 - \lambda_2 D_4 = 0 \tag{61}$$
$$A_3\lambda_1 q_1 \cosh\lambda_1\beta_3 + B_3\lambda_1 q_1 \sinh\lambda_1\beta_3 + C_3\lambda_2 q_2 \cos\lambda_2\beta_3 + D_3\lambda_2 q_2 \sin\lambda_2\beta_3 - \lambda_1 q_1 A_4 - \lambda_2 q_2 C_4 = 0 \tag{62}$$
$$\gamma E(E_3 \cos\gamma\beta_3 - F_3 \sin\gamma\beta_3) - \kappa G[B_4(\lambda_1 - q_1) + D_4(\lambda_2 + q_2)] = 0 \tag{63}$$
$$\kappa G[A_3(\lambda_1 - q_1)\sinh\lambda_1\beta_3 + B_3(\lambda_1 - q_1)\cosh\lambda_1\beta_3 - C_3(\lambda_2 + q_2)\sin\lambda_2\beta_3 + D_3(\lambda_2 + q_2)\cos\lambda_2\beta_3] + E\gamma E_4 = 0 \tag{64}$$

Eqs. (41-64) can be expressed conveniently in the following matrix equation.

$$[\Delta(\omega,\xi)]_{24\times24}\{C\}_{24\times1} = \{0\}_{24\times1} \tag{65}$$

where $\{C\}=\{A_1, B_1 \ldots F_4\}^T$ are unknown arbitrary constants.
For non-trivial solution

$$|\Delta(\omega,\xi)| = 0 \tag{66}$$

Evaluation of Eq. (66) numerical method yields natural frequencies of portal frame with crack.

2.3. Formulation for Portal frame with crack located in horizontal segment

The modelling of portal frame with crack located in horizontal segment (Fig.3) is done in the similar way as explained in the preceding section. The characteristic equations of type (66) can be obtained by incorporation of the following compatibility conditions at two junctions and crack location with associated boundary conditions.

$$\left.\begin{aligned} &\text{at}\quad \eta_1 = \beta_1,\quad \eta_2 = 0;\quad v_2(0) = u_1(\beta_1),\quad -v_1(\beta_1) = u_2(0),\quad v_2'(0) = v_1'(\beta_1),\quad \phi_2'(0) = \phi_1'(\beta_1) \\ &\qquad \kappa G[v_2'(0) - \phi_2(0)] = Eu_1'(\beta_1),\quad \kappa G[v_1'(\beta_1) - \phi_1(\beta_1)] = -Eu_2'(0) \end{aligned}\right\} \tag{67}$$

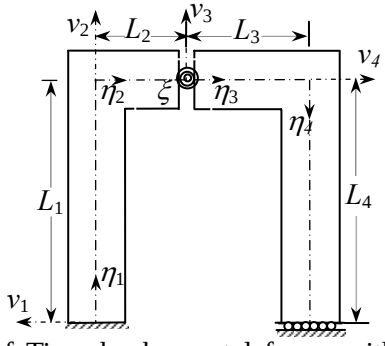

Figure 3. Schematic of Timoshenko portal frame with crack located in horizontal segment represented by torsional spring.

$$\text{at} \quad \eta_3=\beta_3, \quad \eta_4=0; \quad \left.\begin{array}{l} v_4(0)=u_3(\beta_3), \quad -v_3(\beta_3)=u_4(0), \quad v_4'(0)=v_3'(\beta_3), \quad \phi_4'(0)=\phi_3'(\beta_3) \\ \kappa G\left[v_4'(0)-\phi_4(0)\right]=Eu_3'(\beta_3), \quad \kappa G\left[v_3'(\beta_3)-\phi_2(\beta_3)\right]=-Eu_4'(0) \end{array}\right\} \tag{68}$$

$$\text{at} \quad \eta_2=\beta_2, \quad \eta_3=0; \quad \left.\begin{array}{l} v_3(0)=v_2(\beta_2),\ \phi_3'(0)=\phi_2'(\beta_2),\ v_3'(0)-\phi_3(0)=v_2'(\beta_2)-\phi_2(\beta_2), \\ v_3'(0)-v_2'(\beta_2)=\xi\phi_2'(\beta_2),\ u_3(0)=u_2(\beta_2),\ u_3'(0)=u_2'(\beta_2) \end{array}\right\} \tag{69}$$

For other end conditions; hinged-hinged and fixed-fixed, of portal frame with crack are as follows.
For hinged-hinged ends:

$$\left.\begin{array}{ll} \text{at} \quad \eta_1=0; & v_1(0)=0, \quad \phi_1'(0)=0, \quad u_1(0)=0 \\ \text{at} \quad \eta_4=\beta_4; & v_4(\beta_4)=0, \quad \phi_4'(\beta_4)=0, \quad u_4(\beta_4)=0 \end{array}\right\} \tag{70}$$

For fixed-fixed ends:

$$\left.\begin{array}{ll} \text{at} \quad \eta_1=0; & v_1(0)=0, \quad \phi_1(0)=0, \quad u_1(0)=0 \\ \text{at} \quad \eta_4=\beta_4; & v_4(\beta_4)=0, \quad \phi_4(\beta_4)=0, \quad u_4(\beta_4)=0 \end{array}\right\} \tag{71}$$

3. Finite element computation for natural frequencies

The natural frequencies of portal frame with and without crack are computed for a numerical verification of the solution to forward problem by a standard finite element software (i.e., ANSYS-11[22]). A frame is discretized by Eight-node quadrilateral shell elements and quarter-point singular elements employed around the crack-tip is as shown in Fig. 4.

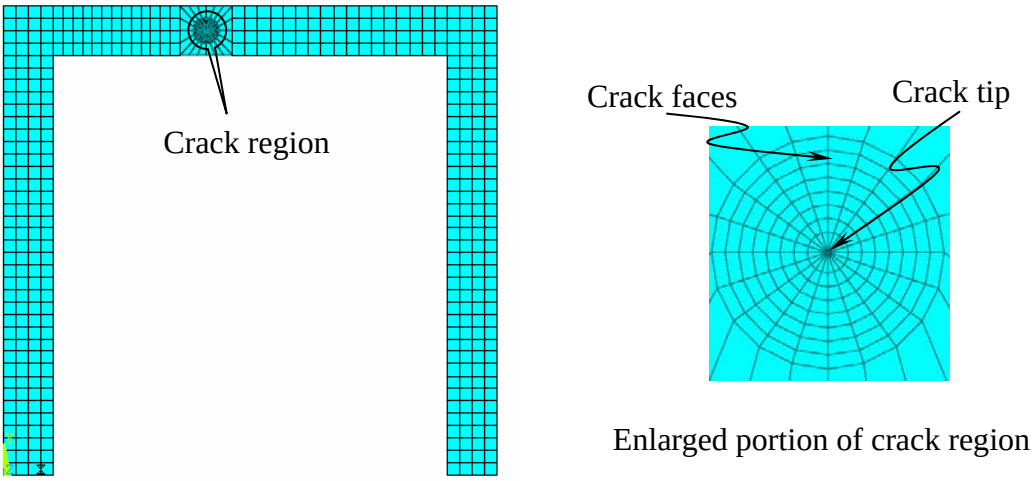

Figure 4. Schematic of finite element modelling of Timoshenko portal frame with crack located in horizontal segment.

4. Results and Discussions

In this study, non-destructive direct solutions for the estimation of the natural frequency of a portal frame with and without crack have been presented. Changes in the natural frequencies of a portal frame due to the presence of a crack may provide additional information for damage detection of these structures. The presence of crack has been theoretically considered by an equivalent torsional spring. To take into account the effects of rotational inertia and shear deformation, Timoshenko beam theory has been employed. The three set of end conditions, fixed-hinged, hinged-hinged and fixed-fixed, have been considered. Crack locations ranging from 20% to 70% of length of segment and crack sizes ranging from 20% to 60% of depth are considered. By means of these boundary conditions and applying suitable compatibility conditions at the cracked section, the characteristic equations have been derived explicitly, whose solution provides the natural frequencies of the portal frame. A MATLAB code has been written to compute the frequencies numerically. The computed natural frequencies have been compared with those obtained by the finite element tool. The geometry of the portal frame with following cross-sectional dimensions and material properties are considered: Length of each no-crack segments (L_i)=0.225m, width (b)=0.0125m and depth (h)=0.025m. The material data employed are: mass density (ρ)= 7800kg/m^3, modulus of elasticity E=210GPa, Poisson's ratio μ=0.3 and Timoshenko shear coefficient κ =5/6. The first three natural frequencies calculated by forward analysis are presented in Tables 1 and 2. The percentage difference in the frequencies taking finite element results as the reference is shown in the Tables 1 and 2. The maximum difference among all results is 7.09% which proves usefulness of proposed method. As expected, the trend of natural frequencies of portal frame with crack, decreases as the crack size increases in comparison with natural frequencies of portal frame without crack (Fig. 5).

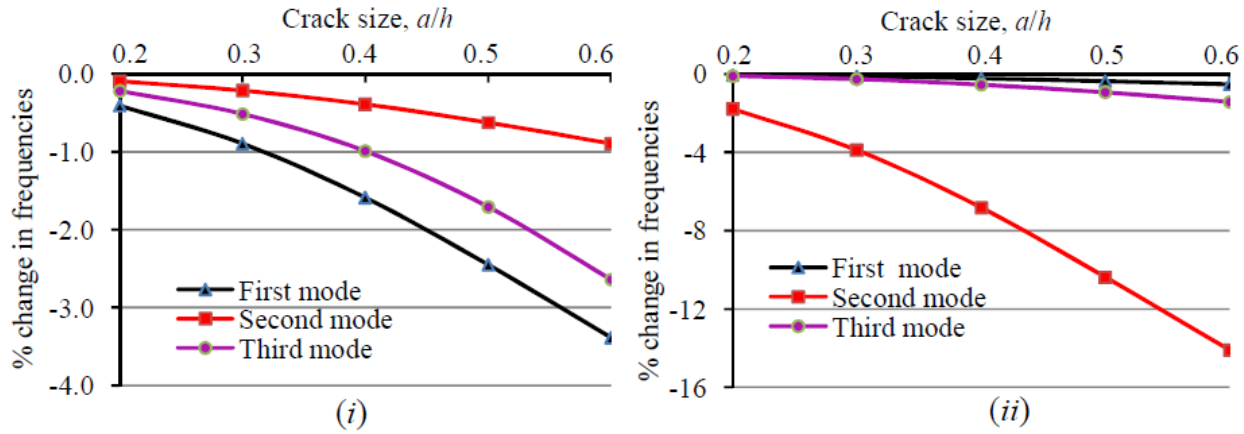

Figure 5. Plot of percentage change in natural frequencies vs. crack size: (*i*) Fixed-hinged ends of frame with crack located in vertical segment at δ=0.4 and (*ii*) Fixed-fixed ends of frame with crack located in horizontal segment at δ=0.4.

5. Conclusion

Solution to forward problems i.e. determination of natural frequencies knowing the crack details in Timoshenko portal frame has been studied. The presence of crack has been modelled by an equivalent torsional spring. It is found that the maximum percentage differences between the natural frequencies computed by analytical approach are less than 7.09% as compared to the finite element result. Changes in the natural frequencies of the portal frame due to the presence of a crack may provide additional information for damage detection of these structures.

Abstract Acoustic Emission (AE) is a promising non-destructive monitoring technique to investigate the damage location and to evaluate the structural health conditions. Based on the tests performed on a masonry bridge, three ingredients –sensor distribution, onset time determination and degree of inhomogeneity– affecting the accuracy of AE localization are discussed. The test result shows a reasonable sensor arrangement is of great importance for the localization capability. The highest accuracy can be achieved for damage sources localized among the sensor distributions. Distances of sources far from the sensor network are less accurate. Onset time determination of an AE signal is another important factor in this technique. A widely used approach, based on the Akaike Information Criterion (AIC), is confirmed to provide more reliable onset time determination of AE signals. Moreover, the inhomogeneity of the test object may lead to errors in the ultrasonic wave travelling model. Different-scale fluctuations and structure variations in the composite structure can result in random variations of the propagation velocity and systematic errors. A new proposed parameter, the degree of inhomogeneity ξ, introduced into the classical method, can effectively decrease the crack localization unavoidable errors due to inhomogeneities in masonry material.

Keywords Acoustic emission, masonry structures, crack localization, structural health monitoring.

1. Introduction

Various masonry structures, such as towers, bridges and historical buildings are widely distributed all over the world. As a consequence of building with old techniques, long-time exposing to the environmental conditions and changing loading regimes, many of these masonry structures are placed in repair and strengthening programs [1, 2]. Prior to repair and rehabilitation, inspections of the structures to estimate the current state in service are essentially required. As one of the non-destructive evaluation and diagnostic techniques, Acoustic Emission (AE) technique is gradually employed in the masonry monitoring [2-5].

Within civil engineering practice, the AE technique is a widely applied non-destructive technique for the detection of damage onset and growth [6, 7]. AE is the class of phenomena whereby transient elastic waves are generated by the rapid release of strain energy when damage occurs within a material. By investigating onset times and other characteristics of acoustic signals, AE techniques provide an insight into the deterioration processes of a tested object [8]. As the onset times of AE signals at different sensors are linked to the propagation speed inside the material, algorithm can be used to locate the emitting sources and to predict their subsequent development [1, 9]. AE is widely used for monitoring metallic [10], rock [11, 12] and concrete structures [13, 14], because AE is well suited for homogeneous or qusai-homogeneous materials with good acoustic transmission. However, its application in heterogeneous materials such as masonry is much problematic [15].

This paper presented the recent research about the accuracy of the crack localization of AE technique in masonry structure, which is one of the most important and challenged topics in AE

applications. The application of AE monitoring in masonry structure is highly complicated, as attenuation and wave propagation are dependent on the heterogeneity of the material. Besides, the presence of voids, cracks and cavities does also influence the AE detection itself. The AE waves, generated at the other side of a large crack to which the sensors are placed, will generally not be detected by AE sensors. This, for example, would be the case between the disconnected layers of a multiple-leaf wall, which is often encountered in historical masonry structures. All these ingredients make the source localization in masonry structure rather difficult [9].

In order to address these issues regarding damage region assessment in masonry, a series of tests were designed and carried out on a masonry model bridge. The results for the tests are discussed in this paper.

2. Source location of AE events and classical localization method

Localization of AE sources is important to assess the regions of active damage in the monitoring technique. Location problems are usually solved by various triangulation techniques based on mathematical analysis of acoustic wave trajectories [16]. This analysis cannot be simply performed if the structure of tested specimen is geometrically complicated. Generally, these techniques depend on the mode of propagation, the elasticity modulus, and signal attenuation due to the heterogeneity and anisotropy of material. In this Section, a general overview on the classical localization method and the corresponding knowledge is depicted.

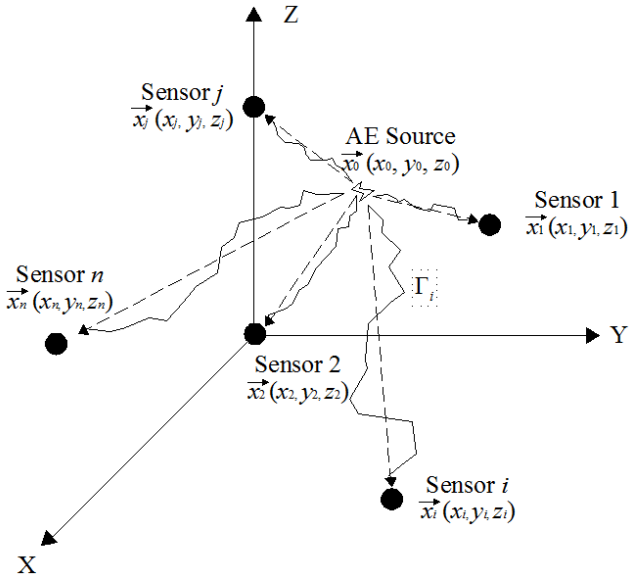

Figure 1. Localization of point AE source involving a generic array of *n* sensors.

As shown in Fig. 1, in a theoretical model with wave propagation velocity v_{Pi}, the onset time t_i^* at sensor $\vec{x}_i$, unknown crack coordinates $\vec{x}_0$ and origin time t_0 can be estimated by an integral along the actual ray path Γ_i:

$$t_i^* = t_0 + \underbrace{\int_{\Gamma_i} (d\Gamma_i / v_{Pi}(\mathrm{r}))}_{\mathrm{I}}, \tag{1}$$

where $v_{Pi}(\mathrm{r})$ is the wave velocity field in the specimen or structure. If the material is homogeneous, Eq. (1) can be simplified as:

$$t_i^* = t_0 + \frac{|\vec{x}_0 - \vec{x}_i|}{v_p} = t_0 + \frac{\vec{x}_{i0}}{v_p}. \tag{2}$$

For each sensor *i* there will be residual r_i between the detected onset time t_i and the calculated onset time t_i^*:

$$r_i = t_i - t_i^*. \tag{3}$$

If t_j is the onset time at another sensor $\vec{x}_j$, the measured onset time difference between sensors *i* and *j* is used. Usually we have:

$$r_{ij}^* = \Delta t_{ij} - \frac{\left(\vec{x}_{i0} - \vec{x}_{j0}\right)}{v_p}, \qquad (i \neq j). \tag{4}$$

If there are more than four onset times available for one event, the problem is overdetermined. These residuals are minimized using the least square method, in which the total error for (*n*-1) equations is simply the sum of all squared time-residuals:

$$\chi^2 = \sum_{i=2}^{n} (r_i^*)^2. \tag{5}$$

Residuals are reduced by applying corrections $\Delta\vec{x}$ and Δv_p to the source parameters, which can be written as:

$$A^T A\vec{r} = -\mathrm{A}(\Delta\vec{x},\ \Delta v_p)^T. \tag{6}$$

Thereby, $\vec{r}$ is the data vector with the residuals for *n* observations of one event. **A**, which is a $(n-1)\times 4$-matrix, contains the partial derivatives of the calculated travel times with respect to the source coordinates, calculated at $\vec{x}_0$:

$$A = \begin{pmatrix} \frac{\partial r_2^*}{\partial x} & \frac{\partial r_2^*}{\partial y} & \frac{\partial r_2^*}{\partial z} & \frac{\partial r_2^*}{\partial v_p} \\ \vdots & \vdots & \vdots & \vdots \\ \frac{\partial r_n^*}{\partial x} & \frac{\partial r_n^*}{\partial y} & \frac{\partial r_n^*}{\partial z} & \frac{\partial r_n^*}{\partial v_p} \end{pmatrix}_{\vec{x}_0}. \tag{7}$$

Due to the linearization of Eq. (6) the problem is solved iteratively until convergence, starting with an initial guess for the crack source location.

3. Experimental setup and operation

According to the aforementioned crack source localization problem in masonry structure, several tests based on a two-arch masonry model bridge are operated in this research.

3.1. Wave velocity test

A series of pencil-lead break tests are performed on the central pier of the bridge to study the attenuation and the velocity properties. The size of the central pier is of 160×50×28 cm, shown in Fig. 2, and it can be considered as a representative masonry solid structure.

Six sensors (S_0~S_5) are used to detect AE signals and the distance between two adjacent sensors increased from $S_{1\text{-}0}$ to $S_{5\text{-}4}$ with an increment of 5 units, shown in Fig. 2. The pencil is broken beneath the sensor S_0 with 5cm distance away in the same surface to study the surface velocity propagation, which is the scenario shown in Fig. 2.

Figure 2. Wave velocity test: (Left) the sketch of the pencil-lead break point and the sensor distribution; (Right) scenario of the velocity test.

The results of the measured velocities are shown in Fig. 3. The velocity named V-homogeneous, is calculated assumed the material is homogeneous [6]. The V-average is the average velocity value of all the calculated velocities in the corresponding test.

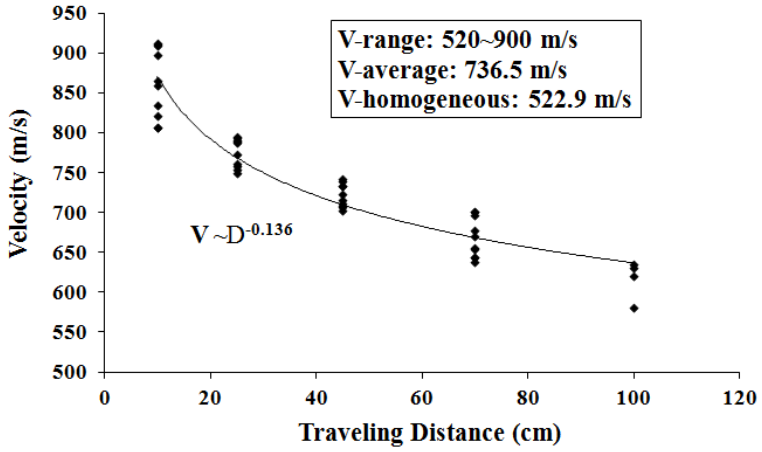

Figure 3. Wave velocity of the AE on the surface of masonry model bridge.

3.2. Sensor distribution and source localization tests

Ad hoc tests are performed to reproduce AE source using pencil-lead break on the right-side surface of the masonry abutment. Six sensors are attached to the surfaces, shown in Fig. 4. In particular, 19 different pencil-lead break points (artificial source) are drawn on this surface, and for each point the tip of a pencil is broken 8 times, so a total of 152 measurements are recorded. For this test 912 AE events from the six sensors are obtained and then sensor distribution and the source localizations of all the 19 points are analyzed in the following sections.

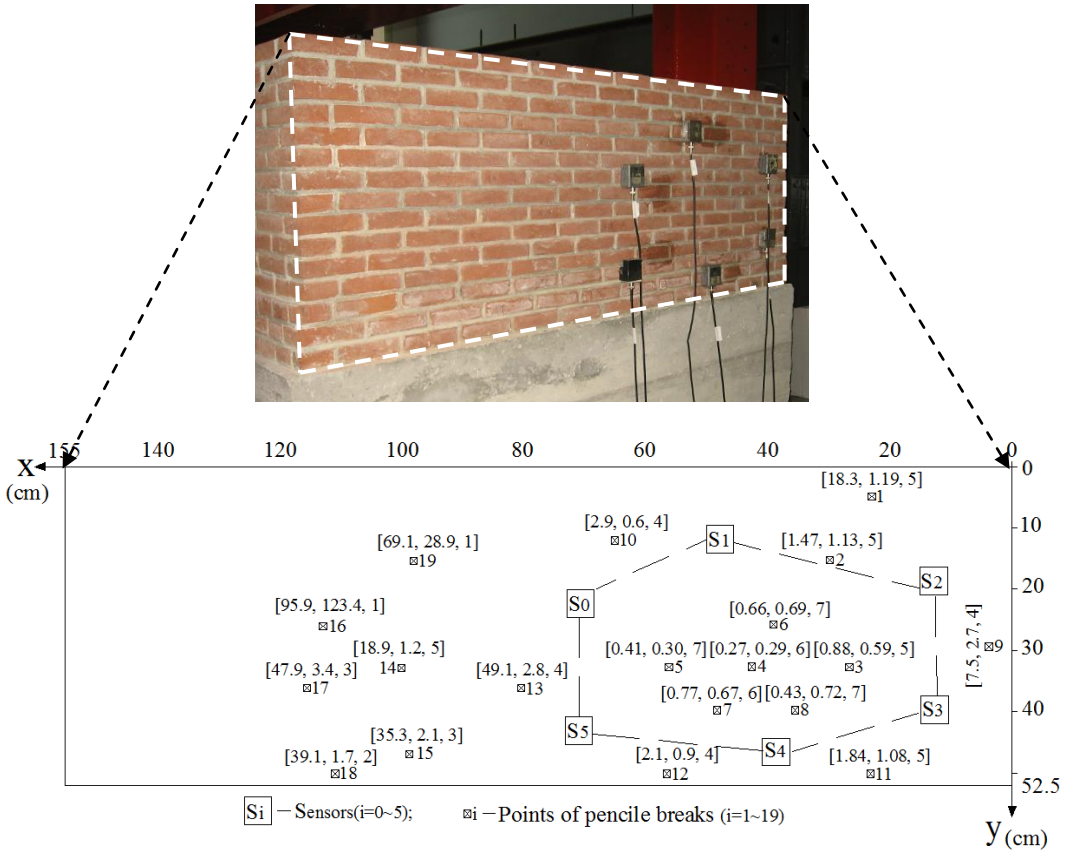

Figure 4. Results of the source localization calculated from the classical and the modified methods. In [*a*, *b*, *c*], *a* is the average error of all the available breaks from the classical method, and *b* is the average error of all the available breaks from the modified method, and *c* is the available breaks which can be used for each point.

4. Accuracy analysis of AE locations based on the test

4.1. Degree of inhomogeneity

The classical localization method can be used in the concrete structures according to the experiences [6-8]. But the localization of AE source in masonry structures is highly complicated, as attenuation and wave velocity are dependent on the heterogeneity of the material (not only the interface between bricks and mortar, but also cracks and cavities in existing structures). The theoretical analysis in Section 2 and the test result in Section 3.1 both illustrate that the classical localization method based on Eq. (2) cannot be used directly in masonry. A modified method based

on the classical method is introduced in the following part.

The basic idea of the localization in masonry is the same as that in concrete. But propagation delay due to the layers in the masonry structures makes the homogeneous assumption is unavailable here. Modifications for propagation delay are implemented.

The geometry distance *ds* is still taken as the calculated path, since the detailed knowledge of the actual wave path Γ, is not possible to be known. But modification can be made for the time-delay according to the velocity property in Fig. 3 to reduce the effect of inhomogeneous property. In the modified model, the classical model result in Eq. (5) is modified into:

$$\chi^2 = \sum_{i=2}^{n} {r_{i1}}^2 = \sum_{i=2}^{n} \left[\vec{x}_{10} - \vec{x}_{i0} - (k_i t_i - t_1) v_1 \right]^2 , \tag{8}$$

where $k_i = \left(d_1 / d_i \right)^{\xi}$ is the modified factor, which is used to modify the effects of the inhomogeneity or propagation delay. The parameter ξ, denoted as degree of the inhomogeneity, in k_i reflects the inhomogeneous degree of the material. The degree of the inhomogeneity ξ is determined from the result of the pencil-lead break wave velocity test, shown in Fig. 3. It reflects the relationship between the calculated velocity and the wave propagation distance. In strictly homogeneous materials, the value ξ is 0 since the wave velocity is a constant value and does not changes with travelling distance. If the material is not homogeneous, value ξ will theoretically increases with the degree of the heterogeneity. The degree of the inhomogeneity ξ in our research is 0.14, which is taken from the relation between the velocity and travelling distance shown in Fig. 3.

4.2. Sensor distribution

The results of the locations are shown in Fig. 4 for both the modified and classical methods. It can be noted that the location accuracy varies with the position of the breaks. The break points can be approximately divided into three groups. The points 3~8 inside the central area of the sensor covered region (the dashed line in Fig. 4) have the best crack source monitoring result for both classical and the modified methods. In the second group, including points 2, 9, 10, 11, 12, points are distributed on the nearby region of the sensor covered region. The rest of the points, far from the sensor network, are in the third group.

For points in the first group, both methods give the ideal result, all the errors are smaller than 6 mm, and most of the crack events can be monitored. For the second group, the modified model shows better results than the classical method. The errors (*a* value in Fig. 4) in the classical method are about 15~75 mm, whereas the counterparts (*b* value in Fig. 4) can be reduced to about 6~27 mm in the modified method. In this condition, about half of the break events can be detected according to the *c* value in Fig. 4. The result from the classical method for the third group is barely acceptable for its exaggerated errors, whereas modified method is still in good conditions. Although the errors were slightly large, about three or four centimeters, the results are still acceptable considering the entire size scale of the surface. Three representative points, 4, 10 and 17 respectively, of the three

groups are selected to give the detailed results in Fig. 5.

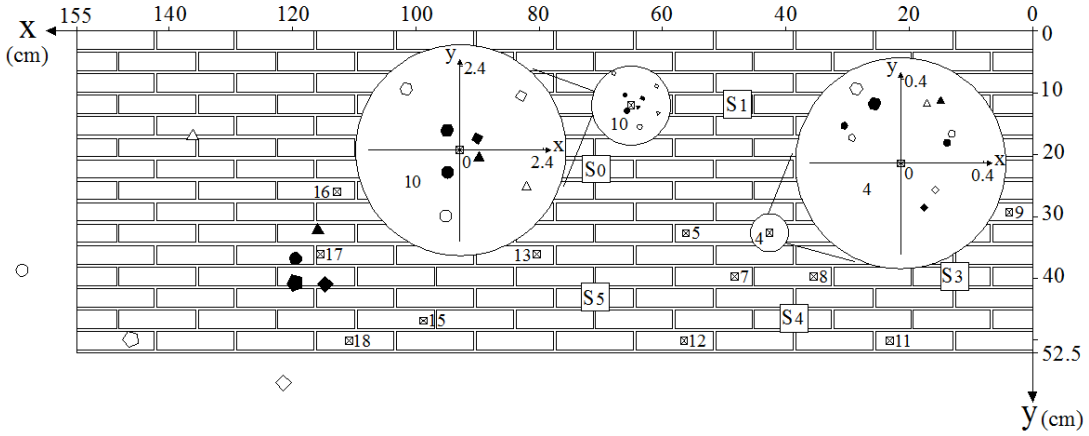

Figure 5. Detailed localization results of the point 4, point 10 and point 17. The solid points represent the results of the modified method and the empty points of the classical method.

4.3. Onset time determination

Source localization is based on the onset times or arrival times of the direct body waves. Theoretically, onset times of the direct body waves, *P*-wave and *S*-wave both can be used for source localization. However, only first wave onset times (*P*-times) are usually measurable, since multiple side reflections, structural noise and sensor response will interfere the later phases.

The true onset time of a crack AE event could be described as the moment when the first energy of a particular signal phase reaches the sensor positions [17]. In signal analysis, the onset time is usually picked as the point where the first difference between the signal and the noise takes place [18]. Determination of the onset time of AE signals is crucial for the whole localization process and is the major premise to affect the localization accuracy [6].

Manually picking is the preferred choice if there are only few events available. It is still necessary to have reliable automatic picking tools, because human analysts cannot manage the vast amount of data recorded in the monitoring. In concrete monitoring, many algorithms have been proposed for automatic detection of onset times and the detailed description can be found in [19]. Two mostly used methods, STA/LTA (STA Short Term Average, LTA Long Term Average) picker by [20] and AIC-picker [6, 21] are employed and investigated for the AE signals in masonry structures. The picking accuracy of the STA/LTA-picker and AIC-picker was quantified by a comparison with picks that were set manually.

For 1122 signals of AE events recorded at the pencil-lead break tests in Sections 3, the differences Δt between the automatic and the manual picks are examined. Fig. 6 shows the results for the STA/LTA-picker and for the AIC-picker, compared to manually picked onset times.

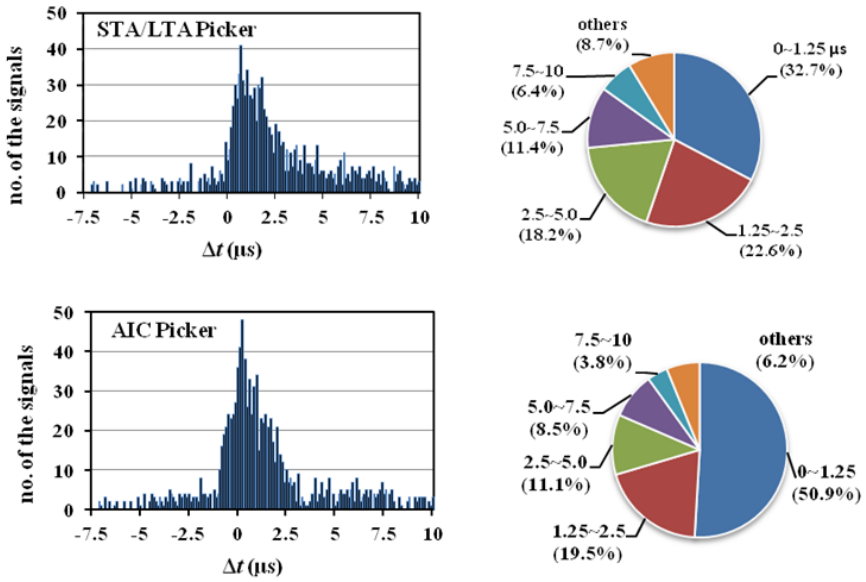

Figure 6. Differences Δt between automatically and manually picked arrival times for the STA/LTA (top) and the AIC-picker (bottom). The pie charts show the performance of both automatic pickers.

The signals have different reading precisions of their onsets, depending on the signal to noise ratio and how impulsive onsets are. The results from the two methods are both acceptable, although the STA/LTA-picker obviously shows a trade-off. With the AIC-picker almost twice as many signals than the STA/LTA-picker are picked in a very good correlation, $\Delta t \leqslant 1.25\mu s$. Also, the number of mispicks with $\Delta t \geqslant 5\mu s$ in the noise and picks too late in the signal could be reduced from 26.5% of that in STA/LTA-picker to 18.5%. Accordingly, the AIC-picker can be suggested as a reliable and accurate algorithm to determine the onset times of AE signals in masonry structures.

5. Discussion and conclusion

With wide existence of masonry structures, the monitoring techniques have received considerable attention due to the increasing demand of the structural retrofit and strengthening. As one of the non-destructive monitoring techniques, acoustic emission technique is employed for the masonry cracking analysis.

For AE applications in monitoring, localization of AE sources is important to offer the information of the active damage region. The investigation of the localization accuracy has shown that monitoring results are greatly influenced by the material of structures. Classical localization method is mostly adopted to realize the localization operation in metal and concrete structures. However, for the masonry structures, the complicated material properties make the classical localization method cannot be applied directly.

The modified localization method proposed in this paper allows giving a reasonable location results. In the modified method, a modified factor k_i related to inhomogeneous or propagation delay is introduced. The degree of the heterogeneity ξ in k_i plays a key role to eliminate the effect of the inhomogeneous of the material. Accordingly, the pencil-lead break velocity tests on the masonry

structure to measure the relation between the wave velocity and travelling distance should be fulfilled before the monitoring. Based on this test result, the value ξ can be obtained and employed in the monitoring process.

The sensor arrangement is another task which should be carefully considered. The investigation of the localization accuracy has shown that the sensor distribution is essential for monitoring AE activity in the specimen. The ideal condition is to ensure that all relevant regions are covered by enough sensors before the monitoring starts. Detected events are only a fractional amount of all recorded AE signals and, again, only a limited number of all detected events can be localized with a sufficient accuracy. For a good imaging of crack progression it is necessary that enough events could be localized. Therefore the proper arrangement of the sensors can give us more available points, which is well testified by the *c* value in Fig. 4.

In conclusion, with the assistance of the reliable onset time picker (AIC-picker) and proper sensor distribution, the source localization in masonry can be realized properly by the modified model.

Abstract. A combined method for investigation of localized deformation processes in carbon fiber reinforced composite specimens is applied in order to reveal characteristic stages of strain and fracture. Stress concentrators have the shape of a circular hole and edge crack of various sizes. Use of simultaneous strain data registration has allowed us to register and compare parameters under analysis during entire time of the experiments. The reasons of similarity and difference of the results are shown and discussed. It is offered to apply the obtained results for the aims of non-destructive testing of structural materials being based on revealing characteristic stages of strain development and a particularly prefracture stage.

Keywords: strain gauging; digital image correlation; acoustic emission; carbon fiber composite, non-destructive testing, health monitoring of structures.

1. Introduction

In compliance with literary data and results of our previous investigations [1, 2] the stage character of deformation development can be registered with various methods of studying and estimation of strain. Each method due to operation principle is sensitive to particular scale level. In situ application of 3 methods: strain gauging, acoustic emission (AE) and digital image correlation (DIC) allows one to obtain complete pattern of deformation and fracture of stressed structural materials. Application of stain gauging and AE is described in papers [3, 4] while use of DIC method is explained in [5, 6].

Thus depending on physical principle of a method used it is possible with high sensitivity to register and characterize quantitatively the deformation processes at each scale. Strain gauging characterizes macroscale level or response of a specimen as a whole on applied stress. DIC (Meso II) describes level which is comparable with macrolevel, because in DIC the area of observation considers with whole width of a specimen under testing. AE (Meso I) complies level generally of debonding on matrix-fiber interface. AE characterizes changes inside material, while DIC method is revealing processes in outer ply of a specimen, that is critical to composite materials with different fiber layers orientation.

For numerical analysis of data information parameters for 3 methods were chosen. For the AE method count rate dN_{AE}/dt was calculated; for DIC - γ shear strain intensity, for strain gauging - $d\sigma/dt$ (time derivative of the external applied stress).

2. Materials and investigation technique

CFRC is pseudo-isotropic composite made of unidirectional carbon fiber layers [0°, 45°, -45°, 90°] sintered in carbon matrix. Dimensions of specimens were taken according to ASTM D5766/5766M. Strain localization degree is varied by different dimensions of stress concentrators (central hole diameter 7; 10; 13 mm; depth of edge crack 14,5; 18; 21,5 mm).

Dimensions of the specimens are presented on Fig.1.

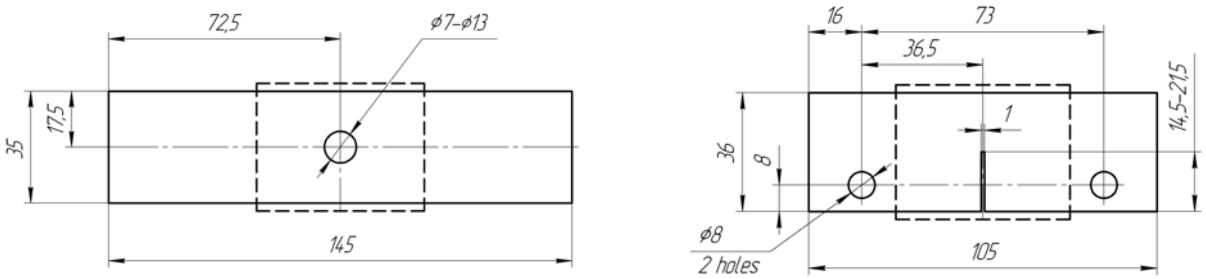

Fig. 1. Scheme of the specimens, thickness 4 mm: a) specimen with central hole; b) specimen with edge crack.

Specimens were stretched under static loads at electro-mechanical testing machine Instron 5582. Strain gauging data was registered using integrated transducer of the testing machine.

Registration of acoustic emission (AE) signals was performed by PC-based hard-software measuring technique [7]. For analysis of acoustic emission data, the derivative on AE events accumulation over loading time (acoustic emission count rate) was calculated as the basic informative attribute of AE data.

Surface imaging was carried out by Canon EOS 550D DSLR camera. The camera has been equipped by telephoto lens Canon EF-S 100-400 mm 1/4-5.6 IS. A certain region of the image was determined for calculation of the average value of shear strain intensity. For example, specimen with central holes the area of the image with the size of 3300×4950 pixels (the physical sizes ~32×52,5 mm) was taken. The sizes of the regions for strain estimation were chosen in order to ensure observation of formation and development of macro scale shear–bands for various types of specimens.

Use of simultaneous registration has allowed us to register and compare parameters under analysis during entire time of the experiments

3. Experimental results

3.1. Macroscale level. Analysis of strain gauging data

Loading diagrams of specimens with central holes and edge cracks are resulted in fig. 2. With increase of the notch dimension for both types of specimens the elongation and ultimate strength at fracture are decreased. The derivative dσ/dt was calculated and is shown on fig. 3.

Further, for comparison of the deformation behavior of specimens with central holes and edge cracks, the results obtained by 3 methods for the composite specimen with ∅7 mm hole and 14,5 mm edge crack are described.

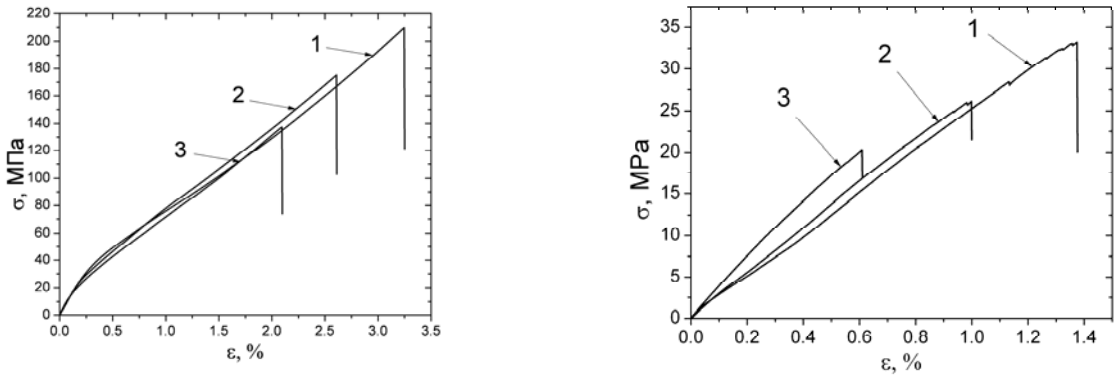

Fig. 2. «σ-ε» graphs: a) specimens with open holes: 1) ∅7mm, 2) ∅10mm, 3) ∅13mm); b) specimens with edge cracks: 1) 14,5mm, 2) 18 mm, 3) 21,5 mm

3.2. Meso I level. Analysis of AE registration data

Dependences of AE count rate versus loading time dN_{AE}/dt for specimens are shown in fig. 3. This parameter was chosen for the analysis as being most "sensitive" to change of a leading scale level of deformation in a specimen under loading. The point graphs of AE count rate were smoothed by average curves. For both types of specimens it is visible, that generation of AE pulses begins practically from the beginning of loading. However appreciable increment of the AE count rate starts at time related to transition of key role of deformation to the meso-scale level.

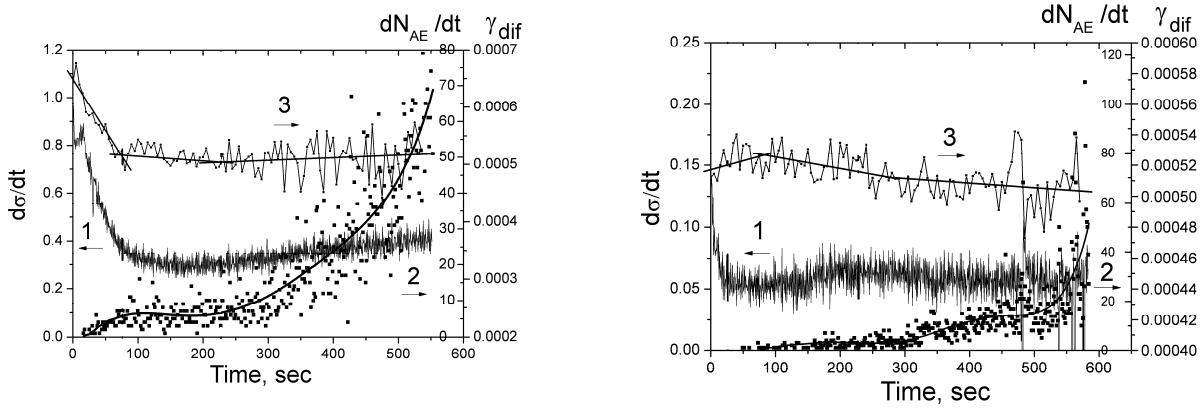

Fig. 3. Combined $d\sigma/dt$ - γ_{dif} - dN_{AE}/dt graphs: a) specimen with central hole: ∅7 mm; b) specimen with edge crack: 14,5 mm.

3.3. Meso II level. Shear strain intensity

The analysis of strain evolution at the meso II level was made by 2 methods of image processing: integral and differential (detailed description of the technique is given in paper [8]). In the first case displacement vectors were mapped by comparison of a first (initial) image with each current ones, while at the differential method of calculation a current and a subsequent images of a deformed specimen surface were compared.

Dependences of the shear strain intensity calculated by the differential method of the image processing which is more sensitive to local strain changes, for both types of specimens are presented in fig. 3. These dependences are sectionally-linear approximated.

4. Conclusions

Combination of DIC and AE data used in the research allows us to examine stage patterns for deformation development at various scale levels. In our previous investigations aluminum specimens were tested [9]. For aluminum specimens at the initial stages of loading the AE method seems to be the most sensitive to deformation processes. At greater degrees of deformation the method of digital images correlation (DIC) more precisely characterizes the change of the key role from meso- to macroscopic scale of the deformation development.

For CRFC specimens AE method have high sensitivity and ability to describe processes inside material, strain gauging characterizes response of specimen on applied stress and allows to identify transition between stages, DIC method can be used to visualize deformation processes with their numerical estimation.

The results are offered to be applied for the aims of non-destructive testing of structural materials being based on revealing characteristic stages of strain development and particularly prefracture stage.

Abstract This paper introduces how to use acoustic emission (AE) technology to monitor dynamic process of crack growth of a segment model of a full size orthotropic steel bridge structure during a 30 day fatigue test. The dimension of the test model is 12.54x2.99x0.6 (LxWxH) meter. Multiple AE sensors were located on different places of the structure. Crack initiation, location and development process were dynamically monitored and recorded. This paper discusses how AE technology is used in the fatigue test of large structure, how is burst crack signal captured, how is crack location identified, what are the behavior of crack developments and how is the result of visual inspection in comparison with the AE technology. The results of the fatigue test monitored with AE have shown that AE is a very valuable technology for monitoring dynamic process of crack development. It can be used not only for various tension, compression and fatigue tests in labs, but also for structure health monitoring in the fields.

Keywords Fatigue Crack, Fracture, Damage, Acoustic Emission, Dynamic Monitoring

1. Introduction

Although orthotropic steel bridge structure is getting more and more widely used, fatigue cracks on the welds and the structure material are still concerns due to the complexity the orthotropic structure and stress concentration in the welds under repeated loadings of the structure[1-2]. It is not uncommon that cracks were found in an orthotropic steel structure that is younger than its design or predicated life age. The actual fracture behavior of orthotropic steel structure were not fully studied and experimentally tested yet.

In fatigue tests of structures or materials, strain or stress measurement is usually a very common way for fatigue crack detection. But, not only the strain measurement cannot tell the development process of the crack growth, but also for a big or complex structure, e.g. a full size orthotropic steel deck, it is hard to predict where the cracks are going to occur and where are the optimum positions that strain gauges should be installed. Each strain gauge can only measure the stress where the strain gauge sticks to and its vicinity, it is not possible to show

crack stresses which are certain distance away from the strain gauge.

On the other hand, it is quite common that cracks were visually inspected in fatigue tests. However, disadvantages of visual inspection are also obvious. First of all, a fatigue test process might need to be stopped in order to have a reliable visual inspection. Secondly, crack initiation is not possible to be visualized due to its microscopic size. Thirdly, if a structure size is big or cracks are located in blocked or inaccessible areas of the structure, the cracks are not able to be picked up by visual inspection. Actually, it is relatively feasible to visually check crack development during fatigue test of small samples, but it is very difficult to know overall crack growing process from a fatigue test of a big structure, e.g. how many active cracks exist in one time? when is each crack initiated? where are cracks located? what are the behaviors of crack growth? This is particular true for a big steel bridge structure test that lasts for days and months.

Although, in some instances, NDT technology, e.g. dye penetration, ultrasonic, eddy current and radiology methods is also used to inspect fatigue cracks, they are actually not real time monitoring technologies, the fatigue testing process has to be stopped in order to perform the NDT tests. Not only it interrupts the fatigue testing process, but also it takes a lot extra time to prepare the NDT test. If the tested part is not a small object, but a very big object like the full size orthotropic steel deck, it would be impossible to inspect the complete structure or to inspect all potential crack areas within a limited time.

In the recent years, acoustic emission (AE) technology is getting more and more widely used in not only fatigue tests in the laboratories, but also active crack detection of bridge structures[3-7]. There are quite a few unique advantages in using AE for crack detection and structure health monitoring, such as

- Real time on-line structure health monitoring
- Very sensitive to crack development or active crack growth
- Global area monitoring with sensors away from exact crack locations
- Location of one or more crack sources
- Suitable for long term Ethernet or wireless remote monitoring

With these advantages, it is possible to answer the questions regarding crack initiation and development of full size steel structures during a fatigue test or actual structure health monitoring. Wang et al[2] has used AE to test a full size orthotropic steel bridge deck, but it only monitored very short time when a crack has already been found before AE applied, there was no crack development process studied.

In this paper, a fatigue test process of a full size orthotropic steel bridge deck with dimension 12.54x2.99x0.6 (LxWxH) meters is studied. Initially, the objective of this test is pretty straight forward, i.e. to find out all fatigue cracks with visual inspection and their corresponding fatigue cycles

when the test is done. However, it was soon realized that this is not a simple task as the structure is too big and it would be not possible to identify real initial crack with its location and actual fatigue cycles with visual inspection. Therefore, AE technology is introduced in the test, it tries to identify in what fatigue cycle that a crack is initiated? How earlier that a crack can be detected by AE than by visual inspection? Can AE locate the crack sources? What is the behavior of crack growth during the fatigue process? Where are the tangible crack locations in the orthotropic steel bridge deck etc.. Experimental results have shown that AE is a very effective tool for monitoring the dynamic process of fatigue crack growth of larger structures.

2. Cracking monitoring with acoustic emission

AE is a phenomenon of rapid energy release of stress concentration in the material. Cracking is associated with stress relief and therefore generation of burst AE signal. AE does not depend on the length and width of the existing crack, but on if the crack is actively opening or growing, no AE exists if there is no active cracking. As such, AE can be effectively used for monitoring crack growth processes.

The frequency range of crack induced AE is usually in between 20 – 1000 KHz which is above the frequency range of auditable sound range. The detectable fracture related AE signal level varies considerably in accordance with materials and cracking status. In a very quiet lab environment, AE induced by material crystal dislocation can be detected with a signal level in 20 dB. On the other hand, AE can also be detected in macro fracture or sudden break of a structure with a signal level in 120 dB with the same AE system without gain adjustment. Figure 1 depicts an active cracking process with AE monitoring. When a crack is growing microscopically or macroscopically, burst type AE is generated at the crack tip with acoustic wave energy travels along the structure with a velocity that is inherent with particular type of material. AE sensors installed in surrounding areas would pick up the acoustic wave energy in a time order depending on the distance between the crack source to the sensors. AE system does the data acquisition and signal processing with filtering, AE feature extraction, crack identification and source location to determine if a crack is in active growing and where is the crack located.

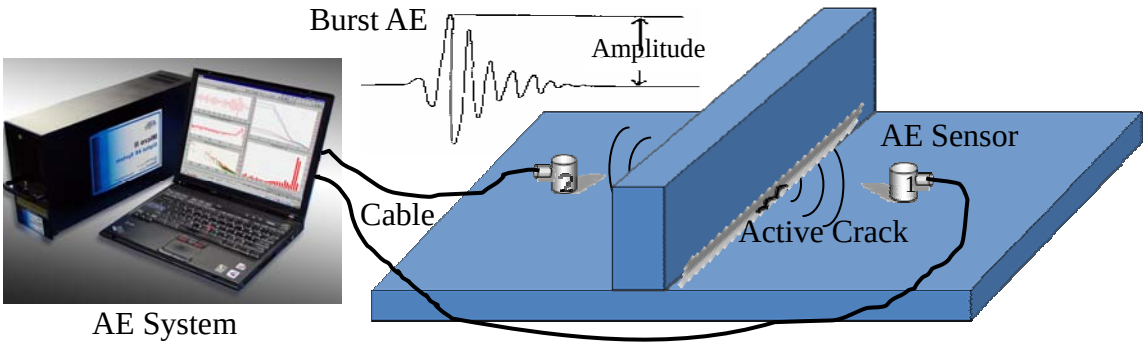

Figure 1. Illustration of active crack monitoring with AE

3. Setup of fatigue test of orthotropic steel bridge deck and AE monitoring

A fatigue test and AE monitoring were conducted on a segment model f a full size orthotropic steel bridge deck. A sketch drawing of the tested model is shown in Figure 2. The dimension of the deck model is 12.54x2.99x0.6 (LxWxH) meter, it consists of 5 U ribs and 4 webs. The deck was alternatively loaded with two actuators at 1 Hz fatigue cycle. The locations of the two actuators are indicated in Figure 2. The intersection areas of the U ribs and the first two webs were monitored with AE. Figure 3 shows photos of the orthotropic steel bridge deck and AE sensors installed. 150 KHz integral preamplifier AE sensors R15I made by Physical Acoustics Corporation were installed on the U ribs in front of the first two webs.

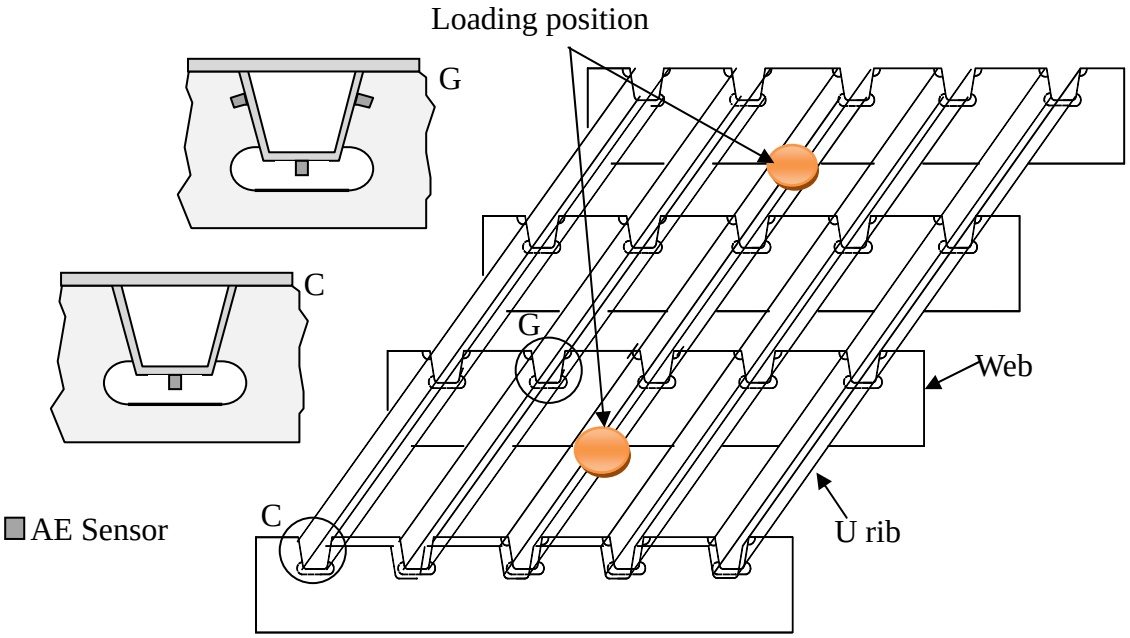

Figure 2. Drawing of the orthotropic steel bridge deck and actuator locations

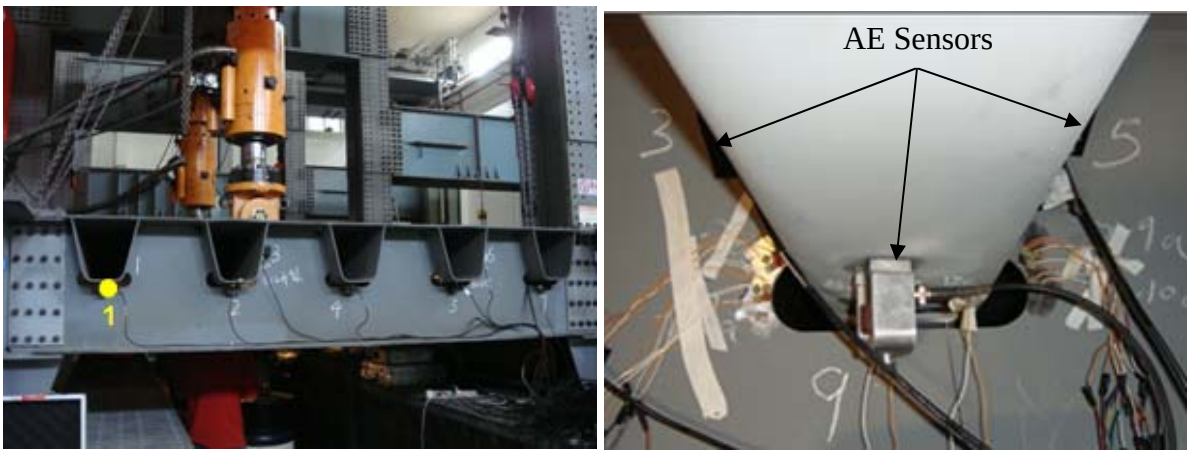

(a) Photo of an orthotropic steel bridge deck (b) Area monitored with 3 AE sensors

Figure 3. Fatigue test and AE monitoring photos

Figure 1 also shows illustrations of sensor installations with one AE sensor and three AE sensors. In the latter case, one sensor is installed at the bottom of the U rib, two more sensors were installed at the left and right side of the U rib respectively to perform crack source location. A 16 channel smart AE monitoring system MicroII made by Physical Acoustics Corporation was used for continuous monitoring of the fatigue test process. The fatigue test lasted for 30 days, the AE sensors were not installed until 7 days or 504 thousands load cycles of the fatigue test.

4. Behavior of acoustic emission in fatigue crack development

During the 30 day fatigue test, visual inspections on the deck were conducted from time to time in each day in order to find out if there is crack initiation or crack growing. Specifically, the visual inspection is focused on

a). areas that AE has indicated crack activity so that to find out if the observed crack matches with the AE indication;
b). if there is a crack in somewhere that AE hasn't picked it up before it is visualized.

In the end of the 30 day fatigue test, the orthotropic steel bridge deck was thoroughly inspected and cracks were found in 12 locations. Among them, 10 of the locations are at the intersections of the U ribs and the lateral webs where AE sensors were installed. 2 of the locations are not in the web area, but in the middle of two webs with crack direction along with the rib length. At all 10 locations where the AE sensors were installed nearby, crack initiations were found by AE well before the visual inspection. However, since there was no AE sensors installed in middle of the webs, the 2 cracks located in the midway of the U ribs were not found by AE because the AE sensors were too far from the crack positions so that the AE signal was greatly attenuated before it reaches to the AE sensor.

In order to illustrate how AE behaviors during crack initiation and development, the AE data in the two of the seven crack locations where AE sensors were installed were analyzed here. The two crack positions are labeled as C and G as shown in Figure 2.

4.1 Case study 1: AE activities at position C

Take the position C as the first example, the elapsed time and the fatigue cycles along with AE monitoring and visual inspection results at location C are shown in Table 1. As is seen in the table, crack initiation was observed about 142.3 fatigue hours or 513 thousand fatigues cycles by the AE. The crack was not visually found until 182.6 fatigue hours or 657.5 thousand fatigue cycles when a 20 mm crack was observed. So, in this example, the AE was able to report the crack initiation in about 40 hours before visual inspection.

On the other hand, the crack initiation and development process can be clearly identified from a time history graph of AE hit activity as shown in Figure 4(a). In this figure, the vertical axis

is the AE hit rate per second, the horizontal axis is the fatigue testing time from 139.9 to 160.2 elapsed fatigue hours. Crack was initiated in about 513 thousand fatigue cycles or 142.3 hours after the fatigue test started, then the AE activity keeps relatively quite which implies that the crack was rest for a while after initiation. In about 6 hours later or 535 thousand overall fatigue cycles, significant crack activity or crack growth that was lasting for about 4 hours was observed. The AE amplitude in this period is shown in Figure 4(b), each dot in the figure represents the amplitude of each AE hit. Trending of the AE amplitudes around 40 dB is clearly seen in the figure, this indicates continuous crack growth in this period though occasionally the amplitude drops below 35 dB. By further zooming the instant signal around 12:00 am of August 3rd in Figure 4(b), the AE amplitudes in less than one minute span are shown in Figure 4(c). The amplitudes are scattered in fairly regular interval which coincides to the fatigue cycle, i.e. one per second. In other words, there is one AE hit or one crack event in every fatigue cycle in this period.

Table 1. Remarks of crack monitoring alone with elapsed fatigue time & cycles at location C

Date	Time of the Day	Elapsed Time (Hours)	Fatigue Cycles (Thousands)	Remarks
2/Aug	14:07	139.9	504	AE monitoring started.
	16:32	142.3	513	AE activity that indicates crack initiation was observed in the first time.
	20:17	146.1	526	AE activity lasting for about 10 minutes was observed.
	22:42	148.5	535	Significant AE activity that indicates continuous fatigue crack development in about 4 hours was observed in the AE.
3/Aug	08:30	158.3	570	**Visual inspection didn't find crack.**
	14:24	164.2	592	**Visual inspection didn't find crack.**
	16:05	165.9	598	Stepwise AE activity that indicates crack growing and resting was observed.
4/Aug	05:50	179.6	647	Long lasted AE activities were observed.
	08:50	182.6	658	**Visual inspection found crack with 20mm long, in 40 hours later than that AE reported crack initiation.**

Besides the continuous cracking activity observed, a stepwise cracking activity was also observed in location C. Figure 5 shows the AE amplitude in about 598 thousand fatigue cycles or 165.9 elapsed fatigue hours. Not only the amplitude shows an increasing trend, but also the amplitude drops down to a lower level and then it increases again. This phenomenon implies crack growing and stress relief during the fatigue process. When micro cracking is build up, the AE amplitude is increased until the stress concentration is big enough to

generate macro cracking which results in stress relief and therefore decrease of the AE amplitude. Then the micro cracking would rebuild up again so that stepwise AE amplitude is observed. Obviously, the micro cracking or stress concentration build up didn't show regular trend, occasionally, sometimes it builds up quickly, sometimes it takes a long resting time before micro cracking is rebuild up again.

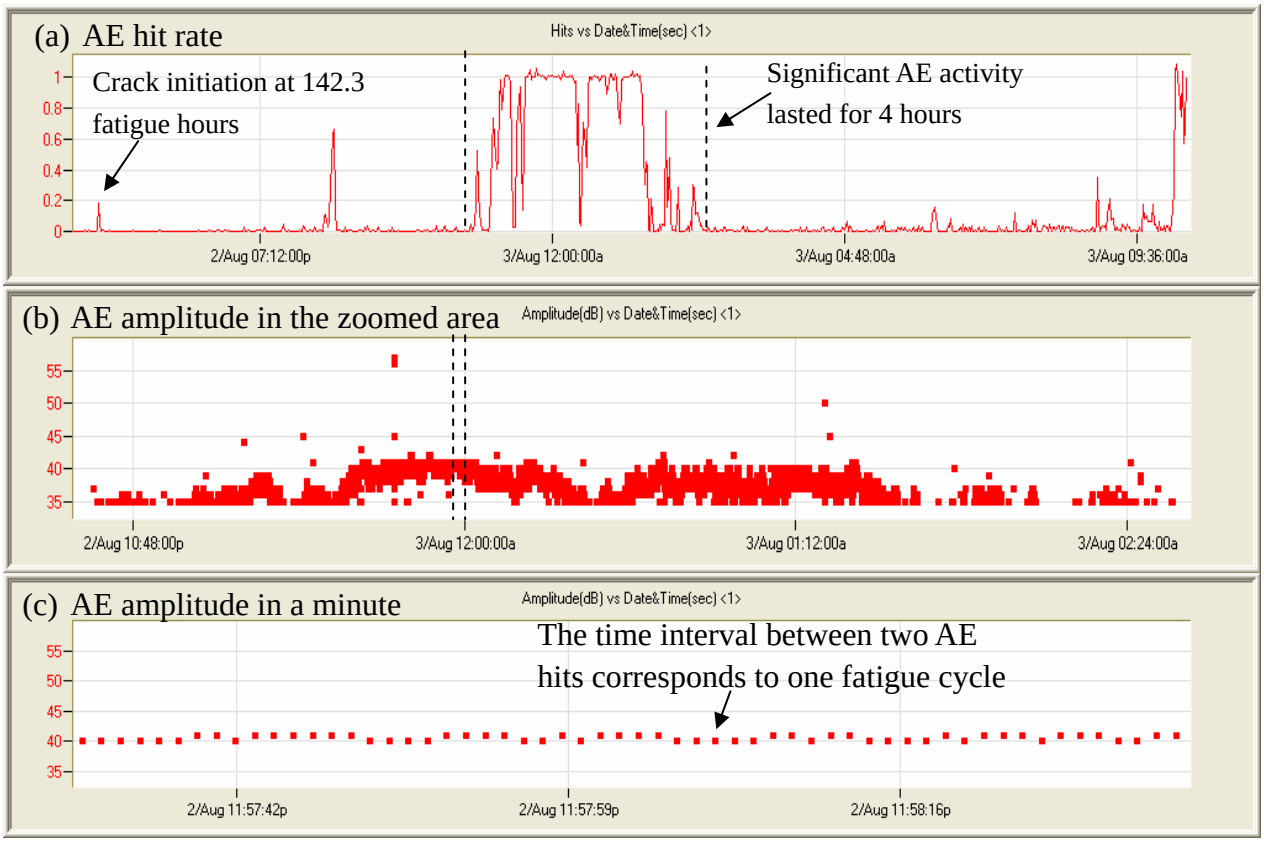

Figure 4. AE hit rate and amplitude at location C from 139.9 elapsed fatigue hours

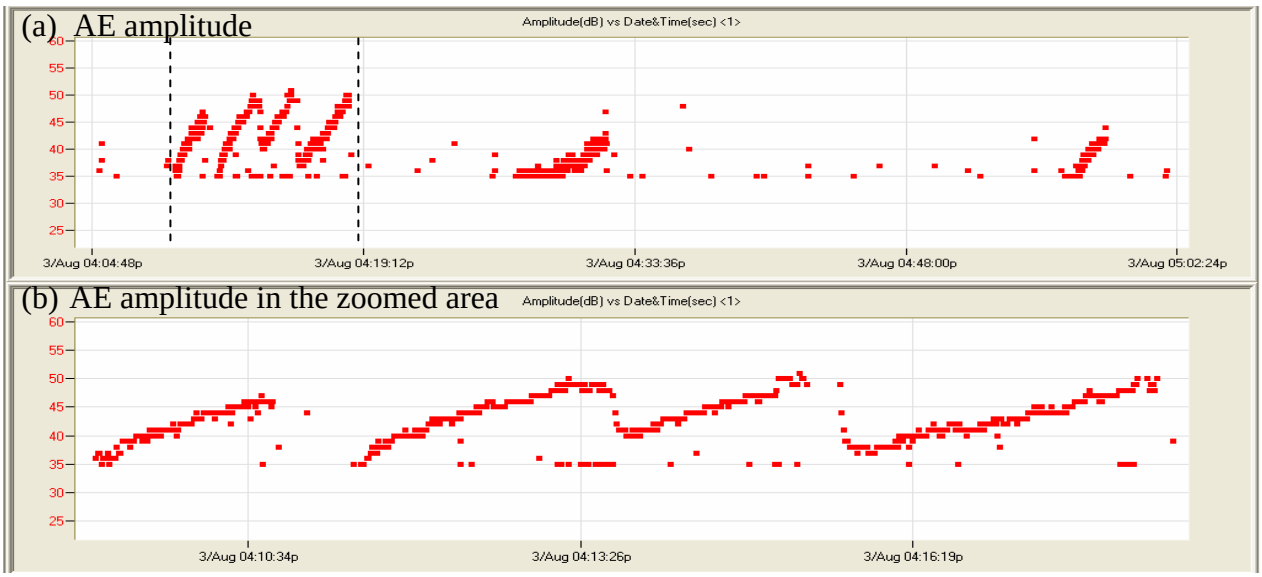

Figure 5. AE hit amplitude versus testing time that shows stepwise crack growth.

4.2 Case study 2: AE activities at position G

The second example is for the crack monitoring of position G of Figure 2. The elapsed time and the fatigue cycles along with AE monitoring and visual inspection results at this position are shown in Table 2. Figure 6 shows the AE hit rate from 139.9 to 237.8 elapsed fatigue hours. AE activity or crack initiation started from 148.4 elapsed fatigue hours or 534 thousand fatigue cycles, then continuous AE activities lasting for over 12 hours were observed, there is also long resting period that no or very rare AE activity was observed after the crack initiation. Since three sensors, numbered as 1, 8 and 2, were installed in position G, crack locations are able to be picked up with the linear location algorithm applied to the AE hits detected by the three sensors. Figure 7(a) shows a distribution of the located crack events along with the linear coordinate of the sensors, it shows two clustered location groups around the sensor 8, one is in between sensors 1 and 8 and another one is in between sensors 8 and 2. These two clustered location groups indicate that two cracks exist in these two areas. However, as is seen in Table 2, visual inspection couldn't find cracks in the following 21 days which it challenged the findings of the acoustic emission.

Table 2. Remarks of crack monitoring alone with elapsed fatigue time & cycles at location G

Date	Time of the Day	Elapsed Time (Hours)	Fatigue Cycles (Thousands)	Remarks
2/Aug	16:07	139.9	504	AE monitoring started.
	22:35	148.4	534	AE activity that indicates crack initiation was observed in the first time.
3/Aug	9:30	159.3	574	Visual inspection didn't find crack.
	13:47	163.6	589	Visual inspection didn't find crack.
4/Aug	8:50	182.6	658	Visual inspection didn't find crack. AE activity was relatively quiet in this period.
5/Aug	8:45	206.5	744	Visual inspection didn't find crack. Significant AE activities with locations were observed in next few days which indicate long lasted continuous fatigue crack development.
	13:07	210.9	760	Visual inspection didn't find crack.
6 – 23 /Aug				AE kept indicating crack activities, but no crack was found with visual inspection at this location in this period.
24/Aug	9:00	662.8	2880	After applying higher load and faster fatigue frequency up to 2 Hz, visual inspection eventually found two cracks in 220mm and 15 mm long respectively.

With continued fatigue cycles, although AE kept indicating crack activities, no crack was found at this monitoring area for over 21 days after the crack initiation was detected with AE.

Before finishing the 30 day fatigue test, accelerated fatigue test parameters, e.g. higher load and faster fatigue test frequency up to 2 Hz, were applied to the structure to speed up the damage process. Then two cracks were eventually visualized in about 22 days after AE detected crack initiation. A photo of the crack location after the overall 30 day fatigue test is shown in Figure 7(b), one crack in 220mm long is located at the web in between sensors 1 and 8, another crack in 15mm long is located along with the weld of the rib in between sensors 8 and 2, these two cracks are located at the same positions that AE technology has reported in about 22 days ago. This illustrates that either the microscopic initial crack was too small to be visualized or the crack was not in the surface of the visible area in early stage of fatigue crack growth. However, AE not only detected the crack initiation and growing process, but also it located crack positions in so many days before visual inspection found the cracks. The visual inspection results eventually proved the effectiveness of the AE technology for dynamic monitoring of fatigue crack process of large structures.

(c) Sketch drawing of crack location

Figure 7. AE crack event location and indications of the cracks found

5. Conclusions

This paper has applied acoustic emission technology for monitoring the dynamic process of fatigue crack initiation and growing of a full size orthotropic steel bridge deck. Experimental results have proven:

1). AE is an effective technology for structure health monitoring, specially AE can monitor the whole dynamic development process from crack initiation and growth to structure fracture. Not only AE can tell when a crack is initiated, but also it can tell where the crack is located and how it develops.

2). AE has much higher sensitivity for active crack identification than any other NDT technologies. It can detect microscopic crack activity and is able to report crack initiation in hours or days in advance of visual inspection and other technologies. This actually draws another inference, i.e. a fatigue test may not be able to find correct material life cycle without using AE for crack detection.

3). In the experiment, it was found that the cracks of the tested deck are not necessarily found in welds, but also it existed in other weak locations of the structure material.

Abstract In previous study, it was demonstrated that smart stress-memory patch and ACM (Atmospheric Corrosion Monitor) sensor are suitable and effective for fatigue and corrosion monitoring, respectively. However, some problems still exist on the smart patch and ACM sensor. First, although "sputtered smart patch", which can estimate crack length wirelessly, has been developed, the crack length could not be estimated accurately sometimes because the resistance of the metal film on it was unstable. Second, it has not been figured out whether the existing patch is applicable to some fatigue condition such as the landing gears of the airplanes. Third, until now the wireless monitoring by ACM sensor has not been developed, and the communication distance of smart stress-memory patch via RFID tag (30 mm) is not sufficient. Therefore, in this research, 1) the measurement accuracy of the ion-sputtered metal film was improved through FEM; 2) whether the existing smart patch is applicable to high-stress low-cycle fatigue environment or not has been figured out; 3) a new wireless device equipped with ZigBee has been developed. By using this device, the wireless monitoring by ACM sensor was realized and the communication distance has been improved to more than 30 m.

Keywords Structural health monitoring, Fatigue, Corrosion, Wireless, Smart stress-memory patch

1. Introduction

Many construction accidents, which are due to the degradation progress, occur to structures, such as bridges, ships, trains, aircraft, power plants and buildings every year. Since these failure accidents brought much risk to our daily lives and industry production, it is important to prevent them in advance. Moreover, it has been well known that fatigue and corrosion are fate factors of such failure. Thus, a sensor which is able to monitor fatigue and corrosion effectively at the same time for a long-term performance is desired. In previous study, it was demonstrated that smart stress-memory patch and ACM (Atmospheric Corrosion Monitor) sensor are suitable and effective for fatigue and corrosion monitoring respectively.

Smart stress-memory patch (hereinafter called "smart patch") is consists of a thin copper specimen with a pre-crack can estimate fatigue damage parameters such as number of cycles, stress amplitude of structures[1-5], which can be estimated from the fatigue crack growth of smart patch fixed on the structure by using two smart patches with different characteristics. Moreover, "sputtered smart patch", which has ion-sputtered metal film and insulating layer on smart patch as a thin crack gage, can estimate crack length by measuring electrical resistance change of the ion-sputtered metal film wirelessly via RFID tag.[6] However, some problems still exist for this application. First, the crack length could not be estimated accurately because sometimes the resistance of the ion-sputtered metal film was unstable and did not increase monotonically as the crack length increased. Second, the communication distance of smart patches via RFID tags only (30 mm) is not sufficient for wireless network system. Third, to prevent the fatigue failure of the landing gears of the airplanes, a sensor which is applicable for high-stress low-cycle fatigue environment is also necessary. It has not been figured out whether the existing smart patch is applicable to such fatigue condition or not.

For corrosion monitoring, ACM sensor consisting of a Fe-Ag galvanic couple was developed and

applied for the evaluation of corrosion of atmospheric environments for long-term performance. By analyzing the magnitude and time variation of the sensor output, I, the occurrence and duration of rain, dew and dry periods, T_{rain}, T_{dew} and T_{dry}, could be distinguished and determined, respectively. And by referencing to the calibrating curve between output of ACM sensor (I) and relative humidity (RH) - empirical I-RH calibrating curve, the amount of deposited sea salt could also be estimated.[7] However, because ACM sensor was powered by battery, AC power or solar battery and the output data of ACM sensor was recorded by a microcomputer, the setting-up places has been restricted and the data collecting costs time and labor. Thus, it is necessary to develop a wireless monitoring method for ACM sensor which can be used for long-term performance as well as smart patch.

In this study, (1) the measurement accuracy of the ion-sputtered metal film on "sputtered smart patch" was improved by changing the shape of the ion-sputtered metal film through FEM; (2) a new wireless device was developed to improve the communication distance between smart patches; (3) fatigue experiments have been executed to figure out whether the existing smart patch is applicable to high-stress low-cycle fatigue environment or not; (4) the wireless monitoring by ACM sensor was realized by using the new wireless device as well as smart patch.

2. Principle

2.1. Estimation of cyclic number and stress amplitude by RFID-based smart patch

A schematic image of the sputtered smart patch is shown in Figure 1. This sensor is composed of an ion-sputtered metal film deposited on the smart patch (a thin copper specimen with a pre-crack).

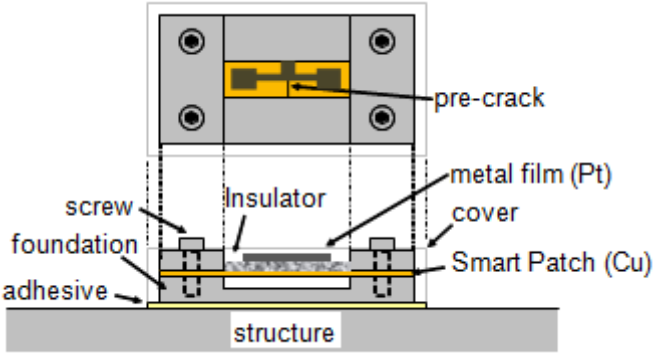

Figure 1. Schematic image of the sputtered smart patch. [6]

The details of the principle of smart patch is described in the previous paper.[1] The cyclic number (N) and stress amplitude ($\Delta\sigma$) of structures can be estimated from the crack length values detected from the two smart patches with different characteristics using the following equations:

$$\Delta\sigma = [C_2 \cdot C_1^{-1} \cdot W_1 \cdot W_2^{-1} \cdot (\pi W_2)^{-m_2/2} \cdot (\pi W_1)^{-m_1/2} \int_{\alpha_0}^{\alpha_1} \{\sqrt{\alpha} f(\alpha)\}^{-m_1} d\alpha \Big/ \int_{\alpha_0}^{\alpha_2} \{\sqrt{\alpha} f(\alpha)\}^{-m_2} d\alpha]^{1/(m_1-m_2)} \quad \cdots\cdots(1)$$

$$N = [C_2^{m_1} \cdot C_1^{-m_2} \cdot W_1^{m_2} \cdot W_2^{-m_1} \cdot (W_2/W_1)^{m_1 m_2/2} \{\int_{\alpha_0}^{\alpha_1} \{\sqrt{\alpha} f(\alpha)\}^{-m_1} d\alpha\}^{m_2} \Big/ \int_{\alpha_0}^{\alpha_2} \{\sqrt{\alpha} f(\alpha)\}^{-m_2} d\alpha\}^{m_1}]^{1/(m_2-m_1)} \quad \cdots\cdots(2)$$

where W is the width of specimen, α_0 is the normalized initial crack length, α is the normalized

initial crack length, C and m are empirical constants of Paris law and $f(\alpha)$ is the shape factor of the stress intensity factor. Indexes 1 and 2 represent smart patch 1 and 2, respectively. By substituting the normalized crack lengths α_1 and α_2 detected from two smart patches into Eqs. (1) and (2), the cyclic number and the stress amplitude can be estimated as shown in Figure 2. Furthermore, fatigue life will be assessed by substituting the estimated cyclic number and stress amplitude into Miner's rule.[8]

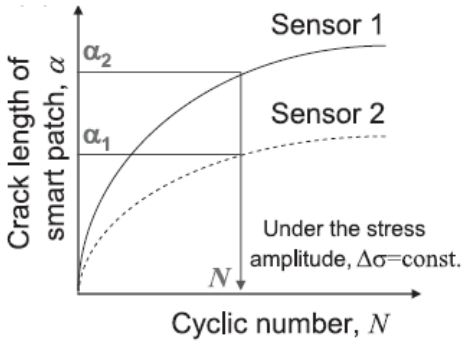

Figure 2. Principle of estimation of cyclic number from crack lengths in two smart patches.[6]

2.2. Estimation of corrosivity in atmospheric environment by ACM Sensor

An ACM (Atmospheric Corrosion Monitor) type corrosion sensor, consisting of a Fe-Ag galvanic couple was developed and applied for the evaluation of corrosivity of atmospheric environments. The sensor was designed considering mass-production and good reproducibility of results, making it convenient for long-term corrosion data acquisition. Besides the sensor output, I, temperature, relative humidity (RH) were also recorded by a microcomputer. By analyzing the magnitude and time variation of I, the occurrence and duration of rain, dew and dry periods, T_{rain}, T_{dew} and T_{dry}, could be distinguished and determined, respectively. And by referencing to the empirical I-RH calibrating curve, the amount of deposited sea salt, Ws, could also be estimated. It was also found that the corrosion loss could be estimated in both indoor and outdoor sites by analyzing sensor output. Corrosivities of some kinds of exposure sites, not only outdoor environments but also indoor environments, were evaluated by using the ACM sensor.

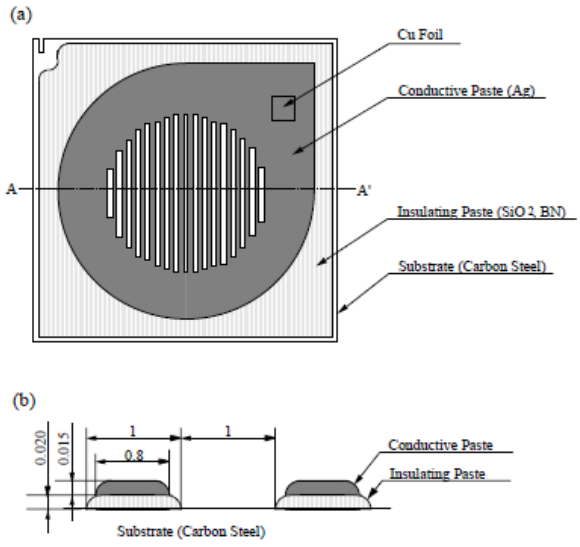

Figure 3. Schematic representation of the sensor.[7]

The sensor is shown schematically in Figure 3. A 0.8 mm thick carbon steel sheet was machined to the size of 64 mm x 64 mm to work as the substrate. After ultrasonically degreasing the substrate in acetone, an insulating paste with BN filler and epoxy resin, was printed on the substrate with a thickness of 20 μm. A conductive paste with Ag filler and epoxy resin was then printed on top of the insulating layer with a thickness of 15 μm. This conductive paste acted as the cathode, and the exposed area of steel substrate, as the anode.

3. Experiment and Simulation

3.1. FEM model to evaluate the measurement accuracy of the metal film

As showed in Figure 4, the crack length could not be estimated accurately because sometimes the resistance of the existing ion-sputtered metal film was unstable and did not increase monotonically as the crack length increased.

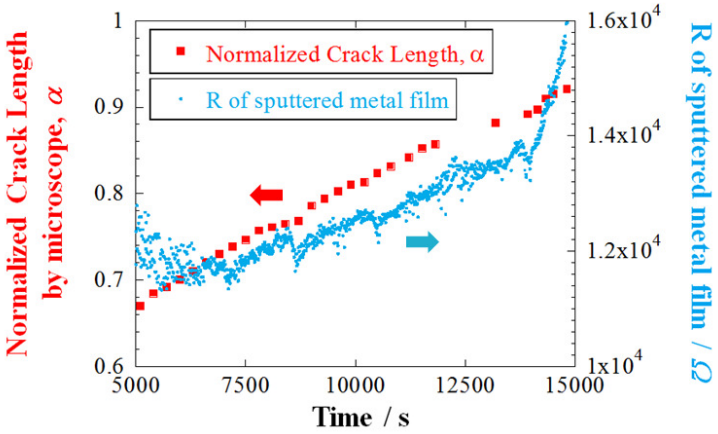

Figure 4. The correlation between normalized crack length observed by microscope and the resistance of sputtered metal film measured by digital multimeter (DMM).

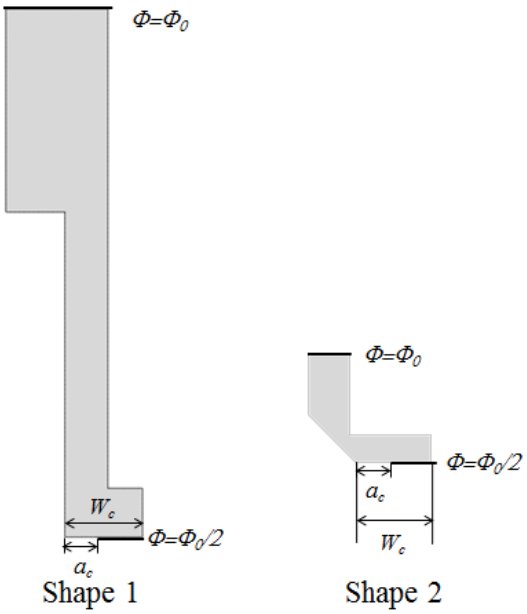

Figure 5. Definition of a_c and W_c in the ion-sputtered metal film, and the boundary condition on FEM.[6]

In order to figure out the optimum shape of the conductive film, electrical potential analysis by FEM was performed by changing the crack length a_c=0 to 1.9 mm under the fixed voltage. Because

the shape of the ion-sputtered film is always laterally zygomorphic, it is suitable to calculate the electric current by adding half of the voltage to half shape of the film. The definition of a_c and W_c (W_c=1.9 mm) of the ion-sputtered film and the boundary condition for FEM are shown in Figure 5. The electric current of metal film was calculated by the integration of current density in analytical results, and the resistance was derived from Ohm's law.

3.2. Wireless Communication

3.2.1 . Using RFID tag

RFID (Radio Frequency Identification) is a technology that transmits information between a reader and tags attached to an object using electromagnetic induction for the purpose of identification. It is widely used as IC tag or IC card. The RFID system is well known for its benefits of low cost, simple measurement, easy configuration and so on. Since tag is powered by electromagnetic induction from the reader, tag itself does not need battery for sensing and data transmission. By using RFID tags, evaluating the fatigue damage has been realized in previous research.[5] The schematic of wireless system for measuring crack length using RFID tag is shown in Figure 6.

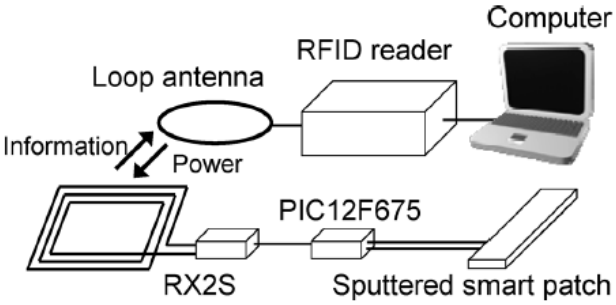

Figure 6. Schematic of wireless system for measuring crack length using RFID tag and reader.[6]

The wireless system composed of sputtered smart patch, RFID tag (RX2S, Yoshikawa RF Systems Co., Ltd.) and microprocessor (PIC12F675, Microchip Technology Inc.), in which the electrical resistance of the ion-sputtered metal film was converted to digital value and transmitted to the RFID reader (RX2100, Yoshikawa RF Systems Co., Ltd.). The RFID reader plays two roles of supplying power to RFID tag and acquiring the measured value from RFID tag by a unique protocol.

3.2.2. Using ZigBee

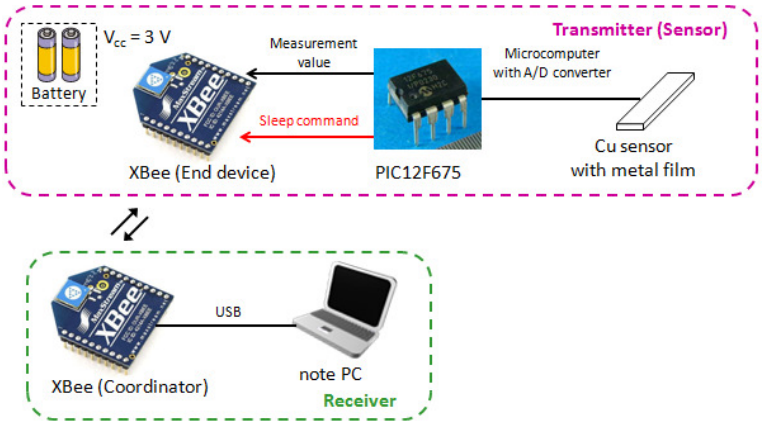

Figure 7. Schematic of new wireless system

To improve the communication distance, a new wireless device equipped with ZigBee (IEEE

802.15.4) was developed. The schematic of new wireless system for measuring crack length using ZigBee is shown in Figure 7. The transmitter contains sputtered smart patch and microprocessor (PIC12F675, Microchip Technology Inc.) as the same as the method.

Moreover, several wireless devices need to transmit with one receiver at the same time, to build the wireless system. The wireless communication among 1 receiver and 4 wireless transmitters has been tested as shown in Figure 8. The distance from transmitters to receiver are 20 m, 30 m, 30 m, 20m, respectively. Moreover, two transmitters were put at about 1 m above the ground, and two were on the ground.

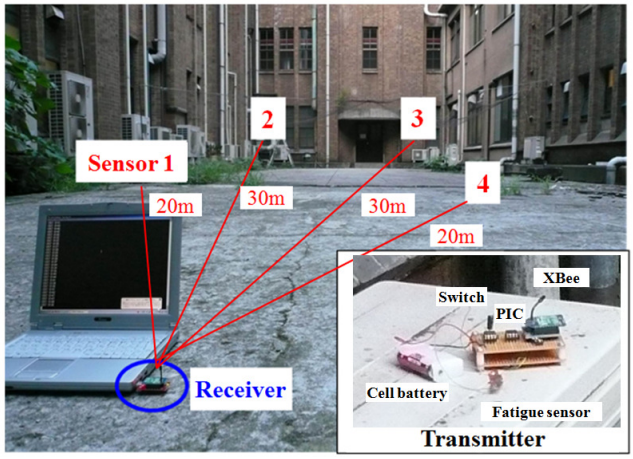

Figure 8. The wireless communication among 1 receiver and 4 new wireless devices and the composition of the new wireless device.

3.3. Fatigue experiment

To figure out whether the existing smart patch is applicable to high-stress low-cycle fatigue environment or not, fatigue experiments have been executed. Smart patch was clamped at both ends on fatigue testing machine with an electro-magnetic actuator (MMT-500N, Shimadzu), and fatigue pre-crack was introduced under maximum strain of 0.002 and strain ratio of 0.5 until total crack length reached about 2.7 mm. Afterwards, fatigue experiments were carried out under constant amplitude strain with maximum strain of 0.004 twice and 0.006 once respectively, strain ratio of 0.5 and frequency of 19 Hz. During fatigue experiments, the crack length of the sputtered smart patch was observed by optical microscope from the ion-sputtered side.

3.4. Wireless monitoring of ACM sensor

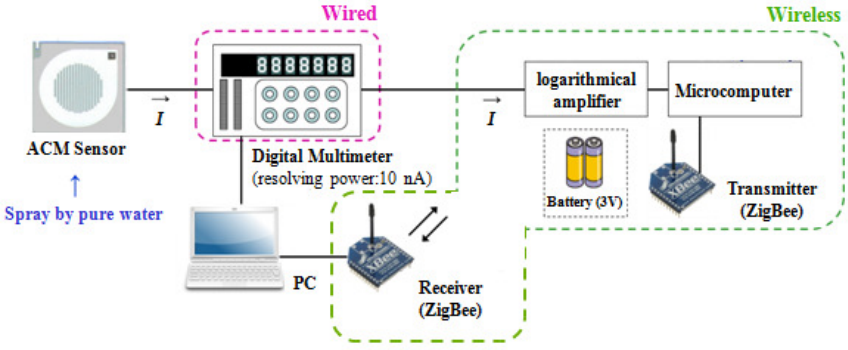

Figure 9. The schematic of the wireless system for ACM sensor

The wireless monitoring by ACM sensor was tested by using new wireless device. Because the output I from ACM sensor is galvanic electric current, and is so small that it is easy to be affected by noises while wireless communication, a wireless device which combines the new wireless device

and logarithmical amplifier (AD8304) was proposed. The schematic of the wireless system for ACM sensor is shown in Figure 9.

The accuracy was evaluated by two measurement systems. One is wired, consisted of digital multimeter. The other one is wireless, consisted of logarithmical amplifier (AD8304), microprocessor (PIC12F675, Microchip Technology Inc.), Battery (3 V), transmitter ZigBee (IEEE 802.15.4) and receiver ZigBee. To imitate different corrosion conditions in the atmosphere (Rain, Dew, Dry), pure water was sprayed to ACM sensor by different times.

4. Results and Discussion

4.1. Evaluation of the measurement accuracy of the metal film by FEM

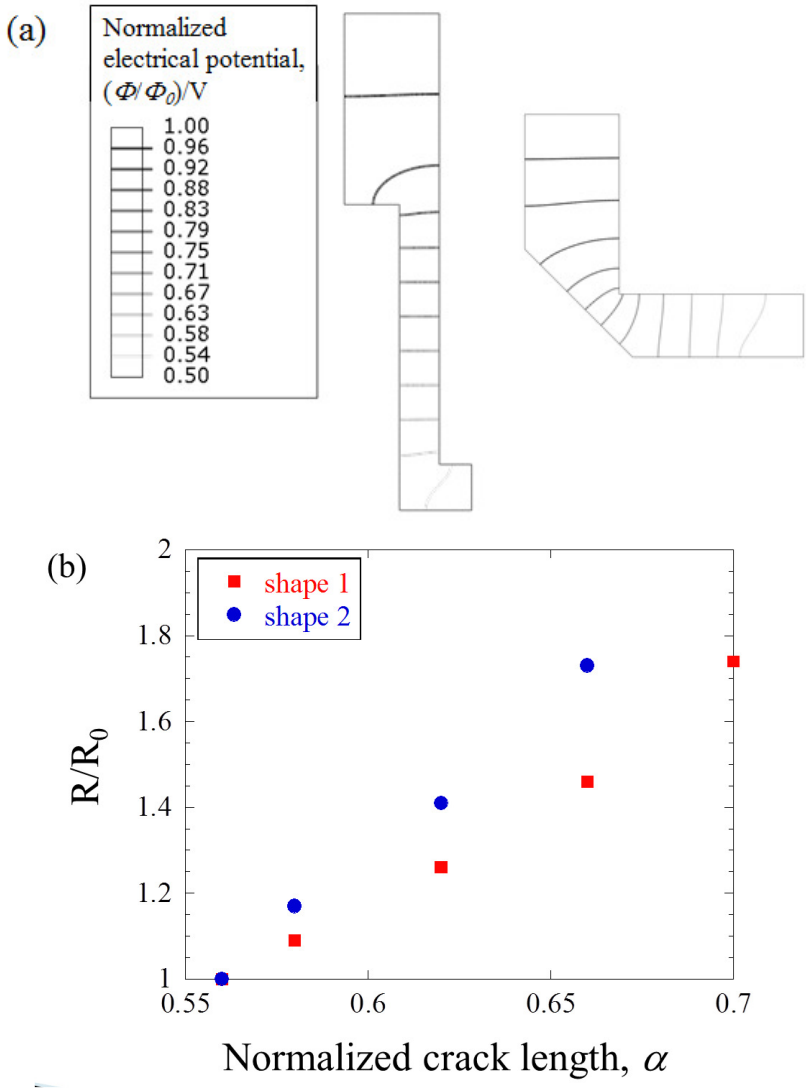

Figure 10. (a) Electrical potential distributions in the ion-sputtered metal film calculated by FEM (a_c=1.3 mm); (b) Relationship between the normalized crack length in sputtered smart patch and the normalized resistance of the ion-sputtered metal film through FEM.

The examples of analytical results about the normalized electrical potential (Φ/Φ_0) distribution are shown in Fig. 10 (a). The relationship between the normalized crack length in sputtered smart patch and the normalized resistance of the ion-sputtered metal film is shown in Fig.10 (b). By changing the shape of the ion-sputtered metal film from shape 1 to shape 2, the increase amount of

normalized resistance R/R_0 at the beginning of crack growth has been improved to about 1.5 times as the conventional. As a result, it is supposed to be an effective way to solve the unstable phenomenon at the beginning of crack growth shown in Figure. 4.

Therefore, the measurement accuracy of the ion-sputtered metal film on "sputtered smart patch" was improved by changing the shape of the ion-sputtered metal film through FEM. Fatigue experiments will be conducted to verify the effectivity of this shape.

4.2. Wireless communication

4.2.1. Using RFID tag

The conventional wireless measuring system, which composed of the ion-sputtered metal film, AD converter and RFID tag, was successfully applied to measure the crack length of sputtered smart patch during fatigue test. However, the communication distance was only 30 mm, and is not sufficient for wireless network system.

4.2.2. Using ZigBee

By using the new wireless device, the communication distance was improved to more than 20 m. The wireless communication was proved to be possible among 1 receiver and 4 wireless devices. Moreover, within 20 m, the loss rate was almost 0, and more than 30 m, the loss rate was near to 5 percent. It could be expected to build a wireless fatigue monitoring system, which will be applied to the real structure such as bridge and ships, by using these new wireless devices.

4.3. Fatigue experiment

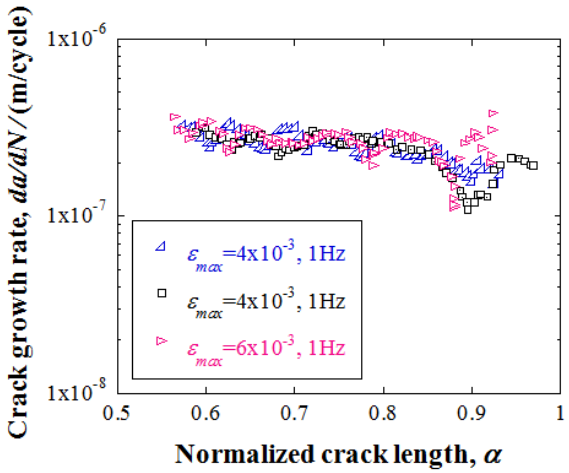

Figure 11. Relationships between the normalized crack length and the crack growth rate

In the high-stress low-cycle fatigue environment, the fatigue crack path of the sensor exhibited a straight line and is possible to measure the crack length easily. Figure 11 shows the relationships between the normalized crack length and the crack growth rate calculated by the incremental polynomial technique under each test condition. Tests performed two times under the same condition (ε_{max}=4x10^{-3}) showed good repeatability. The crack growth rate was almost constant with fatigue cycles in the range of α=0.54 to 0.86, and it decreased slightly before increasing in the range of α>0.86. The crack growth rate did not change a lot even through the maximum strain changed. This tendency is quite different from that of the low-stress fatigue environment. Further research is

needed to figure out the reason for this result.

4.4. Wireless monitoring of ACM sensor

It was possible to make ACM sensor wireless by using the new wireless device and logarithmical amplifier. Figure 12 shows the output of ACM sensor estimated by wireless and wired systems. Both of them show very good coincidence during three periods (Rain, Dew, and Dry). Moreover, by using the logarithmical amplifier, the electricity in the dry period could be distinguished more remarkably than by multimeter. Thus, it was confirmed that the output of ACM sensor can be transmitted wirelessly by the combination of the new wireless device and logarithmical amplifier.

	log *I* (μA)	*I* (μA)
Rain	0.1~1.5	1.3~31.6
Dew	-1.9~-1.2	0.013~0.063
Dry	-2	0.01

Current I of ACM sensor during different periods[9]

Figure 12. The output of ACM sensor estimated by wireless and wired systems

5. Conclusion

In this study, (1) the measurement accuracy of the ion-sputtered metal film on "sputtered smart patch" was improved by changing the shape of the ion-sputtered metal film through FEM. (2) a new wireless device equipped with RFID and ZigBee was developed. By using this device, the communication distance between smart patches was improved to more than 20 m. The wireless communication among 1 receiver and 4 transmitters has been tested and proved to be possible. (3) the existing smart patch was proved to be not applicable to high-stress low-cycle fatigue environment through fatigue experiments because the crack growth rate did not change a lot even through the maximum strain changed, which tendency is quite different from that of the low-stress fatigue environment. Further research is needed to figure out the reason for this result. (4) the wireless monitoring by ACM sensor was realized by combining new wireless device and logarithmical amplifier.

Abstract Smart stress-memory patch is a novel sensing method in structural health monitoring for evaluating fatigue damage. The patch can estimate the number of cycles and stress amplitude using fatigue crack growth properties in Paris region of thin metal sheets. In this study, near-threshold fatigue crack growth behavior in thin pure copper sheet was investigated under strain-controlled testing to improve the measuring range and accuracy. Using a function describing the initiation as well as the stable growth of fatigue cracks, the relationship between stress intensity factor range and crack growth rate was successfully fitted to one equation regardless of strain amplitude. Based on these experimental results, a new equation for estimating fatigue cycles and stress amplitude from fatigue crack length of two specimens was derived. This equation overcame the limitation that the patch requires two or more materials with different fatigue characteristics. The new equation needs only one material for simultaneous estimation of fatigue cycles and stress amplitude, and the measuring range can be controlled by geometry of specimen. Since this patch needs neither power supply nor wiring, it provides a great potential for long-term structural health monitoring with easy maintenance and low cost.

Keywords Fatigue crack growth, Finite element method, Copper, Structural health monitoring, Smart stress-memory patch

1. Introduction

Structural health monitoring (SHM) is highly required to ensure the reliability of bridges, ships, trains, aircraft, power plants and industrial machines. Especially, a long-term sensing method of fatigue damage is very important to avoid the fracture caused by cyclic loading. Strain gauge, FBG (Fiber Bragg Grating) sensor and wireless strain sensing systems are utilized to monitor strain and to evaluate fatigue damage. However, there are several problems on the practical use such as necessity of wiring, electrical power supply and complicated measuring devices. Concept of smart stress-memory patch (hereinafter called "smart patch") was proposed to overcome above problems in the previous papers [1-6]. Sensor in smart patch consists of a thin metal sheet with a pre-crack, and the number of fatigue cycles and stress amplitude on structure can be estimated from fatigue crack growth in the sensor. Smart patch is a promising technique for long-term SHM because it needs neither power supply nor wiring. Furthermore, the patch is successfully applied to batteryless wireless system to measure the crack length in the sensor using RFID [4].

The fatigue crack growth behavior in the sensor under stress-controlled fatigue test has been investigated to estimate stress amplitude and fatigue cycles [1, 2]. However, when the patch is attached to structure, the sensor is subjected to strain-controlled loading under the change in strain of the structure. Therefore, it is necessary to evaluate fatigue behavior in the sensor under strain-controlled conditions for application of smart patch to structure. While most studies about fatigue in thin metal sheet have focused on stress-life (S-N) and strain-life (ε-N) curves for reliability of microelectronic products [7-10], the fatigue crack growth behavior under strain-controlled testing has not been enough explored in detail.

In this study, fatigue crack growth behavior of the sensor (thin pure copper sheet) was evaluated under uniaxial strain-controlled fatigue testing in order to obtain the characteristics of the attached sensor to structure. The scattering in crack growth was also examined by a stochastic model to assess the error in estimation of fatigue cycles and stress amplitude. From these observations, a method to evaluate fatigue cycles and residual fatigue life of structure using smart patch was proposed.

2. Principle of smart stress-memory patch

The details of the principle were described in the previous paper [5]. A schematic image is shown in Fig. 1 (a). Sensor in the patch consists of a thin metal sheet with a pre-crack. Since fatigue damage in structure tends to occur in structural component, more than one sensor is attached, for example, close to the welded part. When the structure is subjected to cyclic loading, the sensor is also cyclically loaded in response to the change of strain in the structure. Then, fatigue crack growth from pre-crack in the sensor will occur according to the cyclic loading. After a certain period, the crack length in each sensor will be measured by optical microscope or wireless measurement of electrical resistance change. The number of fatigue cycles (N) and stress amplitude ($\Delta\sigma$) on the structure can be estimated from the crack length detected from two sensors with different characteristics as shown in Fig. 1 (b).

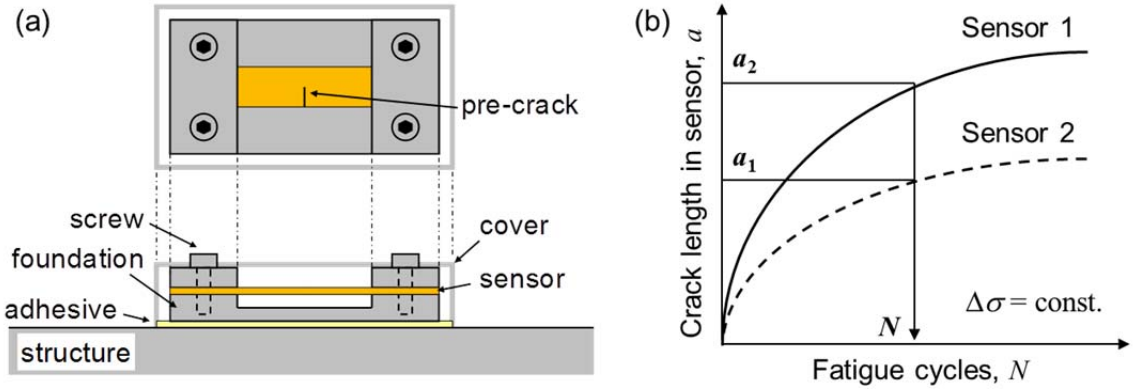

Figure 1. (a) Schematic image of smart stress-memory patch and (b) principle to estimate cyclic number from crack length.

3. Experimental procedure

3.1. Materials

The sensors were made of electrodeposited (ED) copper and nickel. These electrodeposited materials tend to have a very small grain size and provides stable crack propagations [11, 12]. The ED-Cu sheet with a thickness of 0.1 mm was cut to rectangular coupons with a dimension of 40 mm × 5 mm, 40 mm × 10 mm and 60 mm × 10 mm, and the ED-Ni sheet with a thickness of 0.05 mm was cut to 40 mm × 5 mm. Specimen geometries are shown in Fig. 2. A single notch with a length of 2.5 mm and a width of 0.3 mm was induced at the center from one side of the coupon. The notch tip was a round-shaped with a radius of approximately 150 μm. Additionally, the notch tip was sharpened to curvature radius of about 30 μm by the blade (High-stainless 100 μm, Feather Safety Razor Co., Ltd.). One side of the coupon was polished to a mirror finish using 3 μm and 1 μm alumina slurry to observe crack length clearly. Afterward, fatigue pre-crack was introduced.

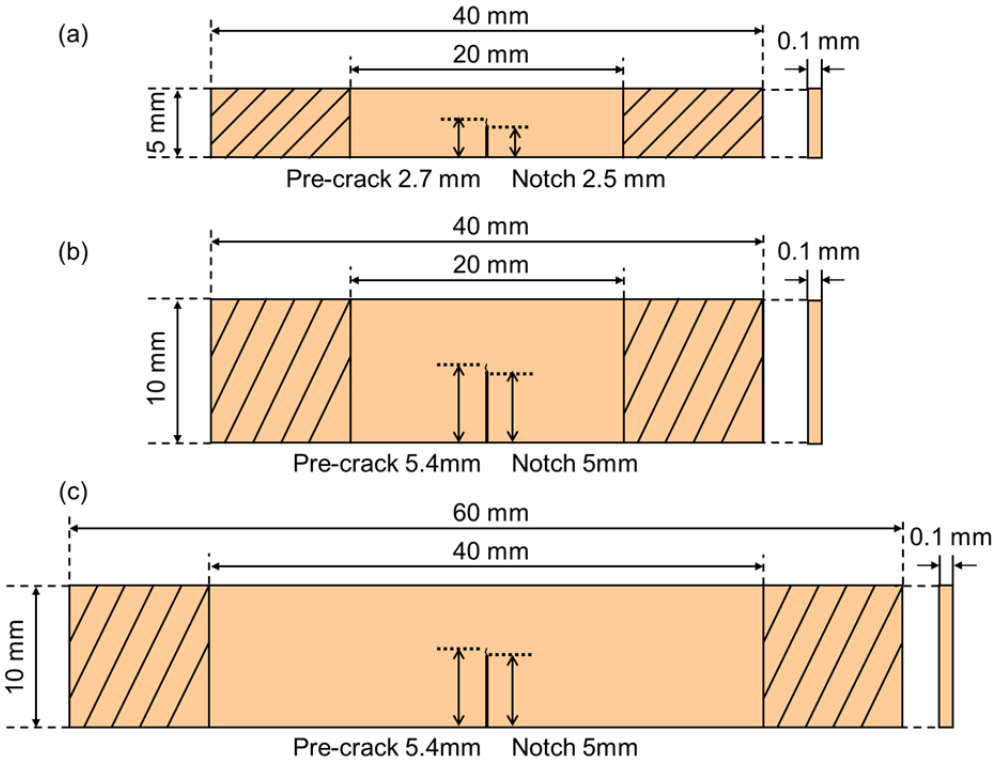

Figure 2. Specimen geometry. (a) Standard type, (b) High-cycle type, (c) High-sensitive type.

3.2. Fatigue test

Both ends of the sensor were clamped in jigs mounted in a fatigue testing machine (MMT-100N, Shimadzu), and the gauge length between the upper and lower jigs is adjusted to 20 mm. Fatigue tests were performed under maximum crosshead displacement (u_{max}) of 20, 25 and 30 μm, displacement ratio of R = 0.1 to 0.5, and frequency of 19 Hz. The strain ratio (R) was 0.1 and maximum strain (ε_{max}) was changed from 0.05 to 0.2 % where the strain is defined as a crosshead displacement divided by gauge length of specimen. The crack length was measured optically with digital microscope (VHX-600, Keyence).

3.3 Stress intensity factor

A proper shape factor, $f(\alpha)$, for the present sensor geometry is necessary to characterize the fatigue crack growth behavior as a function of stress intensity factor range, ΔK. It is commonly known that the stress intensity factor of single edge-cracked tension specimen with prescribed end displacements can be expressed by

$$K = \sigma\sqrt{\pi a}\cdot f(\alpha,\beta),\quad \sigma = \frac{Eu}{L},\quad \alpha = \frac{a}{W},\quad \beta = \frac{L}{W}, \tag{1}$$

where W is width of the specimen, L is gauge length of the specimen, a is crack length, E is Young's modulus, u is displacement on the specimen, α is normalized crack length and β is ratio of the gauge length to the width. Although the shape factor has been investigated in the range of β = 0.5 to 1 [13], the present sensor has the higher value of β = 2.0 to 4.0.

In order to evaluate shape factor of the sensor, linear elastic stress analysis was performed by finite element method (FEM). Geometry and boundary conditions for the simulation are shown in Fig. 3 (a), where Young's modulus was 120 GPa, Poisson ratio was 0.34 and L, W and u was changed as the same as experimental conditions. The model was sectioned into quadrilateral plane stress elements

with size of 0.05 mm × 0.05 mm. In the analysis, ten integration paths were defined from the crack tip to the outside, and the *J*-integral was calculated for normalized crack length ($\alpha = a/W$) ranging from 0.1 to 0.9. Since the *J*-integral reached a constant value from the fifth path in each condition, the constant value was used for calculation of stress intensity factor. Under plane stress conditions, the stress intensity factor can be described by

$$J = K^2/E, \tag{2}$$

and the shape factor was solved using eq. (1) and (2) as a function of stress intensity factor range, as shown in Fig. 3(b). The shape factors can be fitted as follows:

$$f(\alpha) = 1.002 - 0.040\alpha - 1.52\alpha^2 + 1.09\alpha^3 \quad (\beta = 2), \tag{3}$$

$$f(\alpha) = 0.896 - 1.43\alpha - 2.71\alpha^2 + 1.02\alpha^3 \quad (\beta = 4), \tag{4}$$

The calculated shape factor of β = 0.5 to 1 showed good agreement with the results by boundary element method (BEM) [13].

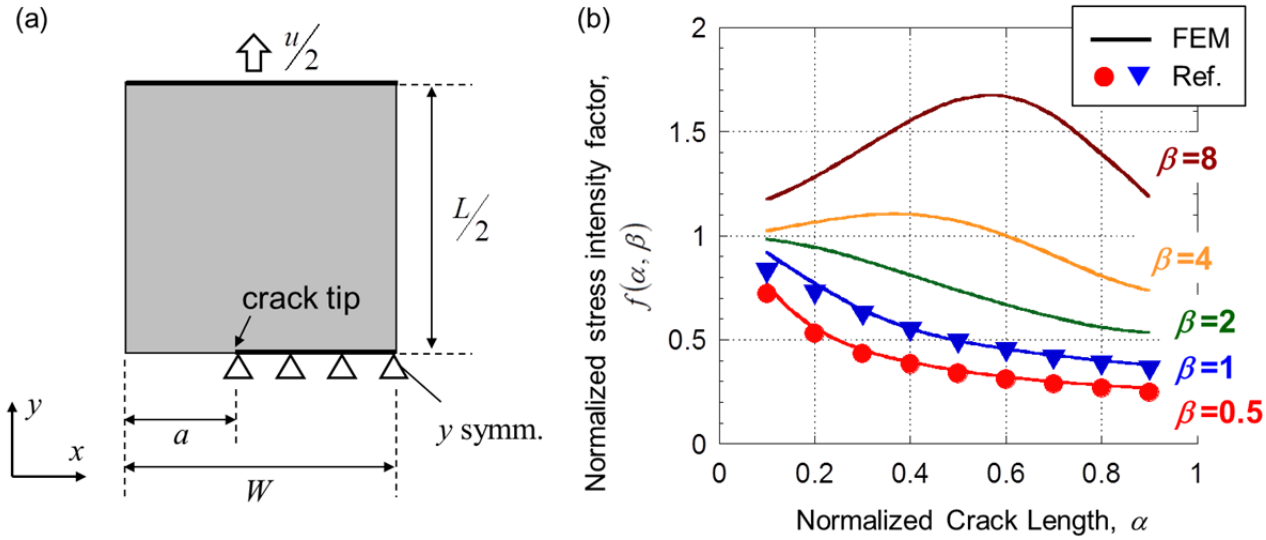

Figure 3. (a) Rectangular plate with prescribed end displacement, (b) Normalized stress intensity factor under plane stress condition.

4. Results

4.1. Fatigue crack growth behavior of ED-Cu

Near-threshold fatigue crack growth behavior in thin pure copper sheet with pre-crack was evaluated under strain-controlled fatigue testing. Fatigue crack path of the sensor exhibited the significantly straight line as shown in Fig. 4 (a). The relationships between the crack growth rate and stress intensity factor range is shown in Fig. 4 (b). The fit curve was analyzed by the following Kohout equation[14]:

$$\frac{da}{dN} = C\left[\left\{\frac{\Delta K}{(1-R)^{1-\beta_w}}\right\}^m - \Delta K_{th0}^m\right] \tag{5}$$

where, C, m, β_w are material constants and ΔK_{th0} is the threshold value of stress intensity factor range with R = 0. The fit is relatively good and the calculated values of the parameters are $C = 1.16 \times 10^{-11}$, m = 2.87, ΔK_{th0} = 4.41 MPa·m$^{1/2}$, β_w = 0.198.

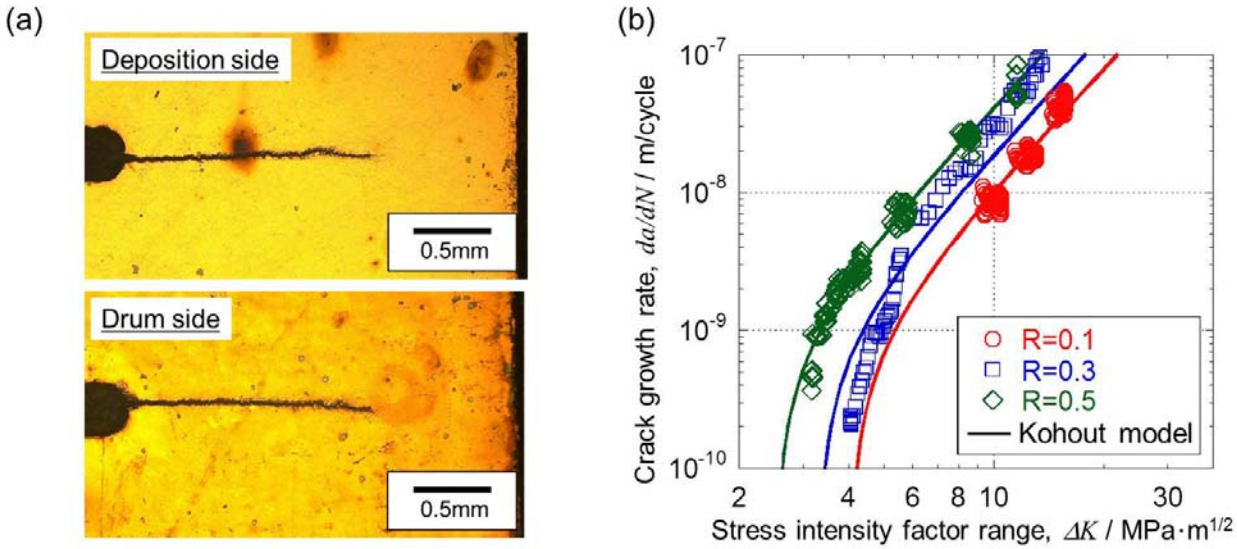

Figure 4. (a) Fatigue crack path of ED-Cu sheet. (b) Relationship between stress intensity factor range calculated from FEM and experimental crack growth rate.

4.2. Fatigue crack growth behavior of ED-Ni

Fatigue tests with ED-Ni were also performed to obtain the sensor characteristics of smart patch. The fatigue crack path observed from the drum side was smooth while the opposite side was relatively rough. The fatigue crack growth behavior of ED-Ni is shown in Fig 5 (b). The experimental results were within Paris region and the effect of strain ration was observed. Therefore, the fit curve was analyzed by the Walker equation:

$$\frac{da}{dN} = C\left[\frac{\Delta K}{(1-R)^{1-\beta_W}}\right]^m \tag{6}$$

The calculated parameters were m =3.26, C =4.54×10^{-12}, β_w =0.556.

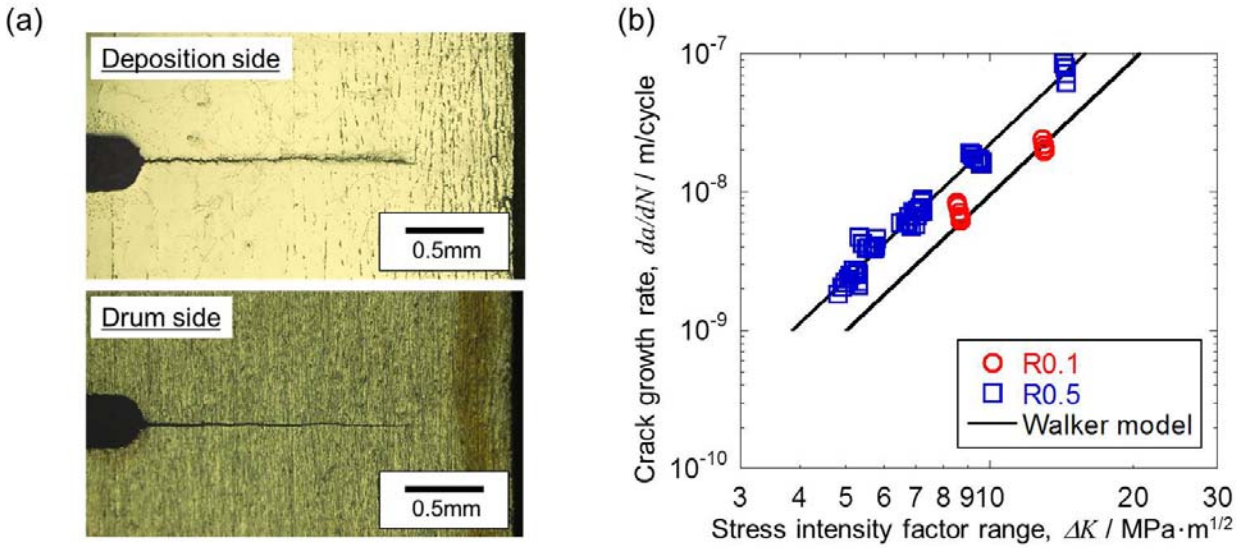

Figure 5. (a) Fatigue crack path of the ED-Ni sheet. (b) Relationship between stress intensity factor range and fatigue crack growth rate in ED-Ni specimen.

4.3. Effect of specimen geometry on fatigue crack growth

Three different specimen geometries were used in the present study. All specimens were made of ED-Cu. The fatigue crack growth rate is shown in Fig. 6 (a). The relationship between stress intensity factor range calculated from FEM and experimental crack growth rate is fitted on one curve regardless of the geometries as shown in Fig. 6 (b).

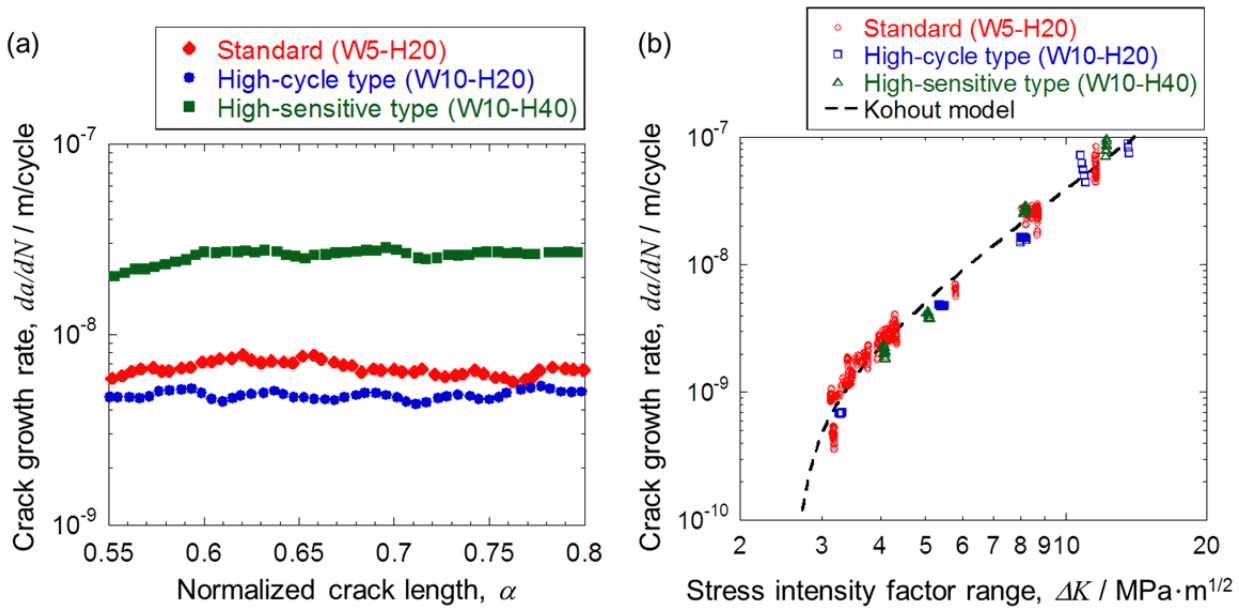

Figure 6. (a) Fatigue crack growth rate of ED-Cu specimens with three geometries. (b) Relationship between stress intensity factor range and fatigue crack growth rate of ED-Cu specimens with three geometries.

5. Discussion

5.1. Fatigue crack growth behavior

Many studies about fatigue behavior in thin metal sheet have shown that fatigue life is associated with the grain structure and specimen thickness using smooth specimen [7-10]. In the present study, fatigue crack propagation experiments were performed with notched specimen under strain-controlled condition. The crack path of the specimen exhibited almost straight line as shown in Fig. 4 (a) and Fig. 5. (a). It allows us to measure the crack length in the sensor easily. Among them, the path observed from the deposition side in ED-Ni was relatively rough due to the development of columnar grains during electrodepositing process. The relationship between stress intensity factor range calculated from FEM and experimental crack growth rate is fitted to one equation regardless of strain amplitude, strain ratio and specimen geometry. Therefore, two specimens made of different materials are needed to apply the principle of smart stress-memory patch. The threshold value of stress intensity factor range was determined by Kohout equation, which is related to the minimum value of detectable stress amplitude.

5.2. Estimation of fatigue damage using two materials

Based on fatigue testing results, a method to evaluate fatigue damage of structure using smart patch will be discussed. When the patch is attached to structure, the sensor is subjected to strain-controlled loading under the change in strain of the structure. A simple model for the attached sensor to structure is depicted in Fig. 7. It is assumed that the far-field stress in the plate is a uniaxial tension ($\sigma_{structure}$) in

elastic region and the sensor is perfectly bonded on the plate. If thickness of the sensor is enough thin, strain distribution in the plate is uniform regardless of the presence of the sensor, and $\sigma_{structure}$ is described as follows:

$$\sigma_{\text{structure}} = E_{\text{strucutre}} \frac{u}{L}, \tag{7}$$

where $E_{\text{strucuture}}$ is Young's modulus of structure, u is the displacement on the sensor and L is gauge length of the sensor, respectively. Using Walker equation, the fatigue cycles, N, is represented as the function of the normalized crack length, α, and the maximum strain, $\varepsilon_{\max}$, as:

$$N = \frac{W_2}{C_2}\left\{E_2\varepsilon_{\max}(1-R)^{\beta_{W2}}\sqrt{\pi W_2}\right\}^{-m_2}\int_{\alpha_{0,2}}^{\alpha_2}\left\{\sqrt{\alpha}f(\alpha)\right\}^{-m2}\mathrm{d}\alpha. \tag{8}$$

Furthermore, when two sensors of different properties are employed, simultaneous equation are given as follows,

$$N = \frac{W}{C_1}\left\{E_1\varepsilon_{\max}(1-R)^{\beta_{W1}}\sqrt{\pi W_1}\right\}^{-m_1}\int_{\alpha_{0,1}}^{\alpha_1}\left\{\sqrt{\alpha}f(\alpha)\right\}^{-m_1}\mathrm{d}\alpha,$$

$$N = \frac{W_2}{C_2}\left\{E_2\varepsilon_{\max}(1-R)^{\beta_{W2}}\sqrt{\pi W_2}\right\}^{-m_2}\int_{\alpha_{0,2}}^{\alpha_2}\left\{\sqrt{\alpha}f(\alpha)\right\}^{-m2}\mathrm{d}\alpha. \tag{9}$$

Indexes 1 and 2 represent sensor 1 and 2, respectively. From these equations, the fatigue cycles and the stress amplitude of structure, $\sigma_{\text{strucuture}}$, are obtained as:

$$N = \left[\frac{{C_2}^{m_1}}{{C_1}^{m_2}}\cdot\frac{{W_1}^{m_2}}{{W_2}^{m_1}}\cdot\left\{(1-R)^{\beta_{W2}-\beta_{W1}}\frac{E_2}{E_1}\sqrt{\frac{W_2}{W_1}}\right\}^{m_1m_2}\cdot\frac{F_1(\alpha_1)}{F_2(\alpha_2)}\right]^{\frac{1}{m_2-m_1}},$$

$$\Delta\sigma_{\text{structure}} = E_{\text{structure}}(1-R)\left[\frac{C_2}{C_1}\cdot\frac{W_1}{W_2}\cdot\frac{\left\{E_2(1-R)^{\beta_{W2}}\sqrt{\pi W_2}\right\}^{m_2}}{\left\{E_1(1-R)^{\beta_{W1}}\sqrt{\pi W_1}\right\}^{m_1}}\cdot\frac{F_1(\alpha_1)}{F_2(\alpha_2)}\right]^{\frac{1}{m_1-m_2}}. \tag{10}$$

In the case that the steel structure ($E_{\text{strucuture}}$ = 200 GPa) is subjected to cyclic loading with the stress ratio of 0.1, the fatigue cycles and the stress amplitude were calculated by eqs. (10) and experimental parameters of ED-Cu and ED-Ni, as shown in Fig. 8. Stress amplitude can be estimated from crack length detected from two sensors with different characteristics. Therefore, it was shown that fatigue cycles on structures can be estimated using smart patch.

Evaluation of fatigue damage of structure is important to avoid the rapture caused by cyclic loading. Cumulative fatigue damage is commonly determined using the Palmgren-Miner rule [15]. In this rule, the amount of fatigue damage, D, is given as the ratio of cyclic number of N / N_{f}, where N_{f} is the number of cycles to failure. Based on many studies about fatigue life of structural components, relationship between stress amplitude and the number of cycles to failure is generally characterized by S-N curve in high-cycle fatigue situations as:

$$N_f = C_{SN}\Delta\sigma^{-m_{SN}}, \tag{11}$$

where C_{SN} and m_{SN} is material constants and $\Delta\sigma$ is stress amplitude [16]. Using the fatigue cycles calculated by smart patch and S-N curve (as shown in Fig. 9(a)), the amount of fatigue damage can be evaluated as shown in Fig. 9 (b). Therefore, it was demonstrated that the health of structure can be estimated using smart patch.

5.3. Estimation of fatigue damage using single material

Another equation for estimating fatigue cycles and stress amplitude from fatigue crack length of two specimens can be derived using near-threshold fatigue crack behavior as shown in Fig. 10. Using Kohout equation, the fatigue cycles, N, is represented as:

$$N = \frac{W_1}{C}\int_{\alpha_0}^{\alpha_1}\left[\frac{d\alpha}{\left\{\varepsilon_{\max}E(1-R)^{\beta_w}\sqrt{\pi W\alpha}\,f_1(\alpha)\right\}^m - \Delta K_{th0}{}^m}\right]. \tag{11}$$

This equation overcame the limitation that the patch requires two or more materials with different fatigue characteristics. Estimation map of fatigue cycles and stress amplitude of steel structure as a function of normalized crack length in two sensors made of same material are shown in Fig. 11. The new equation needs only one material for simultaneous estimation of fatigue cycles and stress amplitude, and the measuring range can be controlled by geometry of specimen. Since this patch needs neither power supply nor wiring, it provides a great potential for long-term structural health monitoring with easy maintenance and low cost.

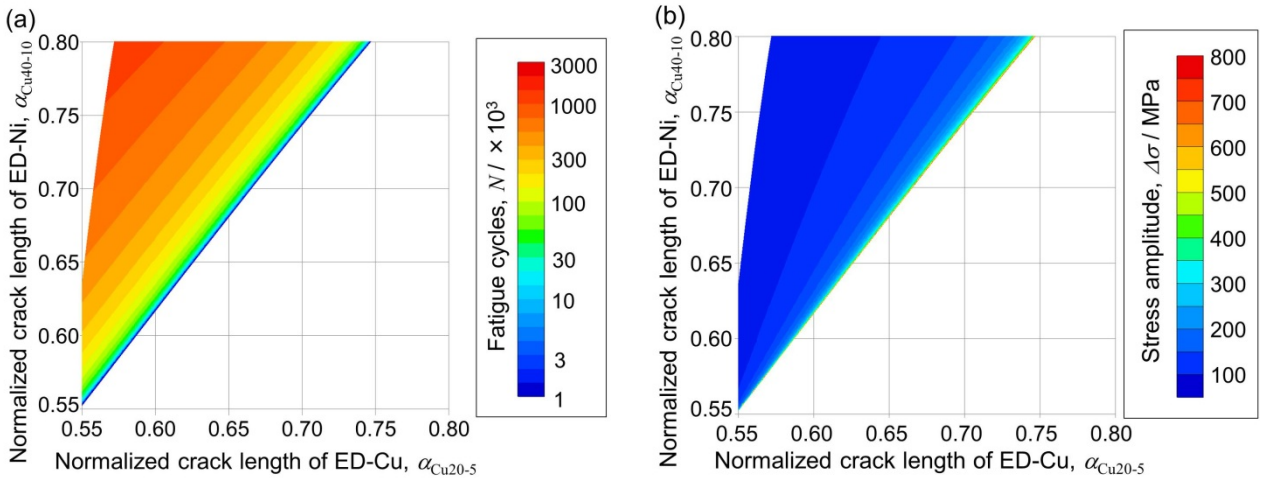

Figure 11. Estimation map of (a) fatigue cycles and (b) stress amplitude of steel structure as a function of normalized crack length in two sensors made of same material.

5. Conclusions

In the present study, near-threshold fatigue crack growth behavior in thin pure copper sheet with pre-crack was evaluated under strain-controlled fatigue testing in order to obtain the sensor characteristics of smart stress-memory patch and the following conclusions were obtained.

(1) Using a function describing the initiation as well as the stable growth of fatigue cracks, relationship between stress intensity factor range and crack growth rate of ED-Cu was successfully fitted to one equation regardless of strain amplitude, strain ration and specimen geometry.

(2) It was shown that the stress amplitude and the cyclic number can be estimated from the crack lengths of two sensors made of ED-Ni and ED-Cu. Furthermore, using S-N curve of structural material, the cumulative fatigue damage could be evaluated as a function of crack length of smart patch.

(3) Based on these experimental results, a new equation for estimating fatigue cycles and stress amplitude from fatigue crack length of two specimens was derived. This equation overcame the limitation that the patch requires two or more materials with different fatigue characteristics.

Abstract A new invented SHM technology, named as Intelligent Coating Monitoring (ICM), was verified by various lab-scale experiments as along with full-scale fatigue tests to inspect ICM capability for monitoring crack initiation and propagation in metal substance. In order to apply the technology to fighter aircrafts, ICM system was validated at real service condition. Firstly, ICM is briefly introduced, including the principle of sensor, the make-up of the system and various lab-scale experiments as well as full-scale fatigue tests for verification and application. Then the installation of ICM system on an operational aircraft structure was given which includes the determination of critical locations that needs monitoring, the selection of sensors corresponding to each monitoring point with certain geometry, the method of sensors splicing and main-/sub-interrogation units fixing and the connection of the above hardware through wires laying to form a ICM system. Finally, the operating situation and the effectiveness of the ICM system under operational environment were validated and summarized.

Keywords Crack monitoring, Aircraft Structure Health, Intelligent coating, Fracture

1. Introduction

At present, the safety of aircraft structures in most of countries is generally maintained by periodic inspection utilizing traditional nondestructive testing (NDT) techniques such as eddy-current, ultrasound, radiography, thermograph etc. However, these inspections often require the disassembly of the structure, which is a difficult and time-consuming procedure. As many locations of fighter aircraft in which cracks are prone to generate or form during full-scale fatigue in aging airframes are hidden in the structure, it is impossible to access for some certain areas. It is reported that recent aircraft crashes such as C-130A and F-15C in USA were resulted from catastrophic structural failure [1], suggesting that the current NDT is not reliable and is not adequate for aircraft safety. Moreover, the catastrophic risk of critical components also increases with the continued operation of aging fighter aircraft beyond its initial design life and in more severe service environments. Consequently, a desired solution is to implant a structural health monitoring (SHM) system on fighter aircraft which have the huge potentials to improve aircraft safety and reduce operational and maintenance cost.

Currently, several candidates of sensors suitable for SHM application have been widely investigated through lab-scale experiments, which include piezoelectric, fiber-optic, MEMS, strain-gages, CVM etc. To validate the effectiveness, some technologies based on different sensors have already installed in the service civil airplanes. For example, Bragg Fibre Gratings, impact and crack monitoring facilities, such as acoustic emission, eddy current and CVM sensors have installed in an AIRBUS A320 and an AIRBUS A340-600. In addition, diverse SHM technology such as crack wires, CVM or acoustic emission sensors were used during the full-scale fatigue test of the fuselage of the Airbus A380 [2]. Moreover, some structural health monitoring (SHM) systems have matured in recent years, allowing SHM systems to be tested on experimental flight tests [3-6]. However, there is a huge gap for SHM technology to translate these laboratory outcomes to practical application on the fighter aircrafts.

Although the effectiveness of detecting crack, the reliability and the durability for many sensors /actuators of SHM have been valiated in the lab-scale experimental condition, it should overcome many barriers in the practical applications, for instance, how to integrate the sensors /actuators to an already “overcrowded” aircraft structures effectively, how to connect them by wires to form a SHM net system which do not conflict with current systems in aircraft, how to optimize the number and location of sensors and how to enhance the reliability of the sensors in order to survive in the severe environments. It is no doubt that the gulf may exist between what has been demonstrated in the laboratory and what has been rigorously validated for operational use, since most of sensors are tested by a limited number of components with simple geometric shape such as plates, shells or shafts with possible some notches. But the real aircraft components usually are heavy-loaded and light weight with more complex geometric and shape. Moreover, it is inevitable to increase the costs and complexity when a prototype concept translates into service.

It is an indispensable step to carry out validating tests for any type of SHM systems under operational environments before they become the application-ready products. Canada Institute for Aerospace Research (IAR) developed a novel National Research Council (NRC)-developed crack detection system called the “Surface Mountable Crack Sensor (SMCS)” which had shown promising results as a means of detecting cracks proved by lab-experiments. In order to put SMCS into real application, a prototype installation of the SMCS was carried out on an operational aircraft [7] which showed that was a very important step in verifying its operation effectiveness.

A new SHM technology called ICM (Intelligent Coating Monitoring) which is mainly based on the intelligent coating sensors has been invented in China [8, 9]. ICM has shown the capability of monitoring crack initiation and propagation verified by a series of coupons with different material and dimensions under fatigue loading. Furthermore various experiments under environmental loading (temperature extremes, thermal shock, high humidity, fluid susceptibility, altitude/pressure) were carried out to test the durability and reliability of ICM system. It should be noted that ICM technology has been applied on several full scale fatigue tests [10]. Besides the achievements mentioned above, the sensors and interrogation units of the ICM system added on an aircraft have very small size and light weigh. Those superiorities make it easier to implant ICM instruments on aircraft structure on the active service as a part of an SHM system than most of other available SHM technologies which usually require heavy instruments.

The goal of the present study is to validate the durability, reliability, longevity and crack detecting capability of the ICM system under real flight conditions and improve various properties. An active service fighter aircraft which was in the overhauling was selected for the study. Total 78 sensors monitoring 42 sites were distributed in different areas of the aircraft such as wing, landing gear, horizontal tail and airframe etc, 12 sub-interrogators connecting all sensors and 2 main-interrogators connecting all sub-interrogators were installed on the aircraft. The aircraft returned to service after installing all the instruments of ICM system on the aircraft. So far, the aircraft with ICM system has been on active service more than 2 years, the data recorded by the system during the period were collected and analyzed once per month. ICM system provides more valuable information in the future applications.

This paper briefly introduce ICM system including the principle of sensor, the make-up of the system and various lab-experiments as well as full-scale fatigue tests for verification, give information about the installation of ICM system on an operational aircraft structure including the determination of critical locations that needs monitoring, the selection of sensors corresponding to each monitoring point with certain geometry, the method of sensors splicing and main-/sub-interrogation units fixing and the connection of the above hardware through wires laying to form a

ICM system, valiate the effectiveness of the ICM system under operational environment and summarize on the experiences and lessons from the study.

2. Description of ICM Technology

2.1. Principle of sensor

The core of ICM technology is intelligent coating sensor which comprises of three layers: the driving layer, the sensing layer and the protective layer，as shown in Figure 1. The driving layer is made of bifunctional nonconductive materials: one function is that crack will also form on the driving layer once cracks generate on the substrate, and further makes the sensing layer split at the same time; secondly the driving layer spaces out the substrate and the sensing layer with good insulating efficiency in conformity to the design requirement. The sensing layer is made up of conductive materials such as Cu, Ag, C, etc and can detect the crack length in the substrate by the variation of electric resistance. As the ICM sensor is about several tens of micrometers, a small surface crack will cause the sensor cracking and the electric resistance rise accordingly, as shown in Figure 2. The increase of electric resistance of the sensor corresponds to the crack growth. The method of ICM is very simple and stable measurement system, which consists of a DC power source, an electric resistor and a data recorder.

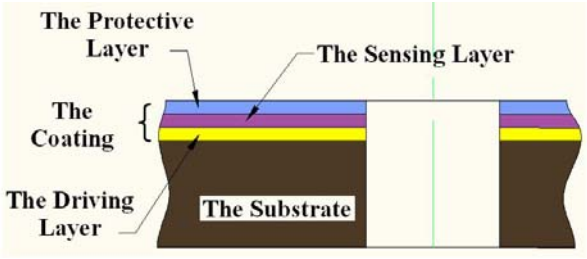

Figure 1 A formation of the intelligent coating sensor

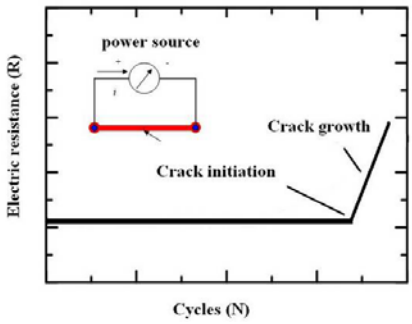

Figure 2 The relationship of eletricc resistance and crack length

2.2. ICM system construction

A typical ICM system consists of hardware and software. The on-board hardware parts include virus sensors, sub-interrogators and main-interrogators, see figure 3. Each sub-interrogator, a chip microcomputer system, consists of switches for signal channel of multi path sensors, conversion circuits for A/D modulus, central process units, digital communication circuits and power circuit and other auxiliary circuits. The sub-interrogators can realize the online measuring and processing of the electric resistance value detected by each cable-connected sensor and transmit the digital

signals to the main interrogator by cables. One sub-interrogator can connect with as many as 8 sensors. A main interrogator comprises of following units: 1) communication unit for sending and receiving the message from each sub-interrogator; 2) storage unit for saving all working parameters and data; 3) date-time unit for recording the date and the time as the resistance value changes of each sensor; 4) man-machine interaction for monitoring working conditions of all sensors through the lights in the main-interrogator and downloading the message to a ground–portable computer through the USB interface for further processing; 5) central process unit for managing all the above units and 6) DC power converting module with wide inputting voltage.

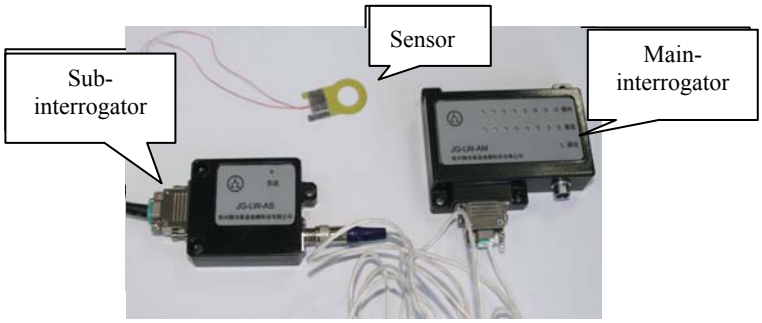

Figure 3 The construction of ICM system hardware

The weight of sensor can be ignored and the weights for a typical sub-interrogator and main interrogator are less than 180g and 80g, respectively. The dimensions of a normal sub-interrogator are 67mmx50mmx16.5mm and the dimensions of a normal main interrogator are 110mmx50mmx 20mm.

The software component is a special developed program for managing the ICM system which can be installed on a portable computer. The program can download and process all the data recorded and saved by the ICM system. Since the system has a huge internal memory, it can store up all recorded data by existing sensors during their lifetime, the intervals for off-board downloading and processing the data can be conducted by users according to their own needs. The possessed data can help users determine whether the ICM integrity has been compromised or real damage like cracks has been appeared on the monitored locations. In addition, the program can also realize real-time monitoring.

2.3. Verification tests

2.3.1. Coupon tests

Figure 4a Five types of specimens

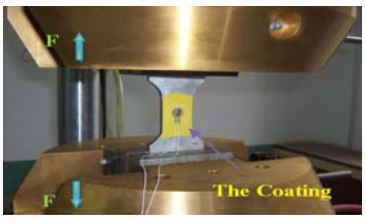

Figure 4b The picture of coupon testing

Fatigue tests were carried out on five types of specimens including riveted lap joint and screwed connection made of 4340M steel, 7074 aluminum alloy and TC4 titanium alloy, as shown in Figures. 4 and 5. All specimens were fatigue loaded with 15 Hz, load ratio R=0.2 and the maximum tension

load P=18KN. As one example, Figure 5 is the relationship between resistance variations measured by sensor spliced on one 7074Al specimen and test load cycles. As the set alarm value was $\Delta R = 0.05\Omega$ in the test, the crack was detected at approximate $5.8x10^4$ cycles. The crack length was about 0.3mm corresponding to $\Delta R=0.05\Omega$ which was measured on the fracture surface by stereoscope analysis.

ICM under different loading ways, such as tension-tension, tension-push and three point bending, has the similar results for crack detection, as depicted in Figure 6. Particularly, ICM sensors are able to monitor the riveted lap and butt joints where fatigue cracks likely commence at holes edges. From above coupon results, it is thought that ICM is suitable to detect small fatigue cracks and monitor their growth.

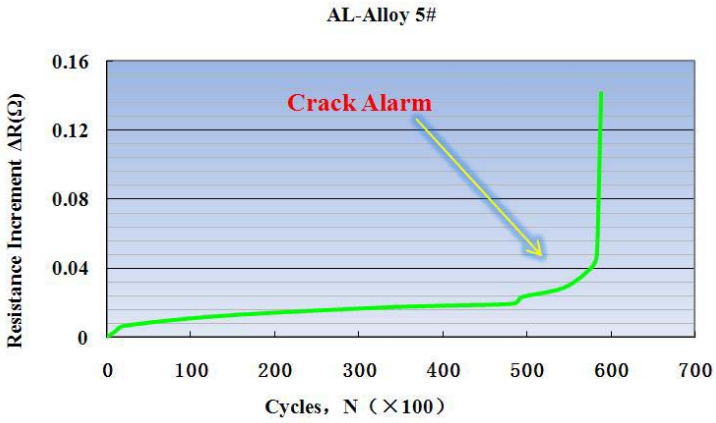

Figure 5 The curve of resistance and load cycle from 7074Al specimen test results

2.3.2. Component tests

Full-scale fatigue tests were carried out using real horizontal tail shafts as specimens. Taking this advantage, ICM system with 5 special sensors spliced on the fatigue critical areas of the shaft determined by finite element analysis has been used during the test, as shown in figure 6. The histories of cracks from initiation, growth till fracture in the shafts were monitored by ICM system during tests. Figure 7 is a resistance-hour curve recorded by ICM system for one of shafts which can verify the effectiveness of crack detection for ICM system in real component.

Figure 6 Some works done for extending the fatigue life of the shaft in a type of fighter aircraft

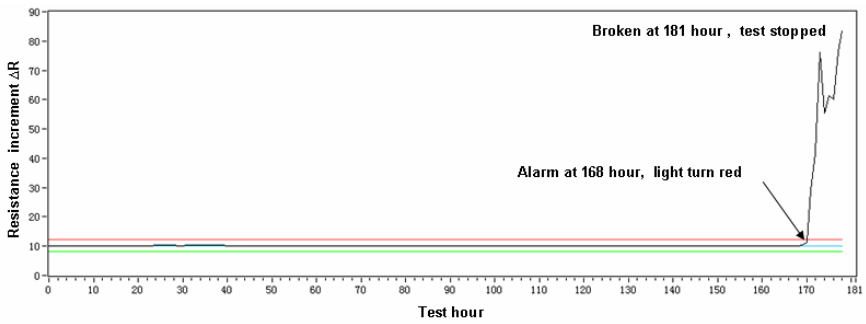

Figure 7 The history of crack length increasing with test time

2.3.3. Full-scale aircraft structure tests

Based on the above coupon and component verification experiments, ICM system has been verified in several full-scale aircraft structure fatigue tests with most sensors spliced at fatigue critical locations where are hidden in the structure and hard to access by the conventional non-destruction inspection methods. For example, ICM sensors were mounted on a full scale central wing fatigue testing aircraft. Figure 8 shows the sensor splicing between two repaired Al-alloy parts with a piece region of rivets which can give alarm signals when the cracks appear at this location. The other example is a full-scale fatigue test for a fighter structure. Total 110 sensors were fixed in 80 key locations inside structures including fuselage frames, wings, empennages and landing gears which formed a net after connected with interrogators for monitoring all locations prone to crack. With the aid of ICM system, some cracks were detected in time. Figure 9a shows sensors distributed in one frame and figure 9b gives the history of crack length increasing with test time in the fractured locations of the frame.

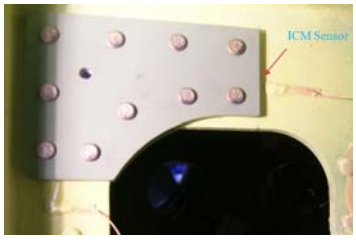

Fig.8. ICM Sensors Monitoring on Central Wing

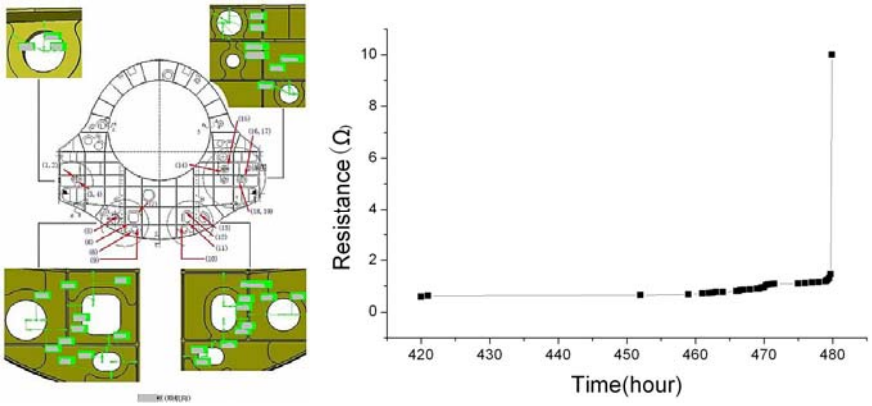

Figure 9 Sensors distributed in one frame (a) and the history of crack length increasing with test time in the fractured location of the frame (b)

At present, ICM system has become an indispensable measure for monitoring damage in most full

scale aircraft fatigue tests carried out in China.

3. Validation study on ICM system under operational environment

From various levels tests mentioned above, it can verify that ICM system can detect damage in the aircraft structure. Furthermore, ICM product have excellent electromagnetic compatibility and environmental adaptability, which were tested by various harsh environmental loading experiments such as high/low temperature extremes, thermal shock, high humidity, fluid susceptibility, altitude/pressure etc. Hence, it is believed that that ICM system is reliable, robust, immune to radio frequency and electromagnetic interferences, easily networked to on-board preprocessing, capable of withstanding environmental conditions and low power which make it easier to obtain approve for installation of ICM hardware on aircraft structure in service. In order to put ICM into the oncoming real application, a study was carried to validate durability, reliability, longevity and crack detecting capability of the ICM system under actual flight condition and improve various properties accordingly.

3.1. Installation of ICM hardware

One of overhauling fighter aircrafts was selected as the subject for the study.Total 78 sensors monitoring 42 fatigue critical sites distributed in different locations of the aircraft including wing, fuselage, horizontal tail and landing gear which were distributed symmetrically along the yaw axes of the aircraft, as listed in Table 1. All those sites determined by full-scale fatigue test and finite element analysis were impossible to access by conventional NDT methods. Each side of sensors was connected by 6 sub-interrogators which were connected by one main-interrogator. Actually two independent ICM systems are responsible for two sides of the aircraft. Figure 10 shows the distribution of ICM hardware in a whole aircraft.

Table 1 Sensors and locations in different structural components (one side of aircraft)

Structural component	The number of locations	The number of sensors
Central Wing	8	15
Forward Fuselage	1	1
Outboard Wing	7	14
Horizontal Tail	2	5
Rear Fuselage	3	4
Total	21	39

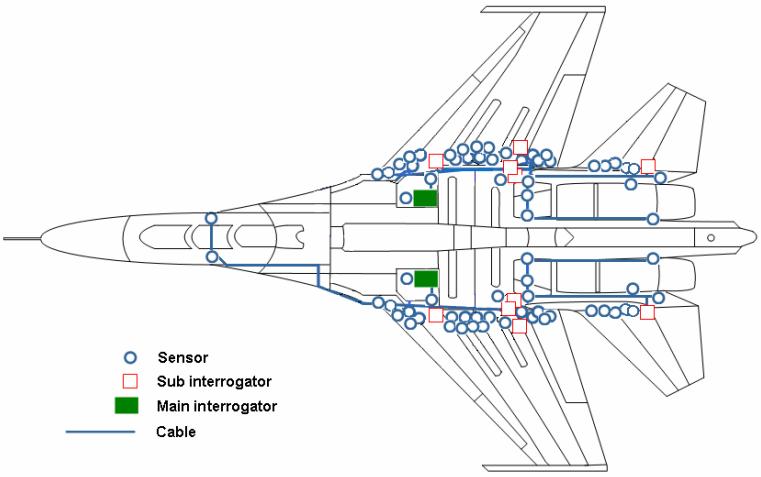

Figure 10 Laying-out of ICM hardware

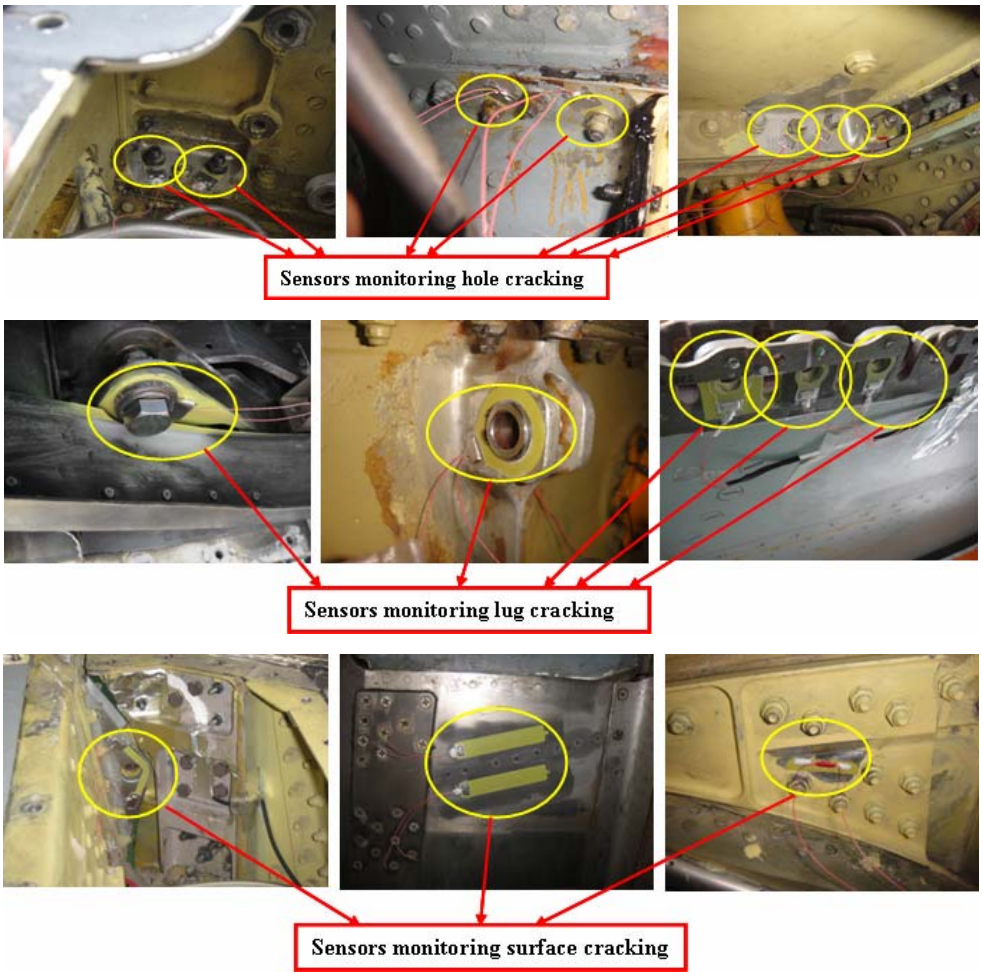
Different shapes of sensors were designed according to their geometries of monitored sites. Figure 11 gives 3 kinds of sensors for monitoring hole, lug and surface cracking which were spliced in different sites on the aircraft. Figure 12 are main interrogator and 6 subinterrogators fixed at the different locations.



Figures 11 Typical sensors spliced in different sites

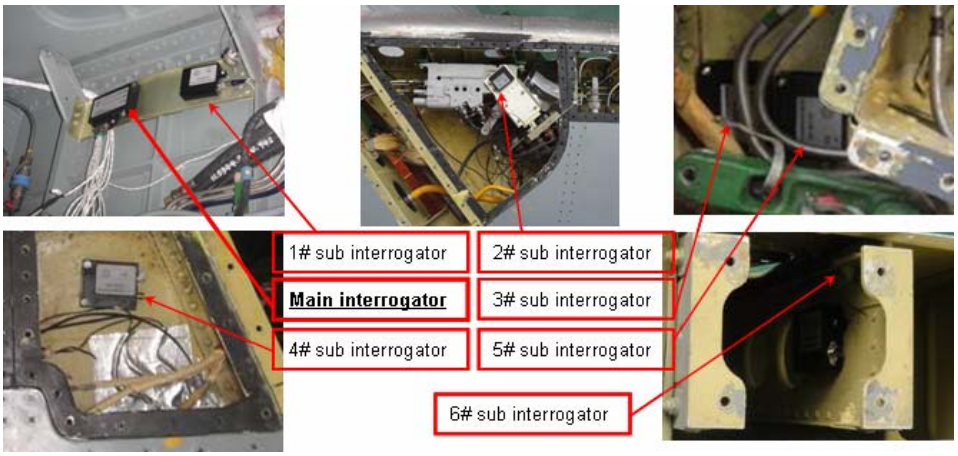


Figure 12 Main interrogator and 6 subinterrogators fixed at the different locations.

3.2. Working situation of ICM system under operational environment

There are two rows of lights on one main interrogator, with each row of 8 lights as shown in figure 13. Therefore one main interrogator can connect with as many as 8 sub interrogators and 64 sensors accordingly. When the ICM system is in working condition, the main interrogator continually checks its sub interrogators one by one with each taking 2~3 seconds for checking its subordinating sensors. During the process, only one light in the first row is on at each turn, which indicates the state of the sub interrogator being checked. If the light is “green”, then the lights in the second row will be “green”, which indicates that all sensors subordinated to this sub interrogator are in good conditions. If the light is “red”, there must be one or more “red” lights in the second row, which indicates that the corresponding sensors are in bad conditions, suggesting that either cracks appear or sensors including wires are broken.

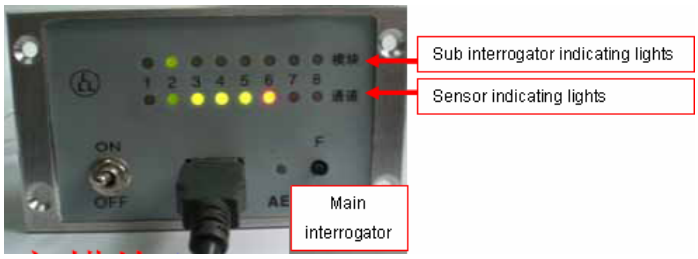

Figure 13 The front view of main interrogator

After installating ICM system, the aircraft returned to the service. In comparison with other same type aircrafts, the only additional thing for the mechanician of the aircraft is to check the lights on the main interrogators fixed in the landing gear cabin shown in Figure 12 before and after every flight. The mechanician can obtain the message immediately once he finds any “red” light based on the data analysis from the system. Besides the data recorded by the ICM system were collected and analyzed once per month. Up to now the aircraft with ICM system has been used more than 2 years, during this period, the working situations for both the aircraft and the ICM system run well as expected except some broken sensors transmit false signals.

4. Summaries

It can prove by the present investigation that ICM system installed on the aircraft structure can monitor cracks which might occur at any specified location, and most sensors along with other hardware can operate normally and effectively under actual condition.

Meanwhile, it is regrettable that some sensors located in the areas of high strain failed in short-time running, thus resulting in false signals. Therefore, more research is needed to design special sensors and corresponding splicing process for those high strain areas. Fortunately, a large progress has been made on this field which will be verified soon.

In a word, ICM prototype installation is a significant first step in validating its effectiveness in operations and putting it into practical applications. Field data including false signals collected from operations provides useful results of the environmental effects on the ICM system and valuable information for ICM improvements.

Abstract In this research work an in-situ method for the characterization of fatigue processes in metastable austenitic steels with electromagnetic acoustic transducers (EMATs) was developed. The austenitic steel AISI 347 (1.4550, X6CrNiNb1810) was investigated in isothermal total strain-controlled tests in the LCF-range at ambient temperature and 300 °C. By means of cross effects between physically based mechanical- and EMAT-measurements, a detailed characterization of cyclic hardening and softening processes as well as fatigue induced phase transformations and changes of specimens topography and crack initiation were performed.

Keywords Austenitic stainless steel, fatigue, phase transformation, α´-martensite, NDT, EMAT

1. Introduction

In power plants as well as in chemical plants, metastable austenitic steels are subjected to monotonic and cyclic thermo-mechanical loading [1-2]. The cyclic deformation behavior of metastable austenitic steels at ambient temperature (AT) and elevated temperature strongly depends on the deformation induced α´-martensite formation. This phase transformation from paramagnetic austenite (fcc) into ferromagnetic α´-martensite (bcc) leads to cyclic hardening and thus to an increase of the fatigue strength [2-4, 8]. At elevated temperatures no α´-martensite formation was observed in the LCF-range. Therefore the fatigue behavior at elevated temperatures depends basically on cyclic hardening processes due to an increase of dislocation density, followed by cyclic saturation and/or softening processes due to changes in dislocation arrangement and density and finally the formation and propagation of fatigue cracks [5-8]. The investigations are focused on the characterization of the fatigue processes at AT and 300 °C and the development of in-situ monitoring methods on the basis of electromagnetic acoustic measurements. EMATs, which generate ultrasonic waves directly in electrically conductive materials without the use of a couplant, were developed at the Fraunhofer Institute for Non-Destructive Testing (IZFP) Saarbrücken in Germany and calibrated to defined fatigue states in collaboration with the Institute of Materials Science and Engineering (WKK) at the University of Kaiserslautern in Germany [8]. The activities at WKK are focused on the characterization of the materials science aspects of the fatigue processes, while IZFP develops electromagnetic acoustic transducers.

2. Experimental procedures

2.1. Experimental setup

The fatigue tests were performed at different constant total strain amplitudes ($\varepsilon_{a,t}$ = 0.8, 1.0, and 1.2 %) at ambient temperature and 300 °C on a servo-hydraulic testing system with a strain ratio of R_ε = -1 using triangular load-time functions and a frequency of 0.01 Hz. Figure 1 shows schematically the experimental setup for both temperatures. Besides electromagnetic non-destructive testing methods using EMAT and a Feritescope® sensor, full mechanical strain-stress hysteresis measurements were performed to allow a microstructure-related description of the cyclic deformation behavior of the metastable austenite. Electromagnetic acoustic transducers use electromagnetic fields to excite ultrasonic waves and therefore have the great advantage that

they can be used for ultrasonic measurements without a coupling medium between the transmitter/receiver and the test object. This set-up allows measurements on sensitive surfaces and objects also at elevated temperatures. Another advantage of EMATs is their very efficient generation of shear waves with both vertical and horizontal polarization for oblique angles of incidence as well as the generation of linearly, radially and elliptically polarized shear waves for the normal incidence [9].

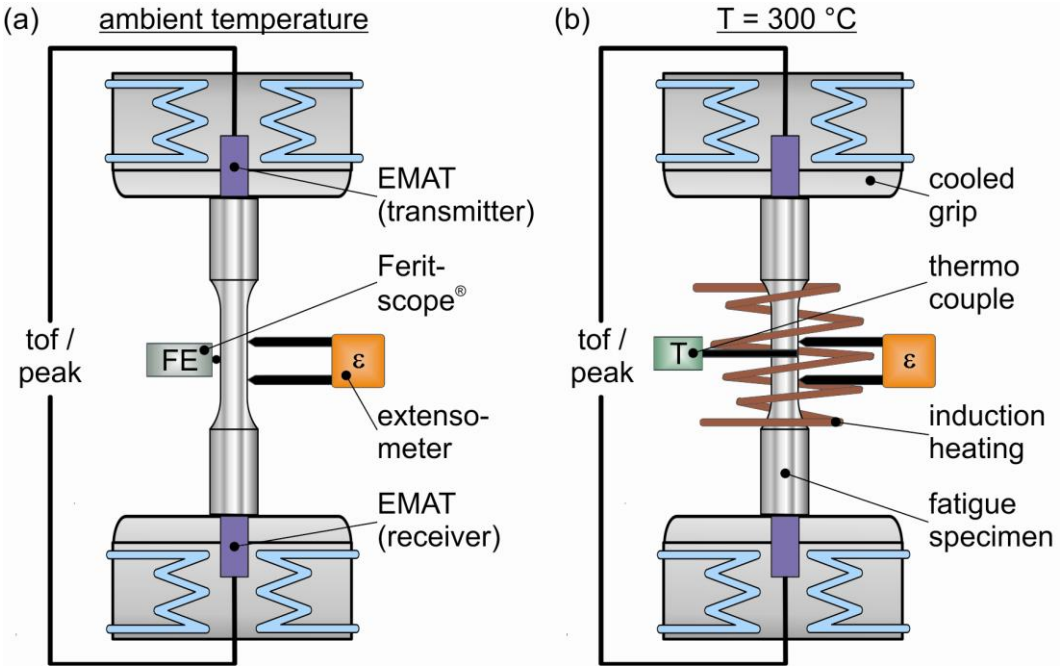

Figure 1. Schematic drawing of the experimental setup:
ambient temperature (a) and T = 300 °C (b)

EMATs generate ultrasonic waves by means of Lorentz forces, magnetostriction or by magnetic forces. Ultrasound generation by means of magnetostriction or magnetic forces requires ferromagnetic materials. Thus, since the investigated material in this project is a paramagnetic austenitic steel, the ultrasonic waves are generated only by Lorentz forces. The excitation of ultrasound by EMATs is performed by the superposition of high frequency eddy currents, induced by a coil with a geometry matched to the wave pattern, and a static or low-frequency magnetic field (Figure 2). The waves are picked up by a receiving coil geometrically identical to the transmitter coil. In this project radially polarized shear waves are generated by the transmitter at the one end and the receiver at the other end [9].

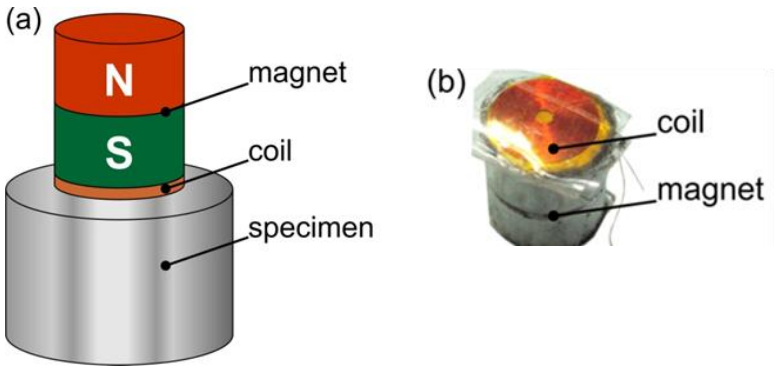

Figure 2. Assembling of an electromagnetic acoustic transducer for radially polarized shear waves: schematic picture (a), photo of a probe (b)

2.2. Material

The investigated material was the Nb-stabilized metastable austenitic stainless steel AISI 347 (1.4550, X6CrNiNb1810). The chemical composition is given in Table 1. The calculation of the austenite stability parameters (e.g. M_{d30} = 26 °C by Angel) results in a metastable state of the test material at ambient temperature. This calculation gives an approximate value, which means, that at a sufficient plastic deformation at ambient temperature an austenite-martensite-transformation can be expected. The initial microstructure (Figure 3) of the investigated steel has a mean grain size of 120 µm and a HV10 hardness of 140 HV. Also Nb-carbides were observed. The chemical composition of these carbides was analyzed via EDX-mapping. As expected the tensile strength, ultimate strain and reduction in area decrease with increasing temperature. At ambient temperature, at a plastic deformation of 66 %, 4.41 FE-% α´-martensite was formed. The α´-martensite formation starts at a total strain of 22 %. Magnetic measurements and micrographs after tensile tests at 300 °C indicated no α´-martensite formation.

Table 1. Chemical composition in weight-%

C	Cr	Ni	Nb	N	Si	Mn	P	S	Al
0.040	17.600	10.640	0.620	0.007	0.410	1.830	0.020	0.007	0.016

3. Results and discussion

3.1. Evaluation of the fatigue behavior with deformation induced α´-martensite formation

Figure 4 shows the development of the stress amplitude σ_a and ferromagnetic martensite fraction ξ (Figure 4a), the change in the mean value of time of flight Δtof_{mean} (Figure 4b) and the change in the mean value of the electromagnetically activated ultrasonic amplitude $\Delta peak_{mean}$ (Figure 4c) versus the number of cycles N in fatigue tests at ambient temperature.

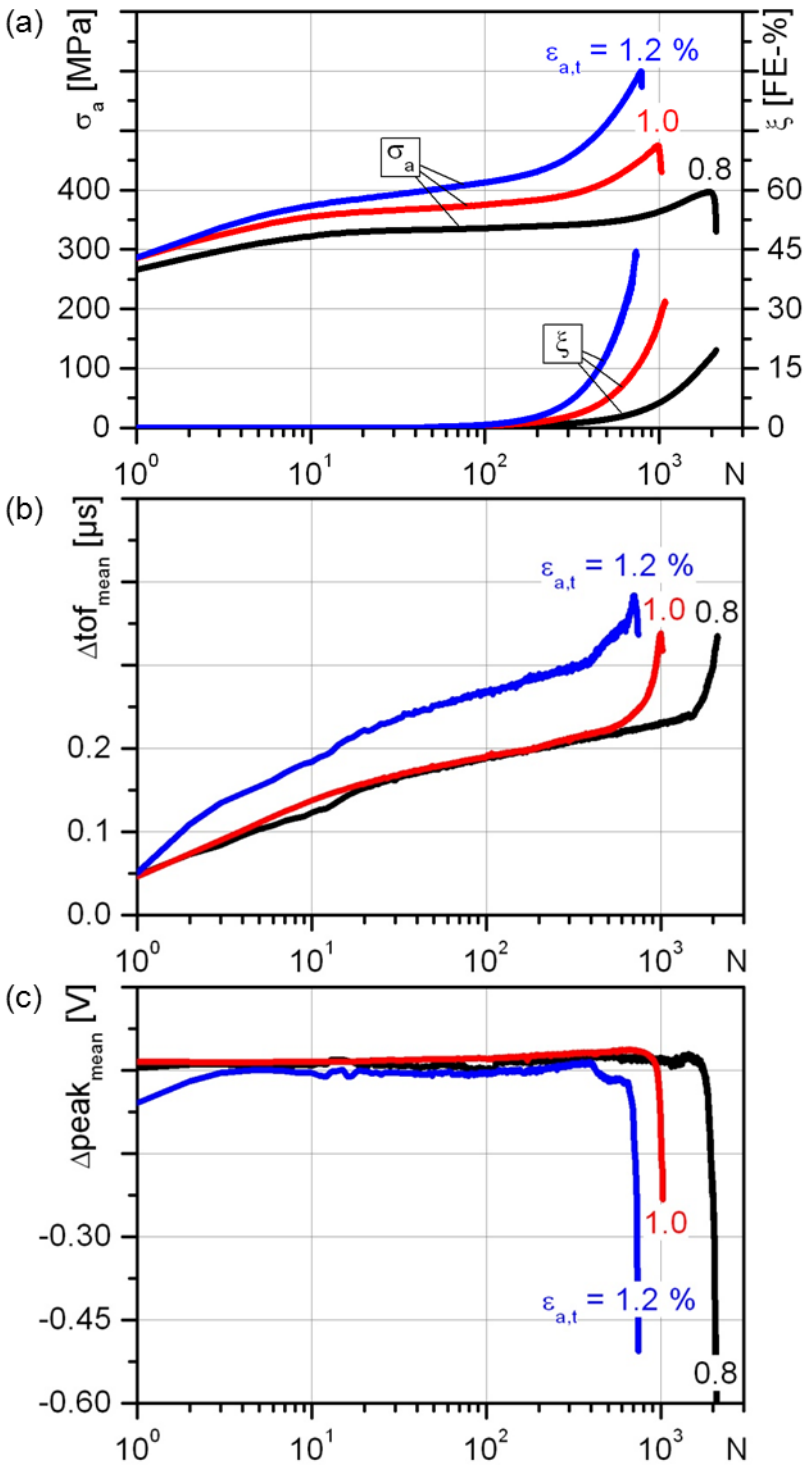

Figure 4. Stress amplitude σ_a and ferromagnetic martensite fraction ξ (a), change in Δtof_{mean} (b) and change in $\Delta peak_{mean}$ (c) vs. number of cycles N at ambient temperature

Due to the change of tof and peak within one cycle, caused by the elongation of the specimen and change of the stress state of the specimen (Figure 7), an arithmetic mean value per load cycle for tof and peak was chosen to characterize the fatigue behavior [8]. The cyclic deformation behavior of the investigated austenite at ambient temperature is predominantly determined by the deformation induced austenite-martensite transformation. After a load dependent number of cycles N, the formation of α'-martensite starts and increases continuously with increasing number of cycles until specimen failure (Figure 4a). The σ_a, N-curves illustrate the cyclic hardening processes, which lead

for $\varepsilon_{a,t}$ = 1.2 % to a maximum stress amplitude in the range of the tensile strength σ_f = 569 MPa of the solution-annealed austenite. Due to an increase of the dislocation density, formation of deformation-induced α´-martensite, development of intrusion and extrusions at the specimen surface and finally the formation of micro- and macro-cracks a continuous increase of the change in the mean value of time of flight Δtof_{mean} from the beginning of the fatigue loading up to specimen failure was observed at ambient temperature (Figure 5). However the electromagnetically activated ultrasonic amplitude $\Delta peak_{mean}$ shows no significant changes until the formation and propagation of micro- and macro-cracks (comp. Figure 4c with Figure 5). Because Δtof_{mean} is more sensitive to microstructural fatigue effects, which lead to an increase of Δtof_{mean} until specimen failure, it isn't possible to detect the state of macro-crack formation and propagation. The change in the mean value of the ultrasonic amplitude $\Delta peak_{mean}$ shows in contrast to Δtof_{mean} a decrease at the fatigue state of macro-crack formation and propagation. Thus it is possible to detect specimen failure at an earlier fatigue state.

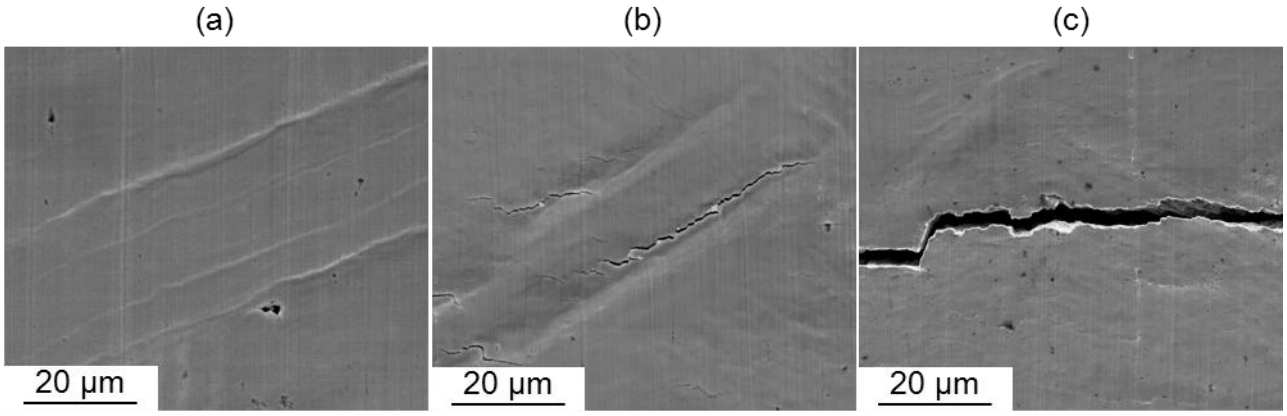

Figure 5. Changes in specimen surface topography at defined fatigue states at ambient temperature: N = 100 slip bands (a), N = 400 micro-cracks (b) and N = 900 macro-crack (c)

3.2. Evaluation of the fatigue behavior without deformation induced α´-martensite formation

Figure 6 shows the development of the stress amplitude σ_a (Figure 6a), the change in the mean value of time of flight Δtof_{mean} (Figure 6b) and the change in the mean value of the electromagnetically activated ultrasonic amplitude $\Delta peak_{mean}$ (Figure 6c) versus the number of cycles N for fatigue tests at 300 °C. The cyclic deformation behavior of the investigated metastable austenite at this temperature is characterized by initial cyclic hardening, followed by cyclic softening before the final stress amplitude drop, associated with the propagation of a fatigue crack. At 300 °C no martensite formation occurs and compared to ambient temperature the stress amplitude is significantly lower. In the Δtof_{mean}, N-curves generally three sections over the fatigue life were observed. In the first section Δtof_{mean} shows similar to σ_a and tests at ambient temperature an initial increase caused by dislocation hardening. The second section follows with a decrease of Δtof_{mean} due to cyclic softening. The third one shows a secondary increase of Δtof_{mean}, which is mainly affected by the development of intrusions and extrusions at the specimen surface and finally the inititation and propagation of fatigue cracks (Figure 6b). In analogy to the investigations at ambient temperature, the change in the mean value of the ultrasonic amplitude $\Delta peak_{mean}$ shows in contrast to Δtof_{mean} a decrease at the fatigue state of macro-crack formation and propagation.

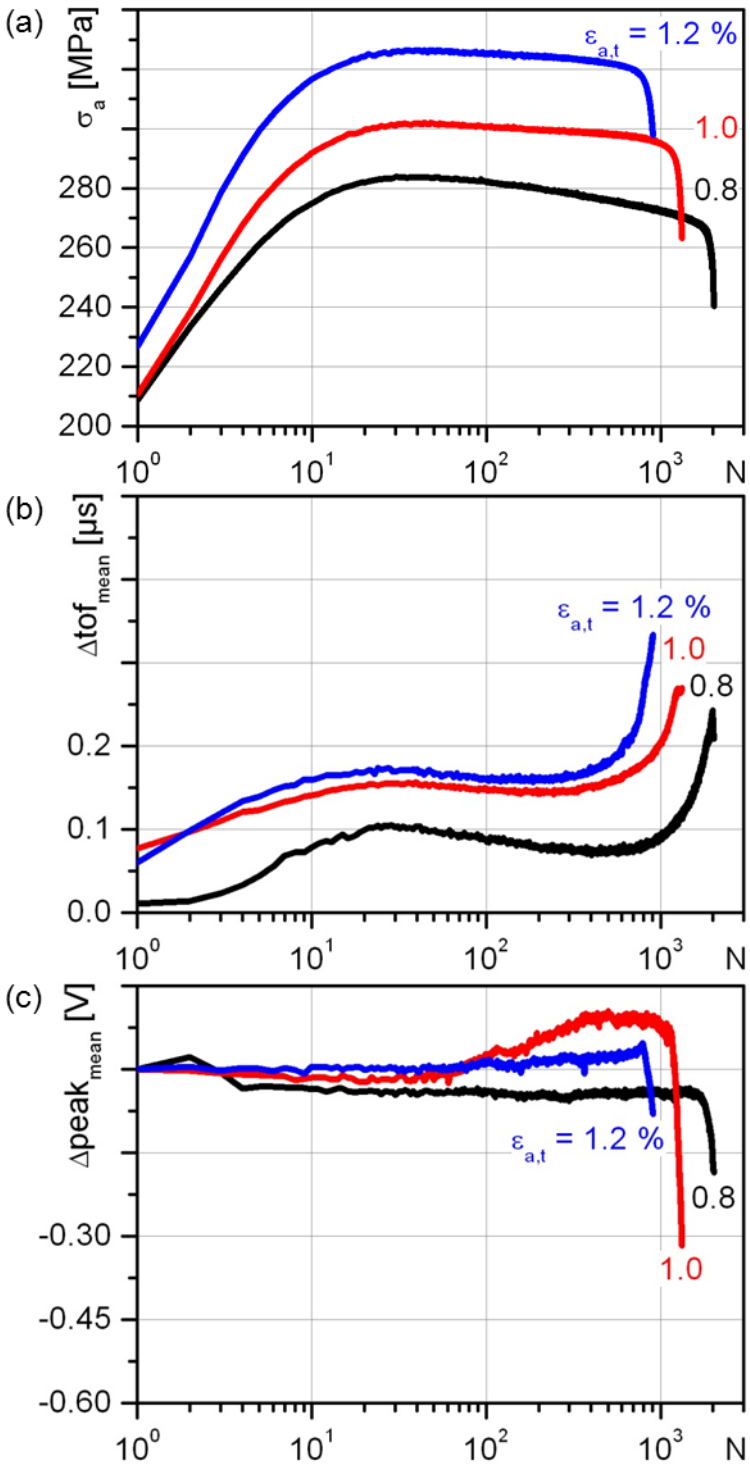

Figure 6. Stress amplitude σ_a(a), change in Δtof_{mean} (b) and change in $\Delta peak_{mean}$ (c) vs. number of cycles N at T = 300 °C

3.3. In-situ monitoring of fatigue damage by means of cross effects between mechanical and EMAT data

Besides the conventional characterization of the cyclic deformation behavior using stress-strain-hysteresis measurements, far-reaching cross effects of physically based data from electromagnetically activated ultrasonic measurements and mechanical strain measurements can be used for in-situ monitoring of fatigue processes. Figure 7 shows stress-strain-hysteresis at defined

number of cycles (N) during total-strain-controlled LCF-fatigue tests with $\varepsilon_{a,t}$ = 1 % at ambient temperature (Figure 7a) and at 300 °C (Figure 7b). The development of stress amplitude and/or plastic strain amplitude is used usually for the characterization of cyclic softening or hardening processes (comp. Figure 4a and 6a). The change of the shape (A) of σ-ε-hysteresis loop occurs due to macro-crack formation at N = 1020 at ambient temperature and at N = 1300 in the test at 300 °C.

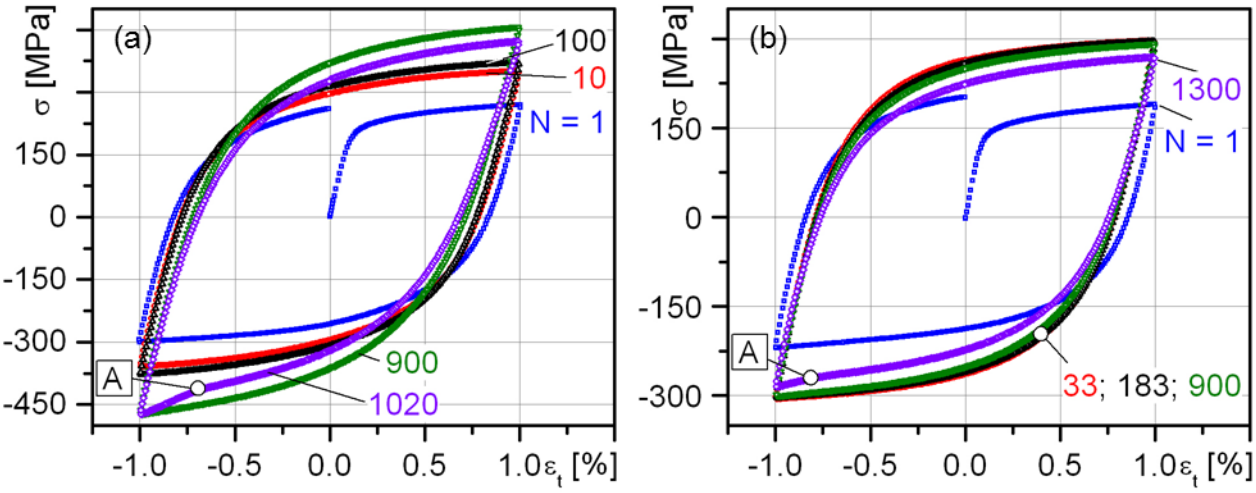

Figure 7. Stress-strain-hysteresis at ambient temperature (a) and T = 300 °C (b)

The time of flight-total-strain-relationship (tof-ε_t) provides, in analogy to the stress-strain hysteresis, information about the actual state of fatigue of the austenitic steel. In the range of elastic-plastic material behavior, the tof-ε_t relation leads to a hysteresis-relationship (Figure 8a) for fatigue tests at ambient temperature and 300 °C (Figure 8b). It can be seen, that an increase/decrease of total-strain (ε_t) leads to increase/decrease of the tof signal. Due to elastic-plastic material behavior, microstructural changes like e. g. increase of dislocation density lead to an increase of the mean value of tof and shift the hysteresis-loop to higher values with increasing number of cycles. In tests at ambient temperature further cycling leads to deformation-induced α´-martensite (Figure 4a), which correlates with an increase of the mean value of tof. Due to changes in dislocation arrangement in tests at 300 °C cyclic softening occurs after N = 183 cycles, which leads to a decrease of the mean value of tof. Furthermore the tof-ε_t-relationship depends on micro and macro-crack initiation and propagation, which also shifts the hysteresis-loop to higher values along the ordinate. In comparison to the σ-ε-hysteresis (Figure 7), a significant change in the shape of the tof-ε_t-hysteresis loop occurs.

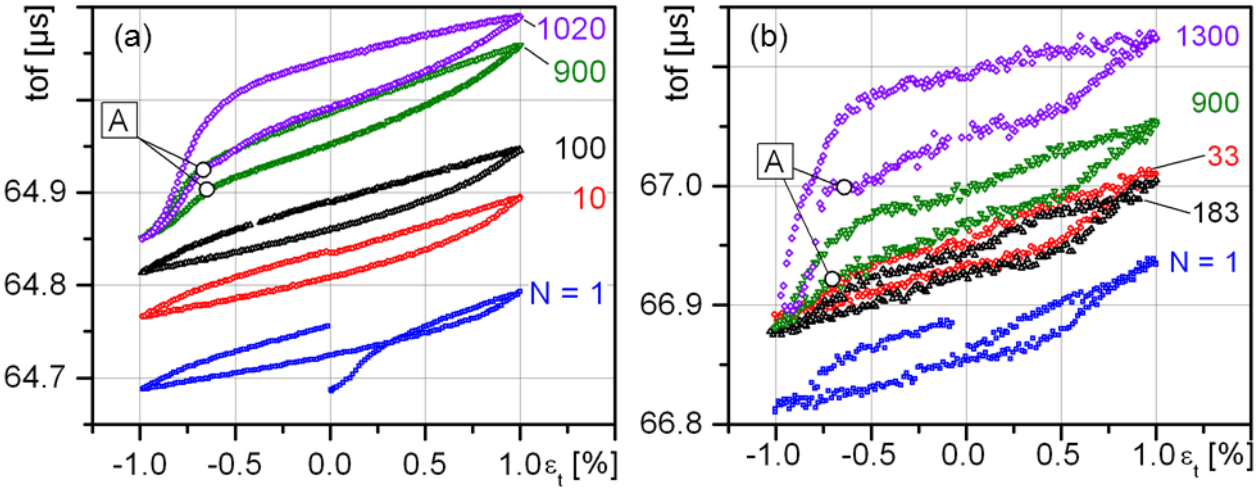

Figure 8. Correlation between time of flight (tof) and total-strain (ε_t) at ambient temperature (a) and T = 300 °C (b)

In analogy to σ-ε_t-, and tof-ε_t-hysteresis, the relationship between the electromagnetically activated ultrasonic amplitude (peak) and total-strain (ε_t) was investigated in fatigue tests at ambient temperature (Figure 9a) and 300 °C (Figure 9b). Generally an increase/decrease of ε_t leads to decrease/increase of peak. The peak is a physically based data, which in comparison to the above mentioned values, describes most sensible the occurrences of macro-crack and less sensible the change in dislocation density and arrangement or initiation of micro-cracks. Hence critical values of the change in the electromagnetically activated ultrasonic amplitude can be defined for structural health monitoring applications, which correlate with macro-cracks.

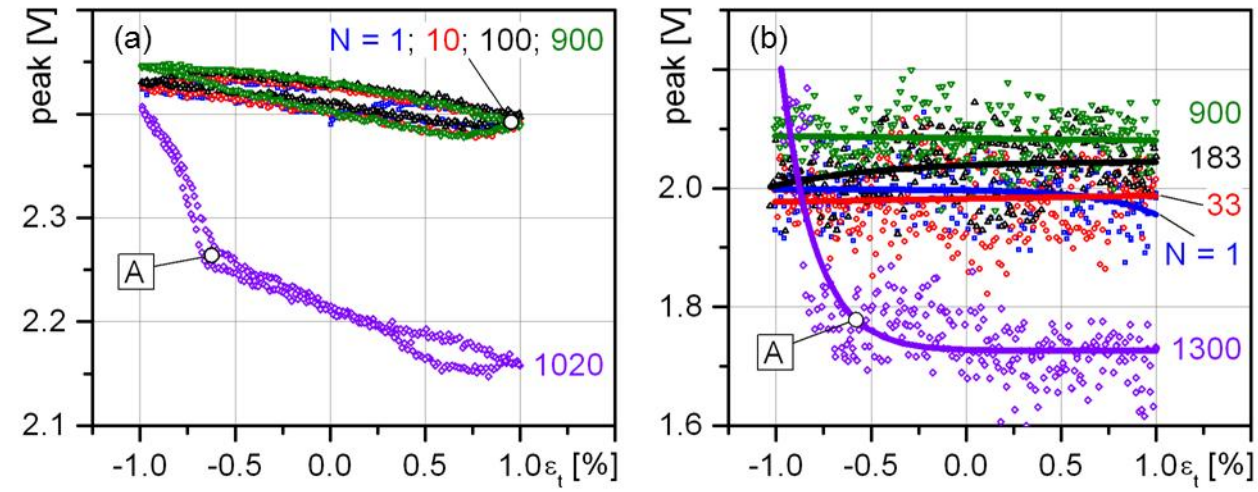

Figure 9. Correlation between electromagnetically activated ultrasonic amplitude (peak) and total strain (ε_t) at ambient temperature (a) and T = 300 °C (b)

3. Conclusions

In total strain controlled fatigue tests at ambient temperature and T = 300 °C the fatigue behavior of the austenitic steel AISI 347 was investigated by conventional stress-strain-hysteresis (σ-ε) measurements and by continuous, in-situ ultrasonic measurements generated with electromagnetic acoustic transducers (EMATs). Far reaching cross effects of EMAT and mechanical strain

measurements enable the recording of a hysteresis relation between time of flight (tof) and total-strain (ε_t) as well as relationship between the electromagnetically activated ultrasonic amplitude (peak) and total-strain (ε_t). The tof-ε_t-hysteresis gives, in analogy to the stress-strain-hysteresis, information about the cyclic hardening and/or softening processes, micro- and macro-crack initiation and propagation. Due to the occurrence of micro-cracks a significant change in the shape of the tof-ε_t-hysteresis curve can be detected earlier compared to σ-ε-hysteresis measurements. The significant changes in the peak values correlate with the development of macro-cracks. This effect can be used for the early detection of critical fatigue states before final failure in the sense of structural health monitoring.

Abstract In this work, we examine an application of AE technique for a probabilistic prediction of the time and place of earthquakes, in order to preserve the inestimable Italian Renaissance Architectural Complex named "The Sacred Mountain of Varallo". This historical site is composed of 45 Chapels, some of which are isolated, while others are part of monumental groups. The Chapels contain over 800 life-size wooden and multicoloured terracotta statues, which represent the Life, Passion and Death of Christ. The site is considered the most notable example in the group of Sacred Mounts of Piedmont, a complex that has been included in the UNESCO World Heritage List since 2003.
The structure of the Chapel XVII of this Renaissance Complex is at risk for its poor structural health and on account of the intensity of the stresses it is subjected to, due to the level of regional seismicity. For the reliability and safety of this masterpiece of cultural heritage, a life-time assessment should take into account the evolution of damage phenomena. Therefore a continuous AE monitoring is performed to assess the structural behavior of the Chapel.
Earthquakes always affect structural stability: the amount of energy released in a seismic event can cause catastrophic damage in a wide variety of ways. Beside this well-known point of view, in this paper it is claimed that the structures of the "Sacred Mountain of Varallo" behave as sensitive earthquake receptors, since the stress propagation through the Earth's crust, which can be considered as an earthquake precursor, can be effectively monitored by means of the AE technique.
In some works, a burst of AE activity is considered as representative of a large amount of stress which is crossing some large crustal area surrounding the AE recording site. Such AE crises are observed some time in advance compared to the earthquake, leading to consider AE records like earthquake precursors.
During the monitoring period, a correlation between peaks of AE activity in the masonry of the "Sacred Mountain of Varallo" and regional seismicity is found. These two classes of phenomena, AE in materials and earthquakes in Earth's crust, though they take place on very different scales, are very similar due to the release of elastic energy from localized sources inside the medium: opening microcracks and hypocenters of earthquakes.

Keywords Acoustic Emission, Structural Monitoring, Cultural Heritage, Earthquake, Seismic Precursors.

1. Introduction: The historic site of the Sacred Mountain of Varallo

The Sacred Mountain of Varallo is located in the italian province of Vercelli. Set on a cliff above the town of Varallo, it is the oldest and most important Sacred Mountain of the Alps (Fig.1). His story began in the late fifteenth century when the Franciscan friar Bernardino Caimi of Milan, returning from the Holy Land where he was guardian of the Holy Sepulchre, decided to reproduce in Varallo the holy places of Palestine [1].

The "New Jerusalem", as it is called the Sacred Mountain, initially intended to represent the distant sites of the Christian tradition for all those people who could never go there (Fig.2). Inside these places are, instead of pictures, paintings and sculptures to evoke the corresponding event in the history of the life of Christ. Already in the early sixteenth century, thanks to the work of the

painter sculptor and architect Gaudenzio Ferrari, the scenes inside the chapels are represented in an ingenious and innovative merging of painting and sculpture, with a strong sense of reality, so that the devotee could feel himself deeply involved by the depicted scene of the Christ's Life and almost part of it (Fig.3). The work of Gaudenzio Ferrari will be taken as a model in the construction of many other Sacred Mountains. In the era of the Counter-reformation, the Sacred Mountain of Varallo assumed the appearance of a path, real but at the same time mystical, that the pilgrim completes following the telling of the story of Christ's Life. The Sacred Mountain is composed of a basilica and forty-five frescoed chapels, populated by over eight hundred statues. For the completion of this extraordinary monument worked important Piedmontese artists, among which there are Bernardino Lanino, Tanzio da Varallo, brothers D'Enrico, Morazzone, and Dionigi Bussola [1].

2. Chapel XVII monitoring set-up

The Acoustic Emission monitoring is conducted on the frescoed masonry walls of the Chapel XVII of the Sacred Mountain of Varallo: the Chapel of the Transfiguration of Christ on Mount Tabor (Fig.4). The construction of the Chapel XVII began in 1572, but the structure was completed only in 1647. In 1664 was built the lantern top as crowning.

The purpose of monitoring by means of AE sensors applied to the frescoed wall, is to detect the possible Acoustic Emission signals from a vertical crack and from a region of the wall in which the frescos show a detachment of plaster. The operations necessary for the AE sensors bonding to the wall are carried out by a group of restorers, which have prepared a film of Japanese paper, on the surface of which is coated a thin layer of "Paraloid".

The "Paraloid" is an acrylic resin (methyl acrylate soluble in ketones, esters, hydrocarbons and chlorinated hydrocarbons) and is used in the field of restoration as a consolidant at low concentrations (2,4%) or as an adhesive at higher concentrations. It allows an excellent waterproof performance and has the advantage of being reversible and long-term stable. The layer of "Paraloid" forms a good protective base for the AE sensors bonding with silicone glue. The sensors are applied to monitor both the vertical crack and the detachment of the plaster (Fig.5).

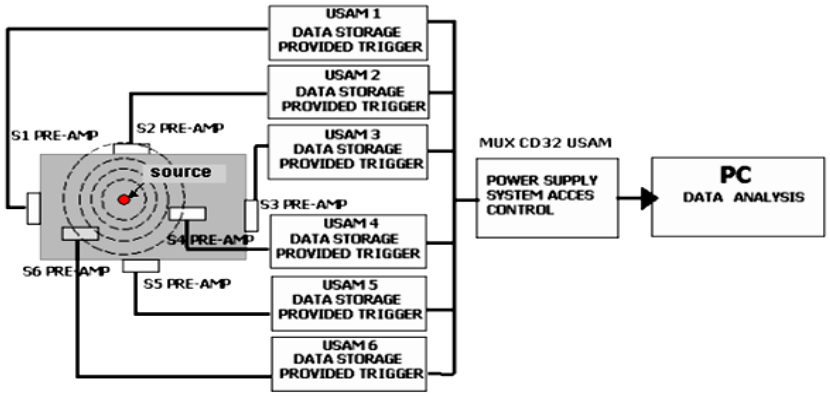

Fig.6. AE Acquisition System.

The Acoustic Emission acquisition system is shown schematically in Fig.6.

The piezoelectric transducers (PZT) are calibrated over a range of frequency between 50 kHz and 800 kHz. The USAM acquisition system consists of 6 pre-amplified sensors, 6 units of data storage provided of triggers, a central unit for the synchronization operations, internal clock and a trigger threshold. The obtained data are: progressive number of each signal, acquisition time, intensity, duration, number of oscillations over the threshold value [2,3].

4. AE and seismic events

Non-destructive testing methods are currently used to evaluate structural damage phenomena and to predict their development over time. In particular, the evaluation of damage in historic buildings is often a complex task [4,5]. It is essential to distinguish between stable damage patterns and damage in evolution toward a catastrophic collapse. Some structural damage can be triggered by

events such as earthquakes. Furthermore, the limited ductility of the masonry, combined with the large size of this type of construction, provides a structural behavior rather fragile [6]. For these reasons, the damage evolution in time can be effectively evaluated by means of the Acoustic Emission technique [7,8,9,10].

Moreover, the statistical distribution of earthquakes shows a complicated behavior space–time, that reflects the complexities of the Earth's crust. Despite this complexity, there is a scaling law universally valid: the statistical distributions of frequency-magnitude of an earthquake provided by the Gutenberg-Richter (GR) law [11].

On the other hand, AE in materials and earthquakes in the crust are very similar and correlated in time, even if they are phenomena that occur at different scales [12]. In both cases there is a release of elastic energy from a source located in the medium: respectively the opening of micro cracks and the seismic hypocenter [13]. This similarity suggests an interpretation in which the seismic events and the AE events can be related in space and time. In this view is therefore possible to search for a correlation between the parameters related to AE and the regional seismicity. As a matter of fact, this approach can be used to identify the warning signals that precede a catastrophic event for a structure since, in many cases, these warning signals can be detected well in advance with respect to the time at which the undesired event will occur [14,15].

Most earthquakes have precursors, ie phenomena that in the short or long term change their activity before the earthquake. In the past, many precursors have been proposed but it is still not clear what is really reliable. Surely any operative scheme of prediction must be based on a combination of more clues. Recently, major efforts in the field of earthquake prediction have focused on the fluctuations of the physical parameters of the crustal rocks of the seismically active continental areas, and on regular intervals in the space-time distribution of earthquakes [16]. The variation in the rate of the regional seismicity is considered as a precursor in the long term. A region which had a small earthquake activity for a remarkable number of years is called "seismic gap". The "seismic gaps" are considered as potential sites for major earthquakes. On the other hand, the increasing pressure in the rock surface in the region of the epicenter produces numerous cracks before the final collapse and, as a result, it causes changes in the properties of rocks. Therefore, the drop in speed of seismic waves caused by the expansion of the rock becomes a significant precursor. Other precursors linked to the expansion of the rocks and the opening of cracks are the crustal tilt and elevation changes, the decrease of the electrical resistivity of the rocks, and the release of radon gas in the atmosphere, which requires small pores to propagate. As the process of damage develops, the water diffuses from the surrounding rocks in pores and micro cracks of increasing size, which in the meantime are forming. The moment the water fills the cracks, the speed of seismic waves grows, the soil lifting stops, the emission of radon from the new cracks is relieved, and the electrical resistivity decreases. The next stage is the beginning of the earthquake, which is immediately followed by several aftershocks in the surrounding area [7,16].

When a crack in the Earth's crust increases, the corresponding AE show progressively lower frequencies, up to abandon eventually the ultrasound field reaching the sonic range: this represents the well known phenomenon of seismic roar. Thus, AE techniques have the potential for effectively monitoring the spread of tensions through the earth's crust. In fact, Italian researchers collected continue AE recordings for many years in the Gran Sasso massif. It was noted a peak of the AE about 400 km away from the epicenter, many months before the occurrence of the earthquake in

Assisi [14,15]. Progressively lower frequencies of detected AE seemed consistent with the theory that high-frequency AE can be associated with the progress of small lesions of the crust, which later coalesce to form defects growing bigger and bigger. In order to correlate the peaks of AE activity to seismic precursors mentioned earlier, it was observed that the fumes of radon occur almost simultaneously with the AE peaks about 7-8 months before the earthquake. Therefore, the potential of earthquake prediction related to the AE monitoring appears promising, since the AE signals may be picked up in advance [14].

4.1. Correlation algorithms between AE and seismic events

Among the various studies on the earthquakes space-time correlation, there is a statistical method that allows to calculate the degree of correlation both in space and time between a series of AE and the local seismic recordings, collected in the same period. This analysis is based on the generalization of the space-time correlation known as the integral of Grassberger-Procaccia [17], defined as follows:

$$C(r,\tau) \equiv \frac{1}{N_{EQ}N_{AE}} \sum_{k=1}^{N_{EQ}} \sum_{j=1}^{N_{AE}} \Theta(r - |x_k - x_j|)\Theta(\tau - |t_k - t_j|) \tag{1}$$

where N_{AE} is the number of peaks of AE activity registered in site and in a defined time window, N_{EQ} is the number of earthquakes recorded in the surrounding area during the same time window, and Θ is the step function of Heaviside ($\Theta(x) = 0$ if $x \le 0$, $\Theta(x) = 1$ if $x > 0$). The index k refers to the recorded seismic events $\{x_k, t_k\}$, while the index j refers to the recorded AE events $\{x_j, t_j\}$.

Therefore, between all possible pairs of recorded AE and seismic events, the sum expressed by the integral of Grassberger-Procaccia is valid for those having the epicentral distance $|x_k - x_j| \le r$ and the temporal distance $|t_k - t_j| \le \tau$. Hence, $C(r,\tau)$ is the probability of occurrence of two events, an earthquake and an AE event, whose mutual spatial distances are smaller than r and mutual temporal distances are smaller than τ.

Anyway, this approach does not consider the chronological order of the two types of event. Since the AE time series and the earthquake sequences are closely intertwined in the time domain, the problem of the predictive ability of the AE peaks is still open, and the records of noise could be the consequences of the progressive development of micro damage. However, a probabilistic response sought by considering the first AE events as precursors and later as aftershocks of an earthquake is utilized. This analysis is performed by using a modified correlation integral [7]:

$$C_{\pm}(r,\tau) \equiv \frac{1}{N_{EQ}N_{AE}} \sum_{k=1}^{N_{EQ}} \sum_{j=1}^{N_{AE}} \Theta\left(r - |x_k - x_j|\right)\Theta\left(\tau - |t_k - t_j|\right)\Theta\left(\pm (t_k - t_j)\right) \tag{2}$$

where "+" and "-" in the Heaviside function are used to take into account that the AE events could be respectively seismic precursors and aftershocks.

5. AE as seismic precursors in The Sacred Mountain of Varallo

5.1. AE monitoring periods

The AE collected data are grouped into two different time windows. The first time window starts from May 9, 2011 and finishes June 16, 2011. The second time window starts July 5, 2011 and finishes September 5, 2011. Both time windows shown in the following involve the monitoring of the vertical crack and of the frescos detachment [2,3].

5.2. Recognizing impending earthquakes by means of AE

In this section, referring to the theories introduced above, we obtain a correlation between seismic and acoustic events through the application of the modified integral of Grassberger-Procaccia.

The data series of AE analyzed are those related to the time periods listed above. The seismic events, taken from the website http://iside.rm.ingv.it/iside/standard/result.jsp?page=EVENTS#result (seismic catalog of INGV, National Institute of Geophysics and Volcanology), are selected introducing search parameters relating to the defined AE monitoring periods and to a radius of 100 km, close to the site of Sacred Mountain of Varallo (Fig.7).

Looking at the temporal distribution of earthquakes in relation to the cumulative AE trend, it can be seen a certain correspondence between AE peaks and earthquake events (Fig.8,9). By applying to the data series the modified correlation integral of Grassberger-Procaccia, we obtain the cumulative probabilities, depending on the radius of interest r and on the interval of occurrence t, considering the peak of Acoustic Emission both as earthquake precursor and as aftershock (Tables 1,2,3,4).

8 weeks	0.0313	0.1336	0.4333
9 weeks	0.0313	0.1341	0.4338

Table 4. Cumulative Probability C^-: AE as Aftershock from July 5, 2011 to September 5, 2011

Comparing the probability values obtained for the period May-June, it can be seen that, regardless of the distance and of the correlation time, the probability that a seismic event follows a peak of Acoustic Emission is always greater than the probability that the same AE peak is an effect of the damage caused by the earthquake (Tables 1,2). In practice, we see that the monitored structure behaves as a good seismic receptor.

It is interesting to note that, for both monitoring periods, within a radius of 60 km from the monitored site, the AE signal still plays its role as a seismic precursor. On the contrary at 80 km and 100 km, the AE behavior follows the variation of the time windows (Tables 3,4). In particular, we can observe a clear reversal of the AE signal behavior from precursor to aftershock for the second

monitoring period (July-September): at 60 km there was a tendency for AE to anticipate earthquakes even though they are effectively correlated only in the long term; at 80 km they are precursive signals only in the short term; at 100 km we see immediately the reversal outlined above, from precursor behavior to aftershock.

In any case, it is worth of the further investigations distinguishing environmental contributions to AE activity on the Chapel XVII due to crustal trembling (external source) from contributions due to structural damage (inner source).

To investigate the nature of these results, true progress can be realistically achieved by discriminating the signals recorded on the basis of a predetermined threshold both in frequency and amplitude, consistently with the physical nature of Acoustic Emissions detected by the sensors. Looking at the USAM data stored, a good choice to discriminate the signals nature, is setting a threshold frequency −for example 30 kHz, which divides the field VLF (Very Low Frequency) from the field LF (Low Frequency)− and a purposeful threshold signal amplitude.

It seems reasonable even from a theoretical point of view, that low frequencies allow the diffusion of the elastic waves in the masonry bulk, both intact or damaged. On the other side, low amplitudes are reasonably related to the fact that an event captured by AE sensors on the monitored structure may have originated from a source physically distant from the site monitored (seismic hypocenter) and therefore is subject to the laws of amplitude damping.

6. Conclusions

Besides the canonical use in Non-destructive Tests, the heuristic potential of AE monitoring of civil structures for earthquakes prediction appears very intriguing. Starting from the assumption that any structure should not be regarded as separated from its environoment, a method of correlating AE activity on the Renaissance Complex of the Sacred Mountain of Varallo subjected to a long-term monitoring with regional seismicity is investigated. Two qualitatively very similar phenomena such as Acoustic Emission and earthquakes become two aspects of a unique phenomenon which looks self-similar.

Furthermore, in this work by applying the modified Grassberger-Procaccia correlation algorithm −with the aim of explaining the correlation between regional seismicity and Acoustic Emission emerging from the Chapel XVII of the Sacred Mountain of Varallo− it is observed that the structure is a good sensitive receptors for earthquakes occurring within a radius of about 60 km.

In any case, it is worth of the further investigations distinguishing environmental contributions to AE activity on the Chapel XVII due to crustal trembling (external source) from contributions due to structural damage (inner source).

Abstract Descriptions of high temperature creep deformation often use the concept of the effective stress, which includes the presence of the internal stress. Many experimental techniques have been applied to measure the internal stress induced by creep deformation. However, there is still a debate about the validity of the measured values. This is partly because the distinction between internal stress and material internal resistance is unclear. In this paper, neutron diffraction measurements, undertaken using the spallation source at the Rutherford Appleton Laboratory, UK, are combined with in-situ loading to investigate the internal state of a Type 316H stainless steel. By undertaking measurements of the lattice strain for different grain families, before, during and after mechanical loading, the internal stress and internal resistance induced by prior creep were determined. The results show that these two parameters are important measures of the internal state, each changing during creep and influencing creep deformation rate. Additionally, internal stress is shown to be dependent on specific crystallographic planes of each grain family. The results are discussed with respect to the underlying mechanisms of creep deformation in stainless steel.

Keywords Internal Stress, Internal Resistance, Creep, Neutron Diffraction, Austenitic Stainless Steel

1. Introduction

Materials may deform by one of several different mechanisms depending upon the applied stress and temperature. It is convenient to present these mechanisms in the form of a deformation mechanism map [1]. More importantly, the use of engineering polycrystalline materials over the operational service life (typically $>10^5$ hours) produces a potential to change the initial microstructure, which can affect the controlling deformation mechanisms in creep [2, 3]. It has been recognised by Biberger and Gibeling [4] that creep deformation rate, $\dot{\varepsilon}_c$, relies on the state of the microstructure, temperature and applied stress. Thus, the deformation rate is described by a kinetic equation of the form:

$$\dot{\varepsilon}_c = f(\sigma_a, T, \hat{\sigma}_1, \hat{\sigma}_2 \cdots \hat{\sigma}_n) \quad (1)$$

where σ_a is the applied stress, T is the temperature, $\hat{\sigma}_1$, $\hat{\sigma}_2$ and $\hat{\sigma}_n$ represent a series of known and unknown internal state parameters which characterise the current state of the material. In addition, creep deformation leads to changes to the internal state parameters. Two of these parameters are considered here: (i) the creation of internal strains arising from strain incompatibility, for example due to the different creep deformation rates of individual grains in polycrystalline materials; (ii) a change in the material resistance. The first is called as internal stress and the second is called as internal resistance, as described by Chen et al. [5].

Many experimental techniques have been developed to provide a quantitative measure of these two terms, such as the widely accepted stress dip test technique [6], analysis of asymmetric X-ray diffraction peak profiles [7], dislocation density and geometrical arrangement obtained using transmission electron microscopy (TEM) [8]. In addition, creep deformation models, incorporating the term internal stress or internal resistance, have been developed to improve the prediction in creep deformation rate. These include models proposed by Estrin and Mecking [9],

Derby and Ashby [10], Esposito and Bonora [11]. However, there are two challenges remaining before those physically based creep deformation models can be adopted for the extension of life of existing power generation plants as well as the prediction of life for the future designs. First, the distinction between internal stress and internal resistance is often confusing and unclear [5]. Second, a reliable and simple measurement technique to quantify these two terms unambiguously is still required.

In this paper, we present a technique, based on neutron diffraction (ND) measurement combined with in-situ tensile deformation, to quantify the internal stress and internal resistance associated with high temperature creep deformation. The evolution of these two terms during creep deformation is measured quantitatively by this method. The crystallographic orientation dependence of the internal stress is discussed with respect to the underlying mechanisms of polycrystalline elasticity and plasticity. A newly developed self-consistent model has been established to interpret the measured results. The model is presented in the companion paper for this conference [12]. The ability of adopting this experimental technique to quantify internal state of the material is critically assessed, followed by concluding remarks.

2. Material and Experimental

2.1. Material

Type 316H austenitic stainless steel, provided by EDF Energy plc., with a chemical composition given in Table 1, was examined. The stainless steel had experienced 65,015 hours service at temperatures in the range of 763K to 803K and it was then subjected to a further thermal ageing at 823K for 22,100 hours. The grain size for this stainless steel was measured using the linear intercept method. The averaged grain size was 87±9μm.

Table 1. Chemical composition (wt.%) of Type 316H stainless steel

C	Si	Mn	P	S	Cr	Mo	Ni	Co	B	Fe
0.06	0.4	1.98	0.021	0.014	17.17	2.19	11.83	0.10	0.005	Bal.

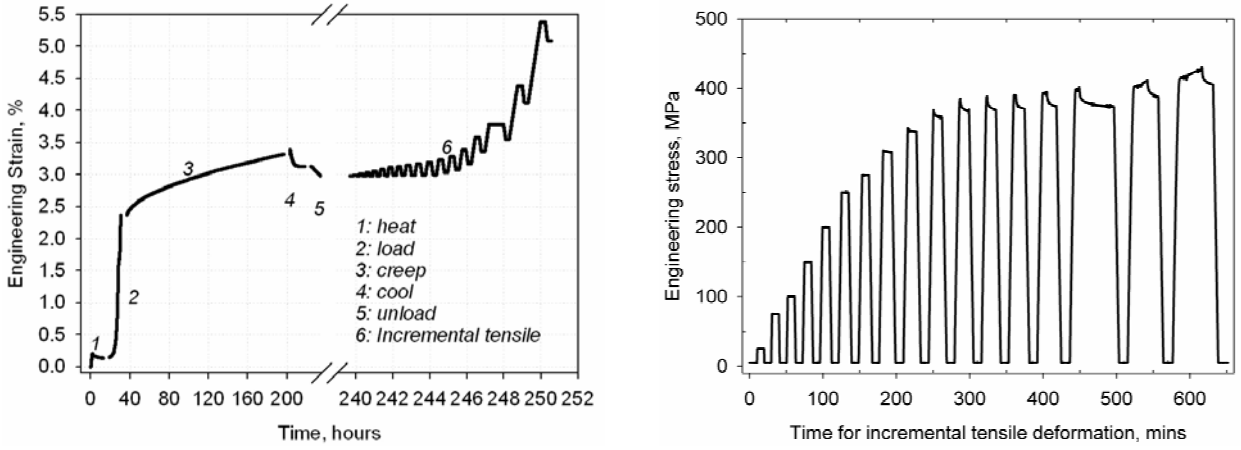
Table 2. Summary of specimens subject to a prior deformation at high temperature (250MPa and 823K)

Specimen ID	Creep test duration	Plastic loading true strain, %	True creep strain, %
Specimen 1	No creep	0	0
Specimen 2	As loaded	1.88	0
Specimen 3	Primary, 160h	2.04	0.92
Specimen 4	Secondary, 1000h	1.98	4.86

2.2. Prior deformation at high temperature

To study systematically the influence of the prior deformation at high temperature on the internal state of the material, four prior deformation states were considered: (i) no creep, (ii) as loaded, (iii) primary creep, and (iv) secondary creep. Four specimens were prepared from the Type 316H austenitic stainless steel. Prior deformation tests at a temperature of 823K were then carried out. A summary is given in Table 2. Uniaxial round bar specimens with a 28.25mm gauge length and 5.65mm diameter were used. These specimens were deformed at 823K and at a constant stress of 250MPa to different stages of creep deformation. The left hand side in Fig. 1 (a) illustrates the strain history for a specimen, which was strained to reach primary creep. The specimen was heated to a temperature of 823K, step 1 in Fig. 1 (a). This was followed by the application of load

to reach the test stress of 250MPa at 823K, step 2 in Fig. 1 (a). Specimen was then creep deformed to a pre-defined creep duration, which was followed by cooling under the applied load to freeze the creep induced dislocation structure. Finally the specimen was unloaded and dismantled at room temperature. This procedure was adopted for each specimen shown in Table 2. Each specimen was then subject to incremental tensile deformation at room temperature and simultaneously measured using neutron diffraction. This is detailed in the next section.



(a) (b)

Figure 1. A schematic diagram of the history applied to the specimen strained to the primary creep, followed by the room temperature incremental tensile deformation: (a) strain history and (b) stress cycles used in the incremental tensile deformation at room temperature combined with ND measurement

2.3. Incremental tensile deformation combined with neutron diffraction (ND)

The time-of-flight neutron diffractometer, at the Rutherford Appleton Laboratory, UK, is optimised to measure elastic strains at precise locations for the bulk material [13]. A pulsed beam of neutrons with a wide energy range travels to the specimen, see Fig. 2 (a), where a small fraction of the beam is diffracted to both detectors located at an angle of 2θ=90°. This arrangement provides a measure of axial strain vector from detector 1 and radial strain vector from detector 2, Fig. 2 (a). The wavelength, λ, of the detected neutrons is defined from their time-of-flight, t.

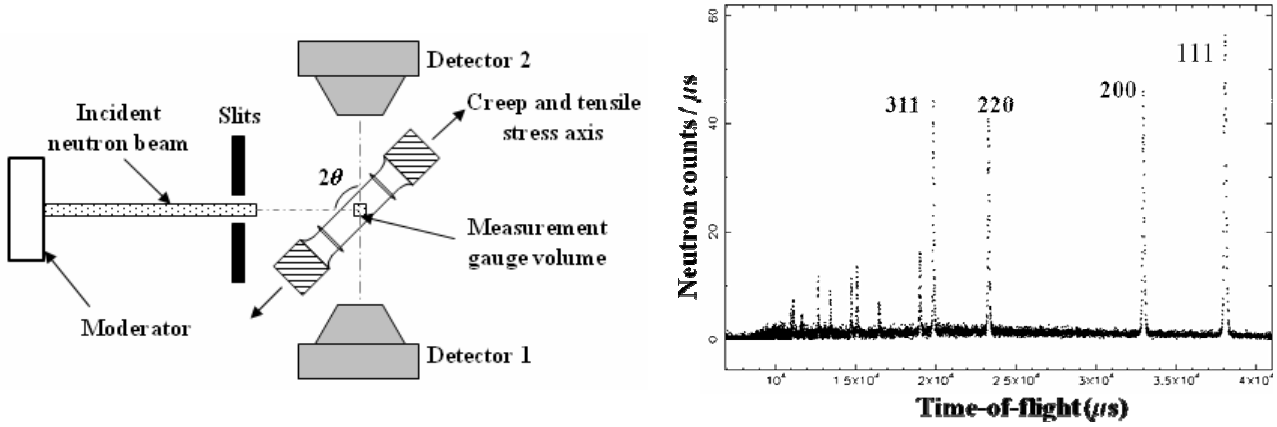
$$\lambda = \frac{h}{m(L_1 + L_2)} t \tag{2}$$

where h is the Planck constant, m is the neutron mass and L_1 and L_2 are the flight paths from the moderator to specimen and from the specimen to detector, respectively. A typical spectrum obtained from stainless steel is shown in Fig. 2 (b). Each diffraction peak, at a specific time-of-flight, according to Bragg's law, $\lambda_{hkl} = 2d_{hkl}\sin\theta$, represents a grain family with $\{hkl\}$ crystallographic orientation under a specific elastic strain. The evaluation of the elastic strain in each grain family of the material requires a measure of the lattice spacing of this grain family under the stress free condition. The elastic strain is determined from the change in the lattice spacing, as compared with the stress free lattice spacing:

$$\varepsilon_{hkl} = \frac{d_{hkl} - d^0_{hkl}}{d^0_{hkl}} \tag{3}$$

where ε_{hkl} is the elastic strain in the $\{hkl\}$ grain family, d_{hkl} is the lattice spacing at a specific strain state and d^0_{hkl} is the stress free lattice spacing. In this paper, four diffraction peaks are considered: {111}, {200}, {220} and {311} grain families, see Fig. 2 (b). In the time-of-flight instrument, the engineering strain can also be approximated from a Rietveld refinement of the

complete diffraction spectrum, see Fig. 2 (b) [13]. By knowing two principal strain vectors, the stress state in each grain family can be calculated from the generalized Hooke's law [14]. In our case, both axial and radial strain vectors have been measured from detectors 1 and 2.



(a) (b)

Figure 2. Neutron diffraction: (a) arrangement of the in-situ tensile deformation specimen in the ENGIN-X neutron diffractometer; (b) typical time-of-flight diffraction spectrum for the investigated stainless steel

In-situ tensile deformation was performed at room temperature on the specimens, which had been subjected to a prior deformation at high temperature, see Figs. 1 (a) and (b). The arrangement of the neutron diffractometer in ENGIN-X with respect to the specimen is shown in Fig. 2 (a). The direction of applied loading for the prior creep deformation and the direction of the incremental tensile deformation were co-axial. As illustrated in Fig. 1 (a), room temperature incremental deformation may be considered to be a continuation of deformation in terms of the total strain accumulated. Fig. 1 (b) shows the applied stress history during the incremental tensile deformation, where the stress level was increased step by step. At the end of each load step, the specimen was held at either a constant stress (elastic region) or at a constant strain (plastic region) for the period of the neutron diffraction (ND) measurement time to provide a measure of d_{hkl}, see Figs. 1 (a) and (b) All the incremental tensile deformation tests were undertaken at a constant strain rate of 5×10^{-6}/s using the ENGIN-X 100kN servo-hydraulic stress rig. A fixed rate was selected because the yield point of stainless steel is very strain rate dependent. An extensometer was attached onto the specimen to measure the bulk axial strain of the material during loading.

A 3mm×3mm×4mm gauge volume was used for the neutron diffraction (ND) measurements to ensure the sampled gauge volume was fully contained within the specimen, as illustrated schematically in Fig. 2 (a). A typical measurement time of 540s was selected to ensure good counting statistics for the diffraction peaks. Some stress relaxation was observed when the stress was higher than 300MPa, Fig. 1 (b). To ensure the stress change was less than 3MPa when measurements were undertaken in the plastic region, a pre-defined delay for starting ND measurements, ranging from 180s to 360s, was adopted. Therefore all the neutron diffraction measurements were undertaken at a relatively constant stress.

2.4. Derivation of internal stress and internal resistance due to creep

The internal stress, due to the prior deformation at high temperature, was quantified directly by the change in the lattice spacing which was measured from each specimen (without being subjected to the incremental tensile deformation). Specimen 1 was not subjected to any prior deformation at high temperature, and therefore was considered to be a reference state that was free of internal

stress. The lattice spacings measured in the other three specimens, Table 2, were then compared with specimen 1:

$$\varepsilon_{hkl}^{i} = \frac{d_{hkl}^{i} - d_{hkl}^{1}}{d_{hkl}^{1}} \tag{4}$$

where ε_{hkl}^{i} is the internal strain in specimen i (i=1, 2, 3 or 4 based on Table 2), d_{hkl}^{1} is the lattice spacing in {hkl} plane measured from specimen 1 and d_{hkl}^{i} is the lattice spacing measured from specimen i (i=1, 2, 3 or 4 based on Table 2).

Internal resistance measurements were undertaken using a combination of loading and unloading steps to enhance the accuracy for the determination of the initial yield point in each specimen, Fig. 1 (b). In practice, the internal resistance is equal to the magnitude of applied stress that produced a deviation from linearity on a peak strain versus applied stress graph (ε_{hkl}-σ_a graph). The deviation from linearity was calculated from the difference between the measured elastic lattice strain and the predicted elastic lattice strain from diffraction elastic constants. It should be mentioned that the internal resistance measured using this method does not take into account the presence of internal stress. Thus the corrected internal resistance in each specimen was evaluated by deducting the magnitude of the pre-existing internal stress from the initially determined internal resistance.

A series of unloading steps to a nominally zero applied stress (5MPa) was adopted during the incremental tensile deformation, Fig. 1 (b). Using this approach it was possible to track the change in the internal stress introduced by room temperature tensile deformation. This can be then added to the pre-existing internal stress due to high temperature deformation to provide a measure of the evolution of internal stress introduced by the general plastic deformation, i.e. the sum of room temperature plastic deformation and high temperature plastic and creep deformations.

3. Results

3.1. Response of lattice strain responses and deviations from linearity

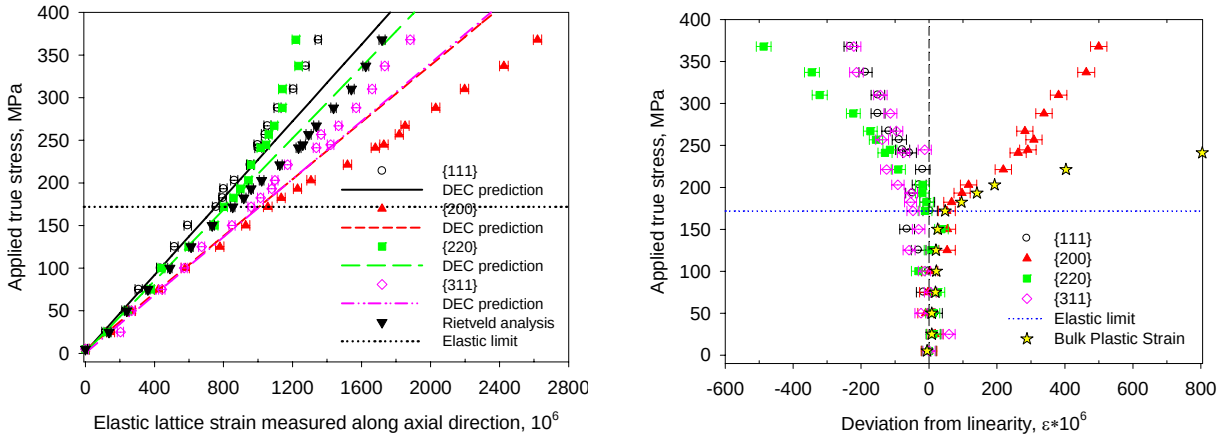
Fig. 3 (a) shows the ND measured lattice strains along the axial direction as a function of increasing applied stress for specimen 1, not subjected to a prior high temperature deformation. The diffraction elastic constants (DECs) for all four grain families were determined from the ND measurement data within the elastic region, the linear portion of the ε_{hkl}-σ_a graph, below the elastic limit illustrated by the dotted line in Fig. 3 (a). A linear least squares regression method was used to fit the data and obtain the DECs. From the region where the applied stress was above the elastic limit, the measured lattice strains for the {220}, {111} and {311} grain families diverged from linearity towards a lower strain value (to the left hand side of the prediction), whereas the {200} lattice strain diverged to a larger strain value (to the right hand side of the prediction). Fig. 3 (b) shows the calculated difference between the ND measured lattice strain and the predicted lattice strain using the DEC for each grain family. After reaching the applied stress of 375MPa, Fig. 3 (b), the difference was about -500×10^{-6} strain (compression) for the {220} grain family, however for the {200} grain family the difference was about $+500\times10^{-6}$ strain (tension). In addition the bulk plastic strain measured by the extensometer provided a consistent prediction of the deviation from linearity, Fig. 3 (b). This data analysis procedure was adopted for each specimen. The DECs and elastic limits of all four specimens are summarised in Table 3. Among the four grain families, {200} grain family was the most compliant and the {111} grain family was the stiffest. The progressive increase in the elastic limit from specimens 1 to 4 was consistent with the increase in the total strain introduced by the prior deformation at high temperature. The uncertainty for the

determination of the DECs is also given in Table 3 for each grain family.

Fig. 4 (a) and (b) show the influence of prior deformation at high temperature on the response of the lattice strains to the applied stress for the {200} and the {220} grain families, respectively. They are illustrated by the deviation from linearity. A negative value indicates the presence of a micro-yielding in a particular grain family and a positive value indicates the effects of sharing load due to yielding of other grain families. The uncertainties shown in the Figs. 4 (a) and (b) are based on the uncertainties in the determination of DECs, summarised in Table 3. This applies to all specimens shown in Figs. 4 (a) and (b). In terms of the {200} grain family, Fig. 4 (a), the magnitude of the deviation from linearity (positive values), decreased to a minimum value from specimen 1 to specimen 3, but increased slightly for specimen 4. The deviation from linearity observed in specimen 3 was typically less than 100×10^{6} and thus was less than the uncertainty. In terms of the {220} grain family, a very small decrease in the magnitude of the deviation from linearity (negative values) was observed from specimen 1 to specimen 3, Fig. 4 (b). However, specimen 4 showed a different lattice strain response, compared with the other three.

Table 3. Summary of diffraction elastic constants (DECs) and elastic limits of specimens

Specimen ID	Prior deformation	$E_{\{111\}}$, GPa	$E_{\{200\}}$, GPa	$E_{\{220\}}$, GPa	$E_{\{311\}}$, GPa	Elastic limit (measured at 0.01% bulk plastic strain), MPa
Specimen 1	No creep	225±12	167±5	209±16	170±16	184
Specimen 2	As loaded	255±21	155±4	211±8	172±8	333
Specimen 3	Primary	264±16	146±6	201±7	204±15	344
Specimen 4	Secondary	254±4	171±9	255±16	208±12	377
Averaged DECs		250±16	160±11	219±24	188±20	

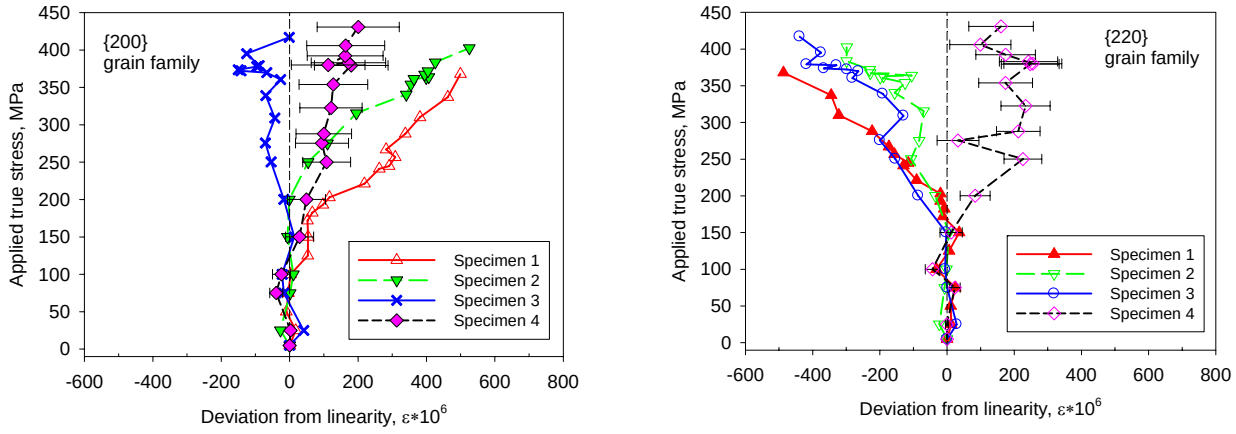


(a) (b)

Figure 3. (a) ND measured elastic lattice strain along the axial direction of specimen 1 for {111}, {200}, {220} and {311} grain families; (b) Deviation of the measured lattice strain from the extrapolated elastic lattice strain using DECs. Note: Measurement uncertainties are from the single peak fitting error

Neutron diffraction measurements undertaken at 5MPa after each step of unloading over the process of incremental tensile deformation at room temperature, see Fig. 1 (b), revealed the evolution of the residual elastic lattice strain. Figs. 5 (a) and (b) show the changes in the residual lattice strains with the increase in the bulk plastic strain measured by the extensometer attached on the specimen, for the {200} and {220} grain families, respectively. In terms of the {200} grain family, specimen 4 which was subjected to prior secondary creep deformation, had the highest compressive residual lattice strain, but specimen 1 had the highest tensile residual lattice strain. In terms of the {220}

grain family, very little residual elastic lattice strain (<150×10^{-6} strain) was accumulated during incremental tensile deformation of specimens subjected to prior deformation at high temperature.



(a) (b)

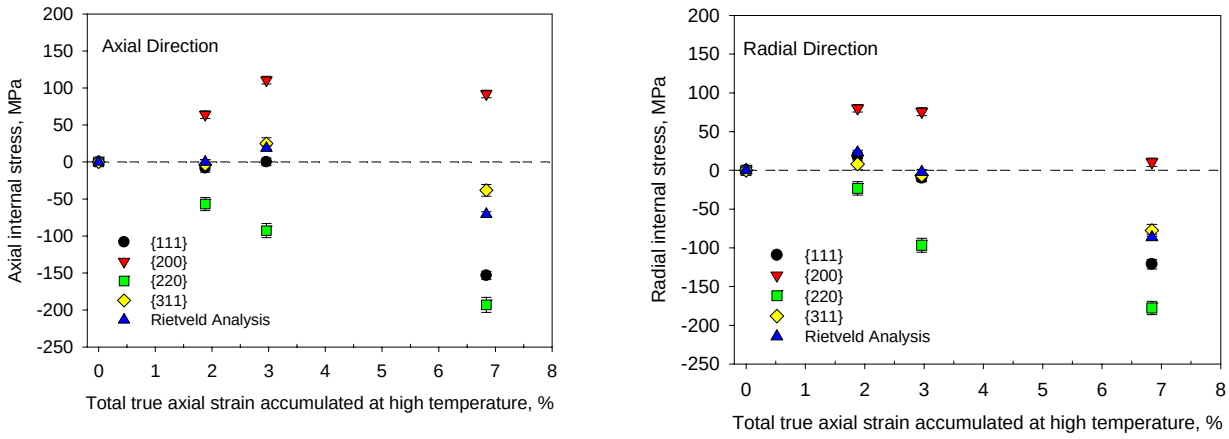
(a) (b)

Figure 5. ND measured elastic lattice strain after each step of unloading, measured at a stress of 5MPa, plotted against the accumulated plastic strain at room temperature: (a) {200} grain family; (b) {220} grain family

3.2. Internal stress

Figs. 6 (a) and (b) show the internal stresses along the axial and radial directions for specimens subjected to prior deformation. In general, an increase in the magnitude of the prior strain led to a higher internal stress. In addition, the internal stress was shown to have a crystallographic orientation dependence: internal stress in {200} grain family was tensile, whereas the other three were compressive. Of the three grain families the {220} grain family contained the highest compressive internal stress. Rietveld refinement predicted an averaged value for four grain families considered in Figs. 6 (a) and (b). It is interesting to note that {200} grain family in specimen 4 (highest total true axial strain) had a very similar value of internal stress compared with specimen 3. However, the {220} grain family in specimen 4 had an increased value of internal stress compared with specimen 3. These two phenomena are consistent with the in-situ observations shown in Fig. 4 (a) and (b), where a very similar lattice strain response was observed in the {200} grain family from specimens 3 and 4; this is different for the {220} grain family.



(a) (b)

Figure 6. Internal stresses in specimens 1 to 4, which were subjected to a prior deformation at high temperature: (a) axial direction and (b) radial direction

3.3. Internal resistance

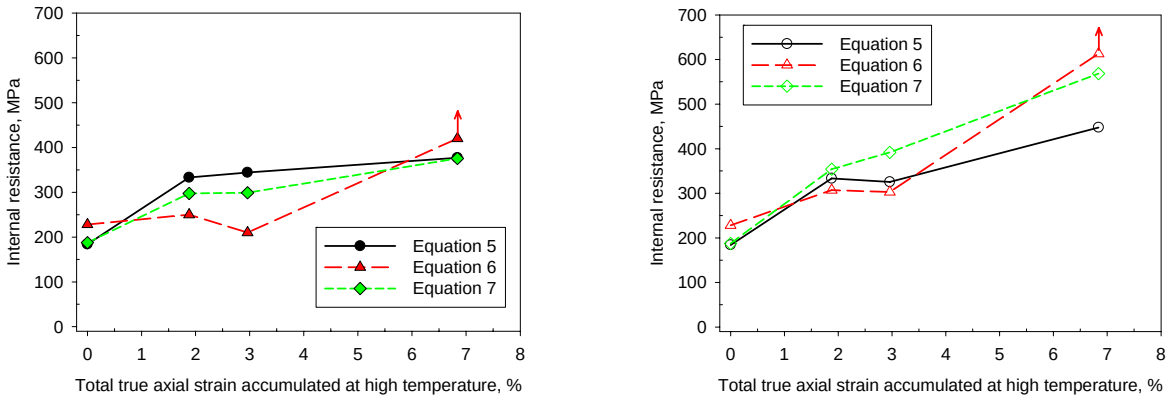
Using the incremental tensile deformation for each specimen combined with neutron diffraction measurements, the magnitude of applied stress required to create room temperature plastic deformation was obtained. This is judged to be a measure of the internal resistance to material flow. Fig. 7 shows the internal resistance in the four specimens summarised in Table 2. Internal resistance obtained from the bulk stress-strain, {220} grain family is shown in Fig. 7. Here, the 0.01% plastic strain is used as a benchmark to determine the yield point for both macro-scale and grain family size-scale conditions. The internal resistance was determined using:

$$\sigma_{bulk}^{ir} = \sigma_a^{0.01\%,bulk} \tag{5}$$

$$\sigma_{220}^{ir} = \sigma_a^{0.01\%,\{220\}} \tag{6}$$

$$\sigma_{220}^{ir} = E_{220} \times \varepsilon_{220}^{0.01\%} \tag{7}$$

Equation 5 provides a measure of the macro-scale internal resistance, σ_{bulk}^{ir}, and was determined from the applied stress required to introduce 0.01% macro-scale plastic strain. Equation 6 provides a measure of the grain family size-scale internal resistance, σ_{220}^{ir}, determined from the applied stress that is required to introduce 0.01% micro-scale plastic strain. This is the deviation calculated in Fig. 4 (b). Equation 7 provides a second choice to measure σ_{220}^{ir}, determined from the 0.01% micro-scale plastic strain, using the DEC for {220} grain family given in Table 3.



(a) (b)

Figure 7. Internal resistance in specimens subjected to prior deformation at high temperature: (a) internal resistance without knowledge of internal stress; (b) internal resistance with knowledge of internal stress

The evaluation of internal resistance without the knowledge of the pre-existing internal stress due to the prior high temperature deformation is shown in Fig. 7 (a). The combination of ND measured internal stresses in section 3.2 and the determined internal resistance produces the correct magnitude of the internal resistance, Fig. 7 (b). The internal stresses determined via Rietveld refinement was used to correct the macro-yield strength, read from each bulk stress-strain curve for the corresponding specimens. In general, the internal resistance of the material increased with an increase in the level of the prior strain induced at high temperature. The points with an upper arrow in Fig. 7 (a) and (b) indicates that the {220} grain family did not yield with the applied stress, as shown by specimen 4 in Fig. 4 (b).

4. Discussion and Concluding Remarks

Internal stress is a consequence of strain incompatibility between grains which deform differently due to their specific orientation. This deformation, arising from slip on {111} <110> system, is accommodated elastically within the various crystallographic grain families. Internal resistance is a reflection of the material internal microstructure that resists plastic deformation. These two terms have been measured using the present ND technique and the success is attributed to the separation of internal stress and internal resistance. The former can be measured after unloading from high temperature deformation by using a microstructure freezing technique. The latter can be measured with the applied stress to evaluate the flow stress. Mecking and Kocks [15], and Follansbee and Kocks [16] proposed a model and experimental method to measure the internal resistance (called a threshold strength) at temperatures of <300K. However, in this case the presence of the internal stress was not taken into account when the internal resistance was determined. The technique proposed in this paper measures the internal resistance and internal stress at both macro-scale and at the scale of grain families. The latter is very important when providing a crystal plasticity based self-consistent model, see Ref [12].

Using this approach it is found that the internal stress is dependent on the specific crystallographic orientation of each grain family, as shown in Fig. 6. The increase in the magnitude of the internal stress, {200} in tension and {220} in compression, corresponds to the increase in the inhomogeneous strain induced by high temperature deformation, summarised in Table 2. High temperature recovery may play a role in accommodating the strain incompatibility, and lead to a small decrease in the measured internal stress, see {200} grain family for specimens 3 and 4 shown in Fig. 6. This indicates that the creep deformation rate is grain orientation dependent, otherwise the accommodation will not decrease strain incompatibility in a polycrystalline material.

The crystallographic orientation dependence of the elastic lattice strain on the applied stress, Fig. 3 (a), is consistent with a previous study by Daymond and Bouchard [17]. The present work specifically explored the influence of the prior deformation at high temperature on the measured elastic lattice strain. It was shown that the {220} grain family no longer yielded after secondary creep deformation, see specimen 4 in Fig. 4 (b). The residual lattice strain, measured after each unloading step of the incremental tensile deformation, revealed a strong influence of creep deformation on the ability of the material to plastically deform in the {220} and {200} grain families, Fig. 5 (a) and (b).

Finally, we have described a method to distinguish between the internal stress and internal resistance based on neutron diffraction measurements combined with in-situ incremental deformation. This could be used to validate the threshold strength concept, proposed by Kocks, Mecking and their co-workers [9, 15, 16]. This has been discussed more fully in a review by Kocks and Mecking [18].

Abstract: Diffusion coatings are widely used to increase oxidation and corrosion resistance of hot superalloy components for gas turbines. The aim of this study is to investigate the effect of coatings (NiAl and PtAl) on the creep fracture mechanism of samples with a substrate of IN792. The samples have been creep tested at two temperatures (850 °C and 950 °C) and different applied tensile stresses, until failure between 205 and 21000 hrs. The observation of cross-sections by SEM shows that the microstructural evolution in the coating is dependent on the diffusion of alloying elements in the sample. Furthermore the time and temperature induced growth of the coating is found to be controlled only by inward diffusion of Al. Grain-boundary cracking is the basic fracture mode in the substrate in all samples irrespective if the crack is initiated from coating or substrate. The analysis of microstructure shows that the diffusion coatings display two types of mechanical behavior - being easily plasticized or cracked - dependent on temperature and type of coating, and therefore can be considered as non-load carrying regions. After recalculating the creep stress to exclude the final effective coating thickness from the total sample thickness, the coated samples showed similar creep rupture behavior as the uncoated samples in the Larson-Miller diagram.

1. Introduction

Due to their excellent high-temperature mechanical properties, superalloys are widely used as base material for components in advanced gas turbine operating at high temperatures [1]. Components with Al-rich coatings become much even more sustainable with better resistance against environmental attack from high-temperature oxidation and corrosion. Aluminide diffusion coatings are widely used to protect the superalloys in a gas turbine at temperatures lower than 1000 °C [2]. Due to the difference of mechanical properties compared to the base material, the effect of coatings on the mechanical behavior of the substrate needs to be considered. At higher temperatures creep of the material become an important issue. There have been some investigations on creep mechanism of superalloys with high temperature coatings, which suggest several effects of coatings: a change in microstructure of the base material; a change of load distribution; introduction of cracks [3,4]. Some valuable creep tests (generally < 1000 hrs) of diffusion coating-superalloy system have been made during the past decades [5-8]. However long-term creep test results (> 1000 hrs) are seldom presented in the best literature surveys. Furthermore in some specific situations, the coating has to be deposited onto the thin part of the component, which makes the effect of coating more critical. The industrial background to this research work actually emanates from problems in the walls of the cooling channels which can be as thin as in the order of millimeters. The aim of this paper is to investigate the mechanical effect of diffusion coatings on thin sectioned superalloy specimens (~ 1 mm) subjected to creep at the operating temperatures.

2. Experimental procedures

Creep samples in the form of sheet were produced from cast of nickel based polycrystalline superalloy Inconel 792 (IN792) with the nominal chemical composition of Ni-12.5Cr-9Co-4.175W-4.175Ta-3.975Ti-3.375Al-1.9Mo-0.08C-0.0175Zr-0.015B (wt.%). A drawing of the specimens is shown in Fig. 1. Two kinds of diffusion coatings - NiAl and PtAl - were deposited onto the specimen surface by the CVD process at 1050-1100 °C for 12-20 hrs. The specimens were solution treated at 1120 °C for 2 hrs and then aged at 845 °C for 24 hrs, followed by air cooling to room temperature. The main phases in the alloy are a solid solution of nickel based γ (disordered FCC) and an intermetallic γ' (FCC_$L1_2$). Four types of specimens were used in this study (Table 1). Specimens coated with only NiAl or PtAl, and specimens coated with NiAl on one side but PtAl on the other including an uncoated reference. The creep samples were tested under different static tensile loads at 850 °C or 950 °C in air until failure. The tested samples were cut as cross sections in their longitudinal direction (loading direction) and then carefully ground and mechanically polished pre, to study the microstructure below the fracture surface. The microscopic characterization was carried out by using a *FEG-SEM Hitachi SU-70* scanning electron microscope (SEM) with an INCA *Oxford Instruments* energy dispersive system (EDS).

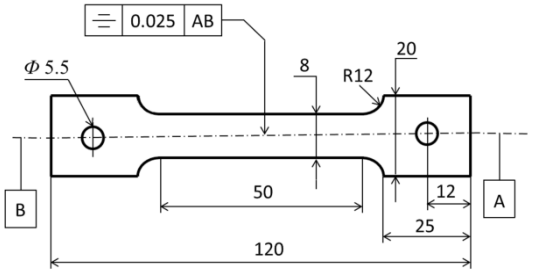

Figure 1. Dimensions of the sheet specimens with thickness of 1 mm (in millimeters).

Sample type	Coating covering	
	One side	Another side
Uncoated	uncoated	uncoated
NiAl-NiAl	NiAl	NiAl
PtAl-PtAl	PtAl	PtAl
NiAl-PtAl	NiAl	PtAl

3. Results and discussion

3.1. Creep test and *effective coating thickness* (*ECT*)

Results from the creep tests are presented as applied stress versus creep life (Fig. 2). The creep lifetime varied largely between 205 hrs and 21000 hrs, depending on the testing temperature and applied stress. As expected, the resistances to creep rupture decreases with increasing test temperature, showing either a shorter creep life under the same applied stress or a lower applied stress for the same creep life. While the PtAl-PtAl at 850 °C shows scattered results and the

NiAl-PtAl has only two data points, a linear relationship between the applied stress and creep life, both plotted in logarithm scale, could be found for the other coated samples.

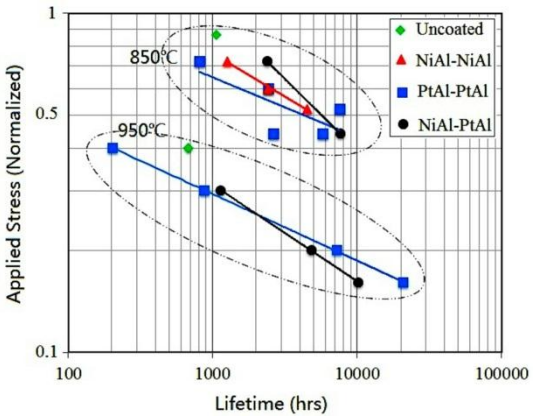

Figure 2. Creep lifetimes of specimens under different applied stresses (normalized) at 850 °C and 950 °C.

Based on their distinctive metallographic features, three characteristic zones are defined for the coatings (Fig. 3): outer zone (OZ), interdiffusion zone (IDZ) and second reactive zone (SRZ). The matrix phases in OZ, IDZ, SRZ and the substrate are respectively β, γ' (or β), γ' and γ. After long creep time at 900 °C the OZ shrinked in NiAl (Fig. 3(a)) but was well stabilized in PtAl (Fig. 3(b)), which indicates that Pt can restrict the β-to-γ' transformation by blocking the outward diffusion of Ti, Co, W and Ta. The enrichment of Cr, Mo and Co in those zones was responsible for the formation of some specific precipitates (i.e. TCP, Cr-α) which were observed in both NiAl and PtAl coatings. The phase identification in this research is achieved by comparing the EDS-detected composition with those given in literatures [1,9-11]. A more detailed analysis of the microstructural changes in the PtAl-PtAl samples could be found in [12].

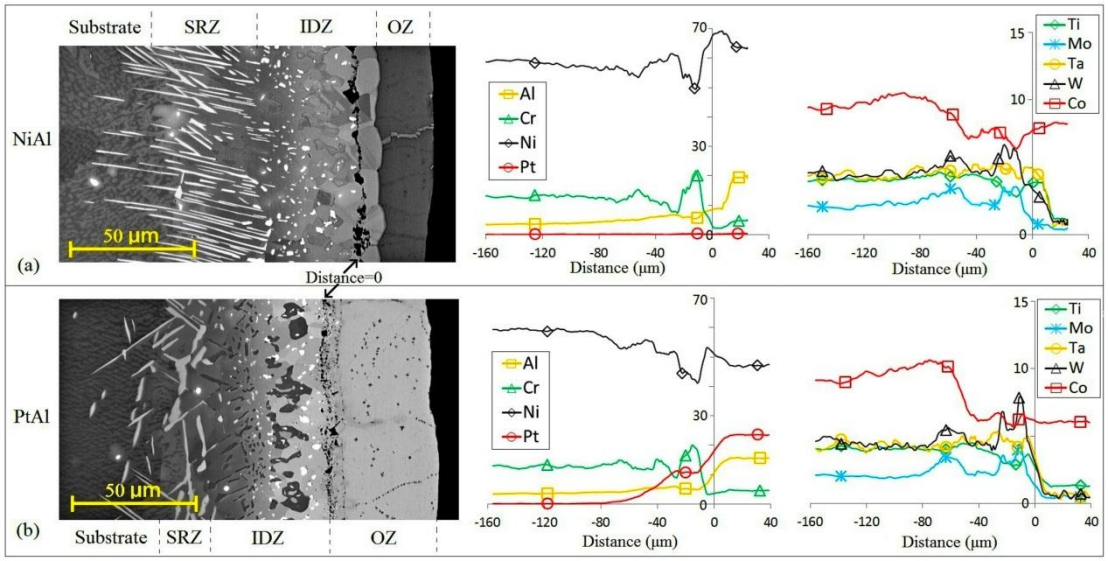

Figure 3. Microstructure and composition profiles (averaged from three different areas) on (a) NiAl side and (b) PtAl side in a NiAl-PtAl sample after creep test at 950 °C with lifetime 10244 hrs.

The micro-hardness tests of cross sections at room temperature show a variation along the diffusion coatings (Fig. 4(a)), verifying the difference in mechanical properties between coating and substrate. This means that the stress partitioning needs to be recalculated by considering the newly developed coating thickness. To encompass the growth of coating due to the diffusion of alloying elements

during the creep test an *effective coating thickness* (*ECT*) is defined, which is the total thickness of OZ, IDZ and SRZ. The inward diffusion of Al in the substrate is pre-assumed to control the movement of coating-substrate interface in both NiAl and PtAl coatings. The statistic results of the *ECT* in Fig. 4 (b) presents a linear correlation with $\sqrt{D^{Al} \times t}$, showing as

$$ECT = ECT_0 + C \times \sqrt{D^{Al} \times t} \quad (1)$$

In Eq. (1) ECT_0 is the original *effective coating thickness* and *C* is a constant. D^{Al} is the diffusion coefficient of Al in the substrate (IN792), calculated by using lower Hashin-Shrtikman bound [13]:

$$D^{Al} = D_{\gamma'}^{Al} + \frac{f_{\gamma}}{1/(D_{\gamma}^{Al} - D_{\gamma'}^{Al}) + f_{\gamma'}/(3D_{\gamma'}^{Al})} \quad (2)$$

In Eq. (2) D_{γ}^{Al} and $D_{\gamma'}^{Al}$ are the diffusion coefficient of Al in γ and γ' phases, f_{γ} and $f_{\gamma'}$ are the volume fraction of γ and γ' phases. The values of D_{γ}^{Al}, $D_{\gamma'}^{Al}$, f_{γ} and $f_{\gamma'}$ (listed in Fig. 4(b)) can be calculated by the software DICTRA [14] with Ni-based thermodynamic and kinetic database – TCNI5 and MOBNI2 [15]. The lower Hashin-Shrtikman bound [13] claims the easier-diffusion (high diffusivity) phase as the matrix phase which is likely the case in IN792 with the solid solution γ as the easier-diffusion and matrix phase. Actually applying another Hashin-Shrtikman bound (i.e. upper bound), which assumes the tougher-diffusion (lower diffusivity) phase as the matrix phase, gives the similar calculated results on diffusivity of Al in IN792 [12]. The paralleled curves in Fig. 4(b) give a coating-independent constant *C* (~ 2.54×10^5) in Eq. (1) for both NiAl and PtAl diffusion coatings, indicating that the coating thickening rate is controlled only by Al inward diffusion in the substrate. However this conclusion needs to be further checked since the statistic data scattering still exists in Fig. 4(b), especially when the $\sqrt{D^{Al} \times t}$ value is lower.

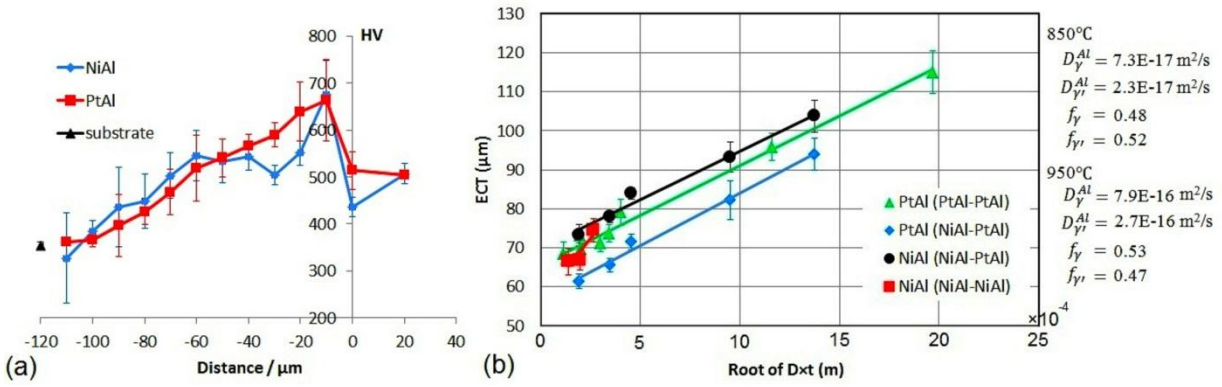

Figure 4. (a) Micro-hardness profiles (Vickers) in NiAl and PtAl measured at room temperature (in the same sample in Fig. 3) and (b) *Effective Coating Thickness* (*ECT*) near fracture surface vs. $\sqrt{D^{Al} \times t}$. The standard deviations (error bar) in both graphs are given by measurement at ~10 regions of the sample.

3.2. Morphology study of creep fracture

Because of heavy oxidation of the fracture surface fractographic analyses cannot be easily applied to study the creep rupture process. Instead, detailed microstructural examinations were carried out on polished lengthwise cross-sections cutting through the mid-width of the creep fractured specimens. The loading direction is in the length direction of the sample and is vertical in all the micrographs shown in this section.

3.2.1. Uncoated

Grain-boundary weakening is generally responsible for the creep failure of polycrystalline materials [16]. In the hot combustion and turbine sections of gas turbine the coarse-grained or even single-crystalline superalloys are commonly used to minimize the effect of grain boundary on creep behavior [1]. For polycrystalline superalloys (e.g. IN792) the addition of few ppm carbon, by forming carbides along grain boundaries, can improve the resistance of grain-boundary sliding [17]. Carbides detached from grain boundary of the superalloy by tensile force were observed by [18,19], which were also observed in the current study in the serrated crack path (Fig. 5(a)). According to the composition measurement by EDS two types of carbides were detected: (Cr,W)-rich $M_{23}C_6$ and (Ti,Ta)-rich MC. $M_{23}C_6$ was only observed along grain boundaries while MC was common both along grain boundaries and inside of the grains. The same microstructures have been reported in IN792 by other researchers [6,20]. The direction of the alignment of cracks is unsurprisingly perpendicular or near-perpendicular to the creep loading direction.

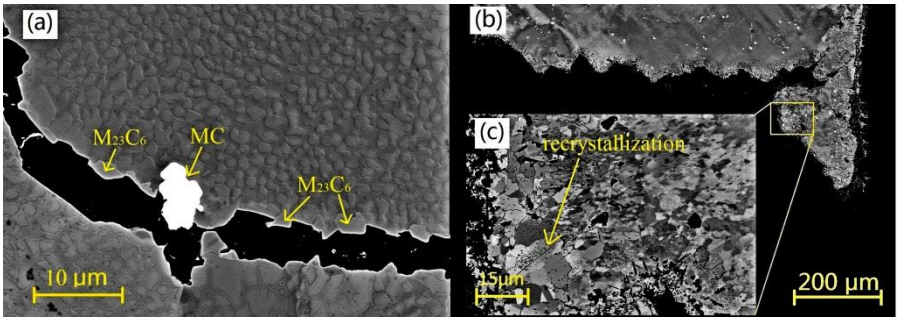

Figure 5. Fractured uncoated sample for 950 °C: (a) serrated grain-boundary crack with carbides, (b) morphology near fracture surface and (c) recrystallization near fracture surface.

The creep tests were conducted in air; consequently oxidation occurred at the sample' surface whether it was covered by coating or not. It has been reported that the surface oxide layer could lower the steady creep strain rate comparing with vacuum creep test (without surface oxidation) [21]. In this study oxidation was also present inside of material when the crack initiated from the surface. However such oxidation was reported to have little effect on the steady creep rate of the sample [6,20]. Fig. 5(b) shows the length-sectional morphology near the fracture surface of the uncoated sample. Since the crack propagates along the grain boundary, the roughness of the fracture surface is grain-size dependent. The appearance of recrystallization along the fracture surface indicates dynamic recrystallization caused by local plastic deformation during crack propagation at the creep testing temperature (Fig. 5(c)). Actually such recrystallization was also commonly observed along the fracture surface in other sample types.

3.2.2. NiAl-NiAl

Ductile-brittle transition temperature (DBTT) reflects the ductility of materials at high temperatures. The definition of DBTT is mainly based upon the amount of plastic deformation during failure. For instance Lowrie et al. [6,20] suggested the temperature above which the fracture strain of the

material was more than 0.6%. The coating can be even super-plastic at high enough temperature [22]. The DBTT of NiAl is 693 °C measured by [23]), which however should also be dependent upon the coating thickness according to the results of [24]. In this type of sample through-coating cracks were commonly found with the oxidation around (Fig. 6(a) and (b)). The formation of γ' in OZ may weaken the strength grain boundary and induce cracks (Fig. 6(c)). When a through-coating crack was meeting or is located near a grain boundary in the substrate, it could continue to penetrate into the substrate, being identified by the "L"-shape crack path near the coating part (Fig. 6(b)). The cracking of the coating makes it a non-load carrying member and leaves the substrate in a somewhat similar creep situation as the uncoated sample.

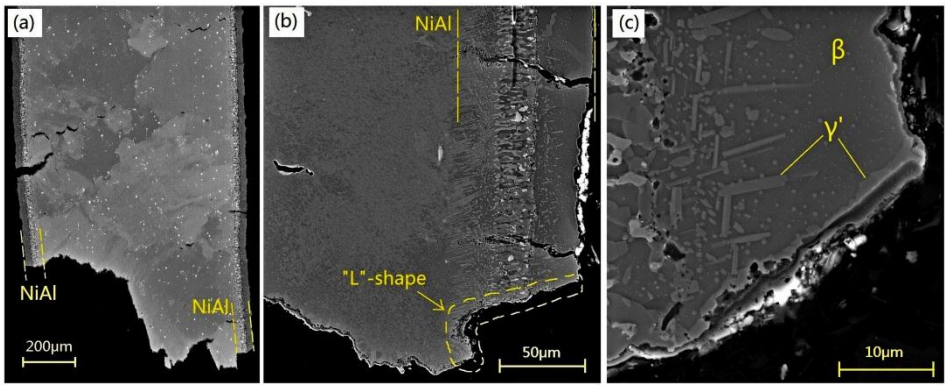

Figure 6. Fractured NiAl-NiAl sample for 850 °C: (a) morphology containing fracture surface, (b) "L"-shape path of though-coating cracks and (c) γ' precipitates in OZ. (The coating part is marked in Fig. 6-8).

3.2.3. PtAl-PtAl

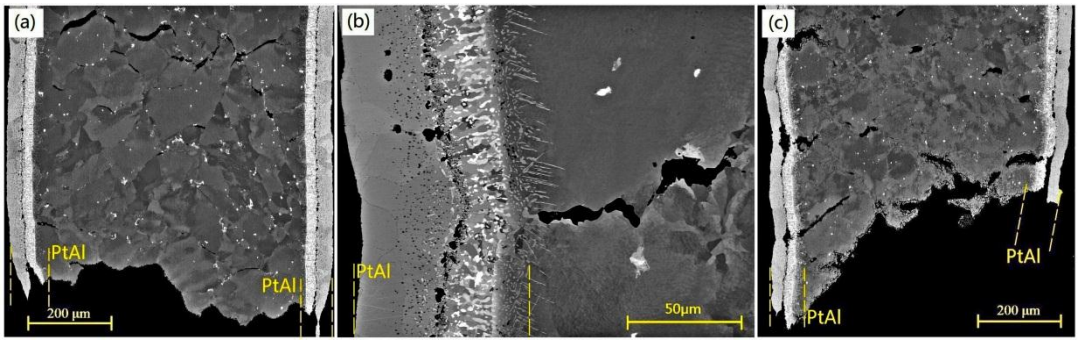

Figure 7. Fractured PtAl-PtAl sample: (a) morphology containing fracture surface (850 °C), (b) crack beneath PtAl (850 °C) and (c) morphology containing fracture surface (950 °C).

The addition of Pt into aluminide diffusion coating was initially intended to slow down the inward diffusion of Al. However the "diffusion barrier" effect by Pt has been demonstrated to be not so effective [25], which can be further supported by the results in Fig. 4 in this study. Although the PtAl coating has a higher DBTT (795 °C [26]) than NiAl (693 °C [24]), no significant through-coating cracks but some ductile deformation shapes were observed in PtAl at 850 °C (Fig. 7(a) and (b)). Addition of Pt prevents the conversion of β to γ' according to the analysing results in section 3.1, which is further demonstrated by the absence of γ' in OZ (Fig. 7(b)). This is probably the reason for the ductile behavior of the OZ in PtAl at 850 °C, different from the brittle behavior of

NiAl (Fig. 6(a) and (b)). Due to the difference of mechanical properties between two characteristic zones, e.g. OZ and IDZ or coating and substrate, some voids/cracks formed at their interface during the creep process at both temperatures (Fig. 7(b) and (c)) but more significant at 950 °C. Toshio [24] also observed such voids in SRZ in PtAl coatings under creep stress. Since the through-coating crack was not formed in PtAl, the "L"-shape crack near the coating part was not observed in this sample type. Either being easily plasticized or producing voids/cracks the coating part lost the ability to carry load during the creep process.

3.2.4. NiAl-PtAl

Comparison of the coating behavior of NiAl in NiAl-PtAl (Fig. 8(a)) with that in NiAl-NiAl (Fig. 6) shows no significant difference at 850 °C. The NiAl can be considered to be ductile at 950 °C since NiAl always shows plastic deformation along the whole cross section of the sample with a few cracks only observed near fracture surface (Fig. 8(b)). The behavior of PtAl looks similar as in PtAl-PtAl type samples at two temperatures: i.e. to be ductile but also to induce cracks beneath the coating or inside of coating.

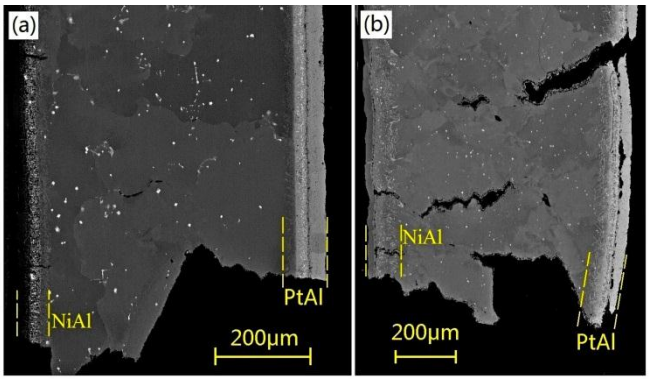

Figure 8. Fractured NiAl-PtAl sample of morphology near fracture surface for (a) 850 °C and (b) 950 °C.

3.3. Summary of creep fracture mechanism

Based on the experimental observations, the crack initiation and propagation mechanisms by which the coating affects the creep fracture behavior are proposed in Fig. 9. For the polycrystalline superalloy grain-boundary separation is always the failure mode in the substrate at 850 °C and 950 °C no matter that the crack initiates from the coating or the substrate. The grain-boundary carbides are beneficial for creep resistance. Due to formation of γ' along grain boundary in outer zone (OZ) at 850 °C NiAl coating can induce active through-coating cracks, which may further penetrate into the substrate along the nearest grain boundary beneath the coating. The γ' in OZ is somewhat restricted in NiAl at 950 °C and in PtAl at both 850 °C and 950 °C, which promotes ductile deformation occurring in the coatings. Even though, PtAl promotes the formation of the voids/cracks either beneath the coating or from inside of coating, caused by the difference of mechanical properties between different characteristic zones. The formed voids/cracks are more active to cause the sample failure at higher temperature.

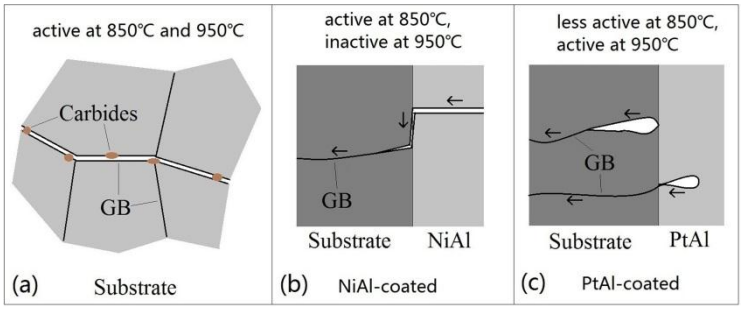

Figure 9. Summary for the crack initiation and propagation mechanism (a) in substrate and by coating's effect of (b) NiAl and (c) PtAl. (GB: grain boundary; Loading direction is vertical; small arrows show the cracking direction)

By using the Larson-Miller approach the creep results in Fig. 2 can be transferred as new ones presented in Fig. 10(a); the plot shows a somewhat negative effect of the coatings lowering the capacity to carry creep stress. Non-loading carrying by coating part above its DBTT was suggested according to some investigations [27]. Being encouraged by the analyses above the applied mechanical load in the creep sample is considered to be mainly carried by the substrate. After recalculating the creep stress by assuming the coating as load-free and excluding the final *effective coating thickness* (*ECT* in Fig. 4) from the total sample thickness, similar performance of coated and uncoated samples is achieved in Larson-Miller diagram (Fig. 10(b)).

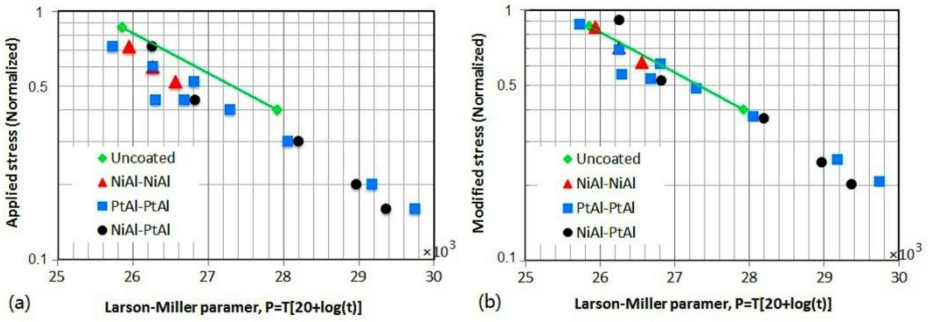

Figure 10. Creep stress (in log-scale and normalized) vs. Larson-Miller parameter (a) before and (b) after stress being modified.

4. Conclusions

In this study the effect of NiAl and PtAl diffusion coatings on the creep fracture mechanism of Ni-based polycrystalline superalloy IN792 is investigated at two temperatures, 850 °C and 950 °C. The following conclusions can be made from this study.

1) The microstructural development of the coating depends on the elemental diffusion during the creep process. The inward diffusion of Al controls the coating thickening rate which seems to be independent of the diffusion coating type.

2) Grain-boundary detachment, which is strengthened by carbides, is the basic cracking mode of the substrate in all samples whether the crack initiated from the coating or the substrate.

3) The diffusion coatings become easily-deformed or induce cracks dependent on coating type and temperature. NiAl is easily deformed at 950 °C but introduces through-coating cracks at 850 °C. PtAl induces voids/cracks in or beneath the coating at both creep temperatures. Those crack initiation modes by PtAl becomes more active when increasing temperature.

4) Based on the results from microstructure analysing, the creep stress of the sample is recalculated by taking the final coating part loading-free. By such stress modification the creep test results of the coated samples are similar with those of the uncoated samples presented in the Larson-Miller diagram. It can be concluded that the applied diffusion coating has a minor influence on the overall creep behavior of the superalloy, but just consuming the effective cross section of the superalloy to carry the creep load.

Abstract Creep and fracture behaviors in a newly developed austenitic stainless steel grade UNS S31035 (Sandvik Sanicro® 25) for use in A-USC power plant have been investigated. This new grade shows very good resistances to steam oxidation and hot corrosion, and higher creep rupture strength than other austenitic stainless steels available today. This makes it an interesting alternative for super-heaters and reheaters in future high-efficient coal fired boilers. This paper will mainly focus on the study of the creep and fracture behaviors of the material at temperatures from 600°C to 750°C by using SEM and TEM. The creep and fracture mechanisms at different temperature and loading conditions have been identified. The interactions between dislocations and precipitates and their contribution to the creep rupture strength have been discussed. In this paper, free temperature model has been used to evaluate the long-term creep behavior of the grade. A creep rupture strength near 100MPa at 700°C for 100 000h has been predicted.

Keywords Heat resistant austenitic stainless steel, Superheater, A-USC, Creep, Fracture

1. Introduction

The demand for electric power is continuously increasing around the world. Meanwhile the consciousness of the environmental impact from human action is growing. Although combustion processes generate carbon dioxide, coal-fired thermal power generation is still one of the most important methods in the medium to long-term future to satisfy this demand, since coal is available at a competitive price and often is the single domestic energy source [1]. However, the biggest challenge facing coal-fired power plants is to improve their energy efficiency. This can be accomplished by increasing the maximum steam temperature and the steam pressure. Conventionally, the heat efficiency of coal-fired power plants has stayed at around 41% in the super critical (SC) condition with a temperature of 550°C and pressure of 24.1MPa. In order to attain a power generating efficiency of about 43%, ultra super critical (USC) conditions with a steam temperature at about 600°C should be reached. By increasing the temperature up to 700°C (A-USC condition) and pressure of above 300 bars, a power plant efficiency of higher than 50% can be reached and CO_2 emission can be reduced by about 45% comparing with that of SC condition [2]. However, the steam data in practice will be limited by the material properties of the boiler tubes, especially tensile strength at elevated temperatures and creep strength combined with corrosion resistance.

A new austenitic stainless steel grade, UNS S31035 (Sandvik Sanicro 25), has recently been developed for the purpose of A-USC [3] in collaboration with a number of different industrial partners within the Thermie-project in Europe, intended for use in super-heaters and reheaters in advanced ultra-supercritical boilers at temperatures up to 700°C. They have been test-installed in different boilers in Europe and have run for more than five years, and are still in very good conditions [4]. In this paper the creep and fracture behaviors of this new grade are discussed.

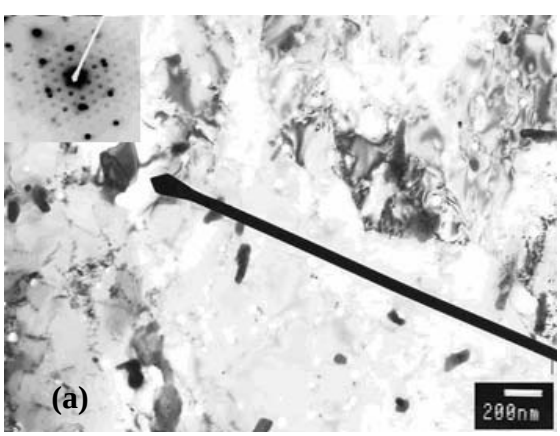
2. Material and experimental

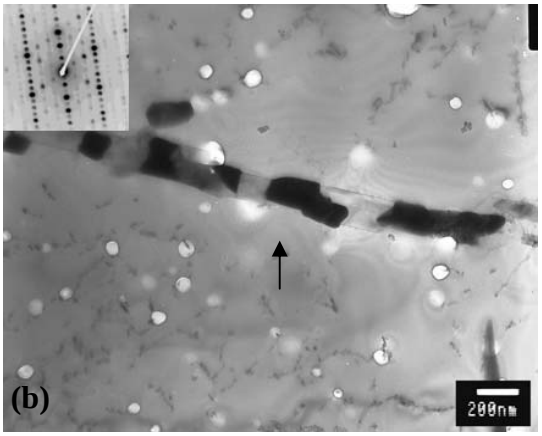
Since austenitic stainless steel grade, UNS S31035, was aimed for use in super-heaters and reheaters with metal temperatures up to 700°C, the design principles for this alloy were to achieve a stable microstructure, high strength by precipitation strengthening with stable nano precipitates and solution hardening, high corrosion resistance with high Cr content. Ni and N that can suppress the formation of sigma phase were added to reach sufficient structural stability and good fabricability. The chemical composition is shown in Table 1.

Table 1 Nominal composition of austenitic stainless steel grade, UNS S31035 (wt%)

C_{max}	Si	Mn	Cr	Ni	W	Co	Cu	Nb	N	Fe
0.1	0.2	0.5	22.5	25	3.6	1.5	3.0	0.5	0.23	Bal.

Figure 1 shows some fine precipitates observed in this newly developed austenitic stainless steel grade, UNS S31035 that can contribute to the improvement of the creep strength. Both intra- and intergranular $M_{23}C_6$ precipitates can be observed (Fig. 1a). In the grain boundaries, they have a $<100>_{\gamma}$ // $<100>_{M23C6}$ coherent relationship to the austenite matrix. Laves phase was observed both randomly within the grains but also ordered on what appears to be former twin boundaries (Fig. 1b). Both coherent Laves phase precipitates with a $[100]_{Laves}$ // $[100]_{\gamma}$ orientation relationship, and incoherent Laves phase precipitates were observed. In the aged material the Laves phase are needle shaped but rather small. In the creep tested materials, these particles are fine and isometric. Copper rich nanoparticles can also be observed. They are round with a size up to 50 nm (Fig. 1c). In this material, a dense distribution of about 10 nm large precipitates was observed (Fig. 1d). Due to the limitation of the TEM, these particles could not be identified, but they are probably MX carbides or carbonitrides. Similar particles have been identified in other analyses. These particles were rather stable [5].





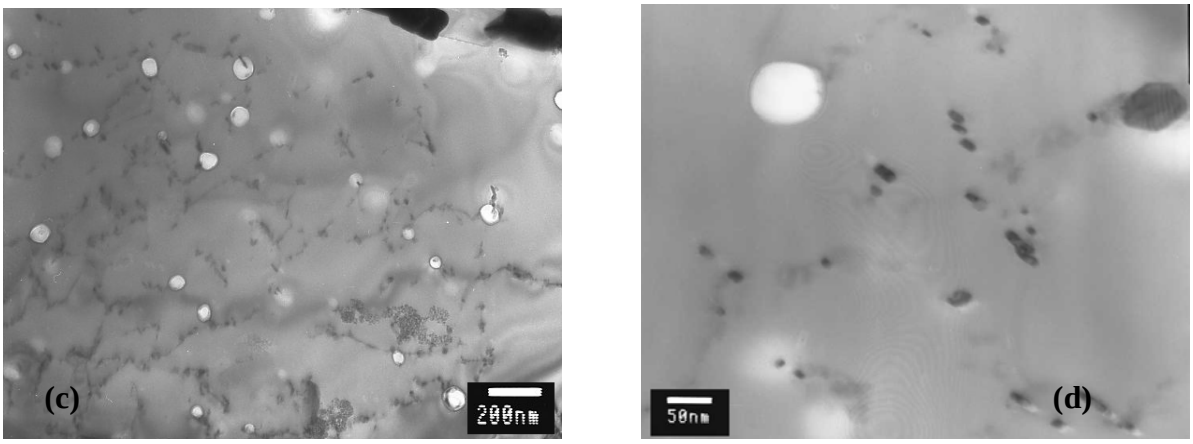


Figure 1. Fine precipitates that contribute to the creep strength of austenitic stainless steel grade, UNS S31035, (a) $M_{23}C_6$, 700°C for 1000 hours, (b) Laves phase, 700°C for 30 000 hours, (c) Copper-rich phase, 700°C for 30 000 hours, (d) Nanoparticles, 700°C for 30 000 hours.

The creep testing on UNS S31035 was performed from 550°C to 800°C. Both stress-rupture testing and creep-strain testing were done. The stress-rupture testing was performed in Escher Wyss (EW) creep testing machines. In these machines multiple samples can be tested simultaneously. The samples (Fig. 2) are mounted in the EW boxes. The tube in which the samples are located is then inserted into the furnace. The load from the compressed spring is applied after the samples have been heated in the furnace for one hour. The creep-strain testing was performed in Bofors machines. The sample was mounted in sample holders in the tube furnace and connected to thermocouples which can measure the temperature continuously. The strain was measured by two extensometers placed outside the furnace. The strain was logged manually regularly during testing to obtain creep curves.

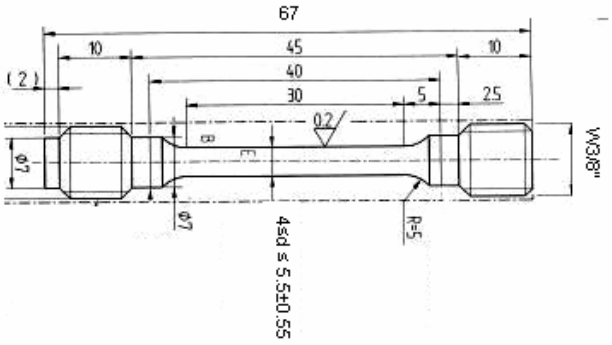

Figure 2. Schematic sample for the creep test.

The microstructure was studied using light optical microscope (LOM), scanning electron microscope (SEM) and transmission electron microscope (TEM). LOM and SEM were used to obtain information on features such as grain size, creep deformation, precipitates and how these changes with time, temperature and stress. TEM was used for phase identification and dislocation structure characterization.

3. Free temperature model

Pressure vessel components are normally designed for a long service time such as 200 000 h. Since creep is a very slow process, creep data for such a time are not available for design. They are therefore calculated by an extrapolation from the creep data of shorter time tests. One recently proposed procedure for extended extrapolation of creep rupture data is the free temperature model that allows for extrapolation by more than a factor of three in time [6, 7]. The procedure is based on a time-temperature parameter (TTP) which has the general mathematical form:

$$P_{TTP} = v(T)\log(t_r) + w(T) \tag{1}$$

where P_{TTP} is the time-temperature parameter, t_r is the time to rupture, and v(T) and w(T) are the functions of temperature. In the proposed procedure these functions are assumed to be polynomials in T. The TTP in Eq. 1 is referred as the free temperature model (FTM). The free temperature model is well suited for austenitic stainless steels where the temperature dependence of the creep rupture curve is non-monotonous [7].

The master curve is expressed by the creep stress as a function of polynomial in the TTP:

$$\log(\sigma) = \sum_{j=0}^{n_P} a_j TTP^j \tag{2}$$

The coefficients a_j are fitted to the creep rupture data and the stress – rupture time relations are derived. The reason for using a polynomial in log (t_r) rather than log (σ) which is the more common approach, is that it has been shown that this improves the accuracy in extended extrapolated values [7]. The extrapolation was performed in a Matlab program. The coefficients to the polynomials are derived by a non-linear least squares fit to the creep data.

To extrapolate the creep rupture data, the polynomials in Eq. 1 were both set to order 3 and the master curve, Eq. 2, was set to a second order polynomial. Figure 3 shows the master curve for the free temperature model of the austenitic stainless steel grade, UNS S31035, which is based on creep data at 550°C, 600°C, 650°C, 700°C and 800°C.

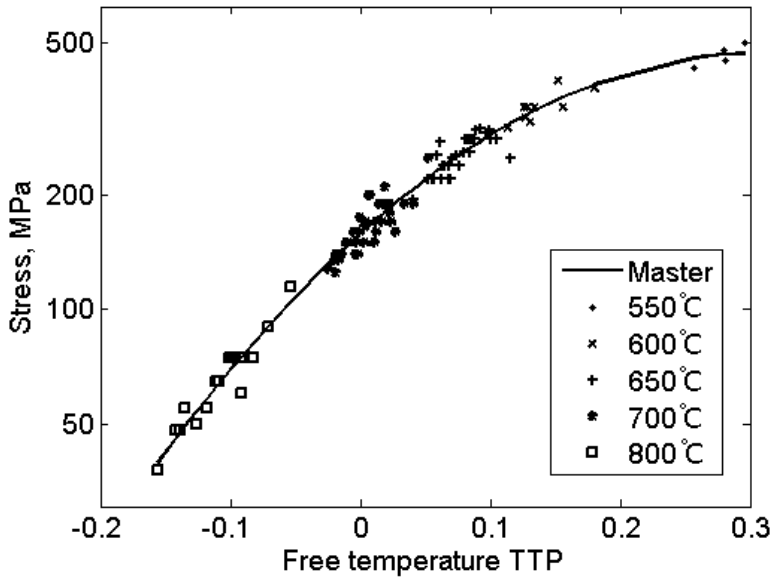

Figure 3 Master curve for austenitic stainless steel grade, UNS S31035, material.

4. Results and discussion

4.1 Creep strength

Up to now, the longest time to rupture from the creep test of this alloy is more than 74 000 h and some samples are still running. Figure 4 shows the results of the creep stress in rupture plots. With linear least squares regression (Larson-Miller relation) to extrapolate the creep rupture data, the predicted 10^5 h creep rupture strength at 700ºC is 104 MPa.

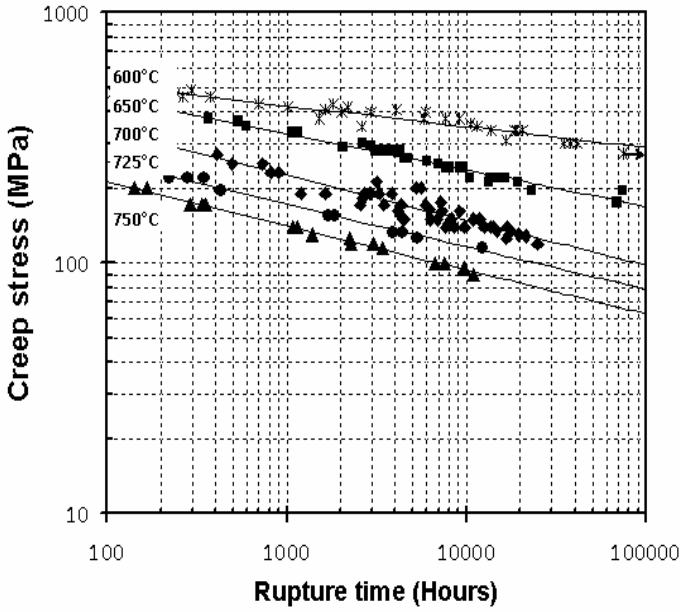

Figure 4 Creep stress versus rupture time of austenitic stainless steel and the linear regressions in the creep data.

The extrapolation was performed three times with rupture data up to 40000 h, 15000 h and 5000 h to verify the stability of the extrapolation. Figure 5a shows the result from the extrapolation. At both 700°C and 650°C the extrapolation overestimates the creep strength of the material when only short time creep data are used. This is common for many parametric methods and it is important that the deviation is not too large. The order of the polynomials and which temperature data sets the model is applied to will also influence the result. These factors are tested until a satisfactory result has been found. The predicted 10^5 h creep rupture strength at 700°C is about 99 MPa.

In Figure 5b, the correlation between the extrapolation and experimental data can be seen. The evaluation satisfies the post evaluation tests (PATs) and other criteria proposed by the European Collaborative Creep Committee (ECCC) [8].

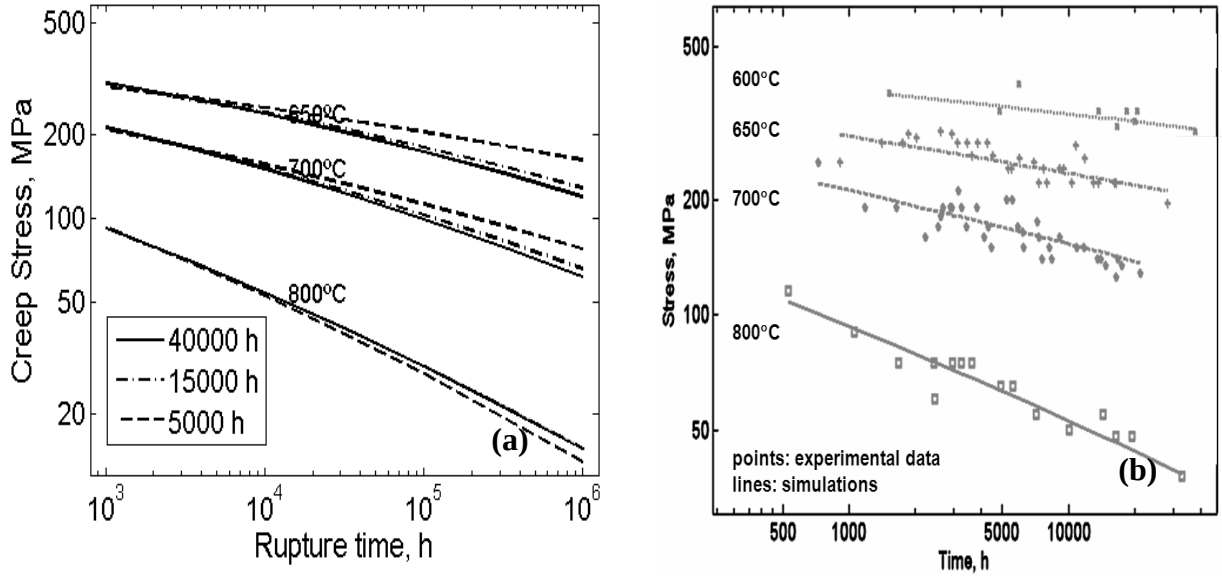

Figure 5 (a). Result from extrapolation with the free temperature model, performed three times with rupture data up to 5000 h, 15000 h and 40000 h, (b). Correlations between the extrapolation with rupture data up to 40000 h and the experimental data.

4.2 Strengthening mechanism

In the temperature range up to 700°C, one of the main creep strengthening mechanisms is the interaction between dislocations and precipitates [9]. Figure 6 shows two examples how interaction between the dislocations and precipitates in austenitic stainless steel grade, UNS S31035, creep specimen tested with 210 MPa at 700°C and with a rupture time of 3153 h. Moving dislocations at the nano-sized particles can be seen. Around the intergranular precipitates, the dislocation density is high which indicates that they function as obstacles for the dislocation movements. This increases the creep strength. Smaller nanoprecipitates such as copper rich particles and MX particles are more effective as obstacles for the dislocation movements. However, they have different mechanisms for dislocation crossing. For the copper rich nanoparticles, dislocations cross the particles mainly by climb / bypass of unit dislocations (Fig. 6a). For the MX nanoparticles, deformation might occur by

shearing of partial dislocations. The shadow around the particle in Figure 6b is believed to be dense dislocations. For MX particles, dislocation loops can be observed around the particles (Fig 6c and d).

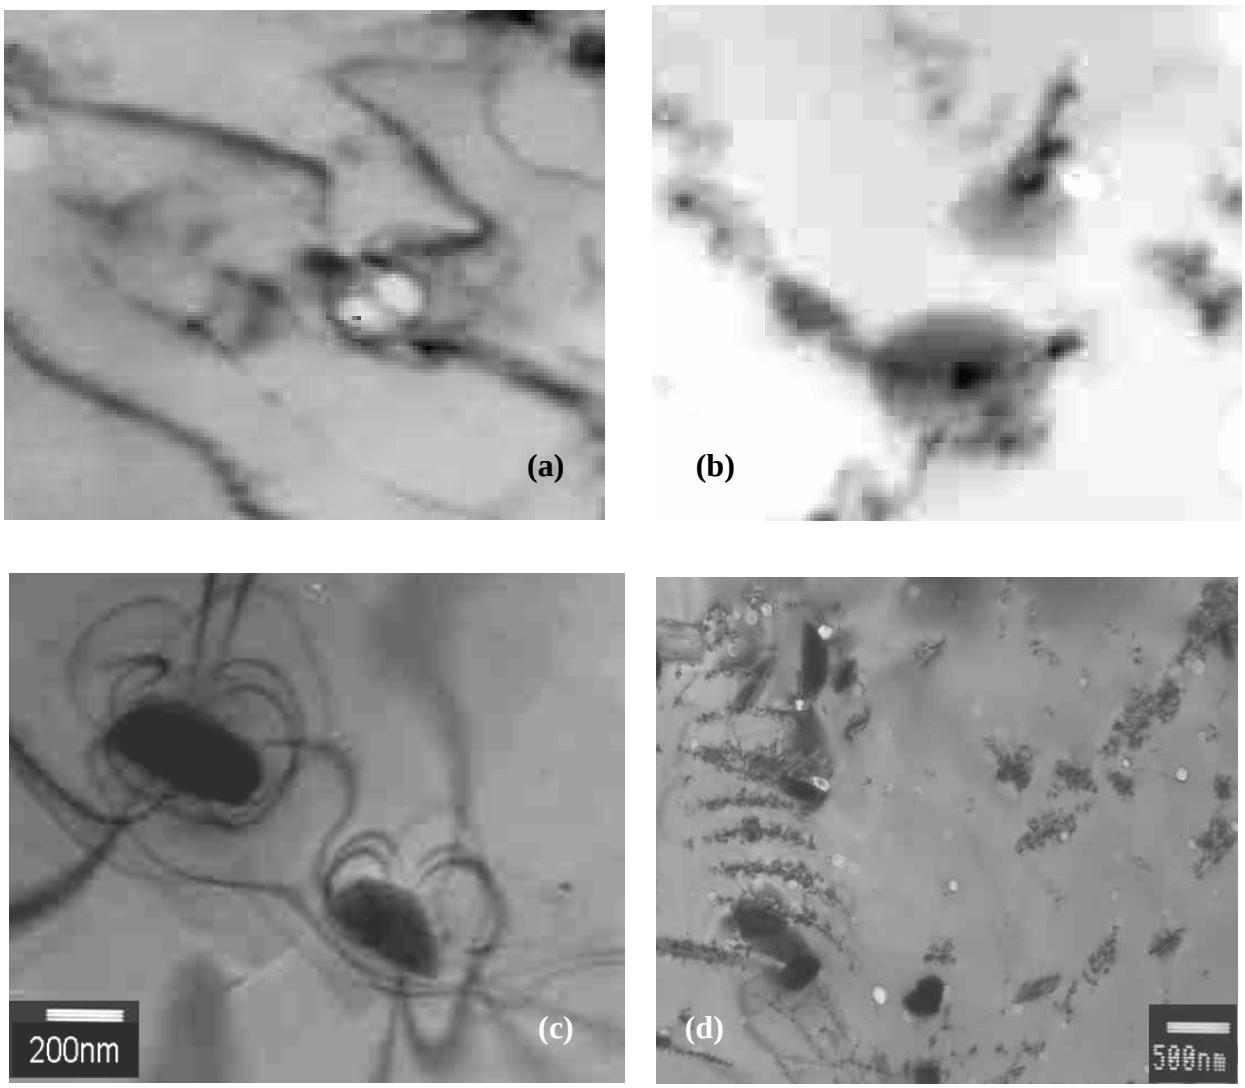

Fig. 6 Dislocation structures, (a). Interaction between dislocations and precipitates, (b). dislocation cloud or cluster near nona Cu-rich particles and MX particles

4.2 Rupture mechanisms

Figure 7 shows an investigation of the fracture modes such as transgranular or intergranular fractures and plastic deformation by creep in UNS S31035 material. A summary of the creep fracture modes are shown in Figure 8.

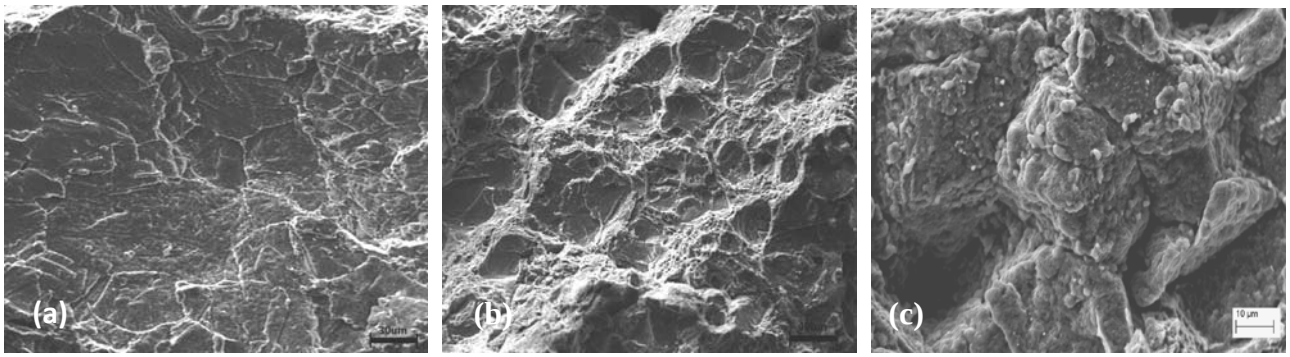

Figure 7 SEM micrograph of creep specimen near the fracture, (a). 700°C/240MPa, 1085h, transgranular cracking, (b). 700°C/210 MPa, 4203h, transgranular and intergranular mixed model, (c). 700°C/150 MPa, 14040 h, intergranular cracking

Plastic deformation and transgranular fracture is the main creep fracture mechanism in UNS S31035 material in the temperature ranges of interest (<700°C). The SEM analysis shows that the crack initiation area was mainly quasi cleavage and then cracks propagated with dimples. At intermediate stresses and temperatures a mixture of inter- and transgranular fracture occurs. The crack initiation often occurs at grain boundaries but propagate through the grains. At relatively low stresses and high temperatures, intergranular fracture could occur. However, plastic deformation can still be observed in these specimens.

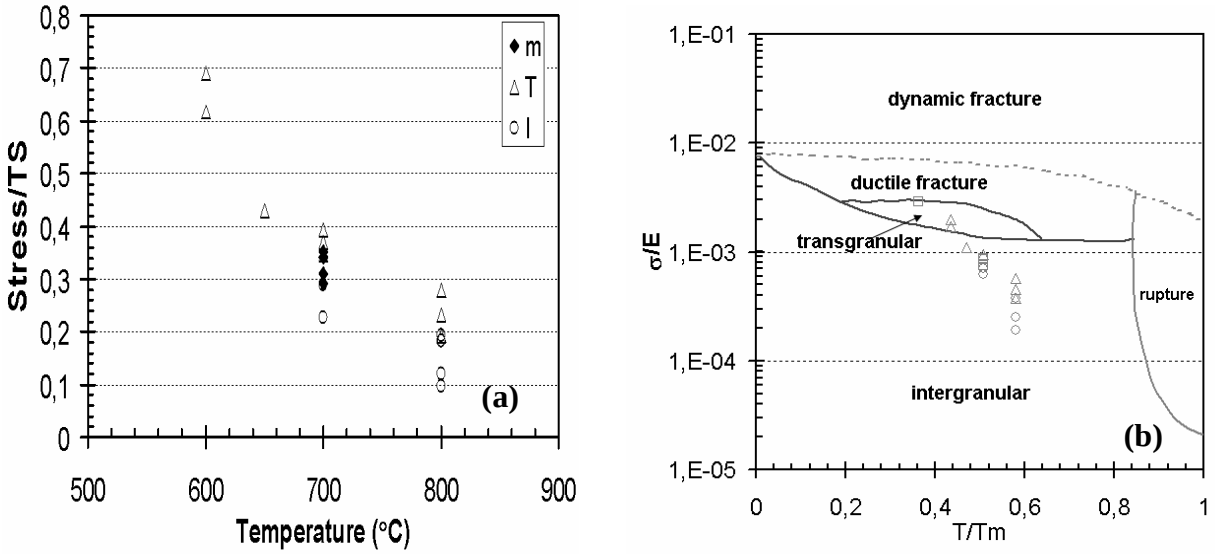

Figure 8 Fracture modes in UNS S31035 at different test conditions.

4. Conclusions

A new austenitic stainless steel grade, UNS S31035 (Sandvik Sanicro 25), has been developed intended for superheater and reheaters for A-USC. Extrapolation from creep data with two methods gives a creep strength of 99 ± 3 MPa at 700°C for 100 000 h, which is higher than that of other austenitic stainless steels available today.

The creep strength is related to intragranular precipitates and nano particles acting as obstacles for dislocation movement.

Plastic deformation and transgranular fracture is the main creep fracture mechanism in the creep test samples of UNS S31035 for high applied stresses, but trend to intergranular fracture with decreasing stresses and increasing temperature.

Abstract As a renewable energy resource, biomass or biomass co-firing in coal-fired power plants with high efficiency are desired which corresponding to elevated temperature and high pressure. An upgrade of the material performance to austenitic stainless steels is therefore required in order to meet the increased demands due to the higher temperature and the more corrosive environment. These materials suffer from creep and fatigue damage during the service. In this study, these behaviours are evaluated using slow strain rate testing (SSRT) with strain rate down to $1*10^{-6}$/s at temperature up to 700°C. The influence of temperature and strain rate on strength and ductility in one austenitic stainless steel and one nickel base alloys are investigated. The damage and fracture due to the interaction between moving dislocations and precipitates are studied using electron channelling contrast imaging (ECCI) and electron backscattering diffraction (EBSD). The deformation and damage mechanisms active during SSRT are essentially the same as under creep. The influence of dynamic strain ageing (DSA) phenomena that appears in the tested temperature and strain rate regime is also discussed, DSA is intensified by increased temperature and decreased strain rate.

Keywords Elevated temperature, slow strain rate, biomass power plant, austenitic stainless steel, nickel base alloy.

1. Introduction

Biomass or biomass co-firing in coal-fired power plants is a contribution to renewable energy resources for sustainable energy production. Also high efficiency which requires higher temperature and pressure is highly desired. However, the materials used in those power plants with increasing temperature and pressure also need to be resistant to the corrosive atmosphere connected to combustion of biomass fuel [1, 2].

In the operating temperature range of biomass or biomass co-firing coal-fired power plants, austenitic materials often show dynamic strain ageing (DSA). The temperature regime of DSA is from 200 to 800°C for austenitic materials [3, 4] and arises during plastic deformation from interaction between solute atoms related to bulk or pipe diffusion and mobile dislocations or forest junctions[5, 6]. Temperature and strain rate directly influence diffusing solute atoms and the mobility of dislocations respectively, which effects DSA [6]. At elevated temperatures (400°C to 650°C) nitrogen and/or substitutional chromium atoms are responsible for DSA [7, 8]. Portevin-Le Châtelier (PLC) effect which is serrated yielding in the stress-strain curve, characterizes DSA. The PLC effect is due to the pinning and unpinning of dislocations or formation of new dislocations [9].

These materials can undertake low deformation rate from 10^{-5}/s (low cycle fatigue) to 10^{-7}/s (creep) during service. This study was focused on damage and fracture mechanisms related to low strain rate and high-temperature in two austenitic materials. Using uniaxial slow strain rate tensile testing (SSRT) at high-temperatures, the influence of low strain rates on these mechanisms could be investigated. Also precipitation due to high-temperature and deformation could be coupled to the damage and fracture behaviour.

2. Materials and experimental details

2.1. Materials

The austenitic stainless steels, AISI 316L and the nickel-base alloys, Alloy 617 were used in this study. Both types were solution treated before testing. Table 1 shows the chemical composition of the materials.

Table 1. Nominal composition of the investigated materials in wt%.

Material	C	Si	Mn	Cr	Ni	W	Co	Cu	Nb	N	Mo	Fe
AISI 316L	0.04	0.4	1.7	17	12	-	-	-	-	-	2.6	Bal.
Alloy 617	0.1	-	-	22.5	53.8	-	12	-	-	0.5	9	1.1

2.2. Tensile deformation

For the slow strain rate tensile testing (SSRT) a Roell-Korthaus and an Instron 5982 tensile test machines were employed. The tensile test machines were equipped with a MTS 653 furnace and Magtec PMA-12/2/VV7-1 extensometer and ElectroHeat Sweden furnace and Epsilon extensometer respectively, both active in air environments. Round-bar specimens with 5 mm in diameter and 50 mm gauge length were used. The tensile tests were carried out at a strain rate of $2*10^{-3}s^{-1}$ down to $10^{-6}s^{-1}$. Three temperatures: room temperature (RT), 650°C and 700°C, were used. Alloy 617 was tested using strain rates $10^{-2}s^{-1}$, $2*10^{-3}s^{-1}$, $10^{-3}s^{-1}$, $10^{-4}s^{-1}$, $10^{-5}s^{-1}$ and $10^{-6}s^{-1}$, AISI 316L was tested using strain rates $2*10^{-3}s^{-1}$ and $10^{-6}s^{-1}$.

2.3. Scanning electron microscopy investigation

For the microstructural investigation of deformation and fracture behaviour the scanning electron microscopy (SEM) techniques electron channeling contrast imaging (ECCI) and electron backscatter diffraction (EBSD) were used. ECCI uses the interaction between backscattered electrons and the crystal planes to generate contrast resulting in an image where local orientation, defects and strain fields are shown as contrast variations [10].

3. Results

3.1. Strain rate and temperature influence on tensile deformation and damage

Low strain rates and elevated temperatures are increasing the probability of dynamic strain ageing (DSA), because the diffusion rate of the solute atoms increases and rate of dislocation movement decreases. During DSA the deformation mechanisms is shifting towards planar deformation [7]. None of the tested materials showed DSA at room temperature, but both materials showed DSA at elevated temperatures for all tested strain rates. For a strain rate of 10^{-6}/s at both elevated temperatures, AISI 316L and Alloy 617 show different types of PLC effects. AISI 316L display B-type and Alloy 617 shows C-type serrated yielding, see fig.1. B-type serrations means that the stress oscillates from a origin stress level and C-type of serration is characterized by a sudden drop in stress and then raises to the normal stress level [8, 9]. Alloy 617 show serrated yielding from low strain values until fracture for all tested strain rates at both elevated temperature except of strain rates 10^{-3}/s and 10^{-4}/s. At both elevated temperatures and strain rate 10^{-3}/s serrated yielding is present at low strain levels up to around 20% but DSA also appears just before fracture, see fig. 1a). For 10^{-4}/s at 650°C serrated yielding disappears after approximately 4% strain and after around 12%

with a few serration drops at 22% strain at 700°C. At room temperature the elongation to fracture increases with decreasing strain rate for AISI 316L, at a strain rate of $2*10^{-3}$/s it is 53% and 66% at 10^{-6}/s, see fig.1b). This behaviour is due to the lower deformation rate that causes the dislocation mobility to decrease and therefore resulting in a lower stress level when using a strain rate of 10^{-6}/s. At elevated temperatures and low strain rates AISI 316L show a decrease in the stress-level during tensile tests due to recovery that could be related to recovery-creep [11], see fig.1b), also features related to dynamic recrystallization can be found in the microstructure (fig.4) [12].

The strain rate influences the ductile response of Alloy 617, as shown in fig. 2 a). From 10^{-2}/s to 10^{-3}/s the ductility increases at both temperatures and continues to increase for strain rates of 10^{-4}/s at 650°C but decrease slightly at 700°C. With even slower strain rates the ductility decreases even more for both temperatures, 700°C have lower ductility than 650°C at a strain rate of 10^{-6}/s but have a higher tensile stress which can explain the differences in ductility. Alloy 617 has much higher ductility (A_{RT}=70.5%) and tensile stress (Rm_{RT}=709MPa) when it is deformed at room temperature than at elevated temperature ($A_{700°C}$=10.3% and $Rm_{700°C}$=489MPa) when using a strain of rate 10^{-6}/s, see fig.2. This behaviour is most likely due to grain boundary embrittlement coused by chromium rich precipitation in the grain boundaries, shown in fig.6.

In the DSA regime nano-twins can show up as a deformation mechanism [13]. AISI 316L material showed nano-twins close to the surface of the specimen. Other deformation mechanism in the microstructure of the SSRT tested samples was slip bands (SB) and planar slip. Fig.3 displays probable future damage due to interaction between slip bands and precipitates (fig.3 b)) and nano-twins and precipitates. Contrast differences that could be related to stress concentrations spots which is or will be future damage can be observed where these interactions appear in fig. 3 b) and c).

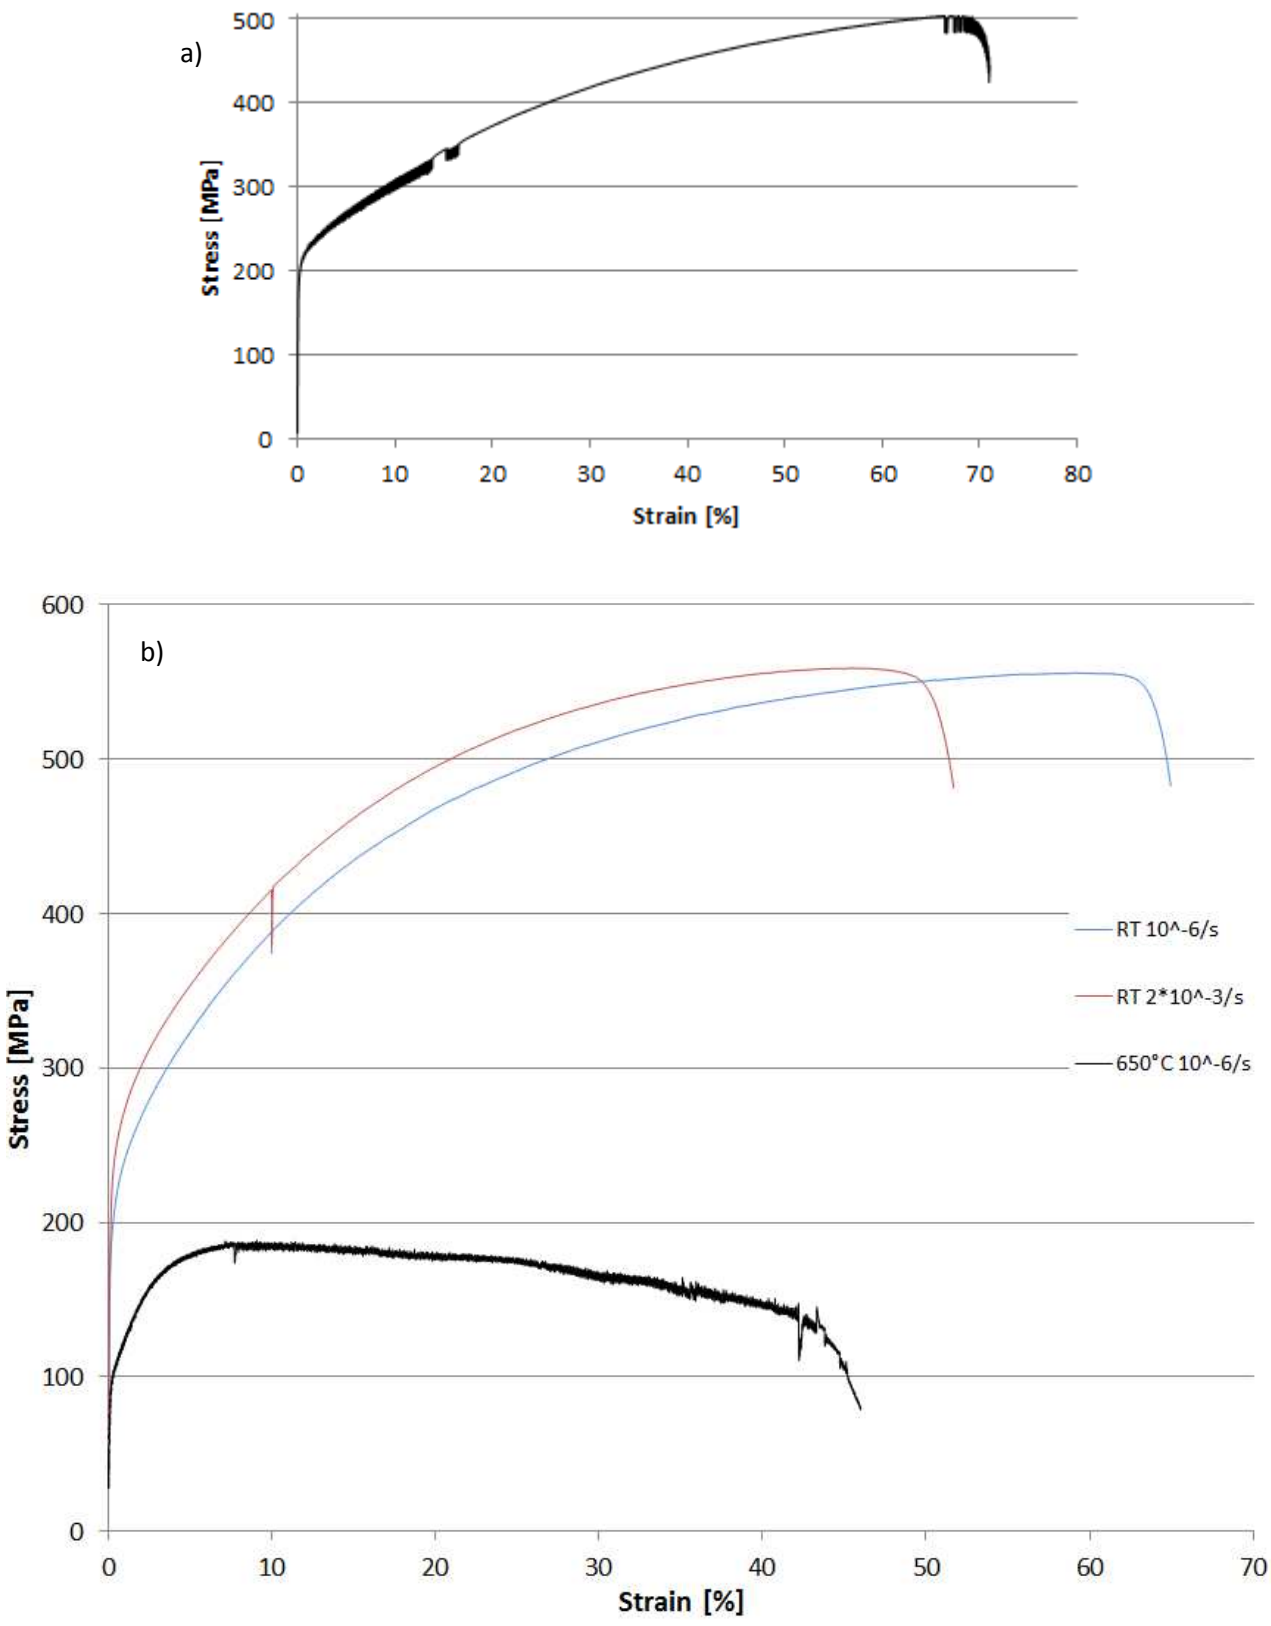

Figure 1. Engineering stress-strain curves showing a) C-type serration in Alloy 617 tensile tested at 700°C using strain rate 10^{-3}/s and b) B-serration in AISI 316L tensile tested at 650°C using strain rate 10^{-6}/s (black curve) and two curves showing AISI 316L tested at room temperature (RT) using strain rates 10^{-6}/s and $2*10^{-3}$/s (blue and red curve respectively).

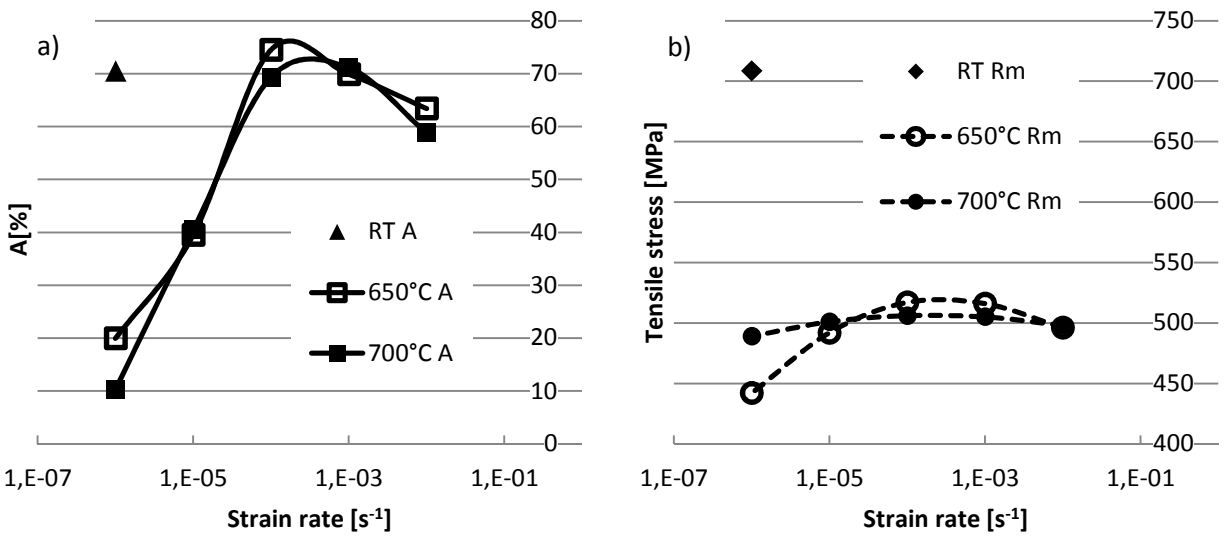

Figure 2. Influence of a) strain rate on ductility (A) and b) tensile stress (R_m) levels for Alloy 617.

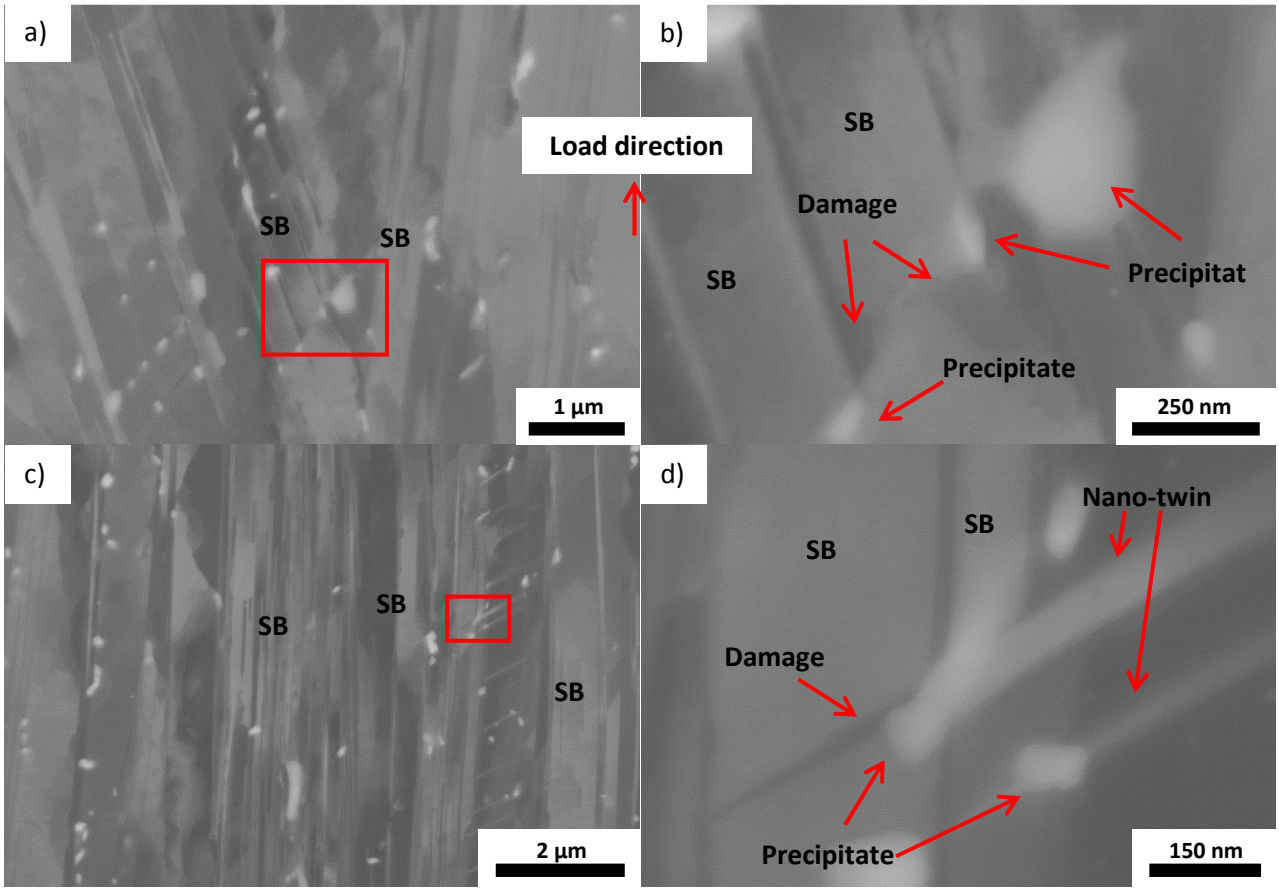

Figure 3. ECCI imaging of AISI 316L deformed to 46% strain, at a strain rate of 10^{-6}/s and 700°C, a) slip bands (SB) with two different directions interacting with precipitates, b) magnification of damage or probable future damage due to interaction between precipitate and slip bands, c) other location with slip bands and nano-twins interacting with precipitates and d) magnification of damage or probable future damage due to interaction between slip bands, nano-twins and precipitate. It is the same load direction in all the pictures.

Other damage behaviour in AISI 316L is shown in fig.4. At room temperature the deformation and damage behaviour is similar for strain rates of $2*10^{-3}$/s and 10^{-6}/s. Common damage appearing away from fracture zone is slip bands creating voids when intersecting with each other, grain boundaries or precipitates. Voids due to intersection between slip bands and grain boundaries, around 15mm away from the fracture surface are displayed in fig. 4 a). Voids also occur due to heavy deformation from shear bands as in fig.4 b). Near the fracture surface the microstructure is heavily deformed from multi-direction slip bands, shear bands and planar slip. Deformation bands with features looking like subcells appear near the fracture surface at room temperature for strain rates of $2*10^{-3}$/ and 10^{-6}/s. At elevated temperature the deformation bands look recrystallized as can be seen in fig. 4 c) and d). The EBSD analysis in fig.5 reveals that the areas that look like recrystallization has taken place (see fig.5 a)) don't show any new grains in AISI 316L at 650°C and a strain rate of 10^{-3}/s. Fig.5 b) shows the local misorientation in gray scale together with inversed pole figure (IPF) in color scale, and the brighter patterns correspond to local misorientation values above 4° and up to 5°. These brighter patterns have good correlation to some of the subcell or grains that can be seen in fig.5 a). The crystallographic orientation differs but doesn't give clear distinction between the supposed subcells or grains and the matrix and thus no evidence of recrystallization is found. The analysis in fig.5 is made in mostly one single grain or annealing twin, showing precipitates in the grain boundaries as white zero-solution in fig.5 b).

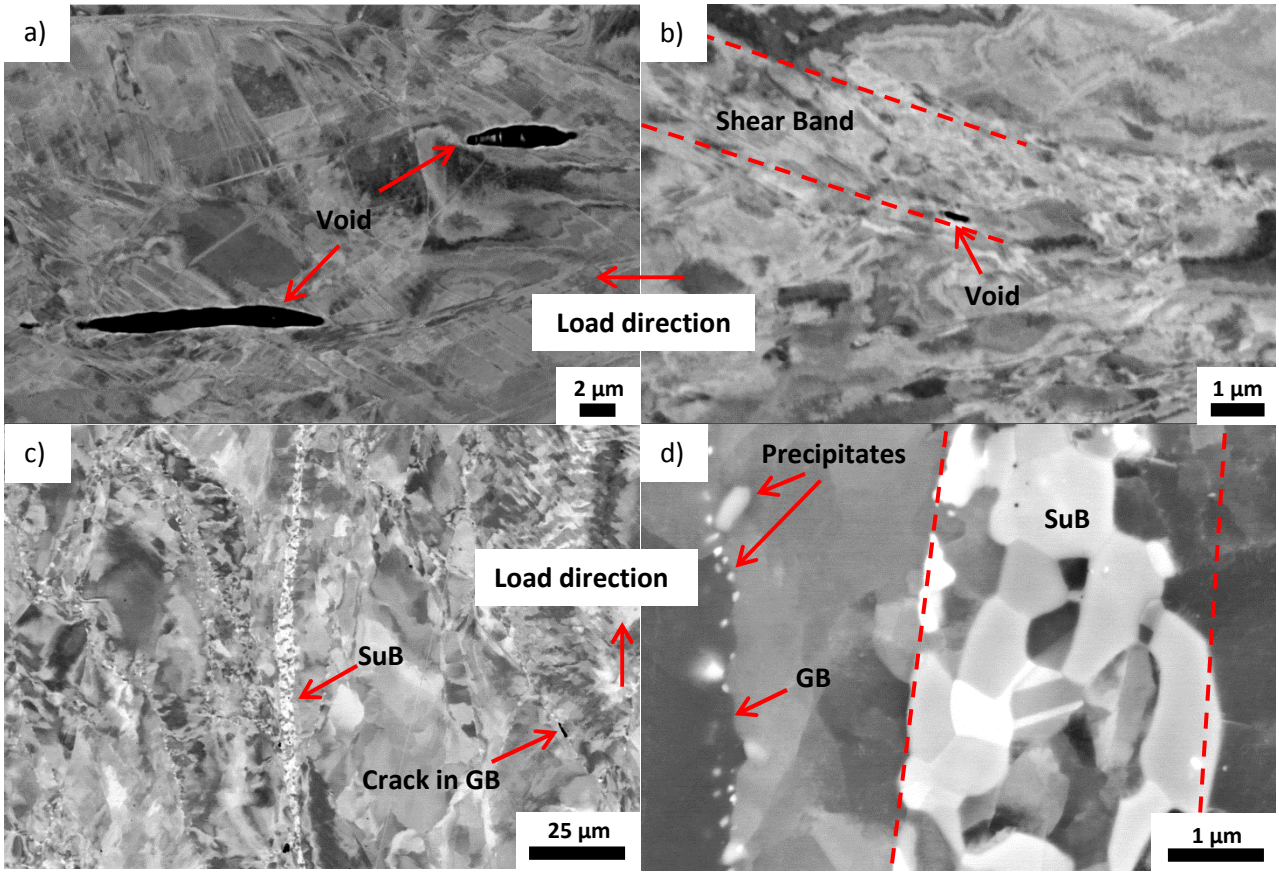

Figure 4. Deformation and damage behavior by ECCI in AISI 316L materials, a) voids from interaction between slip bands and grain boundaries (GB) at RT and strain rate $2*10^{-3}$/s, b) void due to deformation from shear band at RT and 10^{-6}/s, c) subcell band (SuB) at 650°C and 10^{-6}/s and d) magnification of subcell band.

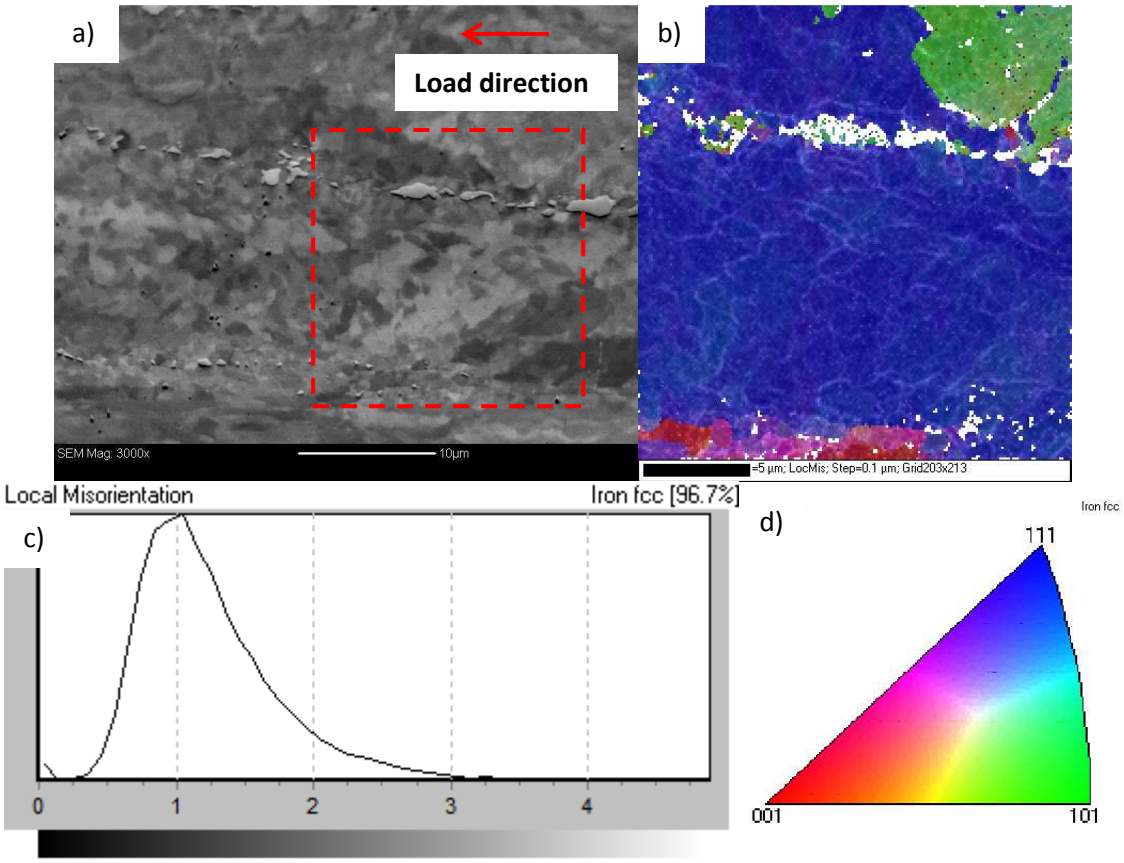

Figure 5. EBDS analysis showing recrystallization or subcell formation in AISI 316L after SSRT at 650°C to fractured using a strain rate of 10^{-6}/s, a) showing analyzed area, b) EBSD analysis displaying local misorientation (bright patterns) tighter with crystallographic orientation in a inversed pole figure (white color means zero-solution), c) local misorientation legend where the y-axis is frequency and x-axis is misorientation angle [°] and d) inversed pole figure legend showing crystallographic orientation.

3.2. Precipitates effect on damage

Both materials undergo precipitation due to the elevated temperature during the long deformation process. Alloy 617 has evenly distributed γ´ precipitates in the matrix and σ-phase in the grain boundaries [14]. AISI 316L get precipitates as Cr-rich carbides, that probably are $M_{23}C_6$ or M_6C, also σ-phase precipitate and they appear both in the matrix and grain boundaries [15]. The deformation time depends on material properties and strain rate, the deformation time varied from 1 minute to 130 hours. The size and amount of precipitates varied with the deformation time or strain rate and temperature, from no precipitate at high strain rates to more and bigger precipitates at the slower strain rates. Damage corresponding to the precipitation can be seen in fig.3 and fig. 6. At low strain rate and elevated temperature, the interaction between a moving dislocation and a precipitate can cause damage in the material. Fig. 6 display internal cracks that have initiate and propagate in the grain boundaries due to deformation and embrittlement from precipitates (Fig.6 c) and d)). Precipitates act as crack initiation points due to high local stress caused by the interaction between dislocations and precipitates.

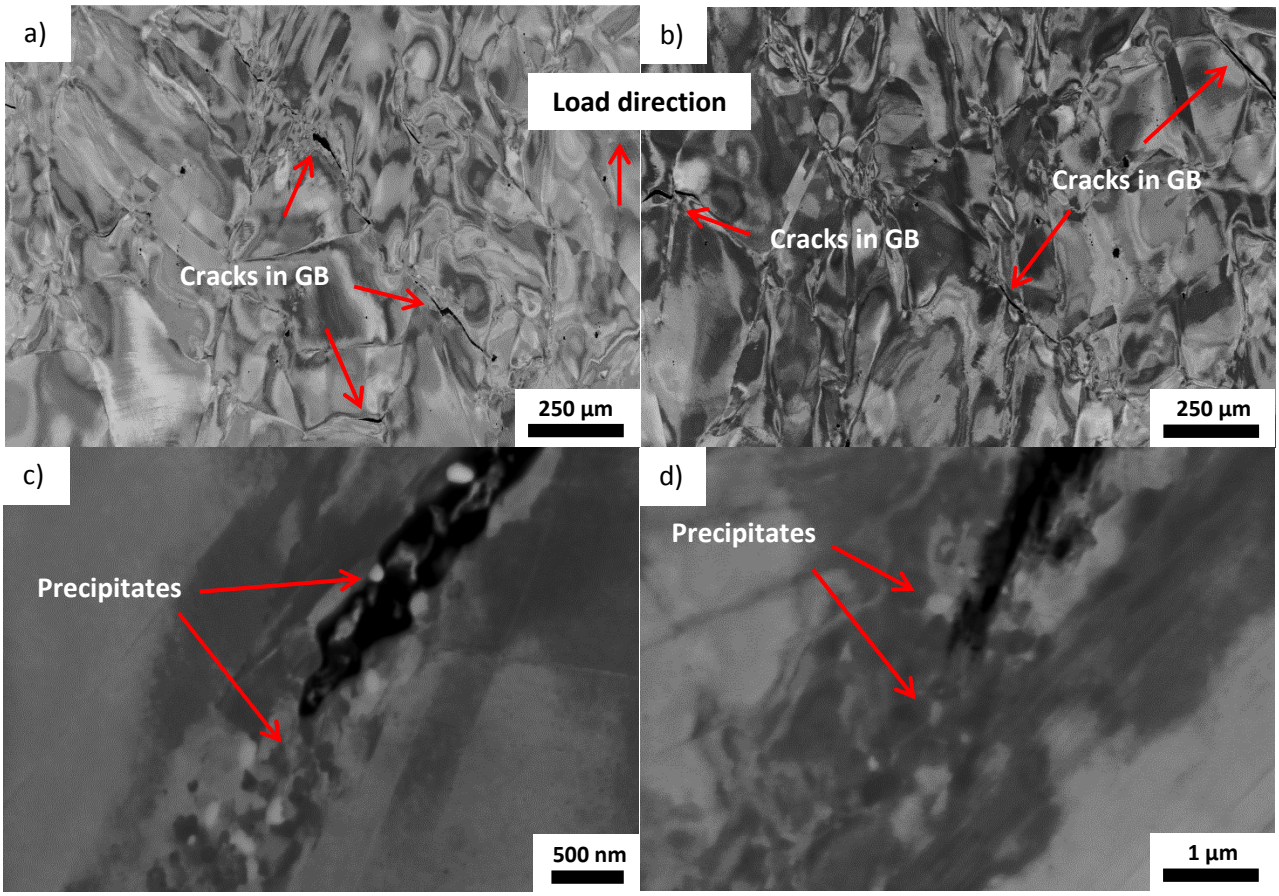

Figure 6. ECCI-picture showing internal cracks in the grain boundaries (GB) in Alloy 617, strain rate 10^{-5}/s and temperature a) 650°C, b) 700°C, c) crack tip, 650°C and b) crack tip, 700°C, tested to fracture. It is the same load direction in all the pictures.

4. Discussion

As known, DSA intensifies with increasing temperature and decreasing strain rate. However, in Alloy 617, DSA is present during the whole tensile deformation at elevated temperature when using a strain rate of 10^{-2}/s, but seems to disappear when the strain reach medium-high levels at an elevated temperature when using strain rates of 10^{-3}/s and 10^{-4}/s. DSA also appear again just before fracture when testing at elevated temperature using a strain rate of 10^{-3}/s. This behaviour could be described as a mismatch of the rates of solute atoms and moving dislocation, which could differ along the stress-strain curve and therefore serrations can appear just before fracture, where the local strain rate might be higher.

At room temperature the strain rate influencing the elongation in AISI 316L, when the strain rate decreases the elongation increases, also the stress level is lower at low strain rate. This is the result of the competition between hardening due to deformation and recovery due to the slow strain rate, where the recovery have more influence at slow strain rates than at higher. The recovery has a lager influence at lower deformations rates due to the fact that the moving dislocation rate decrease which affect the hardening to decrease. At high temperature the recovery probably can be an effect of creep, due to increasing diffusion rate and low deformation rate [11]. No clear microstructural signs as higher density of voids have been seen but they may be vanished due to high plastic deformation when the specimen is deformed to fracture. However, another sign that can be related to creep have been discovered, cell or subcell structure probably formed by creep deformation, from the EBSD-

analysis it is shown that the areas that look like recrystallization only have up to 5° misorientation which gives evidence for cell or subcell structures formed by creep deformation. According to the ECCI investigation there is areas and/or bands that display such cell or subcell structure, see fig.4c) and d). Further investigations are needed to confirm whether the cell or subcell structure is formed due to creep deformation in the AISI 316L material.

Elevated temperature and low strain rate decrease the ductility due to grain boundary embrittlement referred as sensitization and in some cases DSA. Sensitization is when chromium diffuses to the grain boundaries creating Cr-rich precipitates [16-19]. For sensitization the ageing time must be long enough for the precipitation to take place. According to literature sensitization occurs in AISI 316 material after less than 1h up to 100h depending on alloy content at 650°C and 700°C [17, 19]. After SSRT with a strain rate of 10^{-4}/s there are precipitates in the grain boundaries but they are too small to produce large scale embrittlement resulting in less internal cracks and larger elongation to fracture. For higher temperatures and long ageing times as in the case of SSRT tests with a strain rate of 10^{-6}/s and 700°C (fig.5 d)), desensitization probably can occur which means that chromium diffuses back into the interfacial region where the precipitate have grown [16, 19]. The desensitization seems to increase or keep the embrittlement of the material constant, see fig.2. In fig.2 b) the tensile stress increases which could refer to a hardening coupled to DSA that explain the large decrease in ductility. As known, precipitates in the matrix play two important roles for the life of the material, the first is to interact with moving dislocation and increase the strength or hardness of the material. The second is to cause stress concentration at the precipitate during dislocation accumulation that will in turn cause initiation of cracking by either precipitate cracking self or in the matrix.

5. Conclusion

After slow strain rate tensile testing at elevated temperatures and subsequent investigation of the microstructure using ECCI the following conclusions has been reached:

- Damage appears at interactions between moving dislocations and precipitates due to local stress concentration.

- DSA is present at all tested strain rates, but disappear at certain strain values for some deformation conditions. This is due to mismatches in the rates of moving dislocations and solute atoms at different strain intervals during the tensile deformation.

- Grain boundary embrittlement is causing damage as internal cracks and lowers the elongation to fracture. Therefore it is strongly affecting the material fracture behaviour at elevated temperature and is affecting for the high-temperature performances during deformation of the tested materials.

- AISI 316L show behaviour similar to creep at low strain rates (10^{-6}/s) and high temperatures.

Abstract Nickel-based superalloys are often selected due to their remarkable mechanical and chemical properties at high temperatures. This makes the material suitable for high temperature applications such as gas turbines and aero engines. By use of single-crystal instead of poly-crystal material, both creep and fatigue properties are enhanced. Superalloys in single-crystal form exhibit an anisotropic behaviour and a tension/compression asymmetry. This makes it interesting to study different crystal orientations in both tension and compression. In this study, high temperature stress relaxation of a Ni-based single-crystal superalloy is investigated. Specimens with three different crystal orientations, ⟨001⟩, ⟨011⟩ and ⟨111⟩, were tested in both tension and compression. Results show an anisotropic stress relaxation behaviour, as well as a tension/compression asymmetry for all directions. During stress relaxation at 750°C, the creep properties decreases in the sequence ⟨001⟩, ⟨011⟩ and ⟨111⟩ in tension, while in compression ⟨001⟩ = ⟨011⟩, ⟨111⟩. However, at 950°C the creep properties are slightly better in the ⟨011⟩ direction compared to the ⟨001⟩ direction.

Keywords single-crystal superalloy, thermomechanical fatigue, stress relaxation

1. Introduction

Ni-based superalloys show remarkable mechanical and chemical properties at high temperatures, which make them a suitable as blade material in gas turbines and aero engines [1, 2]. The superalloys consist of the typical γ/γ′-microstructure, where the γ′-phase works as strengthener in a matrix of γ. The strengthening γ′-phase has an $L1_2$-ordered structure and is rich of Al, Ta and Ti. By using a single-crystal material instead of poly-crystal material both creep and fatigue properties are enhanced [3]. Gas turbine blades in single-crystal form are most common casted with the ⟨001⟩ crystallographic direction upwards, since this direction has the lowest stiffness of all crystal directions. Low stiffness implies good fatigue properties, which is of great importance for gas turbine blade components. Single-crystal superalloys exhibit an anisotropic behaviour and they also show a tension/compression asymmetry [4-7] .

Stress relaxation testing of superalloys is often associated with shorter hold times at high temperatures during thermomechanical fatigue (TMF) testing, for example hold times of 5 min during each cycle [8, 9]. However, Zhang et al. [10] applied a hold time of 1h at 900°C in compression at each cycle during TMF testing. In that study, three different stages of stress relaxation during the TMF tests were found, and each stage was connected to a specific microstructural behaviour. Other research showed that when applying hold times of 30-60 minutes during tensile loadings at temperatures from 700 to 1000°C, the stress relaxed to an asymptotic stress value after the hold time [11]. At high temperatures and loads a directional coarsening of the γ/γ′-microstructure is obtained. This phenomenon is called rafting and it is a diffusion controlled directional coarsening of the γ′-particles [12]. The orientation of the rafting is dependent on whether the alloy has a positive or negative lattice misfit [13]. Rafting doesn't always have to be negative for the material. For instance, research has shown how pre-rafting can improve creep properties [14]. Also isothermal high-temperature fatigue lives have proven to be enhanced by a pre-rafted

microstructure, instead of having the more common microstructure with γ′-cuboids in a γ-matrix [15, 16].

The aim of this study is to investigate the long-term stress relaxation behaviour of a Ni-based single-crystal superalloy. Due to anisotropy and the well-known tension/compression asymmetry, three different crystal orientations are tested in both tension and compression.

2. Experimental procedure

The Ni-based single-crystal superalloy MD2 with chemical composition Ni-5.1Co-6.0Ta-8.0Cr-8.1W-5.0Al-1.3Ti-2.1Mo-0.1Hf-0.1Si in wt.%, was used in this study. Prior testing, the material was solution heat treated at 1275°C for 8 h followed by a two-stage aging process with 3 h at 1100°C and 24 h at 850°C. Test specimens were machined from cast bars and the deviation from the ideal orientation was less than 10° for all specimens.

The tests were performed in an Instron servo-hydraulic TMF machine, and were conducted as strain controlled TMF cycles with a temperature range from 100°C to either 750°C or 950°C. During each cycle, a hold time of 100 h was applied at maximum temperature (T_{max}) and maximum strain. After the 100 h hold time, the temperature was lowered to 100°C and zero strain before the second cycle was initiated. Each specimen was subjected to two TMF cycles, and no specimens were cycled to fracture. Consequently, a hold time of total 200 h at T_{max} was applied for each specimen. Fig. 1 displays a plot of the TMF cycle. For a T_{max} of 750°C, the ⟨001⟩, ⟨011⟩ and ⟨111⟩ directions were tested. However, for a T_{max} of 950°C, only the ⟨001⟩ and ⟨011⟩ directions were tested. The total mechanical strain range ($\Delta\varepsilon_{mech}$) was chosen in order to obtain approximately the same inelastic strain for all specimens. Since the different crystal orientations have different Young's modulus, different $\Delta\varepsilon_{mech}$ were used for the different crystal directions. The ⟨001⟩ oriented specimens were subjected to a $\Delta\varepsilon_{mech}$ of 1%, the ⟨011⟩ specimens to 0.7%, and the ⟨111⟩ specimens were subjected to 0.6%. For each direction and T_{max}, one specimen was subjected to an in-phase TMF cycle (IP-TMF), and the other specimen was subjected to an out-of-phase TMF cycle (OP-TMF). An IP-TMF cycle implies tensile stress relaxation at T_{max} while OP-TMF implies compressive stress relaxation at T_{max}.

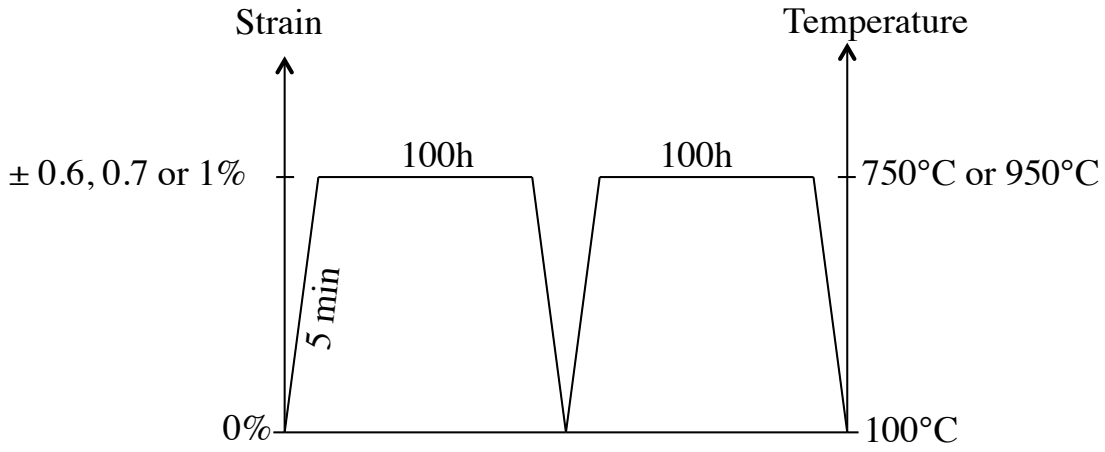

Figure 1. The TMF cycle used in the stress relaxation tests.

After the tests, all specimens were examined by stereomicroscopy before they were cut parallel to the loading direction for further microstructural investigation by scanning electron microscopy (SEM). The SEM samples were prepared by grinding and mechanical polishing, but no samples were etched. The microstructure investigation was performed in a Hitachi SU70 SEM, using voltages from 10 to 20 kV.

3. Results

3.1. Stress relaxation testing

Results from the tests with a T_{max} of 750°C show that the ⟨011⟩ oriented specimens demonstrates a serrated yielding behaviour during the loading phase. This was visible in both tension (IP) and compression (OP). However, the yielding for both the ⟨001⟩ and ⟨111⟩ directions during the loading phase was more stable, i.e. no serrated yielding was observed. In addition to the serrated yielding for the ⟨011⟩ direction, those specimens also demonstrated a clear noise during the loading phase. On the other hand, both the ⟨001⟩ and ⟨111⟩ directions were more quite. For the specimens subjected to stress relaxation at T_{max} of 950°C no serrated yielding and no noise was observed during the loading phase.

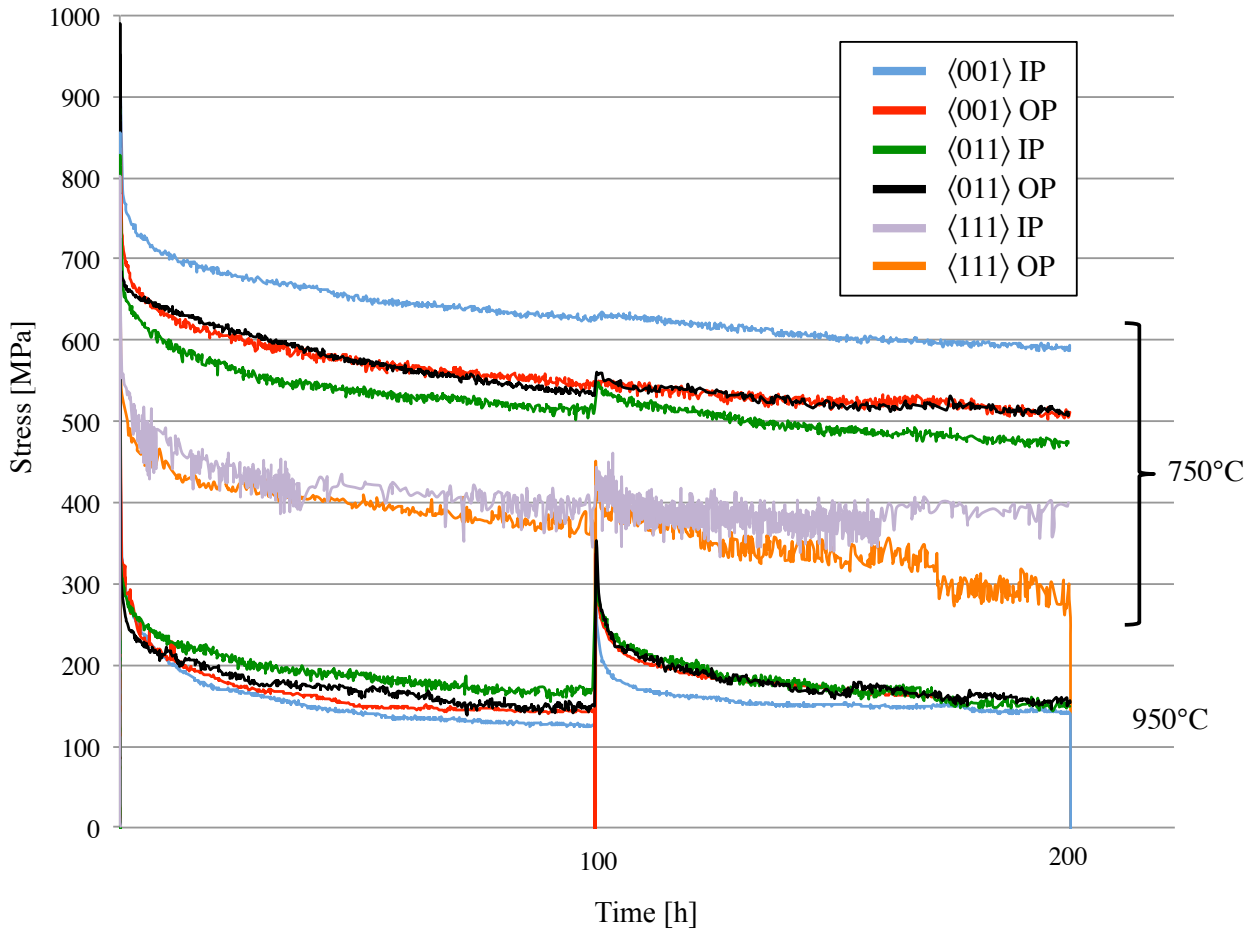

Figure. 2. Stress relaxation over 200 h for all crystal orientations tested.

Fig. 2 displays how the stress is relaxing during the 200 h hold time for all specimens. The figure shows that the stresses relax to lower stress states at 950°C compared to 750°C. The other significant differences in the stress relaxation behaviour are summarized below.

All crystal orientations show a tension/compression asymmetry. However, the asymmetry is most pronounced the ⟨001⟩ direction at 750°C. Here, tensile loading leads to a higher stress state compared to compressive loading, and the difference in stress is approximately 80 MPa after 200 h. The ⟨011⟩ oriented specimens show an opposite behaviour at this temperature; tensile loading leads to a lower stress state compared to compressive loading. Another difference at this temperature, is that the unloading after 100 h leads to an increase in stress state for the ⟨011⟩ direction when the material is loaded into the second 100 h TMF cycle. However, after some time the material relaxes and adapts into the pre-unloading behaviour. For the ⟨001⟩ direction the unloading after 100 h does not have an influence on the stress state.

Concerning the ⟨111⟩ oriented specimens, they relax to a significant lower stress state compared to both ⟨001⟩ and ⟨011⟩ directions. After the first 100 h TMF cycle, the stress is approximately 360 MPa for the ⟨111⟩ direction, while both ⟨001⟩ and ⟨011⟩ directions are well above 500 MPa. It should be noted that the stress relaxation in the ⟨111⟩ direction is very unstable compared to the other directions. The instability should be attributed to TMF machine instabilities, rather than any microstructural difference between the three directions. One reason can be that the high stiffness in the ⟨111⟩ direction makes it more difficult for the TMF machine to take care of instabilities.

At 950°C, only the ⟨001⟩ and ⟨011⟩ directions were tested. At this temperature, an opposite tension/compression asymmetry is observed compared to 750°C. The ⟨001⟩ direction is stronger in compression than tension, while the ⟨011⟩ direction is stronger in tension than compression. Here the unloading after 100 h also seems to influence the specimens to a greater extent compared to 750°C. A significant higher stress state is observed in the beginning of the second TMF cycle. This is the case for both ⟨001⟩ and ⟨011⟩ directions at 950°C, but only for the ⟨011⟩ direction at 750°C.

3.2. Microscopy

Crystallographic deformation bands across the specimens are found on the ⟨011⟩ oriented materials subjected to hold times at 750°C, both in tension (IP) and compression (OP). See Fig. 3a for the ⟨011⟩ oriented specimen subjected to 750°C in compression. Neither the ⟨001⟩ nor ⟨111⟩ oriented specimens show similar deformation bands at this temperature. However at 950°C, both ⟨001⟩ and ⟨001⟩ oriented specimens show crystallographic deformation bands (the ⟨111⟩ direction was not tested at this temperature). Another difference between the two temperatures is that the deformation bands become more distinct at 950°C compared to 750°C. All slip traces are consistent with slip along the {111}⟨110⟩ slip systems. In Fig. 3b, the more distinct deformation bands are visible. This figure shows the deformation bands on the ⟨011⟩ oriented specimen subjected to tensile stresses at 950°C. Here, slip traces on different {111} planes are found. In Fig. 3c, the deformation bands on the ⟨001⟩ oriented specimen subjected to tensile stresses are shown. In this case, in addition to the crystallographic deformation bands, also wavy deformation bands are found. This indicates that several slip systems are active during deformation in this direction at 950°C.

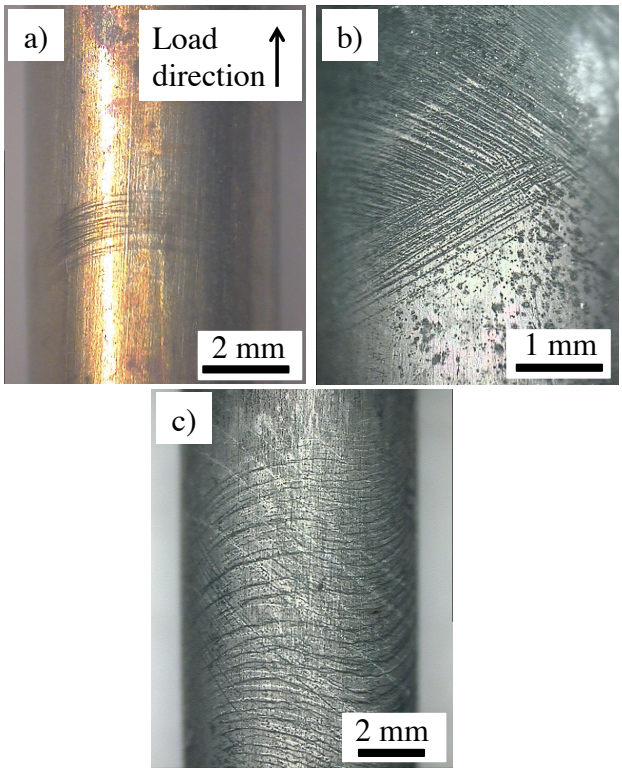

Figure. 3. Deformation bands on specimen surfaces, a) the ⟨011⟩ specimen subjected to 750°C in compression (OP), b) the ⟨011⟩ specimen subjected to 950°C in tension (IP), and c) the ⟨001⟩ specimen subjected to 950°C in tension (IP).

After cutting the specimens parallel to the loading direction all specimens were investigated by SEM. Fig. 4 provides a backscattered electron image where the deformation bands inside the specimen are clearly visible at low magnification. However, at higher magnification the crystallographic deformation bands are often difficult to detect. The SEM investigation shows that the deformation bands are neither twinning nor shearing of the γ/γ′-microstructure. Sometimes precipitation of topologically-close-packed (TCP) phases are visible within the deformation bands. Even though most deformation bands are difficult to detect at higher magnification, occasionally more distinct deformation bands are visible, see Fig. 5 for such a distinct deformation band. Most likely, both types of deformation bands are bundles of glide bands. Other than the crystallographic deformation bands, the specimens show very little deformation within the γ/γ′-microstructure. However, small amounts of twins are detected in the microstructure for the ⟨001⟩ specimen subjected to compression at 750°C, see Fig. 6. Here parallel twins propagates through the γ′-cuboids.

Rafting of the γ/γ′-microstructure is visible in specimens subjected to holdtimes at 950°C. The rafting direction is dependent on whether the superalloy has a negative or positive misfit between the γ′- and γ-microconstituents, and if the loading is tensile or compressive. The alloy used in this study (MD2) has a negative misfit which implies that tensile loaded specimens show a N-type of rafting, while material loaded in compression show a P-type of rafting. Fig. 7 displays N-type of rafting; the previously cuboidal γ′-particles are here coarsened and oriented Normal to the load direction. On the other hand, Fig. 5 shows P-type of rafting where the coarsened γ′-particles are oriented Parallel to the load direction.

4. Discussion

The MD2 alloy exhibits an anisotropic creep behaviour as well as a tension/compression asymmetry during stress relaxation, see Fig. 2. It can also be seen that the ⟨111⟩ direction has the worst creep properties at 750°C. This direction relaxes to a significant lower stress state compared to both ⟨001⟩ and ⟨011⟩ direction during the stress relaxation tests. At 750°C, the ⟨001⟩ and ⟨111⟩ specimens are stronger in tension than compression. However, for the ⟨011⟩ specimens the opposite behaviour is observed; compressive loading leads to a higher stress state compared to tensile loading. At 950°C, an opposite tension/compression asymmetry is observed: the ⟨001⟩ direction is stronger in compression than tension, and the ⟨011⟩ direction is stronger in tension than compression. It seems that there is a change in tension/compression asymmetry when going from 750°C to 950°C. That the tension/compression asymmetry changes with temperature has been showed by Ezz et al. [6] who studied the tension/compression asymmetry for the critical resolved shear stress (CRSS) for a single-crystal superalloy. They showed that the CRSS is higher in tension than compression at 750°C for orientations close to [001] in the stereographic triangle. On the other hand, for materials close to [011] and [111] in the stereographic triangle, there was a smaller asymmetry in CRSS at this temperature. At higher temperatures the asymmetry decreased. Present study shows that there is a change in tension/compression asymmetry also in stress relaxation behaviour, however the reason to this is still to be determined.

The ⟨011⟩ oriented specimens showed a serrated yielding behaviour during loading into the first TMF cycle in the tests at 750°C. This behaviour is attributed to two things; the fact that only one slip system is active during deformation in this direction and the effect of dynamic strain ageing (DSA). Serrated yielding behaviour of the ⟨011⟩ direction has previously been reported in the literature [17-20]. One explanation for this has been that only one slip system is active during deformation of the ⟨011⟩ direction while multiple slip systems are active during plastic deformation in the ⟨001⟩ direction [17]. The reason to single slip for the ⟨011⟩ direction is attributed to the lower symmetry, i.e. less equivalent slip systems, for this direction compared to the ⟨001⟩ and ⟨111⟩ directions. When several slip systems are active at the same time, there is always one slip system where the dislocations can propagate and a more stable yielding is observed. On the other hand, if

only one slip system is active, the dislocations are sometimes stopped if the stress is not large enough and a more serrated yielding is obtained. The fact that deformation bands are found only on the ⟨011⟩ specimens at 750°C can also be attributed to the fact that only one slip system is active in this direction and temperature. The deformation bands on the surfaces are topographic differences, which are more probable to obtain when only one slip system is active compared to the case when several systems are active. This since slip on several systems will lead to a more homogeneous surface. The serrated yielding behaviour of the ⟨011⟩ direction at 750°C can also be attributed to dynamic strain aging (DSA). Localized deformation bands are found on these specimens, and those deformation bands are likely glide bands with a high dislocation density. DSA is the interaction between solute atoms and moving dislocations, and is favoured in areas with a high dislocation density, i.e. within those localized deformation bands.

A clear noise was heard from the ⟨011⟩ oriented specimens when loading into the first TMF cycle for tests at 750°C. This behaviour of the ⟨011⟩ direction has been reported before when acoustic emission (AE) was used to measure noise during plastic deformation [21]. In that study, loading in the ⟨011⟩ direction led to higher AE signals and higher noise compared to ⟨001⟩. It is thus likely, that during loading of the ⟨011⟩ direction at this temperature, in which serrated yielding occurs, a high noise is created for each serration.

4. Conclusions

From this study it can be concluded that the Ni-based single-crystal superalloy MD2 shows an anisotropic creep behaviour as well as a tension/compression asymmetry during stress relaxation. At 750°C, the tensile creep properties is best for the ⟨001⟩ direction, followed by the ⟨011⟩ direction while the ⟨111⟩ direction has the worst creep properties. At the same temperature in compression, the ⟨001⟩ and ⟨011⟩ directions show similar creep properties, and also here the ⟨111⟩ direction shows the worst creep properties. During stress relaxation at 950°C, the creep properties are slightly better in the ⟨011⟩ direction compared to the ⟨001⟩ direction for both compressive and tensile loadings.

Abstract The modeling of subcritical growth of inclined crack under creep condition is considered. In the first part of this paper the stress state near the tip of inclined crack for power creep law in the cases of plane stress and plane strain is calculated. To calculate the stress state near the tip of an inclined crack the Airy's stress function is used. The resulting nonlinear fourth order differential equation is formulated as two-point boundary value problem and is solved by shooting and Newton's methods.

The modeling of creep crack growth is based on Rabotnov-Kachanov damage theory and the criterion of crack growth ω=1 at the distance d from the crack tip, calculated for equivalent or maximum stress. The crack growth rate and the crack trajectory are calculated both for plane stress and plane strain and for n = 1, 3, 5, 7 and considered in the second part of this paper.

Keywords inclined crack, creep, stress distribution.

1. Introduction

Let us consider an infinite plate of a nonlinear elastic-creep material with a crack of the length 2a, located at the angle α to the axis *x* and loaded by the stress σ_∞ along the axis *y* (Figure 1). It is required to determine the stress state near the tip of inclined crack for the plane stress and the plane strain conditions. It should be noted that the problem of uniaxial tension of inclined crack is statically equivalent to the mixed tensile and shear loading by the stresses $\sigma_\infty \cos^2\alpha$ and $\sigma_\infty \cos\alpha \sin\alpha$, respectively (Fig. 1).

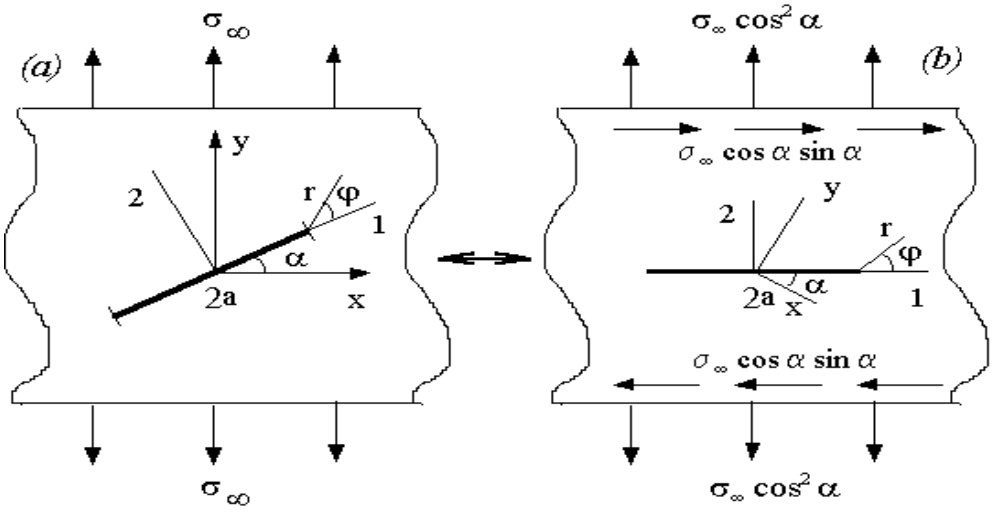

Figure 1. The geometry of the inclined crack.

2. Statement of the problem

2.1. Main equations

Let us consider the polar coordinate system (r, φ) associated with the tip of inclined crack (Fig. 1). The equilibrium equations and the Cauchy relations in the polar coordinate system for the plane strain or stress conditions are [1-3]:

$$\frac{\partial \sigma_{rr}}{\partial r}+\frac{1}{r}\frac{\partial \sigma_{r\varphi}}{\partial \varphi}+\frac{\sigma_{rr}-\sigma_{\varphi\varphi}}{r}=0,\quad \frac{1}{r}\frac{\partial \sigma_{\varphi\varphi}}{\partial \varphi}+\frac{\partial \sigma_{r\varphi}}{\partial r}+2\frac{\sigma_{r\varphi}}{r}=0. \tag{1}$$

$$\varepsilon_{rr}=\frac{\partial u_r}{\partial r},\quad \varepsilon_{\varphi\varphi}=\frac{u_r}{r}+\frac{1}{r}\frac{\partial u_\varphi}{\partial \varphi},\quad 2\varepsilon_{r\varphi}=\frac{1}{r}\frac{\partial u_r}{\partial \varphi}+\frac{\partial u_\varphi}{\partial r}-\frac{u_\varphi}{r}, \tag{2}$$

The constitutive equations for an incompressible material with a power creep law have the following form [1-2]:

$$\varepsilon_{ij}=(3/2)B\sigma_e^{n-1}s_{ij} \tag{3}$$

where ε_{ij} is the strain rate tensor, $s_{ij}=\sigma_{ij}-(1/3)\sigma_{kk}\delta_{ij}$ is the deviator of σ_{ij} stress tensor, $\sigma_e=\sqrt{(3/2)s_{ij}s_{ij}}$ is the equivalent stress, B is the material constant, n is the index of nonlinearity.

The equivalent stress σ_e for the plane stress and the plane strain is calculated as

$$\sigma_e=\sqrt{\sigma_{rr}^2-\sigma_{rr}\sigma_{\varphi\varphi}+\sigma_{\varphi\varphi}^2+3\sigma_{r\varphi}^2},\quad \sigma_e=\sqrt{(3/4)(\sigma_{rr}-\sigma_{\varphi\varphi})^2+3\sigma_{r\varphi}^2} \tag{4}$$

The strain compatibility equation in polar coordinates, resulting from Eq. (2), has the following form [1-3]:

$$\frac{1}{r}\frac{\partial^2}{\partial r^2}(r\varepsilon_{\varphi\varphi})+\frac{1}{r^2}\frac{\partial^2\varepsilon_{rr}}{\partial\varphi^2}-\frac{1}{r}\frac{\partial\varepsilon_{rr}}{\partial r}-\frac{2}{r^2}\frac{\partial}{\partial r}(r\frac{\partial\varepsilon_{r\varphi}}{\partial\varphi})=0. \tag{5}$$

Taking into account Eq. (1), Eq. (3) and Eq. (4), the strain compatibility Eq. (5) can be rewritten in the stress terms for the plane stress (a) and the plane stain (b) conditions as the follows:

$$\frac{1}{r}\frac{\partial^2}{\partial r^2}\left[\sigma_e^{n-1}r\left(\sigma_{\varphi\varphi}-\frac{1}{2}\sigma_{rr}\right)\right]+\frac{1}{r^2}\frac{\partial^2}{\partial\varphi^2}\left[\sigma_e^{n-1}\left(\sigma_{rr}-\frac{1}{2}\sigma_{\varphi\varphi}\right)\right]-$$
$$-\frac{1}{r}\frac{\partial}{\partial r}\left[\sigma_e^{n-1}\left(\sigma_{rr}-\frac{1}{2}\sigma_{\varphi\varphi}\right)\right]-\frac{3}{r^2}\frac{\partial}{\partial r}\left[r\frac{\partial}{\partial\varphi}\left(\sigma_e^{n-1}\sigma_{r\varphi}\right)\right]=0, \tag{6a}$$

$$\frac{1}{r}\frac{\partial^2}{\partial r^2}\left[\sigma_e^{n-1}r\left(\sigma_{\varphi\varphi}-\sigma_{rr}\right)\right]+\frac{1}{r^2}\frac{\partial^2}{\partial\varphi^2}\left[\sigma_e^{n-1}\left(\sigma_{rr}-\sigma_{\varphi\varphi}\right)\right]-$$
$$-\frac{1}{r}\frac{\partial}{\partial r}\left[\sigma_e^{n-1}\left(\sigma_{rr}-\sigma_{\varphi\varphi}\right)\right]-\frac{4}{r^2}\frac{\partial}{\partial r}\left[r\frac{\partial}{\partial\varphi}\left(\sigma_e^{n-1}\sigma_{r\varphi}\right)\right]=0, \tag{6b}$$

Thus, the main equations in stress terms for the power law constitutive equation (Eq. 4) are the equilibrium equations (Eq. 1) and the strain compatibility condition for the plane stress (Eq. 6a) or the plane stain (Eq. 6b), accordingly.

2.2. Airy's stress function

To solve the system of Eq. (1) and Eq. (6a) or Eq. (1) and Eq. (6b) it is often used the Airy's stress function $F(r, \varphi)$, defined as follows [1-3]:

$$\sigma_{rr} = \frac{1}{r}\frac{\partial F}{\partial r} + \frac{1}{r^2}\frac{\partial^2 F}{\partial \varphi^2}, \quad \sigma_{\varphi\varphi} = \frac{\partial^2 F}{\partial r^2}, \quad \sigma_{r\varphi} = \frac{1}{r^2}\frac{\partial F}{\partial \varphi} - \frac{1}{r}\frac{\partial^2 F}{\partial r \partial \varphi}. \tag{7}$$

Substituting Eq. (7) in the strain compatibility equation for plane stress and plane strain conditions (Eq. 6a or Eq. 6b, accordingly), we obtain the following nonlinear differential equation for the Airy's stress function $F(r, \varphi)$:

$$\frac{1}{r}\frac{\partial^2}{\partial r^2}\left[\sigma_e^{n-1}\left(r\frac{\partial^2 F}{\partial r^2} - \frac{1}{2}\left(\frac{\partial F}{\partial r} + \frac{1}{r}\frac{\partial^2 F}{\partial \varphi^2}\right)\right)\right] + \frac{1}{r^2}\frac{\partial^2}{\partial \varphi^2}\left[\sigma_e^{n-1}\left(\frac{1}{r}\frac{\partial F}{\partial r} + \frac{1}{r^2}\frac{\partial^2 F}{\partial \varphi^2} - \frac{1}{2}\frac{\partial^2 F}{\partial r^2}\right)\right] -$$
$$-\frac{1}{r}\frac{\partial}{\partial r}\left[\sigma_e^{n-1}\left(\frac{1}{r}\frac{\partial F}{\partial r} + \frac{1}{r^2}\frac{\partial^2 F}{\partial \varphi^2} - \frac{1}{2}\frac{\partial^2 F}{\partial r^2}\right)\right] - \frac{3}{r^2}\frac{\partial}{\partial r}\left[\frac{\partial}{\partial \varphi}\left(\sigma_e^{n-1}\left(\frac{1}{r}\frac{\partial F}{\partial \varphi} - \frac{\partial^2 F}{\partial r \partial \varphi}\right)\right)\right] = 0, \tag{8a}$$

where

$$\sigma_e^2 = \frac{\partial^2 F}{\partial \varphi^2}\left(\frac{2}{r^3}\frac{\partial F}{\partial r} + \frac{1}{r^4}\frac{\partial^2 F}{\partial \varphi^2} - \frac{1}{r^2}\frac{\partial^2 F}{\partial r^2}\right) + \frac{\partial F}{\partial r}\left(\frac{1}{r^2}\frac{\partial F}{\partial r} - \frac{1}{r}\frac{\partial^2 F}{\partial r^2}\right) -$$
$$-3\frac{\partial^2 F}{\partial r \partial \varphi}\left(\frac{2}{r^3}\frac{\partial F}{\partial \varphi} - \frac{1}{r^2}\frac{\partial^2 F}{\partial r \partial \varphi}\right) + \left(\frac{\partial^2 F}{\partial r^2}\right)^2 + \frac{3}{r^4}\left(\frac{\partial F}{\partial \varphi}\right)^2,$$

or

$$\frac{1}{r}\frac{\partial^2}{\partial r^2}\left[\sigma_e^{n-1}\left(r\frac{\partial^2 F}{\partial r^2} - \left(\frac{\partial F}{\partial r} + \frac{1}{r}\frac{\partial^2 F}{\partial \varphi^2}\right)\right)\right] + \frac{1}{r^2}\frac{\partial^2}{\partial \varphi^2}\left[\sigma_e^{n-1}\left(\frac{1}{r}\frac{\partial F}{\partial r} + \frac{1}{r^2}\frac{\partial^2 F}{\partial \varphi^2} - \frac{\partial^2 F}{\partial r^2}\right)\right] -$$
$$-\frac{1}{r}\frac{\partial}{\partial r}\left[\sigma_e^{n-1}\left(\frac{1}{r}\frac{\partial F}{\partial r} + \frac{1}{r^2}\frac{\partial^2 F}{\partial \varphi^2} - \frac{\partial^2 F}{\partial r^2}\right)\right] - \frac{4}{r^2}\frac{\partial}{\partial r}\left[\frac{\partial}{\partial \varphi}\left(\sigma_e^{n-1}\left(\frac{1}{r}\frac{\partial F}{\partial \varphi} - \frac{\partial^2 F}{\partial r \partial \varphi}\right)\right)\right] = 0, \tag{8b}$$

where

$$4\sigma_e^2 = \frac{\partial^2 F}{\partial \varphi^2}\left(\frac{6}{r^3}\frac{\partial F}{\partial r} + \frac{3}{r^4}\frac{\partial^2 F}{\partial \varphi^2} - \frac{6}{r^2}\frac{\partial^2 F}{\partial r^2}\right) + \frac{\partial F}{\partial r}\left(\frac{3}{r^2}\frac{\partial F}{\partial r} - \frac{6}{r}\frac{\partial^2 F}{\partial r^2}\right) -$$
$$-12\frac{\partial^2 F}{\partial r \partial \varphi}\left(\frac{2}{r^3}\frac{\partial F}{\partial \varphi} - \frac{1}{r^2}\frac{\partial^2 F}{\partial r \partial \varphi}\right) + 3\left(\frac{\partial^2 F}{\partial r^2}\right)^2 + \frac{12}{r^4}\left(\frac{\partial F}{\partial \varphi}\right)^2.$$

2.3. Near crack tip asymptotic

In the polar coordinate system the Airy's stress function $F(r, \varphi)$ near a crack tip has the following asymptotic representation [4-6]:

$$F(r,\varphi) = Kr^{\lambda} f(\varphi), \tag{9}$$

where $\lambda = (2n+1)/(n+1)$, $K = (J/BI_n)^{1/(n+1)}$, $J = \oint\left(\frac{n}{n+1}B\sigma_e^{n+1}\cos\varphi - \sigma_{ij}n_j\frac{\partial u_i}{\partial x}\right)ds$ is the path-independent contour integral (usually named as Cherepanov-Rice-integral or J-integral) and

$$I_n = \int_{-\pi}^{\pi}\left[\cos\varphi\left(\frac{n}{n+1}s_e^{n+1} - \frac{1}{n+1}\left(s_{rr}u_r + s_{r\varphi}u_\varphi\right)\right) - \sin\varphi\left(s_{rr}\left(u_\varphi - \frac{\partial u_r}{\partial\varphi}\right) - s_{r\varphi}\left(u_r + \frac{\partial u_\varphi}{\partial\varphi}\right)\right)\right]d\varphi$$

is the dimensionless constant.

Taking into account Eq. (7) and the asymptotic behavior (Eq. 9) of Airy's stress function $F(r, \varphi)$, the stress tensor σ_{ij} and the equivalent stress σ_e near a crack tip can be written as follows:

$$\begin{aligned}
\sigma_{rr} &= Kr^{\lambda-2}(\lambda f(\varphi) + d^2 f/d\varphi^2) = Kr^{\lambda-2}s_{rr}(\varphi),\\
\sigma_{\varphi\varphi} &= Kr^{\lambda-2}(\lambda(\lambda-1)f(\varphi)) = Kr^{\lambda-2}s_{\varphi\varphi}(\varphi),\\
\sigma_{r\varphi} &= Kr^{\lambda-2}(1-\lambda)(df/d\varphi) = Kr^{\lambda-2}s_{r\varphi}(\varphi),\\
\sigma_e &= Kr^{\lambda-2}s_e(\varphi),
\end{aligned}$$

where $s_e(\varphi)$ is the dimensionless function, written for the plane stress and the plane strain conditions, respectively, as the follows:

$$s_e^2 = \lambda^2(\lambda^2-3\lambda+3)f^2(\varphi) + 3(\lambda^2-2\lambda+1)(df/d\varphi)^2 + \lambda(3-\lambda)f(\varphi)(d^2f/d\varphi^2) + (d^2f/d\varphi^2)^2,$$

$$s_e^2 = \lambda^2(\lambda^2-4\lambda+4)f^2(\varphi) + 4(\lambda^2-2\lambda+1)(df/d\varphi)^2 + 2\lambda(2-\lambda)f(\varphi)(d^2f/d\varphi^2) + (d^2f/d\varphi^2)^2$$

Compatibility equations (8a) and (8b) for the asymptotic of Airy's stress function $F(r, \varphi)$ (Eq. 9) can be rewritten as non-linear ordinary differential equation for the unknown function $f(\varphi)$ [7-8]:

$$\begin{aligned}
&n(\lambda-2)s_e^{n-1}\left[((2-\lambda)n-3)(d^2f/d\varphi^2) + \lambda\left(2n\left(\lambda^2+3\right) + \lambda(3-7n) - 6\right)f(\varphi)\right] +\\
&+\frac{d^2}{d\varphi^2}\left[s_e^{n-1}\left(2d^2f/d\varphi^2 - \lambda(\lambda-3)f(\varphi)\right)\right] + 6(\lambda-1)((\lambda-2)(n-1)+\lambda-1)\frac{d}{d\varphi}\left[s_e^{n-1}df/d\varphi\right] = 0, \quad (10a)
\end{aligned}$$

$$\begin{aligned}
&n(\lambda-2)s_e^{n-1}\left[((2-\lambda)n-2)(d^2f/d\varphi^2) + \lambda(\lambda-2)(n(\lambda-2)+2)f(\varphi)\right] +\\
&+\frac{d^2}{d\varphi^2}\left[s_e^{n-1}\left(d^2f/d\varphi^2 - \lambda(\lambda+2)f(\varphi)\right)\right] + 4(\lambda-1)((\lambda-2)(n-1)+\lambda-1)\frac{d}{d\varphi}\left[s_e^{n-1}df/d\varphi\right] = 0. \quad (10b)
\end{aligned}$$

Thus, the equation (10a) or (10b) is a non-linear differential equation of fourth order for unknown asymptotic Airy's stress function $f(\varphi)$. To solve this equation and to determine the stress field near a crack tip it is necessary to add four boundary conditions.

2.4. Boundary conditions

The first two boundary conditions are the conditions of the free crack surfaces, i.e. $\sigma_{\varphi\varphi} = \sigma_{r\varphi} = 0$ at $\varphi=\pi$. Hence, two boundary conditions for asymptotic Airy's stress function $f(\varphi)$ are the follows:

$$f = df/d\varphi = 0\,,\ \varphi=\pi. \tag{11}$$

For mode I or mode II crack tip two additional boundary conditions are the symmetry conditions, i.e. $\partial\sigma_{rr}/\partial\varphi = \sigma_{r\varphi} = 0$ (mode I) or $\sigma_{\varphi\varphi} = \partial\sigma_{r\varphi}/\partial\varphi = 0$ (mode II) at $\varphi=0$. In this case two additional boundary conditions for asymptotic Airy's stress function $f(\varphi)$ are the follows:

$$df/d\varphi = d^3 f/d\varphi^3 = 0\,,\ \varphi=0 \text{ (mode I) or } \ f = d^2 f/d\varphi^2 = 0\,,\ \varphi=0 \text{ (mode II).} \tag{12}$$

Thus, for Eq. (10a) or Eq. (10b) with boundary conditions (Eq. 11) and (Eq. 12) it is obtained two-point boundary value problem for asymptotic Airy's stress function $f(\varphi)$. This problem can be solved by shooting method [9], when adding to symmetry conditions (Eq. 12) two additional boundary conditions

$$f = c_1, d^2 f/d\varphi^2 = c_2 \text{ (mode I) or } df/d\varphi = c_1, d^3 f/d\varphi^3 = c_2 \text{ (mode II) at } \varphi=0$$

the above-mentioned two-point boundary value problem reduces to the Cauchy problem. The Cauchy problem is usually solved by using the Runge-Kutta method [9], when choosing the values of additional boundary constants c_1, c_2 in such way as to satisfy the main boundary conditions at $\varphi=\pi$ (Eq. 11).

The boundary conditions (Eq. 12), followed from symmetry conditions, does not valid for mixed mode of loading or for inclined crack under tension (Fig. 1). In this case the boundary conditions at $\varphi=0$ can be represented as the follows [7-8]:

$$f = c_0, df/d\varphi = -\lambda c_0 tg\alpha, d^2 f/d\varphi^2 = c_1, d^3 f/d\varphi^3 = c_2\,,\ \varphi=0. \tag{13}$$

The constant c_0 is determined from some additional condition (named as normalization condition). Traditionally the normalization condition is selected in the form of $\max_{\phi} \sigma_e(\varphi) = 1$ [5-6].

The last two constants c_1, c_2 are sought by shooting method - to choose these constants, so that at $\varphi=\pi$ the boundary conditions (Eq. 11) are valid.

3. Method of solution

To solve this problem let us denote $f(\pi) = f_1(c_1, c_2)$, and $df(\pi)/d\varphi = f_2(c_1, c_2)$. In order to satisfy the main boundary conditions (Eq. 11) it is necessary to find the solution of the following system of two nonlinear algebraic equations:

$$f_1(c_1, c_2) = 0, \quad f_2(c_1, c_2) = 0. \tag{14}$$

It should be noted that the functions $f_1(c_1, c_2)$ and $f_2(c_1, c_2)$ are not given in analytical form, but are found numerically by solving the above-mentioned Cauchy problem for different values of c_1 and c_2. The system of nonlinear equations (Eq. 14) can be solved by the Newton's method. Newton's method is an iterative method for solving the system of nonlinear algebraic equations [9]. Rewrite the general formula of Newton's method for the system (Eq. 14) as the follows:

$$f_{1,1}^k c_1^{k+1} + f_{1,2}^k c_2^{k+1} = f_{1,1}^k c_1^k + f_{1,2}^k c_2^k - f_1^k,$$

$$f_{2,1}^k c_1^{k+1} + f_{2,2}^k c_2^{k+1} = f_{2,1}^k c_1^k + f_{2,2}^k c_2^k - f_2^k,$$

where c_i^k is the value of the parameter c_i at the *k*-th step of iteration, $f_{i,j}^k$ is the value of derivative of function f_i with respect to c_j, computed at the *k*-th step of iteration, *i,j=1,2; k= 1,2,3,…*

To calculate numerically the values of $f_{i,j}^k$ it is used the right finite difference scheme:

$$f_{1,1}^k = (f_1^k(c_1^k + \delta, c_2^k) - f_1^k(c_1^k, c_2^k))/\delta,$$
$$f_{1,2}^k = (f_1^k(c_1^k, c_2^k + \delta) - f_1^k(c_1^k, c_2^k))/\delta,$$
$$f_{2,1}^k = (f_2^k(c_1^k + \delta, c_2^k) - f_2^k(c_1^k, c_2^k))/\delta,$$
$$f_{2,2}^k = (f_2^k(c_1^k, c_2^k + \delta) - f_2^k(c_1^k, c_2^k))/\delta,$$

where δ *is* a small number.

Thus, to find the next approximation (c_1^{k+1}, c_2^{k+1}) of the parameters c_1 and c_2 it is necessary to integrate three time the Cauchy problem by Runge-Kutta method for the values of parameters (c_1^k, c_2^k), $(c_1^k + \delta, c_2^k)$ and $(c_1^k, c_2^k + \delta)$.

The above-described method of solving the nonlinear differential equation (Eq. 10a) or (Eq. 10b) has been tested for correctness and accuracy and compared with some known analytical or numerical results. Thus, in the case $n=1$ there exist analytical expressions for the stress tensor components for any inclined cracks [1-3]. For mode I ($\alpha = 0$) it is known the analytical result for the case $n=\infty$ and

the numerical results for $n>1$ [5-6]. Testing has shown that for $n=1$ the value of the relative error does not exceed 10^{-6}. The results of calculations based on above-described method as for the case $n=\infty$ as for $n>1$ practically coincided with the numerical results from [5-6].

4. Results of calculations

Some results of calculations for stress distribution around the crack tip for plane stress and plane strain conditions are shown on the Figures 2-5.

4.1. Plane stress

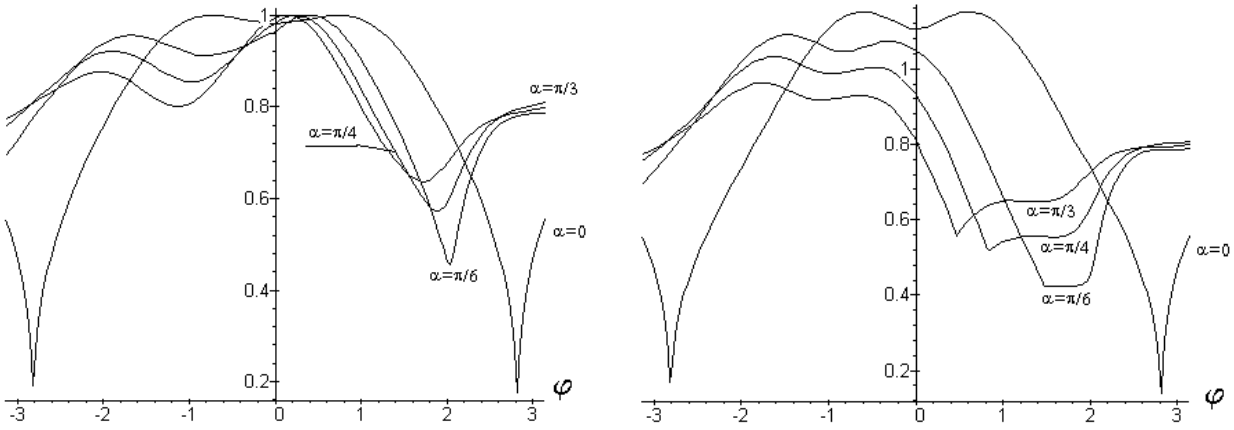

Figure 2. The distribution of the equivalent stress σ_e and the maximum stress $\sigma_{\max}$ around the crack tip for $n=3$ (plane stress).

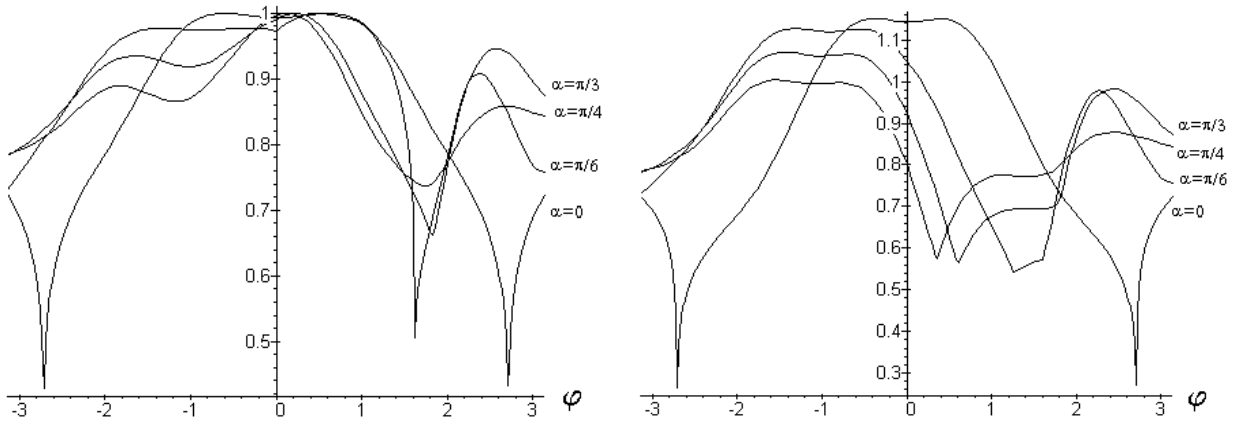

Figure 3. The distribution of the equivalent stress σ_e and the maximum stress $\sigma_{\max}$ around the crack tip for $n=7$ (plane stress).

4.2. Plane strain

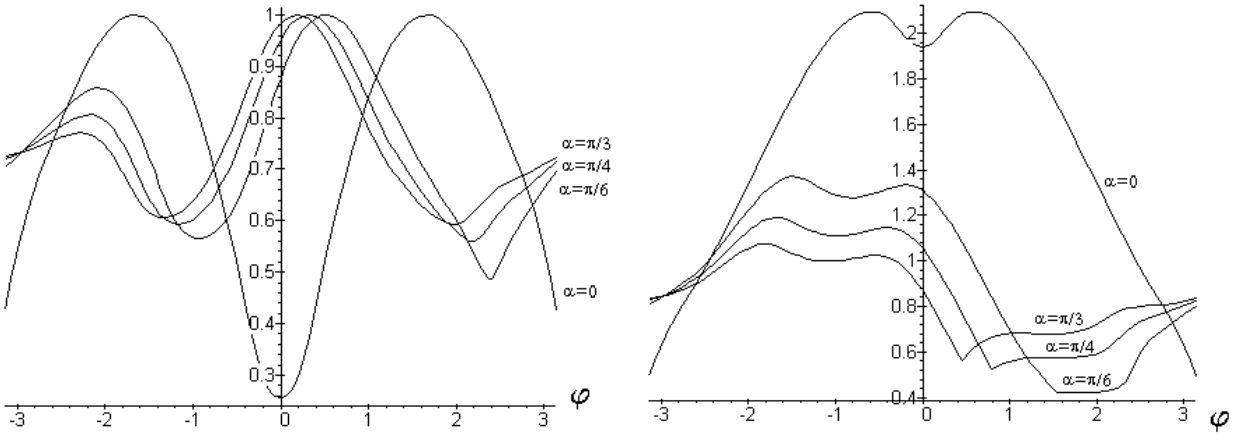

Figure 4. The distribution of the equivalent stress σ_e and the maximum stress $\sigma_{\max}$ around the crack tip for *n=3* (plane strain).

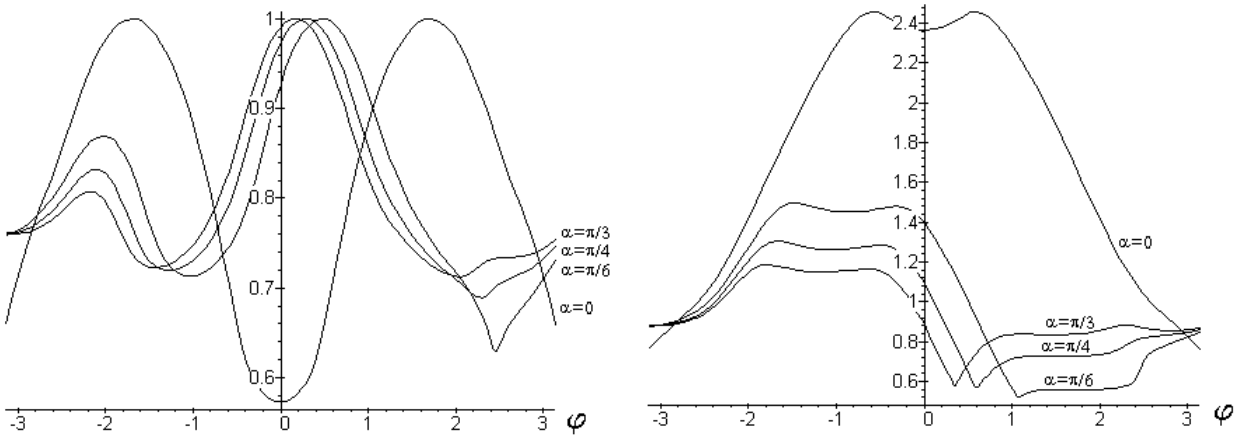

Figure 5. The distribution of the equivalent stress σ_e and the maximum stress $\sigma_{\max}$ around the crack tip for *n=7* (plane strain).

Abstract The aim of this research is to understand the influence of notches under thermomechanical fatigue (TMF) in a directionally-solidified (DS) Ni-base superalloy. Experiments were performed utilizing linear out-of-phase (OP) and in-phase (IP) TMF loadings on longitudinally-oriented smooth and cylindrically-notched specimens. Several notch severities were considered with elastic stress concentrations ranging from 1.3 to 3.0. The local response of the notched specimens was determined using the finite element method with a transversely isotropic viscoplastic constitutive model. Comparing the analysis to experiments, the locations observed for crack nucleation in the notch, which are offset from the notch root in DS alloys, are consistent with the maximum von Mises stress. Various local and nonlocal methods are evaluated to understand the life trends under OP TMF. The results show that a nonlocal invariant area-averaging method is the best approach for collapsing the TMF lives of specimens with different notch severities.

Keywords notched specimens, thermomechanical fatigue, Ni-base superalloy, notch analysis

1. Introduction

Components in the high pressure turbine section of gas turbine engines undergo complex thermomechanical loads during engine cycle transients. Turbine blades contain stress elevating features such as cooling holes or fir-trees that can have a detrimental effect on component endurance and make endurance prediction difficult. The surrounding material around these stress elevators undergo cyclic inelastic deformation providing a source for fatigue crack nucleation [1, 2]. To improve component level endurance prediction methodologies, the effect of stress elevators on thermomechanical fatigue (TMF) needs to be addressed.

Few studies have targeted the problem of determining crack initiation of notched specimens under TMF. Presently, no accepted methods exist for predicting TMF crack initiation life at notches. Studies on the TMF of circumferentially-notched specimens fabricated from a rotor steel, 1CrMoV, found that uniaxial life results could be used to predict the notch endurance given that conditions at the notch root were comparable [3, 4]. Large spatial gradients were shown to reduce the driving force for creep damage and fatigue crack growth away from the notch root in notched specimens. For identical crack initiation criteria, this effect could potentially increase the measured endurance as physically small cracks grow slower in notched specimens.

A study on the TMF of notched specimens of Ni-base superalloys by Kupkovits and Neu [5] found that damage mechanisms present in notched specimens are identical to smooth specimens. Notched specimen geometries corresponding to theoretical elastic stress concentration factors of $k_t = 2$ and $k_t = 3$ were studied. Under $500°C \leftrightarrow 950°C$ OP TMF conditions loaded in the longitudinal (L) orientation, the reduction in life was identical for both of these notches in contrast to isothermal fatigue where the more severe notch had a greater knockdown factor [6]. The same held true under $500°C \leftrightarrow 750°C$ OP TMF. Fatigue-environmental damage mechanisms were observed in notched OP TMF $500°C \leftrightarrow 950°C$. All notched specimen experiments resulted in crack nucleation at the location of maximum Hills' or von Mises equivalent stress similar to isothermal fatigue studies [6].

This work identified the need to explore the TMF life behavior of less severe notches geometries to understand the transition in fatigue behavior from smooth specimens ($k_t = 1$) to the more severely notched specimens ($k_t \geq 2$).

This paper focuses on the role of notch severity on TMF life expanding the work described in Kupkovits and Neu [5] by considering milder notches. The notch response is evaluated using a transversely isotropic viscoplasticity model to further understand the gradients in the cyclic stress-strain response that influence of notch severity on life. Local and several nonlocal methodologies for life assessment are evaluated to determine which approaches exhibit the most promise for assessing notches under TMF.

2. Methods

2.1. Smooth and notched specimen experiments

One cylindrical smooth specimen ($k_t = 1$) and four different cylindrically-notched specimens (k_t = 1.3, 1.7, 2 and 3 based on isotropic elastic behavior) were utilized in TMF experiments. The net section diameter for all notched specimens was 6.35 *mm*, same as the diameter of the smooth specimen. The outside diameter for all notched specimens was 9.53 *mm*.

2.2. Material

The DS Ni-base superalloy, with primary alloying elements (in wt. %) 0.07C, 8.1Cr, 9.2Co, 9.5W, 3.2Ta, 0.5Mo, 5.6Al, 0.7Ti, 1.4Hf, was received in cast slabs consisting of columnar grains in the long direction of each slab with grain diameter varying from 200 μm to 1 *mm* with an average grain diameter of 0.5 *mm*. A standard heat treatment was applied to the slab to produce a microstructure representative of an in-service blade material. The microstructure consists of FCC matrix (γ) containing cuboidal γ' precipitates. The γ' in the as-received and heated-treated material had an average volume fraction of 60% and a bi-modal size distribution of cuboidal 500 *nm* and fine secondary precipitates in the γ channels of 75 *nm* in size.

All specimens were loaded in the longitudinal direction. All experiments were fully reversed with a minimum temperature of $T_{\min} = 500°C$. Maximum temperatures of $T_{\max} = 950°C$ and $T_{\max} = 750°C$ were utilized to study the effects of maximum temperature on damaging mechanisms and TMF life. A servohydraulic test frame with induction heating was used for all experiments. Axial displacements within the gage section were measured using a high temperature extensometer with 12.7 *mm* gage section. A 180 *s* cycle time was used with constant heating and cooling rates. K-type thermocouples spot welded to the ends of the gage section for the smooth specimens or near the notch on the notched specimens were utilized to provide a feedback signal for close-loop control of specimen temperature.

Experiments performed on smooth specimens were conducted in mechanical strain control in accordance with ASTM E2368-04 for thermomechanical fatigue testing. All notched specimen experiments were performed in force control and displacements across the gross notch section were measured using a high temperature extensometer with 12.7 *mm* gage length.

A crack initiation criterion was established to identify a crack depth of 0.5-1.0 *mm* for both mechanical strain-controlled and force-controlled experiments. For mechanical-strain controlled experiments (smooth specimens) a 10% load trend variation was used. As material hardening, softening or creep processes can result in a continuously changing load history, a 10% variation of the stabilized trend constitutes crack formation. For force-controlled experiments (notched specimens) an analogous method was implemented; initiation was defined when a 10% variation in the mechanical extensometer displacement signal occurred.

3. Results

3.1. Out-of-phase TMF 500°C↔950°C

OP TMF lives obtained in force control on smooth and circumferentially notched specimens are shown in Fig. 1. Notched specimens $k_t = 2$ and $k_t = 3$ follow the same life trend, indicating that increasing the notch severity beyond $k_t = 2$ is not more detrimental to OP TMF life. Experiments on the milder notch geometry $k_t = 1.3$ show that under the applied conditions, the effect of the notch is negligible as lives follow the smooth specimen life trend. Lives corresponding to $k_t = 1.7$ fall between the two bounds represented by the $k_t = 1/k_t = 1.3$ and $k_t = 2/k_t = 3$ trends.

Cracks that lead to final failure nucleated at a location away from the notch root, as shown in Fig. 2. Cracks nucleate furthest from the notch root in the bluntest notch, $k_t = 1.3$. The nucleation location approaches the notch root with increasing notch severity.

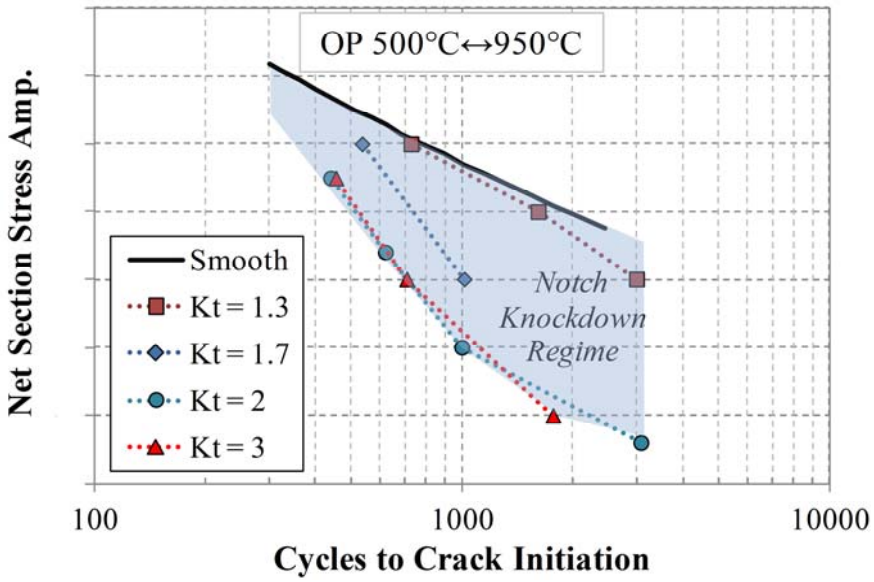

Figure 1. Crack initiation life under $500°C \leftrightarrow 950°C$ OP TMF for each notched specimen geometry.

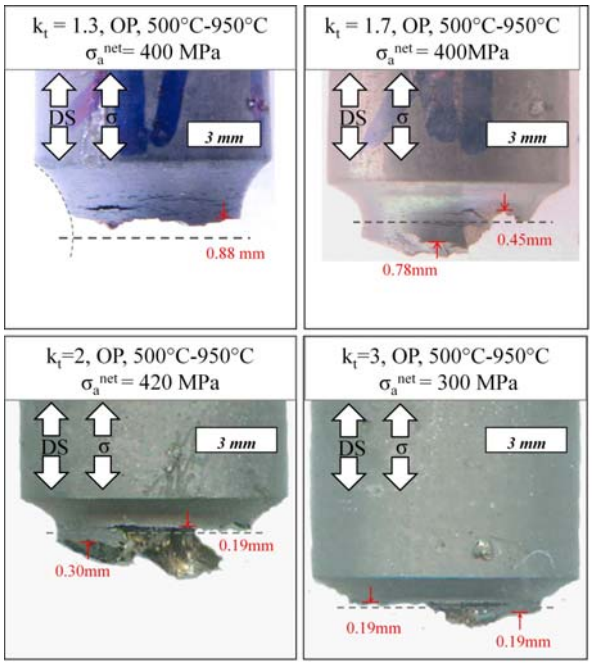

Figure 2. Fracture images indicating the location of crack initiation relative to the notch root.

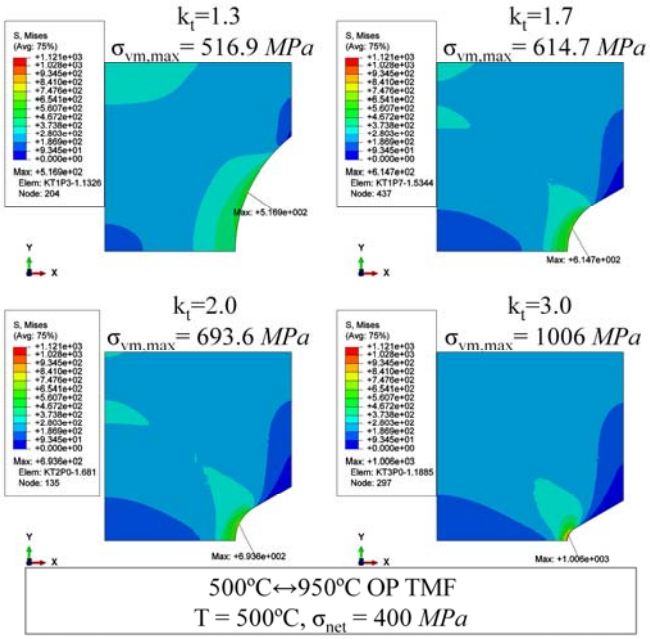

Figure 3. Von Mises equivalent stress at minimum temperature (tensile load).

The local notch response was predicted using a continuum based constitutive model within the ABAQUS finite element framework [7]. A model taking into account plasticity and creep was not available for the alloy studied and instead a transversely isotropic viscoplasticity model corresponding to another DS Ni-base superalloy was used [8]. The alloy studied exhibits higher yield strength in the virgin condition and a lower modulus. Nevertheless both superalloys exhibit the characteristic increase in yield strength around 750°C followed by a sharp decrease in strength. As such numerical results should be adequate for qualitative comparison.

The finite element meshes utilize linear quadrilateral elements throughout the domain. The cylindrically notched specimens were modeled using axisymmetric boundary conditions along with symmetry conditions at the net section to reduce the model to a quarter cross section of the extensometer gage section. A uniform pressure was applied to the top surface corresponding to the applied force. All TMF simulations of notched geometries were performed by first prescribing the mean temperature with no applied pressure. Then three reversals were applied, first loading to maximum temperature and applying the corresponding force for either OP or IP loading. Under the first peak force at elevated temperature, a great deal of initial yielding and hardening occurs. As such the cyclic response is taken as the final two reversals which better represent steady-state cyclic loading.

The stress responses at minimum temperature under the same OP TMF conditions are shown in Fig. 3. for an applied 400 *MPa* net section stress. The location of maximum von Mises stress during peak tension begins away from the notch root but approaches it with increasing notch severity. Similarly, the location of maximum equivalent inelastic cyclic strain approaches the notch root with increasing notch severity [9].

3.2. In-phase TMF 500°C↔950°C

Results from IP TMF are shown in Fig. 4 with the OP TMF knockdown regime region shown for

comparison. IP TMF lives of the $k_t = 1.3$ notch follow the smooth trend. This indicates that under IP TMF, as well as OP TMF, the $k_t = 1.3$ notch does not have a significant detrimental effect on TMF fatigue life.

3.3. Out-of-phase TMF 500°C↔750°C

The influence on initiation life from reducing the maximum temperature under OP TMF to $750°C$ is shown in Fig. 5. Even under the lower applied maximum temperature, notch geometries $k_t = 2$ and $k_t = 3$ follow the same life trend. Additional experiments within this temperature regime show that notch geometry $k_t = 1.3$ displays a small decrease in life compared to the smooth trend and $k_t = 1.7$ is slightly less damaging than exhibited by $k_t = 2 / k_t = 3$.

Under $T_{\max} = 750°C$ OP TMF, some oxidation is present along interdendritic regions and grain boundaries, but overall the contribution from environmental processes is small. Under higher temperature $T_{\max} = 950°C$ OP TMF, several secondary fatigue-environmental cracks oriented perpendicularly to the applied load are observed. There is no evidence of environmental-fatigue secondary cracks under IP TMF as seen under OP TMF.

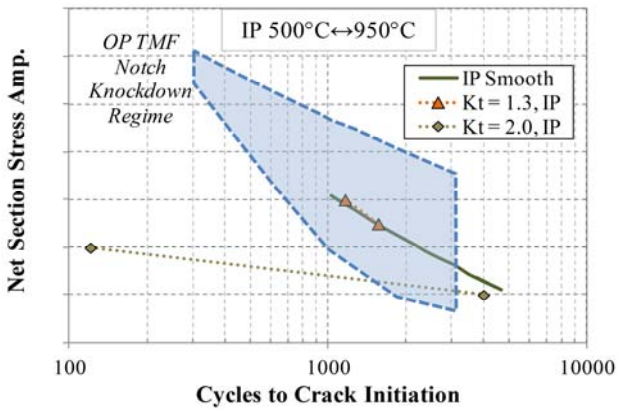

Figure 4. Crack initiation life under $500°C \leftrightarrow 950°C$ IP TMF for each notched specimen geometry.

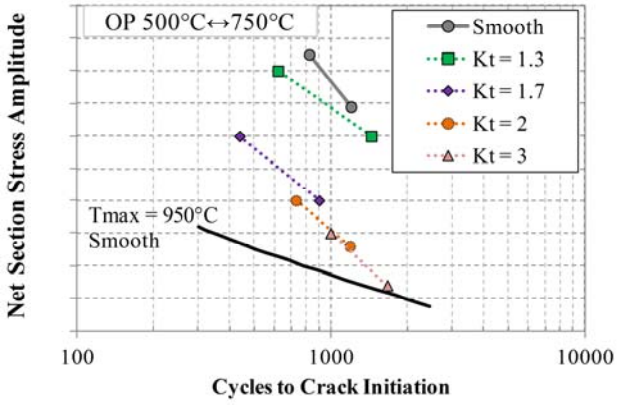

Figure 5. Crack initiation life under $500°C \leftrightarrow 750°C$ OP TMF for each notched specimen geometry.

4. Implications for life modeling

Most life modeling approaches tend to predict that increases in notch severity result in lower lives. It is apparent that a nonlocal approach will be needed to evaluate notched lives under TMF to predict the experimental results. In the next exercise, we evaluate some popular domain averaging schemes [10-14] to determine what methods work best in predicting the observed trends in lives. Here, we focus on OP TMF under $500°C \leftrightarrow 950°C$ to maintain a constant mechanism of damage. As shown earlier, the crack nucleation locations under OP TMF loading coincide well with the maximum von Mises stress and equivalent inelastic strain range. To keep the damage model simple for evaluation, a generalized energy-based damage parameter [15] that couples these two drivers is used,

$$D_O = \Delta\varepsilon_e^{in}\sigma_{e,\max} \tag{1}$$

where $\Delta\varepsilon_e^{in}$ is the equivalent inelastic strain range and $\sigma_{e,\max}$ is the maximum value of the von Mises equivalent stress over one cycle which occurs in tension for OP TMF. Since the loading is uniaxial, the loading in the vicinity of the notch is approximately proportional and hence using equivalent values is acceptable for this exercise for ease of computation.

As a baseline, the maximum D_O parameter for each geometry and applied load is shown in Fig. 6. As expected, this local approach gives high values for the D_O parameter and is highly conservative [3, 10-14, 16]. The local approach incorrectly predicts increasing damage with increasing notch severity, which is totally inconsistent with the observed experimental lives. A regression analysis using a power law relationship was used to attempt to correlate the maximum D_O parameter to lives, as shown in Fig. 7. This procedure does not collapse the life data.

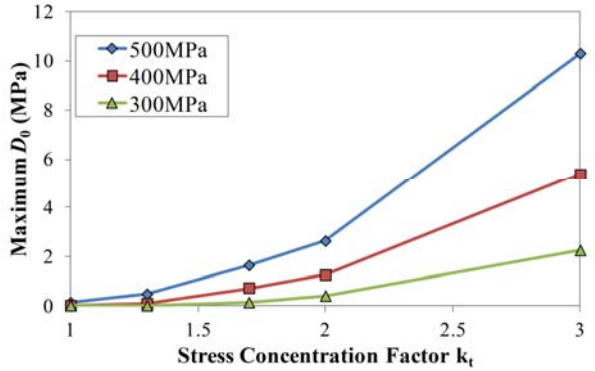

Figure 6. Maximum D_O parameter for all specimen geometries $500°C \leftrightarrow 950°C$ OP TMF.

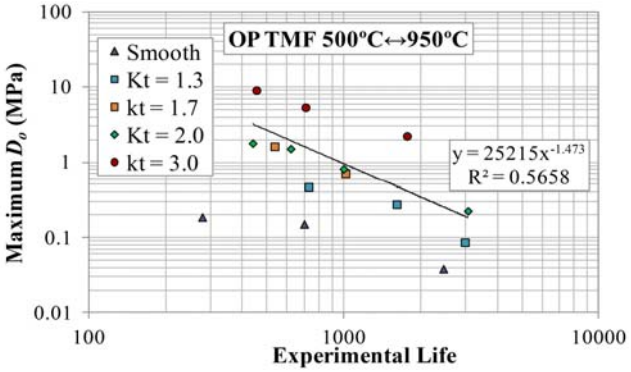

Figure 7. Correlation of maximum D_O parameter with experimentally determined OP TMF lives.

Rather than utilizing a local maximum quantity, nonlocal approaches utilize an averaged quantity over a domain or a point some distance away from the maximum. The simplest implementation is utilizing a point value some critical distance away from a key local quantity. Nonlocal quantities include averaging domains over a line, area or within a volume. The averaged generalized damage parameter can be defined as,

$$\bar{D}_O = \frac{1}{D}\int_D D_O \, dD \tag{2}$$

where D is the averaging domain; line, area or volume. Nonlocal approaches on isotropic materials typically utilize a line or point method as the response is centered about the notch root [10-12, 14]. However, for the transversely isotropic response of directionally-solidified (DS) alloys when loaded longitudinally, cracks are observed to initiate away from the notch root. Additionally the maximum equivalent inelastic strain range and maximum von Mises stress occur away from the notch root and the response changes during loading, with temperature, applied load level and across specimen geometries. Directions of relevant spatial gradients change with applied conditions and do not coincide with surface normals or crystallographic directions. As such an area averaging approach was used on the response predicted by the axisymmetric finite element method. As the domain represents an axisymmetric volume, in this case this is also equivalent to a volume averaging scheme.

A critical area approach [11, 13] was first evaluated for determining the integration domain. This method identifies the domain within which the damage quantity is a percentile of the maximum value,

$$A_{crit} = A\left(D_O \geq P \cdot \max\left\{D_O\right\}\right) \tag{3}$$

where A is the total area of the section of interest, A_{crit} is the critical area and P is a value between 0 and 1 that represents the percentile quantity used to define the critical domain. The critical area for all notch geometries based on 95-percentile (P = 0.95) under a 500 *MPa* applied net section stress is shown in Fig. 8. The size of the critical area decreases with increasing notch severity due to increases in the spatial gradients in the damage parameter.

The area averaged damage parameter using a 95-percentile area domain is shown in Fig. 9 for each notch geometry and three applied net section stresses. This method exhibits similar trends as using the local damage approach; increases in notch severity always produce additional damage in conflict with experimental observations.

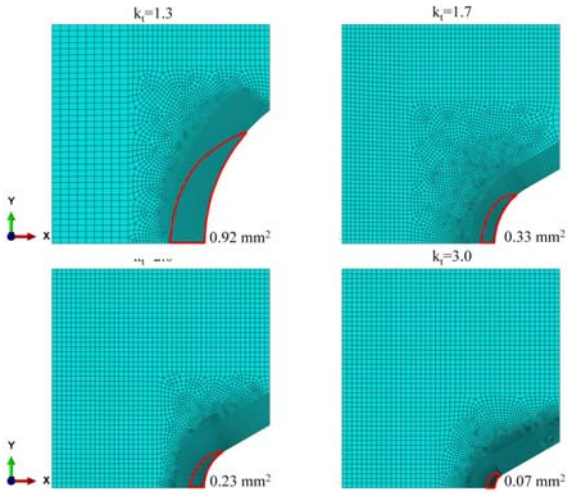

Figure 8. OP TMF $500°C \leftrightarrow 950°C$ 95-percentile critical areas based on D_O parameter.

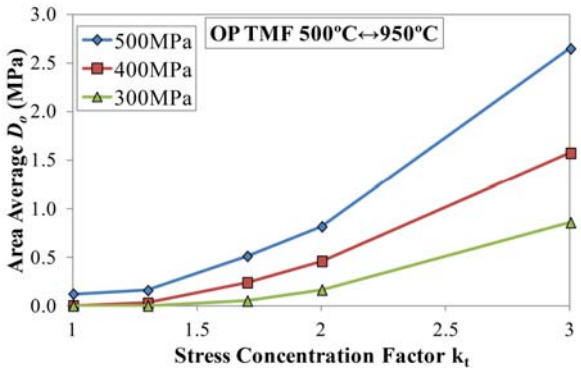

Figure 9. Nonlocal 95-percentile critical area $\bar{D}_O$ as a function of applied load and stress concentration.

Invariant averaging domains have been used successfully in notch and component analysis [11, 12, 16]. For evaluating this approach, two methods are implemented: (1) a surface-sweep of the notch surface into the component as seen in Fig. 10(a) and (2) a circular-sweep within the component centered about the location of the maximum damage parameter shown in Fig. 10(b). An iterative method was utilized to achieve the desired critical area domain for each component as the axisymmetric component areas are irregular. A bisection zero finding method was implemented to reduce the residual $R_i = \left|A_{crit} - A\left(L_i\right)\right|$ to a satisfactory tolerance by iterating on the critical length L.

The area scale was parametrically varied to achieve an optimum domain for the largest net section stress amplitude case as shown in Fig. 11. Increasing the averaging area decreases the area average damage parameter as one might expect. As the averaging area increases, the difference in the driver between $k_t = 2$ and $k_t = 3$ lives becomes indistinguishable which is consistent with

experimental observations. Hence, both experimentally observed notch life sensitivity trends at low and high notch severity values are captured simultaneously with a single parameter variation.

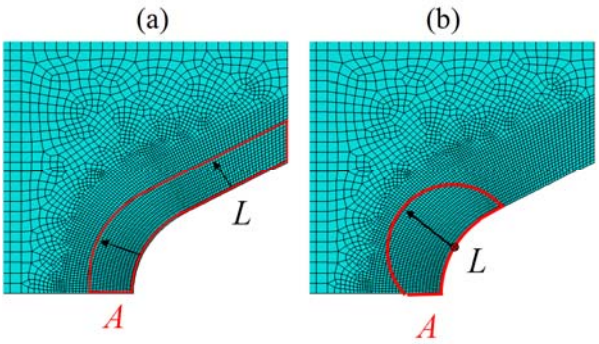

Figure 10. Domain for area averaging $k_t = 2.0$ notch using (a) surface-sweep method and (b) circular-sweep method.

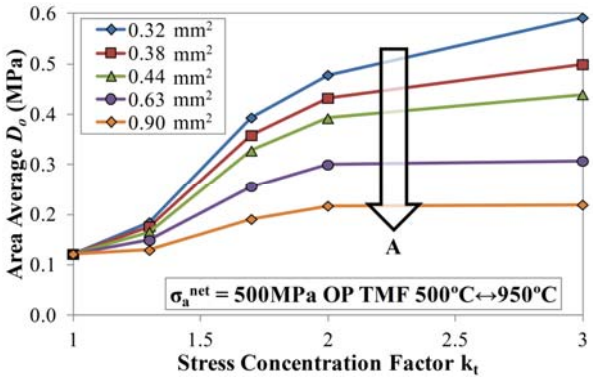

Figure 11. Surface-sweep nonlocal average $\bar{D}_O$ parameter for OP TMF under 500 *MPa* net section stress for increasing area domain.

Optimal areas for predicting $k_t = 1/k_t = 1.3$ and $k_t = 2/k_t = 3$ OP TMF notch life sensitivity trends were found to be 0.90 mm^2 and 0.77 mm^2 for surface-sweep and circular-sweep domains, respectively. The sweeping length scale, *L*, is shown for each method and notch geometry in Table 1.

Table 1. Sweeping Length Scales for Optimized Area Domains

Surface-Sweep		Circular-Sweep	
k_t	L (μm)	k_t	L (μm)
1.3	276	1.3	686
1.7	386	1.7	670
2	413	2	678
3	476	3	735

The surface-sweep scale is smaller than the circular-sweep scale as the sweeping area is performed over the entire notch surface length. The length scale changes to preserve the same size area for averaging the damage parameter in each notch geometry. Relevant length scales here are larger than the 200 μm length scale for point and line methods utilized by Moore and Neu for isothermal fatigue of the some notch geometry and material [16]. Naik et al. [14] found the line average domain to be between 20 μm and 100 μm for notched Ti-6Al-4V with stress concentrations varying between 2 and 4. For a notched Al alloy, Susmel and Taylor [12] utilized a 244 μm length scale for implementing a point method approach and a 154 μm length scale for a line method approach. In the same study Susmel and Taylor also investigated low-carbon steel and utilized 492 μm and 396 μm scales for point and line methods, respectively. It is critical to note however that the length scales obtained from the literature were determined from a line-method approach, whereas here an area method approach is utilized. As such it is expected that the scale will be larger here. Additionally, as the columnar grain size is fairly large in this alloy, and hence the relevant length scale can be expected to be on the same order as the grain size (0.2 *mm* to 1.0 *mm*).

The correlation of the area averaged damage parameter with experimental OP TMF life is shown in Fig. 12. Both averaging methods improve the life predictability as compared against the local method and critical area nonlocal approaches presented previously. With the exception of one life

value, all predictions are within a factor of two utilizing either averaging method.

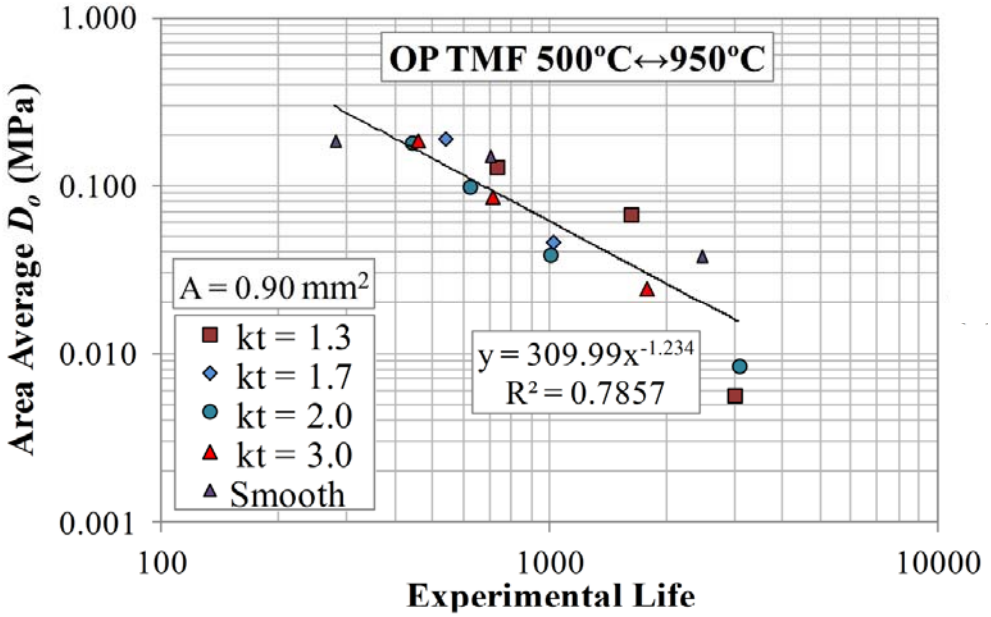

Figure 12. Correlated nonlocal $\bar{D}_O$ against experimentally determined OP TMF lives using the invariant area surface sweep method.

5. Conclusions

- For OP TMF $500°C \leftrightarrow 950°C$, the $k_t = 1.3$ notch represents the lower bound of fatigue notch sensitivity as there is no appreciable knock-down in life relative to the smooth life trend. For $k_t \geq 2$, the fatigue life is also insensitive to the severity of the notch. The $k_t = 1.7$ notch falls in between the $k_t = 1 / k_t = 1.3$ and $k_t = 2 / k_t = 3$ trends.
- In DS alloys loaded longitudinally, the OP TMF cracks in notched specimens nucleate away from the notch root. The nucleation location approaches the notch root with increasing notch severity and increasing applied force amplitude for a given notch geometry. These trends are captured in a computational stress-strain analysis using either von Mises equivalent stress or the cyclic inelastic equivalent strain range cyclic response parameters.
- For OP TMF with smaller maximum temperature, $500°C \leftrightarrow 750°C$, the $k_t = 1.3$ notch exhibits a small knock-down in life relative to the smooth life trend. The $k_t = 1.7$ notch falls in between the $k_t = 1.3$ and $k_t = 2 / k_t = 3$ life trends.
- Under IP TMF $500°C \leftrightarrow 950°C$, the $k_t = 1.3$ notch also follows the smooth specimen life trend similar to OP TMF.
- Neither local nor critical-domain nonlocal methods adequately collapsed notched and smooth OP TMF $500°C \leftrightarrow 950°C$ life data.
- A nonlocal invariant area-averaging method was utilized to collapse all experimental data that included variations in notch severity and force amplitude onto a single trend. Two schemes were implemented to define the invariant area-averaging domain; one based on the maximum value of the generalized damage parameter and a circular sweep of the surrounding domain and another based on the domain around the entire notch surface. Both methods worked reasonably well.

Abstract Aluminum 7050 alloy is one of the primary alloys for the aviation industry owing to its excellent mechanical properties. However, this alloy has several poor physical properties that affect its solidification, such as relatively low thermal conductivity and large solidification range. These properties tend to increase the hot tearing susceptibility of the alloy, which makes it difficult to produce by direct-chill (DC) casting. Accurate knowledge of the mechanical behavior of the alloy during solidification is therefore crucial to ensure safe control of the casting process. Present work focuses on measuring the tensile mechanical properties of an as-cast AA7050 in the temperature range where hot tearing mainly occurs, i.e. from solid fractions of 0.85 to 1.0, or the solidus. Through these experiments, we extracted mechanical properties such as strain-rate sensitivity and ductility of the alloy in the super-solidus temperature range. The data obtained from this work will be useful in thermo-mechanical computer simulations aimed at reducing the hot tearing occurrence during DC casting, thus optimizing the production rate in the casting house.

Keywords AA7050, DC Casting, solidification, hot tearing, tensile mechanical properties

1. Introduction

AA7050 is one of the most used alloys for aerospace industries owing to its excellent mechanical properties such as high tensile strength, good fracture toughness and stress corrosion resistance [1, 2]. This alloy is usually produced via a vertical direct-chill (DC) casting method because of the robustness and relative simplicity of such process [3]. Despite its superior qualities, AA7050 is known to be susceptible to hot tearing due to its wide solidification range and relatively high thermal expansion coefficient [4]. Hot tearing usually occurs during DC casting, at the end of solidification when the alloy is in a semi-solid state but most of the liquid has been solidified and the remaining liquid resides at the grain boundaries [5]. The presence of such a defect causes the rejection of the ingot or lowers the quality of the cast product which subsequently affects its economical value [6]. In order to minimize the occurrence of hot tearing, it is critical to understand the mechanical properties in this solidification range [7]. Therefore, in this work, we investigated the tensile mechanical behavior of the alloy – which is the dominant stress mode related to hot tearing during DC casting, in the range of solid fractions of 0.85 and 1.0 (just before it is fully solidified), where hot tearing is most likely to occur. Such tensile mechanical properties will be useful input for a numerical process simulator aiming at minimizing the occurrence of hot tearing during DC casting, thus, optimizing the production rate in the aluminum cast house.

2. Experimental procedure

The tensile specimens used for the experiment were cut from an ingot produced via DC casting at Tata Steel (IJmuiden, The Netherlands). The ingot was DC cast using a conventional bore mold

from the melt that has been degassed in the furnace. The chemical composition of the alloy is given in Table 1.

Table 1. Chemical composition of AA7050.

Main alloying elements, wt pct					
Zn	Cu	Mg	Zr	Ti	Al
6.15	2.2	2.1	0.13	0.03	balance

The specimens were tested using a set-up developed at SINTEF Materials and Chemistry with an Instron 5944 series tensile test machine equipped with a 2-kN load cell. The specimen was heated up using an induction heating coil system which was controlled by a Eurotherm™ temperature controller. A quartz-glass tube coated with boron nitride aerosol on the inside, was used to enclose the center part of the sample in order to avoid liquid breakout during the fully melt phase. The coating was intended to prevent the sticking of the liquid aluminum onto the quartz tube which might affect the force measurement due to the added friction resistance. The experimental cycle (for both re-melt and mechanical testing temperature) is shown in Figure 1.

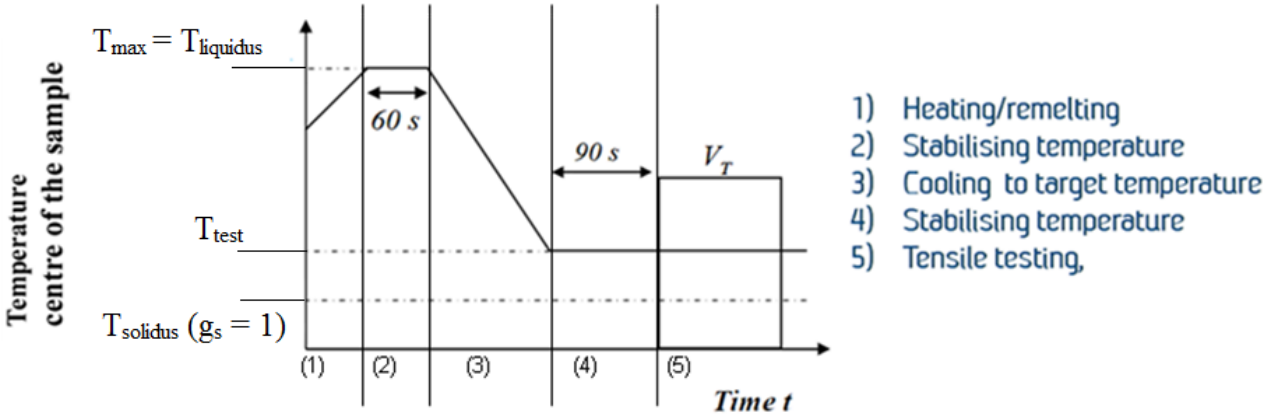

Figure 1. Experimental cycle of the tensile test.

The test cycle that we used in our experiment was as follows. First, we heated up the sample from room temperature up to T_{max} = 635 °C, which is the liquidus of an AA7050 alloy based on the JMat-Pro software (Figure 2). Then we held the sample at T_{max} for 60 seconds to assure that the central part of the specimen is fully liquid. Subsequently, we cooled down the sample to the test temperature with a cooling rate of 1 °C/s. We then held the sample at this test temperature for approximately 90 seconds to let the temperature in the specimen stabilize. Then we performed the mechanical tensile testing of the sample at a certain displacement rate until the force value was approximately zero after the fracture.

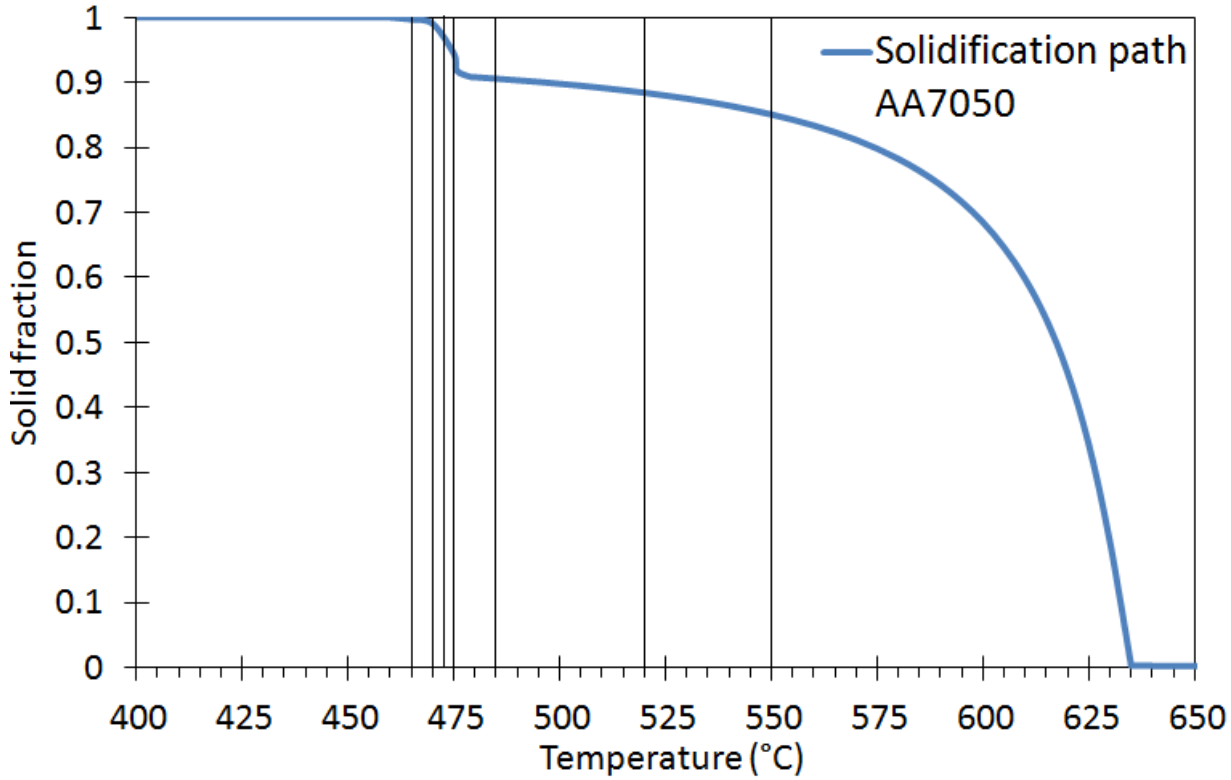

Figure 2. The solidification path of an AA7050 alloys as calculated by JMat-Pro software (Scheil calculation).

The test temperatures that we used in this work corresponded to solid fractions (f_s) between 0.85 and 1.0. We took data at several points within this range such as at 0.85, 0.88, 0.9, 0.94, 0.97, 0.99 and 1.0 or in terms of temperature – at 550, 520, 485, 475, 473, 470 and 465 °C, respectively. The solidification path of this alloy was calculated by JMat-Pro software and is shown in Figure 2, the vertical lines in such a figure show the temperature points where we performed the data acquisitions. To observe the displacement-rate sensitivity behavior of the alloy in this temperature range, we used two different displacement rates. For each combinations of the test (temperature–displacement rate), we repeated the test three to four times to obtain statistical information of the test. The fracture surface of the samples was observed in a Jeol JSM-6500F scanning electron microscope (SEM) at the tip of the failed specimens.

3. Results and discussion

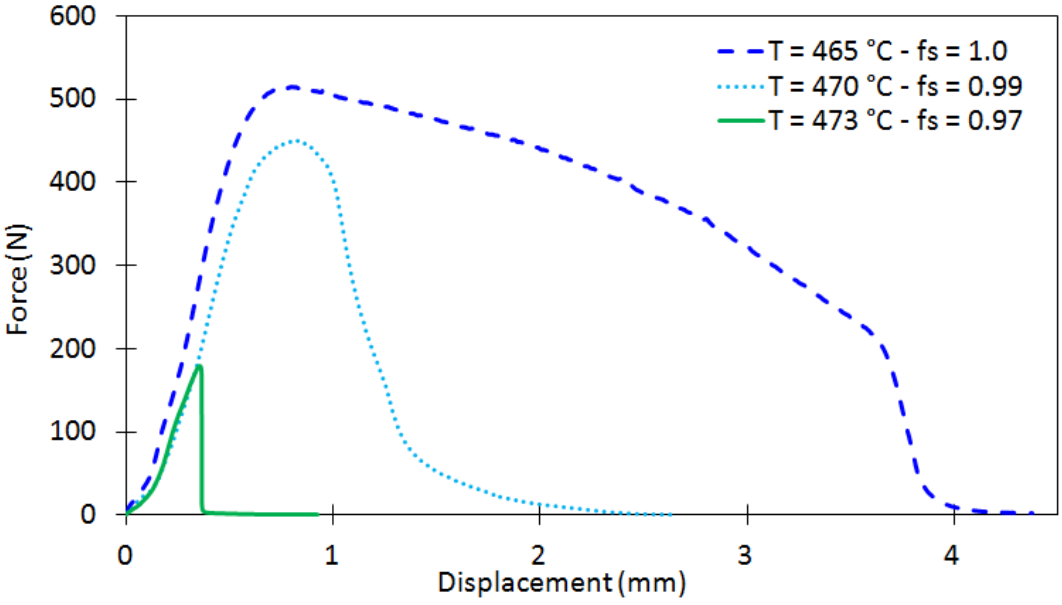
3.1 Mechanical properties

From the tensile tests, we obtained force–displacement curves at different temperature points and displacement rates. The force–displacement curves with a displacement rate of 0.2 mm/min are shown on Figure 3 and with a displacement rate of 2 mm/min, on Figure 4. Due to the large scaling range of the force value, at the displacement rate 0.2 mm/min, we divided the entire data into two sets: The data from f_s = 1.0 down to f_s = 0.97 are shown in Figure 3a and the data from f_s = 0.97 down to f_s = 0.85 are shown in Figure 3b.

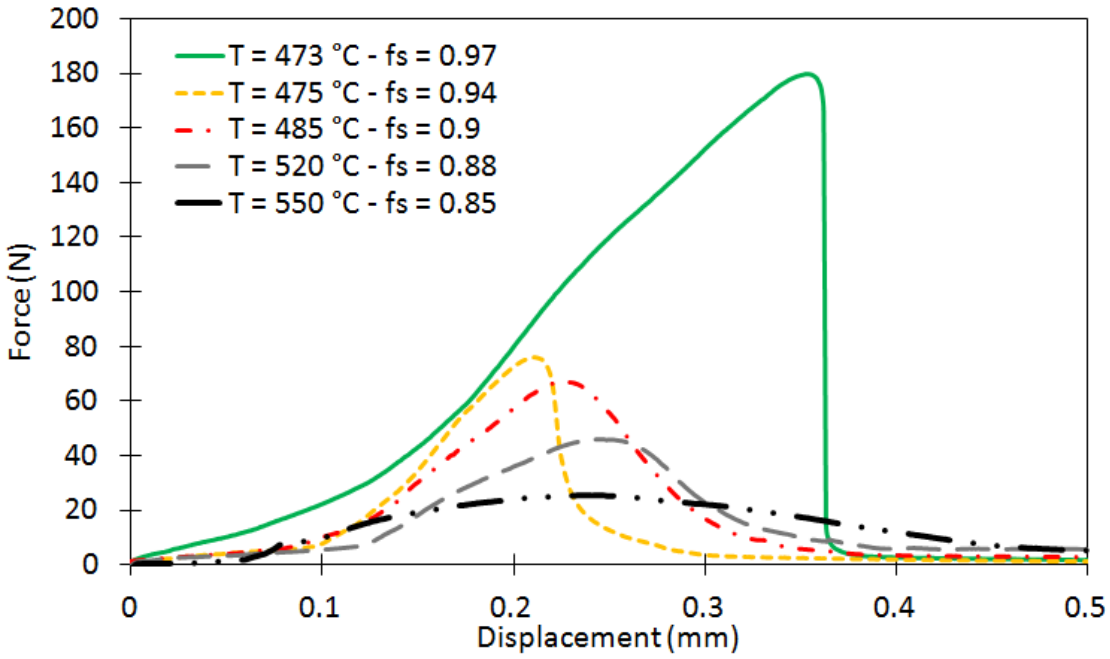
Figure 3 shows that at the displacement rate 0.2 mm/min, the height of the peak force in general

decreases as the solid fraction reduces. In addition, the shape of the curve also changes quite significantly from $f_s = 1.0$ (when the alloy is fully solid) to $f_s = 0.97$ (refer to Figure 3a) and then it changes again as the solid fraction decreases further, from $f_s = 0.97$ down to $f_s = 0.85$ (refer to Figure 3b). Such a transition in the force–displacement curve can be interpreted as a change in the mechanical behavior regime. From Figure 3, we observed two mechanical properties transitions. First, when the alloy behavior changes from ductile at $f_s = 1.0$ to brittle at $f_s = 0.97$. The sharp drop in ductility and strength at $f_s = 0.97$ informs us that the alloy fails in a brittle manner. The second transition in the mechanical behavior of the material occurs when the solid fraction of the alloy decreases from $f_s = 0.97$ to $f_s = 0.85$. As the solid fraction decreases, the end part of the curve (after peak force) changes, i.e. the slope of the curve is not as steep as for $f_s = 0.97$ and the slope gradually becomes shallower as the solid fraction decreases. Finally at the lowest solid fraction in this test ($f_s = 0.85$), the curve resembles a shallow symmetric hump with a long 'tail'. This might be caused by the sufficient liquid presence in the alloy, thus it is as if the alloy is dragging viscous liquid. Another possible explanation is, as suggested by Eskin *et al.* [8], that the main mechanism of deformation is grain boundary sliding thanks to the presence of sufficient interdendritic liquid surrounding the grain at such solid fraction.

Similar force–displacement curve shape change is also observed at a displacement rate of 2 mm/min. As shown in Figure 4, at $f_s = 0.99$, the force exhibits a sharp drop after the sample reaches fracture point which is interpreted as a brittle behavior of the alloy. As solid fraction decreases to $f_s = 0.94$, the peak force significantly decreases despite the similar curve shape with the preceding case. The main shape distinction is that the curve at $f_s = 0.94$ has a 'tail' after the sharp drop, which could be explained due to the additional amount of liquid at such solid fraction as compared to the higher solid fraction. At $f_s = 0.90$, the peak force is reduced even more and the shape of the force–displacement curve is significantly changed as compared to the two other curves at this displacement rate.



(a)



(b)

Figure 3. Force–displacement curves at a displacement rate of 0.2 mm/min for the solid fraction ranges from $f_s = 1.0$ – fully solid to $f_s = 0.97$ (a) and from $f_s = 0.97$ to $f_s = 0.85$ (b).

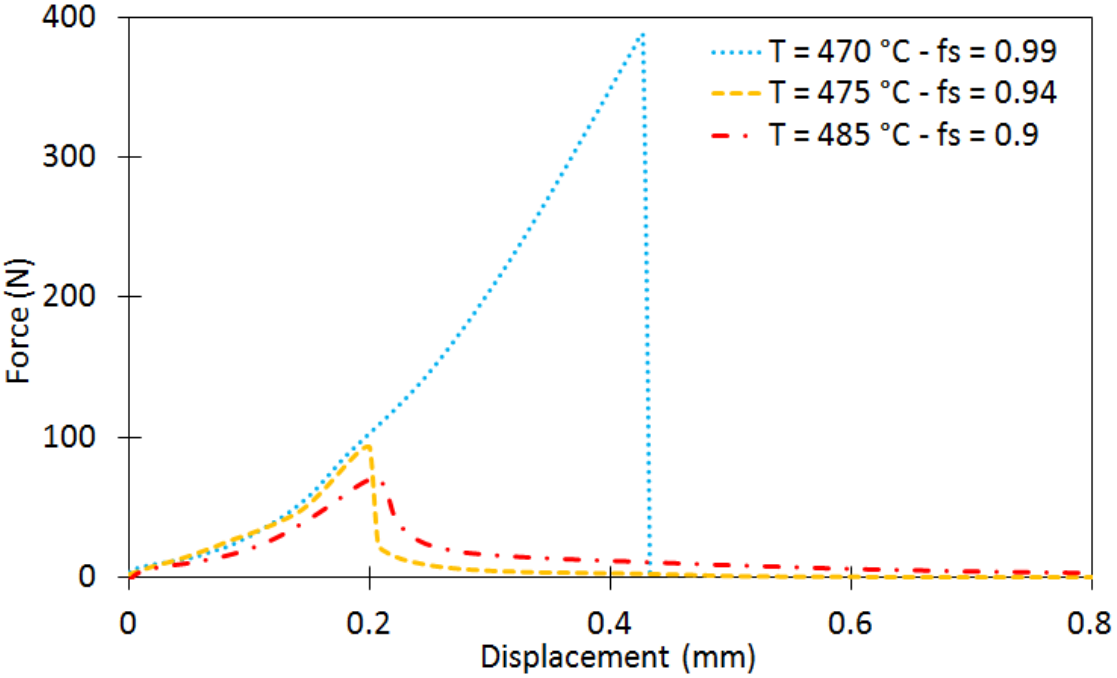


Figure 4. Force–displacement curves at a displacement rate of 2 mm/min for solid fractions from $f_s = 0.99$ to $f_s = 0.9$.

The evolution of the peak force of the alloy with respect to the temperature is shown in Figure 5. For both displacement rates, the peak force rapidly increases as the temperature is lowered below 475 °C. Therefore, we can argue that the grain coalescence occurs between $f_s = 0.94$ and $f_s = 0.97$. These values are supported by a few other works on different alloys [9, 10]. The temperature range

from 475 to 470 °C also coincides with the brittle fracture behavior and the eutectic solidification domain. One can also notice that the alloy starts to become sensitive with respect to displacement rate, the largest sensitivity at the lowest temperatures. In addition, one can observe that the error bars (standard deviation) are larger when the sample becomes brittle and smaller if it is ductile.

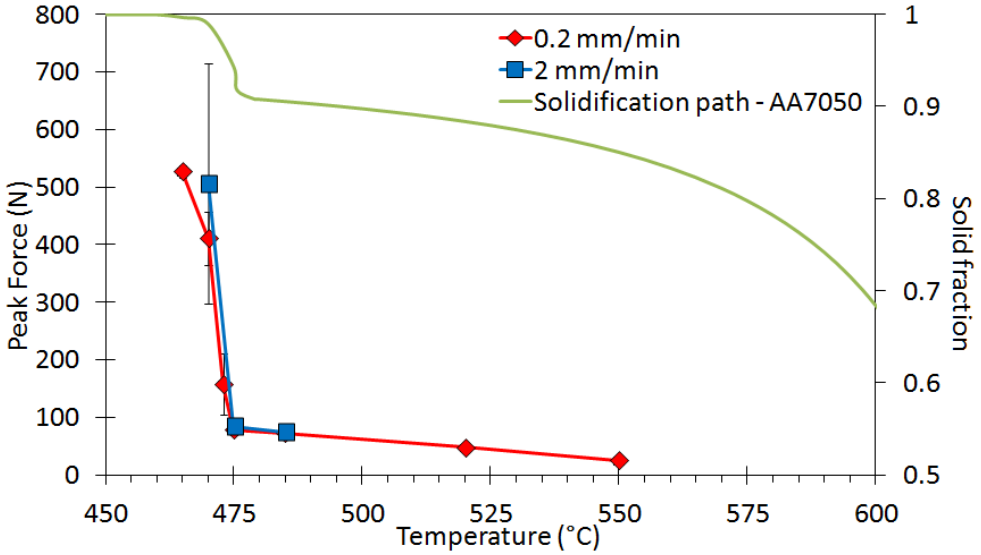

Figure 5. Comparison in peak forces between two different displacement rates at different temperature points (left vertical axis) and corresponding solid fractions (right vertical axis). The error bars are shown; when not visible they are smaller than the size of the data point.

The ductility of the alloy at different temperature points is shown in Figure 6. For both displacement rates, one can see that the ductility of the alloy starts to drop significantly as the temperature increases above 465 °C. The lowest ductility value for both displacement rates was found at a temperature of 475 °C or f_s = 0.94, which corresponds, according to the solidification path in Figure 2, to the beginning of the eutectic solidification. As the temperature increases further above 475 °C, the ductility starts to develop gradually up to 550 °C. If extrapolated to higher temperatures, the temperature dependence of the ductility points would resemble the shape of the classical brittle temperature range curve [8].

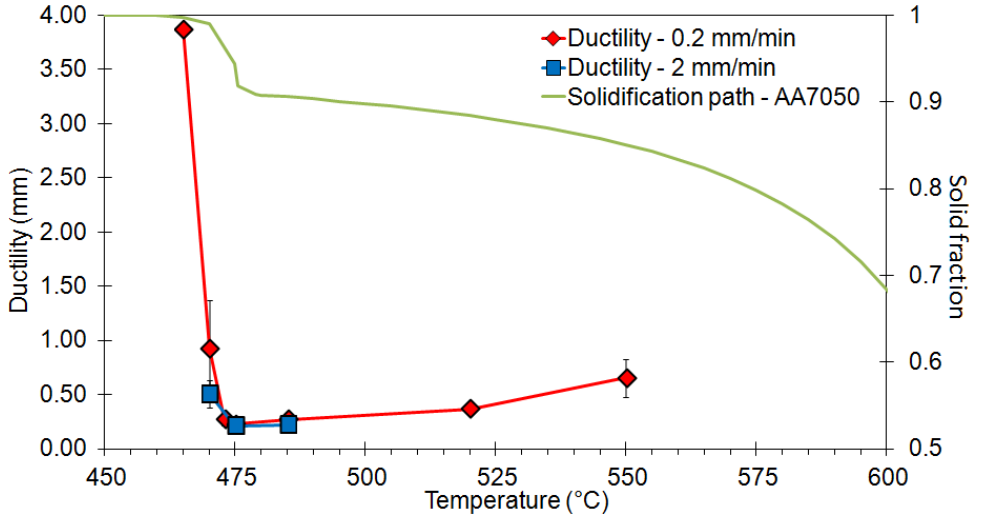

Figure 6. Comparison of the ductility of the alloy at different temperature points (left vertical axis) with respect to its respective solid fraction of the alloy (right vertical axis).

The displacement rate has a small effect on the mechanical behavior. The main difference is that at 470 °C the four tests at 2 mm/min gave a brittle behavior while at 0.2 mm/min two tests showed a brittle behavior the other two giving a ductile response. At temperature of 475 °C, there is a slight change in curve shape with different displacement rates. The most significant change is the shape of the curve after the peak force was reached. At lower displacement rate, the decrease is more gradual compared to the slope at 2 mm/min. This behavior is reasonable, because at 0.2 mm/min, the alloy has more time to compensate the deformation.

3.2 Fracture surface analysis

To analyze the behavior during fracture, we performed SEM analysis of the fracture surfaces at four different conditions, i.e. at two deformation rates and at solid fractions of 0.99 and 0.94, reflecting the transition from brittle to ductile behavior (see Figures 3–5). From all of the fracture analysis performed, we found that in general, the fracture mode is mixed between inter-granular (with dendritic morphology) and intra-granular. We observed such a mixed fracture mode at both solid fractions and displacement rates (figure 7). Moreover, features that possibly attest for broken dendrite arms (features within the dashed white ellipses in Figure 8a) were found for all conditions.

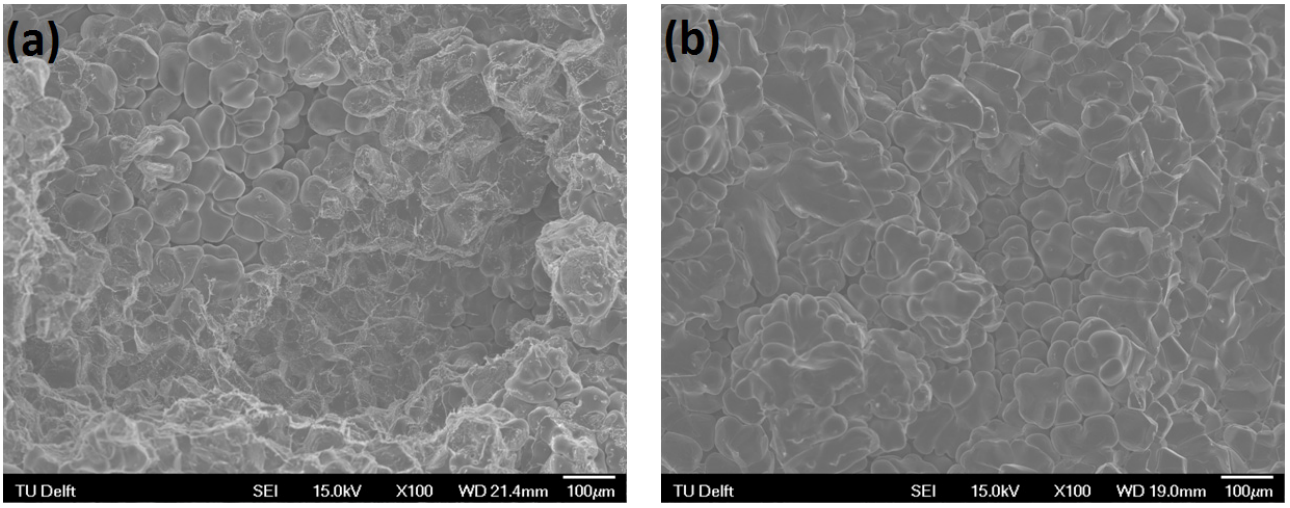

Figure 7. Examples of mixed-mode fracture surface at $f_s = 0.99$ with 0.2 mm/min displacement rate (a) and $f_s = 0.94$ with 2 mm/min displacement rate (b).

The higher solid fraction ($f_s = 0.99$) and lower displacement rate (0.2 mm/min) shows deformation of the solid and interdendritic liquid phases as evidenced in Figure 8b. While with a higher displacement rate (2 mm/min) and same solid fraction the interdendritic liquid phases have different shape (Figure 8c). The shape differences could be explained as the interdendritic liquid has more time to deform and rearrange at lower displacement rate compared to the higher one. At lower solid fraction ($f_s = 0.94$), for both displacement rates, the interdendritic liquid raptures [11] (features within the dashed white ellipses in Figure 8d) and the solid bridges fracture in a brittle fashion as illustrated in Figure 8d. Interestingly, such interdendritic liquid features are rarely found at the higher solid fraction.

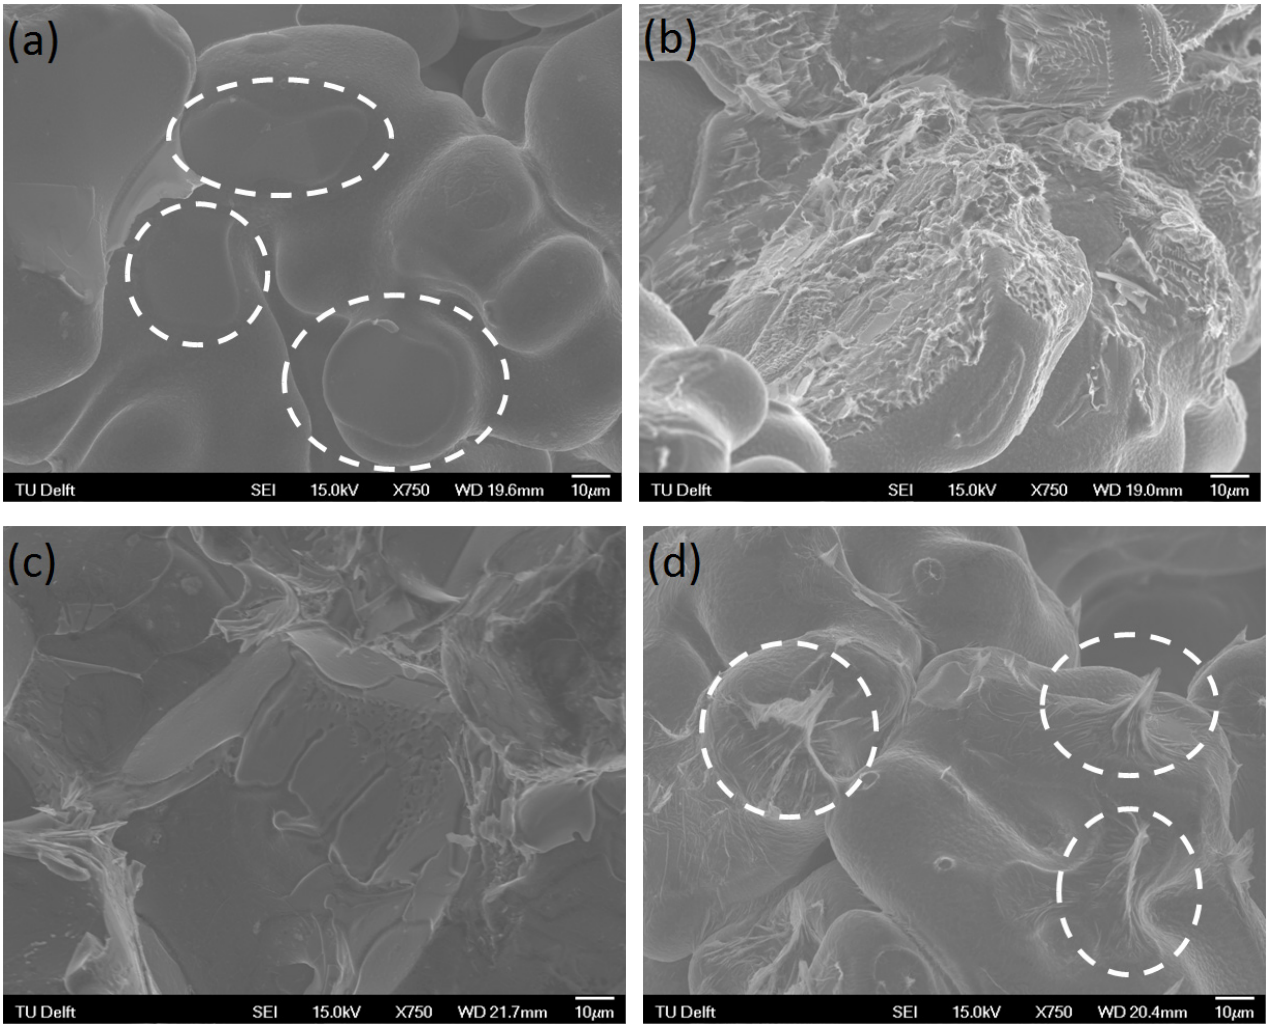

Figure 8. Pictures of fracture surface analysis using SEM: (a) Examples of broken dendrite arms, (b) example of extra-deformed eutectics, (c) example of layer-like eutectics and (d) examples of features that resemble necking of the interdendritic liquid stretched during fracture.

4. Summary

We can summarize the results obtained from the experiments as follows:

1. From the shape of the force–displacement curves, we found that in the range of f_s = 1.0 (fully solid) to f_s = 0.85, the alloy has three different mechanical behavior regimes; ductile (between f_s = 1.0 and f_s = 0.99), brittle (between 0.99 and 0.9) and then ductile again (between 0.9 and 0.85).
2. The grain coalescence in AA7050 occurs between f_s = 0.94 and f_s = 0.97. This is showed by the sharp increase in peak force between the mentioned solid fractions.
3. The alloy has almost no displacement rate sensitivity at high temperatures (below f_s = 0.94) but it has positive displacement rate sensitivity starting at f_s = 0.94 and at higher solid fractions.
4. The alloy produces a ‘classically’ shaped brittle temperature range curve with the minimum of ductility reached at 475 °C, and the alloy gains again ductility as the liquid fraction increases in the alloy.
5. From SEM fracture surface analyses at different data points showed in Figure 7, it is found

that in general the fracture mode is mixed between inter- and intra-granular. Additionally, at higher solid fraction, the morphology of eutectic is different at different displacement rates (Figure 8b and 8c). Sites that resemble necking of interdendritic liquid was observed at samples that were tested at lower solid fraction (Figure 8d), independent of displacement rate used during the test.

Abstract Fatigue crack growth (FCG) behaviors of a widely-used nickel-based directionally solidified (DS) superalloy were investigated. Direct-current potential drop method was employed to capture the crack length according to ASTM E647. Standard compact tension (CT) specimens in longitudinal, transverse and diagonal directions were cast and tested at T_0 and T_0+250^{0}C to reveal the orientation and temperature dependence. Moreover, the post-test fractography were observed through SEM and OM to understanding the underlying mechanism responsible for the fracture modes. Results suggested that cracks in all three orientations propagated transgranularly, no obvious differences were found between each other, and thus, the orientation dependence appeared to be very weak, all da/dN-DK curves in three orientations fell into one narrow band. However, temperatures showed significant dependence in diagonal directions, while in transverse direction the dependence became weak and even none in longitudinal orientation. Finally, methods for characterizing the FCG behaviors in different orientations and at both temperatures were proposed, which were able to explain the orientation and temperature dependences.

Key words Fatigue crack growth, directionally solidification, nickel-based superalloy

1. Introduction

Superalloys, either in the conventionally-cast (CC) or directionally solidified (DS) forms may contain porosity and shrinkage cracks, so that the life of rotating components, such as turbine blades, may be limited by crack propagation from these defects. It is therefore of interest to determine the resistance of the oriented grain structure, produced by DS, to the propagation of fatigue cracks [1]. Although lots of research have been focused on the fatigue crack growth behaviors of superalloys, few have shed light on those behaviors of directionally solidified superalloys[1-6]. In 1976, Scarlin [1] investigated the fatigue crack growth behaviors of nickel-based IN738 DS, and high cycle fatigue crack growth rates had been measured at room and high temperatures and for crack propagation both parallel and perpendicular to the solidification directions. However, comparable crack growth rate seemed to be found in his results. Okazaki et al [2] conducted low cycle fatigue tests to study the stage-I short crack growth behavior RENE80+Hf and CM247LC DS at 600^{0}C. Later, Highsmith et al [4, 6] and Yoon et al [5] studied the FCG behaviors of nickel-base GTD-111 DS, both in longitudinal and transverse directions, where the stress ratio effects and temperature effects were focused on, respectively. For DS material, it is seen that only crack growth in

longitudinal and transverse directions are interested and investigated. However, the diagonal direction is very often used as loading components during actual service; therefore more studies concerning this particular direction should be done.

The current DS material is a newly cast and wrought nickel-base directionally solidified (DS) superalloy, to meet the requirement for development of more efficient engine operation with higher operating temperatures and stresses. In the current paper, FCG behaviors of DS material have been evaluated at T_0 and T_0+250^{0}C, and in longitudinal, transverse and diagonal orientations. The effects of temperatures and grain orientations on the FCG behaviors are investigated in associated with fractographic analysis (For confidential, some of the test data are normalized).

2. Material and experimental procedure

The nominal chemical compositions of the material are listed in Table 1. The original slabs were directionally solidified to produce a longitudinal direction which corresponds to [001] crystal orientation. The directionally solidified direction along the axis of the bar was determined to be within 5^0 of dispersion using the X-ray diffraction technique.

Table 1. Nominal compositions of the current DS material (wt.%)

Al	B	C	Cr	Mo	Ta	Ti	W	Ni
3.40	0.0125	0.08	11.6	1.65	4.80	3.90	3.50	Bal.

FCG tests were conducted by using the direct-current electric potential drop method (DC-PDM) described in ASTM E647. Standard compact-tension (CT) specimens (48*50*10) were machined using electron-discharge machining techniques from the heat treated slabs. Prior to standard FCG tests, all specimens were pre-cracked at room temperature with a frequency of 10 Hz to eliminate the effect of machining notches. Lengths of all pre cracks were in a range of 2-3 mm. FCG tests were conducted in accordance with the requirements of ASTM E647 [7]. All tests were running loading control by a computer-control, closed-loop servo-hydraulic testing machine, with a fixed load ratio of 0.1 and frequency of 10 Hz. At both temperatures, two repeated specimens were tested in each grain orientation, one with standard FCG tests with constant loading, the other with threshold testing by decreasing loading, whose derating ratio is 0.1.

The crack length data in region II of each specimen, with or without threshold value test, are computed by two methods, i.e., the secant method (also known as point-to-point technique) as well as the seven-point incremental polynomial method, as described in [7]. Conventionally, the secant method gives a result that most reflects the actual conditions, such as crack growth rate change, fluctuation and so on, while the polynomial method produces a more smooth da/dN curve. In the subsequent analysis, results from the seven-point polynomial method will be used to compare the temperature as well as orientation effects.

For the standard C(T) specimens, the stress intensity factor ranges were calculated by the following equation as:

$$\Delta K = \frac{\Delta P}{B\sqrt{W}} \frac{(2+\alpha)}{(1-\alpha)^{3/2}} \left(0.886 + 4.64\alpha - 13.32\alpha^2 + 14.72\alpha^3 - 5.6\alpha^4\right) \quad (1)$$

where $\alpha = a/W$, a is computed crack length, W takes a constant value of 40, and P is the applied load.

3. Results and discussion

Three types of specimens with different orientations were machined from cast plates. Figure 1 indicates the schematic images of these three types of CT specimens, where the different-color cylinders indicate crystal grains. Totally 12 specimens were tested at T_0 and T_0+250^{0}C, with crack growth in longitudinal, transverse and diagonal directions, respectively.

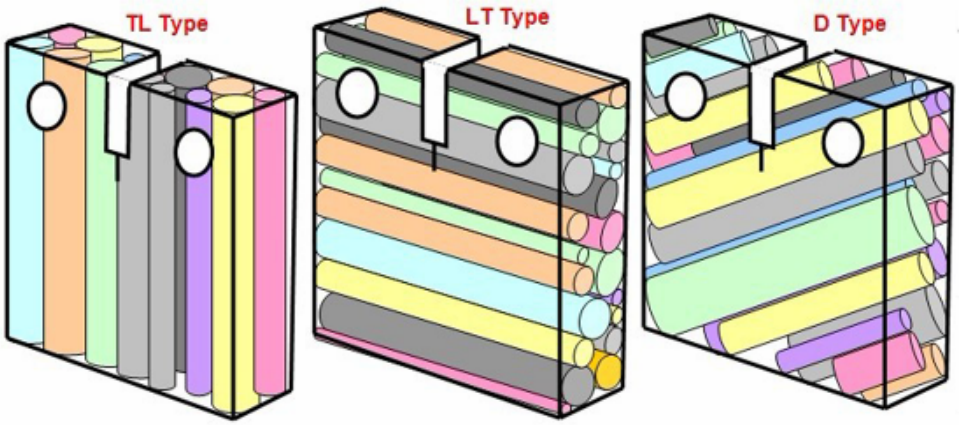

Figure 1. Schematic images of three types of C(T) specimens

3.1. Effect of orientation on FCG rates

The overall crack growth rate versus stress intensity factor values in Paris regime, i.e., $da/dN - \Delta K$ curves, are depicted in Figure 2, from which one can conclude that the orientation dependence is very weak, i.e., crack growth data in all orientations fall into one narrow [1/3, 3] band. Meanwhile, when using Paris law to obtain linear regression of all crack growth data, the correlation coefficient can be up to 0.88.

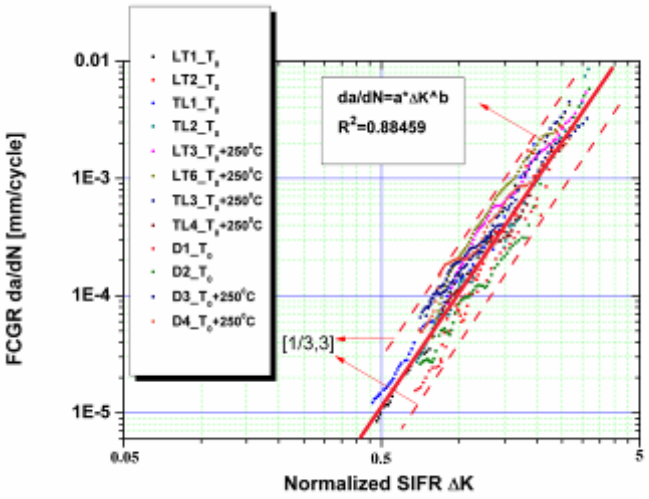

Figure 2. Fatigue crack growth behaviors for all DS specimens in Region II

Figure 3 shows the crack growth behaviors for the three types of specimens tested at T_0. Generally, comparable crack growth rate data can be found in longitudinal and transverse directions, while those in diagonal direction seem to be lower, especially in the high-ΔK regime. That's to say, there is no significant difference between crack growth rate in longitudinal and transverse directions, while specimens in diagonal direction have a much lower crack growth rate, and the difference becomes larger when it is up to the high-ΔK regime.

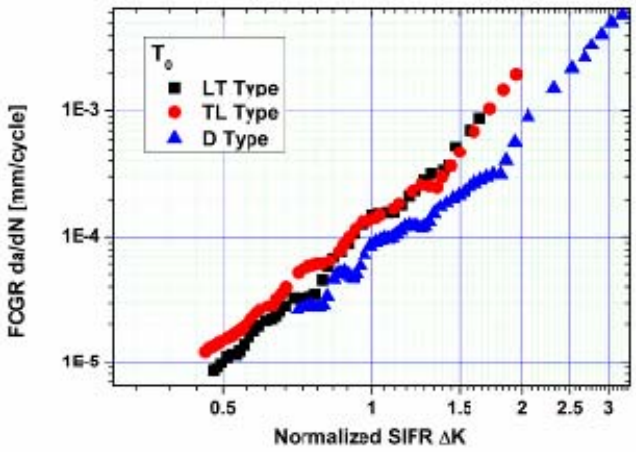

Figure 3. Crack growth behaviors of three types of specimens tested at T_0

However, at T_0+250^{0}C, the orientation dependence becomes even weaker, as can be seen in Figure 4. Cracks that travel in longitudinal and transverse directions also have a comparable crack growth rate; but different with those at T_0, cracks in diagonal directions still travel with a comparable rate, and no obvious difference can be found, even in the high-ΔK regime.

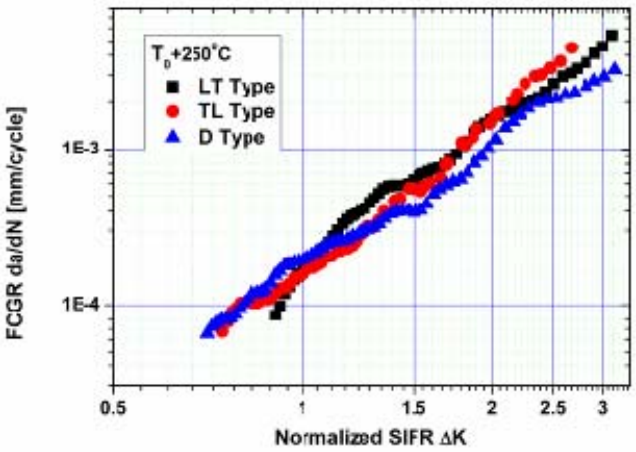

Figure 4. Crack growth behaviors of three types of specimens tested at T_0+250^{0}C

3.2. Effect of temperature on FCG rates

Figure 5 compares the growth rate of cracks traveling in longitudinal direction at both temperatures. In longitudinal direction, cracks seem to grow equally fast at both temperatures, and no obvious differences can be found between T_0 and T_0+250^{0}C.

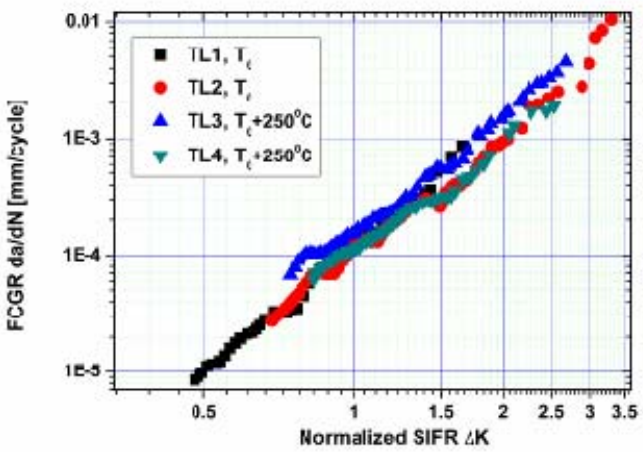

Figure 5. Crack growth behaviors of TL type specimens at T_0 and T_0+250^{0}C

In Figure 6, weak temperature dependence can be found on the LT type crack growth rate, i.e., cracks grow slightly faster at T_0+250^{0}C than at T_0.

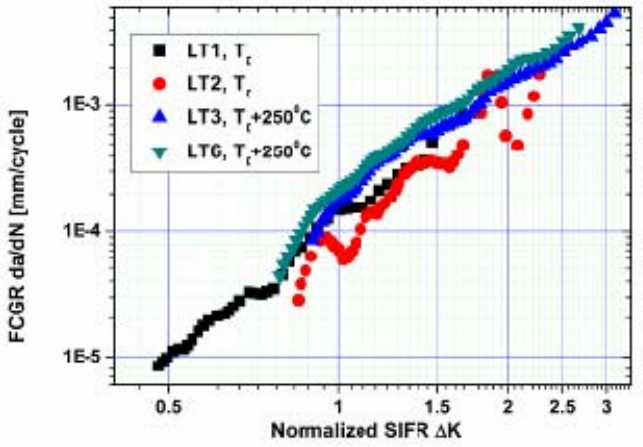

Figure 6. Crack growth behaviors of LT type specimens at T_0 and T_0+250^{0}C

Figure 7 compares the growth behaviors for diagonal cracks traveling both at T_0 and T_0+250^{0}C, from which one can conclude that apparent temperature effect can be found on the diagonal crack growth. Generally, cracks propagate much faster at T_0+250^{0}C than at T_0, especially in the low-ΔK regime. Subsequently, the growth rate at both temperatures become more and more close to each other as ΔK arise, and they take nearly the same value when normalized $\Delta K \approx 2.5$. After that, cracks at T_0 start to exceed those at T_0+250^{0}C, until the final break.

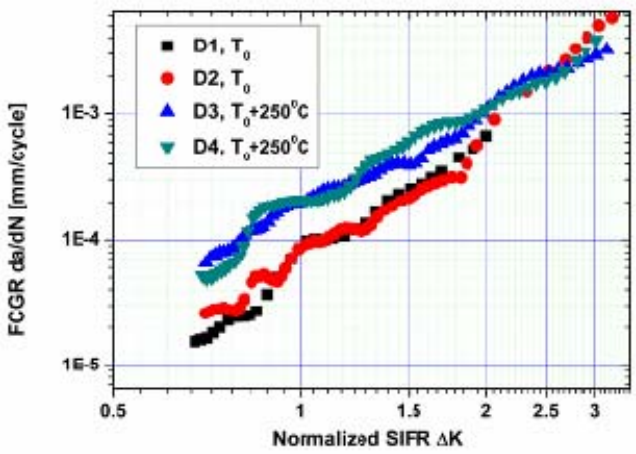

Figure 7. Crack growth behaviors of D type specimens at T_0 and T_0+250^{0}C

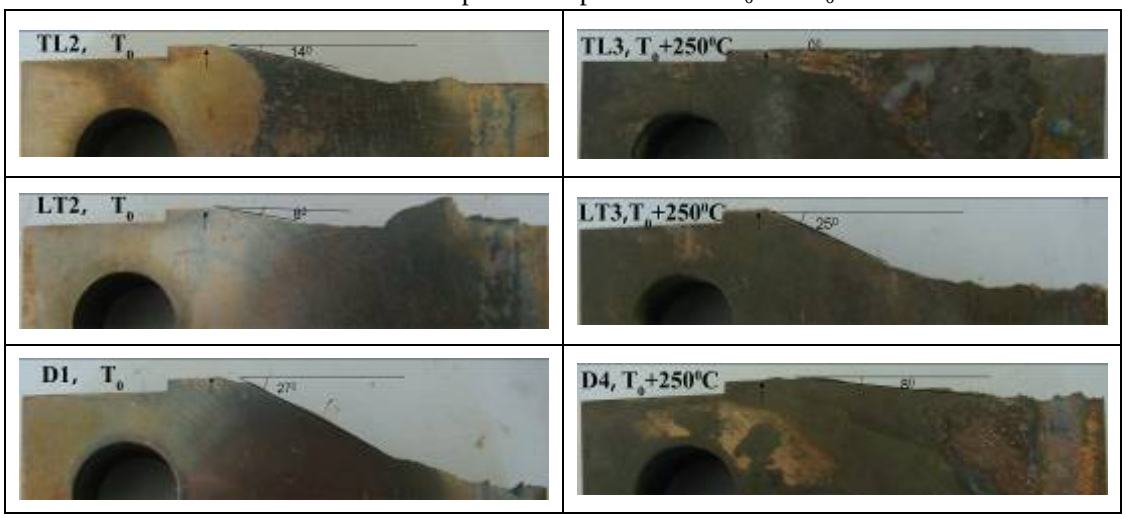
3.3. Fractography

All FCG tests were run until the specimen was separated into two parts. The fracture surfaces of all post-test specimens were observed through SEM and OM to understand the underlying mechanisms responsible for different damage modes. In regard to crack propagation behavior of single crystal superalloys, it is well known that cracks tend to propagate on <111> slip planes at low temperature, while cracks usually propagate normal to loading direction independent of crystal orientation at high temperature [8-11]. The former cracking behavior is called stage-I cracking, and the latter is called stage-II cracking. In current project, both stage-I and stage-II cracking modes can also be found, as can be seen by the side faces of fracture surfaces.

Table 2 lists the side faces of specimens tested at both temperatures, in which cracks propagated from left to right, and a black arrow in each figure corresponds to a machined notch tip. For TL type specimens (i.e., cracks propagate along the longitudinal direction), crack follow an angle of $\alpha \approx 14^0$ to the loading direction at T_0, which seems as a stage-I cracking mode, while both at T_0+250^{0}C show stage-II type of cracking modes. For LT type specimens (i.e., cracks travel along the transverse direction), trends are totally reversed, i.e., cracks at T_0 follow an angle of $\alpha \approx 8^0$ to the loading direction, while those at T_0+250^{0}C all travel along a constant angle of $\alpha \approx 25^0$; For diagonal specimens, stage-I cracking mode can also be seen at lower temperature ($\alpha \approx 27^0$), while at higher temperature, cracking surfaces show stage-II type cracking mode ($\alpha \approx 8^0$). To sum up, cracks in different orientations show different cracking modes, namely, cracks travel along longitudinal and diagonal directions show stage-I cracking at lower temperature and stage-II cracking at higher temperature, which is in accordance with literature. However, cracks travel in

transverse direction show a different trend.

Table 2. Side faces of post-test specimens at T_0 and T_0+250^{0}C



Note that for all the fracture surfaces, no angles were found through the thickness direction, i.e., all fracture surfaces are totally perpendicular to the specimen surfaces, and no inclinations were found.

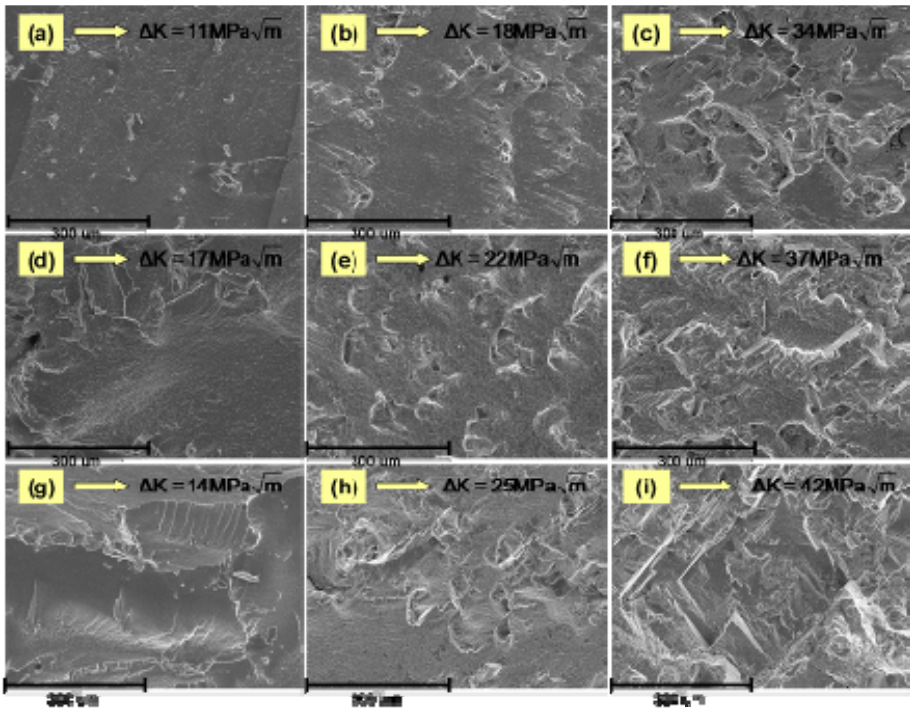


Figure 8. Fracture surfaces in various ΔK regimes at T_0 (a)-(c) TL type (d)-(f) LT type (a)-(c) D type

A more detailed examination results on the fracture surfaces in various ΔK regimes are presented in Figure 8. At low ΔK regimes, all fracture surfaces are smooth and very fine fatigue striations were observed on the fracture surfaces, indicating a slow but steady cracking stage, as can be seen in Figure 8 (a), (d) and (e); however, at higher ΔK regime a more textured fracture morphology with cracks was observed, and there were lots of claw-like barriers lying on the path (see Figure 8 (b), (e)

and (h)). This type of barrier is very common for most the specimens in all three orientations, and it is supposed that the effect of this kind of barrier on crack growth is much more important than the crystal boundaries. As ΔK arises, extensive crystal facet formations have been found for all three orientations. The reasons may be, as ΔK become so large that the local barriers can hardly produce any effective resistance, thus a predominant crack can easily and quickly travel though a crystal grain, and the appearance of crystal facet is attributed to the need for rapid energy dissipation by the advancing crack. Such energy dissipation is the fastest when cracks travel along the easiest path, i.e., the slip facets of each grain.

Figure 9 shows the typical claw-like barriers that have been widely found in the crack paths. It is suggested that when crack tip starts to reach these local barriers, it has been stopped due to the existence of these barriers, and as cyclic loading going on, new cracks start to re-initiate from these barriers; Subsequently, as the new cracks keeps growing and finally coalesce with the original crack, these barriers are seen to be passed through. Therefore it is inferred that these claw-like barriers do play an important role in cracks growth, and sometimes the effect of these barriers are so huge that the role of grain boundaries can hardly be seen. Besides, worth mentioning that in the previous pre-test procedure where some same C(T) specimens made of CM 247LC DS were conducted FCG tests, very few or no claw-like barriers had been found in their crack paths, so those specimens showed significant orientation dependence, and explanations associated with grain boundaries' resistance were made and it seemed that these explanation did work. As a result, there is reason to believe that due to the existence of numerous claw-like barriers in all three orientations, crack growth behaviors show weak orientation dependence for this DS material.

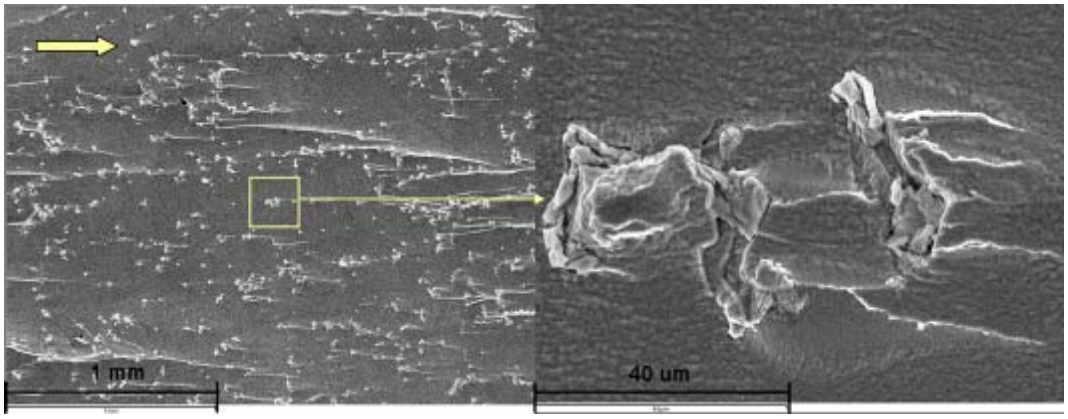

Figure 9. Typical claw-like barriers in the crack path

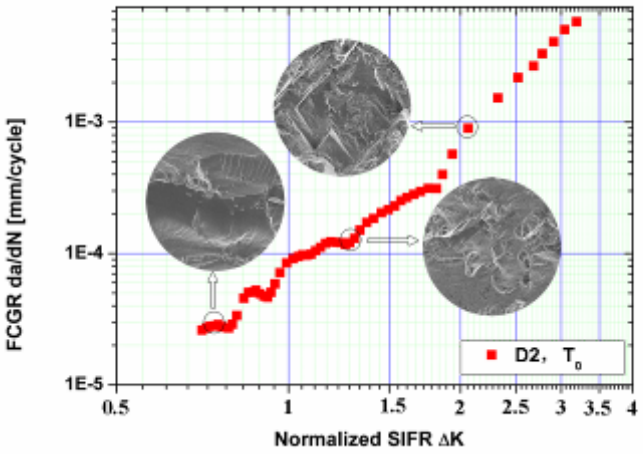

Figure 10. Crack growth rate corresponding to their typical microscopy

To sum up, cracks in all three orientations follow a similar propagation characteristic as ΔK arising. Figure 10 shows the typical microscopy corresponding to different ΔK regimes. It can be seen that as ΔK keeps increasing, the fracture surfaces become rougher and rougher. Meanwhile, more crystal facets appear when ΔK exceeds region II and runs into the fast-propagation region III.

4. Conclusions

Fatigue crack growth behaviors of a newly developed DS superalloy have been studied to investigate the effects of temperatures and orientations. Test specimens were subjected to two temperatures (T_0 and T_0+250^{0}C) and three crystal orientations (longitudinal, transverse and diagonal). Following conclusions can be drawn:

1) Weak orientation dependence have been found, and all $da/dN - \Delta K$ curves fall into a [1/3,3] narrow bond. Generally cracks in longitudinal and transverse directions have comparable crack growth rate, while those in diagonal direction propagate more slowly, especially in low-ΔK regimes;

2) Temperature dependence seems to vary in different orientations, i.e., cracks travel in longitudinal orientation show no temperature dependence, while those in transverse orientations show a little temperature dependence, and temperatures do have large effect on cracks travel in diagonal direction;

3) At lower temperatures, stage-I type cracking mode has been found in longitudinal and diagonal directions, while stage-II type cracking mode has been found in transverse direction; Besides, at higher temperatures, stage-II type cracking is preferred in longitudinal and diagonal directions, while stage-I type cracking is preferred in transverse direction.

Abstract The numerical approaches to simulate creep crack growth can be divided into two different categories. The first category is employing conventional fracture mechanics, in which the rate of crack growth is predicted by correlating it with a fracture mechanics parameter. The second category gaining much attention is on the basis of damage mechanics concept. In this paper, three dimensional analyses of creep crack growth are performed for 316 stainless steel specimens subjected to tension at high temperature with a semi-elliptical surface crack. Using two independent finite element analyses based on the fracture mechanics and continuum damage mechanics respectively, crack growth behaviors including crack profile development, crack size and propagation time are investigated and compared with each other and corresponding experimental data. The comparisons enable to show the different capabilities of the two approaches in predictions of creep crack growth.

Keywords Creep crack growth, Fracture mechanics, Continuum damage mechanics, Finite element analysis

1. Introduction

The increased computational power and programming capabilities have given impetus to the numerical prognoses of the structural integrity and service-ability throughout the lifetime of structures at high temperature. During the past decades, the numerical approaches to simulate creep crack growth have developed into two different groups. The first group is employing conventional fracture mechanics, in which the crack growth rate is predicted by correlating it with a fracture mechanics parameter such as stress intensity factor or C^*-integral [1-4]. The second group is based on damage mechanics concept [5]. When the creep damage variable reaches a critical value, material failure is considered to occur, and thus crack growth can be characterized by a completely damaged element zone ahead of the initial crack tip [6-9]. Alternatively, a node-release technique has been employed to simulate the separation of the crack face [10-14]. However, little research has been successfully conducted in applying the two approaches to three dimensional analysis of creep crack propagation. Furthermore, there is a need for a better understanding of the different capabilities of the two approaches in predictions of crack growth under creep conditions.

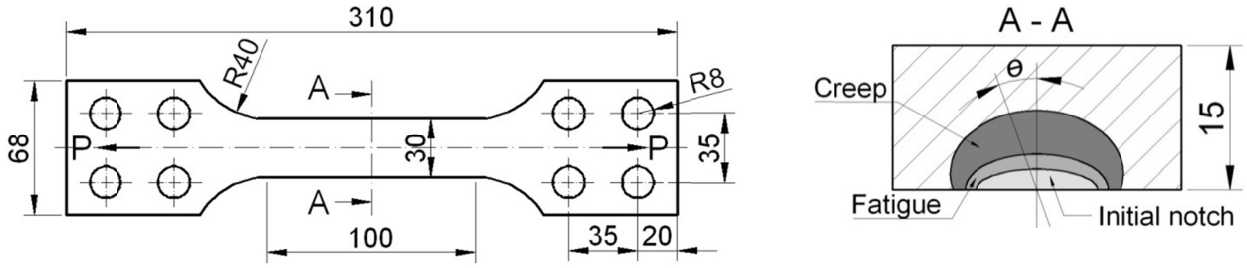
In this paper, three dimensional analyses of creep crack growth are performed for 316 stainless steel specimens subjected to tension at high temperature with a semi-elliptical surface crack. Section 2 briefly describes the conventional fracture mechanics models and a damage-based model recently proposed by the authors. The main idea of the two approaches in conjunction with the finite element (FE) method is demonstrated in Section 3. Subsequently, Section 4 shows the comparisons of

predictions using two independent analyses based on the two methods respectively. The conclusions are made in Section 5.

2. Mechanical model

2.1 Geometrical description

Thumbnail crack specimens tested at 600ºC by Hyde [15] subjected to static loads of tension are considered in the study, as shown in Fig. 1. The crack region can be divided into three parts: initial notch, fatigue crack and creep crack. In this work, attention is mainly paid to the creep crack region. Two specimens with extensive creep crack growth are chosen, of which test conditions are summarized in Table 1.



(a) (b)

Figure 1. Geometry of a thumbnail crack specimen: (a) a whole geometry; (b) an enlarged section view on A-A.

Table 1. Test conditions for the thumbnail crack specimens tested at 600 ºC.

Specimen No.	Initial creep crack size (mm)		Load (N)	Test duration (h)
	at $\theta = 0º$	at $\theta = 90º$		
5	2.88	4.33	90800	2760
6	3.50	4.37	90700	1200

2.2 Elasticity-secondary creep and creep fracture parameter

Basically, the time-dependent deformation characteristics for 316 stainless steel can be described by the following classical elastic-secondary creep constitutive relation

$$\dot{\varepsilon} = \frac{\dot{\sigma}}{E} + A\sigma^n, \tag{1}$$

where $\dot{\varepsilon}$ and $\dot{\sigma}$ denote the derivative of strain and stress corresponding to time; E is the Young's modulus; A and n are steady-state creep coefficient and steady-state creep exponent respectively. The material constants employed in FE analysis are listed in Table 2 [1, 9, 15].

For structures operated under creep regime, C^* is a proper fracture mechanics parameter to describe the crack growth. With regard to actual components such as plates and pipes, the values of C^* need to be determined by using FE methods. Then, with the transition time from small scale creep to the steady state ignored, the crack growth rate is represented in the following form:

$$\frac{da}{d\tau} = C(C^*)^q, \tag{2}$$

where τ, C and q denote the time, creep crack growth coefficient and exponent, respectively. Provided C^* has the unit of $Nmm^{-1}h^{-1}$, C and q for tests of compact tension (CT) specimens of 316 stainless steel at 600ºC [15] are also shown in Table 2.

Table 2. Material properties of the 316 stainless steel tested at 600ºC.

E (MPa)	ν	A ($MPa^{-n}h^{-1}$)	n	C	q	ε_f (%)
148000	0.3	1.47×10^{-29}	10.147	2.774×10^{-2}	0.958	27

2.3 Creep-damage model

The continuum damage mechanics model can trace its roots to Kachanov and Rabotnov's work [16, 17]. Since then there have been many attempts to develop an appropriate model [5, 18-20]. Recently, the authors presented a creep-damage model to simulate creep fracture, which is capable of characterizing the full creep curve and can reasonably reflect the influence of stress state on creep deformation and damage. More detailed description and validation of the proposed creep-damage model can be found in Refs. [21, 22]. The proposed model is as follows:

$$\dot{\varepsilon}_{ij}^c = \frac{3}{2} A\sigma_e^{n-1} s_{ij}\left[1+\beta\left(\frac{\sigma_1}{\sigma_e}\right)^2\right]^{\frac{n+1}{2}}, \tag{3}$$

and

$$\dot{\omega} = \frac{\dot{\varepsilon}^c}{\varepsilon_f^*}, \tag{4}$$

where A and n are material constants. ε_{ij}^c, s_{ij}, σ_e and σ_1 are the creep strain tensor, deviatoric stress tensor, equivalent stress and maximum principle stress, respectively. ω, $\dot{\varepsilon}^c$ and ε_f^* denote the damage variable, creep strain rate and multi-axial creep failure strain, respectively. β is a stress-independent function reflecting material behavior, having the form

$$\beta = \frac{2\rho}{n+1} + \frac{(2n+3)\rho^2}{n(n+1)^2} + \frac{(n+3)\rho^3}{9n(n+1)^3} + \frac{(n+3)\rho^4}{108n(n+1)^4}, \tag{5}$$

where the micro-crack damage parameter, ρ, depends primarily on the number of micro-cracks per unit volume and their average diameter. Suppose the damage variable is given as the reduction of the effective area in the cell, we can obtain

$$\rho = \frac{2(n+1)}{\pi\sqrt{1+3/n}}\omega^{3/2}. \tag{6}$$

It is known that the creep ductility significantly depends on the stress state. In this work, a modified multi-axial ductility model, which can describes the behavior of creep cavity growth more appropriately than the widely-used Cocks-Ashby model [23], is employed:

$$\frac{\varepsilon_f^*}{\varepsilon_f} = \exp\left[\frac{2}{3}\left(\frac{n-0.5}{n+0.5}\right)\right] \Big/ \exp\left[2\left(\frac{n-0.5}{n+0.5}\right)\frac{\sigma_m}{\sigma_e}\right], \tag{7}$$

where ε_f is the uniaxial creep failure strain and σ_m is the hydrostatic stress. In this work, the optimum value of ε_f for tests of uniaxial specimens of 316 stainless steel at 600ºC is found to be 0.27, as listed in Table 2.

3. Finite element framework

3.1 Using fracture mechanics approach

To predict the crack growth behavior of thumbnail crack specimens under creep conditions, fracture mechanics approach has been used in conjunction with the FE method. Numerical simulations of creep crack growth, which have been based on a step-by-step analysis procedure, are described as follows:

(a) Creating of the FE models. One quarter of the specimen containing a semi-elliptical surface crack has been created using the codes ABAQUS [24] and ZENCRACK [25] due to symmetry of both the geometry and loading. About 10,000 elements of type C3D8I for each model have been adopted. Note that extremely refined meshes are generated in the crack tip zone to obtain accurate results.

(b) Calculations of values of C^*. Values of C^* at a set of points which constitute the crack front can be calculated using the equivalent domain integral (EDI) method provided by the codes ABAQUS. In the study, the crack front has been divided into 16 sections, so values of C^* at 17 points are recorded in every step.

(c) Calculation of the increment of the crack size. The steady-state creep crack growth can be represented by Eq. (2), according to which, the creep crack growth increment at each point along the crack front, Δa_i, can be calculated as

$$\Delta a_i = \left(\frac{C_i^*}{C_{\max}^*}\right)^q \Delta a_{\max}, \tag{8}$$

where C_i^* and $C_{\max}^*$ are C^* at an arbitrary point and the maximum value along the crack front, respectively; $\Delta a_{\max}$ denote the maximum crack growth increment at the point where $C_{\max}^*$ occurs.

(d) Establishment of a new crack profile. Based on the creep crack increment at each point along the crack front, a set of new points can be determined. And then, a new crack profile can be created by using codes ZENCRACK.
(e) Returning to stage (a). The crack continued to extend through the stages from (a) to (d) until a termination condition is reached.

3.2 Using continuum damage mechanics approach

Creep damage modeling has been also carried out using the codes ABAQUS with the elastic-plastic-creep properties of 316 stainless steel tested at 600ºC [1, 9, 15]. The total strain can be calculated by

$$\varepsilon^{tol} = \varepsilon^{e} + \varepsilon^{p} + \varepsilon^{c}, \tag{9}$$

where $\varepsilon^{e}, \varepsilon^{p}$ and ε^{c} are elastic, plastic and creep strain components, respectively. The true stress-strain data beyond the yield point is used as input to FE analysis and a Mises flow rule with isotropic strain hardening is employed. To define the time-dependent and damage-coupled creep behavior, Eq. (3) is implemented into the ABAQUS user subroutine, CREEP. Eq. (4) is also embedded in CREEP to determine the damage accumulation. Creep damage variable, ω, is in the range of 0 to 0.99. When ω at a Gauss point reaches 0.99, all the stress components are sharply reduced to a small plateau and thus crack growth can be characterized by a completely damaged element zone ahead of the initial crack tip. Another user subroutine, USDFLD, is employed to embody this failure simulation technique.

Using this numerical method, three-dimensional creep damage analyses are performed to simulate the creep crack growth in thumbnail crack specimens. One quarter of the model consisting of about 10,000 eight-node C3D8R elements is modeled exploiting the symmetry conditions. The mesh size in the vicinity of the crack front is 200μm, which has been proved to provide excellent predictions in Ref. [21].

4. Results and discussion

4.1 Predictions using fracture mechanics approach

To achieve accurate predictions of crack growth using fracture mechanics approach, it is essential to choose a proper maximum crack growth increment, $\Delta a_{\max}$, in Eq. (8). Comparison of crack depth variations predicted using five different maximum crack growth increments, $\Delta a_{\max} = t/300$, $t/150$, $t/75$, $t/30$ and $t/15$, for the thumbnail crack in specimen 5 is shown in Fig. 2. It can be seen that the difference between the crack depth variations cannot be neglected when the maximum crack growth increment is relatively large ($\Delta a_{\max} = t/30$ and $t/15$). For $\Delta a_{\max} = t/300$, $t/150$ and $t/75$, however,

difference between predictions is extraordinarily hard to identify on the plot, which demonstrates the convergence of the relation between the crack depth and propagation time does exist. In this paper, the maximum crack growth increment is selected as $t/150$, which is small enough to achieve a required accuracy of crack growth time.

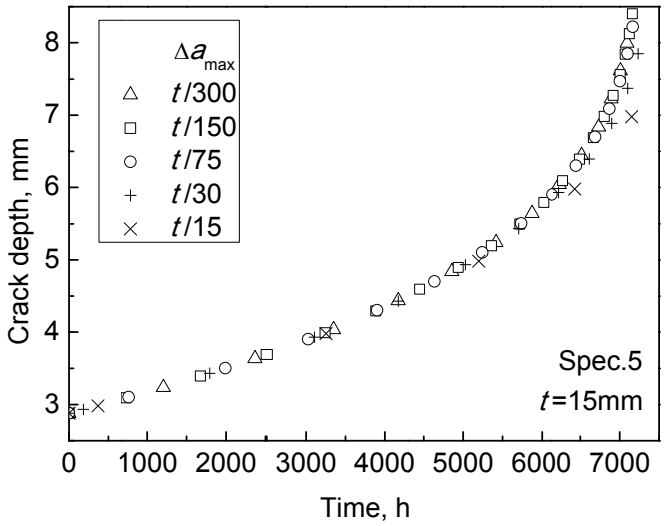


Figure 2. Comparison of crack depth variations predicted using five different maximum crack growth increments

Fig. 3 shows the predicted creep crack shape developments for thumbnail cracks in specimens 5 and 6 with the initial semi-elliptical crack front. It can be found that the increment along depth direction is always more considerable than that along surface direction at each step. As a result, the accumulative increment of crack depth is obviously larger than that of half crack length.

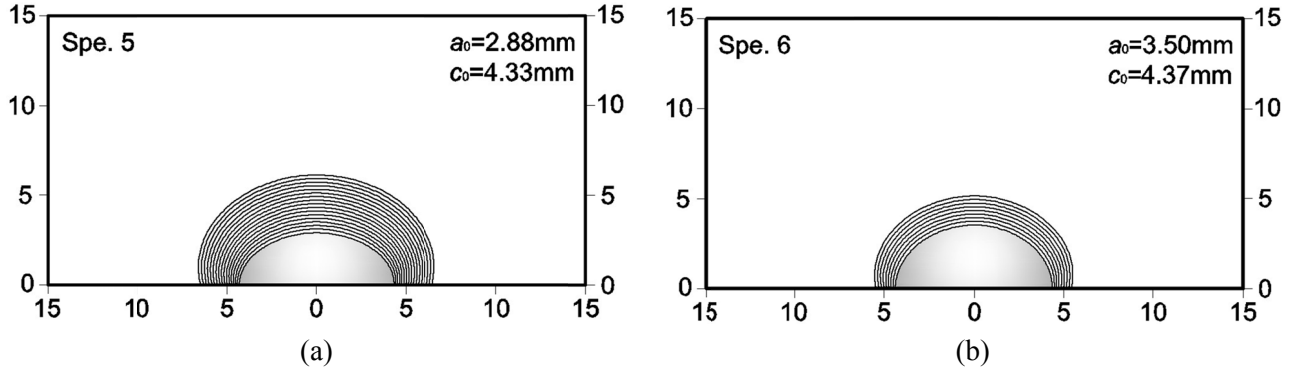

Figure 3. Predicted creep crack shape evolutions resulting from fracture mechanics approach: (a) specimen 5; (b) specimen 6

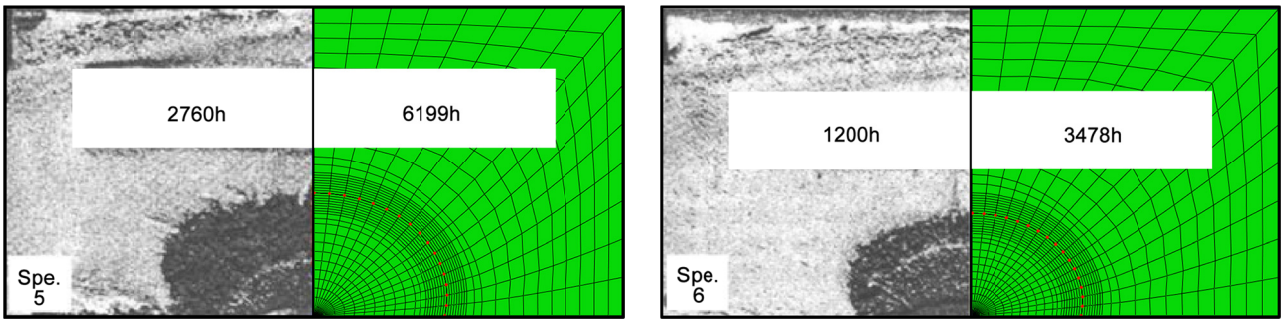
Fig. 4 depicts the tested specimen photos taken from Ref [9, 15] and predictions using fracture mechanics approach for specimens 5 and 6. It can be said that the predicted crack fronts are similar to the experimental results for both specimens. Nevertheless, the predicted propagations times are 2~3 times as long as the actual test durations. This is mainly because that creep crack growth coefficient and exponent, C and q, in Eq. (2) are obtained from the correlation of $\mathrm{d}a/\mathrm{d}t$ and C^* for tests of CT specimens instead of the investigated thumbnail crack specimens. For a given C^*, the

crack growth rate for a crack in a CT specimen can be considerably lower than in a thumbnail crack specimen due to the different constraint effect of varied types of specimens.

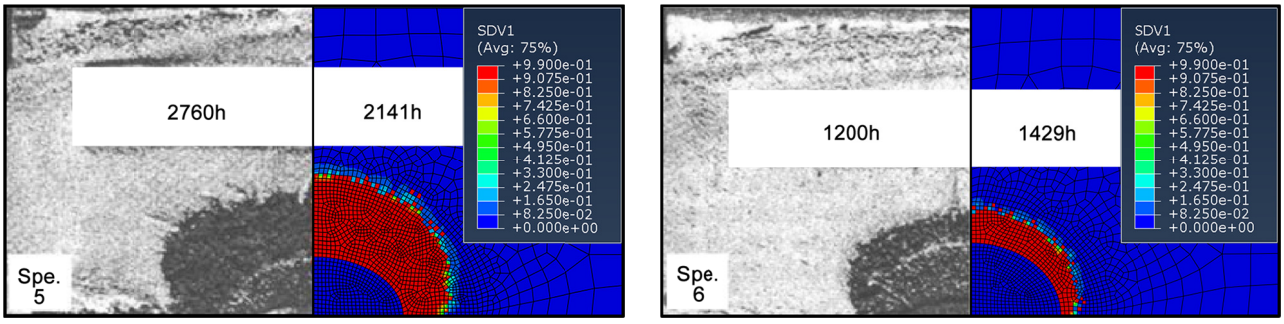


(a) (b)

Figure 4. Comparisons of tested specimen photos with predictions using fracture mechanics approach: (a) specimen 5; (b) specimen 6

4.2 Predictions using continuum damage mechanics approach

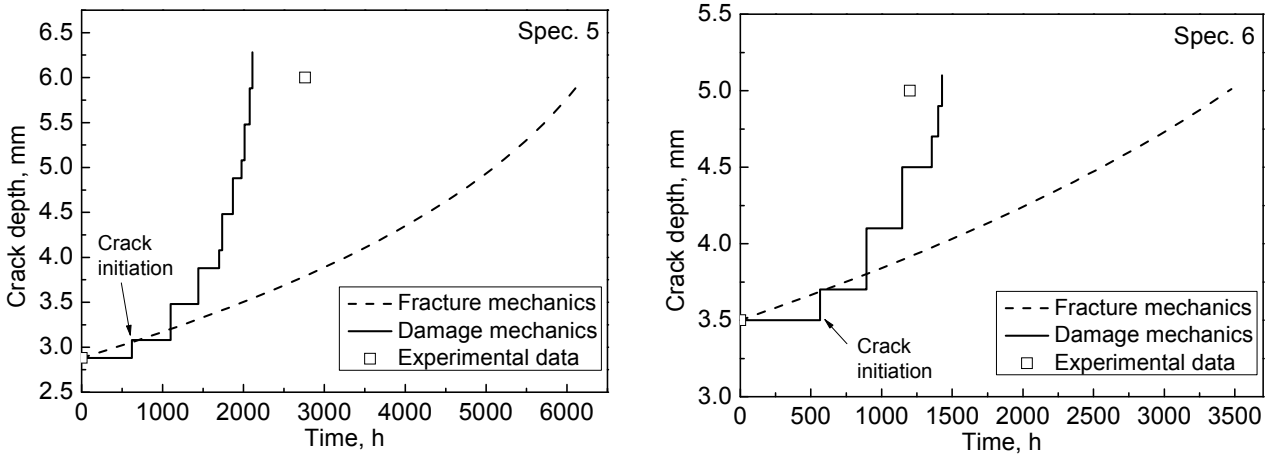
Predicted crack profiles using continuum damage mechanics approach are compared with the tested specimen photos in Fig. 5. Obviously, the FE predicted crack fronts match very closely to the experimental results. One can also find that the crack propagates with larger increment at $\theta = 0^{\circ}$ (approximately under plane-strain condition) than that at $\theta = 90^{\circ}$ (approximately under plane-stress condition) due to the constraint effect. Propagation times predicted by the numerical simulation are also in good agreement with the test durations. These encouraging results prove the validity and predictive capability of the proposed creep-damage model presented in Eqs. (3) and (4).



(a) (b)

Figure 5. Comparisons of tested specimen photos with predictions using continuum damage mechanics approach: (a) specimen 5; (b) specimen 6

Fig. 6 provides comparisons of crack depth variations predicted by using fracture mechanics and continuum damage mechanics approaches. It is clear that damage mechanics predictions are more closely to the experimental data. In addition, the crack initiation times, nearly 500 hours, can also be predicted by continuum damage mechanics approach. When C^*-type method is employed, no information regarding crack initiation can be obtained.



(a) (b)

Figure 6. Comparisons of crack depth variations predicted by using fracture mechanics and continuum damage mechanics approaches

5. Conclusions

The main conclusions drawn from the study are listed as follows:

(a) For fracture mechanics approach, the convergence of the relation between the crack depth and propagation time does exist if the maximum crack growth increment is small enough.

(b) Both fracture mechanics and continuum damage mechanics approaches in conjunction with the FE technique can give reasonable predictions of the crack profile when compared with the experimental results of thumbnail crack specimens tested under tension.

(c) The propagation time can also be appropriately predicted by the damage mechanics approach, while it is far from satisfactory when using the facture mechanics method. For the purpose of a more accurate prediction, the different constraint effects between the CT and thumbnail crack specimen need to be carefully considered.

(d) The crack initiation time can also be predicted by the damage-based approach presented in the study.

Abstract

Selective laser melting is an additive manufacturing technology where metal powder is melted by a laser source layer-wise, forming a solid, dense metallic component. With the selective laser meting process, near net shape components can be manufactured directly from a 3D-model. The model is sliced into thin layers and a powder is spread onto a build platform. In the next step, the powder is fused by a laser as dictated by the model. The laser energy is intense enough to permit full melting (welding) of the particles to form solid metal. The process is repeated layer by layer until the part is complete. A number of materials are available, including steel, aluminium, titanium and, in recent time, also superalloys. The material investigated in the current project is a nickel base superalloy composition-wise equivalent to Hastelloy X, a solution strengthened superalloy typically used in large welded components exposed to high temperatures in oxidizing as well as reducing environments.

Microstructurally, the material is different from both a hot-rolled, as well as a cast material due to the manufacturing process. Since the SLM process involves laser melting of powder particles in the size range of <50μm, the structure resembles of a weld structure, however on a smaller scale. Due to the layer-by-layer build strategy, the material will exhibit anisotropy.

In the current project, high temperature mechanical fatigue and creep tests are performed. The microstructure is evaluated and the influence on the mechanical properties is discussed. Anisotropy in mechanical properties is discussed and the underlying factors of the anisotropy are analyzed.

Keywords Additive manufacturing, Hastelloy X, fatigue, creep, anisotropy

1. Introduction

Selective laser melting (SLM), or, as the industry standard denotes the process, laser sintering, is an additive manufacturing process where metal powder is melted by a laser source layer-wise, forming a solid, dense metallic component. SLM belongs to a group of manufacturing processes recognized as rapid prototyping (RP). RP processes are well established for manufacturing of parts of plastic materials or metallic materials that can more or less easily be melted [1, 2]. Examples are 3D-printing [3] as patented by Massachusetts Institute of Technology, selective laser sintering (SLS) [4] developed at University of Texas at Austin and selective laser melting (SLM) [5] initially developed at the Fraunhofer Institute ILT in Aachen.

With the SLS process it is possible to melt materials like bronze [6]. Materials with a high melting point can be mixed with a lower melting point material in order to form a composite of, for instance, bronze as a matrix with embedded particles of steel or nickel [6].

With the SLM process, near net shape components can be manufactured directly from a CAD model. The model is sliced into thin (max 100µm thick) layers. Powder is spread onto a metallic build platform and the powder is fused in layers with a laser as dictated by the CAD model. The laser energy is intense enough to permit full melting (welding) of the particles to form solid metal. The process is repeated layer by layer until the part is complete. Examples of metallic materials commercially available for the SLM process are stainless steels AISI 304L [7] and 316L [8, 9], Aluminium alloys [10], Titanium Ti6Al4V [4] and also more temperature resistant materials such as Inconel 625 [4].

The laser melting manufacturing process can, as mentioned, be described as a layer-by layer process, where powder is distributed on a powder bed, Figure 1. After powder distribution, the powder is melted and a metal slice is formed on the powder bed.

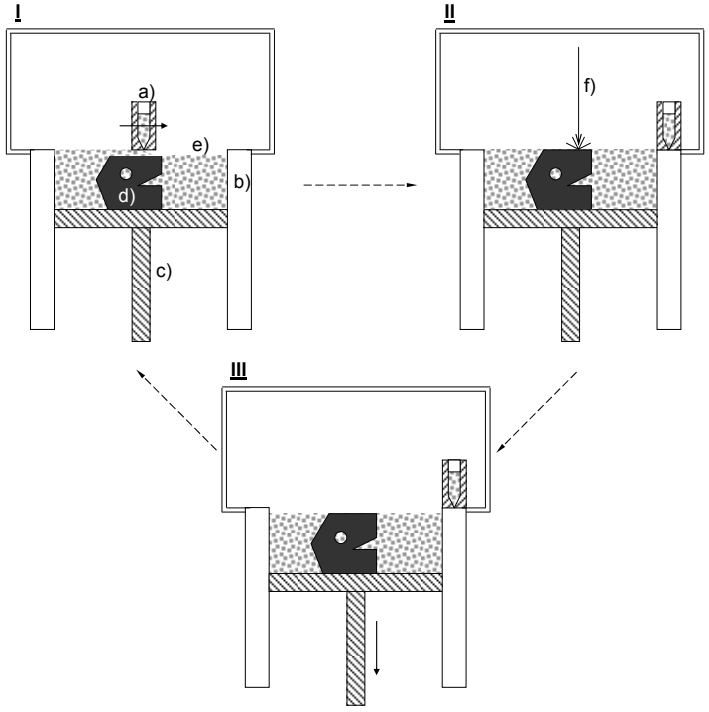

Figure 1. Schematic description of the SLM process. a) Powder is distributed on a powder bed, the build platform. b) The powder is melted by a laser beam and a slice of solid metal is formed. c) The powder bed is lowered and the process is repeated until a finished component is formed.

I: A powder distributer travels over the powder bed cavity contained by the build chamber walls b) and build plate c). Molten and solidified powder constitutes the component d) surrounded by unmolten powder e). II: A laser beam f) melts the powder layer and creates a new slice of solid material in the component d). III: A ram lowers the build platform c) and the process is repeated until

a finished geometry is formed. After finalization, the remaining loose powder is removed and the component is cut off from the build platform.

2. Experimental details

Since no harmonized nomenclature exists in the literature for specimen build / loading direction relative to build platform or build direction, it is necessary to give a reference to nomenclature used in the current paper. If the build platform is taken as reference, a specimen being built in the build platform plane (perpendicular to the build direction) the specimen build and loading direction is designated 0°. Any specimen build and loading direction tilted towards the normal of the build platform plane (i.e. a vector defining the machine global build direction) would be designated with a build angle $0° < \alpha \leq 90°$. Due to the nature of the SLM process, the layer-wise build-up of material is normally done with a scan strategy so that the material will be isotropic in the build plane. For each layer the scanning pattern is rotated and in a component the material will contain welds in many different directions. Any rotation of a specimen in the plane is considered to give corresponding results and the material can be considered as orthotropic [11]. The findings have been verified for 1.4404 [12]. The present definition of specimen build direction / loading direction is graphically visualized below, Figure 2.

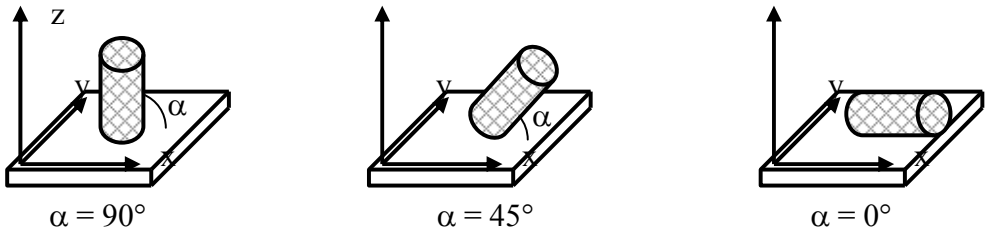

Figure 2. Definition of specimen build and loading direction relative to the build platform plane. A specimen "0°" would be a specimen in any direction in the build plane and a specimen "α°" ($0° < \alpha < 90°$) would be a specimen built out of the build platform. An angle $\alpha = 90°$ would indicate a specimen being built parallel to the SLM equipment build direction.

2.1. Process

Material manufacturing has been done in an Eosint M270 Dual Mode equipment. The atmosphere during building is Argon and the atmosphere is monitored by an oxygen probe throughout the entire process to ensure that the oxygen level is kept below a maximum level. A layer thickness of 20μm was used and for each new layer the laser beam rotated the scanning pattern and shifted the scanning pattern in order to avoid in-plane property variations.

2.2. Material11

For the material manufacturing, a nickel base superalloy in accordance to Hastelloy X (originally developed by Haynes International) has been used. The material is Ar gas atomized and sieved to a fraction suitable for selective laser melting applications, indicating a powder distribution from

10-45µm. The nominal composition of Hastelloy X is shown below as reference, Table 1.

Table 1. Nominal composition of Hastelloy X hot-rolled material.

Ni	Cr	Fe	Mo	Co	Si	Mn	W
Bal.	22	18	9	1.5	<1	<1	0.6

During SLM manufacturing the material is built up layer-wise with a layer thickness of 20µm. The typical powder morphology is shown below, Figure 3. The material is well atomized without large amounts of satellites, fused/bonded particles or inhomogenities.

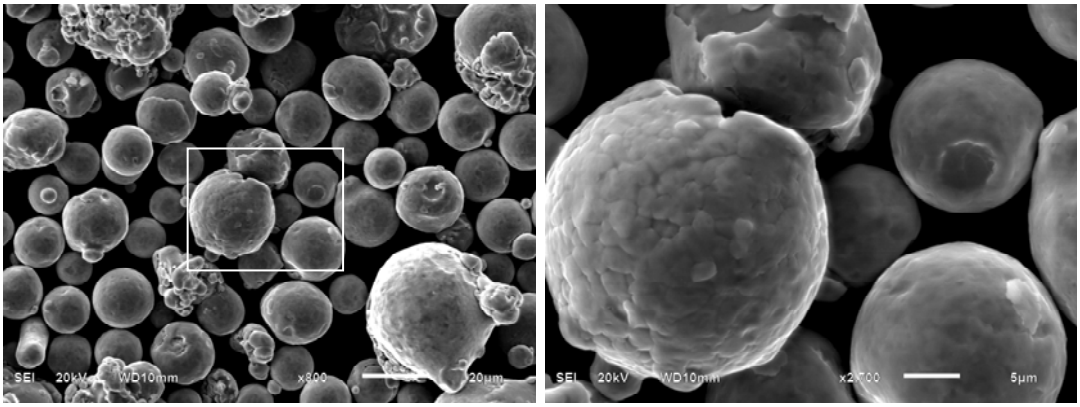

Figure 3. Scanning electron microscopy image of recycled Alloy X powder morphology. The powder is relatively free from satellites and sintered/bonded particles. Some coarse particles are present, a result of the powder being recycled.

Material has been built in different directions relative to the build plane as defined in Figure 2 above. Evaluations are done in the 0°, 45° and 90° directions. For testing of selective laser melted material properties presented in the current paper testing has been conducted on as-manufactured material. Reference material in hot-rolled condition is typically not available in any other condition than the standard solution heat treated material state. Therefore, comparative data for standard Hastelloy X material is included as reference. For Alloy X material manufactured by the SLM method, the best heat treatment route is not per say a standard solution heat treatment. In fact, the material is in the as-manufactured state very homogeneous with no segregations opposite to what could be expected from, for instance, a casting process. I.e., from a segregation point of view, a solution heat treatment would not necessarily be beneficial.

2.3. Mechanical testing and evaluation

Material testing has been performed at ambient and elevated temperature. At ambient temperature, the material has previously been shown to exhibit anisotropy in tensile properties [13, 14]. The current work tries to evaluate some of the high temperature properties of the selective laser melted Alloy X material with respect to thermomechanical fatigue (TMF) and creep loading. The resulting fracture surfaces and microstructures are evaluated by light optical and scanning electron microscopy. Etching of the material is done as electrolytic etching in 10% oxalic acid in distilled

water with a voltage of 6V and a time of 15-25s depending on specimen size. In the current paper, material properties are only evaluated for bulk material, i.e. all material was machined to final specimen dimensions and no influence from the rough surface is taken into consideration.

The thermomechanical data referenced below have been conducted as in-phase (IP) TMF between 50°C and 800°C and a hold time of 5 minutes at maximum temperature. Creep testing is performed at 816°C.

3. Results

3.1 Initial microstructure

The typical as-manufactured microstructure is shown below, Figure 4. The microstructural anisotropy is obvious. As seen in Figure 4, the material has a weld-like structure. Due to the conditions during manufacturing, the material will undergo rapid solidification. In the literature, in the melt pool solidification region, temperature gradients up to 3500 K/mm on the surface are indicated [15]. The resulting grain size will be fine-grained as seen in Figure 5.

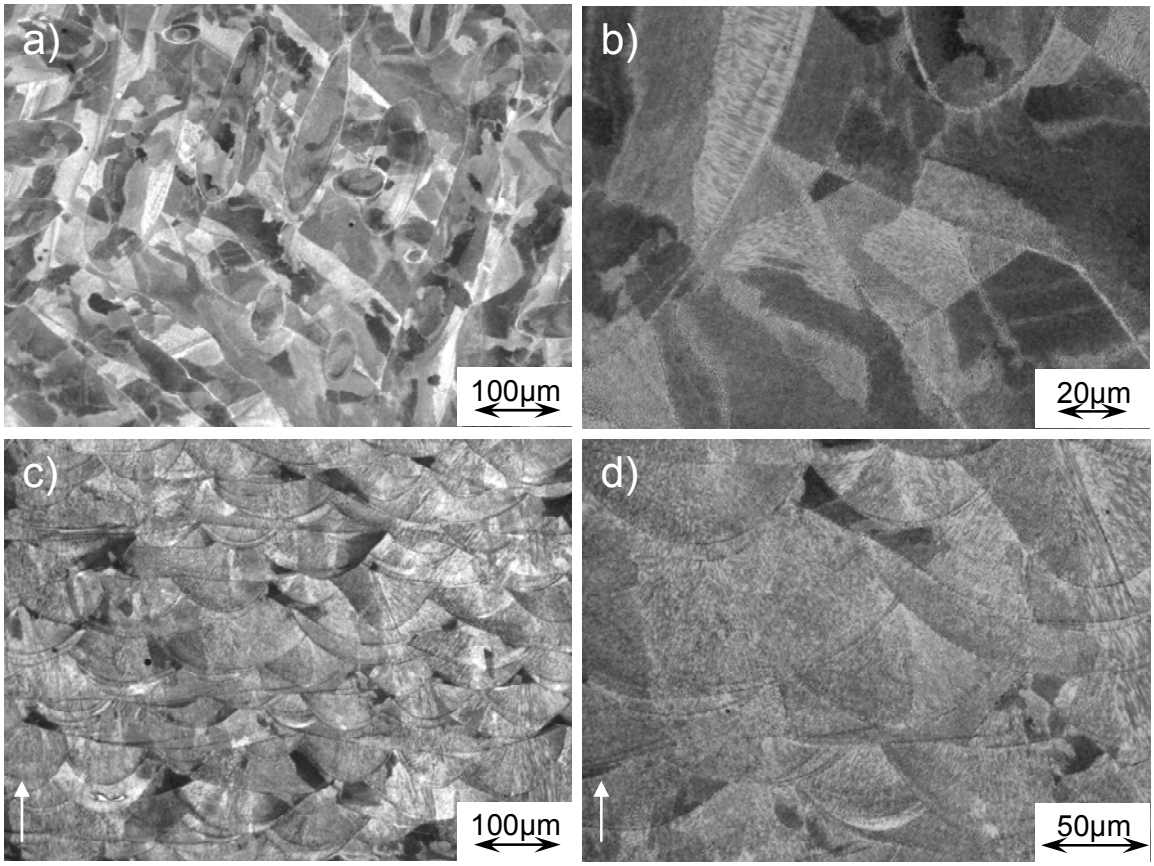

Figure 4. As manufactured microstructure. Top views (a, b) are light optical micrographs, bottom views (c, d) are corresponding scanning electron microscope images. Left views (a, c): Arrow indicates the build direction. The build plane is horizontal and below the bottom of the figure. Right views (b, d): The build direction is out of the plane, the build plane is in the plane of the figure.

From Figure 4 the micrographs a columnar structure can be observed. The grain structure is not

easily detected, therefore an EBSD analysis has been performed. An example of the results is shown below, Figure 5.

It is obvious that the structure is columnar and that the microstructure has a coupling to solidification. In the process, the build plate is kept at a constant temperature and the solidified material is surrounded by loosely packed metal powder, i.e. the metal powder will act as insulation for heat from the weld process. The columnar structure is an indication on conditions for heat transfer. Since the columnar structure is vertical in the image, the cooling gradient is mainly normal to the build platform.

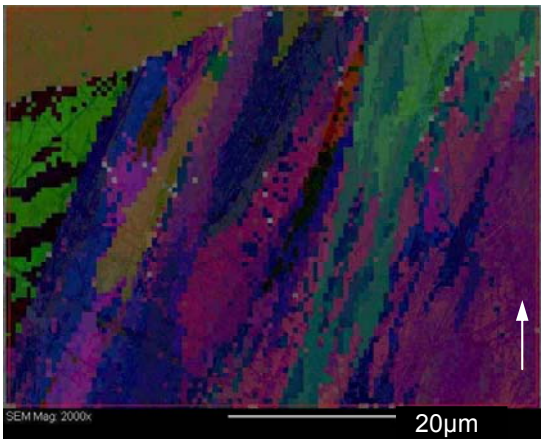

Figure 5. EBSD image of as-manufactured Alloy X. Build direction is indicated by an arrow in the figure.

3.2 Fatigue testing

Testing of the material at low temperature has been conducted as low cycle fatigue testing in strain control with a triangular wave shape and a strain ratio R_ε=1. Results are shown below, Figure 6.

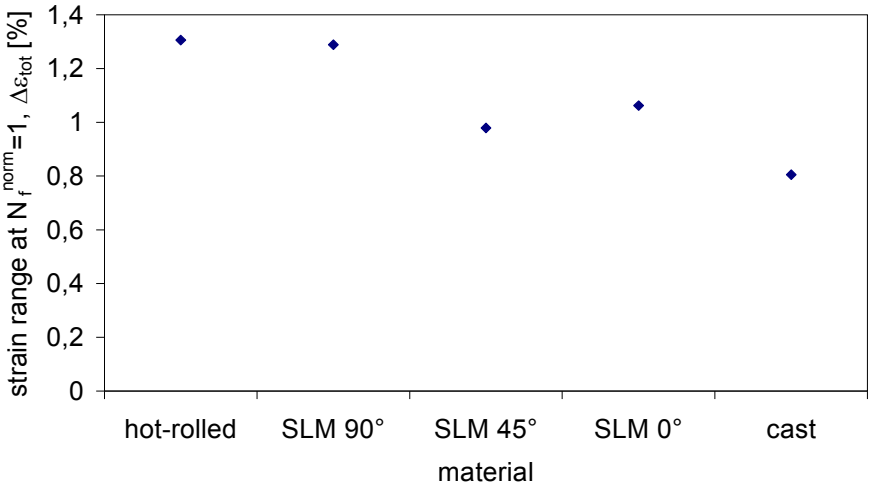

Figure 6. Normalized low cycle fatigue test results at ambient temperature.

Fracture surfaces of fatigue tested material have been evaluated by light optical microscopy and scanning electron microscopy. Corresponding typical micrographs are shown below, Figure 7 and

Figure 8.

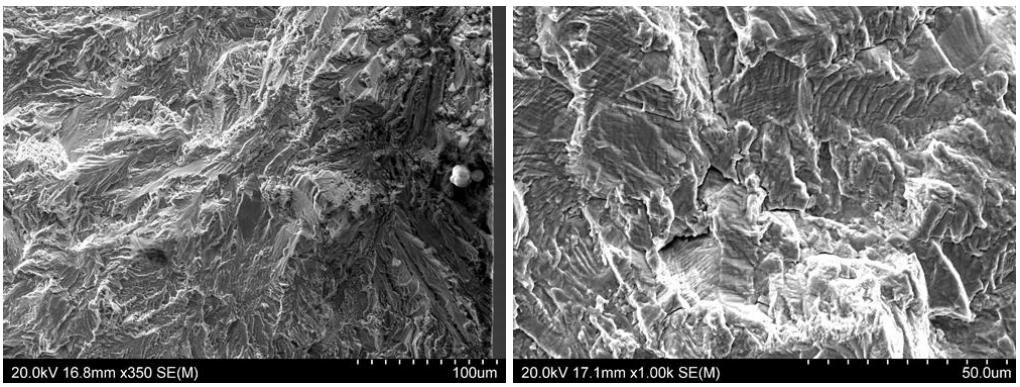

Figure 7. Fracture surface, low cycle fatigue testing, test temperature 20°C.

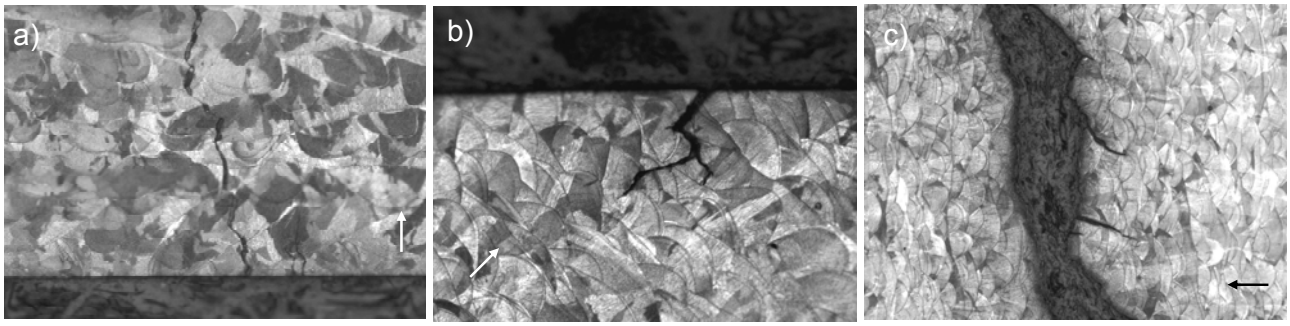

Figure 8. Crack patterns, low cycle fatigue, test temperature 20°C. In the figure, a) is 0° build direction, b) is 45° build direction and c) is 90° build direction. Loading direction is horizontal in the figure.

At high temperature, the testing has been performed as thermomechanical fatigue testing in strain control using a trapezoid wave form with hold time at T_{max} and a strain ratio R_ε=0. Normalized results from the thermomechanical testing are presented in Figure 9. In the figure, the relative strain value "1" indicates the normalized strain for a hot-rolled material to yield a certain fatigue life.

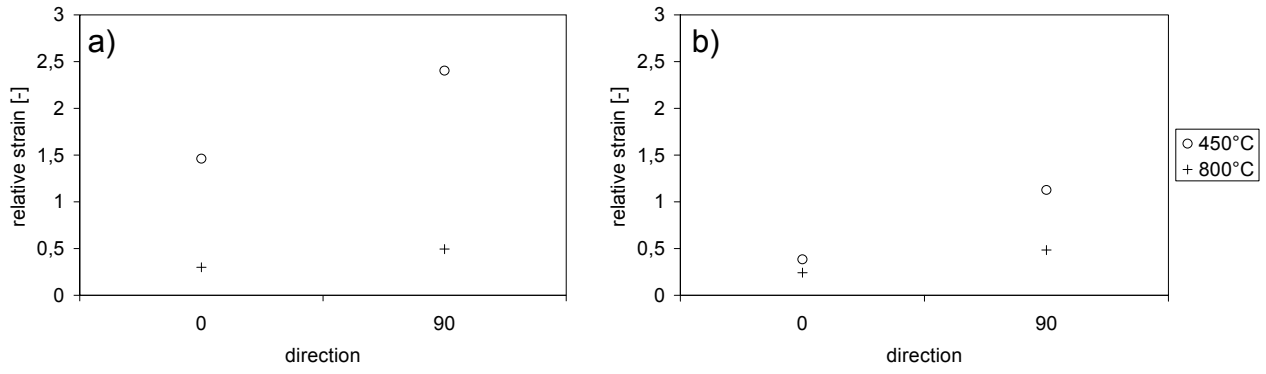

Figure 9. Normalized average data from thermomechanical fatigue test results. Strain measurements are relative to the strain that for a hot-rolled bar will yield a) 500 cycles and b) 1000 cycles.

For comparison, the fracture surfaces have been evaluated and typical fracture patterns at 450°C and 800°C are presented in Figure 10 and Figure 11 respectively.

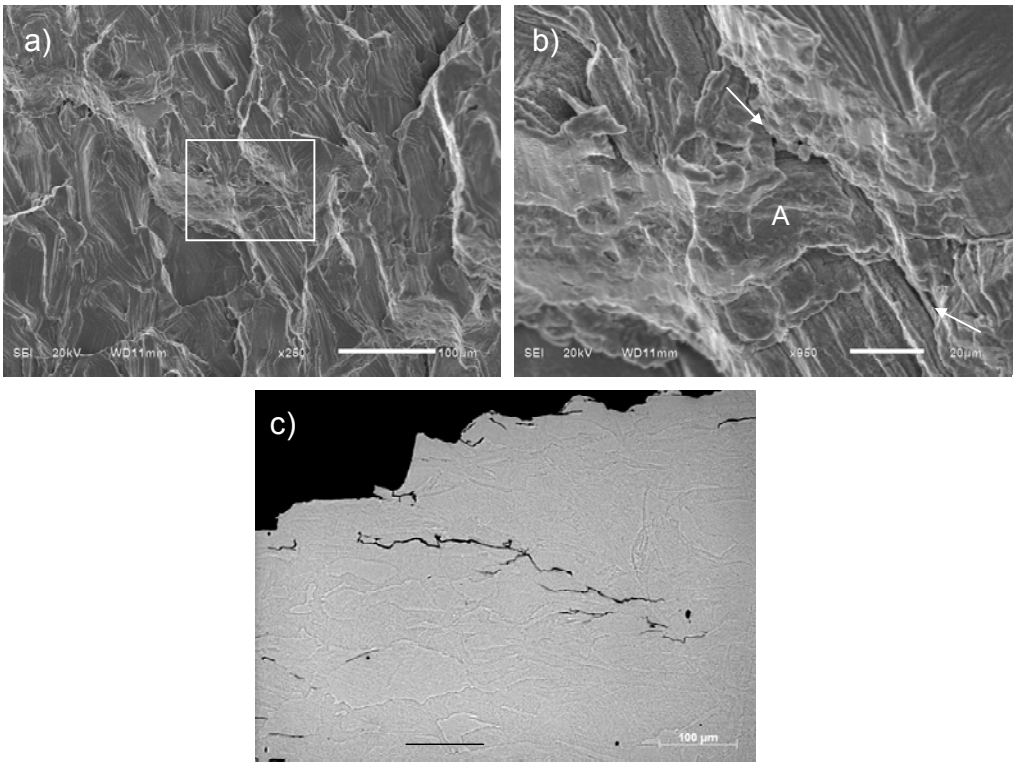

Figure 10. Fracture surface, elevated temperature 450°C, build direction 0°, thermomechanical fatigue testing. Fracture is intercrystalline with crack branching as indicated by arrows in right figure. Area "A" is an area with poor bonding.

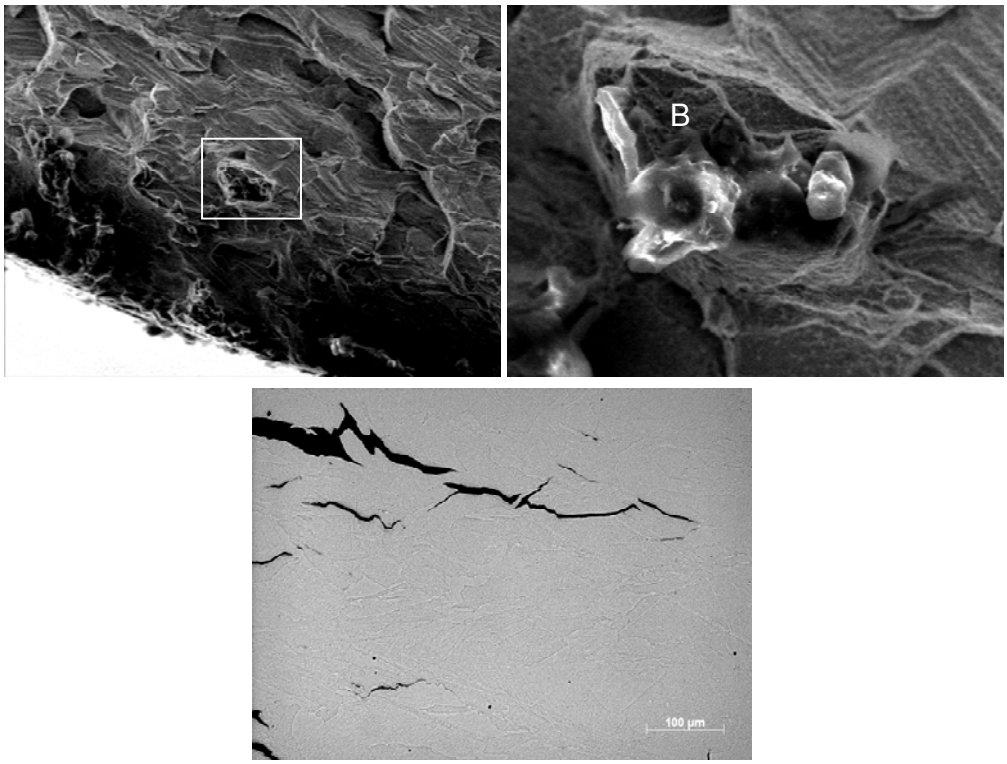

Figure 11. Fracture surface, elevated temperature 800°C, build direction 0°, thermomechanical fatigue testing. Fracture is intercrystalline with crack branching as indicated by arrows in right figure. Area "B" is an area containing an inhomogenity (partly molten particle).

3.3 Creep testing

Results from stress rupture testing of SLM material is presented below, Figure 12. In the figure, the relative creep rupture life "1" indicates the normalized life for a hot-rolled material to yield a certain creep life. Corresponding fracture surfaces and crack patterns are shown in Figure 13.

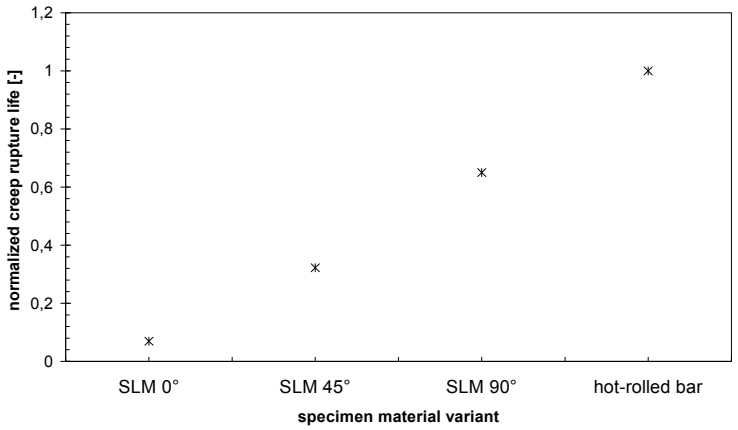

Figure 12. Stress rupture testing at 815°C. Comparison of SLM material and hot-rolled Hastelloy X.

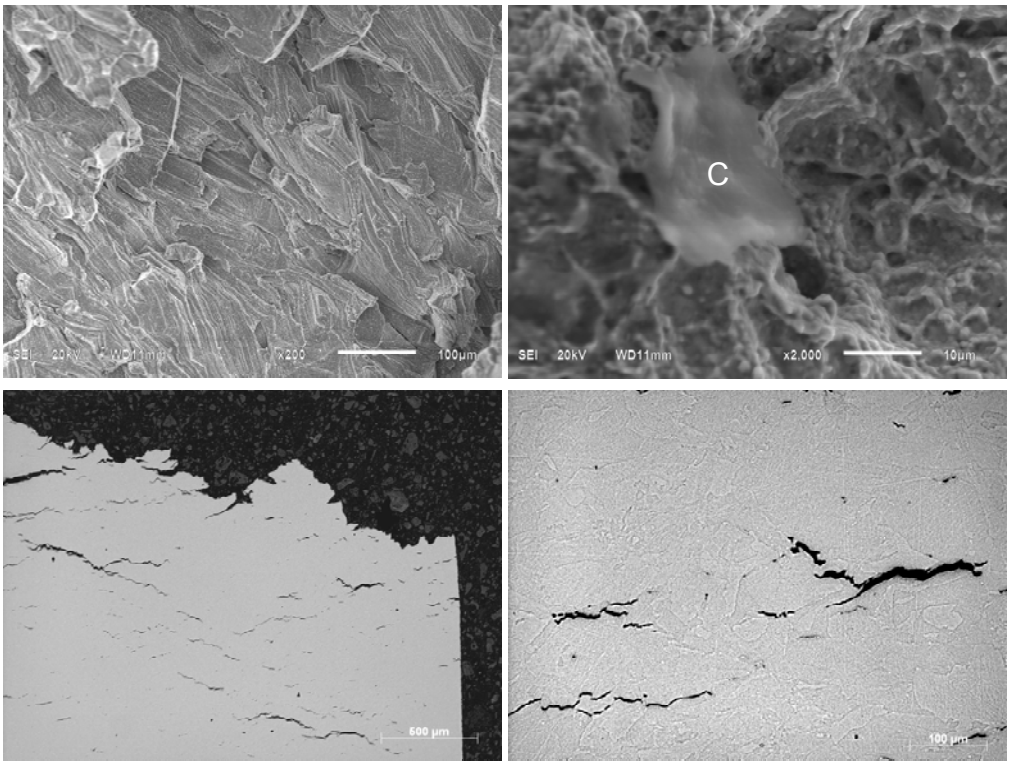

Figure 13. Fracture surface, test temperature 815°C, build direction 0°, creep testing. Fracture is intercrystalline with multiple crack sites. Area "C" is an area with poor bonding (internal flaw) to the surrounding.

4. Discussion

The tensile strength anisotropy has previously been indicated for Hastelloy X [13, 14, 16] and other alloys [11, 12, 17]. Here the anisotropy is obvious both in creep testing and in fatigue. The trend is that the 90 degree direction acts as the most fatigue and creep resistant direction. In this direction

the material will act as a less fine grained and creep properties are then likely to be improved due to a grain size effect. In fatigue the 90° direction is more ductile [13, 14]. This fact could be beneficial if, for instance the material contains a number of defects and individual defects play an important role in crack initiation. A more ductile material can possibly accommodate an increased stress field around an inclusion through a larger local plastic zone avoiding cracking. The microscopy evaluation shows that the material is isotropic from a microstructure point of view in a plane parallel to the build plane. In the 90° direction the microstructure is different, as shown in microstructure photos and EBSD. Taking both previous tensile, current fatigue and creep results into account, the conclusion is that the material is orthotropic.

Fracture surfaces indicate that both creep and fatigue testing at elevated temperature are very similar. Hence it cannot be excluded that creep play a role already at 450°C for this material, especially if the material is fine-grained.

5. Conclusions

A nickel-based superalloy manufactured by selective laser melting was investigated by mechanical testing and microstructural evaluations. The material is observed to have a layered weld-like structure. Due to the manufacturing process properties, a columnar grain structure is present. It is shown from mechanical testing that the material is orthotropic with respect to mechanical properties.

Fatigue properties in the 90° direction are comparable to hot rolled material at temperatures below temperatures where creep could be expected. However, in other directions < 90° the material is less resistant to crack initiation. The biggest concern with selective laser melted materials appears to be creep related. It is shown here that the creep properties are inferior to hot rolled material in all directions $0° \leq \alpha \leq 90°$ and that the material cannot compare to a standard hot-rolled material regarding creep. It is shown that the grain size is small, and it is well known that changes in grain size have a strong influence on both mechanical strength and creep properties.

Abstract To determine and quantify the influence of creep-fatigue interactions on the crack behaviour of P91 steel creep-fatigue crack growth (CFCG) tests were carried out with holding times up to 60 minutes and compared to results from fatigue crack growth (FCG) and creep crack growth (CCG) tests.
It was found that the introduction of a holding time influences the crack initiation time but not the crack propagation. With holding times of 60 minutes, the difference between CCG and CFCG tests is very small.
To characterise the fracture mode metallographic analyses were performed on selected specimens after CFCG tests. The crack path is inter-granular and an area of high cavity density was identified around the crack tip in all specimens. By comparing CFCG, FCG and CCG results, it can be finally noticed that specimens with a holding time of 6 and 60 min show a similar crack growth rate as samples under creep loading.

Keywords martensitic steel, creep-fatigue, crack initiation, crack growth

1. Introduction

In components operated at high temperature, there is always some amount of interaction between fatigue, creep and the environment. This is typically the case in power plants where steam generating service start-ups or load changes produce changes in steam conditions and transient temperatures. In the last decades, it has been proven that in the creep-fatigue range, the lifetime of components is significantly shorter, particularly when hold periods are introduced between strain cycles. These interactions can be enhanced due to environmental effects such as for instance internal or surface oxidation. They are finally more pronounced for some materials, can be neglected for others. In this work, the crack behaviour of the steel P91 was investigated in creep-fatigue tests. The aim of this analysis is to gain information about how the crack behaviour of this steel is influenced by creep-fatigue-environment interactions at high temperature.

2. Experimental Details

2.1. Material

The base material P91 (X10CrMoVNb9-1) being under investigation, comes from a thick pipe with outer diameter of 492 mm and wall thickness of 85 mm. Its chemical composition is given in Table 1. These values are in accordance with the EN10216 requirements [1]. The P91 pipe was used in [2] for the investigation of similar welds under creep conditions. A classical Post Weld Heat Treatment (PWHT) was therefore used to relax the stresses that were induced by the welding process.

Table 1. Chemical composition of P91 used in this work

		Chemical composition in mass (%)										
		C	**Si**	**Mn**	**P**	**S**	**Cr**	**Mo**	**Ni**	**Al**	**Nb**	**V**
[1]	Min	0,08	0,20	0,30	-	-	8,0	0,85	-	-	0,06	0,18
	Max	0,12	0,50	0,60	0,02	0,010	9,5	1,05	0,40	0,04	0,10	0,25
this work	Meas.	0,104	0,27	0,46	0,014	0,003	8,17	0,9	0,16	0,02	0,064	0,194

In order to optimize the full-use of the already acquired database, the P91 samples investigated in this work where submitted to the same heat treatment as follows: austenitising at 1050°C for 10 min with air cooling, tempering at 750°C for 70 min and PWHT at 760°C for 2 h as it is often performed for components with welds.
The microstructure of P91 consists of tempered martensitic, see Fig. 1. During creep, fatigue or creep-fatigue interactions, the microstructure of such steels is instable. A drop in the dislocation density, an augmentation of the subgrain size leading to an equiaxial microstructure and a growth in the size of precipitates such as carbides $M_{23}C_6$ ($Cr_{23}C_6$) and carbonitrides MX (VN, VC, NbC) in the matrix are influencing the global deformation behaviour.

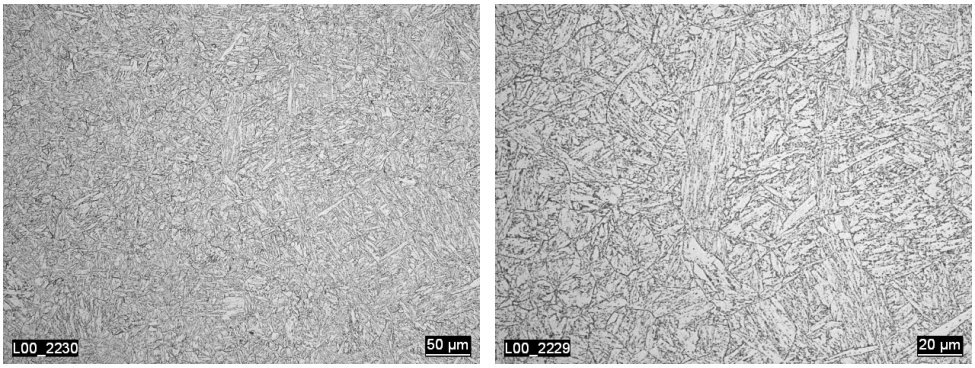

Figure 1. Microstructure of P91-steel, light optical images

2.2. Mechanical testing

For the crack growth tests side-grooved Compact Tension specimens C(T)-25 were used. The starter notch was realised by fatigue pre-cracking. All samples have an a_0/W-ratio in the range of 0.52 to 0.60. Creep Crack Growth tests (CCG) were performed according to ASTM E 1457-07 [3]. Creep-Fatigue Crack Growth tests (CFCG) were performed with a load ratio $R = F_{min}/F_{max}$ of 0.1 and with hold periods at maximum load of 6 and 60 min according to ASTM E 2760-10 [4]. Fatigue Crack Growth tests (FCG) were performed with a load ratio R = 0.1 and frequency of 0.5 Hz. All tests were carried out at 580°C and 600°C.
During the tests, the load line displacement was measured by means of capacitive high temperature strain gauges. The crack propagation was monitored online using the Alternating Current Potential Drop (ACPD) technique. At the end of each experiment, the potential drop signal was calibrated with the final crack length measured on the fractured specimens. For this, the specimen was broken up under liquid nitrogen after the test and the crack length was measured according to [3].

3. Description of crack initiation and crack propagation under creep and fatigue conditions

Crack initiation and crack propagation under creep conditions can be described by the usual fracture mechanics parameter C* and the stress intensity factor K_I.
- In linear-elastic fracture mechanics the stress intensity factor K_I is generally used for components with predominantly linear-elastic behaviour. Only a small plastic or creep zone at the crack tip can be assessed using this parameter. For side grooved C(T)-specimens the stress intensity factor is calculated as:

$$K_I = \frac{F}{\sqrt{B \cdot B_N \cdot W}} \cdot \left(2 + \frac{a}{W}\right) \cdot f\left(\frac{a}{W}\right) \quad (1)$$

$$f\left(\frac{a}{W}\right)=\frac{\left[0.886+4.64\cdot\left(\frac{a}{W}\right)-13.32\cdot\left(\frac{a}{W}\right)^2+14.72\cdot\left(\frac{a}{W}\right)^3-5.6\cdot\left(\frac{a}{W}\right)^4\right]}{\left(1-\frac{a}{W}\right)^{1.5}} \tag{2}$$

where F is load, B is specimen thickness, B_N is net thickness of side grooved specimens, a is crack length and W is test piece width.

- Components with stationary creep (not only at the crack tip) are assessed using the integral C*. In case of the experimental determination of the parameter C* approximation formulae can be used for a number of fracture mechanics specimens [5], which are basically functions of the load line displacement rate due to creep [3]:

$$C^* = \dot{v}_C \cdot \sigma_{net} \cdot \eta \tag{3}$$

with load line displacement rate $\dot{v}_C$, net section stress σ_{net} and the factor η depending on specimen geometry (η = [2+0.522•(1-a/W)] for C(T)-specimens).

For the evaluation of C(T)25-specimens the following equation was used:

$$C^* = \dot{v}\cdot\frac{F}{B_N\cdot c}\cdot\frac{h_1}{h_3}\cdot\frac{W/a-1}{\beta\cdot\eta} \tag{4}$$

where h_1 and h_3 are geometrical functions, c=W-a, and β: 1,071 for plain stress condition.

One of the validity criteria, which decide on the suitability of the relevant parameter, is the transition time t_1 [3]:

$$t_1 = \frac{K_I^2}{C^*\cdot(n+1)\cdot E'} \tag{5}$$

If t_1 is smaller than the crack initiation time $t_1 << t_i$ for the initiation criterion (Δa_i=0.5 mm) the parameter C* is more appropriate for the description of crack behaviour under creep conditions.

In order to describe the creep crack growth rate either the parameters C* or stress intensity factor K_I can be used, dependent on the situation in the component. Typically, the creep crack growth rate depending on the respective fracture mechanics parameter is presented as follows:

$$\frac{da}{dt} = C_1\cdot(K_I)^{m1} \tag{6}$$

$$\frac{da}{dt} = C_2\cdot(C^*)^{m2} \tag{7}$$

where C_1, C_2, m_1 and m_2 are material constants.

Fatigue crack behaviour can be described by threshold values for the beginning of cyclic crack growth and by the Paris-law [6] for the crack propagation:

$$\frac{da}{dN} = C_3\cdot(\Delta K)^{m3} \tag{8}$$

with C_3 and m_3 as material specific constants.

3. Results and Discussion

3.1. Crack initiation under creep-fatigue loading

The results of creep-fatigue crack growth tests as a function of stress intensity factor and initiation time are shown in Fig. 2 a compared to the creep crack growth tests and in Fig. 2 b compared to fatigue crack growth tests. In addition, the literature data from [7] are shown there.
An effect of holding time (HT) on the creep crack initiation time for the technical initiation criterion (Δa_i=0.5 mm) is observed, whereby the influence of HT of 6 min for both test temperatures is greatest. For lower loaded sample at 600°C (HT=6 min), the influence of the holding period on the initiation time is significantly lower than for the higher loaded specimen. This indicates the time-dependence during the holding period and the creep process seems to be dominant. If the holding time is one hour, the difference between the results of creep crack growth test and creep-fatigue crack growth test is small, especially at 600°C. The differences between the two specimens with short and long holding time at 580°C are not significant. This means that a reduction in time is expected due to cyclic stress for crack initiation. Literature data from [7] show no influence of the holding time on crack initiation time, so that these results can be described independently of the holding time by the creep curve in the investigated area (see Fig. 2 a).
Fig. 2 b shows the dependency of the cyclic stress intensity factor as a function of the number of cycles to crack initiation at Δa_i = 0.5 mm. It can be seen that the creep-fatigue specimens with short holding times are closer to the experiments under pure cyclic loading.

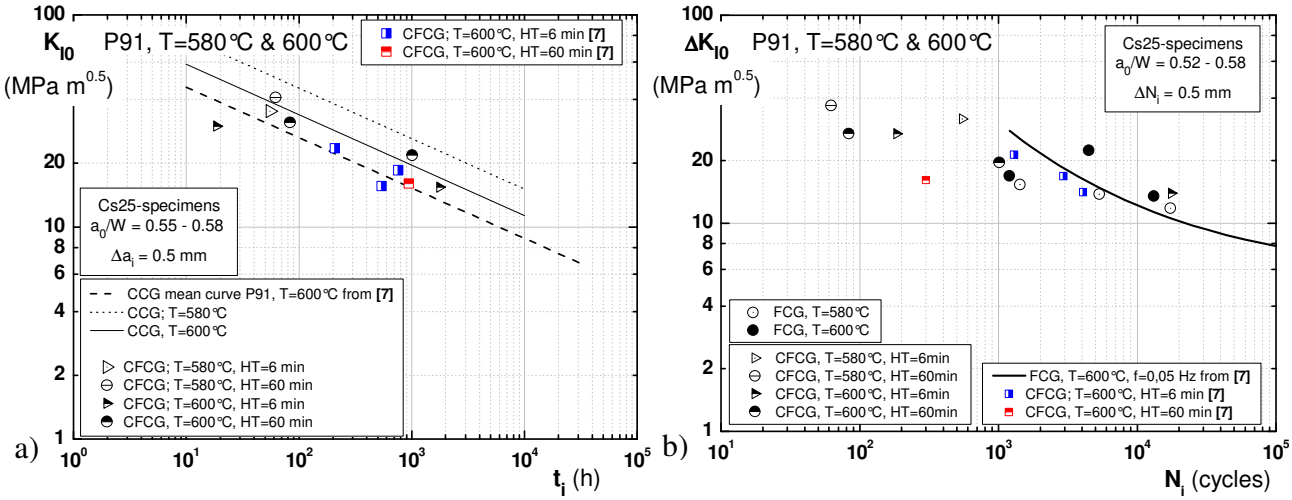

Figure 2. a) Stress intensity factor K_{I0} over time for Cs25-specimens (T=580°C & 600°C) under creep-fatigue loading compared to P91-steel mean curve for creep at 600°C from [7]; b) Cyclic stress intensity factor ΔK_{I0} over cycles for Cs25-specimens (T=580°C & 600°C) under creep-fatigue loading compared to the results under fatigue loading at 580°C and 600°C

In Fig. 3 the parameter C* is shown depending on the time to the crack initiation (determined at Δa=0.5 mm) under creep-fatigue condition. As expected, the creep-fatigue samples with longer holding periods are closer to the curve of creep crack growth tests.

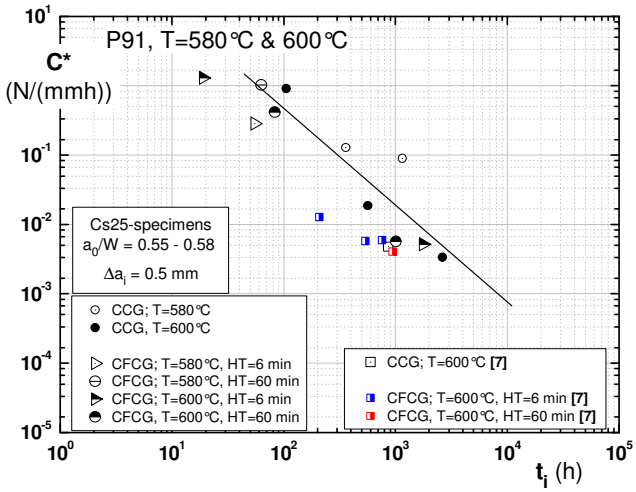

Figure 3. C* parameter over time for Cs25-specimens (T=580°C & 600°C) under creep-fatigue loading compared to P91-steel from [7]

3.2. Crack propagation under creep-fatigue loading

The comparison of CFCG- and CCG-experimental results shows (see Fig. 4 a and Fig. 4 b) that the specimens with a holding time of 6 min and 60 min have similar crack growth rates as samples without holding time, regardless of which of the two parameters describing the crack behaviour is used. No influence of holding time on crack initiation as described in the last section is observed for crack propagation. Thus, the cyclic loading has only an influence on the crack behaviour in the initial phase. In the holding time period the creep loading is dominant. Metallographic studies confirmed this observation so far (see next section).

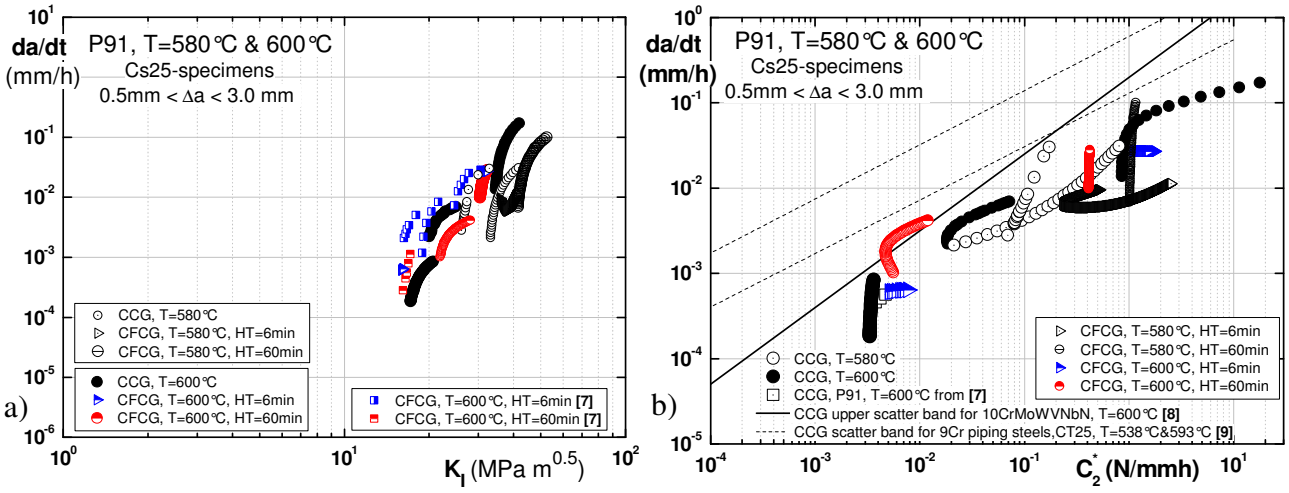

Figure 4. Creep-fatigue crack growth rate over a) stress intensity factor K_I and b) parameter C* for Cs25-specimens (T=580°C & 600°C) compared to literature data from [7-9]

In Fig.5 the results of fatigue crack growth tests at 580°C and 600°C are reported. The influence of temperature on the fatigue crack growth behaviour can be seen. The fastest crack growth rates are observed at 600°C. The results obtained in this work are similar to literature data from [9] for P91 at 565°C and a frequency f of 0.1 Hz. One sample at 600°C is slightly above the Paris-law curve, which can be explained by the different test temperature. It is also evident that results of CFCG-tests at 580°C and 600°C cannot be described by the Paris-law. The cyclic crack-growth rate increases if a hold time is imposed at maximum load. As the hold time increases, a change from cycle dependent to time dependent behaviour can be observed.

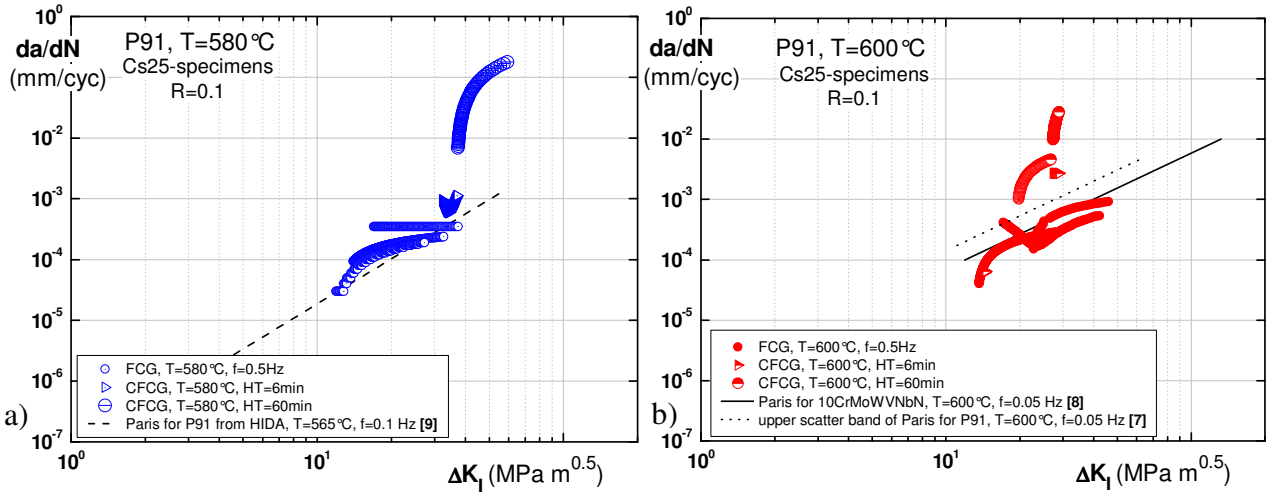

Figure 5. Creep-fatigue crack growth rate over ΔK_I for Cs25-specimens at a) T=580°C and b) T=600°C compared to literature data from [7-9]

3.4. Metallografic investigations

In Fig. 6 and Fig. 7, the crack paths for selected specimens of different crack growth tests are shown. A comparison of CCG-tests and CFCG-tests with a short and long holding time of 6 min and 60 min and under fatigue loading shows the different mechanisms that play a significant role in the crack propagation process.

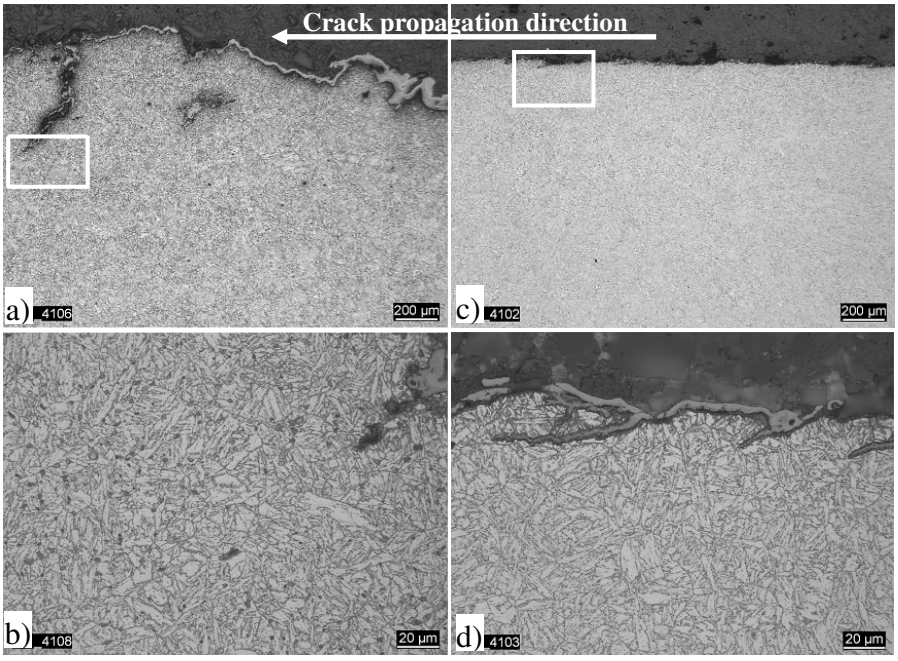

Figure 6: a) Specimen after CCG-test at 600°C, b) detail view from a); c) Specimen after FCG-test at 600°C, d) detail view from c)

A large amount of creep cavities is found on the prior austenite grain boundaries at the crack tip and along the crack path of a creep crack growth tested specimen (see Fig. 6a and b). Due to the strong oxidation of the crack surface, the crack cannot be clearly identified as inter-granular. Nevertheless, by comparing this specimen with the sample tested under pure fatigue loading (see Fig. 6 c and d), it is clear that the crack paths are different. This was already visible on the fracture surface. The surface of the specimen tested under fatigue loading was smooth, which suggests that the crack was

propagating trans-granular. This has been confirmed in an light-optical investigation of a cross section.

For the samples tested under creep-fatigue loading (see Fig. 7) the crack behaviour was found to be independent on the holding time similarly like specimens tested under creep loading (Fig. 6 a, b). Around the crack tip an area of high cavity density was identified and the crack path under creep-fatigue loading is comparable with the crack path under pure creep condition. Also along the crack path creep cavities were observed.

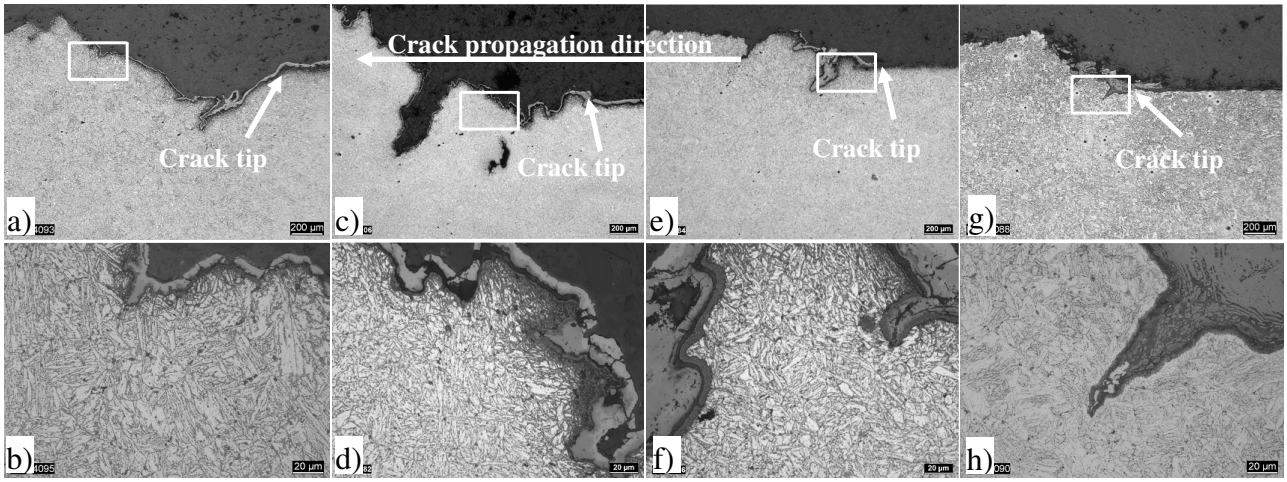

Figure 7: Specimen after CFCG-test at 580°C with a), b) HT=6 min (b) detail view from a)), c), d) HT=60 min (d) detail view from c)), at 600°C with e), f) HT=6 min (f) detail view from e)), g), h) HT=60 min (h) detail view from g))

3.3. Creep-fatigue interactions

The crack propagation rate da/dN under creep-fatigue loading is influenced by two failure mechanisms, and therefore depends on the load level, the mean stress, the stress ratio R and the temperature. Generally, there are three different areas [10]. At high frequencies, the crack growth per cycle is independent of frequency, because the cycle duration is so short that no time remains for creep crack growth. With decreasing frequency, the crack growth per cycle da/dN is greater. The time between two load cycles is then sufficiently large, so that fatigue crack growth and creep crack growth can overlap. With further decreasing frequency of the fatigue crack propagation loses its meaning. The crack propagation is now determined only by creep crack growth.

In literature [11, 12] different relationships exist to describe the crack growth under creep-fatigue loading, for example the following equation recommended for creep-ductile materials (see also [4]):

$$\frac{da}{dN} = C_0(\Delta K)^{n0} + \int_0^{t_h} C_1((C_t)_{avg})^q dt \tag{9}$$

According to [11] the final equation can be:

$$\frac{da}{dN} = C_0(\Delta K)^{n0} + C_1 K^{2m} t_h^{\,1-m} + C_2 C^{*m} t_h \tag{10}$$

with t_h as holding time. The first term is a pure-fatigue contribution reflecting no effect of hold time and corresponding to crack-growth behaviour at short hold times and high frequencies. This term can be evaluated if the Paris-law coefficients are available. For further evaluation, the coefficients from Table 2 will be used. The second term shows a nonlinear power-law dependence of

crack-growth rate on hold time and pertains to intermediate hold times and frequencies where creep-fatigue interaction is present. The coefficient C_1 was adopted from literature data for 1CrMoV-steel and 304 stainless steel [11]. A value between 10^{-7} and 10^{-6} for different materials at high temperature was found to be appropriate. For further evaluations a value of 10^{-6} was assumed, see Table 2. The third term including the C* parameter shows a linear dependence of crack growth on hold time and corresponds to purely creep-dominated crack growth occurring at long hold times and low frequencies [11]. Using the solutions for stress intensity factor K, and C* by appropriate Norton-law coefficients, the values from Table 2 are applied for the assessment.
With the accumulation rule according to Eq. (10) the results of creep-fatigue tests on P91-steel were evaluated under creep-fatigue loading and $R = F_{min} / F_{max}$=0.1. The assessment was carried out for C(T)-25 samples with a_0/W – ratio of 0.55.

Table 2. Material related parameters for describing the crack growth rates of P91

		Fatigue		Interaction		Creep	
		C_0	n_0	C_1	m	C_2	m
Eq. 10	580°C	8,85E-08	2,49	1E-06	0,66	4,21E-02	0,66
	600°C	8,85E-07	1,91				
Eq. 11	580°C	8,85E-08	2,49	-	-	6,17E-13	0,70
	600°C	8,85E-07	1,91	-	-		

The comparison between calculated and experimentally determined values is shown in Fig.8. The calculated values are overestimated for both temperatures and holding times. The creep portion is dominant in this case, so that the crack growth can be described based on creep only using C*. The biggest uncertainty here is the determination of C* with the Norton-approach, as the results are strongly influenced by changes in the Norton coefficients.

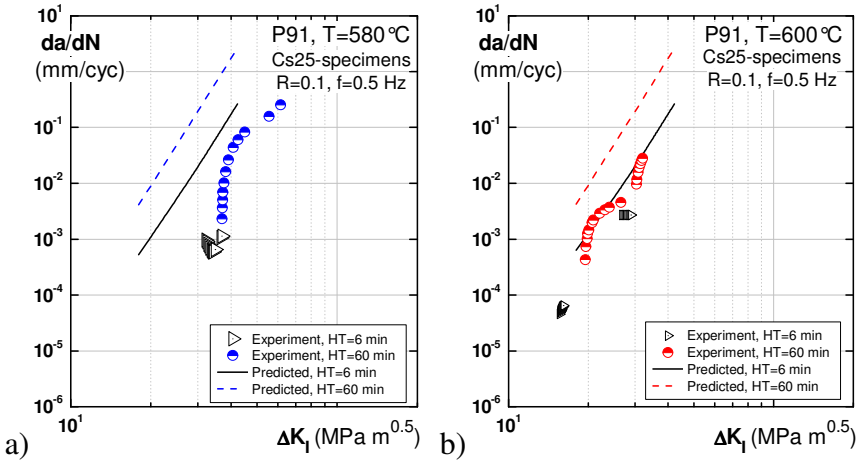

Figure 8. Creep-fatigue crack growth rate over ΔK_I for Cs25-specimens at a) T=580°C, b) T=600°C

Another commonly used approach based also on simple linear superposition of creep crack growth and fatigue crack growth is the model applying the fracture mechanics parameters ΔK for fatigue load and K for creep load [7]:

$$\frac{da}{dN}_{CFCG} = \frac{da}{dN}_{FCG} + \frac{1}{f} \cdot \frac{da}{dt}_{CCG} = C_0 (\Delta K)^{n0} + C_2 K^m \cdot t_h \qquad (11)$$

The results of the evaluation by this rule are shown in Fig. 9. It can be seen that this approach describes the behaviour under creep-fatigue loading much better, although the material is creep-ductile. At 580°C and the hold time of 6 min the influence of the fatigue proportion on the

crack growth can be recognize. For a holdtime of 60 min it is obviously that the behaviour is time dependent. At 600°C and both holding times, it is apparent that the rule describes the crack growth behaviour of creep-fatigue specimens quite well. Fig. 9e shows the dependence on the crack growth rate at 600°C on the holding time for a constant value of ΔK=27.2 MPam$^{0.5}$. In this case, the cycle/time dependent transition for this material can be expected at holding times greater than 0.1 minutes.

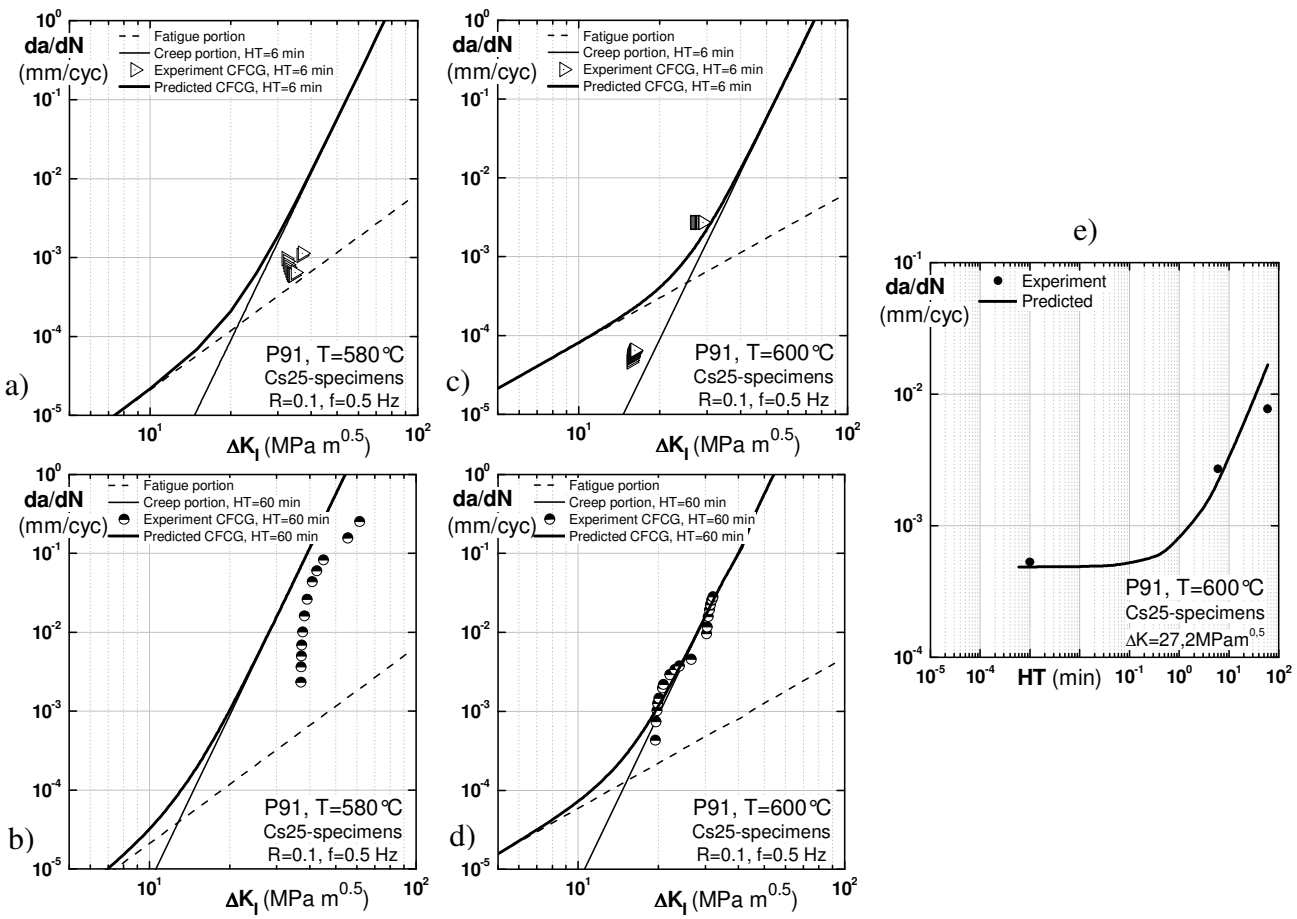

Figure 9. Creep-fatigue crack growth rate over ΔK_I for Cs25-specimens at a)&b)T=580°C, c)&d) T=600°C, e) Creep-fatigue crack growth rate over holding time for ΔK_I =27.2 MPam$^{0.5}$ at 600°C

4. Summary

The results of investigations on P91-steel show, that the creep crack initiation behaviour can be described by the parameter C* and by the stress intensity factor K_I. Due to the high creep ductility of P91 the C*-parameter is preferable. An effect of holding time (HT) on the creep crack initiation time is observed, whereby the influence of 6 min HT for both test temperatures is greatest. If the holding time is 60 min the difference between the creep crack growth test and creep-fatigue crack growth test is small, especially at 600°C. At 580°C the influence of short and long holding time on the crack initiation time for two creep-fatigue experiments is comparable. This means that a reduction in time is expected due to the cyclic stress for the crack initiation in the investigated range.

The crack propagation behaviour of P91-steel under creep conditions can be described both by the parameter C* and the stress intensity factor K_I. The Paris-law describes fatigue crack propagation. An influence of the temperature on crack propagation under fatigue loading can be observed, crack growth rate increases with increasing temperature. By comparing CFCG- and CCG-experimental

results, it can be noticed that specimens with a hold time of 6 min and 60 min have similar crack growth rate as samples without holding time, regardless of which of the two parameters describing the crack behaviour is used. Contrary to the influence of hold time on crack initiation almost no influence is observed on crack propagation. Hence, cyclic loading has only an influence on the crack behaviour in the initial phase. In the holding period creep loading is dominant.
Metallographic analyses show that the crack propagates inter-granularly under creep load and a large amount of cavities are found on the prior austenite grain boundaries near to the crack tip. Under fatigue loading trans-granular cracks without cavities were observed. For the samples tested under creep-fatigue loading the crack behaviour was found to be independent of the holding time. Around the crack tip an area of high cavity density was identified and the crack path under creep-fatigue loading is comparable to the crack path under creep condition.
The crack propagation under creep-fatigue loading is influenced by two failure mechanisms, and therefore depends on the load level, the mean stress and the temperature. With decreasing frequency the mechanisms changes from cycle dependent at high frequencies to time dependent at lower frequencies. In literature, different relationships exist to describe the crack growth under creep-fatigue loading, which were investigated in this study. It has been shown that the accumulation rule based on stress intensity parameter K_I better describes the crack growth behaviour of P91 under creep-fatigue loading. If the creep portion is described by parameter C*, the crack growth behaviour is overestimated. This may be the effect of the relatively large scatter of experiments data, or may result from uncertainties in the determination of C*.

Abstract One of the many challenges in the behaviour of structures is to understand if the presence of residual stress plays an important role in contributing to failure of a structure operating at high temperature. A typical example is the reheat cracking, associated with the austenitic stainless steel welded components, where the presence of residual stress is seen as a major factor. A review of previous methods that introduce residual stresses into specimen indicated that a method that doesn't introduce microstructural changes during the generation of residual stresses should be sought. The purpose of this paper is to describe a new method of introducing long range residual stresses at high temperature. The method uses a three bar structure with an initial misfit introduced into the central bar to represent a long range residual stress. The rig was designed so that the induced residual stresses could be characterised easily without using time consuming residual stress measurement techniques. Initial results demonstrated that the magnitude and the interaction of the residual stress with the applied loading is a function of the initial misfit displacements and the relative stiffness of the components of the system. Additionally, the subsequent behaviour of the system, with and without the application of additional loading, is governed by (a) the degree to which the misfit is accommodated by plastic and creep strain and (b) the elastic follow-up provided by the system. The paper describes the design of a test rig and laboratory tests conducted to validate the method.

Keywords Residual stress, Creep, Elastic follow-up, 316H stainless steel

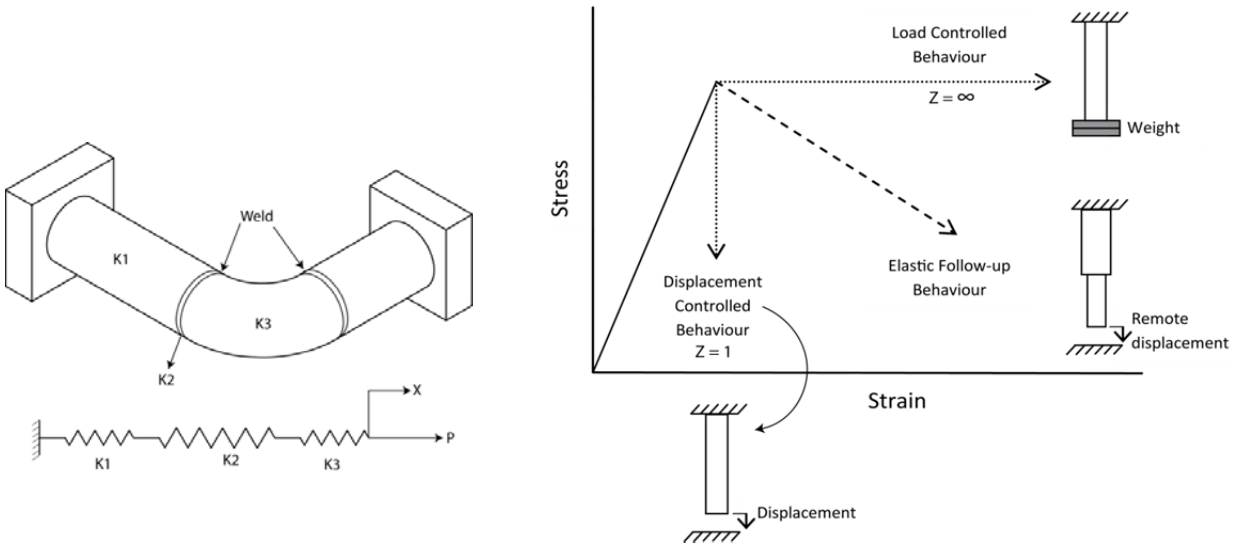
1. Introduction

Residual stress plays an important role in the component life assessment of the structures. Such stresses may arise usually as a consequence of the manufacturing process and final fabrication. Welding is a typical manufacturing process where, unless the component is subjected to post-weld heat treatment, the residual stress can attain a value close to or equal to the yield stress. Fabrication can also lead to additional locked-in stresses developed from the fitting-up of the different parts of an assembly [1]. Residual stresses are usually treated as secondary stresses. However, in certain circumstances they must be classed as primary. For example, in a cracked structure where the fit-up residual stresses do not self-equilibrate across a ligament, the residual stresses may provide a significant contribution to the plastic collapse of the ligament. Whether they do or not depends on how the residual forces change as a crack grows and plastic deformation accumulates in the structure. This in turn depends on the level of elastic follow-up (EFU). A typical practical case where we expect to see the effect of EFU is shown in fig 1 for a pressurized piping system. As shown schematically, the system and its welds can be treated as a series of springs with the pipe having stiffness K1, K3 and the weld with stiffness K2. When the pipe is built-in and welded we would expect that long range residual stresses to be present and are represented as an initial far field displacement X. The pipe will also be subjected to internal pressure and consequently the system is also subjected to external load P. Elastic follow-up is expected when part of a structure (the area around the welds) reduces its stiffness (either through creation of plasticity and/or the growth of crack) relative (i.e. EFU) to the surrounding material. This would result in additional strain accumulation and relaxation of the initial stresses created during the welding and fit-up.

Many methods have been proposed to generate well defined residual stress fields in laboratory test specimens. In the context of investigating the influence of residual stress on creep, the following

methods have been developed: pre-compression [2-6], quenching [7], side punching [8], Borland specimens [9], ring-weld specimens [10] and electron beam (EB) welding [1, 11, 12]. These methods produce either long-range or short-range residual stress fields. Quenching, Borland specimens and ring welding methods result in specimens with a residual stress field throughout the entire volume. On the other hand, side punching, in-plane compression and EB welding methods result in a residual stress field being set up in a very localised part of the specimen. The second group of methods rely on local, rather than global, incompatible displacements to set up the residual stress field.

Another important observation is that the in-plane compression and EB welded specimens require the introduction of a sharp notch by for example electro-discharge machining, prior to creep testing. Introducing such a notch redistributes the residual stresses and so, care must be taken to ensure that the required levels of residual stress remain in the specimen after this redistribution. Consider the in-plane compression method as an example. Here, a volume of material local to the semi-circular stress raiser deforms plastically and this plastic zone resists the relaxation of the surrounding material. If a long notch is introduced such that it extends through the plastic zone and into the surrounding elastic zone then the elastic zone is free to relax and the residual stress field is lost [11].



(a) (b)

Figure 1. (a) Built-in welded pipe bend (P is load, X is displacement) (b) Stress-strain behaviour of a local volume

In all the above methods the magnitude and distribution of residual stress are found by time consuming methods i.e. neutron diffraction. Also, in all the cases various and nominally identical specimens are manufactured to determine the stress distribution. For example in case of cylinder quenching by Hossain [7], three specimens were manufactured and the neutron diffraction method was used to measure the stress distribution after quenching, short term ageing (1.25 hrs) and long term ageing (1800 hrs). In all of the above methods, residual stress is introduced at room temperature and when the specimen is subjected to high temperature the magnitude of residual stress is reduced drastically (≈30% reduction) [2-8] due to the lower yield strength at high temperature. In all the cases, the residual stress at high temperature was determined using finite element analysis.

In order to study the effect of residual stress, it is desirable that the method chosen to induce residual stress in the specimen causes no other changes which might influence creep. It is also desirable that residual stress fields set up in the laboratory creep specimens are representative of the long range residual stress fields found in engineering structures.

Of the various methods reviewed only side punching, in-plane compression and EB welding have been used to study the effect of residual stress and applied load on creep under load control conditions. These techniques can also be used to carry out displacement controlled tests. In practical circumstances relaxation of residual stress in one section is compensated by changes in residual stress distribution in other sections to keep the complete structure in equilibrium, i.e. components are often subjected to combined displacement and load controlled situations as shown in fig 1b. It is not possible to study this effect using the reviewed samples and techniques.

A new method is presented that introduces residual stress in a controlled manner such that the stress can be calculated easily at any time and without the use of time consuming residual stress measurement techniques.

2. Three bar structure

The new method is based on a classical three bar model and is developed to introduce long range residual stresses through strain incompatibility. This model (or system) has several key features relevant to the high temperature problems of creep crack initiation and growth. The magnitude and the interaction of the residual stress with the applied loading are a function of the initial misfit displacements and the relative stiffness of the components of the system. The subsequent behaviour of the system, with and without the application of additional loading, is governed (a) by the degree to which the misfit is accommodated by plastic and creep strain and (b) the elastic follow-up provided by the system.

2.1. Model

Figure 2 shows the three bar structure model consisting of two outer bars ‘B’ and a central bar combination of bar ‘A’ and a compact tension, C(T) specimen. The bars A and B are able to deform elastically and have stiffness K_{in} and K_{out} respectively. An initial misfit, ‘X’ exists between the bars so that joining the bars together introduces fit-up residual stresses into the system, with tension in bar A and balancing compression in bar B. The residual force in the middle bar does not self equilibrate across a section but the tensile residual force in middle bar is in equilibrium with the net compressive force in the outer bars. The structure can be subjected to the applied load ‘P’ so that when plasticity, creep or crack growth occurs in the C(T) specimen and the overall EFU factor, Z is given by

$$Z = Z_{eff} Z_s \tag{1}$$

where,
$$Z_{eff} = \left(\frac{1+\alpha_{eff}}{\alpha_{eff}}\right) \text{ and } Z_s = \left(\frac{1+\beta}{\beta}\right)$$

$$\beta = \frac{K_{in}}{K_s}\ , \quad \frac{1}{\mathrm{K_{eff}}} = \frac{1}{\mathrm{K_S}} + \frac{1}{\mathrm{K_{in}}}\ , \quad \alpha_{eff} = \frac{2K_{out}}{K_{eff}} \tag{2}$$

and K_s is the stiffness of the specimen.

A detailed derivation of this is given in [13]. Figure 3 shows the overall elastic follow-up factor as a function of relative effective stiffness ratio. When the elastic follow-up factor is in excess of 6 (or 1/Z=0.167) these conditions essentially correspond to load controlled conditions, where as an elastic follow-up factor of more than 1.25 (or 1/Z=0.8), represents displacement controlled conditions.

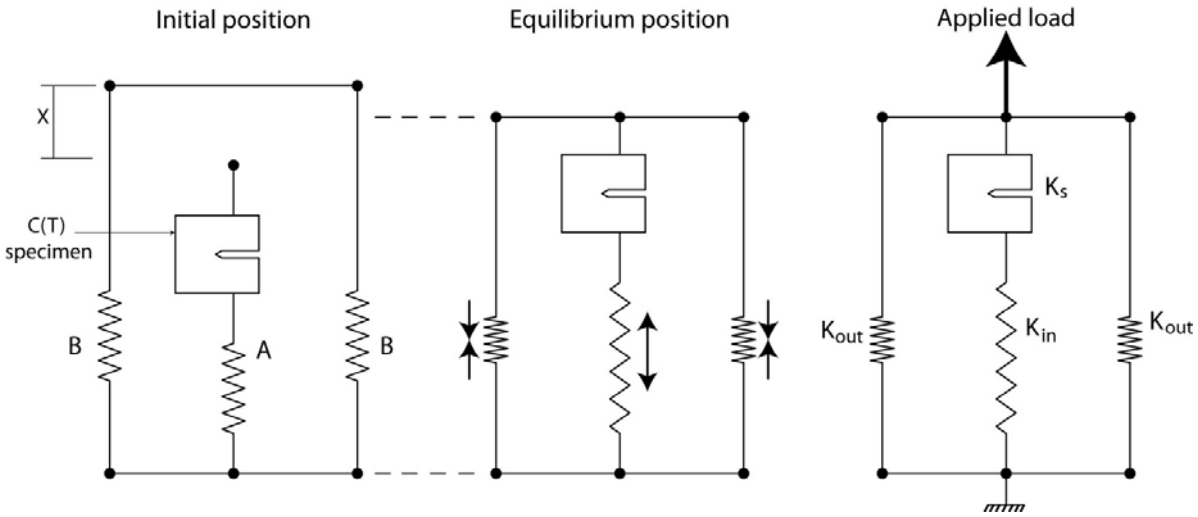


Figure 2. Three bar structure

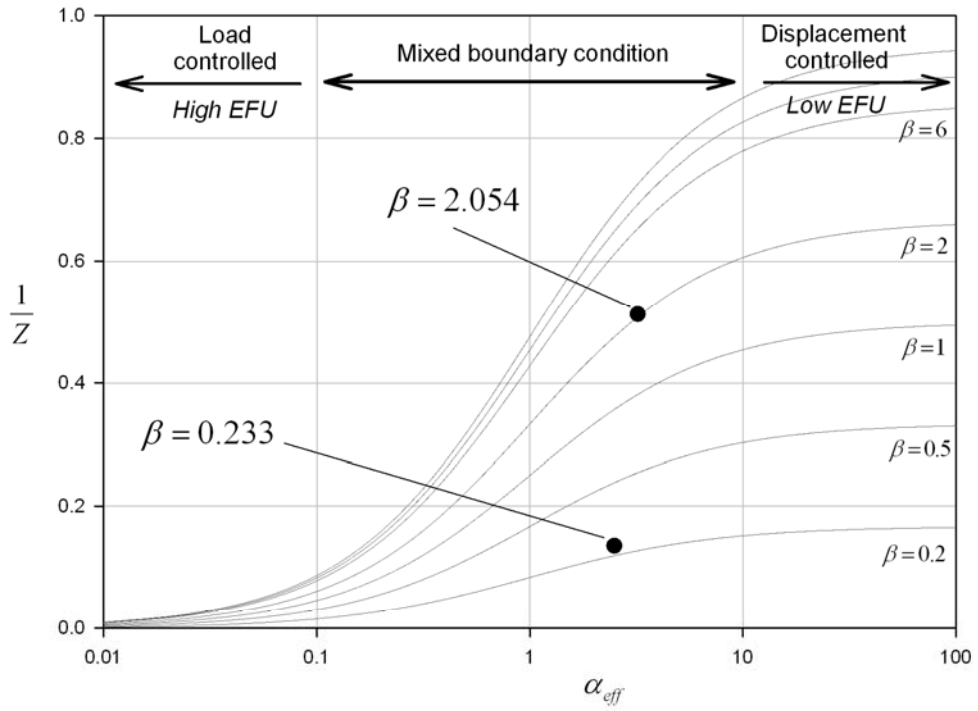

Overall EFU Z	1/Z	β	Diameter of bar (mm)		Overall length (mm)
			Middle	Side	
1.86	0.538	2.054	25.4	19.05	714
6.61	0.151	0.233	10	10	864

Figure 3. Variation of overall EFU with effective stiffness ratio in three bar structure

2.2. Behavior of the structure with applied load

Figure 4 shows loading conditions and relaxation during plasticity for a representative three bar structure. AA' gives the initial misfit, OB and OB' give the residual force in middle and outer bars respectively. When the structure is further subjected to external load, the force in the middle bar increases from B to C. At point C yielding of specimen starts and the specimen takes no further load and follows line CD while outer bar remains in the elastic range and follows path A'D'. Until yielding at point C, the initially induced residual force remains constant in the middle and outer bars and follows paths B-1 and B'1' respectively. As the applied load increases and the amount of plastic deformation in the specimen becomes equal to the initial misfit, the residual force reduces to zero. The rate of residual force relaxation for a mixed boundary condition follows path 1-2. The gradient of relaxation curves (1-3,1-2 or 1-4) depend upon the elastic follow-up factor. Structures having high EFU will follow path 1-4 while low EFU structures will follow path 1-3. Hence, the influence of initial residual stress present in a structure is dependent on the associated level of EFU.

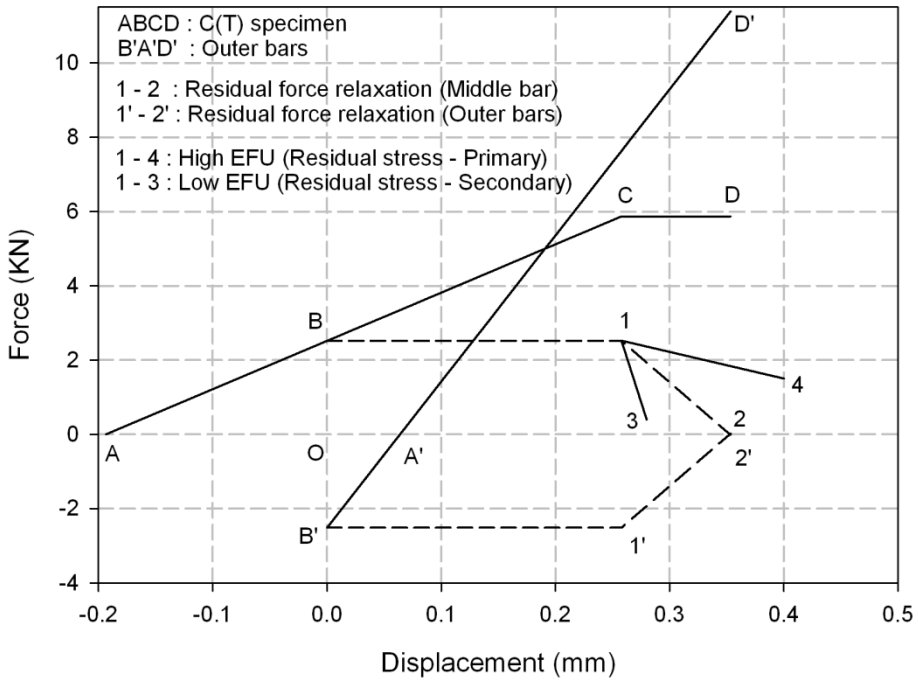

Figure 4. Loading and subsequent relaxation of a three bar

3. Experimental studies

3.1. Design of test rig

An experimental three bar test rig was designed based on the conceptual model discussed in the earlier section. Since the design was centered around a conventional cylindrical furnace with a maximum internal diameter of 130 mm for a creep test frame, the design was constrained to the available maximum diameter of the furnace, the overall length of the structure (1000 mm), the ease of assembly, the ability to introduce known residual stress at high temperature and then to apply a predetermined load to the assembly. The overall arrangement of the test rig is shown in fig 5 and the material properties of the components for the test rig are tabulated in table 1. The middle bar was a combination of 316H stainless steel C(T) specimen and a Nimonic bar of diameter 25.4 mm while the side bars were Nimonic bars of diameter 19.05 mm. These dimensions are selected to provide an EFU value of about 2 (as shown in fig 3). All bars were screwed to a top and bottom end piece

made from EN24T steel. Two linear voltage displacement transducers (LVDT) were mounted on each side of the upper and lower end to measure the total displacement of the structure. Also, two additional LVDTs were connected to the C(T) specimen to measure load line displacement. Four high temperature strain gauges (ZFLA-3-11) were mounted on the middle and side bars at 90^0 intervals to measure the residual force. In total seven thermocouples (3-specimen, 1-room, 3-strain gauge) were connected to measure the specimen temperature, room temperature and temperature at the point of application of strain gauges. A direct current potential drop (PD) system was connected to the C(T) specimen to measure crack initiation and growth. The overall arrangement was fitted into a creep test rig so that an external load was applied to the assembly via a lever arm arrangement.

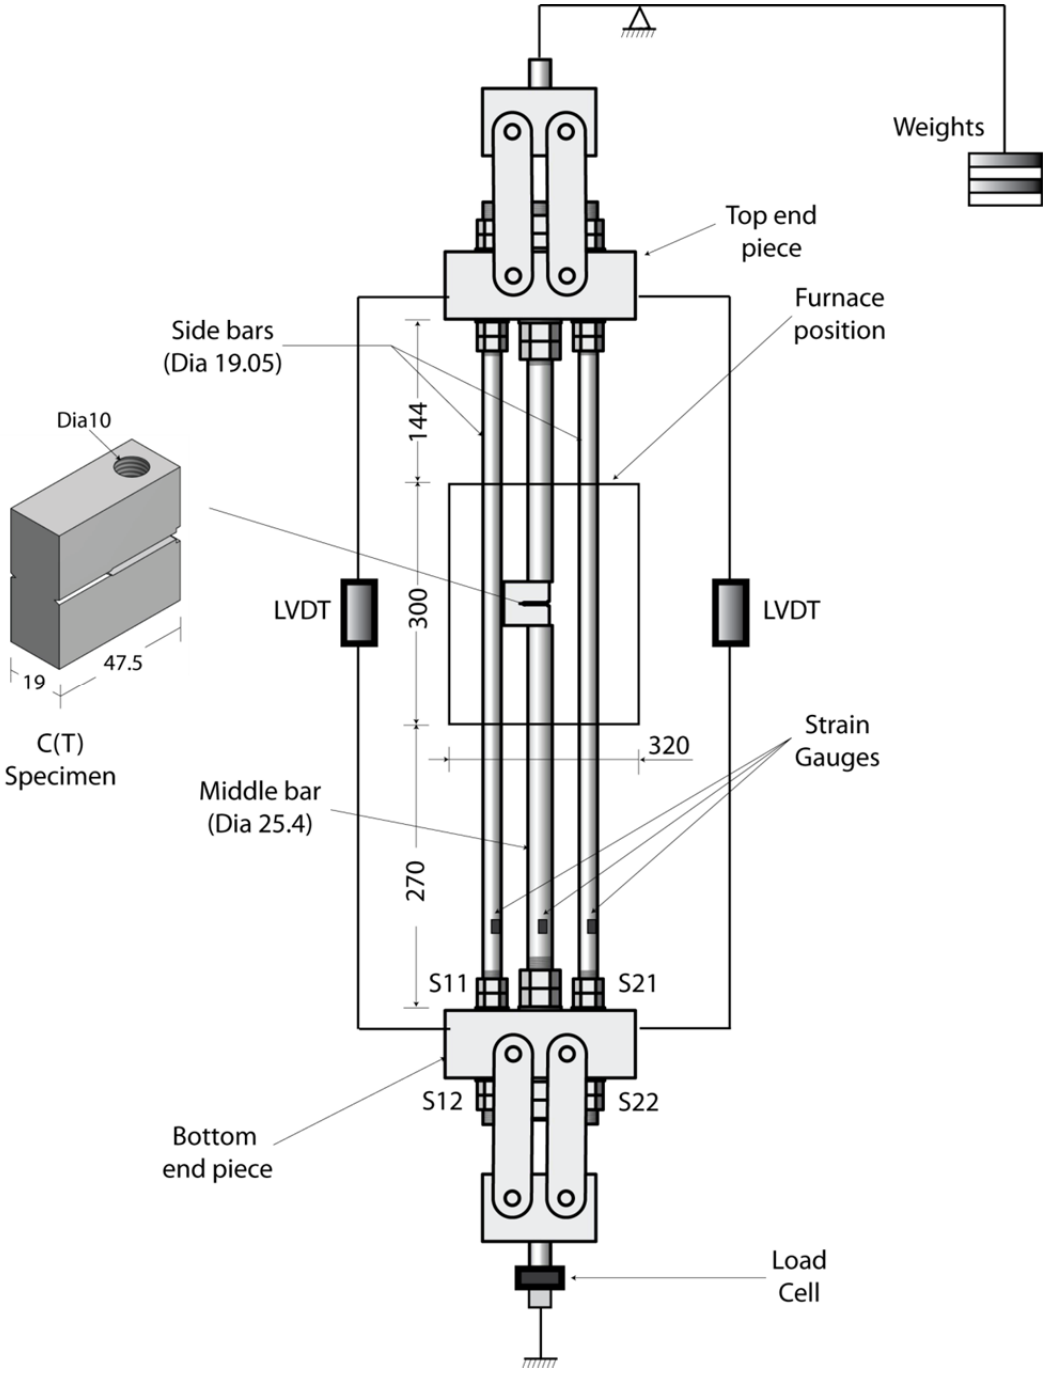

Figure 5. Three bar test rig (All dimensions in mm)

3.2. Calibration tests

A series of calibration tests were conducted and divided into two categories; preliminary tests and an load-unload test. Tests were carried out at high temperature and using a 316H stainless steel C(T) specimen. The C(T) specimen was manufactured as per ASTM 1457 but using a screw fitting arrangement rather than pins to load the specimen. This was adopted to ensure accurate measurement of stiffness rather than conventional pin loading. To restrict the crack growth, a 1 mm diameter hole was introduced at the end of standard 0.1 mm wide EDM notch.

Preliminary tests were conducted to determine the stiffness of bars, specimen and determine the overall elastic follow-up value for the rig experimentally. Two applied load tests, within the elastic region, were conducted such that in each case the temperature of the C(T) specimen was maintained at 550^0C. In the first test only the middle bar with the C(T) specimen was connected to both end pieces. In the second test both the side bars are connected to the top and bottom end bars but the middle bar with C(T) specimen was connected only to the top end piece such that it was free to move (i.e. used to record the C(T) specimen temperature). In each case, the load cell, the temperature at different locations, strain gauge, total displacement and CMOD were measured. The results from these tests are discussed later.

The second category of test was a load-unload test undertaken to understand the relaxation of residual force with applied load. First, a residual stress was introduced into the structure. The middle bar with the C(T) specimen was connected to both end pieces. Side bars were connected to only the top end piece and were free to move through the clearance holes in the bottom end piece. All instruments were then connected to the test rig and the furnace was heated to achieve 550 ^{0}C for the C(T) specimen. This arrangement permitted free thermal expansion of the bars and the specimen. When a stable temperature was achieved, nuts S11 and S21 (shown in fig 5) were screwed down, so that the top and bottom end pieces were forced apart. This resulted in the middle bar loaded in tension and the side bars carried the balancing compressive forces. The force in each bar was determined via the strain gauges. Finally when the desired residual force was introduced into the structure, nuts S12 and S22 on side bars were fixed. Having introduced the desired residual stress into the C(T) specimen, the entire assembly was repeatedly loaded and unloaded to progressively higher load levels. The residual force in all three bars, load line displacement of C(T) specimen, potential drop readings and overall extension of the rig were recorded for both load and unload path.

Table 1. Properties of materials for three bar structure

Material	Young's Modulus (GPa)	Yield Strength (MPa)	Tensile Strength (MPa)
316H stainless steel at 550^0C	151	172	444
Nimonic 80A at 550^0C	187	875	1210
EN24T Steel at room temperature	210	680	925

4. Results and discussion

The theoretical value of the overall elastic follow-up of the rig was calculated using the equations provided in [13]. Results from the preliminary tests consisted of measured strains, applied load, CMOD, overall displacement of the rig, accurate measurement of the diameters and length of the bars. The initial tensile tests measured the stiffness for each element of the assembly. Table 2 compares the experimental values obtained from preliminary test with theoretical values. It is evident from the results that a good agreement was found.

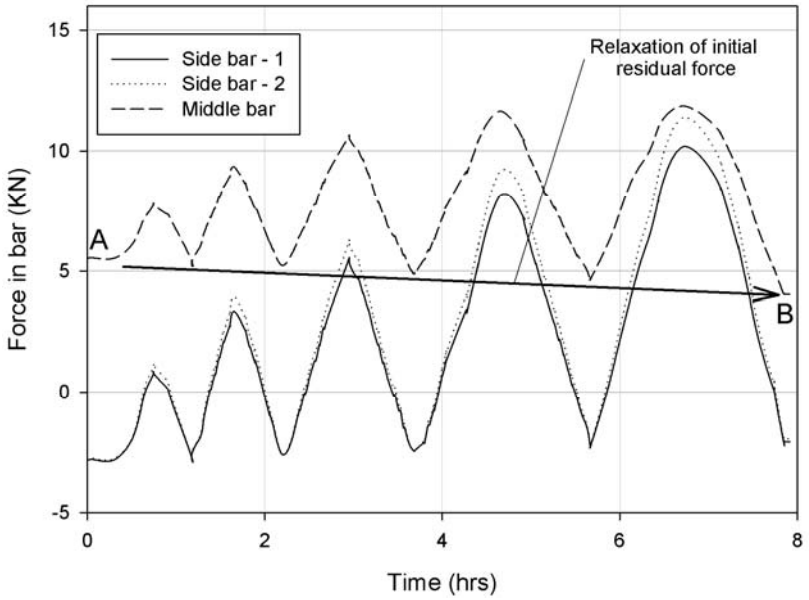

Figure 6. Variation of force in all bars with time

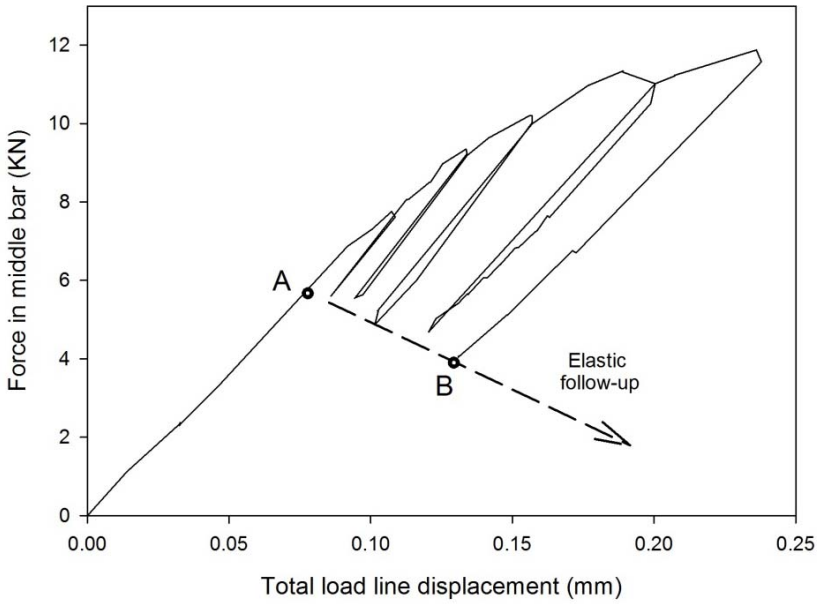

Figure 7. Load versus total load line displacement for C(T) specimen

The test results from the second category of tests are shown in fig 6, and give the details of variation of the residual force and its relaxation as the applied load increased. It is observed that under equilibrium condition, the total compressive residual force in the side bars was approximately equal

to the tensile residual force in middle bar. During the cyclic loading process, the tensile residual force in middle bar relaxed from 5.65 KN to 3.8 KN while the compressive residual force in the side bars relaxed from 2.8 KN and 1.9 KN.

Figure 7 shows the load acting on C(T) specimen against total load line displacement measured during the cyclic loading phase of the test. The following points should be noted. First at point 'A' the C(T) specimen was subjected to a tensile load of 5.65 KN while the total load applied to the assembly was zero. This tensile load corresponds to the initial level of preload in the assembly at the start of the cyclic loading phase of the test.

Second, five unloading lines did not return to the CMOD point 'A' from which the test started. This was due to the accumulation of plastic deformation in the specimen. It can be seen that about 0.06 mm of plastic CMOD had accumulated at the final unloading step. Also, the gradient of each of the unloading lines remained constant. This shows there has been no crack growth during cyclic loading and the same was recorded by PD system.

Third, the line AB corresponds to the locus of unloaded points and reveals that the initial preload relaxed, as plastic deformation accumulated in the specimen thereby reducing the misfit. At point B, with an applied load of zero, the 3.8 KN load on the C(T) specimen corresponds to the level of preload remaining in the assembly i.e. 33% reduction in the initial preload level. An important feature of the behaviour of this assembly is that the relaxation line AB has a slope dependent on the relative stiffness of the assembly and in turn corresponded to the EFU associated with the structure. To achieve different values of EFU, different combinations of diameters of the middle and the side bars can be used. For example, in the present rig if the dimensions are changed so that the middle and side bars diameter is 10 mm and overall height is 864 mm, one can achieve overall EFU of 6.61 (1/Z=0.151) as shown in fig 3.

5. Concluding remarks

Four methods of inducing residual stress in laboratory creep specimens were reviewed. These include quenching, side punching, in-plane compression and welding methods. It was found that the ability of these methods to provide insight into the effect of residual stress on creep in engineering structures is limited. These methods cause micro-structural changes to the material as well as inducing residual stress. Also, the short-range residual stresses produced by some of the methods do not accurately represent the long-range residual stresses found in many engineering structures. In each of these methods residual stress measured at room temperature before the start of test will change when the specimen is subjected to high temperature. None of the methods determine the effect of residual stress on creep and complete structure when the residual stress relaxes. We therefore conclude that new methods which can induce long-range residual stress without causing micro-structural change in the material and can represent combine boundary condition are required.

A new method based on a three bar structure illustrated that residual stresses can be induced into a specimen at high temperature in a controlled manner and can be characterised easily without the use of time consuming measurement techniques. The proposed method does not cause any micro-structural change in the specimen and provides details of residual stresses distribution in complete structure at any time. Calibration tests revealed that the structure replicates mixed boundary conditions. Different combinations of diameters of the middle and side bars can be used to achieve different elastic follow-up factors and can therefore study the influence of EFU on initial residual stress and structure as a whole. The new method and the test rig designed can be used for both cracked and uncracked specimens to carry out short and long term creep tests.

Abstract In this paper, a three bar structure is examined to simulate the behaviour of a component subjected to combined applied and residual stresses. This structure (or system) permits long-range residual stress to be created in a compact tension (CT) specimen through the introduction of a misfit. The magnitudes of the residual and applied stresses in the CT specimen are a function of the initial misfit displacements, applied load and the relative stiffness of the components of the system. The prediction of cracking initiation under combinations of residual and apply loads are investigated when the compact tension specimen creep according to a power law. We find that the creep crack initiation time is sensitive to the assumed creep constants and is significantly different under different loading conditions. The effect of residual stress on the crack initiation time is dependent on the ratio of the residual stress to the total stress. Overall, this study provides important insights into the assumptions adopted in structural analysis for creep crack initiation.

Keywords Crack initiation, Residual stress , elastic follow-up, 316H stainless steel

1. Introduction

Many components operating at high temperature are subjected to combinations of applied and residual stresses, especially welded steel sections. Evidence from industry is that the presence of residual stress is a contributing factor for initiation and growth of creep cracks, which has important consequences for the lifetime of components at high temperature. A typical practical example is reheat crack initiation observed in stainless steel welded components where the presence of residual stress is seen as a major factor [1]. In this paper, the purpose is to better understand whether the existence of residual stress plays an important role in contributing the crack initiation in components driven by a combination of applied and residual stress at elevated temperature. Previous work involved generating residual stresses directly into specimens using a variety of methods. A recent review of this work [2] concluded that in order to improve our understanding of the effects of residual stress on fracture new methods should be sought that do not introduce microstructural changes during the generation of residual stress. Therefore, in this paper we develop a simple method of introducing long range residual stress through strain incompatibility in a classical three bar model. An additional force can applied to the three bar structure system to simulate the behaviour of a component subjected to combined applied and residual stresses. The subsequent creep behaviour is governed by the materials properties and elastic follow-up provided by the system. Elastic follow-up is a consequence of the presence of a region of differing stiffness relative to the remainder of the structure. [3].

In parallel to a series of laboratory tests [4], an analysis is presented to predict creep crack initiation for different levels of elastic follow-up. We find is that the crack initiation time is sensitive to the assumed creep constants and is significantly different under different loading conditions. The effect of residual stress on the crack initiation time is dependent on ratio of the residual stress to the total stress. Overall, this study provides important insights into the assumptions adopted in structural analysis for creep crack initiation.

2. Response of the three bar system

In this analysis, the response of the three bar system will be determined for a system containing an initial misfit, (state 0). The system consists of 2 outer bars (Bar 3) and an inner bar (Bar 2) connected in series to a CT specimen. A long range residual stress is introduced in state 1. State 2 corresponds to the system subjected to external loading as shown in Fig. 1.

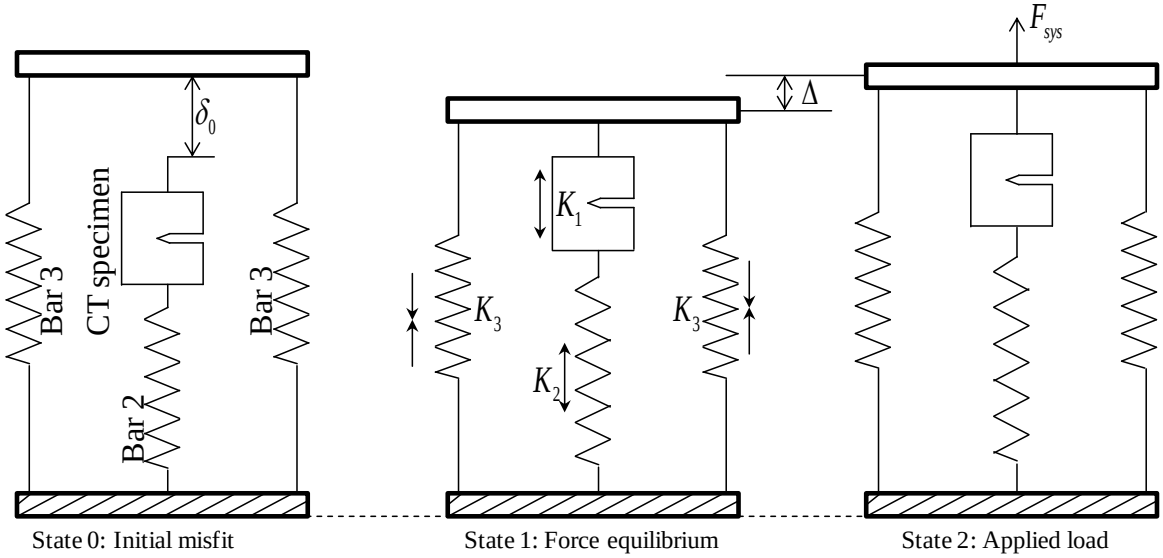

Figure 1. Parallel bars with an initial misfit subjected to an applied load.

In state 1, an initial residual stress field is introduced into system through the introduction of an incompatibility misfit. The displacements in the bars due to the misfit are:

$$\delta_1 = \left[\gamma/\left(\alpha_{eff}+1\right)\right]\delta_0 \qquad \delta_1+\delta_2 = \left[\alpha_{eff}/\left(\alpha_{eff}+1\right)\right] \qquad \delta_3 = -\left[1/\left(\alpha_{eff}+1\right)\right]\delta_0 \tag{1}$$

where δ_0 is the initial misfit, δ_1, δ_2 and δ_3 are the displacements in the CT specimen, and bars 2 and 3 respectively, K_1, K_2 and K_3 are the stiffness for the CT specimen, and bars 2 and 3 respectively. Various ratios for the stiffness of the components are given by

$$\beta = K_2/K_1 \qquad \gamma = 2K_3/K_1 \qquad \alpha_{eff} = 2K_3/K_{eff} \qquad 1/K_{eff} = 1/K_1 + 1/K_2 \tag{2}$$

The structure is then loaded through a rigid block (state 2) such that the displacement Δ for the whole system is given by:

$$\Delta = F_{Sys}/\left(K_{eff}+2K_3\right) \tag{3}$$

and the displacements in the bars are given by

$$\delta_1 = \left(\frac{\gamma}{\alpha_{eff}+1}\right)\delta_0 + \left(\frac{\beta}{\beta+1}\right)\Delta \qquad \delta_2 = \left(\frac{\alpha_{eff}}{\alpha_{eff}+1}\right)\delta_0 + \left(\frac{1}{\beta+1}\right)\Delta \qquad \delta_3 = -\left(\frac{1}{\alpha_{eff}+1}\right)\delta_0 + \Delta \tag{4}$$

The presence of elastic follow-up in the system results in a slower stress relaxation rate when compared to classical stress relaxation. There is also additional strain accumulation in the CT specimen. As an approximation, the creep strains accumulated in the CT specimen are considered to be a scalar factor Z times the creep strain which would be accumulated in the corresponding laboratory relaxation test (at the same initial stress, dwell time and temperature). Z is called the elastic follow-up factor and is given by [5].

$$Z = \left(\Delta\varepsilon_{\text{inc}} + \Delta\varepsilon_{\text{el}}\right)/\Delta\varepsilon_{\text{el}} \qquad \text{where} \qquad \Delta\varepsilon_{\text{el}} = \Delta\sigma_{ref}^{Total}/E_1 = \Delta F_1/L_{ref}K_1 \tag{5}$$

where $\Delta\varepsilon_{inc}$ is the incremental strain accumulation in specimen during creep stress relaxation; and $\Delta\sigma_{\text{ref}}^{\text{Total}}$ is the change of total reference stress on the CT specimen; ΔF_1 is the change in load on the CT specimen and L_{ref} is the reference length of the CT specimen.

For state 1 the incremental strain accumulation is given by

$$\Delta\varepsilon_{\text{inc}}^{\text{state-1}} = \left[\Delta F_1/2K_3 + \Delta F_1/K_2\right]/L_1 \tag{6}$$

In state 2, the strain accumulation in specimen has two different solutions. The first solution corresponds to the total reference stress on the CT specimen at any time being greater than the initial residual stress

$$\sigma_{ref-t}^{Total} \geq \sigma_{ref-0}^{Rs}, \text{ and } \Delta\varepsilon_{\text{inc}}^{\text{state-2}} = \Delta\varepsilon_{\text{inc}}^{\text{state-1}}; \tag{7}$$

The second solution corresponds to when the total reference stress at a given time is less than the initial reference stress from the residual stress, ie:

$$\sigma_{ref-t}^{Total} < \sigma_{ref-0}^{Rs} \qquad \Delta\varepsilon_{\text{inc}}^{\text{state-2}} = \left[\Delta F_1/\left(2K_3 + K_{eff}\right)\right]/L_1 \tag{8}$$

Combining Eqs. 5-8, the solutions for Z are as follows

State 1 :

$$Z_1 = 1 + 1/\gamma + 1/\beta = \left[\left(1+\alpha_{eff}\right)/\alpha_{eff}\right]\left[\left(1+\beta\right)/\beta\right] \tag{9}$$

State 2:

$$\sigma_{ref-t}^{Total} \geq \sigma_{ref-0}^{Rs} \qquad Z_2 = Z_1 \tag{10a}$$

$$\sigma_{ref-t}^{Total} < \sigma_{ref-0}^{Rs} \qquad Z_2 = 1 + \left[1/\left(\gamma + \beta/\left(\beta+1\right)\right)\right] \tag{10b}$$

Equations 9 and 10 show that Z for states 1 and 2 are the same if the current total reference stresses in the CT specimen is larger than the initial reference residual stress. When the current total reference stress is smaller than the initial reference residual stress, a new solution for Z for state 2 is given by Eq. 10. Those results are based on the assumption that only the CT specimen creeps while the reminder of the structure remains elastic. Z_1, Eq. 9, is independent of the initial stress and the creep deformation behavior of the CT specimen, i.e., Z is a constant geometrical value

dependent on the stiffness of the system. However, Z_2 is influenced by the stress in the CT specimen.

3. Creep of a three bar system

We now consider the behavior of states 1 and 2 with the aim of determining how the stress relaxes in the three bar system due to creep. The stress-strain and creep properties of the materials are required and hence the first part of this section presents relevant material properties for a Type 316H stainless steel. The solution for the stress relaxation of states 1 and 2 are given in the second part of this section.

3.1 Creep rupture and creep crack growth properties

Tensile, steady state creep rate and creep crack initiation properties of Type 316H Austenitic stainless steel at 550 ℃ are summarized in Table. 1. Tensile properties of Type 316H Austenitic stainless steel were measured at a strain rate of 1.5% per min [6]. The relevant creep data are taken from Douglas [7] and fitted using a simple power law as shown in Fig. 2a. The steady state creep rate is given by

$$\dot{\varepsilon} = D\sigma^m \tag{11}$$

where $\dot{\varepsilon}$ is the creep rate in $1/\mathrm{h}$, σ is the applied stress in MPa and D and m are material constants. A regression fit to data shown in Fig 2a provided values for the constants D and m. Values are shown in Table 1 for mean, upper and lower bound fits. The upper (UB) and lower bound (LB) curves correspond to ± 1 standard deviations on the mean, assuming the slope is constant.

Seven creep crack tests using CT specimens were completed with test times ranging from about 60 to 16600hrs [8, 9]. The relationship between the applied reference stresses and time t_i (h) to initiate a crack equal to 0.2mm is shown in Fig. 2b. The initiation time t_i is given by

$$t_i = C\sigma_{ref}{}^f \tag{12}$$

where σ_{ref} is the plane stress reference stress in MPa for pre-cracked CT specimens, and C and f are the corresponding material constants. A regression fit to data shown in Fig. 2b provided values for the constants C and f. These are shown in Table 1.

Table 1. Tensile, steady state creep rate and time corresponding to crack extension of 0.2mm properties of Type 316H Austenitic stainless steel at 550 ℃ [6].

Material properties (MPa)	Steady state creep rate properties	Creep crack initiation properties
Young's Modulus: 160000	n: 10.154	f: -5.45
Yield stress: 145	D: $10^{-29.54}$	C: 5×10^{15}
0.2% proof stress: 194	Upper bound (UB) and lower bound (LB) factor on D: 2.72	
UTS: 648		

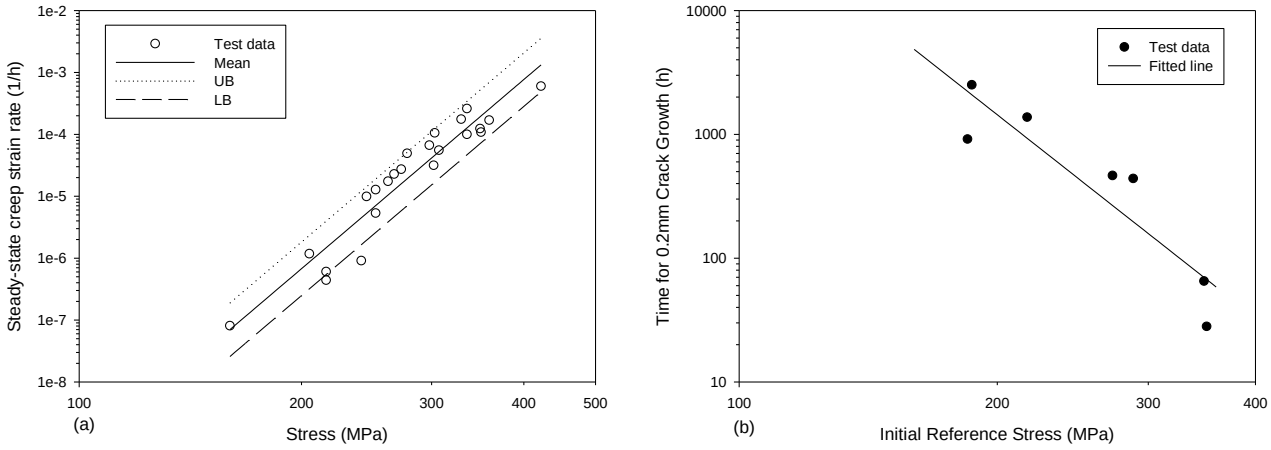

Figure 2. Material properties of Type 316H Austenitic stainless steel at 550 ℃ (a) Minimum creep strain rate, illustrating the mean, upper and lower bound regression fits ; (b) Time to crack initiation with respect to the reference stress.

3.2. Determination of stress relaxation in the three bar system

In order to simplify the analysis, the following three assumptions were made. a) The misfit and the applied load may be sufficient to cause plasticity in the CT specimen, but the surrounding structure remained elastic. The CT specimen was always at the creep temperature and creep only occurred in the specimen. b) For state 2, the applied force on the assembly was constant during the test period. Finally, c) the forces between the specimen and the elastic elements were always in equilibrium.

3.2.1 Relaxation of residual stress alone

Stress relaxation is a reduction of stresses with time due to the conversion of elastic strain to inelastic strain under constant total strain. For a material that follows a power creep law the reference strain rate in CT specimen can be expressed in terms of a reference stress, where

$$\dot{\varepsilon}_{ref} = D\sigma_{ref}^{\ n} \tag{13}$$

In a CT specimen the relationship between force, displacement, reference stress and strain, and stress intensity factor are given by [10]

$$\sigma_{ref} = F_1/B_n W m_L \qquad \varepsilon_{ref} = \delta/L_{ref} \qquad L_{ref} = E_1 B_n W m_L/K_1 \qquad F_1 = K_1\delta \qquad K_1 = BE_1/f(\alpha/W) \tag{14}$$

$$\text{where} \quad f(\alpha/W) = \left(\frac{1+\alpha/W}{1-\alpha/W}\right)^2 \left[\begin{array}{l} 2.163+12.219(\alpha/W)-20.065(\alpha/W)^2 \\ -0.9925(\alpha/W)^3+20.609(\alpha/W)^4-9.9314(\alpha/W)^5 \end{array}\right] \tag{15}$$

$$\text{and} \quad m_L = \sqrt{(1+\varphi)(1+\varphi(\alpha_0/w)^2)} - (1+\varphi(\alpha_0/w)) \qquad 0 \le \alpha_0/W \le 1 \tag{16}$$

where σ_{ref} is the plane stress reference stress, ε_{ref} L_{ref} are the reference strain and length respectively of a CT specimen, E_1 is the elastic modulus, δ is the load line displacement; a_0, B_n

and W are the initial crack depth, width, net thickness of a CT specimen respectively. The constant m_L given by Eq. 16 is for plane stress and a von-Mises yield criterion with $\varphi = 2/\sqrt{3}$. It can be shown that the change in reference stress with time for the three bar system in state 1 is given by

$$\tau^{Rs} = \left[1 \Big/ \left(1 + (1/Z_1)\, AE_1 (n-1) \left(\sigma_{ref-0}^{Rs}\right)^{n-1} t\right)\right]^{1/n-1} \qquad \text{where} \quad \tau^{Rs} = \sigma_{ref-t}^{Rs} \Big/ \sigma_{ref-0}^{Rs} \tag{17}$$

where σ_{ref-t}^{Rs} and σ_{ref-0}^{Rs} are the current and initial reference residual stresses respectively in the CT specimen.

For a time much greater than

$$t \gg 1 \Big/ (1/Z)\, AE_1 (n-1) \left(\sigma_{ref-0}^{Rs}\right)^{n-1} \tag{18}$$

Equation 17 is approximately independent of the initial reference stress. The influence of the magnitude of initial reference stress is greatest during the early stages of the relaxation process.

As an example; take an initial residual reference stress of 200MPa. Using equation 17 together with creep behavior described by equation 13, and the material constants in Table 1, the predicted residual stress relaxation using mean, upper and lower bound creep constants and different elastic follow-up factors are shown in Fig. 3. The results show that the stress relaxation behavior is sensitive to the creep constants and also significantly affected by the elastic follow-up. For Z=1, there is no strain accumulated in the specimen; therefore the total strain across the entire cross-section of specimen remains zero during the relaxation process. This is equivalent to the stress relaxation in a bolt that holds two rigid flanges together. For Z>1, there is slower stress relaxation and extra strain is accumulated in the CT specimen.

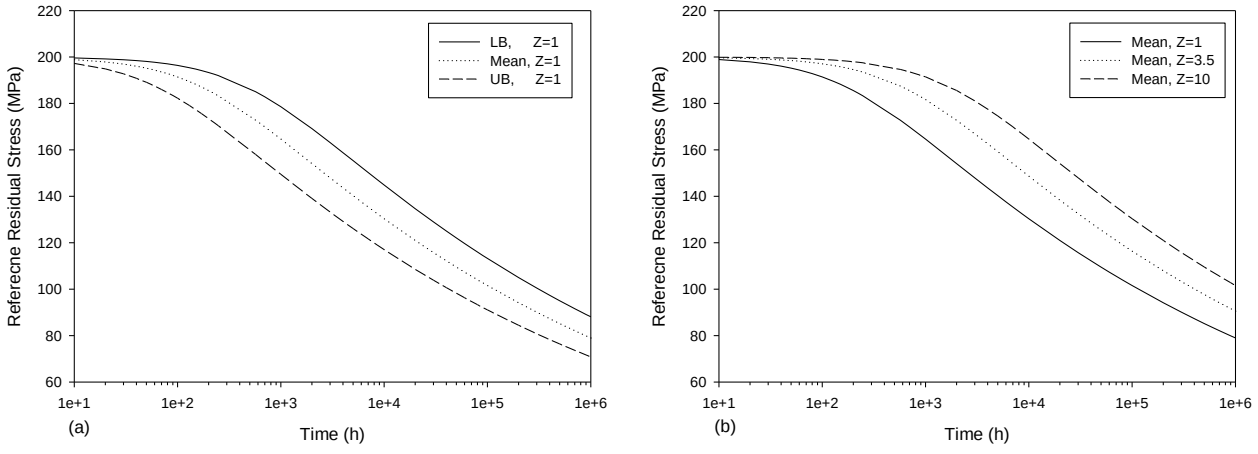

Figure 3. Prediction of reference residual stress relaxation from an initial value of 200MPa (a) using mean, and upper and lower bound creep constants and Z=1, (b) with mean creep data and different values of Z.

3.2.2 Relaxation of combined residual and applied stress

In state 2 the initial total reference stress (equal to residual plus applied stresses), and the elastic

follow-up factor change during total stress relaxation. The relaxation of the total reference stress for combinations of residual and applied loading is similar to Eq. 17, where

$$\tau^{Total} = \left[1 \Big/ \left(1 + \left(1/Z_2 \right) AE_1 (n-1) \left(\sigma_{ref-0}^{Total} \right)^{n-1} t \right) \right]^{1/n-1} \qquad \text{where} \quad \tau^{Total} = \sigma_{ref-t}^{Total} \Big/ \sigma_{ref-0}^{Total} \tag{19}$$

$$\eta = \sigma_{ref-0}^{Rs} \Big/ \sigma_{ref-0}^{Total} \qquad \sigma_{ref-0}^{Total} = \sigma_{ref-0}^{Rs} + \sigma_{ref-0}^{Applied} \qquad \sigma_{ref-t}^{Rs} = \sigma_{ref-0}^{Rs} - (\sigma_{ref-0}^{Total} - \sigma_{ref-t}^{Total}) \tag{20}$$

where τ^{Total} is the normalized total reference stress, η is the ratio of the initial residual to the total stress in the CT specimen. $\sigma_{ref-t}^{Total}, \sigma_{ref-0}^{Total}, \sigma_{ref-0}^{Rs}$ and σ_{ref-t}^{Rs} are the reference total stress and residual stresses at time t and 0 respectively. From Eqs. 7 to 10, the change from Z_1 to Z_2 occurs when $\tau^{Total} = 1 - \eta$. This corresponds to when the residual stress is relaxed to zero.

Therefore

$$t \le \frac{1-(1-\eta)^{n-1}}{\left(1/Z\right) AE_1 (n-1) \left(\sigma_{ref-0}^{Total} \right)^{n-1} (1-\eta)^{n-1}}, \text{ Z=Z}_1; \tag{21a}$$

$$t > \frac{1-(1-\eta)^{n-1}}{\left(1/Z\right) AE_1 (n-1) \left(\sigma_{ref-0}^{Total} \right)^{n-1} (1-\eta)^{n-1}}, \text{ Z=Z}_2 \tag{21b}$$

Now consider a three bar structure system with properties so that the relative stiffness ratios are $\beta = 0.25, \text{and } \gamma = 0.2$. From Eqs 9 and 10 $Z_1 = 10$ and $Z_2 = 3.5$. Assume an initial residual reference stress of 200MPa and subject the CT specimen to additional applied stress to give a total reference stress equal to 330MPa. For this case $\eta = 0.606$. The relaxation of the total and residual stresses is shown in Figure 4, again using the creep law given by Eqn 11 with creep constants given in Table 1. The change from Z_1 to Z_2 occurs when the total stresses relaxes to $(1-\eta)\, 330MPa = 130MPa$. This corresponds to a time where the residual stress relaxes to zero as shown in Figure 4a. Also Figure 4a shows that the residual stress decreases significantly due to the presence of the applied load.

Now consider the case when the total reference stress is 330MPa and residual stress is such that the ratio $\eta = 0.5 \; and \; 0.75$. The stress relaxation behaviour for these two different values of η is shown in Figure 4b. The solid line represents the stress relaxation path for $Z_1 = 10$ and the dashed line represents the stress relaxation for $Z_2 = 3.5$.

When $\eta = 1$ the residual stress accounts for 100% of total stress and stress relaxation corresponds to $Z_1 = 10$. When $\eta = 0$ this represents the case when there is no residual stress and the applied stress accounts for 100% of the total stress. Stress relaxation corresponds to $Z_2 = 3.5$.

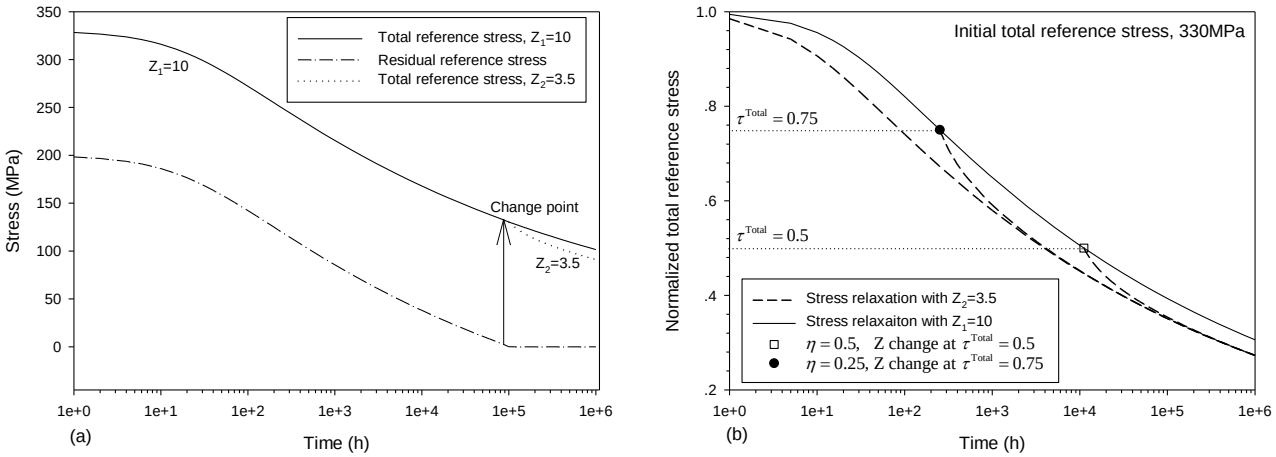

Figure 4. Initial total reference stress 330MPa (a) $\eta = 0.606$, the changing of residual reference stress with total reference stress (b) The relationship between total reference stress relaxation with different η.

4. Prediction of crack initiation

In this section crack initiation will be examined for two different cases. (1) Relaxation of a residual stress in the absence of any external stress. This represents stress relief cracking situations. (2) Relaxation in the presence of a superimposed applied stress. This simulates crack initiation for combined residual and applied stresses.

4.1 Prediction of crack initiation for residual stress alone

By combining Eqs 12 and 17 together with the creep deformation and crack initiation properties listed in Table. 1, the predicted time to crack initiation for a three bar system for state 1 is given by

$$\int_0^{t_i} \frac{1}{C}\left[(1/Z_1)(n-1)DE_1 t + (\sigma_{Spec-0}^{Rs})^{1-n}\right]^{f/(n-1)} dt = 1 \tag{22}$$

Equation 22 is solved numerically to obtain the initiation time. Predicted creep crack initiation times are shown in Fig 5, for initial residual stresses ranging from 75MPa to 400MPa.

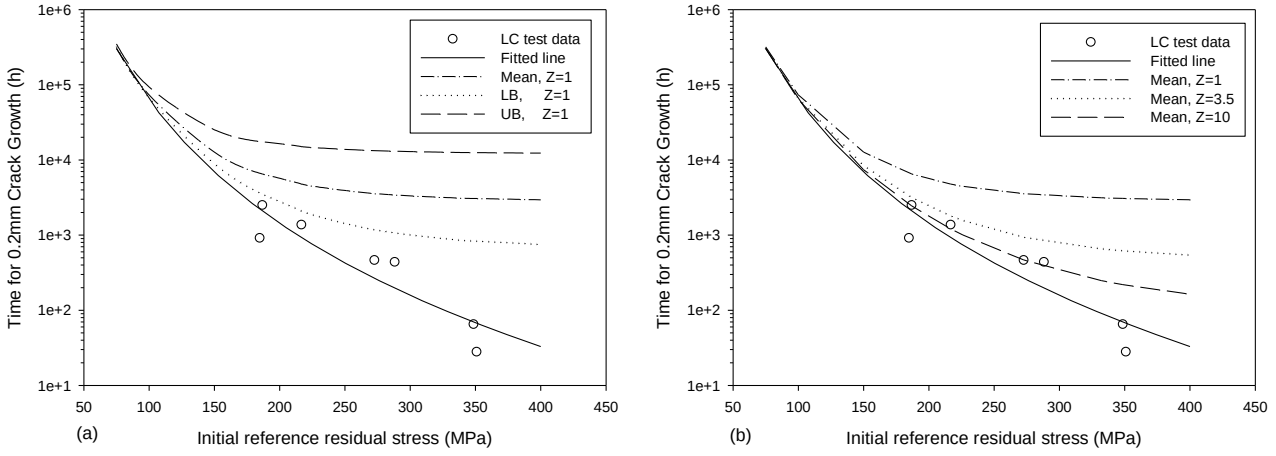

Figure 5. The prediction of crack initiation time with different initial reference residual stress, (a) illustrating the mean, upper and lower bound value (b) with different EFU factor with mean value.

Mean, lower and upper bound creep properties together with Z=1 were assumed for Fig 4a and mean creep properties and different elastic follow-up factors in Fig 4b. The results illustrate that the predictions are sensitive to the creep constants and elastic follow-up factors respectively. However, the initiation times for different constants and different Z tend to converge to similar initiation times for low initial reference stresses.

4.2 Prediction of crack initiation for combined residual and applied stress

By combining Eqs. 12 and 19 with the creep properties listed in table 1, the time for crack initiation can be obtained. If the initiation time is less than t_1 given by

$$t_1 \le \frac{1-(1-\eta)^{n-1}}{(1/Z)AE_1(n-1)\left(\sigma_{ref-0}^{Total}\right)^{n-1}(1-\eta)^{n-1}} \tag{23}$$

Then the initiation time is solved from Eqn. 22.

If, however, the initiation time is greater than t_1 then the initiation time is obtained by solving

$$\int_0^{t_1}\frac{1}{C}\left[(1/Z_1)(n-1)DE_1t+(\sigma_{Spec-0}^{Rs})^{1-n}\right]^{f/(n-1)}dt+\int_{t_1}^{t_i}\frac{1}{C}\left[(1/Z_2)(n-1)DE_1t+(\sigma_{Spec-t_1}^{Rs})^{1-n}\right]^{f/(n-1)}dt=1 \tag{24}$$

Solutions obtained by numerically solving equations 22 and 24 are shown in Figure 6. When the system is under load control the initiation time is 91 hours. If the same system is under displacement control (ie the initial stress is entirely residual and Z_2 ~1) the initiation time is 3132 hours. If was assumed that $\beta = 0.25, \text{and}\, \gamma = 0.2$ and therefore $Z_1 = 10$ and $Z_2 = 3.5$. When the stress (of 330MPa) on the CT specimen arises from applied loading along then Z=3.5 and the initiation time is 659 hours. In contrast if the CT specimen is subjected to a residual stress equal to 330MPa, the Z_1 =10. And the initiation time is 248 hours.

The influence of different ratios of residual to total stress (η) are shown in Fig 6b. Applied stress conditions lie to the left hand side while conditions where residual stress conditions dominate lie on the right hand side of the horizontal scale.

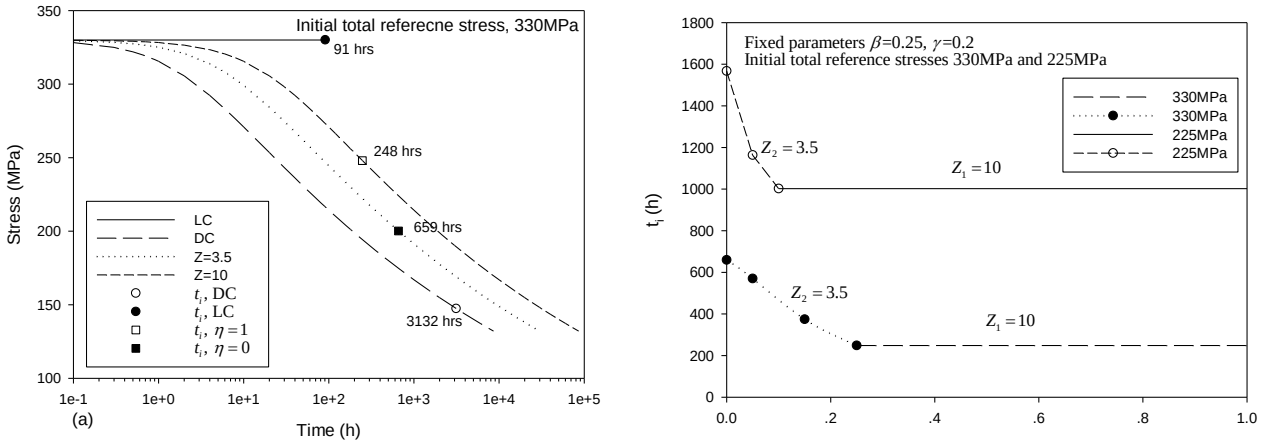

Figure 6. (a) The crack initiation time for initial total reference stress 330MPa under the displacement control, load control and mixed boundary control (b) the crack initiation time with different η and two different reference stresses.

4. Discussion and concluding remarks

A three bar structure has been designed to simulate the behaviour of a component subjected to combined applied and residual stresses. The properties of the three bar system are determined depending when the long range residual stress (state 1) is induced and following application of an external load (state 2). Closed form solutions of the elastic follow-up factor for states 1 and 2 are given and we find that the expression for elastic follow-up factor in state 2 changes when corresponding residual stress relaxes to zero.

Calculations performed to predict creep crack initiation in the presence of long range residual stress in Type 316H austenitic stainless steel provide results that yield significant insight to the behaviour of the system. Sensitivity studies have been included to determine the influence of changes in the material creep properties and the effects of elastic follow-up factor on stress relaxation. We find that the predictions of crack initiation are sensitive to both the creep constants and elastic follow-up factors respectively. However, the initiation times for different constants and different Z tend to converge to similar values for low initial reference stresses.

In state 2, the effect of residual stress on crack initiation is found to depend on the value of total stress (residual stress plus stress created by applied load) and the ratio of the residual stress to total stress. The elastic follow-up factor decreases significantly in state 2 when all of the residual stress has relaxed to zero.

Creep-Fatigue Crack Growth Using Digital Image Correlation

Jeffrey L. Evans[1,*]

[1] Department of Mechanical and Aerospace Engineering, University of Alabama in Huntsville, Huntsville, Alabama 35899, USA
* Corresponding author: jeff.evans@uah.edu

Abstract Creep-fatigue crack growth tests are cyclic tests that have a hold period at the maximum load. This hold period, or dwell, is the period during the test when the time-dependent mechanisms operate. The length of the dwell period has been shown to affect the fatigue crack growth rate. During the hold period, crack tip blunting (due to creep deformation) and crack extension can be measured using 2-D digital image correlation (DIC). DIC requires a random speckle pattern on the flat surface being investigated. The speckle pattern is a unique pattern and, as the surface is strained, locations on the pattern will move to new positions relative to a previous strained condition. The images are compared and an algorithm calculates the strain. The camera can be positioned to view the crack tip and measure crack extension and crack opening displacement (COD). This provides a means by which the crack tip creep deformation can be determined during the hold period, providing valuable information regarding the crack tip kinetics and crack driving force. This paper will evaluate this technique for creep-fatigue crack growth measurements and provide preliminary data for a Ni-base alloy.

Keywords Creep-Fatigue, Crack Growth, Digital Image Correlation

1. Introduction

A number of important industrial applications require materials to be subjected to elevated temperatures, cyclic stresses, and potentially aggressive environments. Creep-fatigue occurs when a combination of these conditions are present. During the dwell period of a creep-fatigue cycle, several damaging effects at the crack tip can take place causing an increase in the crack growth rate. The crack tip driving force therefore could be influenced by a number of active processes, such as oxidation, oxygen diffusion, and creep deformation [1]. Understanding the kinetics of these various processes is essential to predicting the behavior of a material under creep-fatigue conditions [2]. Some studies and techniques have been proposed to evaluate the rates of these processes [3]. It is quite challenging to experimentally disassociate the different processes and arrive at the exact contribution provided by each process. Oxygen diffusion along the grain boundaries is clearly a culprit in embrittling some materials such as nickel-base alloys [4]. This diffusional process is, in part, driven by the crack tip stress. Rapid stress relaxation, therefore, has been proposed to reduce the crack growth rate [5]. Quantifying the re-distribution of stresses and strains at the crack tip is critical to predicting the crack growth rate during creep-fatigue.

One technique developed in the last 25 years that could be used to help interrogate the crack tip during creep-fatigue is digital image correlation [6]. This noncontact experimental technique allows for the observation of the strains using an image analysis technique [7]. The surface of a test specimen has to be prepared, having a unique speckle pattern. The random speckles are then used as reference points for determining amounts of displacement and strain measurements to be calculated with respect to a starting reference image. This technique has been used to determine crack tip displacements during creep crack growth as well as fatigue crack growth. This paper gives some preliminary results using a 2-D digital image correlation system to determine the crack tip displacements and crack growth rates for the nickel alloy Hastelloy X at elevated temperature with creep-fatigue conditions.

2. Experimental Procedure

The material used in this study was Hastelloy X (see Table 1 for the chemical composition), which was acquired in the annealed condition in the form of a cold finished plate with a thickness of 6.35mm. From this plate a sample was removed in the T-L orientation for the creep-fatigue test.

Table 1. Nominal chemical composition of Hastelloy X in weight %

Alloy	Ni	Fe	Cr	Mo	Cu	Co	W	Ti	C	Mn	Si	Al	Other
Hastelloy X	Bal.	18	22	9	<0.50	1.5	0.6	<0.15	0.1	<1	<1	<0.5	<0.08

From this plate a sample was removed in the T-L orientation for the creep-fatigue test with the geometry shown in Figure 1.

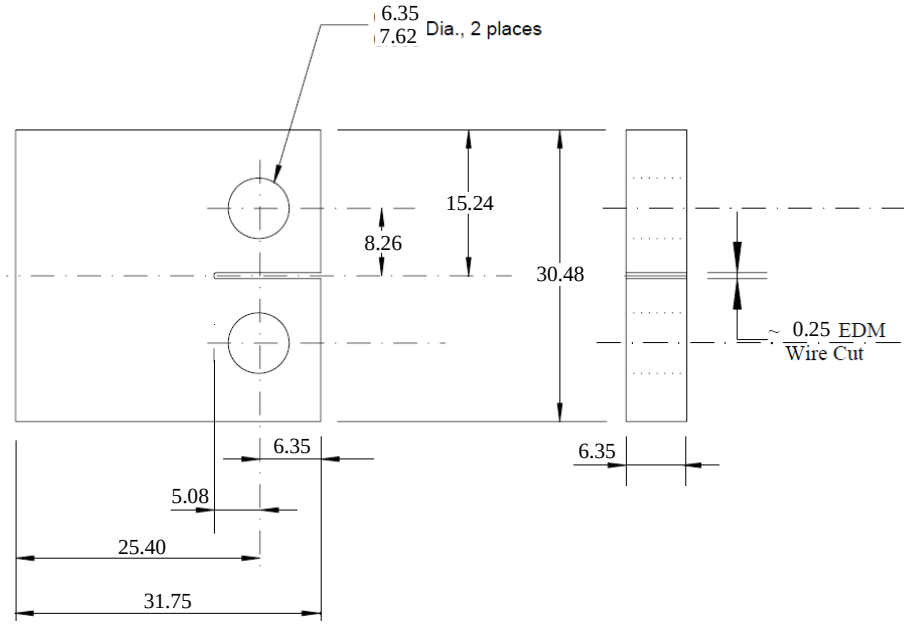

Figure 1. Creep-fatigue specimen geometry (dimensions are in mm)

The specimen was then prepared for the noncontact digital image correlation. A high contrast random, speckle pattern was applied in two steps. First a flat white high temperature ceramic based coating (VHT Flame Proof^{TM}) was applied to one surface of the specimen. After the coating had dried, a mist of a flat black high temperature coating was sprayed over the white coating layer to provide the contrasting speckle pattern.

The specimen was fatigue pre-cracked for ~2.5mm, ending with $\Delta K = 27.6$ MPam$^{1/2}$. The fatigue pre-cracking and creep-fatigue test were conducted using a 100kN MTS servo-hydraulic test system. The creep-fatigue test was performed using a trapezoidal waveform with a 1.5 second ramp up, a 120 second dwell at max load, and a 1.5 second ramp down. A loading ratio of R=0.05 was used. The test was conducted in laboratory air at 650ºC ± 3 ºC. The elevated temperature was applied using a 1.2kW Ameritherm induction heater and monitored using a two-color optical infrared thermometer.

The Correlated Solutions Vic-2D digital image correlation system was used to capture images and analyze crack tip displacements. Images were captured at a rate of ~6 images per second using a 5MP Point Grey camera. Images were captured for only a few cycles at a time collecting ~730 images per cycle.

3. Results and Discussion

3.1. Crack tip strain

The displacement measurements and strain calculations presented herein were performed for cycles number 9 and number 62 during the creep-fatigue test. The measurements were made with respect to an unloaded reference image. The strain measurements were made on a small region around the crack and crack tip as is shown in Figure 2.

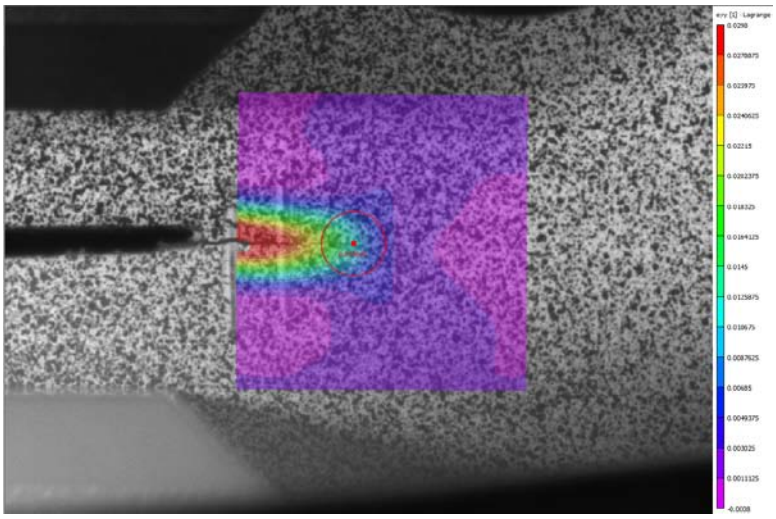

Figure 2. Representative image of the digital image correlation strain calculation. Inside the red circle is the region around the crack tip that was used for the strain measurements.

The crack tip strain was measured for the 120 second hold period of cycle 9 and cycle 62 of the creep-fatigue test using the region contained by the red circle in Figure 2. The strain was calculated for the y-direction using the Lagrange tensor, and the results for cycles 9 and 62 are shown in Figure 3.

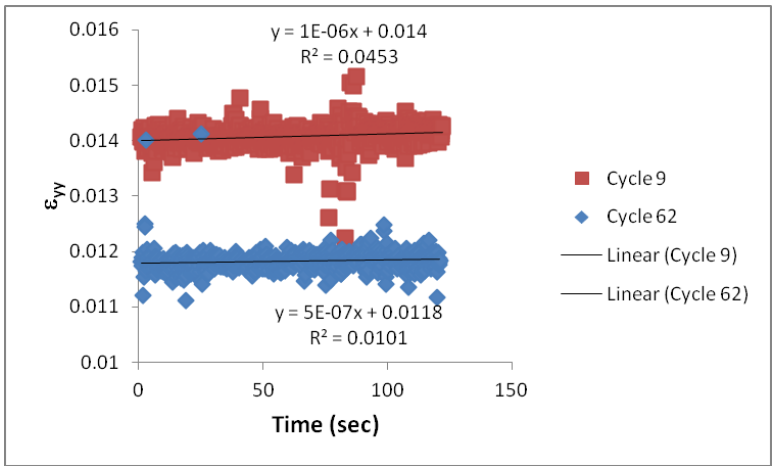

Figure 3. The crack tip strain during the creep-fatigue hold period for cycles 9 and 62.

During the hold period the strain measured had some noise present in the ~730 data points used for each cycle. This may be due to the thermal effect on the air between the camera and the sample. Nevertheless, a small positive slope was the trend for both cycles. Therefore a crack tip creep rate for this 120 second period was determined. During cycle 9 the creep rate was $1x10^{-6}$ and it was $5x10^{-7}$ during the hold period of cycle 62. This at least indicates that a crack tip creep rate can be measured on this material at 650ºC for a 120 second hold period using digital image correlation.

Also, the results showed that the magnitude of the strain is higher for cycle 9 than cycle 62. It is not clear what has produced this result. It may be that the images were taken with a resolution too low to accurately see the crack tip. Therefore, when the local selection was made to extract the data from the crack tip, the exact location may have differed between the two cycles.

3.2. Crack Opening Displacement (COD)

COD measurements were also measured for cycles 9 and 62. These measurements were made relative to the unloaded reference image. A linear measurement of COD was performed across a small region within the selected area shown in Figure 4.

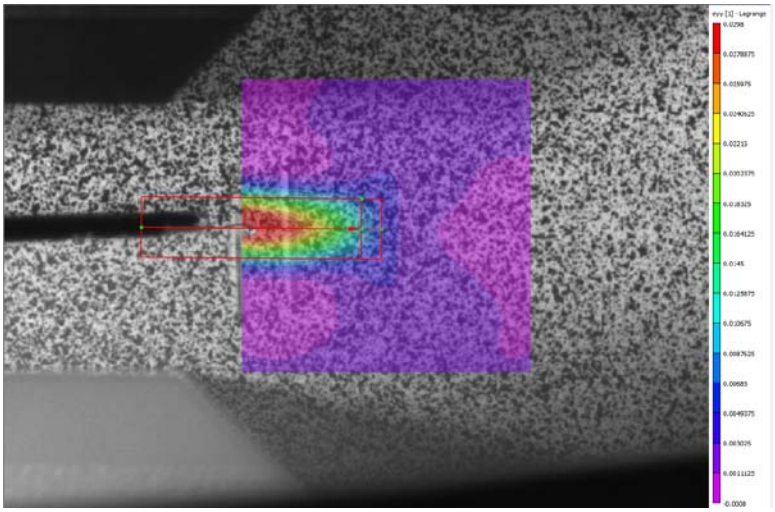

Figure 4. The crack opening displacement measurement was made along a linear region shown in the red rectangular box.

COD data (in pixels) was then extracted at a location across the EDM notch (i.e. the far left point in the red rectangle shown in Figure 4). The COD data was taken from the beginning (the first two seconds), the middle (seconds 60 and 61), and the end (seconds 119 and 120). The twelve data points at each location were then averaged. The results are shown in Figure 5.

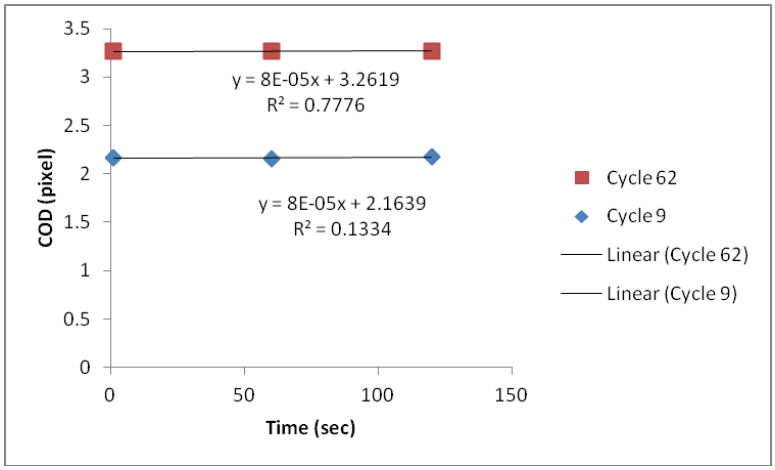

Figure 5. The COD measurements during the creep-fatigue hold period for cycles 9 and 62.

The COD measurements were clearly higher for cycle 62 than for cycle 9. This is what would be expected, since at a later point in the test the crack would have grown causing a larger COD measurement. Also, for both cycles the slope is positive, indicating that the crack opening increased during the hold period.

4. Conclusions

DIC was used to measure both the crack tip deformation and crack opening displacement during a 120 second hold period of a creep-fatigue crack growth cycle. The crack tip strain measurements can be used to determine crack tip creep rates during a creep-fatigue cycle. The results for both the strain measurements and the COD measurements showed that a positive slope existed over this 120 second period. The results shown herein are only for a very limited study, and it is expected that a greater understanding of the crack tip behavior could be gained by conducting these tests over many more cycles and different test conditions. Nevertheless these results suggest that creep and crack opening take place during the hold period studied for this material under these conditions and that they can be measured using the DIC system.

Abstract The research project aiming to commercialize 700˚C class pulverized coal power system; advanced ultra-super critical (A-USC) pressure power generation has been conducted in Japan from 2008. In A-USC boilers, Ni base or Ni-Fe base alloys are used for high temperature parts at 650-700˚C and advanced high Cr ferritic steels are planning to be used at the temperatures lower than 650˚C. Because the high B-9Cr steel developed in National Institute for Materials Science (NIMS) has improved creep strength in welds, it is one of the candidate materials for A-USC boilers. In the present paper, the creep tests of the dissimilar welds between Ni base alloy and high B-9Cr steel for A-USC boilers were conducted at 650˚C. In the heat affected zone (HAZ) of the high B-9Cr steels, fine-grained microstructures were not formed and grain size of the base metal was retained. Free boron on the grain boundaries is considered to affect the mechanisms of the α-γ transformation during weld thermal cycle. Consequently, the Type-IV failure was not occurred in the present dissimilar welds and their creep rupture lives were 5-10 times longer than those of the conventional 9Cr steel welds at 650˚C.

Keywords A-USC boiler, High B-9Cr steel, Dissimilar weld, Creep

1. Introduction

Research project aiming to commercialize 700 ˚C class pulverized coal power system; A-USC power generation, with 46-48 % power generation efficiency, and to reduce CO_2 emissions more than 10 % has been conducted from 2008 in Japan. In the A-USC boiler, Ni base or Ni-Fe base alloys such as Alloy 617, Alloy 263 and HR6W are planning to be used for high temperature parts at 650-700 ˚C, and advanced high Cr ferritic steels are planning to be used at the temperatures lower than 650 ˚C. In the dissimilar weld between Ni base alloy and high Cr steel, Type-IV failure and thermal-fatigue (creep-fatigue) are the major concerns. Because the 9Cr-3W-3Co-VNb steel containing higher boron and lower nitrogen (high B-9Cr steel) developed in NIMS has improved creep strength in the HAZ and weld joint [1, 2], it is one of candidate materials for A-USC boilers [3].

In the present paper, creep tests of the dissimilar welds between high B-9Cr steels and Ni base alloys for A-USC boilers (Alloy 617 and Alloy 263) were conducted at 650 ˚C. Microstructures and creep damages in the welds were investigated.

2. Experimental procedure

Two kinds of the high B-9Cr steels; MARBN10 steel (9Cr-3W-3Co-VNb-0.01B-0.003N) and MARBN12 steel (9Cr-2.6W-3Co-VNb-0.01B-0.007N) were prepared. The chemical compositions are shown in Table 1. In the present steels, about 0.01% boron was added aiming to strengthen the grain boundaries. Nitrogen content was lower than 0.01 % to avoid the formation of boron nitride (BN) and to maximize the grain boundary strengthening effect of boron. MARBN12 steel contains higher nitrogen than MARBN10 steel. These steels were normalized at 1100 ˚C for 1 h and tempered at 800 ˚C for 1 h.

Four kinds of dissimilar welds between high B-9Cr steels (MARBN10 and MARBN12) and Ni base alloys for A-USC boilers (Alloy 617 and Alloy 263) were prepared by gas tungsten arc (GTA)

welding using the filler wire of Inconel 82 as shown in Fig. 1. The groove configuration of these welds was U with 20 ˚ of groove angle. After welding, all the weld joints were given post weld heat treatment (PWHT) at 740 ˚C for 4 h. Weld defects were not detected in the radiographic examination and magnetic particle testing. The distribution of micro Vickers hardness of the MARBN10 steel-Alloy 263 weld after PWHT and before creep condition is shown in Fig. 2.

Creep tests of the base metals were conducted using round bar-type specimens 6 mm in diameter and 30 mm in gauge length. Creep tests of the dissimilar weld joints were conducted at 650 ˚C using the smooth plate-type specimens 17.5 × 5 mm in section and 100 mm in gauge length as shown in Fig. 3.

Table 1. Chemical compositions of the present high B-9Cr steels (wt. %)

	C	Si	Mn	P	S	Cr	W	Mo	Co	Ni	V	Nb	N	O	B	Sol.Al

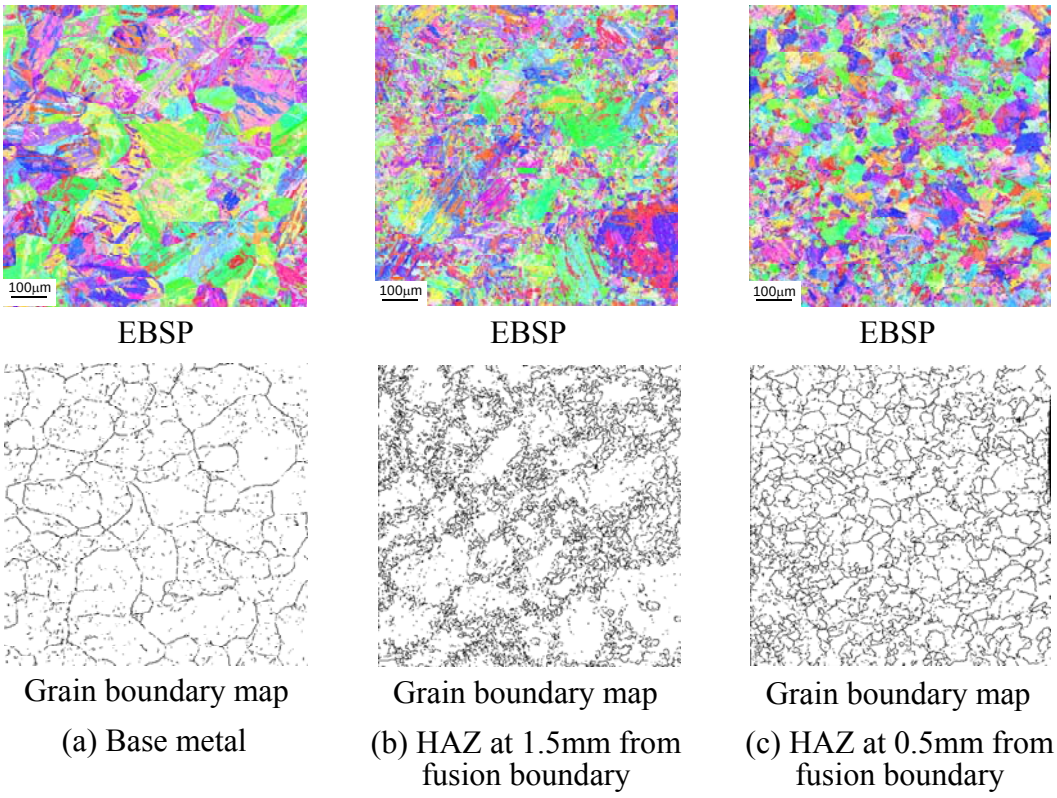

Figure 4. EBSP images and grain boundary mapping (15-48˚) for the base metal and HAZ of the high B-9Cr steel in the MARBN10 steel-Alloy 263 weld joint

3. Results and discussion

3.1. Microstructures of HAZ in the dissimilar welds

Figure 4 shows the EBSP (electron backscattered pattern) images and grain boundary maps of the base metal and HAZ of the high B-9Cr steel in the dissimilar welds between MARBN10 steel and Alloy 263. In the grain boundary map, grain boundaries with misorientation from 15 ˚ to 48 ˚ were drawn and their length was measured. We have reported that the fine-grained structures were not formed in HAZ of weld joints for the 9Cr-3W-3Co-VNb steel with boron and low nitrogen [1, 2]. The base metal of the present steel shows the tempered martensitic structures having the grain boundary length of 2.07 cm and KAM of 1.83 (Fig. 4(a)). The micro Vickers hardness of the

present base metal was 220-235 as shown in Fig. 2. In the conventional high Cr steels, fine-grained HAZ structures 5 μm in the average grain size were observed in the area at about 1.5 mm from the fusion boundary. In the present high B-9Cr steels, however, the fine-grained structures were not formed at a distance of 1.5 mm from the fusion boundary. In this region, the grain size of the base metal was retained and small grains formed only on the prior-austenite grain boundaries (Fig. 4(b)). The grain boundary length was 5.99 cm, KAM was 1.94, and hardness was 243 for the microstructure of Fig. 4(b). At a distance of 0.5 mm from the fusion boundary, recrystallization occurred; however their grain size was more than 10 μm (Fig. 4(c)). The grain boundary length was 4.94 cm, KAM was 2.22, and hardness was 266 for the microstructure of Fig. 4(c). The KAM corresponds well to the hardness.

In the conventional high Cr steel welds, Type-IV creep damages form in the fine-grained HAZ with average grain size of about 5 μm; consequently creep strength of welds decreases than base metal [4, 5]. These results mentioned above in Fig. 4 confirm that the HAZ microstructures of high B-9Cr steel are considerably different from those of the conventional high Cr ferritic steels, and soluble free boron is essential for suppression of grain refinement during weld thermal cycle. We consider that the free boron decreases the grain boundary energies, and suppresses the nucleation of γ phase from grain boundaries by diffusional transformation, and causes the martensitic reverse transformation. The similar phenomena of the martensitic reverse transformation that the original grain size and crystal orientation was retained after heating up to A_{C3} transformation temperature were also reported in the maraging steels [6] and 12Cr turbine rotor steels containing boron [7].

3.2. Creep strength of dissimilar weld joints

Figure 5 shows the relations between stress and creep rupture time of the base metal of high B-9Cr steels and four kinds of the present dissimilar weld joints at 650 ˚C. Open symbols show the rupture times of the base metal and dissimilar weld joints for the MARBN10 steel, and solid symbols show those for the MARBN12 steel. The creep strength of base metal of the high B-9Cr steels was higher than that of the conventional 9Cr steel (Gr.92 steel) due to the grain boundary strengthening effect of boron. The creep strength of base metal of MARBN12 steel with 0.007 % N was higher than that of MARBN10 steel with 0.003 % N.

The creep rupture tests of the dissimilar weld joints were conducted at 650 ˚C for 160, 140, 120 and 100 MPa. The dissimilar welds using the high B-9Cr steel show 5-10 times longer creep rupture times than the Gr.92 steel weld at 100 MPa. The differences of the creep strength between dissimilar welds and base metals are small up to 20000h at 650 ˚C, and we are now investigating the creep strength at lower stress conditions; 90 and 80 MPa.

The dissimilar welds fractured in the base metal of high B-9Cr steel for the short term test conditions and in the fusion boundary between high B-9Cr steel and Ni base filler wire (Inconel 82) for the long term test conditions. The failure in the fusion boundary was observed at the stresses lower than 120 MPa for the MARBN10 steel welds and lower than 140 MPa for the MARBN12 steel welds. All the present dissimilar weld joints using high B-9Cr steels did not show the Type-IV failure in HAZ and consequently the creep rupture lives were much longer than those of the conventional 9Cr steel welds that showed the Type-IV failure at the present creep test conditions. This means that the microstructures and creep strength of HAZ was considerably improved in the high B-9Cr steel, which contains 0.01 % boron and low nitrogen (<0.01 %), due to the effect of soluble boron.

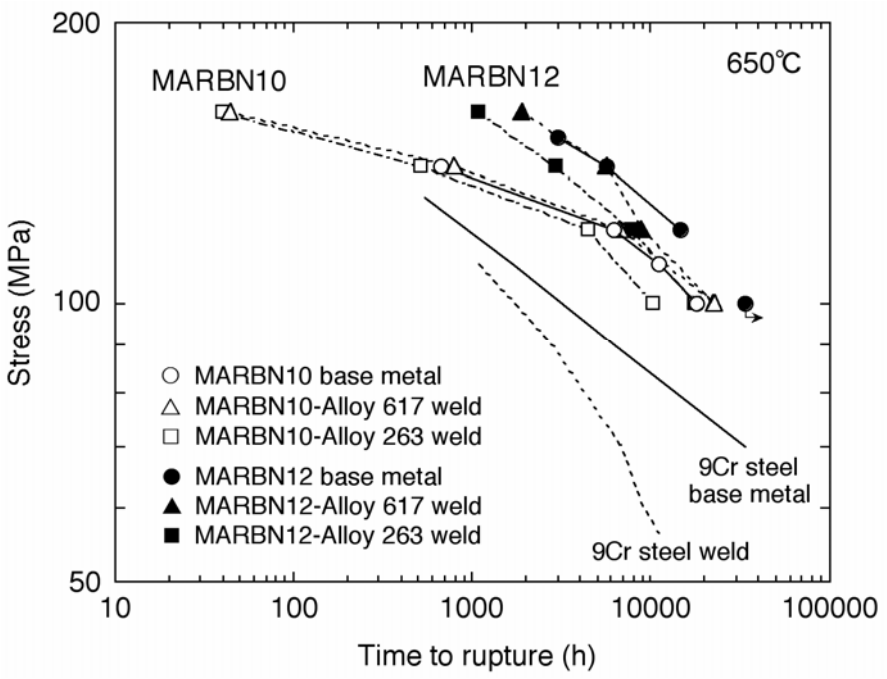

Figure 5. Creep rupture times of the base metals of the high B-9Cr steels and the dissimilar weld joints between high B-9Cr steels and Ni base alloys for A-USC boiler at 650 ˚C

(a) MARBN10 steel-Alloy 617 weld joint, 650 ˚C, 100MPa, 22766h

(b) MARBN12 steel-Alloy 617 weld joint, 650 ˚C, 100MPa, 22518h

Figure 6. Dissimilar weld joint specimens creep ruptured at 650 ˚C and 100MPa for 22000h

We have investigated the microstructures and creep damages in the crept welds. Figure 6 shows the dissimilar weld joint specimens creep ruptured at long-term test condition. It was observed that a creep crack initiated in the fusion boundary at the lower surface of U-groove and then propagated toward to the HAZ of the high B-9Cr steel.

Figure 7 shows microstructures and creep damages observed in the HAZ of the dissimilar welds between MARBN12 steel and Alloy 617 ruptured at 650 ˚C and 140 MPa for 5619h. In the HAZ at 1.5 mm from the fusion boundary, small amounts of creep voids were observed as shown in Fig. 7. This area corresponds to Fig. 4(b) where the grain size of the base metal was retained and small grains formed only on the prior-austenite grain boundaries. Creep voids in the HAZ of high B-9Cr

steel were observed on the prior-austenite grain boundaries with large grain size. It is considered that the void coalescence and crack formation, which causes Type-IV failure, is suppressed and consequently the life of weld is improved in these HAZ microstructures of high B-9Cr steel compared with the fine-grained HAZ microstructures of conventional high Cr steels.

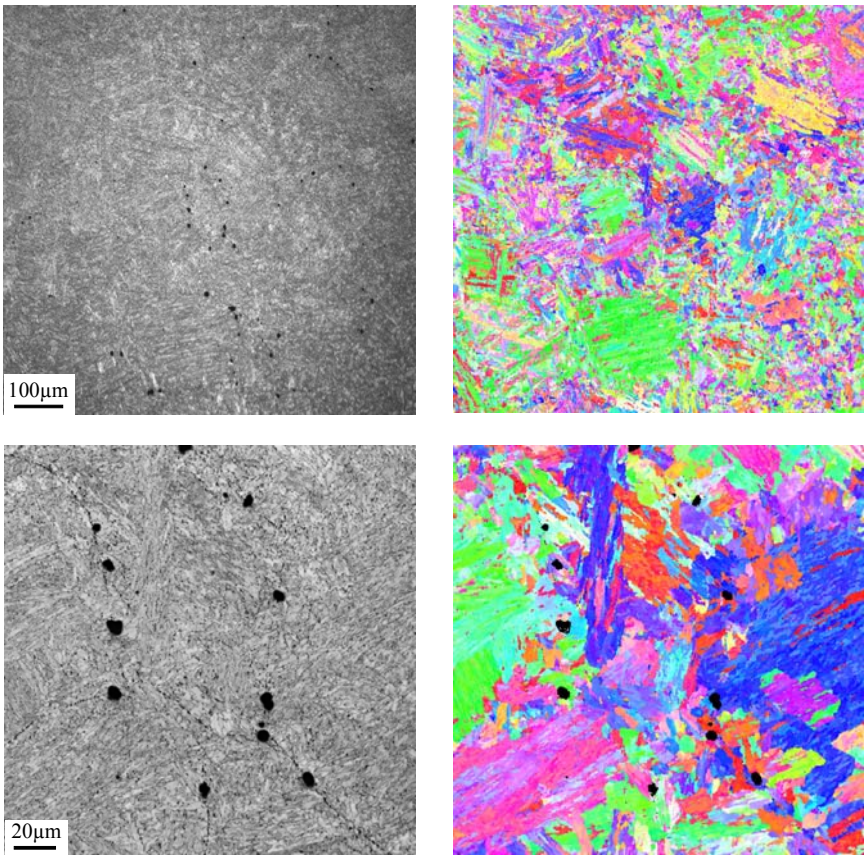

Figure 7. Microstructure and creep damage in the HAZ of the MARBN12 steel-Alloy 617 weld joint creep ruptured at 650 ˚C and 140 MPa for 5619 h

4. Conclusions

In the present paper, creep tests of the dissimilar welds between high B-9Cr steels and Ni base alloys, which are planning to be used in the 700 ˚C class pulverized coal power system (A-USC), were conducted. The results can be summarized as follows:

(1) For the high B-9Cr steels, fine-grained microstructures as shown in the conventional high Cr steels did not form in the HAZ. Free soluble boron is considered to decrease the grain boundary energy and change the mechanisms of the α-γ transformation during the weld thermal cycle.
(2) The creep rupture lives of the present dissimilar welds between high B-9Cr steels and Ni base alloys were 5-10 times longer than those of the conventional 9Cr steel welds at 650˚C.
(3) The failure locations of the dissimilar weld joints were base metal or fusion boundary. Small amounts of creep voids were observed in the HAZ with large grain size; however Type-IV failure did not occur for about 20000 h at 650˚C.

Abstract

Variable demand and an increasing range of electricity supply methods are such that steam plant must perform under cyclic operation. Indeed, the multiplicity of generating options means that even defining a 'typical' cycle is difficult. Quantification of the range of potential damage mechanisms is even more complex. In response to the need for greater understanding of cyclic performance issues in high energy components, in 2006 EPRI initiated a series of Annual Expert Workshops on Creep Fatigue. These discussions identified key issues and areas for development related to the design and performance under transient operation. Summary documents, produced from each of the annual meetings, have helped guide this international effort in the field of creep-fatigue. It is apparent that a coordinated effort is critical to ensuring that outcomes are meaningful and effective. Excellence in science and engineering is necessary in aiding the electricity supply industry to meet current challenges associated with safe and reliable operation of plant. The present paper documents the current state of knowledge on creep fatigue behaviour and outlines achievements from the EPRI collaborative work. The overall goal of this effort is to provide the basis of a comprehensive approach to design and life management of components that are subject to creep-fatigue conditions.

Keywords Creep, Fatigue, Flexible Operation

1. Introduction

Utilities increasingly need to adopt generating practices that involve cycles. The number, magnitude, and complexity of the cycles associated with transient type operation have all increased. Thus, starts and stops as well as changes in generating output can lead to problems associated with thermal and /or mechanical loading as well as potential issues with water chemistry and corrosion. For components which operate at high-temperature, damage associated with transient operation is frequently called *creep-fatigue*. However, even in this group of components, specifics of damage mechanisms will vary widely. A schematic illustration of the primary options is shown in Fig 1.

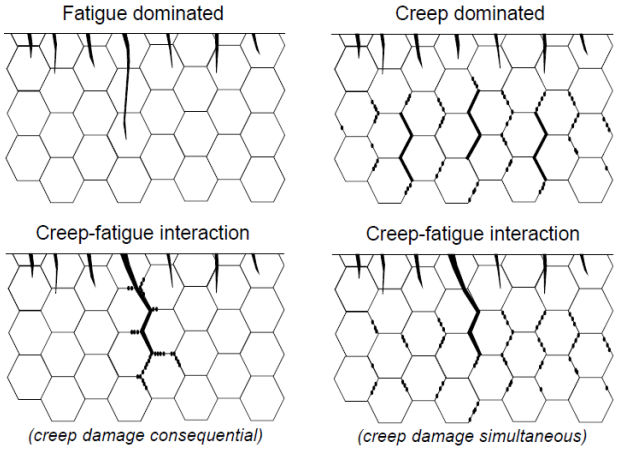

Figure 1. Schematic illustration of different forms of creep-fatigue type damage seen in high energy components.

While many examples of fatigue dominated and creep dominated in-service damage can be presented, the most problematic situation from a predictive point of view is when the effects are interactive. Under these conditions the primary concern is whether damage accumulates more quickly than would be expected for either mechanism alone. As power generating systems seek maximum flexibility from available plants, increasing numbers of components must operate in creep-fatigue conditions. Moreover, recent installation of combustion turbines and heat recovery steam generators have increased the number of materials and components that operate in high-temperature, cyclic conditions. In addition, high-efficiency coal plants operate with even higher steam and metal temperatures than those of traditional plants. Thus, creep-fatigue damage will occur more frequently and in more materials, including low-alloy ferritic steels, austenitic steels, nickel-based alloys, and creep-strength-enhanced steels.

The present paper documents the current state of knowledge on creep fatigue behaviour and outlines achievements from the EPRI collaborative work.

2. Achievements

EPRI's long-range research program (Technology Innovation) initiated a set of activities in 2006. The initial goals of the work were to:

- Examine how problems of Creep-Fatigue assessment are addressed internationally
- Identify deficiencies that exist with current knowledge and approaches, and
- Recommend improvements in application of the available technology and identify future Research and Development needs.

EPRI's overall approach to establishing solutions to assessing creep fatigue performance has involved facilitating discussion at annual expert workshops, preparation of critical reports and publications, facilitating the preparation and review of new ASTM standards for laboratory creep fatigue testing and establishing a platform and associated knowledge base of materials behavior. EPRI's Fossil Materials & Repair Program has funded many specific activities, but the overall success of this effort is due to broad international collaboration with participants bringing their own resources and expertise together including focusing their scopes of work for the benefit of the group. Key elements of these achievements are presented here.

2.1. Expert Workshops

A series of EPRI facilitated Formulative Expert Workshops has succeeded in presenting up-to-the-minute information concerning the current state-of-knowledge of creep-fatigue damage interaction. The meetings have been hosted at different global locations and the presentations made at these workshops have been published by EPRI, Table 1. In addition, the discussions held resulted in the development of an agreed listing of key issues for future consideration. These issues have been reviewed and updated as necessary and continue to be used to guide current and future work.

Table 1. Annual Expert Creep Fatigue Workshops

Analytical evaluation of creep crack initiation has been considered using different methods. The most widely used overall approaches are ASME, Rules for the Construction of Nuclear Facility Components, Class 1 Components in Elevated Temperature Service, Boiler and Pressure Code, Section III, Division 1— Subsection NH [1], TRD 301, Annex I—Design: Calculation for Cyclic Loading due to Pulsating Internal Pressure or Combined Changes of Internal Pressure and Temperature [2], RCC-MR, Design and Construction Rules for Mechanical Components of FBR Nuclear Islands, Section I [3] and R5, An Assessment Procedure for the High Temperature Response of Structures,[4] .

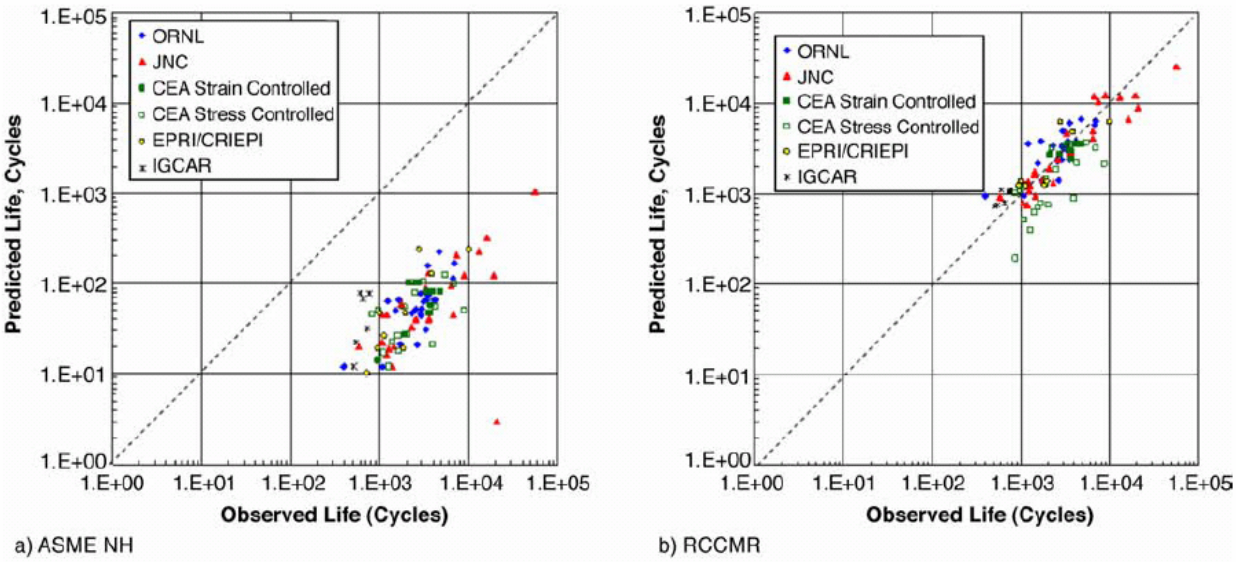

Figure 2. Comparison of the results of different methods of analysis of the same data set of creep fatigue data from Grade 91 steel, performed (a) using ASME NH [1] and (b) using RCCMR [3].

The difference in the approaches leads to very different predictions for creep fatigue behaviour. For example, the recommended interaction line for Grade 91 steel originally proposed in ASME – NH was very conservative. At least some of this excessive conservatism arises because this alloy exhibits complex behavior during cyclic tests at high temperature, and use of time fraction without considering stress-relaxation and strain-softening effects yields a very conservative outcome. The level of conservatism using the standard ASME NH approach is demonstrated by consideration of the results shown in Fig 2(a). Clearly, the calculated lives are at least 10 times less than the observed behavior. Application of an improved methodology, such as that developed in the French Code RCCMR, indicates that by accounting for the metallurgical complexities, the prediction comes into reasonable agreement with the observed behavior, see Fig 2(b).

2.2. Detailed Reports

The EPRI initiative has focused effort in specific agreed areas. One significant activity has been to facilitate preparation of State of Knowledge and other documents on Creep-Fatigue Damage

Interaction. A summary of these Milestone reports is provided in Table 2. It is apparent that the two main methods used to asses creep damage are:

- Time fraction
- Strain fraction (ductility exhaustion)

While these general terms describe the overall methodologies, there are also many variations in the detailed application. These variations and the assumptions that are often required to support the analysis frequently make definitive engineering judgments on accuracy difficult.

2012	Review and analyses of Creep-Fatigue data. Metallographic Atlas and examples of damage	In press

Whether time summation or strain summation is chosen, investigators have usually been at pains to demonstrate an agreement with experimental failure data to within a factor of two. This has generally been managed by increasing use of ‘partitioning’ rules or other degrees of sophistication so that the original models begin to lose their attractiveness – the most robust have proved to be those which are the easiest to use. By tracing some of the history of the damage laws, it appears that the time fraction rule originally took peak stress as the reference and was therefore conservative. Attempts to integrate down a relaxation curve and refine the appropriate time led to non-conservative predictions of life. Thus the interaction diagram was made bi-linear which restored conservatism.

There have been similar difficulties with analyzing ductility data for strain fraction. One basic question must be asked - which is the most physically correct ductility to take? The assumption of an average strain rate by taking ductility divided by time to failure is not necessarily an accurate reflection of secondary creep rate if both primary and tertiary stages of creep are large. Nevertheless, all models acknowledge the decreasing ductility (of whichever form) with decrease in strain rate, and there seems now to be a general acceptance that the ductility exhaustion approach is consistent and less prone to difficulties with scatter. In many cases, however, one may be forced to apply the time fraction rule because of data restrictions – it is highly unlikely that in long-term stress rupture

tests that specimens were fitted with extensometry to determine relevant strain rates, and further there is no guarantee that associated end-of-test ductility values are available.

2.3. Standardization

Many countries have established guidelines and procedures for creep fatigue testing. However, there were differences in detail between many of the recommendations. A key activity facilitated by the EPRI work was thus development of specific ASTM Creep - Fatigue Standards. Currently efforts have resulted in two standards:

- ASTM Standard: Test Method for Creep Fatigue Testing, ASTM E2714-09. This method covers the determination of mechanical properties pertaining to creep-fatigue crack formation in nominally homogeneous materials. It is primarily aimed at providing the material properties required for assessment of defect-free engineering structures containing features that are subject to cyclic loading at temperatures that are sufficiently high to cause creep deformation.
- ASTM Standard: Test Method for Creep-Fatigue Crack Growth Testing, ASTM E2760-10. This test method is concerned with developing creep-crack growth data under cyclic conditions which is used in some more sophisticated assessments of in-service materials when large flaws may be present.

As part of the review and acceptance process by ASTM, the provisional Standards listed above must be evaluated for a precision and bias statement through a round robin test program. A round robin testing program is now complete for ASTM E2714-09[5] (details below) and the precision and bias statement will be added in the next revision of the standard. Planning, preliminary testing, and specimen blank fabrication are now complete for ASTM E2760-10 with round robin testing expected in 2013.

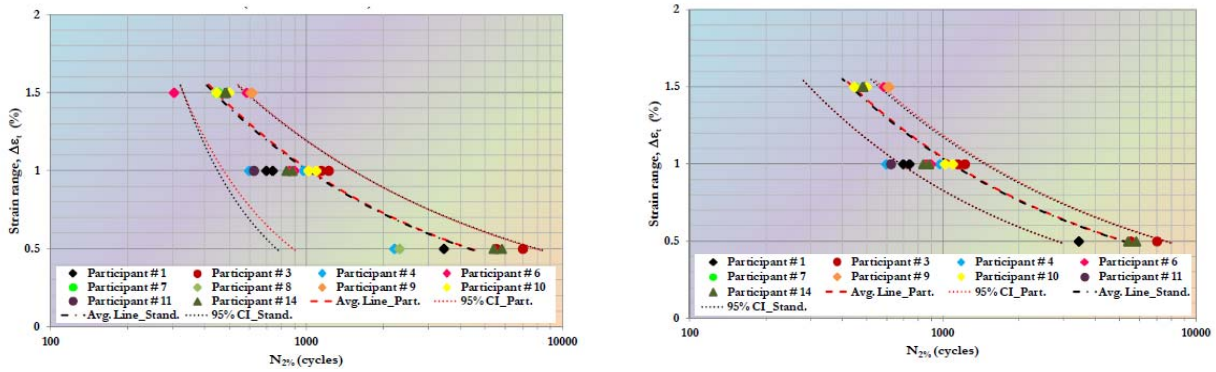
The round robin test program for ASTM E2714-09 utilized Grade 91 steel test blanks (modified 9%Cr-1Mo-V) provided by EPRI. Sixteen laboratories around the world agreed to participate in the study with 13 eventually reporting their test results to EPRI and the ASTM Task Group on Creep-fatigue Crack Formation (E08.05.08). Strain controlled creep-fatigue tests were conducted at 625C at three stain amplitude. Each laboratory followed the provisional standard, but variations in specimen geometry, heating methods, and numbers of tests were acceptable. Statistical analysis of the inter- and intra-laboratory variability was conducted. EPRI highly recommends metallographic assessment as part of the post-test evaluation to see if creep or fatigue damage dominated the failure or if a true creep-fatigue interaction was found. Most laboratories did not do this, so additional post-test metallography was conducted.

Assessment of the data required development of an improved analytical method, not currently prescribed in the standard, to determine the cycles to crack formation. The analysis of the data found the variability factor for the 95% confidence interval bands increased at longer hold times and lower strains. One significant finding was that post-test inspection of specimens was necessary to determine if a test was valid (or not). Uneven heating due to the use of induction heating methods or failures due to bending were not identified by the testing laboratory, but post-test inspection and metallography resulted in some tests being rejected. Fig 3 shows an example of data before (a) and after post-test assessment for validity (b). The round robin (RR) research produced the following recommendations:

- From the results of the RR, the current precision and bias statements in the standard should be modified (this activity is underway)

- The current standard should be modified to include post-test metallographic analysis to ensure that the dominant crack(s) form within the gage length of the specimen and if bending and/or extensive bulging was present in the test specimen warranting rejection of the data.
- A cautionary note should be added in the standard to warn users of the possible effects of heating methods on the C-F lives of test specimens.
- A more in-depth test program should be considered using the available material to characterize the C-F properties of P91 steel and to also investigate the effects of heating methods on the C-F lives.

In addition to these standards, the experts group has produced a code of practice for short-crack growth under creep fatigue conditions [6].



(a) (b)

Figure 3. Comparison of data produced as part of the creep-fatigue RR test program, (a) showing all the data while (b) shows the only data for tests which met the criteria for validity. The 95% confidence interval bands decrease significantly when post-test metallographic evaluation is used to eliminate invalid tests.

3. Discussion

It is clear that updated methodologies for estimating damage in service components should distinguish between sequential damage, for example, steady operation leading to creep followed by cyclic performance resulting in fatigue, and interactive damage, i.e. under conditions where the damage processes lead to rapid damage development. This is particularly important for alloys where time and/or cyclic microstructural changes occur. Damage accumulation in creep-fatigue should be described by a formulation that includes a term giving the influence of creep on fatigue and vice versa. In other words, where damage is truly interactive, the capacity for creep must be reduced due to the fatigue, and the capacity for fatigue must be reduced by creep.

Moreover, the challenges associated with using curve fitting approaches for parametric fitting of experimental data must be considered because although reasonable fits can be obtained to an existing data set, the accuracy of parametric data extrapolations may not be guaranteed. In all cases, there is a major requirement for the results of experimental and analytical programs to be supported by meaningful post test metallographic examination. Thus, post test examination should be performed to document the type, density and character of damage present recording at the very least whether the primary damage is intergranular or transgranular.

The practicality of using complex constitutive equations with many variables also needs to be considered. While design approaches, particularly for turbine components, may be carried out based on detailed knowledge, it is apparent that in-service assessment methods that are slightly conservative and can be applied without the need for extensive materials testing and/or complex stress analysis are required. This is particularly true for boilers and piping. This issue is illustrated by consideration of Fig 4. Here different analytical approaches have been applied to creep fatigue results from Grade 92 steel [7]. The relatively simple strain fraction method results in a consistently conservative prediction of behaviour. In contrast a more detailed modified strain fraction approach shows a much less conservative outcome. Indeed, with this analysis, experimental results and predictions are scattered on both sides of the line showing matching agreement, and all data are well within ±2. The continued validation of simple, sensibly conservative methods for at-risk plant components is necessary because of the implementation of new alloys and operating regimes.

Finally, it is important to note that the effect of Oxidation on Creep - Fatigue Damage interaction and Component Performance must be considered in specific circumstances of the component and details of the in-service environment. It is established that surface scales can lead to damage initiation in some component applications. Thus, when developing laboratory test programs it is important to ensure that the experimental damage mechanisms are relevant to in-service behavior.

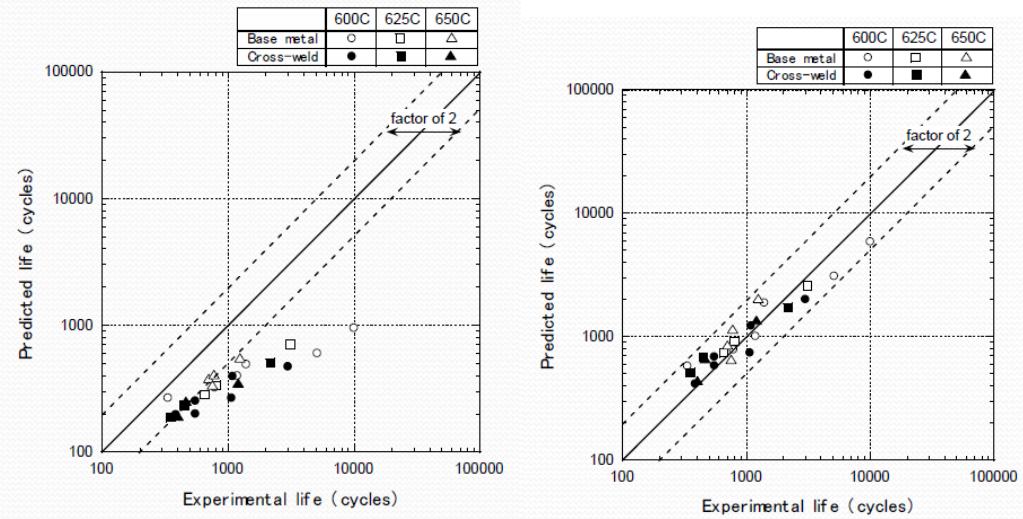


Figure 4. Comparison of Experimental and predicted Creep Fatigue lives for Grade 92 steel tested in the range 600 to 650°C. Analysis was performed using a strain fraction rule in (a) and a more complex Modified Strain Fraction rule in (b). **[7]**

4. On-going Commitment

There are relatively few examples where comprehensive data sets have been established without the need for significant assumptions and/or extrapolations. As an example, challenges with application of the strain fraction/ductility exhaustion methodology often occur because measurements of strain: time behavior are not available. In addition, there are many different suggestions for the appropriate value to use for Strain to Fracture. These variations include:

- Data averaged from available information for the alloy
- Simplified methods for total strain, for example, made using the product of the minimum creep rate and time to failure

- Estimates based on relationships describing creep strain with time for applicable stress/ temperature combinations
- Strain to Failure, Elongation/Reduction of Area, or other measured value for different conditions extrapolated to the conditions of interest

Moreover, although significant information exists for the most widely used boiler and turbine steels; in most cases testing has concentrated on generating parent properties. Thus, less laboratory data exist for weld metals, heat-affected zone (HAZ), or overall weldment performance, even though in many boiler applications, in-service damage in components operating at high temperature frequently occurs associated with welds.

EPRI is working with members of the expert group to establish comprehensive data compilations on the most widely used alloys. It is planned that analysis of the data sets compiled will result in published material data sheets suitable for base line type analysis. Alloys for which Data Compilation Books or 'Creep-fatigue data sheets' are planned include:

– Steels used in Boiler Headers and Piping, for example P22, P91 (X10CrMoV9-1), P92, E911,

– Alloys used in turbine rotors and discs (IN718, IN706, X12CrMoWVNbN10-1-1, IN617, etc.

An example of high temperature creep rupture, deformation and ductility data for Grade 91 steel is shown in Fig 5. The output analysis of this type of data would be included in the envisaged Creep-fatigue datasheets. The plan to produce master creep, fatigue, and creep-fatigue equations most relevant to plant operational conditions is critically important as the data input often becomes the most important source of uncertainty in life assessment calculations. Before releasing these summary equations and curves, the Creep-Fatigue datasheets will be provided to the EPRI expert working group for evaluation and approval. Adoption of standardized equations will aid current needs for creep-fatigue assessment as well as future developments in more sophisticated analytical approaches and in new materials.

5. Concluding Remarks

In general, creep-fatigue design considerations are intended to prevent crack initiation, where crack initiation is defined arbitrarily as the presence of cracks that can be detected visually, for example, 1 mm in length. The difference between crack initiation and failure life in a normal laboratory specimen is often a small proportion of the total life, and it can be argued that the failure endurance of a small specimen corresponds to the endurance at crack initiation in a large component. A recent discussion identified the following as primary classification of component types of concern:

- Thick sections, especially welds,
- Changes in section and complex geometries,
- Welds in low ductility (creep brittle) materials,
- Non-stress relieved welds,
- Thin section welds with defects.

The general consensus regarding methods of assessing crack initiation is the following:

- Time-fraction-type stress-based creep damage is insufficient for predicting life reduction due to creep holds. This is especially the case at the small strain ranges of practical interest. This effect cannot be properly described using creep-time fraction on an interaction diagram.

- Calculation of ductility-exhaustion-type strain-based creep damage tends to overestimate the creep fraction used per cycle when all inelastic strain during a hold period is counted. However, use of a modified stress ductility approach or equivalent appeared to provide the best method of assessment.
- As an initial approach to component assessment it seems that application of an easy to use conservative method offers a practical way of undertaking bounding type calculations. Use of these approaches must consider lower bound materials data and simplified stress analysis for both parent and welds.
- For second level assessments there are advantages to use of probabilistic assessment using validated inelastic analysis. Since this approach requires considerable effort on materials relationships and validation of models it will only be used for a very select number of components
- As Power plant operation now involves an increasing range of cyclic operation, issues of creep and cyclic damage increasingly a concern. The following questions summarize topics of focus for EPRI:
    - How to *predict field damage* using available models/ methodologies? Required accuracy? Important attributes?
    - *Monitoring*. Need for instrumentation in performing a component assessment?
    - Availability of relevant materials data to *assessment of an ageing plant (coal or HRSG pressure parts, rotors)*?
    - *Design*. Can we improve on the design for cyclic high temperature service? Should there be design life based on hours, cycles, and oxidation?
    - What is required for practical component assessment?

It is clear the groundwork laid by EPRI on creep-fatigue damage with the collaboration, assistance, and dedication of a large international experts group was a timely activity due to increased cyclic plant operation. While many tasks are now complete, more work is needed. The international group will continue to meet with key activities on completing standardization, developing creep-fatigue datasheets, and focusing on application case studies to improve component assessments.

Acknowledgements

Thanks to the support and contributions from the invited experts the discussions were successful in identifying key issues and perhaps more importantly developing solutions to these challenges. Support for this work has included the involvement of the following Bob Ainsworth, Dave Dean and Mike Spindler , British Energy (now EdF),UK; Ashok Saxina , Galgotias University, India (formerly University of Arkansas); Stuart Holdsworth, EMPA, Switzerland; Yukio Takahashi, CRIEPI, Japan; Bilal Dogan (formerly of GKSS and EPRI); Peter Skelton, consultant UK (formerly CEGB and Imperial College); Warwick Peyton, ANSTO, Australia; Toshimitsu A. Experimental requirements of small and large scale dynamic fracture mechanics testing

Wolfram Baer

BAM Federal Institute for Materials Research and Testing, Berlin, Germany
Corresponding email address: wolfram.baer@bam.de

Abstract The paper deals with experimental requirements of dynamic fracture mechanics tests in general with special focus on ductile cast iron materials. This is based on instructions for dynamic measurement techniques provided by the standards ASTM E 1820 and BS 7448-3 which were compared and rated.
The low blow multiple specimen technique using a drop tower was investigated for crack resistance curve determination on SE(B)25x25 specimens. It was shown that no detrimental effects should be expected from the second impact of the rebounded striker. Strain gage instrumentations for direct force measurement according to the standards provided different results. The ASTM position should be preferred. Important conclusions were drawn concerning hidden friction in drop towers from a comparison of electro-optically measured displacement and calculations from force-time record.
Full blow large scale tests on SE(B)140x280 specimens were performed using a servo-hydraulic test system to determine dynamic fracture toughness values. Different strain gage instrumentations were compared with respect to their force measurement capability. For displacement measurement only a non-contact electro-optical camera technique was applicable. An appropriate method of instrumentation was identified whose results show good agreement with numerical simulations of the tests.
It can be concluded that the recommendations of the test standards provide different results. Therefore, they must not simply be transferred to the own specific test requirements. It is regarded absolutely essential for dynamic fracture mechanics tests in general that all measuring techniques are being validated in advance.

Keywords dynamic fracture mechanics testing, ductile cast iron, measurement

1. Introduction

Design and safety assessment of components subjected to high strain rate or impact (dynamic) loading require adequate material data. Therefore, the focus of this paper is on the experimental determination of dynamic fracture mechanics material data.
The problem of how to measure basic quantities like force and displacement correctly and with sufficient precision in dynamic fracture mechanics tests has still been an experimental challenge, although such tests have been performed for at least 40 years. Advice given on that by test standards such as BS 7448-3 [1] or ASTM E 1820 [2] is fairly limited. The ISO standard 26843 [3] on the determination of dynamic fracture toughness using precracked Charpy specimens (PCVN) is still being drafted while comparable contents has recently been included in the very new annex 17 of [2].
A major lesson to be learned from experience is that the first step of experimental dynamic fracture mechanics investigations should always be to establish an appropriate test method. This seems to be trivial only in the first instance. In fact, the material behavior mainly governs the test techniques which are applicable. Many materials - such as the ductile cast iron (DCI) investigated here - substantially change their deformation, damage and fracture behavior from ductile to brittle by increasing loading rate, decreasing temperature and/or increasing stress triaxiality. Unfortunately, this does not happen suddenly so that the corresponding measuring techniques have to be adapted with deliberation.
As will be shown below, transferability of measuring techniques from one lab to another, from small to large scale tests or vice versa and of more or less common advice from standards to the own very special task cannot simply be taken for granted. In contrary, it is of vital importance to validate the basic measured quantities independently before using the data for further analyses and

to establish material characteristics. Basically this should be a matter of course. But it is time and money consuming and studying the literature often reveals an opposite practice.
Usually, conventional techniques as machine load cells and clip-on transducers cannot be applied to measure the true mechanical response of the specimen due to the short duration of dynamic fracture mechanics tests (microseconds up to milliseconds), inertial effects and resulting signal oscillations. The information which is given on that by relevant test standards [1,2] is shortly summarized in Table 1. Table 1 is limited to single edge bend specimens (SE(B)) since this type of specimen is primarily tested under dynamic loading at BAM.

Table 1. Standard information on force and displacement measurement in dynamic fracture mechanics tests on SE(B) specimens with thickness/width-ratios $1 \leq B/W \leq 4$

Informa-	BS 7448-3 [1]		ASTM E 1820 [2]		
tion on	Main body	Annex A	Annex A13	Annex A14	Annex A17
loading rate	$3 < \dot{K} < 3000$ MPa√m/s	$\dot{K} > 3000$ MPa√m/s	$\dot{K} > 2{,}75$ MPa√m/s, not for impact or quasi--impact testing (free-falling or swinging masses), minimum loading time 1 ms	$\dot{K} > 2{,}75$ MPa√m/s, minimum test time to be calculated to avoid presence of a significant kinetic energy component in the specimen relative to the internal energy and to assure applicability of static J-integral equations	no restriction on impact velocity provided the time to fracture is greater than the calculated minimum test time
force measurement	machine load cell	resistance strain gages attached to both sides of the specimen, wired as two quarter bridges, positions: W/2 from ligament and at W/2 in width	machine load cell as used for static plane strain fracture toughness test generally suitable, but response characteristic to be checked to avoid inertial effects	on-specimen force measurement recommended (remote load cells allowed if requirements are met), full bridge of 4 strain gages on the specimen midplane at the specimen span quarter points (on upper and lower specimen side)	strain gage instrumented striker
displacement measurement	direct load line displacement via horizontal comparator bar	approximation by test machine ram displacement	the same transducers as used for static plane strain fracture toughness test generally suitable, but response characteristic to be checked to avoid inertial effects	fibre-optic transducers	calculation from force/time record, no measurement
COD measurement	clip gage	-		cantilever beam displacement gages like in static fracture toughness testing down to loading times of 1 ms	-

Table 1 outlines the bottom line for a user when dynamic fracture mechanics tests have to be drafted. The first thing to note about Table 1 is that the recommendations of [1] and [2] regarding strain gage positions for force measurement are very different. This mirrors the status in the literature including for instance early basic studies of Ireland [4, 5] or Trudeau [6] which are still frequently cited. Some own experimental results will be discussed below.
With respect to load line displacement measurement BS [1] does not provide a convenient method for higher loading rates. The recommendation to approximate the test machine ram displacement is rated not sufficient. Compared with this, ASTM [2] at least indicates that non-contact optical methods are suited and inertial effects shall be avoided.

2. Experiments

The paper reports on experimental fracture mechanics impact investigations on bend type specimens of DCI materials. Depending on the DCI's material behavior [7], two types of tests have been investigated: a small scale low blow multiple specimen technique using a drop tower was investigated for crack resistance curve determination as well as large scale full blow tests on SE(B)140 specimens were performed. Different experimental aspects of the test methods are discussed here. Mechanical properties, microstructural aspects and the values of the fracture mechanics characteristics of the materials are not in the focus of this paper. They will be reported elsewhere.

2.1. Small scale low blow tests

When the DCI material exhibits R-curve behavior, it is still first choice to use the low blow multiple specimen technique for dynamic crack resistance curve determination. Unfortunately, single specimen techniques, as the key curve method, have not been proved successfully to be appropriate and to provide enough precision with DCI materials at dynamic loading conditions [8]. Primary goal of the investigations was to setup a multiple specimen test method to determine dynamic crack resistance curves in the temperature range from ambient to -40 °C. Series of small scale low blow tests on SE(B)25 specimens (length 138 mm, width 25 mm, thickness 25 mm, $a_0/W = 0.5$) were performed by use of a drop tower test system (Fig. 1) at stress intensity rates in the linear-elastic range of approximately $3 \cdot 10^5$ MPa$\sqrt{}$ms^{-1}.

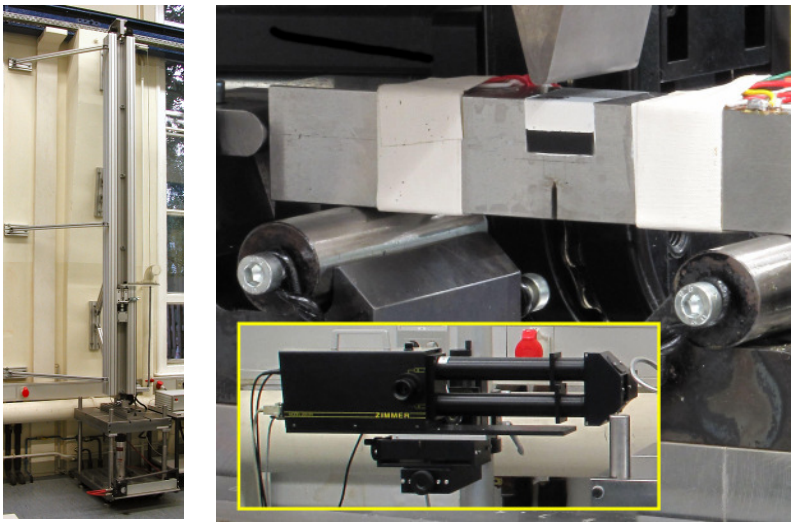

Figure 1. Left: BAM drop tower test system with $v_{0max} \approx 8$ ms^{-1}, max. energy $\approx$ 300 J, right: test setup with SE(B)25-specimen instrumented for opto-electronic measurement of load line displacement.

Fig. 2 shows different strain gage instrumentations which were compared with respect to their force measurement capability. All strain gages were statically calibrated before the tests.

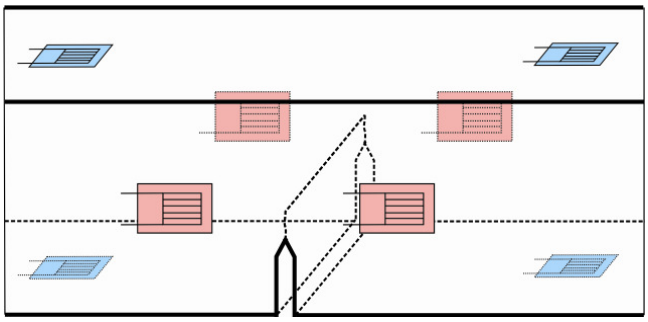

Figure 2. Strain gage instrumentations for direct force measurement on SE(B)25-specimens, blue: ASTM full bridge at specimen quarter points, red: 2 BS half bridges at W/2.

Basic principle of low blow tests is that a defined amount of energy is transferred to the specimen by a single hit of the striker causing deformation and stable crack growth. Therefore, it has either to be realized that second and following hits of the rebounded striker are prevented or that they are of such a magnitude that they will not cause crack growth in the specimen. Catching of the rebounded striker is practically impossible due to the low rebound height and the corresponding short time. Fig. 3 and Fig. 4 show force-time records of a low blow test on a DCI SE(B)25-specimen with $a_0/W = 0.5$ at -40 °C. The first hit of the striker causes the first force peak (low blow test) and the peaks (impulses) 2 to 4 are caused by the successively rebounding striker. After the test a stable crack growth of 0.62 mm was measured on the fracture surface ($a_E/W = 0.52$). As can be seen from comparison of the force signal height with the yield load of the specimen after the first hit ($a_E/W = 0.52$) or even assuming a maximum crack length of $a_{max}/W = 0.55$, the magnitude of the second and following impulses is clearly below the yield loads. This holds for BS- as well as ASTM-strain gage force measurement. The differences between ASTM- and BS-records will be discussed below. For the nonce, it can be concluded that second and following impulses cause only elastic deformation and do not contribute to crack growth so that they can be ignored.

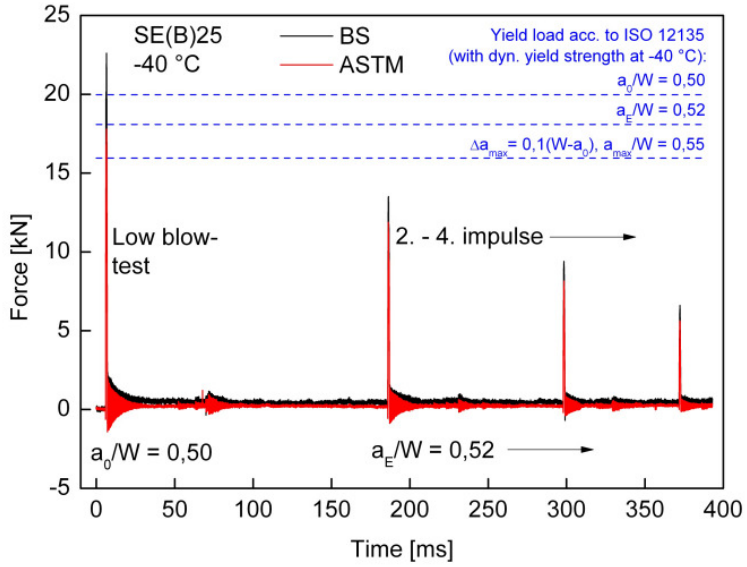

Figure 3. Force-time records of a low blow test, DCI, SE(B)25-specimen, $a_0/W = 0.5$, -40 °C.

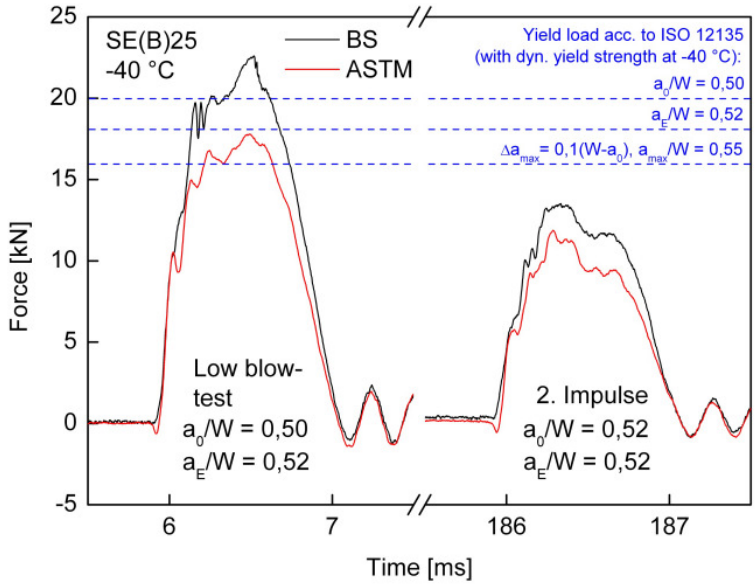

Figure 4. Details of force-time record from Fig. 3, DCI, SE(B)25-specimen, $a_0/W = 0.5$, -40 °C

As already indicated above, strain gage instrumentations according to ASTM and BS provide different results independent from temperature, Fig. 5, left. To clarify this, reference tests under quasistatic loading had been performed with the same instrumentation, Fig. 5, right. They revealed that the ASTM signal widely conforms to the reference while BS significantly differs and displays a remaining tensile force at the end of the test when the specimen is fully unloaded. In order to investigate if plasticity at the BS W/2 positions causes these differences (note: W = B and not W = 2B), a test with BS strain gages at a distance of W from the ligament was performed. A significant improvement could not be achieved. Therefore it is concluded for low blow tests that strain gages at ASTM positions work well with the investigated SE(B)25-specimens while BS positions cannot be recommended.

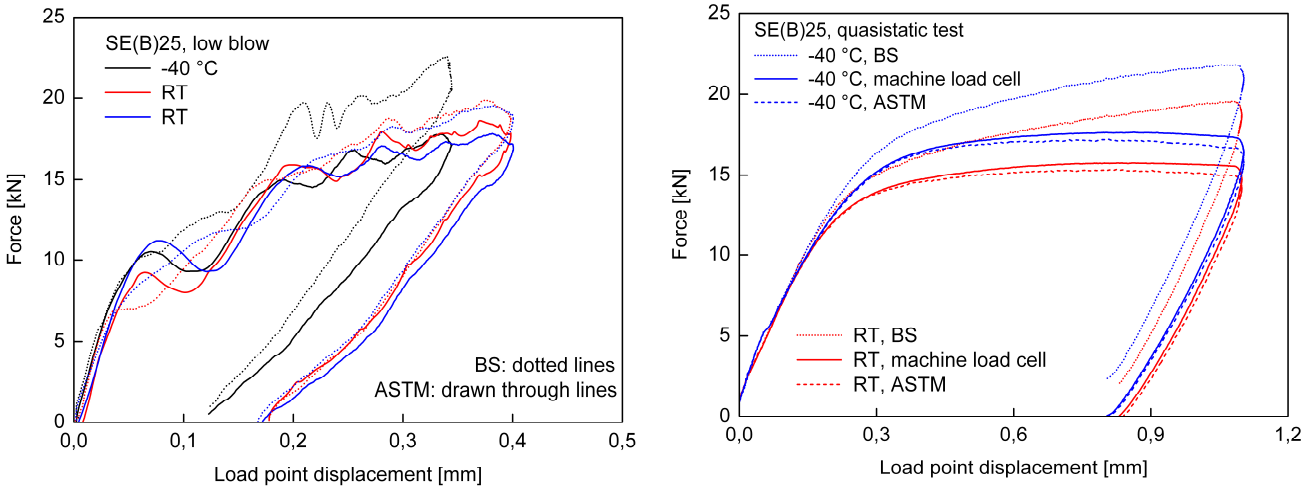

Figure 5. Comparison of ASTM and BS strain gage force measurements on SE(B)25-specimens in low blow tests (left) and quasistatic tests (right).

Basically, the load line displacement in tests using instrumented pendulum impact machines or drop towers can be determined by double integration of the force-time record. This is considered an attractive way to provide displacement data when expensive non-contact measuring equipment is not available or not applicable. However, as can be seen from Fig. 6, left, tremendous differences/errors may occur between the calculated values and the reference measured by an

independent and verified method. The errors were due to slight energy losses by hidden friction which may easily occur especially in larger drop towers. Therefore, the drop tower was constructively optimized and the tests were repeated, Fig. 6, right. The calculated and the measured displacement values are now nearly equal so that dynamic fracture mechanics tests could even be performed without having special equipment for displacement measurement available. But it must be considered an absolute essential prerequisite that this procedure can only be followed when the substance of Fig. 6 had been proven in advance. Further technical information on the camera and the validation of the corresponding measurement results is given at the end of chapter 2.2.

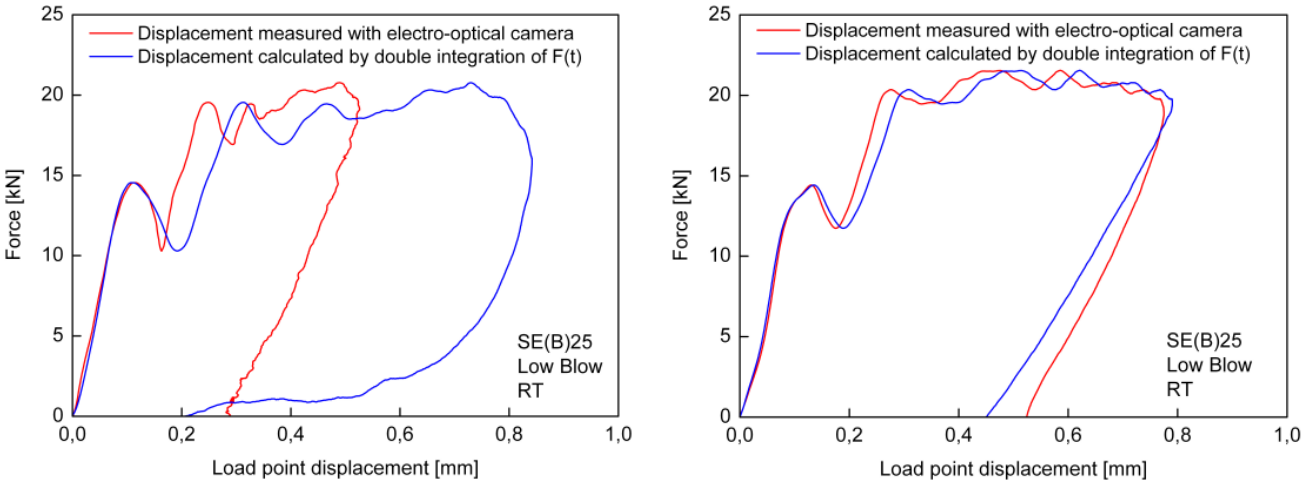

Figure 6. Force vs. calculated and measured displacement,

The question of how to detect initiation of stable crack initiation in dynamic fracture mechanics tests has not yet been resolved satisfyingly. Reported techniques like magnetic emission, acoustic emission or near crack tip strain gages seem to work in special cases but cannot be seen as robust methods nor generally be applicable. Additionally, they do not seem to work with DCI reproducibly enough. Therefore, an alternative technique based on the detection of stable crack initiation by failure of strands of a crack propagation sensor attached to the ligament was investigated here, Fig. 7. Two different sensor positions - (1) first strand right in front of the initial crack tip on the specimen surface (Fig. 8, left) as well as (2) sensor at the initial crack tip on the specimen surface (Fig. 8, right) - were investigated. It was observed that in both cases the crack sensors provide discrete signal jumps in quasistatic and dynamic tests on SE(B)25 specimens at RT and -40 °C. Nevertheless, with position (1) there is a large scatter of detected initiation forces F_{ini} of $0.5F_{max} \leq F_{ini} \leq 1.0F_{max}$. Material scatter may be a possible reason. But it seems more likely to

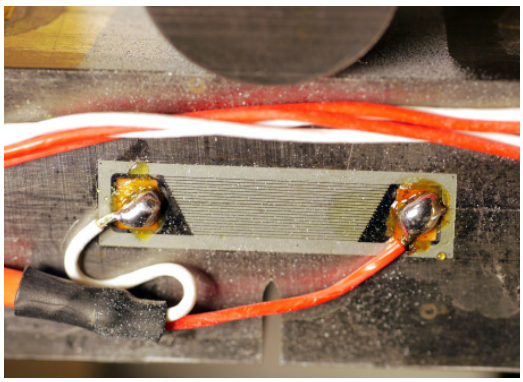

Figure 7. Crack sensor in front of the crack tip of a SE(B)25-specimen.

be due to the sensor position and analysis method. The sensor was placed only based on the nominal position of the precrack tip on the specimen surface. The real, measured initial crack length across the specimen thickness is not taken into consideration. Therefore, sensor position (2) on the crack was investigated. With (2) failure of the n-th strand positioned at the post-test measured mean initial crack length a_0 indicates crack initiation. Scatter of the crack initiation forces F_{ini} can still be observed with this procedure, $0.86F_{max} \leq F_{ini} \leq 1.0F_{max}$. But it is clearly lower than with method (1), although the tests were performed at -40 °C this time. Nevertheless, the data base for method (2) is still too small to finally rate the appropriateness of the technique.

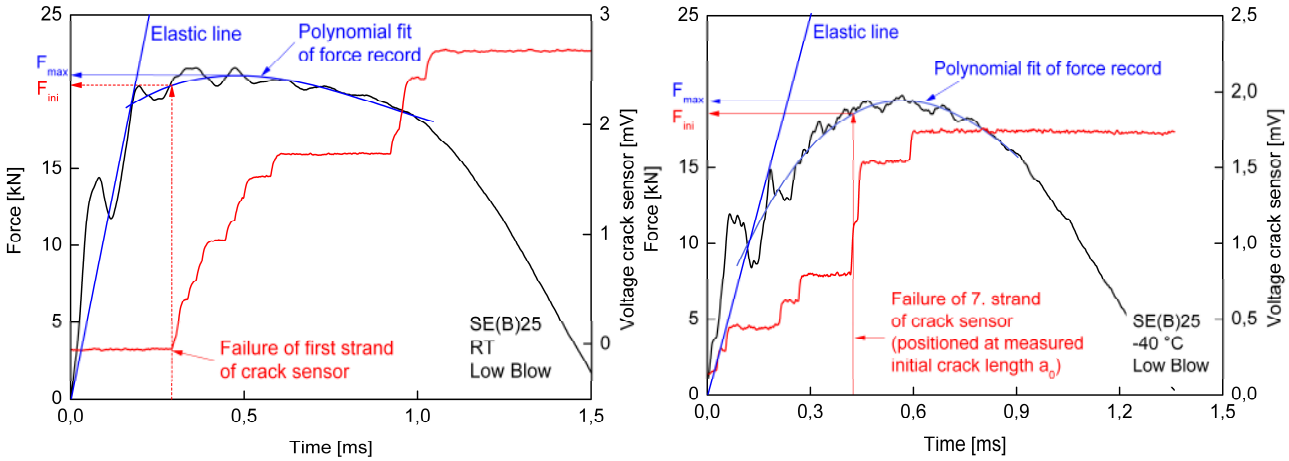

Figure 8. Principle of detection of stable crack initiation by failure of crack sensors, left: (1) crack sensor position at crack tip and failure of the first strand, right: (2) crack sensor position on the crack and failure of the n-th strand positioned at the measured initial crack tip.

2.2. Large scale full blow tests

A large wall thickness is typical for many applications of DCI such as casings or transport and storage cask for radioactive materials. In order to investigate how the fracture mechanics characteristics of small specimens, which could even be determined within quality assurance procedures, correspond to the results of large specimens with component-like thicknesses, series of large scale full blow tests were performed. Since large specimens do not show R-curve behavior under dynamic loading at -40 °C, a test method was developed for determination of dynamic fracture toughness values with SE(B)140 specimens (length 1350 mm, width 280 mm, thickness 140 mm, $a_0/W = 0.5$) at -40 °C by use of a servo-hydraulic impulse loading test system (max. 1 MN and 8 ms^{-1}). As with small scale testing, different strain gage instrumentations (Fig. 9) including as per BS and ASTM were compared with respect to their force measurement capability with SE(B)140 specimens at impact conditions and a stress intensity rate of $5 \cdot 10^4$ MPa$\sqrt{m}s^{-1}$. All strain gages were statically calibrated before the tests. Further details are reported for instance in [9].
Fig. 10 displays an example of force–time records and crack sensor signals. The test can roughly be assorted into 3 phases. During phase I, the rubber mat between striker and specimen is compressed and finally cut. After that, in phase II, the actual loading of the specimen takes place at a significantly higher but nearly constant loading rate compared to phase I. The stress intensity rate which is characteristic for the test is calculated as differential quotient in phase II.
Phase III is characterized by unstable cleavage crack growth until final fracture of the specimen. In phase III, the force signals F1–F4 and F2–F3 are not considered for further analysis with respect to the underlying test goal to determine dynamic fracture toughness at initiation of unstable cleavage fracture. The good agreement of the signals F1–F4 and F2–F3 illustrates the high symmetry of

loading. As expected, the machine load cell only provides a damped and less sensitive force signal which is delayed in time.

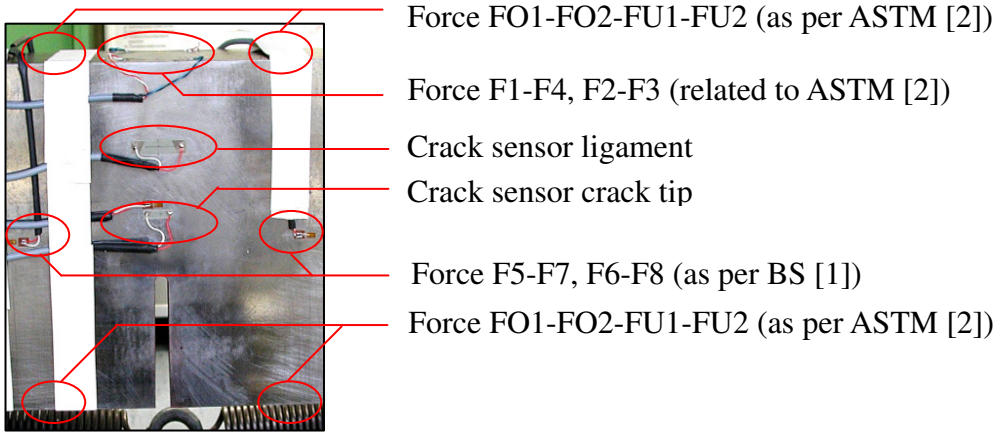

Figure 9. Strain gage instrumentation and crack sensors in and near the ligament of a SE(B)140-specimen.

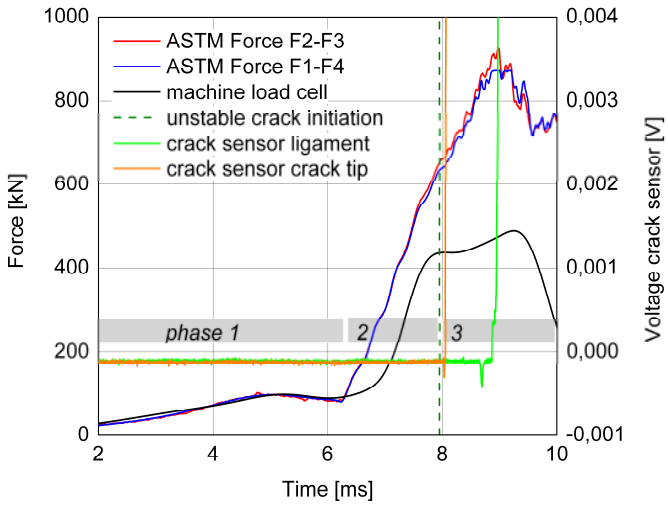

Figure 10, Signals from a dynamic SE(B)140 fracture mechanics test.

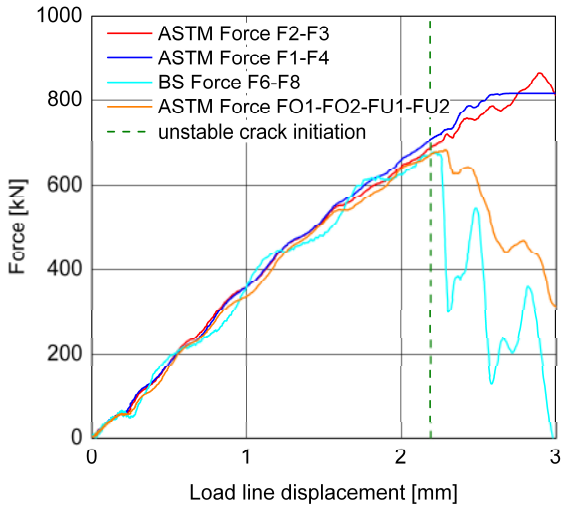

Figure 11a, Examples of force-displacement records of dynamic SE(B)140 fracture mechanics tests.

Finite element simulations of the SE(B)140 impact tests in [10] showed a good agreement between time dependent F1–F4 and F2–F3 force signals and numerically determined force-time data. The calculated crack tip loading in terms of K at the experimentally provided time of cleavage crack initiation corresponds very well to the experimental K_{Id} value.

Common feature of all test series is that the ASTM strain gage positions F1-F4 and F2-F3 show smallest dynamic effects, best sensitivity and reproducibility up to unstable crack initiation. Fig. 11 exemplarily shows the responses of different ASTM as well as BS force strain gage instrumentations for several specimens. As Fig. 11a reveals, the signals of ASTM and BS strain gage positions may nearly coincide. But in most of the cases the BS signals are below ASTM and show much more dynamic effects, Figs. 11b and 11c. Mostly, the ASTM half bridges F1-F4 and F2-F3 provide comparable signals to the ASTM full bridge FO1-FO2-FU1-FU2 up to unstable crack initiation. Nevertheless, the F1-F4 and F2-F3 signals show slight advantages in reproducibility and, very important, they offer valuable redundancy of measurement and simultaneously information on loading symmetry.

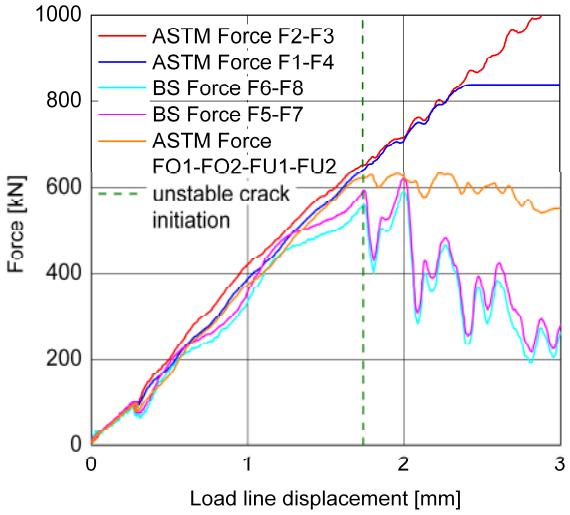

Figure 11b, Examples of force-displacement records of dynamic SE(B)140 fracture mechanics tests..

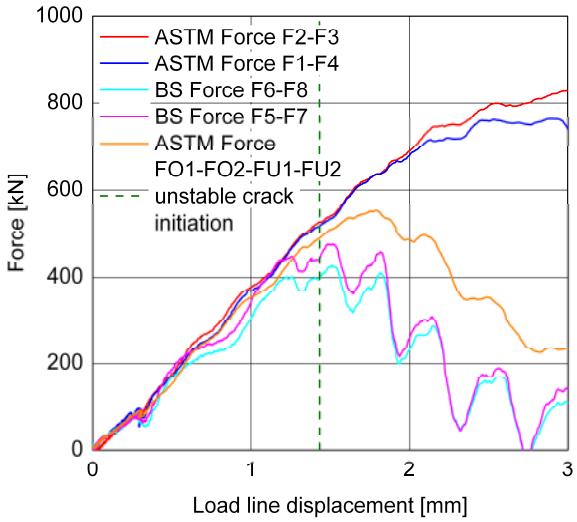

Figure 11c, Examples of force-displacement records of dynamic SE(B)140 fracture mechanics tests.

Generally, the F1-F4 and F2-F3 signals do not instantly show sharp drops at unstable crack initiation as it is known from Type I, II or III brittle behaviour of small PCVN specimens as per Annex 17 of [2] but keep rising until the crack has reached the crack sensor in the ligament, Fig. 10. This is not of concern when stable crack growth is absent and the test is only analyzed until unstable crack initiation. Nevertheless, this underlines the necessity of an adequate experimental method for detection of unstable crack initiation.

In this study, a method was elaborated where the initiation of unstable cleavage crack extension is indicated by fracture of the first strand of a crack sensor (Fig. 9) close to the crack tip (first steep signal rise in Fig. 10). However, since this crack sensor is not positioned at the crack tip directly but some millimeters in front of, a correction of the initiation time is necesssary. This is done by means of the crack velocity which is calculated from the known distance between the two crack sensors and the time measured between their responses. Since the distance between the crack tip and the first crack sensor is known too, the corrected time of unstable cleavage crack initiation can then be calculated. Due to the very limited plasticity in the ligament no problems related to sensors stripping away from the specimen surface were observed.

Since tactile displacement measurement devices are much too slow, the load line displacement was measured using an electro-optical camera, Fig. 12, as practiced with the small scale dynamic tests.

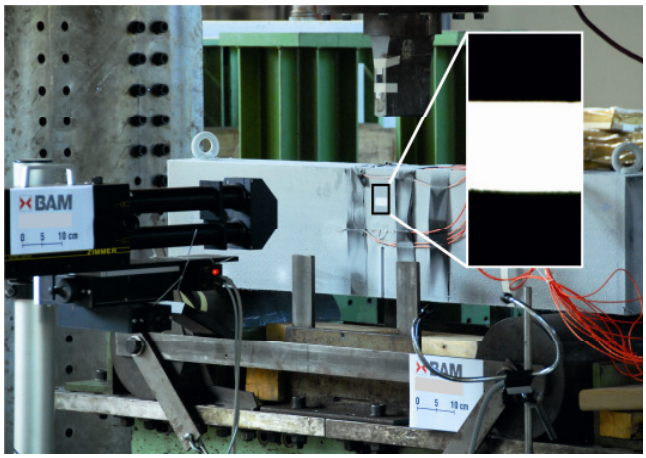

Figure 12. Electro-optical camera for measurement of load line displacement in dynamic SE(B)140-specimen tests.

The camera has two objective lenses, each of which tracing a black-white contrast on the specimen ligament so that two redundant displacement signals can be provided. The camera measurement technique is validated statically by gauge blocks and dynamically by comparison of the results of elongation measurement at rupture in dynamic tensile tests with the corresponding manually determined values.

3. Summary and conclusions

Experimental aspects of dynamic fracture mechanics tests on bend type specimens were discussed and different techniques for the measurement of force, displacement and crack initiation were investigated. It can be concluded that the fairly limited recommendations of the test standards may provide significantly different results. Therefore, they cannot simply be transferred to the own specific experimental tasks. It must be considered an absolute essential prerequisite that the used measuring techniques are validated in advance. The detection of unstable crack initiation by crack sensors in K_{Id} tests works well. Compared to that, the use of crack sensors to detect stable crack initiation in low blow R-curve tests needs further enlargement of the data base to finally rate the technique.

Abstract Action of the high-current electron beam leads to an intensive heating of a surface layer of the irradiated metal. Rapid temperature increase can cause melting of the surface layer and generate intensive stresses in it. Release of these stresses induces fast expansion of the molten metal and, on the contrary, results in tension. Tension of the melt activates nucleation, growth and coalescence of vapor bubbles, it means, fracture and fragmentation of the metallic melt. In present work we numerically investigate kinetics of the liquid metal fracture and fragmentation under the dynamic tension initiated by the powerful electron irradiation. Metal is treated as a two-phase medium consisting of vapor bubbles in liquid metal at the first stage of the evolution and of liquid drops in vapor at the second stage. Two-level approach is used: on the macroscopic level, the irradiated metal is treated as a two-phase heterogeneous medium in the one-velocity approximation, while on the microscopic level, the exchange of energy, mass and volume between both phases are described including grow or decrease of size of the vapor bubbles or liquid drops. Generation of ultra-dispersed particles of copper at the high-current electron beam irradiation is numerically investigated.

Keywords Liquid metal, Dynamic fracture, Electron irradiation, Heterogeneous medium, Vapor bubbles

1. Introduction

Action of the high-current electron beam on the metals can be used for production of the ultrafine metal particles [1,2]. The process of particles formation passes through several stages. At the first stage, during the irradiation, fast beam electrons lose their energy in the substance, which leads to the metal heating and formation of the high pressure region inside the energy release zone [3-5]. The next stage is an expansion of the heated and "compressed" layer of metal, which generates tensile stresses (negative pressure) in it. Destruction of the expanded metal begins at the expense of nucleation and growth of cavities. The higher temperature of the surface layer leads to the lower threshold of the negative stress, required for the destruction [6,7].

Complete destruction of the liquid phase takes place when the cavities grow up thus much to coalescence with each other forming a singly connected vapor phase, while the remaining liquid is fragmented on drops. The following expansion of the vapor-drops mixture (aerosol) is accompanied by the metal evaporation and condensation on drops. At the sufficient level of the enclosed energy, the liquid drops can be fully evaporated with formation of pure vapor. In turn, the adiabatically expanding vapor can become oversaturated, which result in the nucleation of liquid drops in it. In the paper [8] the condensation of the metal particles from the pure vapor, obtained at the complete evaporation under the action of the high-current electron beam, was numerically investigated; it was shown, that the homogeneous nucleation and the coagulation of the drops determine the size of the produced metal nanoparticles.

Meanwhile, the electron beam irradiation leads to the incomplete evaporation in the most cases. A part of metal remains condensed in the form of liquid drops. During the adiabatic expansion these drops become the centers of condensation; their quantity determines the quantity and size of the formed ultrafine metal particles. In this report a mathematical model of the ultrafine metal particles formation in the case of incomplete evaporation is described. Kinetics of evaporation and condensation of metal irradiated by the high-current electron beam is numerically investigated.

Metastable version of the wide-range equations of state [9,10] has been used for the description of superheated liquid and supersaturated vapor.

2. Mathematical model of substance dynamics with evaporation and condensation

Metal was treated as a two-phase medium consisting of the vapor bubbles in liquid metal on the first stage and of the liquid drops in vapor thereupon. Size of bubbles and drops (about $0.1\ \mu\text{m}$) is less than the typical length scale of the problem (the last one is of the order of electron rage in substance about $10 \div 1000\ \mu\text{m}$). It allows using of the continuous approximation in which both phases are described by continuous fields of parameters: concentration and radius of bubbles (drops), pressure, temperature, density and volume fraction of liquid and vapor phases in each point of space. Estimations showed that the phases must have approximately the same velocities; therefore we have used a one-velocity approximation. Substance dynamics has been described by the continuum mechanics equations. The beam action has been taken into account through energy release of fast electrons. Generation and growth of vapor bubbles and consequent evolution of drops have been described by kinetic equations for phase transition [11]. A simple scheme of transition from the bubbles in liquid to the drops in vapor (a percolation problem) has been constructed.

We consider the 1D problem: substance moves along z-axis. At different stages of evolution the medium means: a) pure condensed metal (solid or liquid); b) liquid metal with trapped bubbles; c) vapor with trapped drops; and, maybe, d) pure vapor. The liquid (or solid) is a carrying agent at stages a) and b), while the vapor is carrying agent at stages c) and d). A dispersed phase consists of vapor bubbles at stage b) and of liquid drops at stage c); and this phase is clearly absent at stages a) and d).

The continuum mechanics equations for substance dynamics in Lagrangian coordinates are the next:

$$\frac{1}{\rho}\frac{d\rho}{dt} = -\frac{\partial v}{\partial z}, \tag{1}$$

$$\rho\frac{dv}{dt} = -\frac{\partial P_c}{\partial z}, \tag{2}$$

$$\rho\frac{dU}{dt} = -P_c\frac{\partial v}{\partial z} + \rho\cdot D, \tag{3}$$

where v is the z-component of substance velocity; P_c is a pressure in the carrying agent phase; D is the energy release function. Here and further the index c denotes the carrying agent phase, while the index d denotes the dispersed phase. Average density of the medium is $\rho = \rho_c\alpha_c + \rho_d\alpha_d$, where $\alpha_{c,d}$ is the volume fraction of corresponding phase. Average specific internal energy U is given by the next expression: $U = \left(U_c\alpha_c\rho_c + U_d\alpha_d\rho_d\right)/\rho$.

Eq. (2) determines the substance velocity v, which is equal for both phases. Eq. (1) and Eq. (3) must be supplemented by several assumptions for determination of the thermodynamic parameters of each phase. We have supposed that the dispersed phase volume is constant during the substance movement as a whole, and it changes only as a result of interaction between the phases; this interaction leads to the bubbles and drops growth or reduction. In these assumptions one can obtain the next equations:

$$\frac{d\alpha_c}{dt} = \alpha_d \frac{\partial v}{\partial z} - w, \tag{4}$$

$$\frac{d\alpha_d}{dt} = -\alpha_d \frac{\partial v}{\partial z} + w, \tag{5}$$

$$\frac{d\rho_c}{dt} = \frac{\rho_c}{\alpha_c}\left(-\frac{\partial v}{\partial z} + w\right) - \frac{J}{\alpha_c}, \tag{6}$$

$$\frac{d\rho_d}{dt} = -\frac{\rho_d}{\alpha_d} w + \frac{J}{\alpha_c}, \tag{7}$$

$$\rho_c \alpha_c \frac{dU_c}{dt} = P_c\left(-\frac{\partial v}{\partial z} + w\right) - Q, \tag{8}$$

$$\rho_d \alpha_d \frac{dU_d}{dt} = -P_c \cdot w + Q. \tag{9}$$

In the Eqs (4)-(9) w is the growth rate of the dispersed phase volume in a unit volume of the medium; it can be expressed as that follows:

$$w = n \cdot 4\pi R^2 \cdot \dot{R} + \left(4\pi/3\right) R_{cr}^3 \cdot \dot{n}, \tag{10}$$

where n is the concentration of the dispersed particles (bubbles or drops) in the medium, and R is radius of this particles; R_{cr} is the radius of critical (nucleating) bubbles.

In the Eq. (6), Eq. (7) J is the growth rate of the dispersed phase mass in a unit volume of substance:

$$J = n \cdot m_1 \cdot \dot{g} + \left(4\pi/3\right) R_{cr}^3 \cdot \rho_v \cdot \dot{n}, \tag{11}$$

where m_1 is the mass of one atom of the substance; g is a number of atoms in the bubble (or in the drop); ρ_v is a saturated vapor density. And, finally, the value Q characterizes the heat exchange between the phases, which tends to equal temperatures of the phases.

The next equation describes the bubbles growth in the liquid at the stage b) and a size change of the liquid drops at the stage c):

$$\ddot{R} = -\frac{3}{2}\frac{\dot{R}^2}{R} + \left[P_d - P_c - \frac{2\sigma}{R}\right] \cdot \frac{1}{R\rho} A - B\frac{8}{3}\frac{\eta}{\rho_c}\frac{\dot{R}}{R^2}, \tag{12}$$

where s is the surface tension and h is viscosity of the liquid metal; A and B are the numerical factors: $A = B = 1$ at the stage b), and $A = 5$, $B = 1,25$ at the stage c). Critical radius of the vapor bubble is equal to

$$R_{cr} = \frac{2\sigma}{P_v - P_c}, \tag{13}$$

where P_v is a saturated vapor pressure. The bubbles nucleation rate is

$$\dot{n} = \frac{c}{\left(2R_{cr}\right)^4} \cdot \exp\left(-\frac{W_{cr}}{kT_c}\right), \tag{14}$$

where c is a sound speed in liquid metal, T_c is a temperature, k is the Boltzmann constant, and is the formation work of the critical bubble:

$$W_{cr} = \frac{16\pi}{3}\frac{\sigma^3}{\left(P_v - P_c\right)^2}. \tag{15}$$

In the case of liquid drops, the condition $\dot{n} = 0$ has been supposed to hold, but the drops can

disappear if the number of atoms in it $g \le 2$ (the complete evaporation).

Number of atoms in each bubble is controlled by the next equation:

$$\frac{dg}{dt} = g\frac{2R}{c}\left[\exp\left(\ln\left\{\frac{P_v}{P_c}\right\} - \frac{4\pi R_1^2\sigma}{3kT_c \cdot g^{1/3}}\right) - 1\right], \tag{16}$$

where

$$R_1 = \left[\left(3m_1\right)/\left(4\pi\rho_v\right)\right]^{1/3}. \tag{17}$$

Pressure and temperature of the caring agent phase and of the dispersed phase have been obtained from the metastable equation of state: $P_{c,d} = P\left(\rho_{c,d}, U_{c,d}\right)$, $T_{c,d} = T\left(\rho_{c,d}, U_{c,d}\right)$. This equation of state has been used for determination of the density ρ_v and pressure of the saturated vapor as well.

Than the bubbles became large enough they merge and form a simply connected phase. On the contrary, the liquid divides on separate drops. These drops are the condensation centers in the expanding and cooling vapor. Number and sizes of the liquid drops are determined by the number and sizes of the vapor bubbles at the moment of merging. We have established this connection in a simplest case of equal distance between the bubbles centers. Bubbles merge then their diameters $2R$ reach the value of a distance between their centers. Single bubble occupy the volume $4\pi R^3/3$, liquid volume per one bubble at this time is $\left(8 - 4\pi/3\right)R^3$. We have assumed that the number of resulting drops is equal to the number of vapor bubbles, and then $\left(8 - 4\pi/3\right)R^3$ is the volume of one liquid drop. Due to the surface tension, the drops obtain a spherical form after the liquid phase division, and the radius of such spherical liquid drop can be estimated as $R_{\mathrm{L}} = \left(6/\pi - 1\right)^{1/3} R \approx R$. It follows, that the merging passes then the vapor volume fracture achieves the value $\alpha_c \approx 0.5$. A number of smaller drops can be formed during the vapor bubbles merging, but we neglect it here.

3. Numerical investigation of the metal fracture

We have numerically investigated the copper irradiation by the high-current pulsed electron beam with parameters: the energy of fast electrons is 1 MeV, the beam current density is 10 kA/cm^2, the pulse duration is 50 ns. The beam action causes the sharp heating of the substance (up to 4900 K) in the energy release zone (Fig. 1) and the formation of area of the high-pressure - up to 17 GPa (Fig. 2). The substance temperature exceeds the melting temperature up to the depth of 0.4 mm; in this layer the metal is melted. Release of the high pressure area results in formation of the compression wave with the amplitude up to 11.5 GPa. The compression wave front is becoming sharper with the time, and it transforms into the shock wave. Reflection from the free (irradiated) surface forms the rarefaction wave, following behind the shock wave. This rarefaction wave creates in the liquid metal the negative stress with the value up to 2.5 GPa, which initiates the fracture of the liquid phase through the generation and growth of the vapor bubbles. The generation and growth of the bubbles result in reduction of the liquid metal volume and, therefore, it releases the tensile stresses; the substance passes in the equilibrium two-phase state. This process restricts the tensile stresses; otherwise, the rarefaction wave amplitude would be the same as the amplitude of the compression wave.

It should be noted that the existence of metastable liquid state leads to propagation of the rarefaction (tensile) wave inside the metal behind the shock wave. Negative stresses in the rarefaction wave can reach 2.5 GPa. Thus, the structure of stresses in the metal differs from that in calculations [4,8],

where an approximation of the equilibrium two-phase state of the liquid and vapor was used for the description of the melted layers of metals. The rarefaction wave can substantially influence on the material modification [12] as well as on the spall fracture of solid metal near its back surface.

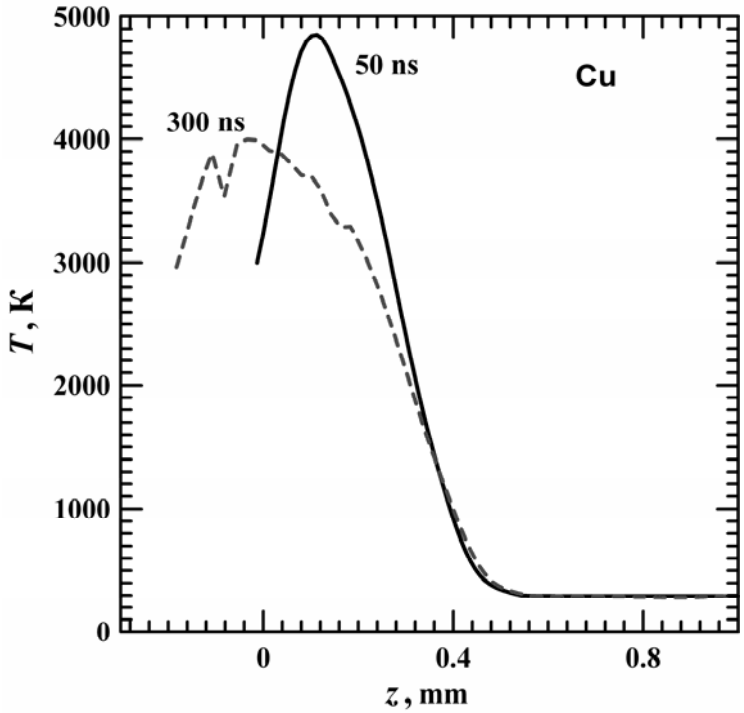

Figure 1. Temperature distributions in copper at the two time moments. Fast electrons energy is 1 MeV, the current density is 10 kA/cm^2, the pulse duration is 50 ns. At the moment of the pulse end, the temperature in the metal layer heated by the beam is maximal and it achieves 4900 K, after than, at the expansion of the "compressed" substance, the temperature becomes lower.

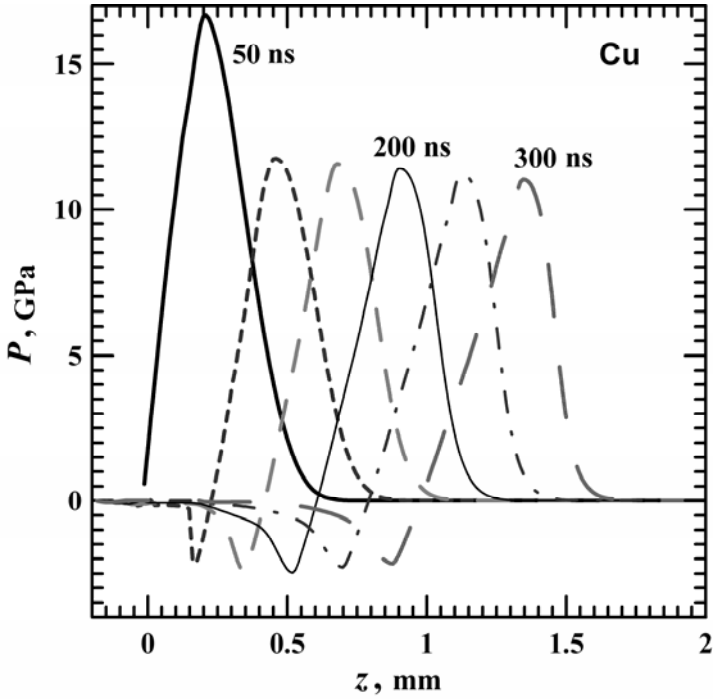

Figure 2. Distributions of pressure at consecutive time moments. High current electron beam irradiation of copper with the electrons energy 1 MeV, the current density 10 kA/cm^2, and the pulse duration 50 ns.

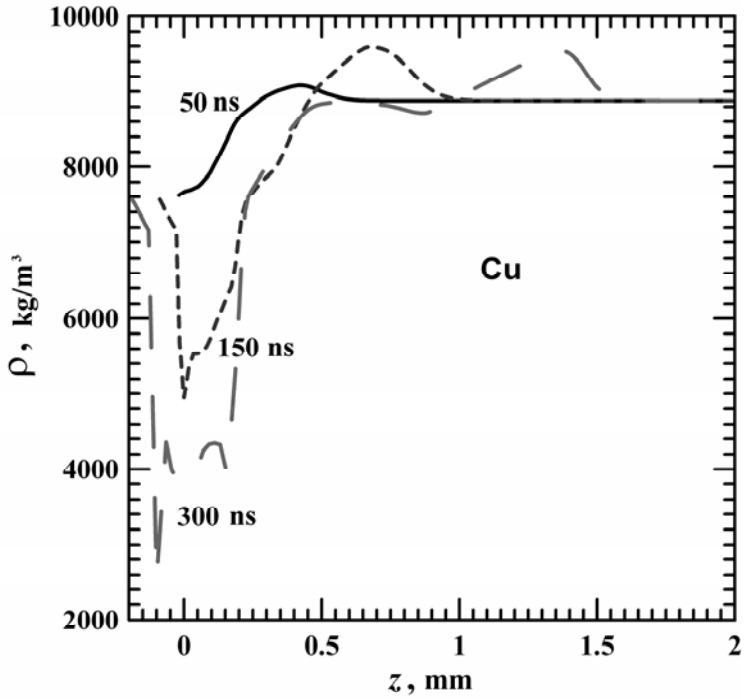

Figure 3. Distributions of the average density of the medium at consecutive time moments. High current electron beam irradiation of copper with the electrons energy 1 MeV, the current density 10 kA/cm^2, and the pulse duration 50 ns.

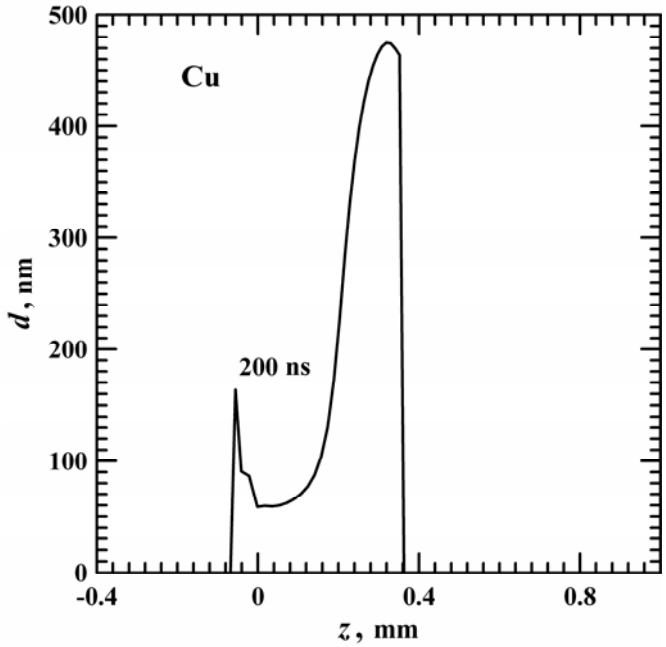

Figure 4. Depth distribution of the vapor bubbles diameters at the moment just before the fragmentation of the liquid phase. The lower bubbles diameters and, consequently, the larger concentrations correspond to the central region of the energy release zone, in which the tension occurs with the higher strain rate. Zero level corresponds here to the absence of the bubbles.

Appearance of the bubbles leads to the decrease of the average density of the two-phase medium (Fig. 3). Concentrations and diameters of vapor bubbles in different layers of the metal differ from

each other (Fig. 4); they depend on the strain rate of tension in the rarefaction wave and on the metal temperature in the layer. When the volume fraction of vapor exceeds the volume fraction of the liquid phase, the consolidation of bubbles begins in the layer; the liquid phase is destructed on the drops (Fig. 5). Gradually the liquid phase fracture takes place in all area, in which the bubbles were generated by the tension. Further evolution of the two-phase medium is reduced to the expansion of droplets accompanied by the droplets coalescence due to the Brownian motion.

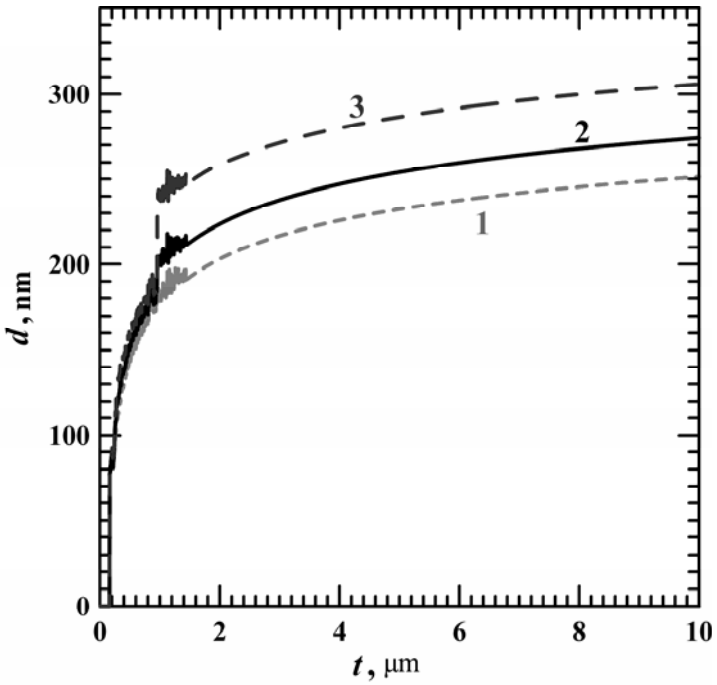

Figure 5. Time evolution of the average diameters of the drops: 1 – average on the number of drops, 2 – average on the drops surface areas, and 3 – average on the mass of the drops. The first drops are formed approximately 200 ns after the irradiation beginning in the layer with the maximal concentration of the vapor bubbles. A sharp increase of the average diameters is observed during the first 1 μs, it is connected with the gradual fracture of the liquid layers with lower concentration and, consequently, with the higher diameters of the vapor bubbles.

3. Conclusions

The mathematical model is proposed and the numerical investigation is performed of the metal fracture and fragmentation in the energy-release zone under the action of the high-current electron beam. The beam heats the metal and converts it in the metastable liquid state, which is destructed under the action of rarefaction wave propagating from the free (irradiated) surface of the metal. The tensile stresses of the value of about 2.5 GPa initiate the generation and growth of vapor bubbles. The following merging of the bubbles results in fragmentation of the simply connected liquid phase on the drops. Under the investigated conditions, the formation of the vapor bubbles begins 30 ns after the end of irradiation pulse. Concentration of the bubbles depends on the metal temperature and on the strain rate of tension in the rarefaction wave. This concentration determines the diameter of the resulting liquid drops, which varies from several tens up to several hundreds of nanometers in different parts of the energy release zone. Existence of the metastable state of expanded liquid results in propagation of the rarefaction wave with negative pressure of the value up to 2.5 GPa behind the shock wave in the deeper solid layers of the irradiated metal, which can substantially influence on the spallation of back surface in solid state as well.

Dynamics of Fragmentation of Fused Quartz Rods

Abstract The dynamic fragmentation was studied in the impact experiments with quartz cylindrical rods using a gas gun. Impact leads to the formation of fracture surfaces, which produce an intensive light emission (mechanoluminescence). Mechanoluminescence was registered by two Photo Multiplayer Tubes (PMT) connected with the oscilloscope. Mechanoluminescence was in form of impulses with typical rise time 2-5 ns and fall time 5-50ns. It was found that the impulse frequency was not decreases monotonically but there was some kind of bursts or avalanches and fragmentation process time is 3-4 orders longer than acoustic time (time needed for compression wave to travel along the specimen). We found that the distribution of intervals between luminescence impulses is a power law distribution.

Keywords Fractoluminescence, scaling, power law, fragmentation

1. Introduction

Per Bak et al. in their paper “Self-Organized Criticality: An Explanation of 1/f Noise” mentioned: “The common feature for these systems is that the power-law temporal or spatial correlations extend over several decades where naively one might suspect that the physics would vary dramatically. Dynamical systems with extended spatial degrees of freedom naturally evolve into self-organized critical structures of states which are barely stable. We suggest that this self-organized criticality is the common underlying mechanism behind the phenomena described above. The combination of dynamical minimal stability and spatial scaling leads to a power law for temporal fluctuations. The noise propagates through the scaling clusters by means of a "domino" effect upsetting the minimally stable states. Long-wavelength perturbations cause a cascade of energy dissipation on all length scales” [2]. To confirm the fact that the fragmentation exhibits SOC, we need to establish the existence of a power law for temporal and spatial quantities. The evidence of the spatial scaling for the fragmentation of brittle materials under different loading conditions was given in paper [1] . For measurement of temporal scale we developed an experimental device to determine the time interval between the impulses of the light reflected from the newly created fracture surfaces. In our investigation (fragmentation of quartz rods under dynamic loading), SOC means that there exist:

•power law distribution of fragment size;
•power law distribution of time interval between the impulses of the light reflected from newly created surfaces.

2. Experiment

The fragmentation statistics was studied in recovery dynamic experiments with fused quartz cylindrical rods which have 10 mm diameter and 120 mm length.

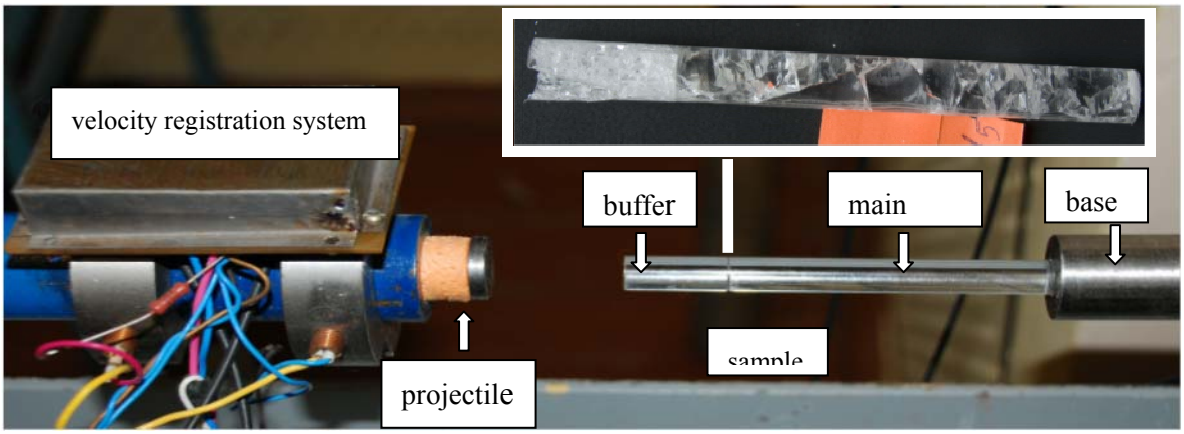

Figure 1. Ballistic set-up. An example of the fragmentation pattern is given in the upper right-hand corner.

Rods were loaded by ballistic set-up, which consisted of a gas gun with bore diameter of 19.3 mm, a velocity registration system and a base where the specimen was placed (Fig. 1). The sectional rod was composed of a buffer and the main part covered by an elastic shell. The buffer was used for realization of uniaxial loading produced by a cylindrical projectile of mass 13.9 g accelerated up to the velocities of 6-50 m/s.

In order to check influence of loading conditions on fragmentation statistics two types of boundary conditions at the rear end were checked. Rear end of the sample was glued to the steel rod and rear end was free [1]. We found that statistics of fragment distribution does not change significantly so next experiments were carried out with a free rear end of the sample. The mass of the fragments corresponding to the maximum of the probability density function is independent of the projectile energy. To obtain the fragment size distribution, the technique described in the previous experiments [1] was used, which made it possible to get the distribution obeying the scaling law. This experiments are presented in the talk "*Scaling Behavior in Quasi Static and Impact Fragmentation of Brittle Materials*" by Davydova M. and Uvarov S. at ICF13. The scheme given in Figure 2 illustrates the experimental technique used to measure the distribution of time quantities.

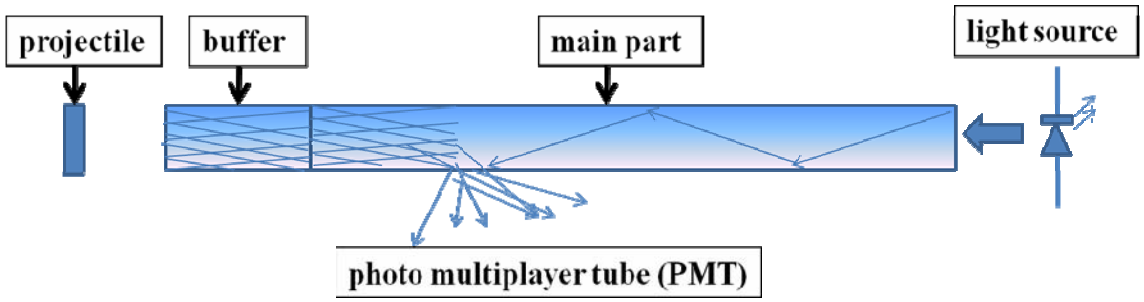

Figure 2. Scheme of the experiment. Light source was used for visualizing the cracks in the sample.

It is known [3] that cracking of quartz leads to emission of light known as a fractoluminescense or mechanoluminescence. The light intensity was registered by the Photo Multiplayer Tube connected

with the oscilloscope (oscilloscope sample rate is 1 GHz). The appearance of the new surfaces produces the impulses with a sharp front with typical rise time about 5 ns (Fig. 3).

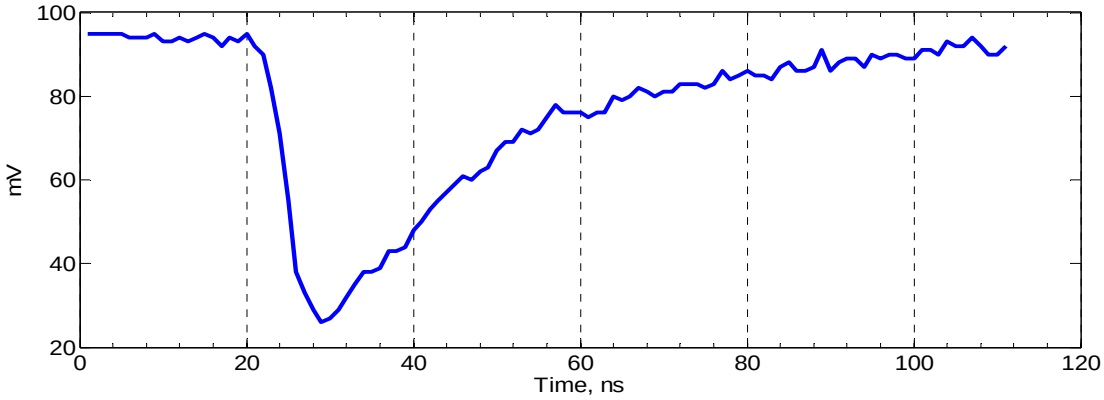

Figure 3. Typical fractoluminescence event.

Figure 4 shows the signal from the oscilloscope. One can note that fragmentation process lasts 2-3 decades longer than loading time (20 μs). Pulse rate does not decrease monotonically; instead of this one can note avalanches or bursts of pulses similar to the avalanches on the sand pile which is common illustration of SOC.

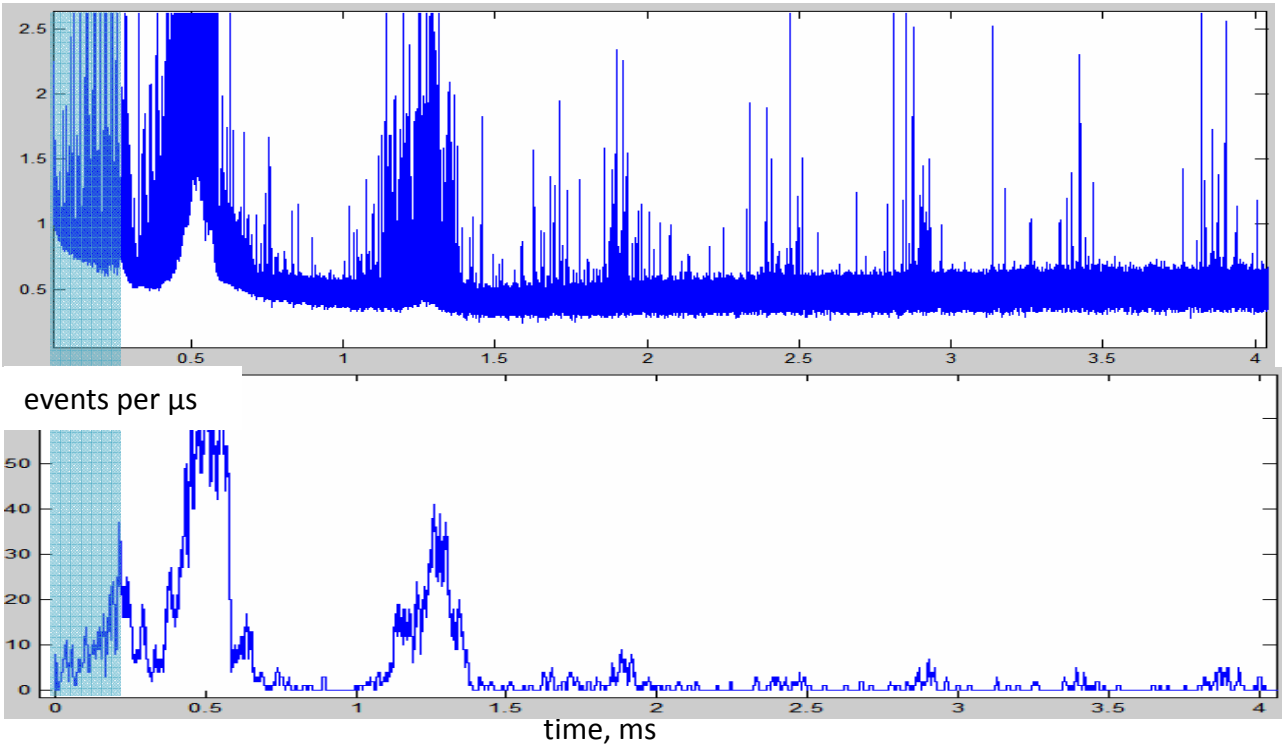

Figure 4. Signal from the oscilloscope (upper, polarity of pulses is reversed) and pulse rate (lower). Time scale is the same for both graphs.

1. Data analysis

The first step of data processing is signal filtration. Because the fractoluminescence pulses have a

very short rise time application of the high-pass filter to the original signal increase signal-to-noise ratio and makes possible to measure time intervals between events. The definition of the size of time interval between the impulses is shown at the Figure 5. The second step involves measuring the distance between the green bars showing a sharp rise in impulse. We consider only the impulses which are above some discrimination level (the red line). Discrimination level is determined by noise level in the way that not more than 1 false positive pulse was detected on the reference signal. Reference signal was taken before loading.

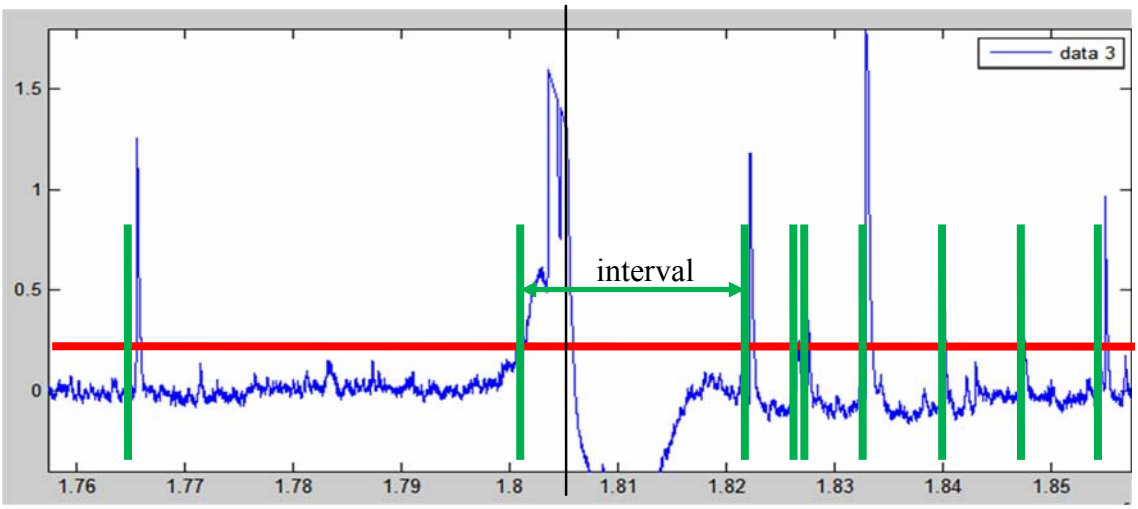

Figure 5. Determination of the size of time interval between the impulses of the light reflected from the fracture surfaces.

The cumulative distribution function of the time interval in the double logarithmic plot (Figure 6) is fitted by the straight line (total number of points 1073).

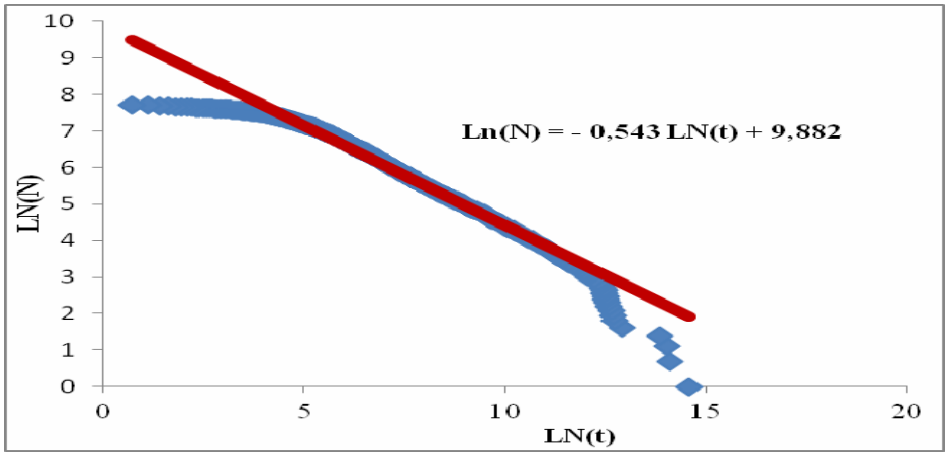

Figure 6. Cumulative distribution function of time interval in the double logarithmic plot.

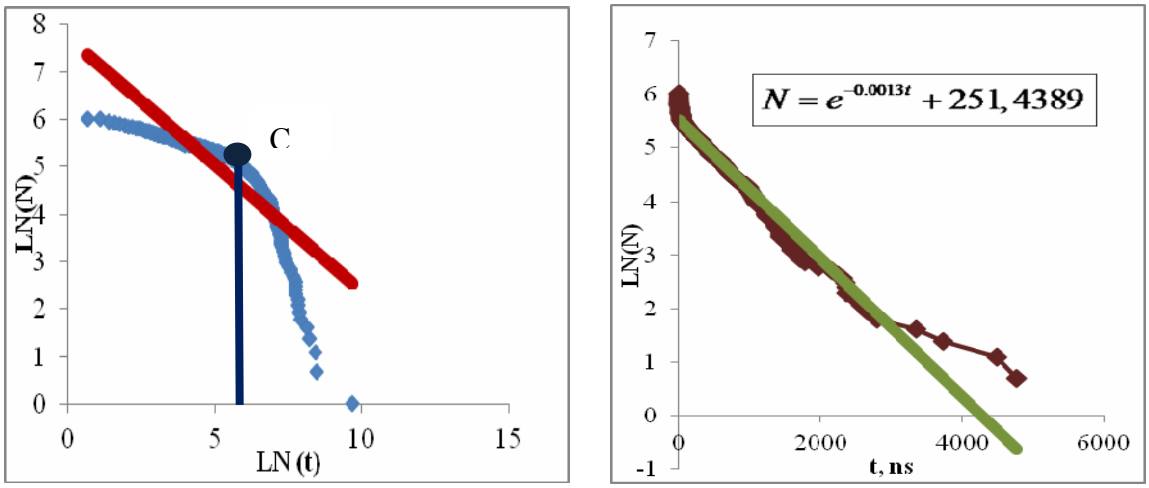
At small sizes (77 points – 7.1761 % of the total number of points), the curve deviates from the straight line because the size of time interval is comparable with the oscilloscope sample rate (1 GHz). The falloff at the largest interval sizes (16 points – 1. 5% of the total number of points) is due to finite-size effects. In this case the time interval is comparable with the process time. The central

part is the line covering 91.3% of the total number of points. The process of light reflection looks like the process of avalanche spreading (Fig. 4). The lower plot represents the event frequency. The events are distributed in blocks. We have analyzed the time interval distribution in avalanches and found that the distribution at the initial stage (marked in blue in Fig. 4) cannot be described by the power law.

The left plot in Figure 7 illustrates the distribution at the initial stage in double logarithmic coordinates. In the right plot in Figure 7, only the vertical coordinate is logarithmic. The time interval distribution is subjected to the exponential law.



a) b)

Figure 7. a) Cumulative distribution function of time interval for initial stage in a double logarithmic plot. b) Cumulative distribution function of time interval for initial stage in a coordinate system Ln (N) –time t.

An exponential functional form requires a characteristic length scale which can be defined as

$$X_{ch} = tV \,, \tag{1}$$

where *Xch=2.6 mm* is the characteristic size, *t* is the x-coordinate of point C (t= 457 ns), and *V=5800 m/s* is the sound velocity in quartz. We suppose that this length scale correlates with the impactor thickness. The initial stage statistics does not change the total statistics, because only 10% of the points belong to the initial stage.

Investigation of the fragments by optical microscopy (Fig. 8.) reveals that surface of the fragments is not smooth so there is no simple relationship between pulse amplitude and crack size as in [3] where cracks are represented as smooth disk-shaped objects.

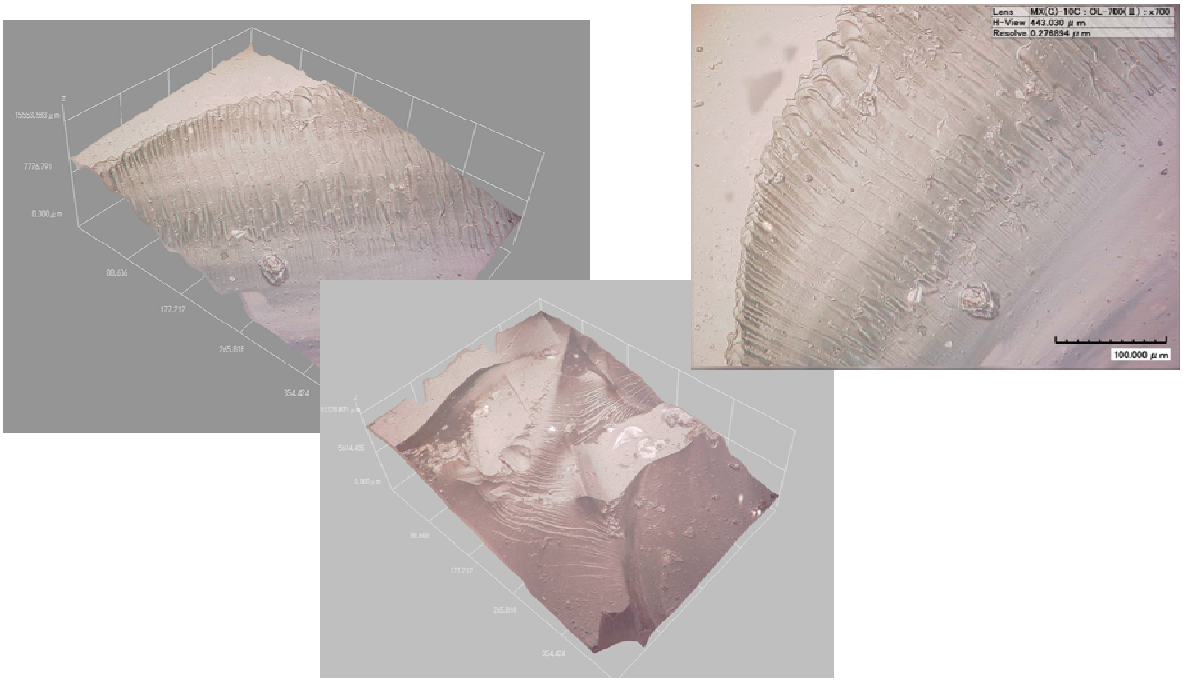


Figure 8. Fracture surface of quartz. Optical microscopy.

3. Conclusions

In our experiments we found that exist:

- Power law distribution of fragment size;
- Power law distribution of time interval between the impulses of the light reflected from newly created surfaces.

So we can suppose that self-organized criticality is the underlying mechanism of fragmentation except initial stage where exponential distribution is observed.

We suppose that the initial stage corresponds to the breaking of bulk specimen and formation of a granular media. The main stage at which most of the fragments was created corresponds to the fragmentation of the granular media formed at the first stage.

Abstract Energetic aspects of erosion fracture are studied. Threshold (minimal) energy needed for initiation of fracture caused by a particle impact is estimated using the incubation time criterion. The dependences of the fracture threshold energy on impact duration are calculated for two different shapes of the impacting particle: sphere and cylinder. The difference in the threshold energy behavior between these two cases is demonstrated and discussed.

Keywords Incubation time criterion, erosion, threshold energy

Introduction

In the present work the problem of dynamic impact of spherical and cylindrical solid particle on elastic half-space is studied. This problem is considered within the framework of fracture mechanics by neglecting of the heat transfer process and wave-process origination. Also there is an assumption that the impact is quasistatic. It permits to use the solution of the problem of quasistatic of the indenter pressing in [1].

This problem plays an important role in practical application, since the short impacts are typical for such industry process as ultrasonic assisted machining [2,3].

Threshold Energy of a Sphere Particle

The normal impact of the spherical rigid particle on the elastic half-space is considered. Hertz solution for the contact problem gives the following temporal dependence of the contact force P on the distance h between the bodies approaching each other:

$$P(t) = k[h(t)]^{3/2}, \tag{1}$$

where $k = 4\sqrt{R}E/\left[3\left(1-\nu^2\right)\right]$, R - particle radius, E and ν - elastic constants of the half-space. If m is the mass of the particle and V is its initial velocity then the time dependence of the approach $h(t)$ can be determined by solving the equation of motion:

$$m\frac{d^2h(t)}{dt^2} = -P(t). \tag{2}$$

The solution of the differential equation (2) can be approximated with high precision by the following expression:

$$h(t) = h_0 \sin\left(\frac{\pi t}{t_0}\right), \tag{3}$$

where $h_0 = \left(\frac{5}{4k}mV^2\right)^{2/5}$ is maximum approach and $t_0 = 2.94\frac{h_0}{V} \approx 3.2\left(\frac{m^2}{Vk^2}\right)^{1/5}$ is the contact time.

Also Hertz solution gives the following expression for the tensile stresses originated on the half-space surface:

$$\sigma_r(t) = -\sigma_\theta(t) = \frac{1-2\nu}{2}\frac{P(t)}{\pi a^2(t)}, \tag{4}$$

$$a(t) = \left(3P(t)\left(1-\nu^2\right)\frac{R}{4E}\right)^{1/3} = \left(P(t)\frac{R^{3/2}}{k}\right)^{1/3}. \tag{5}$$

Parameter $a(t)$ defines the radius of the contact area and its value depends on the contact time. Values $\sigma_r(t)$ and $\sigma_\theta(t)$ correspond to maximum values of main stresses in cylindrical coordinates. Therefore, the radial component of stresses $\sigma_r(t)$ is considered, since usually tensile stresses lead to fracture. Below $\sigma_r(t)$ is denoted by $\sigma(t)$.

The expressions (3)-(5) can be used to determine the expression for the threshold energy of the spherical particle. By threshold energy we mean the minimum quantity of energy, which is necessary to spend on initiation of the threshold fracture pulse during impact intersection. In this work the incubation time criterion is applied for fracture prediction [4]:

$$\frac{1}{\tau}\max_t \int_{t-\tau}^{t} \sigma(R,V,s)ds = \sigma_c \ . \tag{6}$$

The static strength of the material σ_c can be experimentally measured. Parameter τ corresponds to incubation time of the fracture. It characterizes the time period for preparing the media to fracture or phase transformation. The incubation time is a material strength constant and its value can be measured experimentally or derived by computational and experimental methods. In the work [5] different interpretations of the incubation time are shown for various problems.

The application of the incubation time criterion caused by this criterion takes into account the process dynamics. The dynamic strength properties of materials appear when the loading duration has a similar value as the incubation time [6,7]. When the time of loading significantly exceeds the incubation time, the media resistance is specified by static strength properties.

After the substitution of the expressions (1), (3) and (5) into (4), the fracture criterion becomes:

$$\frac{1-2\nu}{2\pi}\frac{k}{R}\sqrt{h_0}\max_t \int_{t-\tau}^{t} \sqrt{\sin\left(\frac{\pi s}{t_0}\right)}ds = \tau\sigma_c \ . \tag{7}$$

The integral in the expressions (7) takes the maximum value at the time $t=(t_0+\tau)/2$. The impact duration, radius and velocity of the particle should be introduced in dimensionless form:

$$\lambda = \frac{\tau_0}{\tau}, \quad R_d = \frac{R}{c_p\tau}, \quad V_d = \frac{V}{c_p}.$$

From now on $c_p = \sqrt{E(1-\nu)/\rho_m(1+\nu)(1-2\nu)}$ is the propagation velocity of the dilatational wave in the elastic media with density ρ_m.

Then, the accepted criterion (7) gives the following expression for calculation of the threshold velocity in dimensionless form:

$$\alpha_d V_d^{2/5} \int_{\frac{\lambda-1}{2}}^{\frac{\lambda+1}{2}} \sqrt{\sin\left(\frac{\pi s}{\lambda}\right)}\left[H(s)-H(s-\lambda)\right]ds = 1, \tag{8}$$

where $\alpha_d = c_p^{2/5}\left(E^4\rho\right)^{1/5}(2\pi\sigma_{cr})^{-1}(1-2\nu)\left(4/3(1-\nu^2)\right)^{4/5}(5\pi/3)^{1/5}$ is dimensionless parameter, ρ is material density of the particle, $H(s)$ is the Heaviside function.

The value of the threshold radius can be calculated from following expression for the impact duration:

$$\lambda = \frac{t_0}{\tau} \approx 3.2\frac{1}{\tau}\left(\frac{\pi\rho(1-\nu^2)}{E}\right)^{2/5}\frac{R}{V^{1/5}}.$$

Then, the threshold radius is determined in dimensionless form by:

$$R_d = \frac{\lambda}{\beta_d} V_d^{1/5}, \tag{9}$$

where $\beta_d = 3.2\left(\pi\left(1-\nu^2\right)\rho c_p^2 / E\right)^{2/5}$ is dimensionless parameter. If the threshold velocity (8) and radius (9) are known, then the threshold energy of the particle can be calculated as:

$$W = \frac{2}{3}\pi\rho R^3 V^2. \tag{10}$$

In dimensionless form, (10) is given by the formula:

$$W_d = \frac{W}{\omega} = R_d^3 V_d^2, \tag{11}$$

where the parameter $\omega = 2\pi\rho\tau^3 c_p^5 / 3$ has the dimension of energy and is determined by material constants. Thus, the quantity W_d determines the minimum dimensionless value of particle energy required for half-space fracture. Figure 1 presents the graphs of dependence of the energy (11) on the impact duration (Fig. 1*a*) and radius (Fig. 1*b*), where the half-space material is zinc and parameters the value $\rho = 3200\,kg/m^3$.

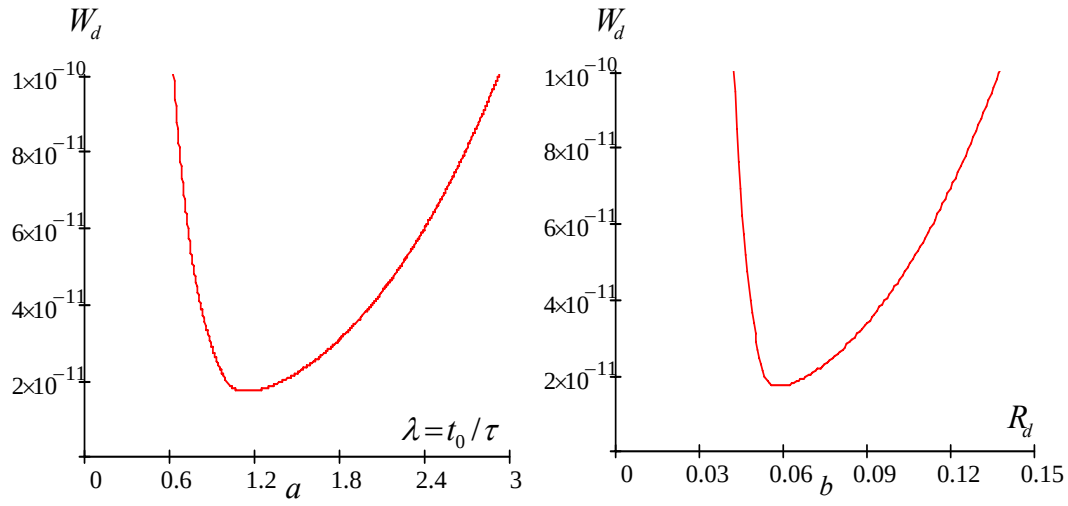

Figure 1. Dependence of the threshold energy of the spherical particle on: *a* – the impact duration, *b* – particle radius

These graphs show that the value of the threshold energy has the marked minimum distinct from equal zero. Hence, it is possible to decrease the energy costs for fracture by controlling such parameters as radius and velocity of particle.

Threshold Energy of a Cylindrical Particle

The similar analysis can be provided for cylindrical particles with a constant circle section of radius R. The cylinder height is equal to $H = 4R/3$, that follows from the assumption that the cylinder mass is equal to the ball mass. In the cylindrical case the contact force $P(t)$ and approach $h(t)$ are related as follows:

$$P(t) = kh(t), \tag{12}$$

where $k = 2RE/\left(1-\nu^2\right)$.

In this case the equation of motion (2) has the exact solution [8]:

$$h(t) = h_0 \sin\left(\frac{\pi t}{t_0}\right), \tag{13}$$

where $h_0 = \sqrt{\frac{mV^2}{k}}$ and $t_0 = \sqrt{\frac{m}{k}}$.

Also, there is the similar expression for maximum tensile stress:

$$\sigma(t) = \frac{1-2\nu}{2}\frac{P(t)}{\pi R^2}, \quad r \to R + 0 \tag{14}$$

After substituting the expression of tensile stress (14) into criterion (6), the integral attains its maximum value at time $t = (t_0 + \tau)/2$. The dimensionless quantities are introduced by analogy with the case of the spherical particle. And the following expressions of dimensionless velocity can be obtained by using criterion (8) and formulas (12) - (14):

$$\alpha_d V_d \int_{\frac{\lambda-1}{2}}^{\frac{\lambda+1}{2}} \sin\left(\frac{\pi s}{\lambda}\right)[H(s) - H(s-\lambda)]ds = 1, \tag{15}$$

where $\alpha_d = (1-2\nu)\left(8E\rho c_p^2 / 3\pi(1-\nu^2)\right)^{1/2}(2\sigma_{cr})^{-1}$ is dimensionless parameter, ρ - is material density of the particle. From the expression of the impact duration it is possible to calculate the value of radius in dimensionless form:

$$R_d = \frac{\lambda}{\beta_d}, \tag{16}$$

where $\beta_d = \pi\left(2\pi\rho c_p^2(1-\nu^2)/3E\right)^{1/2}$ is dimensionless parameter.

The threshold energy can be calculated by formula (10) and in dimensionless form by formula (11), where cylinder velocity and radius are determined by (15) and (16) respectively.

Figure 2 presents the graphs of dependence of the energy on impact duration (Fig. 2*a*) and radius (Fig. 2*b*), where the half-space material is zinc and parameters the value $\rho = 3200\,kg/m^3$.

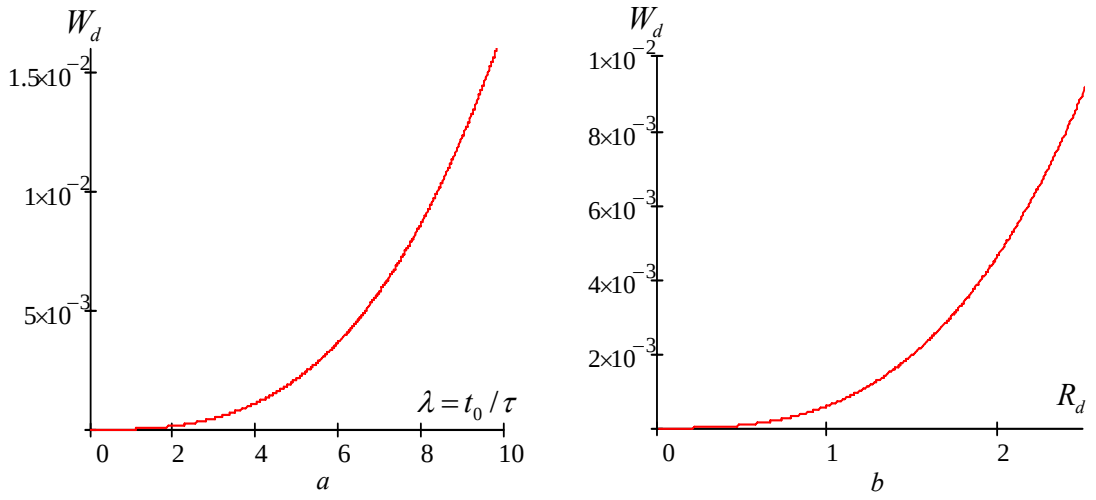

Figure 2. Dependence of the threshold energy of the cylindrical particle on *a* – the impact duration, *b* – particle radius

Fig. 2 shows that in case of cylindrical particle the threshold energy dependence is a monotone increasing function in contrast with the case of the spherical particle.

Results and Discussion

For the explanation of the difference in threshold energy behavior between both cases the following should be marked. The problems of the penetration with spherical and cylindrical indenters are fundamentally different. In case of the cylindrical particle, the contact area is a constant value during the penetration process, whereas for spherical particle, the contact area is a variable quantity. Also, in cylindrical case the points belonging to contact area border are singular and the stresses take out infinity in these points. But sphere indentation is attended with the finite values of stresses in all points of the contact region. The fact that the energy is zero for the zero impact duration and radius in the cylindrical case (Fig. 2) can be explained by the fact that the problem of penetration of a cylinder into a half-space is an idealized problem. When considering small particles, it is impossible to neglect the roundedness of the cylinder angles near the basis, and this model becomes unsuitable.

Quantitative analysis of microcracks ensemble induced by shock-wave loading of metallic targets (vanadium and iron).

Abstract Results of analysis of microstructure evolution of metallic samples (vanadium and iron) subjected to shock-wave loading are presented. The influence of loading velocity both on predominant mechanisms of structure deformation and fracture as well as regularities of microcracks ensemble evolution is investigated.

Keywords shock-wave loading, spall, microstructure analysis

1. Introduction

Understanding the material behavior under shock-wave loading has been paid a much attention for several decades because of its both practical and theoretical issues. Experimental results obtained till nowadays reveal highly complicated character of spall fracture. Changes of microstructure of material is one of the key factors among others, which reveals in nucleation, growing and coalescence of microcracks and microvoids, recrystallization processes, ets. It is not trivial problem to consider several microstructure mechanisms, for example nucleation and growing of recrystallized grains and evolution of defects (cracks, microvoids). Different kinetic models of metal behavior under dynamic loading usually use quantitative parameters characterizing size, shape or orientation of defects (microcracks or microvoids) in order to describe the role of microstructure. However there is still a big gap between experimental data and modeling results since the lack of complex information about kinetics of fracture and defect distribution corresponding to different loading rates. In the current work results of experiments on shock-wave loading of metallic targets are presented and microdefects evolution regularities during spall formation are discussed.

2. Experiment

Shock-wave loading of flat metallic samples was carried out one stage gas gun. Using of coarse-grained vanadium and polycrystalline iron as a target material allowed us to investigate deformation and fracture behavior of single crystallites (on vanadium samples) as well as typical polycrystalline metal behavior (iron samples). Dimensions of cylindrical samples and corresponding mean grain size are presented in table 1. In order to obtain different loading conditions, velocity of accelerated plate-projectile was varied in the interval 230… 375 m/s which is slightly above the velocity at which spallation occurs. Analysis of spall surface and inner microstructure changes was made with using of SEM (Quanda 600) and digital optical microscope Hyrox 7700. Preparation for investigation of inner microstructure included mechanical polishing and etching of sample sections made along the loading direction.

Table 1. Dimensions of samples

Material	Diameter, mm	Thickness, mm	Mean grain size
Vanadium	200	5	4 mm
Iron	200	10	50 mkm

3. Fracture surface analysis

Figure 1 represents the microphotographs of spall fracture surfaces of two materials under study. A highly coarse-grained structure of vanadium samples allowed one to define boundaries between crystallites (figure 1, left), and study the fracture regularities inside separate crystallites. It was shown that fracture surfaces of such crystallites consist of cleavage facets, ad the fraction of plastic deformation is significantly low (figure 2, left). Evidences of low fraction of plasticity in fracture of vanadium samples were obtained also from measurements of free surface velocity. In the central part of each cleavage facet a crack formation occurs, different stages of such cracks growing were observed. With increasing of projectile velocity relief of cleavage facets becomes smoother, which reflects higher fracture velocity, and the fraction of plastic deformation is getting lower.

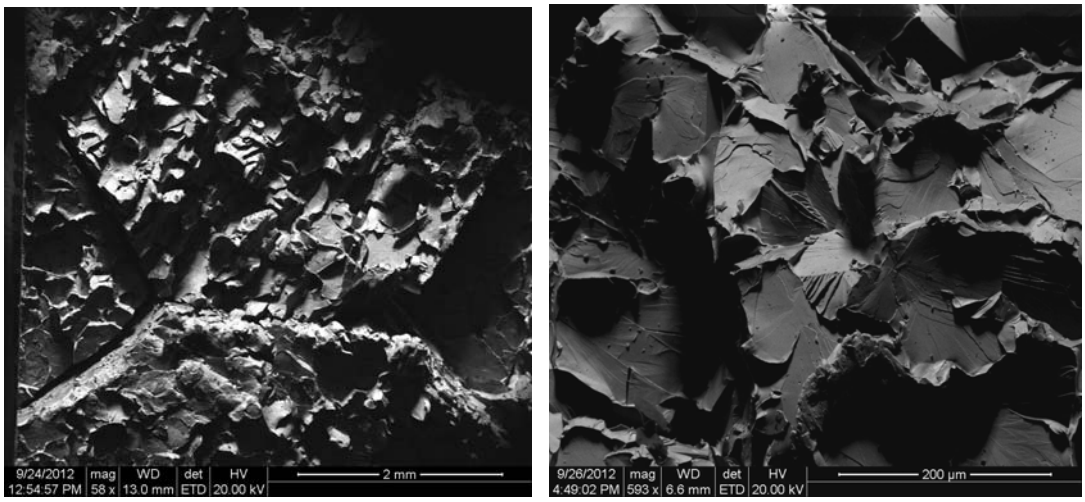

Figure 1. Microphotographs of fracture surfaces of two materials: left - coarse-grained vanadium (projectile velocity 280 m/s), right – polycrystalline iron (projectile velocity 300 m/s).

Fracture surfaces of polycrystalline iron-targets consist of intergranular cleavage facets with more inhomogeneous character because of much lower grain size (figure 1, right). In central part of facets, which size is corresponding to grain size scale, a formation of microvoid is usually occurs. Typical picture of such fracture surface elements is presented on figure 2, right. Increasing of projectile velocity in investigated interval didn't reveal any qualitative changes in fracture surface relief.

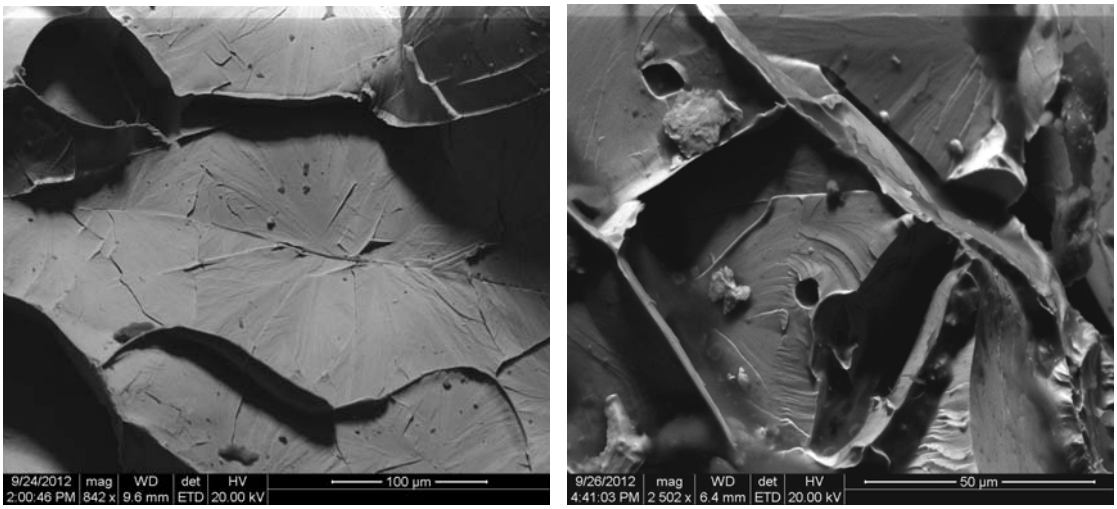

Figure 2. Elements of fracture surface relief on two materials: left picture – vanadium, right picture – polycrystalline iron.

3. Inner structure changes

Increasing of loading velocity for iron samples leads to qualitative changing of structure deformation: in the case of minimum developed projectile velocity there are some separately arranged highly deformed grains (fig. 3, left), whereas the number of such grains in target corresponding to maximum loading velocity is much bigger (fig. 3, right).

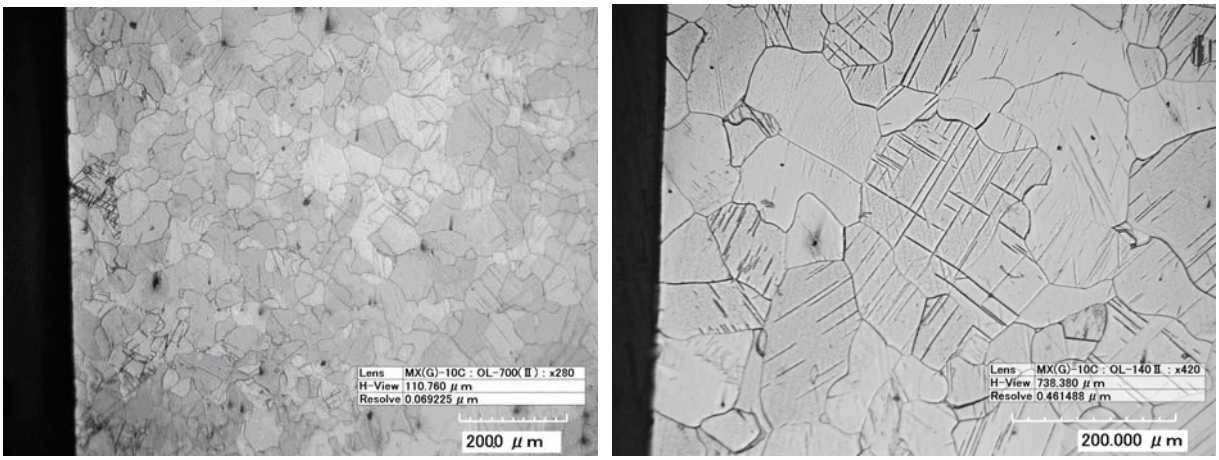

Figure 3. Microstructure near the loaded surface of deformed iron samples corresponding to different projectile velocity: left picture – 230 m/s, right picture – 260 m/s.

Shock-wave loading initiates dynamic recrystallization processes in iron targets. Near the loaded surface dynamic recrystallization usually takes place on grain boundaries, while near the spall area new grains can nucleate on microcracks (fig. 4). Besides, the higher projectile velocity the less deviation of grain size caused by intensive growing of recrystallized grains.

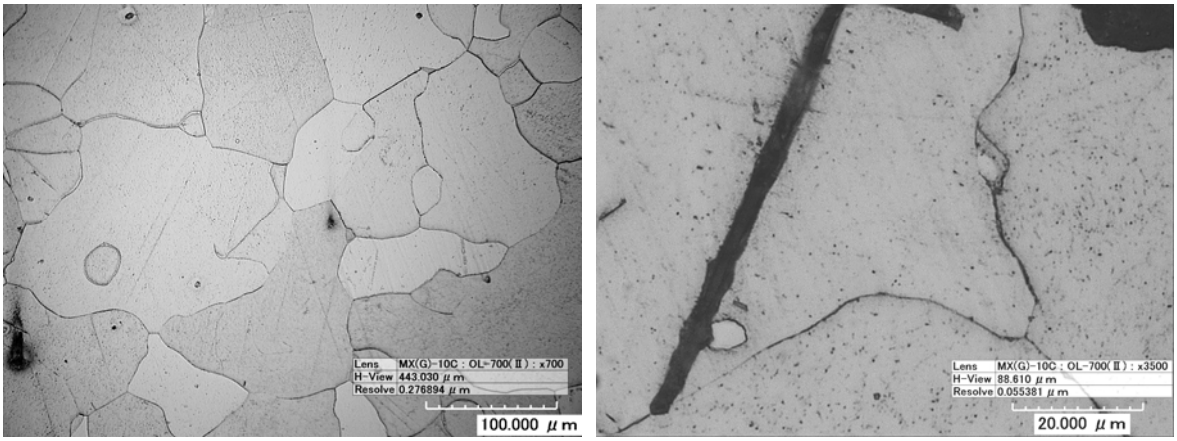

Figure 4. Microstructure of deformed iron samples corresponding to different projectile velocity: left picture – 230 m/s, right picture – 260 m/s.

Another feature of high-speed loading of targets is accumulation of misorientations in subgrain boundaries, resulting in fragmentation of initial grains. Far enough from spall region this transformation of low-angle boundaries to high-angle boundaries has crystallogeometrical character (fig. 5, left) whereas near the spall fracture surface presence of shear mode of deformation is observed (fig. 5, right).

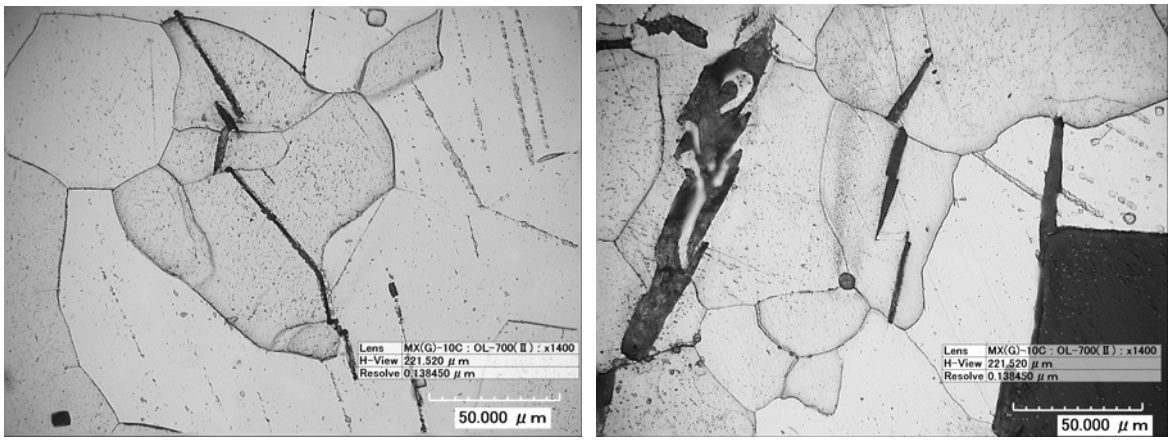

Figure 5. Fragmentation of initial grains: left picture – far from fracture surface, right picture – directly near the fracture surface. Projectile velocity 245 m/s

4. Conclusions

Results of microstructure analysis of metallic samples (coarse-grained vanadium and typical polycrystalline iron) subjected to shock-wave loading of different intensity are presented and structure relaxation mechanisms taking place during such loading in two investigated materials are discussed. An important role of dynamic fragmentation in the case of iron samples was established. Obtained data will be used for quantitative analysis of structure changes under high-speed loading of different intensity.

Abstract Engineering plastics provide superior performance to ordinary plastics for wide range of the use. For polymer materials, dynamic stress and strain rate may be major factors to be considered when the strength is evaluated. Recently, high speed tensile test is being recognized as a standard testing method to confirm the strength under dynamic loads. In this study, therefore, high speed tensile test is analyzed by the finite element method; then, the maximum dynamic stress and strain rate are discussed with varying the tensile speed and maximum forced displacement. The strain rate concentration factor found to be constant independent of tensile speed, which is defined $K_{t\dot{\varepsilon}}$ as the maximum strain rate appeared at the notch root over the average nominal strain rate at the minimum section. The maximum strain rate is controlled by the tensile speed alone independent of the magnitude of the forced displacement. It is found that the difference between static and dynamic maximum stress concentration (σ_{max}-σ_{st}) at the notch root is proportional to the tensile speed when u/t$\leqq$5000mm/s.

Keywords Stress Concentration, Notch, Dynamic Stress, Strain Rate, Finite Element Method

1. Introduction

Engineering plastics are widely used in everyday products. Typically, a suitable engineering plastic is chosen for its range of enhanced physical properties. It is know that polycarbonate has superior impact and perforation resistance compared with other polymers, or indeed compared with some structural metals [1]. Most thermoplastics far below their glass transition temperature T_g give a brittle fracture when deformed in uniaxial tension. However, polycarbonate is an exception and deformed in a ductile manner. However, Izod impact studies of notched specimens show that the fracture mode changes from ductile to brittle below T_g. To investigate the brittle-ductile transition, which is affected by temperature and loading speed [2, 3], a high-speed tensile test is being recognized as a standard testing method in recent years. Generally, bluntly notched specimens failed in a fully ductile manner, and sharply notched specimens failed in brittle manner depending on the strain rate at the notch root.

It should be noted that Izod and Charpy impact tests are not suitable for evaluating the impact strength of real products because the impact speeds do not correspond to the real failure. In the high-speed tensile test, it is necessary to obtain the strain rate correctly to understand the impact strength of the polymer specimen. For smoothing specimens, the strain rate can be determined as $\dot{\varepsilon} = u/tl$ from the specimen length l and the tensile speed u/t. On the other hand, for notched specimens, it is necessary to measure the strain at the notch root by strain gauge measurement, for example. However, because only the average value of the strain concerning the gauge width can be measured. It is not easy to measure the strain at the notch root.

In the previous studies for dynamic stress concentration, circular holes [4] and elliptical holes [5] were investigated under step load [6, 7] and pulse load [7, 8]. In addition, several review papers for

impact problems are also available [9–11]. However, there are few studies on the strain rate concentration for notched specimens under various tensile speed. Therefore, in this paper, the finite element method is applied to analyze the notched specimens under various tensile speed. Then, the dynamic stress concentration factor and the strain rate factor will be discussed with varying tensile speed and maximum values of forced displacement.

2. Static stress concentration and specimen geometry

In this study, the material analyzed is assumed as polycarbonate, which has especially high impact strength among the polymeric materials. Young's modulus is assumed as E = 2.3GPa, Poisson's ratio ν = 0.37. Figure 1 shows the geometry of the double-edge-notched specimen, with dimensions of notch root radius $\rho = 0.03mm$ and $0.2mm$, notch depth t = 5mm, and opening angle 90º. The notch root radius $\rho = 0.03mm$ corresponds to the radius of fillet appearing at polymer products generally. The notch root radius $\rho = 0.2mm$ corresponds to the radius of the notched specimens used in the Izod and Charpy test. When the high-speed tensile test is performed, both ends of the specimen are gripped by rigid chuck, then forced displacement is applied to the end under constant speed. Figure 2 shows FE models for analysis. Here Model 1 has the notch radius $\rho = 0.03mm$, and Model 2 has $\rho = 0.2mm$. Figure 2(c) shows the notch root detail in Model 1, and Fig. 2(d) shows the notch root detail in Model 2. Minimum mesh size of the notch root is $e = \rho/243$ each model. Figure 3 shows the boundary conditions given to the end portion of the analysis models. Figure 3(a) shows boundary conditions in the rigid chucks, and Fig.3(b) shows a tensile stress boundary conditions

generally used. Table 1 shows the effect of boundary conditions on the static stress concentration factor. From Table 1, it is seen that the stress concentration factor is almost the same between the rigid grip tension and simple tension. Also, Table 1 shows the FE model in Fig. 2 shows less than 1% error compared to the exact stress concentration factor obtained by the approximate formula[12].

3. Dynamic stress concentration for high speed tensile test specimen

Figure 4 shows the forced displacement u given at the end of the specimen. The average stress σ_{gross} is also indicated, which is expressed as $\sigma_{gross}(t) = 0.867E \cdot u(t)/l$ from FEM. The stress at the

minimum section is expressed as $\sigma_{net} = (D/d)\sigma_{gross}$. Here, we consider 5 cases as shown in Table 2. Table 2 shows the tensile speed and the maximum forced displacement at the grip end with the time of that appear. In Case 5, the tensile speed $u/t = 5000\,mm/s$ corresponds to the impact speed when someone drops a call phone to the ground. The maximum displacement 1.5mm corresponds to the brittle fracture appears for high speed tensile test. The maximum displacement 0.1mm corresponds to an example of nondestructive case of for high speed tensile test.

Figure 5 shows the dynamic stress at the notch root A for Cases 1-5. Also Fig. 5 shows the detail of the dynamic stress oscillation with each case. From Fig. 4 and Fig. 5, it is seen that the maximum dynamic stress $\sigma_{\max}$ appears at almost the same time of the maximum forced displacement. Defined the maximum value of dynamic stress as $\sigma_{\max}$ in each case. After several oscillations due

Table 2. Maximum displacement and tensile speed given at the grip end

	Case		①	②	③	④	⑤
Condition	Maximum displacement	$u_{\max}$	0.1 mm t=0.00100s	0.1 mm t=0.00029s	1.5 mm t=0.00429s	1.5 mm t=0.00150s	1.5 mm t=0.00030s
	Tensile speed	u/t	100 mm/s t<0.00100s	350 mm/s t<0.00029s	350 mm/s t<0.00429s	1000 mm/s t<0.00150s	5000 mm/s t<0.00030s

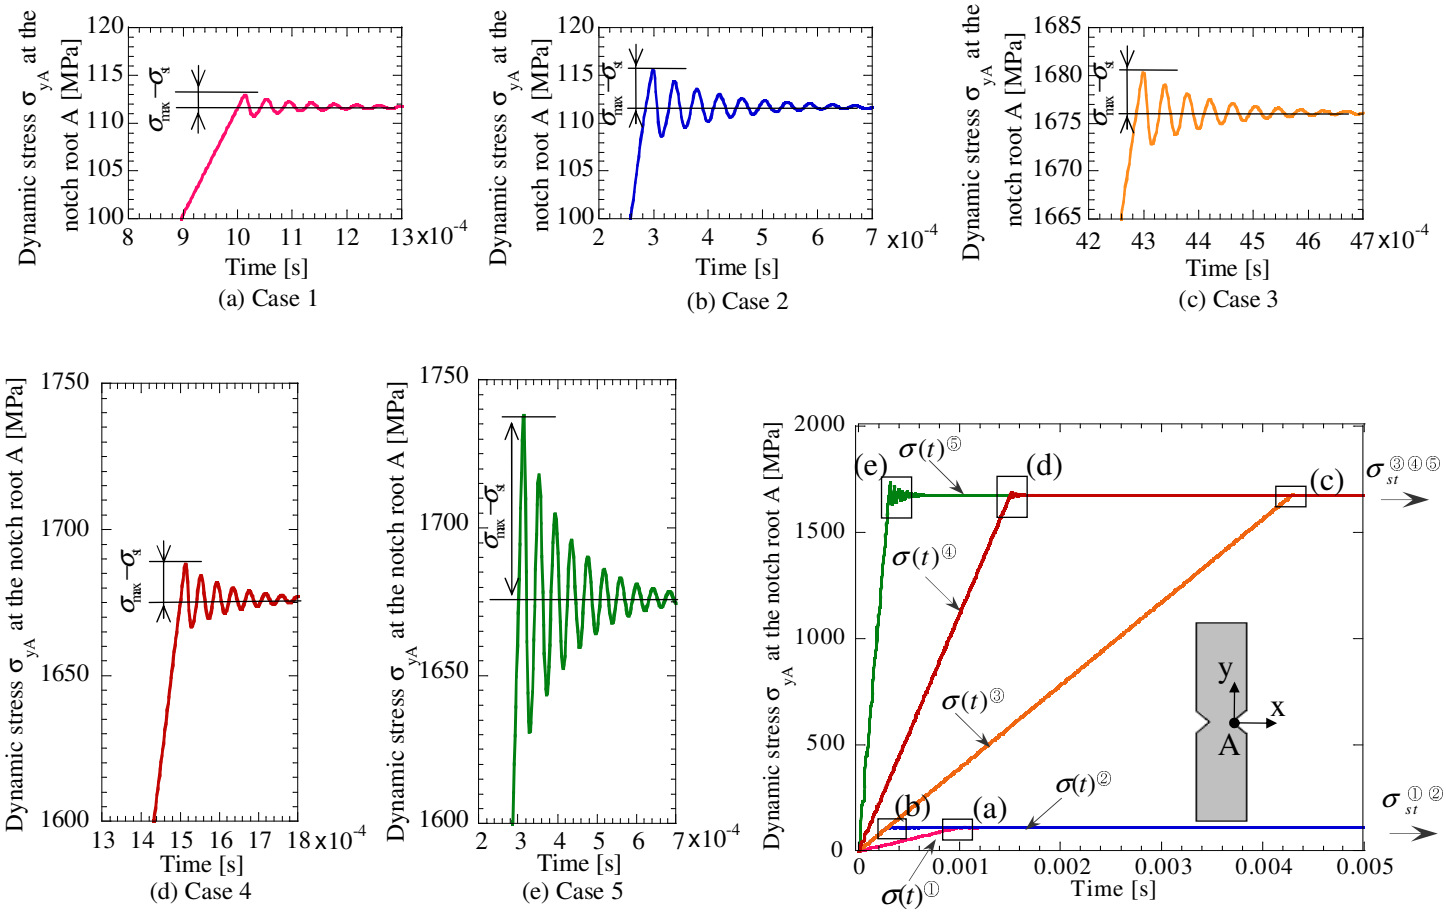

Figure 5. Dynamic stress at notch root A for ρ=0.03mm

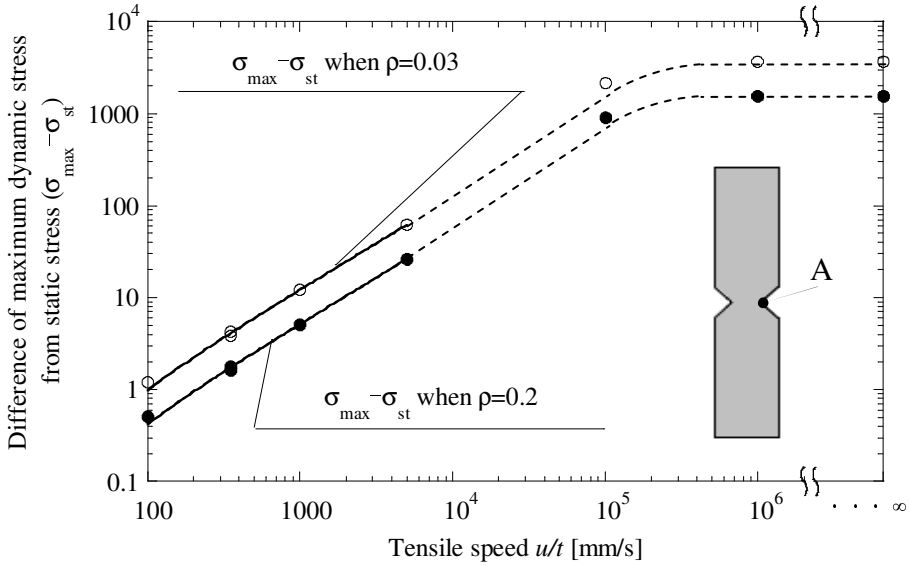

Figure 6. Difference between the static and dynamic maximum stress concentration ($\sigma_{\max} - \sigma_{st}$) vs. tensile speed

to the stress wave, dynamic stress approaches the static stress σ_{st}. From the comparison between Case 3 and Case 4, it is seen that of the maximum dynamic stress oscillation $(\sigma_{\max} - \sigma_{st})$ at the notch root A is always the same although the final displacement of Case 3 is 15 times larger than that in Case 2. It is may be concluded that the maximum dynamic stress oscillation $(\sigma_{\max} - \sigma_{st})$ is controlled by the tensile speed. Figure 6 shows the relationship between the tensile speed u/t and $(\sigma_{\max} - \sigma_{st})$ for $\rho = 0.03mm$ and $0.2mm$. Here the results for $u/t = 10^5, 10^6\ mm/s$ and step load $u/t = \infty$ are also indicated when the maximum displacement is 1.5mm. It is seen that $(\sigma_{\max} - \sigma_{st})$ is proportional to the tensile speed when $u/t \le 5000\,mm/s$. However, $(\sigma_{\max} - \sigma_{st})$ becomes constant when $u/t \ge 10^5\ mm/s$.

4. Strain rate concentration for high speed tensile test specimen

Figure 7 shows the strain rate at the notch root A for Cases 1-5. The strain rate increases dramatically at the start of applying forced displacement, Then, after several oscillations, the strain

rate becomes constant. After stopping the forced displacement, several oscillations appear again, then it eventually converges to zero. From the comparison between Case 3 and Case 4, it is seen that the same maximum strain rate $\dot{\varepsilon}_{\max}$ and the same converged strain rate $\dot{\varepsilon}_{const}$ are observed although the final displacement $u_{\max}$ of Case 3 is 15 times larger than that in Case 2. It may be concluded that the strain rate concentration is controlled by the tensile speed. Figure 8 shows the

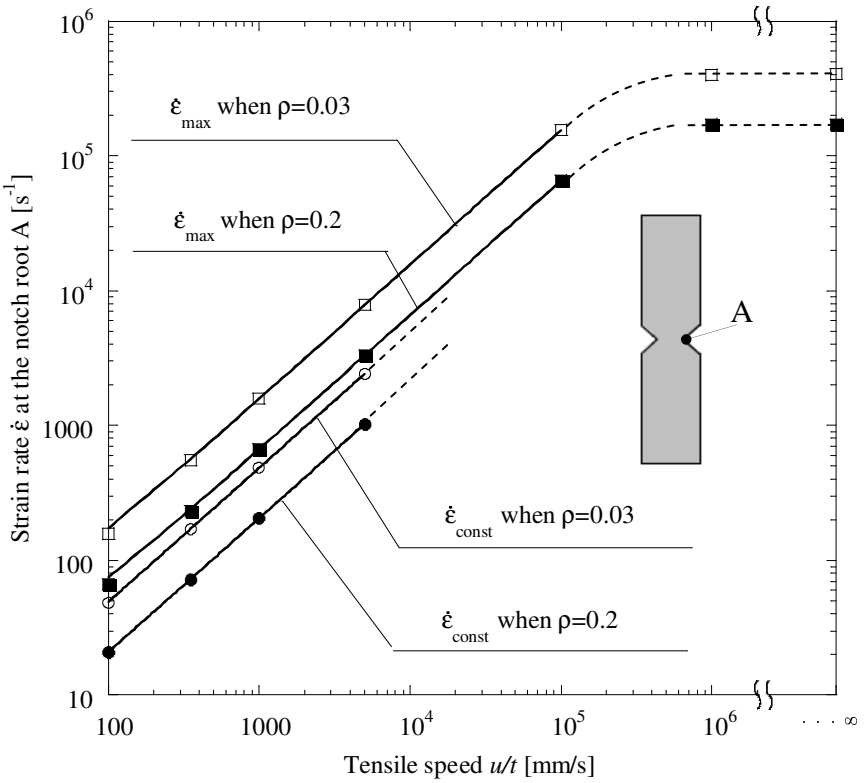

Figure 8. Maximum strain rate and converged strain rate vs. tensile speed

relationship between the tensile speed u/t and the strain rate for $\rho = 0.03mm$ and $0.2mm$. Here the results for $u/t = 10^5, 10^6\ mm/s$ and step load $u/t = \infty$ are also indicated when the maximum displacement is $1.5mm$. It is seen that the strain rate is proportional to the tensile speed when $u/t \le 5000\,mm/s$. However, the strain rate becomes constant when $u/t \ge 10^5\ mm/s$.

5. Dynamic stress and strain rate distributions of the minimum section

Figure 9(a) and Fig.10(a) show the dynamic stress distributions at the minimum section when the maximum dynamic stress appears. From Fig. 9(a), it is seen that the maximum dynamic stress $\sigma_{\max}(t)$ at the notch root when $\rho = 0.03mm$ is 14.48 times than that of the nominal stress $\sigma_{nom}(t)$ at the minimum section at each time for Case 1 –Case 5. On the other hand, from Fig. 10(a), it is seen that the maximum dynamic stress $\sigma_{\max}(t)$ at the notch root when $\rho = 0.2mm$ is 6.43 times than that of the nominal stress $\sigma_{nom}(t)$ at the minimum section at each time for Case 1 –Case 5. The stress concentration factor coincides with the static stress concentration factor obtained by Noda–Takase [12]. Figure 9(a) and Fig.10(a) show the strain rate distributions at the minimum section when the maximum strain rate appears. From Figure 9 (b), it is seen that the maximum strain rate $\dot{\varepsilon}_{\max}(t)$ at notch root when $\rho = 0.03mm$ is 22.87 times than that of the nominal strain rate $\dot{\varepsilon}_{nom}(t)$ at the minimum section for Case 1 –Case 5. From Fig. 10 (b), it is seen that the maximum strain rate $\dot{\varepsilon}_{\max}(t)$ at the notch root when $\rho = 0.2mm$ is 8.72 times than that of the nominal strain rate $\dot{\varepsilon}_{nom}(t)$ at the minimum section for Case 1 –Case 5.

6. Conclusion

Recently, high-speed tensile test is being used as a standard testing method to evaluate impact strength of the materials. For polymeric material, the strain rate and dynamic stress concentration is

significant factors, when we use this material as cellphone bumper. However, it is not easy to measure the dynamic stress or strain rate accurately at the notch root by experiment. In this study, therefore, dynamically and elastic FEM is applied to the high-speed tensile test for notched specimens. Then, the dynamic stress and strain rate concentrations have been discussed under various tensile speeds. The conclusions can be made the following way.

(1) It may be concluded that the strain rate concentration factor $K_{t\dot{\varepsilon}} = \dot{\varepsilon}_{\max}(t)/\dot{\varepsilon}_{nom}(t)$, which is defined by the maximum strain rate $\dot{\varepsilon}_{\max}(t)$ at the notch root over the average strain rate $\dot{\varepsilon}_{nom}(t)$ at the minimum section at each time, is always constant and controlled by the notch shape alone independent of the tensile speed.

(2) It is found that the difference between the static and dynamic maximum stress concentration ($\sigma_{\max} - \sigma_{st}$) at the notch root increases is proportional to the tensile speed when $u/t \le 5000\,mm/s$.

(3) It is found that the strain rate of the notch root increases is proportional to the tensile speed when $u/t \le 5000\,mm/s$.

Abstract Pseudoelasticity is one of the main characteristics of shape memory alloys (SMAs), allowing them to recover their initial state after undergoing large deformation. This is due to the martensitictransformation (MT) occurring in the material, turning the austenitic phase into a stress-induced martensitic phase when a mechanical load is experienced. Even if such an effect was largely studied in the past decades under quasi-static loading, the dependence of this effect of the loading rates was rather poorly documented. Only some studies have reported the strain rate dependence of the macroscopic behaviour of SMAs, but no detailed observation of the transformation process under impact loading is available.
This paper investigates the influence of the loading rate applied to a NiTi SMA at the level of the MT, providing experimental data of not only the macroscopic stress-strain curves, but also the corresponding observation of the heterogeneous strain field during the test. Main testing results are obtained under tensile loading. Experiments were conducted at three different levels of prescribed velocity : 0.01 mm/s, 1 mm/s and 5000 mm/s, using a classical loading machine for the quasi-static cases and a Split Hopkinson Tensile Bar (SHTB) for the dynamic cases. The observations of the heterogeneous strain field during the tests were made using a digital image correlation (DIC). Additional results under double shear test at various loading rate will be also presented.

Keywords Impact testing, Phase transition; NiTi shape memory alloy; Domain patterns and domain spacing; Strain rate.

1. Introduction

Shape memory alloys (SMA) have a great potential of applications in a lot of innovative technologies owing to two specific properties: the shape memory effect and pseudoelasticity [1]. In particular, NiTi-based SMA are widely used as biomaterials (to manufacture heart artery stents for instance) or in mechanical applications such as actuators, smart materials in the automotive industry, household appliances, and so on. The ability of NiTi alloys to undergo large strains is due to the transformation, under mechanical loading, of initial austenite to stress-induced martensite (SIM). This specific stress-induced martensitic transformation is associated to a mechanism of propagation of bands into the specimen as in localization phenomena (Luders bands, Portevin-Le Chatelier effect [2], compaction of foams ([3-4]), which leads to a non-homogeneous strain state ([5-7]).
Technically, the observation of the bands and the influence of strain rate on the propagation of the martensitic transformation has been initiated fifteen years ago ([6-8]). New measuring techniques, such as Digitial Image Correlation (DIC) that catches the measurable difference of strain between elastically loaded austenite and mechanically transformed martensite([9-10]), as well as the Infrared thermography (IRT) that takes advantage of the fact that the transformation of austenite into martensite is exothermic ([11-12]), have been used in the last decade. In the open literature, particular results are reported about the nucleation sites and the number of bands ([13]), the propagation of the transformation front, or the effect of stress concentration ([14]).

Under higher strain rates (more than 10 /s), some authors have studied the strain rate sensitivity of NiTi in compression ([15-19]) with Split Hopkinson Pressure Bars (SHPB), a system commonly used for accurate measurement of dynamic and macroscopic stress-strain responses of materials

([20-21]). It appears that SIM transformation is rate-dependent so that the stress triggering the transformation process increases with strain rate. There are also a few papers that present some experimental results with tensile Hopkinson bar tests (strain rate up to 1.67 /s in[22] and up to 1200 /s in [15]). Unfortunately, all these results under impact loading rate are only based on macroscopic measurements which are the nominal strain or stress. The observation of the transforming regions of NiTi alloys is not yet reported, probably due to the experimental difficulty to get these results at such strain rates. Thus, the description of nucleation sites, number of bands, transformation front velocity under higher strain rate are almost unknown. There is no available shear testing results under impact loading.

The present work wishes to provide a measurement of NiTi SMA behavior under tensile as well as shear loading up to an intermediate strain rate regime around 100 /s (3 decades higher than previous studies). In addition, heterogenous strain fields due to transforming regions is measured, coupled with a tensile Hopkinson bar system. For this purpose, strain fields of the sample are measured by Digital Image Correlation procedures using pictures captured with a high speed camera.

2. Experimental setup and macroscopic results

2.1 Tensile tests

2.1.1 NiTi specimens and quasi-static tests

The material of this study is taken from NiTi polycristalline cold-rolling sheets, in the cold-rolling direction. The metallurgical composition is 50.7 wt.% Ni and 49.3 wt.% Ti ([23]). All the experiments are performed at room temperature, clearly above the characteristic temperature A_f so that for stress-free condition the specimen is in a full austenite state. A single plate specimen, dog bone shaped, as schematically presented in the upper left corner of figure 1, is used for all the experiments. In its central part, the specimen is 60 mm long, 2.6 mm wide and 0.5 mm thick.

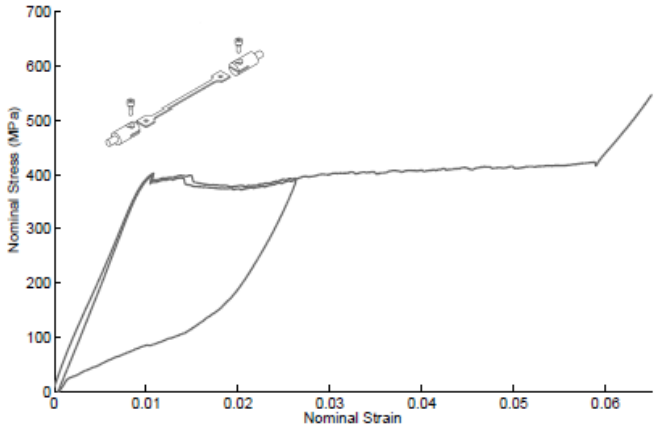

Fig. 1: Static strain-stress curve for a prescribed velocity of 0.01 mm/s ($1.4x10^{-4}$ /s), at room temperature

For the fixation in the grips, the width is 10 mm so that the fillet radius of 10 mm leads to a stress concentration. It is observed that this triggers the SIM transformation at both ends of the central part of the specimen. This is acceptable because the paper is focused on propagation of the transformation, not on its nucleation. For all the experiments, the specimen is fixed between two

tabs that can further be screwed (i) in the bars for dynamic tensile experiment, (ii) in a clamping system for static experiments. This allows to be more confident in the comparison of experimental results obtained with different devices. We could ensure that there is no sliding of the specimen during monotonic static or dynamic tension experiments due to the presence of a screw that fits into one hole machined into each end of the specimen. Quasi-static tensile tests were performed on an electromechanical Instron device so there was no heating of the specimen through the gripping system. Experiments were done at two different prescribed velocities : 0.01 mm/s ($1.4x\ 10^{-4}$/s) and 1 mm/s ($1.4x\ 10^{-2}$/s). Each experiment was repeated twice in order to check repeatability of the measurements. The nominal stress-strain curve obtained at 0.01 mm/s is shown in figure 1.
Three domains appear on the curve. First the elastic tension of the initial austenite phase for strains up to 0.01. Then the stress plateau associated to the pseudoelastic domain of interest in this study begins. It corresponds to the stress-induced martensitic (SIM) transformation for strains up to 0.06. One unloading-reloading cycle has been performed in the pseudoelastic domain in order to show that the reverse transformation is effectively reversible. It can be noticed that two serrations are visible at the beginning of the pseudoelastic domain. This phenomenon is due to the heterogeneity of the martensitic transformation ([12]). At a third stage, the supposed "fully" martensitic specimen is submitted to elastic tension. The vocabulary "fully martensitic" refers in fact to the end of the SIM transformation process even if it has been documented that probably all austenite has not been transformed yet ([24]). In this experiment, maximal strain is under 0.08 and there is no evidence of plastic deformation during tension.

2.1.2 The tensile Hopkinson bar experiment

The use of Hopkinson bars as a measurement technique has been introduced at the end of the 19th century and has led to many developments in the field of analysis of material behaviour under dynamic loading ([20], [25]). Hopkinson bar measurement allows to obtain an accurate measurement of dynamic forces and velocities at both ends of the specimen. The device used in this study is a Split Hopkinson Tensile Bar (SHTB) as schematized in figure 2. The apparatus is composed of two bars of 10 mm diameter, called the input and the output bars, made of maraging steel. The specimen (equipped with its end tabs) is tightly screwed at the end of each bar. The tabs are manufactured in the same material as the bars and designed so as to minimize any mass effect by matching the same acoustic impedance as the bars. The loading principle is the following: first a tensile elastic energy is stored in the input bar along a length L between points A and B of the input bar, then this energy is suddenly released from point B so that an incident tension pulse reaches the specimen ([26]). The initial elastic energy controls the subsequent strain and strain rate applied to the specimen. The initial load N_0 is applied with a hydraulic jack, and, to perform a test at an initial velocity of around 1000 mm/s, an initial load of around 5 kN is applied.

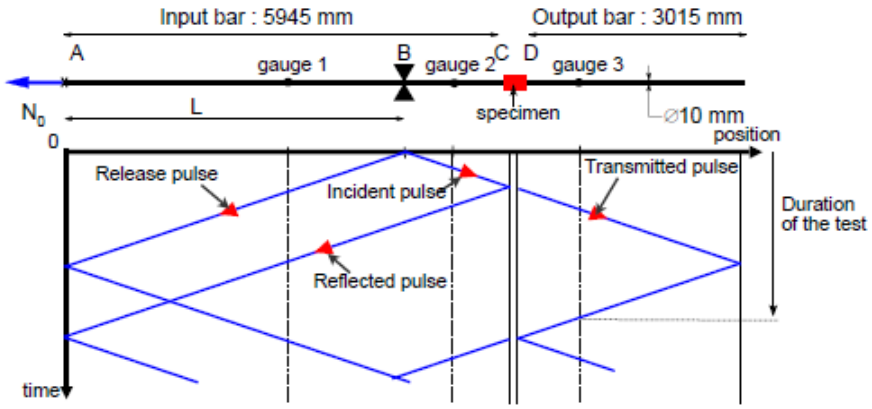

Fig. 2: Split Hopkinson Tensile Bar dimensions and corresponding lagrange diagram.

A significant increase of stress level is observed with impact strain rate, as shown in Figure 3.

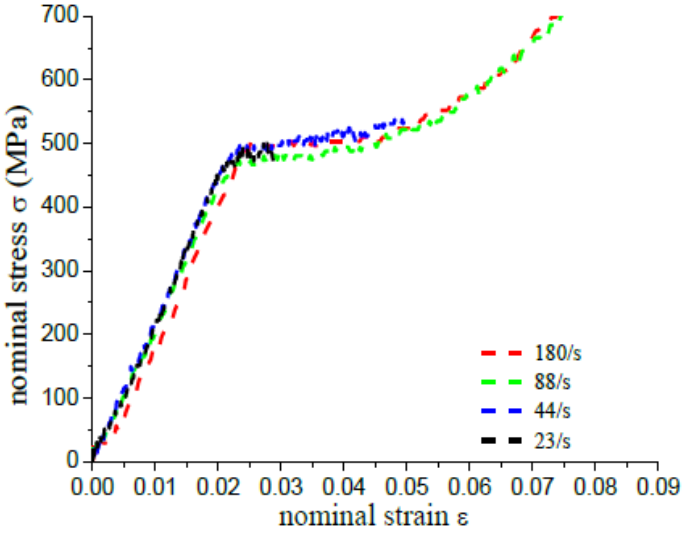

Figure 3 Stress strain curves at intermediate strain rates

2.2. Shear tests

Double shearing test can be realized which might prevent from geometrical instabilities. Divers versions of this test had been developed in the past decades [27-29]. A modified double shearing device to better fit with the 60mm-diameter Split Hopkinson pressure bar was developed by Merle [30]. Figure 4 shows the clamping device and specimen for the shearing tests. The specimen has two symmetric shearing zones of 3mm width and 20mm length. The clamping device is composed of the two moving coaxial pieces.

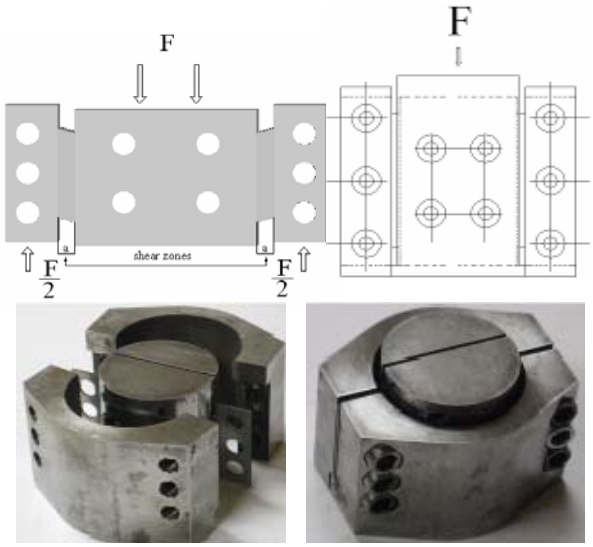

Fig. 4 Double shear specimen and shear device

Quasi-static tests were performed using a classical hydraulic testing machine with the device mentioned above. Dynamic tests were performed using the split Hopkinson of aluminum bars with a diameter of 60mm with 4m long incident bar and 2.5m long transmitted bar. The schematic drawing of the bars is shown in figure 5.

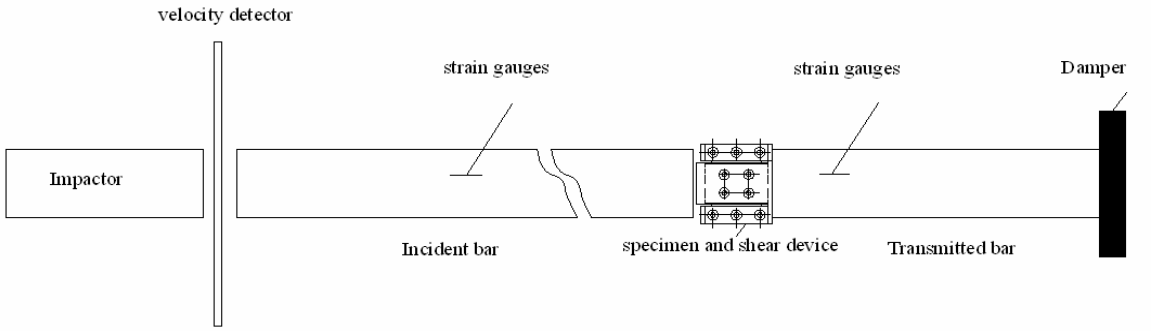

Fig.5 Schematic drawing of 60mm aluminum Hopkinson bar and device

Based on the plane shear assumption, the equivalent strain is calculated with measured displacement between the two clamping pieces d (Eqn 1.) and equivalent stress with the force F (Eqn 2).

$$\varepsilon_{eq} = \frac{\mathrm{d}}{l\sqrt{3}} \tag{1}$$

$$\sigma_{eq} = \tau\sqrt{3}\,,\ \tau = \frac{F}{S}. \tag{2}$$

Figure 6 shows first results at various strain rate. The same tendency of stress increases is also

observed.

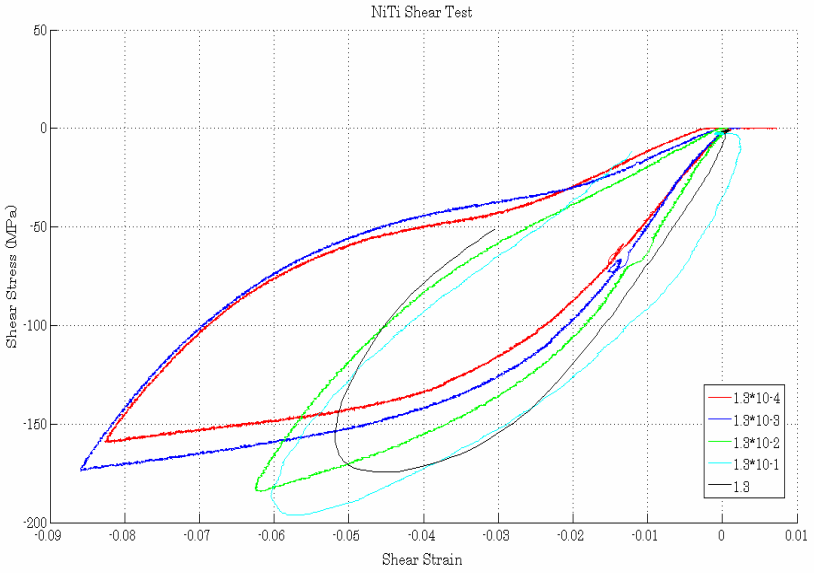

Figure 6 Shear stress-strain curves at various strain rates

3. Measurement of strain fields

3.1 Digital Image Correlation (DIC) setup

To acquire images, different devices were used, depending of the performed test. For low frequency acquisition, a reflex camera (Canon EOS) was used and for high frequency acquisition, fast cameras (PHOTRON) were used. The main difference between the two ways to get pictures is that for fast camera, the resolution is lower than for reflex camera. Subsequently, the spatial resolution is poorer for dynamic tests: the resolution of the fast camera is in inverse proportion to frame rate even if, for the last test, a more efficient camera was used in comparison with the previous test. This impact directly the accuracy of the optical measurement. In order to allow DIC computations, a speckle was applied on the observed surface of the specimen with black and white paint. Moreover, in order to avoid heating of the specimen surface, the lighting was done with LED lights during the quasi-static experiments and with short time light exposition of the specimen during the dynamic experiments. The principle of the used DIC computation program (CorreliQ4) is given in [31-32]. A first analysis of DIC results allows to give qualitative information on the phenomena taking place during the tests. Basic observation on figure 7, resulting from a quasi-static tensile test at 0.01 mm/s, shows that only two admissible strains are visible: a 1 % strain zone (supposed to be the austenitic phase) and a 6 % strain zone (supposed to be the stress-induced martensitic phase). An enlargement of the SIM region during the test can be observed.

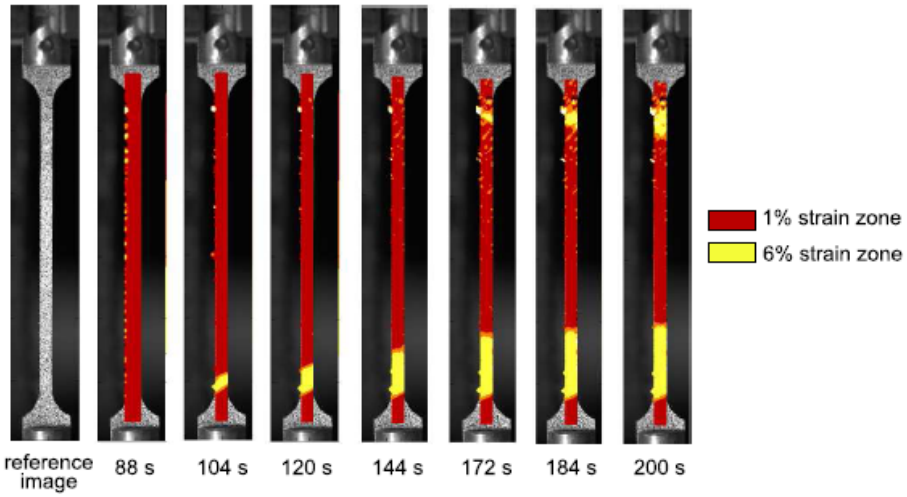

Fig. 7: Strain maps for quasi-static tensile test performed at 0.01 mm/s

The same image analysis can be also applied to the double shear tests. Figure 8 shows a strain map of shear tests. In contrast with tensile test, a rather homogeneous strain field was observed.

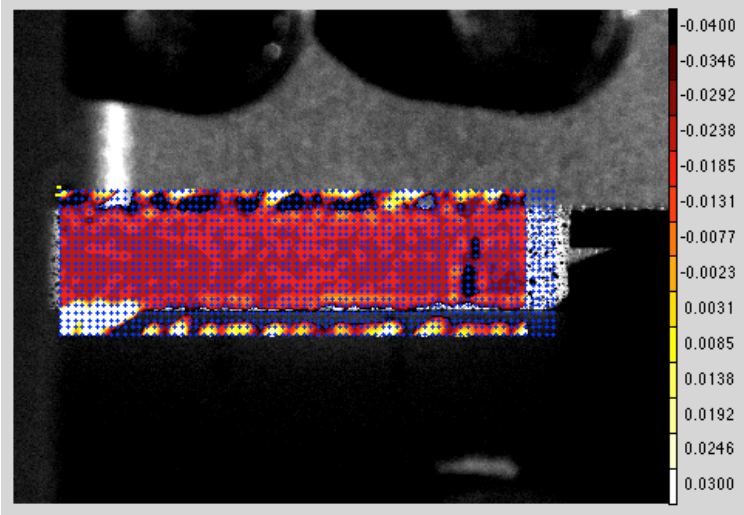

Figure 8, strain field measurement during shear tests

4 Conclusions

This paper used Split Hopkinson pressure bar system and high-speed testing machine to investigate the pseudoelastic deformation of a NiTi plate specimen at various strain rates. It provides original results of the strain rate dependence under not only tensile but shear loadings. In addition, the image analysis were used in all the testing which allows a measurement of strain fields.

Abstract An impermeable crack in a piezoelectric strip at arbitrary position under in-plane mechanical and electric impact loadings is considered. Due to the asymmetry of the geometry, this crack problem is a mixed-mode one. Fourier and Laplace transforms are applied to reduce the mixed boundary value problem of the crack to a system of singular integral equations. The asymptotic fields near the crack tip are obtained in explicit form and hoop and shear stress intensity factors are defined. Laplace inversion transforms are applied to get the dynamic hoop stress intensity factors. The crack kinking phenomena is investigated by applying the criterion of maximum hoop stress intensity factors. Numerical results show that the geometry of the cracked strip and the electric loadings have effects on the singular field distributions around the crack tip, and the hoop stress intensity factors are influenced by the material parameters, the electric loading and the geometric size ratios.

Keywords Mixed-mode crack, Piezoelectric Strip, Singular integral equations, Crack kinking; Hoop stress intensity factor

1. Introduction

Piezoelectric materials can be made into various functional devices, such as sensors and actuators, which are widely used in modern industrial fields. Due to the brittleness and low fracture toughness of piezoelectric materials, dynamic fracture analysis of piezoelectric materials has drawn considerable attentions. Dynamic anti-plane crack propagation in piezoelectric materials has been studied by Li and Mataga [1, 2]. Shindo et al. [3] obtained dynamic stress intensity factors of a cracked piezoelectric medium in a uniform dielectric field. The problem of a Griffith crack moving along the interface of two dissimilar piezoelectric materials was solved by Chen et al. [4] using the integral transform technique and it is shown that the stress and electric displacement are dependent on the speed of the crack and the material coefficients. Chen and Yu [5] investigated a semi-infinite crack in a piezoelectric medium subjected to antiplane impact loading. Mode-I transient response of a piezoelectric strip containing a center-situated crack under in-plane mechanical and electric impacts was investigated by Wang and Yu [6], and it was found that the intrinsic mechanical-electrical coupling plays a significant role in the dynamic fracture response of in-plane problems.

Crack kinking is an important phenomenon in the fracture of piezoelectric materials in response to electro-mechanical loading. Zhu and Yang [7] modeled the crack kinking in a piezoelectric solid by continuous distribution of edge dislocations and electric dipoles, and the solution was formulated via the Stroh formalism. The mixed-mode crack initiation in piezoelectric strip was studied by Wang and Noda [8] using the method of Fourier transform and singular integral equations. Hu and Zhong [9] considered a moving mode-III crack in a functionally graded piezoelectric strip. They found that the gradient of the material properties can affect the magnitudes of the stress intensity factors, and a high crack moving velocity can change the propagation orientation of the crack.

In this paper, the mixed-mode crack in a piezoelectric strip under in-plane electrical and mechanical impact loadings is studied. Fourier transform is employed to reduce the mixed boundary

value problem of the crack to solving a system of singular integral equations. The asymptotic fields near the crack tip are obtained in an explicit form and the hoop and shear stress intensity factors are then determined. The crack kinking phenomenon is investigated by applying the maximum hoop stress intensity factor criterion. The coupled electro-mechanical effects on the crack-tip fields are investigated and the influence of the geometric feature of the strip on the crack kinking is discussed.

2. Problem statement and method of solution

Consider a transversely isotropic, linear piezoelectric material and denote the rectangular coordinates of a point by (x, y, z). The constitutive equations can be written as

$$\begin{Bmatrix}\sigma_{xx}\\ \sigma_{zz}\\ \sigma_{xz}\end{Bmatrix}=\begin{bmatrix}C_{11} & C_{13} & 0\\ C_{13} & C_{33} & 0\\ 0 & 0 & C_{44}\end{bmatrix}\begin{Bmatrix}\partial u_x/\partial x\\ \partial u_z/\partial z\\ \partial u_x/\partial z+\partial u_z/\partial x\end{Bmatrix}+\begin{bmatrix}0 & e_{31}\\ 0 & e_{33}\\ e_{15} & 0\end{bmatrix}\begin{Bmatrix}\partial\phi/\partial x\\ \partial\phi/\partial z\end{Bmatrix}$$
$$\begin{Bmatrix}D_x\\ D_z\end{Bmatrix}=\begin{bmatrix}0 & 0 & e_{15}\\ e_{31} & e_{33} & 0\end{bmatrix}\begin{Bmatrix}\partial u_x/\partial x\\ \partial u_z/\partial z\\ \partial u_x/\partial z+\partial u_z/\partial x\end{Bmatrix}-\begin{bmatrix}\lambda_{11} & 0\\ 0 & \lambda_{33}\end{bmatrix}\begin{Bmatrix}\partial\phi/\partial x\\ \partial\phi/\partial z\end{Bmatrix} \quad (1)$$

where u_x, u_z are components of the displacement vector and ϕ is the electric potential, $C_{11}, C_{13}, C_{33}, C_{44}$ are elastic constants, e_{15}, e_{31} are piezoelectric constants, and $\lambda_{11}, \lambda_{33}$ are dielectric permittivities, σ_{ij} and D_i ($i, j = x, z$) are components of stress and electric displacement, respectively.

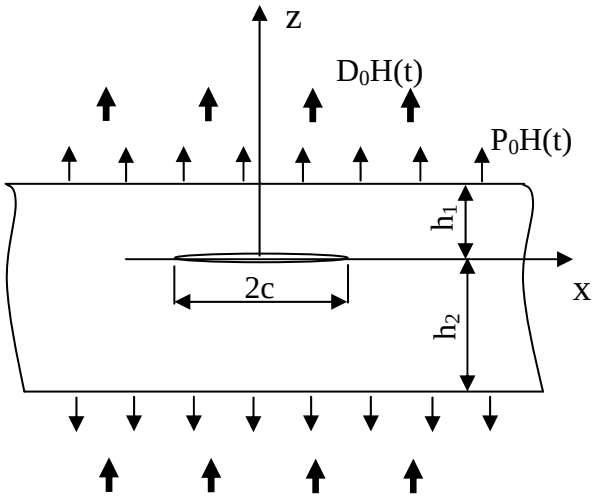

Figure 1. A cracked piezoelectric strip under in-plane mechanical and electric impact loadings

Studied in this paper is a Griffith crack of length $2c$ in a piezoelectric strip of width $h_1 + h_2$, with the poling direction perpendicular to the crack plane, as shown in Fig. 1. Uniform impact

normal stress $P_0\mathrm{H(t)}$ and impact electric displacement $D_0\mathrm{H(t)}$ are applied on the edges of the strip, where H(t) is the Heaviside step function. As shown in Fig. 1, symmetry conditions are used to allow for consideration of only the region ($x \geq 0,\ -h_2 \leq z \leq h_1$). In this paper the impermeable electric boundary condition on the crack faces is employed.

Application of Laplace transform leads to the governing equations in the Laplace domain as follows:

$$\begin{aligned} &C_{11}u^*_{x,xx} + C_{44}u^*_{x,zz} + (C_{13}+C_{44})u^*_{z,xz} + (e_{31}+e_{15})\phi^*_{,xz} = \rho p^2 u^*_x \\ &(C_{13}+C_{44})u^*_{x,xz} + C_{44}u^*_{z,xx} + C_{33}u^*_{z,zz} + e_{15}\phi^*_{,xx} + e_{33}\phi^*_{,zz} = \rho p^2 u^*_z \\ &(e_{31}+e_{15})u^*_{x,xz} + e_{15}u^*_{z,xx} + e_{33}u^*_{z,zz} - \lambda_{11}\phi^*_{,xx} - \lambda_{33}\phi^*_{,zz} = 0 \end{aligned} \tag{2}$$

where p is the Laplace transform parameter and the superscript * denotes the quantities in the Laplace transform domain.

The corresponding boundary conditions and continuity conditions in the Laplace domain are:

$$\sigma^*_{zz}(x,h_1,p) = \sigma^*_{zz}(x,-h_2,p) = P_0/p,\ \ \sigma^*_{xz}(x,h_1,p) = \sigma^*_{xz}(x,-h_2,p) = 0 \qquad (x \geq 0) \tag{3}$$

$$D^*_z(x,h_1,p) = D^*_z(x,-h_2,p) = D_0/p$$

$$\sigma^*_{zz}(x,0^+,p) = \sigma^*_{zz}(x,0^-,p),\ \ \sigma^*_{xz}(x,0^+,p) = \sigma^*_{xz}(x,0^-,p) \qquad (x \geq 0) \tag{4}$$

$$D^*_z(x,0^+,p) = D^*_z(x,0^-,p)$$

$$\sigma^*_{zz}(x,0,p) = 0,\ \ \sigma^*_{xz}(x,0,p) = 0,\ \ D^*_z(x,0,p) = 0 \qquad (0 \leq x < c) \tag{5}$$

$$u^*_z(x,0^+,p) = u^*_z(x,0^-,p),\ \ u^*_x(x,0^+,p) = u^*_x(x,0^-,p) \qquad (x \geq c) \tag{6}$$

$$\phi^*(x,0^+,p) = \phi^*(x,0^-,p)$$

Fourier transform is applied to Eq. (2) to obtain the solutions as

$$u^{*(n)}_x(x,z,p) = -\sum_{j=1}^{3}\int_0^\infty a_j\gamma_j\left[A^{(n)}_j(\xi,p)\sinh(\gamma_j\xi z) + B^{(n)}_j(\xi,p)\cosh(\gamma_j\xi z)\right]\sin(\xi x)d\xi \tag{7}$$

$$u^{*(n)}_z(x,z,p) = \sum_{j=1}^{3}\int_0^\infty \left[A^{(n)}_j(\xi,p)\cosh(\gamma_j\xi z) + B^{(n)}_j(\xi,p)\sinh(\gamma_j\xi z)\right]\cos(\xi x)d\xi + T_1 z/p \tag{8}$$

$$\phi^{*(n)}(x,z,p) = -\sum_{j=1}^{3}\int_0^\infty b_j\left[A^{(n)}_j(\xi,p)\cosh(\gamma_j\xi z) + B^{(n)}_j(\xi,p)\sinh(\gamma_j\xi z)\right]\cos(\xi x)d\xi + T_2 z/p \tag{9}$$

where T_j $(j=1,2)$ are constants and a_j, b_j $(j=1,2,3)$ are known functions defined in Appendix A, the superscripts $(n)=(1),\ (2)$ denote the fields quantities in the upper ($0 \leq y \leq h_1$) and lower ($-h_2 \leq y \leq 0$) parts of the piezoelectric strip, respectively, and $A^{(n)}_j(\xi,p)$, $B^{(n)}_j(\xi,p)$, $(n=1,2;\ j=1,2,3)$ are unknowns to be determined; γ_j ($j=1-3$) are the roots of the following characteristic equation:

$$\begin{vmatrix} C_{11}+\rho p^2/\xi^2-C_{44}\gamma^2 & (C_{13}+C_{44})\gamma & (e_{31}+e_{15})\gamma \\ (C_{13}+C_{44})\gamma & C_{33}\gamma^2-\rho p^2/\xi^2-C_{44} & e_{33}\gamma^2-e_{15} \\ (e_{31}+e_{15})\gamma & e_{33}\gamma^2-e_{15} & \lambda_{11}-\lambda_{33}\gamma^2 \end{vmatrix}=0 \tag{10}$$

Note that the sixth-order characteristic equation (10) has six roots which occur in pairs with the same magnitude but opposite signs, and for complex roots, they always appear in conjugate pairs. In Eqs. (7-9), the roots γ_j ($j=1-3$) with $\mathrm{Re}(\gamma_j)>0$ are chosen by requiring a positive internal energy for the system to be in a steady state, as stated by Suo et al. [10].

The stress and electric displacement components can be expressed as follows

$$\sigma_{xz}^{*(n)}=-\sum_{j=1}^{3}\int_0^\infty \xi f_j\left[A_j^{(n)}(\xi,p)\cosh(\gamma_j\xi z)+B_j^{(n)}(\xi,p)\sinh(\gamma_j\xi z)\right]\sin(\xi x)d\xi \tag{11}$$

$$\sigma_{zz}^{*(n)}=P_0/p-\sum_{j=1}^{3}\int_0^\infty \xi g_j\left[A_j^{(n)}(\xi,p)\sinh(\gamma_j\xi z)+B_j^{(n)}(\xi,p)\cosh(\gamma_j\xi z)\right]\cos(\xi x)d\xi \tag{12}$$

$$\sigma_{xx}^{*(n)}=\sigma_0/p-\sum_{j=1}^{3}\int_0^\infty \xi q_j\left[A_j^{(n)}(\xi,p)\sinh(\gamma_j\xi z)+B_j^{(n)}(\xi,p)\cosh(\gamma_j\xi z)\right]\cos(\xi x)d\xi \tag{13}$$

$$D_z^{*(n)}=D_0/p-\sum_{j=1}^{3}\int_0^\infty \xi m_j\left[A_j^{(n)}(\xi,p)\sinh(\gamma_j\xi z)+B_j^{(n)}(\xi,p)\cosh(\gamma_j\xi z)\right]\cos(\xi x)d\xi \tag{14}$$

where $\sigma_0=C_{13}T_1+e_{31}T_2$ and the coefficients f_j, g_j, q_j, m_j are defined in Appendix A. By applying the boundary conditions (3) and (4), the unknown functions $B_j^{(1)}(\xi,p)$, $A_j^{(2)}(\xi,p)$, $B_j^{(2)}(\xi,p)$ ($j=1-3$) can be expressed by the independent unknowns $A_j^{(1)}(\xi,p)$ ($j=1-3$) as

$$\begin{aligned} &B_j^{(1)}(\xi,p)=\sum_{i=1}^{3}R_{ji}^{(1)}(\xi,h_1,p)A_i^{(1)}(\xi,p),\quad B_j^{(2)}(\xi,p)=\sum_{i=1}^{3}Q_{ji}(\xi,h_1,h_2,p)A_i^{(1)}(\xi,p) \\ &A_j^{(2)}(\xi,p)=\sum_{i=1}^{3}T_{ji}(\xi,h_1,h_2,p)A_i^{(1)}(\xi,p) \end{aligned} \tag{15}$$

where $R_{ji}^{(1)}(\xi,h_1,p)$, $T_{ji}(\xi,h_1,h_2,p)$ and $Q_{ji}(\xi,h_1,h_2,p)$ are known functions. Introduce the auxiliary functions $\Phi_i(x,p)$ ($i=1-3$) such that

$$\begin{Bmatrix}\Phi_1(x,p)\\ \Phi_2(x,p)\\ \Phi_3(x,p)\end{Bmatrix}=\frac{\partial}{\partial x}\begin{Bmatrix}u_x^{*(1)}(x,0^+,p)-u_x^{*(2)}(x,0^-,p)\\ u_z^{*(1)}(x,0^+,p)-u_z^{*(2)}(x,0^-,p)\\ \phi^{*(2)}(x,0^-,p)-\phi^{*(1)}(x,0^+,p)\end{Bmatrix} \tag{16}$$

By applying the solutions (7-9) and using the Fourier inverse transform, the independent unknowns can be obtained as

$$\begin{Bmatrix} A_1^{(1)}(\xi,p) \\ A_2^{(1)}(\xi,p) \\ A_3^{(1)}(\xi,p) \end{Bmatrix} = -\frac{2}{\pi\xi}\begin{bmatrix} Y_{11}(\xi,p) & Y_{12}(\xi,p) & Y_{13}(\xi,p) \\ Y_{21}(\xi,p) & Y_{22}(\xi,p) & Y_{23}(\xi,p) \\ Y_{31}(\xi,p) & Y_{32}(\xi,p) & Y_{33}(\xi,p) \end{bmatrix}\begin{Bmatrix} \int_0^c \Phi_1(s,p)\cos(s\xi)ds \\ \int_0^c \Phi_2(s,p)\sin(s\xi)ds \\ \int_0^c \Phi_3(s,p)\sin(s\xi)ds \end{Bmatrix} \tag{17}$$

where $Y_{ij}(\xi,p)$ $(i,j=1-3)$ are known functions. Satisfaction of the mixed boundary conditions (5) and (6) on the crack face plane leads to the simultaneous singular integral equations

$$\begin{aligned} &\int_{-1}^{1}\left\{\kappa_{m1}(s,x,p)\Psi_1(s,p)+\sum_{j=2}^{3}\left[\frac{U_{mj}^0}{s-x}+\kappa_{mj}(s,x,p)\right]\Psi_j(s,p)\right\}ds=\frac{-\pi T_m}{p} \\ &\int_{-1}^{1}\left\{\left[\frac{U_{31}^0}{x-s}+\kappa_{31}(s,x,p)\right]\Psi_1(s,p)+\sum_{j=2}^{3}\kappa_{3j}(s,x,p)\Psi_j(s,p)\right\}ds=0 \end{aligned} \qquad (m=1,2) \tag{18}$$

where $T_1=P_0$, $T_2=D_0$, $\Psi_i(s,p)=\Phi_i(cs,p)$, $\kappa_{ij}(s,x,p)$ $(i=1,2,3)$ are known kernel functions, the constants U_{ij}^0 are defined as $U_{ij}^0=\lim_{\xi\to\infty}U_{ij}(\xi,p)$ and $U_{ij}(\xi,p)$ are known functions. The functions $\Psi_i(s,p)$ $(i=1-3)$ satisfy the single-valuedness condition:

$$\int_{-1}^{1}\Psi_i(s,p)ds=0, \quad (i=1-3) \tag{19}$$

and $\Psi_i(s,p)$ may be expressed as

$$\Psi_i(s,p)=H_i(s,p)\big/\sqrt{1-s^2} \tag{20}$$

where $H_i(s,p)$ $(i=1-3)$ are unknowns to be solved.

Use the Lobatto-Chebyshev method [11], singular integral equations (18) can be reduced to the following algebraic equations:

$$\sum_{i=1}^{n}A_i\left\{[\kappa_{m1}(x_k,s_i,p)]H_1(s_i,p)+\sum_{j=2}^{3}\left[\frac{U_{mj}^0}{s_i-x_k}+\kappa_{mj}(x_k,s_i,p)\right]H_j(s_i,p)\right\}=\frac{-\pi T_m}{p} \quad (m=1,2) \tag{21}$$

$$\sum_{i=1}^{n}A_i\left\{\left[\frac{U_{31}^0}{x_k-s_i}+\kappa_{31}(x_k,s_i,p)\right]H_1(s_i,p)+\sum_{j=2}^{3}[\kappa_{3j}(x_k,s_i,p)]H_j(s_i,p)\right\}=0 \tag{22}$$

$$\sum_{i=1}^{n}A_iH_j(s_i,p)=0 \qquad (j=1,2,3) \tag{23}$$

where,

$$s_i = \cos\left[\frac{(i-1)\pi}{n-1}\right], \quad (i=1,2,...,n); \quad x_k = \cos\left[\frac{(2k-1)\pi}{2(n-1)}\right], \quad (k=1,2,...,n-1)$$
$$A_i = \frac{\pi}{2(n-1)}, \quad (i=1,n); \quad A_i = \frac{\pi}{(n-1)}, \quad (i=2,3,...,n-1) \tag{24}$$

3. Asymptotic fields near the crack tip

Once functions $H_j(s,p)$ ($j=1,2,3$) are obtained from solving the algebraic equations (21-23), following the procedure in Li and Lee [12], the asymptotic expressions of the electro-elastic fields near the crack tip can be determined by introducing a polar coordinate system (r,θ) with the origin at the right crack tip, as follows

$$r = \sqrt{(x-c)^2 + z^2}, \quad \theta = \tan^{-1}\left[z/(x-c)\right] \tag{25}$$

The hoop and shear stresses at an angle θ near the right tip of the crack are obtained from the following relations in terms of the polar coordinates (r,θ)

$$\sigma^*_{\theta\theta}(r,\theta,p) = \sigma^*_{zz}(r,\theta,p)\cos^2\theta + \sigma^*_{xx}(r,\theta,p)\sin^2\theta - \sigma^*_{xz}(r,\theta,p)\sin 2\theta$$
$$\sigma^*_{r\theta}(r,\theta,p) = \sin 2\theta\left[\sigma^*_{zz}(r,\theta,p) - \sigma^*_{xx}(r,\theta,p)\right]/2 + \sigma^*_{xz}(r,\theta,p)\cos 2\theta \tag{26}$$

Define the hoop stress intensity factor and shear stress intensity factor associated with the hoop and shear stresses at an arbitrary angle θ as [13]

$$K^*_{\theta\theta} = \lim_{r\to 0}\left(\sqrt{2r}\,\sigma^*_{\theta\theta}\right), \quad K^*_{r\theta} = \lim_{r\to 0}\left(\sqrt{2r}\,\sigma^*_{r\theta}\right) \tag{27}$$

Substituting Eqs. (26) into (27), the hoop and shear stress intensity factors in the Laplace domain can be obtained as:

$$K^*_{\theta\theta} = \sqrt{c}\sum_{j=1}^{3}\left\{\begin{array}{l}(g_j^0\cos^2\theta + q_j^0\sin^2\theta)\left[(-1)^n H_1(1,p)Y^0_{j1}\Lambda_{1j}(\theta) + \sum_{k=2}^{3} H_k(1,p)Y^0_{jk}\Lambda_{2j}(\theta)\right] \\ -f_j^0\sin 2\theta\left[H_1(1,p)Y^0_{j1}\Lambda_{2j}(\theta) - (-1)^n\sum_{k=2}^{3} H_k(1,p)Y^0_{jk}\Lambda_{1j}(\theta)\right]\end{array}\right\} \tag{28}$$

$$K^*_{r\theta} = \sqrt{c}\sum_{j=1}^{3}\left\{\begin{array}{l}\frac{(g_j^0 - q_j^0)\sin 2\theta}{2}\left[(-1)^n H_1(1,p)Y^0_{j1}\Lambda_{1j}(\theta) + \sum_{k=2}^{3} H_k(1,p)Y^0_{jk}\Lambda_{2j}(\theta)\right] \\ +f_j^0\cos 2\theta\left[H_1(1,p)Y^0_{j1}\Lambda_{2j}(\theta) - (-1)^n\sum_{k=2}^{3} H_k(1,p)Y^0_{jk}\Lambda_{1j}(\theta)\right]\end{array}\right\} \tag{29}$$

where $0 \le \theta \le \pi$ when $n=1$ for the upper part and $-\pi \le \theta \le 0$ when $n=2$ for the lower part of the cracked layer, respectively; the angular functions $\Lambda_{1j}(\theta)$ and $\Lambda_{2j}(\theta)$ ($j=1,2,3$) are given in the following form

$$\Lambda_{nj}(\theta) = \sqrt{\frac{\sqrt{\cos^2(\theta) + \left[\gamma_j^0\sin(\theta)\right]^2} + (-1)^n\cos(\theta)}{2\left[\cos^2(\theta) + \left[\gamma_j^0\sin(\theta)\right]^2\right]}} \qquad (k=1,2) \tag{30}$$

in which the constants $g_j^0, q_j^0, f_j^0, Y_{ij}^0, \gamma_j^0$ are defined in Appendix A.

Note that by setting the angle θ equal to zero and using the relations in Eqs. (30), the common expressions for the Mode-I and Mode-II stress intensity factors can be obtained. The dynamic hoop and shear stress intensity factors can be obtained by performing the Laplace inverse transform to Eqs. (28) and (29) as

$$K_{\theta\theta}(\theta,t)=\frac{1}{2\pi i}\int_{Br}K_{\theta\theta}^{*}(\theta,p)\exp(pt)dp,\quad K_{r\theta}(\theta,t)=\frac{1}{2\pi i}\int_{Br}K_{r\theta}^{*}(\theta,p)\exp(pt)dp \tag{31}$$

where "Br" stands for the Bromwich path of integration. Different criteria have been proposed to predict the direction of crack branching [14]. Here we use the maximum hoop stress intensity factor criterion to predict crack kinking.

4. Numerical results and discussions

To study the effect of electro-elastic interaction on the stress field near the crack tip, the electric loading parameter $L_D=e_{33}D_0/(\lambda_{33}P_0)$ is introduced. The material constants of PCM-80 [15] are used in the following numerical calculation:

$$\begin{aligned}
&C_{11}=17.0\times10^{10}(\mathrm{N/m^2}),\ C_{13}=11.5\times10^{10}(\mathrm{N/m^2}),\ C_{33}=16.5\times10^{10}(\mathrm{N/m^2})\\
&C_{44}=3.05\times10^{10}(\mathrm{N/m^2}),\ e_{15}=13.7\ (\mathrm{C/m^2}),\ e_{31}=-5.99\ (\mathrm{C/m^2}),\\
&e_{33}=15.6\ (\mathrm{C/m^2}),\ \lambda_{11}=95.2\times10^{-10}(\mathrm{C^2/Nm^2}),\ \lambda_{33}=68.4\times10^{-10}(\mathrm{C^2/Nm^2})\\
&\rho=5.5\times10^{3}(\mathrm{Kg/m^3})
\end{aligned} \tag{32}$$

The variation of the normalized dynamic hoop stress intensity factors (HSIFs) $\frac{K_{\theta\theta}(t)}{P_0\sqrt{c}}$ with normalized time tV_s/c at different angles θ are displayed in Fig. 2. The shear wave velocity is defined as $V_s=\sqrt{c_{44}+\frac{e_{15}^2}{\lambda_{11}}\Big/\rho}$. Without loss of generality, the geometric size of the strip is taken to be $h_1/c=1,\ h_2/c=5$, and the applied electric loading parameter $L_D=+0.5$. Fig. 2 shows that the HSIFs increase as time increases, and reach their peak values at about $tV_s/c=3.5$, and then decrease and oscillate about their static values, until when $tV_s/c\to\infty$, HSIFs reduce to the static values. The peak values of the HSIF at $\theta=20$ degrees are bigger than that of $\theta=0$ degrees, which means that the crack tends to deviate from the original crack plane, provided that the material has the same fracture toughness in every direction.

Fig. 3 shows the variation of peak values of the dynamic hoop stress intensity factors versus angles θ when $L_D=+0.5$. For the case $h_1\neq h_2$, the maximum value of the HSIFs appears at an angle different from the original crack plane, which implies that the crack may kink in this particular direction. When $h_1/c=1,\ h_2/c=5$, the crack kinks at about $\theta=+20$ degrees, and in another case $h_1/c=5,\ h_2/c=1$, the crack kinks at about $\theta=-20$ degrees. It is evident that the

possible crack kinking direction is oriented toward the thinner side of the strip. This is in agreement with [16] and [8] for the static mixed mode crack problem. It also agrees with the physical phenomenon that surface cracking is more likely to happen, due to the mechanism the crack kinks into the direction toward the surface of the body. The maximum value of the HSIFs appear at the angle $\theta = 0$ in the symmetric case when $h_1 = h_2$, which implies that the crack may propagate along the extension of original crack plane.

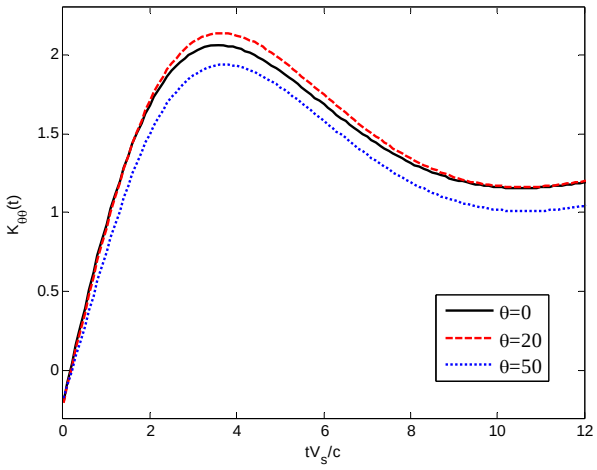

Figure 2. Dynamic hoop stress intensity factors for different angles

when $L_D = +0.5$, $h_1/c = 1$ and $h_2/c = 5$

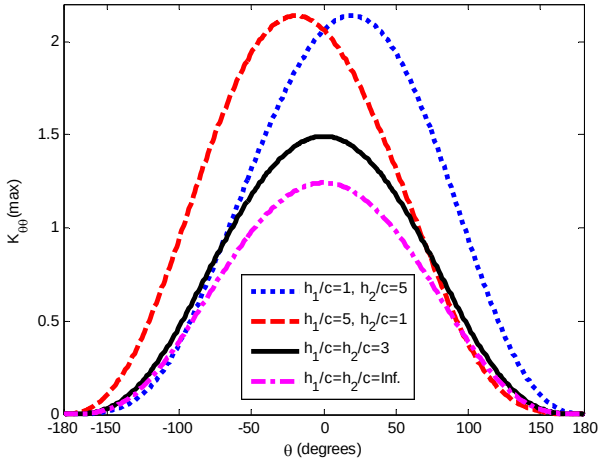

Figure 3. Maximum values of the normalized hoop stress intensity factors

versus angles when $L_D = +0.5$

Fig. 4 shows the effect of electric loading on the variation of normalized dynamic HSIFs at the angle $\theta = 20$ degrees. The electric loading parameter L_D affects the initial value and the peak value of the dynamic HSIFs. At the very beginning, a positive electric load leads to a lower initial value of the HSIF than negative electric load, whilst the peak value of the dynamic HSIFs induced by the positive electric load is higher than that for the negative electric load.

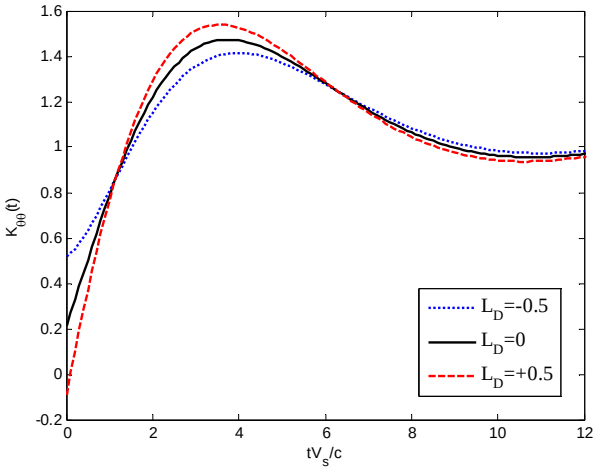

Figure 4. Dynamic hoop stress intensity factors for different electric loadings L_D

when $\theta = 20$ degrees and $h_2 = 2h_1 = 4c$

5. Concluding remarks

An impermeable crack in a piezoelectric strip under in-plane dynamic mechanical and electric loadings is studied. Fourier transforms are applied to reduce the mixed boundary value problem of the crack to dual integral equations, which are further expressed in terms of singular integral equations. Asymptotic fields near the crack tip are obtained in an explicit form and the corresponding field intensity factors are determined. The crack kinking phenomenon is investigated by applying the maximum hoop stress intensity factor criterion. Numerical results show that the geometry of the strip and the electric loading dominate the singular field distribution around the crack tip, and the hoop stress intensity factors are controlled by the material parameters, the electric loadings and the geometric size ratios.

Appendix A

The constants in Eqs. (14) and (15) are defined as

$$T_1 = (\lambda_{33}P_0 + e_{33}D_0)/(C_{33}\lambda_{33} + e_{33}^2), \quad T_2 = (e_{33}P_0 - C_{33}D_0)/(C_{33}\lambda_{33} + e_{33}^2) \tag{A.1}$$

$$\begin{Bmatrix} a_j \\ b_j \end{Bmatrix} = \begin{bmatrix} C_{11} + \rho p^2/\xi^2 - C_{44}\gamma_j^2 & e_{31} + e_{15} \\ (C_{13} + C_{44})\gamma_j^2 & e_{33}\gamma_j^2 - e_{15} \end{bmatrix}^{-1} \begin{Bmatrix} C_{13} + C_{44} \\ C_{33}\gamma_j^2 - C_{44} - \rho p^2/\xi^2 \end{Bmatrix} \tag{A.2}$$

$$f_j = C_{44}(a_j\gamma_j^2 + 1) - e_{15}b_j,\ \ g_j = (C_{13}a_j + e_{33}b_j - C_{33})\gamma_j$$
$$q_j = (C_{11}a_j + e_{31}b_j - C_{13})\gamma_j,\ \ m_j = (e_{31}a_j - \lambda_{33}b_j - e_{33})\gamma_j \tag{A.3}$$

$$g_j^0 = \lim_{\xi\to\infty} g_j,\ \ q_j^0 = \lim_{\xi\to\infty} q_j,\ \ f_j^0 = \lim_{\xi\to\infty} f_j,\ \ Y_{ij}^0 = \lim_{\xi\to\infty} Y_{ij}(\xi, p),\ \ \gamma_j^0 = \lim_{\xi\to\infty} \gamma_j(\xi, p) \tag{A.4}$$

Paper Template for Digital Speckle Interferometry Method for Research of Dynamic Processes

Michael N. Osipov[1], Anton N. Chekmenev[1], Yury D. Sheglov[1]

[1] Department of mathematic and mechanic, Samara State University, 443011, Ac. Pavlova str., 1, Russia
osipov@samsu.ru

Abstract The new digital speckle interferometry method for research of processes in mechanics of fracture, fatigue and strength of solid materials and structures in real time is considered. The new method is based on simultaneous registration of information by the standard digital speckle interferometry method and registration of distribution of intensity in the single speckle. Such decision allows to investigate fracture processes in real time; to increase sensitivity and accuracy of measurements; to expand a range of measured displacements. Besides, an offered method of the analysis of distribution of intensity in the single speckle allows will get rid of own noise inherent of interferometric methods of coherent optics.

In work theoretical and experimental results on realization of an offered method are presented. The optoelectronic scheme the digital speckle interferometer for registration at the same time speckle interferograms and intensity distribution in the single speckle is presented. The algorithm of processing of speckle interferograms on an offered method is presented.

It is shown that dynamic displacements can be measured with high resolution, in large range of measured value of displacements and in the large frequency range and in real time by this new method.

Keywords Experimental mechanics, Dynamic processes, Optical methods, Digital speckle interferometry, Processing and analysis of images and signals

1. Introduction

One of the main problems of solid mechanics, both fundamental, and the applied character, in many respects of a strength and durability of elements of designs, research of dynamic tasks is defining. Development of technique sets a task of increase of reliability of created and already working elements of designs subjecting to dynamic loadings. Existing mathematical models of the mechanics of fracture and settlement methods of forecasting don't allow to consider all real service conditions of designs fully. Experimental researches are necessary for confirmation of mathematical models of the mechanics of fracture and ensuring demanded parameters of designs at dynamic and static loadings. It demands development of the experimental measuring means, allowing to receive both qualitative, and quantitative data at dynamic and static loadings.

Optical contactless methods of researches gain now the increasing scientific and applied importance. Contactless methods have no impact on research elements of designs when carrying out experimental measurements that leads to increase of accuracy and reliability of received results. Considerable interest causes application of nondestructive interferometric methods for research of dynamic processes, both fundamental, and applied character. Optical, including laser interferometers, demand performance of a number of conditions which limit their practical application: the reflecting studied surface has to be optically smooth; the rigid mutual adjustment and fixing of elements of optical system is required. It should be noted also that interferometric methods, at practical application, demand use of lasers with a large spatial and time coherence that imposes additional restrictions when using data of systems in actual practice.

At the present stage it is necessary first of all to allocate from interferometric methods the digital holographic and speckle interferometry [1-4]. However, it is well known that at application of the

holographic and speckle interferometry there is a number of restrictions, which connected with existence of own noise (speckles), which lead to reduction of sensitivity and accuracy of measurements. Besides, speckle noise leads to restriction of measurement of displacements with great values of a gradient. Also we will note that existence of own noise (speckles) complicates processing of interferential pictures, both in the holographic, and the speckle interferometry and becomes impossible at research of high-frequency vibrations, because the contrast of interference fringes is falls. A problem of processing of the holographic and speckle interferograms the huge attention is paid [5-7]. Standard methods of the digital holographic and speckle interferometry, as a rule, don't allow to observe dynamic processes of solid mechanics in real time as at researches are generally used: averaging method in time; method of two expositions or pulse method.
In this work the new method of registration dynamic displacements of a research surface of object in large range of measured value of displacements and in the large frequency range on the basis of the analysis of distribution of intensity in the single speckle is considered. Such decision allows to overcome restrictions which are connected with existence of own noise (speckles) in the holographic and speckle interferometry and to register dynamic displacements in real time.

2. Speckle and practical application

2.1. Speckle pattern

When lighting by coherent radiation a rough surface because of scattering of a coherent radiation in space the complicated interference pattern, which is called speckle pattern, is formed. The characteristic kind of speckle pattern is presented in Fig. 1.

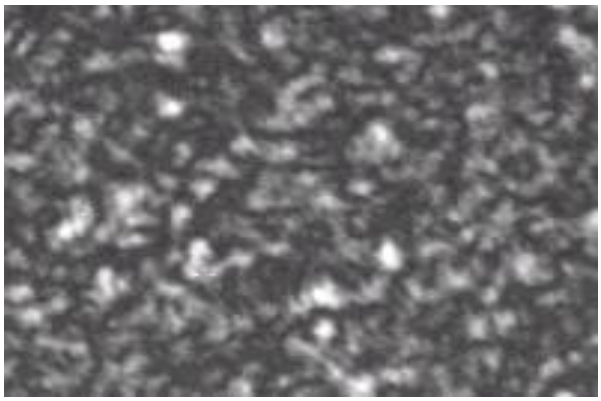

Figure 1. Photography of speckle patterns

Distinguish two kind of speckle patterns: a) the objective - formed in space at the expense of an interference of a large set of the reflected beams from a rough surface, and which can be registered directly without optical system on a photographic material; b) the subjective - formed and recorded on a photographic material by means of optical system in the plane of the image of a researched rough surface.
The sizes, longitudinal — L and transversal – H, of a speckle in objective and subjective speckle patterns are estimated on known formulas [1]:

$$L = \frac{4\lambda}{\alpha^2}, \tag{1}$$

$$H = 1{,}22\frac{\lambda}{\alpha}, \tag{2}$$

where λ is the wavelength of a laser, α – the relation of diameter of the lighted area of a research surface to distance from a research surface to a point of registration of the speckle for objective speckle pattern; α – the relation of diameter of an entrance aperture to focal length of optical system for subjective speckle pattern.
The dynamic processes arising on a surface of research object, lead to change of parameters speckle pattern (size and intensity) in space and in time that is connected with change of a phase of the reflected secondary spherical waves. Therefore, according to the analysis of existential behavior of the speckle pattern it is possible to investigate the dynamic and static processes of a research surface.

2.1. Proposed solution

As it was noted, parameters of the speckle pattern, changing in space and in time, are: longitudinal and transversal sizes; distribution of the intensity.
Let's estimate possibility of research of dynamic processes at the expense of measurement of parameters of the speckle pattern.
From Eq. (1) and (2) follows that the sizes of the subjective speckle pattern don't depend on dynamics of a research surface as α is a constant, and are therefore connected only with characteristics of optical system. Thus, the subjective speckle pattern doesn't allow to register displacements of a research surface, at the expense of measurement of the sizes speckle. On the other hand, registration subjective speckle pattern allows to tie rigidly its spatial arrangement in the image plane to a concrete point of a research surface. For registration of displacements in it cases are used methods of two expositions or averaging in time with the subsequent processing of interferograms.
Let's carry out a similar assessment for the objective speckle pattern. At dynamic displacements of a research surface of change of the sizes of a speckle for objective speckle pattern according to Eq. (1) and (2) will be defined by the following ratios:

$$L = \frac{4\lambda(r \pm \Delta r)^2}{D^2}, \tag{3}$$

$$H = 1{,}22\frac{\lambda(r \pm \Delta r)}{D}, \tag{4}$$

where r – distance from a research surface to a point of registration of the speckle; $\pm\Delta r$ – the value of displacement of a research surface; D – diameter of the lighted area of a research surface.
From the analysis of Eq. (1) and (2) follows that the transversal and longitudinal sizes of a speckle will change at very small value, as under real conditions of measurements $\Delta r/r \approx 0$. Therefore, as well as in a case with the subjective speckle pattern to define dynamics of a research surface at the expense of measurement of the sizes objective speckle pattern also it is almost impossible.
Let's consider possibility of definition of dynamics of a research surface, at the expense of registration of change of intensity of the speckle.
Change of intensity of a speckle occurs at the expense of change of its phase which depends on change of an optical way at displacement of a research surface. Change of value of a phase of the speckle on $\pm\pi$ $(2n+1)$, (where n=0,1,2. …) leads to change of intensity of the speckle from the minimum value to maximum or on a turn.
For registration of change of a phase of the speckle is necessary to use the reference beam of a laser radiation which is imposed on the speckle pattern, and therefore the secondary interference pattern in the form of fringe pattern is formed. Width of secondary interference fringes d is defined by well-known equation [8]:

$$d = \frac{\lambda}{2\sin(\frac{\Theta}{2})}, \tag{5}$$

where Θ – angle between the reference beam of a laser radiation and the focused scattered laser radiation from a research surface which forming image of this surface with speckle pattern in the plane of the photodetector.
The kind of speckle pattern with the secondary interference pattern is presented in Fig. 2.

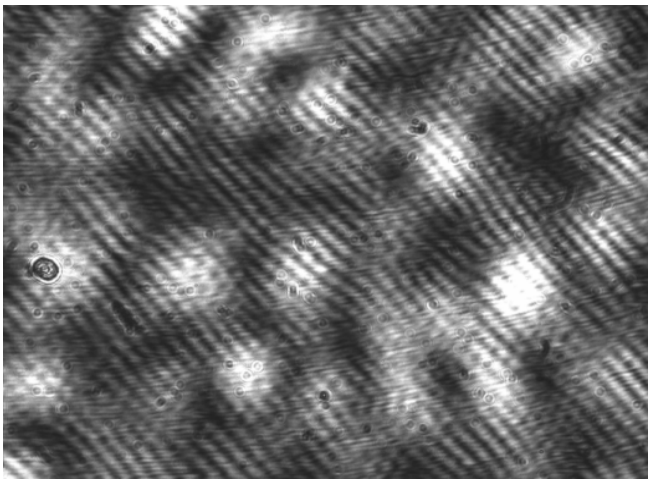

Figure 2. Photography of the speckle pattern with the secondary interference pattern

It is offered for effective registration of change of intensity of the single speckle to satisfy the following conditions: width of secondary interference fringes has to be agreed with the transversal size of the single speckle, and also with size of a sensitive cell of the photodetector.
For agreement of the transversal size of the single speckle with size of a sensitive cell of the photodetector it is necessary that the following ratio was carried out:

$$H \geq h, \tag{6}$$

where h – size of a sensitive cell of the photodetector.
Performance of this condition is achieved by sampling of the parameter α of a optical system, as appears from of Eq. (2).
In order that the sensitive cell of the photodetector could measure change of a phase of the single speckle it is necessary that width of secondary interference fringes d was more or equally of the size of a sensitive cell of the photodetector that is the following ratio was carried out:

$$d \geq h, \tag{7}$$

Performance of this condition is achieved by sampling of a angle of a convergence Θ between the reference beam and the focused scattered laser radiation from a research surface which forming image of this surface with speckle pattern in the plane of the photodetector, as appears from Eq. (5).
Performance of conditions – Eq. (6) and (7) – leads to that intensity of the single speckle, as whole, will change from minimum to the maximum value (or on the contrary) depending on displacements of a research surface.
Thus, measurement of intensity of the single speckle allows to investigate dynamic processes in a solid mechanics. Application in the offered method of high-speed photodiodes expands the frequency range of measured dynamic displacements.

2. 2 Measurement system

Realization of this method, based on the analysis of change of intensity of the single speckle, for measurement of dynamic processes in solid mechanics it is offered to carry out according to the optical scheme presented in Fig. 3.
By means of optical system L2 the rough surface of a research object O is lighted with laser radiation and is focused on the CCD TV. Let's emphasize, that as it was noted above, in the plane of a CCD matrix the image of object covered speckles is fixed. That allows to record on CCD TV a image of the research object with binding speckles to concrete points of this object.
If to direct the reference beam (in Fig. 3 it isn't shown) on a CCD matrix, as a result, we will receive standard the digital speckle interferometer which allows to make measurements of displacements with restrictions indicated in Introduction.

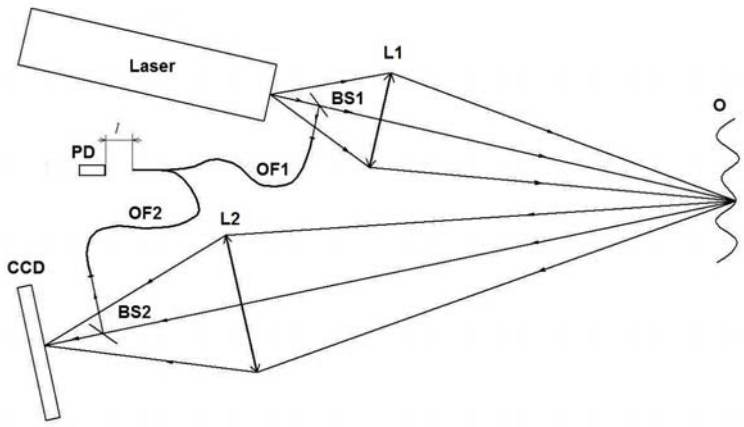

Figure 3. Optical scheme for dynamic measurement

Measurement of dynamic processes in solid mechanics is offered to be carried out according to the analysis of change of intensity of the single speckle. Standard CCD matrixes, as a rule, aren't the high-speed photodetector. Therefore they aren't capable to register of change of intensity of the single speckle in the wide frequency range. For overcoming of this restriction in the optical scheme it is offered to use in addition the high-speed photodetector PD, allowing to analyze of intensity of the single speckle in the wide frequency range.
For allocation single speckle, by means of the beam splitter BS2 the image of the single speckle goes on an entrance end face of an optical fiber OF2 which output end face is agreed with the high-speed photodetector PD. Diameter of a core of an optical fiber of OF2 has to be agreed with the transversal size of a speckle, that is the ratio (Eq. 6) has to be carried out.
For creation of a reference beam by means of the beam splitter BS1 the part of radiation of the laser L goes on an entrance end face of an optical fiber OF1 which output end face is also agreed with the high-speed photodetector FD. The output ends of optical fibers OF1 and OF1 are combined so that conditions (Eq. 6 and Eq. 7) were satisfied. The change of intensity of the single speckle is registered by the photodetector PD and is recorded in the PC for processing and visualization.

3. Theory

Let's consider for the offered optical scheme formation of distribution of intensity in the single speckle when performing conditions (Eq. 6 and Eq. 7). Let's write down values of vectors of electric intensity on the photodetector PD for waves passed through both optical fibers in the following kind:

$$\vec{E}_1 = \vec{E}_0 e^{i(kx_1 - \omega t + \varphi)}, \tag{8}$$

$$\vec{E}_2 = \vec{E}_0 e^{i(kx_2 - \omega t + \varphi)}, \tag{9}$$

where – E_0 amplitude of electric intensity of an electromagnetic field (we assume for simplification of calculations that it is identical in both optical fibers); $k=2\pi/\lambda$ – wave number; ω– circular frequency of laser radiation; φ– an initial phase which also is considered identical to both optical fibers; x_1 – distance from beam splitter BS1 to the photodetector PD on optical fiber OF1; x_2 – distance from beam splitter BS1 to the photodetector on optical fiber OF2.
Distance from beam splitter BS1 to the photodetector on an optical fiber OF2 recorded in the following kind:

$$x_2 = r_0 + r \pm 2\Delta r, \tag{9}$$

where r_0 – distance from beam splitter BS1 to a research object O; r – distance from a research object O to the photodetector PD on optical fiber OF2; $\pm\Delta r$ – the value of displacement of a research surface.
As the photodetector registers intensity, than the distribution of the intensity in an interference pattern of the single speckle will record in the following kind:

$$I(x,t) = \left|\left(\vec{E}_1 + \vec{E}_2\right)^{+}(\vec{E}_1 + \vec{E}_2)\right|^2 \approx 2E_0^2\left\{1 + \cos\left[k\left(x_1 - r_0 - r \mp 2\Delta r\right)\right]\right\}, \tag{10}$$

where the top index (+) means that vector value of electric intensity of an electromagnetic field is transposed and in a complex interfaced.
As appears from Eq. (10), and as it was noted above, intensity of a speckle changes from minimum to maximum values (or on the contrary) at change of value of a phase baked on $\pm\pi$ $(2n+1)$, (where n=0,1,2…) which is connected by dynamics of a research surface, that is with change Δr in time.
Change of intensity of the single speckle on an entrance of the photodetector it will be transformed to change of output signal of the photodetector which (see Eq. 10) can be expressed as follows:

$$u(t) = A + B\cos[\varphi(0) - \varphi(t)], \tag{11}$$

where $u(t)$ – the output voltage of the electrical scheme of the photodetector; A – the output bias voltage which is related to the average intensity of the single speckle; B – amplitude of useful output voltage which is defined by parameters of the optoelectronic scheme which related to a displacement of a research surface and kind of the optical scheme; $\varphi(0) = k(x_1 - r_0 - r)$ – initial value of a phase difference between the reference beam and the object beam forming speckle pattern in plane of a optical image. This phase difference can change but remains to constants in the time of measurements; $\varphi(t) = \pm 2k\Delta r$ is the change of a phase in single speckle related with change of the optical path in the object arm of a optical scheme at dynamic displacements of a research surface.
From the analysis of a Eq. (10) and (11) follows that change of output voltage of the photodetector depends on phase change $\varphi(t)$ characterizing dynamics single speckle related with movement of a research surface. As intensity single speckle changes from minimum to maximum or on the contrary, respectively and output voltage from the photodetector changes from the minimum value – $u(t)_{min}$ to the maximum value – $u(t)_{max}$ or on the contrary.
The theoretical results of behavior of the output voltage $u(t)$ in respect of vibrating displacements of the investigation surface are demonstrates in Fig. 4. The dashed curve represents the vibrations of

the investigation surface with amplitude increasing in time. The solid curve represents the theoretically calculated output voltage signal.

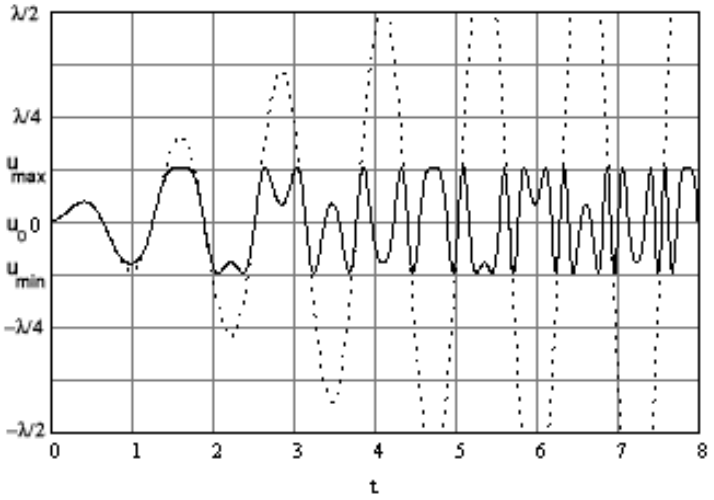

Figure 4. Theoretical curves of behavior output signal *u(t)* at the increasing amplitude of the investigation surface

3.1. Assessment of range of measurements

From the analysis of Eq. (10) and (11) follows that change of output voltage from minimum to the maximum corresponds to displacements of the investigation surface at a value equal $\lambda/4$.
Then, when demonstrate the constant direction - not sign-variable - for determination of value of full movement it is enough to define number of changes of the output single from maximum to the minimum. At sign-variable movements that corresponds to vibration loadings, character of an output signal of the photodetector has features.
The analysis of Eq. (10) and (11) shows that at vibrations of the investigation surface with amplitudes it is less or equally $\lambda/8$ the output voltage of the photodetector corresponds to a form of vibrations of this surface. With amplitudes of vibrations of the investigation surface more $\lambda/8$ the output voltage of the photodetector won't correspond to a form of vibrations of this surface that as it is visible in Fig. 4. In this case development of additional algorithm of interpretation of an output signal of the photodetector is required.
For registration of vibrations without additional processing of an output signal, as appears from Eq. (10) and (11), it is necessary to choose $\varphi(0)$ equal $\frac{\pi}{2}(2n+1)$ (where n=0,1,2…). This condition means that at the initial moment of measurements output voltage from the photodetector has to be established so that its value corresponded to value equal:

$$u(0) = \frac{u_{\max} + u_{\min}}{2} = A \tag{12}$$

It is reached by corresponding change of a phase of the reference beam. Under these conditions amplitude B of measured vibrations of the investigation surface will correspond to value equal $\lambda/8$.

4. Results and conclusion

Realization of this method, based on the analysis of change of intensity of the single speckle, was used for the investigation of wave processes in a plate subjected shock loading. Fig. 4 shows the

experimental behavior of the output voltage *u(t)* of the photodiode, which is obtained on high-speed storing oscillograph at the investigation of wave processes in a plate subjected shock loading. The comparison of the theoretical and experimental results allows us to make a conclusion that the represented above assumptions are valid.

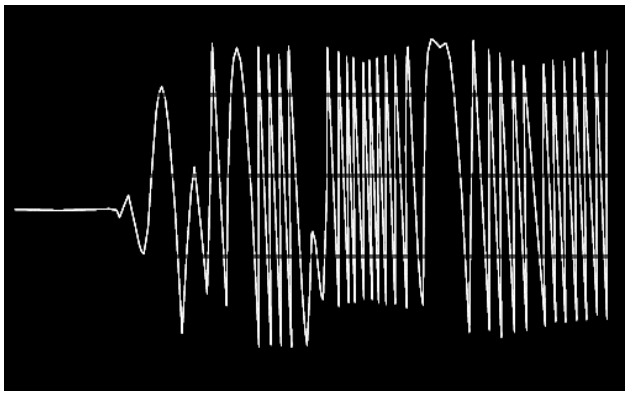

Figure 5. Experimental oscillogram of the output signal from the photodetector

In the experimental arrangement laser LCM-S-111-50-NP25 with wavelength λ = 532 nm and coherence length more 50 m is used. For the measurement of the dynamic displacements with very high frequency p-i-n photodiode with frequency range 20 MHz.

Thus, the new method of registration dynamic displacements of the investigation surface of object in large range of measured value of displacements and in the large frequency range on the basis of the analysis of distribution of intensity in the single speckle is considered.

Advantage of the offered method is that its use doesn't demand a careful adjustment of elements of optical system and allows to overcome restrictions which are connected with existence of own noise (speckles) in the holographic and speckle interferometry and to register dynamic displacements in real time.

Crack Propagation in PMMA Plates under Various Loading Conditions

Ivan Smirnov*, Yuri Sudenkov

St. Petersburg State University, 198504, Russia
* Corresponding author: ivansmirnov@math.spbu.ru

Abstract The experimental results of the dynamics of crack propagation in polymethylmethacrylate plates under quasi-static and dynamic loading are presented. Registration of the cracks was made by the method of slit-scanning of an image using a streak camera. Either a crack trajectory or caustic at the crack front was recorded in the experiments. It is shown that crack front extension has a stepwise character for any type of loading. However the average speed at the quasi-static loading increases smoothly up to the maximum value, and the average speed at pulsed loading takes the maximum value rather instantly. The value of the stress intensity factor at the moment of crack start under dynamic loading essentially exceeds the corresponding value for quasi-static loading. Furthermore, under dynamic loading, the crack speed depends on the thickness of the sample.

Keywords Crack propagation, Dynamic loading, Quasi-static loading

1. Introduction

Despite the fact that our knowledge constantly updates with experimental data about the process of fracture, questions about the conditions of initiation, propagation and stop of fracture remain actual. The problem is compounded by the fact that the data, which are used to develop the theoretical approaches, have been obtained at different scales, with different spatial and temporal resolution of recording equipment, under various load conditions and energy exchange of a sample and external environment.

Crack propagation in quasi-brittle and brittle materials has been studied for many decades. However, there is no complete understanding of the crack development process. Experimental results on quasi-static tensile of plates with a notch [see e.g. 1] lead to the conclusion that the speed of a crack is a monotonic function of time, and the relationship between the speed of a crack and the stress intensity factor can be described by an L-shaped curve. Studies of cracks in plates under dynamic load [2] showed that the speed of a crack is constant, but the corresponding stress intensity factor can change. In papers [3, 4] showed that the speed of a crack is unstable and stepwise. Such divergence of results suggests an idea about need of carrying out "systematizing" experiments which will allow to look at the behavior of strength characteristics of a material in terms of the scale factors, structural features and characteristics of energy input into the material.

In this work we have made an attempt to conduct the generalizing study of crack propagation process in brittle and quasi-brittle materials under quasi-static and dynamic loads. The loading schemes have been applied by analogy to the schemes in [1-4]. The quasi-static loading was carried out by slow uniaxial tension of plane samples with a starter notch. The dynamic load was carried out by means of electrical explosion of a wire between edges of a notch in a plane sample. Polymethyl methacrylate was chosen as the model material. PMMA shows quasi-brittle fracture and

its transparency gives the chance to see a crack extension and to control it by photo recording methods. Crack propagation was registered by a streak camera which allowed to receive the time sweep of crack trajectory with the resolution 40-400 ns.

2. Experimental Technique

Our experiments were performed on the samples of injection molding PMMA with the parameters: density ρ = 1180 kg/m^3, longitudinal sound velocity C_L = 2750±25 m/s, transverse sound velocity C_{TR} = 1400±25 m/s, modulus of elasticity E = 5.9 GPa.

The quasi-static loading was carried out on a tensile testing machine. The dumbbell-like plane samples with the dimensions of the working part of 93×35×5 mm were used. To initiate the crack, a notch was made by a razor blade in the middle of the working area. The notch depth was 0.4 - 1.3 mm.

The dynamic loading was realized by means of the setup for electrical explosion of conductors. The capacitor capacity was C = 1.0 μF; the charge voltage, $U \leq 25$ kV; the stored energy, $E \leq 312$ J. The samples were in the form of square plates (200×200 and 98×128 mm) with a side notch. The sample thickness was 5, 8 and 10 mm. The notch was 50 mm in length and 0.5 mm in width. The size of the greater samples was selected so that to remove the influence of reflected waves on the process of crack propagation during the registration time. The localized pressure pulse was generated by electrical explosion of a wire. The exploding wire (∅ 0.2 mm) was placed between the edges of the notch perpendicular to the plane of the plate at the distance of 24-31 mm from the notch base. A lavsan film was used to create the acoustic contact between the wire and notch edges. The same sample was used several times.

The registration of crack front extension was carried out by means of a streak camera (K008) using the method of slit-type scanning of an image. For this purpose, a beam of light was directed at the expected place of crack propagation at an angle to the plane of the sample. The camera recorded the space-time scan of the beam of light reflected from the surface of the growing crack. In the quasi-static tests, the synchronization of the camera was made on the change of intensity of a laser beam passing through the notch base. In the case of dynamic loading, the synchronization was carried out on the signal from a current sensor. The detailed diagrams of the experiments are presented in [5].

The registration of caustic near with a crack tip was carried out on the basis of schemes of receiving shadow optical images described in [6]. The change of caustic was registered by scanning the real image with help the streak camera. However, the diameter of caustic was registered along crack extension rather than across (as generally accepted). Note that it may affect quantitative estimates because of the large singularity at the back of caustic.

The calculation of the stress intensity factor was made according to the following formula [6]

$$KI(t) = \frac{2\sqrt{2\pi}F(v)}{3(3.17)^{5/2} z_0 cd} D(t)^{5/2},$$
$$F(v) = \frac{[4\alpha_1\alpha_2 - (1+\alpha_2^2)^2]}{[(\alpha_1^2 - \alpha_2^2)(1+\alpha_2^2)]},\ \alpha_j = (1 - \frac{v(t)^2}{c_j^2})^{1/2} \quad (j = 1,2) \tag{1},$$

where *KI* is the stress intensity factor of a crack in tension; $D(t)$ is the change in the diameter of the caustic; z_0 is the distance from the object to the image; c is the shadow optical constant; d is the thickness of the sample; c_1 and c_2 are the speeds of longitudinal and transverse waves respectively; $v(t)$ is the speed of the crack.

3. Results and Discussion

3.1. Quasi-static Tests

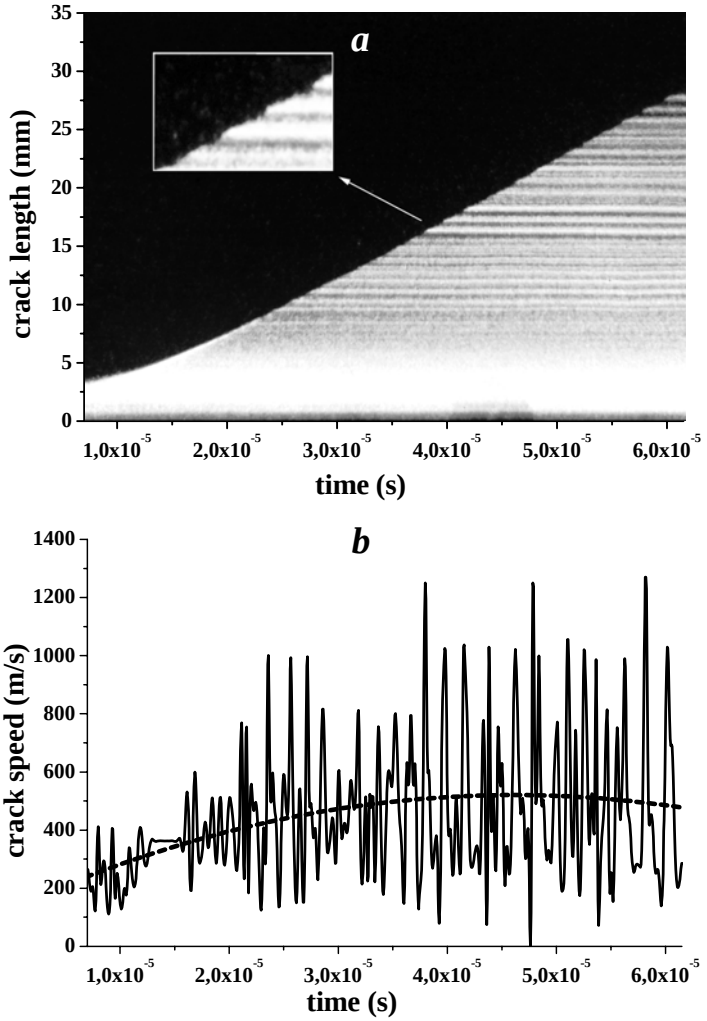

Figure 1. Crack propagation under quasi-static tension of plane samples of PMMA: a) slit scan of the crack tip trajectory; b) fluctuation of the crack front speed; dashed line is the mean speed (polynomial fitting).

Fig. 1a shows the typical trajectory of the crack front under quasi-static tensile of PMMA plates

with a notch. The speed of the crack front is shown in Fig. 1b. The speed was obtained by differentiating of the crack trajectory according to the formula of the central difference derivative. Note that the applied scheme synchronization does not allow you to capture the initial part of the crack trajectory.

Comparison of the crack trajectory and the fracture surface shows that the beginning of an unstable behavior of the crack corresponds to the beginning of the "ribbed" surface structure [3,7] with the distance between the ribs about 1 mm. The most pronounced oscillation frequency of the crack front speed is in range of 400-700 kHz. The similar dependence of crack propagation speed was also obtained in [3]. In this work, the speed of a crack was determined by change in electrical resistance of an aluminum layer deposited on the sample surface. It was shown that the crack front oscillations correlated with the profile of the fracture surface, and the critical speed of the transition to the unstable regime $V_c = 0.34C_R$ (C_R is the Rayleigh wave speed) does not depend on the geometry and thickness of a sample and the tensile rate.

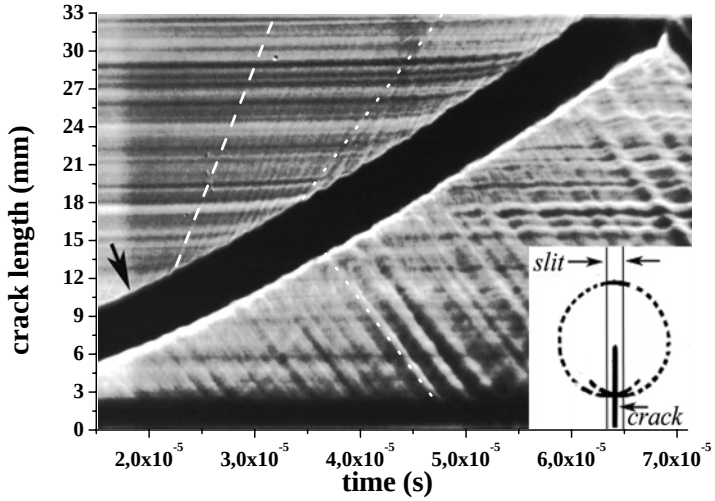

Figure 2. Slit scan of the stress-wave pattern at a crack tip under quasi-static tension of plane samples of PMMA.

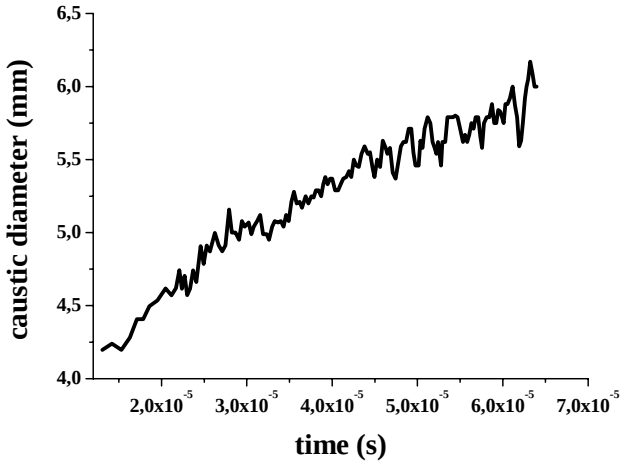

Figure 3. The caustic diameter at crack propagation in quasi-static tests.

The temporary scan of the caustic image was made to track change of stress fields in the process of crack propagation, Fig. 2. There is a clear qualitative picture, namely that elastic waves travel from the crack tip with a certain frequency. This frequency falls into the frequency range obtained during the registration of the crack trajectory (Fig. 1). The black arrow indicates the beginning of a distinct emission of elastic waves from the crack tip. There are two sets of lines that correspond to the longitudinal (dash line) and transverse speeds (dotted line). Fig. 3 shows the change of the caustic diameter at the crack propagation.

3.2. Dynamic Tests

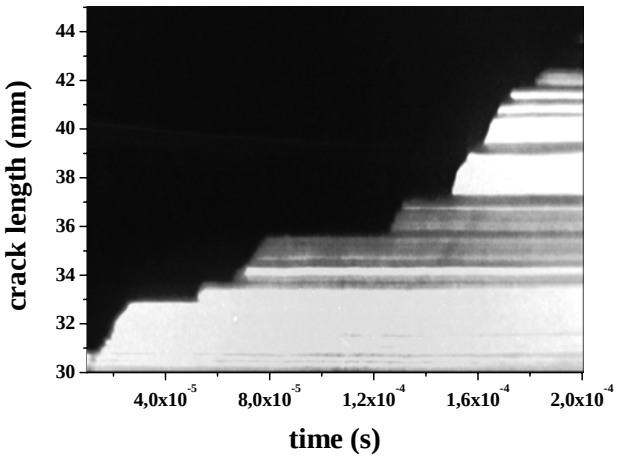

Figure 4. Crack propagation in case of dynamic loading of plates with a notch.

Fig. 4 shows the typical trajectory of crack extension obtained under pulsed pressure on the edges of the notch in the plates of PMMA. The stepped form of crack trajectory is associated with an arrival of elastic waves reflected from lateral faces of a sample. Therefore, the greatest interest is the first step of crack development without influence of reflected elastic waves. For this purpose the samples were made with such sizes that energy of reflected waves was not enough to re-start the crack. The typical trajectory of cracks obtained in these samples is shown in Fig. 5a; and the corresponding crack speed is shown in Fig. 5b.

The maximum fluctuations of the crack speed, as well as in the quasi-static tests, fall on the rougher area of the fracture surface. Unlike the quasi-static [3, 8] or the dynamic [9, 10] tests, here the return order of formation of characteristic zones of fracture surface is observed: fragmentary (large pieces), scaly, parabolic and mirror.

The scan of caustic in the dynamic tests is complicated by presence of elastic waves emanating from the point of application of pressure to the crack edges, and presence of "residual" caustic before and after crack propagation, Fig. 6. In Fig. 7 shows the characteristic change of the stress intensity factor at the crack tip and the corresponding change of the crack speed. It can be seen that the stress intensity factor, at which began the crack extension, substantially exceeds the static value K_{Ic} for a crack start.

The caustic at the crack tip begins to increase after the arrival of the Rayleigh wave; and the crack starts only through some microseconds. In general, the stress intensity factor decreases after the crack start together with the average speed of the crack.

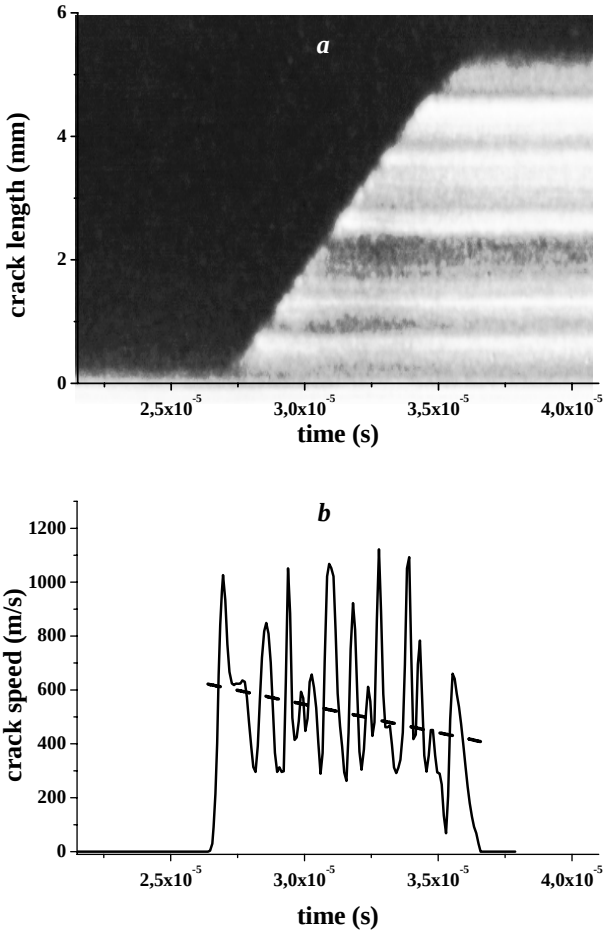

Fig. 5. Crack propagation under a localized pulse load on notch edges: a) slit scan of the crack tip trajectory; b) fluctuation of the crack front speed (dashed line - the mean speed).

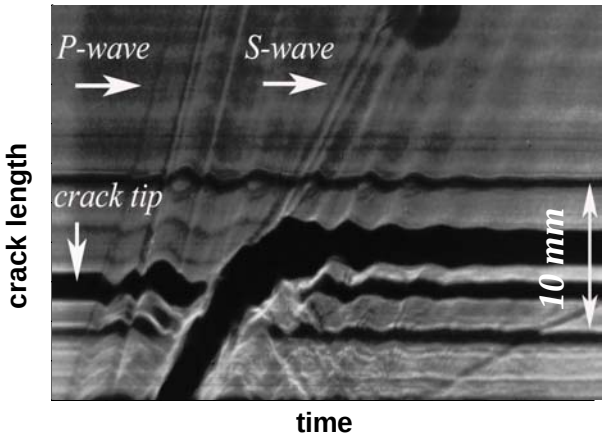

Figure 6. Stress waves in dynamic tests.

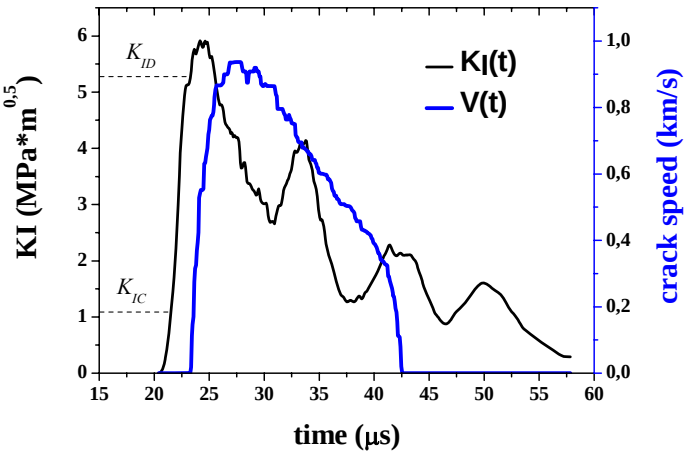

Figure 7. The dynamic stress intensity factor and the corresponding crack speed in dynamics tests.

3.3. Discussion

The results obtained by a single method for recording of dynamics of a crack in plates of PMMA allow to mark out similarities and differences in stages of a fracture process in fragile and quasi-fragile materials under quasi-static and dynamic loads. The slit scan of the development process of a crack front allows to estimate the crack speed on different time intervals, and thus the spatial scale (either the section of a crack front or the all front).

The experiments demonstrate the general property of spasmodic development of a crack front and qualitative agreement with the results obtained by other authors [3, 4]. The average speed of crack propagation in our experiments, both in the quasi-static and dynamic tests, did not exceed $0.5C_R$, but the instantaneous crack speed could approach the Rayleigh wave speed C_R on the "jumps".

The oscillations of the crack front speed correlate with changes of a profile of fracture surface. The observed dynamics of cracks may be related to a pre-fracture zone before the tip of a main crack [9-12], i.e. development of micro damages ensemble in the area of high stresses. The characteristic view of such pre-fracture zone, registered in the dynamic tests after stopping a crack, is shown in Fig. 8.

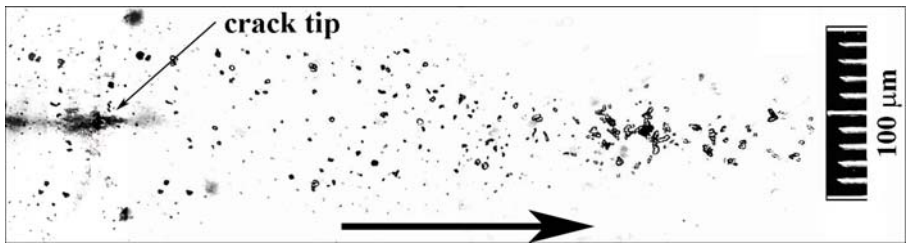

Figure 8. Magnified view of the pre-fracture zone before a crack tip. The photo was made after stopping the crack in dynamic tests. The arrow indicates the direction of crack propagation.

The principal difference between the two ways of loading is the behavior of the average speed of

cracks. Under quasi-static uniform extension of the plates, the average speed over smoothly reaches a maximum value. This fact is consistent with the results of [1]. In the case of pulse pressure on the notch edges, the average speed takes a maximum value almost instantly and then can be considered by a constant. That was observed in [4].

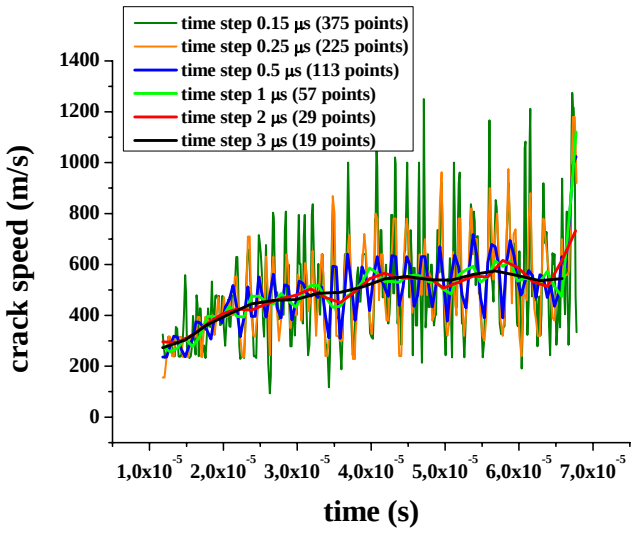

Figure 9. Speed of crack front extension depending on a time interval of registration of the crack front position.

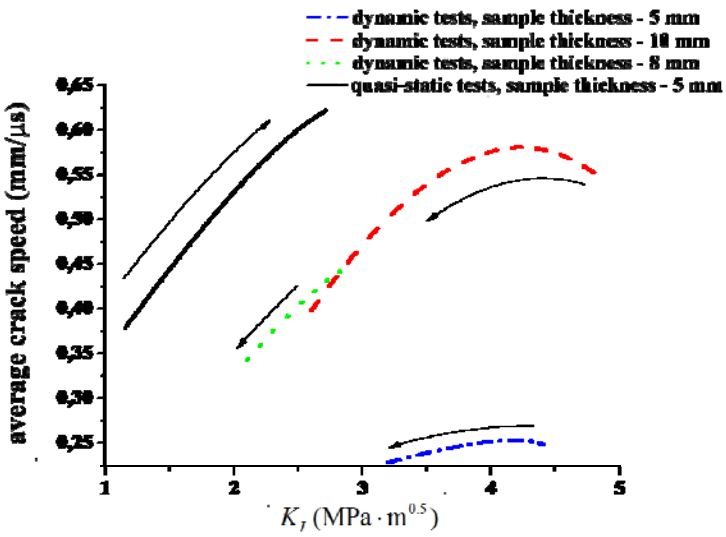

Figure 10. Average crack speed versus instantaneous stress intensity factor in plates of PMMA under different loading conditions.

The difference of experimental results for the same character of loading (see e.g. 1 and 2, 3 and 4) can be explained by resolution of recording equipment. Fig. 9 shows the crack speed in the quasi-static tests at different time intervals of the "fixing" moments of the crack locations. In [2, 4] "continuous" registration of a crack front position was applied (the electric signal from a resistive bridge or the slit scan of an image), while in [1, 3] single shooting with a given frame rate was used. Moreover, in [2, 4] the position of the crack front was registered, while in [1, 3] caustics or

isochromatics, which are integral characteristics of stress fields at the crack tip, were captured.

Another one important difference between the results at the different loading conditions is the values of the fracture characteristics. The stress intensity factor at the moment of the crack start in the dynamic tests significantly exceeds its analog in the quasi-static tests. Figure 10 shows dependence of the average speed of the crack on the dynamic stress intensity factor. It is clear that the shape of the curve depends on the method of obtaining mean values of the crack speed and the SIF. In this case, the average was obtained by means of polynomial approximation.

The dash curves were received in the dynamic tests at the same charge of the condenser, but at different thickness of the samples. It can be seen that the crack speed depends on the state of stress at the crack tip. Reduction of the thickness of the sample leads to reduction of the crack speed.

In contrast to the quasi-static tests, the stress intensity factor and the average crack speed in the dynamic tests decrease with crack growth that well correlates with change of a roughness of the fracture surface. This fact can be explained by the quantity of input elastic energy in the crack tip. In case of the quasi-static tests there is a constant supply of mechanical energy in the system "grips-sample". However, in the case of a dynamic load on the crack (such source of loading as a pulse laser, an explosion of explosives or a conductor, etc.), only the final quantity of energy injects in a sample; and the fracture characteristics are defined by the pulse energy and the possible rate of absorption of this energy in the area of the crack tip.

4. Summary

The study of the dynamics of crack propagation in plates of PMMA under quasi-static and dynamic loading was carried out.

It is shown that under both the quasi-static and dynamic testing conditions the change in the instantaneous crack front speed has a stepwise character. However the behavior of the mean speed depends on the type of loading. In the case of quasi-static loading, the crack accelerates to its maximum value smoothly. In the case of pulse loading, the crack accelerates to its maximum value almost immediately. At the same time the limiting value of the stress intensity factor under impact loading of a crack significantly exceeds its limit value for quasi-static loading.

The analysis shows that the differences observed in experimental results on study of crack propagation can be explained by the different time resolution of recording equipment. Moreover, results significantly depend on duration and intensity of loading, as well as on the stress state in the area of fracture.

Abstract Grid cylindrical structure with infinite variety of cell shape and arrangement receives much concern, which results in many applications of these structural materials in aerospace and aviation engineering. However, the complexity of structure will bring high time-consuming in calculation and unanticipated self-contract in researching dynamic performance. Equations were used to get the equivalent material properties by theoretical derivation. Then dynamic mechanical properties of both equivalent structure and grid cylindrical structure were investigated. In detail, the dynamic deformation and energy absorption characteristics of the structure under different lateral impact velocities were analyzed by software LS-DYNA. The relative density and the relative thickness of the grid cylindrical structure to equivalent performance effect were taken into account. The results show that when relative density and relative thickness are defined in certain range, the equivalent method has high accuracy. This equivalent method provides a reference for the impact properties of complex grid cylindrical structure with arrangement periodically.

Keywords Grid structure, Homogenization, Deformation mode, Energy absorption, Effective property

1. Introduction

Grid structure has been widely used in aerospace, automotive industry, civil materials, biological engineering, transportation and other applications because of excellent energy absorption, high load carrying capacity, high specific strength, high specific stiffness and low structural weight [1,2]. It not only contains mesoscopic mechanics characteristics, but also has whole macro performance. These characteristics make the anti impact properties of structure greatly improved. In addition, the designability of cell geometric topological provides a broad platform for the development of grid structure. Therefore, the scientists and mechanical experts pay great attention to study grid structure in order to acquire better integrated design.

At present, impact resistance performance, energy absorption capability and dynamic mechanical properties of grid structure have been studied by many scholars. For example, The elastic response of triangular, hexagonal and quadrilateral grid structure has been obtained in by Hohe et al.[3,4].The deformation mode and load carrying capacity of hexagonal grid structure were studied by the numerical simulation in by Ruan et al. [5,6] and Zou et al.[7].The formulas of bearing capacity and energy absorption ability were deduced through the deformation model of hexagonal grid structure in the high speed impact, and the energy distribution was discussed in Hu et al.[8]. Researched in Hong[9] and Zarei et al.[10] is the impact direction angle on in-plane dynamics performance. The mechanical properties of grid structure filled with circle cells were researched through experiment and numerical simulation in Papka et al.[11,12].Nevertheless, all of the above researchers adopt discrete element method to solve the problem of the periodic grid structure, which not only costs a lot of computation resources, but also is infeasible sometimes [13].

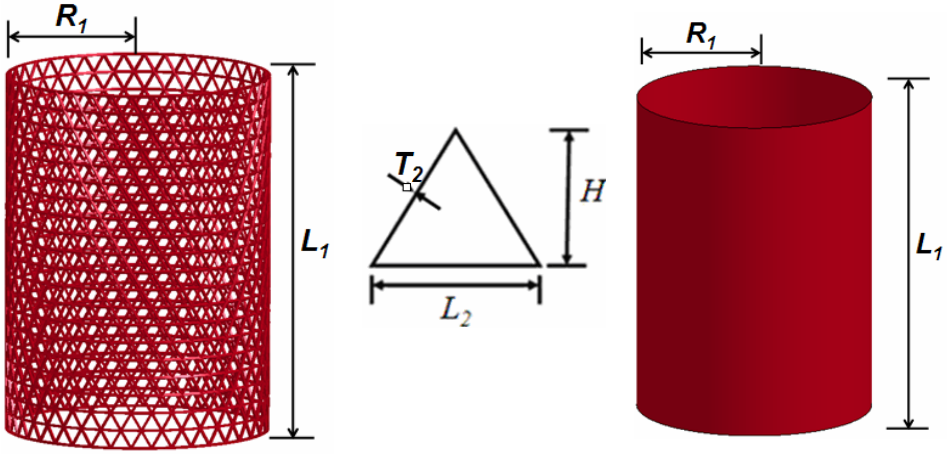
In order to simplify performance research of grid structure, the equivalent elastic constants have been explored over the last few years. Gibson and Ashby [14] have investigated the equivalent elastic

constants of grid structure excluding the cell size factor. In other words, they calculated the equivalent elastic constants, which only considering the cell microstructure and volume fraction ratio. In addition, some correlative research works have been done by Andrews [15], Yan and Cheng [16]. Wei[17] deduced the basic equation of elasticity of grid structure according to the principle of minimum potential energy and FEM, gave the elastic matrix based on the equivalent of virtual strain energy, and got the equivalent of density based on the equivalent of the kinetic energy. It is verified that the method has a good precision and is appropriate for such kind of analysis in the engineering field.

The grid cylindrical structure is equivalent to an isotropic shell with homogeneous thickness through the equivalent of unit cell mechanics properties. The energy absorption capacity, deformation model of grid cylindrical structure and equivalent continuum cylindrical structure were studied under the impact load. Meanwhile, the influence of the relative density and relative thickness to equivalent accuracy of grid cylindrical structure were considered.

2. Calculation model and method

Finite element models of grid cylindrical structure filled with stagger-arranged triangular cell and equivalent to continuum cylindrical structure with the same thickness were established as shown in figure 1. The dimensions of the two structures are: radius R_1=100mm, length L_1=272mm, and thickness T_1. And the shape of cell is equilateral triangle with length L_2=15.7mm, height H=13.6mm and thickness T_2. The numbers of circumferential and axial cell are 40 and 20 respectively. For boundary conditions, all the nodes at upper and lower ends of cylindrical structure are constrained. Those two cylindrical structures are lateral impacted by rigid sphere with a certain speed, which radius R_2=30mm, horizontal direction X_1=100mm, vertical direction$Y_1=L_1/2$.



Grid structure Triangle Continuum structure

Figure 1. Finite element models of cylindrical structure

Cell-wall was modeled using Beam161 with Hughes-Liu element algorithm and rectangular cross section shape, and the material properties assumed to be perfect elastic. The number of the total elements is 24400 with each cell-wall divided into 10. In this numerical simulation, sphere was modeled using 3D Solid 164 , of which material property is plastic-kinematic, and yield stress is 76Mpa. All degree of sphere freedom was confined except lateral impact direction. The density of

both cell-wall and sphere is 2700 Kg/m^3, elastic modulus is 69Gpa, poisson's ratio is 0.3. Mesh sensitivity studies revealed that additional mesh refinements did not improve the accuracy of the calculations appreciably. The automatic single-surface contact type with the principle simple, rarely arouse the hourglass effect, no numerical noise and the momentum conservation accurate penalty function method is adopted.

3 Equivalent processing

Cell-wall was assumed to be 'two force rod' model as shown in Figure 2. Young's modulus and density of cell-wall matrix are E_s and ρ_s. The tensile load and internal force distribution on X_1 and X_2 direction can be found out through the force equilibrium condition. Then according to harmonize deformation of cell-wall, the relation of equivalent stress and strain can be established.

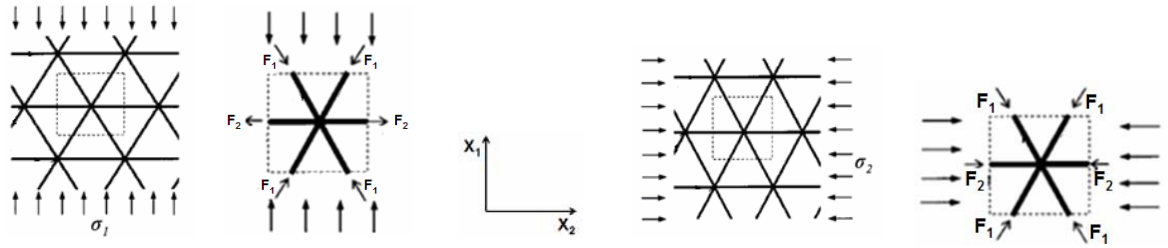


Figure 2. Triangle-grid structure under two cases of compression load [18]

The relative density is defined as $\rho = \rho^* / \rho_s$, where ρ^* is the equivalent density of grid structure, and ρ_s is the density of cell-wall matrix.

The material parameters of equivalent homogeneous shell [18] are:

Relative density: $\rho = \dfrac{\rho^*}{\rho_s} = \dfrac{3T_2}{L_2 \sin 60} = \dfrac{2\sqrt{3}T_2}{L_2}$, Young's modulus: $E_1 = E_2 = \dfrac{\rho}{3} E_s = \dfrac{2\sqrt{3}T_2}{3L_2} E_s$, Poisson's ratio: $\upsilon_{12} = \upsilon_{21} = \dfrac{1}{3}$, Shear modulus: $G_{12} = \dfrac{\rho}{8} E_s = \dfrac{\sqrt{3}T_2}{4L_2} E_s$

4 Result analysis and discussion

When structure is subjected to an impact load, the governing equations can be expressed as following [19]:

Equation of mass conservation:

$$\rho' V_{ij} = \rho_0 V_0 \tag{1}$$

where ρ' denotes the current density, V_{ij} represents the current volume, and ρ_0 denotes the initial density.

Equation of momentum conservation:

$$\sigma_{ij,j} + \rho' f_i = \rho' \ddot{u}_i \tag{2}$$

where σ_{ij} represents the Cauchy stress, f_i represents the body force density, and $\ddot{u}_i$ denotes the acceleration.

Equation of energy conservation:

$$\dot{E} = V s_{ij} \dot{\varepsilon}_{ij} - (p+q) \dot{V} \tag{3}$$

where s_{ij} and p denote the deviatoric stresses and hydrostatic pressure, respectively. q represents the bulk viscosity, δ_{ij} denotes the Kronecker delta (if i = j; otherwise δ_{ij} =0), and ε_{ij} denotes the strain rate tensor.

The proportion of hourglass energy has a crucial effect on energy conservation. Hughes-Liu integral was used in Beam element calculation, and full integral was adopted in the process of homogenization equivalent for continuous shell element. The relationship of internal energy and hourglass energy of grid cylindrical structure and equivalent continuum cylindrical structure are shown in figure 3(c-continuum cylindrical structure, g-grid cylindrical structure). It can be seen that the hourglass energy proportion is far less than 5%, which is required in simulation calculation. If the hourglass energy having a good control, we believe that energy is conservative, and calculation accuracy is high in the whole impact process.

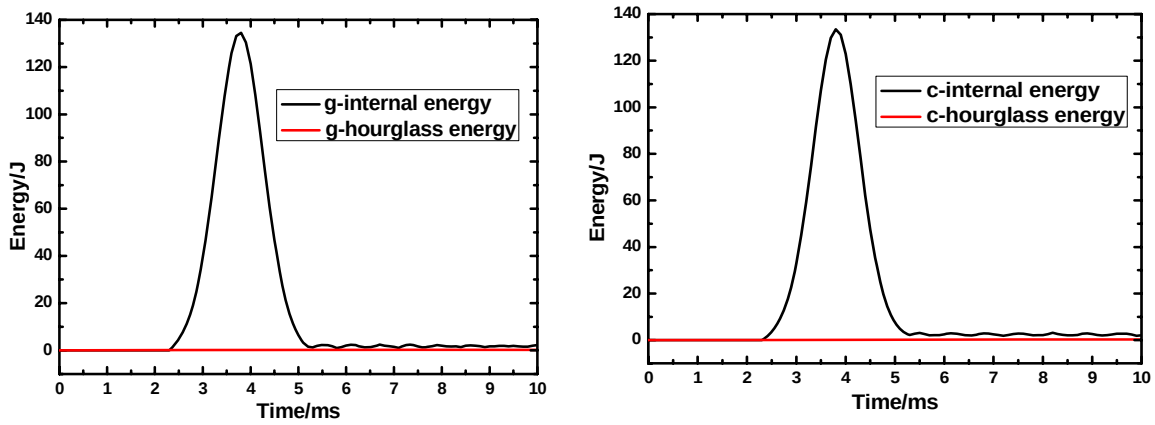

Figure 3. The relationship of internal energy and hourglass energy

4.1 The effect of the impact velocity

There are two main influence factors to impact resistant ability of cylindrical structure: structure deformation and energy absorption. When the sphere impacts to two kinds of structure at the velocity of 30 m/s, the displacement variation of structure is acquired before the sphere reflected back as shown in figure 4 (c-continuum cylindrical structure, g- grid cylindrical structure). It is obvious that the deformation of structure is basically identical before 3.1ms. With the increase of impact, the deformation error of structure is gradually increase. And the deformation of continuum cylindrical structure is larger about 6% than that of grid cylindrical structure at this stage.

This is because that the energy is absorbed through global deformation of the structure in the initial stage of impact. At this time, the difference of the two kinds of structure is not obvious and the deformations are approximately the same. With the proceeding of impact, the local deformation of structure becomes gradually obvious and concentrates to the impacted area. The influence of grid performance and arrangement mode to the impact resistance properties of structure is gradually reflected. Some energy is additionally absorbed by distortion of grid. Therefore, deformation of the continuum cylindrical structure is larger than that of grid cylindrical structure at this stage.

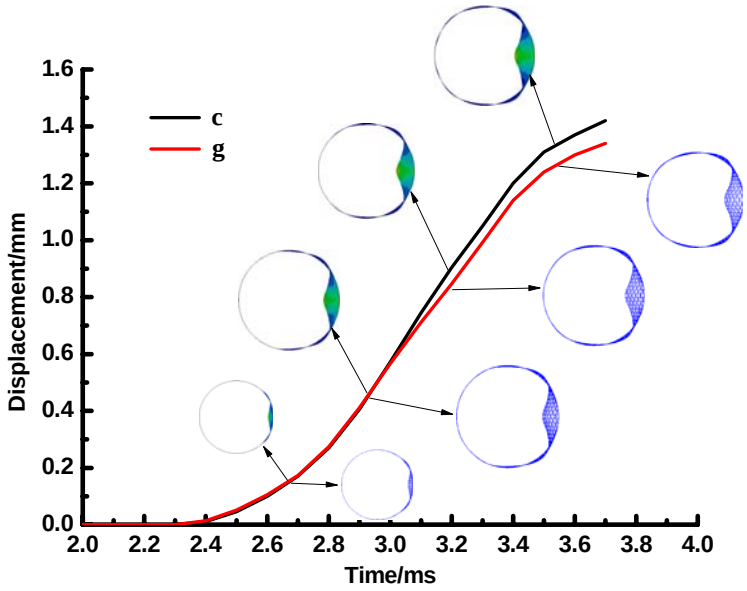

Figure 4. The deformation comparison of the two kinds of structures

Figure 5 depicts the deformation comparison of the two kinds of structure under different velocity. As can be seen from the graph, with the increase of impact velocity, deformation of structure is heightened, and deformation of continuum cylindrical structure is a little higher than that of grid cylindrical structure. It is obvious that the deformations of the two structures are agreement better at great impact velocity. The reason is that the coupled interaction between cells of grid cylindrical structure is small at the lower impact velocity. But cell shape and configuration mode has great influence on the structural deformation, which leads to the grid cylindrical structure can absorb more energy than the continuum cylindrical structure in small deformation. However, the coupling effect between grids will lead to the deformation more integrated and more closer to the deformation of the continuum cylindrical structure with the increase of impact velocity. So the deformation process is more similar and equivalent effect is better at higher velocity.

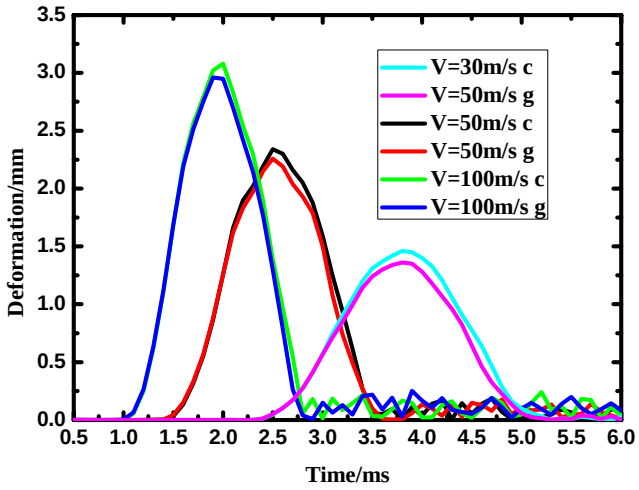

Figure 5. The deformation comparison of two kinds of structure under different velocities

4.2 The effect of the relative density

The relative density of grid cylindrical structure is changed by cell-wall thickness T_2, and other

parameters are constant. Take the relative density were 0.11, 0.22, 0.27, 0.3, 0.44, 0.88. When the impact velocity of the rigid ball is 10m/s, the deformation variation curve of structure is shown in figure 6.It is revealed that the homogenization equivalent method of grid structure is reasonable in a certain relative density range. When the relative density ranges from 0.2 to 0.4, the equivalent effect of structure is good, and the error is controlled within 10%. But, when the relative densities are 0.11 and 0.88, the errors are 30% and 104%, respectively. The impact performance of grid cylindrical structure has not been reflected really. Then, this kind of equivalent method is failure.

The relative density has a great influence on equivalent properties of structure. Grid cylindrical structure has a tendency to local deformation, and grid topology structure form has greater influence on deformation of structure. But the topology form has no influence on equivalent continuum cylindrical structure, which is the major reason to cause different deformations of structure.

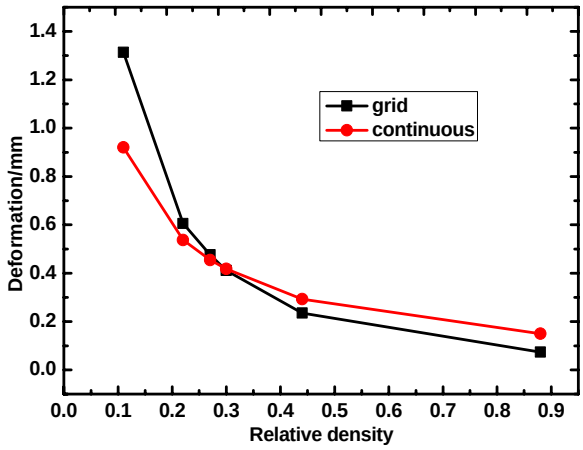

Figure 6. The relationship of relative density and deformation

4.3 The effect of the relative thickness

The relative thickness is defined as T_2/T_1, which is changed by thickness of the cylinder structureT_1. Take the relative density were 0.41、0.61、1.22、2.44 respectively. When the relative density is 0.27, the largest deformation change of structure with the increase of relative thickness is shown in figure 7.When the relative thickness less than 1.2, the maximum deformations of the two structure are almost to be equal. But the relative error has reached 23% at the relative thickness up to 2.44. It can be seen that with invariable thickness of grid cylindrical structure, the thicker the cylindrical structure is, the better the equivalent result is. However, the out-of-plane performance of grid cylindrical structure will gradually highlight with the increase of the thickness of the cylindrical structure, which will result in the failure of the equivalent method.

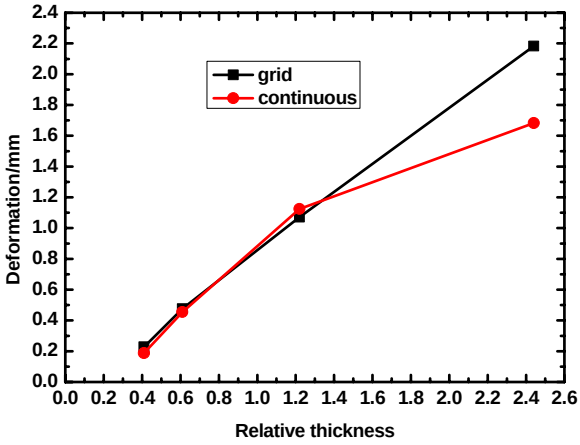

Figure 7. The relationship of the relative thickness and deformation

5. Concluding remarks

Based on the results obtained in the present work, the following main conclusions can be drawn:

(1) The relative density of grid cylindrical structure plays an important role in the homogenization process.

(2) It can be seen that the equivalent method is credible in a certain dimensionless parameter of relative density or relative thickness range.

(3) The deformation of grid cylindrical structure is smaller than that of the homogeneous equivalent for continuous shell structure under impacting, but the biggest error is controlled within 10%. So the equivalent method is reasonable in a certain range.

Abstract

Dynamic mode I fracture toughness of nano-rubber modified epoxy were investigated using the split Hopkinson tension bar (SHTB) facility, with loading rates up to 3×10^4 MPa·√m/s. The quasi-static toughness of those nanocomposites were also measured with an Instron machine at two loading rates of ~0.04 MPa·√m/s and 5 MPa·√m/s, respectively. The materials tested are: neat epoxy; and 2, 6 and 10 wt.% nano-rubber particles, respectively, in epoxy. Special specimens with a single-edge crack in the finite width direction were designed for mode I toughness testing with the SHTB. In addition, pulse shaping technique was used to optimize the loading stress wave for accurate measurements with the SHTB. The results indicated that the presence of nano-rubber could improve the fracture toughness of the bulk composites in the range of loading rates studied. However, high loading rates might have degraded the cavitation capability of the nano-rubber and hence decreased the toughness of the rubber-modified epoxies compared to low loading rates.

Keywords Nano-rubber modified epoxy, fracture toughness, high strain rate, Hopkinson bar

1. Introduction

Epoxies have gained growing attention from industries for its specific properties, such as high modulus and strength. Epoxy products have also been widely used as structural materials, e.g., window of vehicles and helmet to resist impact and explosion. However, the low toughness of epoxy is always the disadvantage in its applications. The advent of nanoparticles has offered one excellent candidate for toughening epoxy to satisfy specific engineering requirements. To add soft or rigid nano-fillers to epoxy can significantly enhance the toughness of epoxy with no serious loss in strength and elastic modulus [1-2]. Owing to the expanded applications of epoxy products, their dynamic responses have drawn increasing attention from both industry and scientific communities, though some polymers have been investigated extensively under quasi-static loading. Sahraoui [3] studied the fracture behaviors of a modified epoxy resin by three different testing machines with loading rates in the range from 5×10^3 to 10^4 MPa·√m/s. Evora [4] measured dynamic fracture

toughness of polyester/TiO_2 nanocomposites with three-point bend specimens, which were higher than their quasi-static fracture toughness. However, there is little known on the dynamic fracture behaviors of epoxies filled with soft nano-rubber particles at high loading rates. But, such results are necessary to understand their performance and reliability as structural materials under those extreme conditions. In this study, ~100 nm diameter nano-rubber particles were used to process epoxy composites and prepare single-edge notched specimens for dynamic toughness measurements with a split Hopkinson tensile bar (SHTB) at a maximum loading rate of 3×10^4 MPa·√m/s. Toughness tests at lower quasi- static rates were also conducted on an Instron machine and the results were analyzed.

2. Materials and specimen

The resin selected was standard diglycidyl ether of bisphenol A(DGEBA) with an epoxide equivalent weight (EEW) of 185 g/mol and Araldite-F was supplied by Sigma-Aldrich in Australia. Spherical rubber particles ~100 nm with excellent dispersion were supplied with 25 wt.% (weight percent) concentration in bisphenol A resin by Kaneka Corporation, Japan. The curing agent was a cycloaliphatic secondary amine, Piperidine, obtained from Sigma-Aldrich.

Material formulations were prepared by mixing plain DGEBA resin with required amounts of nano-rubber master batch. Three weight fractions of nano-rubber particles were made, 2 wt.%, 6 wt.% and 10 wt.% nano-rubber particles in epoxy (denoted by R2, R6 and R10 hereafter), respectively. Samples with neat epoxy were also made to study the effect of nano- rubber. After adding the curing agent to the mixture, it was poured into two pre-heated moulds for curing at 120℃ for 16 h. One mould was fabricated for Compact Tension (CT) specimens following ASTM D5045-99 [5]; the other was for making bulk materials, which were cut into beams $4.5\times14\times65$ mm^3 for dynamic fracture tests. Figure 1 shows the TEM microstructures of R10, which indicates clearly nanoparticles dispersed uniformly in the epoxy matrix.

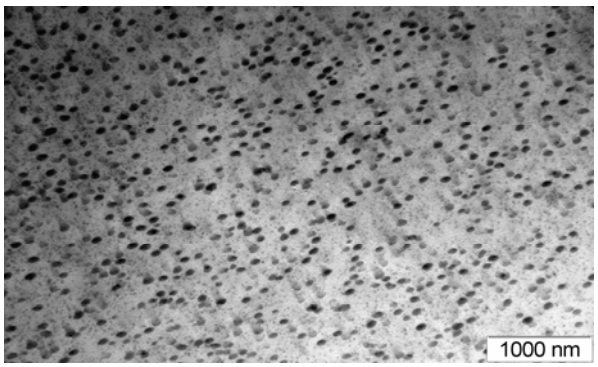

Figure 1. Nano-rubber dispersion of R10

All samples were first heated for 2 h at 80℃to remove any residual stress owing to surface polishing. A natural crack was then obtained by tapping a fresh razor blade at a specimen notch tip. The length a of the CT specimens was between 0.45W and 0.55W [5].

Figure 2. Quasi-static testing of CT specimen with the loading fixture

3: Experimental Work

3.1 Quasi-static fracture toughness tests with CT samples

Quasi-static tests were conducted on CT specimens in a screw-driven Instron 5567 machine with full control of loading rates in the range of 1 to 100 mm/min and full records of load and displacement (see Figure 2).

3.2 Dynamic fracture experiments

Dynamic fracture toughness tests were conducted on the SHTB facility to obtain the tensile stress-strain curves at high strain rates from 10^2 to 10^3 s^{-1} [6, 7]. SHTB consists basically of a striker tube, an incident bar and a transmitted bar (see Figure 3). The specimen was cemented between the incident and transmitted bars.

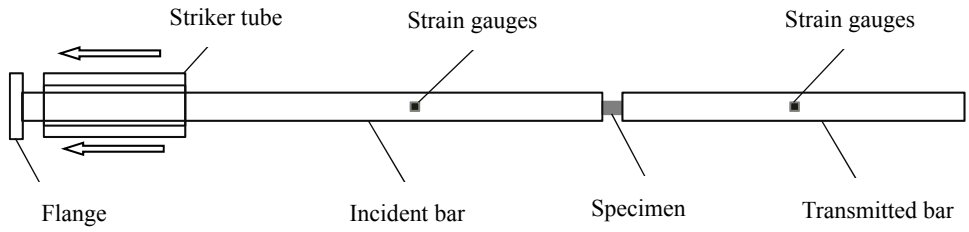

Figure 3. Schematic drawing of the SHTB test

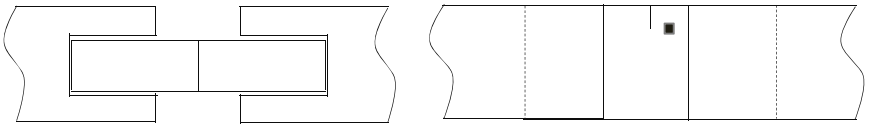
While testing, the striker tube was projected towards the flange by a gas gun. Upon impacting, an incident wave $\varepsilon_i(t)$ was generated, and reflected at the flange free end, presenting tensile stress wave, and then propagated backwards to the interface between the incident bar and the specimen. At this interface, part of the incident wave, $\varepsilon_r(t)$ was reflected back into the incident bar. The rest went through the specimen and, finally developed the transmitted wave, $\varepsilon_t(t)$ in the transmitted bar. The incident, reflected and transmitted waves were recorded by the strain gauges and the dynamic strain recording machine.

From one-dimensional wave theory, the stress at the bar end is given by:

$$\sigma_I(t) = E(\varepsilon_i(t) + \varepsilon_r(t)) \tag{1}$$

$$\sigma_T(t) = E\varepsilon_t(t) \tag{2}$$

where E is Young's modulus of incident and transmitted bars; $\varepsilon_r(t)$ and $\varepsilon_t(t)$ are reflected and transmitted waves, respectively. Aluminum bars 15 mm diameter were used. Impact velocities of the striker tube were applied by controlling the pressure of the gas gun to achieve desired loading rates. Specimens were designed to suit the Hopkinson bars and essentially single-edge notched tension (SENT) geometry (see Figure 4).



(a) Lateral view of fixed specimen (b) Top view of fixed specimen

Figure 4 Fixture of dynamic toughness specimen and arrangements of strain gauge and crack

The specimen, with the size of 4.5mm×14mm×65mm, was cemented and embedded 20 mm into the bars. The strain gauge glued near the crack-tip was used to ascertain the crack initiation time [8]. The pulse shaping technique was employed to trim and optimize the incident stress, and to achieve stress equilibrium in the specimen in a short time [9]. At least 3 repeated tests were conducted for each material.

4. Results and Discussion

4.1 Calculation of fracture toughness

For the CT tests, the fracture toughness is calculated by [5]

$$K_{IC} = \frac{P}{B\sqrt{W}} f(a/W) \tag{3}$$

where P is fracture initiation load, and

$$f(\frac{a}{W}) = f(\alpha) = \frac{2+\alpha}{(1-\alpha)^{3/2}}(0.886 + 4.64\alpha - 13.32\alpha^2 + 14.73\alpha^3 - 5.6\alpha^4) \tag{4}$$

For the SENT specimen under dynamic loading, the fracture toughness is obtained from [10]

$$K_{IC} = \sigma\sqrt{\pi a} \cdot F_I(\alpha), \alpha = \frac{a}{W} \tag{5}$$

where σ is fracture stress on the specimen width, and

$$F_I(\alpha) = 1.12 - 0.231\alpha + 10.55\alpha^2 - 21.72\alpha^3 + 30.39\alpha^4 \tag{6}$$

The fracture stress σ is calculated from the transmitted stress σ_T:

$$\sigma(t) = \frac{A_{Bar}}{A_{Specimen}} \sigma_{\mathrm{T}}(t) \tag{7}$$

In all the tests, the loading rate is defined by:

$$\dot{K}_I = \frac{K_{IC}}{t_c} \tag{8}$$

where K_{IC} is critical stress intensity factor and t_c is time interval from the start of loading to when the crack starts to propagate. A typical load-time curve recorded by the Instron machine for a CT specimen is shown in figure 5.

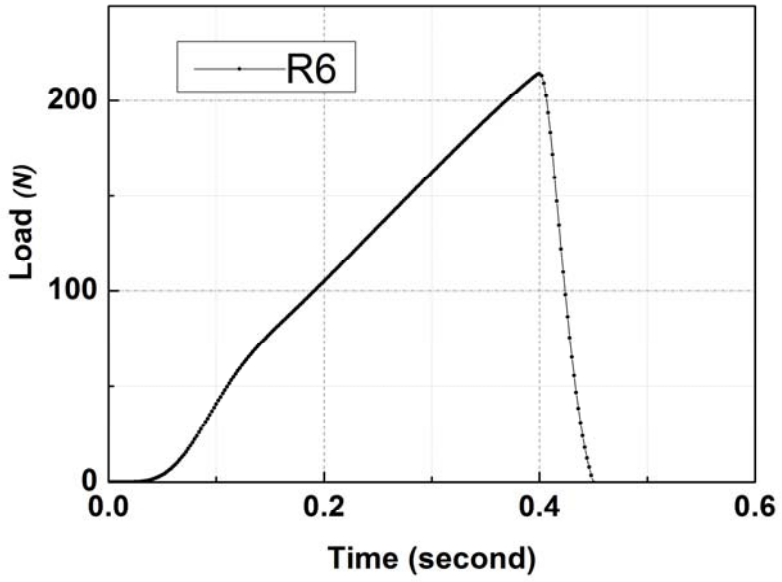


Figure 5 Load-time curve of a R6 CT specimen under a crosshead rate of 100 mm/min

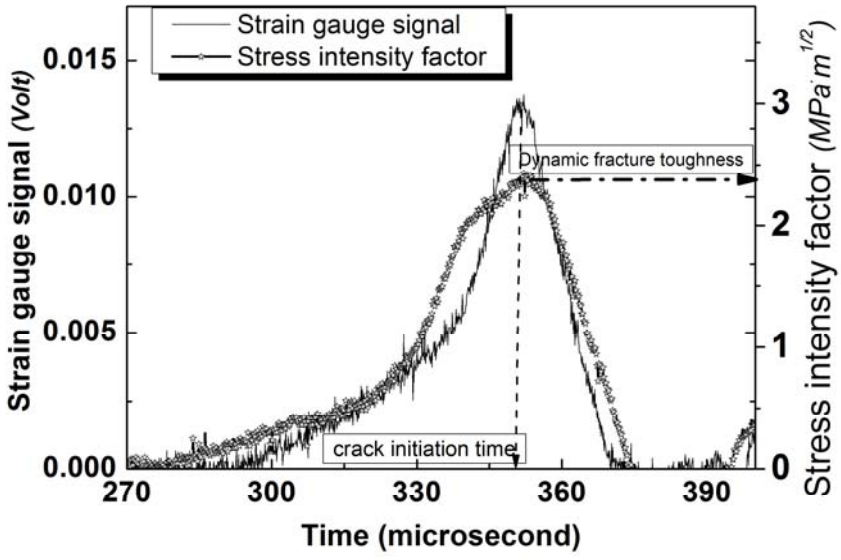

Figure 6 Toughness-time and strain signal-time curves of R6 from SHTB test

For the dynamic toughness tests, it is essential to ascertain the critical time at crack initiation. The strain measured from the strain gauge would drop dramatically when the crack was about to propagate because the strains accumulated around the crack-tip would be released once the crack moved away. Figure 6 shows the strain signal-time curve from which the stress intensity factor-time curve can be determined.

The quasi-static loading rates were 0.04 MPa·√m/s for the crosshead rate of 1 mm/min and 5 MPa·√m/s for 100 mm/min, respectively. The SHTB tests gave a much higher loading rate at ~3×10^4 MPa·√m/s. The results of all tested materials are shown in Figure 7.

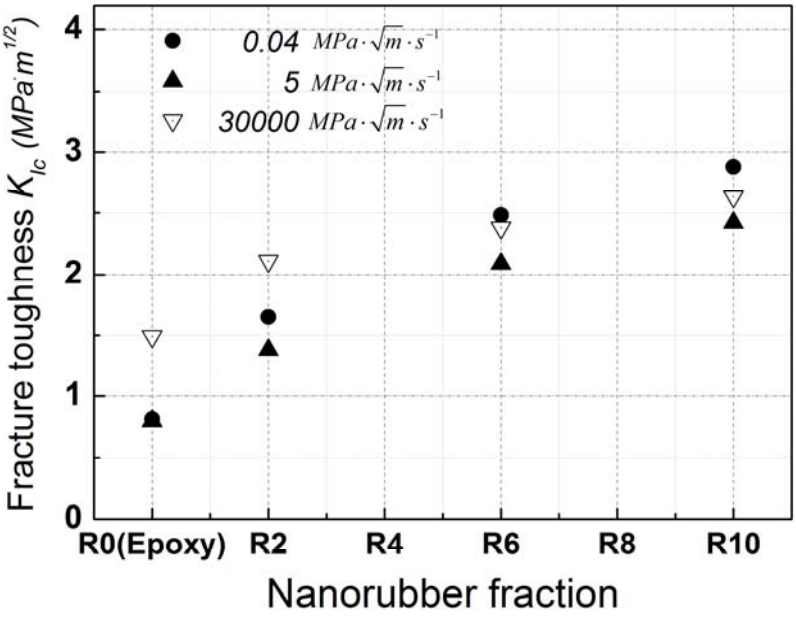

Figure 7 Effect of loading rate and nano-rubber weight fraction on fracture toughness

4.2 Nano-rubber fraction and loading rate effects

Figure 7 shows clearly the improving toughening effect with increasing nano-rubber fraction. This trend is true for all three loading rates implying nano-rubber particles can improve the toughness of epoxy even at a high loading rate. However, compared to the lower loading rates, 5 and 0.4 MPa√m/s, the toughness increased by the rubber content under high loading rate, 3×10^4 MPa√m/s, is less significant. For example, under quasi-static loading, 0.04 MPa√m/s, the toughness of R6 is more than 3.0 times the toughness of epoxy. But under high loading rate, 3×10^4 MPa√m/s, the toughness of R6 is only ~1.8 times the toughness of epoxy. It is possible that rubber particle cavitation is reduced due to the increased cavitation strength of the nanorubber under high loading rate. Future study will be conducted to clarify the rubber particle toughening mechanisms under different loading rates.

The results in Figure 7 show the crack growth responding to different loading rates. For neat epoxy, the toughness K_{ICm} is ~1.8 times larger at the dynamic loading rate of 3×10^4 MPa√m/s, compared to the quasi-static loading rates of 5 and 0.4 MPa√m/s, due to thermal blunting of the crack-tip

induced by adiabatic heating [11]. In rubber modified epoxy, R2, R6 and R10, although thermal blunting owing to localized adiabatic heating at the crack-tip may happen, its dependence at this high loading rate could be weak. Instead, the toughening mechanisms of rubber cavitation and matrix plastic deformation [2] are dominant and favored by the low loading rates, leading to the results displayed in Figure 7, especially when the rubber content is high. Again, further studies on the effects of loading rates on the relative amount of thermal blunting, cavitation and matrix plastic flow in these materials are essential to confirm the toughness results obtained.

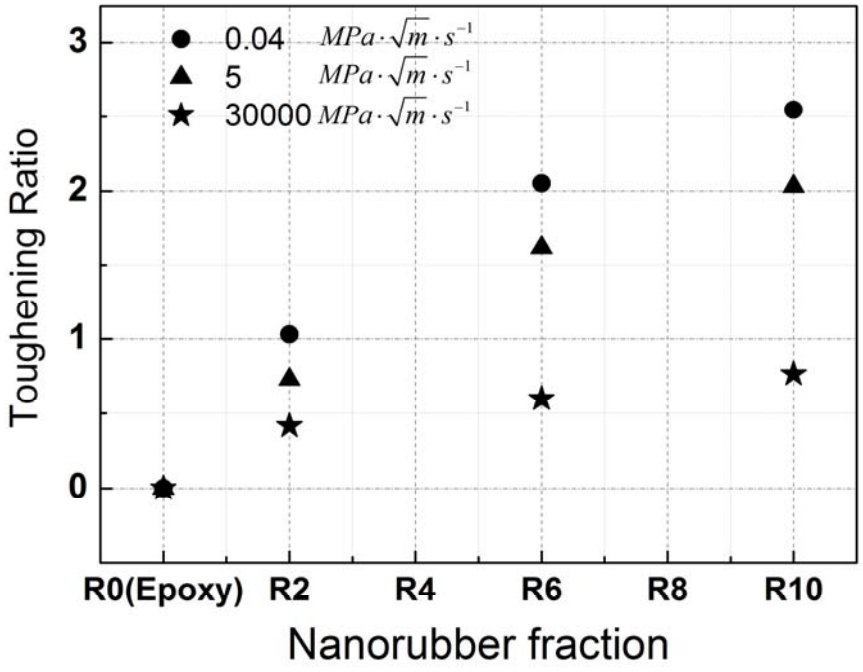

Figure 8 Normalized nano-rubber toughening efficiency of composites

A filler-toughening ratio parameter, η, can be used to evaluate the toughness increase associated with the nano-rubber particles. Thus, η is calculated from:

$$\eta = \frac{K_{IC} - K_{ICm}}{K_{ICm}} \tag{9}$$

where K_{IC}, K_{ICm} are the toughness values of nano-rubber filled epoxies and neat epoxy matrix, respectively. Hence, η is a ratio of the net toughness caused by the nano-rubber presence over the net toughness of the epoxy matrix. Figure 8 plots the toughening efficiency parameter η of nano-rubber based on equation (9). In Figure 8, the toughening ratio of R2, R6 and R10 at each loading rate was best fitted, and their slopes could be found to have a distinct trend: it drops with increasing loading rates. As explained in the above section, this may be due to the reduced rubber cavitation and matrix plastic flow under the high strain rate.

5. Summary and Conclusions

The fracture performance of nano-rubber filled epoxies under a wide range of loading rates from

quasi-static (0.04 MPa·√m/s) to Hopkinson bar (3×10^4 MPa·√m/s) tests were examined in terms of the fracture toughness and the toughening efficiency. Some important conclusions are summarized below:

1: The toughness of the nanocomposites increases with nano-rubber weight fraction.

2: The toughness of neat epoxy and 2 wt% rubber modified epoxy increases under dynamic loading due to thermal blunting.

3: The filler toughening efficiency drops with increasing loading rate. This is because increasing loading rates limit some toughening effects, such as cavitation and matrix plastic deformation, of rubber particles.

Abstract Low velocity perforation of an aeronautical aluminum alloy sheet 2024 T3 subjected to impact is studied in this paper. The main objective is to compare experimental results and simulations by analysis of the failure. The perforation test is made with an instrumented 3 meter drop test. The striker has a large diameter (45 mm) and a conical shape. Sheets' thickness is 2 mm. The influence of the impact velocity is analyzed. A phenomenological behavior law of the sheet's material is implemented in the finite element code Abaqus/Explicit. Thus, 3D simulations of perforation are performed using a damage evolution law and a ductile failure criterion. To understand the phenomenon, the perforation force and the sticker velocity will be analyzed. Simulations are validated by experimental tests and compared with an analytical model.

1. Introduction

An increased attention in impact issues is paid by authors working on various engineering fields like aeronautic [1], naval [2], and automotive [3]. Impact on ductile material involves high strain rates effects [4] and temperature effects [5]. Thus, the knowledge of material dynamic behavior is necessary. Particular constitutive laws are known to be adapted for this type of issue [6]. The ductile target perforation is a specific case of impact studies. Perforation tests can be classified in categories according to the test velocity is high [7] or low [8], or according to the different striker's geometries (diameter, nose shape,…). An energetic approach is recommended to understand perforation issue. The energy absorbed by the target during impact E_a can be calculated using the difference between the initial kinetic energy and the final kinetic energy [8]. The ballistic limit V_{bl} is known to be the minimal initial velocity involving perforation. In order to have a better understanding of the rupture phenomenon and in order to compare with simulation results, it is necessary to know the force applied to the target and/or the striker displacement, during impact. This is the reason why some authors use the Hopkinson bar theory [9] [10] or an instrumented pneumatic accelerator or drop test [9] to be able to plot the curve of the force versus the time and/or the displacement. Low velocity perforation of an aeronautical aluminum alloy sheet 2024 T3 subjected to impact is studied in this paper. Unlike Rodriguez-Martinez [8] who studied the perforation of thin target (1 mm), the idea is here to work with thicker plates (2 mm) and with a larger striker (45 mm).

A two-pronged approach for perforation is proposed here: an experimental approach with the use of a drop test and a modeling approach including a finite element (FE) approach and an analytical approach. Results are compared and discussed.

2. Drop test: Perforation of 2024 T3 aluminum alloy sheets

2.1. Material

Aluminum alloys are known for their high mechanical characteristics against their density. The 2024 T3 aluminum alloy (2024 AA) is used in aeronautical structural parts as planes' fuselage or wings. The process route of this precipitation hardening material, alloyed with copper, is well known: a casting, a homogenizing, a hot rolling, a solute heat treatment at 495°C, a water quench, a cold work to obtain higher strain, and to finish a natural aging. This is the T3 heat treatment [11]. The chemical composition of the 2024 aluminum alloy is presented in Table 1.

Table 1. Chemical composition in %wt of the 2024 AA [12].

Al	Cu	Mg	Mn	Fe	Si	Zn	Ti	Cr
Bal.	4.76	1.38	0.65	0.22	0.08	0.07	0.03	0.01

2.2. Experimental setup

An instrumented drop test is used to perforate 2024 AA sheets (Fig. 1). A 5 kg test trolley slides on two bars from various height positions. Weights can be added to this trolley. Under the trolley a piezoelectric force sensor and a conical striker are fixed. This dynamic force sensor is calibrated for a range of validity from 0 to 100 kN and is used to measure the perforation force during impact with a relative error less than 5%. The striker is composed of a 60° conical nose and a 45 mm diameter cylindrical part. This cylindrical part is 10 mm long. A laser sensor (error of 0.5%) is used to measure the trolley's displacement. Two high speed cameras are used to measure the striker displacement and to take picture of the sheet's perforation. A mirror enables the observation beneath the sheet.

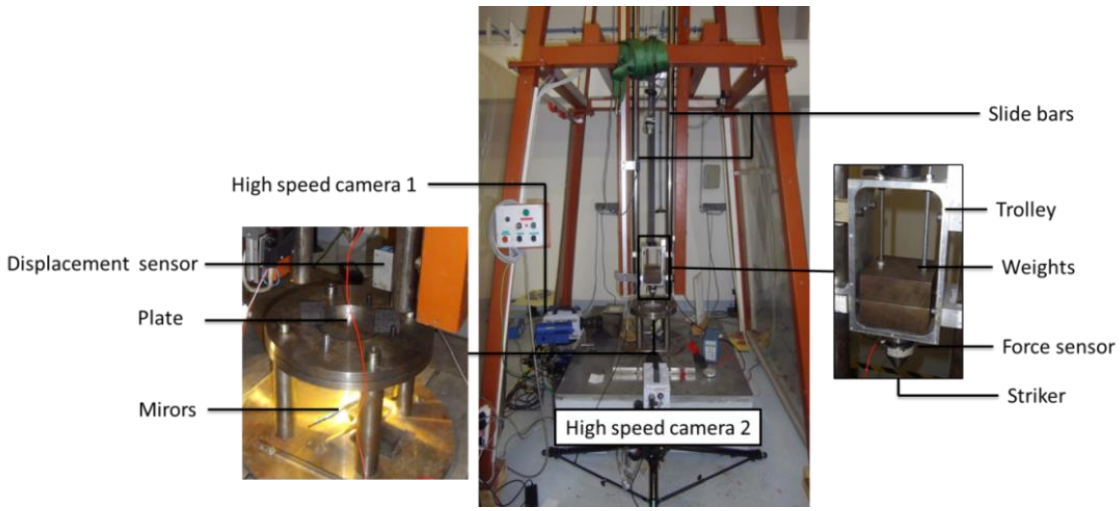

Figure 1. Instrumented drop test.

Twelve drop tests are performed to perforate a 2 mm 2024 AA sheet. The initial impact velocity and the striker total mass of each test are given in Table 2. If the striker perforates the sheet, values are in bolt font. The impact velocity evolves from 2.7 m/s to 6.9 m/s. The striker total mass is taken equal to 13 kg. The main objective is to find the ballistic limit velocity, to study the residual velocity and to analyze fracture and the force during impact.

2.3. Experimental results

2.3.1. Description of the perforation test

A 2 mm 2024 AA sheet is impacted by the striker. Thus, the striker nose induces plastic strain in the center of the sheet. More than four cracks appear, two in the laminated direction, two in the transversal direction, and sometimes in the 45° direction (Table 2). If the conical nose does not go through the plate, the striker bounces. If the conical nose goes through the sheet, the force sensor hits the sheet involving a bounce. All are analyzed before this bounce.

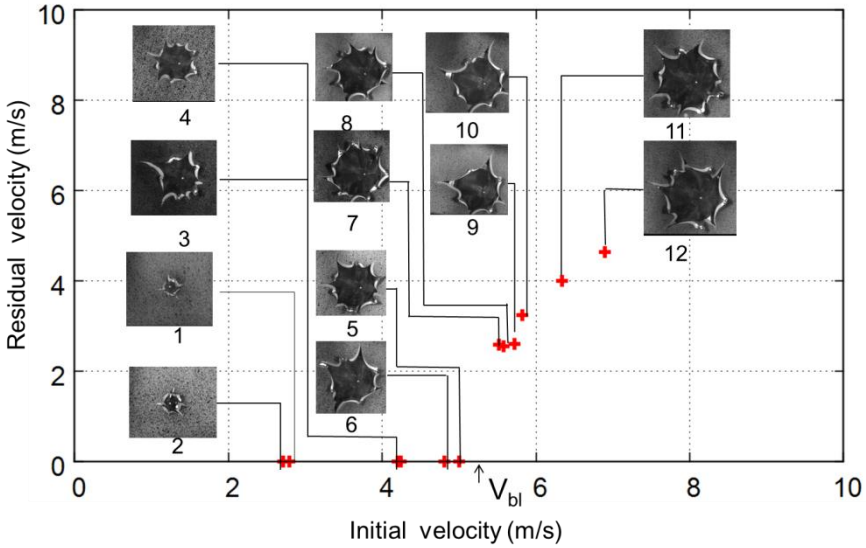

Figure 2. Residual velocity versus initial velocity.

2.3.2. Velocity results

It is usual to plot the residual velocity of the striker as a function of the initial velocity. In Fig. 2, if the striker does not perforate the sheet completely, the residual velocity is taken equal to 0. Classical results show that starting from the ballistic limit the velocity V_{bl} is a continuous growing curve [8]. Here this hypothesis is confirmed. In Fig. 2, pictures are taken at the end of the perforation (before the bounce). Thus it can be concluded, that using a 13 kg conical striker, the ballistic limit velocity to perforate a 2 mm sheet of 2024 AA is between 5 and 5.52 m/s. To obtain a better approximation of the ballistic limit velocity, the definition of the absorbed energy during perforation is used. This

energy is calculated as the difference between the initial kinetic energy and the final one and given in Table 2 for each test. The ballistic limit velocity V_{bl} can be estimated using the average absorbed energy E_a = 161 J as:

$$V_{bl} = \sqrt{\frac{2E_a}{m_{striker}}} \quad , m_{striker} = 13kg \tag{1}$$

It can be concluded that the ballistic limit velocity is equal to 5.0 m/s with an error of +/- 3%.

2.3.3. Force during impact

The force induced by the sheet on the striker can be plot during impact with the help of the force sensor (Fig. 6). Firstly, when the striker is reaching the sheet, a force peak can be observed. Secondly, cracks appear and so the force is continuously growing to be maximal when the striker cylindrical part is reached (test 7 to 12) or when the striker start to bounce back (test 1 to 6). After, the force is decreasing. If the conical nose goes through the sheet, the force sensor will hit the sheet involving a new increase of force.

2.4. Conclusion on experimental results

It can be concluded that the ballistic limit velocity is about 5 m/s +/- 3% using a 13 kg striker. Four or more than four petals always appear in the sheet during perforation. The perforation absorbed energy tends to be constant and equal to 161 J for impact velocity between 5 m/s and 7 m/s.

3. Modeling of perforation

Experimental tests are compared with two models: an analytical model based on energetic consideration and a shell finite elements model.

3.1 Perforation analytical model

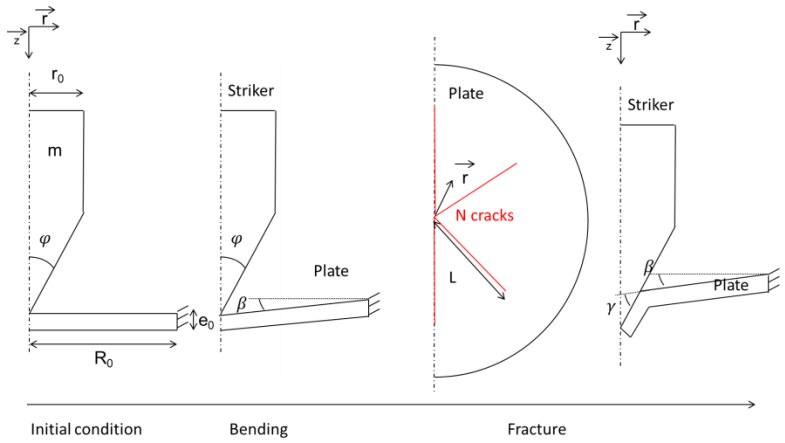

Figure 3. Analytical model.

An energetic approach for perforation is proposed by Nazeer [13]. A conical nose striker impacting thin plates involves bending deformation, stretching deformation and N cracks' propagation (fig 3).

The idea is to adapt this model in order to study the ballistic limit velocity and the residual velocity of the striker and with the hypothesis that the radius of the dimple is equal to the sheet radius. The elastic bending work is neglected. Thus, the total perforation work W is the sum of the bending plastic work W_b the stretching plastic work W_s, the petals' bending work W_{bf} and the fracture work W_f ($W = W_b + W_s + W_{bf} + W_f$). The perforation work is the absorbed energy and so with the definition of the absorbed energy, the residual velocity V_r is given as a function of the initial velocity V_0:

$$W = \frac{1}{2} m_{striker}(V_0^2 - V_r^2) \quad \rightarrow \quad V_r = \sqrt{V_0^2 - \frac{2W}{m_{striker}}} = \sqrt{V_0^2 - \frac{2(W_b+W_s+W_{bf}+W_f)}{m_{striker}}} \tag{2}$$

To obtain the ballistic limit velocity, the initial velocity is taken equal to V_{bl} and the residual velocity V_r equal to 0 m/s. Thus, we obtain:

$$V_{bl} = \sqrt{\frac{2W}{m_{striker}}} = \sqrt{\frac{2(W_b+W_s+W_{bf}+W_f)}{m_{striker}}} \tag{3}$$

where

- the bending work W_b is given as a function of the yield stress σ_y, the initial thickness e_0 the sheet's radius R_0 and the bending angle β (calculated as a function R_0 and the striker displacement z as $\tan(\beta) = \frac{z}{R0}$). by:
$$W_b = \pi \sigma_y e_0^2 R_0 \beta \tag{4}$$
- the stretching work W_s of the sheet is given as a function of the yield stress σ_y, e_0, R_0, and the stretching strain ε_s by $W_s = (\pi R_0)^2 \sigma_y e_0 \ \varepsilon_s$. The stretching strain can be defined thanks to the evolving surface area of the sheet and its original area $\left(\varepsilon_s = \ln\left(\sqrt{R_0^2 - z^2}/R_0\right)\right)$:
$$W_s = (\pi R_0)^2 \sigma_y e_0 \ \ln\left(\sqrt{\frac{R_0^2 - z^2}{R_0^2}}\right) \tag{5}$$
- the bending work W_{bf} involved by each petals can be written as a function of the number of petals N, the striker radius r_0, the thickness e, and γ the petals bending angle ($\gamma = \frac{\pi}{2} - \varphi - \beta$) as (see Fig. 3):
$$W_{bf} = \frac{\pi \sigma_y r_0 e^2 \gamma}{2} \frac{2+N}{1+N} \tag{6}$$
- the Fracture work W_f is due to crack propagation. It can be given as a function of the fracture toughness G, the thickness e and the length of fracture L by $W_f = NGeL$.The thickness e can be express with the stretching strain as $e = e_0/\sqrt{1 + z_b/R_0^2}$. L is taken equal to the projection of the striker on the bending sheet ($L = \sqrt{r_0^2 + z_b^2}$). The parameter z_b, is the ultimate bending striker displacement the parameter. Thus the fracture work is given by :
$$W_f = NGe_0 \ln\left(\sqrt{\frac{R_0^2 - z_b^2}{R_0^2}}\right)\sqrt{r_0^2 + z_b^2} \tag{7}$$

Here the angle of the conical striker is 60°, its mass is equal to 13 kg, and its diameter is 45 mm. The sheet thickness is 2 mm and its diameter is 148 mm. The static yield stress is $\sigma_y = 340\ MPa$, the number of petals is taken equal to 4 and the ultimate bending striker displacement z_b is 3 mm.

3.2 Finite element model for perforation

3.2.1 Material behavior law of 2024 T3 AA

A classical Johnson Cook behavior law [6] is used in the finite element code Abaqus [14] to model the viscoplastic behavior where A, B, n, m, C and $\dot{\varepsilon}_0$ are material parameters, Tmelt is the melt temperature and Troom is the room temperature. The stress σ can also be written as a function of the plastic strain ε^p , the plastic strain rate $\dot{\varepsilon}^p$, and the temperature T :

$$\sigma = \left(A + B\varepsilon^{p\,n}\right)\left(1 + Cln\left(\frac{\dot{\varepsilon^p}}{\dot{\varepsilon_0}}\right)\right)\left(1 - \left(\frac{T-T_{room}}{T_{melt}-T_{room}}\right)^m\right) \tag{8}$$

The elastic behavior is isotropic (E=74 GPa, ν=0.3). Above a plastic strain threshold, voids appear, grow and coalesce in the material, to produce the rupture [15]. To define this damage, a damage variable D is used in the model. The evolution of D can be written using the Johnson Cook dynamic damage model [16]. The damage D is dependent on the plastic strain rate, materials parameters m, D1, D2, D3¸D4 and D5, the hydrostatic pressure p, the equivalent stress σ_{eq}, the melt temperature Tmelt and the room temperature Troom :

$$\dot{D} = \frac{\dot{\varepsilon^p}}{\varepsilon_R} = \frac{\dot{\varepsilon^p}}{\left(D_1 + D_2\, e^{\frac{D_3 p}{\sigma eq}}\right)\left(1 + D_4 ln\left(\frac{\dot{\varepsilon^p}}{\dot{\varepsilon_0}}\right)\right)\left(1 - D_5\left(\frac{T-T_{room}}{T_{melt}-T_{room}}\right)^m\right)} \tag{9}$$

Lesuer [12] used an isotropic Johnson Cook hardening and a Johnson Cook rupture model for a 2024 AA with the parameters presented in Table 3. The strain rate parameter $\dot{\varepsilon}_0$ is taken equal to $1s^{-1}$, T_{room} equals 298 K and T_{melt} equals 775 K. Parameters D_1 and D_2 are determined to predict the residual velocity after impact, according to the presented experiment. Because of the temperature dependence, the specific heat cp is taken equal to 897 J/kg/K, the inelastic heat fraction equal β to 0.9 and the conductivity equal to 237 W/m/K.

Table 3. Johnson Cook hardening and fracture law parameters [12] (**modified in bolt fonts**)

A (MPa)	B (MPa)	n	C	m	D_1	D_2	D_3	D_4	D_5

3.2.2 3D finite element model.

A 3D finite element simulation is carried out using ABAQUS/Explicit. Shell elements are known to be well adapted for solving thin sheets' perforation issues [17]. Thus the 2024 AA sheet is modeled with 3200 S4RT elements and 1869 S3RT elements with the JC law presented above (Table 3.) For stability reason, five integration points are taken in the sheet's thickness. An analytical rigid surface is used to model the conical striker. The trolley mass is applied on the striker reference point. Interaction between the striker and the sheet is modeled by a perfect contact (hard contact and frictionless). Elements are deleted when the damage D is equal to 1. The sheet is clamped at the edges. The initial velocity is applied on the striker reference point. The striker moves only along the vertical direction. Temperature effects are taken into account but will not be discussed here. Initial

velocities of simulations are taken similar to experimental drop tests (2.7 m/s, 4.2 m/s, 5 m/s, 5.5 m/s, 5.8 m/s, 6.3 m/s and 6.9 m/s) and another one equal to 8 m/s.

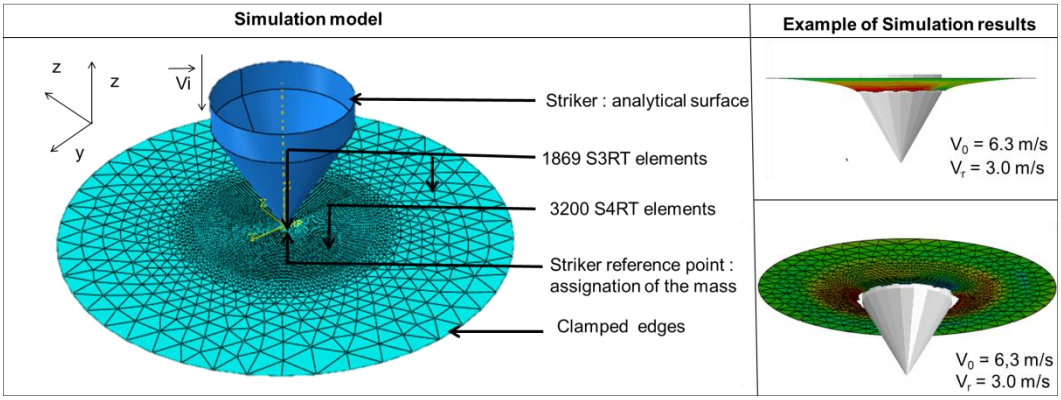

Figure 5. Shell finite elements model and simulation results.

4. Results and discussions

4.1. Perforation force

Drop tests force during impact is compared to numerical results. In Fig. 6, forces are plotted for an initial velocity of 5.8 m/s. Simulation's force is noised because of numerical instabilities. That's the reason why a centered average numerical force is plotted. It can be noticed that the first force peak is not simulated. The numerical model does not take in consideration friction effects and failure propagation and thus the numerical force underestimates the measured force. As the measured force, the numerical force rises during the perforation until a maximal force, equal to 8.8 kN, versus 9.6 kN for the measured force.

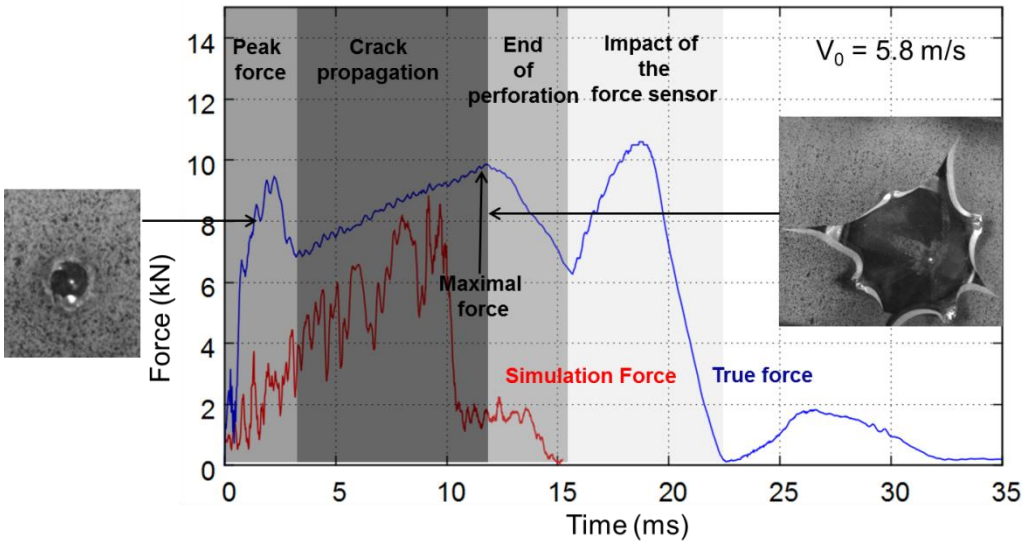

Figure 6. Force during impact versus time for an initial velocity of 5.8 m/s (test 9).

4.2. Discussion on the ultimate bending striker displacement before perforation

The ultimate bending striker displacement before perforation z_b, is used to calculate the residual velocity for the analytical model. It can be determined by drop tests' results and finite elements' results, and is equal to the displacement of the striker before rupture. For an initial velocity of 5.8 m/s, z_b is equal to 2.9 mm and 3.5 mm respectively for simulation and experiment. The hypothesis to take z_b equal to 3 mm for the analytical model is in good agreement.

4.3. Velocity discussions

Velocity's results are discussed by plotting the residual velocity as a function of the initial velocity (Fig. 7). Analytical model's results (N=4, z_b=3mm) are in good agreement with drop tests' results. Simulations tend to underestimate residual velocities, but results are close to experimental ones.

A good ballistic limit velocity correlation is found. With the analytical model, it is equal to 5.0 m/s. With the finite elements model, it is between 5 and 5.5 m/s. The experimental ballistic limit velocity is about 5.0 m/s.

Experimentally, the absorbed energy by the sheet during impact rises with the initial velocity until a maximal energy (about 161 J), reached for the ballistic limit velocity (Fig. 7). Drop tests' results give an average maximal absorbed energy for perforation of 161 J. In the analytical model, this maximal absorbed energy for perforation is the addition of plastic work and fracture work and is equal to 168 J. Because of the use of a rate dependent model, simulations show that the absorbed energy continues to rise beyond the ballistic limit velocity and exceeds 180 J.

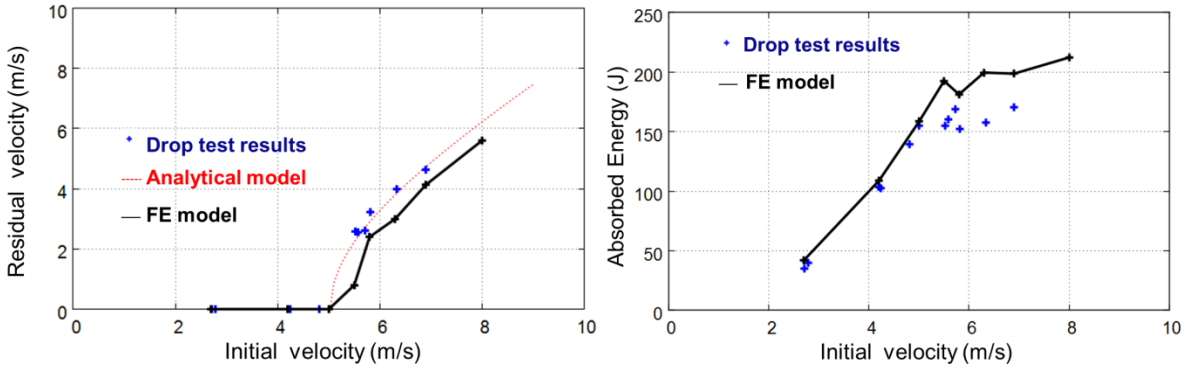

Figure 7. Residual velocity versus initial velocity and absorbed energy versus initial velocity.

4.4. Discussion on the number of petals.

More than four petals appear during perforation tests (Table 2). Because of the use of the "kill element" process, no petal is observed in FE simulations. It was already explained that results from the analytical model are number of cracks dependent. In this model, an evolution of the number of petals leads to an augmentation of the absorbed energy during impact and thus a decrease of the residual velocity. For example, for an initial velocity equal to 6.9 m/s the residual velocity is 4.7 m/s,

4.6 m/s and 4.5 m/s for respectively 4, 5 and 6 petals. This tendency is not confirmed by drop tests' results (Table. 2).

5. Conclusion and remarks

Thin sheets of 2024 AA were perforated, on a drop test, by a 60° and 45 mm diameter conical striker for a range of velocity from 2.7 m/s to 6.9 m/s. The energy needed to perforate is about 160 J. Four or more than four petals always appear in the sheet during perforation. A numerical model and an analytical model were proposed. Shell element model coupled with Johnson Cook viscoplastic and damage laws is adapted to simulate the perforation of thin sheet of aluminum alloy. The ballistic limit velocity, the residual velocity as well as the impact are in good agreement with experimental data. It can be shown that simulated force during impact is below the experimental force. The analytical model also predicts the residual velocity.

Simulations using an anisotropic material model for rolled sheets are underway and predict petals' formation during perforation (Fig. 8). Future analysis of pictures taken by high speed camera, beneath the sheet, will permit to perform image correlation for strain measurements in order to correlate the simulated strain field and the experimental strain field and therefore to better analyze the crack propagation (fracture criterion).

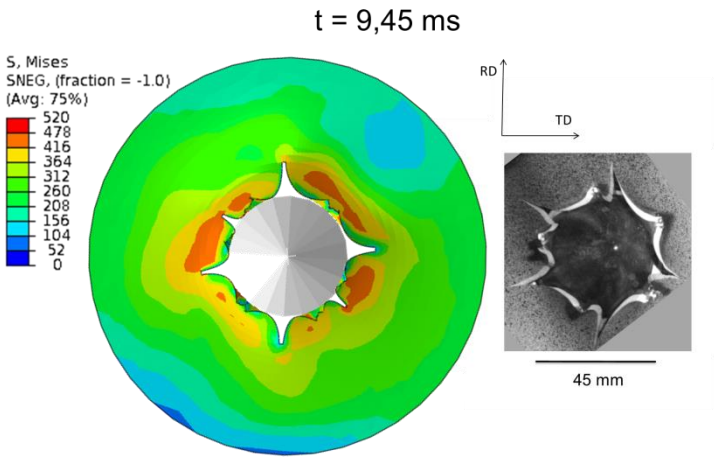

Figure 8. Simulation versus experiment for an initial velocity of 6.9 m/s using an anisotropic material model.

Abstract This paper examines the perforation of Weldox460E steel plates struck normally by rigid conical-nosed projectiles through numerical simulations. The modified Johnson-Cook constitutive relation and the Gruneisen equation of state for metal plates are implemented in ABAQUS/Explicit as a user-defined material model by means of a subroutine (VUMAT). Numerical simulations are conducted on the perforation of Weldox460E steel plates struck normally by conical-nosed projectiles and flat-ended projectiles, it is shown that the numerical results are in good agreement with experiments. Finally, the effects of various cone angles of conical-nosed projectiles on the failure modes of metal plates and the energies absorbed for perforation are discussed.

Keywords Metal plates; Conical-nosed projectiles; Impact; Perforation; Numerical simulation

1. Introduction

An understanding of the response of structures subjected to intense dynamic loads which produce large inelastic deformation and failure is very important for safety calculations and assessment in various engineering such as nuclear, chemical, transport, offshore, naval, aerospace, and defense industries. In particular, the deformation and perforation behavior of plates is important for the design of offshore and protective structures against projectiles, fragments generated from explosion or dropped objects. The problem has been extensively studied in the past, and several studies are available in literature. Comprehensive reviews on the subject can be found in the papers by Backman and Goldsmith [1], Corbett et al. [2], and Goldsmith [3].

Borvik et al. [4-6] carried out experimental and axi-symmetric numerical investigation of Weldox steel plates struck normally by blunt, hemispherical and conical nosed projectiles. The effects of target strength and projectile nose shape on the failure modes and ballistic limits of steel plates are studied. Rosenberg et al. [7] examined the process of ductile plate perforation by sharp-nosed rigid projectiles through 2D numerical simulations, and the normalized resisting stress exerted by the plates can be simply related to the normalized thickness of the plates.

Iqbal et al. [8, 9] performed three-dimensional numerical simulations to study the behavior of ductile targets subjected to normal and oblique impact by sharp nosed cylindrical projectiles. Gupta et al. [10] dealed with the experimental and numerical investigations of aluminum target plates impacted by blunt, ogive and hemispherical nosed steel projectiles, and the effect of projectile nose shape, impact velocity and plate thickness on the deformation of the target plates was studied. Sun [11] carried out axi-symmetric numerical simulations of Weldox460E steel plates struck normally by flat-ended and conical-nosed projectiles using a viscoplastic constitutive model combined with ductile damage.

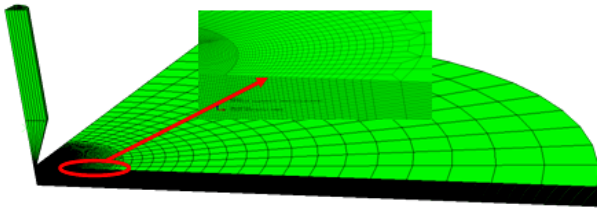
In this paper, numerical simulations are conducted on the perforation of Weldox460E steel plates struck normally by rigid conical-nosed projectiles and flat-ended projectiles. The modified Johnson-Cook constitutive relation and the Gruneisen equation of state which are valid for metals subjected to impact for large strains, high strain rates and high temperatures are implemented in ABAQUS/Explicit as a user-defined material model by means of a subroutine (VUMAT). Comparisons of the numerical results and the experiments show that the finite element models developed here are reliable. Based on the verified finite element model, numerical simulations are performed on the perforation of 6mm thick Weldox460E steel plates struck normally by conical-nosed projectiles with various cone angles, and the effects of various cone angles on the failure modes of metal plates and the energies absorbed for perforation are discussed.

2. Numerical simulation

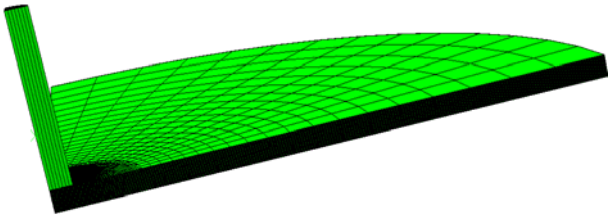
In this section, numerical simulations are conducted on the perforation of Weldox460E steel plates struck normally by rigid conical-nosed projectiles and flat-ended projectiles, the cone angles of which are equal to 180^{o} as a special case of conical-nosed projectiles, using dynamic finite element code ABAQUS/Explicit. The targets was modelled using the modified Johnson-Cook constitutive relation which was implemented as a user-defined material model by means of a subroutine (VUMAT).

2.1. Finite element model

Finite element model in this section is based on the experiments of normal impact of Weldox460E steel plates by conical-nosed projectiles and flat-ended projectiles [4][12]. The projectiles have a nominal mass (G) and diameter ($d=2a$) of 197g and 20mm, respectively. The total length (L) and the cone angle (θ) of the conical-nosed projectile is 98mm and 33^{o}, and the total length (L) of the flat-ended projectile is 80mm. Projectiles were manufactured from Arne tool steel which has high strength and hardness, and it was observed that the plastic deformation of the projectiles was very small after perforation. In order to save CPU time and raise computational efficiency, projectiles are assumed to be rigid here. The target plates, having a span diameter ($S=2R$) of 500mm, were restrained at their periphery with respect to all degree of freedoms. Quarter models are used in the 3D finite element analysis, as seen in Fig. 1.



(a) Conical-nosed projectile



(b) Flat-ended projectile

Figure 1. Finite element model for Weldox460E steel plate struck normally by conical-nosed and flat-ended projectile.

As shown in Fig.1, the target was meshed with eight node brick elements, and all the meshes contained three regions: a finely zoned region which had noticeable effect on computational accuracy, a coarsely zoned region which did not have noticeable effect on computational accuracy, and a transitional region between the two regions above. The meshing method adopted here resolved the contradiction between mesh size and computational accuracy and efficiency to some extent. The element size in finely zoned region was taken to be 0.3mm×0.3mm×0.3mm approximately [5][9]. The diameter of the finely zoned region was 18mm (about 1.5 times as great as projectile diameter). The element size in transitional region and coarsely zoned region was increased from the central part to the outer part of the target. The element type used in the model was 8-node reduced integration elements (C3D8R). Contact between the projectile and target was assigned using the general contact algorithm. The value of coefficient of friction was hard to be measured accurately from experiments, and often taken to be 0~0.05 in literatures for penetration and perforation of metal plates by conical-nosed projectiles [5][7][11][13], and a coefficient of friction of 0.03 was considered here. For the perforation of Weldox460E steel plates by flat-end projectiles, a coefficient of friction of 0.0 was considered [10-12].

2.2. Constitutive relation

The modified Johnson-Cook constitutive relation is adopted for Weldox460E steel target [6]. The model includes linear thermoelasticity, the von Mises yield criterion, the associated flow rule, isotropic strain hardening, strain-rate hardening and softening due to adiabatic heating, and is valid for metals subjected to large strains, high strain rates and high temperatures. The equivalent stress is expressed as

$$\sigma_{eq} = \left(A + B\varepsilon^{n}{}_{eq}\right)\left(1 + \dot{\varepsilon}^{*}_{eq}\right)^{c}\left(1 - T^{*m}\right) \tag{1}$$

where A，B，C，n，m are material constants; ε_{eq} is the equivalent plastic strain; $\dot{\varepsilon}^{*}_{eq} = \dot{\varepsilon}_{eq}/\dot{\varepsilon}_{0}$ is the dimensionless strain rate, where $\dot{\varepsilon}_{0}$ is a user-defined reference strain rate; $T^{*} = \left(T - T_r\right)/\left(T_m - T_r\right)$ is the homologous temperature, where T is the absolute temperature, T_r is the room temperature, T_m is the melting temperature of the target material, respectively.

Johnson and Cook also developed a failure criterion that accounts for temperature, strain rate

and strain path in addition to the triaxiality of the stress state. The damage variable D has the basic form

$$D = \sum \frac{\Delta \varepsilon_{eq}}{\varepsilon_f} \tag{2}$$

where $\Delta\varepsilon_{eq}$ is the increment of accumulated plastic strain and ε_f is the fracture strain given as

$$\varepsilon_f = \left(D_1 + D_2 \exp\left(D_3 \sigma^*\right)\right)\left(1 + \dot{\varepsilon}^*_{eq}\right)^{D_4}\left(1 + D_5 T^*\right) \tag{3}$$

where D_1、D_2、D_3、D_4、D_5 are material constants, $\sigma^*=\sigma_H/\sigma_{eq}$ is the stress triaxiality ratio and σ_H is the mean stress. The temperature increment (ΔT) during perforation is calculated as

$$\Delta T = \int_0^{\varepsilon_{eq}} \chi \frac{\sigma_{eq} d\varepsilon_{eq}}{\rho_t C_p} \tag{4}$$

where ρ_t is the material density, C_p is the specific heat, χ is the coefficient that represents the proportion of plastic work converted into heat.

The damage variable D (Eq. 2) takes values between 0 (undamaged) and 1 (fully broken). When the damage variable D equals to 1, the damaged element will be removed from the mesh in the simulations. Meanwhile, the erosion strain (ε_c) of 2.0 is defined in the simulations in order to ensure that elements which are heavily deformed will not stop the computation process. The erosion strain (ε_c) of 2.0 is high enough to avoid any problems with mass erosion in the target [7]. When the equivalent plastic strain (ε_{eq}) is greater than the erosion strain (ε_c), the element will be removed.

The Gruneisen equation of state is employed, viz.

$$P = \rho_t C_0^2 \frac{\lambda}{(1 - s_1 \lambda)^2}\left(1 - \frac{\Gamma_0 \lambda}{2}\right) + \Gamma_0 \rho_t E_m \tag{5}$$

where P is hydrostatic pressure, C_0, S_1 and Γ_0 are material constants, E_m is specific internal energy of target material, and $\lambda = 1 - V/V_0$, where V is current volume and V_0 is initial volume.

The material parameters for Weldox460E steel target given in Table 1 are taken from Dey et al. [6]. E is the elastic moduli and ν is the Poisson's ratio of the target.

2.3. Simulation results

Fig.2 shows comparisons of the simulation results and the experimental data obtained by Borvik et al. [4] in terms of residual velocity for 12mm thick Weldox460E steel plates struck normally by conical-nosed projectiles with diameter (20mm), mass (197g) and cone angle (θ=33^o). Fig.3 shows comparisons of the simulation plot and the experimental image of the target after full perforation when the strike velocity of the projectile is 300.3m/s.

Table 1. Material parameters for Weldox460E steel targets [6]

E (GPa)	210	D_3	-2.969
ν	0.33	D_4	-0.014
ρ_t (kg/m^3)	7850	D_5	1.014
A (MPa)	499	C_p (J/kgK)	452
B (MPa)	382	χ	0.9
n	0.458	T_m (K)	1800

D_2	1.936		

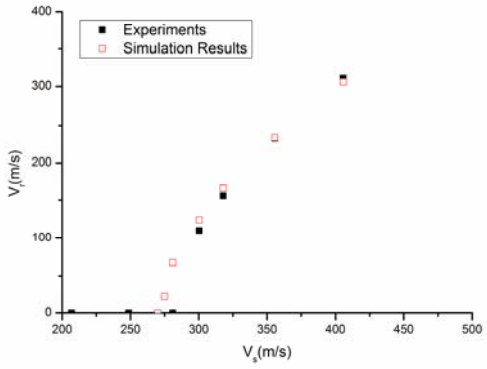

Figure 2. Comparisons of the simulation results with the experimental data [4] in terms of residual velocity for 12mm thick Weldox460E steel plates struck normally by conical-nosed projectiles.

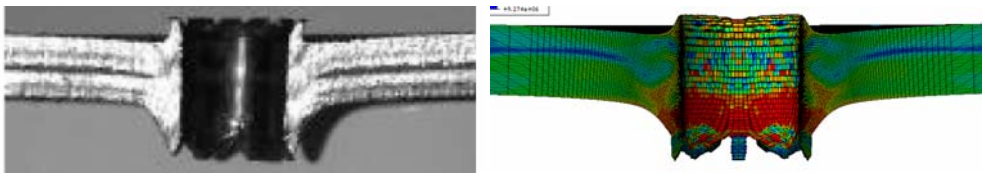

Figure 3. Comparisons of the simulation plot and the experimental image of 12mm thick Weldox460E steel plate after full perforation.

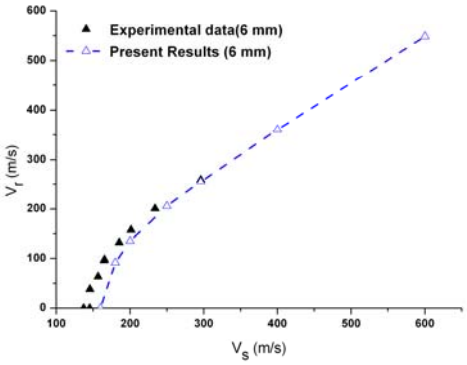
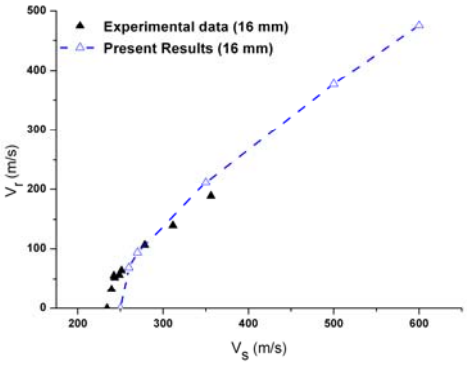
Fig.4 shows comparisons of the simulation results and the experimental data obtained by Borvik et al. [12] in terms of residual velocity for 6mm and 16mm thick Weldox460E steel plates struck normally by flat-ended projectiles with diameter (20mm), mass (197g). Fig.5 shows comparisons of the simulation plot and the experimental image of the plate after full perforation.

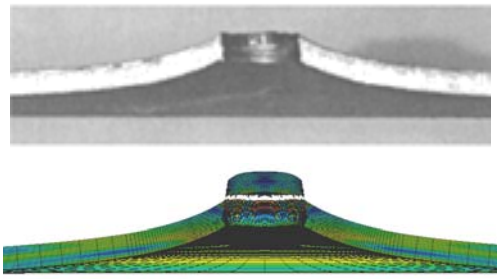


(a) 6mm thick Weldox460E steel plates

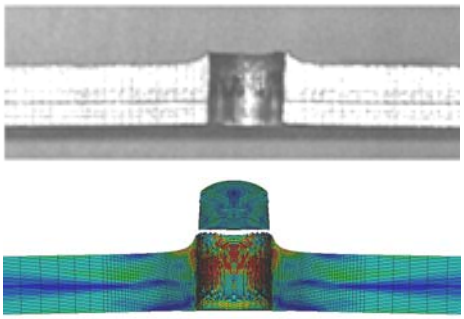


(b) 16mm thick Weldox460E steel plates

Fig.4 Comparisons of the simulation results with the experimental data [12] in terms of residual velocity for 6mm and 16mm thick Weldox460E steel plates struck normally by flat-ended projectiles.



(a) 6mm thick Weldox460E steel plates



(b) 16mm thick Weldox460E steel plates

Fig.5 Comparisons of the simulation plot and the experimental image of 6mm and 16mm thick Weldox460E steel plate after full perforation.

It is evident from Fig.2 to Fig.5 that the simulation results are in good agreement with the experimental results, and the finite element model is reliable. Based on the present FE model, perforation of 6mm thick Weldox460E steel plates struck normally by rigid conical-nosed projectiles with various cone angles will be analyzed in the following section.

3. Numerical simulations for conical-nosed projectiles with various cone angles

In this section, the perforation behaviors of 6mm thick Weldox460E steel plates under normal impact by conical-nosed projectiles with cone angle θ=20°、60°、100° and 140° are analyzed by numerical simulations. The projectiles with various cone angles have the same effective length L_{eff}, $L_{eff}=4M/\left(\rho_t \pi d^2\right)$, the diameter ($d$) and the mass ($M$) of which are 20mm and 197g, respectively. Thus, the total lengths of projectiles with θ=20°、60°、100° and 140° are 111.2mm, 88.9mm, 83.9mm and 81.2mm, respectively. The strike velocities of the projectiles are 200 m/s.

Fig.6 shows the perforation process of 6mm thick Weldox460E steel plate under normal impact by conical-nosed projectile with θ=20° through numerical simulation. It can be seen clearly from Fig.6 that the materials accumulated aside the perforation hole is formed by radial expansion. Thus, it is deduced that the dominant failure mode here is ductile hole enlargement with global deformation.

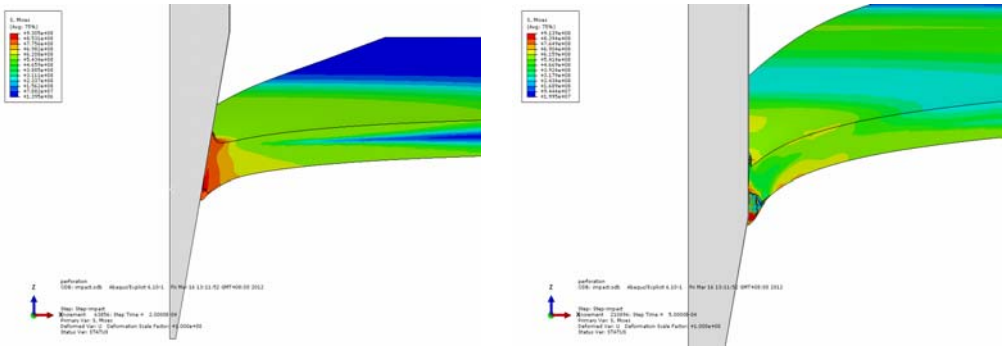


Figure 6. The perforation process of 6mm thick Weldox460E steel plate under normal impact by projectile with θ=20° through numerical simulation.

Fig.7 shows the perforation process of 6mm thick Weldox460E steel plate under normal impact by conical-nosed projectile with θ=60° through numerical simulation. It can be seen clearly from Fig.7 that local bending occurs for the materials beside the projectile, and the dominant failure mode is classified to petalling with global deformation.

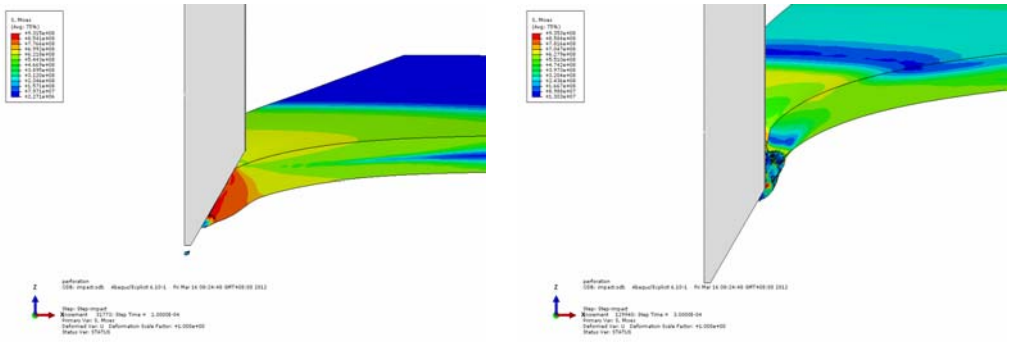

Figure 7. The perforation process of 6mm thick Weldox460E steel plate under normal impact by projectile with θ=60^{o} through numerical simulation.

Fig.8 shows the perforation process of 6mm thick Weldox460E steel plate under normal impact by conical-nosed projectile with θ=100^{o} through numerical simulation. It can be seen from Fig.8 that a plug of diameter larger than the diameter of the projectile is ejected. The crack occurs firstly at the distal surface of the plate, and then propagates to the frontal surface of the plate, finally a full plug is ejected due to stretching and shearing. The plug is formed due to the mixed failure mode of stretching and shearing, and the failure mode here is classified to discing with global deformation.

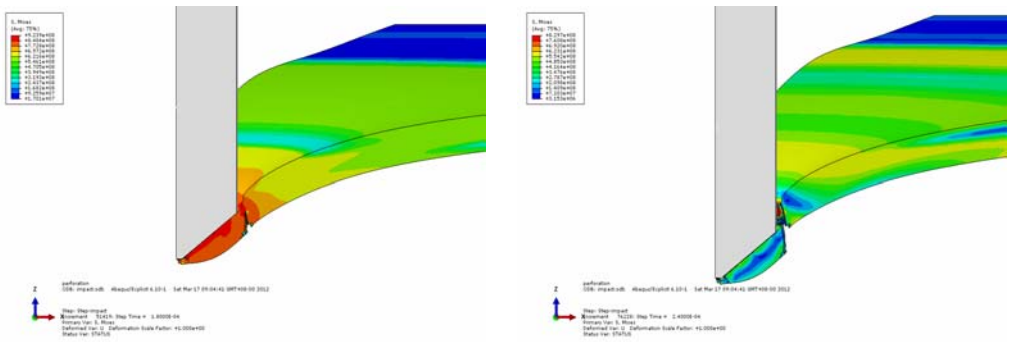

Figure 8. The perforation process of 6mm thick Weldox460E steel plate under normal impact by projectile with θ=100^{o} through numerical simulation.

Fig.9 shows the perforation process of 6mm thick Weldox460E steel plate under normal impact by conical-nosed projectile with θ=140^{o} through numerical simulation. It can be seen from Fig.9 that a plug is ejected which is similar to that in Fig.8, but the difference is that the diameter of the plug here is less than that in Fig.8, which is approximately equal to the diameter of the projectile. The plug is formed mainly due to the failure mode of shearing, and the failure mode here is classified to plugging with global deformation.

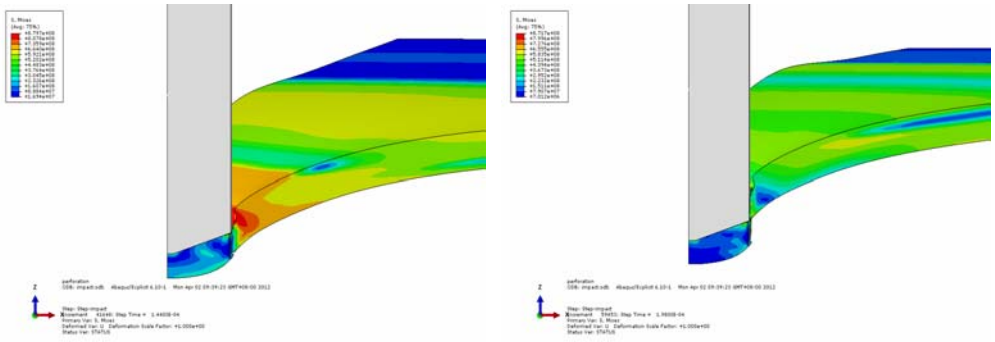

Figure 9. The perforation process of 6mm thick Weldox460E steel plate under normal impact by projectile with θ=140^o through numerical simulation.

As seen from Fig.6 to Fig.9, it is shown that projectile cone angle has significant effect on the perforation modes of 6mm thick Weldox460E steel plates and that for smaller cone angles plates fail by ductile hole enlargement, for medium cone angles plates fail by petalling and for larger cone angles plates fail by discing or plugging.

Fig.10 shows the numerical residual velocity V_r for 6mm thick Weldox460E steel plates struck normally by conical-nosed projectiles with θ=20^o, 60^o, 100^o and 140^o.

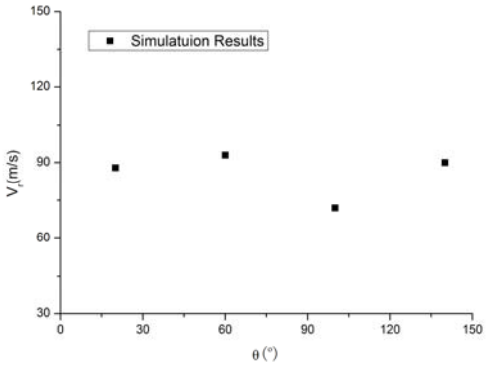

Figure 10. Numerical residual velocity V_r for 6mm thick Weldox460E steel plates struck normally by conical-nosed projectiles with various cone angles

As shown in Fig.10, the residual velocity of projectile is closely related to the failure mode of the target plate, and the residual velocity is not always decreasing sensuously with the increment of the projectile cone angles. The residual velocities for various projectile cone angles θ=20^o, 60^o, 100^o and 140^o in present simulations are 88m/s, 93m/s, 72m/s and 90m/s, respectively. The energy dissipated for the perforation of target plate failed in ductile hole enlargement with global deformation struck normally by conical-nosed projectile with θ=20^o is larger than that for the perforation of target plate failed in petalling with global deformation struck normally by conical-nosed projectile with θ=60^o. The energy dissipated for the perforation of target plate failed in discing with global deformation struck normally by conical-nosed projectile with θ=100^o is larger than those by projectile cone angle θ=20^o and 60^o, and obviously larger than that for the perforation of target plate failed in plugging with global deformation struck normally by conical-nosed projectile with θ=140^o. It is found that the energy dissipated by discing is maximum.

3. Conclusions

In the present paper, a numerical study has been conducted on the perforation of Weldox460E steel plates subjected to impact by rigid conical-nosed projectiles at normal incidence using dynamic finite element code ABAQUS/Explicit. The targets was modelled using the modified Johnson-Cook constitutive relation which was implemented as a user-defined material model by means of a subroutine (VUMAT). The numerical results are in good agreement with the experiments in terms of the patterns of targets after full perforation and the residual velocities, it is shown that the finite element models developed here are reliable. Based on the verified finite element model, numerical simulations are performed on the perforation of 6mm thick Weldox460E steel plates struck normally by conical-nosed projectiles with various cone angles. It is found that the energy dissipated for the perforation is closely related to the failure mode of the target plate, and the energy dissipated is not always increasing sensuously with the increment of the projectile cone angles. It is shown that the energy dissipated by discing is maximum.

Abstract
Advanced ceramic materials are frequently used in the machining of hardened steels, aerospace alloys and other abrasive materials. While these materials have many superior properties such as high hardness and abrasive resistance they are still prone to premature failure due to fracture. Accurate fracture properties of such materials are scarce, especially in the dynamic regime. The current work presents a novel combined experimental-numerical approach to determine dynamic fracture behavior. In recent years, much attention has been given to the study of dynamic behavior of materials under stress-wave loading. Experimentation with a modified Kolsky bar and a concurrent numerical investigation using the finite volume method was used in this study. The inherent difficulties in producing large amounts of advanced ceramic means that experiments must be carried out using very small samples. As a result the apparatus has been miniaturised to accommodate such specimen dimensions. The incident and reflected wave histories obtained experimentally in conjunction with the time to fracture of the specimen predicted numerically are used to determine fracture toughness at a number of loading rates.
Presented is a novel and simple test method to determine fracture properties of advanced ceramics using a miniaturised Kolsky bar. Results indicate a change in fracture toughness at increased rates of loading. This may be due to the complicated underlying microstructure of the materials under investigation, which behave differently under varying loading rates.

Keywords Dynamic Fracture, miniaturized Kolsky bar, advanced ceramics

1. Introduction

As opposed to static fracture toughness, no standard methodology yet exists for the determination of the dynamic fracture toughness of materials. Under static conditions the stress intensity factor at the crack tip is proportional to the applied load, under dynamic loading this does not hold true. This is due to the inertial effects, which result from the transient loading conditions. Other factors affecting the determination of dynamic fracture toughness include wave propagation within the test specimen and the accurate determination of crack initiation.

Traditionally dynamic fracture experiments were performed using the instrumented Charpy pendulum [1]. In this test setup strain gauges mounted on the hammerhead measure the response resulting from the impact on a specimen, [2, 3]. While this test method is well established and easily performed there exists a number of drawbacks. During the dynamic impact strong inertial forces affect the load applied at the crack tip. The hammer impact load is recorded by the strain gauge located at its head and this is used to determine the fracture parameters through the resulting load-time history. However due to the inertial forces present the applied load recorded by the

hammer head will be significantly different to that experienced at the crack tip. The impact of the hammer on the specimen will generate longitudinal and traverse stress waves within the specimen and these stress waves will influence the stress intensity factor at the crack tip [4]. Experimental results from the Charpy test are therefore difficult to interpret, as large inertial oscillations are often present in the load-time histories.

To overcome the limitations posed by traditional dynamic test methods much attention has recently been given to the study of dynamic behavior of materials under stress wave loading using a modified Kolsky bar, [5, 6, 7]. The Kolsky bar apparatus allows for fracture testing at rates greater the 10^6 MPa$\sqrt{m}$ s^{-1} therefore simulating more realistic loading conditions experienced by super-hard materials during operation. Both the tensile and compressive loading configurations have been adopted for fracture testing. For the most part compressive stress pulse loading has been most popular and following on from the standard quasi-static setup the high rate-bending configuration has proliferated. Detailed descriptions of all Hopkinson bar fracture tests can be found in a review paper by Fengchun *et al*. [8].

Fracture toughness values presented in this paper should be considered to be measured or apparent fracture toughness's, (K_{1db}) as opposed to the critical dynamic fracture toughness, (K_d). This is due to the effect of notch tip blunting in dynamic fracture tests and the effect of finite notch root radii on the overestimation of the fracture toughness as outlined by Williams and Hodgkinson, [9].

2. Experimental Set-up

2.1. One-Point Bend Fracture apparatus

The one-point bend set-up is a modification of the traditional Kolsky bar apparatus [10], where the transmission bar has been removed. The apparatus consists of a single instrumented cylindrical bar of length 300 mm and diameter 3 mm, Fig. 1. In a typical test a striker impacts the leading edge of the incident bar setting up a longitudinal stress wave. This wave propagates down the incident bar towards the specimen and subsequently reflects at the bar/specimen interface. A portion of the wave is transmitted through the interface into the specimen causing fracture. The degree to which the wave is reflected or transmitted depends on the impedance of the bar and specimen material and will be discussed later. It is of the upmost importance that the striker contact with the incident bar be a planar one. This ensures a trapezoidal wave will be generated and avoids any spurious wave reflection at the impact interface. The compressive wave can be well controlled in terms of duration and amplitude by varying the length and velocity of the striker respectively. The striker must remain less then half the incident bar length so to allow complete unloading of the striker before the arrival of the reflected wave from the impact end. The striker and incident bar both must be made of the same material. In a one-point bend configuration the specimen maintains a single point of contact with the loading apparatus. That is, the specimen remains unsupported throughout the test with no supports to restrain the free-body motion of the specimen. In this way the specimen will fracture due to inertia alone.

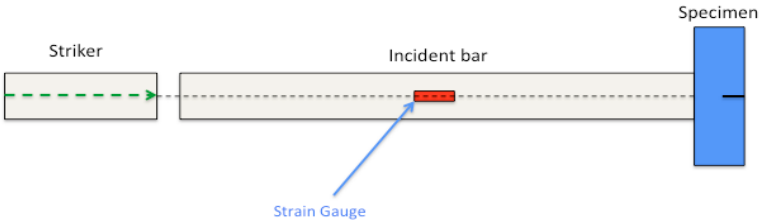

Figure 1. One-Point Bend apparatus

2.2. Material

Tests were carried out using SENB geometries. Due to inherent manufacturing constraints advanced ceramic materials have limitations on available specimen dimensions. Initial testing was carried out on PMMA with specimen span of 18 mm, height of 6 mm and thickness of 3 mm. Testing on the ceramic material was carried out on specimens with a span of 28.5 mm, height 6.25 mm and thickness of 4.76 mm. Future testing will involve specimens whose dimensions are further restricted with a span of 14 mm, height of 5 mm and thickness of 2 mm. The PMMA specimens were notched at 45-degree angle to a depth of 1 mm. Pre-cracks were subsequently introduced using a razor blade. Tests were preformed only on specimens whose pre crack was straight. For brittle materials like ceramics pre cracking is not an option and so samples had a notch root radius of 150 µm for all grades with a notch depth of 1.5 mm. Table 1. shows static fracture toughness values for PMMA and ceramic A and B. The PMMA tests were carried out using the standard three-point bend method, [11]. Static fracture results for the advanced ceramics A and B were taken from a previous study, [12] using a three-blunt notch analytical approach.

Table 1. Static Fracture toughness values

Material	K_{Ic}(MPa$\sqrt{m}$)
PMMA	1.61
Ceramic A	7.70
Ceramic B	2.80

3. Fracture Toughness determination

3.1. Data Reduction

The load applied to the specimen is given below and is based on one-dimensional wave theory, [10]:

$$P(t) = EA_0[\varepsilon_I(t) + \varepsilon_R(t)], \tag{1}$$

where E and A_o are the Young's modulus and cross-sectional area of the bar respectively. The particle velocity at the end of the incident bar is given by:

$$v = C_0[\varepsilon_I(t) - \varepsilon_R(t)], \tag{2}$$

where C_0 is the longitudinal wave velocity of the pressure bar. Integration of the velocity will also yield displacement at the end of the bar.

It is important to note that specimens must be sufficiently brittle so to fully fracture before they loose contact with the incident bar. Once the specimen leaves the end of the bar a free end boundary condition prevails and the above equations are no longer applicable. Up to this time Eq. (1) can be

used to determine the load applied to the specimen up to the point of fracture.

3.2. Fracture time (t_f) Determination

To determine fracture time a small uncalibrated strain gauge was mounted on the specimen close to the crack tip, Fig. 2. The location of the strain gauge is important, as it must be placed within the elastic region but outside the damage zone to yield accurate results [6]. Upon loading, stress within the specimen builds up and the gauge experiences a voltage change. As the crack passes the gauge an unloading wave is generated and a drop of the measured voltage indicates this. The time from the initial voltage rise to the drop off represents the fracture time. Due to the finite size of strain gauges it is difficult to place them exactly at the crack tip. In order to more accurately determine the fracture time a hybrid experimental/numerical approach is undertaken here. Modeling of the fracture specimen using the finite volume method (FVM) was done in OpenFOAM [13,14]. Strain gauge locations on the experimental samples were accurately measured and this data was adopted for the modeling work. Time up to unloading was found to agree well between the two methods. By combining experimental and numerical data increased accuracy of fracture time determination can be ensured.

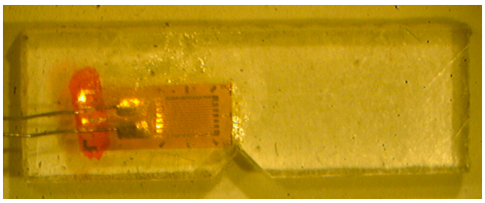

Figure 2. Strain gauge for fracture time detection

3.3. Temporal Stress Intensity Factor Determination

3.3.1. Applied load method

Dynamic fracture toughness (K_{Id}) can be determined as the critical stress intensity factor value at the crack tip at the instant of crack initiation. For Mode I fracture it is approximated as:

$$K_{Id} = K_I(t_f), \tag{3}$$

A closed form solution to predict the SIF from the measured load is applied here [15].

$$K_I(t) = \frac{3SP(t)}{4BW^{3/2}} \frac{\sqrt{\alpha}}{(1-\alpha)^{3/2}(1+3\alpha)} (1.72 + 0.23\alpha + 1.04\alpha^2 - 0.39\alpha^3), \tag{4}$$

where *P(t)* is the applied load to the sample and α is the ratio of crack length to width of the specimen (*a/W*). It has been demonstrated that this equation is valid for different crack to width ratios [8].

3.3.2. Crack tip strain

Another method for determining the SIF evolution experimentally is shown in Eq. (5). This method

relies on the direct measurement of the strain field near the crack tip by means of a strain gauge.

$$K_I(t) = \frac{\varepsilon_y(t) E \sqrt{2\pi r}}{Cos\frac{\theta}{2}\left[1 + Sin\frac{\theta}{2} Sin\frac{3\theta}{2} - \nu(1 - Sin\frac{\theta}{2} Sin\frac{3\theta}{2})\right]}, \quad (5)$$

where r is the radial distance from the crack tip to the strain gauge and θ is the angle from the crack path, [6].

4. Results & Discussion

4.1. PMMA Tests

All tests were performed at ambient temperature. The static fracture toughness has also been determined for comparison. Fig. 3(a) shows a typical incident and reflected strain trace from a fracture test. The striker velocity leaving the muzzle was approximately 8.5 m/s determined using a high-speed camera, which results in a particle velocity of 6 m/s at the load point of the apparatus from Eq. (2). Using Eq. (1) the load applied to the specimen was determined and is illustrated in Fig. 3(b). For this test the value of (a/W) was 0.33 and using Eq. (4) the temporal SIF was found as shown in Fig. 4.

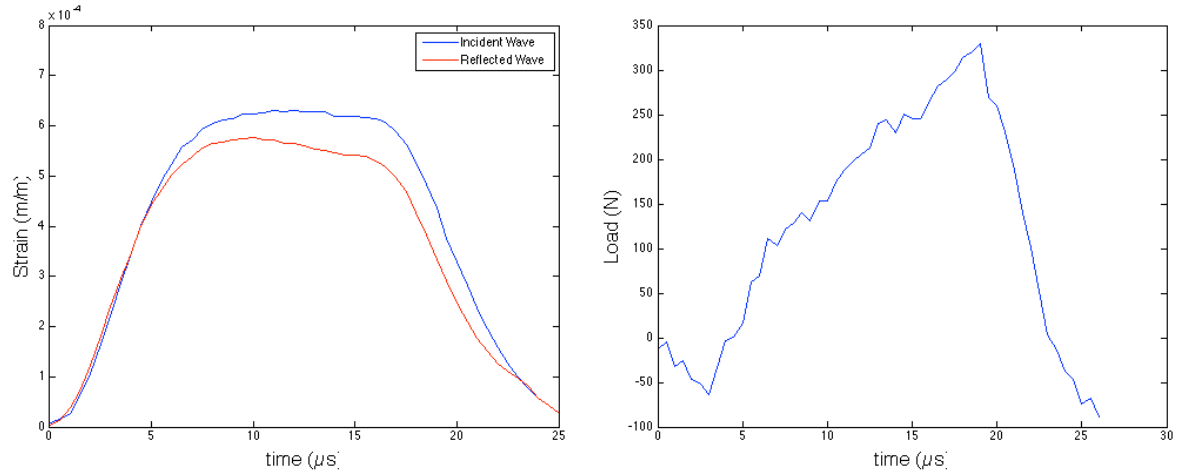

Figure 3(a). Superposition of incident and reflected strain trace, (b) Variation of applied load with time

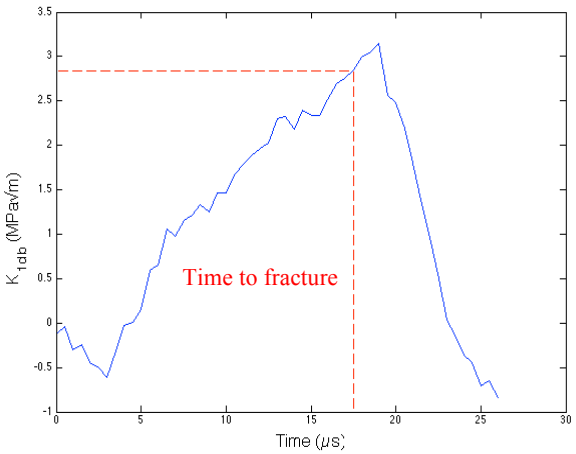

Figure 4. Stress intensity evolution for PMMA at 6m/s

Using both experimental and numerical methods the time to fracture was determined to be 17.5 μs. This yields an apparent dynamic fracture toughness for PMMA of 2.75 MPa√m from the above analysis, Fig. 4.

A number of other tests were carried out at varying loading rates. Fig. 5 shows the stress intensity evolution for a test performed at a velocity of 9.5 m/s. The variation in amplitude of the oscillations between the two tests is as a result of the increased rate of loading.

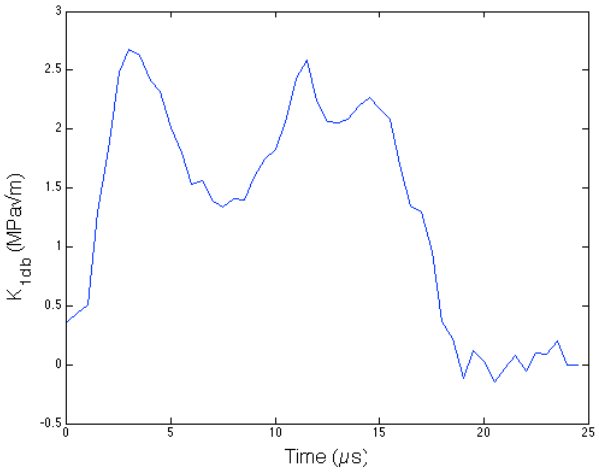

Figure 5. Stress intensity evolution For PMMA at 9.5m/s

Fracture time for the above test was 14.5 μs, which corresponds to an apparent toughness of 2.19 MPa√m. These results agree well with other authors, [5] and show fracture toughness for PMMA increases at dynamic loading rates.

The use of Eq. (5) was shown to greatly underestimate the temporal SIF. For this equation to yield accurate results it is important that the strain measurements be made within the singular zone. The strain gauges used in these tests were 1.5mm in length. Relative to the samples being tested these dimensions are quite large, and while care was taken in their placement, the strain measurements were recorded outside the singular zone therefore leading to inaccurate results. As a result of this the use of strain gauges will be restricted to determining the fracture time for later tests. It should be noted that the use of smaller strain gauges might avoid this problem.

A third method was also tested for comparison. This test procedure uses an impact response curve (IRC) for determination of dynamic fracture toughness, [16,17,18]. This method makes use of the relationship between the dynamic fracture toughness and time to fracture. The IRC is determined once for a specific test condition (impact velocity, specimen material and geometry) using FVM simulation with a contact procedure and subsequently only requires the time to fracture found through experimentation in order to determine the dynamic fracture toughness for successive tests of similar setup.

Fig. 6(a) and (b) show the IRC's determined for an OPB test setup at a particle velocity of 6 m/s using a Young's modulus of 6 GPa and 3 GPa respectively, corresponding to the dynamic and static moduli used by Ivanković and Williams, [19]. In order to determine the IRC for each case the sample was prevented from fracturing. The strain was determined directly at the crack tip in the model within the singular zone, and Eq. (5) was used to calculate the temporal SIF's for these cases. Using the time to fracture determined experimentally from an equivalent test setup the apparent

dynamic fracture toughness is found to be 3.44 MPa√m in the case where the material modulus is taken to be 6 GPa, and 2.84 MPa√m when the modulus is 3 GPa. The model with the higher, dynamic, Young's modulus is shown to overestimate the dynamic fracture toughness when compared to the load-point method presented above. Conversely, when the static Young's modulus of the material (3 GPa) is employed the model predicts an apparent dynamic fracture toughness similar to that of the load-point method, 2.84 MPa√m versus 2.75 MPa√m. This suggests that the static Young's modulus may be a more appropriate measure for this test setup. This point is further reinforced by noting that the quarter period of oscillation (14 µs) of the IRC developed using the dynamic Young's modulus, Fig. 6(a), is less then the experimentally determined fracture time of 17.5 µs, Fig. 4.

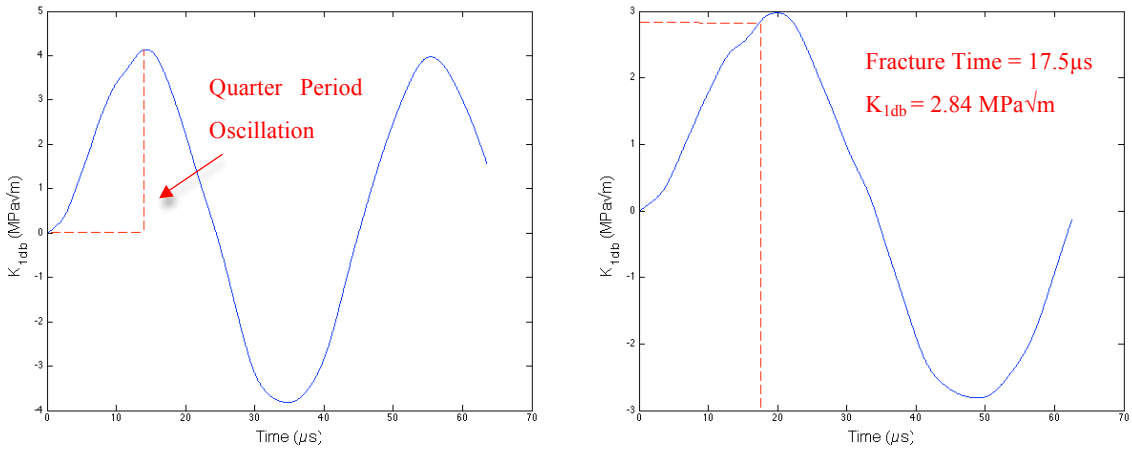

Figure 6(a). Impact Response curve Young's Modulus: 6 GPa, (b) Impact Response curve Young's modulus: 3 GPa

4.2 Advanced Ceramic Tests

A number of tests were carried out on ceramic samples. Due to the inherent difficulty in introducing pre-cracks into hard brittle materials all samples were tested with a blunt notch of 150µm in radius. As a result of this the dynamic fracture toughness values are apparent values. Static fracture toughness values were taken from previous testing [12]. Fig. 7 shows a typical strain trace superimposed on a FVM simulation test with a contact procedure implemented at the incident bar/specimen interface [20]. Very good agreement is observed between experimental and numerical tests. The samples were not instrumented during this round of tests and so only the SIF evolution from the one-dimensional analysis will be calculated. Fig. 8 shows the incident and reflected strain for two tests on samples A and B. The two grades of advanced ceramic vary in both inclusion grain size and second phase material and are denoted A and B. It can be seen from the trace that the degree to which the incident wave is reflected is very similar in both cases. This is to be expected, as at increased rates of loading the values of fracture toughness for both grades of material have been previously shown to be similar [21]. Fig. 9 shows the SIF for both grades of advanced ceramic. The time to fracture for these events was not recorded as mentioned above so a value of fracture toughness at these rates cannot be obtained. It is of interest for future work to instrument the samples using minute strain gauges close to the crack tip as per the PMMA testing. The wave speed velocity in these samples is in the region of 11,000 m/s, resulting in an extremely rapid fracture event. With this in mind future work will also focus on developing the numerical model further to ensure the most accurate determination of fracture time possible.

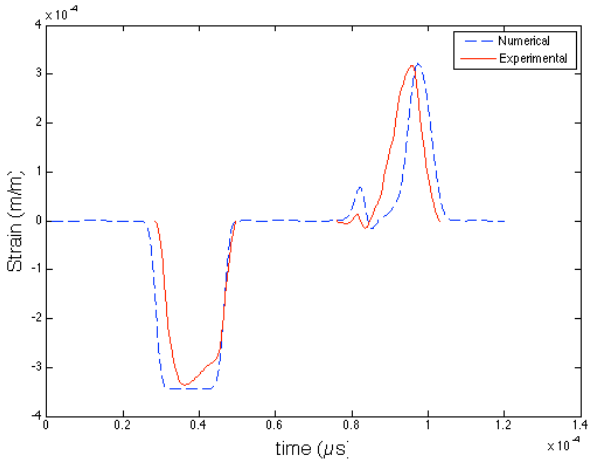

Figure 7. Numerical and experimental incident and reflected wave for ceramic sample

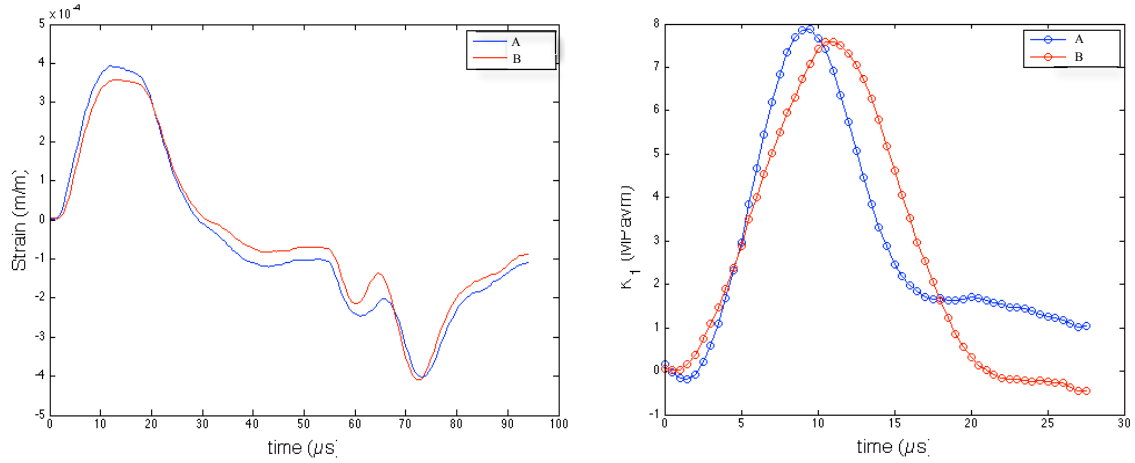

Figure 8(a). Experimental trace from tests on advanced ceramic A & B, (b) SIF evolution for advanced ceramic A & B from Eq. (5)

The difference in the incident and reflected waves in the ceramic tests is much greater than that of the PMMA tests. This is due to the difference in mechanical impedance between the test specimens and the tungsten carbide bar where more of the incident wave was transmitted through the bar/specimen interface. It is desirable to test specimens with similar impedance to that of the bar. In the case of advanced ceramics the impedance difference is low and as a result there is a notable difference between the incident and reflected traces, which allows for the clearer data analysis.

With PMMA its mechanical impedance is much lower then that of the tungsten carbide bars. In view of this fact it is not surprising that the reflected and incident signals are of similar amplitude as very little of the incident wave can be transferred to the specimen for fracture. For relatively low impedance materials it is recommended that a low impedance bar be used as the loading apparatus.

5. Conclusions

A novel experimental method for determining the dynamic fracture toughness of super-hard materials where specimen dimensions are limited was presented. This was achieved using a miniaturized Kolsky bar in one-point fracture. Preliminary tests were undertaken to determine the dynamic fracture toughness of PMMA. It has been shown that at increased loading rates the fracture

toughness of PMMA increases. A comparison of methods to determine SIF evolution was examined. One method using the applied load up to the point of fracture, another method, measuring strain directly on the sample close to the crack tip and a third through the use of an impact response curve. It was shown that strain measurements directly on the sample greatly underestimate the SIF. This is due to the strain measurements being erroneous as they were taken outside the singular zone. The impact response curve yielded apparent dynamic fracture toughness very similar to that of the load-point method. The strain used to calculate the IRC was measured directly on the crack tip in the model, which should lead to a more accurate calculation of SIF even when using static formula. Future testing will focus on detailed experimental work concurrent with numerical analysis to investigate the validity of these methods with emphasis on the use of impact response curves to determine dynamic fracture toughness. No attempt has been made to explain the observed increase in apparent fracture toughness at this stage, although it is in the scope for future testing.

The dynamic SIF evolution of two grades of advanced ceramic was investigated. At high rates of loading the fracture toughness of these grades was shown to decrease from their static values. A numerical model of the one-point bend set up has also been developed and excellent agreement between experimental and numerical results has been achieved. Future work will focus on further development of the model to determine the fracture time, a vital fracture parameter for accurate determination of dynamic fracture toughness.

Abstract The propagation characteristic of stress wave impinging at the interface between initially stressed film and substrate is analyzed to reveal the effect of residual stress on the fracture behavior of such layered structure. In particular, the response of the layered structure to both stress wave and residual stress is investigated based on an axis-symmetric model including a centric coin-shape interface crack. The dispersion of the stress wave and the dynamic stress concentration around the interface crack tip are discussed with the crack surface contacting behavior being involved in the model. It is revealed that the strain energy release rate at the crack tip would be dependent on the interface crack length. The results also indicate that the residual stress would influence greatly the in-plane stress of the film and therefore determine the fracture pattern of the film.

Keywords Layered structure, Residual stress, Stress wave, Interface crack

1. Introduction

The impact method with coated bullet was developed by Wu et al [1] to evaluate the interface adhesion of film to substrate. In such measurement, an initial compressive stress pulse is produced by impacting the substrate of the specimen under test with the coated front end, of which the reflection would induce tensile stress around the tested interface. Theoretically, the initial compressive pulse can be calculated as

$$p_0 = -v_0(\rho c)_1(\rho c)_2 / ((\rho c)_1 + (\rho c)_2) . \quad (1)$$

Where v_0 is the relative impinging velocity of the bullet to the specimen, $(rc)_1$ represents the acoustic impedance of the bullet coat and $(rc)_2$ the acoustic impedance of the specimen substrate [2]. The experimental results have revealed that the reflection of the input compressive pulse could separate the film off the substrate clearly [2]. Moreover, it is also indicated that the initial stress state of the specimen may influence the fracture behavior of the film and the interface. Generally speaking, the initial stress, also known as residual stress, varies according to the material treatment processes. Actually, the previous research verified that the film stress and the interface stress around the impact region edge will be greatly changed by the initial stress state in the specimen subjected to coated bullet impact [3].

The fracture may arise first within the film or at the interface depending on the comparison of the stress level to the toughness of the film or the interface. Once the interface crack exists before the specimen is impacted, the interface crack may influence the propagation and evolution of the impinged stress pulse. Therefore, this present work focus on the behavior of the interface crack between the film and substrate under impact test. First, the axis-symmetry cracked model was set up to investigate the impact responses of the structure with treating the initial impact as an input compressive stress pulse as shown in Fig. 1. Then, the propagation and evolution of the stress pulse and thereafter the deformation, stress and strain energy of the specimen are calculated for the cases of different crack length. Finally, the influence of the residual stress on the impact response of the cracked specimen is investigated for the three cases of initially stress free, initially compressed and

initially tensioned film.

2. Theoretical formula and modeling

The axis-symmetry model sketch is shown in Fig. 1, in which the symbol *t_s=5mm* and *t_f* =0.25mm represents the thickness of the substrate and film, respectively; *r_s=50mm* is the radius of the specimen, *r_b=7.5mm* indicates the coverage radius of the impact region. And *l_c* represents the interface crack length and will be set as 10~100 percent of the magnitude of *r_b*. Moreover, the two parameters defining the compressive pulse are $\Delta\tau$ =0.05μs and p_0 =800MPa. The symmetry constraints are applied at the symmetry axis and the displacement at the boundary of the circular specimen are restricted as shown in Fig. 1.

The densities of the substrate and film are 7850kg/m^3 and 8800kg/m^3, respectively. The ideal elasticity is assumed for the specimen and the elastic modulus of the substrate and film are 200e9 Pa and 210e9 Pa, respectively. The Poisson's ratio of the substrate and film are 0.29 and 0.31 respectively.

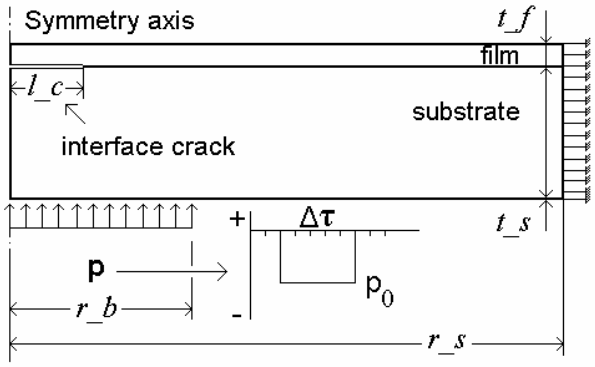

Fig. 1 Model sketch of the system of film and substrate with interface crack

The discretized model is shown in Fig. 2. In detail, the film is divided as five segments through its thickness. Thus, the linear element size is nearly one fifth of the film thickness. The contact elements are adopted at the crack surface for both the film and substrate, for which the coulomb friction law is used to simulate the probable surface friction induced shearing between the crack surfaces.

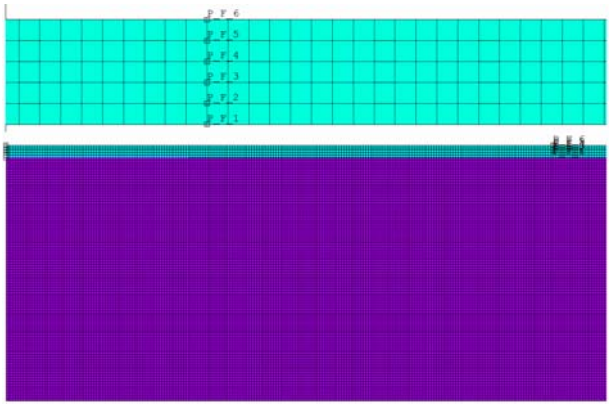

Fig. 2 Discretized model of the film and substrate

As far as the initial stress state is considered, three cases are analyzed. That is, the results denoted by NRS represents the case of the initially stress free film; TRS represents the case of that the film

being initially biaxial tensioned to 300MPa; CRS corresponds to the case that the film being initially biaxial compressed to -300MPa.

3. Results and discussion

The interface normal stress acting at the center point of the impacted region is shown in Fig. 3, which is named as SY_I and the symbol '+' and '-' represent the film side of the interface crack surface and the substrate side, respectively. It is indicated that the interface crack would permit the transmission of compressive stress pulse while deny the transmission of tensile stress. It is also shown that the normal stress is almost continuous across the interface, as one can see that the two curves corresponding to the results of the two nodes across the interface almost identical.

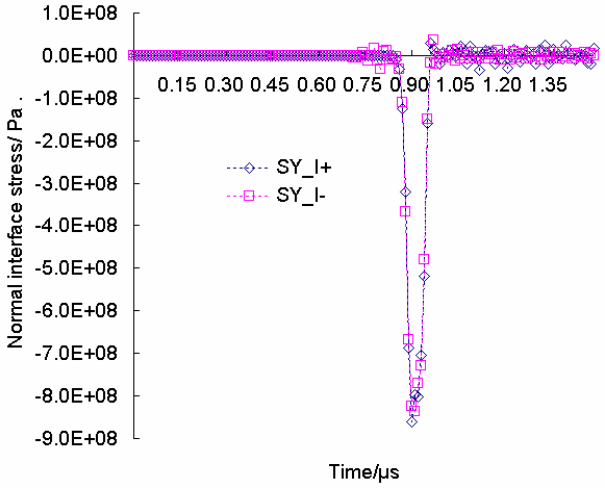

Fig. 3 Normal stress acting at the interface center point

The interface normal stress acting at the third interface node numbered from the interface crack tip is shown in Fig. 4, which is denoted by SY_INTE2 with the symbols '+' and '-' of the same meaning as aforementioned. Great tensile stress pulse appears after the reflection of the transmitted part of the input stress pulse at the free surface of the film. This is thought to be the principle driving force for the interface crack extension.

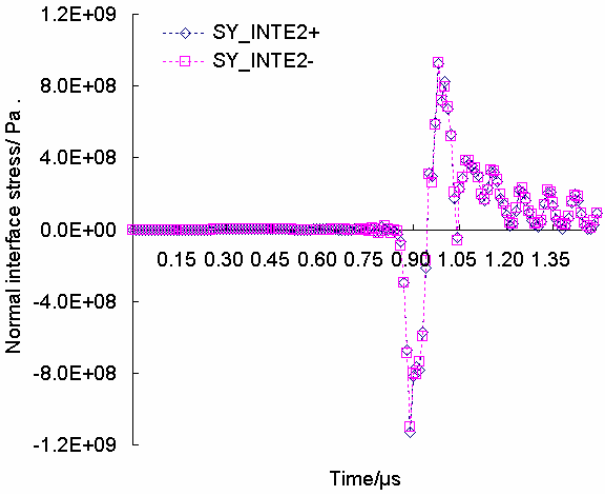

Fig. 4 Normal stress acting at the outer node close to the interface crack tip

The normal stress and shear stress contours for the time point t=1.03μs are shown in Figs.5 and 6,

respectively. It is to be noted that the deformation is magnified by 100 times to reveal the details of the interface crack. Obvious crack open displacement and stress concentration can be found around the crack tip. Moreover, the difference in the normal stress acting where before and after the crack tip the obstructing effects of the interface crack on the propagation of the tensile stress pulse.

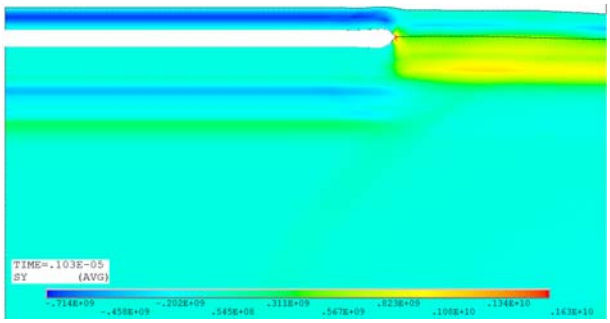

Fig. 5 Magnified contour of stress component SY at the time point t=1.03μs

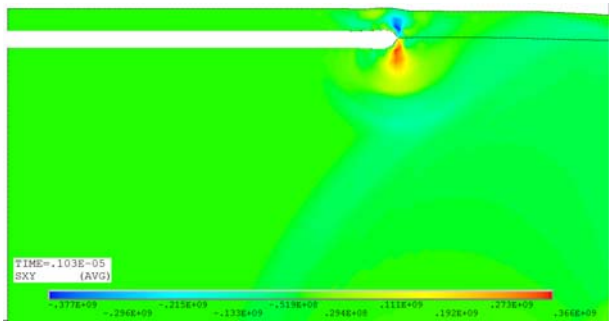

Fig. 6 Magnified contour of stress component SXY at the time point t=1.03μs

The crack open displacement at the node 5μm away from the crack tip is further shown in Fig. 7. It is verified again that the crack is always open after the compressive pulse transmits across the interface crack, although some slight fluctuation arises due to the quick reciprocating of the film under impacting.

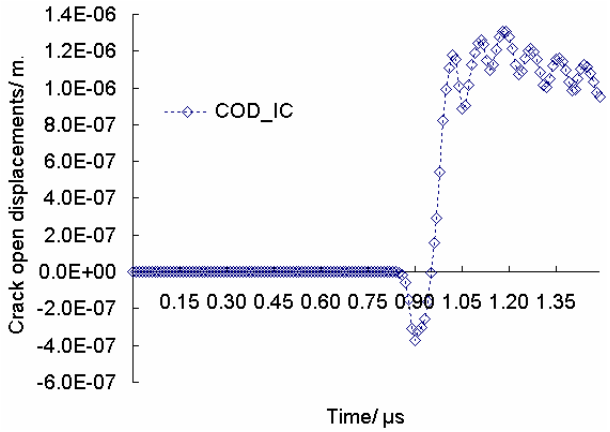

Fig. 7 Crack open displacement at the inner node 5μm away from the crack tip

The peak values of normalized dynamic strain energy release rate [4] (DSERR) versus crack length are shown in Fig. 8 for the model under the three initial stress states, in which the time value in bracket denote the time point when the peak value arises. One can see that the maximum DSERR appears when the crack length if about 65 percent of the impact region radius. One can also see that the peak value of DSERR almost all appears around the time point t=1μs if the crack length is less than 75 percent of the impact region radius, while the time when peak value arises will be

postponed obviously with the increasing of crack length. This may partly due to the dispersion of the stress wave around the impact region edge.

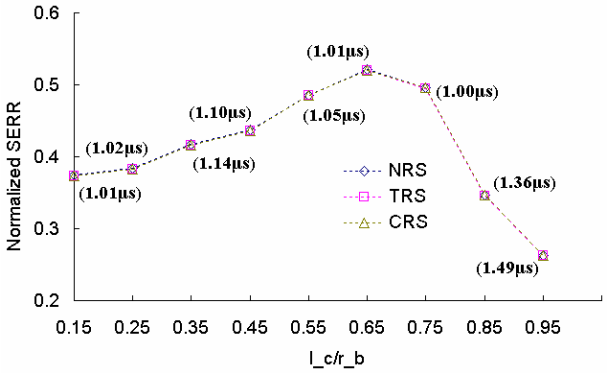

Fig. 8 Peak values of normalized strain energy release rate versus crack length

Anyway, these results in Fig. 8 indicated that the strain release rate is not altered by the in-plane residual stress in the film. Moreover, the interface stresses are neither influenced by the residual stress, as shown in Figs.9 and 10. However, the film stress will be greatly dependent on the residual stress states, which can be found in Fig. 11. A high degree of similarity of the three curves corresponding to the three initial stress states is also in the nature of things considering the ideal elasticity consumption adopted in this model.

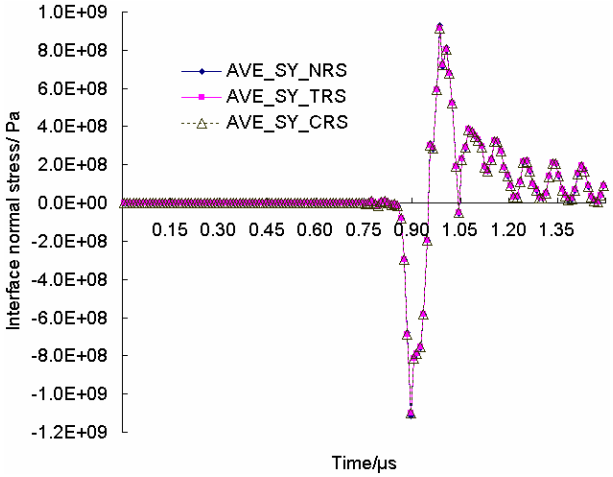

Fig. 9 Normal stress acting at the outer node close to the interface crack tip for the three initial states

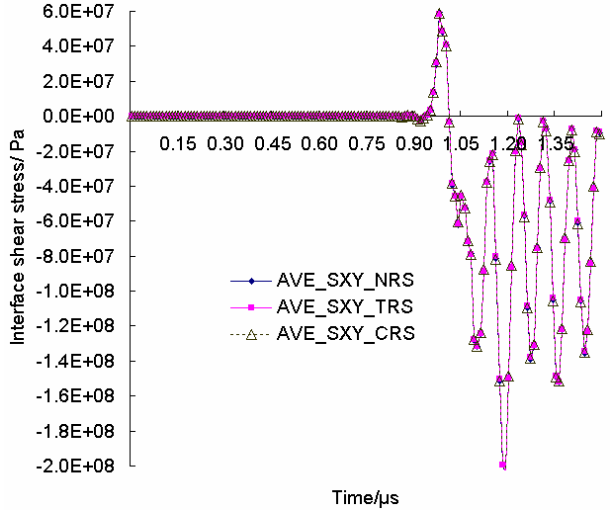

Fig. 10 Shear stress acting at the outer node close to the interface crack tip for the three initial states

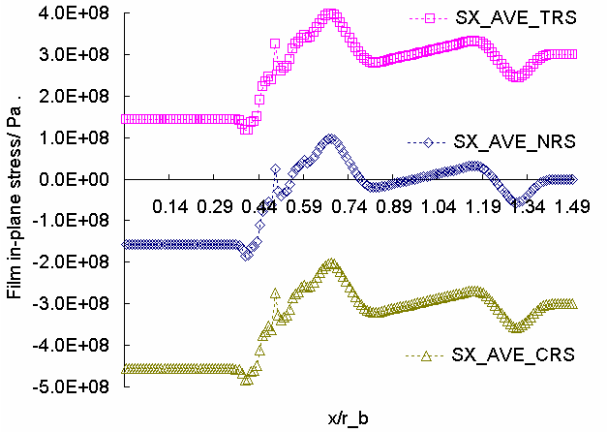

Fig. 11 Film stress at the instant t=1.03μs for the three initial states

For the moment, these results may be theoretically explained by the fact that the action direction of the residual stress is parallel to the interface. Therefore, the load component contributing to the interface separation developed by the in-plane residual stress would be slight when the deflection of the coating is small as considered in the present article. Even so, we hope more physical experimental outcome can be obtained to further support the present cognizance. Actually, a group of relevant tests are undertaken though much difficulty arises in the many sides of it, especially at the quantitative definition of the residual stress and the observation of the interface crack state.

It is also worthwhile to note that these theoretical results are basically drawn from linear dynamic analysis. Such linear modeling could not include the large deformation of the coating, which may lead to more obvious effect of the in-plane residual stress on the interface stress and therefore the interface crack behavior. Moreover, as reveled by Wu [3], the residual stress would influence greatly the total in-plane stress in the coating, which will affect the cracking of the coating under impact. Once the coating fractures around the impact region edge, the interface crack would be arrested around the edge. In comparison, if the coating can endure the impact and maintain intact, the partially released residual stress would affect greatly the interface crack behavior.

4. Conclusions

The model was set up to investigate the behavior of interface crack between the film and substrate subjected to stress wave, in which the crack surface contacting was considered. The dynamic deformation, stress and strain energy versus different crack lengths are calculated for the cases of three initial stress states, that is, initially stress free film, initially compressed film and initially tensioned film.

The history of the normal stress acting at the interface center node indicate that the interface crack permits the transmission of compressive stress while denies the transmission of tensile stress. The dynamic open displacement at the inner node 5μm away from the crack tip further reveals that the crack surfaces seldom contact after separating by the first compressive pulse.

The initial stress state would almost not influence the strain energy release rate of the interface crack or the interface stress around the crack tip if only small strain is taken into account in the modeling. Anyway, the film stress will be greatly changed by the residual stress, which will ultimately determine the fracture of the film.

Abstract Fibre-metal laminates(FMLs) that consists of three layers of 2024-T3 aluminium alloy sheets and two layers glass/epoxy composite were studied in this work. The specimens were designed and produced. Low-velocity impact tests were performed successfully on FMLs, using an instrumented falling weight machine. For comparison purposes, similar tests were set up and were carried out on monolithic 2024-T3 sheets. Damage mode and feature of them were compared and studied. ABAQUS software was used to simulate dynamic response and damage evolution of FMLs during impact. It is shown that FMLs have better impact resistance properties than pure aluminum sheets because of the fibre. The damage of FMLs has three clear different steps to damage during impact. The simulation and experiment results agree well with each other.

Keywords Fibre-metal laminates(FMLs), low-velocity impact, damage mode

1. Introduction

Fibre-metal laminates(FMLs) is a type of hybrid material which consists of alternating layers of thin metallic sheets bonded together with fiber reinforced layers[1-8]. During the last decades the application of FMLs in various structures has become increasingly popular, especially in aerospace structures, for its improved fatigue and impact properties [1-5]. There are many articles about experimental [1-3] and modeling [6,7] investigation, regarding to impact resistance of FMLs. While there are a limited number of articles concerning theoretical modeling of impact response of FMLs [8]. Despite of lots of work concerning the impact of FMLs have done, their impact properties still need more understanding and attention.

In this study, low-velocity impact damage resistance of FMLs caused by dropped tools or collisions between service cargo (less than 10 m/s) in aircraft is investigated via both experimental and numerical simulations.

2. Experimental investigation

The FMLs studied in this work were consists of three layers of 2024-T3 aluminium alloy sheets 0.254 mm in thickness and two layers of [0/90/90/0] glass/epoxy composite with each prepreg 0.15 mm in thickness. For comparison purposes, monolithic 2024-T3 sheets of 2 mm in thickness were also studied. According to standard ASTM-D-7136[9]，All specimens were cut into rectangle panels with dimensions of 150×100 mm^2 . There are two types of FMLs specimens, type A with the rolling direction of aluminium sheet or 0 fibre direction parallel to the short side and type B parallel to the long side, and one type of aluminium specimens with rolling direction parallel to the short side. The low-velocity impact tests were conducted using an Instron-Dynatup 9250 instrumented drop-weight impact tester and used an impactor with a 16 mm diameter hemispherical steel head of a total

weight of 6.9025 kg. Tests were performed in the different energies ranging from 5J to 123J. The time history of impact force and impactor displacement was obtained by the test machine. After impact, the residual displacement, indentation depth and the crack length of back surface have been measured.

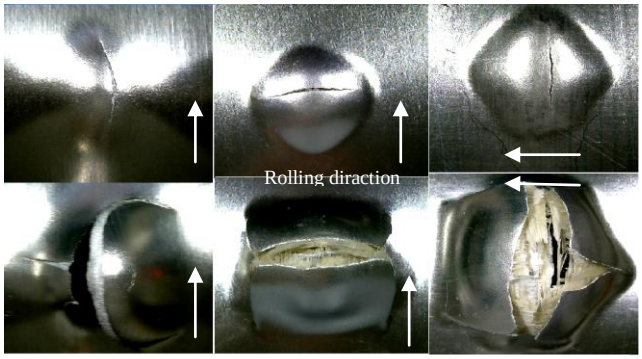

Figure 1. Damage at the non-impacted side of AL and FMLs

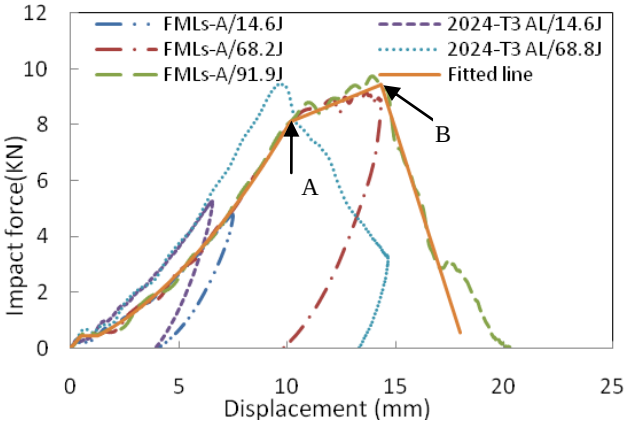

Figure 2.Force-displacement curves

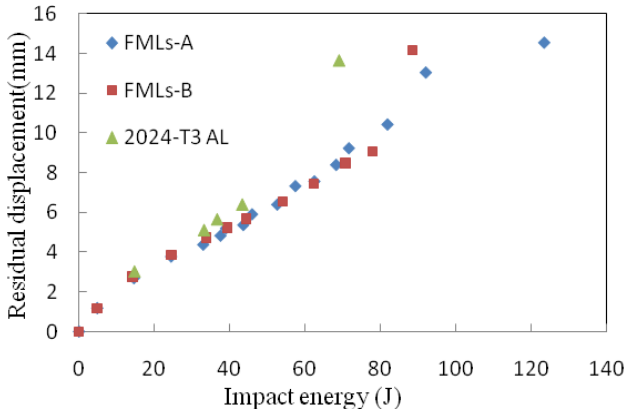

Figure 3.Residual displacement against impact energy

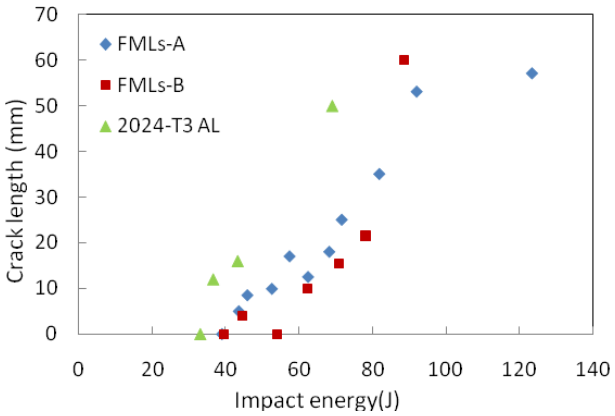

Figure 4. Crack length against impact energy

In Fig.1, damage after the different impact energy was shown and compared between FMLs and 2024T3 sheets. For monolithic 2024-T3 sheets, the first crack was found at non-impact side at impact energy of 36.5J, and almost completely penetrated at energy of 68.8J. The shape of crack was first in rolling direction and growth into "C" shape with high energies. Whereas, for both types of FMLs A and B, the initial crack at non-impact side were found at energy of 43.5J and crack at impact side appeared at 71.5J. It is differently from others work, the first crack found there were perpendicular to rolling direction of aluminium alloy sheets and the adjacent fibre direction. The shape of crack at non-impact side of FMLs was grown into "H" shape at energies of 71.5J. There are little difference between two types of FMLs for the force-displacement curves, indentation depth ,the crack length and others permanent were almost the same at one energy level (see figure 3 and 4). Force-displacement curves were compared in figure 2. It were shown that the route of them kept the same before crack were appeared during loading stage for FMLs and monolithic 2024-T3 sheets respectively, and the quadratic equation can be used to relate the force with displacement. While the path is not coincident in unloading stage, but their slope were basic paralleled that is the

same quadratic equation can be used [5]. There are two inflection points A and B at the force-displacement curves of FMLs. Inflection point A was caused by the crack generation at non-impact side of aluminium alloy sheet, and point B was the ultimate load of FMLs under low-velocity impact which was closed to the ultimate load of monolithic 2024-T3 sheets. The FMLs exhibit aluminium dominated behavior before first crack generated and exhibit fiber dominated failure behavior after the crack generated. The solid line in figure 2 was acquired by fitting the force-displacement curves of FMLs using quadratic and liner segmented function.

3. Numerical simulation

To clarify the relationship between the internal and external damages, dynamic explicit analysis was carried out using the finite element software ABAQUS. The impactor and each layer in three dimensions in the FMLs were modeled as separate parts, see figure 5. Interface layers were inserted into each layer to model interlaminar delamination. The boundary conditions of model FMLs were held four edges fixed. An initial velocity in the vertical direction is prescribed to the impactor, simulating the impact velocity measured during the tests.

The Isotropic elasticity and metal plasticity with ductile damage initial criterion and linear fracture energy damage evolution were used to simulate aluminum alloy failure mechanisms. Orthotropic elasticity in the plane stress field was used for each of the prepreg layers and interfaces layers. The Hashin damage initiation criteria and fracture energy damage evolution implemented in ABAQUS was applied to each ply in the prepreg layers to simulate their failure mechanisms. While the failure of interface layers were modeled as cohesive layers with the max traction-separation damage initial criteria and linear fracture energy damage evolution laws [10].

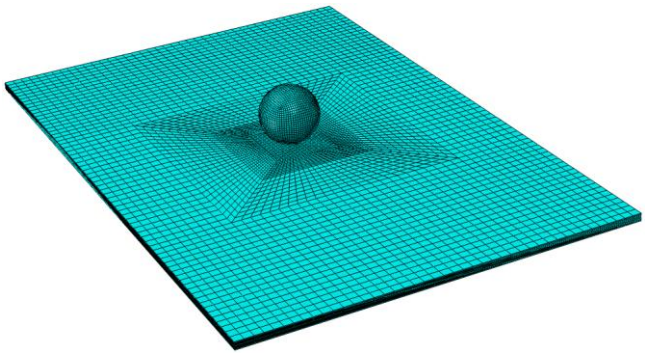

Figure 5. Finite element model

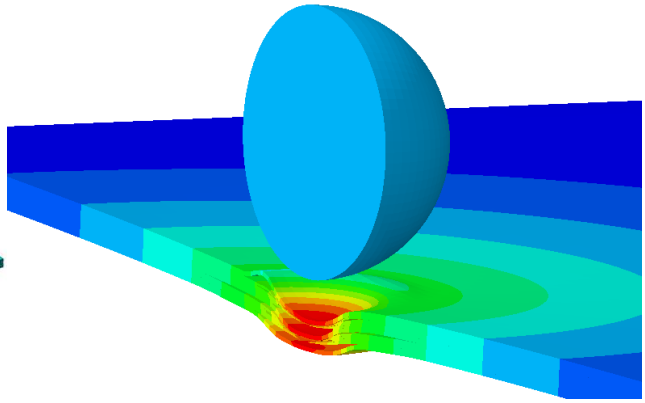

Figure 6. The failure mode of the FMLs subjected to 14.6J impact

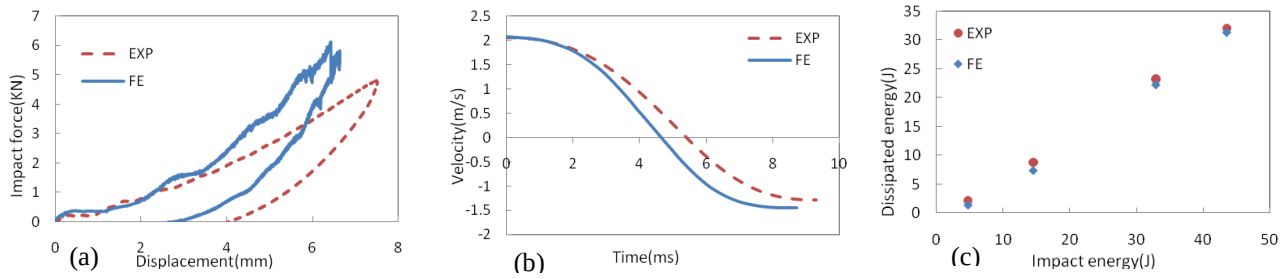

Figure 7. The *F-d* (a), *v-T*(b) and U_d *-U*(c) curves of experiment and finite element results

The finite element model corresponds well with the test results reasonably. Figure 6 shows the

damage of finite element model subjected to the impact energy of 14.6J. This half-specimen plot shows residual depth and interlaminar delamination occurring after impact completed. The experimental and simulated impactor reaction force-displacement and velocity histories curves corresponding to14.6J impacts on the FMLs were plotted in Figure 7(a, b). The experimental tests were not correctly replicated by the simulation results for the maximum impact force was higher, the maximum displacement was lower and impact time was shorter, while the tendency of them was reasonable the same, and the final velocities were much at one, that is the dissipated energies were almost the same. The dissipated energies against several impact energies were plotted in figure 7(c).

4. Conclusion

This study presented an experimental and numerical investigation on low-velocity impact behaviors of the fibre metal laminates (FMLs). Experimental results show that the impact resistance of FMLs was higher than monolithic 2024-T3 sheets for the first crack energy about 15% higher and completely penetration energy about 34% higher. While, the impact resistance of two types of FMLs, which were cut into rectangle panels with the long edge parallel to 90 and 0 fibre separately, were almost the same. Good agreement between finite element results and experimental results such as the internal delamination and dissipated energies were obtained, and hence the model was validated.

Analysis of the synergetic effects of blast wave and fragment on concrete bridges

Haiqing Zhu[1,*], Xiedong Zhang[1], Ying Li[1]

1. School of Transportation, Wuhan University of Technology, Wuhan 430070, China

* Corresponding author: zhq7751@163.com

Abstract: The complicated loading caused by explosions is not well understood, so the effect is often simplified when calculated. In order to increase the bridge protective level, a penetrating study of the mechanism of the synergetic effect of blast wave and fragment is necessary. Numerical simulation is used to analyse the dynamic response characteristics and the damage performances of the reinforced concrete bridge. Three conditions were designed to research the synergetic effect of the blast wave and fragment on the bridge. The research indicates that the synergetic effect is larger than the arithmetic sum of the effect of blast wave and fragment separately, which should be taken into account in the protection of bridge.

Keywords: Blast wave, Fragment, Synergetic effect, Dynamic response

1. Introduction

Several decades has witnessed that destroying bridges is the best efficient way to restrict the enemy for cutting off the transportation line and blocking supply in the local conflict. Moreover in many developing areas, infrastructure construction is blooming, blast is the fastest way to demolish the old un-qualified bridges. When bomb or missile exploding, blast wave and fragment are produced and both them impacted on the bridges. In recent years, either blast destroy bridges or fragment penetrate concrete is studied very well. But the complicated combined loading caused by synergetic blast wave and fragment is not well known. However design a blast test to research the synergetic effect is insecure and expensive. Numerical analysis using AUTODYN is the appropriate mean to study the mechanism before material test.

2. Loading characteristics

2.1 Blast wave characteristics

When explosions occur, the energy released at a lighting speed, which produce gas mixture with high temperature (3.5×10^3—4×10^3℃) and high pressure (1×10^4—3×10^4MPa). Since the air initial pressure and density is low, explosive product diffused at a high speed will compress the air nearby, increasing the air pressure, density and temperature drastically, which will develop into blast wave. The blast wave spread rapidly, during the energy spread and deplete, the speed of the blast wave will decay rapidly. When the volume of the explosive product expands big enough, the pressure in it will drop to the original level P_0 of the air nearby. However the product volume will keep expanding to a maximum because of the inertia effect. Then the negative pressure area will occur because the average pressure of the product is lower than the original pressure P_0, and the air nearby will compress the product conversely, which will increase the product pressure. For the air, the first expansion—compression impulse is worthy of study. Classical blast wave spread in air is shown as figure 1.

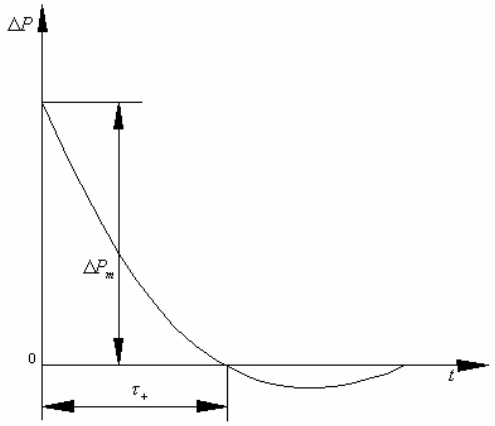

Figure.1 Pressure maximum of the blast wave

The expansion law of the explosive product can be simplified to the polytropic index equation of state [1].

$$PV^{\gamma} = const \tag{1}$$

P is the pressure of the explosive product; V is the volume of the unit quality; γ is the polytropic index, related to the component and density of the explosive product, γ enlarges when the density value increase.

AUTODYN is precise in explosions analysis for its BLAST boundary conditions. In this research, 2kg TNT exploding 2m above the bridge is simulated by AUTODYN [4].

2.2 Fragment characteristics

A large amount fragments are produced when explosion take place, these fragments with high speed will penetrate the bridges.

Mott formula is the most widely used to calculate the fragments' quality [1].

$$\mu^{0.5} = Kt_0(t_0 + d_i)^{1.5}(1 + \frac{M_0}{2m_t})^{0.5} \Big/ d_i \tag{2}$$

$$m_p = 2\mu \tag{3}$$

m_t is the payload quality(kg); m_p is the fragment average quality(kg); t_0 is the thickness of the cartridge case(m); d_i is the internal diameter of the cartridge case(m); K is the explosive material factor($\mathrm{kg}^{1/2}/\mathrm{m}^{3/2}$).

Gurney formula considering cylindrical payload is used to calculate the fragments' initial speed [1].

$$v_0 = \sqrt{2E}\sqrt{\frac{C/m_t}{1 + 0.5C/m_t}} \tag{4}$$

v_0 is the initial speed of the fragments(mgs^{-1}); C is the quality of the explosive materials ($kggm^{-3}$);

$\sqrt{2E}$ is the Gurney factor(or Gurney specific energy), Gurney found the linear relation between the Gurney factor and explosive speed D_e through many tests.

$$\sqrt{2E}=520+0.28D_e \tag{5}$$

In order to simplify the research, this paper chooses spherical fragments with diameter 0.05m and initial speed 1700 ms^{-1}.

3. Models and material parameters

3.1 Bridge model

In order to explain the mechanism clearly, a simple square section with 1m length of each side is used. The superior border has 3 longitudinal steels with diameter 6mm and inferior border has 3 longitudinal steels with diameter 12mm, shown as figure 2.

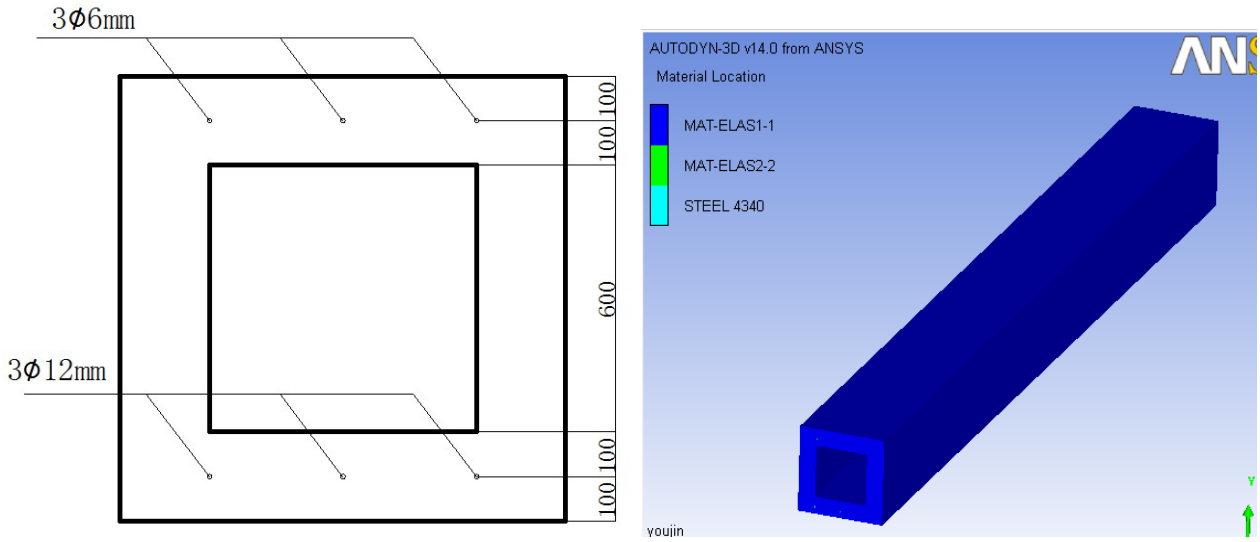

Figure.2 Beam section and 3-D model

3.2 Constitutive relation of the concrete

RHT model [2] was built by Riedel, Hiermaier and Thoma in 1999. The premise of the model formula is that the internal energy of the porous-material and compact-material under the same pressure and temperature are equal. The thermo-motive performances of the concrete under high pressure and the compression behaviors under low pressure will be described clearly by RHT. When the concrete is compacted enough, its state equation is shown as figure 3.

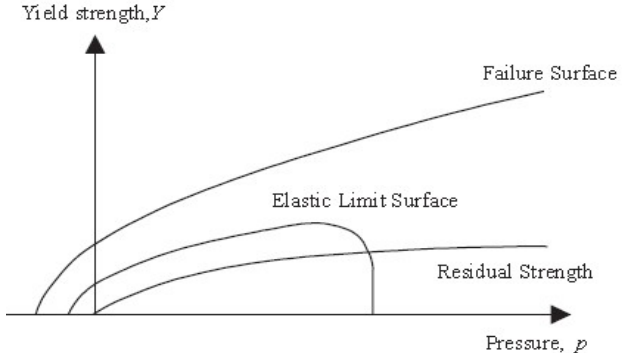

Figure.3 RHT constitutive relation of concrete

3.3 Dynamic constitutive relation of the fragment and steel

In order to describe the structure response to the explosive impact load, several conditions should be taken into account: the strain strengthening phenomenon of the material, the material behaviors under large strain, high strain rate and high temperature, even the material behaviors under the influence of the strain state change and the load history change.

Johnson-cook (JC) strength model [3] is widely used in commercial nonlinear finite-element because of its simple form, distinct concept and precise veracity. JC model is a kind of empirical viscoplasticity constitutive relation, it can describe the hardening effect, strain rate effect and softening temperature effect of metal materials very well.

$$\sigma = (A + B\varepsilon^{n})(1 + C\ln \dot{\varepsilon}^{*})(1 - T^{*m}) \tag{6}$$

$$T^{*} = (T - T_{r})/(T_{m} - T_{r}) \tag{7}$$

σ is equivalent stress(N), ε is equivalent strain, $\dot{\varepsilon}^{*} = \dot{\varepsilon}/\dot{\varepsilon}_{0}$ is dimensionless plastic strain rate, $\dot{\varepsilon}$is static experiment strain,， T is the sample surrounding temperature, T_r is room temperature, T_m is fusion point.

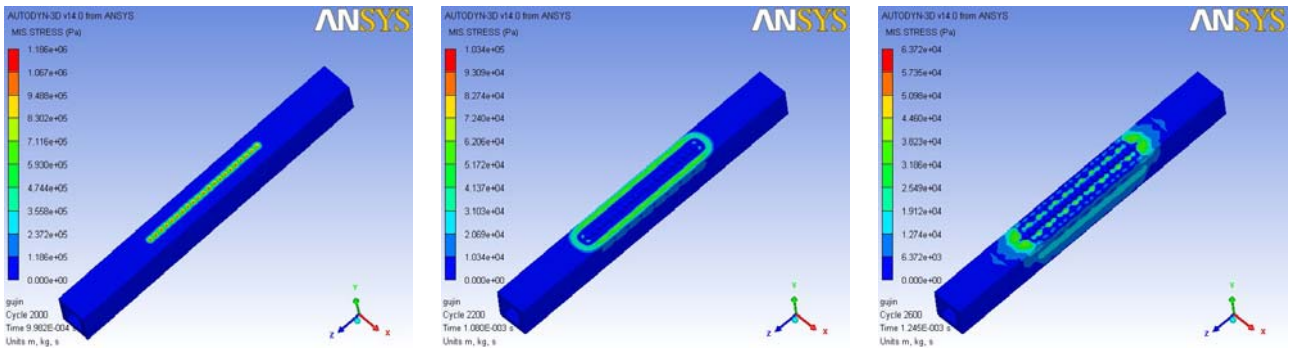
$(A + B\varepsilon^{n})$ describes strain strengthening effect; $(1 + \ln \dot{\varepsilon}^{*})$ describes strain rate strengthening effect; $(1 - (T^{*})^{m})$ describes softening temperature effect. Parameter value shown as follows.

Table1 JC constitutive relation parameters of 4340steel

A(MPa)	B(MPa)	n	C	m	$\dot{\varepsilon}$	T_m (K)
791	510	0.26	0.014	1.03	1	1793

4. Results and analysis

4.1 Damage process of the synergetic effect



0.998ms 1ms 1.245ms

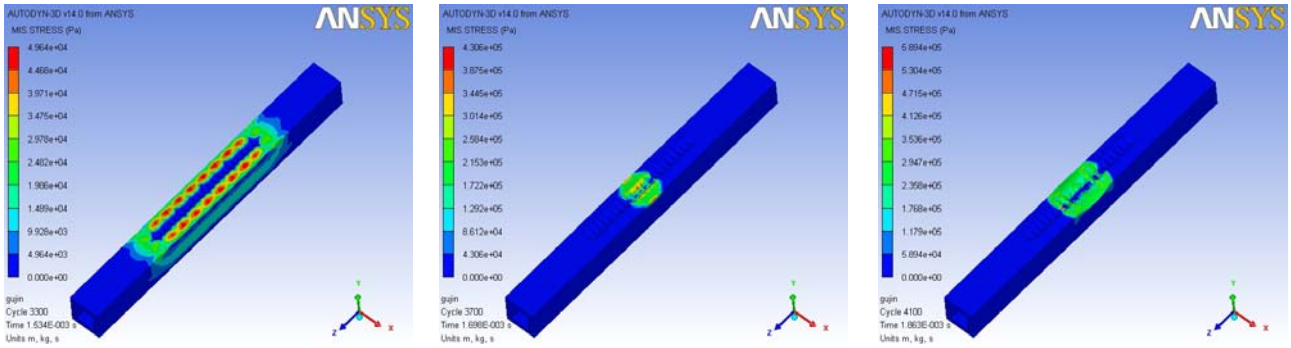


Fig.4 Damage process of the synergetic effect

Because the blast wave and fragments arrive at the bridge at different time, the failure mechanism of the bridge will change at different moment. The failure process of the bridge is divided into 4 stages in AUTODYN.

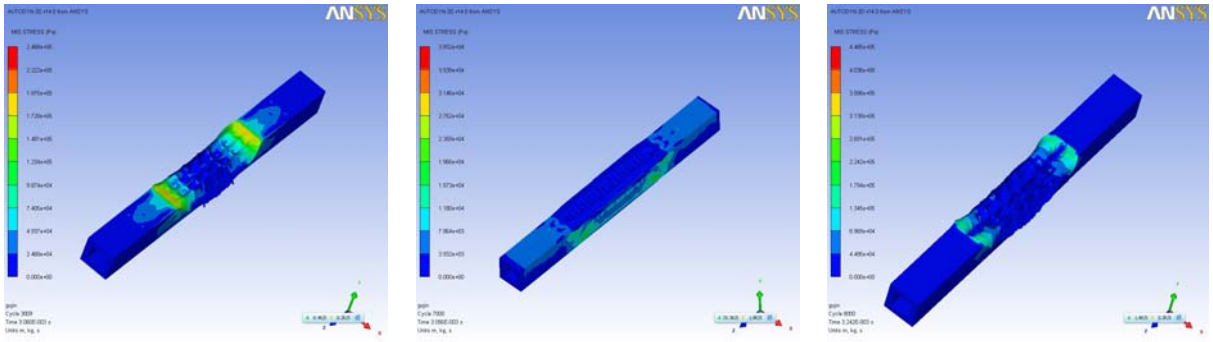
1st stage(0.998ms-1.245ms): The fragments arrive at the bridge upper surface, the stress wave begin to spread from the upper surface to the lower border in the beam. The fragments with high speed begin to smash the beam to pieces.

2nd stage(1.245ms-1.698ms): The fragments penetrate the beam further, reaching the longitudinal steels, leading a obvious deformation to the longitudinal steels. And the stress wave spread along the longitudinal steels and stirrups, the stress in the corner of the stirrups become larger.

3rd stage(1.698ms-3.33ms): The crest of the blast wave arrive the bridge surface, encountering with the fragments and effect the beam together. Some local deformations begin to occur in the concrete, and expand towards the lower border of the beam. The mid-span of the beam begin damaged.

4th stage(3.33ms- last): Because the fragments are crushed in pieces and its speed decreased, the vibrating beam will became static under the remainder blast wave and its own inertia gradually.

4.2 Failure modes contrast



(a)blast loading (b)fragment loading (c)combined loading

Fig.5 failure modes of the concrete beam

Fig.5 (a) when blast loading effect on the bridge separately, the largest deformation occurs in mid-span, steels restrict the beam became more damaged. Some beam border became damaged.

Fig.5 (b) when fragment loading effect on the bridge separately, some pits and holes occur on the beam surface, the longitudinal steels become curved and stressed the main pressure. Fragments pieces splash nearby during the penetrating process.

Fig.5 (b) when combined loading effect on the bridge, the beam damaged seriously. The longitudinal steels yield under the fragments effect and then expand the deformation because of the blast impact wave. The biggest displacement occurs in mid-span, many pits and holes occur on the beam surface, and seriously damage the beam border.

4.3 Dynamic response of the bottom midpoint

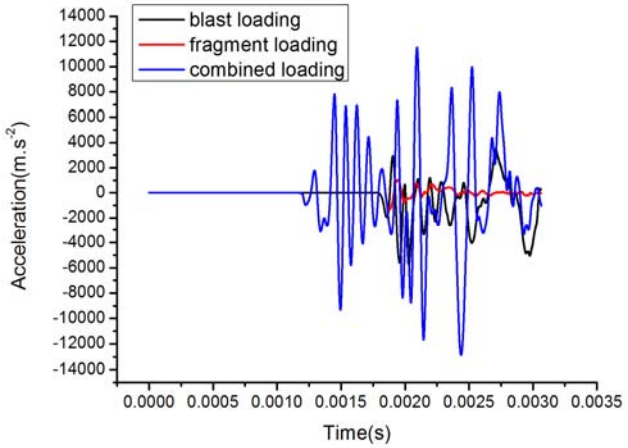


Fig.6 acceleration of the bottom midpoint

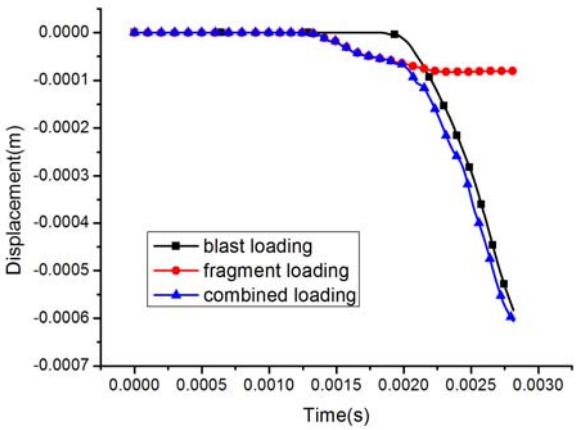

Fig.7 displacement of the bottom midpoint

Figure 6 and 7 indicate that the acceleration response under synergetic effect is larger than the response under fragment or blast wave effect separately, further more larger than the sum of the separate responses. And the displacement response under the synergetic effect is larger than the separate responses.

5. Conclusions

(1)The concrete bridges will be damaged seriously by the synergetic effect of blast wave and fragment.
(2)The synergetic effect to damage the bridge embodied in two ways: impact on the global bridge and destroy the local beam, which will decrease the loading capacity of the bridge.
(3)The acceleration changed seriously under the synergetic effect which should be taken into account in antiknock design.

Abstract Tensile instability, as characterized by the Considère law, is one of the factors governing formability of metallic sheets. During tensile deformation, material thins in a narrow band due to shear localization, prior to final fracture. Strain rate value within the localized necking band tends to be higher than outside it and final fracture is governed both by the nature of the shear localization as well as the strain rate differential between the neck and the material outside the neck. This paper reports the dependence of shear localization and fracture on plastic anisotropy of the material. Three types of automotive sheet materials, namely IF steel (BCC structure), AA5754 aluminum alloy (FCC) and AZ31 magnesium alloy (HCP) are examined. Digital image correlation is used to follow the development of deformation pattern during tensile tests. The results show that both narrowing and thinning of the tensile sample occur in IF steel, while only thinning occurs in AA5754 and only narrowing occurs in AZ31. These differences arise from the differences in the plastic anisotropy of the three materials, as measured by their r-values. Even though all three materials exhibit ductile fracture, the damage and fracture processes in the three materials differ from each other.

Keywords Shear localization, Plastic anisotropy, automotive sheets, r-value, fracture

1. Introduction

In response to the more stringent regulations on fuel consumption in vehicles, lighweighting via the utilization of aluminum and magnesium alloys are being seen to replace steels for automotive body structural applications. Aluminum can reduce the vehicle weight by 20-30% while magnesium 40-50% compared to a full steel vehicle. A 10% weight reduction will save 6-8% in fuel and related GHG emissions. However, formability of aluminium and magnesium sheets is inferior to that of conventional interstitial free (IF) steel. The formability of alloy sheet can be limited either by instability or fracture depending on the operation [1]. The forming limit is usually defined as the locus in uniform strain space required for the onset of localized necking while the fracture limit is defined as that required for material separation. In uniaxial tension strain path, tensile instability or diffuse necking, as characterized by the Considère law, is one of the factors governing formability of metallic sheets. Further, material thins in a narrow band due to shear localization, prior to final fracture. Strain rate value within the localized necking band tends to be higher than outside it and final fracture is governed both by the nature of the shear localization as well as the strain rate differential between the neck and the material outside the neck. This forms the foundation of the so-called Marciniak-Kuczynski (M-K) approach [2] for forming limit diagram (FLD) analysis. While M-K approach has been successfully applied to prediction of FLD of numerous sheet materials including steels and aluminum alloys, it is commonly recognized that the success of such approach for aluminum alloys depends significantly on the selection of yield functions that represent the effect of plastic anisotropy and texture. On the other hand, whether or not thinning occurs in magnesium alloys is challenged by many experimental observations. For example, for AZ31 sheets, it has been reported that very little thinning occurs during uniaxial tension at room temperature [3] and the deformation process becomes more complicated as a variety of deformation mechanisms become activated at

different elevated temperatures [4-5].

This paper reports the dependence of shear localization and fracture on plastic anisotropy of the material. Three types of automotive sheet materials, namely IF steel (BCC structure), AA5754 aluminum alloy (FCC) and AZ31 magnesium alloy (HCP) are examined. Digital image correlation (DIC) [6-7] is used to follow the development of deformation pattern during tensile deformation. The role of anisotropy in relation to damage and fracture process is also examined through a variety of surface analysis techniques including optical microscopy, scanning electron microscopy (SEM), electron backscatter diffraction (EBSD) and X-ray tomography.

2. Experimental

The three sheet materials used in the present study were 0.7 mm thick IF steel, 2mm thick AA5754 in O-temper and 2mm thick AZ31 in O-temper. IF steel has a BCC structure, AA5754 FCC and AZ31 HCP.
The initial texture is measured by EBSD using TSL OIM software for all three materials. Uniaxial tensile tests are performed at room temperature using ASTM E-8 specimens. Prior to the tests, an ink pattern is applied to each specimen surface. A commercial available optical strain measuring system, Aramis based on digital image correlation is used for DIC measurements.

Plastic anisotropy of metallic materials is usually represented by the plastic strain ratio, r-value, that is defined as [8]

$$r = \frac{\varepsilon_w}{\varepsilon_t} = -\frac{\varepsilon_w}{\varepsilon_l + \varepsilon_w} \tag{1}$$

where ε_l, ε_w, and ε_t are longitudinal, width, and thickness strains, respectively. As thickness strain is difficult to measure, longitudinal and width strains are usually measured to determine the r-value based on the incompressibility criterion along with the assumption of uniform strain distribution over the gage length [8]. In practice, r-value represents material resistance to thinning. In steels, it is generally accepted that higher the r value, higher the FLD.

However, in materials with small amount of plasticity, r-value is not a sensitive parameter. Another parameter, the contraction ratio, q-value, similar to a Poisson's ratio in elasticity, has been proposed and defined as [9]

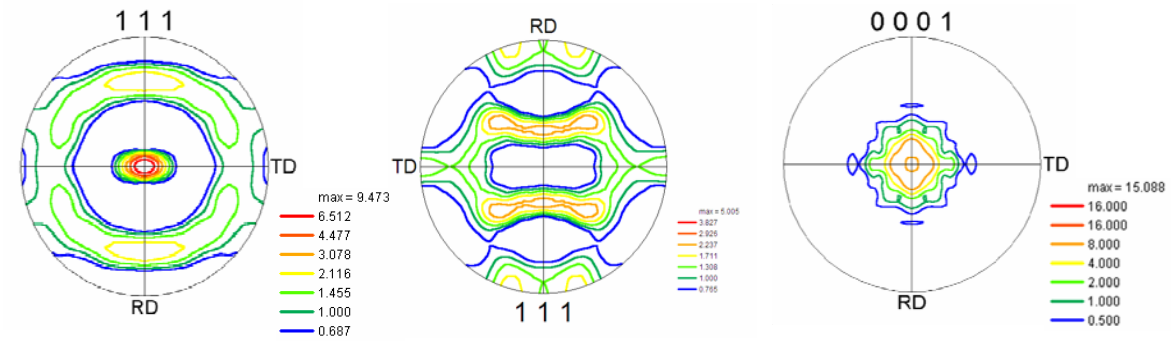
$$q = -\frac{\varepsilon_w}{\varepsilon_l} \tag{1}$$

It is easily seen that $q=r/(1+r)$.

After tensile tests, necked and fractured specimens are collected for damage and fracture observations using optical microscopy, SEM and X-ray tomography.

3. Results and discussion

Fig. 1 shows the initial texture of IF steel, AA5754 and AZ31 sheets, the later having the basal texture while the former sheets exhibit typical rolling texture.



(a) IF steel (b) AA5754 (c)AZ31

Fig. 1 Initial textures of the three alloys

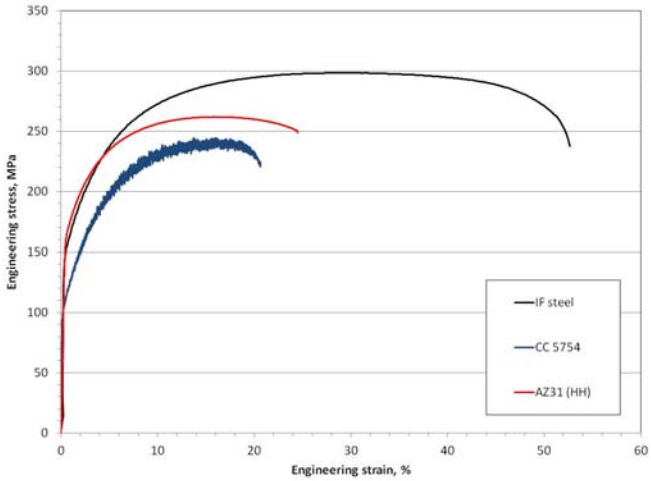


Fig. 2 Engineering stress – engineering strain curves of three alloys

From the engineering stress-engineering strain curves of the three materials (Fig. 2), it is seen that the uniform strain to ultimate tensile stress is 29.6%, 18.0% and 15.8% for IF steel, AA5754 and AZ31, respectively. This is commonly accepted as the strain where diffuse necking is initiated in the materials.

While only diffuse necking can be identified on stress-strain curves, the sequence of deformation occurring during tensile tests, especially the initiation and development of localized necking can be clarified for each material from tensile strain maps obtained from DIC measurements (Fig. 3).

From Fig. 3, it is seen that both thinning and narrowing occurs in IF steel, only thinning in AA5754 and only narrowing in AZ31 following the diffuse neck formation. It is also seen in Fig. 3 (a) and (c) that localized necking occurs in both IF steel and AA5754 before fracture, however, no localized necking occurs in AZ31.

Fig. 4 Line scan of cross section for post-necking strain development in three alloys

Fig. 4 shows the line scans taken through the strain maps at different stages of the deformation. In Fig. 4 (a) and (c), correspondng to IF steel and AA5754, tensile strains become intense in a more and more narrow band while strain outside this area remains unchanged or even is slightly lowered. These are the typical signatures of localized necking in metallic materials. Together with Fig. 3 (a) and (c), it is concluded that localized necking occurs in IF steel and AA5754 sheet materials. However, when looking closely at AZ31 line scan data in Fig. 4 (e) and (f), one observes that both tensile and width strain keep evolving as the global strain increases. This indicates that no localized necking occurs in AZ31. Instead, it transits directly from diffuse necking into final fracture process [3, 14].

From the local strain development (Fig. 5), it is seen that deviation between local and global strains is more significant in IF steel and AA5754 comparing to AZ31.

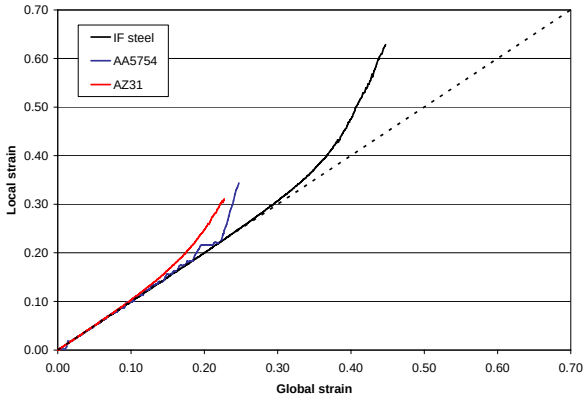

Fig. 5 Local versus global strain in three alloys

It is well known that in AA5754 deformed at room temperature at quasi-static strain rates, premature necking occurs due to the Portevin-Le Chatelier (PLC) effect (e.g. illustrated in the first three maps in Fig. 3 (c)) [1]. A simple model has been established to account for the effect of PLC band strain on reduction of uniform strain to UTS [1]. It is also reported that at a certain combination of temperature and strain rate (e.g. -50 °C and 6×10^{-4}/s), the PLC effect and accompanying premature necking can be removed [1]. It is also reported that the formability of AA5754 can be improved by enhancing specific texture components (e.g. cubic texture) [10]. Traditionally, it is accepted that the higher plastic strain ratio, i.e. r-value, the better formability. In the discussion below, the relationship between plastic anaisotropy and formability is further examined in light of the above observations.

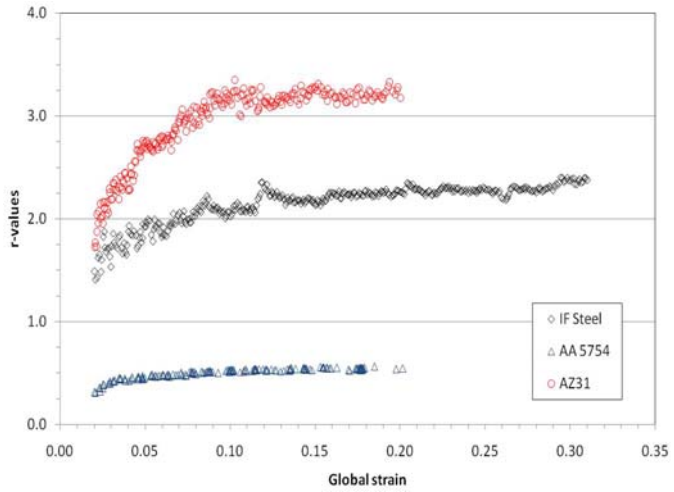

Fig. 6 r-values development in three alloys

When plotting the r-value evolution in the three materials used in the present study (Fig. 6), it is seen that the r-value in AZ31 is the highest (3.2). However AZ31 has the lowest formability in the uniaxial tensile deformation. Eq. (1) is derived with the assumption that material deforms in

length, width and thickness directions and when the material deforms more in width direction than thickness direction to produce a higher r-value, it has improved formability. The contribution of each strain component to r-value and q- value may provide insight into the origin of the anomalous relationship between formability and r-value for AZ31. Fig. 7 shows the relationship between the q-value and strain for the three materials.

It is seen in Fig. 7 that AZ31 has the highest q-value, i.e. most of the deformation is actually concentrated in the width direction while AA5754 has the lowest q-values, with least deformation along the width direction.

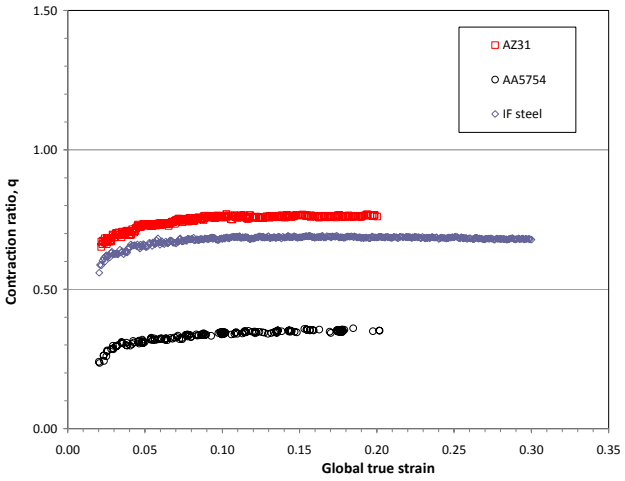

Fig. 7 q-value development in three alloys

Fig. 8 shows the thickness strain in the three materials calculated using the incompressibility criterion. It is clear that there is very little thinning in AZ31, consistent with the q-value results in Fig. 7.

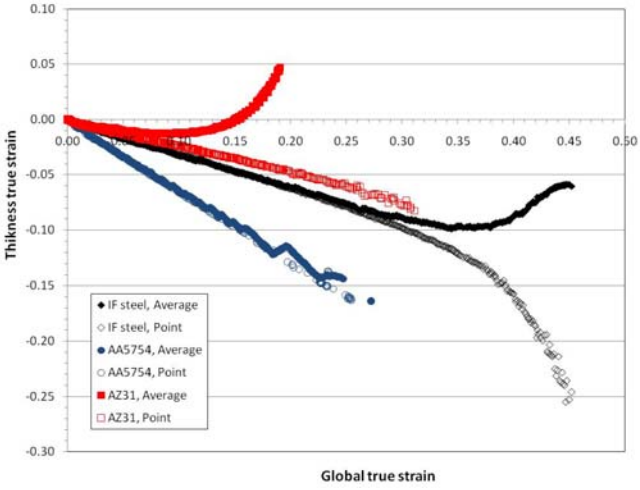

Fig. 8 Thickness strain evolution in three alloys. Note that ‘‘average’’ denotes thickness strain estimated from both tensile strain and width strain from given gage lengths while ‘‘point’’ denotes thickness strain at a point within necked area.

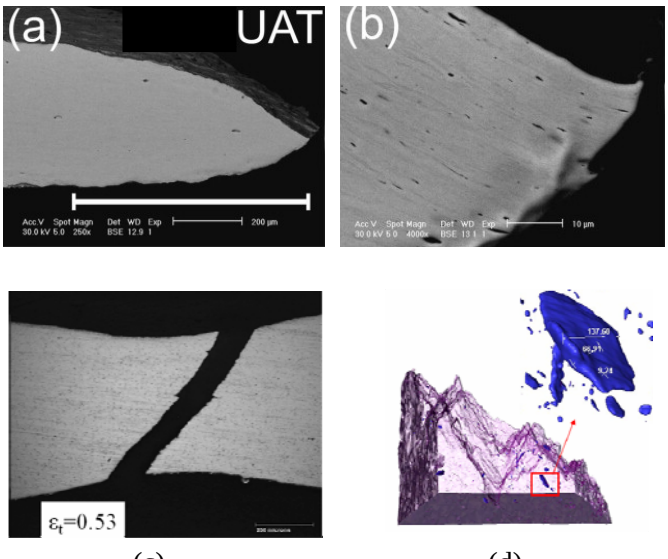
The relationship between damage and shear localization in literature continues to remain ambiguous. Ductile fracture process generally includes three stages, namely void nucleation, void growth and void coalescence. A number of continuum mechanics models have been developed [11-12] to describe this sequence of events. However, the interplay between shear localization and void formation often depends on the materials studied and this effect is not captured in continuum mechanics (macro scale) models. There is very little quantitative data on the development of the complex sequence of damage events in materials such as the ones studied here to ascertain if the existing models can capture any differences in the sequence of events arising from the anisotropic nature of the deformation described above at the microscale.

In IF Steel, limited void growth from aluminum oxide particles has been observed [13] prior to localization in uniaxial tension. It is concluded that damage does not play a role before (or upon) localization, but only beyond localization (Fig. 9 (a) and (b)) [13]. It is in contrast with the observations in other steel alloys [11].

In AA5754, void nucleation is observed only in the very final stage of the tensile deformation and the damage is very localized near the fracture surface [14-16]. This suggests that damage may be a consequence of the fracture process rather than a trigger that determines material ductility (Fig. 9 (c)). Further, it is observed that particle distribution as random particles or in stringers affects the final fracture process. For example, anisotropic distribution of stringers in continuous cast AA5754 sheets significantly reduces the fracture strains [17].

In AZ31, it is revealed by X-ray tomograpghy that microcracks formed at the later stage of diffuse necking (Fig. 9 (d)) contribute to the final fracture without transition into localized necking [18].



(c) (d)

Fig. 9 Damage and fracture in (a) and (b) cross section of a fractured IF steel specimen [13] showing void growth within localized shear bands, (c) cross section of a fractured AA5754 tensile specimen showing no damage or voids just underneath the fracture surface and (d) fracture surface of an AZ31 alloy tensile specimen revealed by X-ray tomography showing microcracks underneath the fracture surface [18].

Clearly, there is a link between the anisotropy in the deformation process and the development of damage and fracture processes in the three sheet materials. Microcrack formation in AZ31 sheets, for example, is strongly related to the twin formation as a result of the inability of textured AZ31 sheet to deform by dislocation mechanisms alone. IF steel on the other hand deforms by dislocation mechanisms which produce vacancies at high strains, leading to void formation which grow and coalesce to drive the material to failure. AA5754 sheets deform by dislocation mechanisms but voids form not from vacancy condensation at large strains as in IF steel but because of matrix-particle interactions in the sheet which then quickly develops to rupture. The above results suggest the need for developing microscale models that account for these differences in the microstructure and deformation mechanisms between different materials. It is expected that the quantitative data provided above can serve as a starting point for linking the anisotropic deformation with damage processes using a multi-scale (micro and macro scale) simulation strategy.

4. Conclusions

In this paper, we report the dependence of shear localization and fracture on plastic anisotropy of three types of automotive sheet materials, namely IF steel (BCC structure), AA5754 aluminum alloy (FCC) and AZ31 magnesium alloy (HCP). The results show that both narrowing and thinning of the tensile sample occur in IF steel, while only thinning occurs in AA5754 and only narrowing occurs in AZ31. These differences arise from the differences in the plastic anisotropy of the three materials, as measured by their r-values. Even though all three materials exhibit ductile fracture, the damage and fracture processes in the three materials differ from each other – mainly void mechanisms arising due to dislocation interactions in IF steel, premature void formation influenced by particle distribution in AA5754 sheets and premature crack initiation caused by twinning in textured AZ31 sheets. The need for micro-macro model development to link material anisotropy with fracture processes is identified for numerical model development.

Crack growth stability analysis with respect to boundary disturbance

Abstract Fracture analysis is a high non-linear problem and affected by uncertainties. Because of the limitation of observing technology, accuracy boundary condition can hardly be obtained. Normally, a stochastic model can be used. The difference between reality and numerical model is deemed as disturbance. This paper presents a three-dimension dynamic stability analysis of crack growth under disturbance in boundary condition by using particle discretization scheme finite element method.
The model is a thin epoxy plate with two anti-symmetric notches located in the middle, under uni-axial tensile in longitudinal direction. Two types of disturbance are considered: (i), the disturbance is added to the initial cracks' configuration. The disturbance is modeled by adjusting the position, size and shape of the notches. It shows that changes of the notches' size and position have significant influence on crack growth in the investigated cases; (ii), the disturbance is applied to the displacement boundary condition, which is far from initial cracks. The variability of crack paths of different model sizes under the same disturbance is estimated. The results of the numerical experiment indicate that as the model size increases, the influence of the disturbance becomes weaker. The Saint-Venant principle still holds in the studied crack growth problem.

Keywords Three dimensional dynamic crack growth, particle discretization scheme, finite element method, boundary disturbance, stability analysis

1. Introduction

Fracture analysis is a hot topic in solid mechanics [1]. Both experiments [2] and numerical methods have been developed to investigate the fracture behavior. The physical experiment is a reliable way. However, it costs a lot of resources to conduct. As the accumulation of experimental data increases, the fracture mechanics of more and more materials can be studied by using numerical method, for its convenience and resources saving. In order to increase the reliability of simulation results, a numerical model needs to be built as accurately as possible. However, the current observation equipments and technology have their limitation. Therefore, differences between reality and numerical model exist. Normally, stochastic model can be proposed, and the average value with variances can be used in numerical simulation. The difference between reality and numerical setting is deemed as disturbance in this paper. Since the crack drastically changes the stiffness matrix and strain energy, the dynamic crack propagation becomes a high non-linear problem. Hence, the results may be affected by these uncertainties. In mathematical view point, instability means that when a small perturbation is added to a system, the results will drastically change.

This paper focuses on studying the effect of the boundary condition disturbance on an elastic dynamic fracture problem. The well known Saint-Venant principle tells that, as the distance between the target and disturbance source increases, the effect of the disturbance decreases. Meanwhile, Oguni et al. [3] states that for dynamic fracture stability analysis, the uncertainties can be deemed as disturbance added to the stiffness matrix. As time increases, the effect may be increased or maintained according to system property. Based on these two theories, for boundary disturbance problems, it can be inferred that the effect of disturbance in boundary condition fades as the distance from area of interest increases, and heightens or maintains as time increases. However, since the property of dynamic fracture problem is nonlinear, the effects need to be quantificationally estimated.

Both experiment and numerical simulation can be used to study the effect of boundary disturbance. However, there is an advantage to examine the boundary disturbance effect by using numerical methods. At least two samples are needed to conduct this comparison study. The ideal situation is that all the settings are the same except that a specified disturbance is added in one of the samples' boundary condition. However, in reality, the variability of samples is hard to control, and the designed disturbance in boundary condition cannot be accurately applied. These uncertainties may lead to side effects on this comparison study. While in the numerical analysis, it is much easier to define identical models and add the specified disturbances exactly.

This paper studies the effect of two kinds of boundary disturbances, say, the near and far field disturbances. Here, the adjective, "near" and "far" are used to describe the distance between the boundary with disturbance and the region where crack grows. The target is a thin epoxy resin plate with two anti-symmetric notches located in the middle, subjected to uni-axial tensile in longitudinal direction. The near field disturbance is modelled by adjusting the position, size and shape of the notches. The far field disturbance is modelled by adding disturbance to the displacement boundary condition, which is far from the notches. Several kinds of disturbances are adopted. In order to study the Saint-Venant principle in the fracture problem, the crack paths of different model sizes under the same disturbance are compared.

For numerical simulation of fracture problems, various kinds of numerical methods have been proposed, such as E-FEM, X-FEM [4], discontinuous Galerkin method [5] and meshfree methods [6]. Besides these methods, the newly developed method, called particle discretization scheme finite element method (PDS-FEM) is another candidate [7,8] to calculate three dimensional dynamic crack propagation, for its numerical efficiency and capability of calculating bifurcation, which is important for brittle materials, such as epoxy resin, rock and concrete.

The content of the present paper is as follows: section 2 briefly introduces the characteristics of the adopted numerical method, PDS-FEM. Section 3 and 4 are devoted to study the effect of near and far field disturbances, respectively. Concluding remarks are pointed out in section 5.

2. PDS-FEM

The key idea of PDS-FEM is the discretization scheme. PDS or particle discretization scheme is a scheme which uses two sets of non-overlapping characteristic functions to discretize a function and its derivative. One set is made for Voronoi tessellation, and characteristic functions of this tessellation used to discretize a function. The other set is made for Delaunay tessellation, and characteristic functions of this tessellation are used to discretize function derivatives.

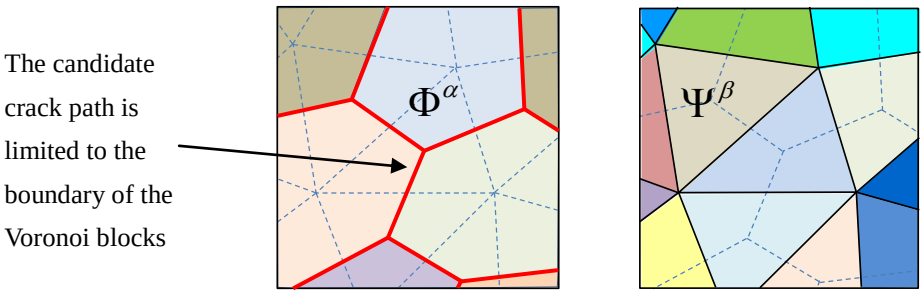

Figure 1. Two dimension decomposition by using particle discretization scheme

Displacement is discretized by the Voronoi, while strain and stress is discretized by Delaunay. As

you can see in Fig. 1, discretized functions are discontinuous everywhere. So, it is easy to model a crack, which is the discontinuity in a function of displacement. The candidate crack paths are limited to the boundary of the Voronoi blocks. For three dimensions decomposition, we can use ordinary tetrahedral mesh instead of triangular mesh as the Delaunay tessellation, and then for each tetrahedral vertex, the Voronoi block containing the vertex is determined by connecting all the centroids of tetrahedrons containing the vertex.

For dynamic analysis, a variation integrator called bilateral symplectic algorithm [9] is adopted as a robust algorithm of the time integration in PDS-FEM [8]. This algorithm is robust for stiffness matrix changes due to crack propagation. Meanwhile it is symplectic, which indicates that the momentum and energy are conserved during the numerical integration.

3. Near field disturbance modeling and simulation

Nowadays, the underground velocity structure and the hypocenter still can hardly be modeled accurately [10-12], let alone the detail fault configuration. According to previous researches, one of the best published results of underground velocity structure modeling with the help of the densest distribution of observation stations in Japan still has more than 10% error [13]. In order to carry out earthquake simulation, the configuration of the fault is always estimated with some variances. The effect of the errors in numerical modeling needs to be estimated. Although far from reality, this section carries out a series of trial simulations to quantificationally study the effect of the cracks' configuration changing on dynamic crack propagation with simple setting.

3.1. Reference model setting

The reference model is a thin epoxy resin plate with two anti-symmetric notches located in the middle, subjected to uniform longitudinal uni-axial tensile; see Fig. 2. The material is set to be linearly elastic; see Table 1. For brittle material, a time dependent material strength failure criterion, call Tuler Butcher criterion is adopted [14]:

$$\int_0^{\tau_f} \left(\sigma_1 - \sigma_0\right)^{\beta} dt \geq K_f \,, \tag{1}$$

where σ_1 and σ_0 are principle stress (tensile stress in this problem) and a threshold stress, τ_f is fracture duration and K_f is the stress impulse for failure. It is assumed that $\beta = 2$ and $K_f = 10^{-8}$. σ_0 is set to be the static tensile strength, and τ_f is assigned to be the time step used in the time integration.

Table 1. Material properties of epoxy resin

Young's modulus (Mpa)	3300
Poisson's ratio	0.38
Tensile strength (Mpa)	35.0
Epoxy density (kg/m^3)	1180

The displacement boundary condition is applied; the bottom end of the model is fixed, and the top end is pulled up in Z direction. The crack tip is modeled as a notch of the height 0.6 mm, the vertical surface of the notch is discretized by 2 elements, averagely. The average mesh size is 1.0 mm at the top and bottom surfaces of the notch. Due to this discretization, the time increment is set as $\Delta t = 7.5 \times 10^{-9}$s.

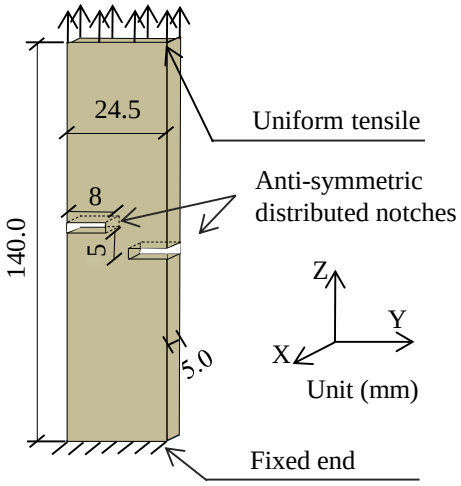

Figure 2. The reference model: epoxy resin thin plate with initial cracks

As aforementioned, the mesh configuration determines the candidate crack paths in PDS-FEM, which introduces local heterogeneity into the target model. In order to reduce the effect of this heterogeneity, finer mesh and lower loading speed can be used. The loading rate is the velocity of the top end, which is set to be V_r = 0.252*m/s*. This velocity is demonstrated to probably generate stable cracks, which means that the crack path solution is not sensitive to the local heterogeneity caused by the mesh setting used in this paper [8]. Also, another mesh with doubled density has been used to make comparison with the current one. The difference is ignorable, which guarantees the availability of current mesh setting for this study.

3.2. Disturbance setting and crack path comparison with reference model

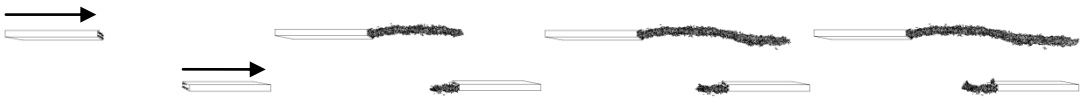
In this sub-section, the near field disturbance is modeled by changing the notches' configuration. The changing is made by adjusting the size, shape and positions of the notches. 3 cases are studied in this part:

(1) Size changing: the left notch size elongates from 8mm to 8.5mm along Y axis, while the right notch size shrinks to 7.5mm.

(2) Position changing: the distance between the anti-symmetric distributed notches changes from 5mm to 4.5 mm.

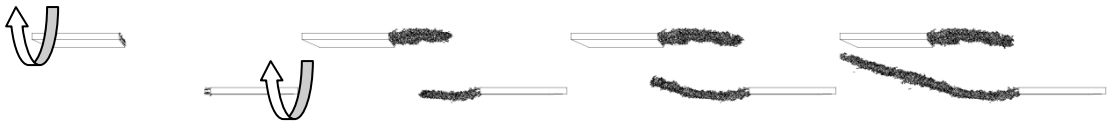
(3) Out-plane rotation: the notch is designed to rotate along the axis, which is parallel with Y axis, and passes through the centroid of the corresponding notch. Two cases are studied in this paper: (a), left and right notches rotate -5°; and (b), the left rotates -5° and the right rotates 5°. The minus sign indicates that the direction of the rotation points to the Y axis' negative direction according to right hand principle.

(a). Reference model without disturbance

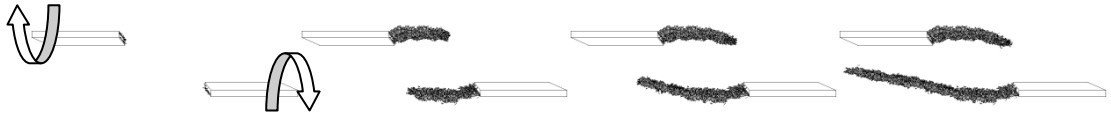


(b). Case 1: left notch elongates 0.5mm, right notches shrinks 0.5mm

(c). Case 2: the two notches get close to each other by 0.5mm



(d). Case 3.a: the two notches rotates 5° in the same direction



(e). Case 3.b: the two notches rotates 5° in the opposite direction

$t = 30\mu s$ $t = 90\mu s$ $t = 120\mu s$ final state

Figure 3. The near field crack path comparison with reference model

Fig. 3 shows the crack growth process and final states of this dynamic analysis with and without disturbance in notches' configuration. Although the modification is small, the crack path solutions of investigated cases show significant difference except for Case 2. The anti-symmetry property of crack paths solution from the analytical analysis becomes lost [15].

4. Far field disturbance modeling and simulation

4.1. Effect of the degree of heterogeneity

Since the observation technology has its limitation, the boundary condition of analysis model is often proposed in a stochastic way, say, the average with some variances is applied. The variances are used to represent the degree of heterogeneity. The boundary condition with larger variances has stronger effects on crack propagation. The first part of section 4 carries out a series of simulations to numerically examine the effect of the heterogeneity.

The model property is the same as Fig. 2, except that the height is changed to 40mm with the notches still located in the center. In order to avoid element failure near the boundary for the sudden changes caused by the disturbances, the strength of elements within 10mm to the top surface is set to be infinite. The initial tension displacement is 0.075mm for reference model, and the loading rate is set to be uniformly 126mm/s for all the cases. The time step is 5.0×10^{-9} s. Four kinds of disturbance are designed as shown in Table 2. In these formulations, "y" is the Y-axis coordinate of the nodes on top surfaces. The disturbances are added only to the magnitude of nodal displacement boundary condition on top surface along +Z direction. The first one is a half period of sine wave, whose wavelength is 16mm. Case 2 and 3 are two and four periods of sine waves, respectively. The 4th case generates a random number between -0.05mm and 0.05mm for each node on top surface. Except for case 4, the disturbance is set to be uniform along X direction. From Fig. 4, it can be observed that it becomes more and more homogeneous from u_{d1} to u_{d4} (the boundary disturbances are added with 0.075mm in this figure.) For case 4, for a specified area, the average of the disturbance on a certain area tends to be 0. By comparing the stress distribution of models with only

these four kinds of disturbance as boundary condition on top surface, u_{d4} leads to weaker effect for far field stress and larger analysis model; see Fig. 5 (a-d).

Table 2. Four kinds of disturbance added to the displacement boundary condition of the nodes on top surface

Case No.	Formulation of disturbance (mm)
1	$u_{d1} = 0.05 \cdot \sin\left(\frac{y+12.25}{8}\pi\right), -12.25 \le y \le -4.25.$
2	$u_{d2} = 0.05 \cdot \sin\left(\frac{y+12.25}{12.25}2\pi\right), -12.25 \le y \le 12.25.$
3	$u_{d3} = 0.05 \cdot \sin\left(\frac{y+12.25}{12.25}4\pi\right), -12.25 \le y \le 12.25.$
4	$u_{d4} = 0.05 \cdot random(-1,1).$

(c). Case 2

(d). Case 3

(e). Case 4

$t = 0\mu s$ $t = 10\mu s$ $t = 20\mu s$ $t = 100\mu s$

Figure 6. The crack growth process under different boundary condition

Fig. 6 shows the simulation results. From case 1 to case 4, the crack growth process becomes gradually closer to the one of reference model. The most significant difference happens in the case 1, whose average value of boundary displacement on the top surface is the largest. While the smallest difference is observed in case 4, since the disturbance is added node-wisely, the average value tends to be zero in a relative smaller area compared with case 2 and 3, and it is numerically proved here that the disturbance of this kind has smaller effect on the far field crack growth as expected.

4.2. Effect of distance

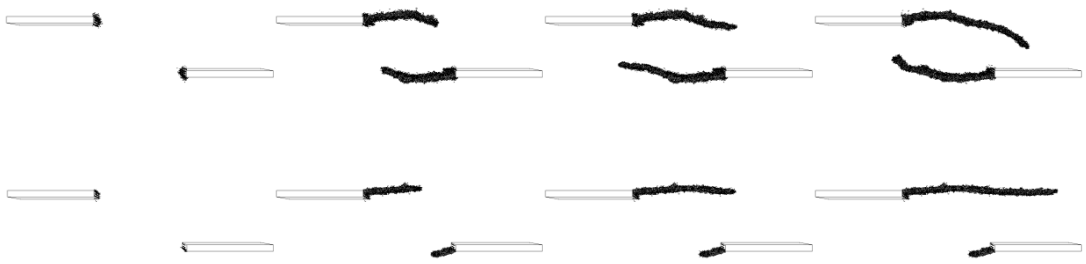
The Saint-Venant principle tells that if the distance from the area with disturbance increases, the effect will decrease. The accuracy of observation data is constrained to a certain range. This error could be ignored, since the additional strain becomes smaller as the size of analysis model becomes bigger. However, since the crack growth is a non-linear process, numerical estimation is needed to decide the size of analysis model to ignore the disturbances in boundary condition.

This target is similar with the reference model in section 3. The only differences are made in the length in Z direction and boundary condition. The model height becomes 80mm, 160mm and 320mm. As the model size becomes bigger, the distance between the notches and the top surface, where disturbance exists, becomes longer. In order to keep the same strain rate of these models, the

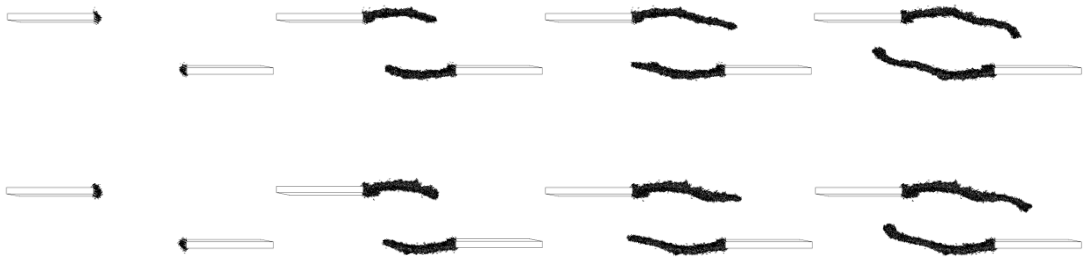
boundary condition is defined as Table 3. The disturbance of Table 2- Case 2 is used in this section. All the models of different heights are assigned with the same disturbance.

Table 3. Boundary condition of models with different sizes

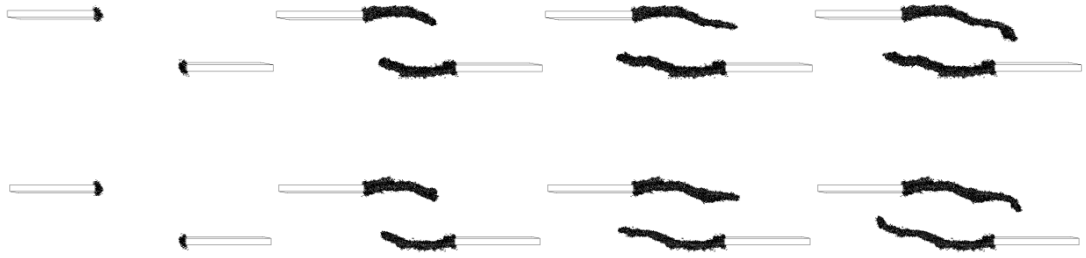
Height of the model (mm)	Initial tension displacement (mm)	Loading rate (mm/s)
80	0.15	252
160	0.3	504
320	0.6	1008



(a). Model of 80mm height without (upper) and with disturbance (lower)



(b). Model of 160mm height without (upper) and with disturbance (lower)



(c). Model of 320mm height without (upper) and with disturbance (lower)

$t = 0\mu s$ $t = 10\mu s$ $t = 20\mu s$ $t = 40\mu s$

Figure 7. The crack path comparison between models with different model height

Fig. 7 shows that the crack path distributions of all the samples without disturbance are anti-symmetric, which are similar to the analytical solution of ideal homogeneous models [14]. Also, these results indicate that the effect of the local heterogeneity generated by these mesh settings can be ignored. As the model size becomes bigger, the difference between models with and without disturbance becomes smaller. For example, the crack path of model of 80mm height with disturbance has one main crack path develop horizontally to the model boundary, the anti-symmetry

of crack paths distribution breaks. While, for the models of 160mm and 320mm height, the crack path solutions are almost the same, which indicates that the designed boundary disturbance has ignorable effect on crack growth for these models sizes. The reasons are: (i), with the same boundary disturbance, the bigger the model is, the smaller the additional stress generated; (ii), as the distance from disturbance becomes bigger, the distribution of additional stress becomes more and more uniform; see the stress distribution comparison between different model sizes in Fig. 5.

5. Conclusion

Nowadays, the observation technology still has some distance to be accuracy enough to generate a numerical model fully describing the real world. With limited data, the differences between numerical modelling and reality exist. For crack propagation problem, which is high non-linear, the effect of the differences is numerically examined by using a simple setting in this paper. For a 3D linear elastic dynamic problem, the near field disturbances lead to significant changes to crack path solution in the invested cases. While, the effect of far field disturbance becomes weaker as the distance from crack tips becomes larger, and becomes stronger as the degree of heterogeneity becomes larger. The Saint-Venant principle still holds in the studied crack growth problem.

Wrinkling and Delamination of Thin Films on Compliant Substrates

Haixia Mei and Rui Huang*

Department of Aerospace Engineering and Engineering Mechanics, University of Texas, Austin, TX 78712, USA

Abstract When the surface of a soft material is coated with a stiff thin film, compression induced buckling instability of the thin film results in surface wrinkles, and wrinkling of the thin film may lead to fracture and delamination. In this work, cohesive interface elements are employed in finite element analysis to simulate progressive wrinkling and wrinkle-induced delamination of an elastic thin film on a compliant substrate. The critical strain for initiation of wrinkle-induced delamination compares closely with an analytical formula based on a strength criterion. Subsequent growth of the delamination crack depends on the interface toughness. Co-evolution of wrinkling and buckle-delamination is simulated using a sufficiently large model. The interaction between the two buckling modes is elucidated.

Keywords: Thin films, Wrinkling, Delamination

1. Introduction

Stiff thin films on compliant substrates are used in a wide range of technological applications, including flexible electronics [1], thin film metrology [2], and micro/nano-fabrication [3]. Similar material structures are abundant in nature [4]. The mechanical interaction between a stiff film and a compliant substrate leads to a rich variety of phenomena that either limit or inspire practical applications of the hybrid system integrating hard and soft materials. In particular, recent interests in micro/nano-scale thin film materials have exploited mechanical instability (buckling and wrinkling) as an enabling mechanism for novel applications. Mechanics of surface wrinkling has been studied extensively over the last decade [5-17]. While most of these studies have assumed perfect bonding between the film and the substrate, it has been occasionally pointed out that wrinkling may cause interfacial delamination [5, 18, 19]. On the other hand, interfacial delamination is a necessary condition for buckling of thin films attached to relatively stiff substrates [20-22]. Simultaneous buckling and delamination has also been observed in compressed thin films on compliant substrates [23-25]. Some experiments have shown both surface wrinkling and buckle-delamination co-existing in the same film/substrate system [18].

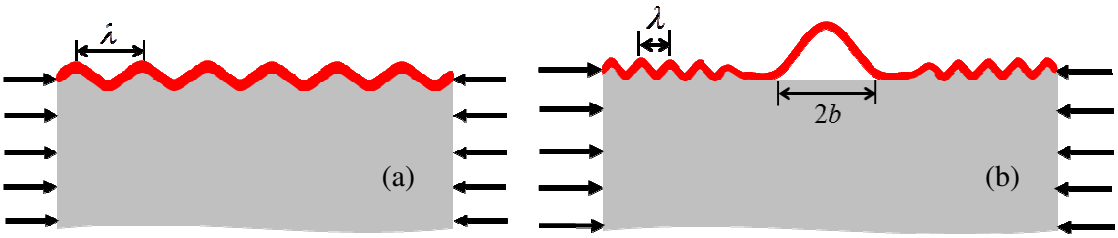

Figure 1. (a) wrinkling with no delamination; (b) Wrinkling and delamination.

In a previous work [18], we proposed a quantitative criterion for selection of the initial buckling mode by comparing the critical conditions for surface wrinkling and buckle delamination. The favored buckling mode at the onset of instability depends on the elastic mismatch between the film and the substrate as well as on the size of pre-existing interfacial delamination. More recently, by analytical and finite element methods, we presented a study on concomitant wrinkling and buckle-delamination for an elastic thin film on a highly compliant substrate [26]. In comparison with a nonlinear finite element analysis, an approximate formula was suggested to estimate the normal traction at the interface and to predict initiation of wrinkle-induced delamination. In this

paper, we present a study on nucleation and subsequent growth of wrinkle-induced delamination using a cohesive zone model.

2. Wrinkling Analysis

Consider an elastic thin film on an elastic compliant substrate, subject to lateral compression. Both the film and the substrate are taken to be linear elastic and isotropic, restricted to small, plane-strain deformation for the present study. Let ε be the nominal compressive strain, relative to the stress-free state. When ε is relatively small, the film/substrate bilayer is uniformly compressed and the surface is flat. When the strain exceeds a critical value, the film buckles and the substrate deforms coherently, forming surface wrinkles (Fig. 1a). The interface between the film and the substrate is assumed to be perfectly bonded in this section. Let h be the thickness of the film, while the substrate is considered infinitely thick. A well-known analytical solution predicts the critical strain for onset of wrinkling [9]:

$$\varepsilon_c = \frac{1}{4}\left(\frac{3\bar{E}_s}{\bar{E}_f}\right)^{2/3}, \tag{1}$$

where $\bar{E} = E/(1-\nu^2)$ is the plane-strain modulus with E for Young's modulus and ν for Poisson's ratio, and the subscripts f and s denote the film and substrate, respectively. The corresponding wrinkle wavelength is

$$\lambda = 2\pi h\left(\frac{\bar{E}_f}{3\bar{E}_s}\right)^{1/3}. \tag{2}$$

In deriving the above analytical solution, the shear traction at the film/substrate interface was assumed to be zero. Alternatively, by assuming zero tangential displacement at the interface, a similar analytical solution can be obtained [8, 13]. The two solutions are identical if the substrate is incompressible ($\nu_s = 0.5$), in which case both the shear traction and tangential displacement are zero. However, when the substrate is compressible ($\nu_s < 0.5$), neither the shear traction nor the tangential displacement is zero at the interface as the film wrinkles. As a result, neither analytical solution accurately accounts for the effect of Poisson's ratio of the substrate [15]. By taking into account both the shear traction and the tangential displacement at the interface, a more accurate analytical solution was developed [26], giving that

$$\varepsilon_c^* = \frac{1}{4}\left(\frac{3\bar{E}_s}{\bar{E}_f}\right)^{2/3}\left[1-\frac{1}{4}\left(\frac{1-2\nu_s}{1-\nu_s}\right)^2\right]^{-2/3}, \tag{3}$$

and

$$\lambda^* = 2\pi h\left(\frac{\bar{E}_f}{3\bar{E}_s}\right)^{1/3}\left[1-\frac{1}{4}\left(\frac{1-2\nu_s}{1-\nu_s}\right)^2\right]^{1/3}. \tag{4}$$

It was shown that, for a compressible substrate ($\nu_s < 0.5$), Eq. (1) underestimates the critical strain and Eq. (2) overestimates the wrinkle wavelength. The difference can be significant, up to about 20% for the critical strain and nearly 10% for the wavelength [26].

Beyond the critical strain, the wrinkle amplitude grows as a function of the nominal strain ε. An approximate solution for the wrinkle amplitude was obtained previously by a nonlinear approach that minimizes the strain energy in the film and the substrate [8, 9], namely

$$A = h\sqrt{\frac{\varepsilon}{\varepsilon_c} - 1}\,. \tag{5}$$

Finite element analysis (FEA) of wrinkling was performed using a two-dimensional (2D) plane-strain model in ABAQUS [26]. By a linear eigenvalue analysis, the finite element model predicted the critical strain for onset of wrinkling and the corresponding eigenmode, in good agreement with the analytical solutions in (3) and (4) when the substrate thickness is sufficiently large. To simulate wrinkle growth beyond the critical strain, a nonlinear post-buckling analysis was performed with the finite element model. Figure 2(a) shows the wrinkle amplitude as a function of the nominal strain for $E_f/E_s = 1000$ and $\nu_f = \nu_s = 1/3$. For comparison, the approximate analytical solution in (5) is plotted as a continuous solid line. The numerical results vary slightly as the amplitude of the initial imperfection (A_0/h) varies. Using a small initial imperfection (A_0/h = 10^{-4}), the numerical results compare closely with the analytical solution, with an abrupt transition at the critical strain. It is thus concluded that the analytical solution (5) is a good approximation for the wrinkle amplitude.

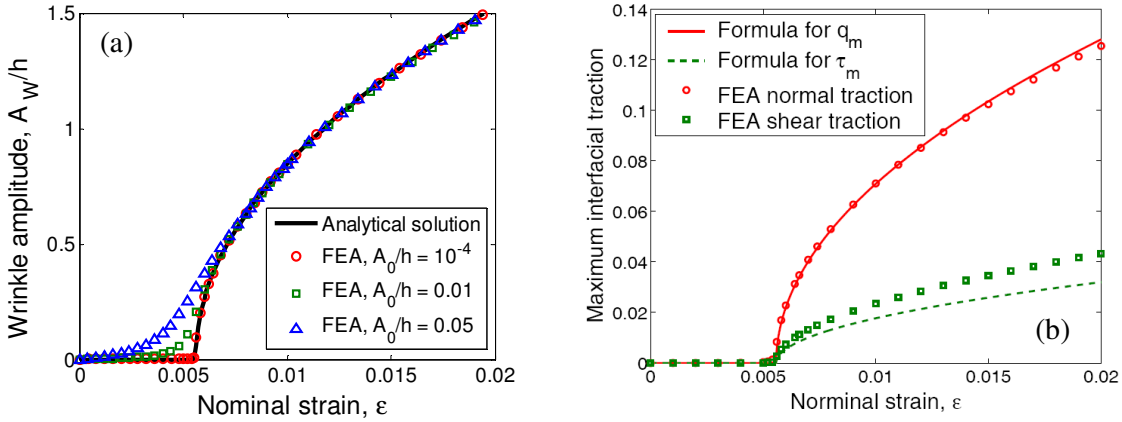

Figure 2. (a) wrinkle amplitude; (b) wrinkling-induced normal and shear tractions.

As the wrinkle amplitude grows, the normal and shear tractions acting on the film/substrate interface increase, which may cause delamination [5, 18, 19]. An approximate formula was derived to estimate the maximum normal traction at the interface [26]:

$$q_m = \frac{4(1-\nu_s)^2}{3-4\nu_s}\bar{E}_s\sqrt{\varepsilon - \varepsilon_c}\,. \tag{6}$$

The maximum shear traction is linearly related to the maximum normal traction, namely

$$\tau_m = \frac{1-2\nu_s}{2(1-\nu_s)}q_m\,. \tag{7}$$

By comparing to the FEA results, as shown in Fig. 2(b), it is found that the maximum normal traction by FEA follows (6) remarkably well, while the formula in (7) underestimates the maximum shear traction. The close agreement for the maximum normal traction suggests that the formula (6) may be used to estimate the critical strain for initiation of wrinkle-induced interfacial delamination. By setting the maximum normal traction equal the interfacial strength ($\hat{\sigma}_{\text{int}}$), the critical strain for initiation of wrinkle-induced delamination is obtained [26]:

$$\varepsilon_{WID} = \varepsilon_c + \left(\frac{3-4\nu_s}{4(1-\nu_s)^2}\frac{\hat{\sigma}_{\text{int}}}{\bar{E}_s}\right)^2. \tag{8}$$

where $\hat{\sigma}_{\text{int}}$ is the peak stress in the normal traction-separation relation for the interface as described by a cohesive zone model [27]. When $\varepsilon > \varepsilon_{WID}$, the interfacial delamination grows concomitantly with buckling (Fig. 1b).

3. Wrinkle-Induced Delamination

To simulate initiation and evolution of wrinkle-induced delamination, a two-dimensional finite element model was constructed in ABAQUS, as illustrated in Fig. 3(a). Both the film and the substrate were modeled by 2D quadrilateral elements (CPE8R). In addition, a layer of cohesive elements (COH2D4) was assigned along the interface to model the interaction between the film and the substrate. The bilinear traction-separation relation, as illustrated in Fig. 3(b), was used to describe the constitutive behavior of the cohesive elements.

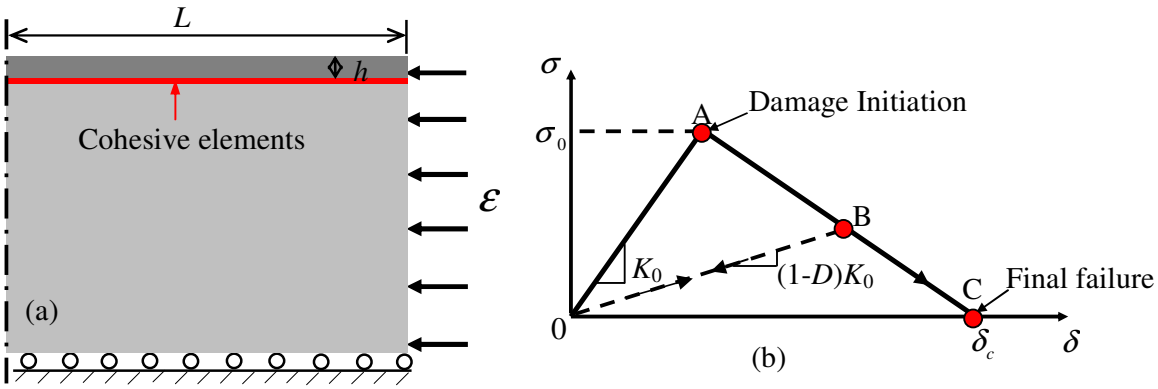

Figure 3. (a) Schematic illustration of the finite element model; (b) Illustration of the bilinear traction-separation law for the cohesive elements in ABAQUS.

A delamination crack along an interface is typically under a mixed-mode condition due to elastic mismatch between the film and the substrate [20]. Consequently, the interfacial properties are required for both modes I and II conditions. For the bilinear traction-separation model, the interfacial properties to be specified include [28]: the initial elastic stiffness K_n and K_s, the cohesive strength σ_n and τ_s, and the interface toughness Γ_I and Γ_{II}. In this section, we ignore the effect of mode mix by taking $K_n = K_s = K_0$, $\sigma_n = \tau_s = \sigma_0$ and $\Gamma_{\text{I}} = \Gamma_{\text{II}} = \Gamma$ for the interface. Previous studies have suggested that the initial elastic stiffness K_0 plays a less important role in cohesive zone modeling. In the present study, the initial stiffness K_0 is taken to be a constant (with $K_0 h / \overline{E}_f = 1$) in all simulations, while the strength (σ_0) and toughness (Γ) are varied. The elastic properties for the film and the substrate are such that $E_f/E_s = 1000$ and $\nu_f = \nu_s = 1/3$.

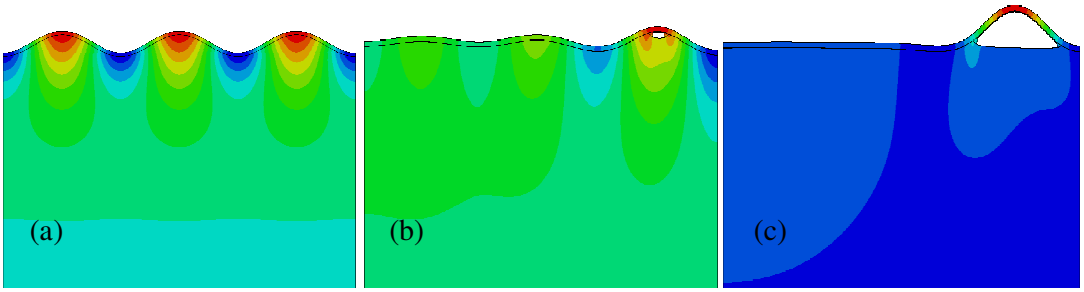

Figure 4. Numerical simulation of progressive wrinkling and interfacial delamination for an elastic thin film on a compliant substrate subject to increasing compression: (a) wrinkling with no delamination; (b) initiation of wrinkle-induced delamination; (c) subsequent growth of interfacial delamination.

Figure 4 shows an example of the numerical simulation. Start from an elastic film perfectly bonded to a compliant substrate (with a small initial perturbation). As the applied compressive strain increases, the film wrinkles first (Fig. 4a), followed by nucleation of an interfacial crack at one of the wrinkle crests (Fig. 4b). Upon subsequent growth of the delamination, buckling of the film becomes localized while the neighboring wrinkles are flattened (Fig. 4c).

In Section 2, initiation of wrinkle-induced delamination is predicted by comparing the maximum normal traction at the interface with the strength of the interface. This strength-based criterion for crack initiation is found to be in good agreement with the numerical results by the cohesive zone modeling approach. With the cohesive interface elements, a nonlinear post-buckling analysis is performed to simulate progressive wrinkling and wrinkle-induce delamination, as shown in Fig. 4. The amplitude of wrinkling or buckling is plotted as a function of the nominal strain in Fig. 5(a) for three different values of the interfacial strength, whereas the interfacial toughness is taken to be a constant, $\Gamma/\overline{E}_f h = 10^{-5}$. For comparison, the wrinkle amplitude without delamination is plotted as a continuous solid line. For each value of the interfacial strength, the wrinkle amplitude follows the solid line before the initiation of delamination. At a critical nominal strain that depends on the interfacial strength, a delamination crack is nucleated and the buckle amplitude at the location of delamination increases abruptly, deviating from the solid line. Thus, the initiation of delamination may be readily observable in experiments by measuring the buckle amplitude.

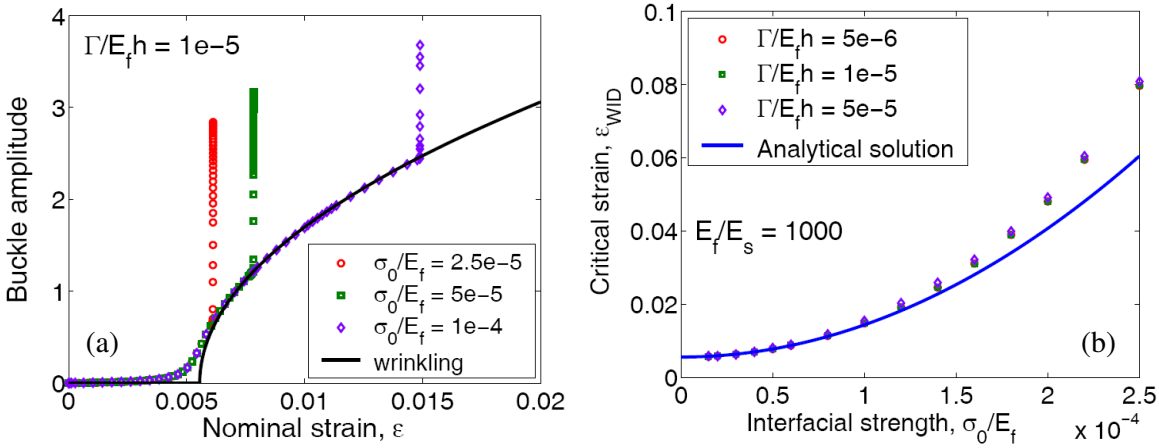

Figure 5. (a) Buckle amplitude as a function of the nominal strain, for three different values of interfacial strength. The solid line represents the wrinkle amplitude by the analytical solution in Eq. (5). (b) The critical strain for initiation of winkle-induced delamination as a function of the interfacial strength.

The critical strain for initiation of wrinkle-induced delamination can be determined from Fig. 5(a). Alternatively, by the cohesive zone model, each cohesive element is characterized by a damage parameter (D), which varies between 0 and 1 during the separation process [28]. Thus, the critical strain for crack nucleation can be determined numerically when the damage parameter reaches 1 for at least one of the cohesive elements. Figure 5(b) plots the critical strain for wrinkle-induced delamination as a function of the interfacial strength, for three different values of interface toughness. For comparison, the critical strain predicted by the analytical formula in Eq. (8) is plotted as the solid line. Clearly, the critical strain is nearly independent of the interface toughness, justifying the strength-based criterion. The numerical results agree closely with the analytical prediction for relatively low interfacial strengths (e.g., $\sigma_0/\overline{E}_f < 10^{-4}$). For higher interfacial strengths, however, Eq. (8) underestimates the critical strain. Apparently, since the critical strain increases with increasing interfacial strength, the linear approximation of the normal traction that leads to Eq. (8) becomes increasingly inaccurate as the strain goes beyond a few per cent.

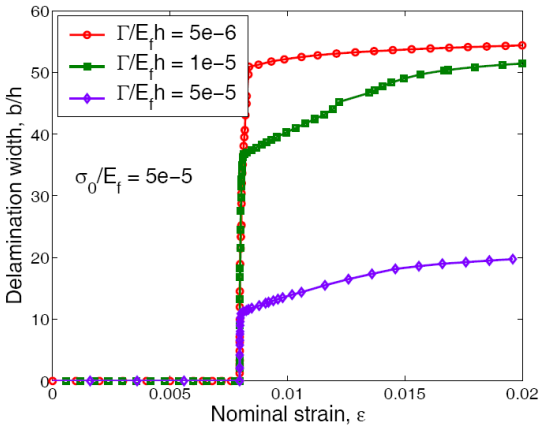

Figure 6. Delamination width as a function of the nominal strain for different values of interface toughness.

While the initiation of wrinkle-induced delamination is independent of the interface toughness, subsequent growth of the delamination crack does depend on the interface toughness. As shown in Figure 6, for an interfacial strength $\sigma_0/\overline{E}_f = 5\times10^{-5}$, the delamination width (b) as a function of the nominal strain is plotted for three different values of interface toughness. The delamination width is determined from the cohesive zone model based on the damage parameters of the cohesive elements. The delamination width remains zero until the critical strain is reached. Upon initiation, the delamination crack grows rapidly, which in turn leads to rapid growth of the buckle amplitude as shown in Fig. 5(a). The growth of the interfacial crack is eventually stabilized with a delamination width depending on the interface toughness. Further increasing the compressive strain, the delamination grows stably. Apparently, under the same nominal strain (greater than the critical strain), the delamination width decreases as the interface toughness increases.

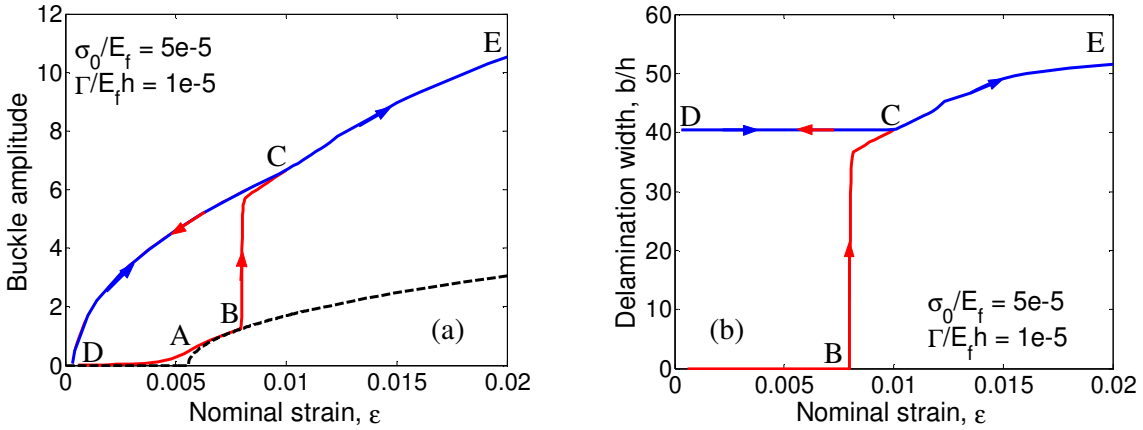

Figure 7. (a) Buckle amplitude and (b) delamination width as a function of the nominal strain during a loading-unloading-reloading cycle.

The cohesive zone elements as implemented in ABAQUS assume an irreversible damage process, which may be used to simulate damage accumulation under cyclic loading. As an example, numerical simulation of a loading-unloading-reloading process is performed, with $\sigma_0/\overline{E}_f = 5\times10^{-5}$ and $\Gamma/\overline{E}_f h = 10^{-5}$. Figure 7(a) shows the buckle amplitude versus the nominal strain. Before the first loading, the interface is perfectly bonded with no damage (D = 0). As the nominal strain increases, wrinkling occurs first at point A (ε ~ 0.00556), and wrinkle-induced delamination initiates at B (ε ~ 0.0076). Subsequently, delamination and buckling co-evolve. The corresponding delamination width is shown in Fig. 7(b). Start unloading at point C (ε = 0.01). The delamination

width remains a constant (b/h ~ 40) during unloading. Meanwhile, the buckle amplitude decreases, following a different path from C to D. The buckle amplitude is nearly zero at D, with the nominal strain (ε ~ 0.000384) corresponding to the critical strain for onset of buckling with b/h ~ 40. Upon reloading, the buckle amplitude follows the same path of unloading from D to C, during which the delamination does not grow. Further increasing the nominal strain beyond C to point E (ε = 0.02), the delamination grows and the buckle amplitude increases. Apparently, the buckle amplitude during reloading follows a drastically different path compared to that for the first loading. Such a behavior qualitatively agrees with an experiment by Vella et al. [25]. However, in their experiment, a discontinuous jump of the buckle amplitude during the first loading was reported, presumably due to the unstable growth of the delamination.

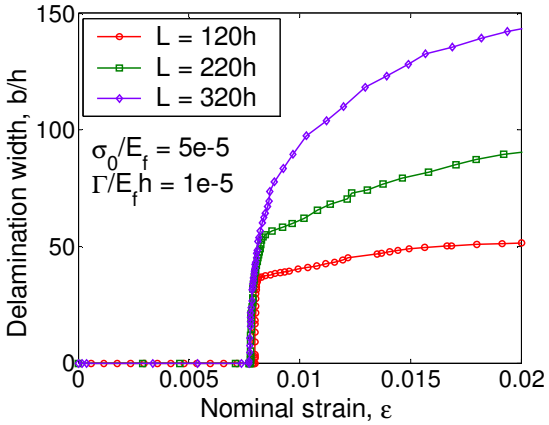

Figure 8. Delamination width as a function of the nominal strain for different lengths used in the finite element model.

It is noted that the growth of buckle-delamination is strongly influenced by the boundary condition. When the crack tip approaches one end of the model, where the symmetric boundary condition is assumed, the energy release rate drops rapidly and the crack is arrested when the energy release rate is less than the interface toughness. Figure 8 shows the delamination width as a function of the nominal strain by finite element models with three different lengths (L). Apparently, as L increases, the delamination width increases upon initiation, while the critical strain for initiation is insensitive to the model size.

With a sufficiently large L/b, the localized buckle-delamination and periodic wrinkles may co-exist [26]. To simulate both initiation and co-evolution of wrinkling and buckle-delamination, the finite element model with cohesive elements is employed with L = 1000h and H = 200h. The bilinear traction-separation relation is assumed for the interface with $\sigma_0/\overline{E}_f = 5\times10^{-5}$ and $\Gamma/\overline{E}_f h = 5\times10^{-5}$. Figure 9 shows the evolution of deformation profiles of the film (solid lines) and the substrate surface (dashed lines) with increasing nominal strain. The film remains flat until the nominal strain reaches the critical strain for wrinkling (ε_W = 0.00556). Beyond the critical strain, periodic wrinkles form as shown in Fig. 9(a) at ε = 0.00758. As the nominal strain increases to the critical value for wrinkle-induced delamination (ε_{WID} = 0.0076), an interfacial crack initiates and grows rapidly, as shown in Figs. 9 (b) and (c) for two strains slightly above the critical strain. The growth of delamination leads to large, localized buckling, which relaxes the compressive stress in the film over a region close to the delamination. As a result, the wrinkles are flattened in the relaxation region. Further away from the delamination, the film remains wrinkled. The size of the relaxation region depends on the relative compliance of the substrate and the delamination width. With continuous growth of the delamination and a finite length (L = 1000h) in the finite element model, all the wrinkles are flatted eventually, as shown in Fig. 9(d).

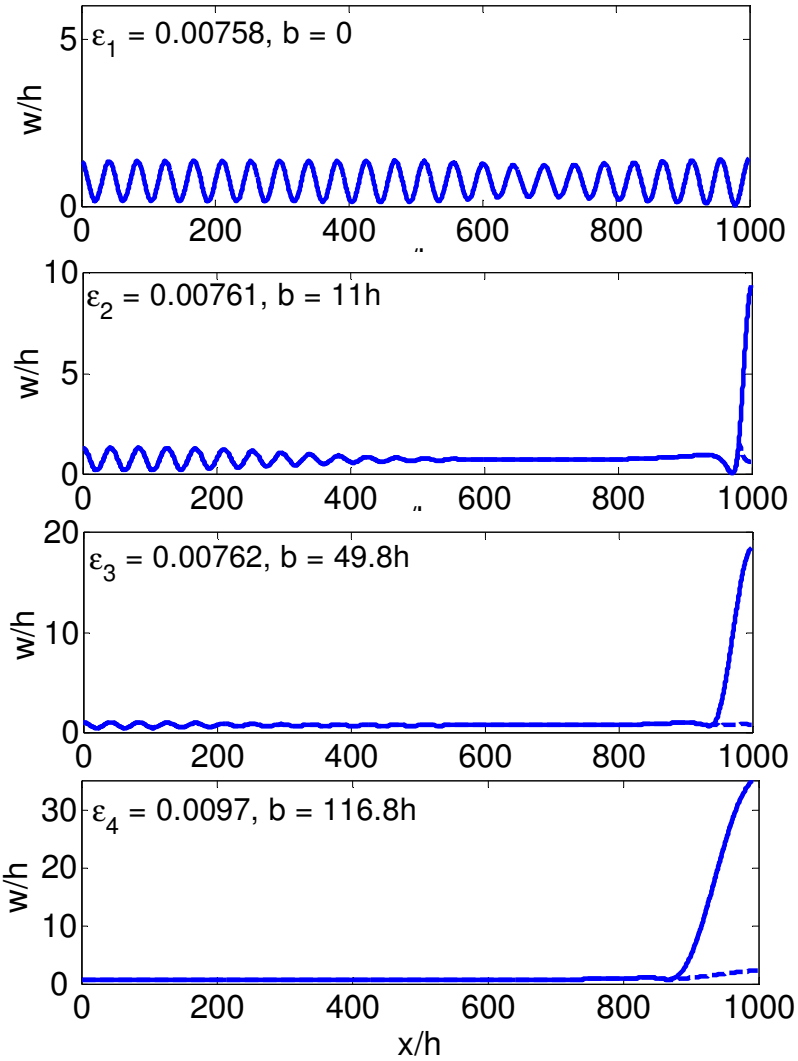

Figure 9. Out-of-plane displacement of the film (solid lines) and the substrate surface (dashed lines) at four different nominal strains: (a) ε = 0.00758; (b) ε = 0.00761 (b = 11h); (c) ε = 0.00762 (b = 49.8h); (d) ε = 0.0097 (b = 116.8h).

4. Summary

Cohesive interface elements are employed in finite element analysis to simulate initiation and growth of wrinkle-induced delamination of an elastic thin film on a compliant substrate. The critical strain for initiation of wrinkle-induced delamination compares closely with an analytical formula based on a strength criterion. Subsequent growth of the delamination crack depends on the interface toughness. Co-evolution of wrinkling and buckle-delamination is simulated using a sufficiently large model. The interaction between the two buckling modes is elucidated.

Abstract For actual operating conditions, wheel/rail contact forces of high-speed train are very difficult to directly measure. Minimizing the role of driving force between wheel and rail is a key point to ensure railway wheel-rail transport systems in good condition and efficient operation in the long-term. A time-domain inversion method for dynamic loads was proposed. Based on the state space equation, dynamic programming methods and the Bellman principle of optimality, the main theoretical derivation of the inversion mathematical model was given. With a high-speed vehicle system as the research object, accelerations of axle box as input conditions, the vertical and horizontal wheel/rail forces were identified. Inverse results were compared with SIMPACK simulation results which had the same kinetic parameters. The results indicate that the vertical and horizontal wheel/rail forces had the same trend with SIMPACK simulation results. Results from the inverse model were also compared with experiment data. The inverse model has high inverse accuracy, and can be used for real-time monitoring of the running train wheel/rail contact forces.

Keywords inverse technique, wheel/rail contact force, SIMPACK simulation, experiment data

1. Introduction

The estimation of dynamic forces acting on a structure is a problem that has been treated with only partial success. Methods for such estimation include in two categories, direct methods and indirect methods. Direct methods use the placement of force transducers into the load paths at the point of force application. Indirect methods use other sensor types placed at locations on the structure that may not necessarily correspond to the force input locations. Many situations require indirect methods because the forces cannot be measured[1]. For example, the train is subject to a wheel/rail impact load when operating because of rail irregularities and crossing turnouts.

Currently, various methods for inverse identification problem associated with indirect force measurements have been proposed, see for example Ref. [2-4] for an overview. Among them, are two main methods: the frequency domain[5,6]and the time domain method [7,8].

The running stability of a vehicle depends on the wheel/rail interaction. Wheel/rail contact forces play an important role to keep the vehicle stable on straight track and make it able to negotiate through curves smoothly. The possibility of gaining information about wheel–rail contact forces in real time and on-board normal rolling stock vehicles has significant value. But due to the complexity of the inverse identification problem in railway vehicle systems, not much research has been performed in this area. Some papers on this subject focused on impact detection at the contact point[9,10]. Commercially available systems for monitoring wheel-rail health are based on strain measurements at a chosen location on the track, and the track strain will be measured when the train passed [11]. A big disadvantage of the application of such a system is the necessity to locate strain measurement points at many locations on the track, not only time consuming but also expensive[12]. There is a great need to formulate a method that can be based on measurements on the vehicle but not on the track.

This paper presents a new method to identify the time history of input excitation based on the dynamic programming equation. The forces were identified in the time domain by a recursive

formula; the response of the structure was reconstructed by using the identified forces for comparison; and the objective function between the identified and measured values were minimized. The dynamic programming technique possesses inherent limitations that cannot be avoided, however, it still effectively solves these problems during the identification process, and greatly reduces the influence from insufficient known qualities and improper boundary conditions, and obtain decent results comparable with the exact forces. The mathematical model is then applied to estimate the wheel-rail vertical load of a high-speed train, and the inversion results are compared with the rolling and vibrating test-bed and the very detailed SIMPACK model simulation results.

2. Basis of load identification theory

The finite element model of an n-DOFs linear elastic time-invariant structure, the dynamic governing equation is given by:

$$M\ddot{X}(t) + C\dot{X}(t) + KX(t) - F(t) = 0 \tag{1}$$

where M, C, and K are the system mass, damping, and stiffness matrices, respectively; $X(t)$ is the displacement vectors of the structure; and F is the vector of the input excitation forces.

Using the state space formulation, Eq. (1) is converted into a set of first order differential equations as follows:

$$\dot{x} = Ax + Bf \tag{2}$$

For the load identification problem, the known responses of the system M, C, and K are used to solve the unknown input vector $f(s)$ which is in discrete form. In order to facilitate the computer solution, these differential equations are then rewritten as discrete equations using the standard exponential matrix representation.

$$x_{i+1} = Cx_i + Df_i \tag{3}$$

$$y_i = Qx_i \tag{4}$$

where, $C = e^{Ah}$ is the exponential matrix, and together with matrix $D = A^{-1}(C - I)$ is the input influence matrix which represents the dynamics of the system and associates with load. Q is a $m \times 2n$ selection matrix related the measurements to the state variables. x_{i+1} denotes the values at the $(i+1)th$ time step of the computations.

The goal is to find the unknown forcing term f that will cause the system described in Eq.(3) to best match the measurements $\hat{y}_i$. The mathematical representation of a best match is to minimize the least squares error between $\hat{y}_i$ and y_i. This is expressed in matrix-vector notation with the inner product of two vectors (.,.). The least error squares are now expressed as:

$$E = \sum_{i=1}^{N} (y_i - \hat{y}_i)^T \lambda_1 (y_i - \hat{y}_i) + (f_i)^T \lambda_2 (f_i) \tag{5}$$

where T is the transpose of a matrix, y_i and $\hat{y}_i$ are the output variables of the system for the identification formula and measurement, respectively. λ_1 and λ_2 are symmetric positive definite matrices that provide the flexibility of weighting the measurement and the forcing terms. The second term is known as the regularization parameter and the method is called the Tikhonov method. The value of λ_2 is very important for the result, fortunately, there exists a method that can be used to estimate the optimum value of λ_2, see the reference [13].

To minimize the least-squares error E in Eq.(6) over the sequence of the forcing vector, the dynamic programming method and Bellman's Principle of Optimality are applied. This leads to defining the minimize value of E for any initial x and the number of stages, n. Thus:

$$F_n(x) = \min_{f_i} E_n(x, f_i) \tag{7}$$

The recurrence formula can be derived by applying the Principle of Optimality:

$$F_{n-1}(x) = \min_{f_{n-1}}[(Qx_{n-1} - \hat{y}_{n-1})^T \lambda_1 (Qx_{n-1} - \hat{y}_{n-1}) + (f_{n-1})^T \lambda_2 (f_{n-1}) + F_n(Cx_{n-1} + Df_{n-1})] \tag{8}$$

This equation represents the classic dynamic programming structure in that the minimizing at any point is determined by selecting the decision f_{n-1} to minimize the immediate cost (first and second terms) and the remaining cost resulting from the decision (the third term). The solution is obtained by starting at the end of the process, $n = N$, and working backward toward $n = 1$. At the end point $n = N$, the minimum is determined from:

$$F_N(x) = \min_{f_N}[(Qx_N - \hat{y}_N)^T \lambda_1 (Qx_N - \hat{y}_N) + (f_N)^T \lambda_2 (f_N)] \tag{9}$$

At this end point the minimum is obtained by choosing $f_N = 0$ which gives:

$$F_N(x) = \min_{f_N}[(Qx_N - \hat{y}_N)^T \lambda_1 (Qx_N - \hat{y}_N)] \tag{10}$$

Eq.(10) can be expanded to:

$$F_N(x) = (x_N, Q^T \lambda_1 Q x_N) - 2(x_N, Q^T \lambda_1 \hat{y}_N) + (\hat{y}_N, \lambda_1 \hat{y}_N) \tag{11}$$

Eq.(11) can be changed as:

$$F_N(x) = (x_N, R_N x_N) + (x_N, S_N) + q_N \tag{12}$$

where $R_N = Q^T \lambda_1 Q$, $S_N = -2Q^T \lambda_1 \hat{y}_N$, $q_N = (\hat{y}_N, \lambda_1 \hat{y}_N)$.

Eq.(12) shows that F_N is quadratic in x_N. It can be proven inductively that all of the F_n are quadratic in x_n, thus for any n we can write:

$$F_n(x) = (x_n, R_n x_n) + (x_n, S_n) + q_n \tag{13}$$

Substituting Eq.(13) into Eq.(8) and minimizing the equation, the optimal forcing term f^*_{n-1}:

$$(2\lambda_2 + 2D^T R_n D) f^*_{n-1} = -D^T S_n - 2D^T R_n C x_{n-1} \tag{14}$$

For simplification the Eq.(14), let:

$$V_n = (2\lambda_2 + 2D^T R_n D)^{-1} \tag{15}$$

$$H_n = 2D^T R_n \tag{16}$$

Eq.(23) can now be written as:

$$f^*_{n-1} = -V_n D^T S_n - V_n H_n C x_{n-1} \tag{17}$$

These are recurrence formulas required to determine the optimal solution of Eq. (6).

Using Pearson product-moment correlation coefficient to measure the relationship between identification results and actual results, usually expressed by γ. The equation can be expressed by:

$$\gamma = \frac{\sum_{i=1}^{n}(F_{Si} - \bar{F}_S)(F_{Ii} - \bar{F}_I)}{\sqrt{\sum_{i=1}^{n}(F_{Si} - \bar{F}_S)^2}\sqrt{\sum_{i=1}^{n}(F_{Ii} - \bar{F})^2}} \tag{18}$$

where, F_{Si} is the SIMPACK simulation value at each time point, F_{Ii} is the identification value at each time point, $\bar{F}_S$ is the standardization variables of the SIMPACK simulation value, $\bar{F}_I$ is the standardization variables of the identification value.

3. Laboratory verification

First, a laboratory test is performed at TPL at Southwest Jiaotong University using the rolling and vibrating test-bed. The car body vertical acceleration, two bogie frames accelerations and four axle boxes accelerations are measured. Unfortunately, because of the limitation of test conditions, we can not measure the vertical and lateral interface forces directly. So we use a set of measured vertical acceleration response as inputs into the inverse vehicle model to identify other components of the vehicle acceleration responses, and compare with the measured results, by this way to verify the inversion model.

Test scenario is shown in Figure 1, the velocity of the rolling and vibrating test-bed is 250 km/h, the form of rail incentive is actual measured line spectrum of Wu-Guang line.

Figure 1. Test scene of the rolling and vibrating test-bed

Using car body, two bogie frames and the first axle box (numbered from left to right) measured vertical acceleration as input into the inverse vehicle model, the fourth axle box acceleration response and the fourth wheel-set vertical force are identified. See figures 2 and 3.

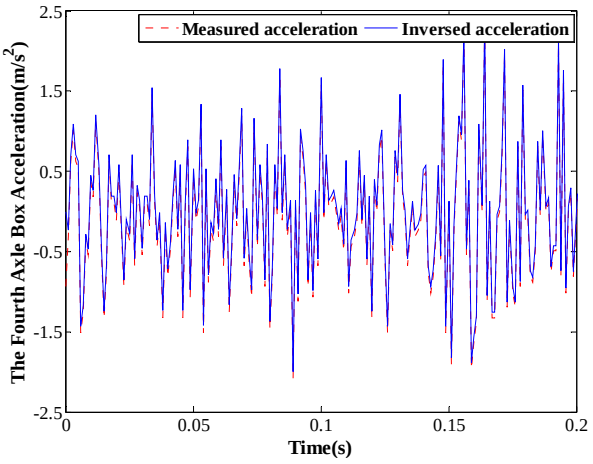

Figure 2. Measured and inversed accelerations for the fourth axle box

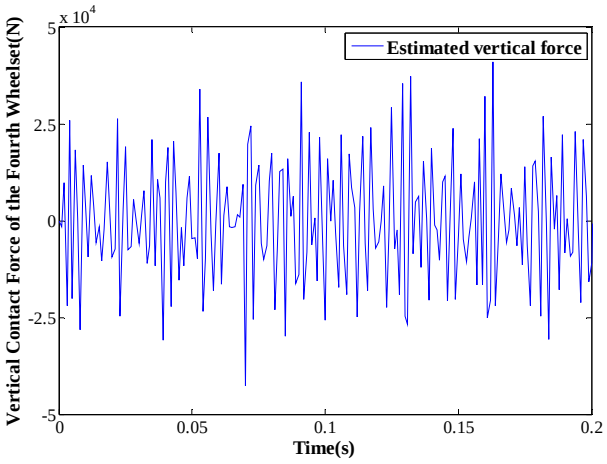

Figure 3. The estimated vertical dynamic contact force for the fourth wheel-set

From figure 2, the acceleration of the fourth axle box which identified by the inverse model is very similar to the measured value, and its correlation coefficient is 0.9756, which can be thought as height correlation. Figure 3 shows the inversed vertical dynamic contact force for the fourth wheel-set, unfortunately, it is unable to be compared with measurement value due to the limitation of test-bed. It is worth noting that, due to the limitation of accelerometers in low frequencies, figure 3 is just the vertical dynamic contact force for the fourth wheel-set, the real vertical force should add the weight reaction force.

4. The application of the inverse model in high-speed train

The commonly used simulation package, SIMPACK, was used to develop a wagon model based on the same parameters as the inverse model. The parameters of the SIMPACK model were the same as the inverse model which was used to generate wheel-rail forces and accelerations at the axle box. These accelerations will be as the input conditions for the inverse mathematical model. In order to make the SIMPACK model replace a practical field test, the vehicle model developed with SIMPACK needs to be a very refined model which includes the nonlinearity of the wheel-rail contact geometry, the nonlinearity of the wheel-rail creep rate and creep forces, the nonlinearity of the vehicle suspension components, and so on.

Taking into account the complexity of the car body systems, as well as many non-linear factors, we need to simplify the body. In this paper, for the vertical and lateral stochastic vibration inverse modeling of the car body, about twenty-seven degrees of freedom are considered.

The measured track irregularity from Beijing to Tianjin was used as the input to the SIMPACK with a simulated velocity of 70 m/s. The resulting axle box accelerations were then used as inputs for the inverse model. The wheel-rail forces were estimated using the MATLAB package. The outputs of the inverse model were the axle box accelerations and wheel-rail reacting forces. The vertical and lateral contact forces of the third wheel-set of the inverse model and the SIMPACK simulation were compared, see Figures 4-5. At the same times, the derailment index which is got from the inverse model and the SIMPACK simulation are also compared. See figure 6.

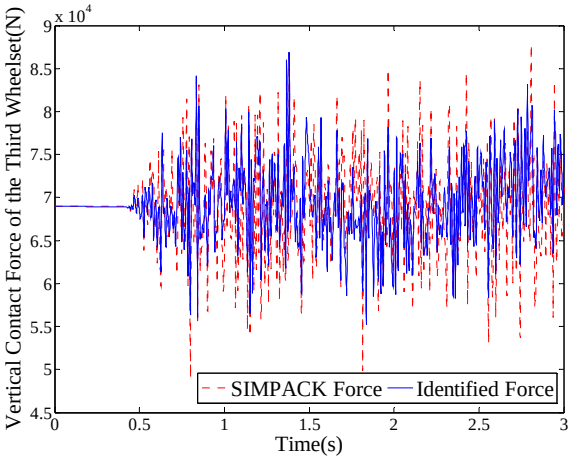

Figure 4. Wheel-rail vertical forces comparison

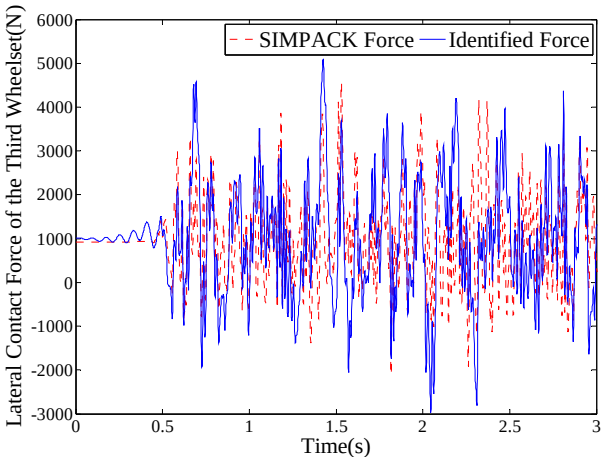

Figure 5. Wheel-rail lateral forces comparison

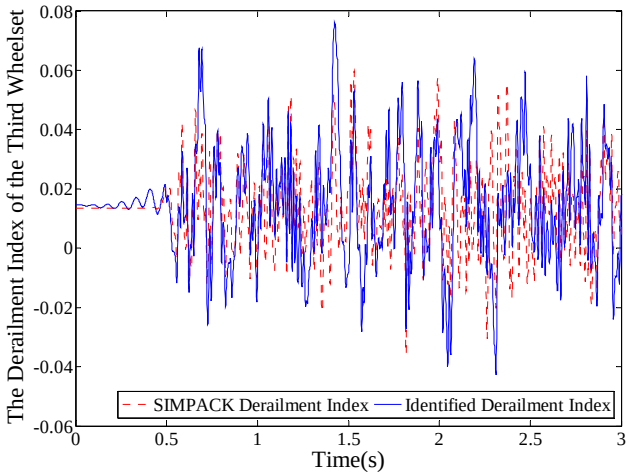

Figure 6. Index coefficient comparison

To compare the results of the SIMPACK simulation and those obtained from the inverse identification method, as shown in Figures 4-5, we can observe that the inverse forces are consistent with the simulation results. Their correlation coefficients are 0.6984 and 0.6235, respectively. By comparing the derailment index, it can be found that the tendencies of the result are also quite accordant.

5. Conclusion

A non-iterative recurrence algorithm for input estimation algorithm mathematical model has been established. Combined with Tikhonovo regularization algorithm, anti-noise ability of the inversion model is enhanced. Based on the response of the accelerations, the method can be applied to the estimation of vertical and lateral contact forces for an operating rail vehicle.

(1)The inversion model is verified by the experiment data of the laboratory test. Using some parts of accelerations which are measured from the rolling and vibrating test-bed to identify the other component of accelerations, and compare with laboratory tests. The results show that the inversion model can be used to identify the unknown output responses for interesting places.

(2) From the time domain, the comparison of the vertical and lateral contact forces results between inverse and SIMPACK models are given. The results show that, the inverse mathematical model has high relatively precision for inversing the wheel/rail contact forces of operation

high-speed vehicle. And their correlation coefficients are greater than 0.5, can be thought as significant correlation.

Since there exist many non-linear factors, such as wheel-rail contact geometry and creep effects, which not only must be taken into account in high-speed train modeling but also make the estimation process of the wheel-rail lateral contact forces are more complex than the vertical contact forces. More research is needed to expand the inverse model which considers the non-linear factors between the wheel and rail. Furthermore, the next step will involve field trial tests to verify the effectiveness of the inverse model.

ABSTRACT

Most seismic migration methods stress primary reflection data, it means that multiples is considered as noise and need to be removed prior to migration process. In fact multiples contain important medium property information which can be utilized to improve the quality of image.

By introducing a background model, the difference between the known background properties and unknown real medium properties is inverted. Each gridpoint act as a scatterer in the background media. In our work, Finite-difference contrast source inversion method will be applied in seismic inversion with full wavefield data including surface-related and internal multiples, without including explicit computation of forward problem at each iteration step, this method can employ an inhomogeneous background medium. By solving an optimization problem to reconstruct the contrast function χ, which is a quantity having some connection with the real velocity distribution in the medium. Result of the process is an accurate angle-dependent reflectivity image as well as angle-dependent velocity model in subsurface.

Key words: migration, inversion, anisotropy, multiple, scatter

1. INTRODUCTION

Generally speaking, there are two possible approaches for velocity estimation from surface recorded seismic data, the two methods differ from the domain in which the information is used to update the velocity model. The first approach is formulated in the data space prior to migration, and it involves matching of recorded and simulated data using an approximate velocity model. The second approach is formulated in the image space after migration, in which it involves measuring and correcting image features that indicate model properties inaccuracies.

Nowadays, migration and inversion have been two different approaches to reveal the subsurface information [4,6,9-11], Their fundamental theory is very different. But we can treat migration and inversion as a same form in mathematics. Although they have different physical meaning. So we can incorporate migration and inversion process together to analyze the seismic data[1].

One of the well-known full nonlinear inversion methods based on the integral equation(IE) formulation is the contrast source inversion (CSI) method[7,8]. The main

disadvantage of this approach based on integral equation formulation is that the background medium is usually a simple homogeneous medium.

Finite-difference based contrast source inversion(FDSCI) method is adaptive to the arbitrary inhomogeneous background medium[2,3,5,12], similar to the IE contrast source inversion method, the unknown contrast source and the unknown contrast function are updated alternately to reconstruct the scatters without requiring the solution of forward problem at each iteration step. An attractive feature of FDCSI approach is that the impendence matrix is only dependent on the background medium, which is invariant throughout the inversion process, Hence, the FD operator needs to be inverted only once and the results can be reused for multiple source positions.

2. THEORY

2.1 Joint migration and inversion

In the joint migration and inversion process, first extrapolate the receiver wavefield from depth level z_{m-1} to z_m, then inversion process is applied at depth z_m, and we will use the wavefield from all depth level which represents the internal and surface-related multiples. In full wavefield inversion process, the difference between the known background properties and the unknown real medium properties is inverted. Each gridpoint act as a point scatterer in the background medium, called as contrast source. The total wavefield in the true medium equals the sum of the wavefield of the primary sources in the background and the wavefield of all point scatterers in the background. The contrasts and the total wavefield are alternately updated until the total simulated wavefield matches the recorded wavefield at the detector positions. After that the full wavefield migration is applied to yield the angle-dependent reflectivity, which is solved as a constrained least-squares minimization problem. The two minimization process is in the same mathematic form[1]:

$$Q^{-}(z_m, z_0) - \left[U(z_m, z_m)P^{+}(z_m, z_0) + V(z_m, z_m)P^{-}(z_m, z_0)\right] = \min \tag{1}$$

In which P represents the incident wavefield and Q refers to response of depth z_m

In the migration process, the matrices U and V represent reflectivity:

$$U(z_m, z_m) = (R_1^{\mathrm{U}}, R_2^{\mathrm{U}}, \mathrm{L}\ \ R_k^{\mathrm{U}}, \mathrm{L}\ ) \tag{2}$$

$$V(z_m, z_m) = (R_1^{\mathrm{I}}, R_2^{\mathrm{I}}, \mathrm{L}\ \ R_k^{\mathrm{I}}, \mathrm{L}\ ) \tag{3}$$

In the inversion process, the matrices U and V are same and represent contrast:

$$U(z_m, z_m) = V(z_m, z_m) = (\chi_1, \chi_2, \mathrm{L}\ \ \chi_k, \mathrm{L}\ ) \tag{4}$$

In the JMI process full wavefield extrapolation is applied from z_{m-1} to z_m, using the

wavefield Q_j^+ and p_j^- at depth level z_{m-1}, this extrapolation step yields an estimate of the total wavefield, being denoted by $< p_j >$ at intermediate depth level z_n $(z_{m-1} < z_n < z_m)$:

$$< p_j(z_n, z_0) >= W_0(z_n, z_{m-1}) Q_j^+(z_{m-1}, z_0) + W_0^*(z_n, z_{m-1}) p_j^-(z_{m-1}, z_0) \tag{5}$$

W, W^* represent propagation operator and its conjugate complex respectively.

Next, a full waveform inversion step is applied:

$$p_j(z_n, z_0) =< p_j(z_n, z_0) > + \Delta p_j(z_n, z_0) \tag{6}$$

$$\Delta p_j(z_n, z_0) = \sum_{l=m-1}^{m} G_0(z_n, z_l) \sum_k \chi_k(z_l, z_l) p_{kj}(z_l, z_0) \tag{7}$$

yielding an update of the velocities in each gridpoint of layer (z_{m-1}, z_m) and an update of the wavefield at z_m, G refers to Green's function:

$$p_j^+(z_m, z_0) = W_0(z_m, z_{m-1}) Q_j^+(z_{m-1}, z_0) + \Delta p_j(z_m, z_0) \tag{8}$$

$$Q_j^-(z_m, z_0) = W_0^*(z_m, z_{m-1}) p_j^-(z_{m-1}, z_0) + \Delta p_j(z_{m-1}, z_0) \tag{9}$$

After completion, the updated velocities in layer (z_{m-1}, z_m) as well as the reflectivity and updated wavefield at depth level z_m are known, we can apply the following migration and inversion process at deeper depth recursively.

2.2 Contrast source inversion

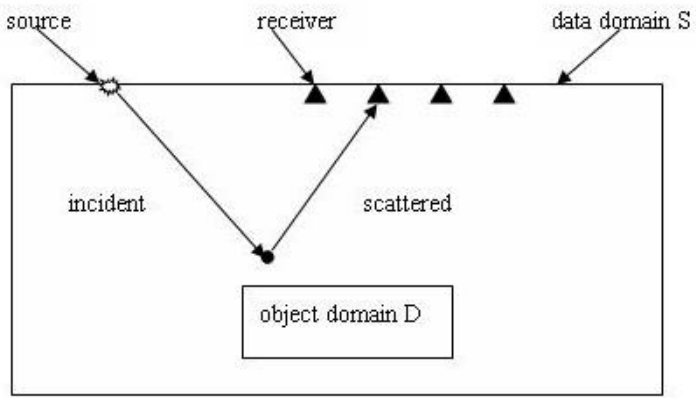

Figure 1. Configuration of the scattering problem

Denote the inversion domain as the object domain D and the data domain S as the domain where the sources and the receivers are located, combination of domain D and domain S are called total domain T (see Figure 1).

Total field $p_j(r)$ satisfies the Helmholtz equation[2,3]:

$$\left[\Delta^2 + k^2(r)\right] p_j(r) = -Q(r, r_j^s), \quad r \in T \tag{10}$$

Where Q is the source term.

We split the total field into its incident and scattered parts:

$$p_j = p_j^{inc} + p_j^{sct} \tag{11}$$

The incident field satisfies the equation:

$$\left[\nabla^2 + k_b^2(r)\right] p^{inc}{}_j(r) = -Q\left(r, r_j^S\right), \quad r \in T \tag{12}$$

Subtracting equation (12) from equation (10), then the scattered field satisfied the equation:

$$\left[\nabla^2 + k_b^2(r)\right] p^{sct}{}_j(r) = -k_b^2(r) w_j(r), \quad r \in T \tag{13}$$

Where $w_j(r)$ are the contrast sources, defined as:

$$w_j(r) = \chi(r)\, p_j(r) \tag{14}$$

In which the contrast function $\chi(r)$ is given by:

$$\chi(r) = \left[\frac{k(r)}{k_b(r)}\right]^2 - 1 = \frac{c^{-2}(r) - c_b^{-2}(r)}{c_b^{-2}(r)} \quad r \in D \tag{15}$$

Here, $c^{-2}(r) = \rho k(r)$ is the velocity of the scattering object, and $c_b^{-2}(r) = \rho k_b(r)$ is the velocity of the background medium.
Equation (13) can be written using operator notation:

$$H_b(p_j^{sct}(r)) = -k_b^2(r) w_j(r), r \in T \tag{16}$$

The solution of equation (16) can be written as:

$$p_j^{sct}(r) = H_b^{-1}\left[-k_b^2(r) w_j(r)\right] = L_b\left[w_j(r)\right], r \in T \tag{17}$$

Introducing an operator M^s that interpolates the field values defined at the finite-difference grids to the appropriate receiver position, the data equation for the contrast function χ can be written as:

$$p^{sct}{}_j(r) = M^s\{L_b[w_j(r')]\} \quad r \in S, r' \in T \tag{18}$$

Introducing an operator M^D that selects fields only on the object domain, we obtain the object equation for the contrast source w_j:

$$\chi p_j^{inc} = w_j - \chi M^D \left\{ L_b \left[w_j \right] \right\} \tag{19}$$

We handle the inverse problem as a minimization of a cost function, being a linear combination of errors in the data equation and the object equation, the method alternatively constructs sequence of contrast sources by a conjugate gradient iterative method such that the cost function is minimized. And the contrast function is then determined to minimize the error in the object equation. The cost function is a superposition of the errors in the data equations and errors in the object equations:

$$F(\chi, w_j) = F^S(w_j) + F^D\left(\chi, w_j\right) = \frac{\sum_j \left\| f_j - M^S \left\{ L_b \left[w_j \right] \right\} \right\|_S^2}{\sum_j \left\| f_j \right\|_S^2} + \frac{\sum_j \left\| \chi p_j^{inc} - w_j + \chi M^D \left\{ L_b \left[w_j \right] \right\} \right\|_D^2}{\sum_j \left\| \chi p_j^{inc} \right\|_D^2} \tag{20}$$

In which f_j is the scattered measured data.

The L_2-norms on domains S and domain D are defined as follow:

$$\left\| v_j \right\|_S^2 = \int_S v_j(r)\overline{v_j(r)}dr \qquad \left\| v_j \right\|_D^2 = \int_D v_j(r)\overline{v_j(r)}dr \tag{21}$$

Where the overbar denote the complex conjugate of a function.

We minimize the cost function (20) by conjugate gradient method, When the updated value of χ is obtained, we can produce the real velocity distribution of the medium. If the value of the cost function is not smaller than the prescribed error criterion, the update step will be repeated until convergence is achieved. The flow of the inversion and migration can be seen in Figure 2.

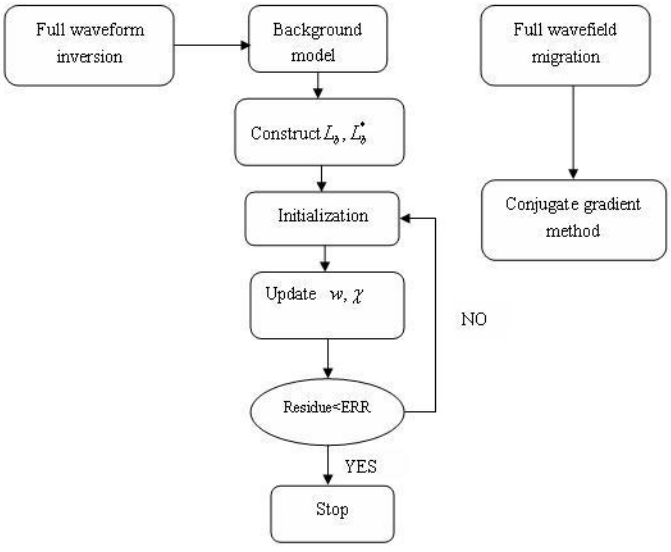

Figure 2. Flowchart of the full wavefield inversion and migration method

SUMMARY

Surface-related and internal multiples can be vital information for revealing the deep subsurface information, because the multiple wavefield can strength the illumination power towards the deeper subsurface. By applying the contrast source inversion method, I wish to produce the accurate velocity distribution and angle-dependent reflectivity of the subsurface model.

Abstract To study the effect of fractu,re fill on the elastic anisotropy of the rock and frequency-dependent attenuation and dispersion in fractured reservoirs, a model for porous and fractured medium is developed. In this model, the fractured medium is considered as a periodic system of alternating layers of two types: thick porous layers representing the background, and very thin and highly compliant porous layers representing fractures. By taking the simultaneous limits of zero thickness and zero normal stiffness of the thin layers, we obtain expressions for dispersion and attenuation of the P-waves. The results show that in the low-frequency limit the elastic properties of such a medium can be described by Gassmann equation with a composite fluid, while the P-wave speed is relatively high at high frequencies for two layers can be treated as 'hydraulically isolated'. However, there appears to be a critical case where no dispersion is observed, which is caused by the balance of fractures compliance and fluid compressibility filling in them.

Keywords porous media, fracture , attenuation, dispersion

1 Introduction

Flow of the pore fluid by the passing wave is widely believed to be the main cause of attenuation and dispersion of elastic waves in porous rocks. In particular, flow that occurs due to spatial variations of rock or fluid properties on mesoscopic scale (larger than the pore size but smallerthan the wavelength) is considered to be significant at seismic frequencies [1-4]. The magnitude of attenuation and dispersion caused by mesoscopic wave-induced flow is proportional to the squared contrast (variance) of spatial variations of rock or fluid properties. Thus attenuation and dispersion are only significant if the contrast of spatial variations is large.

In recent years, two situations with large contrast in rock/fluid properties have been identified: partial saturation and fractured rock. Partial saturation refers to the situation where a rock is saturated with a mixture of two immiscible fluids with large difference between their properties (say, liquid and gas). When an elastic wave propagates through such a rock, the patches of rock saturated with gas and liquid will deform differently, resulting in pressure gradients and fluid flow [5-8]. Fractured rock refers to a situation where a porous rock is permeated by open fractures. When a wave propagates through such a rock, fractures will deform to a greater extent than the porous background, resulting in fluid flow between pores and fractures [9-13]. These situations (partial saturation and fractures) are usually treated separately: analysis of wave propagation in a partially saturated rock usually ignores variations in elastic properties of the solid frame, while the porous rock permeated by fractures is usually assumed to be saturated with a uniform fluid. However, in some situations, particularly when a fluid such as water or carbon dioxide is injected into a tight hydrocarbon reservoir, fractures may be filled with a different fluid (with capillary forces

preventing fluid mixing). In this paper we consider the simplest situation of this kind: a porous rock saturated with one fluid and permeated by a single set of aligned planar fractures filled with another fluid. For such a medium, we derive a dispersion equation following a method originally proposed by Brajanovski et al. [12] for a porous fractured medium saturated with a single fluid.

The paper is organized as follows. First, we review the theory in case of a medium saturated with a single fluid. Then we extend the method to the situation where the porous background and fractures are saturated with different fluids and derive the corresponding dispersion equation, which yields expressions for dispersion and attenuation due to wave induced flow between pores and fractures. To explore the behavior of attenuation and dispersion, we explore various limiting cases and present several numerical examples. Finally, we discuss the physical nature of the results obtained.

2 Liquid saturated porous and fractured medium

Brajanovski et al. [12] developed a model for a porous medium with aligned fractures. The medium comprises a periodic (with spatial period H) stratified system of alternating layers: relatively thick layers of a background material (with a finite porosity ϕ_b) and relatively thin layers of a high-porosity material representing the fractures. This double porosity model is a limiting case of a periodically layered poroelastic medium studied by White et al. [1] and Norris [14]. Norris showed that for frequencies much smaller than Biot's characteristic frequency $\omega_{\mathrm{B}} = \eta\phi/k\rho_{\mathrm{f}}$, and also much smaller than the resonant frequency of the layering $\omega_{\mathrm{R}} = V_{\mathrm{p}}/H$, the compressional wave modulus of a periodically layered fluid-saturated porous medium composed of two constituents, *b* and *c*, can be written in the form:

$$\frac{1}{C_{33}} = \frac{h_{\mathrm{b}}}{C_{\mathrm{b}}} + \frac{h_{\mathrm{c}}}{C_{\mathrm{c}}} + \frac{\left(\frac{\alpha_{\mathrm{b}}M_{\mathrm{b}}}{C_{\mathrm{b}}} - \frac{\alpha_{\mathrm{c}}M_{\mathrm{c}}}{C_{\mathrm{c}}}\right)^2}{\sqrt{\frac{i\omega\eta_{\mathrm{b}}M_{\mathrm{b}}L_{\mathrm{b}}}{C_{\mathrm{b}}k_{\mathrm{b}}}}\frac{H}{2}\cot\left(\sqrt{\frac{i\omega\eta_{\mathrm{b}}C_{\mathrm{b}}}{k_{\mathrm{b}}M_{\mathrm{b}}L_{\mathrm{b}}}}\frac{h_{\mathrm{b}}H}{2}\right) + \sqrt{\frac{i\omega\eta_{\mathrm{c}}M_{\mathrm{c}}L_{\mathrm{c}}}{k_{\mathrm{c}}C_{\mathrm{c}}}}\frac{H}{2}\cot\left(\sqrt{\frac{i\omega\eta_{\mathrm{c}}C_{\mathrm{c}}}{k_{\mathrm{c}}M_{\mathrm{c}}L_{\mathrm{c}}}}\frac{h_{\mathrm{c}}H}{2}\right)}, \tag{1}$$

In Eq. (1), both constituents are assumed to be made of the same isotropic grain material with bulk modulusK_{g}, shear modulus μ_{g} and density ρ_{g}, but they have different solid frame parameters: porosityϕ, permeability k, dry bulk modulus K, shear modulus μ and thickness fraction h. The layers b and c may be saturated with different fluids with bulk modulus K_{f}, density ρ_{f} and dynamic viscosity η, as indicated by adding 'b' and 'c' in the subscript. Parameter $C_j = L_j + \alpha_j^2 M_j$ denotes the fluid-saturated P-wave modulus of layer j given by Gassmann's equation [15], where $\alpha_j = 1 - \frac{K_j}{K_{\mathrm{g}}}$ is Biot's effective stress coefficient, M_j is pore space modulus defined by $\frac{1}{M_j} = \frac{\alpha_j - \phi_j}{K_{\mathrm{g}}} + \frac{\phi_j}{K_{\mathrm{f}j}}$ and $L_j = K_j + 4\mu_j/3$ is the dry P-wave modulus of the layer j.

To construct a model for a porous medium permeated by parallel fractures, Brajanovski et al. [12] considered parameters with subscript b to represent the porous background, and parameters with subscript c to represent fractures (cracks). They then assumed fractures to be very thin and very

compliant layers and thus considered Eq. (1) in the limit $h_c \to 0$, $K_c \to 0$ and $\mu_c \to 0$ such that both K_c and μ_c (and hence $L_c \to 0$) are O(h_c). By assuming that both pores and fractures are saturated with the same fluid with the viscosity $\eta_b = \eta_c = \eta$, Brajanovski et al [12] obtained the equation

$$\frac{1}{C_{33}} = \frac{1}{C_b} + \frac{\left(\frac{\alpha_b M_b}{C_b} - 1\right)^2}{\sqrt{\frac{i\omega\eta M_b L_b}{C_b k_b}}\frac{H}{2}\cot\left(\sqrt{\frac{i\omega\eta C_b}{k_b M_b L_b}}\frac{h_b H}{2}\right) + \frac{1}{Z_N}}, \tag{2}$$

Where $Z_N = \lim_{h_c \to 0} \frac{h_c}{L_c}$ is the normal excess fracture stiffness of the dry frame given by Schoenberg and Douma [16]. Implicit in the derivation of Eq. (2) was an assumption

$$K_f \gg h_c / Z_N, \tag{3}$$

When both pores and fractures are saturated with a liquid, Eq. (2) exhibits significant attenuation and velocity dispersion. However the model is limited to the case where the fluid is the same in both matrix pores and fractures, and there is an upper limit on the fluid compressibility (Eq. (3)). Below we develop a model that overcomes these limitations.

3 Arbitrary fluid in the fractures

The analysis in the previous section suggests that the effect of fracture fill on the overall modulus of the porous and fractured medium depends on how the fluid bulk modulus scales with h_c as $h_c \to 0$. To analyze this effect, we use the following parameterization

$$K_{fc}/K_g = B h_c, \tag{4}$$

where *B* is a dimensionless nonzero constant that defines the type of fluid in fractures, liquid, gas or intermediate. If *B* is large enough (e.g., if the fluid is a liquid), K_{fc} may satisfy the condition (3). In this case, taking the limit $h_c \to 0$ in Eq. (1), we obtain Eq. (2) with fluid properties K_f and η replaced by the corresponding values for the fluid in the pores K_{fb} and η_b. Conversely, $B = 0$ corresponds to dry fractures.

When $h_c \to 0$, we have $K_c \to 0$, and $\phi_c \to 1$, and thus $\alpha_c \to 1$, $M_c \to K_{fc}$, and $C_c \to L_c + K_{fc}$. Combining these results with the parameterizations (4), and considering $\cot(x) \approx 1/x$ for any complex x with $|x| \ll 1$ and $\cot\left(\sqrt{ix}\right) \to i$ for any real $x \gg 1$, Eq. (1) in the limit $h_c \to 0$ can be simplified as

$$\frac{1}{C_{33}} = \frac{1}{C_b} + \frac{Z_N}{1 + Z_N B K_g} + \frac{\left(\frac{\alpha_b M_b}{C_b} - \frac{Z_N B K_g}{1 + Z_N B K_g}\right)^2}{\sqrt{\frac{i\omega\eta_b M_b L_b}{C_b k_b}}\frac{H}{2}\cot\left(\sqrt{\frac{i\omega\eta_b C_b}{k_b M_b L_b}}\frac{H}{2}\right) + \frac{B K_g}{1 + Z_N B K_g}}, \tag{5}$$

Eq. (5) is the approximation of Eq. (1) for a porous and fractured medium with an arbitrary fracture fill.

Here, we have introduced a dimensionless constant *B* to define the type of fracture fluids, so that we can attain gas and liquid limiting cases. Additionally, we can define low and high frequencies with respect to fluid flow between fractures and background. Therefore, in the following section, we derive and analyze some limiting cases of fluids and frequencies.

4 Limiting cases

4.1 Fluid limits

4.1.1 Liquid in fractures

If the fluid in the fractures is liquid, then $B \gg 1$ and Eq. (5) gives

$$\frac{1}{C_{33}} = \frac{1}{C_{\mathrm{b}}} + \frac{\left(\frac{\alpha_{\mathrm{b}} M_{\mathrm{b}}}{C_{\mathrm{b}}} - 1\right)^2}{\sqrt{\frac{i\omega\eta_{\mathrm{b}} M_{\mathrm{b}} L_{\mathrm{b}}}{C_{\mathrm{b}} k_{\mathrm{b}}}} \frac{H}{2} cot\left(\sqrt{\frac{i\omega\eta_{\mathrm{b}} C_{\mathrm{b}}}{k_{\mathrm{b}} M_{\mathrm{b}} L_{\mathrm{b}}}} \frac{H}{2}\right) + \frac{1}{Z_{\mathrm{N}}}}}, \tag{6}$$

Note that Eq. (6) is exactly the same as Eq. (2). This shows that the result of Brajanovski et al [12] is valid not only if both pores and fractures are saturated with the same liquid, but also when the two liquids are different.

4.1.2 Dry or nearly dry fractures

When fractures are dry or nearly dry, Eq. (5) cannot, strictly speaking, be used because it was derived by assuming that B is nonzero. Instead, we take the limit $B \to 0$, directly in Eq (1). This gives

$$\frac{1}{C_{33}} = \frac{1}{C_{\mathrm{b}}} + Z_{\mathrm{N}} + \frac{\left(\frac{\alpha_{\mathrm{b}} M_{\mathrm{b}}}{C_{\mathrm{b}}}\right)^2}{\sqrt{\frac{i\omega\eta_{\mathrm{b}} M_{\mathrm{b}} L_{\mathrm{b}}}{C_{\mathrm{b}} k_{\mathrm{b}}}} \frac{H}{2} \cot\left(\sqrt{\frac{i\omega\eta_{\mathrm{b}} C_{\mathrm{b}}}{k_{\mathrm{b}} M_{\mathrm{b}} L_{\mathrm{b}}}} \frac{H}{2}\right)}}, \tag{7}$$

Incidentally, exactly the same result is obtained by taking the limit $B \to 0$ in Eq. (5). This means that Eq. (5) is valid even in the limit of small B. Eq. (7) gives the P-wave modulus for a porous medium with dry or gas-filled fractures, and it is quite different from Eq. (5) for liquid case. To further analyze the reason for the difference, we derive the limiting cases of low and high frequencies next.

4.2. Frequency limits

4.2.1 Low frequencies

In the low-frequency limit $\omega \to 0$, the cotangent function in Eq. (5) can be replaced by the inverse of its argument. Thus, Eq. (5) is reduced to

$$\frac{1}{C_{33}} = \frac{1}{C_{\mathrm{b}}} + \frac{1}{\frac{1}{Z_{\mathrm{N}}} + BK_{\mathrm{g}}} + \frac{\left(\frac{\alpha_{\mathrm{b}} M_{\mathrm{b}}}{C_{\mathrm{b}}} - \frac{BK_{\mathrm{g}}}{\frac{1}{Z_{\mathrm{N}}} + BK_{\mathrm{g}}}\right)^2}{\frac{M_{\mathrm{b}} L_{\mathrm{b}}}{C_{\mathrm{b}}} + \frac{BK_{\mathrm{g}}}{1 + Z_{\mathrm{N}} BK_{\mathrm{g}}}}}, \tag{8}$$

In the low frequency limit, the fluid pressure should be fully equilibrated between pores and fractures. Thus in this limit the result must be consistent with the anisotropic Gassmann equations for a fractured medium saturated with a single composite fluid [17] with a bulk modulus defined by

$$\frac{1}{K_{\mathrm{f}}^*} = \frac{S_{\mathrm{fb}}}{K_{\mathrm{fb}}} + \frac{S_{\mathrm{fc}}}{K_{\mathrm{fc}}}, \tag{9}$$

Eq. (9) is known as the Wood equation, and corresponds to so-called uniform saturation of the partial saturation theory [7, 8, 18]. So, if we replace K_{b} with K_{f}^* in Eq. (5), and then take the low

frequency limit, we can also get the same expression as given by Eq. (8).

To clarify the physical meaning of the low-frequency Eq. (8) we again consider liquid and dry (or gas) cases. For liquid-filled fractures (large *B*), we have

$$\frac{1}{C_{33}} = \frac{1}{C_{\mathrm{b}}} + \frac{\left(\frac{\alpha_{\mathrm{b}} M_{\mathrm{b}}}{C_{\mathrm{b}}} - 1\right)^2}{\frac{M_{\mathrm{b}} L_{\mathrm{b}}}{C_{\mathrm{b}}} + \frac{1}{Z_{\mathrm{N}}}}, \tag{10}$$

while for $B \ll 1$

$$\frac{1}{C_{33}} = \frac{1}{L_{\mathrm{b}}} + Z_{\mathrm{N}}, \tag{11}$$

The liquid limit, Eq. (10), corresponds exactly to the low frequency limit of the result of Brajanovski et al [12], with only the bulk modulus of the liquid in the pores affecting the overall modulus. This result may be understood from Eq. (10), which shows that when the bulk moduli of the two fluids are comparable, the effect of the fracture fluid is negligible for its relatively small saturation. In turn, Eq. (11) is exactly the modulus of the dry medium [12, 16]. This is because when K_{fc} is very small (much smaller than $h_{\mathrm{c}} K_{\mathrm{fb}}$), Wood Eq. (10) for the effective fluid modulus reduces to

$$\frac{1}{K_{\mathrm{f}}^*} = \frac{S_{\mathrm{fc}}}{K_{\mathrm{fc}}}, \tag{12}$$

and thus $K_{\mathrm{f}}^* \to 0$, which means that the whole porous and fractured model can be considered as dry or nearly dry medium. Physically, this is the result of the fact that at low frequencies, the pore pressure is equilibrated between pores and fractures, so when the pressure in fractures is zero, thus is also zero in the pores. This is the drained – or dry – limit.

4.2.2 High frequencies

In the high-frequency limit $\omega \to \infty$, the cotangent function in Eq. (5) can be replaced by i. So, we can get the expression of P-wave modulus at high frequencies

$$\frac{1}{C_{33}} = \frac{1}{C_{\mathrm{b}}} + \frac{1}{\frac{1}{Z_{\mathrm{N}}} + B K_{\mathrm{g}}}, \tag{13}$$

In liquid and gas cases we have

$$\frac{1}{C_{33}} = \frac{1}{C_{\mathrm{b}}}, \tag{14}$$

and

$$\frac{1}{C_{33}} = \frac{1}{C_{\mathrm{b}}} + Z_{\mathrm{N}}, \tag{15}$$

respectively.

Note that at high frequencies, the fluid pressure does not have time to equilibrate between pores and fractures, and thus they can be considered 'hydraulically isolated' [12, 17]. Thus the P-wave modulus in this limit corresponds to the modulus of a porous medium with isolated fractures. In the liquid case, the modulus given by Eq. (14) is the same as if there were no fractures. This is because liquid can stiffen the otherwise very compliant fractures so that P-wave velocities for waves propagating parallel and perpendicular to layering are both approximately equal to the modulus of the background medium [12, 16, 19]. Conversely, when fractures are dry, the P-wave modulus (15) is the same as for a medium with dry isolated fractures (cf Eq. (11)).

.

5 Numerical examples

Our main result, Eq. (5), shows that the P-wave modulus is complex-valued and frequency dependent regardless of fluid saturation of fractures. This means that waves will have attenuation and dispersion.

To explore these effects, we compute the complex phase slowness in the direction normal to the fractures $V_p^{-1}=\sqrt{\rho_{\mathrm{b}}/C_{33}}$, where $\rho_{\mathrm{b}}=(1-\phi_{\mathrm{b}})\rho_{\mathrm{g}}+\phi_{\mathrm{b}}\rho_{\mathrm{fb}}$ is mass density of the fluid-saturated background (the effect of fractures on the density can be ignored as their volume fraction is negligibly small). This complex phase slowness can be used to evaluate the frequency dependence of the P-wave phase velocity and attenuation for waves propagating perpendicular to fractures. The P-wave phase speed is the inverse of real part of the complex phase slowness, and the attenuation Q.is given by half the ratio of the real part to the imaginary part of the complex phase slowness.

Now, we rewrite Eq. (5) as a function of normalized frequency Ω [12]

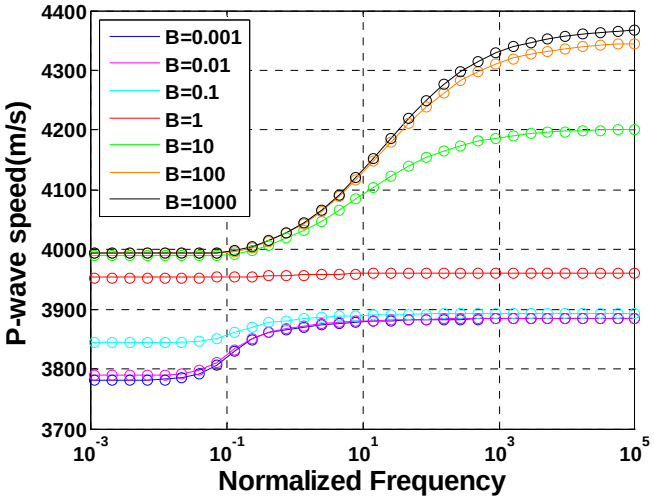
$$\frac{1}{C_{33}}=\frac{h_{\mathrm{b}}}{C_{\mathrm{b}}}+\frac{1}{\frac{L_{\mathrm{b}}(1-\delta_{\mathrm{N}})}{\delta_{\mathrm{N}}}+BK_{\mathrm{g}}}+\frac{\left(\frac{\alpha_{\mathrm{b}}M_{\mathrm{b}}}{C_{\mathrm{b}}}-\frac{BK_{\mathrm{g}}}{\frac{L_{\mathrm{b}}(1-\delta_{\mathrm{N}})}{\delta_{\mathrm{N}}}+BK_{\mathrm{g}}}\right)^2}{L_{\mathrm{b}}\sqrt{i\Omega}*\cot\left(\frac{h_{\mathrm{b}}C_{\mathrm{b}}}{M_{\mathrm{b}}}\sqrt{i\Omega}\right)+\frac{BK_{\mathrm{g}}}{1+\frac{\delta_{\mathrm{N}}}{L_{\mathrm{b}}(1-\delta_{\mathrm{N}})}BK_{\mathrm{g}}}},\tag{16}$$

where $\Omega=\frac{\omega H^2\eta_{\mathrm{b}}M_{\mathrm{b}}}{4C_{\mathrm{b}}k_{\mathrm{b}}L_{\mathrm{b}}}$ is the normalized frequency and $\delta_{\mathrm{N}}=\frac{Z_{\mathrm{N}}L_{\mathrm{b}}}{1+Z_{\mathrm{N}}L_{\mathrm{b}}}$ is a dimensionless (normalized) fracture weakness with values between 0 and 1 [16]. All our calculations are made for a water-saturated sandstone using quartz as the grain material (K_{g}=37GPa, ρ_{g}=2.65×10^{3}kgm^{-3}). The dependency of bulk and shear moduli of the background dry on porosity was assumed to follow the empirical model of Krief et al. [20].

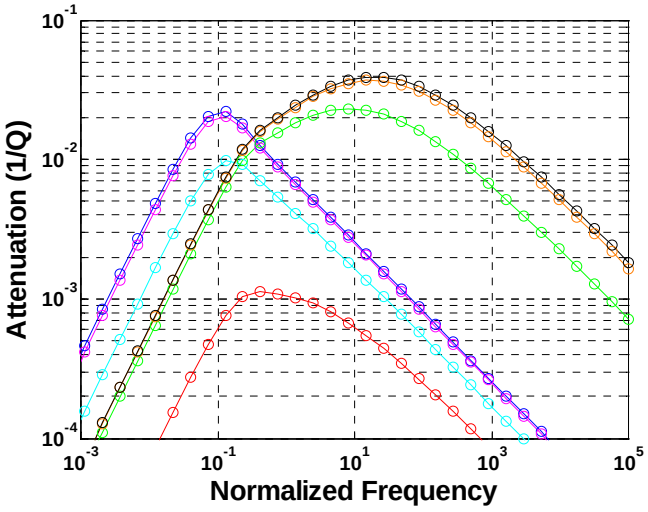
To explore the validity of our approximation, we compare the attenuation and dispersion results with the original Norris [14] model, Eq. (1). For the Norris model, we set fracture parameters to satisfy the assumptions of the approximation (h_{c}=0.001, ϕ_{c}=0.999, δ_{N}=0.2, k_{c}=200mD, η_{fc}=18.1e^{-6}Pa.s). Then, the P-wave speeds and inverse quality factor Q^{-1} are calculated for different values of B, and the results are shown on Fig. 1.Alternatively, we could have given an input value to K_{fc} and then computed B using Eq. (4). However, we prefer to evaluate the results for different values of the dimensionless constant B.

Fig. 1 shows diepersion and attenuation of P-waves propagating along the symmetry axis (normal to fracture plane) for different values of parameter B. Symbols show the values obtained by our approximation, Eq. (5), while the curves correspond to the Norris general solution, Eq. (1). We see that for the whole range of parameter B, the approximation matches the general model very accurately. Curves of dispersion and attenuation have a shape typical for a relaxation phenomenon. It is interesting that dispersion and attenuation is significant for both liquid-filled (B=1000) and dry (B=0.001) fractures, but is much lower for intermediate values of the parameter B. This somewhat

surprising observation can be explained as follows. When both pores and fractures are filled with liquids, the compression caused by the wave will compress the fractures to much greater extent than the background porous material (since fractures are much more compliant than pores), causing the fluid to flow from fractures into pores. Conversely, when the pores are saturated with a liquid and the fractures are dry (or filled with very compressible gas), the compression will cause the flow from pores into fractures (it will be easier to compress gas than deform the fractures). Thus, at some intermediate value of the fluid compressibility (or parameter B), there will be no flow at all, and hence no dispersion or attenuation.



(a)



(b)

Figure 1. Frequency dependency of P-wave velocity (a) and inverse quality factor Q^{-1} (b) computed using our approximation (17) and Norris model (1) for different values of the parameter B.

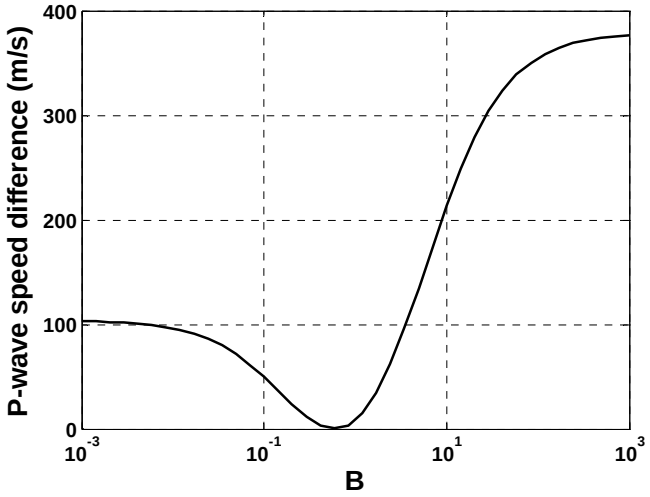


Figure 2. Dispersion magnitude (difference between high- and low-frequency velocities) as a function for parameter B. As B increases, the dispersion first decreases, reaches zero, and then increases again.

Fig. 2 shows the dispersion magnitude (difference between high- and low-frequency velocities) as a function for parameter B. As B increases, the dispersion first decreases, reaches zero, and then increases again. We also see that the dispersion is almost insensitive to B both for very small and very large values of B (corresponding to highly compressible gases and liquids, respectively), but quite sensitive to B for values of B in a range around the critical value where dispersion reaches zero. This critical value can be obtained by equating low- and high-frequency limits, Eqs (8) and (13). This gives

$$B^* = \frac{\alpha_\mathrm{b} M_\mathrm{b}}{C_\mathrm{b} - \alpha_\mathrm{b} M_\mathrm{b}} \frac{1}{K_\mathrm{g}} \frac{1}{Z_\mathrm{N}}, \tag{17}$$

The value B^* given by Eq. (17) corresponds to a critical fracture fluid modulus case, where there will be zero dispersion and attenuation in the general porous and fractured model. For the parameters used in the numerical example of Fig. 1, Eq. (5) gives $B^* \approx 0.59$. This value is quite close to 1.0, and thus we see very small dispersion and attenuation for $B = 1$.

6 Conclusions

We have developed a model for wave propagation in a porous medium with aligned fractures such that pores and fractures can be filled with different fluids. The model considers the fractured medium as a periodic system of alternating layers of two types: thick porous layers representing the background, and very thin and highly compliant porous layers representing fractures. The results show that in the low-frequency limit the elastic properties of such a medium can be described by Gassmann equation with a composite fluid, whose bulk modulus is a harmonic (Wood) average of the moduli of the two fluids. At higher frequencies, the model predicts significant dispersion and attenuation. The dispersion and attenuation are the highest when both pores and fractures are saturated with liquids. The dispersion and attenuation are also significant (but somewhat weaker) when the pores are filled with a liquid but fractures are dry or filled with a highly compressible gas. However, there is an intermediate case where no dispersion is observed. This can be explained by observing that when the medium is uniformly saturated with a liquid, wave-induced compression causes flow from fractures into pores due to high compliance of the fractures. Conversely, when

pores are filled with a liquid but fractures are filled with gas, flow will occur from pores into fractures due to high compressibility of gas. Thus an intermediate case exists where there is no flow and hence no dispersion or attenuation.

Abstract In this paper, the dynamic response and sound radiation of sandwich plate subjected to an acoustic excitation under thermal environment are analyzed. The thermal environment is a uniform temperature load. Thermal stress is considered as the membrane force in the plate, while the change of the material property due to the thermal load is ignored. The acoustic excitation applied on the sandwich plate is assumed to be a plane wave. Coupling of the structural vibration and acoustic medium is considered. The equivalent non-classical theory, which takes the effects of rotational inertia and shear deformation into account, is utilized to get the analytical solutions. The effects caused by thermal environment and acoustic excitation are discussed. It is found that the rise of thermal load decreases the natural frequencies and moves response peaks to the low-frequency range. The acoustic excitation doesn't influence the natural characteristics of the sandwich plate, but the incident angle is relative to the number of evident peaks on the response curve. The comparisons of the analytical results and those computed by VA one show the accuracy of the theoretical method.

Keywords Sandwich plate, Thermal environment, Acoustic excitation, Dynamic response

1. Introduction

Sandwich plates are extensively used in the thermal protection system, which is utilized to protect the structure from the damage caused by the high temperature resulting from aerodynamic heating. During the course of the flight, the sandwich plate is exposed to high temperature and harsh mechanical, acoustic excitation. In order to use them efficiently, a good understanding of the dynamic and acoustic characteristics of the sandwich plate under such situation is necessary.

Vibro-acoustic problems of the structures under thermal environment are of great concern. N. Ganesan et al [1, 2] have analyzed vibration and sound radiation characteristics of composite plates under thermal environment numerically. Li et al [3-5] have carried out vibro-acoustic analyses for structures under thermal environment, including the broadband vibro-acoustic response based on hybrid FE-SEA [3], the influence of thermal stress with numerical method [4], and analytical solution for the dynamic and acoustic characteristics of an isotropic plate in thermal environments using classical plate theory [5]. Although a lot of vibro-acoustic problems under thermal environment have been analyzed, few studies can be found for sandwich plates, especially, lack of theoretical investigations.

The aim of this paper is to analyze the vibration and acoustic characteristics of a sandwich plate subjected to an acoustic excitation under thermal environment. Based on the equivalent non-classical theory, this study considers the effects of the shear deformation and the rotational inertia but ignores the compressional deformation. The coupling between the plate and the acoustic medium is taken into account. The influences caused by the thermal environment and the incident angle of the plane wave on the sandwich plates are deeply discussed in the present study.

2. Fundamental formulations

A sandwich plate with dimensions of $a \times b \times (2h_1 + h_2)$ is considered here, as shown in Fig. 1. The plate consists of two isotropic materials for facings and core respectively. The subscripts in the parameter expressions identify the specific materials, 1 for those of facings and 2 for those of core.

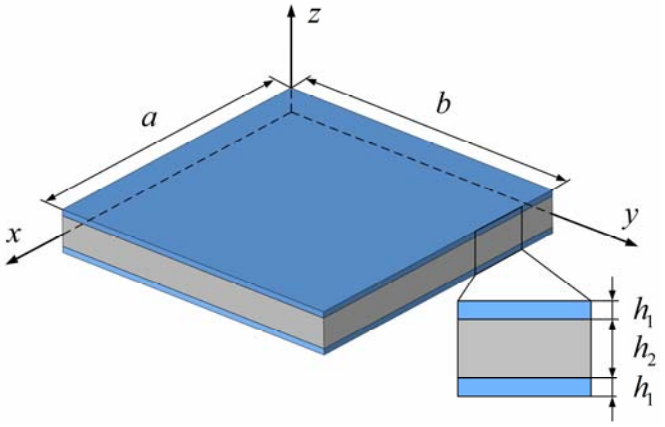

Figure 1. Sandwich plate model

2.1. Governing equations

Based on the non-classical theory, and by adopting the Власов assumption, the governing equations for dynamic analysis considering the membrane forces can be derived as [6]:

$$\begin{cases} \dfrac{G_z h}{k_\tau}\left(\nabla^2 w+\dfrac{\partial \beta_x}{\partial x}+\dfrac{\partial \beta_y}{\partial y}\right)-\rho h\dfrac{\partial^2 w}{\partial t^2}+N_x\dfrac{\partial^2 w}{\partial x^2}+N_y\dfrac{\partial^2 w}{\partial y^2}+2N_{xy}\dfrac{\partial^2 w}{\partial x\partial y}+q=0 \\ D\left(\dfrac{\partial^2 \beta_x}{\partial x^2}+\dfrac{1-\nu}{2}\dfrac{\partial^2 \beta_x}{\partial y^2}+\dfrac{1+\nu}{2}\dfrac{\partial^2 \beta_y}{\partial x\partial y}\right)-\dfrac{G_z h}{k_\tau}\left(\beta_x+\dfrac{\partial w}{\partial x}\right)-\rho J\dfrac{\partial^2 \beta_x}{\partial t^2}=0 \\ D\left(\dfrac{\partial^2 \beta_y}{\partial y^2}+\dfrac{1-\nu}{2}\dfrac{\partial^2 \beta_y}{\partial x^2}+\dfrac{1+\nu}{2}\dfrac{\partial^2 \beta_x}{\partial x\partial y}\right)-\dfrac{G_z h}{k_\tau}\left(\beta_y+\dfrac{\partial w}{\partial y}\right)-\rho J\dfrac{\partial^2 \beta_y}{\partial t^2}=0 \end{cases} \tag{1}$$

where $h=2h_1+h_2$, N_x, N_y and N_{xy} are membrane forces, for this paper, they are generated by thermal stresses. G_z, D, ν, ρh and ρJ are equivalent compositional parameters defined as:

$$G_z=\left[1-3\left(\frac{h_2}{2h}-\frac{h_2^3}{6h^3}\right)\right]\frac{E_1}{2(1+\nu_1)}+3\left(\frac{h_2}{2h}-\frac{h_2^3}{6h^3}\right)\frac{E_2}{2(1+\nu_2)} \tag{2}$$

$$D=\frac{2E_1}{3(1-\nu_1^2)}\left[\left(\frac{h}{2}\right)^3-\left(\frac{h_2}{2}\right)^3\right]+\frac{E_2}{3(1-\nu_2^2)}\left[\left(\frac{h_2}{2}\right)^3-\left(-\frac{h_2}{2}\right)^3\right] \tag{3}$$

$$\nu=\frac{1}{3D}\left\{\frac{2E_1\nu_1}{1-\nu_1^2}\left[\left(\frac{h}{2}\right)^3-\left(\frac{h_2}{2}\right)^3\right]+\frac{E_2\nu_2}{1-\nu_2^2}\left[\left(\frac{h_2}{2}\right)^3-\left(-\frac{h_2}{2}\right)^3\right]\right\} \tag{4}$$

$$\rho h=2\rho_1 h_1+\rho_2 h_2 \tag{5}$$

$$\rho J=\frac{2}{3}\rho_1\left[\left(\frac{h}{2}\right)^3-\left(\frac{h_2}{2}\right)^3\right]+\frac{1}{3}\rho_2\left[\left(\frac{h_2}{2}\right)^3-\left(-\frac{h_2}{2}\right)^3\right] \tag{6}$$

The plate is assumed to be stress-free at the reference temperature T_0. If the plate works under the temperature T, different from T_0, the stress state of the plate will be changed due to the thermal stresses. In this study, all edges are assumed to be simply supported with no in-plane displacement and the temperature is assumed to be uniformly distributed, so the thermal stresses caused by the temperature can be expressed as Eq. (7) [7]:

$$\sigma_x = -\frac{E_i}{1-\nu_i}\alpha_i \Delta T \qquad \sigma_y = -\frac{E_i}{1-\nu_i}\alpha_i \Delta T \qquad \sigma_{xy} = 0 \qquad (i = 1 \text{ or } 2) \tag{7}$$

where $\Delta T = T - T_0$.

The stress resultants caused by thermal stress can be obtained by integrating Eq. (7) along the thickness:

$$N_x = \sum_{k=1}^{3} \frac{-E_k \alpha_k h_k \Delta T}{1-\nu_k} \qquad N_y = \sum_{k=1}^{3} \frac{-E_k \alpha_k h_k \Delta T}{1-\nu_k} \qquad N_{xy} = 0 \tag{8}$$

2.2. Natural frequency and mode

Considering the boundary condition, the modes can be assumed as Eq. (9):

$$\begin{aligned} W_{mn}^{(p)} &= A_{mn}^{(p)} \sin\frac{m\pi}{a}x \sin\frac{n\pi}{b}y \\ \bar{\Psi}_{xmn}^{(p)} &= B_{mn}^{(p)} \cos\frac{m\pi}{a}x \sin\frac{n\pi}{b}y \\ \bar{\Psi}_{ymn}^{(p)} &= C_{mn}^{(p)} \sin\frac{m\pi}{a}x \cos\frac{n\pi}{b}y \end{aligned} \tag{9}$$

Suppose the displacement responses to be expressed as Eq. (10):

$$w = W_{mn}^{(p)} \mathrm{e}^{\mathrm{i}\omega_{mn}^{(p)}t} \qquad \beta_x = \Psi_{xmn}^{(p)} \mathrm{e}^{\mathrm{i}\omega_{mn}^{(p)}t} \qquad \beta_y = \Psi_{ymn}^{(p)} \mathrm{e}^{\mathrm{i}\omega_{mn}^{(p)}t} \tag{10}$$

Substituting Eq. (10) into Eq. (1) and letting q to be zero, Eq. (11) can be obtained:

$$\begin{aligned} &\frac{G_z h}{k_\tau}\left(\nabla^2 \mathrm{W}_{mn}^{(p)} + \frac{\partial \Psi_{xmn}^{(p)}}{\partial x} + \frac{\partial \Psi_{ymn}^{(p)}}{\partial y}\right) + \rho h \omega_{mn}^{(p)2} \mathrm{W}_{mn}^{(p)} + N_x \frac{\partial^2 \mathrm{W}_{mn}^{(p)}}{\partial x^2} + N_y \frac{\partial^2 \mathrm{W}_{mn}^{(p)}}{\partial y^2} + 2N_{xy} \frac{\partial^2 \mathrm{W}_{mn}^{(p)}}{\partial x \partial y} = 0 \\ &D\left(\frac{\partial^2 \Psi_{xmn}^{(p)}}{\partial x^2} + \frac{1-\nu}{2}\frac{\partial^2 \Psi_{xmn}^{(p)}}{\partial y^2} + \frac{1+\nu}{2}\frac{\partial^2 \Psi_{ymn}^{(p)}}{\partial x \partial y}\right) - \frac{G_z h}{k_\tau}\left(\Psi_{xmn}^{(p)} + \frac{\partial \mathrm{W}_{mn}^{(p)}}{\partial x}\right) + \rho J \omega_{mn}^{(p)2} \Psi_{xmn}^{(p)} = 0 \\ &D\left(\frac{\partial^2 \Psi_{ymn}^{(p)}}{\partial y^2} + \frac{1-\nu}{2}\frac{\partial^2 \Psi_{ymn}^{(p)}}{\partial x^2} + \frac{1+\nu}{2}\frac{\partial^2 \Psi_{xmn}^{(p)}}{\partial x \partial y}\right) - \frac{G_z h}{k_\tau}\left(\Psi_{ymn}^{(p)} + \frac{\partial \mathrm{W}_{mn}^{(p)}}{\partial y}\right) + \rho J \omega_{mn}^{(p)2} \Psi_{ymn}^{(p)} = 0 \end{aligned} \tag{11}$$

Substituting Eq. (9) into Eq. (11), one can get a homogeneous linear equations set about $A_{mn}^{(p)}$, $B_{mn}^{(p)}$ and $C_{mn}^{(p)}$. In order to get one set of solution, let 1, $b_{mn}^{(p)}$ and $c_{mn}^{(p)}$ take the place of them

respectively, where $b_{mn}^{(p)} = B_{mn}^{(p)} / A_{mn}^{(p)}$ and $c_{mn}^{(p)} = C_{mn}^{(p)} / A_{mn}^{(p)}$. Thus mode shapes can be rewritten as Eq. (12):

$$\begin{aligned} W_{mn}^{(p)} &= \sin\frac{m\pi}{a}x\sin\frac{n\pi}{b}y \\ \bar{\Psi}_{xmn}^{(p)} &= b_{mn}^{(p)}\cos\frac{m\pi}{a}x\sin\frac{n\pi}{b}y \\ \bar{\Psi}_{ymn}^{(p)} &= c_{mn}^{(p)}\sin\frac{m\pi}{a}x\cos\frac{n\pi}{b}y \end{aligned} \tag{12}$$

If a homogeneous linear equations set exists nonzero solutions, its determinant of the coefficient matrix should be zero. Thus the natural frequency can be obtained by solving Eq. (13):

$$\begin{vmatrix} \frac{G_z h}{k_\tau}(-\frac{m^2\pi^2}{a^2}-\frac{n^2\pi^2}{b^2})+\omega_{mn}^{(p)2}\rho h-\frac{m^2\pi^2}{a^2}N_x-\frac{n^2\pi^2}{b^2}N_y & -\frac{G_z h}{k_\tau}\frac{m\pi}{a} & -\frac{G_z h}{k_\tau}\frac{n\pi}{b} \\ -\frac{G_z h}{k_\tau}\frac{m\pi}{a} & D(-\frac{m^2\pi^2}{a^2}-\frac{1-\nu}{2}\frac{n^2\pi^2}{b^2})-\frac{G_z h}{k_\tau}+\rho J\omega_{mn}^{(p)2} & -\frac{1+\nu}{2}D\frac{mn\pi^2}{ab} \\ -\frac{G_z h}{k_\tau}\frac{n\pi}{b} & -\frac{1+\nu}{2}D\frac{mn\pi^2}{ab} & D(-\frac{n^2\pi^2}{b^2}-\frac{1-\nu}{2}\frac{m^2\pi^2}{a^2})-\frac{G_z h}{k_\tau}+\rho J\omega_{mn}^{(p)2} \end{vmatrix}=0 \tag{13}$$

While $\omega_{mn}^{(p)} = 0$, the critical buckling temperature can be acquired.

By putting the natural frequencies into the equations, the coefficients can be obtained:

$$b_{mn}^{(p)} = \frac{\frac{G_z h}{k_\tau}(-\frac{m^2\pi^2}{a^2}-\frac{n^2\pi^2}{b^2})+\omega_{mn}^{(p)2}\rho h-\frac{m^2\pi^2}{a^2}N_x-\frac{n^2\pi^2}{b^2}N_y}{\frac{G_z h}{k_\tau}(\frac{m\pi}{a}+\frac{n\pi}{b}\frac{D(-\frac{m\pi}{a}-\frac{1-\nu}{2}\frac{an^2\pi}{b^2m})-\frac{G_z ha}{k_\tau m\pi}+\frac{\rho J\omega_{mn}^{(p)2}a}{m\pi}+\frac{1+\nu}{2}D\frac{m\pi}{a}}{D(-\frac{n\pi}{b}-\frac{1-\nu}{2}\frac{bm^2\pi}{a^2n})-\frac{G_z hb}{k_\tau n\pi}+\frac{\rho J\omega_{mn}^{(p)2}b}{n\pi}+\frac{1+\nu}{2}D\frac{n\pi}{b}})} \tag{14}$$

$$c_{mn}^{(p)} = \frac{\frac{G_z h}{k_\tau}(-\frac{m^2\pi^2}{a^2}-\frac{n^2\pi^2}{b^2})+\omega_{mn}^{(p)2}\rho h-\frac{m^2\pi^2}{a^2}N_x-\frac{n^2\pi^2}{b^2}N_y}{\frac{G_z h}{k_\tau}(\frac{m\pi}{a}\frac{D(-\frac{n\pi}{b}-\frac{1-\nu}{2}\frac{bm^2\pi}{a^2n})-\frac{G_z hb}{k_\tau n\pi}+\frac{\rho J\omega_{mn}^{(p)2}b}{n\pi}+\frac{1+\nu}{2}D\frac{n\pi}{b}}{D(-\frac{m\pi}{a}-\frac{1-\nu}{2}\frac{an^2\pi}{b^2m})-\frac{G_z ha}{k_\tau m\pi}+\frac{\rho J\omega_{mn}^{(p)2}a}{m\pi}+\frac{1+\nu}{2}D\frac{m\pi}{a}}+\frac{n\pi}{b})} \tag{15}$$

Considering Eq. (14), Eq. (15) and Eq. (12), one can determine the mode shapes.

2.3. Dynamic analyses

Dynamic responses of the sandwich plate which is subjected to a plane sound wave are discussed in this section.

2.3.1. Acoustic load

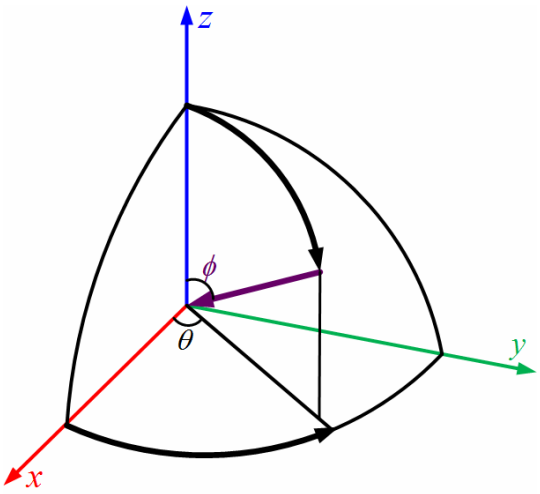

Figure 2. Incident plane wave

The incident angles of plane sound wave are shown in Fig. 2. If neglect the vibration of the plate, the incident and reflected sound pressure can be expressed as Eq. (16-17) [8]:

$$p_i(x,y,z=\frac{2h_1+h_2}{2},t)=P_i\,\mathrm{e}^{\mathrm{i}\omega t-\mathrm{i}k[\sin\phi(x\cos\theta+y\sin\theta)+\frac{2h_1+h_2}{2}\cos\phi]} \tag{16}$$

$$p_r(x,y,z=\frac{2h_1+h_2}{2},t)=P_i\,\mathrm{e}^{\mathrm{i}\omega t-\mathrm{i}k[\sin\phi(x\cos\theta+y\sin\theta)-\frac{2h_1+h_2}{2}\cos\phi]} \tag{17}$$

The dynamic response of an elastic plate excited by the incident wave can modify the resultant sound wave. The plate and acoustic medium have the same normal velocity on the interface. Use Rayleigh's integral (Eq. 18) to calculate the scattered sound pressure produced by the elastic vibration of the plate [9].

$$p_s(x,y,z=\frac{2h_1+h_2}{2},t)=-\frac{\rho_0\omega^2}{2\pi}\int_{S_0}\frac{e^{-\mathrm{i}k\sqrt{(x-x_0)^2+(y-y_0)^2}}}{\sqrt{(x-x_0)^2+(y-y_0)^2}}w(x_0,y_0)dS_0\mathrm{e}^{\mathrm{i}\omega t} \tag{18}$$

An additional pressure components, associated with the wave transmitted into the other side of plate, is added to the loading term in the governing equations. The two plate surfaces partake in identical motions, and the acoustic medium on both sides of the plate are of the same. The phase is, however, different. Thus, on the plate surface this transmitted pressure p_t takes the value $-p_s$ [8].

$$p_t(x,y,z=-\frac{2h_1+h_2}{2},t)=\frac{\rho_0\omega^2}{2\pi}\int_{S_0}\frac{e^{-\mathrm{i}k\sqrt{(x-x_0)^2+(y-y_0)^2}}}{\sqrt{(x-x_0)^2+(y-y_0)^2}}w(x_0,y_0)dS_0\mathrm{e}^{\mathrm{i}\omega t} \tag{19}$$

Resultant acoustic excitation is of the form:

$$q(x,y,t)=p_i+p_r+p_s-p_t \tag{20}$$

Considering Eq. (16-19) and Eq. (20), the loading (Eq. 21) can be obtained:

$$q(x,y,t)=2P_i\cos(\frac{2h_1+h_2}{2}k\cos\phi)\,\mathrm{e}^{\mathrm{i}\omega t-\mathrm{i}k\sin\phi(x\cos\theta+y\sin\theta)}-\frac{\rho_0\omega^2}{\pi}\int_{S_0}\frac{e^{-\mathrm{i}k\sqrt{(x-x_0)^2+(y-y_0)^2}}w(x_0,y_0)}{\sqrt{(x-x_0)^2+(y-y_0)^2}}dS_0\mathrm{e}^{\mathrm{i}\omega t} \tag{21}$$

2.3.2. Vibration responses

Based on mode superposition principle, the dynamic displacement responses can be expanded as Eq. (22):

$$\begin{aligned} w(x,y,t) &= \sum_m \sum_n \sum_p W_{mn}^{(p)}(x,y) T_{mn}^{(p)}(t) \\ \beta_x(x,y,t) &= \sum_m \sum_n \sum_p \Psi_{xmn}^{(p)}(x,y) T_{mn}^{(p)}(t) \\ \beta_y(x,y,t) &= \sum_m \sum_n \sum_p \Psi_{ymn}^{(p)}(x,y) T_{mn}^{(p)}(t) \end{aligned} \tag{22}$$

Assume the time-dependent factor to be $e^{i\omega t}$. Thus,

$$T_{mn}^{(p)}(t) = T_{mn}^{(p)} e^{\mathrm{i}\omega t} \tag{23}$$

Substituting Eq. (22-23) into Eq. (1), in view of the Eq. (11) and the orthogonality for the modes, one can acquire Eq. (24),

$$T_{mn}^{(p)} Z_{mn}^{(p)} + \sum_{k,l,q} Z_{mn}^{kl} T_{kl}^{(q)} = F_{mn} \tag{24}$$

in which:

$$Z_{mn}^{(p)} = \left(\omega_{mn}^{(p)2} - \omega^2\right)\left\{\frac{ab}{4} \times \left[\rho h + \rho J \times (b_{mn}^{(p)^2} + c_{mn}^{(p)^2})\right]\right\}$$

$$F_{mn} = \int_0^a \int_0^b \left\{2P_i \cos\left(\frac{2h_1 + h_2}{2} k \cos\phi\right) \mathrm{e}^{-\mathrm{i}k \sin\phi (x\cos\theta + y\sin\theta)}\right\} \sin\frac{m\pi x}{a} \sin\frac{n\pi y}{b} dxdy$$

$$Z_{mn}^{kl} = \frac{\rho_0 \omega^2}{\pi} \int_0^a \int_0^b \int_0^a \int_0^b \frac{e^{-\mathrm{i}k\sqrt{(x-x_0)^2 + (y-y_0)^2}}}{\sqrt{(x-x_0)^2 + (y-y_0)^2}} \sin\frac{k\pi x_0}{a} \sin\frac{l\pi y_0}{b} \sin\frac{m\pi x}{a} \sin\frac{n\pi y}{b} dx_0 dy_0 dx dy$$

Solving Eq. (24), one can obtain the displacement response. By taking derivative with respect to t, the velocity can be acquired. In accordance with the Rayleigh's integral, the sound pressure at the observation point (x_p, y_p, z_p) above the plate can be got using the velocity (Eq. 25):

$$p(x_p, y_p, z_p, t) = \frac{\mathrm{i}\omega\rho_0}{2\pi} \mathrm{e}^{\mathrm{i}\omega t} \int_\Omega \frac{v(x,y) \cdot \mathrm{e}^{-\mathrm{i}kR}}{R} \mathrm{d}A \tag{25}$$

3. Validation

A simply supported rectangular sandwich plate with dimensions of 400×300×10 mm is considered here for numerical studies, which are carried out to test the validity of the analytical solution.
0.5 mm and 9 mm are the thickness for the facings and the core respectively. The properties for them are listed in Table 1. Structural damping ratio is taken as 0.001.
Use Nastran to test the natural frequencies and modes with FEM (finite element method). The comparisons of the analytical results with those got by numerical approach are shown in Table 2, from which one can see that the two sets of results match with each other very well.

Table 1. Material properties

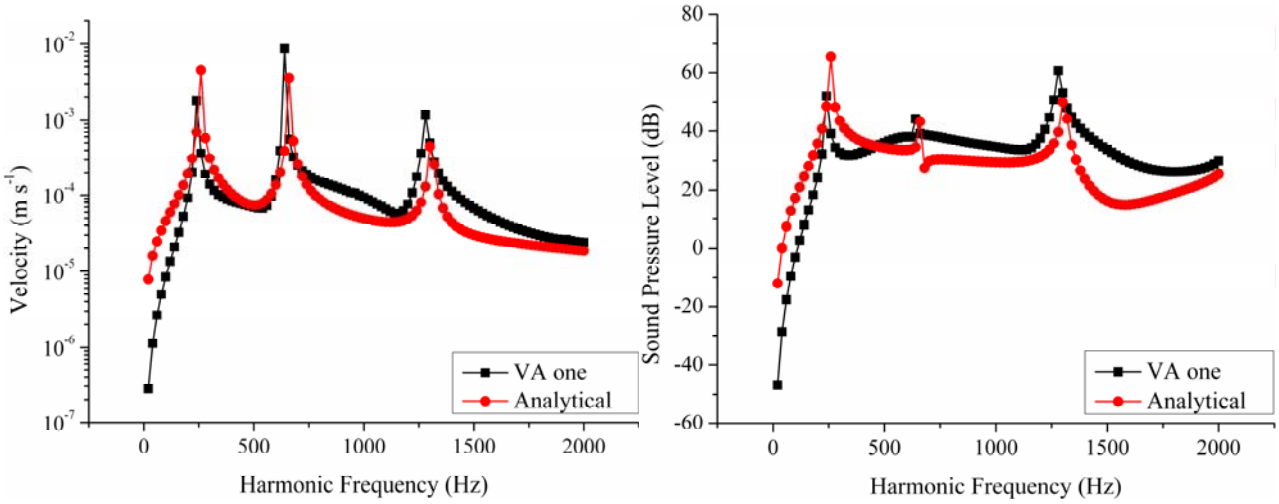
Material	Young modulus	Poisson'	Density	Coefficient of thermal expansion

	(GPa)	ratio	(kg m^{-3})	(℃$^{-1}$)
Facing	70(1+0.001i)	0.3	2700	2.3E−5
Core	7(1+0.001i)	0.3	1000	1.8E−5

Table 2. Comparisons of the natural frequencies

Modes	With temperature load of 50℃		
	Numerical (Hz)	Analytical (Hz)	Error (%)
(1,1)	245.56	255.44	4.02
(2,1)	645.10	659.75	2.27
(1,2)	955.35	963.44	0.85
(3,1)	1290.6	1304.5	1.07
(2,2)	1318.9	1346.7	2.11
(3,2)	1928.3	1970.6	2.19
(1,3)	2079.4	2079.7	0.02
(4,1)	2166.4	2174.8	0.39

Numerical dynamic responses, used to test the analytical solutions, are obtained using VA one. FEM is utilized to acquire the velocity response, caught at (0.1m, 0.1m), while BEM (boundary element method) is used to get sound pressure level, caught at (0.1m, 0.1m, 3m).



a. Velocity b. Sound Pressure Level

Figure 3. Comparisons of dynamic responses $\Delta T = 50\,°C$ $\phi = 30°$ $\theta = 0°$

From Fig. 3, one can find out that the trends of the response are of the same. There are both three evident peaks on each curve. So far, it could be believable that the present analytical solution is correct based on the above mutual validation.

4. Discussion

4.1. Different thermal loads

Thermal load can change the intrinsic property and influence the dynamic characteristics of the

sandwich plate. To understand the effects caused by the thermal load, several uniform temperature loads, $\Delta T = 0°C, 50°C, 90°C$, are imposed on the plate, whose buckling temperature is verified to be $94°C$.

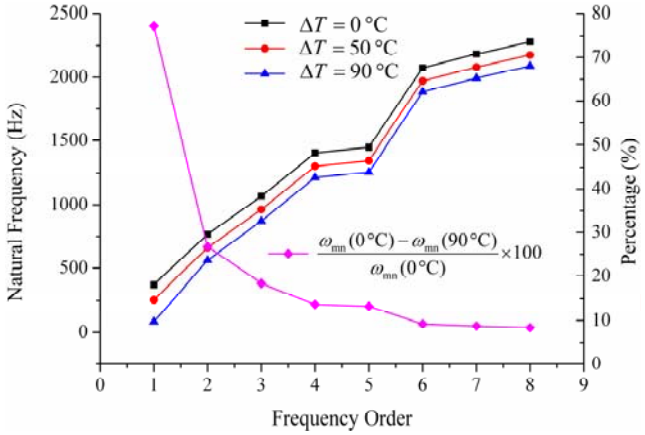


Figure 4. Natural frequency and relative difference

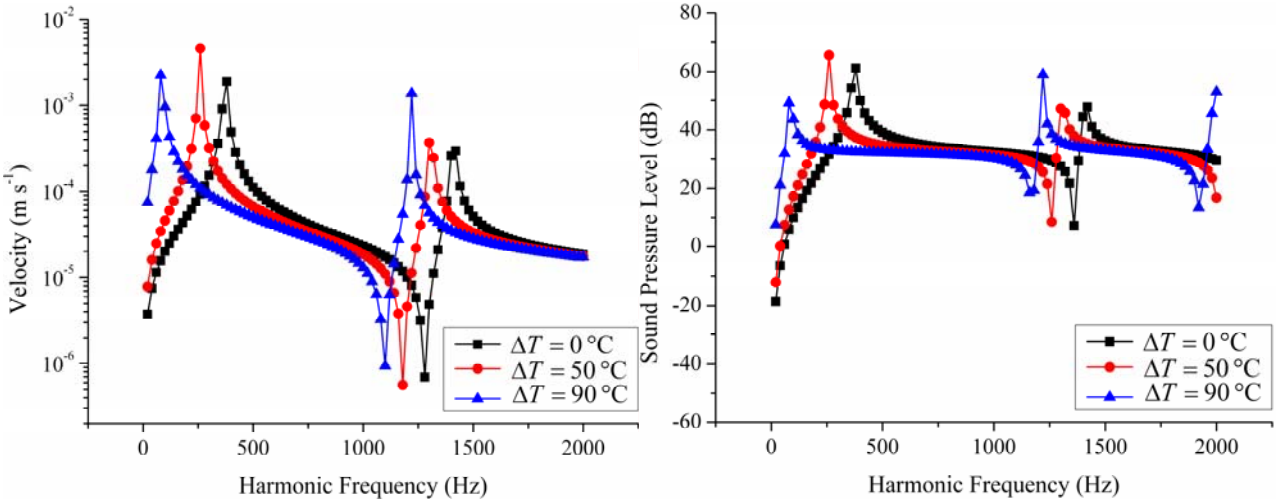
The natural frequencies of the sandwich plate subjected to different thermal load are shown in Fig. 4, from which the trend that the natural frequencies reduce with the temperature rising can be seen obviously. The modes for the plate are the same under different temperature. The relative frequency difference of the first natural frequency is much greater than others, which means the effect induced by thermal load is more obvious in fundamental frequency.

The incident sound wave which is perpendicular to the plane is applied to the plate. The velocity response at (0.1m, 0.1m) and the sound pressure level responses at (0.1m, 0.1m, 3m) are shown in Fig. 5, from which, one can observe that with the thermal load increasing, the peaks of vibration and acoustic responses float to low-frequency range.

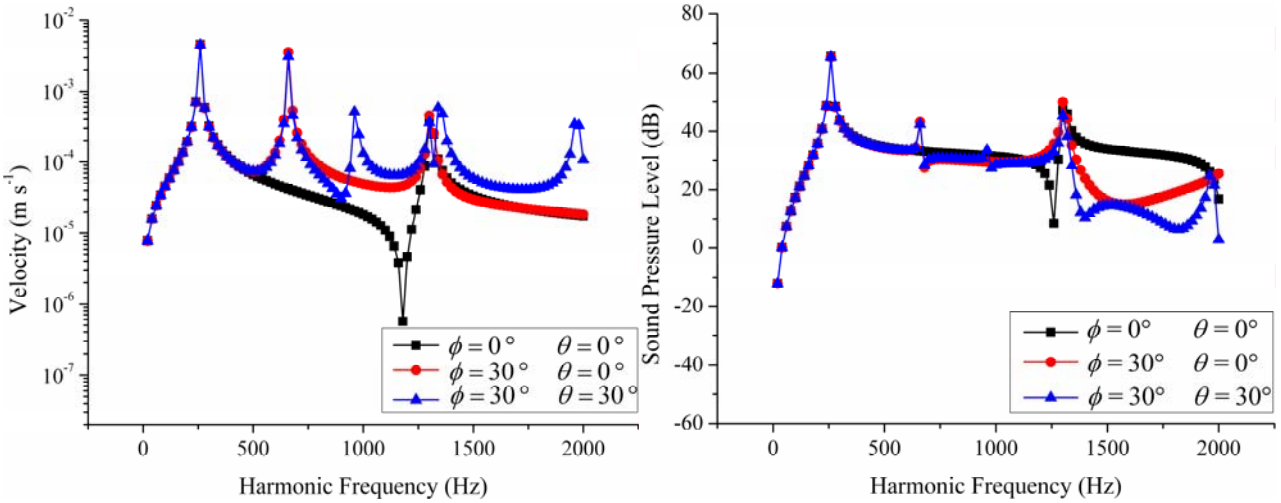


a. Velocity b. Sound Pressure Level

Figure 5. Dynamic responses

4.2. Different incident angles

Plane waves with incident angle of $0°-0°$, $30°-0°, 30°-30°$ are applied on the sandwich plate to discuss the influence caused by the incident angle. Different from the thermal load, the plane sound wave doesn't change the natural characteristics of the plate. Only the dynamic response is affected. The plate is also subjected to a uniform temperature load of $50°C$.



a. Velocity b. Sound Pressure Level

Figure 6. Dynamic responses

From Fig. 6, It is found that the number of the evident peaks is associated with the incident angle of the acoustic excitation. Because the excitation can't influence the natural frequency, the frequencies of peaks on each curve correspond to the natural frequencies of the sandwich plate under the temperature rise of $50°$. The first-order natural mode is markedly excited by all these three sound wave. The three curves are overlapping in the low frequency.

5. Conclusion

In this paper, a method to analyze the dynamic response and sound radiation of the sandwich plate under thermal environment is presented.

The influences caused by thermal environment and acoustic excitation on the sandwich plate are discussed in this paper. Sandwich plates subjected to different thermal loads present different natural property. The natural frequencies decrease and the modes remain the same when the thermal load rises. Thermal environment influences fundamental frequency remarkably, while the effect is less obvious in high natural frequency domain. On the other hand, the dynamic responses are also changed by the thermal load. As the thermal load increases, the peaks of response float to low-frequency range.

The plate imposed on the plane sound wave with different incident angle is analyzed. The acoustic excitation can't affect the natural characteristics of the plate, but the dynamic response is highly associated with the incident angle of the plane wave. Plane waves with different incident angles can excite different number of the evident peaks on the response curve, but the corresponding frequency of each peak can't be affected.

Abstract Silica aerogels are nanoporous ultralight materials with extreme materials properties: the highest specific surface area of any material; slowest speed of sound through any solid material; excellent thermal insulators. Using molecular dynamics and the Tersoff potential, re-parameterized to simulate silicon dioxide, we have modeled the porous structures of silica aerogels. Our study shows that this potential is more suitable for modeling thermal properties in amorphous silica than the widely-used BKS potential. Increasing densities of aerogel samples are generated using an expanding and quenching process. Analysis of the fractal dimensions indicates a good fit with previous theoretical and experimental results. Each sample's thermal conductivity is determined using reverse non-equilibrium molecular dynamics. Results indicate that the power-law fit of our data reflects the power-law exponent found in experimental studies. The results are also of the same order of magnitude as experimental bulk aerogel, but they are consistently higher. Analysis of the pore size distribution shows, firstly, that such a disparity is due to limited pore sizes represented in a finite nano-sized system, and secondly, that increasing system length scales leads to corresponding increases in the pore sizes that can be represented. Furthermore, we attempt to determine the mechanical properties, such as Young's modulus of aerogel by using the same potential. We can conclude from all these results that our model is very suitable for modeling the mechanical and physical properties of bulk silica aerogel, and that an appropriate system length scale can be chosen to suit the pore size regime of interest.

Keywords molecular dynamics, silica aerogel, nanoporous ultralight materials.

1. Introduction

Silica aerogel is an exceptionally percolated material [1], made from various sol-gel processes and supercritical drying. Some silica aerogel's properties include very low density and extremely high thermal resistance [2, 3]. Previous experimental studies characterized silica aerogel's thermal conductivity and transport mechanisms, and found that the solid thermal conductivity scaled with density via a power law:

$$\lambda_s = C\rho^{\alpha} \tag{1}$$

where α was approximately 1.6 for densities between 0.3 to 1.0g/cm^3 [4]. Previous numerical studies characterizing the properties of silica aerogel [5, 6] include accurate reproductions of the porous and fractal nature of silica aerogels [7-9]. Murillo *et al.* [9] devised an expanding, heating and quenching method to model silica aerogels, obtaining good fits for the elastic moduli in comparison with experimental results. Ng *et al.* [6] employed negative pressure rupturing with the van Beest, Kramer and van Santen (BKS) potential [10, 11], and determined their thermal conductivities. It was found that the power-law fit of the data corresponds to experimental bulk sintered aerogel.

In this study, new methods are used to attain a closer fit of the thermal conductivity, in comparison with experimental data. We have found that the Tersoff potential, re-parameterized to model silicon dioxide, is more suitable than the BKS potential in predicting the thermal conductivity of amorphous silica. The solid thermal conductivity of silica aerogels are determined using reverse non-equilibrium MD (RNEMD) simulations, by generating the porous samples using the method by

Murillo et al. [9] and obtaining aerogel densities in the range of 0.3 to 1.0g/cm^3. The results are plotted and compared against experimental data [4]. The mechanical property, such as Young's modulus is simulated by using same method. The Young's modulus of aerogel with densities in the range of 0.3 to 1.0g/cm^3 is presented also.

2. Simulation Methods

The simulations are performed on the LAMMPS [12] software. The interaction potential used is the Tersoff potential [13], re-parameterized to model interactions between silicon and oxygen [14]. From comparison studies using the BKS potential and Tersoff potential, it is found that the Tersoff potential is more suitable for thermal conductivity studies. , while, the BKS potential augmented with a "24-6" Lennard Jones potential can prevent uncontrollable dynamics at very high temperatures [15]. Using the method by Murillo *et al.* [9], porous aerogel structures can be formed by expanding, heating and quenching, producing aerogels in the density range of 0.3 to 1.0g/cm^3. RNEMD [6, 16-18] can be used to determine the thermal conductivity at each aerogel density, where energies are swapped once every 0.025ps, while the system is kept an average temperature of 300K. This amount of swapping ensures a rapid convergence of the simulated temperature gradient, and produced a linear response within the simulation cell. The system is allowed to equilibrate for a further 1.0ns till a fully linear response has been obtained, and finally, the temperature gradient is averaged over another 50ps. The total solid thermal conductivity can be found by averaging over 5 independent samples at each density. To investigate the Young's modulus with the strain rate 0.0005ps^{-1} for 200ps, the tension tests are carried out on samples of different densities.

3. Results and Discussions

3.1. Thermal conductivity of dense amorphous silica

The thermal conductivity of increasing lengths of amorphous silica is compared with experimental results to validate our MD scheme. These amorphous silica samples are generated by quenching β-cristobalite, from 5000K to 300K. Their thermal conductivities are determined, as shown in Fig. 1 with their error bars.

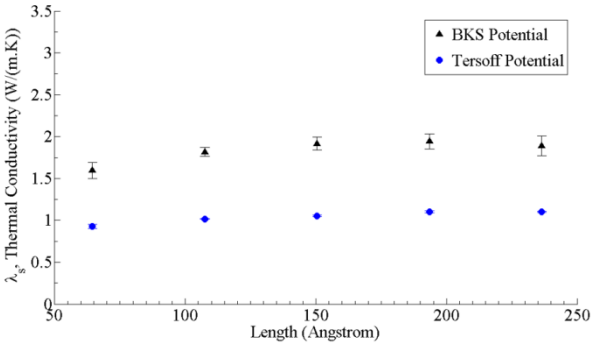

Figure 1. Amorphous silica of various lengths and their thermal conductivities

As the system length increases, so do the thermal conductivity, such that the BKS potential significantly overshoots the thermal conductivity of bulk amorphous silica, which lies between 1.37 – 1.4W/(m.K) [19]. The Tersoff potential plateaus at 1.10 ± 0.01W/(m.K) shows an almost linear dependence with increasing length scales. By extrapolating the results to an infinite length scale, thus representing bulk amorphous silica, the Tersoff potential can give a much better estimation of bulk thermal properties. The inverse of the thermal conductivities versus the inverse of the lengths

($1/\lambda_s$ vs 1/L) are plotted and extrapolated in Fig. 2.

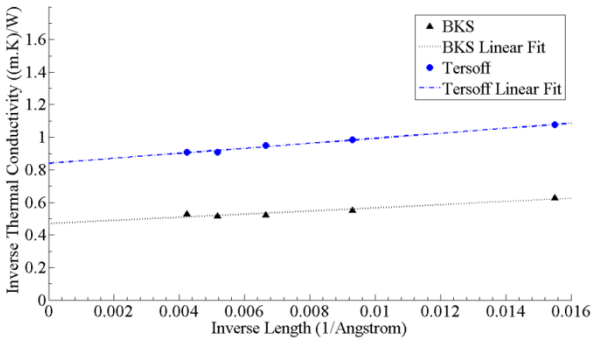

Figure 2. The inverse of the thermal conductivities for amorphous silica systems and their linear extrapolation to infinite lengths

This method gives values of 2.13W/(m.K) for the BKS potential, and 1.19W/(m.K) for the Tersoff potential, at bulk length scales. This gives an error of 55% overestimation for the former, and 13% underestimation for the latter, clearly showing that the re-parameterized Tersoff is much more capable of reproducing bulk thermal properties than the BKS potential can. This is analyzed further by examination of the vibrational density of states (vDOS) of each potential, as shown in Fig. 3, which are obtained through the discrete Fourier transform of the velocity autocorrelation function (VACF) [20].

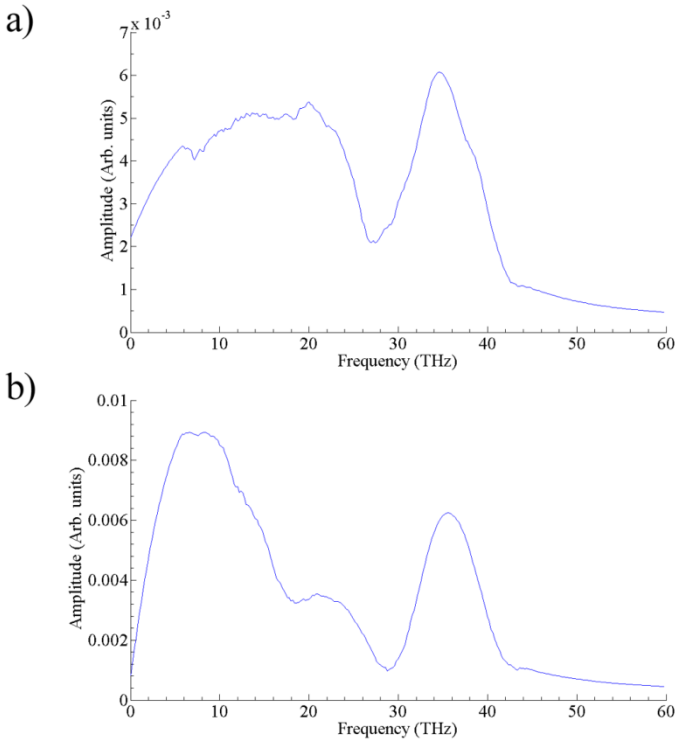

Figure 3. vDos of a) BKS, and b) Tersoff potential

The Tersoff potential clearly shows, as shown in Fig. 6b, the same peaks near the frequencies of 10.5THz, 24.0THz and 36.0THz determined from previous experimental and theoretical results by Laughlin *et al.* [21]. However, the BKS potential, in Fig. 6a, showes no apparent peaks below the 30THz region. Thus, from all these methods presented, we can conclude that the re-parameterized Tersoff potential is a far superior alternative in the thermal characterization of bulk amorphous

silica than the BKS potential.

3.2. Structural correlations of porous silica aerogel

Using the method discussed in Section 2, percolated silica aerogel was simulated on a cubic system of 52,728 atoms, with densities ranging from 0.3 to 1g/cm^3. Fractal dimensions are determined using the method proposed by Kieffer *et al.* [7], where the total radial distributions for each density are calculated, and power-law decays are superimposed on the peak structures to determine the fractal dimensions. These results are plotted in Fig. 4 below along with their error bars, as well as data from previous theoretical studies by Murillo *et al.* [9].

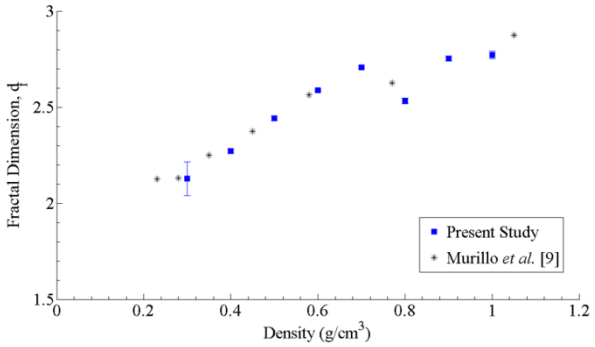

Figure 4. Decreasing fractal dimensions as density decreased

The variation of the fractal dimension, d_f, with density agrees with those found in previous theoretical and experimental studies. Experimental silica aerogel fractal dimensions varies with processing conditions, where it is approximately 1.8 under basic processing conditions, and about 2.2 to 2.4 in both acidic and neutral conditions [22].

3.3. Thermal conductivity of porous silica aerogel

Fig. 5 shows the data obtained, from RNEMD, as a log-scale plot with their corresponding errorbars, and the power-law fit of the data.

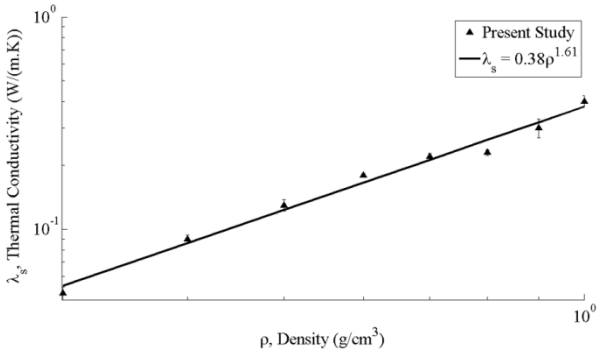

Figure 5. Log-scale plot of the power-law variation of thermal conductivity with density

Thermal conductivity is found to decrease as density decreases, in a non-linear fashion. At the lowest density of 0.3g/cm^3, the thermal conductivity also reaches its lowest value of 0.05 ± 0.003W/(m.K). The power-law exponent, α, of experimental bulk aerogel was found to be 1.6 in the density range of 0.3 to 1.0g/cm^3 [4]. Our results show an α value of 1.61 in this density range, correlating very well with experimental results. Our model is also advantageous in that very low densities are achievable, much lower than 0.1g/cm^3, without any adverse phenomena. A downside

of our current model is that thermal conductivities at each density were 5 times higher than experimental aerogels. The most significant reason is that our model is unable to attain micropores. This can be seen in the pore size distribution of samples of increasing aerogel length scales. Shown in Fig. 6, these plots are calculated using PSDsolv [23], which determines the relative probability of finding pores of different sizes. At a density of 0.3g/cm^3, we generate two different samples with system lengths of 180Å (our current system length at 0.3g/cm^3), and 277Å.

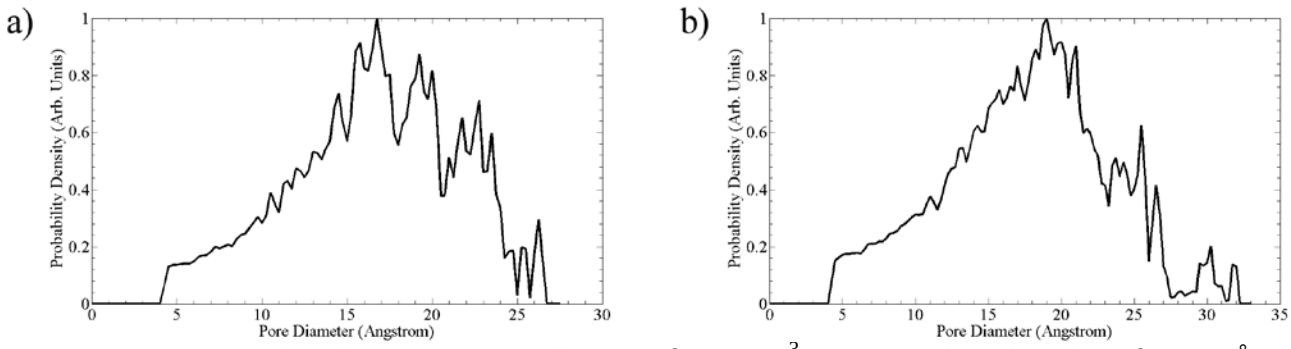

Figure 6. Pore size distribution (PSD) at density of 0.3g/cm^3, at system length scales of a) 180Å, and b) 277Å

The largest pore sizes accessible increase from 27.5Å to 32Å in diameter, as the system length scales increase. The pore sizes attainable are nowhere near the micron-sized diameters in bulk experimental silica aerogels.

3.4. Young's modulus

Using the method discussed in Section 2, the Young's modulus of silica aerogel with different densities ranging from 0.3g/cm^3 to 1.0g/cm^3 are obtained through MD simulation as shown in Fig. 7. A power-law fitt can be used to describe the relationship between Young's modulus and density of samples [9]. From Fig. 7, the exponent of the relationship between Young's modulus and density can obtained and the exponent value is about 2.4313. This value has slightly difference with the result from Murillo *et al*. [9] which was 3.11, while the magnitude of the constant of Young's modulus is almost the same. The discrepancy mainly results from the different interactive potential.

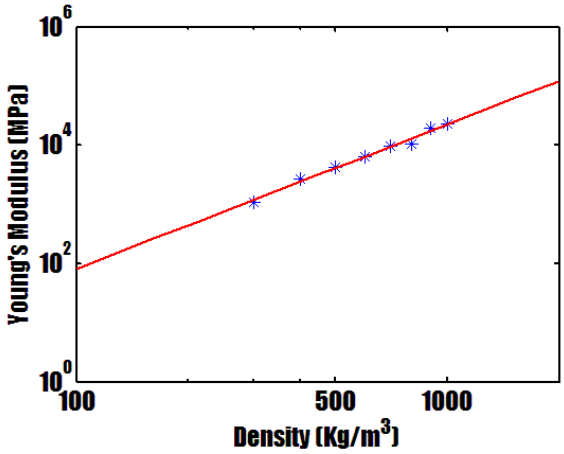

Figure 7. Relation between Young's Modulus and density. (Red line refers to the power-law fitting line, and the blue dots refers to the simulation data.)

4. Conclusions

We have used MD and the re-parameterized Tersoff potential to model the porous structures of silica aerogels. We demonstrate that this potential is suitable for modeling thermal properties in amorphous silica. Using a quenching and expanding process, different densities of aerogel samples are generated. Good fits with previous results are obtained when the fractal dimensions are analyzed. Through RNEMD, their thermal conductivity is determined and the power-law fit of our data corresponds well with experimental studies. Thermal conductivities are also consistently higher than experimental bulk aerogel and analysis of the pore size distribution shows limited pore sizes could be the key issue here.

Abstract The effect of damage on mechanical properties of closed-cell foams is numerically investigated. Representative 3D cell structures are considered for the finite element analysis. In the first instance the mechanical properties were obtained on un-damaged structures. The obtained numerical values for Young's modulus and Poisson's are compared with experimental results. Two types of experimental methods were used to determine the mechanical properties of rigid polyurethane foams: Static compression tests providing stress – strain curves and mechanical properties as Young's modulus, yield stress, plateau stress, densification and Digital Image Correlation used for identification of the damage mechanism, observation of bands of deformation, Young's modulus and Poisson's ratio. The influence of density on mechanical properties is also investigated. Two types of damages/defects were defined randomly in finite element analyses by considering missing cell walls and filled cells. The results show that the missing cell walls create a decrease of Young's modulus, while the filled cells produce the increase of Young's modulus.

Keywords Rigid foams, Damage, Mechanical properties, Numerical analysis, Micromechanical models

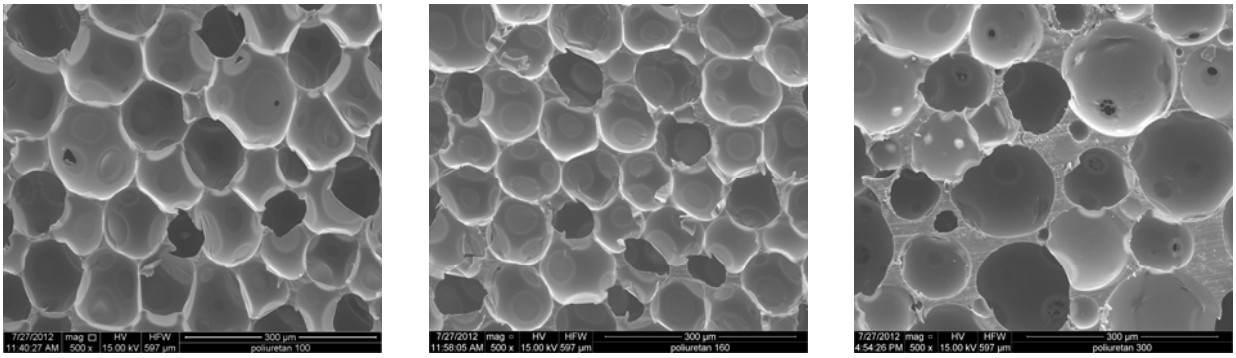
1. Introduction

Polyurethane foam materials are widely used as cores in sandwich structures. The main characteristics of PUR foams are lightweight, high porosity and good energy absorption capacity, [1,2]. Foam materials crush in compression, while in tension they fail by propagation of a single crack, [3]. Many attempts were performed in order to determine experimentally the compression properties of plastic foams [4-13]. On the other hand, analytical micro-mechanical models based on deformation and fracture of single cell were developed to predict the mechanical properties of foams in compression [14,15]. In recent years the finite element analysis (FEA) micro-mechanical models were used in order to study the effect of damage of cellular structure on the compression properties [16,17]. Usually these models were constructed using 2D beams.

This paper presents the results of mechanical properties for three polyurethane foams under compression loading investigating the effect of density, loading direction and loading rate. The Digital Image Correlation (DIC) technique is employed during compression tests in order to identify the damage mechanisms of foams. Afterwards, using a 3D representative volume of the foam, the effect of damage (missing cells and filled cells) was studied.

2. Experimental program

In order to identify the mechanical properties of the rigid polyurethane (PUR) foams an extensive experimental program was performed. Closed cell rigid PUR foams with three different densities (100, 160 and 301 kg/m^3) were considered for the experimental program, Fig. 1.



a. density 100 kg/m^3 b. density 160 kg/m^3 c. density 301 kg/m^3

Figure 1. SEM microstructures of closed cell rigid PUR foams (500x).

2.1. Static compression tests

Static compression testes were carried out using a LBG 100kN universal testing machine in the Strength of Materials from POLITEHNICA University of Timişoara, respectively on a Walter+bai 50 kN static and fatigue testing machine from Laboratory of Strength of Materials from University POLITEHNICA of Bucharest. Tests were performed according to ASTM D 1621 at room temperature. Cubic specimens with 50 mm length were used for foam densities 100 and 160 kg/m^3 and with 25 mm length for the 301 kg/m^3 density. The engineering stress-strain diagram shows the non-linear behavior of polyurethane foams in compression, Fig. 2. The following regions could be identified: an initial linear elastic response leading to yield, a small softening in stress after yield, a post-yield plateau and a final sharp rise in compressive stress, corresponding to foam densification. It can be observed that density has a major influence on the behavior of PUR foams.

The influence of the loading direction: in plane (rise direction) and out of plane (transverse direction) is shown in Fig.3. Foam behaviour in transverse direction shows a small hardening after the yield point and no softening.

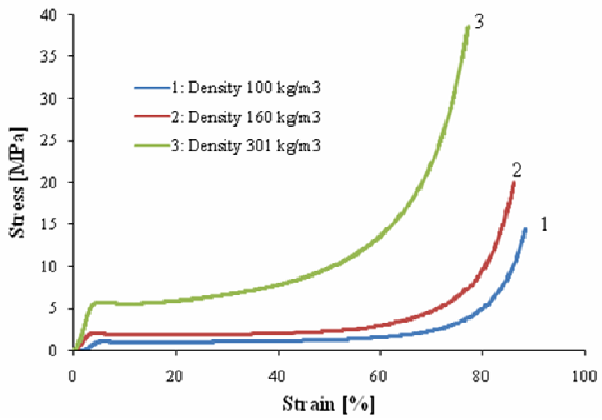


Figure 2. Effect of density.

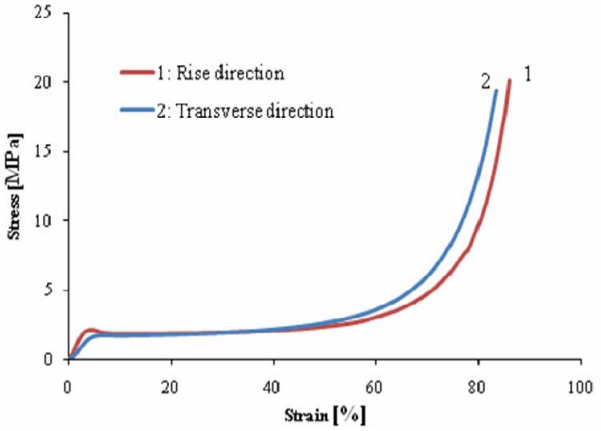

Figure 3. Effect of loading direction.

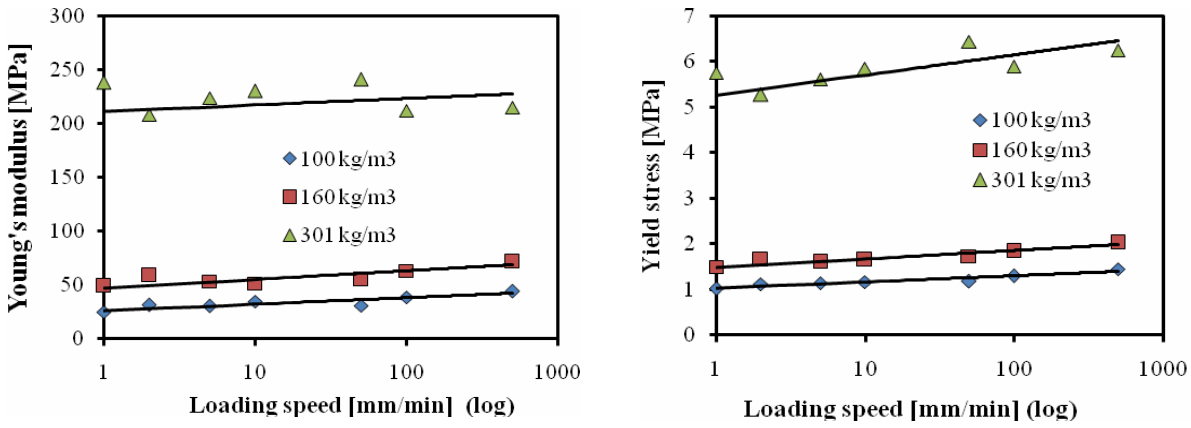
The compression properties (Young's modulus, yielding stress, plateau stress and densification strain) obtained for the three investigated rigid PUR foams are summarized in Table 1 for a 5 mm/min loading rate.

Table 1. Compression properties of rigid PUR foams

Foam density [kg/m^3]	100		160		301	
Loading direction	rise	transverse	rise	transverse	rise	transverse
E [MPa]	40.38	31.92	81.76	50.83	202.25	201.83
σ_y [MPa]	1.15	1.17	2.09	1.77	5.74	6.69
σ_p [MPa]	1.06	1.14	1.88	1.83	5.98	6.65
ε_d [%]	56.2	55.4	54.4	52.4	54.8	52.5

Young's modulus, yield stress and plateau stress increases with density. For low density foams Young's modulus values are higher in the rise direction, while for the foam with 301 kg/m^3 density Young's modulus are equal in both direction. Also the densification strain is slightly higher in rise direction for all investigated foams. The yield stress and plateau stresses are quite similar in both directions for low density foams, but are higher in transverse direction for foam with 301 kg/m^3 density.

Loading rates between 0.6 and 500 mm/min were used to investigate the influence of loading rate. It could be observed in Fig. 4 that increases in loading rate produces an increase of Young modulus (with approximately 50 % for foam densities 100 and 160 kg/m^3, respectively with 80 % for 301 kg/m^3 foam density) and yield stress (with approximately 67 % for foam densities 100 and 160 kg/m^3, respectively with 73 % for 301 kg/m^3 foam density).



a. Young's modulus b. Yield stress

Figure 4. Effect of loading rate on mechanical properties of PUR foams.

2.2. Digital image correlation investigations

The damage mechanisms of the foams were investigated by the 2D (DIC) technique, using a 5 MPixels camera and by applying a random speckle of paint on the specimen surface. Some analyses were done by using the 3D approach and 2 MPixels cameras. In this case the ARAMIS system was calibrated using a 35 x 28 mm caliber and a facet of 27 x 15 pixels; thus a 44 % facet overlap has been obtained.

Images were recorded at different loads and then processed with the ARAMIS system. A typical engineering stress-strain curve for the foam with 160 kg/m^3 density and major strain plots taken in the relevant parts of the curve is shown in Fig. 5. It can be observed that on the yield point crush bands inclined approximately 45^0 occur, tendency which extends on the plateau and densification

regions.

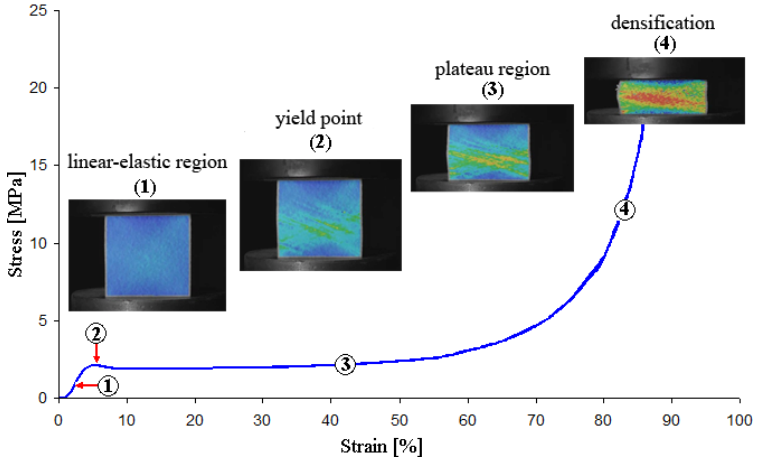


Figure 5. Engineering stress–strain curve with major strain images from ARAMIS system

The DIC measurements in the linear-elastic region allow the determination of Young's modulus E, and Poisson's ratio ν.

For the foam with a density of 301 kg/m^3 (closer to a porous solid) the deformation bands tend to be less inclined. For a loading speed of 1 mm/min in Fig. 6 are shown the following: the current stage in the engineering stress-strain curve (here one in the plateau region is chosen), the vertical displacements and Mises strains in that moment, and the variation of the Mises strains along a vertical line taken in the middle of the specimen (figure upper-left) at different stages of loading – the one represented hereby being depicted by a red curve. In the last registered stage (the last curve) the foam deteriorates significantly – close to 100% – and the curve becomes discontinuous.

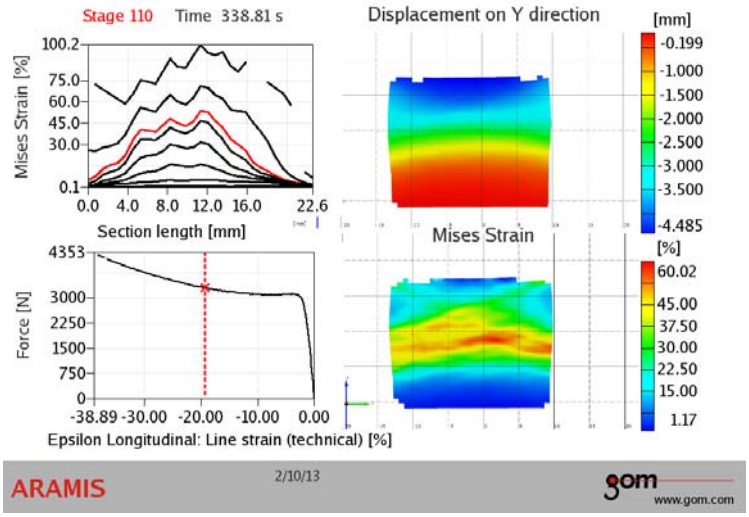

Figure 6. Mises strains and vertical displacements in the plateau region

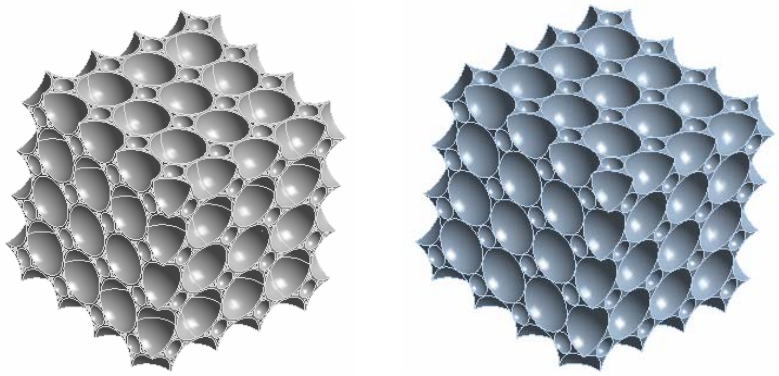
3. Numerical simulation

Based on the statistical analysis of the closed cells microstructures the geometric parameters were determined and the 3D representative volume (RVE) of the foams was built. Two strategies were considered: a model based on tangent hollow spheres for low density foams (Fig. 7a), respectively a solid cube from which were extracted spheres for higher density foams (Fig. 7b). Polyurethane was considered the material for the cell walls with Young's modulus E_s=1600 MPa and Poisson's ratio

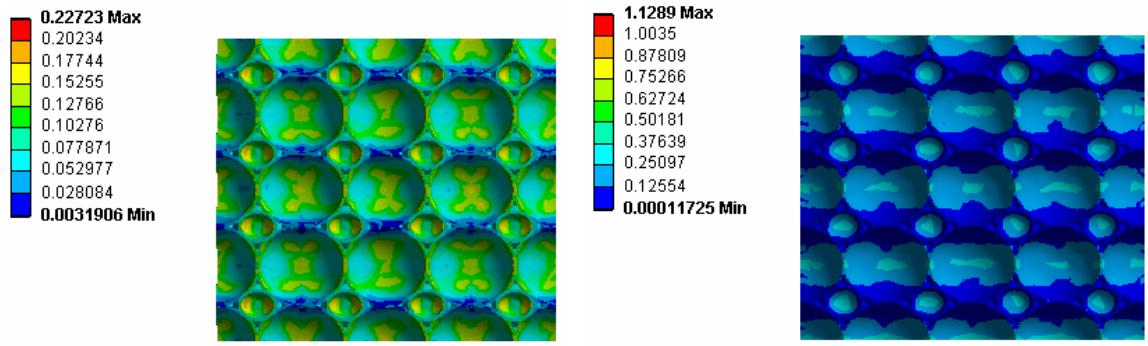
ν= 0.4.



a. Hollow spheres b. Solid with spherical cells

Figure 7. 3D models of the foam RVE

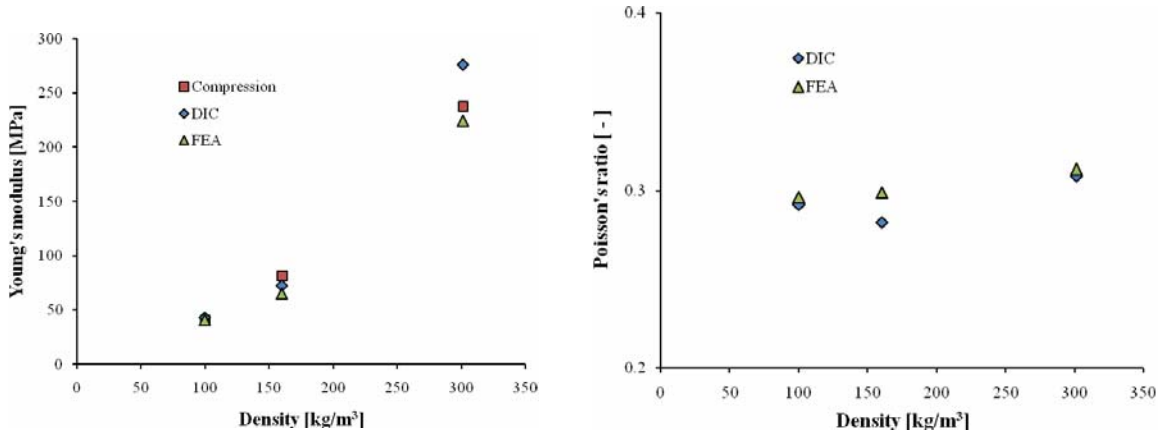
Imposing the periodic boundary conditions and a displacement on the top of the RVE the elastic properties (Young's modulus and Poisson ratio) were determined. Figure 8 presents the results of the equivalent Mises strain.



a. Hollow spheres b. Solid with spherical cells

Figure 8. Equivalent Mises strains

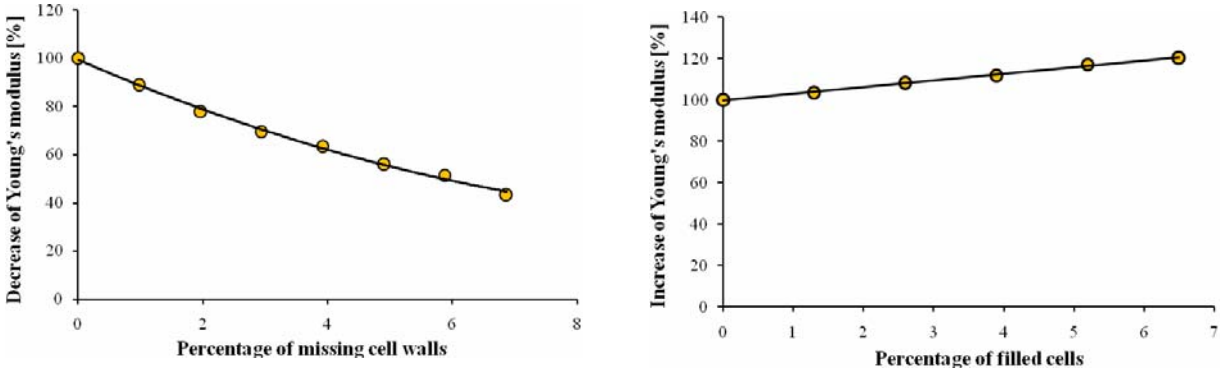
Figure 9 presents a comparison between experimental (compression and DIC) and numerical results of Young's modulus (Fig. 9a) and Poisson's ratio (Fig. 9b). A good agreement was obtained between experimental and numerical values for Poisson's ratio and Young's modulus for low density foams. For the higher density foam (301 kg/m^3) a difference of 16% was obtained between compression and DIC values of Young's modulus which could be explained on different methodologies used to record the specimen deformations.



a. Young's modulus b. Poisson's ratio

Figure 9. Comparison between experimental and numerical values of elastic properties of PUR foams

Missing cell walls (for each cell only a single wall was eliminated) and filled cells were considered in the FE analyses in order to investigate the effect of the damage of cellular structures on mechanical properties. Figure 10 presents the influence of damage expressed in terms of normalized Young's modulus (ratio between Young's modulus for damaged structure and for undamaged structure). It can be observed that 7% of missing cell walls decrease the Young modulus with 57%, while 7% of filled cells produce an increase of Young's modulus with 20.5%.



a. Missing cell walls b. Filled cells

Figure 10. Comparison between experimental and numerical values of elastic properties of PUR foams

4. Conclusions

Two experimental methods (compression tests and Digital Image Correlation) were used to determine the mechanical properties of rigid polyurethane foams. The effect of density, loading rate and loading direction were investigated. Ranking the investigated parameters it could be observed that the density has the major influence on mechanical properties, followed by strain rate, and the minor influence is the loading direction.

DIC measurements prove to be a powerful tool in establishing the local damage characteristics and the bands of deformation for the PUR foams. The density of the foam appears to influence the inclination of the deformation bands.

Finite Element Analysis was performed on 3D representative models to predict the elastic constant of polyurethane foams. The predicted values are in good agreement with the experimental ones which validates the numerical methodology. Then the effect of damage, represented by missing cell walls and filled cells, on Young modulus was systematically investigated.

Abstract Optimal designs of the resistance of metallic corrugated sandwich plates under blast loading are studied numerically and analytically. The dynamic response of metallic sandwich plates under blast loading is numerically analyzed. Comparisons among the corrugated sandwich plates made of the same material and equivalent weight are conducted. The study of weight optimization is carried out, such as the relative core density, core height, the ratio of core height to half-length of the unit, and the thickness ratio of the top face sheet to bottom one. Based on the optimal designs, the sandwich plates possessing better performance are obtained. Three-dimensional finite element (FE) simulations are performed and the FE predictions are in good agreement with the theoretical predictions.

Keywords Sandwich plate, Sinusoidal plate core, Dynamic response, Optimal design

1. Introduction

Lightweight structures have been widely used in engineering, such as vehicles, ships, aircrafts and spacecrafts. Sandwich structures are typical lightweight structures with a number of advantages, e.g. ultralight, high ductility, high crashworthiness, high strength to weight ratio, high stiffness to weight ratio, multifunction. Lightweight metallic sandwich beams, plates and panels with various cores have received great attention. Several kinds of metallic cores are developed, such as metallic foams, lattice materials and corrugated cores [1-3].

In the past decades, some work has been devoted to analyzing the dynamic response of sandwich structures subjected to blast loading. Fleck and Deshpande [4] theoretically investigated the dynamic response of fully clamped metal sandwich beams under uniform transverse blast loading. Subsequently, Qiu et al. [5] developed an analytical model for dynamic response of fully clamped sandwich beams under impulsive loading over a central patch. More recently, Qin and Wang [6] and Qin et al. [7] derived new yield criteria for symmetric and geometrically asymmetric metal sandwich structures, in which the effect of core strength is incorporated. Based on the yield criterion, Qin and Wang [8] and Qin et al. [9] analytically studied the dynamic response of fully clamped metal sandwich beams subjected to impulsive loading using the membrane factor method, in which the interaction of bending and stretching is considered.

Xue and Hutchinson [10] numerically studied the dynamic response of metal sandwich plates subjected to air blast loading. The study of weight optimization was carried out for pyramidal truss, square honeycomb and folded plate with respect to the respective geometric parameters, including core and face sheet thickness, core member aspect ratios and relative density. Zhang et al. [11] numerically studied the resistance of the trapezoidal plate core sandwich plates, and the FE predictions were compared with analytical solutions, showing good agreement. In additions, numerical calculations were carried out to study the dynamic response of metal sandwich panels,

beams and plates with different kinds of cores [12-14] subjected to underwater blast loading and air blast loading.

The objective of this study is to numerically and analytically investigate the optimal design of dynamic response of corrugated metal sandwich plates with sinusoidal plate core. This paper is organized as follows. Firstly, the problem is stated and the topology of sandwich plate with sinusoidal plate core is introduced in Section 2. The analytical solutions to predict the dynamic response of asymmetric sandwich plates are presented in Section 3. In Sections 4 and 5, the analytical solutions of the dynamic response of the sandwich plates under impulsive loading are compared with the finite element results. Furthermore, the study of weight optimization is carried out, such as relative core density, core height, the ratio of core height to half-length of the unit, and the thickness ratio of top and bottom face sheets. Finally, concluding remarks are presented in Section 6.

2. Statement of the problem

Here, we consider a metal sinusoidal plate core sandwich plate with infinite length in x direction under impulsive loading I, as shown in Figs. 1 and 2(a). Clamped conditions are imposed along the two sides in z direction. The top and bottom face sheets with thicknesses h_t and h_b are perfectly bonded to the sinusoidal plate core with the height of the core H_c, as shown in Fig. 2(b). The half-width of the sandwich plate and half-length of the unit cell are L and l, and the thickness of the core web is h_c. The relative core density $\bar{\rho} = \rho_c / \rho_s$ with ρ_c and ρ_s being the density of the core and core web material, respectively, can be calculated as $\bar{\rho} = h_c \cdot l_s \cdot \tan\phi / H_c^2$ [15], where l_s is the arc length of the core web in the half unit cell and $\tan\phi = H_c / l$.

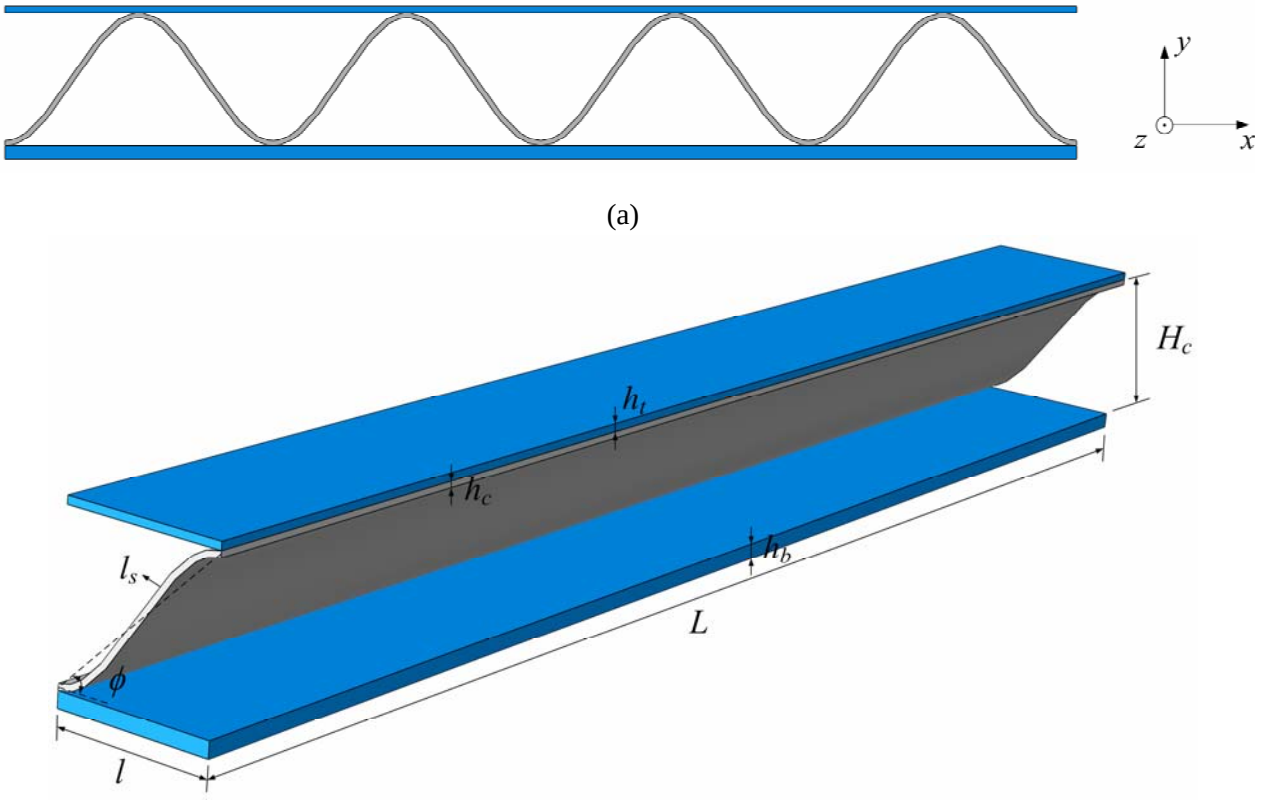

Figure 2. Sketches of the metallic corrugated sandwich plates with sinusoidal plate core. (a) Topology of the sandwich plate, and (b) a quarter of unit cell for the sandwich plate

3. Analytical solutions for the dynamic response of asymmetric sandwich plates

In this section, employing the similar procedure to the plastic-string model [15] for the dynamic response of symmetric sandwich plates, the analytical solutions for dynamic response of the fully clamped asymmetric sandwich plates under the impulsive loading *I* are obtained shown in Fig. 1.

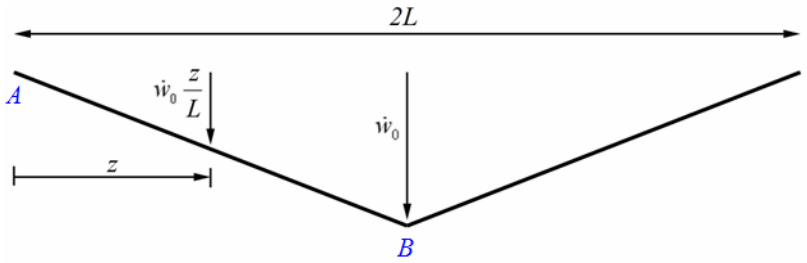
It is assumed that the top and bottom face sheets obey the rigid-perfectly plastic law with the yield strength σ_Y, and the metal sandwich core is modeled as a rigid-perfectly-plastic-locking (*r-p-p-l*) material with a plateau-stress level of σ_{nY} and a critical densification strain ε_D.

The phase of core compression is the same as that for dynamic response of symmetric sandwich beam [4]. It is assumed that the longitudinal plastic membrane force N_p is insensitive to the degree of the core compression [4], and then obtained

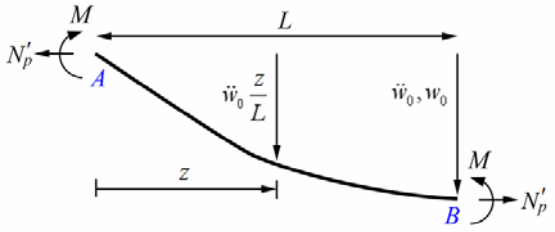
$$N_p' = N_p = \sigma_Y b\left(h_t + h_b\right) + \sigma_{lY} b H_c \tag{1}$$

where *b* is the length in *x* direction, σ_Y is the yield strength of face sheet material, and σ_{lY} is the longitudinal compressive strength of core.

The velocity field is assumed as $\dot{w}=\dot{w}_0 z/L$ when $0\le z\le L$, where $\dot{w}_0$ is the velocity at the midspan of the plastic-string, shown in Fig. 3(a) for half of the plastic-string. In the phase of dynamic structural response for the plastic-string model [15], the dynamic response of symmetric sandwich beam is dominated by axial (membrane) force alone. However, the asymmetric sandwich beam has axial (membrane) force N_p' and bending moment *M*, shown in Fig. 3(b). This is because that the plastic neutral surface of asymmetric sandwich structure is usually different from the geometric surface, and the geometric and plastic neutral surfaces of the symmetric sandwich beam are coincident.



(a)



(b)

Figure 3. Sketches of the deformation process of a fully clamped plastic-string. (a) The velocity field and (b) a free body diagram of the half of the plastic-string.

Considering the conservation of the moment of momentum for half of the sandwich plate shown in Fig. 3(b) with respect to the fixed end support Point *A* at time *t*, we have

$$M + N_p' w_0 - M = -\frac{d}{dt}\int_0^L \left(\rho_s b h_t + \rho_s b h_b + \rho_c b H_c\right)\dot{w}z\,dz \tag{2}$$

where w_0 is the deflection at the midspan. The continuity conditions are $w_0(t=0)=0$ and $\dot{w}_0(t=0)=V_f$, where the final common velocity of the core and two face sheets at the end of the core compression stage $V_f = I/\left(\rho_s h_t + \rho_s h_b + \rho_c H_c\right)$ [4]. If $\dot{w}_0\left(t=T_f\right)=0$, the motion of the plastic-string ends. Then, the maximum deflection $w_1 = w_0\left(t=T_f\right)$ and structural response time T_f of the asymmetric sandwich plate can, respectively, be written as

$$w_1 = \frac{IL}{\sqrt{3\left(\sigma_Y h_t + \sigma_Y h_b + \sigma_{lY} H_c\right)\left(\rho_s h_t + \rho_s h_b + \rho_c H_c\right)}} \tag{3}$$

and

$$T_f = \frac{\pi}{2} L \sqrt{\frac{\rho_s h_t + \rho_s h_b + \rho_c H_c}{3\left(\sigma_Y h_t + \sigma_Y h_b + \sigma_{lY} H_c\right)}} \tag{4}$$

To simplify analysis, we introduce the following nondimensional geometric and property variables of the sandwich plate:

$\bar{H}_c = \frac{H_c}{L}$, $\bar{h} = \frac{h_t + h_b}{2H_c}$, $\alpha = \frac{h_t}{h_b}$, $\bar{w}_1 = \frac{w_1}{L}$, $\bar{I} = \frac{I}{\left(\rho_s h_t + \rho_s h_b + \rho_c H_c\right)\sqrt{\sigma_Y / \rho_s}}$, $\bar{\sigma}_l = \frac{\sigma_{lY}}{\sigma_Y}$ and

$\bar{T}_f = \frac{T_f}{L\sqrt{\rho_s / \sigma_Y}}$.

Then, Eqs. (3) and (4) yield the following dimensionless maximum deflection and structural response time of the asymmetric sandwich plate,

$$\bar{w}_1 = \frac{\bar{I}\beta}{\sqrt{3}} \tag{5}$$

and

$$\bar{T}_f = \frac{\pi}{2\sqrt{3}}\beta \tag{6}$$

respectively, where $\beta = \sqrt{\frac{\bar{\rho} + 2\bar{h}}{\bar{\sigma}_l + 2\bar{h}}}$.

Substitution of the equation of normalized longitudinal compressive strength $\bar{\sigma}_l$ for sinusoidal plate core [15] into Eqs. (5) and (6) yields the following dimensionless maximum deflection and structural response time of the asymmetric sandwich plate with sinusoidal plate core,

$$\bar{w}_{1s} = \frac{\bar{I}}{\sqrt{3}} \tag{7}$$

and

$$\bar{T}_{fs} = \frac{\pi}{2\sqrt{3}} \tag{8}$$

Eqs. (5), (6), (7) and (8) can reduce the solutions for the dynamic response of symmetric sandwich plates under the impulsive loading [15].

4. Numerical calculations

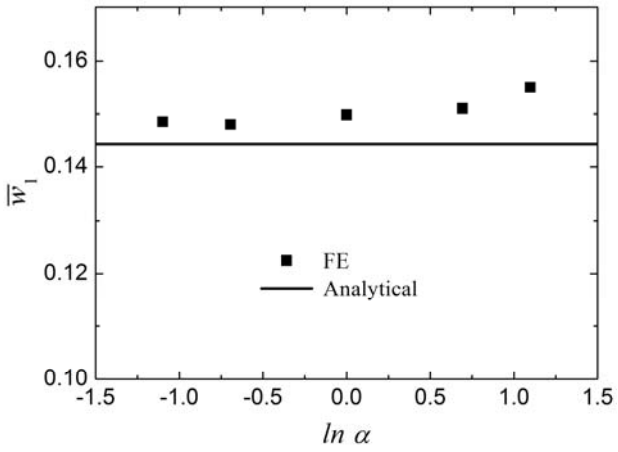
Finite element calculations are carried out to predict the dynamic response of the corrugated sandwich plates with sinusoidal plate cores. All simulations have been carried out using ABAQUS/Explicit code. Eight-node linear brick elements with reduced integration (Type C3D8R) are used to model the face sheets and core webs in ABAQUS/CAE software. The uniform distributed impulsive loading *I* per area is applied to the top face sheet of the sandwich plate as a uniform initial velocity $V_0 = I/\rho_s h_t$ [10,12]. Periodic boundary conditions are applied at each end of the repeating unit in *x* direction, and symmetrical boundary conditions about the centerline are adopted. The computational model of the corrugated sandwich plate is shown in Fig. 1(b). All the contact of the plates is modeled by using a general contact algorithm with a frictionless contact option in ABAQUS/Explicit. The vertical, horizontal and rotational displacements of nodes at the ends of the plate are zero. The face sheets and core web are made of stainless steel with yield strength $\sigma_Y = 400\text{MPa}$, Young's modulus $E_s = 200\text{GPa}$, yield strain $\varepsilon_Y = 0.2\%$, elastic Poisson's ratio $v_e = 0.3$, density $\rho_s = 7850\,\text{kg/m}^3$ and linear hardening modulus $E_t/\sigma_Y = 12$, respectively. It is assumed that the face sheets and core web materials have sufficient ductility to be able to sustain deformation without fracture. The face sheets and core webs are modeled as J_2 flow theory of plasticity.

5. Results and discussion

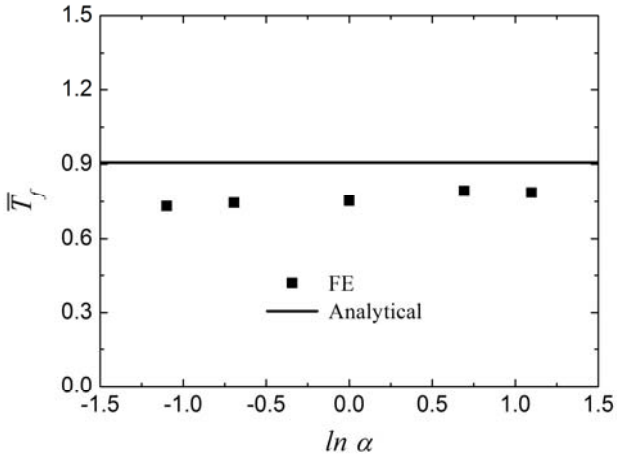
5.1. Effect of the asymmetric factor

Comparisons of the analytical solutions and numerical results for the normalized maximum deflection $\bar{w}_1$ of the bottom face sheets and the nondimensional structural response time $\bar{T}_f$ for the asymmetric sandwich plates subjected to $\bar{I} = 0.25$ are shown in Figs. 4(a) and (b), respectively. The sandwich plates with sinusoidal plate core have $\bar{H}_c = 0.1$, $\bar{h} = 0.08$, $\phi = 45^o$, $\bar{\rho} = 0.055$ and $L = 1\text{m}$. In Fig. 4(a), it is seen the analytical solutions based on Eq. (7) are in good agreement with the numerical results and underestimates the numerical ones a little. Actually, the discrepancies between the analytical and numerical solutions lie in that the analytical procedure does not consider the effects of the wrinkling of face sheets and cores, the strain hardening of the metal material, the effect of shear force and the reduction in momentum provided by the supports in the core compression phase. The discrepancies in high impulsive loading may be due to the assumption that there is full densification of the core in the analytical solution while in the numerical solution there is no distinct densification in the core. In Fig. 4(a), it is seen that the numerical result for the smallest maximum deflection occurs in the case of $\alpha = 0.5$. Moreover, seen the deformed configurations at the impulse value $\bar{I} = 0.25$ in Figs. 5(a) and (b), the deformation of top and bottom face sheets in the case of $\alpha = 2$ both almost keeps horizontal at the midspan, while the top face sheet of the sandwich plate in the case of $\alpha = 0.5$ occurs more evident deformation in the location far away the core web relative to the location bonded to the core. In Fig. 4(b), the analytical

solutions based on Eq. (8) for the structural response time agree well with the numerical results. The numerical results for the structural response time keep almost a constant for the several cases of α.



(a)



(b)

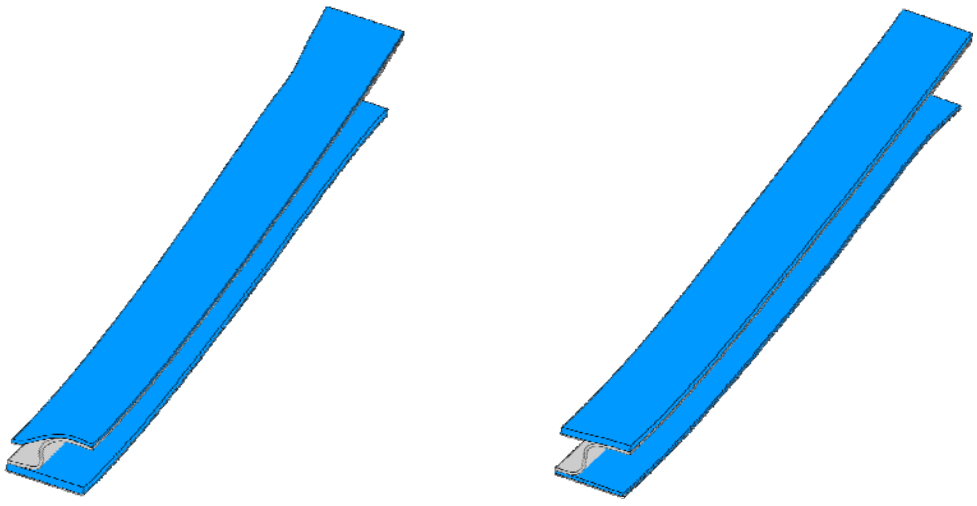

Figure 5. Deformed configurations of sinusoidal plate core sandwich plates subjected to $\overline{I} = 0.25$. (a) The case of $\alpha = 0.5$, (b) the case of $\alpha = 2$

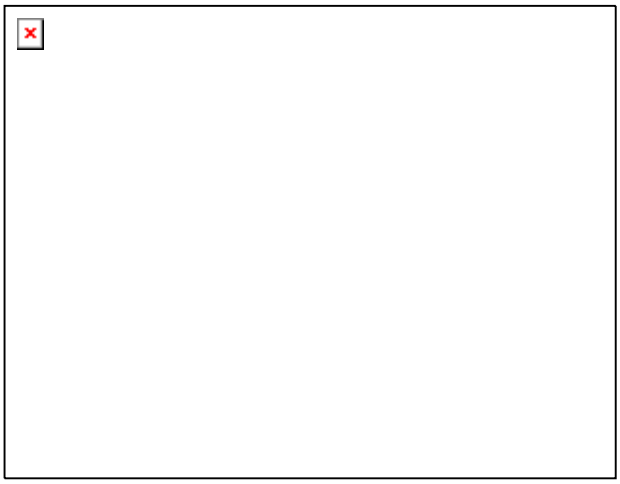
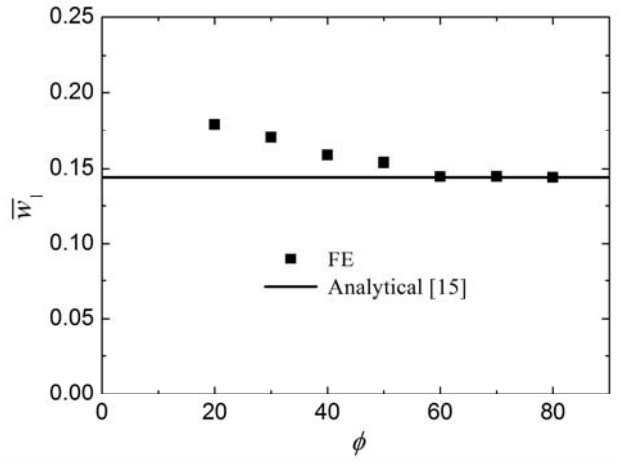
5.2. Effect of the core height

Fig. 6(a) show the effect of the normalized core height $\bar{H}_c$ to the normalized maximum deflection $\bar{w}_1$ of the metal sandwich plates under $\bar{I}=0.25$, in which $\alpha=1$, $2\bar{h}\bar{H}_c+\bar{\rho}\bar{H}_c=0.02$, $\phi=45^o$, $\bar{\rho}=0.04$ and $L=1\text{m}$. Obviously, the analytical solutions [15] agree well with the numerical results for the moderate $\bar{H}_c$, and underestimate and overestimate numerical results for the cases of small and big $\bar{H}_c$. It is readily seen that the angle ϕ significantly affects the numerical results for maximum deflection of bottom face sheets in Fig. 6(a). The normalized maximum deflection of bottom face sheet has smallest value when $\bar{H}_c=0.28$.



(a)



(b)

Figure 6. The effect of the (a) normalized core height $\bar{H}_c$ and (b) angle ϕ to the normalized maximum deflection $\bar{w}_1$ of the bottom face sheets of sandwich plates

5.3. Effect of the ratio of core height to half-length of the unit

Comparisons of the analytical [15] and numerical solutions for the normalised maximum deflection $\bar{w}_1$ of the bottom face sheets of the sandwich plates versus the angle ϕ are shown in Fig. 6(b). The angle ϕ is varied and other values ($\bar{I}=0.25$, $\bar{H}_c=0.1$, $\bar{h}=0.08$, $\bar{\rho}=0.04$, $\alpha=1$ and

$L=1\text{m}$) are fixed. The analytical solutions agree well with the numerical results for the case of big ϕ. The maximum deflection decreases with the increasing of ϕ, and remains more or less constant when ϕ exceeds 60^0. In other words, when ϕ is bigger than 60^0, the blast-resistance performances of the bottom face sheets of the sandwich plates are good.

5.4. Effect of the relative core density

The effect of relative core density $\bar{\rho}$ to the normalized maximum deflection $\bar{w}_1$ of the metal sandwich plates subjected to $\bar{I}=0.25$ is shown in Fig. 7, in which $\bar{H}_c=0.1$, $2\bar{h}\bar{H}_c+\bar{\rho}\bar{H}_c=0.02$, $\phi=45^o$, $\alpha=1$ and $L=1\text{m}$. The analytical solutions [15] are a little smaller than numerical results in a whole, and the bottom face sheet has the smallest maximum deflection at a relative core density 5.5%.

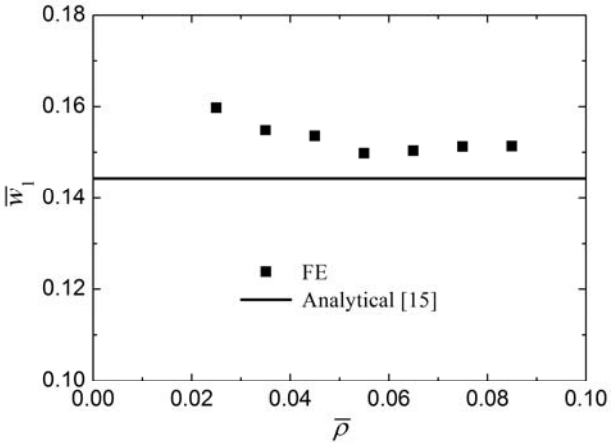


Figure 7. The effect of the relative core density $\bar{\rho}$ to the normalized maximum deflection $\bar{w}_1$ of bottom face sheets of the sandwich plates

6. Concluding remarks

The dynamic response of corrugated sinusoidal plate core sandwich plates under the impulsive loading has been investigated. Good agreement between the analytical predictions and numerical results is achieved. The optimizations of topology with respect to the respective geometric parameters have been obtained. It is shown that the axial force plays an important role in the dynamic large deflection response of corrugated metal sandwich plates and the present analytical procedure is simple and efficient.

Evaluation of Microstructure Effect on Anisotropic Mechanical Properties of Hot Rolled AZ31 by AE Analysis

Kousuke Matsumoto[1,*], Takashi Yasutomi[1], Manabu Enoki[1]

[1] Department of Materials Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan

Abstract Anisotropic properties of twinning and slip deformation of hot rolled and extruded AZ31 Mg alloy have been reported in our previous researches. AE (Acoustic Emission) measurement has been done during the tensile test of specimen with various angles between tensile direction and rolled or extruded direction. AE energy had good correlation with twinning area and 0.2% proof stress. It has been also reported that twinning stress has higher grain size dependence than the stress required for activation of slip because the Hall-Petch slope for twinning is larger than that for slip. In this research, tensile test specimen were prepared from rolled AZ31 with various angles between tensile and rolling directions. In order to change grain size of hot rolled AZ31 Mg alloy, the specimens were annealed at various temperatures. Then in-situ measurement of AE signals was conducted during the tensile test. The mechanical deformations occurring actually were found by EBSD (Electron Backscatter diffraction) and observation of fracture surface. According to the result, the effect that grain size of hot rolled AZ31 Mg alloy gives to anisotropic mechanical properties during the tensile test was quantitatively evaluated by AE analysis.

Keywords Acoustic Emission, AZ31, Annealing, Anisotropy, Twinning

1. Introduction

Mg alloy is a light structural metal with high specific strengths; therefore, its alloys are the most attractive materials to be utilized in the automotive and transportation industries. This is due to their lower density compared to that of other structural materials such as steels and aluminum alloys. However, their poor mechanical properties at the room temperature are considered as an important fault. Grain size refinement is a major way to improve mechanical properties. At this point, Hall-Petch relationship predicts that the material strength increases with decreasing grain size. Its hexagonal close-packed structure also characterizes its mechanical properties. In the former research, anisotropic mechanical properties during tensile test of extruded AZ31 Mg alloy is evaluated by AE analysis [1-6]. In this research, the specimens were produced from hot rolled AZ31 Mg alloy with various angles between tensile and rolling directions. These specimen were annealed at various temperatures in order to change their grain sizes. The effect of various grain sizes on mechanical properties was evaluated by AE energy.

2. Experimental procedure

2.1. Material

The material used in this study was hot rolled AZ31 sheet (Mg – 3.04 % Al – 1.06 % Zn – 0.38 % Mn) with a thickness of 3 mm bought from Osaka Fuji Corporation. The as-received specimen had an average grain size of 9.8μm. In order to change grain size, the as-received specimens were annealed at 285°C for 30 min and 450°C for 30 min. The grain sizes after annealing were 13.5 and 17.9μm for the first and latter conditions, respectively.
To study the anisotropy of mechanical properties, the specimens were prepared with various angles between tensile and rolling directions of 0°, 15°, 30°, 45°, 60°, 75° and 90°, shown in Fig. 1. All tests were carried out at a constant strain rate of 1.67×10^{-4} /s.

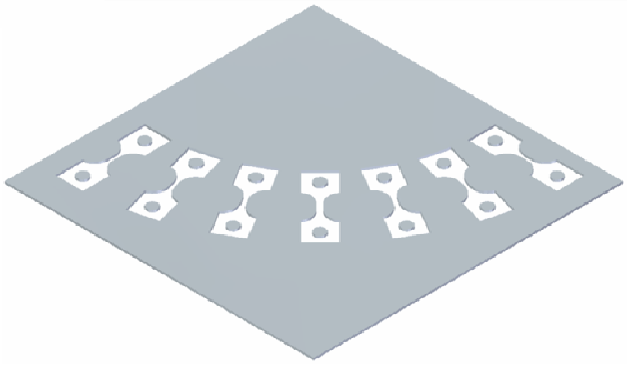

Figure 1. Procedure of cutting specimens

2.2. AE measurement during tensile test

AE measurements were applied with 4 channels in order to remove friction noise from jig of tensile test machine. Positions of AE sensors are shown in Fig. 2. AE sensors used in this study were M304A (Fuji ceramics, Japan). Continuous Waveform Memory (CWM), which was developed by our group, was used to perform AE measurements [7]. The high pass filter was set at 100 kHz. All AE signals are wavelet transformed in order to emphasize dependence of time and frequency. Various threshold levels were set from 60dB to 80dB with an interval of 5dB to detect signals with wide range of amplitude. Then, the data was integrated.

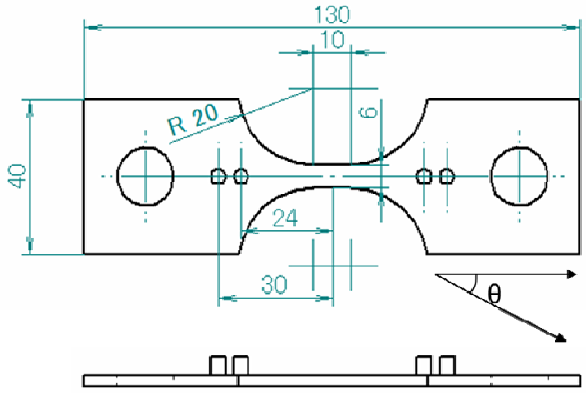

Figure 2. AE sensors positions

2.3. EBSD test

Electron Backscatter Diffraction (EBSD) analysis was performed to evaluate the texture during the tensile testing. The software used in this study was OIM-Analysis 5 of TSL Solutions. Specimens before deformed and after deformed until a strain value of 3% were cut and then polished by a machine called “Cross section Polisher” (CP), which utilizes an argon iron beam to mill the sample. This method prevents any damages from mechanical polishing and therefore the suitable surface for EBSD is easily obtained. Then, automated EBSD scans were performed in the stage control mode with TSL data acquisition software with a step size of 1.5 μm. Average grain size and Schmid factor were calculated from this result. Schmid factor used in this paper is an average value of each grain.

3. Result and discussion

3.1 Microstructure

Initial microstructure of specimens is shown in Fig. 3. As annealing temperature increases, there are less small grains, and the average grain size is larger. Fig 4(a) shows average Schmid factor for twinning of all grains of each angle. In each annealing condition, Schmid factor for twinning is larger at 60° to 90° than another angle. From this tendency, it follows that twinning deformation occurs easily in 60° to 90° specimens. Fig 4(b) shows pole figure for (0002) before tensile test. The (0002) vector shapes ring seen from the RD direction.

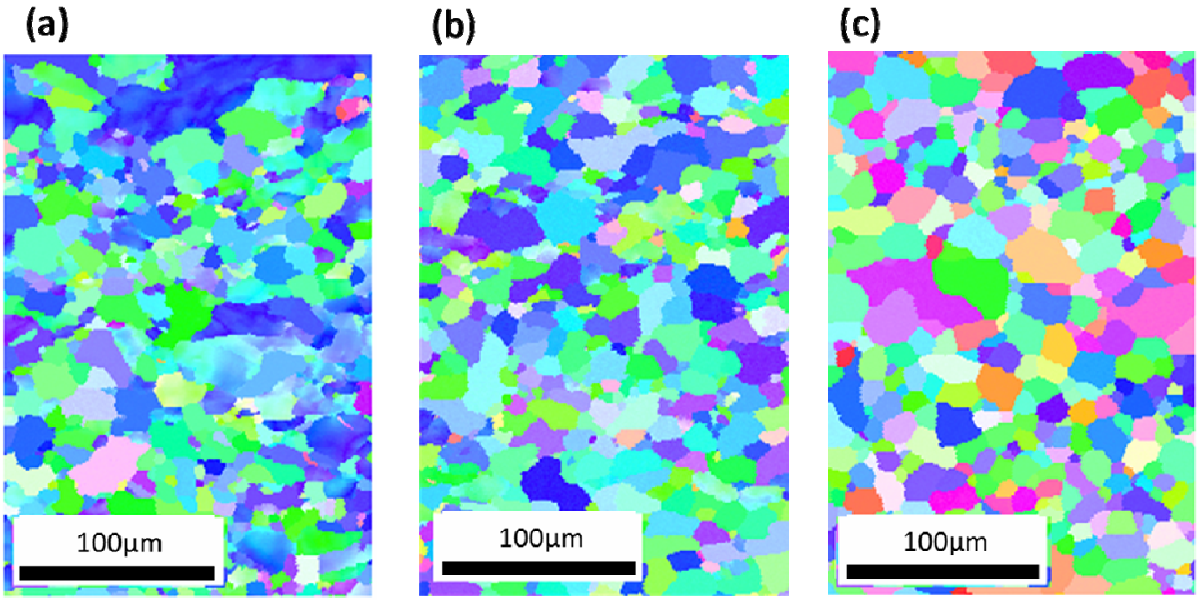

Figure 3. IPF map of (a) as-received, (b) 285°C annealed and (c) 450°C annealed specimens before tensile test

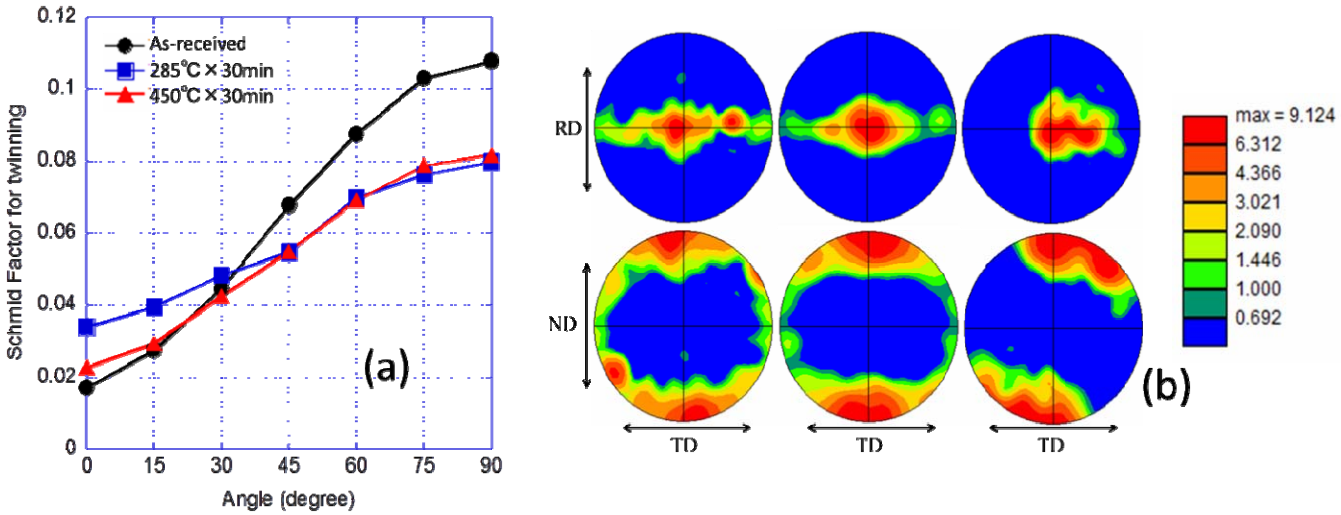

Figure 4. (a) Schmid factor for twinning and (b) pole figure for (0002) before tensile test

3.2. Mechanical properties

Fig. 5 shows strain-stress curve of (a) as-received specimen and (b) 450°C annealed specimen of

each angle. Before and after annealing, nominal stress and strain has different figure in each angle. In other words, strain-stress curve shows anisotropy in each annealing conditions. However, the strength of anisotropy differs by annealing.

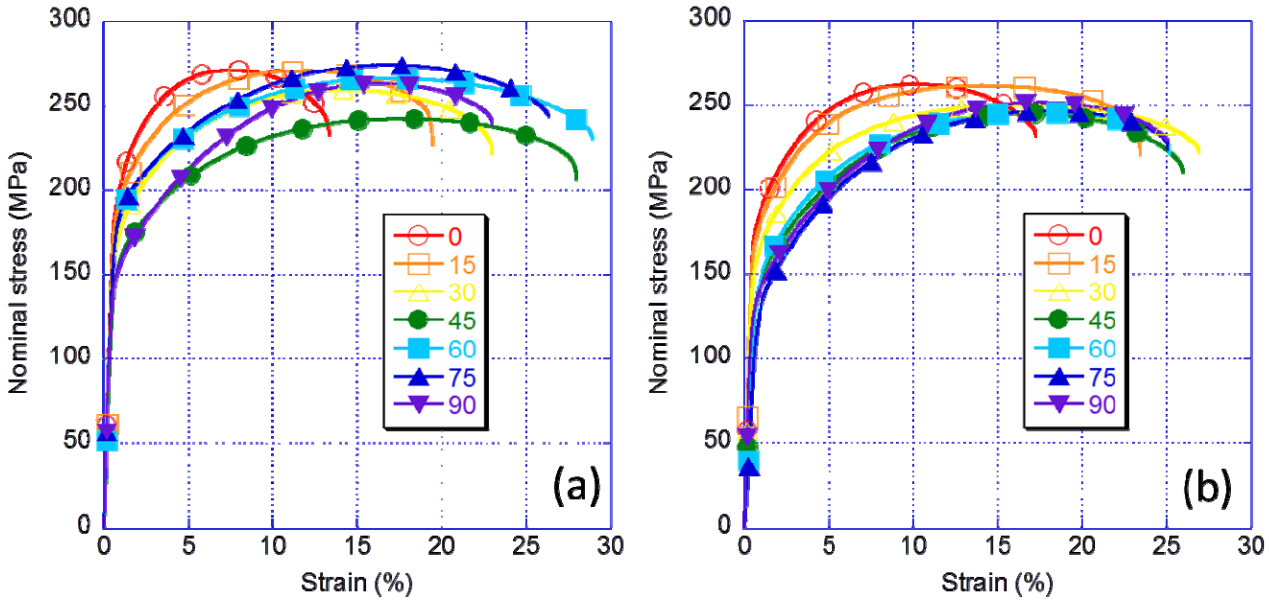

Figure 5. Strain-stress curve of (a) as-received specimen and (b) 450°C annealed specimen

In order to analyze this result, ultimate tensile stress (σ_{max}) and maximum strain (ε_{max}) are plotted in Fig. 6. From Fig. 6(a), ultimate tensile stress is high in 15° and 75°, and is especially low in 45°, so we can see strong anisotropy in as-received specimens. However, in 285° and 450°C annealed specimens, ultimate tensile stress become higher in 45°, and lower in other angles, so it can be said that anisotropy is weakened by annealing. Fig. 6(b) shows that strain also has anisotropy. Strain of as-received specimens is extremely high in 45° to 75°, but by annealing, strain of 0° to 30° becomes higher, on the other hand, strain of 45° to 75° becomes lower. By annealing, strain of 30° to 90° is flat, so it can be said that anisotropy is weaken by annealing.

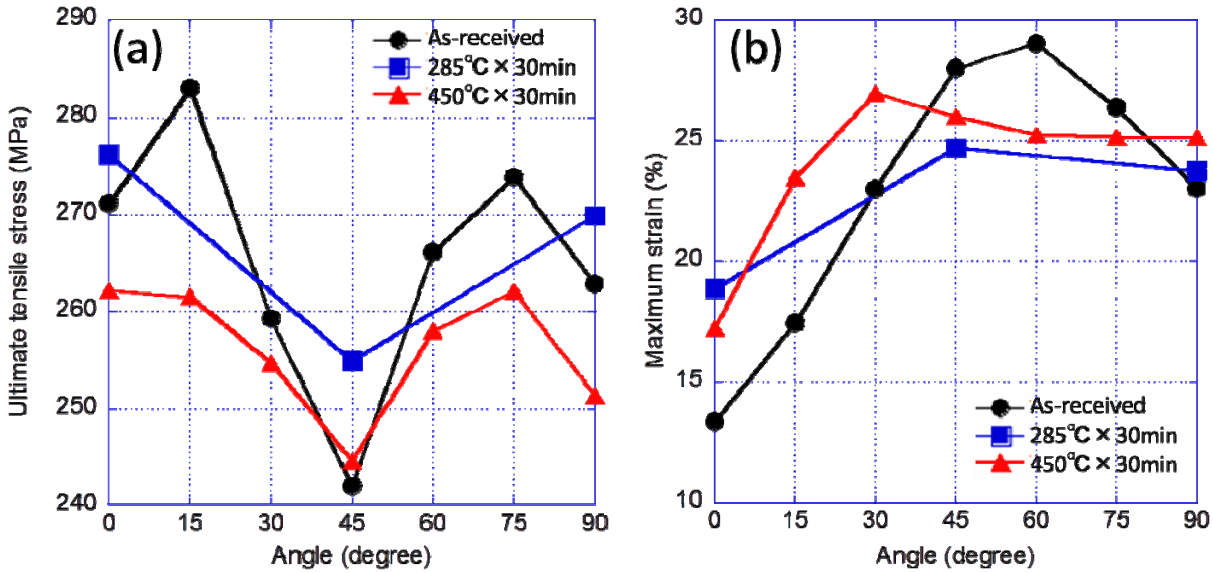

Figure 6. (a) Ultimate tensile stress and (b) Maximum strain of each specimen

However, 0.2% proof stress of each specimens shows different tendency from the former result. Fig. 7 plots 0.2% proof stress of each angle of as-received and 450°C annealed specimens. In both annealing conditions, 0.2% proof stress has anisotropy. Though ultimate tensile stress and maximum strain decreases their anisotropy of all angles by annealing, 0.2% proof stress changes of only 60° to 90° by annealing. In these angle, 0.2% proof stress become high by annealing, and it can be said that anisotropy become even strong in this part. In 0° to 45°, the value of 0.2% proof stress is almost the same in each annealing condition. It is the highest in 0° of all angles and gradually decreases to 45°.

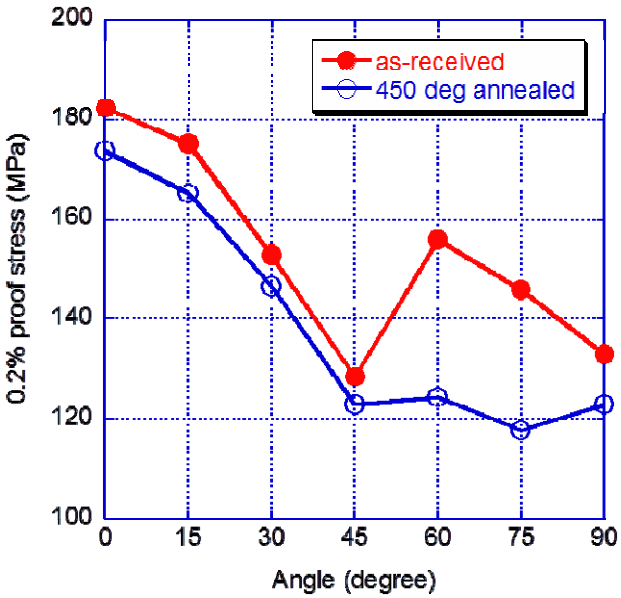

Figure 7. 0.2% proof stress of each angle of as-received and 450°C annealed specimens

3.3. AE measurement

AE result is show in Fig. 8 and Fig. 9. AE measurement was conducted during the tensile test, from start of the test to just before fracture. In each graph, AE result and time stress curve are plotted together in order to connect result of AE measurement and mechanical properties. *x* axis is time, *y* axis is nominal stress and peak frequency of AE signals, and *z* axis is magnitude of AE signals. The value of peak frequency and magnitude is used after wavelet transformed. In all specimens, AE magnitude is high at yield point, so main AE source is related to yielding mechanism. After that, AE magnitude becomes lower gradually as strain increase. In both Fig. 8 and Fig. 9, there are many resemble point. AE magnitude is far higher in 90° than 0° and 45°. Peak frequency is wide range in yield point, but after yielding, AE magnitude is high in high frequency, from about 500 kHz to 600 kHz. The second highest AE magnitude is in frequency of about 300 kHz. In 0°, maximum strain is lowest of all angles, so AE signals is detected in the early time. After annealing, these tendencies are the same. However, AE magnitude of 0° becomes much lower than 45° and 90°.

In order to analyze this AE result, the relationship between AE energy and nominal stress is plotted in Fig. 10. AE energy is calculated as square of AE magnitude and this AE signal is released when nominal stress increases 1 MPa. In Fig 10(a) to (c), AE energy peak (E_{peak}) is extremely high in 90°. AE energy is released from low nominal stress, about 50 MPa, to high nominal stress, about 250 MPa. It is well explained by the fact that AE signals are released at yield point of each specimen.

The nominal stress where AE energy is peak (σ_{AEp}) is low in 90° compared with 0° and 45°. The nominal stress at which AE energy starts to be released ($\sigma_{AEstart}$) is also low, in 90°.

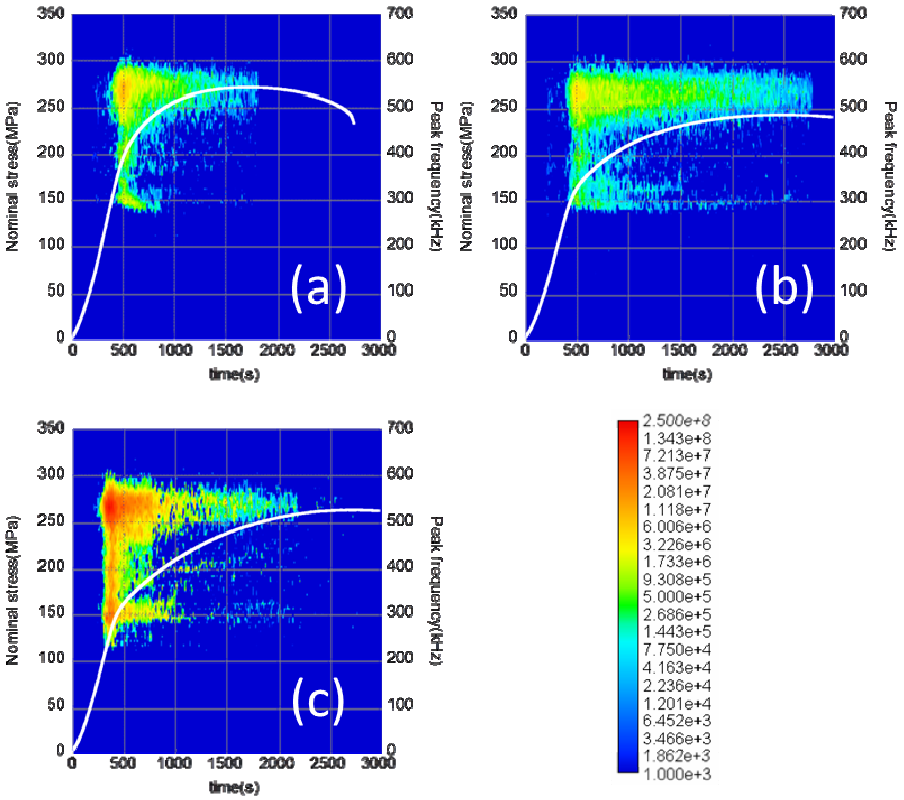

Figure 8. AE magnitude and peak frequency of as-received specimen of (a) 0°, (b) 45° and (c) 90°

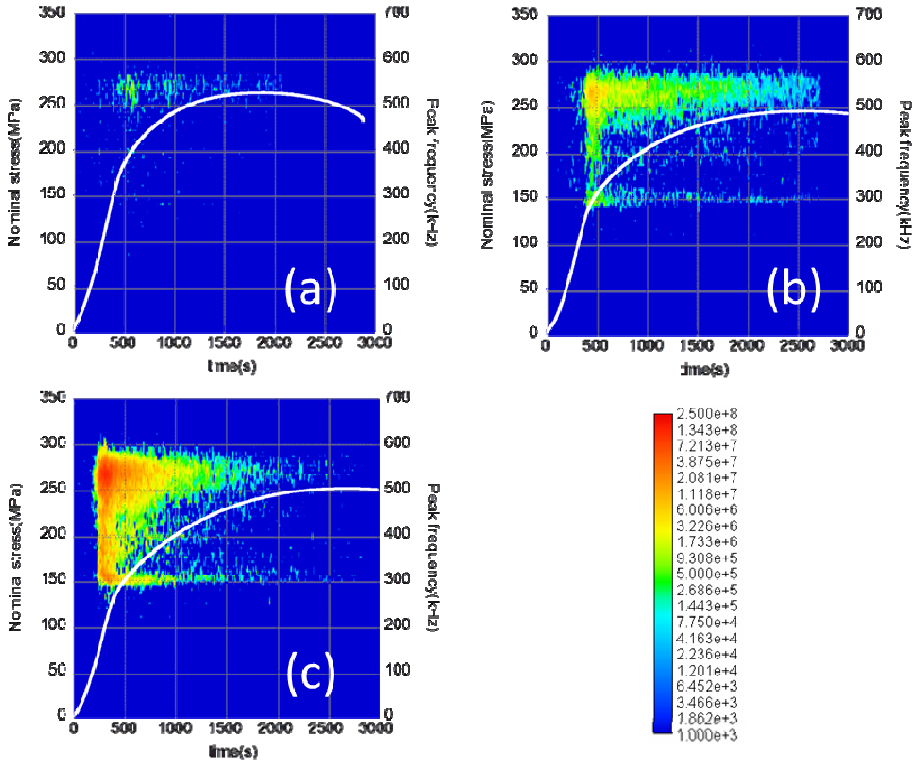

Figure 9. AE magnitude and peak frequency of 450°C annealed specimen of (a) 0°, (b) 45° and (c) 90°

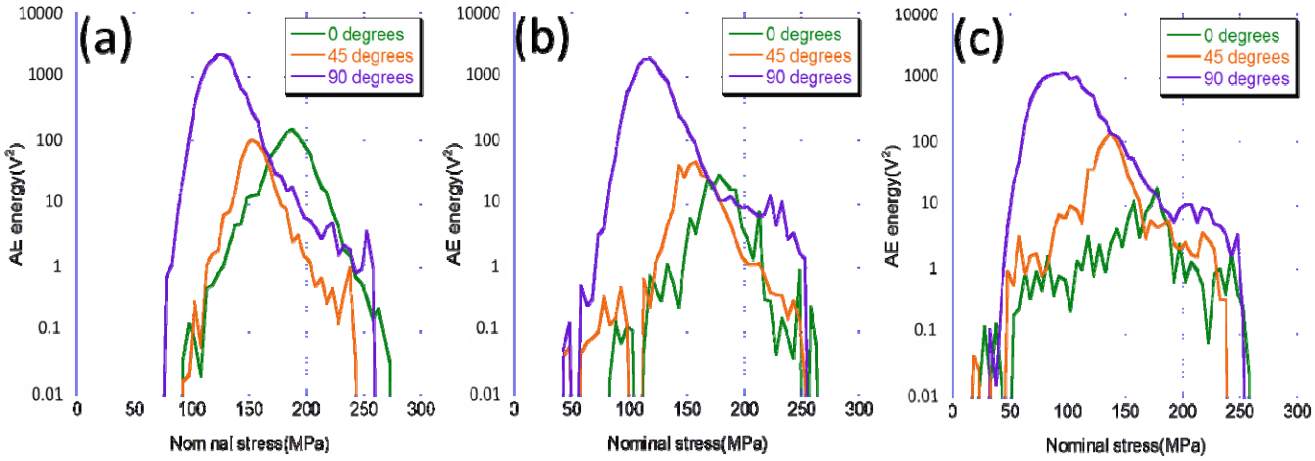

Figure 10. AE energy peak of (a) as-received, (b) 285°C annealed and (c) 450°C annealed specimen

For detail analysis, σ_{AEp} and E_{peak} is plotted in Fig. 11. In each annealing condition, σ_{AEp} become lower and E_{peak} become higher as the angle increases. This tendency is the same in each annealing condition, as-received, 285°C annealed and 450°C annealed. The value is also almost the same. It can be said that σ_{AEp} become lower and E_{peak} become higher when the angle is large for some reason of deformation mechanism.

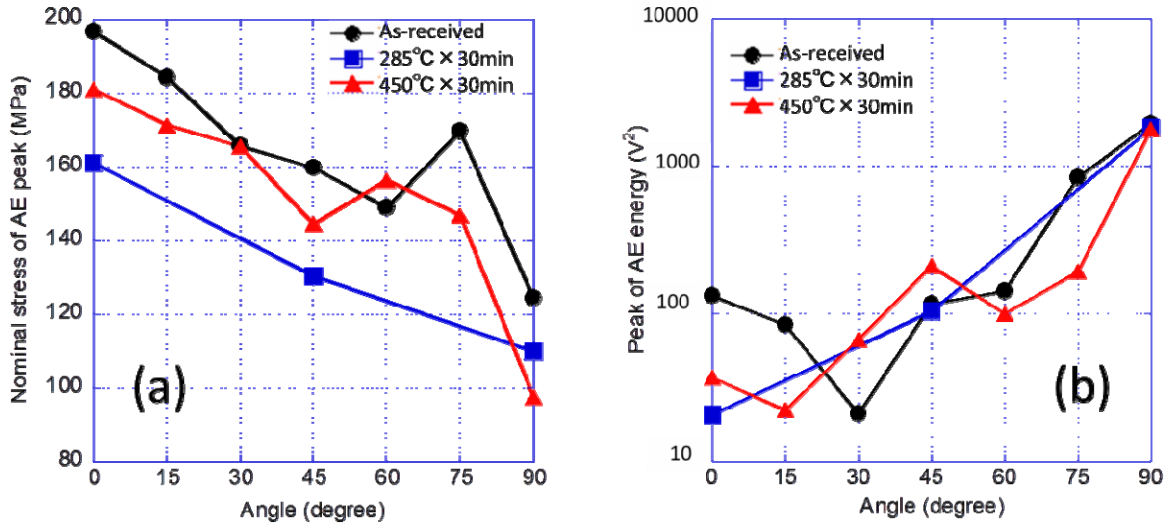

Figure 11. Relationship between tensile angle and (a) nominal stress of AE peak and (b) peak of AE energy of each specimen

In order to see why σ_{AEp} become lower and E_{peak} become higher when the angle is large, x axis is changed to Schmid factor for twinning in Fig. 12. By changing x axis from angle to Schmid factor for twinning, the AE result is connected with mechanical behavior. The abstract of graph is the same as Fig. 10, so it can be said that when Schmid factor for twinning is large, nominal stress of AE peak is low and peak of AE energy is high. The AE result is mainly caused by twinning deformation. When Schmid factor for twinning is large, twinning deformation occurs easily. At low nominal stress twinning deformation occurs, so AE signals released by twinning are detected at lower stress. For the same reason, peak of AE energy is high because the ease of twinning deformation occurring makes more twinning deformation.

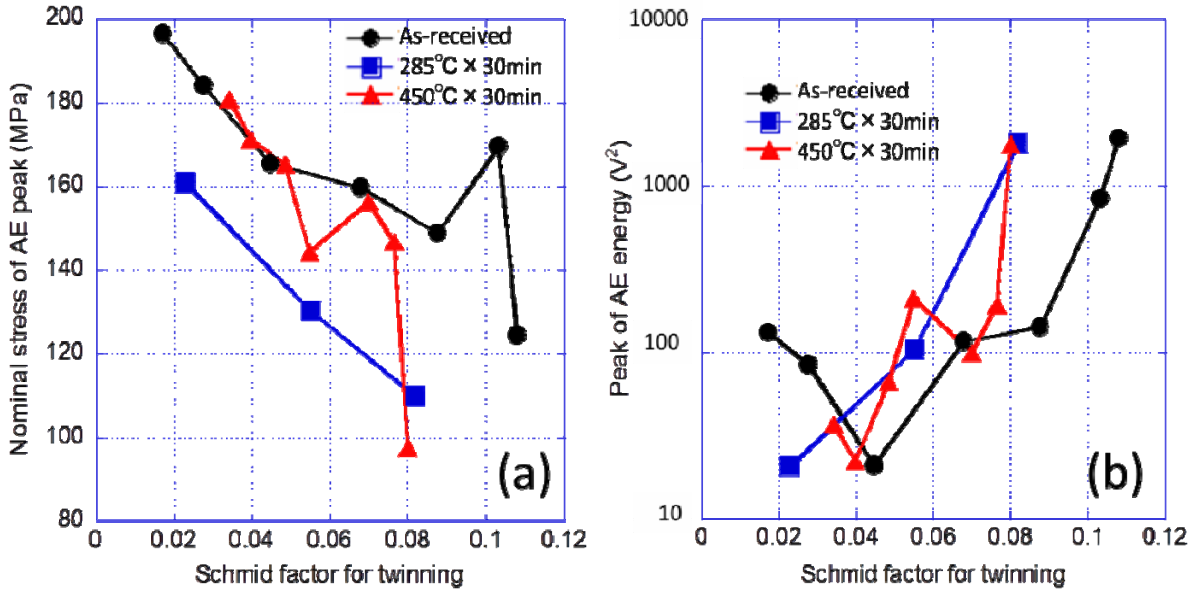

Figure 12. Relationship between Schmid factor for twinning and (a) nominal stress of AE peak and (b) peak of AE energy of each specimen

Fig. 13 shows $\sigma_{AEstart}$ of each angle and each annealing condition. $\sigma_{AEstart}$ is defined as the stress at which AE energy is over 0.01 V^2. At this point, AE energy is especially higher than noise level, and it is easily said that AE energy is released by certain mechanical behavior other than noise. After annealing, in both 285°C and 450°C, $\sigma_{AEstart}$ is almost the same, and the value is less than 20 MPa. However, before annealing, $\sigma_{AEstart}$ is over 30 MPa and has anisotropy. It can be said that when annealed, nominal stress at which AE energy starts to be released is lower and has weaker anisotropy.

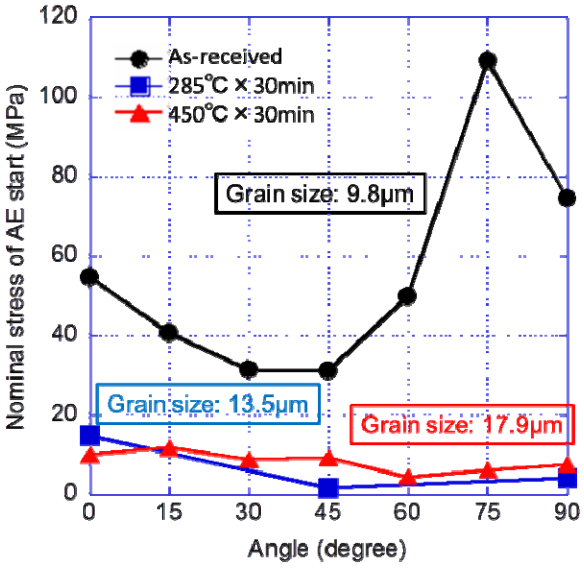

Figure 13. Nominal stress of AE start of each specimen

Fig. 14(a) plotted the relationship between grain size and σ_{AEp}. D is an average grain size, d to the negative one-half power. By annealing, d become larger and D becomes smaller. In each angle, there is linear relationship between D and σ_{AEp}. In other words, Hall-Petch equation, which is shown below, is formed in this result;

.

k, the slope of this equation is larger as the angle increases. Fig. 14(b) shows relationship between *k* and Schmid factor for twinning. In each annealing condition, *k* become larger as Schmid factor for twinning is larger. When Schmid factor for twinning is large, twinning deformation can easily occur, and AE signals are dominated by twinning deformation. Additionally, slope of Hall-Petch equation is larger in twinning than that in slip [8]. For these reason, there is linear relationship between Schmid factor for twinning and k.

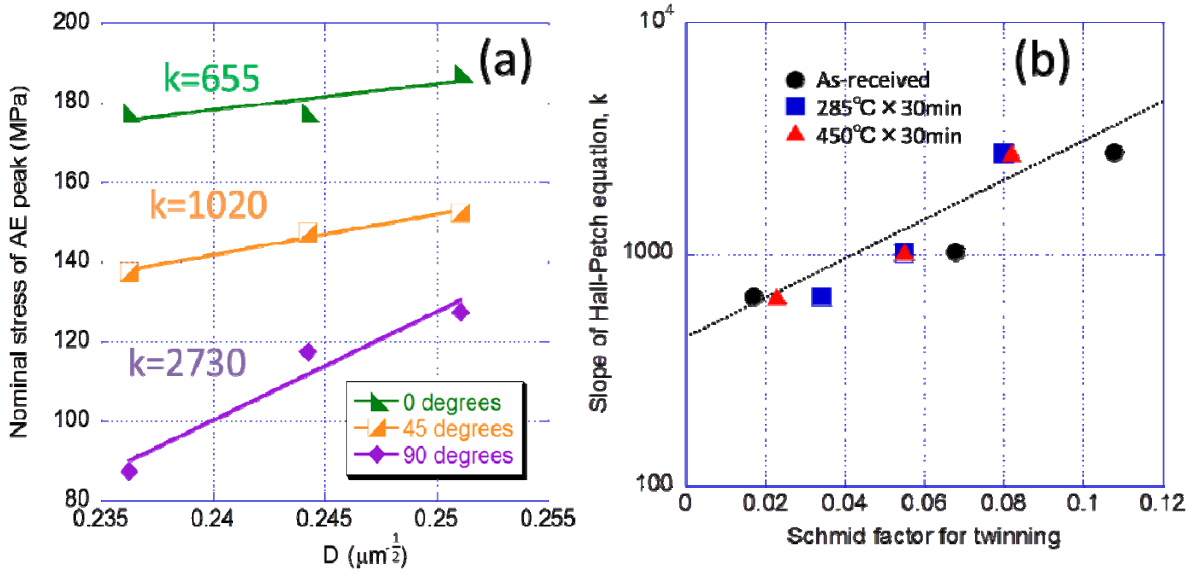

Figure 14. (a) Hall-Petch equation and (b) relationship between slope of the equation and Schmid factor for twinning

4. Conclusion

In the present study, microstructure effect on mechanical properties of AZ31 extruded magnesium alloy is evaluated by AE test and EBSD test, and following conclusions were drawn;

(1) The result of tensile test showed that anisotropy of mechanical properties is weakened by annealing.

(2) Nominal stress of AE energy peak and peak of AE energy were dominated by twinning deformation, so these value changed as Schmid factor for twinning changed.

(3) Nominal stress of AE start showed strong annealing dependence. After annealing, the stress was less than 20 MPa and anisotropy disappeared.

(4) The relationship between nominal stress of AE peak and grain size was well explained by Hall-Petch equation.

(5) Slope of Hall-Petch equation changed as Schmid factor for twinning because twinning deformation is main mechanical behavior in this study.

Abstract In the current work, a novel kenaf fiber reinforced composite sandwich panel was developed and fabricated. The kenaf fiber composites as sandwich face sheets were prepared at 55% (by weight) fiber content. PVC foams were joined using epoxy resin adhesive to fabricate sandwich structures. A series of mechanical tests, such as tensile, three-point bending and double cantilever beam, were carried out to know the mechanical behaviors of sandwich panels. Fracture and failure modes were also reported and discussed. The results show kenaf fiber reinforced composite sandwich panels have potential application in engineering construction of buildings.

Keywords Natural fiber, Sandwich, Mechanical properties, Failure analysis

1. Introduction

In recent years, the use of sandwich structures continues to increase rapidly due to their advantages, such as high strength/weight and stiffness/weight ratios, excellent heat resistance and favorable energy-absorbing capacity. They have been widely used in the satellites, aircraft, ships, automobiles, rail cars, wind energy systems, and bridge and civil constructions [1]. Most sandwich specimens analyzed in the past studies were made of polymer foam cores with composite face sheets or with metal face sheets [2–4]. Additionally, more assembly techniques, such as screw fasteners, adhesively joints, or blazed bonding, can be applied for bonding the core material and the face sheet. These applications and novel manufacturing techniques increase the requirement for the mechanical strengths of the sandwich structures in practical designs.

Another question is that environmental protection becomes increasingly important. Thus, the use of natural fibers as reinforcements of polymer-based composites has been of great interest to many researchers [5–7]. Due to many advantages, such as low density, high specific strength and modulus, relative non-abrasiveness, ease of fiber surface treatment and wide availability. More important, they are renewable and biodegradable. In fact natural fibers are also much cheaper than synthetic fibers and could replace synthetics in many applications.

If according to the design concept of sandwich structures, the natural fibers are used to fabricate the sandwich panel, it is predictable that such a "sandwich structure" with lightweight, high strength, bio-degradable and environmental friendly properties could be obtained. However, few studies have addressed this aspect. The objective of this work was to develop a novel sandwich structure based on natural fiber and PVC foam materials. Fabrication method including sheet molding compound (SMC) and bonding technique was introduced. A series of mechanical tests, such as tensile, bending and fracture properties, were carried out to understand the mechanical behaviors.

2. Materials preparation

Kenaf bast fiber was supplied by Kengro Corp (Charleston, MS, USA). It was short fiber form and

with a length of 5~8mm. The unsaturated polyester resin (UPR) was provided by Ashland Chemicals (AROPOL 6585) with density of 1.12 g/cm^3. The curing agent was obtained from Acros Orgaincs. The sandwich core was Divinycell H-grade H35 PVC foam (DIAB AB Group).

Kenaf fibers reinforced unsaturated polyester resin (UPR) composites were fabricated first as the face sheet of sandwich structure. Then polyesters, fibers, and curing agent were initially weighed to ensure the total fiber loading was 55 wt.%. Each mixture of sandwich face sheet was put into a steel mold and pressed at 5MPa for 2 min to form a mat. Then, the polyester resin with curing agent was poured into the mold and the mat was hot-pressed under a pressure of 5MPa and at a temperature of 150^{o}C for 2 hours. When the fabrication was accomplished, all the panel samples were put into a drier at room temperature for 48 hours for further investigation. The compliant PVC foam core were joined with the upper and lower kenaf fiber reinforced UPR composite panels using epoxy resin.

3. Mechanical properties of sandwich composites

3.1. Tensile test

Tensile specimens were cut from the composite panels. The tensile strength and modulus of the kenaf fiber composite panel were tested on the basis of three replicates with a MTS 810 universal testing system (USA) in accordance with the procedure described in ASTM D 638-10 [8]. The specimen dimensions were 100×20×1.60 mm^3 (Length × Width × Thickness). A tensile fixture was used, with a constant gauge of 60 mm and a crosshead speed of 0.50mm/min. An FEI Quanta Environmental Scanning Electron Microscope (ESEM; FEI Company, Oregon, USA) were used to examine the fracture morphology of the specimens.

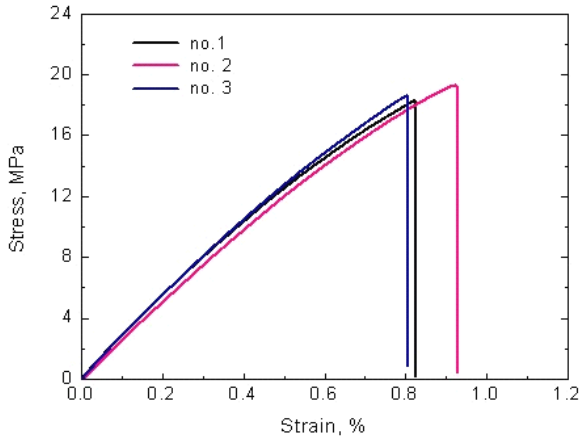

Figure 1. Tensile stress versus strain of kenaf fiber reinforced UPR composite panels

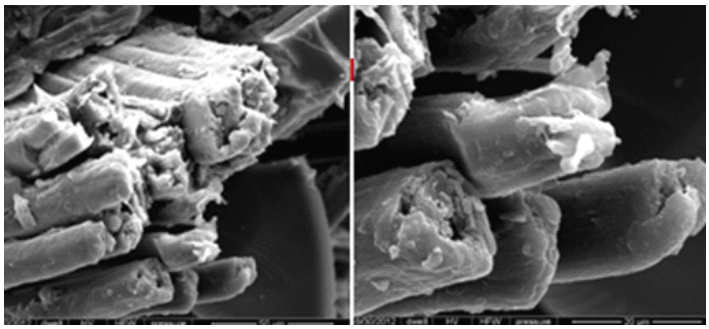

Figure 2. SEM micrographs of composites after tensile failure

In the present study, the tensile properties of the kenaf fiber reinforced UPR composites are displayed in Fig. 1 and summarized in Table 1 showing the peak load, tensile strength, strain at break and young's modulus. Among all tested specimens, kenaf fiber reinforced UPR composites exhibited relative high strength and stiffness characteristics. The tensile stress of sandwich specimens was about 18.21~19.32MPa. On the other hand, the failure strains was 0.81~0.92%. The young's modulus of sandwich panel was 2.05~2.39GPa. Fig. 2 shows the fracture micrograph of kenaf fiber reinforced UPR composites. Good interfacial adhesion of kenaf fiber with polyester resin can be found even though there are some local micro voids. Fiber breakage is the major failure mode.

Table 1. Tensile test results of kenaf fiber reinforced UPR composites

Specimen	Peak load (N)	Max stress (MPa)	Strain at break (%)	Elastic modulus (GPa)
1	582.72	18.21	0.82	2.22
2	621.39	19.32	0.81	2.39
3	594.28	18.86	0.92	2.05

3.2. Bending test

To investigate the characteristics of bending behavior of this novel sandwich panels and also to analyze the shear effects of PVC foam core, three point bending tests were carried out. Sandwich specimens for three-point bending test were cut from the whole sandwich panels. The bending load and deflection of the sandwich composites were tested on the basis of five replicates with a MTS 810 universal testing system (USA) in accordance with the procedure described in ASTM D 7264 [9]. The specimen dimensions were 140×28×28.80 mm^3 (Length × Width × Thickness). Three-point bending fixture was used, with a constant span of 110 mm and a crosshead speed of 2.0mm/min.

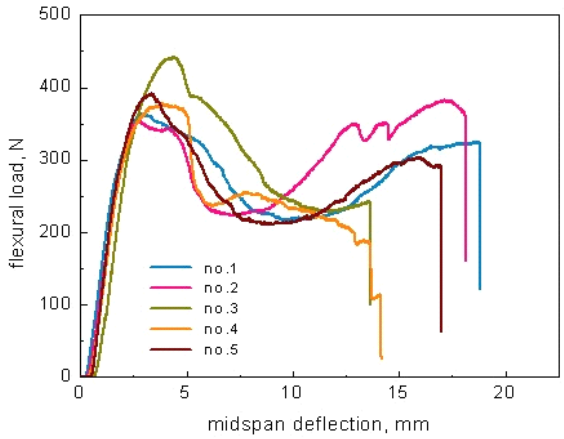

Figure 3. Flexural load versus mid-span deflection of sandwich composite specimens

Fig. 3 shows the flexural load and mid-span deflection of sandwich composite specimens. It could be seen that the whole three-point bending deformation tests included three similar stages for all of specimens. They were linear elastic stage, depressed region and final fracture. The bending properties of sandwich composites were also summarized in Table 2 showing the maximum load, deflection at break, bending stress of face sheet, shear stress in the core, local indentation stress and main failure modes. According to the analysis of [10] , bending stress in face sheet of all tested specimens were 7.79~9.45MPa. The maximum shear stress in the core was 0.29MPa. It was denoted that no shear failure initiated in the sandwich composites. Due to local concentration of loading at mid-span, the major failure mode was local indentation. In the present study, kenaf fiber

was randomly distributed in the unsaturated polyester resin matrix. Bending strength was relative high at rich levels of fiber loading. Otherwise, at a relative low level of fiber loading, due to the limitation of resin strength, during the whole stress transfer process, fracture tended to occur in the voids between fiber and resin. Meanwhile those could be used to explain the low stress fracture in no.1 specimen of experimental results, shown in Fig. 4.

Table 3. Three-point bending test results of sandwich composites

no.	Maximum load (N)	Max Deflection (mm)	σ_f (MPa)	τ (MPa)	σ_{lc} (MPa)	Failure modes
1	365.30	18.82	7.79	0.24	1.37	Upper skin fracture, local indentation
2	381.13	18.17	8.13	0.25	1.43	local indentation
3	443.14	13.65	9.45	0.29	1.67	local indentation
4	378.92	14.19	8.08	0.25	1.42	local indentation, crack in the core
5	391.17	17.01	8.34	0.26	1.47	local indentation

*where,bending stress in the face sheet σ_f , shear stress in the core τ and local indentation stress σ_{lc} were as follows [10]:

$$\sigma_f = \frac{M_{\max}}{t_f hb} \tag{1}$$

$$\tau = \frac{V_{\max}}{hb} \tag{2}$$

$$\sigma_{lc} = \frac{P}{A} \tag{3}$$

$M_{\max}$ is the maximum moment, t_f is the thickness of face sheet, h is the distance between centroids of the face sheets, and b is the specimen width, $V_{\max}$ is the maximum shear, P is the applied load and A is local crushing area.

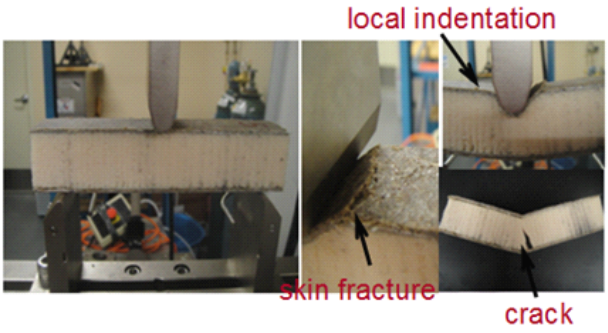

Figure 4. Three-point bending experiment set-up and main failure modes

3.3. Double cantilever beam test

The objective of this part experimental investigation was to understand the fracture behavior and

performance of this novel sandwich composite. The double cantilever beam of the sandwich composites were tested on the basis of three replicates with a Shimadzu universal testing system (model SCG-5KNA, Japan) in accordance with the procedure described in ASTM D 5528 [11]. The specimen dimensions were 160×30×28.8 mm3 (Length × Width × Thickness) with a 25 mm pre-crack. A tensile fixture was used, with a piano hinge amounted on the upper and lower sandwich face sheet and a crosshead speed of 2.0mm/min, shown in Fig. 5. During the process of test, the digital camera was used to real-time record the fracture behavior of the pre-crack and also used to take pictures of the typical fracture behavior.

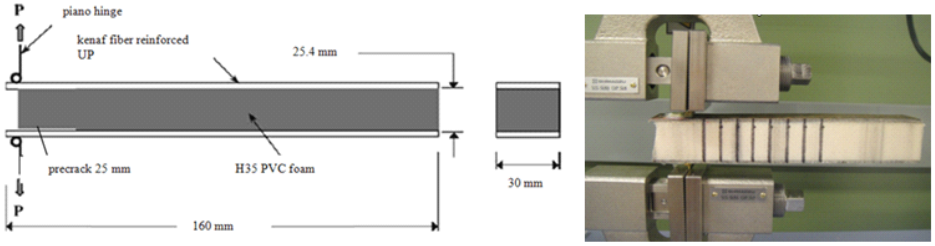

Figure 5. The dimension of double cantilever beam specimens and experiment set-up

A typical load against displacement curve of sandwich specimens during the DCB tests is shown in Fig. 6. The process of fracture can be approximately categorized into four stages based on the observation results and the characteristic load against displacement behavior at each stage, named as I, II, III and IV. In stage I, the load increased approximately linearly to the point A along with the increasing of the open displacement. From the point A to the point B (the stage II), the load against open displacement curve became non-linear. In this stage, the interlaminar delamination initiated between upper sandwich face sheet and PVC foam core and pre-crack developed stably. When stage II fracture completed, the load decreases rapidly from the point B to the point C (the stage III). In stage III, the interlaminar delamination propagated unstably. Beyond the point C, the interlaminar delamination propagation slowly went on. Due to the relative lower randomly distributed fibers in the upper face sheet, skin brittle fracture was found in no.2 specimen.

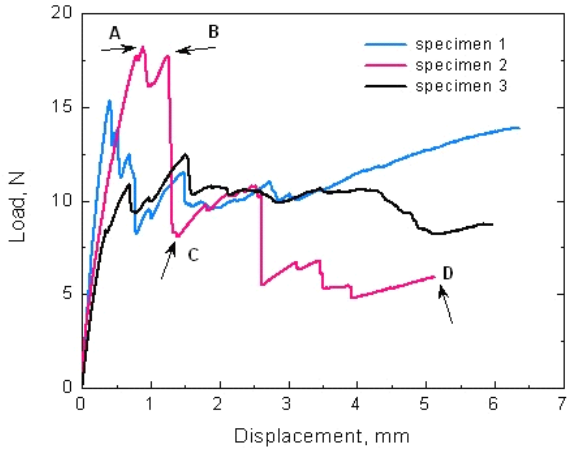

Figure 6. Load against open displacement curves for sandwich composite

According to [12], the strain energy release rate during crack propagation was calculated by,

$$G_c = \frac{\Delta U}{ba} \tag{4}$$

Where, G_c is strain energy release rate, b is the width of the specimen and a is the incremental crack length during the process of test, the energy or work ΔU, is equal to the area under load vs.

displacement curve. In order to calculate the work required to propagate the crack, for all of the specimens, load vs. open displacement of stage II were selected. Meanwhile, the DCB results were summarized in table 4 showing the peak load, open displacement and strain energy release rate Gc. Also compared with some published works, one was for honeycomb sandwich and another was for copper-epoxy interface, it was denoted that this novel sandwich structure exhibited better interlaminar fracture behaviors.

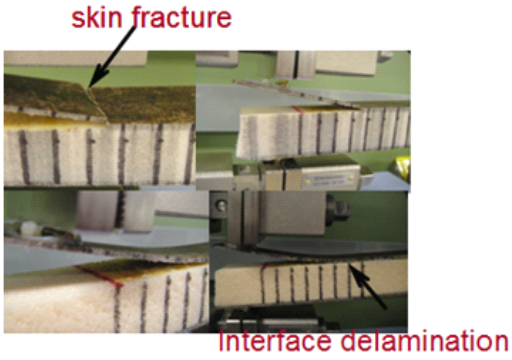

Figure 7. Fracture behavior and propagation of interlaminar delamination of sandwich composite

Table 4. Double cantilever beam test results of sandwich composites

Specimen	Peak load (N)	Open displacement (mm)	Energy release rate (kJ/m^2)	Main failure mode
1	15.37	0.41	0.476	Interface delamination
2	18.27	0.89	0.277	upper skin fracture
3	12.48	1.50	0.423	Interface delamination

4. Conclusions

The following results are obtained,
(1) A novel natural fiber reinforced UPR composite sandwich structure is developed and fabricated.
(2) Mechanical properties results show the elastic modulus of kenaf composite material is about 2.05~2.39GPa. Main failure mode in three-point bending tests is local indentation, while the equivalent flexural stiffness is about 1476~1592N/mm. Meanwhile failure mechanism analysis is accomplished by digital camera and SEM.
(3) Due to lightweight, relative high strength, high elastic modulus and absorb energy, this kind of sandwich structures can be potentially used in civil engineering constructions.

Thermal Stability of Microstructure and Mechanical Properties of Ultrafine-Grained Pure Titanium

Shankun Chen, Qiaoyan Sun*, Lin Xiao, Jun Sun

State Key Laboratory for Mechanical Behavior of Materials, Xi'an Jiaotong University, Xi'an 710049, PR China

* Corresponding author: qysun@mail.xjtu.edu.cn

Abstract Thermal stability of microstructure was investigated of ultrafine-grained (UFG) pure titanium subjected to anneal at 300°C, 400°C, 500°C and 600°C. Hardness variety was used to evaluate the effect of annealing temperature on mechanical properties in UFG titanium. Microstructural observation showed that the average grain size slightly increased in UFG pure titanium annealed below 400°C, while the dislocation density significantly decreased. As the annealing temperature increased to 500°C and 600°C, the average grain size dramatically increased and dislocation density sharply reduced. The hardness almost remained constant, when the annealing temperature was 300°C, while it gradually decreased, as the annealing temperature increased to 400°C. The hardness dramatically decreased in the samples annealed at 500°C and 600°C. The relationship between the microstructural stability and mechanical property variety in UFG Ti during annealing is discussed.

Keywords Ultrafine-grained pure titanium, Thermal stability, Grain size, Hardness

1. Introduction

Research on the ultrafine processing of grains in metals and alloys has attracted a lot of attentions since Prof Valiev and co-workers firstly produced the refined microstructures of less than 1 micron, which has a superior high strength, in copper via equal channel angular pressing (ECAP) technique two decades ago [1-4]. Ultrafine-grained (UFG) metals and alloys have demonstrated the higher combination of strength and ductility than the coarse-grained counterparts. The UFG titanium shows higher corrosion resistance than coarse-grained one due to rapid passivation [5]. Several severe plastic deformation (SPD) techniques have been used to fabricate UFG or nano-grained metals. For example, high pressure torsion (HPT) used for Cu, Cu-Zn, and Cu-Sn alloys [6,7], cumulative roll bonding (ARB) used for some fcc and hcp metals [8-10]. Thermal stability is a big concern for ultrafine-grained materials. Majid Hoseini et.al found that UFG pure titanium had a good thermal stability of microstructure below 450°C [11]. The grain growth activation energy (Q) is close to the self-diffusion activation energy in Ti [12,13]. Although the ultrafine processing of pure titanium has been well studied, little information is available on the thermal stability of mechanical properties and microstructure in UFG pure Ti. The objective of this paper is to study microstructural stability and mechanical property variety in UFG titanium subjected to anneal at different temperatures.

2. Experimental procedure

The UFG pure Ti sheets of 0.2mm in thickness were produced by repeat-rolling with a reduction of 97.5% in thickness at 450°C. Then these sheets were isothermally annealed at 300°C, 400°C, 500°C

and 600°C respectively for 20 minutes in the VTHK-350L vacuum furnace under 10^{-3} Pa. The heating rate was 8-10°C/min. The samples of 30mm×30mm were cut along rolling direction of plates for microstructural examination and micro-hardness measurement. TEM foils were thinned to about 70-80μm by mechanical grinding, and then electronically thinned with a twin jet electropolisher at 25V and -30°C. TEM examinations were carried on with a JEOL JSM-200CX TEM at 160KV. Texture was determined using an X'Pert PRO XRD equipped with a Cu-Kα ray source. Micro-hardness was measured in Tukon 2100B tester with a load of 20g holden for 10 seconds.

3. Results and discussion

3.1 Microstructure evolution of UFG Ti at different annealing temperatures

The optical microstructure in UFG pure Ti samples subjected to anneal at different temperatures is shown in Fig. 1. The as-rolled deformed microstructure remained (Fig.1(a)) and grain boundaries became obscure when the annealing temperature was below 400°C, as shown in Fig. 1(b) and (c). However, as the annealing temperature increased to above 500°C, equiaxed grains were observed, as shown in Fig. 1(d) and (e). Furthermore, the grain size increased with the annealing temperature. The average grain size increased to 3μm and 7μm, respectively, when the annealing temperature increased to 500°C and 600°C.

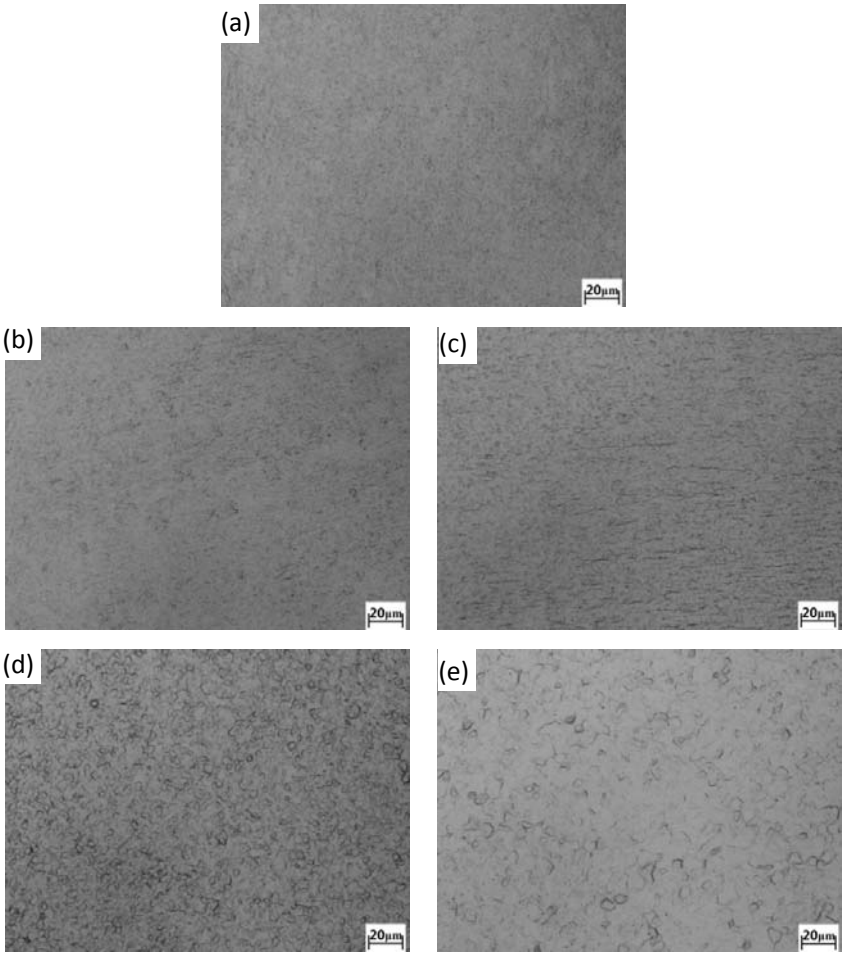

Figure 1. Optical microstructure in UFG Ti samples annealed at different temperatures: (a) as-repeat rolled; (b) 300°C; (c) 400°C; (d) 500°C; (e) 600°C.

TEM examination shows the variety of deformed substructure and grain size with the annealing temperature, as shown in Fig. 2(a) to (e). The ultrafine-grains with a high density of dislocations were produced in the as-rolled samples (Fig.2(a)). The less well-defined grain boundaries and high density of dislocation tangles were the predominant features in the samples subjected to anneal below 400^{o}C, as shown in Fig.2(b) and (c). High density of dislocation cells were formed at 300^{o}C (Fig. 2(b)). Grain boundaries became distinguishable at 400^{o}C (Fig.2(c)). When the annealing temperature was higher than 500^{o}C, well-defined grain boundaries were observed. Most dislocations in the interior of grains disappeared, as shown in Fig.2 (d) and (e). The diameter of grains in the sample annealed at 400^{o}C is larger than that annealed at 300^{o}C. Grain obviously grew and grain size significantly increased as the annealing temperature increased to 500^{o}C and 600^{o}C. The effect of annealing temperature on grain sizes of UFG Ti are summarized in table 1. There is not an obvious increase of grain size under 400^{o}C. It indicates that the deformed microstructure remained stable under 400^{o}C. However, grains apparently grow when the annealing temperature increased to 500^{o}C and 600^{o}C. In other words, microstructural stability was lost over 500^{o}C.

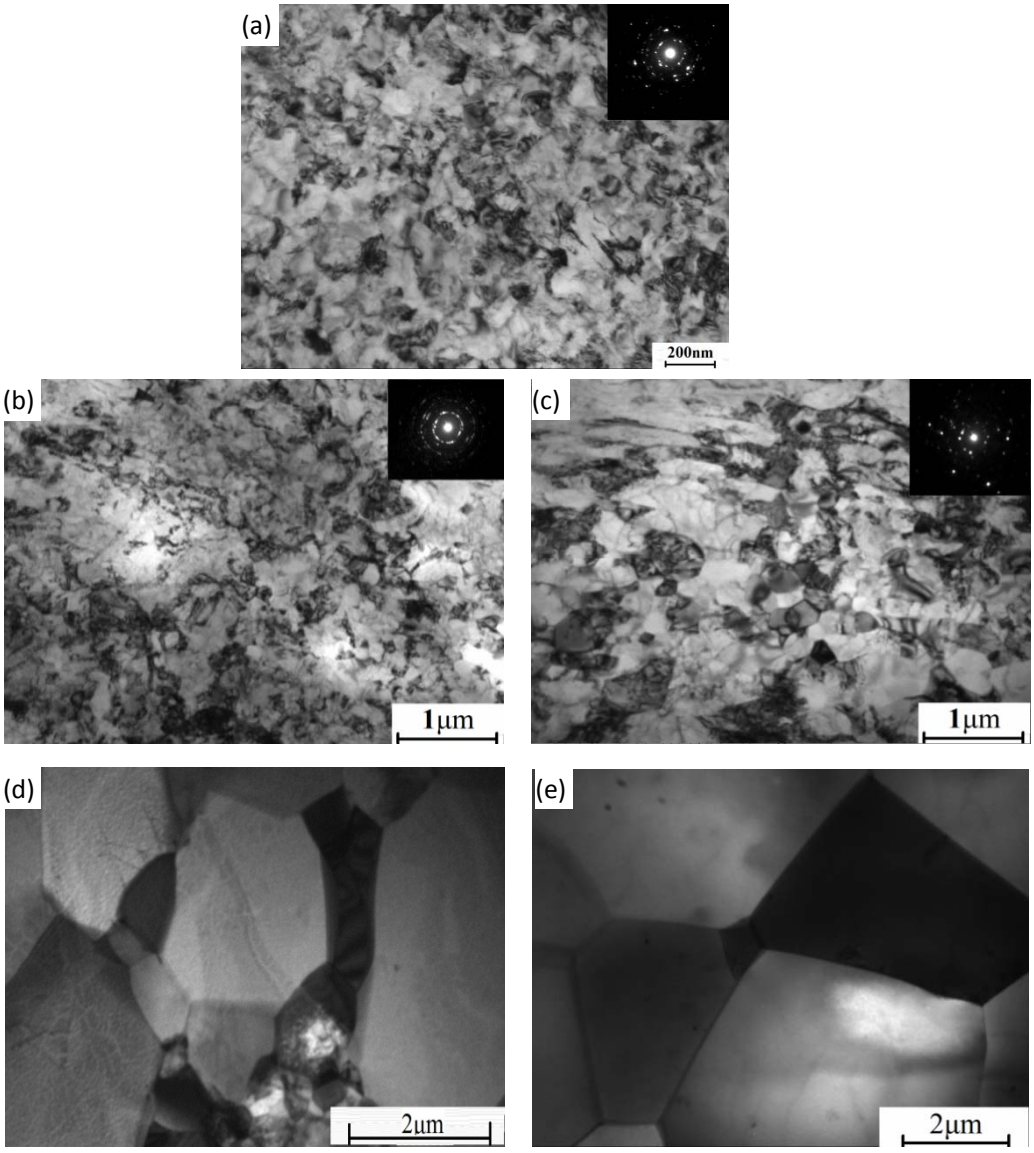

Figure 2 . TEM micrographs in UFG pure titanium annealed at different temperatures:
(a) as-repeat rolled; (b) 300^{o}C; (c) 400^{o}C; (d) 500^{o}C; (e) 600^{o}C.

Table 1. The average grain size in the UFG pure titanium samples annealed at different temperatures

Annealing temperature (^{o}C)	25	300	400	500	600
Average grain size (μm)	0.1	0.2	0.2	3	7

Microstructural observation showed that the average grain size slightly increased when the annealing temperature was less than 400^{o}C. However, the grain size dramatically increased when the annealing temperature was higher than 500^{o}C, as shown in Fig 3. When the annealing temperature is below 400^{o}C, grain size remains constant; however, the distortion and defects in crystal lattice disappear leading to a decrease of the internal stress. When the annealing temperature was higher than 500^{o}C the recrystallization took place in the deformed UFG pure Ti. As a result, the dislocation density remarkably decreased and well-developed grain growth occurred.

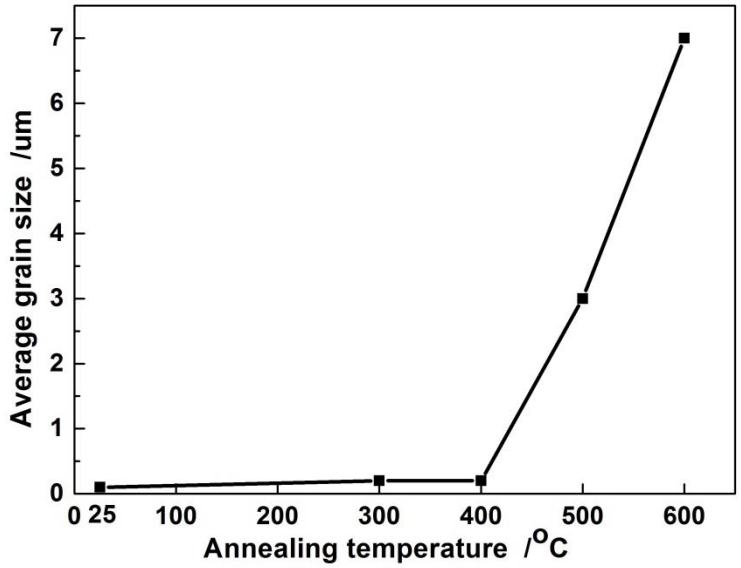

Figure 3. Average grain sizes in UFG pure Ti annealed at different temperatures.

The effect of annealing temperature on texture in UFG titanium is showed in Fig 4. The XRD curve in the initial UFG pure Ti shows that the highest peak is {0002} as shown in Fig 4(a). With increasing annealing temperature to 500°C, the highest peak becomes {10-10}, as shown in Fig 4(b). It means that the lattice rotation took place in UFG titanium during recrystallization.

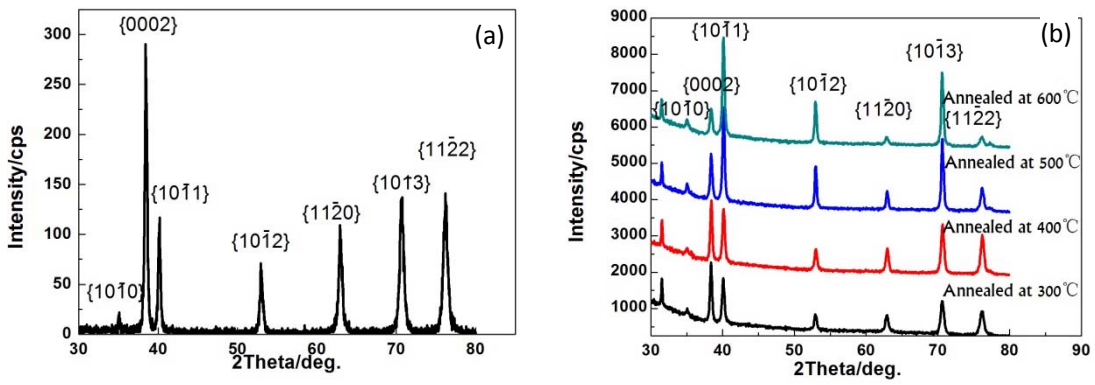

Figure 4. XRD curves of UFG pure titanium annealed at different temperatures

Based on microstructural observation with OM and TEM, it is demonstrated that the microstructure

in UFG pure Ti remains a good thermal stability below 400°C.

3.2 Decrease in hardness during annealing

Hardness was measured in the UFG samples annealed at different temperatures, as shown in Fig 5. The hardness almost remained a constant below 300°C. However, the hardness dramatically decreased when the annealing temperature increased to above 400°C, especially 500°C. The hardness of sample annealed at 600°C is close to that of coarse-grained titanium. This means that the stability of mechanical properties could be kept in the UFG pure Ti below 400°C.

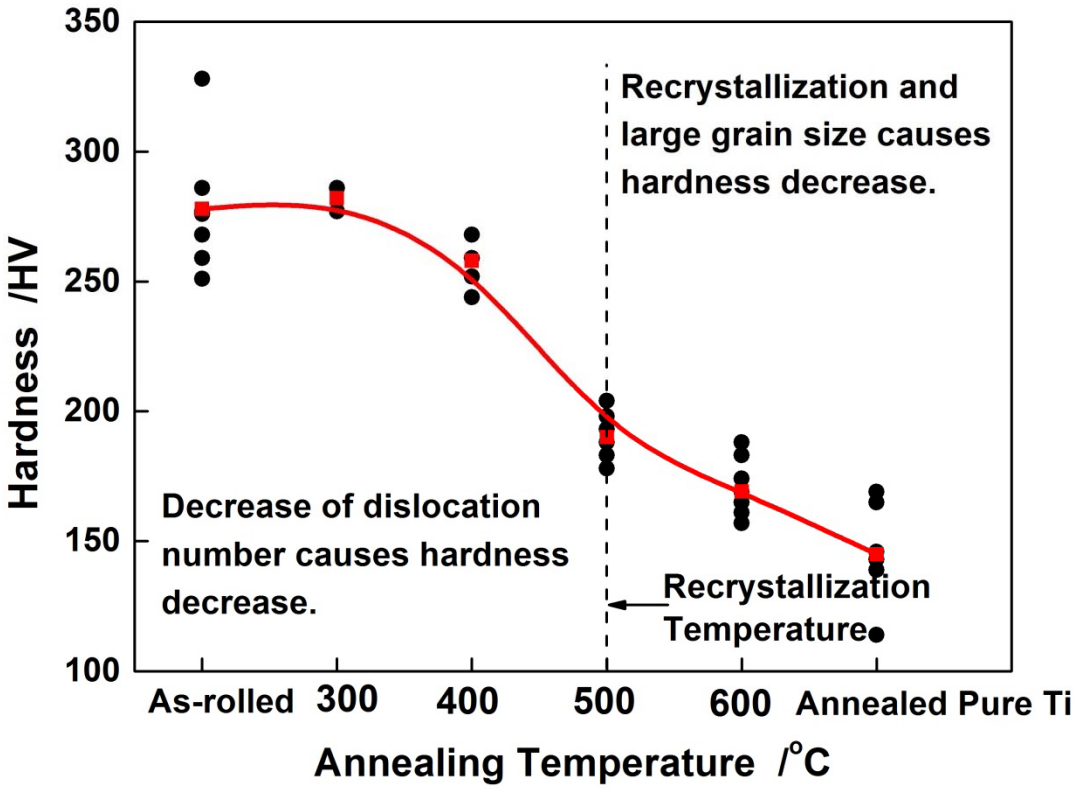

Figure 5. Effect of annealing temperature on micro-hardness in UFG pure titanium

The decrease of hardness in the UFG Ti could be attributed to the following two reasons. When the annealing temperature is below 500°C, the decrease of dislocation density is a predominant factor. While, as the annealing temperature increase to above 500°C, recrystallization and grain growth predominately contributed to the decrease of hardness.

4. Conclusions

1) The average grain size of UFG pure titanium slightly increased when the annealing temperature is lower than 400°C. The microstructure remains stable under 400°C. While the grain size dramatically increased as annealing temperature increased to 500°C or higher. Recrystallization and grain growth took place in ultrafine-grained Ti as annealing temperature is above 500 °C.
2) The rolling texture orientation of UFG pure Ti is {0002} and it disappears when the sample is annealed at 500°C and 600°C.
3) The hardness of UFG Ti slightly decreased when the annealing temperature was lower than

400°C. While, the hardness dramatically decreased as the annealing temperature increased to above 500°C. In former, the decrease of hardness is attributed to the decrease of dislocation density. In the latter, dramatic decrease in hardness results from the recrystallization and grain growth.

Abstract Analysis of fractured lightweight structures has been performed in this paper. In particular a sandwich beam under three point bending containing a crack in the core material very close to the upper skin interface and parallel to the longitudinal beam axis is investigated. A numerical study of the fractured sandwich beam is developed calculating the stress intensity factors in order to investigate the fracture very close to upper skin interface under mixed-mode loading conditions. In addition a cohesive damage model is presented to simulate crack propagation and kinking into the core under mixed-mode loading conditions. The crack considered, is analyzed with static non-linear two- dimensional finite element analyses.

Keywords Lightweight structure, Crack Propagation, Stress Intensity Factor, Cohesive Model

1. Introduction

Lightweight composite structures are widely used in aerospace, marine and other modern industrial applications. Sandwich structures used in these applications consist of a lightweight foam core bonded to thin laminas to achieve high values of specific strength and stiffness. One of the main advantages of sandwich structures is their ability to provide increased flexural rigidity without an increase of the structural weight. The core is usually made of PVC, wood, a honeycomb material or lately carbon foam bonded to tough carbon fiber reinforced polyetheretherketone (PEEK) skins. In sandwich structures the foam is typically the weakest part and is the first to fail under static or cyclic loading because it transfers the applied loads as shear stresses. In addition a very critical problem in sandwich structures is the debonding problem between the face and core materials [1-5]. Unstable cracking propagation and kinking in core materials represents one of the weakest failure modes in sandwich composites. The fracture behavior in lightweight composites has been directed toward the understanding of crack propagation, and at the same time toward improving the durability of composites against fracture. A crack flaw may be introduced during processing or subsequent service conditions. It may result from low velocity impact, from eccentricities in the structural load path, or from discontinuities in structures, which induce a significant out-of-plane stress. In our paper a composite beam under three point bending and/or asymmetric three point bending is studied. In the core material of the beam an initially small crack is considered. In this study a computational analysis is developed based on an experimental investigation in composite beams under flexural loading [2]. From the numerical simulations stress intensity factors are calculated using the Finite element method and combined with crack propagation criteria predict the crack kinking into the core under flexural loading. On the other hand cohesive crack models [6, 7] are widely used to simulate crack growth and kinking phenomena. In order to develop numerical methodologies to simulate crack propagation in composite structures, cohesive damage models have attracted much interest [8-13] due to their well established advantages compared to the stress based

and fracture mechanics methods. Taking into consideration that the application of cohesive damage models in sandwich structures for the numerical simulation of the crack propagation is very limited [11-13]; a cohesive model in terms of cohesive parameters will also propose in this study in order to simulate crack propagation and kinking into the core of sandwich structures.
Thus the scope of this study is to numerically investigate the crack propagation and crack kinking into the core of lightweight structures under mixed mode loading conditions and to present a cohesive damage model appropriate to simulate crack propagation into the core. Results from the computational analysis predict the crack growth and kinking under flexural loading.

2. Specimens and Loading Material Testing.

The geometric and the loading conditions for the sandwich are shown in Fig. 1. The sandwich is composed of PVC-core and face sheets from isotropic glass (Table 1). The dimensions of the test specimen were $L = 228.6$ mm (support span) and $b = 63.5$ mm (width). The core thickness was $t_2 = 12.7$ mm and the face sheet thickness was $t_1 = 2.28$ mm. The overall thickness was 17.26 mm.

Static tests were first conducted to generate ultimate strength data [2]. Flexural fatigue tests on sandwich beams were performed at room temperature under load control at a stress ratio of 0.1, using a sinusoidal wave form. Fatigue data was generated for a minimum of three specimens at stress levels of 90%, 85%, 80%, 75%, 70%, 65% and 60% of the ultimate flexural strength. Three distinct damage events take place before the failure of the specimen.

At first crack initiation and propagation was observed on the compression side just below the top face sheet/core interface. This delamination crack was about 1-1.5mm below the interface. The crack runs parallel to the beam axis from the point of initiation towards the end support (Fig. 1). This first damage event occupies about 85% of the fatigue life. The propagated crack kinks at a certain distance and shears through the core thickness. The crack reaches the bottom face sheet/core interface. Finally, delamination takes place at bottom face/core interface using the separation of the core from the face sheet. This is also a rapid event and occupies the remaining 7-8% of fatigue life.

Table 1. Specimen properties

Material	$E\ \left(N/mm^2\right)$	ν
Face sheets (isotropic glass)	16300	0.3
PVC foam core (R75 by DIAB [5])	80	0.4

From the plot of the crack lengths via N (number of cycles) at different stress levels in [2], it is observed that the length of the crack depends on the stress level. Lower is the stress level; the longer is the crack in damage event-1. Thus, at lower stress levels $\left(r = 0.65, 0.70, 0.75\right)$ the first damage event dominates the fatigue life and consequently the crack propagation near the top face core-skin interface, may be used to develop a failure model for sandwich composites.

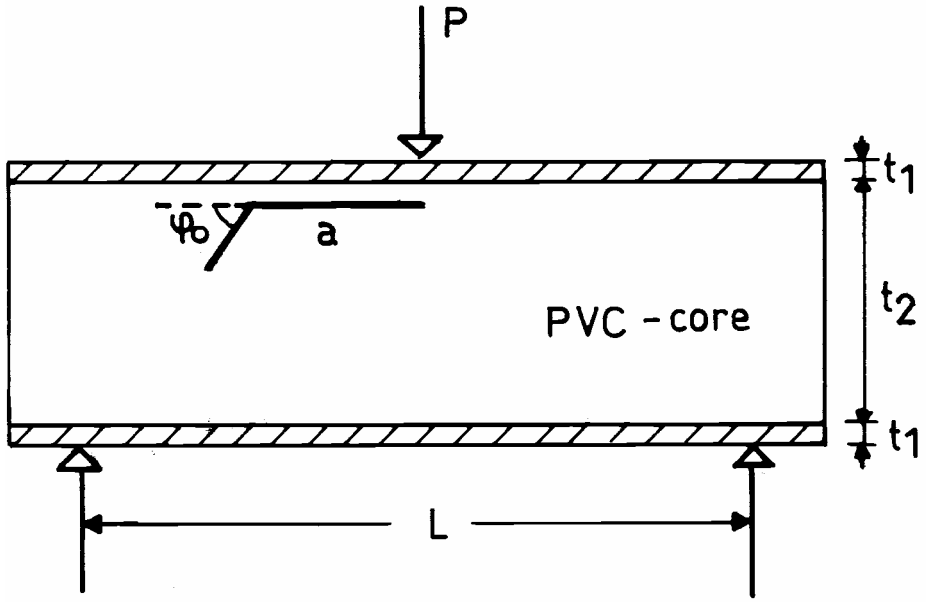

Figure 1. Crack propagation in the core of a sandwich beam under flexural loading

3. Crack Kinking Analysis.

The cracked sandwich beam is analyzed using the finite element method. Because of high stress gradients around the interface, fairly fine mesh consisting of two dimensional plane strain elements was used. The assumption of plane strain is justified throughout.

The finite element analysis is performed with the use of the general purpose finite element programs. The 6 node and 8 node two-dimensional plane strain triangular elements (plane 6) were used in order to model the beam. The frictionless contact area at the crack surfaces is modeled with 2-node linear contact elements, in order to prevent one surface from entering into the other. Singular elements (mid-side nodes at ¼) were used at the two crack tips.

In order to analyze the first damage event, a small crack is considered at about $1.5mm$ below the interface under the central load introduction and parallel to the beam axis. This small crack is considered propagating under the interface. For the different crack lengths the stress intensity factors,

$$\Delta K_1 = K_I^{\max} - K_I^{\min}, \quad \Delta K_{II} = K_{II}^{\max} - K_{II}^{\min}, \tag{1}$$

are calculated automatically from the finite element analysis for the left and right crack tip. The ΔK_I and ΔK_{II} ratios are given in Fig. 2, considering the lower stress level $r = 0.70$ and for the load P to be taken equal to $0.7P_{\text{ultimate}} \left(= 943.46N\right)$, where P_{ultimate} the static failure load of the beam.

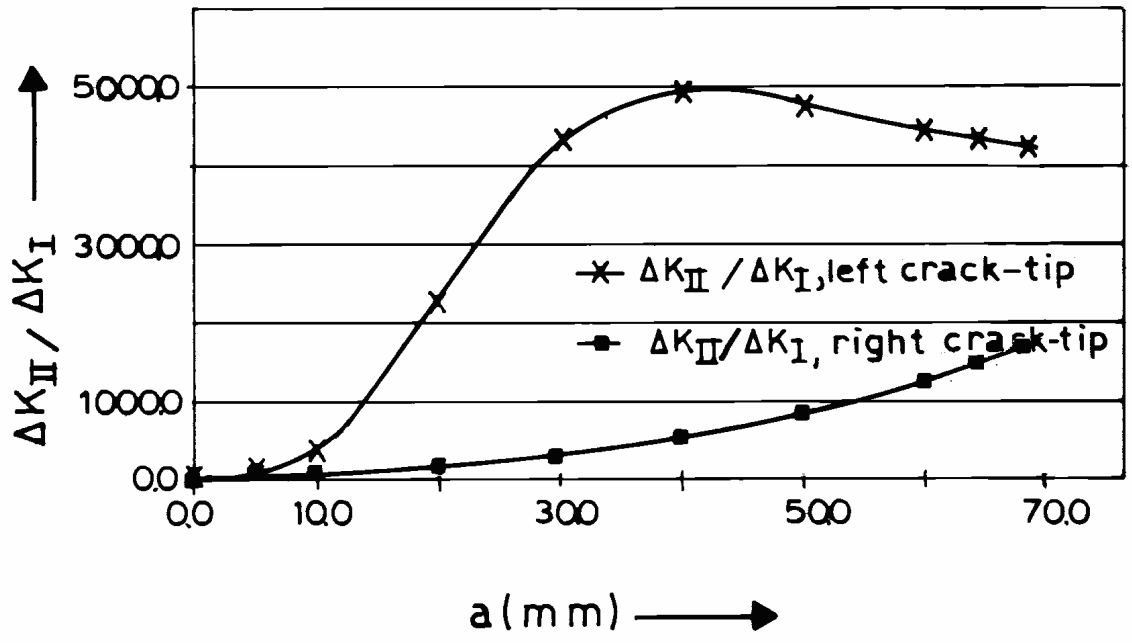

Figure 2. $\Delta K_{II}/\Delta K_I$ ratios for left and right crack-tip for different crack lengths

From the experimental investigation initiation of the crack kinking takes place for a crack length a about $65 \sim 70(mm)$, in an angle φ_0 (Figure 1) of $45° \pm 5°$. Two different crack propagation criteria have been examined to estimate which one should be used in outer to model crack kinking in cross linked PVC sandwich foam cores. At first the Energy density factor criterion [14] is used. According to this criterion, crack initiation occurs in the radial direction in which the local energy density possesses a stationary value. The energy W per unit area A, is expressed by:

$$\frac{dW}{dA} = \frac{S}{r}, \tag{2}$$

where r is the radial distance from the crack tip and S is the strain energy density factor which represents a material element in the distance r from the crack tip. The distance r from the crack tip is assumed to be small compared to the crack length a, and S is given by:

$$S = a_{11}K_I^2 + 2a_{12}K_I K_{II} + a_{22}K_{II}^2 \tag{3}$$

where

$$a_{11} = \frac{1}{16G}\left((1+\cos(\varphi))(\kappa-\cos(\varphi))\right), \quad a_{12} = \frac{1}{16G}\sin(\varphi)(2\cos(\varphi)-(\kappa-1))$$
$$a_{22} = \frac{1}{16G}\left((\kappa+1)(1-\cos(\varphi))+(1+\cos(\varphi))(3\cos(\varphi)-1)\right) \tag{4}$$

and, φ the angle related to the plane of the crack, G the shear modulus of the core material, $\kappa = 3-4\nu$ (plain strain).

The minimum energy density possesses a stationary value which is derived from

$$\frac{\partial S}{\partial \varphi} = 0 \quad \textit{at which} \quad \varphi = \varphi_0 , \tag{5}$$

where φ_0 is the crack propagation angle with respect to the plane of the crack with the minimum energy density.

From the numerical calculations and the core material considered (Table 1), we have:

$$\varphi_0 = \pm 80^\circ ,$$

which is too high comparing with the kinking angle from the experimental investigation.

Secondly the maximum hoop stress is used [15]. The tangential stress component at the vicinity of the crack tip is given by:

$$\sigma_{\theta\theta} = \frac{1}{\sqrt{2\pi r}}\cos\left(\frac{\varphi}{2}\right)\left\{\frac{1}{2}K_I(1+\cos(\varphi))-\frac{3}{2}K_{II}\sin(\varphi)\right\} \tag{6}$$

where r is the distance from the crack tip and $\sigma_{\theta\theta}$ the tangential stress.

According to the maximum hoop stress criterion the crack will propagate in the direction in which $\sigma_{\theta\theta}$ obtains its maximum. The direction of $\max \sigma_{\theta\theta}$ can be found by the relations

$$\frac{\partial \sigma_{\theta\theta}}{\partial \varphi} = 0 , \quad \frac{\partial^2 \sigma_{\theta\theta}}{\partial \varphi} < 0 \tag{7}$$

From the numerical calculations, the following kinking angle is derived

$$\varphi_0 = 42^\circ ,$$

which is in agreement with the test results.

4. Proposed Damage Model

The proposed damage model [8, 11] based on interface finite elements is presented in order to simulate damage onset and growth into the core of a sandwich structure. A linear constitutive relationship between stresses σ and relative displacements δ between homologous points of the interface elements with zero thickness is considered. At first developing the pure-mode model, the constitutive equation before damage starts to grow, is given by:

$$\sigma = D\delta \tag{8}$$

where D is the diagonal matrix containing the penalty parameters (d) in each mode. The values of the penalty parameter must be quite high in order to hold together and prevent interpenetration of the element faces. According to a considerable number of numerical simulations [8, 11], it was determined $d = 10^6 \text{N/mm}^3$. For this value the produced results converge and numerical problems during the nonlinear procedure have been avoided.

After the peak stress $(\sigma_{u,i})$ is reached a gradual softening process between the stress and the relative displacement is observed and is defined as:

$$\sigma = \left(I - E\right) D\delta \tag{9}$$

where I is the identity matrix and E is a diagonal matrix containing the damage parameter:

$$e = \frac{\delta_{u,i}(\delta_i - \delta_{o,i})}{\delta_i(\delta_{u,i} - \delta_{o,i})},\ i = I, II, \tag{10}$$

and, $\delta_{o,i}$, is the displacement corresponding to the onset of damage, and δ_i is the current relative displacement. In pure-mode loading, the strength along other directions is abruptly cancelled. The maximum relative displacement, $\delta_{u,i}$ for which complete failure occurs, is obtained by equating the area under the softening curve to the respective critical fracture energy:

$$G_{c,i} = \frac{1}{2}\sigma_{u,i}\delta_{u,i} \tag{11}$$

In thick composite structures under flexural loading such as in ship hulls, failure is more likely to occur under a mixed-mode situation. Therefore, a formulation for interface elements having zero thickness should include a mixed-mode damage model, which, in this case, is an extension of the pure mode model. Damage initiation may be predicted by using the following criterion [8, 11]:

$$\begin{aligned} &(\frac{\sigma_I}{\sigma_{u,I}})^2+(\frac{\sigma_{II}}{\sigma_{u,II}})^2=1 && \text{if} \quad \sigma_I>0 \\ &\sigma_{II}=\sigma_{u,II} && \text{if} \quad \sigma_I\le 0 \end{aligned} \tag{12}$$

where $\sigma_{u,I}$, $\sigma_{u,II}$ represent the ultimate normal and shear stresses, respectively and it is assumed that normal compressive stress does not induce damage. Providing an equivalent mixed-mode displacement:

$$\delta_e=\sqrt{\delta_I^2+\delta_{II}^2} \tag{13}$$

and a mixed-mode ratio:

$$\beta=\frac{\delta_{II}}{\delta_I} \tag{14}$$

and taking into considering Eq. (8), we have from Eq. (12):

$$(\frac{\delta_{om,I}}{\delta_{o,I}})^2+(\frac{\delta_{om,II}}{\delta_{o,II}})^2=1 \tag{15}$$

where $\delta_{om,i}(i=I,II)$ are the relative displacements at damage initiation, which correspond to the critical interface stresses $\sigma_{um,i}$. Combining Equations (13)-(15), the value of the equivalent mixed-mode displacement leading to damage initiation (δ_{om}) results:

$$\delta_{om} = \frac{\delta_{o,I}\delta_{o,II}\sqrt{1+\beta^2}}{\sqrt{\delta_{o,II}^2 + \beta^2\delta_{o,I}^2}} \tag{16}$$

The mixed-mode damage propagation is simulated considering the linear fracture energetic criterion:

$$\frac{G_I}{G_{Ic}} + \frac{G_{II}}{G_{IIc}} = 1 \tag{17}$$

The released energy in each model at complete failure can be obtained from the area of the triangle:

$$G_i = \frac{1}{2}\sigma_{um,i}\delta_{um,i} \tag{18}$$

being $\delta_{um,i}(i = I, II)$, the relative displacement in each direction for which complete failure occurs. From Equations (8), (11), (13), (14), (17) and (18), the mixed mode relative displacement leading to total failure (δ_{um}) can be obtained:

$$\delta_{um} = \frac{2(1+\beta^2)}{e\delta_{om}}\left[\frac{1}{G_{Ic}} + \frac{\beta^2}{G_{IIc}}\right] \tag{12}$$

The values of δ_e, δ_{om} and δ_{um} are introduced into Eq. (10), instead of δ_i, $\delta_{o,i}$ and $\delta_{u,i}$, thus setting the damage parameter under mixed mode. The mixed mode model proposed is general and it can be applied under any combination of modes.

The same sandwich beam considered in section 3 under three point bending with a crack parallel to the beam axis very close to the upper skin interface (Figure 1), is solved numerically. But in this case we adjust the model according to the demands of the previous analysis. Different models with different cohesive parameters, different crack lengths, different crack positions and orientations, may be confronted. The element type used in this analysis is the four-node two dimensional plane strain elements CPE4 [16]. Different mesh configurations were used in the vicinity of the crack tip and the cohesive layer in order the convergence of the solution to be succeeded. The cohesive layer is placed over the entire plane of crack propagation (Figure 3) by implementing the procedure given in Abaqus [15].

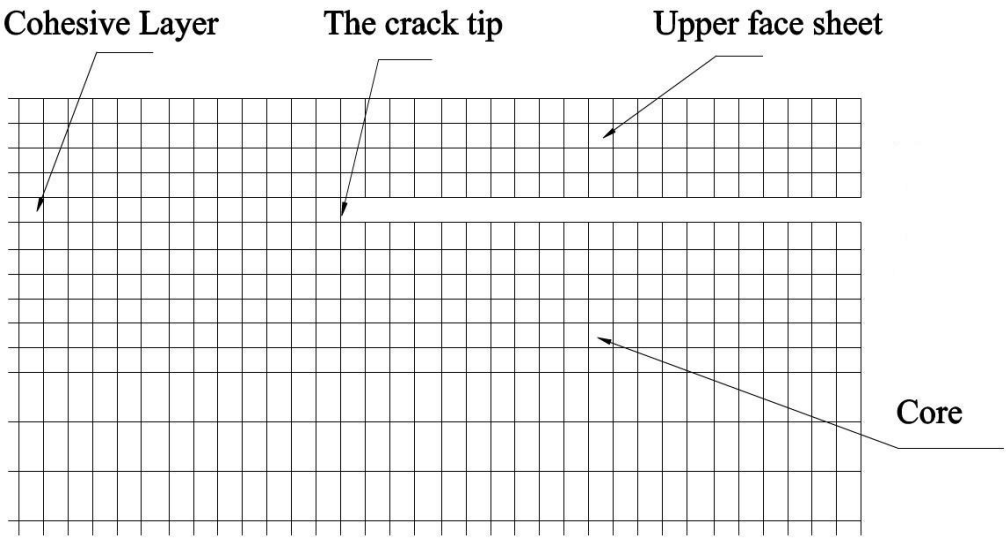

Figure 3. The finite elements mesh at the crack tip.

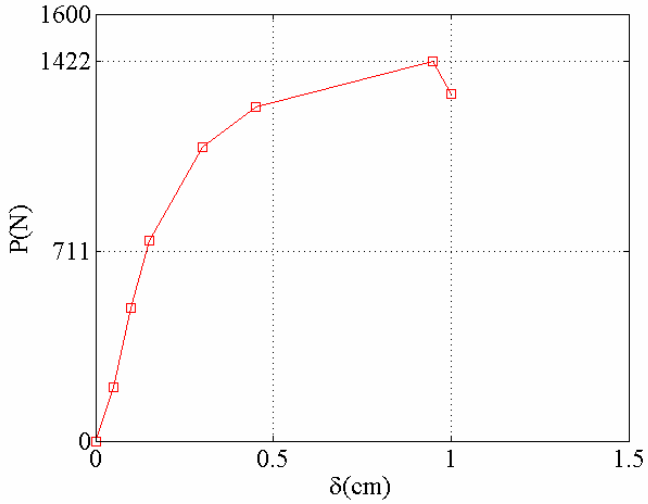

Figure 4. Numerical and experimental results for mixed mode loading

The fractured sandwich beam is modeled according to a mesh generator proposed in [5] which imposes the discretion of the areas of the beam regarding the mesh density and quality in three different regions according to the length of the crack and to crack distance from the upper interface [5]. This discretion is a prerequisite in order to avoid the worthless consumption of computational resources and time. The model shown in Fig. 3 corresponds to the maximum crack length $a \approx 70\text{mm}$ in which about 22500 elements have been used in the finite element analysis. The experimental data and the numerical predictions according to the proposed cohesive law are shown in Figure 4. At the load at failure ($P \simeq 1422\text{N}$) kinking of the crack into the core and catastrophic failure was observed.

5. Conclusions.

In this paper two procedures have been considered for lightweight structures in order to simulate crack propagation and kinking into the core of sandwich structures very close to the upper skin

interface under mixed mode loading conditions. In the first one the crack kinking analysis based on linear fracture mechanics approach and to crack propagation criteria, was considered. Stress intensity factors were calculated and the crack kinking into the core was predicted. In the second one a cohesive damage model was developed to simulate crack propagation and kinking into the core in terms of cohesive parameters. The damage model was implemented in a finite element model. The numerical applications analyzed were in good agreement with the experimental results and in addition predict satisfactory the crack propagation and kinking into the core.

Abstract The purpose of this study was to characterize the microstructural change and fatigue resistance of electron beam welded (EBWed) dissimilar joints between Ti-6Al-4V and BT9 (Ti-6.5Al-3.5Mo-1.5Zr) alloys after two types of post-weld heat treatment (PWHT), namely only aging and solution treatment followed by aging (STA). It was observed that no significant microstructural change occurred in the FZ after only aging and the high hardness in the fusion zone (FZ) remained, while coarse acicular α occurred in the FZ in the STA condition, leading to a reduced hardness. Both types of post-welded joints were cyclically stable at lower strain amplitudes of 0.2-0.6%, and exhibited cyclic softening at higher strain amplitudes of 0.8%-1.2%. As the total strain amplitude increased, cyclic stress amplitude increased, while the fatigue life decreased. Fatigue crack initiation occurred from the specimen surface or near-surface defects and propagation was characterized mainly by the formation of characteristic fatigue striations.

1. Introduction

Welding is one of the most widely used and economical joining processes for titanium alloys, which makes it possible to create composite structures in the welded joints for various purposes. However, in the electron beam welding (EBW) and laser beam welding, the fusion zones are known to exhibit poor ductility due to the large prior β grain size and a wholly or partially martensitic microstructure [1]. The low thermal conductivity of titanium alloys causes superheating in the heat-affected zone (HAZ), increases the grain size and gives rise to residual stresses in the HAZ, exerting a negative effect [2]. It is necessary to adjust unstable microstructure of the as-welded joints [3]. The post-weld heat treatment (PWHT) is one of the commonly-used methods which could stabilize microstructure, decrease the inhomogeneity of the structure and increase the mechanical properties of the welded joint. Arenas and Acoff [4] reported that PWHT promotes the formation of γ phase in the fusion zone of a gas tungsten arc (GTA) welded gamma titanium aluminide alloy. Guo *et al.* [5] observed that there was no significant hardness increase in fusion zone (FZ) at Ti-64 side of a dissimilar linear friction weld between Ti-64 and Ti-6246 alloys after PWHT. Tuppen *et al.* [6] performed stress-controlled fatigue tests to determine S-N curves of diffusion-bonded dissimilar Ti-6Al-4V/Ti-4Al-4Mo-2Sn-0.5Si titanium alloy joints. Fu *et al*. [7] studied the effects of electron beam local heat treatment (EBLHT) on strain-controlled fatigue properties of EBWed Ti-6Al-4V alloy joints, and their results showed that Ti-6Al-4V alloy joints with and without EBLHT exhibited cyclic softening and the fatigue life of the joints after EBLHT could increase by 30%. Despite the extensive studies on the weldability of titanium alloys, it is unknown if the PWHT would have a significant effect on the microstructure and cyclic deformation behavior of electron beam welds between Ti-6Al-4V and BT9 (Ti-6.5Al-3.5Mo-1.5Zr) alloy. The aim of this study was, therefore, to identify the effect of two common PWHT processes, namely aging with or without solution heat treatment, on the microstructure and fatigue performance of welded joints.

2. Material and Experimental Procedure

The materials used in the present study were forged 10 mm thick Ti-6Al-4V and BT9 titanium

alloys, with the chemical compositions listed in Tables 1 and 2, respectively. Both alloys were machined into the plates of 140 mm × 80 mm × 10 mm, and then mechanically and chemically cleaned before welding. EBW was performed using HDZ-15B EBW machine with an accelerating voltage (V) of 60 kV, an electron beam current (I_b) of 68 mA, an focus current (I_f) of 2230 mA, and a welding speed (v) of 500 mm/min.

Table 1. Chemical composition of Ti-6Al-4V titanium alloy

Element	Al	V	Fe	C	N	H	O	Ti
Content (wt.%)	6	4	0.3	0.1	0.05	0.015	0.2	balance

Table 2. Chemical composition of BT-9 titanium alloy

Element	Al	Mo	Zr	Si	Fe	C	N	H	O	Ti
Content (wt.%)	6.5	3.5	1.5	0.3	0.25	0.1	0.05	0.012	0.15	balance

PWHT was carried out in a vacuum furnace at a vacuum degree of 10^{-2} Pa. One of the welded joints was subjected to solution treatment at a temperature of 950°C for 1 h followed by furnace cooling and then aging at 550°C for 4 h followed by air cooling, and the other joint was directly subjected to aging at a temperature of 550°C for 4 h followed by air cooling. Microstructures were examined (after etching using Keller's reagent) via optical microscopy. Microhardness was determined across the welded joint of mid-thickness (i.e., at a distance of 5 mm from the bottom surface) using a computerized Buehler hardness tester with a load of 500g and a dwell time of 15s at an interval of 0.1 mm.

Fatigue specimens with a gauge length of 12 mm and a width of 3 mm were machined perpendicularly to the welding direction using electro-discharge machining (EDM). The gauge area was ground up to #600 SiC papers to remove the EDM cutting marks and to achieve a smooth surface. Total strain-controlled, pull-push type fatigue tests were conducted in air at room temperature using a computerized Instron 8801 fatigue testing system at different strain amplitudes up to 1.2%. A triangular waveform with a strain ratio of R_s=-1 was applied at a constant strain rate of 1×10^{-2} s^{-1}, where R_s is the ratio of the minimum strain to the maximum strain. The strain-controlled test at low strain amplitudes was continued until 10,000 cycles, after which it was changed to load control at 50 Hz. At least two specimens were tested at each strain amplitude. Fatigue crack initiation site and crack propagation mechanisms were examined on the fracture surfaces of failed samples using SEM.

3. Results and Discussion

3.1 Microstructure

Fig.1(a) and (b) show the microstructure of the two BMs, respectively. It is seen that both Ti-6Al-4V and BT9 had a typical bimodal microstructure, consisting of a combination of equiaxed α grains and inter-granular $\alpha + \beta$ lamellae. However, Ti-6Al-4V contained more equiaxed α grains than BT9. Fig.1(c), (d) and (e) show a significant microstructural changes in the FZ and HAZ after EBW between Ti-6Al-4V and BT9 alloys. The FZ was mainly composed of acicular and fine martensite α' (Fig.1(d) and (e)) due to the rapid cooling during EBW. The HAZ at Ti-6Al-4V side also consisted of acicular martensite α' (Fig.1(e)) but larger in size. The inner-HAZ at BT9 side consisted of a mixture of acicular martensite α', primary α and metastable β (Fig.1(d)), while the outer-HAZ mainly consisted of primary α and metastable β (Fig.1(c)). Fig.2 shows the microstructure of the joints in the aging condition. From these optical images, no significant

difference of microstructures in both FZ and HAZ was observed between the as-welded and the aging conditions, which was in agreement with the previous observations on the electron beam and laser beam welding of Ti-6Al-4V alloy [7,8]. Fig.3 shows the microstructure of the joints in the PWHT condition of solution heat treatment followed by aging (STA). After STA the microstructure of both FZ and HAZ at Ti-6Al-4V side (Fig.3(a)) became coarse α platelets with interlamellar β, which was due to high solution temperature and slow cooling rate, while α platelets, primary α and interlamellar β appeared in the HAZ at BT9 side (Fig.3(b)).

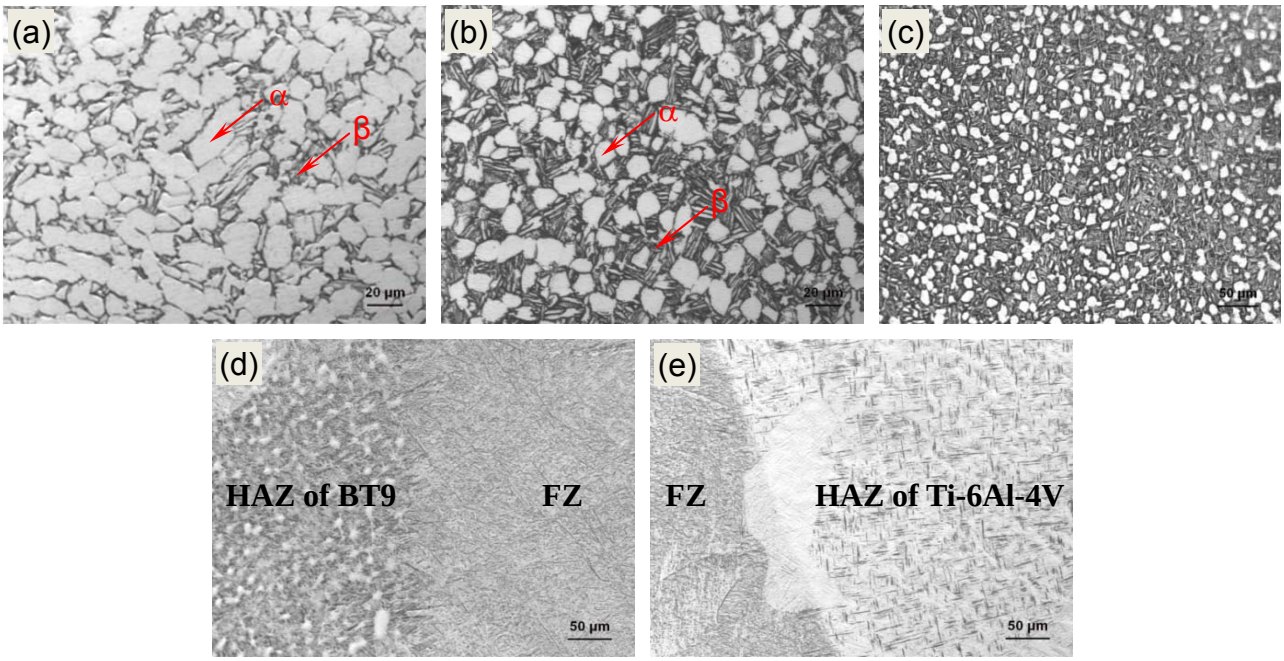

Figure 1. Microstructure of as-welded joint between Ti-6Al-4V and BT9 alloys (a) Ti-6Al-4V BM, (b) BT9 BM, (c) outer-HAZ of BT9, (d) HAZ of BT9 and FZ, and (e) FZ and HAZ of Ti-6Al-4V

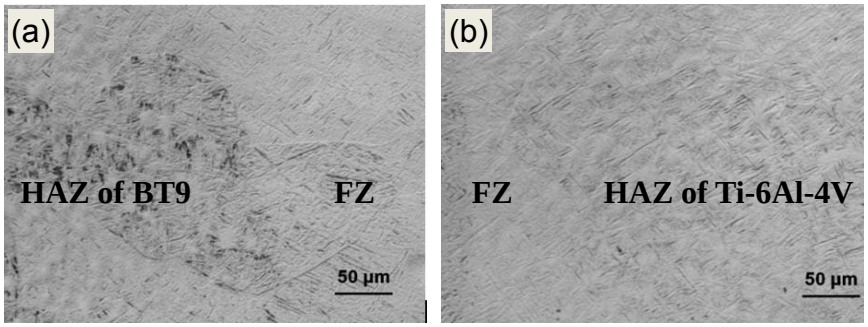

Figure 2. Microstructure of the post-welded joint after aging (a) HAZ of BT9 and FZ, and (b) FZ and HAZ of Ti-6Al-4V

3.2 Microhardness

Vickers microhardness profiles across the dissimilar joint between Ti-6Al-4V and BT9 with and without PWHT are shown in Fig.4. It is seen from Fig.4(a) that an asymmetrical hardness profile across the weld was obtained with an average hardness values of about 300 HV for Ti-6Al-4V BM and approximately 320 HV for BT9 BM, respectively. The higher hardness value in the FZ was due to the formation of martensite in the FZ, as shown in Fig.1(d) and (e). It is observed that the hardness value in the HAZ on the Ti-6Al-4V side was higher than that of the Ti-6Al-4V BM, the hardness value in the inner-HAZ on the BT9 side was also higher than that of the BT9 BM.

However the hardness value in the outer-HAZ was slightly lower than that of the BT9 BM, meaning that a narrow soft zone appeared due to the appearance of β phase as shown in Fig.1(c). The aging treatment at 550°C (Fig.4(a)) led to the elimination of the soft zone at the BT9 side and a slightly higher hardness in the FZ. The increase of hardness was mainly due to the presence of the fine α' and precipitation of some secondary α phase in the β phase both in FZ and HAZ. These results are similar to those reported by Kabir *et al.* [9]. In addition, the microhardness values in the HAZ were also observed to decrease gradually as the distance increased from the FZ border line. This was attributed to the decreasing fine α' and secondary α phase in the HAZ. However, after STA the hardness value in the FZ and HAZ was only slightly higher than or nearly the same as that of the BMs due to the coarse lamellar $\alpha + \beta$ structure (Fig.4(b)). It is of special interest to observe that the narrow soft zone in the outer-HAZ on the BT9 side disappeared as well after STA due to the decomposition of β phase.

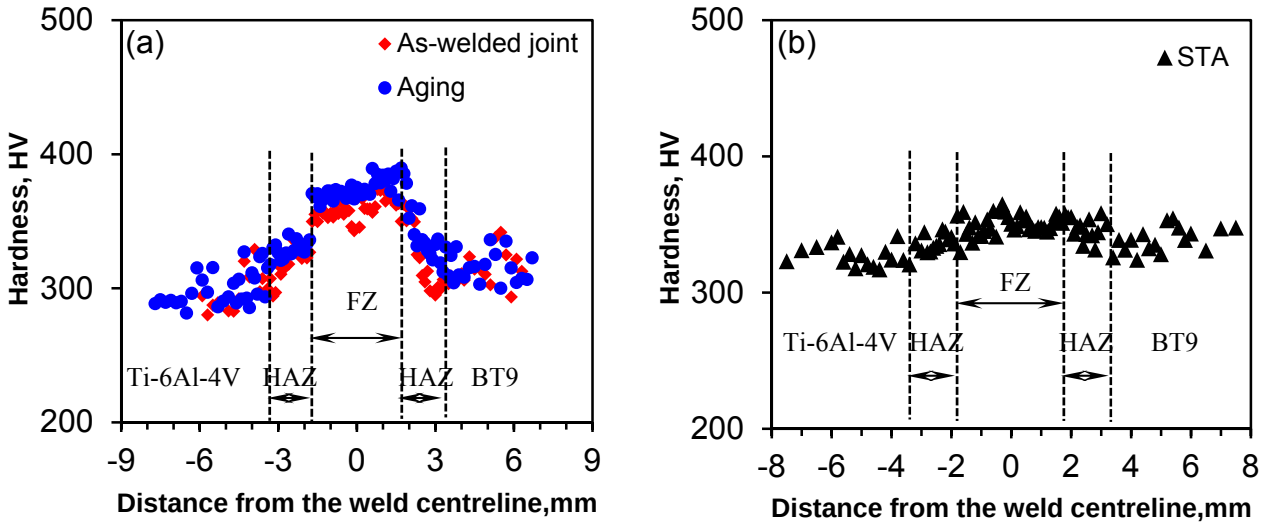

Figure 4. Hardness distribution of the welded joint in (a) as-welded and aging conditions, and (b) STA condition

3.3 Hysteresis loops

The hysteresis loops of the first cycle and mid-life cycle at a total strain amplitude of 1.2% are plotted in Fig 5(a) and (b), respectively. It is seen that the initial tensile (or ascending) phase of the first quarter cycle represented indeed a tensile stress-strain curve tested at a strain rate of 1×10^{-2} s^{-1}. Then the tensile yield strength (YS) of the post-welded joints can be determined from the initial

quarter cycle, and the obtained YS is listed in Table 3. The YS of the post-welded joints in the aging and the STA conditions were almost equal. In addition, the first and mid-life hysteresis loops in both aging and STA conditions were basically symmetrical (Fig.5(a) and (b)). Similar symmetrical hysteresis loops were also observed in titanium alloy [10-13].

3.4 Cyclic deformation response

Figs 6 (a) and (b) show the evolution of cyclic stress amplitude as a function of the number of cycles at different strain amplitudes in the aging and STA conditions, respectively. It is seen that as the applied total strain amplitude increased, cyclic stress amplitude increased and the fatigue life decreased. In both aging and STA conditions, the stress amplitude remained basically constant or stable at the lower strain amplitudes (0.2-0.6%); as the strain amplitude increased (0.8-1.2%) cyclic softening basically occurred, since the post-welded joints lay in a relatively hardened state. Similar cyclic softening characteristics have been documented for titanium alloy under strain-controlled LCF tests [10,14].

Table 3. Fatigue parameters in the aging and STA conditions

Fatigue parameters	σ_y, MPa	n'	K', MPa	σ'_f, MPa	b	ε'_f	c	σ'_y, MPa
Aging	938	0.119	1776	1408	-0.079	0.057	-0.54	865
STA	941	0.116	1759	1412	-0.078	0.109	-0.63	875

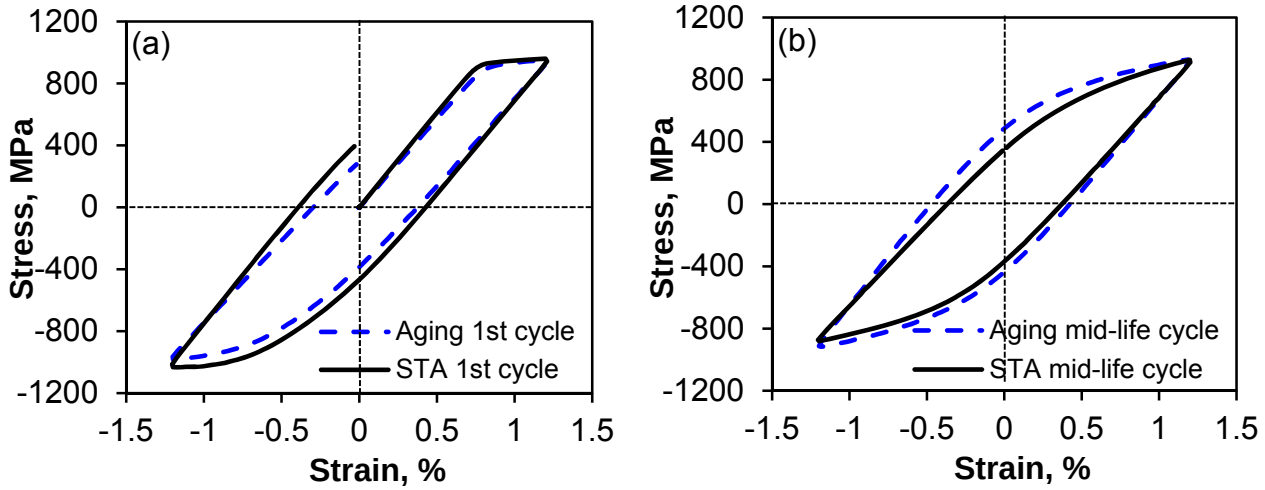

Figure 5. The hysteresis loops at a total strain amplitude of 1.2% and strain ratio of $R_\varepsilon = -1$ for different heat treatment conditions (a) 1st cycle, and (b) the mid-life cycle

Cycling hardening/softening in metals and alloys is known to be dominated by the initial state of the material and the applied strain amplitude. When a material is in its soft/annealed state ($\sigma_{UTS}/\sigma_y \geq 1.4$), cyclic hardening would occur. However, in the hardened state ($\sigma_{UTS}/\sigma_y < 1.2$), cyclic softening would take place [15]. In this study, both types of the post-welded joints exhibited initial cyclic stabilization followed by cyclic softening at the higher strain amplitudes of 0.8-1.2%. The increased degree of cyclic softening with increasing applied strain amplitude might be attributed to the rearrangement and partial annihilation of high density dislocations resulting from EBW [16].

3.5 Fatigue life and fatigue parameters

Fig.7 shows the fatigue lifetime curves of the post-welded joints after aging and STA. Both types of PWHT led to a similar trend of increasing fatigue life with decreasing strain amplitude, and the STA

samples exhibited a slightly lower fatigue life than that of the aging samples at lower strain amplitudes due to the coarser α phase. Based on Basquin equation and Coffin-Manson relation, the total strain amplitude could be expressed as elastic strain amplitude and plastic strain amplitude [15], i.e.,

$$\frac{\Delta\varepsilon_t}{2}=\frac{\Delta\varepsilon_e}{2}+\frac{\Delta\varepsilon_p}{2}=\frac{\sigma'_f\left(2N_f\right)^b}{E}+\varepsilon'_f\left(2N_f\right)^c \quad (1)$$

where E is the Young's modulus, N_f is the fatigue life or number of cycles to failure (the entirety of $2N_f$ is the number of reversals to failure), σ'_f is the fatigue strength coefficient, b is the fatigue strength exponent, ε'_f is the fatigue ductility coefficient, and c is the fatigue ductility exponent. In addition, cyclic deformation behavior is normally considered to be related to the portion of the plastic strain amplitude and is independent of the elastic strain amplitude, which could be expressed by the following equation [15],

$$\frac{\Delta\sigma}{2}=K'\left(\frac{\Delta\varepsilon_p}{2}\right)^{n'}, \quad (2)$$

where $\frac{\Delta\sigma}{2}$ is the mid-life stress amplitude, $\frac{\Delta\varepsilon_p}{2}$ is the mid-life plastic strain amplitude, n' is the cyclic strain-hardening exponent and K' is the cyclic strength coefficient. The obtained fatigue life parameters evaluated on the basis of Equs (1) and (2) were summarized in Table 3. It is also observed that the cyclic strain hardening exponent (n'), the cyclic strength coefficient (K'), fatigue strength coefficient (σ'_f), and cyclic yield strength (σ'_y) of the post-welded joint after aging were nearly the same as that of STA. In general, a smaller absolute value of fatigue strength exponent (b) and fatigue ductility exponent (c) and a larger value of fatigue strength coefficient (σ'_f) and fatigue ductility coefficient (ε'_f) represent a longer fatigue life. This implies that a longer fatigue life of a material in the strain-controlled tests requires a good combination of both high strength and superior ductility. In spite of such a seemingly conflicting effect of the exponent pair (b and c) and the coefficient pair (σ'_f and ε'_f) on the fatigue life, the exponent pair would be expected to play a greater role in the sense of exponential functions. In comparison with STA, the absolute value of c in the aging condition was smaller (while b was nearly the same), and the value of ε'_f was also smaller (while σ'_f remained nearly the same). The combined role of these fatigue life parameters gave no substantial difference between the aging and STA conditions, as also seen in Fig.7. It should be noted that in evaluating the above fatigue life parameters the strain amplitude was limited to a range in-between 0.4% and 1.2%, excluding the strain level with run-out data at which some fatigue samples did not fail at or above 10^7 cycles.

3.6 Fractography

The fracture location of both types of post-welded joints mostly lay in the Ti-6Al-4V BM. Only one sample in the STA condition failed in the HAZ at Ti-6Al-4V side, which might be due to the formation of the coarse α in the HAZ (Fig.3). Fracture surfaces of the fatigued specimens were examined using SEM. Fig.8(a) and Fig.9(a) show an overall view of fracture surfaces of the post-welded joints in the aging and STA conditions at a total strain amplitude of 0.4%, containing regions of fatigue crack initiation, propagation, and final fast fracture. It is seen from these low magnification images that fatigue crack initiated from the specimen surface or near-surface defect, and the river line patterns appeared in both aging and STA conditions which were irregular and

broken and flowed along the crack propagation direction. Fig.8(b)-(c) and Fig.9(b)-(c) show the images near the crack initiation sites and in the crack propagation zone of the fatigued samples at higher magnifications in the aging and STA conditions. In the near-initiation area, a mix of fatigue striations and cleavage-like features could be seen in both aging and STA conditions. Fatigue crack propagation zone was mainly characterized by typical fatigue striations which were perpendicular to the crack propagation direction in both aging and STA conditions.

4. Conclusions

1. The microstructure across the dissimilar welded joint exhibited a considerable change, mainly consisting of acicular and fine martensite α' both in the FZ and HAZ of Ti-6Al-4V side, and acicular martensite α', primary α and metastable β in BT9 side, while both BMs of Ti-6Al-4V and BT9 had a microstructure of equiaxed α grains and inter-granular $\alpha + \beta$ lamellae. There was no significant difference in the microstructure of both FZ and HAZ between the as-welded and the aging conditions. However, after STA the microstructure of the FZ and HAZ at Ti-6Al-4V side mainly consisted of coarse α platelets with interlamellar β, while α platelets, primary α and interlamellar β were observed in the HAZ at BT9 side.
2. A characteristic asymmetrical microhardness profile across the dissimilar welded joint was observed with a higher value on the BT9 side than on the Ti-6Al-4V side. The hardness in the FZ was higher than that of both BMs due to the formation of α' martensite arising from the rapid cooling during EBW. A narrow soft zone in the outer-HAZ of BT9 side was observed due to the presence of β phase, while the hardness in the HAZ of Ti-6Al-4V side was higher than that of the Ti-6Al-4V BM. After aging treatment at 550°C the high hardness in FZ remained nearly the same or slightly higher and the narrow soft zone disappeared due to decomposition of β. However, the hardness value of the post-welded joint after STA in both FZ and HAZ was slightly higher than or nearly the same as that of BMs due to the presence of coarsened α.
3. The post-welded joints in both aging and STA conditions displayed cyclic saturation or stabilization in the entire cyclic deformation process at low strain amplitudes up to 0.6%, while cyclic softening occurred after initial cyclic stabilization at higher strain amplitudes. With increasing strain amplitude, the stage of initial cyclic stabilization became gradually shorter.
4. The fatigue life of the aging condition was slightly longer than that of the STA condition at the lower strain amplitudes. In general the strain-controlled fatigue resistance of the post-welded joints in both aging and STA conditions was roughly equivalent.
5. The fatigue fracture of the post-welded joints after aging and STA treatment occurred mostly in Ti-6Al-4V BM. Fatigue crack initiation occurred from the specimen surface or near-surface defect, and crack propagation was mainly characterized by the characteristic fatigue striations coupled with secondary cracks in both aging and STA conditions.

Abstract Two thin plates with a stabilizing medium placed between them can be an ideal component for large and lightweight structures with increased strength, stiffness and stability. The application of the novel chiral cellular geometry will lead to the development of structural components with superior elastic and impact resilient properties. This paper proposes the design of lightweight square sandwich panels with aluminum sheets and a core made with a chiral geometry network having parallelogram-shaped nodes. Finite element analyses were undertaken in order to characterize the behavior of the considered panels as having supported edges, and loaded under lateral pressure. Also, the loading in torsion was analyzed in the case when two opposite corners are supported and in the other two corners equal and opposite normal forces are applied. For this loading experimental measurements were also done by using strain gages. The new meta-tetrachiral configurations under investigation can provide significant improvements in the mechanical performance of sandwich components, and may also be considered for advanced designs.

Keywords Sandwich panel, Auxetic core, Meta-chiral topology, Finite element analysis, Strain gage

1. Introduction

The strength and the stiffness properties of a sandwich panel are dependent to a great extent both on the behavior of the faces and of the structure used as core. Classical honeycomb core adopts a saddle shape (anticlastic curvature) upon out-of-plane bending, because its Poisson's ratio is positive. In order to manufacture curved panels, cellular cores that exhibit auxetic properties (negative Poisson's ratio) are used, because of their tendency to form dome-shaped surfaces. Consequently, curved sandwich panels with auxetic cores are basic components of advanced structures, first of all in the aircraft and automotive fabrication. It is evident that the analysis of the behavior of cores and sandwich panels under mechanical and thermal loading is of importance for designers.

In paper [1], the finite element method has been applied to characterize the mechanical properties of re-entrant (auxetic) honeycombs which may be used as cores for sandwich panels with any special properties. In the last two decades, a number of cellular structures have been extensively analyzed [2]-[9]. Especially the periodic core structures with chiral topologies, which contain a number of interconnected basic blocks, have attracted considerable attention. A basic block is "chiral" if it is not super imposable on its mirror image. A basic block is consisting of a node with a number of 3, 4 or 6 ligaments attached to it (Fig. 1). Also, left handed or right handed blocks may be constructed.

In the case of a chiral structure, the nodes are attached on the opposite sides of the same ligament (Fig. 2, a). It is possible to attach the nodes on the same side of each ligament and the corresponding structure will be denominated anti-chiral (Fig. 2, b). A hybrid construction, containing some nodes which are attached to the same side of the ligaments and some others to opposite sides of the ligaments, will be referred as meta-chiral (Fig. 2, c). In two-dimensions (2-D), the nodes may be circular, hexagonal, square, rectangular or with other geometry.

There are many papers which deal with the geometries and the properties of auxetic materials, but there is little information on the behavior of the sandwich panels with chiral configured cores. In this paper, the meta-chiral structure with parallelogram-shaped nodes as in Fig. 3 will be analyzed separately, and as a core of a sandwich panel.

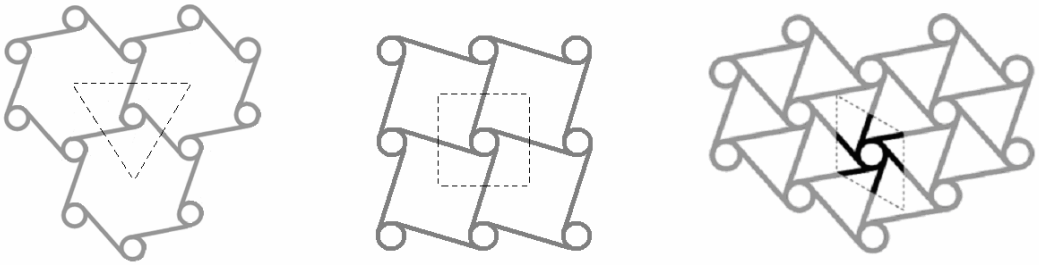

Figure 1. Basic blocks for three chiral structures: a) trichirals, b) tetrachirals, c) hexachirals

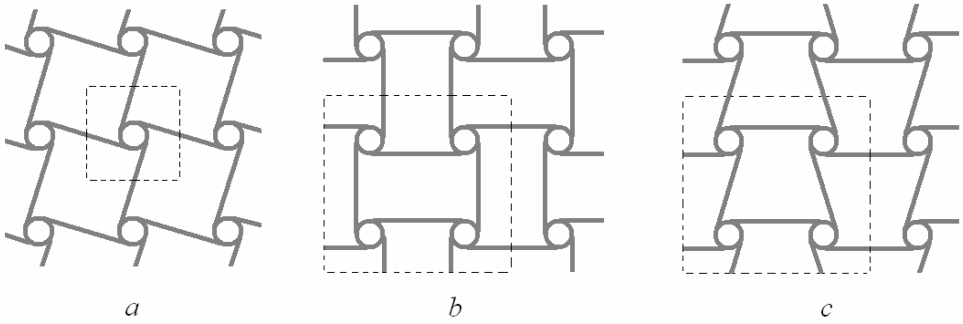

Figure 2. Structures from components of order 4:
a) tetrachirals, b) anti-tetrachirals, c) meta-tetrachirals

It is to note that in the analytical evaluations of auxetic in-plane properties of 2-D chiral, anti-chiral and meta-chiral structures, two different approaches were used: a) rigid ligaments and nodes, connected together through ideal hinges [2]; b) flexible ligaments connected with rigid or deformable nodes [9]. Also, it is possible to evaluate the out-of-plane mechanical properties of a chiral lattice analytically or by means of finite element analysis (FEA) [8,9].

2. Geometry of the analyzed structure and the finite element model

The behavior of the panel presented in Fig. 3 was evaluated by using a FEA model, with ANSYS [10]. The sandwich panel has sheets made from an aluminum alloy (1050 H24) of thickness t_f = 1 mm, glued with araldite AW 106/HV953 U to the core made from rigid polyurethane strips having a section of 5 x 25.4 mm inside the panel and 10 x 25.4 mm on the border of the panel.

The FEA makes possible the characterization of the sandwich panels under several aspects: rigidity, state of stress, fundamental eigenfrequencies and modes of vibration, stability. There were analyzed several cases of loading:

1) simply supported plate, loaded by a lateral pressure of 0.07 MPa;
2) cylindrical bending with the panel supported on two opposite edges and loaded by a lateral pressure of 0.05 MPa;
3) cylindrical bending with the panel supported on the other two opposite edges and loaded by the same lateral pressure of 0.05 MPa;

4) torsion of the panel by applying two equal forces in opposite corners and restricting the movement of the other two corners [11].

In the numerical model the adhesive was considered only in between the upper and lower aluminum sheets and the chiral core which presumably behaves as a monobloc structural component, although the core was built as a "puzzle" from separate parts glued between them.

For the used materials the following material parameters were adopted: aluminum – E = 69000 MPa, v = 0.33, σ_u = 138 MPa (ultimate strength), $\sigma_{y\,0.2}$ = 132 MPa (0.2% offset yield limit), density 2700 kg/m^3; araldite AW 106 – E_a = 1350 MPa, v_a = 0.45, σ_{ua} = 33 MPa, τ_{ua} = 23 MPa, density 1500 kg/m^3; rigid polyurethane foam – E_f = 220 MPa, v_f = 0.3 , density 301 kg/m^3. The allowable stresses will be considered as 100 MPa in aluminum, 5 MPa in the polyurethane foam and 20 MPa in the adhesive.

The dimensions of the panel are: a = 400 mm, b = 48 mm, c = 32 mm, t_f = 1 mm (thickness of the sheets), t_a = 0.3 mm (thickness of the adhesive), t_c = 25.4 mm (thickness of the core), t_s = 5 mm (thickness of the strips used to built the core), t_b = 10 mm (thickness of the border).

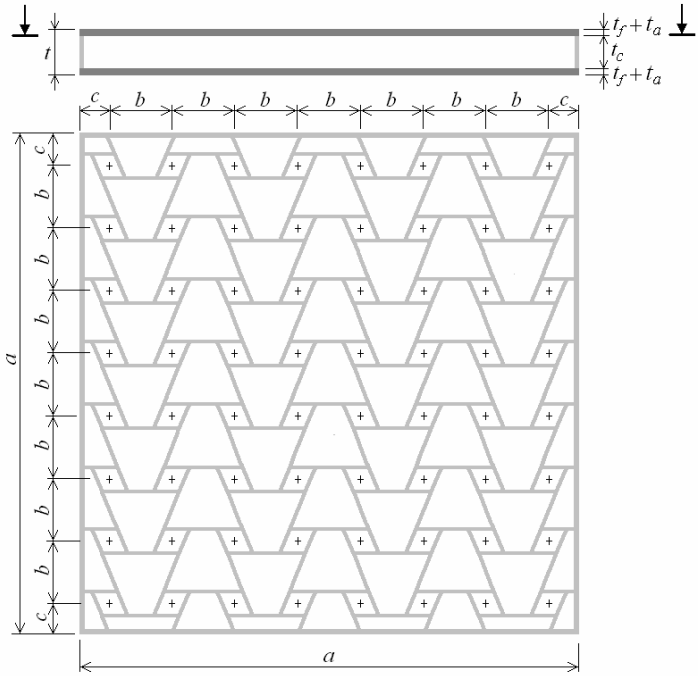

Figure 3. Geometry of the analyzed panel

In generating the chiral network (Fig. 4) was used the basic block obtained by adding to the configuration from Fig. 5 its own image in mirror. The FE mesh is done by using solid 8-noded elements (Brick 8), and resulted as having 134728 elements and 185706 nodes. Two layers of elements were used over the thickness of the strips which form the chiral core and through the thickness of the sheets, and one layer of elements through the thickness of the adhesive.

After a preliminary study it was established that a geometrically nonlinear analysis (large displacements) doesn't lead to results clearly different from the ones obtained in a small

displacement analysis, therefore all the following calculations were done only in the second hypothesis.

By using the densities of the materials mentioned previously the total mass of the sandwich panel resulted as 1.335 kg, from which the mass of the sheets is 65% (0.864 kg), of the core is 31% (0.418 kg), and of the adhesive as 4% (0.053 kg). It is to observe that the mass of proposed chiral foam core represents 35% of the mass corresponding to a compact core made from the same foam and having the same overall sizes, which is of 1.2 kg.

Data were considered in the SI system, therefore in the figures displacements were obtained in meters, and stresses in N/m^2 (10^6 N/m^2 = 1 N/mm^2 = 1 MPa).

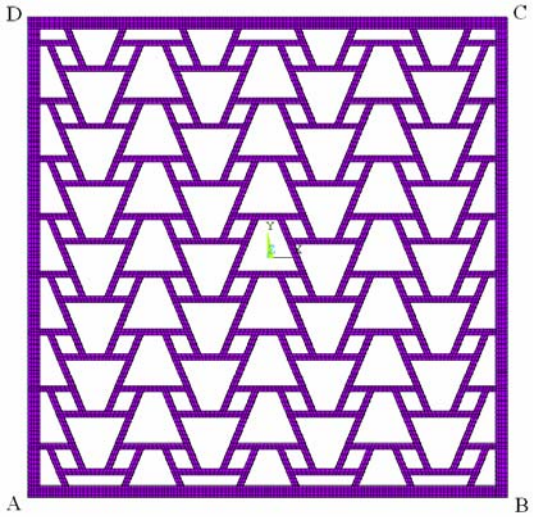

Figure 4. The core discretized with 8-node brick-type finite elements

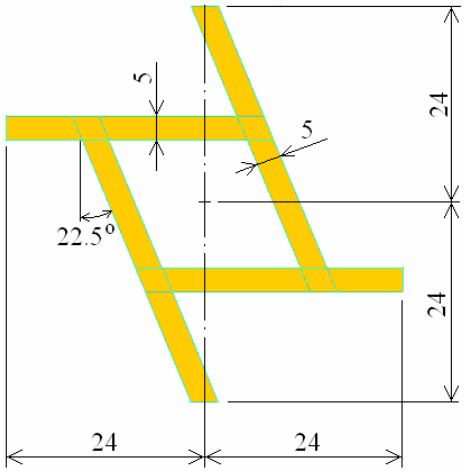

Figure 5. Geometry of the basic semi-block of the meta-tetrachiral core

3. Evaluation of in-plane auxetic properties of the core

The chiral core was initially analyzed separately in order to establish the coefficients of transversal contraction (or of transversal swelling), notated as ν_{xy} and ν_{yx}. The displacements in the plane XY (median plane of the core) were established in two situations (Fig. 4):

I displacements blocked in the direction X on the edge AD and an imposed displacement on the opposite edge (UX = 1 mm);

II displacements blocked in the direction Y on the edge AB and an imposed displacement on the opposite edge (UY = 1 mm).

In general, if L_x and L_y are the overall dimensions of the panel (length and width), the two values of the "Poisson's coefficients", associated to the situations defined in I and II are to be calculated with the relations:

$$\nu_{xy} = -\left(\Delta L_{y,I} / L_y\right) / \left(\Delta L_{x,I} / L_x\right), \qquad \nu_{yx} = -\left(\Delta L_{x,II} / L_x\right) / \left(\Delta L_{y,II} / L_y\right). \tag{1}$$

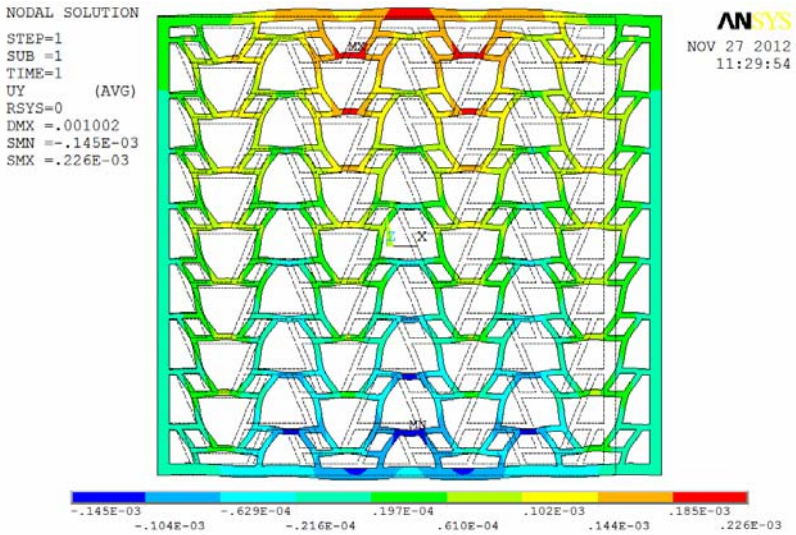

Figure 6. Deformed shape of the core when a relative displacement of 1 mm between the vertical sides is imposed

The results presented in Figs. 6 and 7 show that $\Delta L_{y,I} = 0.226 - (-0.145) = 0.371$ mm, and $\Delta L_{x,II} = 0.159 - (-0.159) = 0.318$ mm. Taking into account that $\Delta L_{x,I} = \Delta L_{y,II} = 1$ mm and that $L_x = L_y = a$, from (1) resulted $\nu_{xy} = -0.371$ and $\nu_{yx} = -0.318$. These negative values show that the core which will be used to build the sandwich panel has auxetic properties.

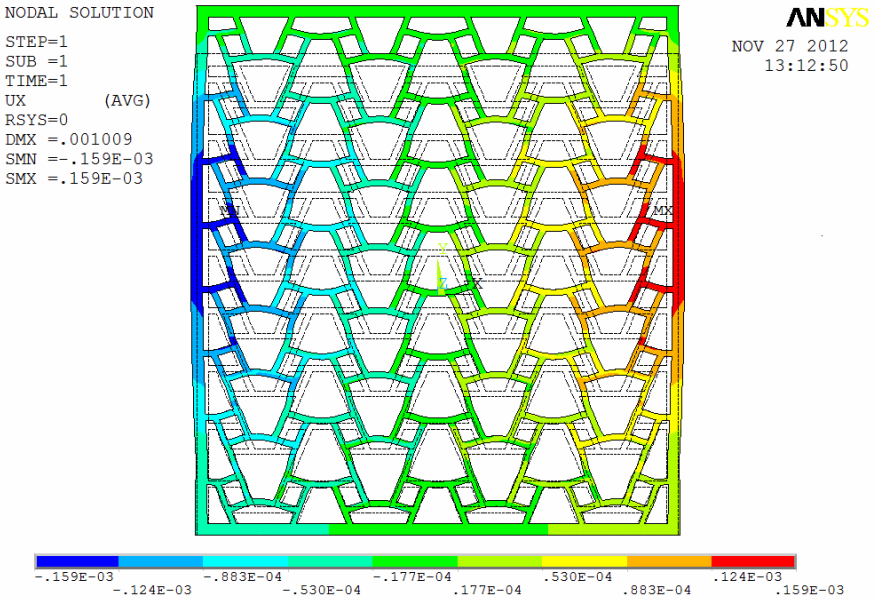

Figure 7. Deformed shape of the core when a relative displacement of 1 mm between the horizontal sides is imposed

4. Results of the FEA in the case of the panel under lateral pressure

4.1. Case of panel simply supported on the contour

The applied loading is a lateral pressure of 0.07 MPa. The obtained results are given in Table 1 and in Figs. 8-13.

It is to be noticed that the maximum von Mises equivalent stresses are lower than the allowable stress values in all the materials. The sandwich plate has a high stiffness as indicated by the maximum deflection (2.589 mm) and a high fundamental eigenfrequency (365 Hz). There is no risk to lose the stability of the plate as the coefficient of safety is 5.97 for the first local buckling mode. Fig. 13 shows a non-uniform distribution of the reactions along the supported contour, thus being explained the increased values of the stresses towards the middle sides of the sheet (Fig. 9).

1	nonlinear	96.6	4.58	7.12	2.581	5.97	365
2	linear	134	8.95	18.4	2.864	8.09	262
3	linear	133	8.93	18.3	2.779	8.24	265

In the two cases of cylindrical bending the stresses in the sheets, but especially in the core are unacceptably high. As the stresses in the foam have to be reduced to half, the loading has to be decreased from 0.05 MPa to 0.025 MPa. If the pressure has an imposed value (as 0.05 MPa) the thickness of the sheets may be increased and/or a foam with higher density and resistance has to be chosen.

It is interesting to notice that the distribution of the reactions along the edges on which the panel is supported is quite uniform (Figs. 14 and 18), but there are peak values in the vicinity of the corners where extreme values of the stresses in all the components were obtained.

Although it was expected to obtain differences between the two cases of cylindrical bending, the results are very similar; this represents an advantage given by the use of the meta-tetrachiral configuration.

5. Results of the FEA in the case of the panel under torsion

The loading scheme is presented in Fig. 20, in each corner of the plate being applied a force of 500 N, which in the numerical model were distributed on squares of 20x20 mm, as to avoid undesired local effects. The obtained results are presented in Figs. 20-23. In the aluminum sheets the maximum equivalent stress obtained in the corners is 65 MPa (Fig. 22), and in the center is 25 MPa (Fig. 23). In Fig. 23 the middle of the panel is considered the origin of the horizontal axis. The equivalent stress in the adhesive was obtained as about 2 MPa along the border of the core, and a maximum value of 6 MPa resulted again in the corners. In the chiral core the equivalent stress was almost zero in the middle area, about 1 MPa in the border, and a maximum value of 2.9 MPa was again obtained in the corners.

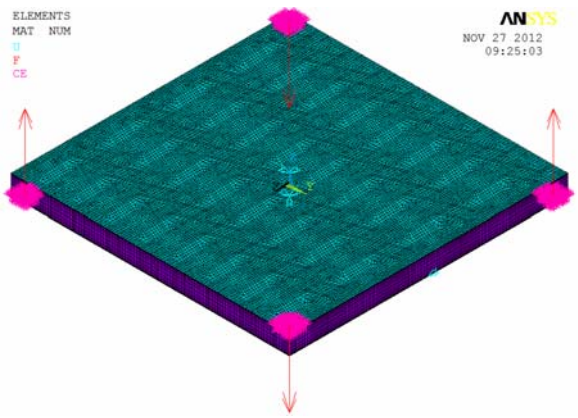

Figure 20. The loading scheme

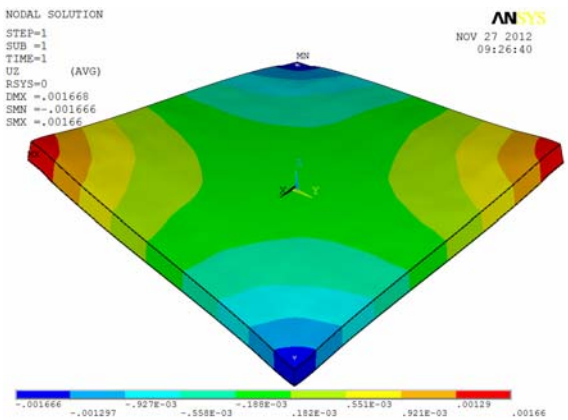

Figure 21. Displacement of the twisted panel

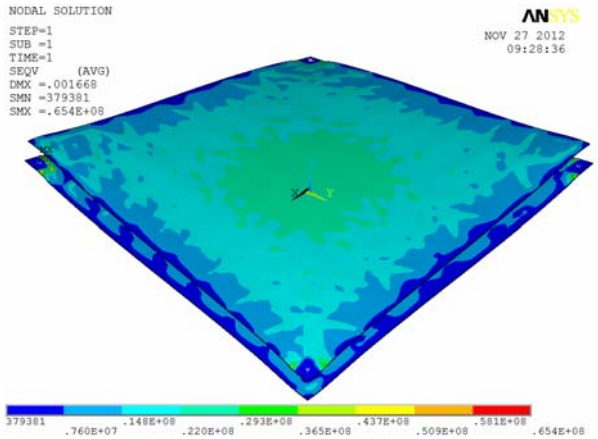

Figure 22. Equivalent stresses in the sheets

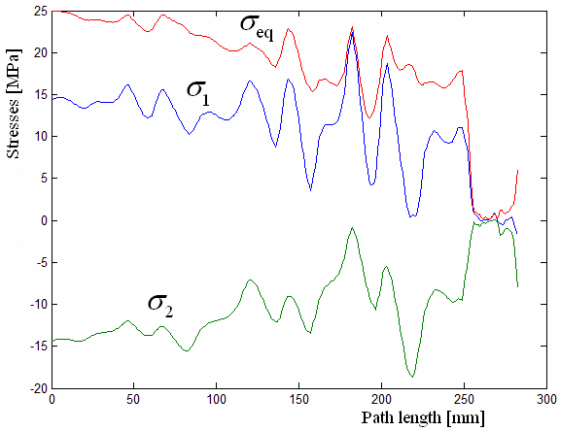

Figure 23. Variation of stresses σ_{eq}, σ_1, σ_2, along a half of the diagonal, on the surface of the panel

6. Experimental evaluation of the sandwich panel under torsion

In Fig. 24 (left) is shown the core of the sandwich panel tested in torsion with the loading scheme from Fig. 24 (right). A strain gage with two measuring grids (SG 1 and SG 2) of type XY93 10/120 (HBM, Germany) was positioned in the middle of the panel along its diagonals in order to measure the principal strains. With these strains were calculated the principal stresses σ_1, σ_2, and then the von Mises equivalent stress, σ_{eq}. For an applied force of 500 N (as in the FEA model) the experimentally established equivalent stress resulted as 23.55 MPa, being a little bit smaller than the 25 MPa value obtained numerically. This result validates the modeling procedure established in the FEA.

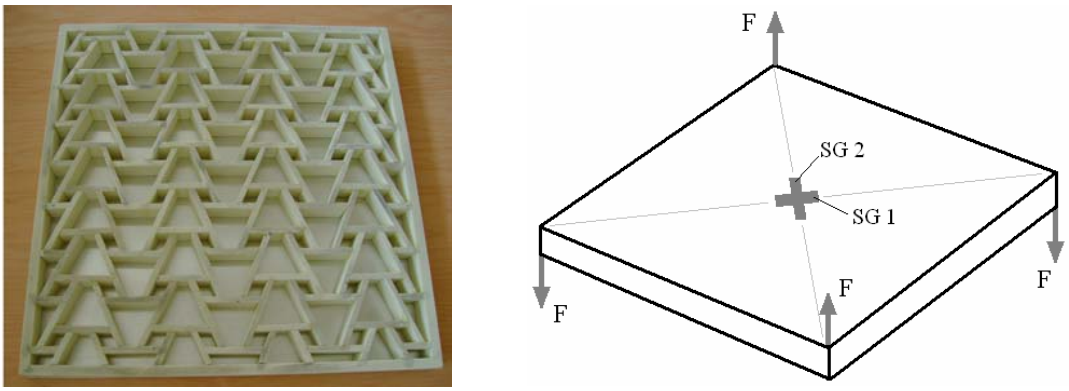

Figure 24. The meta-tetrachiral core manufactured from rigid foam strips and the loading scheme

7. Conclusions

The meta-tetrachiral core analyzed hereby is a new solution which has auxetic properties, and the resulting sandwich panel is stiff and light. Although it has only one plane of symmetry its behavior in bending (Table 1) is almost the same on the two in-plane directions.

This type of geometry, characterized by robust cells having thick walls, confers an important advantage concerning the local stability of the core.

We intend to use this meta-tetrachiral core for curved sandwich panels. By changing the geometry of the basic block (Fig. 5) one can obtain similar chiral core geometries with properties which worth to be investigated. Due to the simple manufacturing technology such panels can be obtained with significant economical advantages.

Abstract The tensile deformation behavior of a nickel-base superalloy under the dynamic loads was investigated the by the optical microscope, scanning electron microscope and transmission electron microscope. The results shown that the yield strength of the alloy increases with the increasing of strain rate, eapacily at the strain rate higher than 10^1 s^{-1}. While with the increasing of strain rate, the fracture elongation decreases at first, then increases rapidly and shows a minimum value at the strain rate of 10^2 s^{-1}. The manner in which the dislocations go through the strengthening phases may be different during the plastic deformation at different strain rates and it is the main reason of the appearance of inflection point in the change of the strength with the strain rate. The obvious increasing of plasticity of the alloy at high strain rate is depended on the deformation twining during the plastic deformation.

Keywords Superalloy, Dynamic load, Deformation behavior, Dislocation

1. Introduction

Superalloy is a kind of important metallic material for engines in the aerospace industry, which is the key point for determination of the thrust and thrust-weight ratio of advanced engines [1-3]. With the rapid developing aerospace industry, the working condition of the superalloy is becoming more and more severe. In traditional aeroengine manufacturing industry, the mechanical properties and deformation behavior of superalloy used for rotating parts under the actual dynamic load is not given full considerations during its designing of structure, composition and microstructure, which is significantly different compared with that under the static load [4-6]. In fact, the Young's modulus, strength, plasticity and ductility will change with the increasing of strain rate [7-10]. Therefore, the study on the deformation behavior of the alloy under the dynamic load is important for the safety of rotating parts used under the service conditions.
The aim of present study is to investigate the strain rate effects on the tensile deformation behavior of a precipitation strengthened nickel-base superalloy used for aero-engine combustor under dynamic loads. And the mechanism for strain-dependence on strength and ductility of the alloy was also discussed.

2. Experimental Procedures

The chemical compositions (wt%) of the alloy are of 0.038 C, 19.970 Cr, 9.990 W, 5.120 Mo, 2.180 Al, 1.290 Ti, 0.020 Mn, 0.080 Si, and balance Ni. The alloy was double vacuum melted, then forged and hot rolled into plates with the thickness of 1 mm After solution treated at 1150 ℃ for 15 min, the alloy was long-term aged at 800 ℃ for 0 h, 100 h, 200 h, 500 h and 1000 h, respectively. The tensile tests of the alloy were performed at room temperature using MTS 810 testing machine and Zwick HTM 5020 high speed tensile testing machine at a strain rates range of 10^{-3} S^{-1} to 10^3 S^{-1}. The resistance strain gage was setupped on the specimens for synchronous collection of the strains and loads during the dynamic deformation with a sampling frequency of 1 MHz. The microstructure evolution, grain size and the tensile fracture surfaces of the tensile specimen were examined using an optical microscope (OLYMPUS GX71), laser scanning confocal microscope (OLYMPUS OLS 3100) and field emission scanning electron microscope (JEOL 7001). The dislocation configuration near the fracture surface was examined by a transmission electron microscope (TECNAI G^2).

3. Results and Discussion

3.1 Strain rate effect on tensile property

Figure 1 shows tensile properties of the alloy aged with different parameters at various strain rates. It shows a similar strain-rate dependence on yield strength: shallow at the strain rates lower than10^1 s^{-1}, and even steeper with increasing of strain rate, especially when the strain rate is higher than 10^2 s^{-1}. It indicates that the plastic deformation mechanism of the alloy begins to change when the strain rate is higher than 10^1 s^{-1}.

The ductility of an alloy aged for different time also shows variation with the increasing of tensile strain rates, as shown in Fig.1b. When the strain rate is increased from 10^{-3} s^{-1} to 10^2 s^{-1}, the fracture elongation decrease obviously, while, then the fracture elongation increased significantly. From the results, it can be concluded that the plastic deformation mechanism of the alloy changed at the strain rate of 10^2 s^{-1}. When the alloy aged with different aging parameters, the increasing of ductility in the alloy aged for 500 h and 1000 h is less than that for 100 h and 200 h.

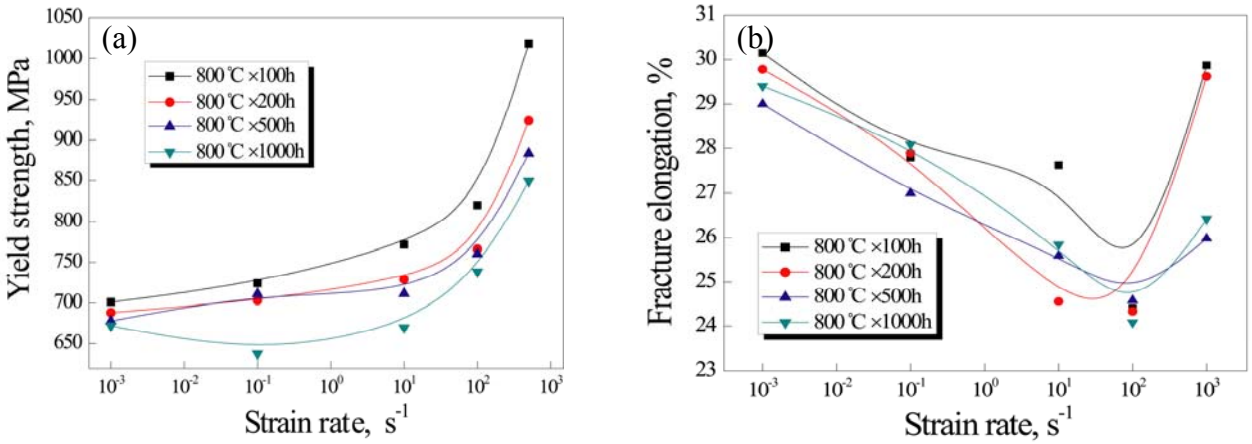

Figure 1. Variation of mechanical properties with the tensile strain rate of the alloy aged by different parameters: (a) yield strength, (b) fracture elongation

3.2 Strain rate effect on tensile fracture morphology

Figure 2 shows the morphologies in fibrous zones of tensile fracture surface of the alloy by aged for 100 h and 100 h with different strain rates. The alloys aged for 100 h and 1000 h exhibit mixed fracture characteristics with ductile and intergranular when the strain rate is lower than 10^{-3} s^{-1}. The small changes can be observed from the fracture morphologies of the alloy with different aging time when the strain rates are increased to 10^3 s^{-1}. It can be found that the percentage of ductile fracture region decreases obviously in the alloy aged for 1000 h as compared with that aged for 100 h at the same strain rate. In addition, the percentage of ductile fracture region in the alloy aged for 1000 h further decreases with the increasing of strain rate and the intergranular fracture characteristics is more apparent.

3.3 Dislocation configurations near fracture surface

Dislocation configurations near the fracture surface in the alloy aged for 200 h at various strain rates are shown in Figure 3. It can be noticed that the dislocation density is not high and it seems no remarkable change with the strain rate of 10^{-3} s^{-1} to 10^1 s^{-1}, while when the strain rate is increased to 10^2 s^{-1}, the dislocation density significantly increases and activation of slip systems can be found with TEM observation. However, when the strain rate is higher than 10^2 s^{-1}, the dislocation density remains stable but dislocation tangles become more severe.

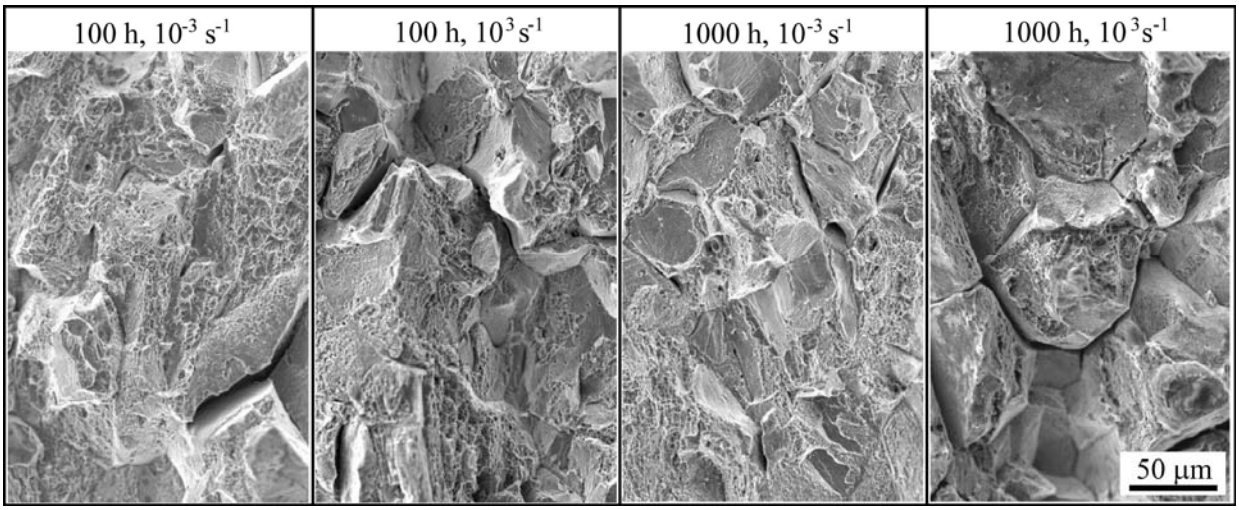

Figure 2. Tensile fracture morphologies in the alloy aged for different time at various strain rates

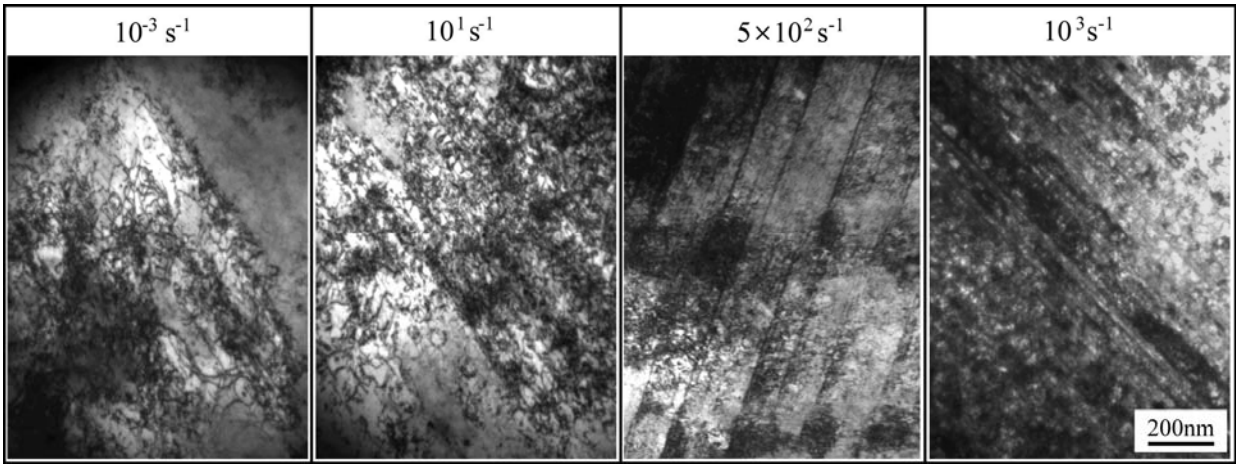

Figure 3. Dislocation configurations near fracture surface in the alloy aged for 200 h at various strain rates

3.4 Mechanism of strain rate effect on dynamic deformation behavior

The stress-strain curves of the alloy aged for 200 h with different strain rates are plotted in Figure 4. It indicates that there is no obvious change of the Young's modulus with the increase of the strain rate. Elastic limit and 0.2% offset yield strength of the alloy increase as the strain rate increase. From Figure 4, it is clear that the stress-strain curves in plastic deformation stage shows strong strain rate-dependence, which is consistent with the results shown in Figure 1. The strength of the alloy exhibits stronger strain rate sensitivity, when the strain rate is upto 10^2 s^{-1}.

It is known that when the force component at a slip system reaches the critical value, the dislocation begins moving. In fact, the dislocation motion is the atom motion in lattice and thus the dislocation motion is time-dependent. As the applied stress increases, the dislocation motion speed increases rapidly. When the specimen undergoes a high loading rate, the acceleration which the dislocation motion needs will be also increased [11]. The dislocation will meet with obstacles continually when it begins moving and this resistance of dislocation motion presents the deformation resistance during plastic deformation from the macroscopic point of view [12]. It is clear that the higher the speed of movable dislocation become, the higher acceleration and resistance of dislocation motion will be.

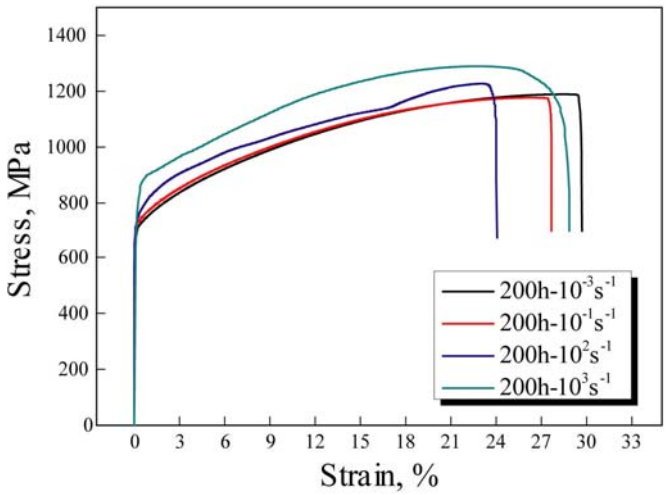

Figure 4. Stress-strain curves of the alloy aged for 200 h at various strain rates

Under the condition of static or quasi-static deformation, the speed of dislocation motion is higher than the deformation speed of materials by the low loading rate. Dislocations have relative enough time for acceleration. At the moment, the acceleration for dislocation moving is very lower, so the time-effect on deformation resistance is not obvious. Therefore, the increasing of yield strength is not high with the increasing of strain rate (lower than10^1 s^{-1}).

When the strain rate is higher than 10^1 s^{-1}, the acceleration of moving dislocation increases, meanwhile, the dislocation moving resistance increases. Consequently, the strength of the alloy increases significantly when the strain rate is higher than 10^2 s^{-1}. It has been found[13] that the dislocation motion is faster at the higher strain rate and the short-range factors inhibiting the dislocation motion such as the Peierls-Nabarro force, thermal vibration of the atoms and electron cloud resistance increases significantly. When the dislocation motion speed exceeds a certain value of about 10^1 $m{\cdot}s^{-1}$, the controlling mechanism of dislocation motion is changed from thermo-activation to short-range damping. And the dislocation motion resistance shows an obvious increase and thus the deformation resistance of the alloy rapidly increases. It indicates that the obvious increasing of the strength as the strain rate higher than 10^2 s^{-1} is related to such factor.

The compatible plastic deformation mechanism of dislocation pile-ups release and crystal rotating exhibits an obvious time-dependence in the alloy when tensile deformation under dynamic loadings [13-15]. And the plastic deformation coordinates by means of activation of dislocation slip systems, as shown in Figure 3. Dislocations are subjected to very high shear stress in a very short time and the shear stress reaches or exceeds the critical resolve shear stress (CRSS) of the dislocation slip systems when the dislocations are not yet ready to move at conventional dislocation slip systems. As a result, the ductility of the alloy shows a marked increase at the same strain rates range as that of the increasing strength.

On the other hard, a large amount of deformation twins have been found near the fracture surface in the alloy, as shown in Figure 5. And the number of deformation twins increases with the increasing of strain rate. Also some dislocation pile-ups around the stacking faults in the crystal can be observed under dynamic loading which is due to the stress concentration. When the dislocation motion is easy, the stress concentration is small. On the contrary, the stress concentration becomes high. It is too late for the dislocations at the dislocation pile-up to move in the alloy during tensile deformation at high strain rate, and thus the stress around the stacking fault increases, which will promote the occurrence of twinning deformation. The existence of a large number of deformation twins in the alloy during tensile deformation at high strain rate makes obvious contribution to increasing of the plastic deformation ability.

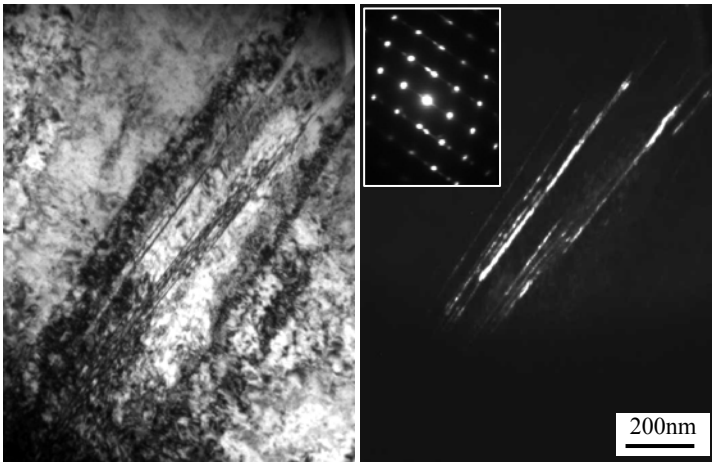

Figure 5. Deformation twins near the fracture surface in the alloy aged for 500 h at strain rate of 5×10^2 s^{-1}

At the same time, the thermal-softening effect often occur caused by heat generation during plastic deformation at higher strain rate [16, 17], which the dislocation moving resistance can be reduced, it also contributes to the increasing of the ductility of the alloy.

4. Conclusions

(1) The yield strength of the alloy exhibits a slight increase when strain rate is lower than 10^1 s^{-1}, while obvious increase when the strain rate is higher than 10^2 s^{-1}.

(2) The fracture elongation of the alloy shows obvious decrease when the strain rate is lower than 10^2 s^{-1}, whereas it shows a rapid increasing when the strain rate is higher than 10^2 s^{-1}.

(3) The deformation resistance of the alloy increases with the increasing of strain rate during deformation at high strain rate due to the increasing of short-range resistance caused by acceleration of dislocation motion. When the strain rate is higher than 10^2 s^{-1}, the significant increasing of the moving dislocation number is the main reason for the increasing of plastic deformation ability. In addition, the twinning deformations as well as thermal-softening caused by the temperature rising at high strain will contribute to the ductility of the alloy too.

Electrical Breakdown of a Metallic Nanowire Mesh

Yuan Li[1,*], Kaoru Tsuchiya[1], Hironori Tohmyoh[1], Masumi Saka[1]

[1] Department of Nanomechanics, Tohoku University, Sendai 980-8579, Japan
* Corresponding author: liyuan@ism.mech.tohoku.ac.jp

Abstract The electrical breakdown of a metallic nanowire mesh induced by Joule heating (i.e., melting) is investigated by solving the corresponding electro-thermal problem, where the effect of electromigration is neglected. A numerical computational program is firstly developed to simulate the temperature profile for a metallic wire mesh and investigate the melting current triggering the melting of mesh segment. The melting process of the mesh structure is investigated by analyzing the variation of melting current with regard to the melting propagation of mesh segment. On this basis, the melting behavior of a system of the mesh equipped with current source is predicted. For both current-controlled and voltage-controlled current source, local instability (i.e., at a constant current/voltage, several mesh segments melt simultaneously) and stable melting (i.e., the increase of current/voltage is necessary for the melting of mesh segment) will happen. Moreover, global instability (i.e., at a constant current, several mesh segments melt until the circuit of mesh opens) will occur only at the mode of current-controlled current source.

Keywords Electrical breakdown, Instability, Joule heating, Metallic nanowire mesh, Stable melting,

1. Introduction

With one-dimensional structure and nanometer-scale diameter, metallic nanowires have shown remarkable electrical, mechanical, optical and chemical properties [1]. Successful assembly of these metallic nanowires into a mesh structure has offered great potential as components for large-scale integrated devices in nanoelectronics and photonics. Recent reports have shown that such mesh can play new roles which are far from the potential of individual nanowires, including transparent conductors, low-cost flexible electronics [2, 3]. It is well known that if an electrically conductive material is subjected to current flow, Joule heating occurs [4]. Joule heating in these metallic nanowires may go beyond degrading the electrical performance of the corresponding metallic nanowire mesh, and therefore deteriorate the reliability of the mesh-based devices. In order to turn around this problem, clarifying the electrical breakdown of a metallic nanowire mesh induced by Joule heating becomes urgent. Up to date, the electrical breakdown of an individual metallic nanowire has been investigated systematically including melting due to Joule heating [5, 6] and due to electromigration [7-10]. The former has been used to cut metallic nanowire in any desirable length [5, 6] for specific purpose, and the latter has been employed to make the nanogap [7, 8] between metal electrodes into which individual molecules can be inserted to measure their electrical properties. However, little is currently known regarding the electrical breakdown of a metallic nanowire mesh, which is expected to show different characteristics because of its unique mesh structure.

In this work, the electrical breakdown of a metallic nanowire mesh induced by Joule heating (i.e., melting) is investigated for the first time. To deal with this type of electro-thermal problem, a numerical simulation method is proposed to determine the associated temperature field for a metallic wire mesh and the variation of the melting current triggering the melting of mesh segment with the melting propagation of mesh segment. By employing the developed computational program, the melting process of a silver (Ag) nanowire mesh structure is clarified by analyzing the variation of melting current during the melting propagation in the mesh. It then indicates the interesting characteristics of the melting behavior for a system of the mesh equipped with current source.

2. Simulation Method for Electrical Breakdown of a Metallic Nanowire Mesh

2.1 Simulation Model and Basic Assumptions

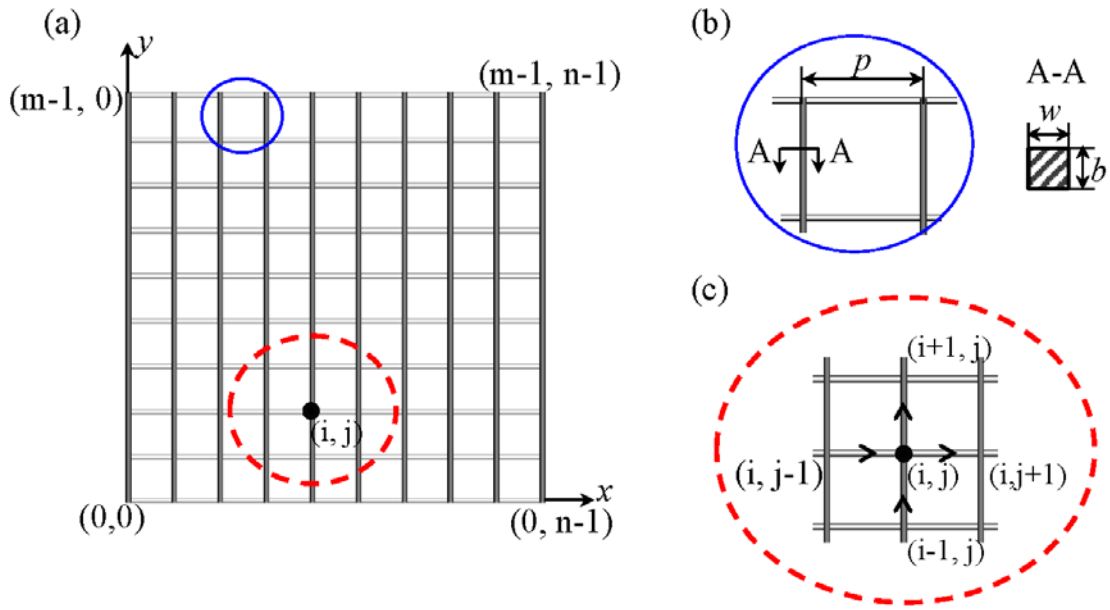

Fig. 1 Schematic illustration of a metallic nanowire mesh (m×n)

A metallic nanowire mesh with size of m×n is schematically illustrated in Fig. 1, which is a uniform rectangular grid of wires with m rows (horizontal wires) and n columns (vertical wires). As shown in Fig.1b, the pitch size is *p*, the wire width and thickness are *w* and *b*, respectively. Due to the complex nature of electro-thermal for a metallic wire mesh, the following assumptions are made: (1) The material of metallic mesh is homogeneous and isotropic; (2) Material properties of metallic mesh are temperature independent; (3) The effect of electromigration is neglected for simplicity.

2.2 Fundamentals of Governing Equations

A mesh node is an intersection of each row and column. Let node (i, j) be the intersection of the $(i+1)^{th}$ row and the $(j+1)^{th}$ column, where i=0, …, m-1; j=0, …, n-1. The wire between two adjacent mesh nodes is called a mesh segment. For the present mesh with size of m×n, the numbers of mesh nodes and mesh segments are m×n and m(n-1)+n(m-1), respectively. The segment between node (i, j-1) and node (i, j) is denoted as $s^{l}_{i,j}$, and the segment between (i, j) and (i, j+1) is denoted as $s^{r}_{i,j}$. Similarly, the segment between node (i-1, j) and (i, j) is denoted as $s^{d}_{i,j}$, and the segment between (i, j) and (i+1, j) is denoted as $s^{u}_{i,j}$. Here, the letters of l, r, d and u stand for the relative positions of the adjacent nodes (i.e., (i, j-1), (i, j+1), (i-1, j), (i+1, j)) to node (i, j), i.e., left, right, down, up, respectively.

For any mesh segment, the current can be calculated using Ohm's law. By considering the node (i, j), the current flowing between four adjacent nodes and it can be obtained as below

$$I_{s^{l}_{i,j}} = j_{s^{l}_{i,j}} A = -\frac{1}{\rho}\frac{U_{(i,j)}-U_{(i,j-1)}}{x_{(i,j)}-x_{(i,j-1)}}A$$

$$I_{s^{r}_{i,j}} = j_{s^{r}_{i,j}} A = -\frac{1}{\rho}\frac{U_{(i,j+1)}-U_{(i,j)}}{x_{(i,j+1)}-x_{(i,j)}}A$$

$$I_{s^{d}_{i,j}} = j_{s^{d}_{i,j}} A = -\frac{1}{\rho}\frac{U_{(i,j)}-U_{(i-1,j)}}{y_{(i,j)}-y_{(i-1,j)}}A$$

$$I_{S^{u}_{i,j}} = j_{S^{u}_{i,j}} A = -\frac{1}{\rho}\frac{U_{(i+1,j)}-U_{(i,j)}}{y_{(i+1,j)}-y_{(i,j)}} A \quad (1)$$

where ρ is the electrical resistivity of material, and A (=wb) is the cross-sectional area of wire. Here, as an example, $I_{S^{l}_{i,j}}, j_{S^{l}_{i,j}}$ are current and current density for mesh segment $s^{l}_{i,j}$; $U_{(i,j)}$ and $x_{(i,j)}, y_{(i,j)}$ are electrical potential and coordinates of node (i, j). It should be noted that as shown in Fig. 1, the origin of the coordinate system is set at the bottom left corner of the mesh, i.e., node (0, 0). The *x*-axis points right and the *y*-axis points up, both of which are taken to be along the wire. Moreover, at any mesh node of (i, j), according to Kirchhoff's current law, we have

$$I_{\text{internal}} + I_{\text{external}} = 0 \quad (2)$$

Here, $I_{\text{internal}}(= I_{S^{l}_{i,j}} - I_{S^{r}_{i,j}} + I_{S^{d}_{i,j}} - I_{S^{u}_{i,j}})$ means the sum of the current flowing into the node (i, j) from different adjacent nodes, and I_{external} represents the external input/output current where the external output current takes the minus value. By considering Eqs. (1) and (2) for all the nodes, the current density at any mesh segment (i.e., $j_{S^{l}_{i,j}}, j_{S^{r}_{i,j}}, j_{S^{d}_{i,j}}, j_{S^{u}_{i,j}}$), and the electrical potential at any mesh node can be obtained.

On the other hand, for any mesh segment, the heat energy, flowing in any mesh segment between two adjacent nodes, can be calculated using Fourier's law of heat conduction as

$$\begin{aligned} Q_{S^{l}_{i,j}} &= q_{S^{l}_{i,j}} A = -\lambda \frac{T_{(i,j)}-T_{(i,j-1)}}{x_{(i,j)}-x_{(i,j-1)}} A \\ Q_{S^{r}_{i,j}} &= q_{S^{r}_{i,j}} A = -\lambda \frac{T_{(i,j+1)}-T_{(i,j)}}{x_{(i,j+1)}-x_{(i,j)}} A \\ Q_{S^{d}_{I,j}} &= q_{S^{d}_{I,j}} A = -\lambda \frac{T_{(i,j)}-T_{(i-1,j)}}{y_{(i,j)}-y_{(i-1,j)}} A \\ Q_{S^{u}_{i,j}} &= q_{S^{u}_{i,j}} A = -\lambda \frac{T_{(i+1,j)}-T_{(i,j)}}{y_{(i+1,j)}-y_{(i,j)}} A \end{aligned} \quad (3)$$

where λ is the thermal conductivity of material. Here, as an instance, $Q_{S^{l}_{i,j}}, q_{S^{l}_{i,j}}$ are heat energy and heat flux for mesh segment $s^{l}_{i,j}$; $T_{(i,j)}$ is the temperature at node (i, j). Moreover, at any mesh node, according to the law of conservation of heat energy, we have

$$Q_{\text{internal}} + Q_{\text{external}} = 0 \quad (4)$$

Here, $Q_{\text{internal}}(= Q_{S^{l}_{i,j}} - Q_{S^{r}_{i,j}} + Q_{S^{d}_{i,j}} - Q_{S^{u}_{i,j}})$ means the sum of the heat energy flowing into the node (i, j) from different adjacent nodes, and Q_{external} represents the external input/output heat energy where the external output heat energy takes the minus value.

It should be noted that when a metallic nanowire is subjected to a steady direct current flow, Joule heating occurs, which, in turn causes increase in temperature of the wire. For simplicity, it is assumed that there is no heat transfer from the surface of the wire to the ambient, and the time-dependence of temperature can be neglected. Then, the heat conduction in the above four mesh segments can be governed by the following one-dimensional Poisson's equations [11]:

$$\begin{aligned} \lambda \frac{d^2 T_{S^{l}_{i,j}}}{dx^2} + \rho j^2_{S^{l}_{i,j}} &= 0 \\ \lambda \frac{d^2 T_{S^{r}_{i,j}}}{dx^2} + \rho j^2_{S^{r}_{i,j}} &= 0 \\ \lambda \frac{d^2 T_{S^{d}_{i,j}}}{dy^2} + \rho j^2_{S^{d}_{i,j}} &= 0 \\ \lambda \frac{d^2 T_{S^{u}_{i,j}}}{dy^2} + \rho j^2_{S^{u}_{i,j}} &= 0 \end{aligned} \quad (5)$$

where $T_{S^{l}_{i,j}}$ as an example is the temperature of mesh segment $s^{l}_{i,j}$.

Using the above Eqs. (3) to (5) for all the nodes, the temperature at any mesh node (i.e., $T_{(i,j-1)}$, $T_{(i,j+1)}$, $T_{(i-1,j)}$, $T_{(i+1,j)}$, $T_{(i,j)}$) can be obtained. For a specific mesh segment, if two ends of it (i.e., two adjacent mesh nodes) have the same temperature, the temperature at its center T^C is also the highest temperature T^{max} in the mesh segment (i.e., $T^C = T^{max}$), which can be calculated [11] as

$$
\begin{aligned}
T^{C}_{S^{l}_{i,j}} &= \frac{\rho}{2\lambda} j^{2}_{S^{l}_{i,j}} \left(\frac{x_{(i,j)}-x_{(i,j-1)}}{2}\right)^{2} + \frac{T_{(i,j)}+T_{(i,j-1)}}{2} \\
T^{C}_{S^{r}_{i,j}} &= \frac{\rho}{2\lambda} j^{2}_{S^{r}_{i,j}} \left(\frac{x_{(i,j)}-x_{(i,j+1)}}{2}\right)^{2} + \frac{T_{(i,j)}+T_{(i,j+1)}}{2} \\
T^{C}_{S^{d}_{i,j}} &= \frac{\rho}{2\lambda} j^{2}_{S^{d}_{i,j}} \left(\frac{y_{(i,j)}-y_{(i-1,j)}}{2}\right)^{2} + \frac{T_{(i,j)}+T_{(i-1,j)}}{2} \\
T^{C}_{S^{u}_{i,j}} &= \frac{\rho}{2\lambda} j^{2}_{S^{u}_{i,j}} \left(\frac{y_{(i,j)}-y_{(i+1,j)}}{2}\right)^{2} + \frac{T_{(i,j)}+T_{(i+1,j)}}{2}
\end{aligned}
\tag{6}
$$

In the present case, most mesh segments have different temperatures at its ends. In view of the very small length of mesh segment of 200μm as shown later in Fig. 3, the temperature at the center of mesh segment is approximately considered as the maximum temperature in mesh segment T^{max} (i.e., $T^C \approx T^{max}$). Once the maximum temperature in a mesh segment T^{max} reaches to the melting point of the material T_m, it is thought that electrical breakdown induced by Joule heating happens at this mesh segment, i.e., this mesh segment melts.

2.3 Computational Procedure

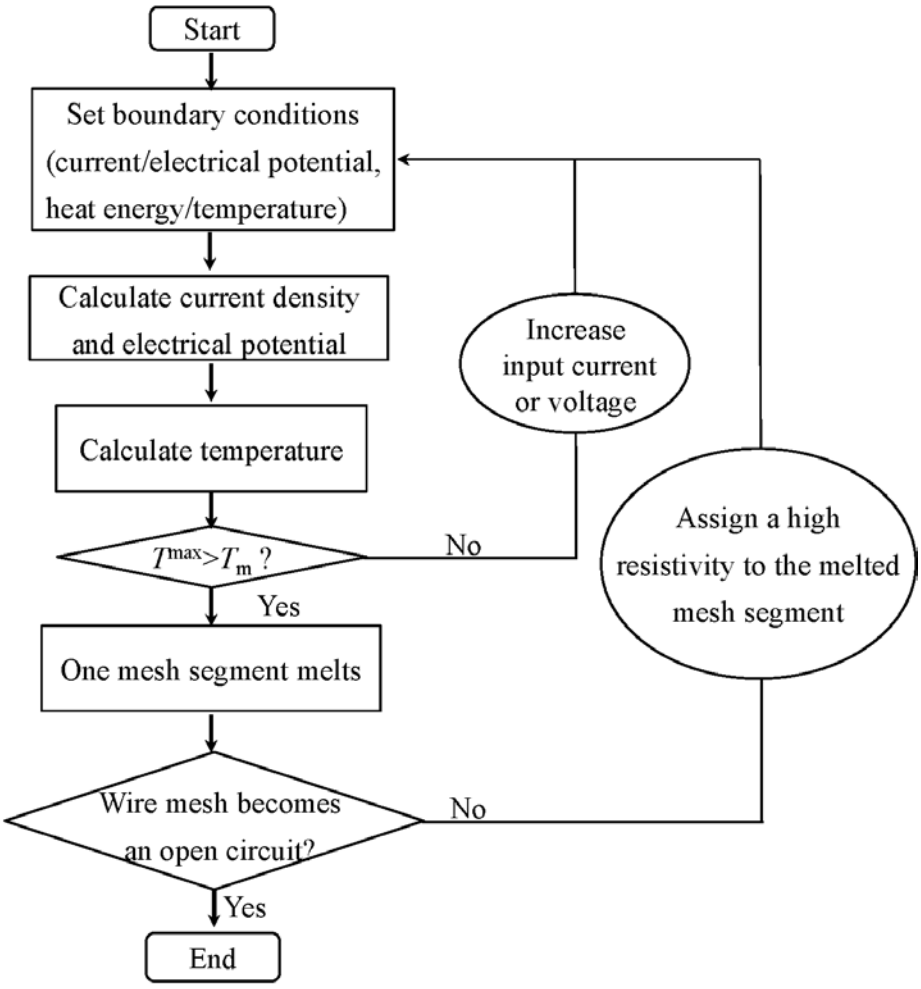

Fig. 2 Flow chart of numerical simulation

A corresponding computational program is developed to solve this electro-thermal problem regarding the electrical breakdown of the metallic nanowire mesh induced by Joule heating. Note that to record precisely the melting current triggering the melting of mesh segment, the increment of current should be tuned to make mesh segment melt one by one. The corresponding simplified flow chart of this program is shown in Fig. 2.

3. Electrical Breakdown of an Ag Nanowire Mesh

3.1 Numerical Model

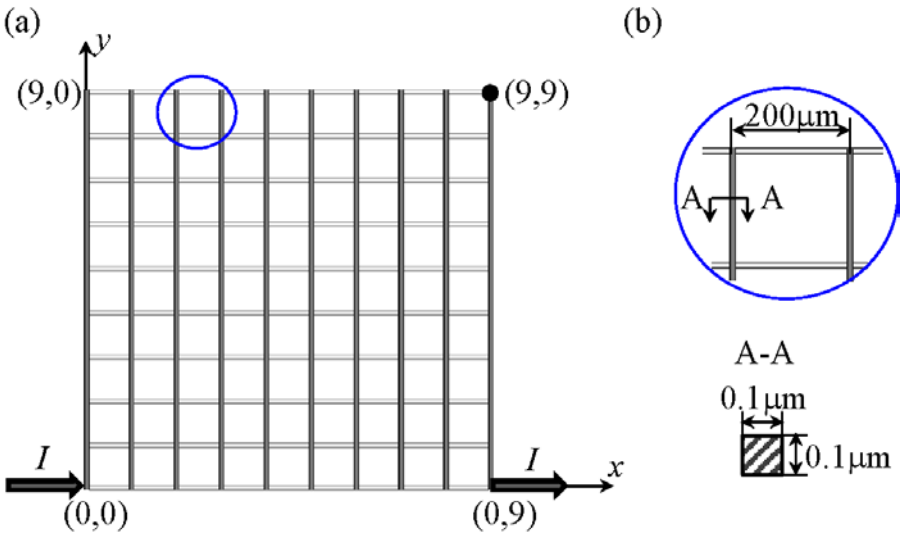

Fig. 3 Schematic illustration of an Ag nanowire mesh (10×10)

Table 1 Physical properties of Ag nanowire

Melting point T_m (K)	873 [12]
Thermal conductivity λ (W/μm·K)	3.346×10^{-4} [13]
Electrical resistivity ρ (Ω·μm)	0.119 [14]

A silver (Ag) nanowire mesh (10×10) as shown in Fig. 3a is considered here. The numbers of mesh nodes and mesh segments are 100 and 180, respectively. The pitch size is p=200μm, both the width and thickness of Ag nanowire are w=b=100nm as shown in Fig.3b. The physical properties of Ag nanowire are listed in Table 1. Note that size effect on the physical properties is taken into consideration for Ag nanowire.

As shown in Fig. 3a, the external current I flows into the mesh from node (0, 0) and flows out of the mesh from node (0, 9), which means that node (0, 0) has an external input current and node (0, 9) has an external output current. For the other nodes, no any external current is given. A constant value is assigned to the electrical potential of node (9, 9). The temperature of boundary nodes (i.e., (i, 0), (0, j), (i, 9), (9, j) where i, j=0,…,9) is room temperature of T_0=300K. There is no any external heat energy for all the other nodes. The developed program is employed to investigate the evolution of the melting current I_m triggering the melting of the mesh segment. Here, in order to make mesh segment melt one by one as much as possible, the increment of the input current is set with a small value of 0.001mA until the melting current is reached. The corresponding melting voltage V_m (i.e., the difference of electrical potential between node (0, 0) and node (0,9)) is also recorded in order to calculate the variation of resistance of the mesh, i.e., R, with regard to the sequential electrical breakdown of mesh segments.

3.2 Results and Discussion

With regard to the melting propagation of mesh segment, the variation of melting current I_m and mesh resistance are shown in Fig. 4a and Fig. 4b. Note that the mesh resistance is the resistance between two mesh nodes where the external current is input and output (i.e., node (0, 0) and node (0, 9)), respectively. Two local parts (c) and (d) in Fig. 4a are enlarged in Fig. 4c and Fig.4d, respectively. In Fig. 4a and Fig. 4c, it is found that when the input current increases up to 0.225mA, the maximum temperature in one mesh segment reaches the melting point of Ag nanowire making the start point of the melting of mesh. For the following melting of the second mesh segment, the melting current decreases to the value of 0.217mA. With the melting propagation of mesh segment, the variation of melting current and voltage shows the repetition of three different trends as marked with arrows in Fig. 4c and Fig. 4d: (I) decrease of both melting current and voltage; (II) increase of both melting current and voltage; (III) decrease of melting current but increase of melting voltage. Finally, the melting of last mesh segment makes the open circuit of the mesh as shown in Fig. 4a. Here, the number of broken mesh segments n_b corresponding to the open circuit of mesh is only 89, which is about one half of the number of the overall mesh segments (i.e., 180) in the intact Ag nanowire mesh. Generally, the nanowire mesh during the whole melting process in this case keeps symmetric, in which the exception is attributed to the minor error during the numerical simulation. On the other hand, the mesh resistance in Fig. 4b increases with the melting propagation of mesh segment, which is independent of the trend of melting current.

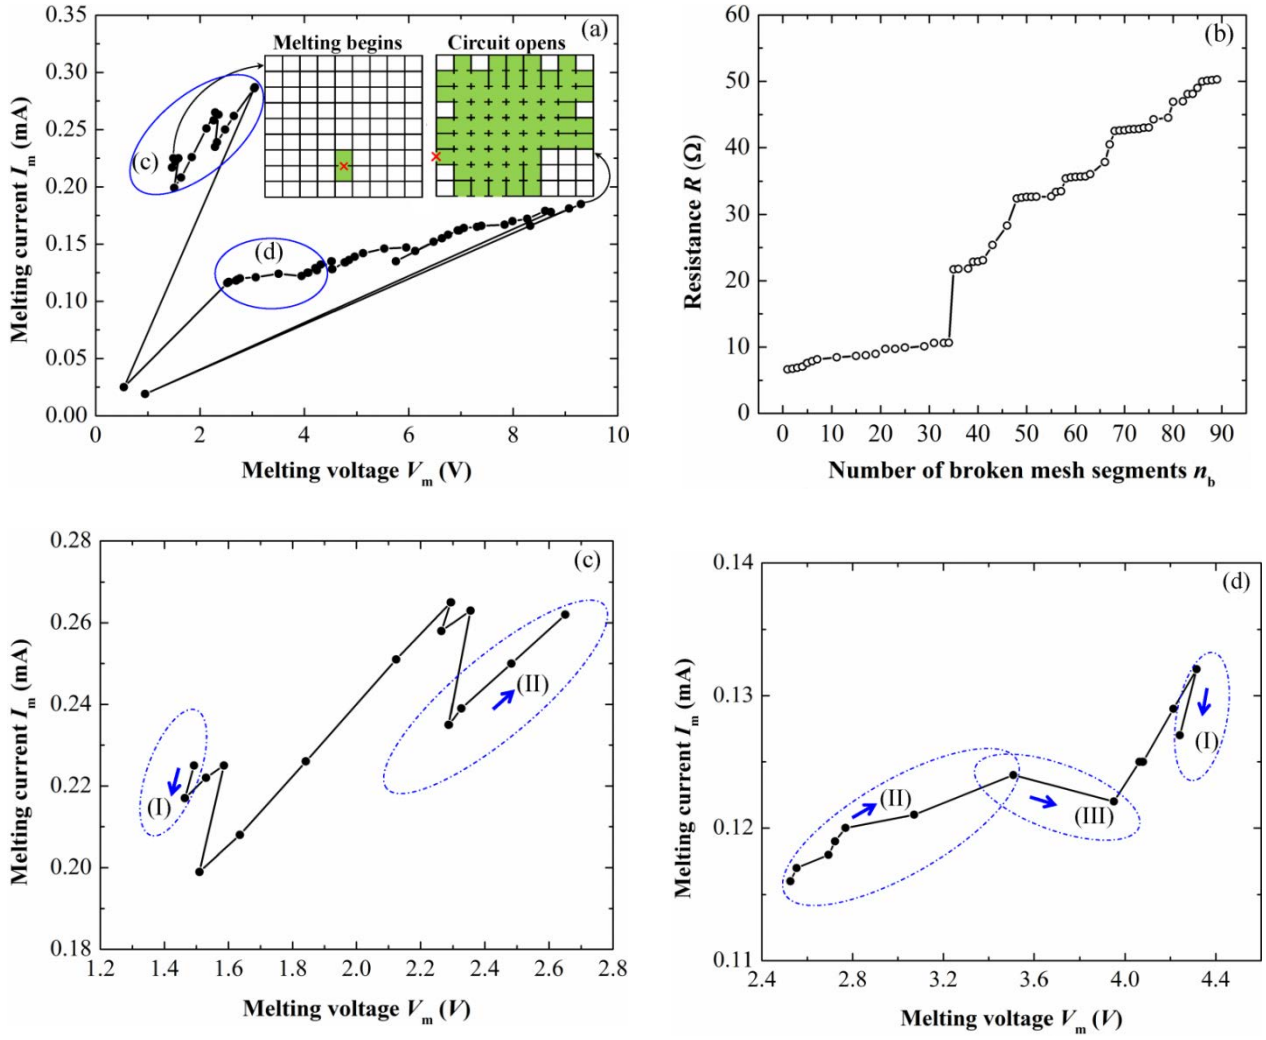

Fig. 4 Numerical melting of an Ag nanowire mesh structure

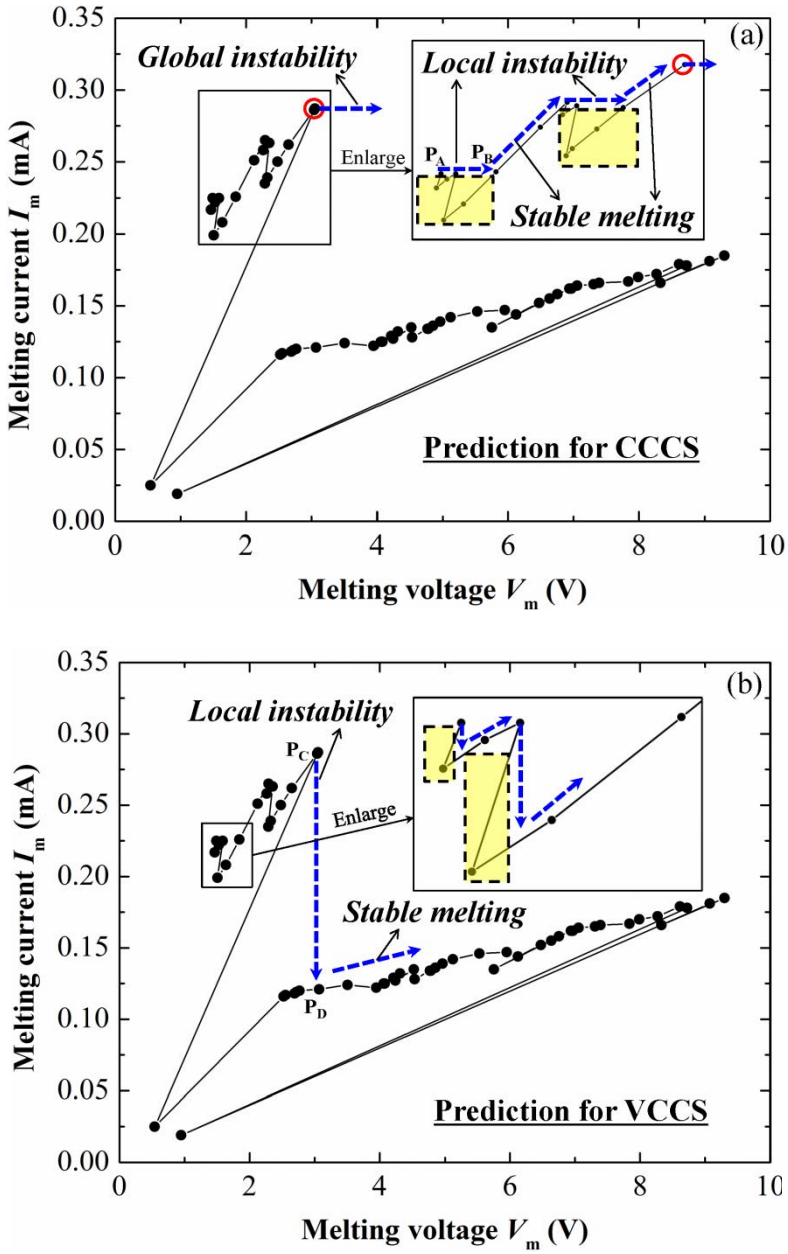

Fig. 5 Predicted experimental melting process of a system of an Ag nanowire mesh equipped with current source
(CCCS: current-controlled current source; VCCS: voltage-controlled current source)

To explain this unique melting behavior of a mesh structure, the melting of an individual nanowire is discussed here to make comparison. The maximum temperature induced by Joule heating in the nanowire increases with increasing current. When the maximum temperature reaches to the melting point of the material, the nanowire will melt, and the melting process of an individual wire is finished. For the mesh structure, on the other hand, the maximum temperature in the mesh, occurring in some place of a mesh segment, initially increases with the increasing current, which is similar with that of the individual nanowire. When the maximum temperature reaches to the melting point of the material, the corresponding mesh segment melts. However, this is just the start point of melting in the mesh structure, and the mesh structure intrinsically takes a consecutive melting

process of large amounts of individual nanowires.

Basically, due to the limit of the properties of current sources, it is difficult to observe the trend of (I) in Fig. 4 (c) and (d) in which both melting current and voltage decrease. Consider a system composed of an Ag nanowire mesh and current source, the corresponding melting behavior can be predicted. As a representative illustration, Fig. 5 is given. For the mode of current-controlled current source (CCCS) in Fig. 5a, such regions with the decrease of current and the subsequent recovery (e.g., the area surrounded by dash rectangular) is difficult to be reproduced in experiment. The dashed arrows indicate the predicted variation of melting current and voltage during experimental melting process of the system. The rightwards dashed arrow means that at a constant current, several mesh segments melt simultaneously leading to the increase of resistance and therefore the increase of the voltage. This phenomenon is defined as ***local instability***, which is a jump (e.g., from point P_A to point P_B in Fig. 5a) when compared to the melting current-voltage curve during numerical melting. The north east dashed arrow indicates that the increase of current is necessary for the further propagation of melting. This behavior is called ***stable melting***. Moreover, the existence of the maximum melting current, marked by a circle in Fig. 5a, tells that if the input current is high enough, the mesh segments will melt simultaneously until the circuit of mesh is open. This phenomenon is denoted as ***global instability***. On the other hand, for the mode of voltage-controlled current source (VCCS) in Fig. 5b, such regions with the decrease of voltage and the subsequent recovery (e.g., the area surrounded by dashed rectangular in the enlarged part) are difficult to realize experimentally. The dashed arrows indicate the predicted variation of melting current and voltage during experimental melting process of the system in a similar strategy with that for the mode of CCCS. There is the repetition of the vertical descent stage and the ascent stage until the circuit of mesh is open. The downwards dashed arrows indicate the vertical descent stages, where the melting of several mesh segments will happen simultaneously at a constant voltage, which shows local instability (e.g., the jump from point P_C to point P_D in Fig. 5b). The north east dashed arrows show the ascent stages, where the increase of voltage is requisite for the melting propagation, which shows stable melting. The only difference from that of CCCS mode is that there is no global instability for VCCS.

4. Conclusions

In the present work, the electrical breakdown of a metallic nanowire mesh induced by Joule heating is investigated by solving the corresponding electro-thermal problem, where the effect of electromigration is neglected for simplicity. A numerical computational program is developed to determine the temperature profile in the mesh, and the melting current triggering the melting of mesh segment. The structural melting of a metallic wire mesh is investigated by clarifying the variation of melting current with regard to the melting propagation of mesh segments. The melting behavior of a system of the mesh equipped with current source in real experiments can then be predicted, in which two modes of current source are discussed in detail. Local instability and stable melting will occur in spite of the mode of current source. Moreover, global instability only happens at the mode of current-controlled current source. This finding deepens the understanding of the electrical breakdown behavior of a metallic nanowire mesh, and may therefore contribute to the development of nanowire-based devices with high reliability.

Abstract Grass like architectures were synthesized directly on Silicon substrate by thermal oxidation method with nickel catalyst at low temperature. Humidity and catalyst played an important role in the fabrication of the grass like architectures. The morphology of the grass-like architectures was controlled by heating temperature. The grass like architectures were observed by scanning electron microscope (SEM, JSM-7000FK), Energy-dispersive X-ray (EDX) and X-ray diffraction (XRD). The grass like architectures were approximately 8-70μm in size with 1-2.5μm width leaves. The growth of grass like architectures affected by oxidation, vertical stress induced, and horizontal compressive stress was studied in details.

Keywords Grass like architectures, Thermal oxidation, Nickel catalyst, Compressive stress

1. Introduction

Cuprous oxide (Cu_2O) is a p-type semiconductor metal oxide with a direct band gap of about 2.17 eV. Due to its unique optical, electrical, and magnetic properties[1–3], and other properties such as simplicity and low cost of preparation, nontoxic nature, and abundance, it has attracted great attention and been widely applied in solar energy conversion[4], photocatalysis[5], sensors[6], negative electrode materials for lithium-ion batteries[7], electrochromism[8], and antibacterials[9]. The fundamental properties of micro/nanostructure semiconductors are found to be dependent on their architectures, including geometry, morphology, and hierarchical structures[10]. Therefore, great efforts have been devoted to artificially control the morphology of Cu_2O micro/nanocrystals in the past several years[11]. Different Cu_2O nano architectures have been synthesized, such as nanowhiskers[12], nanowires[13], nanocubes[14], nanorods[15], nanospheres[16], nanoflowers[17], nanocages[18]. A variety of methods have been reported to synthesize nanoflowers of different materials. These methods include hydrothermal synthesis[19], sol–gel method[20], chemical vapor deposition[21], ultrasonic pyrolysis[22], electrodeposition method[23], and solution routes[24].

Herein, we have developed novel syntheses of grass like Cu_2O architectures on silicon substrate with nickel-based catalyst at a low temperature. Although many studies proposed the evolution of different structures, the ability to manifest the precise growth mechanism of Cu_2O micro/nanostructures is still quite limited. In this work, the growth mechanism of Cu_2O grass-like architecture on silicon substrate was studied through the phenomenon of several contrast experiments.

2. Experiment

Commercial silicon wafer with a thickness of 0.50 mm was cut into square samples which were 20mm×20mm in size. The substrates were then ultrasonically (BRANSONIC1510) cleaned with acetone, washed with ethanol and de-ionized water sequentially to dissolve the contaminations. Nickel based catalyst used in this experiment was the high temperature electrically conductive coating material (Pyro-DuctTM 598-C, AREMCO, INC.). Catalyst was manually daubed on the silicon substrate as the shape of islands with diameter around 2-3 mm. Cu powder was dispersed around Ni on the substrate. Grass like architectures were then synthesized by heating the sample in wet air atmosphere at 200°C temperature for 3h.

After the heating process, morphologies of the oxidized specimens were characterized by the scanning electron microscopy (SEM, JSM-7000FK), Energy-dispersive X-ray (EDX) and X-ray diffraction (XRD).

3. Results and discussion

3.1. Experiment results

As shown in Fig. 1 grass like architectures, which were 8-70 μm in size with 1-2.5 μm width leaves grew mainly at the edge of the catalyst island. The contrast experiments showed that without the nickel based catalyst there would be no grass like architectures growing on the Si substrate even after the same heating process. Meanwhile, there was no grass like architectures growing on Si substrates which were heated at thermostatic drier and vacuum tank. Therefore, the catalyst, humidity and oxygen atmosphere were considered to be three of the important factors to affect the growth of grass like architectures.

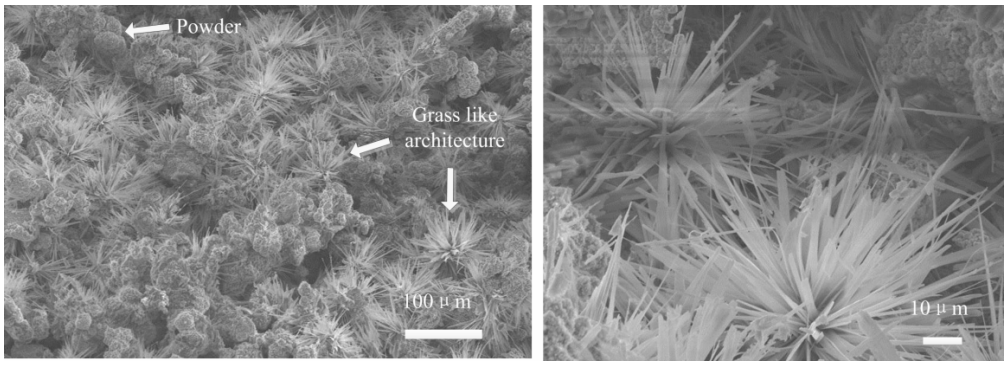

Figure 1. SEM image of grass like architectures

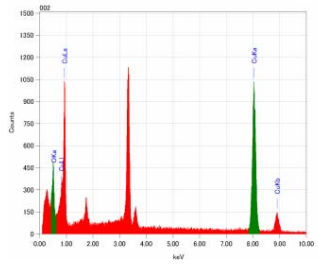

Element	Weight%	Atomic%
O K	12.17	35.50
Cu K	87.83	64.50
Totals	100	

Figure 2. EDX spectra of grass like architectures on Si substrate

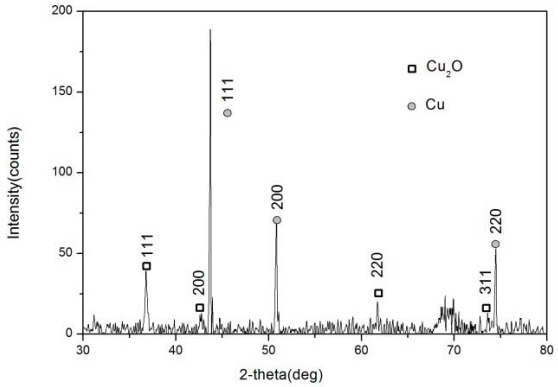

Figure 3. XRD spectra of grass like architectures on Si substrate

Energy-dispersive X-ray (EDX) analysis (Fig.2) indicates that the architectures are composed of Cu elements (35.50%) and oxygen elements (64.50%). The architecture was composed of Cu_2O

grass-like architectures, as confirmed by the X-ray diffraction (XRD) spectrum (Fig.3). The sharp diffraction peaks also indicate the sample is highly crystalline.

3.2. Discussion

The oxide formation appears to proceed via the diffusion of both copper and oxygen. Subsequently, oxidation takes place at the interface between the oxygen in the air and the Cu ions of the copper powders. Cu ions migrate from the inner of powder to the interface, according to stress induce mechanism. Meanwhile, the oxygen diffuses from outside to inside of interface in the opposite direction, according to Flick's first law[25]. As in figure 4, it was suspected that core(Cu)-shell(Cu_2O) composite structure developed in the Cu powder. It was in accord with the aforementioned EDX and XRD results, which were that the composition of grass like architectures was the Cu_2O and the powder was composed of Cu and Cu_2O.

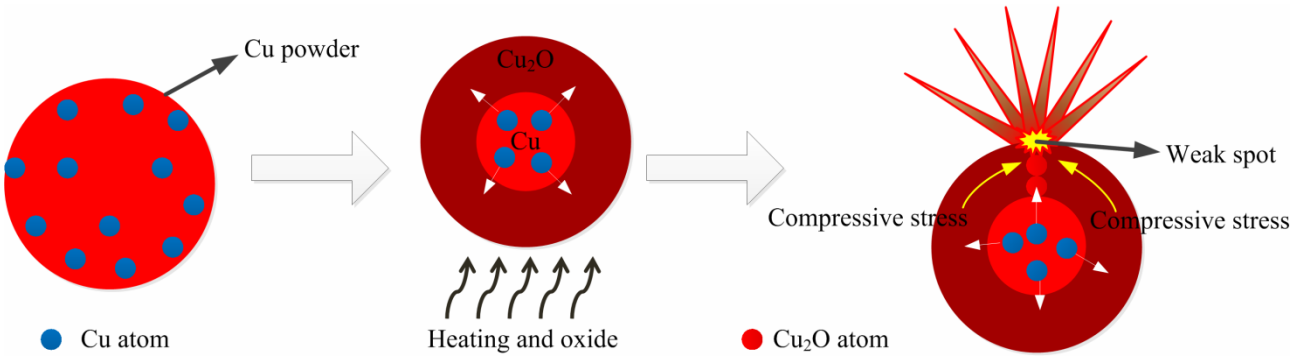

Figure 4. Schematic of atoms migration and its simplified mechanical model

Nickel based high temperature electrical conductive material played an important role in this process. It had the similar character as colloid nickel which has shown to be potential catalysts for selective hydrogenation, such as high surface-to-volume ratio for catalyst. However, colloid nickel can not resist the high temperature environment which is an essential factor for the formation of grass like architectures in our experiments. In our case, environment humidity supplied efficient water vapors from which nickel, as hydrogen absorption catalysts, would absorb hydrogen and left bivalent oxygen ions with two chemical bonds.

Normally, at 200ºC there would have nanowires generated at the surface. However, in our case it was suspected that the tangential direction compressive stress was increased by the composition effect of catalyst, humidity and oxidation during the heating process, as shown in Figure 4. The atom accumulated at the grain boundary under the oxide layer. Finally, with long enough heating time grass like architectures sprouted from the weak spots at the surface of the oxide layer.

It was suspect with longer heating time the core-shell composite structure in the Cu powder would disappear and the powder would be completely oxidized.

4. Conclusion

In summary, grass like architectures which were 8-70μm in size with 1-2.5μm width leaves has been successfully fabricated by thermal oxidation approach. The microstructures and compositions of the samples were characterized by SEM, EDX and XRD. The formation mechanism of grass like architectures were examined and proposed. The results showed that tangential direction compressive stress caused by the oxide layer of the Cu powder surface played a critical role in the

formation of grass like architectures. Compared with other methods for fabricating copper oxide grass like architectures, the method proposed in the paper featured simplicity and cheapness.

Abstract In this paper, a novel way that simulated the micro-crack initiation due to void nucleation under thermal fatigue was proposed using the combination of finite element modeling and Monte Carlo method. A 3D model that simulated the dynamic void nucleation process was constructed using the commercial FEA software ANSYS. The strain and thermal energies of the model due to the applied loads at elevated temperature are calculated. After manually including the grain structures, surface and bonding energies, a number of vacancies were randomly generated and they moved and nucleated according to the energy distributions of the model. To consider the problem at microscopic scale while still maintaining acceptable accuracy, two models are constructed, namely a real-sized full model and a micro-scale sub-model that included the microstructure. The impurities and the residue stresses that may affect the void nucleation process were included in the sub-model as well. The simulation results showed that the vacancies tended to nucleate at the "weak spots".

Keywords Metal fatigue, micro-crack initiation, finite element modeling

1. Introduction

Fatigue is the progressive damage to the material under cyclic loading and unloading. Cracks initiate at the stress concentration centers such as the surfaces, persistent slip bands or grain boundaries. The material eventually fractures even if the load is below its yield strength limit [1].

The initiation of the crack is due to the nucleation of tiny voids during the fatigue process [2]. Many simulation and experimental work had been conducted in the literature to study the crack initiation process using various approaches. For example, Piques *et al.* proposed a crack initiation model in 316L stainless steel based on the intergranular damage accumulation in the crack tip stress-strain field [3]. Nowack *et al.* studied the crack initiation and propagation of a Al 7475 sample under biaxial loading using the modified EVICD approach [4]. Haddar *et al.* developed a 2D model that simulated the crack initiation and shielding effects under thermal fatigue using the linear accumulation damage model [5]. Fine *et al.* predicted the fatigue crack initiation in single crystal iron and copper using the continuum models [6].

However, all the above-mentioned methods are modeled at macroscopic scale (i.e. mm scale). In fact, the voids inside the metal become visible at the size of 1 μm [7], which means the nucleation of the tiny voids start at microscopic scale. Such small crack is outside the regime of the conventional Paris's law and thus the traditional lifetime prediction cannot be applied. Furthermore, at micrometer scale, the change in lattice orientation affects the anisotropic stress distributions near the grain boundaries and this effect should not be ignored.

There is a number of reported works that studied the impact of microstructures on fatigue crack initiation. Vehoff *et al.* predicted the crack initiation at the grain boundary interfaces using the combination of the EBSD methods and the finite element stress analysis [8]. A microstructure sensitive crack nucleation criterion based on the local effective stresses and the non-local plastic strains and strain gradients was proposed by Kirane *et al.* [9]. Manonukul *et al.* developed a polycrystal plasticity finite element model that simulated the fatigue crack initiation based on the

critical resolved shear stress and the critical accumulated slip [10]. However, the dynamic void nucleation process under the applied loads was unable to be observed using the above methods.

Monte Carlo method, based on repeated random sampling algorithm [11], can be used to predict the grain size and structure [5], the crack growth and propagation [12, 13], the fatigue life and S-N curves [14, 15]. Monte Carlo method can also be used to simulate the diffusion and nucleation of the atoms under the applied loads (e.g. current, temperature, stress, etc.) [16-18]. To study the dynamic void nucleation and crack initiation process under fatigue, a novel way was introduced in this paper by incorporating the Monte Carlo method into the finite element models. Using this method, the dynamic motion of the atoms and vacancies before, during and after certain load cycle under the effects of temperature, stress, microstructure and surface condition forces and can be examined. The crack is assumed to initiate at the location of the void nucleation. Pure Al samples are used in this work.

2. Simulation Setup

The simulation is first performed on a dog-bone Al sample with the dimension shown in Figure 1. The chemical composition and the material properties measured from the sample are shown in Table 1 and 2 respectively.

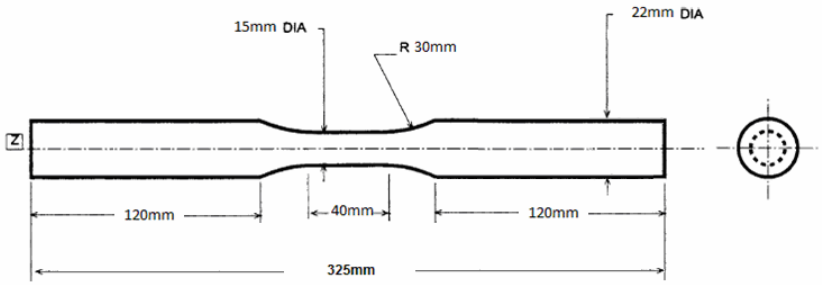

Figure 1. The dimension of the Al sample

Table 1. Chemical composition of the Al sample

ppm (parts per million)														
Al	Si	Fe	Cu	Mn	Mg	Cr	Ni	Zn	Ti	Ga	Pb	B	V	Zr
99.996%	6.20	2.20	0.10	3.90	1.00	1.20	0.30	2.70	1.10	5.50	0.10	0.80	2.40	0.80

Table 2. Physical properties of the Al sample

Young's Modulus (GPa)	Poisson's Ratio	Density (kg/m^3)	Thermal Expansion ($1/^oC$)	Yield Strength (GPa)	Thermal Conductivity ($W/m\cdot^oC$)	Specific Heat ($J/kg\cdot^oC$)
70	0.35	2700	2.24×10^{-5}	280	221.75	899.56

The initial temperature of the sample is assumed to be 27 ^oC and it is placed inside an oven with a constant temperature of 100 ^oC and heated up for 10 minutes. The convection heat transfer coefficient of the sample is 25 $W/m^2\cdot^oC$ [19]. A force of 5 kN is applied at one side of the sample and the other side is fixed and is not free to move. Finite element SOLID 69 and SOLID 45 is used in the thermal and structural-thermal simulation in ANSYS respectively.

To include the microstructure and the surface effects, a 70 μmx60 μmx30 μm sub-model is cut out from the central surface of the dog-bone sample (i.e. the full model), and the grain structures are added to the sub-model according to the EBSD map of this surface. The meshed full model and sub-model are shown in Figure 2. The nodal temperature and stress values extracted from the full model simulation are used as the boundary conditions for performing the sub-model simulation.

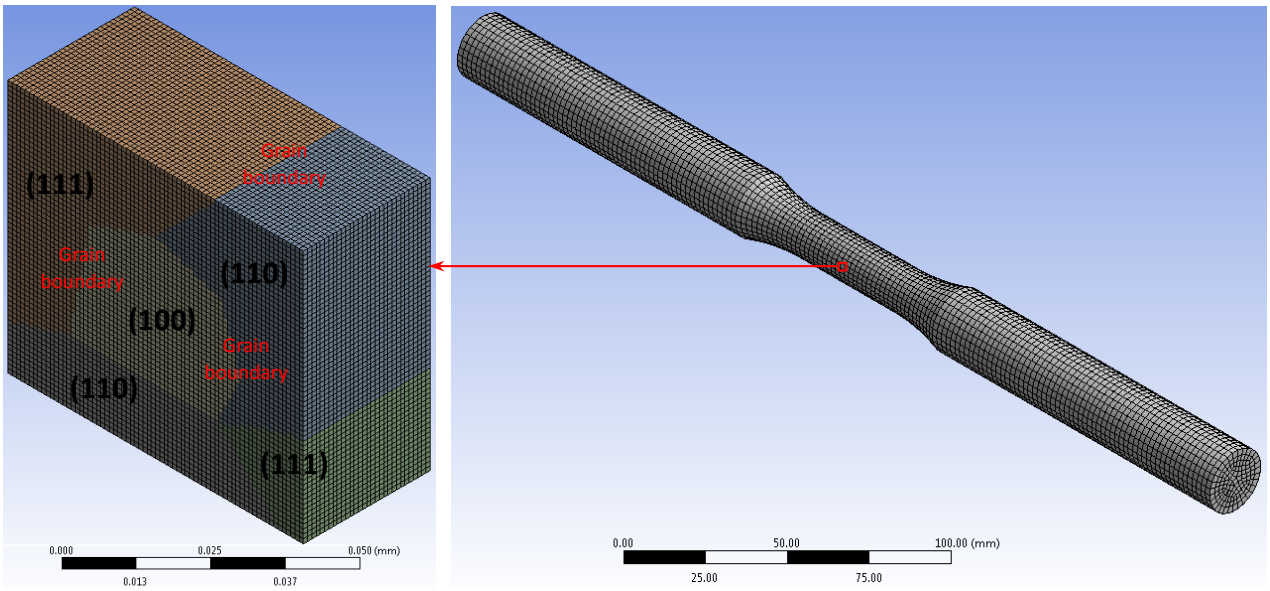

Figure 2. The micro-scale sub-model (left) cut out from the real-sized full model (right)

The nucleation of the voids is due to the movement of the atoms and the vacancies in the material, which is in turn determined by their energy states. With the presence of the external and internal factors, the atoms move and fill in the position of their neighboring vacancies in order to lower the total energy state of the system. The continuous movement causes the nucleation of the voids and the formation of the micro-cracks.

There are three types of energies that determine the total energy state of an atom, namely the thermal energy, the strain energy, and the pairing energy. The thermal and strain energy are external excitations due to the applied temperature and force respectively. The pairing energy is the energy required to excite the atom from its lowest energy state and free it out from its surrounding atoms. The pairing energy is the sum of the total bonding energy of the atom with its nearest neighbors, and is affected by the lattice orientation, the presence of the vacancies and impurities, as well as the surface condition.

The external excitations rise the energy state of the atom and when they are high enough to overcome the energy barrier (i.e. the pairing energy), the atom will become unstable and move to its neighboring vacant lattice site, as shown in Figure 3.

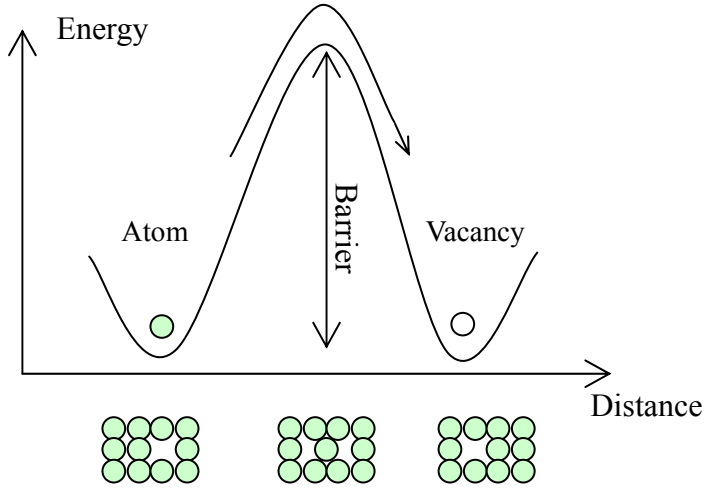

Figure 3. The movement of an atom from its original position into a vacant lattice site

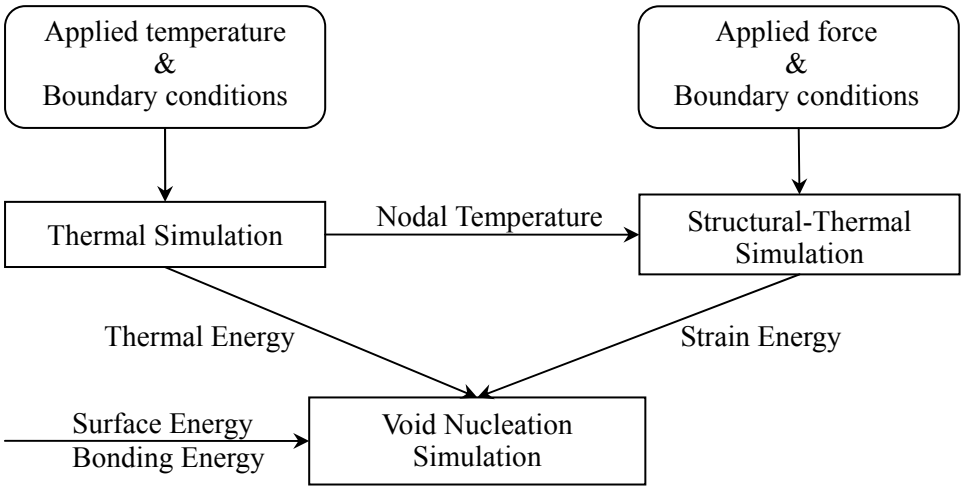

Figure 4. The flow chart of the ANSYS simulation

Figure 4 shows the flow chart of the ANSYS simulation. Based on the values computed in the thermal and structural thermal simulations, the thermal and strain energy are calculated using Equation (1) and (2) respectively [20],

$$E_{th} = N \times \frac{3}{2} k_B T \tag{1}$$

$$E_{str} = E_e^{el} + E_e^{pl} = \frac{1}{2}\{\sigma\}^T \{\varepsilon^{el}\} vol_e + \{\sigma\}^T \{\Delta\varepsilon^{pl}\} vol_e \tag{2}$$

where N is the number of the atoms, T is the location temperature, k_B is the Boltzmann's constant, E_e^{el} and E_e^{pl} are the elastic and plastic strain energy respectively, $\{\sigma\}$ is the stress vector, $\{\varepsilon^{el}\}$ is the elastic strain vector, $\{\Delta\varepsilon^{pl}\}$ is the plastic strain increment, and vol_e is the volume of the atom.

Depending on the position of the atom and the types of its neighboring atoms, the bonding energy are classified as the following categories in our simulation, as shown in Figure 5.

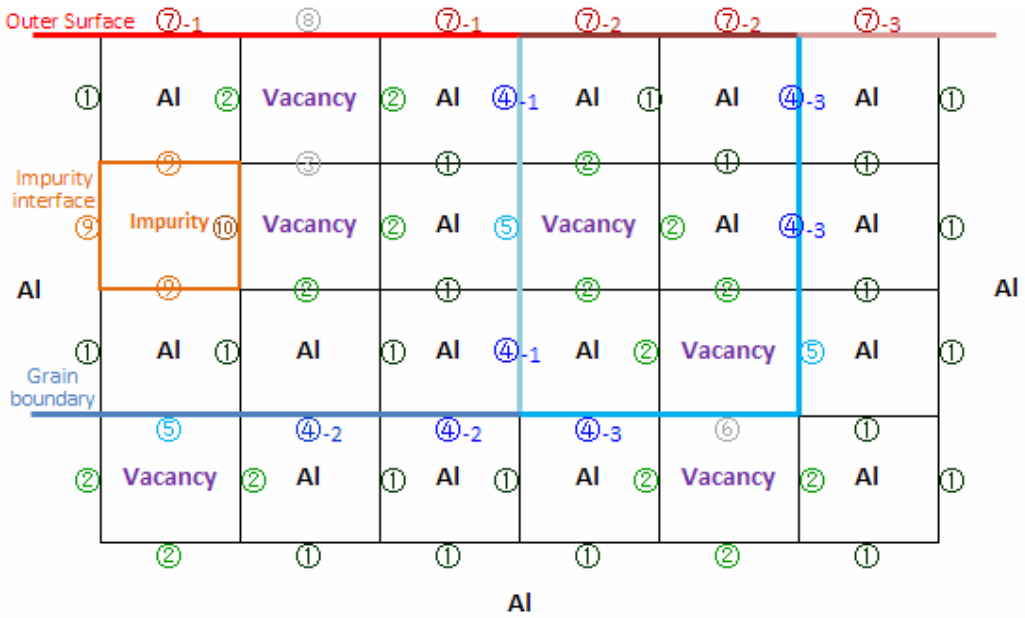

Figure 5. Different types of bonding energies used in the simulation in 2D view

(1) Inside the grain:
- Type 1: bonding energy between the Al atoms

- Type 2: bonding energy between the Al atom and the vacancy
- Type 3: bonding energy between the vacancies

(2) On the grain boundary:
- Type 4: bonding energy between the Al atoms on the grain boundary
- Type 5: bonding energy between the Al atom and the vacancy on the grain boundary
- Type 6: bonding energy between the vacancies on the grain boundary

(3) On the surface:
- Type 7: surface energy of the Al atoms with different lattice orientation
- Type 8: surface energy of the vacancies

(4) In contact with the impurity (if any):
- Type 9: adhesion energy between the Al atom and the impurity
- Type 10: bonding energy between the vacancy and the impurity

The bonding energy between the Al atoms inside the grain is 1.50 eV [21]. The bonding energy between the Al atom and the vacancy is 0.29 eV [22], and that between the vacancies is assumed to be zero. The surface energies of Al for lattice orientation (100), (110), and (111) are calculated as 0.95, 1.02 and 0.79 J/m^2 respectively using the density function theory (DFT) and the VASP software [23]. The surface energy of the vacancy is assumed to be zero. The bonding energy for the atoms on the grain boundary is approximated to be 40% of that inside the grain [24, 25]. The adhesion energy between the Al atom and the impurity (e.g. Si) is 1.09 J/m^2 [26], and 0.20 eV is used as the bonding energy between the vacancy and the Si impurity [27]. The Young's Modulus of Al for lattice orientation (100), (110), and (111) are calculated as 63.05, 71.88 and 76.05 GPa respectively [28].

The probability of atom to fill in its neighboring vacant lattice site is calculated using Equation (3) [16],

$$Probability = \exp\left(-\frac{\Delta E_{th} + \Delta E_{str} + \Delta E_{pair}}{N \times k_B T}\right) \tag{3}$$

where ΔE_{th}, ΔE_{str} and ΔE_{pair} are the change in thermal, strain and pairing energy between the target position and the original position of the atom respectively.

To begin the void nucleation simulation, 0.01% to 0.1% vacancies are randomly generated inside the sub-model depending on whether it is inside the grain or on the grain boundary [29, 30]. A few Si impurities are generated on the grain boundary as well. As the voids are only visible at micrometer scale [7], we assume the initial size of the vacancy to be 1 μm^3, which is also the size of one element in the sub-model. The thermal and strain energy of each element are calculated using Equation (1) and (2), and the pairing energy is calculated based on the position of the element and the number and type of its neighboring elements. In the Monte Carlo subroutine, a vacant site is randomly selected and total change in energy between the selected vacancy and its neighboring elements are computed. The neighboring element exchange position with the vacancy (i.e. fill in the position of the vacant site) if the probability of movement is larger than 0.5 [25]. The continuous position swapping process results in the movement of the vacancies and the nucleation of the voids.

3. Results and discussions

The position of the vacancies at the beginning, during and the end of the simulation after 1500 Monte Carlo cycles are shown in Figure 6(a) (b), and (c) respectively.

(c)

Figure 6. The vacancy position (a) at the beginning (b) during and (c) at the end of the simulation. The red dots are the vacancies and the blue dots are the impurities.

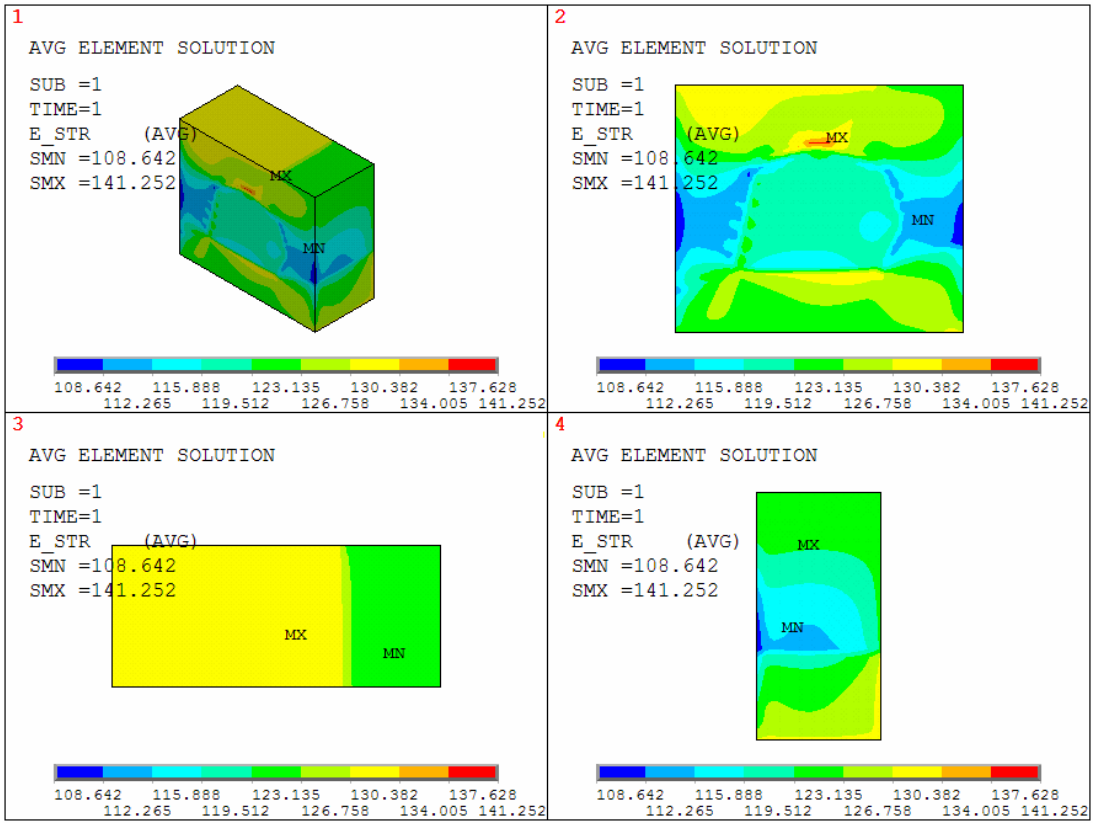

Figure 7. The strain energy distribution of the sub-model. High strain energy concentration is found at grain boundary triple point region.

From Figure 6, it can be seen that most of the vacancies nucleate at the grain boundary triple point region, as shown by the arrows and circles. This is because the stress inhomogeneity between different grains causes the concentration in strain energy along the grain boundary, especially at the triple point, as can be seen in Figure 7. Hence the vacancies tend to move to these regions in order to lower the total energy of the system. On the other hand, the presence of the impurities increases the stress around them slightly. This causes a slight instability in energy in the regions around the impurities. Therefore the impurities are able to attract some of the vacancies as well, and a few red spots are found around the blue spots in Figure 6.

The presence of the residue stress may increase or decrease the stress state on the sub-surface depending on whether it is tensile or compressive. This can affect the void nucleation process as well. The simulation is performed again with 10% increase in sub-surface stress due to tensile residue stress and the final vacancy position is shown in Figure 8. It can be seen that the presence of the residue stress attracts some vacancies to the surface, as shown by the arrows and the rectangle in Figure 8. Additional cracks may form at this region.

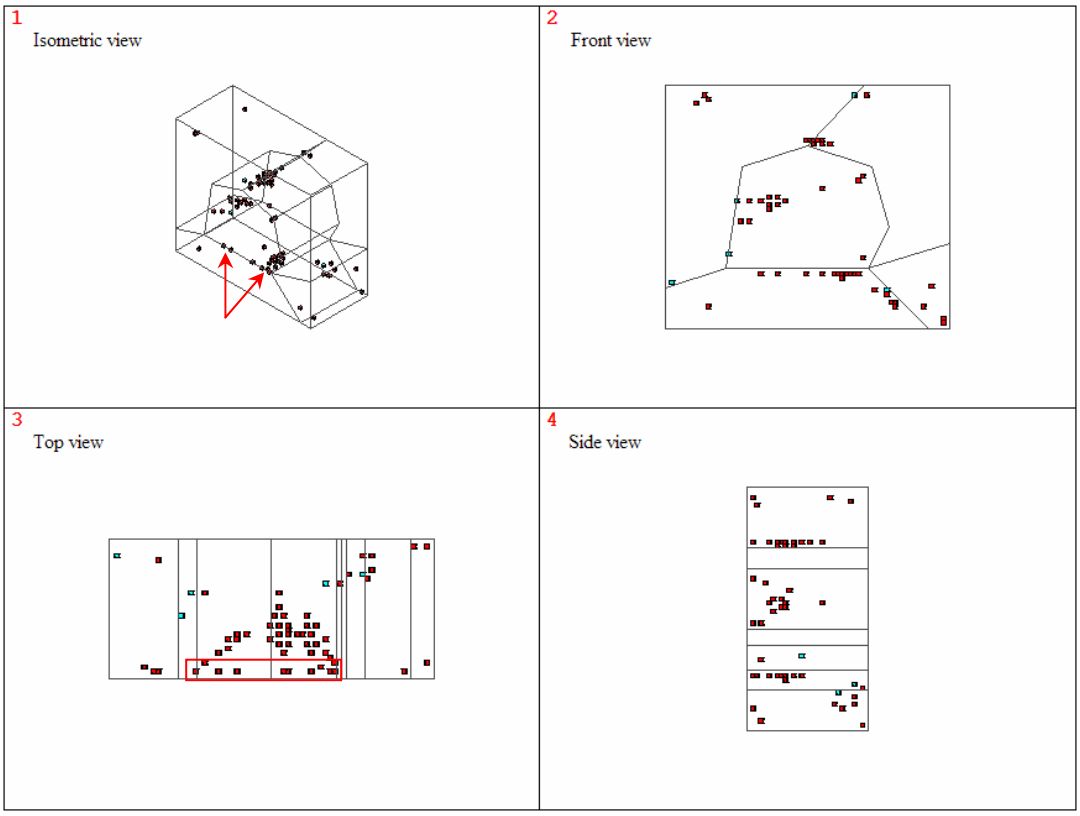

Figure 8. The vacancy position at the end of the simulation with the presence of the residue stress.

4. Conclusions

A finite element model that simulated the void nucleation process under thermal fatigue using the combination of finite element modeling and Monte Carlo method was presented in this paper. The simulation was first performed on a real-sized full model that contained the real time temperature and stress profile of the sample. The simulation was then carried out on a micro-scale sub-model that contained the microstructure and the imperfections, as well as different bonding and surface energies caused by the change in lattice orientation. The movement of the vacancies due to the uneven energy distributions of the model was observed and the void nucleated at the region with higher strain energies (i.e. the “weak spot”). Experimental verification of our method is underway.

Abstract The high current density occurring in integrated circuits induces electromigration (EM) of the metal lines used for electric wirings. A void is formed by EM in the line material and the growth of void leads to the line failure. Recently, multilevel interconnection is widely used in electronics devices and MEMS by connecting upper and lower metal lines through vias. The reservoir structure is often constructed in the multilevel interconnection. It is known that there is threshold current density of EM damage in multilevel interconnection with vias. It is important to evaluate the threshold for determination of allowable electric current in the interconnection. In this study, a numerical simulation technique for analyzing the atomic density distribution generated by EM in the line is applied to evaluate the EM risks of metal line in several kinds of the multilevel structures. The thresholds of current density leading to EM change were calculated through the simulations. We confirmed that the atomic density distribution in the line was essential to increase the threshold and to prevent EM damage in the line. And we also showed the simulation technique was useful in the design of safety structure of electric wirings in integrated circuits.

Keywords Integrated Circuit, Reliability, Electromigration, Multilevel Interconnection, Allowable Current Density

1. Introduction

The high current density occurring in integrated circuits induces electromigration (EM) of the metal lines used for electric wirings. EM is a phenomenon that metallic atoms are transported by electron wind and that void, due to depletion of metallic atoms, is formed in the metal line. As the voids are growing the current density in the metal line increases and then the excessive Joule heating leads to metal line failure. Recently, multilevel interconnection is widely used in electronic devices and MEMS by connecting upper and lower metal lines through vias. The structure of interconnect tree and reservoir structure are constructed in the multilevel interconnection. Reservoir structures have an overhang from via connection, and it is usually located at vias on both anode and cathode sides as shown in Fig. 1. Reservoir structure gives delay of EM failure in multilevel interconnection by increasing margin of critical void length. The effect is caused by metallic atoms supplied from the overhanging parts as atom's reservoir to the metal line. The transportation of atoms is induced by tensile stress at the connection part on cathode side via as a result of EM. It is known that there is threshold current density j_{th} of EM damage in multilevel interconnection with vias. It is important to evaluate the threshold for determination of allowable electric current in the interconnection. Some research groups have developed evaluation method of j_{th} [1]. The threshold current density is also evaluated by numerical simulation. The building-up process of atomic density distribution in the line is simulated. And the simulation is based on a governing parameter for EM damage in polycrystalline line AFD^*_{gen} [2]. The parameter is applicable to two-dimensional line shape. Sasagawa et al. have evaluated j_{th} of several kinds of interconnect tree structure [3].
In this study, a numerical simulation technique for analyzing the atomic density distribution generated by EM in the line is applied to evaluate the EM risks of metal line in several kinds of the reservoir structures. The threshold j_{th} of several kinds of straight via-connected line with reservoir are evaluated by the numerical simulation. From the evaluation results, reservoir effects on the threshold current density are discussed.

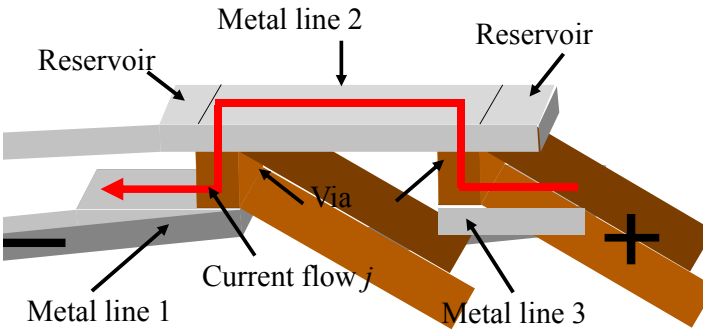

Figure 1. Multilayer interconnection with reservoir structure

2. Simulation method

The governing parameter for EM damage is used for constructing the numerical simulation [2]. The parameter is given by formulation of divergence of atomic flux due to EM. The atomic flux vector **J** is represented by Eq. (1).

$$|\mathbf{J}| = \frac{ND_0}{kT}\exp\left\{-\frac{Q_{gb}+\kappa\Omega(N-N_T)/N_0-\sigma_T\Omega}{kT}\right\}\left(Z^*e\rho j^*-\frac{\kappa\Omega}{N_0}\frac{\partial N}{\partial l}\right) \qquad (1)$$

where N is atomic density, D_0 a prefactor, k Boltzmann's constant, T the absolute temperature, Q_{gb} net activation energy for atomic diffusion, κ the constant relating the change in stress with the change in atomic density under restriction by passivation, N_T the atomic density under tensile thermal stress σ_T, N_0 the atomic density at a reference condition, Ω the atomic volume, Z^* the effective valence and e the electronic charge. ρ is the temperature-dependent resistivity. Symbols j^* and $\partial N/\partial l$ are the components of the current density vector and atomic density gradient in the direction of **J**, respectively. In Eq. (1), the back flow of atoms due to the stress gradient and the effect of the stress generated in the metal line on diffusivity are taken into account.

Grain boundary diffusion is assumed as dominant diffusion mechanism in the simulation, because wide Cu lines covered with passivation layer were supposed. According to literature [4, 5], in wide Cu interconnects, grain boundaries become preferential EM paths rather than lattice and interface diffusions. Sasagawa et al have introduced a grain texture model for calculating atomic flux divergence [6]. So we used the governing parameter for EM damage based on the model even for Cu lines.

Considering atoms going in and out at a unit rectangle, atomic flux divergence in polycrystalline line is formulated as given in Eq. (2).

$$
\begin{aligned}
AFD^{*}_{\mathrm{gb}\theta} = {} & C^{*}_{\mathrm{gb}} N \frac{4}{\sqrt{3}d^{2}} \frac{1}{T} \exp\left\{ - \frac{Q_{\mathrm{gb}} + \kappa\Omega\left(N - N_{\mathrm{T}}\right)/ N_{0} - \sigma_{\mathrm{T}}\Omega}{kT} \right\} \times \\
& \left\langle \sqrt{3}\Delta\varphi \left\{ \left(j_x \cos\theta + j_y \sin\theta \right) Z^{*} e\rho - \frac{\kappa\Omega}{N_0} \left(\frac{\partial N}{\partial x} \cos\theta + \frac{\partial N}{\partial y} \sin\theta \right) \right\} \right. \\
& - \frac{d}{2}\Delta\varphi \left\{ \left(\frac{\partial j_x}{\partial x} - \frac{\partial j_y}{\partial y} \right) Z^{*} e\rho \cos 2\theta - \frac{\kappa\Omega}{N_0} \left(\frac{\partial^2 N}{\partial x^2} \cos\theta + \frac{\partial^2 N}{\partial y^2} \sin\theta \right) \cos 2\theta \right. \\
& \qquad \left. + \left(\frac{\partial j_x}{\partial y} + \frac{\partial j_y}{\partial x} \right) Z^{*} e\rho \sin 2\theta - 2 \frac{\kappa\Omega}{N_0} \frac{\partial^2 N}{\partial x \partial y} \sin 2\theta \right\} \\
& - \frac{\sqrt{3}}{4} d \frac{\kappa\Omega}{N_0} \left(\frac{\partial^2 N}{\partial x^2} + \frac{\partial^2 N}{\partial y^2} \right) - \frac{\kappa\Omega / N_0}{kT} \\
& \quad \times \left[\frac{\sqrt{3}}{4} d \left\{ Z^{*} e\rho \left(j_x \frac{\partial N}{\partial x} + j_y \frac{\partial N}{\partial y} \right) - \frac{\kappa\Omega}{N_0} \left(\frac{\partial N}{\partial x} \frac{\partial N}{\partial x} + \frac{\partial N}{\partial y} \frac{\partial N}{\partial y} \right) \right\} \right. \\
& \quad \left. - \frac{d}{2}\Delta\varphi \left\{ Z^{*} e\rho \left(j_x \frac{\partial N}{\partial y} + j_y \frac{\partial N}{\partial x} \right) - 2 \frac{\kappa\Omega}{N_0} \frac{\partial N}{\partial x} \frac{\partial N}{\partial y} \right\} \sin 2\theta \right] \\
& + \frac{\sqrt{3}d}{4T} \left\{ \frac{Q_{\mathrm{gb}} + \kappa\Omega\left(N - N_{\mathrm{T}}\right)/ N_{0} - \sigma_{\mathrm{T}}\Omega}{kT} - 1 \right\} \\
& \quad \left. \times \left\{ Z^{*} e\rho \left(j_x \frac{\partial N}{\partial y} + j_y \frac{\partial N}{\partial x} \right) - \frac{\kappa\Omega}{N_0} \left(\frac{\partial N}{\partial x} \frac{\partial N}{\partial x} + \frac{\partial N}{\partial y} \frac{\partial N}{\partial y} \right) \right\} \right\rangle, \qquad (2)
\end{aligned}
$$

where C^{*}_{gb} represents the product $D_0\delta$ /k denoting the effective width of the grain boundary by δ, d the average grain size, and $\Delta\varphi$ a constant related to the relative angle between grain boundaries as shown in Fig. 2. The quantities j_x and j_y are components of the current density vector $\boldsymbol{j}$ in Cartesian coordinates, x and y. θ is angle between microstructure unit shown as rectangular in the figure and x axis.

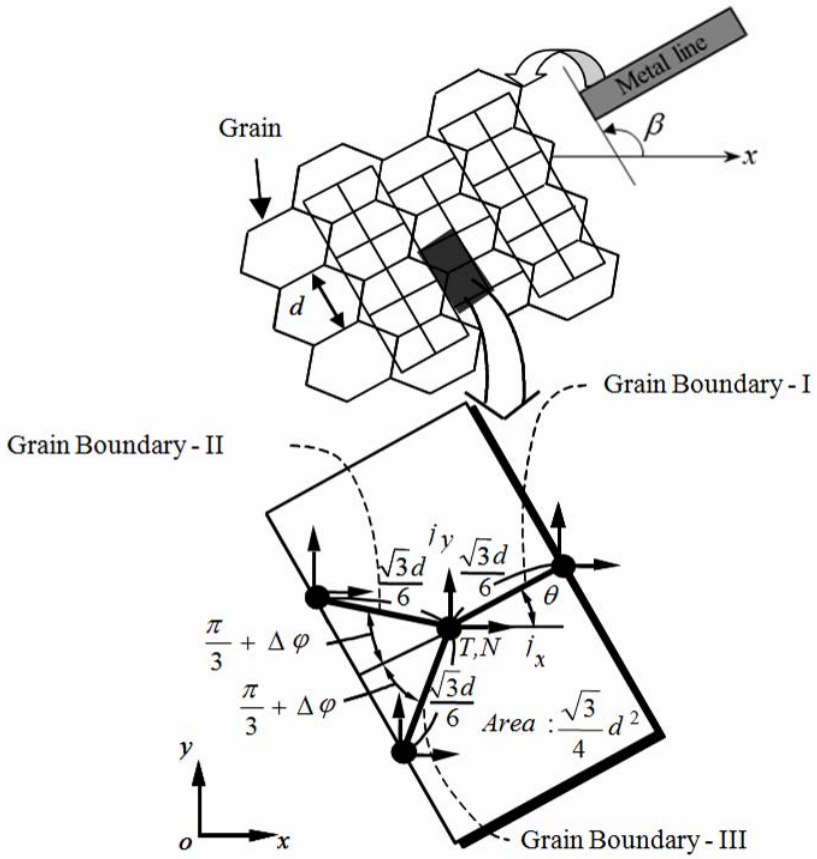

Figure 2. A model of polycrystalline structure

The expectation value of the only positive values of $AFD^*_{gb\theta}$ is obtained, and it represents the parameter governing EM damage, AFD^*_{gen}, concerning void formation in a polycrystalline line as

$$AFD^*_{gen} = \frac{1}{4\pi}\int_0^{2\pi}\left(AFD^*_{gb\theta} + \left|AFD^*_{gb\theta}\right|\right)d\theta \qquad (3)$$

It means the number of atoms decreasing per unit time and unit volume.

At line ends, boundary condition with respect to atomic flow has to be given for the formulation of the parameter at line ends. Namely, there is no coming-in at cathode end of the line and no going-out at anode one. The boundary condition can be expressed by possible zero flux within the microstructure unit being assigned to each θ-range as listed in Table 1 [7].

Table 1. Boundary condition concerning atomic flux

Range-I	Range-II	Range-III
$-2\pi/3+\Delta\varphi+\beta<\theta\leq-\pi/3-\Delta\varphi+\beta$	$-\pi/3-\Delta\varphi+\beta<\theta\leq\beta$	$\beta<\theta\leq\pi/3+\Delta\varphi+\beta$
$J_{II}=J_{III}=0$	$J_{II}=0$	$J_I=J_{II}=0$
Range-IV	Range-V	Range-VI
$\pi/3+\Delta\varphi+\beta<\theta\leq2\pi/3-\Delta\varphi+\beta$	$2\pi/3-\Delta\varphi+\beta<\theta\leq\pi+\beta$	$\pi+\beta<\theta\leq4\pi/3+\Delta\varphi+\beta$
$J_I=0$	$J_I=J_{III}=0$	$J_{III}=0$

Thus, considering coming and going of atoms within the microstructure unit, the atomic flux divergence at the line end, $AFD^*_{\mathrm{gen}|\mathrm{end}}$ is expressed by Eq. (4).

$$AFD^*_{\mathrm{gen}}\big|_{\mathrm{end}} = \frac{2}{\sqrt{3}\pi d^2}\frac{C^*_{gb}N}{T}\exp\left(-\frac{Q_{gb}+\kappa\Omega(N-N_T)/N_0-\sigma_T\Omega}{kT}\right)\Bigg[\ 6D_x\sin\beta-6D_y\cos\beta$$
$$+\frac{\sqrt{3}}{4}\pi d\Bigg\{\ -\frac{\kappa\Omega}{N_0}\left(\frac{\partial^2 N}{\partial x^2}+\frac{\partial^2 N}{\partial y^2}\right)-\frac{\kappa\Omega/N_0}{kT}\left(D_x\frac{\partial N}{\partial x}+D_y\frac{\partial N}{\partial y}\right)$$
$$+\frac{1}{T}\left(\frac{Q_{gb}+\kappa\Omega(N-N_T)/N_0-\sigma_T\Omega}{kT}-1\right)\left(D_x\frac{\partial T}{\partial x}+D_y\frac{\partial T}{\partial y}\right)\Bigg\}\ \Bigg] \qquad (4)$$

where $D_x=Z^*e\rho j_x-\kappa\Omega/N_0(\partial N/\partial x)$, $D_y=Z^*e\rho j_y-\kappa\Omega/N_0(\partial N/\partial y)$. $AFD^*_{\mathrm{gen}|\mathrm{end}}$ expresses the amount of flux divergence at line end and represents the number of atoms decreasing per unit volume and unit time.

Using the governing parameter of EM damage, numerical simulation of atomic density distribution in interconnect is performed under some kinds of input current density, j, at a certain substrate temperature, T_s. The line to be evaluated is two-dimensionally divided into elements and building up process of atomic density distribution is simulated by changing the atomic density of each elements based on the parameter. The boundary condition with respect to temperature is given on both line ends and that with respect to current density is given on via position. Atomic flow is insulated around the metal line. The end-parameter $AFD^*_{\mathrm{gen}|\mathrm{end}}$ is used in elements at cathode and anode ends and on via and AFD^*_{gen} is used for elements except both line ends.

The computational procedure is shown in Fig. 3. At first, the distributions of current density and temperature are calculated by two-dimensional FE analysis. The governing parameters are calculated in each element from the analysis results and the film characteristics. Next, the atomic density related to θ, N^*, is calculated based on the value of the governing parameter. The atomic density in each element N is calculated by averaging N^* among all θ's value. By the repetitive calculation, the atomic density distribution in the line grows with time. The iteration is performed until the atomic density reaches a critical atomic density for damage initiation N^*_{min} or holds a steady state. If atomic density becomes steady state without reaching N^*_{min}, the input current density given in the simulation would be less than j_{th}.

3. Evaluation

We evaluated four line structures as shown in Fig.4. Sample 1 has no reservoir at both ends of line. Sample 2 has two reservoirs located on both vias. Sample 3 has a reservoir located only on the cathode via. And Sample 4 has a reservoir located only on the anode via. In each sample, the reservoir having shorter length was evaluated. After the simulation with current density smaller than the threshold, a steady state distribution of atomic density should be got without reaching critical atomic density N^*_{min}. The smallest value of the atomic density N^* in all elements at steady state is plotted against supposed current density j. From an intersection point of the line of the smallest atomic density N^* and the critical density, the threshold current density is evaluated.

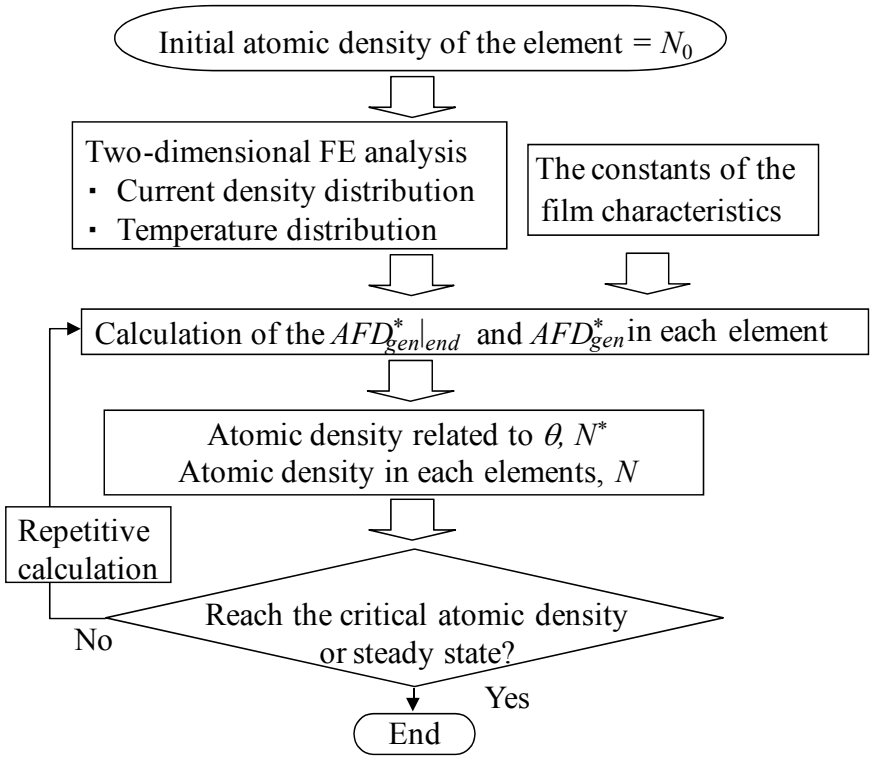

Figure 3. Computational procedure for evaluation of the threshold current density

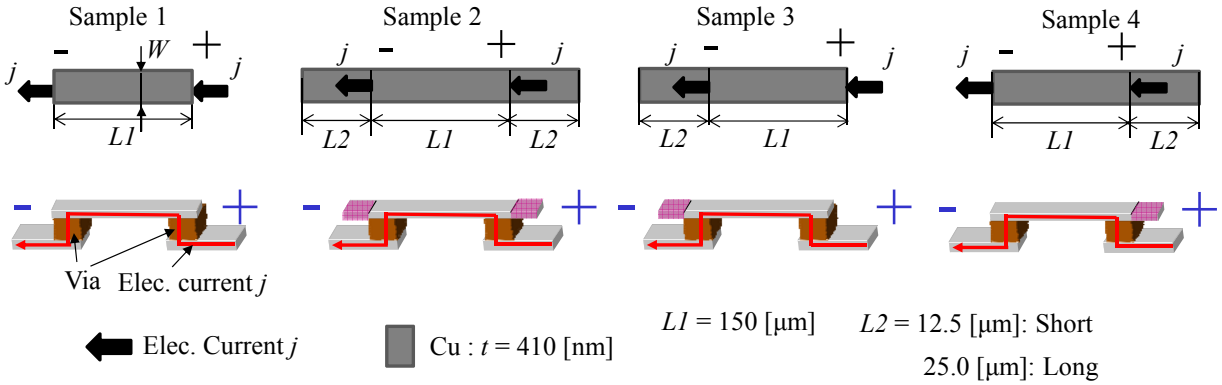

Figure 4. The dimension and structure of the supposed lines

In this simulation, Cu line is assumed having characteristic constants listed in Table 2 [8]-[12]. We supposed three values of input current density, 0.2, 0.4 and 0.6 MA/cm^2. The operating temperature is assumed 573K for all samples.

Table 2. Characteristic constants used in simulation

Characteristic constants	Value	Reference	
D_0 [μm²/s]	3.35	[8]	
Q_{gb} [eV]	1.1	[9]	
Ω [μm³]	3.00×10^{-11}		
Z^*	1	[10]	
ρ_0 [Ωμm]	0.0345 at 573[K]	[11]	
α [K⁻¹]	0.0043 at 573[K]	[11]	
κ [GPa]	42.5	[12]	Cited from results for Al interconnect
N^*_{min} [μm⁻³]	8.40×10^{10}	[12]	
N^*_{max} [μm⁻³]	8.56×10^{10}	[12]	
d [μm]	0.8		

4. Results and discussion

Figure 5 shows the smallest atomic density calculated in the long type reservoir case. The values of threshold current density j_{th} were determined in each sample and listed in Table 3. No reservoir and both reservoirs cases (Sample 1 and 2) were almost the same values. The j_{th} in the cathode reservoir case (Sample 3) showed larger value than those of others. On the other hand, anode reservoir case (Sample 4) showed smaller value than no reservoir case (Sample 1).

According to Eq. (1), if current density is the same, driving force of EM is same. So at steady state, the slope of atomic density corresponds to each other. On the other hand, current density in reservoir is almost zero, and there is not driving force of EM. So at steady state, the slope of atomic density in reservoir becomes almost horizontally. According to conservation law of mass, atomic density distribution in Sample 3 must be shifted upward globally from distribution in Sample 1.

In comparison of length of reservoir, change in j_{th} from Sample 1 or 2 was enhanced by extension of the reservoir.

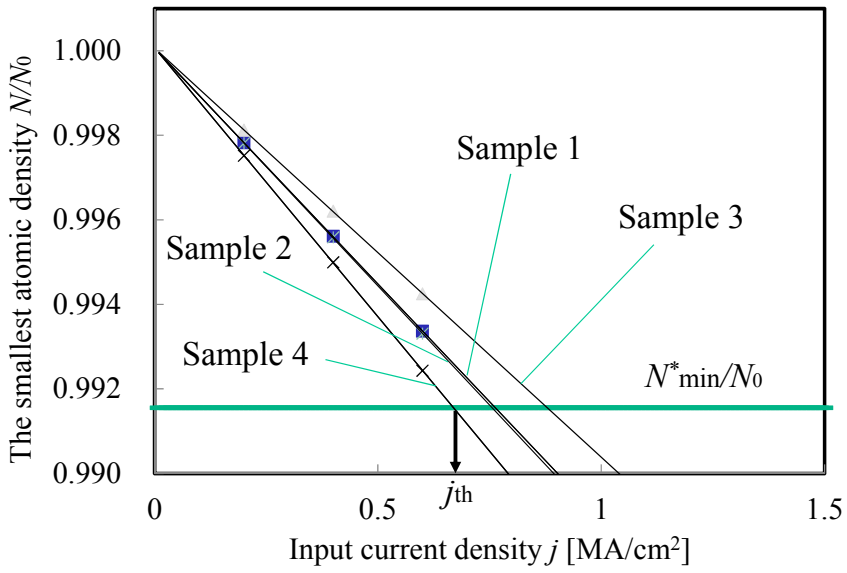

Figure 5. Results of threshold current density in simulation of long type (L_2 =25 μm) reservoir

Table 3. Threshold values of current density j_{th} [MA/cm^2] obtained from simulations

Sample type		1: none	2:+-	3:-	4:+
Reservoir length	Short	0.77	0.76	0.82	0.71
	Long		0.76	0.88	0.67

5. Conclusions

The numerical simulation technique was applied to evaluation of reservoir structure and AFD^*_{gen} -based evaluation of j_{th} was carried out. We found that if a reservoir is located only on the cathode via, the threshold current density of EM damage is increased. And it was concluded that this phenomenon is caused by the change in atomic density distribution among a metal line.

Abstract: Microelectromechanical systems (MEMS) are usually fragile to wear problems. In this research, a bulk-fabricated side-wall Si-MEMS tribotester with the feature of on-chip buckle loading mechanism was designed and used to study the wear life and the mechanisms of early stage wear of resonant MEMS devices in different gas environments. Two distinguishable wear mechanisms are recognized: (1) in dry N_2 or O_2/N_2 mixture environments, wear exhibited an adhesive feature that the instantaneous wear rate is inversely proportional to the wear depth; (2) if corrosive vapors, such as fatty alcohols, are introduced into the environment, chemical reaction can limit the wear rate as a constant. In more complex situation, such as trifluoroethanol vapor, the rubbing process shows a transition from a short adhesive wear phase to a corrosive wear process. The thermal- and tribo-solvolysis could not give a full explanation of the life-time tests for the tested fatty alcohols. Therefore, there must be derivative reactions of grafting groups at silicon surfaces, which cause the instability of such groups. A mechanochemical mechanism is established to understand the stability of grafting groups in friction situation. Compared with fatty alcohols, fluoroalcohol is much more stable and can be used as vapor lubricant for Si-MEMS devices.

Key words: MEMS, wear, solvolysis, mechanochemistry

1. Introduction

Microelectromechanical systems (MEMS) are a class of IC-compatible sophisticated mechanisms to realize highly controllable precision motions at micro/nano scales. Compared with the failure modes of fracture and fatigue, tribological problems, including adhesion, friction and wear, are the main factors which give rise to device failure at such scales owing to the high surface-to-volume ratios of these devices [1]. Until now the adhesion problem can be solved by lowing down the surface energy using self-assembly monolayers (SAM), such as fluoro-substituted tris(dimethylamino)silane [2]. However, SAM could not provide persistent protection of contacting surfaces from wear to achieve enough life-time [2-4]. To overcome the wear problem, lubricant needs to be able to diffuse onto the moving part continuously. Two instances of vapor phase have been successfully used to lubricate tribo-MEMS devices, one is perfluorodecanoic acid vapor using for protecting the aluminum protrusion in Digital Micromirror Device^{TM} [5], and the other is 1-pentanol vapor which is effective to prolong the life-time of silicon micro-tribotester fabricated by Sandia National Laboratory [6]. The possible reasons for the good lubricity of these two lubricants are not exactly the same. For the perfluorodecanoic acid, the competitive adsorption may reduce the corrosion of water on aluminum material, while the 1-pentanol can react with silicon in a soft manner to avoid adhesive wear, which is the most common wear mechanism of silicon materials [7]. In order to expand applications of MEMS, looking for a suitable lubricant and understanding the wear mechanism at micro scales becomes particularly important.

For tribo-MEMS, devices are easy to fail at the early stage of wear, only allowing for blunt rough asperities and a small number of wear debris. To study the early stage of wear, a

bulk-fabricated side-wall micro tribotester is designed to test the wear life of silicon in different vapor environments. In this paper, we first introduce the tribotester and the experimental details. In Section 3, adhesive and corrosive wear are distinguished by the motion mode of the driving shuttle. In Section 4, we analysis the corrosive wear of fatty and fluoro- alcohols, pointing out that the solvolysis can not give a full explanation of tribochemical reactions of fatty alcohols on silicon surfaces. A mechanochemical mechanism is proposed to understand the stability of grafting groups in the presence of friction, helping to explain the stability of fluorocarbon chains on silicon surfaces.

2. Experimental details

Every 50-μm-thick Si-MEMS tribotester consists of a driving shuttle and a pair of loading frames (Fig. 1). The on-chip buckle structure can push the loading frame over a certain displacement to maintain a deflection of the restriction beam to realize 2.7μN or 5.2μN normal loads. For each tribotester, a loading frame and its corresponding restriction beam serves as the reference pair working in the ethanol vapor environment, and the opposite pair is used to study the effects of other environments, such as dry nitrogen or fluoroalcohol vapors. The friction pair to be tested is blown by dry nitrogen or the bubbled vapor stream with saturation lower than 20%. This design can be as far as possible to cancel the interference of device fluctuation in fabrication [8] and give more reasonable judgments of anti-wear effect of candidate lubricants.

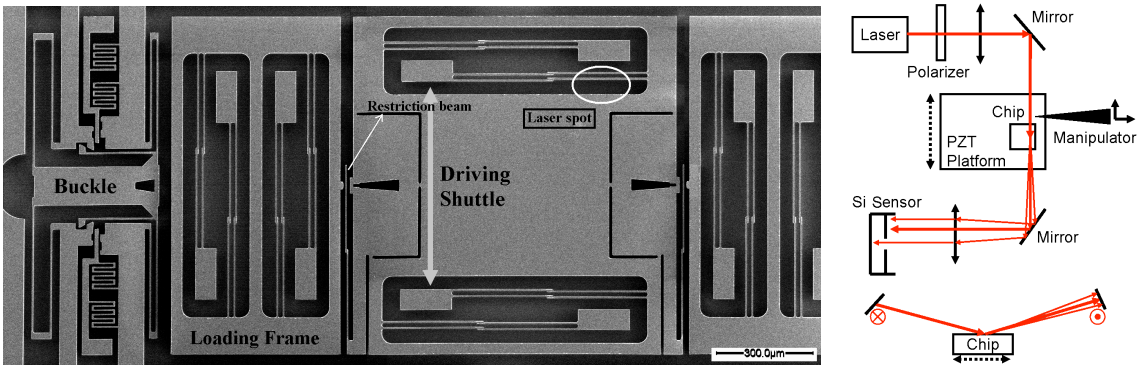

Figure 1. The bulk-fabricated micro- tribotester and the optical path to monitor the vibration of the driving shuttle, top view (up) and side view (down).

To drive the friction pair, the tribotester is stuck to a home-made one dimensional piezoelectric platform to force the shuttle vibrating near its nature frequency. The typical oscillation amplitude of the shuttle is about 4.5μm at 3850Hz. This method can offer a driving force no more than 10μN. And the on-chip buckle loading method avoids the necessity of finding the zero-point in a trial-and-error way. Thus this tribotester can be sensitive enough to observe the early stage of wear from its real starting point in MEMS devices.

The vibration of the shuttle can reflect the friction/wear process. A HeNe 633nm laser focuses onto the edge of the shuttle to reflect a speckle filed. The light intensity of the carefully chose point in this speckle field denotes the position of the shuttle. Since the air resistance is measured only 1/20 of the average friction force, the vibration degradation ΔC ($\Delta C=C_0-C$, C_0 is the vibration amplitude under empty load) reflects the real-time friction force ρ, which has a relationship of $\rho \propto \sqrt{\Delta C}$ deduced from the vibration equation under suitable simplifications [9].

3 Adhesive and corrosive wear mechanisms

After a short while vibration, the tribotester would stop owing to the overlarge friction. Figure 2 shows the worn morphologies of loading heads and restriction beams failed in nitrogen and ethanol vapor environments. On restriction beams only the feature of blunt peaks can be found and the bearing area is no more than 6% of the total nominal contact area. Hence these devices failed at the early stage of wear. The reason of blunt peaks can be inferred from the morphologies of the loading heads, where the worn area concentrated in a small region less than 5μm×5μm with more wear features. For samples in nitrogen atmosphere, scratches and pie-like wear debris distributed on the wear scars, while glass-like materials around bearing spots without scratches were found on samples working in ethanol vapor atmosphere. These glass-like materials can decompose in wet hydrofluoric acid vapor and is considered as the reaction products of silicon and ethanol in rubbing conditions. Therefore wear in nitrogen is attributed to adhesive type while in ethanol vapor it is corrosive type.

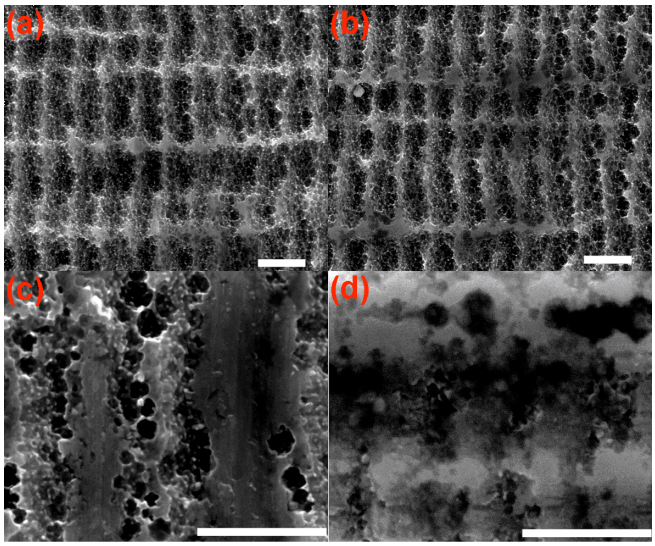

Figure 2. Worn morphologies of driving shuttles (a, b) and loading heads (c, d) after device failure. (a, c) Dry nitrogen atmosphere. (b, d) Ethanol vapor environment. The scale bar is 1μm.

The two wear mechanisms can be further convinced by the shuttle vibration degradation. Assuming each initial rough peak has a parabolic shape $h = r_0 \cdot r^2$ and the average friction force ρ is proportional to the total bearing area $A = N \cdot A_0 = N(\pi \cdot h / r_0)$. For adhesive wear, combining the classical Archard wear equation [10, 11]

$$\frac{A \cdot \Delta h}{v \cdot \Delta t} = \frac{\Delta V}{\Delta s} = \lambda_1 A_r \tag{1}$$

(V is the wear volume, s is the sliding length, v is the sliding speed, and λ_1 is the wear coefficient) and the simplified relationship between atomic contact area A_r and normal load F_n of $A_r=\lambda_2 \cdot F_n$ [12], the transient wear rate is inversely proportional to the wear depth as

$$\frac{dh}{dt} = \lambda_1 \lambda_2 v \frac{F_n}{A} = \left(\frac{\lambda_1 \lambda_2 v \cdot r_0}{\pi \cdot N} \right) \frac{F_n}{h}, \tag{2}$$

which induces $h \propto \sqrt{t}$ or $\rho \propto \sqrt{t}$. And for corrosive wear in strong media, only the reacted materials

will be worn out and the wear rate is limited by the reaction rate, which depends on the activation energy E_a of silicon and adsorbed small molecules:

$$h_0 = \frac{dh}{dt} = d_a K \cdot f_0 \exp[-(E_a - \mathrm{d}E)/k_b T], \tag{3}$$

where d_a is the silicon atom diameter and K is a probability multiplier to express the uniform assignment of multi-contact wear. dE is a modifier for sharp contact between fresh asperities. Since the initial shape can be worn out quickly in bulk-fabricated devices, dE is omitted to prevent redundant discussion [13]. Therefore, the transient wear rate is a time-independent constant, which induces $h = h_0 \cdot t$ or $\rho \propto t$. Therefore, using the relationship of $\rho \propto \sqrt{\Delta C}$, two modes of ΔC should be observed at the beginning of wear.

Figure 3 shows the shuttle vibration degradation in nitrogen and ethanol vapor conditions. The initial degradation can be fitted by the $\Delta C \propto t$ or $\Delta C \propto t^2$ quite well, consistent with the analysis of wear mechanisms from surface morphologies.

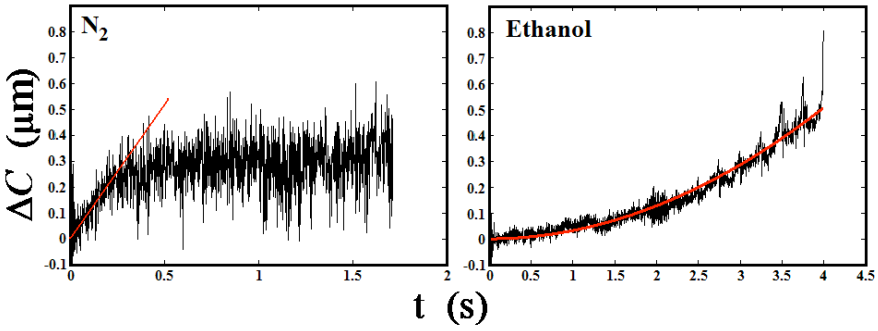

Figure 3. The typical vibration degradation of the driving shuttle in nitrogen and ethanol vapor environments. $\Delta C = d \cdot t^2$ (red line) is used to fit the data for ethanol vapor condition.

More kinds of gas environments have been tested on our tribotesters. In addition to dry nitrogen, O_2/N_2 mixture, n-hexane vapor and HFE 7100 ($CF_3(CF_2)_3OCH_3$) vapor also exhibit adhesive type. According to the density functional theory (DFT) calculation, n-hexane and HFE 7100 have very limited reactivity with silicon materials. Oxygen is easy to react with silicon in tribo-conditions [14]. However, lacking of inert groups, oxygen can not saturate dangling bonds to avoid atom bridges between couple surfaces. Besides ethanol, typical corrosive wear can be found in short chain fatty alcohols, such as methanol and hexanol, as well as propylene oxide. More complex wear processes are observed in water and fluoroalcohol vapor conditions, where a short linear vibration degradation can usually be found before the time-square degradation. Using the DFT calculation, fluoroalcohols show a weaker reactivity than fatty alcohols (Sec. 4). Hence they can not passivate initial sharp asperities as effectively as fatty alcohols to avoid adhesive wear. The reason for the boundary lubrication behavior of water is not very clear. A possible explanation is that silicon surfaces passivated by –OH groups still has possibilities to form atom bridges like Si-O-Si to cause adhesive wear when the local stress is high enough.

Using the time scaling of $\rho \propto \sqrt{t}$ and $\rho \propto t$, the worn area increases in a manner of $t^{3/4}$ and $t^{3/2}$ for adhesive and corrosive wear, respectively. For conventional macro structures, corrosive wear is usually more harmful since it has a superlinear growth. However, for MEMS devices, the permitted

wear volume is light and the wear process fails at its early stage. Near the initial point, the $t^{3/2}$ curve increases slower than that of $t^{3/4}$. That means if suitable chemical reactions are introduced into micro- tribo-devices, corrosive wear can exhibit a longer life-time than adhesive type (Fig. 4).

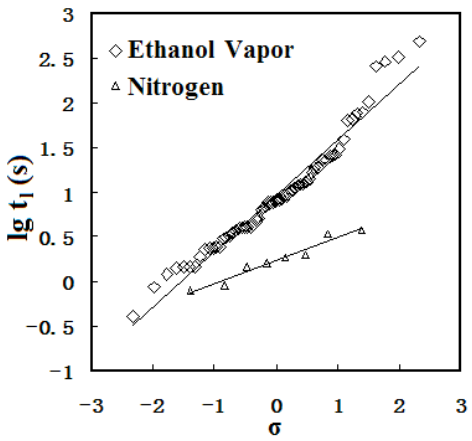

Figure 4. The log-normal distribution of life-time (t_l) in nitrogen and ethanol vapor environments.

4. The life-time test in corrosive vapor environments

Since the initial wear is sensitive to chemical conditions, several vapor environments are tested to study their lubrication effects, including methanol, ethanol, propanol, isopropanol, 2,2,3,3-tetrafluoropropanol, 2,2,2-trifluoroethanol, hexanol, propylene oxide and water. Their life-times compared by the reference pairs in ethanol vapor environments are shown in Fig. 5. According to these results, fluoroalcohols are better lubricant than fatty alcohols.

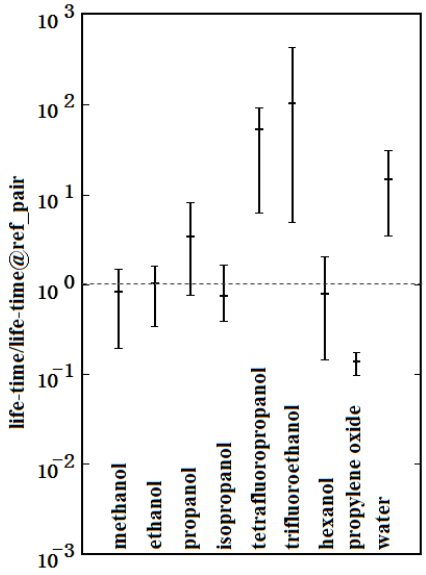

Figure 5. The life-time ratio of different corrosive vapors. The error bars denote the maximum and minimum values for each case.

A basic question is what chemical reactions happen on tribo-surfaces that make fluoroalcohol a better lubricant. For silicon material, especially the silicon dioxide, solvolysis (i.e., hydrolysis for water and alcoholysis for alcohols) is the most important reaction when the environment is filled by

active agents [15-21]. The solvolysis of silicon dioxide with water and fatty alcohols has been studied broadly. In our wear tests, however, the driving frequency is high enough and it is believe that there is not sufficient time to form fully native oxide on tribo-surfaces. Hence the reaction substrate is determined to be silicon instead of silicon dioxide. To compare the solvolysis reactivity of different compounds, the activation energy E_b of reaction

$$\equiv Si_2 - \underset{\|}{Si_1} - OR_1 \quad + \quad R_2OH \quad \rightarrow \quad \equiv Si_2 - H \quad + \quad \underset{\|}{Si_1} \begin{matrix} -OR_1 \\ -OR_2 \end{matrix} \tag{4}$$

is calculated in the framework of the density functional theory where Si(111) cluster model Si_7H1_6 is used (Fig. 6). The calculation is carried out with the Dmol3 software packaged in Material Studio v5.5, employing the BP functional and the DND basis set. Similar model is also used to calculate the hydrolysis barriers for SiO_2(111) and $(HO)_3Si$-O-$Si(OH)_3$, which gives the same transient structures and reaction energies given by Gaussian [22]. The virtual reaction

$$H_{15}Si_6 \equiv Si - OH \quad + \quad HO - Si \equiv H_3 \quad \rightarrow \quad H_{16}Si_6 = \underset{|}{\overset{OH}{Si}} - O - Si \equiv H_3 \tag{5}$$

is used to estimate the upper limit of E_b (149.7kJ/mol) for ROH compounds, where the H-H-H plane in HO-Si≡H_3 is parallel to the Si(111) surface.

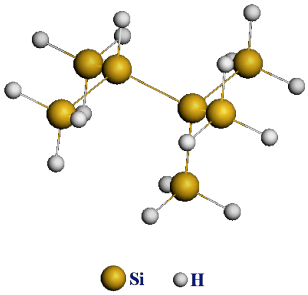

Figure 6. The Si_7H_{16} cluster model used in DFT calculation. H atoms are fully restricted.

Besides the thermal-solvolysis there can be another way to graft carbon chains onto silicon atoms, which depends on the dangling bonds formed in the rubbing process. The friction force in dry nitrogen environment is only several times larger than that in above vapor conditions. Since almost all the driving work in dry nitrogen condition is consumed on the formation of silicon dangling bonds, it is supposed that dangling bonds still forms in vapor conditions. In this paper we ignore the dynamic details in the formation of dangling bonds and use the reaction

$$\equiv Si_1 \bullet \quad + \quad ROH \quad + \quad \bullet Si_2 \equiv \quad \rightarrow \quad \equiv Si_1 - OR + \equiv Si_2 - H \tag{6}$$

to judge the reactivity of dangling bonds with different small molecules and define this reaction in terms of tribo-solvolysis. Two unsaturated Si atoms are used in this reaction to avoid odd number of electrons in DFT calculation. The distance from one Si atom to the other is set to be two times of equilibrium distance to contain the adsorbed small molecules. The energy of Si··Si is 351kJ/mol higher than Si-Si of equilibrium state and the energy change ΔE in Reaction (6) is used as the reactivity of tribo-solvolysis.

Figure 7 shows the DFT calculation results of E_b and ΔE. E_b and ΔE at the reference point are 149.7kJ/mol and -351kJ/mol, respectively. The distance Δ from each compound to the reference

point in kJ/mol can be considered as the activation energy E_a in Eq. (3). Since worn depth of failure devices is about 100-150nm as a constant, the life-time t_l in each vapor environment is theoretically expressed by

$$\lg(t_l / t_{l\_ethanol}) = (\Delta_{ethanol} - \Delta) \times 0.1744. \quad (7)$$

Figure 8 shows the experimental relationship of t_l and Δ of vapors in Fig. 4. Two approximate linear regions are found, one consists of water and fluoroalcohols with the slope of 0.05 and the other includes fatty alcohols with the slope of 0.01. The deviation of the slope from 0.1744 to 0.05 in Region II can be expressed by the non-corrosive stage of the initial wear. And for fatty alcohols, the significant deviation from the theoretical expectation suggests that only the thermal- and tribo-solvolysis is not able to give a full explanation of the tribo-reactions.

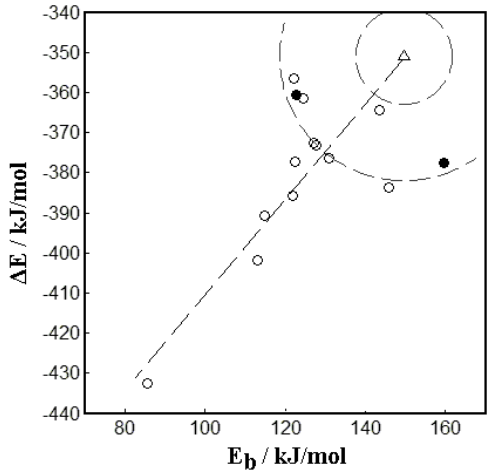

Figure 7. The DFT calculation results of E_b and ΔE. Δ: The reference point, ○: Volatile solvent, ●: Less volatile solvent. Dashed lines are used to guide the sight: along the straight line from top right to bottom left - the reference point, trifluoroethanol, 2-methoxyethanol, propanol, pentanol, hexanol, octanol and propylene oxide, along the arc line from top left to bottom right - tetrafluoropropanol, glycol, isopropanol, ethanol, methanol, 2-methoxyethanol, water and phenol.

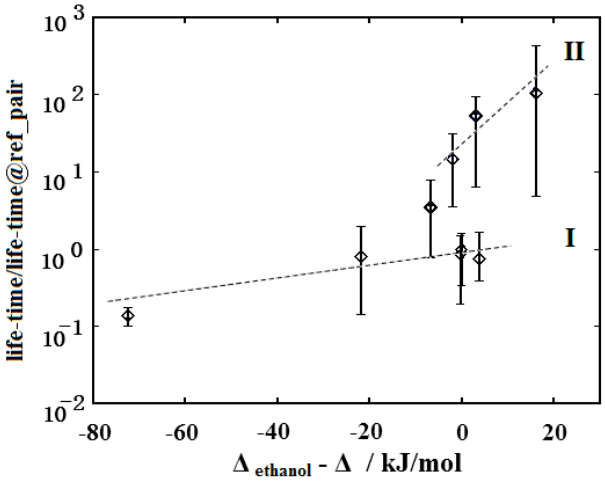

Figure 8. The relationship of life-time test and Δ. From left to right: Region I - propylene oxide, hexanol, propanol, methanol, ethanol and isopropanol, Region II – water, tetrafluoropropanol and trifluoroethanol.

Here we suggest a mechanochemical mechanism to understand the possible degradation routines for grafting groups on silicon surfaces. In tribo-conditions, the dangling bonds may not only form at top silicon atoms but also form by the rupture of grafted carbon groups. Consider the quasi-static vertical stretching of the end carbon atom on hexanol grafted at Si(111) surface in Figure 9. Using the DFT calculation by the Si_7H_{16} model, the chain will break at the end C-C bond, releasing the $CH_3\cdot$ radical. This character gives an explanation of the "tribochemical polymerization" [23] of short C_xH_y compounds found by TOF-SIMS in pentanol lubricating experiments, including surface-MEMS devices [24] and macro- ball(SiO_2)-on-disc(Si) experiments [23]. Figure 10 shows the rupture details of different grafted alcohols. Before a critical strain of approximately the same, the Si-O-R chain is stretched uniformly. And at the critical strain (about 0.2), the chain "breaks" at the end C-C bond, where the energy increase is about 0.86~1.25 times of forming a Si··Si pair. However, different chains have different trends to release carbon radicals. For hexanol, there is a jump at the break point and the CH_3 group is almost fully released to form radical. For ethanol, the jump is not significant and the CH_3 group still has some quantum connection with the main chain when the strain is more than 0.2. The situation of propanol is between ethanol and hexanol. But for fluoroalcohols, the CH_xF_{3-x} group can not get rid of the influence of main chain as fatty alcohols since the Si-O-R chain relaxes in a continuum manner. Therefore, the fluoroalcohols is much more stable than fatty alcohols when they are grafted on silicon surfaces and the latter can degrade by local mechanochemical effect. The longer the alcohol, the easier to break. This degradation may be harmful for lubrication and fluoroalcohols are better lubricant than fatty alcohols.

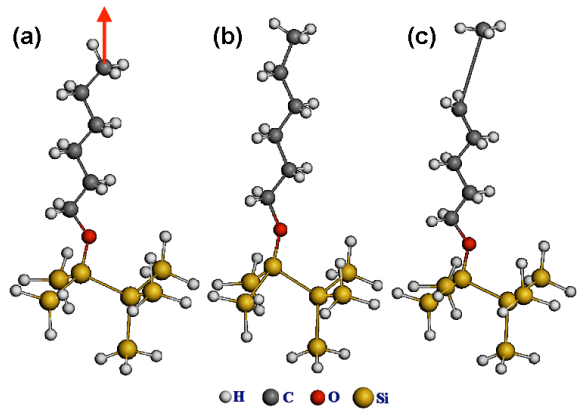

Figure 9. The quasi-static stretching of grafted hexanol on Si_7H_{16} cluster. (a) Initial state, (b) just before C-C break, (c) just after C-C break.

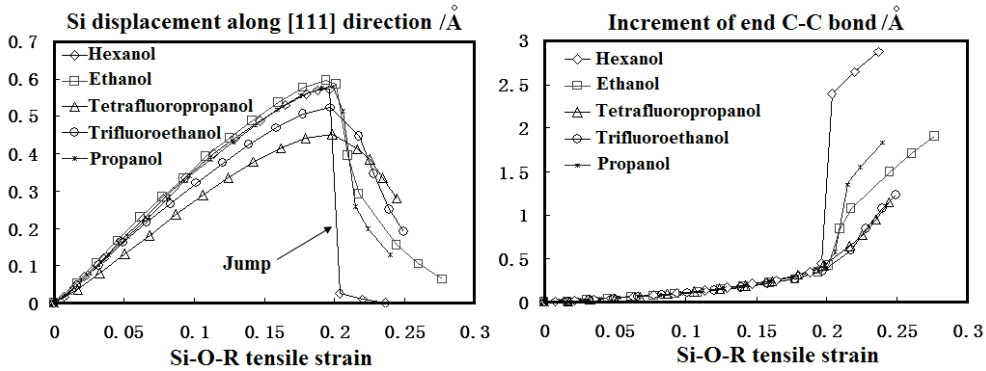

Figure 10. The tensile responses of different grafted alcohols on Si(111) surface.

5. Conclusion

In this research, a bulk-fabricated side-wall Si-MEMS tribotester is fabricated to study the life-time and wear process in different gas environments. By using the on-chip buckle loading method and the resonant driving strategy, the early stage of wear can be studied and classified into adhesive and corrosive types, depending on the gas environment. Since the permitted wear is quite light in MEMS devices, introducing a suitable corrosive vapor, such as alcohol, can relieve the initial wear to prolong the life-time. For fatty alcohols, the thermal- and tribo- solvolysis may not give a full explanation of tribo-reactions. A mechanochemical mechanism is proposed to understand the possible degradation of grafted alcohols on silicon and fluoroalcohols exhibit much more stable than fatty alcohols in the DFT calculation. The average wear life-time ratio in 2,2,2-trifluoroethanol vapor is about 100 times larger than that in ethanol vapor, so trifluoroethanol can give an effective lubrication for silicon devices.

Abstract In this paper, the radiation effects of 1MeV protons on hydrogenated amorphous SiC films are studied by simulation and experiments. The molecular dynamics simulation by SRIM-2012 software package indicates that compared to crystalline SiC, hydrogenated amorphous SiC may suffer less radiation damage. SiC films with a thickness of 500nm are deposited on silicon substrates by PECVD, and then annealed at about 450℃. The prepared hydrogenated amorphous SiC films are irradiated by 1MeV protons in an electrostatic tandem accelerator at a flux of about 1.4×10^{12} cm^{-2} s^{-1} for 2 hours. The mechanical changes in irradiated silicon carbide films are investigated by nano-indentation and nano-scratch method. The irradiated film suffers a decrease in hardness and Young Modulus, but keeps nearly the same friction coefficient and surface topography as the contrast films.

Keywords Silicon Carbide, Mechanical degradation, Radiation damage

1. Introduction

Silicon carbide was considered as an excellent candidate for Micro-Electro-Mechanical Systems, especially in harsh environments applications [1]. Compared to crystalline SiC, low-stress PECVD SiC thin film is more attractive for CMOS compatible MEMS structures and devices [2]. As with space applications, MEMS devices are working in a complex radiation environment with massive energetic particles and photons. Space radiation induces electrical and mechanical degradation in materials. MEMS structures and devices would suffer mechanical failures and electrical failures after large doses of radiation [3,4]. In recent researches, the radiation effects on crystalline SiC were studied. Microstructural, electrical, mechanical degradation and amorphization of crystalline SiC under ion and neutron irradiation were reported [5–7].

In this work, we focus on the radiation effects of 1MeV protons on amorphous SiC films. SRIM-2012 software package is used to calculate the ions distribution in multiple layers of SiC/Si target. PECVD SiC films are deposited and annealed. The prepared SiC films are irradiated by 1MeV protons at a flux of about 1.4×10^{12} cm^{-2} s^{-1} for 2 hours. The radiation induced mechanical degradations are investigated by nano-indentation and nano-scratch method.

2. Simulation

SRIM-2012 software package, which concerns the stopping and range of ions in matter [8], is used to calculate the ions distribution in SiC and SiC/Si target.

Table 1. The projected range of crystalline SiC and H-SiC.

Samples	Atoms(%)			Projected Range (um)
	Si	C	H	
SiC	50	50		14.95
H-SiC	43	47	10	16.39

Since amorphous SiC films grown by PECVD generally contain a large number of hydrogen atoms, the projected ranges of 1MeV protons in crystalline SiC and hydrogenated amorphous SiC (H-SiC)

were calculated. As the results shown in Table 1, the projected range of crystalline SiC is shorter than hydrogenated amorphous SiC. Due to the existence of hydrogen atoms, hydrogenated SiC with the same width as crystalline SiC may suffers less radiation damage. As the distribution of incident protons in multiple layers of SiC/Si target is showed in Fig. 1, the protons are clustered at the center of projected range.

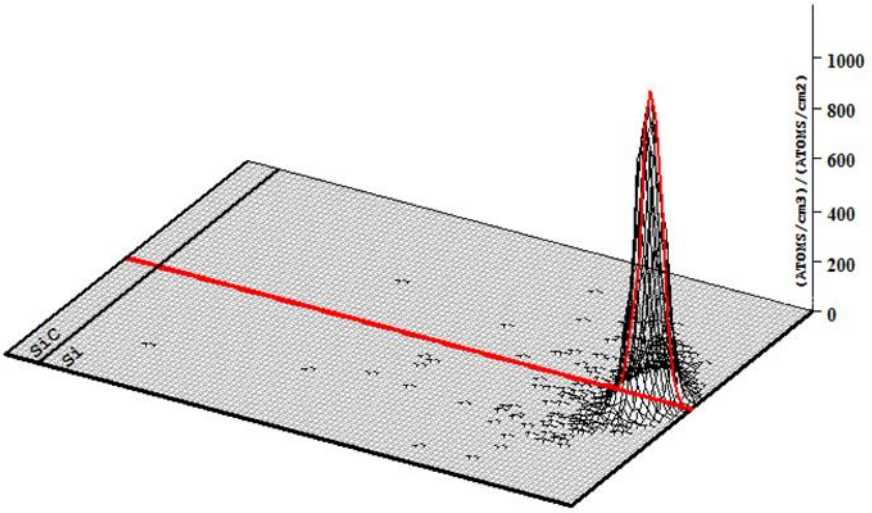

Figure 1. The distribution of incident protons in SiC/Si target.

3. Experiments

3.1 Preparing of amorphous silicon carbide films

500nm amorphous SiC films are deposited on 4 in. (100) silicon substrates by PECVD at 300 ℃. Some of the PECVD parameters are listed in Table 2. In order to get low-stress SiC films which are appropriate for fabricating MEMS structures, a furnace annealing process at about 450 ℃ for about 50 minutes is performed. Thus, the SiC films could be adjusted with a low tensile stress.

Table 2. Parameters of PECVD

Parameters of PECVD	Values
Flow rate of CH4 (sccm)	400
Flow rate of Ar (sccm)	400
Flow rate of NH3 (sccm)	5
Flow rate of SiH4 (sccm)	20
Pressure (mTorr)	1000
Power (W)	300
Temperature (℃)	300

3.2 Radiation on amorphous silicon carbide films

The prepared silicon carbide films were radiated by energetic protons in an electrostatic tandem accelerator at room temperature for 2 hours.

Table 3 illustrates some parameters of radiation experiments. In the accelerator, protons was accelerated to 1MeV. The protons beam was focused on a spot about 2×2 cm^2. The current of the protons beam is 0.9μA, thus the flux reaches 1.4×10^{12} cm^{-2} s^{-1}.

Table 3. Parameters of Radiation experiments

Current	Beam spot size	Flux	Time
0.9μA	4cm^2	1.4×10^{12}/cm^2 s	2h

4. Results and discussion

By nano-indentation, nano-scratch and other methods, the surface roughness, reflectivity, hardness, Young modulus and friction coefficient of irradiated SiC films are measured and analyzed. Deposited amorphous SiC films were employed as contrast samples.

4.1 Surface roughness and reflectivity

Surface topography of the films was observed by nano-indentation scan. As the 3D and plane topography showed in Fig. 2, the irradiated films demonstrates a similar surface topography with the contrast one. The average surface roughness of the irradiated silicon carbide film is 27nm, while the contrast one is 29nm.

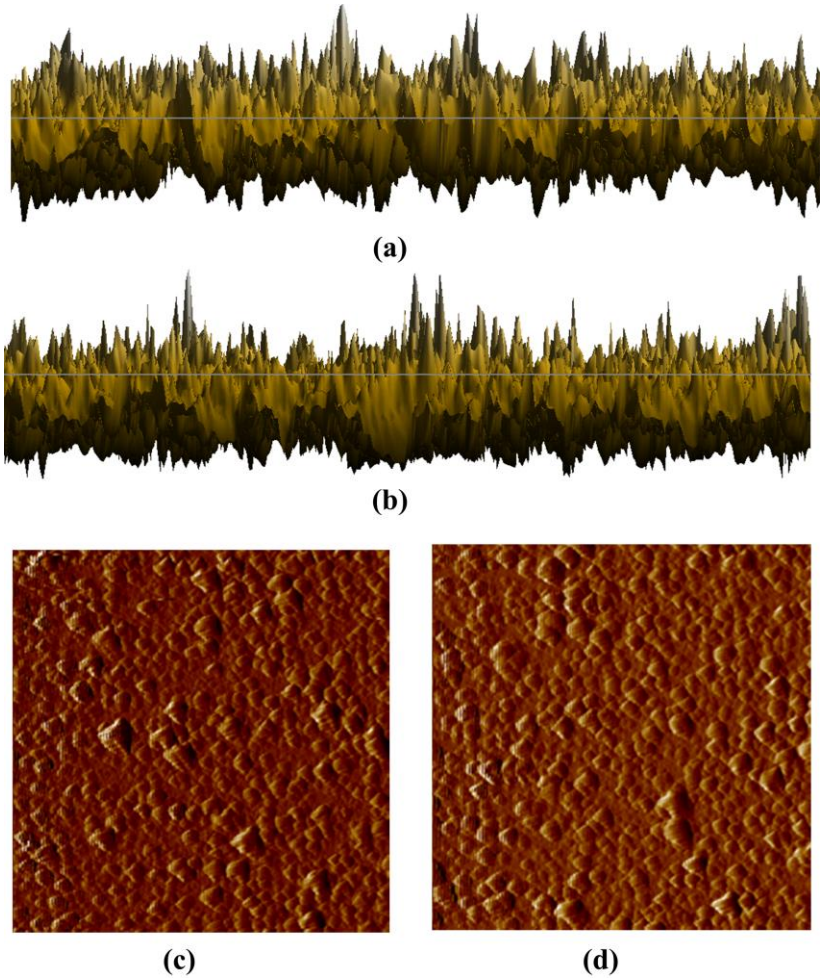

Figure 2. (a) 3D surface topography of irradiated SiC films;
(b) 3D surface topography of contrast SiC films;
(c) Plane surface topography of irradiated SiC films;
(d) Plane surface topography of contrast SiC films.

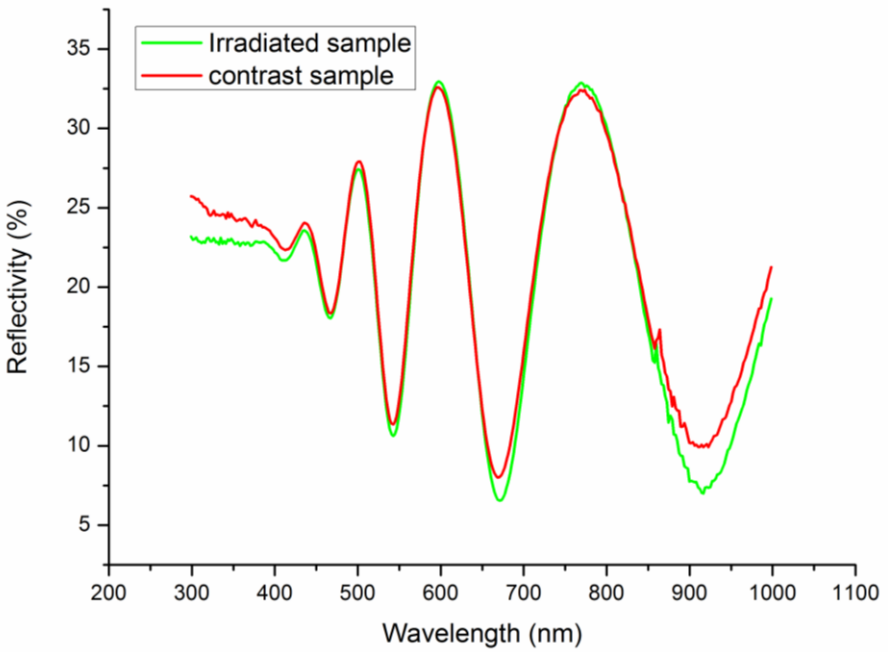

Figure 3. Integrating sphere reflectivity spectrums of SiC films

Integrating sphere reflectivity spectrums of the irradiated films and contrast films are measured at a wavelength range from 300nm to 1000nm. As Fig. 3 shows, the two kind of films demonstrate quite similar spectrums.

4.2. Hardness and Young modulus

Nano-indentation method was employed to measure and calculated the hardness and Young modulus of the films. The displacement in the irradiated films at the maximum load force of 10000μN is 367nm, while the contrast one is 230nm. Fig. 4 shows the load-displacement curves of the films at a load force of 1500μN.

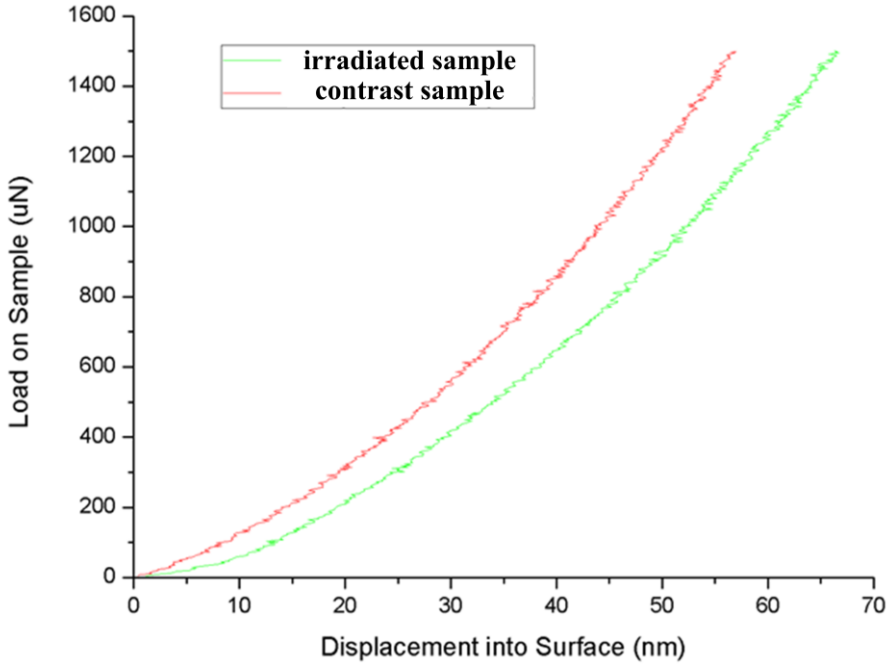

Figure 4. Load-displacement curves of the films in nano-indentation process

The average hardness and Young modulus of the films are calculated and listed in Table 4. The irradiated films demonstrate both lower hardness and young modulus than the contrast one, i.e., the contrast film is more robust than the irradiated film.

Table 4. The average hardness and Young modulus of the films.

Samples	Hardness (GPa)	Young modulus (GPa)
Irradiated samples	9.22	103.54
Contrast samples	10.66	114.46
Difference	15.6%	11%

4.3. Friction coefficient

Nano-scratch method was employed to measure friction coefficients of the films. Load force of 2000μN and 5000μN were used, the results are listed in Table 5. Allowing for the influence of surface roughness of the films, the friction coefficients of the two kinds of films demonstrates no significant difference at each load force. Fig. 5 shows the friction coefficients of the films at a load force of 5000μN during a nano-scratch scan process of 6μm.

Table 5. Friction coefficients at different load force.

Samples	Load Force(μN)	Friction coefficient
Irradiated sample	2000	0.108
	5000	0.154
Contrast sample	2000	0.096
	5000	0.151

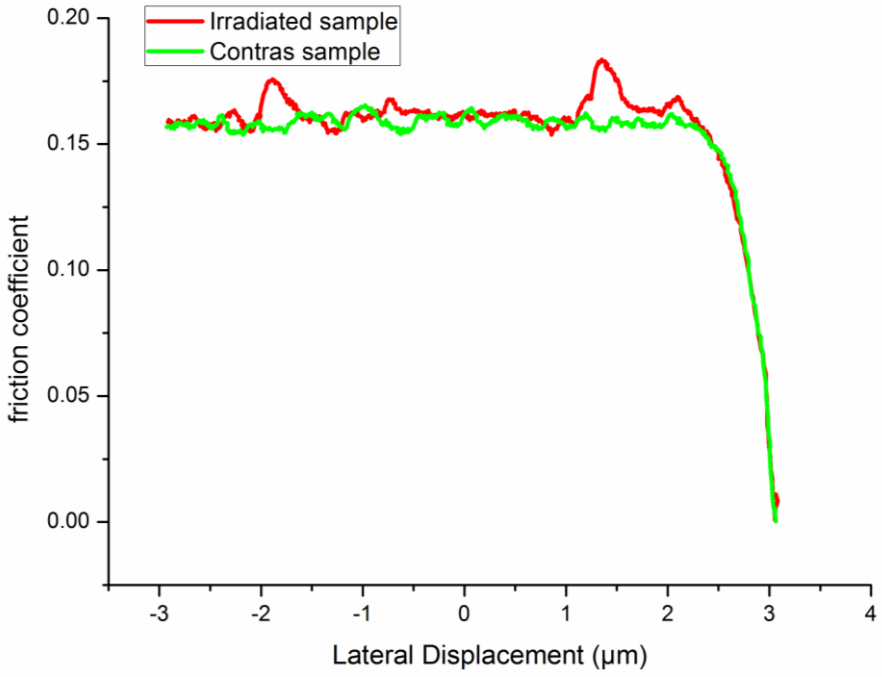

Figure 5. Friction coefficients at a load force of 5000μN during a nano-scratch scan process .

5. Conclusion

The radiation effects of 1MeV protons on amorphous SiC films are studied. According to calculated results of SRIM-2012 software package, the projected range of crystalline SiC is shorter than hydrogenated amorphous SiC. Hydrogenated SiC with the same width as crystalline SiC may

suffers less radiation damage. 500nm SiC films are deposited on 4 in. (100) silicon substrates by PECVD, and then annealed to obtain low stress SiC films. The prepared SiC films are irradiated by 1MeV protons in an accelerator at room temperature for 2 hours. The irradiated film suffers a decrease in hardness and Young modulus, but keeps the same in friction coefficient and surface topography as the contrast films.

Abstract In droplet-based microfluidics, two different types of microsystems are used for droplet manipulation - covered systems based on parallel-plate devices, and open systems based on single-plate devices. Ejecting droplets from covered systems into an open system is an essential operation to build a complete analysis system combining the advantages of both covered and open systems. This paper presents theoretical study and experimental results for ejecting a water and/or oil droplet from a covered into an open system. We use a force analysis method to determine the condition required for a droplet to cross the open/covered edge and demonstrate droplet movements using electric actuation. A bevelled edge structure is developed to facilitate the final liquid-solid separation process, greatly reducing the required actuation voltage.

Keywords electrowetting, electrowetting-on-dielectric (EWOD), microfluidics, dielectrophoresis

1. Introduction

Droplet-based microfluidics (or digital microfluidics) is a fast-developing liquid-handling technology that manipulates liquids in the form of discrete droplets. In integrated devices for droplet-based microfluidics, liquid droplets in contact with dielectric surfaces are moved by applying AC or DC potentials across electrodes patterned beneath the dielectric. There are two types of microsystems for electric actuation of liquid droplets: the covered system, in which voltages are applied across electrodes in both the top and bottom plates, [1-5] and the open system, in which voltages are applied across electrodes on a single plate. [6-10] The mechanism for droplet actuation has been attributed to electrowetting (EW) forces for conductive liquids [1-12], and to dielectrophoretic (DEP) forces for dielectric liquids. [13-16] When voltage is applied across electrodes in a device, a liquid droplet can move towards the activated electrode.

Study on droplet manipulation is usually done in either covered microsystems or open microsystems. The covered system is capable of achieving all the basic fluidic operations- droplet dispensing [3-5,18], moving [1,2], splitting [3,5] and merging [3], and controls droplet volume reliably through dispensing. [4,18] The open system, while lacking the capacity of dispensing or splitting droplets, [5] allows direct access to liquid handling tools on the surface and analytical equipments. Thus, the concept of dual open/covered microsystem combining the advantages of both covered and open systems is developed. [20,21] A covered section dispenses liquid droplets with desired volume and further analytical operation or liquid droplet handling is done on an open section. To achieve this scheme, it is essential to eject a droplet from a covered into an open section of a chip. In this paper, we analyze the possibility of such a motion for both water and oil droplets, and demonstrate experimental results to compare with the results of modeling. A bevelled edge on the top plate makes it possible to minimize the contact area between droplet and the top plate, thus easily separating the liquid-solid interface.

2. Water droplet ejection

An integrated device consisting of a covered section and an open section is illustrated in top and

side views in Figure 1 (a) and (b). The bottom plate consists of a patterned array of addressable electrodes, and the top plate in the covered section is coated with a transparent indium tin oxide (ITO) layer as a continuous ground electrode. The electrodes on bottom plate are coated with a dielectric layer, and both the top and bottom surfaces are covered with Teflon-AF as a hydrophobic film.

To evaluate the prospect of droplet movement from covered to open section by electrical actuation, we conduct force analyses to compare the driving forces with resisting forces. These results provide an estimate for the required voltage for a droplet to achieve such a motion.

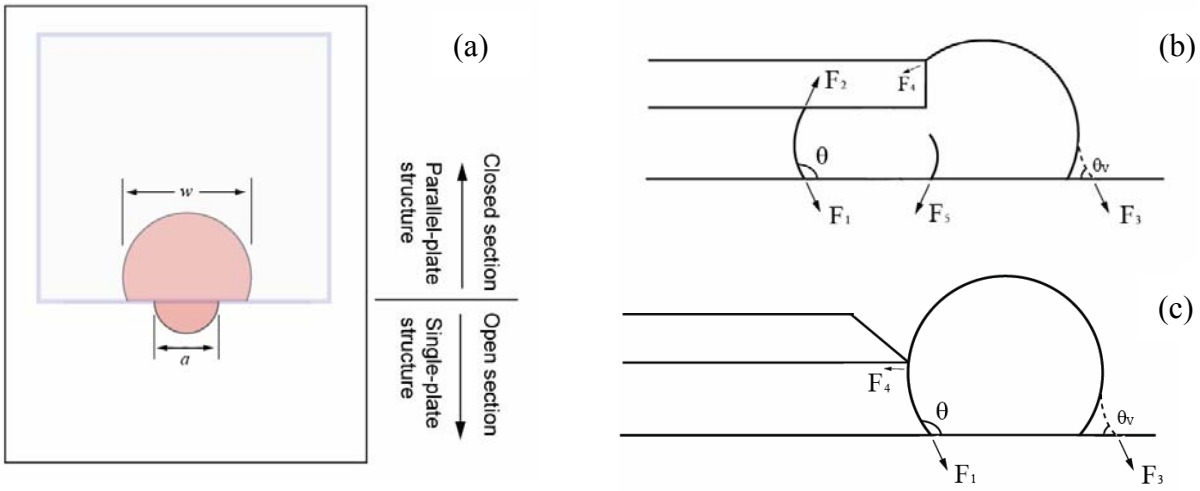

Figure 1. Force balance analysis of a water droplet ejection from covered into an open section. (a) Top view of a water droplet at the covered/open boundary. (b) Forces exerted on a water droplet when it is being moved toward the open section. (c) Liquid-solid separation with beveled edge.

2.1. Force balance analysis

The forces exerted on the droplet at the covered/open interface are illustrated in Figure 1 (b). We can distinguish two distinct contributions in the plane of the structure: the capillary force and the EW force. The capillary force is

$$F_c = F_1\left|\cos\theta\right| + F_2\left|\cos\theta\right| \quad (1)$$

and the EW force is

$$F_{EWOD} = F_3\left|\cos\theta_V\right| + (F_1 - F_5)\left|\cos\theta\right| \quad (2)$$

where $F_1 = F_2 = \gamma w$, $F_3 = \gamma a$, $F_5 = \gamma(w\text{-}a)$. w and a are contact lengths of the droplet in covered and open sections respectively, γ is the surface tension of the liquid droplet. θ_V and θ are the droplet contact angle with and without applied voltage.

When the water droplet is being moved from the covered section to the open substrate, the influence of F_4 can be neglected as there is no motion for the upper portion of droplet that contacts the edge of the ITO plate. Thus, the total force acting on the drop is:

$$F_{total} = F_3\left|\cos\theta_V\right| + (F_1 - F_5)\left|\cos\theta\right| + F_2\left|\cos\theta\right| \quad (3)$$

The three force components in equation (3) tend to move the droplet toward the open section, so we may expect that the droplet gets out the covered section easily. In fact, the water droplet tends to move out even without external applied voltage, in which case the net force becomes $F_2|\cos\theta|$.

When the droplet emerges from the covered section, it still tends to stick to the Teflon-coated ITO plate due to the low interfacial tension between water and Teflon. To facilitate the separation of the liquid droplet and the top plate, we bevel the edge of the top plate as shown in Figure 1 (c). Here the total force acting on the droplet is

$$F_{total} = (F_1|\cos\theta| + F_3|\cos\theta_V|) - F_4 = \gamma a(|\cos\theta| + |\cos\theta_V|) - \gamma a \quad (4)$$

Using $\theta = 115°$, $F_{total} > 0$ gives $\theta_V < 55°$. Because of the contact angle saturation effect, it is not easy to reduce the contact angle of a water droplet to lower than 55° by EW actuation. However, the electromechanical approach of EW theory shows that the EW force experienced by the droplet is independent of the surface profile. [13,14] This result indicates that contact angle saturation does not necessarily limit the maximum EW force that can be applied to a droplet. [17] Converting the contact angle to applied electric voltage by the Lippmann-Young equation, we get V > 105V as the voltage requirement for liquid-solid separation.

2.2. Experimental results of water droplet ejection

We fabricate a number of covered/open integrated devices on glass substrates to test droplet ejection motion. The bottom substrate consists of aluminum electrodes, a 0.5 μm spin-on-glass (SOG) dielectric layer, and a 1μm Teflon-AF layer. The top substrate is coated with an ITO layer and also a 1μm Teflon-AF layer. The spacing between top and bottom substrate is set to be 100 μm.

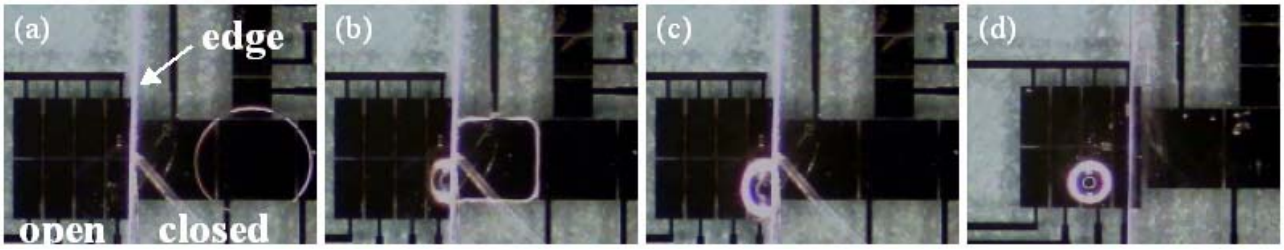

Figure 2. Moving a water drop from covered to open section. (a) The water droplet is initially placed in covered section. (b) The droplet is moved towards covered/open boundary by EW actuation using 100 V_{rms} 100 Hz AC. (c) The droplet enters open section as soon as it arrives at the boundary. (d) The droplet is successfully separated from top plate after applying 300 V_{rms} voltage.

Figure 2 shows video frames of water droplet motion from the covered to the open section. A water droplet is first injected into the covered section, and moved toward the covered/open interface by EW actuation. When the droplet reaches the interface, it is ejected rapidly but still sticks to the top plate. See Figure 2 (c). We then apply voltages ranging from 100 to 300 V_{rms} to separate the droplet and the top ITO plate. Separation is only successful at 300 V_{rms}.

To lower the required voltage for droplet/top plate separation, we bevel the edge of the top ITO plate to minimize the contact area between water droplet and Teflon surface. See Figure 3. Now the droplet can be easily separated by applying a voltage of 90 V_{rms}, which is even lower than the predicted value of 105 V. This is probably because the direction of force F_4 in Figure 1 (c) is not exactly horizontal, making the separation voltage somewhat lower.

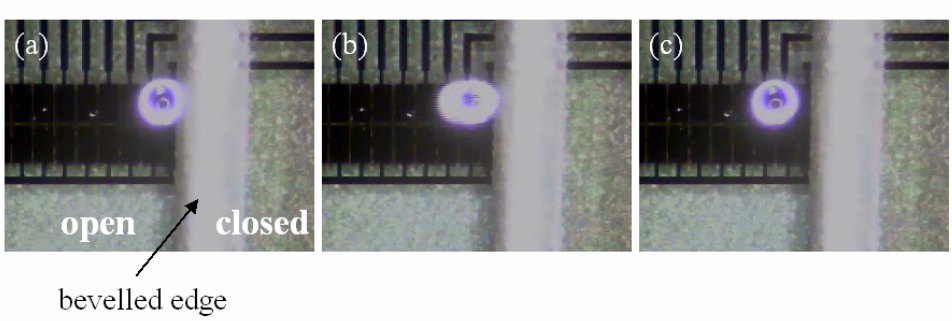

Figure 3. Separating a water drop and ITO plate with bevelled edges. The voltage applied is 90 V_{rms} 100 Hz AC.

3. Oil droplet ejection

Oil droplets have low surface tension and usually small contact angles on solid surfaces. It is likely that an oil droplet will find its way into cracks or small channels due to the capillary effect. As a consequence, it is very difficult to eject an oil droplet from covered into an open section.

3.1. Force balance analysis

The tendency of a liquid to enter narrow channels is commonly recognized as the capillary effect. A classic textbook example is the liquid rising in a vertical glass tube as shown in Figure 4 (a). For our apparatus, the liquid droplet moves horizontally and the goal is to use electrical actuation to overcome the capillary effect. To evaluate the requirements to accomplish this operation, we conduct a force analysis to compare the driving force and resisting forces as shown in Figure 4 (b). The total force acting on the oil drop is:

$$F_{total} = F_{DEP} - F_2\cos\theta - F_4\sin\theta + (F_3\cos\theta + F_5\cos\theta - F_1\cos\theta)$$

$$\approx F_{DEP} - F_2\cos\theta - F_4\sin\theta \qquad (5)$$

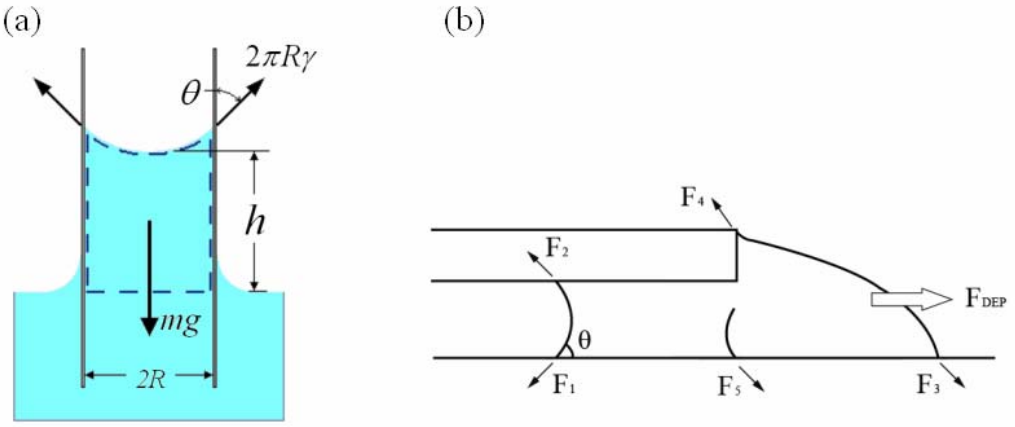

Figure 4. (a) Force analysis for a capillary tube. (b) Force analysis of an oil droplet at the covered/open boundary.

According to our device setup, [18,19] the minimum required voltage to achieve $F_{total} > 0$ is 1292 V and 1555 V for silicone oil and mineral oil, respectively. These high voltages are much greater than the dielectric breakdown voltages of 750 V, so it is impossible to achieve the desired movement by direct actuation. Furthermore, the oil droplet tends to get separated even the DEP force is large enough to overcome the resisting forces. We can understand this issue by considering a quasi-static process where the two plates are slowly separated as shown in Figure 5. The oil droplet sandwiched between parallel plates has a contact angle $\theta < 90°$. The vertical component of the surface tension forces at the upper (or lower) edge and the middle of drop are respectively:

$$F_{edge} = \gamma 2\pi R \sin\theta \tag{6}$$

$$F_m = \gamma 2\pi r \tag{7}$$

As the plates separate, both R and r decrease. Gradually F_{edge} will exceed F_m because r can approach 0. Then, the droplet breaks into two droplets, one each on the top and bottom substrates.

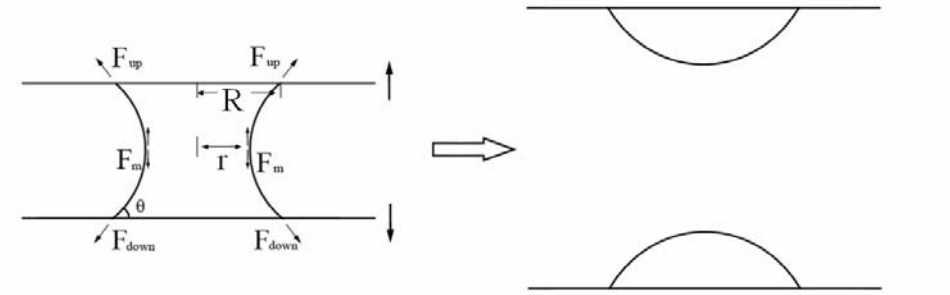

Figure 5. Breaking up of the oil droplet in parallel-plate structure when the two plates are separated far enough from each other.

A solution to this problem is to employ an oleophobic surface for the top plate. When the contact angle is > 90°, R at the upper edge is smaller than r, the oil droplet can be ejected without separation. And the total force acting on the oil droplet become

$$F_{total} = F_{DEP} + F_2 \left|\cos\theta^*\right| - F_4 \sin\theta \tag{8}$$

where θ^* is the oil contact angle against top surface, $\theta^* > 90°$. As F_2 and F_4 counterbalance each other mostly, the oil droplet can be ejected into an open section by DEP actuation.

3.2. Experimental results of oil droplet ejection

We fabricate an oleophobic surface on textured Si wafer and use it as the top plate for oil droplet ejection tests. The fabrication process of oleophobic Si microstructures is similar to that of Tuteja [22] and of Wu [23]. Figure 6 shows a mineral oil droplet sandwiched between a Teflon coated glass substrate (bottom) and a textured Si substrate (top) actuated by DEP. When the oil droplet is delivered to the covered/open boundary, continuous actuation moves the oil droplet to the open section, see Figure 6 (c).

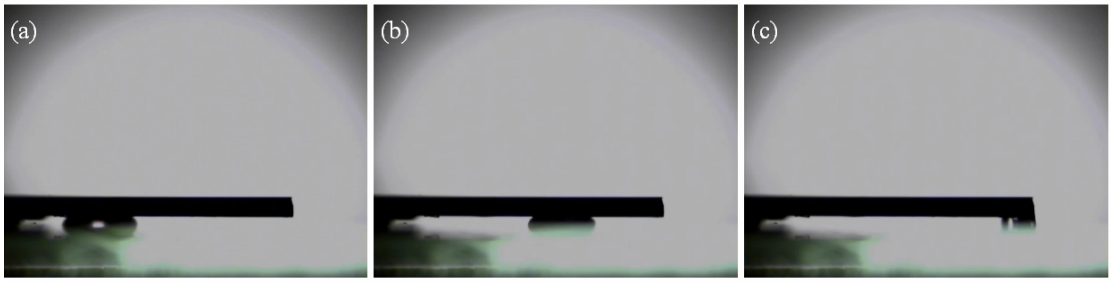

Figure 6. Side view showing the ejection of a mineral oil droplet. The spacing between Teflon coated glass substrate (bottom) and textured Si substrate (top) is 200 μm. The applied voltage is 560 Vrms 100 Hz AC.

The ejected oil droplet on open surface also sticks to the top plate. A beveled edge on the top plate may facilitate the detachment of the oil droplet. Further effort to fabricate an oleophobic beveled structure on the top plate is needed.

4. Conclusion

In this paper, we present theoretical predictions and experimental results on droplet ejection from covered into open microfluidic systems. We use a force balance analysis to predict the condition required to achieve such a motion. This model shows that it is easy to move a water droplet from covered to open section, but oil droplets always tend to stay in a covered section. Ejecting an oil droplet by direct DEP actuation is impossible on Teflon coated surfaces. An oleophobic surface must be used to complete this movement for oil droplet.

Experimental testing of the various predictions is done to demonstrate droplet ejection movements. To detach the water droplet from the top plate, we use a bevelled edge to minimize water-Teflon contact area and thus reduce the applied voltage. For oil droplets, we successfully use an oleophobic Si structure to achieve covered to open movement. Further study to bevel the Si structure is needed.

Abstract This paper presents a method of fabricating surface fastener for the application of mechanical and electrical room temperature bonding based on core shell nanowire array. This surface fastener consists of core shell nanowire array with the copper core and parylene shell. The copper nanowire array on the silicon substrate was prepared through template-assistant electro-deposition, which provided the electrical conductive function. The parylene shell was deposited on Cu nanowire array through CVD method, which provided surface compliance to increase contact areas, thereby realizing larger bonding strength. Through pressing core shell nanowire arrays against each other, the van der Waals forces between the interpenetrating nanowires had a contribution to the room temperature. This room temperature bonding technology may enable the exploration of a wide range applications involving assembly of components in the micro electronics.

Keywords Core shell, Nanowire, Surface fastener

1. Introduction

The continuous trend towards miniaturization and functional density enhancement makes an urgent demand to improve the bonding technology in the surface mount technology. The traditional bonding technology utilizes the solder. However, solder has relatively high electrical properties and copper-tin intermetallics have poor mechanical propertities[1]. An all-copper connection technology has been introduced, but the annealing temperature range of 350-450°C is too high for cost-efficient organic broads or substrates[2]. Moreover, the surface-activated bonding method has been reported, which can be performed at room temperature[3, 4].However, the high electrical resistance (above 1000Ω) may prohibit it application in electrical interconnection. Therefore, to create a bonding technology which not only has good mechanical and electrical property but also does not need high processing temperature is always a destination for the researchers.

With the efficient utilization of von der Waals forces, the gecko can firmly attach to and rapidly detach from varied kinds of surfaces. Many methods have been used to replicate this adhesion mode by some well-arranged micro and nanostructure arrays. Some gecko-inspired adhesive designs with nanowire arrays were cast through porous membranes available from commercial suppliers[5, 6]. Moreover, some special polymer micro and nanostructures, such as mushroom-shaped fibers[7], wedge-shaped fibers[8], bent fibers[9], spatula tips[10], led to bigger strength but also a more complicated manufacturing process. Recently, by using vertically aligned multiwalled carbon nanotube (MWCNT) with curly entangled end segment[11], the extremely high shear adhesion (~100 N/cm^2) was obtained, which was ten times higher than gecko's adhesion strength. Compared with the template method, the chemical vapor deposition method used to fabricate MWCNT is expensive and need high processing temperature.

Recently, a new kind of bonding technique based on core/shell nanowire structure has been demonstrated[12]. Moreover, electrical connector can be obtained through depositing a thin metal film on the nanowires[13]. Although this structure can achieve mechanical interconnection at room room temperature, the high temperature in the fabrication process and the relatively high electrical resistance prohibit their application in the bonding technique in micro electronics. In this paper,

copper/parylene core/shell nanowire surface fastener was investigated and showed much better electrical properties. The copper nanowire array on the silicon substrate was prepared through template-assistant electro-deposition, which provided the electrical conductive function. The parylene shell was deposited on Copper nanowire array through CVD method, which provided surface compliance to increase contact areas, thereby realizing larger bonding strength. In term of pressing the two nanowire array against each other, high adhesion strength was obtained at the same time due to the von der Waals forces between the interleaved nanowires. The according electricity resistance measurement showed that the electrical resistance of core/shell nanowire array was small.

2. Experiment details.

2.1. Electrodeposition of copper nanowires

Polycarbonate (PC) membranes (ISOPORE, Millipore Inc.) containing 0.1 μm diameter pores were used as the templates. The cathode was fabricated through sputtering 50 nm Cr adhesion layer and 100 nm Au seed layer on the substrate. With the help of isolation holders, the PC template was fixed right above the substrate. Copper nanowire arrays were then synthesized by electrodepostion under a constant current of approximately 0.003A. The electro-deposition electrolyte used was a 0.4 M $CuSO_4 \cdot 5H_2O$ solution, adjusted at pH=2 with sulfuric acid. The electro-deposition was performed at room temperature and without stir. After etching in methylene chloride to remove the PC membrane, the freestanding copper nanowire array on the substrate was obtained.

2.2. Parylene coating

As shown in figure 1, parylene-N was deposited on copper nanowire arrays by using a DACS-LAB deposition system. A typical deposition condition used in this work was 160°C for the vaporization of the parylene dimmer precursor, 650°C for the pyrolysis of the dimmer into monomers, and 60mTorr for the vacuum chamber. Through controlling the amount of the loaded precursor, the according thickness of parylene shell could be obtained.

2.3. Testing of parasitic resistance and bonding strength

The samples were connected to each other under the preload of 29.4N，and then the parasitic resistance was measured by the four-point probe method (figure 3a) after the preload was completely removed. During the measurement, electrical current from 0 to 20 mA was applied by the current source to the four-point probe measuring circuits and U-I curves were generated. The shear bonding strengths were tested by measuring the maximum forces that the surface fasteners could afford. The weights of a balance ranging from 1g to 1kg were used to fulfill this testing.

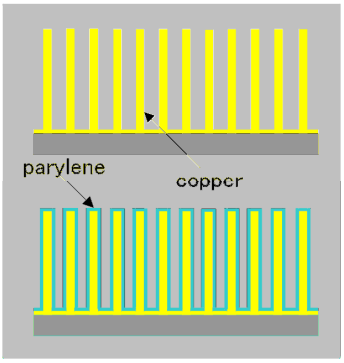

Fig. 1 Schematic of parylene coating

3. Results and discussion

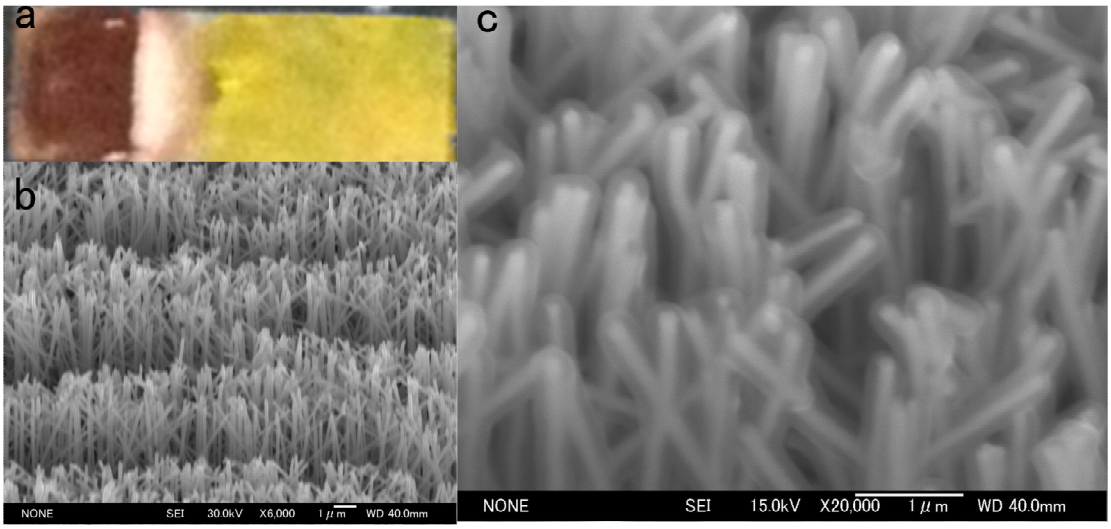

Fig. 2 (a) Photograph of the sample (b) SEM image of the fabricated nanowire array (c) SEM of the nanowire array after the parylene coating

As can be seen in figure 2a, it was easy to distinguish the fastener area from the Au film via their surfaces because the former became red in color. Scanning electron microscopy (SEM) observation (figure 2b) indicated that copper nanowire array grew on all the red area and the length of the nanowire array was uniform in most areas. From figure 2c, many relative dark shells around the bright wires could be observed. Because the parylene is non-conductive, it is darker than the copper in SEM image. The thickness of the shell was measured to be about 50nm.

The voltage-current (*U-I*) curve of interconnected fasteners is shown in figure 3b. The solid line in the figure was obtained through linear fitting of the measured values. Typical Ohmic contact performance was observed and parasitic resistance of 0.82 Ω can be extracted from the slopes of the fitted line. This result is possible to be used as the electrical bonding in surface mount. Figure 4 shows photograph of surface fasteners sustaining a weight of 500g in the shear direction. This bonding strength corresponded to the adhesion strength of 50 KPa. The purpose of our research is to develop a new mechanical and electrical room temperature bonding in surface mount. Regarding to the room temperature bonding or solder in surface mount, there are some design guidelines about the ratio between the component's weight and the bonding area. According to the standard value for second side reflow mounting (R=30g/in^2)[14]. If we consider this weight-area ratio to be R=50g/cm^2, which is more than ten times than the standard value. The bonding strength (S=50kPa) can withstand an acceleration of $a=S/R$=100N/kg>10*g (g=9.8N/kg is the acceleration of gravity). This result means that this room temperature bonding technique can be used in most equipment.

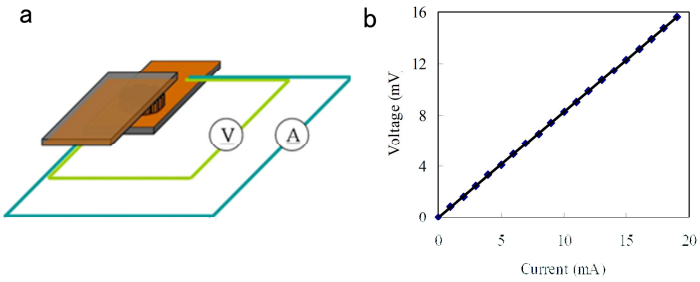

Fig. 3 (a) Schematic of four-point probe measurement (b) Measured *U-I* curves of the bonding

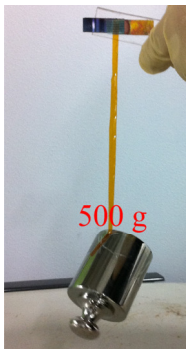

Fig. 4 A photo showing a weight balance of 100g hanging on the interconnected NSFs

4. Conclusions

In conclusion, a new kind of surface fastener composed of copper/parylene core/shell nanowire arrays has been proposed through which electrical and mechanical bonding can be realized at room temperature. Electrical measurement indicated that the electrical resistance of the interconnected nanowire array on the fastener is around 0.82 Ω under the preload of 29.4 N. The bonding strength of approximately 50 kPa was obtained. Therefore, this kind of core/shell nanowire surface fastener is hopeful to be used as electrical and mechanical room temperature bonding in the surface mount.

Abstract In this paper, an array-shaped anchor for microdevice (fabricated by silicon-on-glass (SOG) process) was designed for improving its bonding strength. This design scheme aims to release the coefficient of thermal expansion (CTE) mismatch induced residual stress and decrease the metal electrode layer or particles induced bonding failure risk. To evaluate the bonding performance of the proposed anchor design scheme, numerical simulation and mechanical experiments are carried out on well-established anchor-beam MEMS devices. The scanning electron microscope (SEM) results indicated that the bond yield of the array-shaped anchor was higher than the single anchor. The fracture tests results demonstrated that the torsional bonding strength of the array-shaped anchor was stronger than that of the conventional single anchor in practical application.

Keywords Particles, Bond yield, Torsional bonding strength, Fracture test

1. Introduction

Due to the development of micromachining technology, various micro electro-mechanical system (MEMS) devices (e.g. inertial micro accelerometers, RF/Microwave Devices, microfluidic devices, optical devices) can be fabricated [1–5]. As an important technique in micromachining, the anodic bonding, also known as field-assisted bonding, was firstly developed in the late 1960s by Wallis and Pomerantz [6–8]. Nowadays it has matured into a flexible technology with lots of applications [9]. One of the important applications is constructing micro anchor (bonded structure) for MEMS devices fabricated by the silicon-on-glass (SOG) process, which provides mechanical support or electrical connect to the movable sensing/actuating functional components. Therefore the bond yield and bonding strength of anchors are two of the main aspects for the reliability of MEMS devices [10].With the devices scaling, the bonding strength need to be considered carefully with limited bonding area. Besides, many factors on the bonding surface will lead to a dramatic degradation of the bonding quality and even the bonding failure when the anchor is small; for instance, the metal electrode layer, particles, contaminations and the CTE mismatch induced residual stress [11]. As a result, conventional single anchor is not the optimal choice for small devices. In this paper, a novel array-shaped anchor is proposed to address the above mentioned bonding degradation issues by dividing the single anchor into four identical sub-anchors. For the first time, the correlation between shape/size and bonding strength of the anchor is studied. Theoretical analysis demonstrates the array-shaped anchor improves bond yield and the shock resistance by reducing the bonding failure risk. In addition, the array-shaped anchor is proved to be a perfect way to release the residual stress for the high anchor (Fig 3) as well. Two series of well-established anchor-beam MEMS devices are fabricated by SOG process. The bond yield and torsional bonding strength of the anchors (both conventional and the array-shaped) are measured for

comparison. The experimental results indicated that the proposed array-shaped anchor is performing well and superior to the conventional single anchor ones.

2. Theoretical analysis

The array-shaped anchor design, consisting of four identical square sub-anchors, is illustrated in Fig.1(b). Bonding parameters, the metal electrode layer, particles, other contaminations on the surface within the bonding area, and the residual thermal stress, all these factors affect bonding strength of microdevices. Theoretical comparison between array-shaped anchor and single anchor on bonding quality and residual thermal stress is conducted.

(a) conventional single anchor (b) array-shaped anchor

Figure 1. The different anchor designs

2.1 Bonding quality

When the anchor is small, the metal electrode layer, particles or other contaminations may lead to a dramatic degradation of the bonding quality, even the bonding failure (Fig. 2(a)). But if it happens to array-shaped anchor, the unaffected sub-anchors without particles can be still bonded successfully (Fig. 2(b)), therefore the average bonding quality is better than that of single anchor ones, namely, the array-shaped anchor design improves the bond yield.

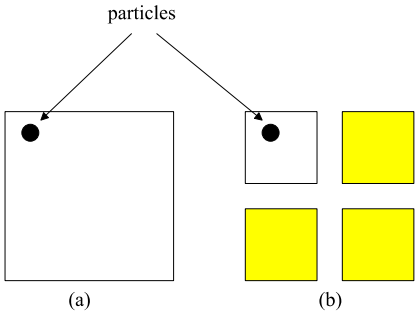

Figure 2. The particles on the surface within the bonding area:
(a) single anchor (b) array-shaped anchor

In addition, the existence of the metal electrode layer or particles will generate defect points on the surface. It is assumed that the ultimate strength of the defect points and normal bonding region is σ_1 and σ_2 respectively ($\sigma_2 > \sigma_1$). When the single anchor's surface stress reaches σ_1, the crack will arise from the defect point, and then propagates until the single anchor fractured because of the brittleness of the monocrystalline silicon (Fig. 2(a)). With regard to array-shaped anchors, when the

surface stress reaches σ_1, the crack will also arise from the defect point, but owing to the sub-anchors without particle contaminations the crack will not propagate. So the ultimate strength of the array-shaped anchor is σ ($\sigma_1 < \sigma < \sigma_2$), which is larger than σ_1, the single anchor's ultimate strength, i.e. improving the shock resistance.

2.2 Residual thermal stress

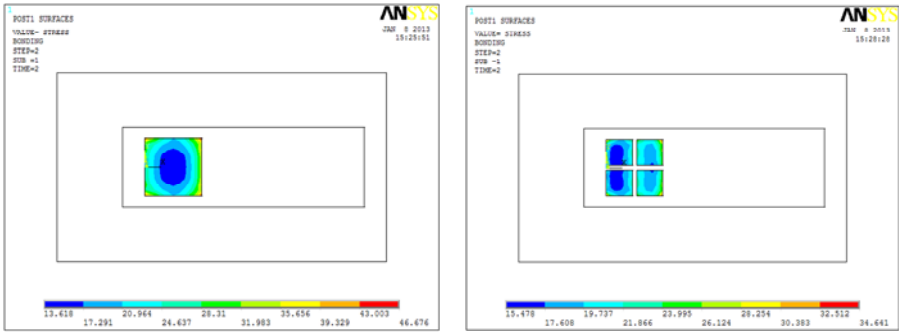
The array-shaped anchor is conducive to release residual stress caused by CTE mismatch. As a result of the size decrease of the bonding surface, the thermal stress of every sub-anchor surface is much lower than that of the single anchor one [12]. The CTE mismatch between different sub-anchors can be remitted by the bending of sub-anchors. In order to demonstrate advantages of the array-shaped anchor the finite element analysis (FEA) is performed. For silicon and glass, parameters applied in the simulation are shown in table 1. Figure 3 shows the residual thermal stress contour of the bonding surface. The highest stress on the bonding surface of single anchor is 46 MPa, while that of the array-shaped anchor is 34 MPa (table 2). It can be concluded from the FEA results that the array-shaped anchor is beneficial to release the thermal stress.

Table 1. Parameters in FEA

	Young modulus	Poisson ratio	CTE	Bonding temperature	Operating temperature
Glass	62.75 Gpa	0.20	3.25E-6	623 K	300 K
Si	169 Gpa	0.28	2.6E-6	623 K	300 K

Table 2. FEA results of Fig. 3

	Type	Anchor height	Side length of anchor (sub-anchor)	Gap between sub-anchors	Highest stress
Figure 3(a)	Single anchor	40 μm	26 μm		46 MPa
Figure 3(b)	Array-shaped anchor	40 μm	12 μm	2 μm	34 MPa



(a)conventional single anchor (b)array-shaped anchor

Figure 3. Contour plot of residual thermal stress of bonding surface (anchor height of 40μm)

Besides, effects of anchor height on thermal stress of the array-shaped anchor are also analyzed.

Figure 4 shows the residual thermal stress contour of bonding surface for the anchor with a height of 4 μm. And detailed results are listed in table 3. It can be concluded that the thermal stress of array-shaped anchor is higher than that of the single anchor. Furthermore, the stress discrepancy reduces as the gap between sub-anchors decreases. The reasons are that sub-anchors could hardly bend when the height of anchors is small, therefore thermal stress cannot be released by bending of the sub-anchors but only by the deformations of the bonding surface. In addition, due to the loss of the bonding surface, the thermal stress of array-shaped anchor is higher. However, this effect can be ignored comparing with ultimate strength in an order of GPa.

Table 3. FEA results of Fig.4

	Type	Anchor height	Side length of anchor (sub-anchor)	Gap between sub-anchors	Highest stress
Figure 4(a)	Single anchor	4 μm	46 μm		85 MPa

(a) (b) (c) (d)

Figure 4. Contour plot of residual thermal stress of bonding surface (anchor height of 4 μm)

3. Experiments

To evaluate the bonding performance of the proposed anchor design experimentally, two series of

well-established anchor-beam MEMS devices (both conventional and the array-shaped) fabricated by SOG process were carried out to test the bonding quality and the bonding strength in practical application. The basic flow of SOG process (Fig. 5) is described as follows:
(a)Define bonding area, i.e. anchor, by advanced silicon etch (ASE).
(b)Form interconnects on glass wafer by lift-off process.
(c)Anodic bonding and KOH etch.
(d)Release structure by deep reactive ion etching (DRIE).

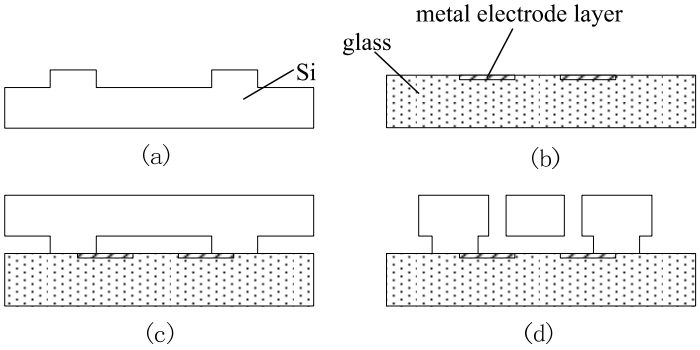

Figure 5. Basic flow of SOG process

3.1 Bonding quality testing device

The bond yield is utilized to evaluate the bonding quality. And various bonding areas are designed to investigate its influence on bond yield for both anchor design schemes. To compare the bond yield conveniently, a similar failure-accelerating method in reliability analysis is introduced. Microdevices are intentionally designed to extreme sizes. On one hand, the anchor is designed to be high enough (anchor height of 30μm). With a higher anchor, the electrostatic force of non-bonding surfaces will reduce and the pressure of bonding surface will decrease accordingly in anodic bonding. As a result, the bonding quality will be poor. On the other hand, the adjacent anchor in a certain direction is designed far enough, because the further adjacent anchor has less assist in anodic bonding of the anchor here.

The structure of the microdevice is shown in Fig. 6. The array-shaped anchor (top) and single anchor (bottom) have the same bonding area. For the array-shaped anchors, in the downward direction, the adjacent anchors are at the same distance with the same bonding area, which excluded the effect of other anchors below. And in the upward direction, the adjacent anchors are the reference anchors, which were at different distances with the same bonding area. From the above analysis it can be concluded that if the distance between the array-shaped anchor and the reference anchor is farther, the bonding quality of the array-shaped anchor would be poorer. For the single anchor, the situation is the same.

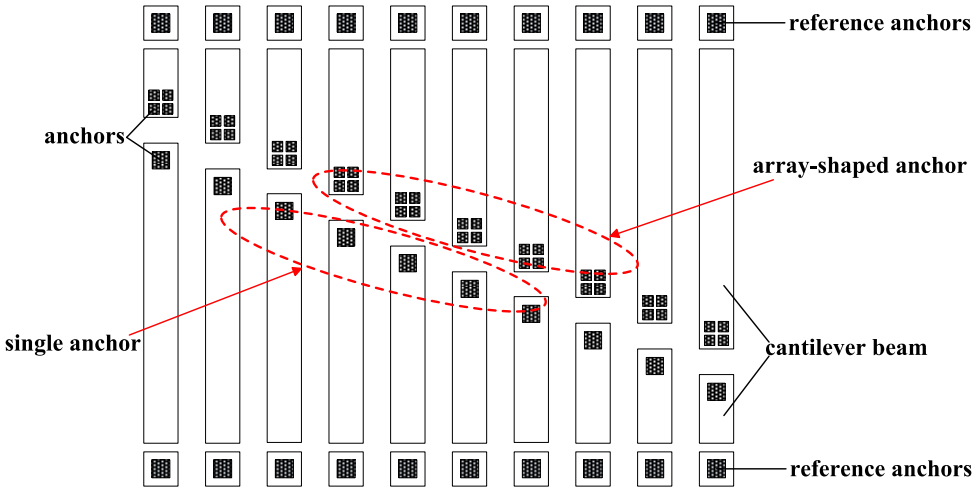

Figure 6. Structure of bonding quality testing device

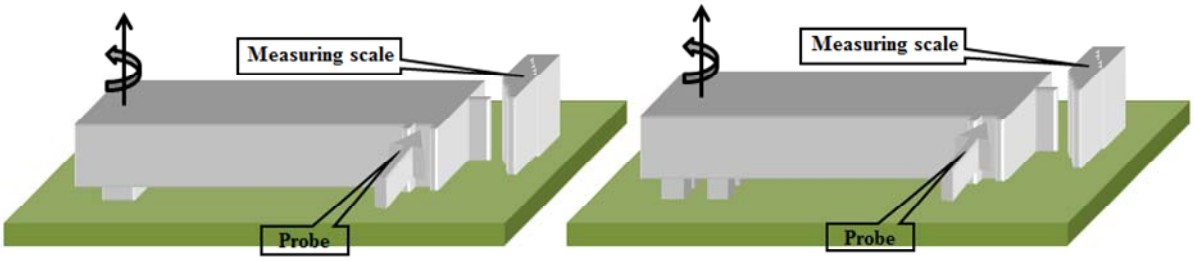
3.2 Torsional bonding strength testing device

For the horizontal-movable MEMS devices fabricated by SOG process, the conventional measuring methods of bonding strength cannot directly reflect the anchor strength in practical application, because the anchor stands torque when the devices are functioning. Therefore, torsional bonding strength testing device with anchor height of 4 μm and beam thickness of 71 μm is proposed (Fig. 7). The anchor bearing torque when the bonding surface fractures is used to characterize the torsional bonding strength. Specific measuring process goes as follows:

(1) Apply force to the top of the cantilever beam by the probe of the probe station;

(2) Increase the displacement of the probe step by step and record the displacement when the bonding surface fractures;

(3) Use the displacement (from (2)) and calculate the torque by FEA.



(a) conventional single anchor (b) array-shaped anchor

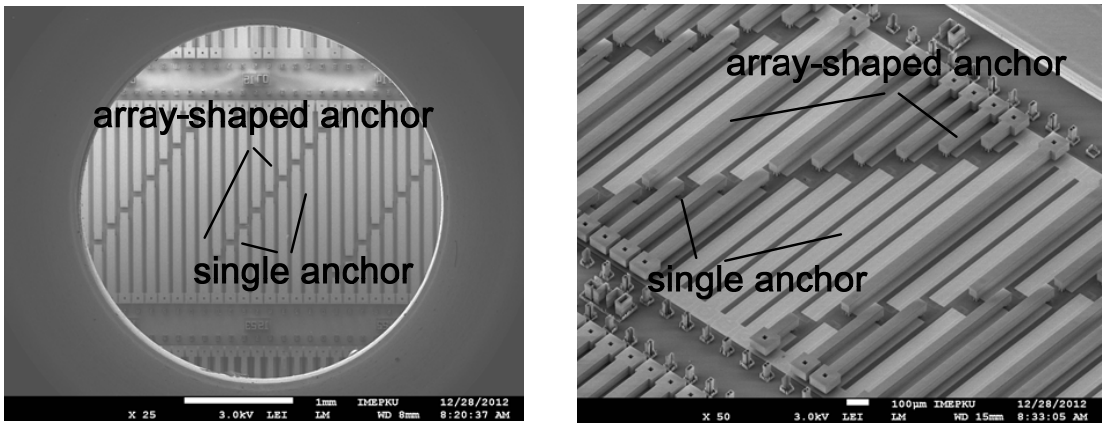
Figure 7. Structure of torsional bonding strength testing device

4. Results and discussion

4.1 Comparison of bonding quality

Figure 8 shows a scanning electron microscope (SEM) photograph of bonding quality testing devices. The cantilever beams of both array-shaped anchor and single anchor don't drop out when the bonding area was large (Fig. 8(a)). And dropping out happens tempestuously when the bonding

area is small (Fig. 8(b)). The result also shows that the situation of single anchor is severer than that of array-shaped anchor (Fig. 8(b)). It can be concluded that the bonding quality of array-shaped anchor (Fig. 9) is higher than that of the conventional single one and the bonding quality become poorer with a further adjacent reference anchor (Fig. 8(b)).



(a) Bonding area of 900 um^2 (b) Bonding area of 196 um^2

Figure 8. SEM photograph of bonding quality testing devices

In order to obtain the bond yield of array-shaped anchor and single anchor, 100 cantilever beams at each bonding area are selected by optical microscope and dropping out situations of them are observed. Figure 10 shows the statistical result, which proves the bonding quality of array-shaped anchor is higher than that of single anchor again. In addition, with the increasing of the bonding area, the bond yield become higher and the bond yield is 100% when the bonding area is bigger than $484\mu m^2$.

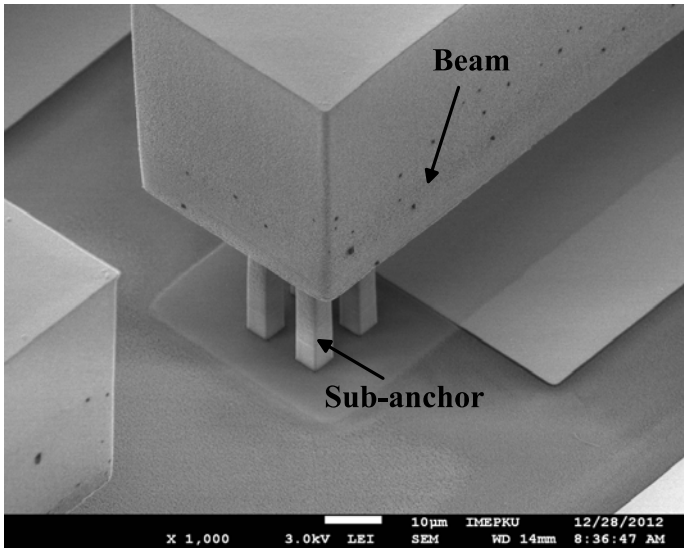


Figure 9. SEM photograph of array-shaped anchor

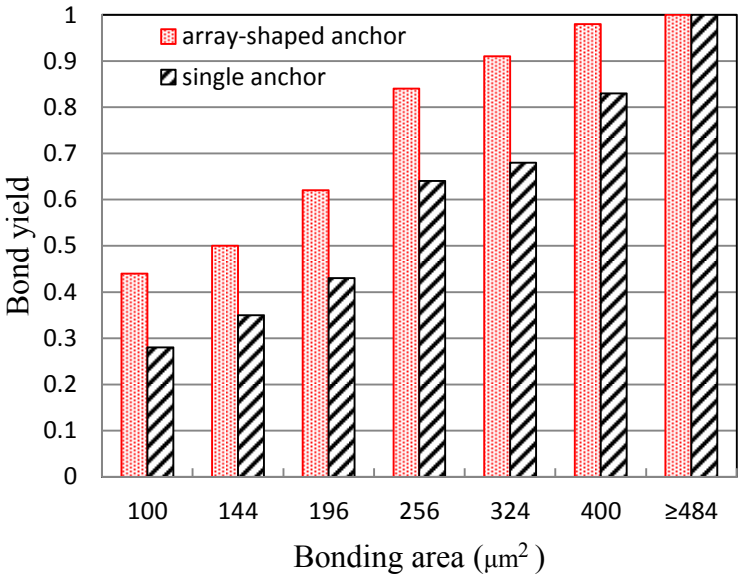

Figure 10. Correlation between bond yield and bonding area

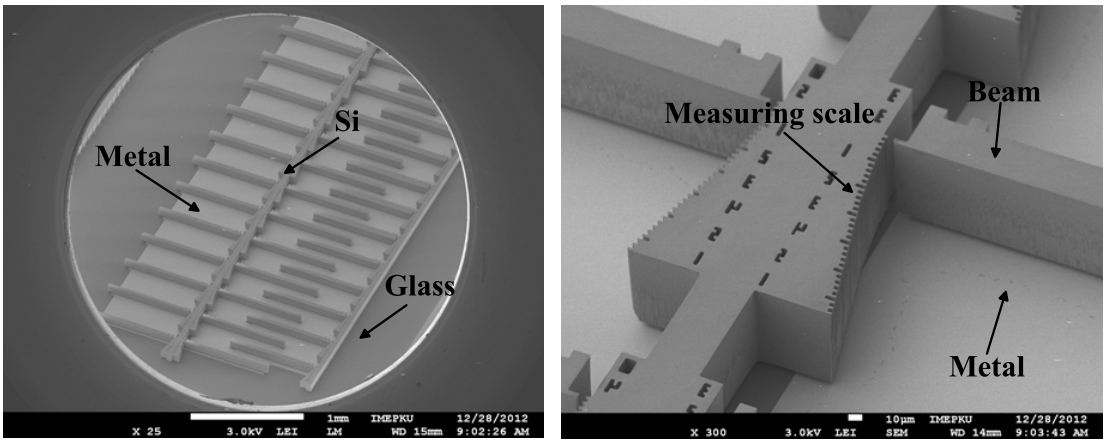
4.2 Comparison of torsional bonding strength

Figure 11 shows a SEM photograph of torsional bonding strength testing devices. To avoid footing effect in DRIE process, protecting metal layer is deposited on glass wafer (Fig. 11(a)). As a result, the actual size of the beam (41.7μm), shown in Fig. 12, is almost the designed size (43μm).



(a) (b)

Figure 11. SEM photograph of torsional bonding strength testing devices

Torsional fracture tests were carried out for both array-shaped anchor and single anchor. Based on the fractured displacements from the fracture tests, the torsional bonding strength is obtained by FEA. Figure 13 shows the correlation between torsional bonding strength and bonding area. The strength of array-shaped anchor is stronger than that of single anchor. And one reason is that the average bonding quality of array-shaped anchor is better than that of single anchor, which can be seen in section 4.1. Another reason is expressed below. There is a low-stress region in the middle of

single anchor bonding surface when the anchor stands torque, and this region contributes little to the bonding strength. However, there is no such low stress region in the array-shaped anchor when it stands torque. Therefore, array-shaped anchor has a stronger torsional bonding strength.

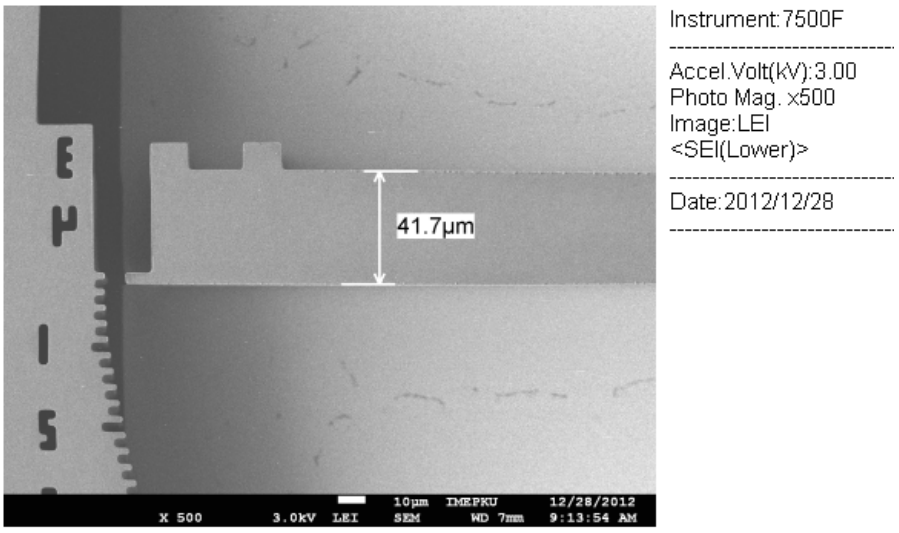


Figure 12. SEM photograph of cantilever beam and measuring scale

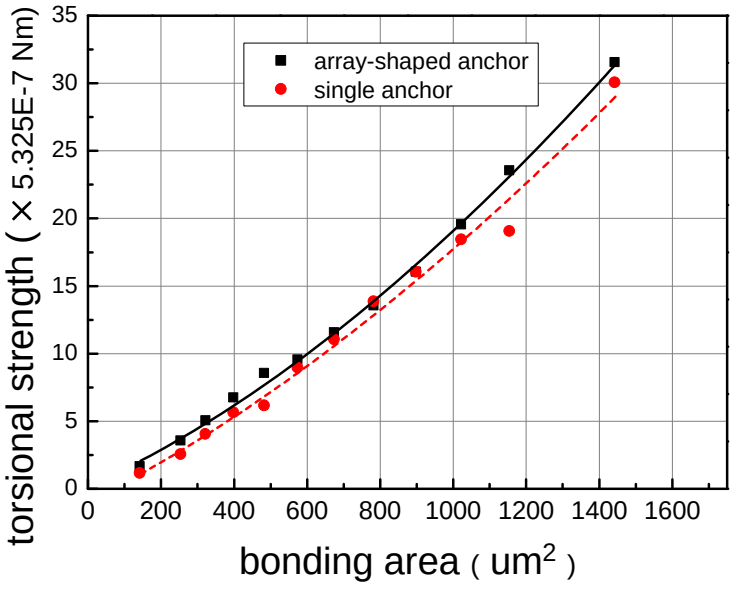

Figure 13. Correlation between torsional bonding strength and bonding area

5. Conclusion

A novel array-shaped anchor design scheme for microdevices fabricated by silicon-on-glass process was proposed. This anchor design was based on bonding strength consideration and consisted of four identical sub-anchors. The bonding quality test has verified that, compared with conventional single anchor, the proposed array-shaped anchor is beneficial to release the CTE mismatch induced

residual stress and decrease the metal electrode layer or particles induced bonding failure risk. Thus the new scheme would achieve a stronger bonding quality and a higher bond yield. From the torsional fracture tests of well-established anchor-beam MEMS devices, we conclude that the torsional bonding strength of array-shaped anchor is stronger than that of single anchor in practical application. This array-shaped anchor has a promising application in microdevice design with scaling-down.

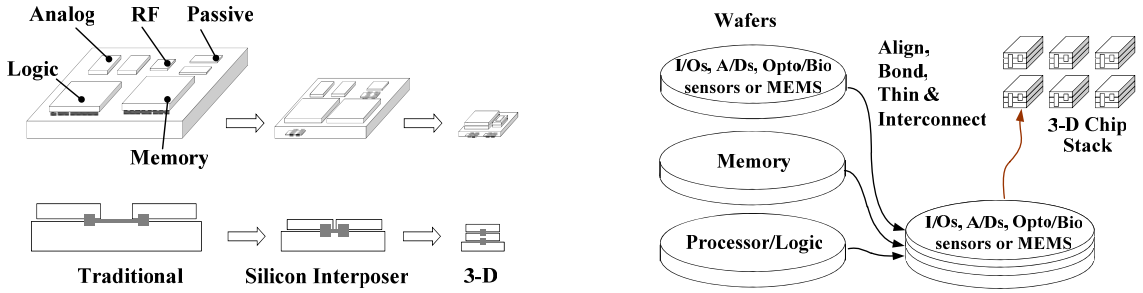
Abstract The MEMS/NEMS devices present an attractive prospect in many areas, especially in aviation and aerospace. Anodic bonding is one of the key technologies for the manufacturing of integrated 3-D structures of these devices. In this paper, based on experiments and detailed analysis, a systematic study will be made in depth for the mechanical behavior of anodically bonded interlayer within micro-scale structures. In accordance with a typical anodically bonded structure from one kind of MEMS micro accelerometer, a series of anodic bonding and mechanical tests were completed, for the behavior of the interlayer under quasi-static loading. The paper also presents the analysis of some important factors which influence the mechanical properties of the anodically bonded structure of Pyrex 7740 Glass/Al/Si. The metal oxidation reaction, dendritic nanostructures, and fractal patterns, which taking place at the bonding interface, were scrutinized. The experimental results demonstrate the thickness effect of the intermediate layer, and that the bonding tensile strength increases with the bonding temperature and voltage, but it decreases with the increase of the thickness of Al intermediate layer. The formation of the nanostructures in the bonding interlayer is also helpful to enhance the anodic bonding strength.

Keywords Anodic bonding, MEMS/NEMS, Intermediate layer,

1. Introduction

Three-dimensional (3-D) integration technologies related to Micro/Nano Electro-Mechanical Systems (MEMS/NEMS) devices is becoming one of focused research areas[1-5]. Anodic bonding is one of the key technologies for the manufacturing of integrated 3-D structures of these devices. In MEMS/NEMS devices, anodic bonding technology, especially for the connection of multilayer materials, offers a great prospect to extend the structural integration of the devices from two-dimensional (2-D) to 3-D, as shown in Figure 1. 3-D integration based on anodic bonding offers the potential for high performance and high-density applications due to lower power consumption, enhanced transmission speeds, better performance, and smaller device size[6].



(a) The integration of devices from 2-D to 3-D (b) 3-D integration for MEMS devices

Figure 1. The trend for the integration of MEMS/NEMS devices (revised from reference [1])

Anodic bonding, also known as electrostatic bonding or field-assisted bonding, was developed as a means to connect metals, alloys or semiconductors to conductive glasses. It is also a highly

promising method for joining certain metals or semiconductors to alkali-ion-conductive glasses at decreased temperatures. Compared to other techniques, the main advantage of anodic bonding is that a strong junction interface can be achieved at a reduced bonding temperature by application of an electric field [7-9]. The temperature for anodic bonding is usually lower than the softening point of glass and the melting points of the materials selected for this purpose. Nowadays, there exists a demand for this straightforward and reliable bonding technique in connecting, packaging, or hermetic sealing of more complex micro/nano structures and integrated microcircuits in MEMS/NEMS devices. The promising applications of MEMS devices are still limited by the reliability of MEMS devices, especially in the applications for military and aerospace systems.
Some previous studies [10, 11] show that one of the important structural failure mode is the stripping of micro anchors from its substrate in some type of MEMS devices. On the basis of the structure of these devices, in this paper, we report some mechanical tests on the micro anchors anodically bonded between Pyrex 7740 glass wafer and aluminum thin film coated on crystalline Si wafer.

2. Experimental

2.1. Specimen preparation

The experimental specimens were made by die-level anodic bonding at different temperatures and voltages. The mesa structures are used to avoid the edge micro cracks due to the chip dicing process. Pyrex 7740 glass wafers of 500 μm thickness and 100 mm diameter were cut into 12 mm ×12 mm square chips. The chemical composition of Pyrex 7740 wafer includes 80.8 Mol% SiO_2, 12.0 Mol% B_2O_3, 4.2 Mol% Na_2O, 2.0 Mol% Al_2O_3, 0.6 Mol% K_2O, 0.2 Mol% MgO, and 0.2 Mol% CaO, as shown in Table 1 [12].

Table 1. Chemical composition of Pyrex 7740 glass wafer (Mol%)

SiO_2	B_2O_3	Na_2O	Al_2O_3	K_2O	MgO	CaO
80.8 %	12.0 %	4.2 %	2.0 %	0.6 %	0.2 %	0.2 %

Si wafers were of 100 mm in diameter (double-side polished, p-type, and wafer surface plane (100), and were patterned into mesas with different-sized squares. There are four types of dice with different mesa spacing, as shown in Figure 2. These mesas were of 10 μm in height and were prepared with a deep reactive ion etch (DRIE) process. These patterned Si wafers were coated by an ARC-12M sputtering system with pure aluminum (99.999%). The coated aluminum thin films were of 500 Å, 950 Å, 1500 Å, and 2300 Å in thicknesses respectively. Then these Si wafers were also diced into squares of 12 mm ×12 mm. All square samples were cleaned by deionized water spray rinse in a 100-class clean room and dried by nitrogen gas under pressure.
A pair of glass chip and well-coated crystalline silicon chip was placed between two stainless steel plates, which acted as plate electrodes, and then between two hot plates. The glass side was connected with the cathode, and the silicon side was connected with anode. The schematic of this bonding configuration is shown in Figure 3.

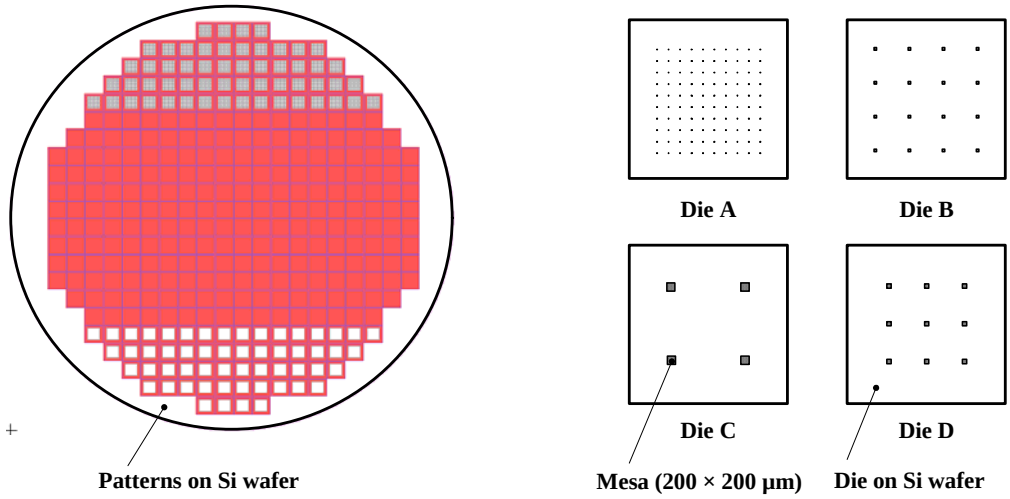


Figure 2. The Silicon wafer patterned with dice

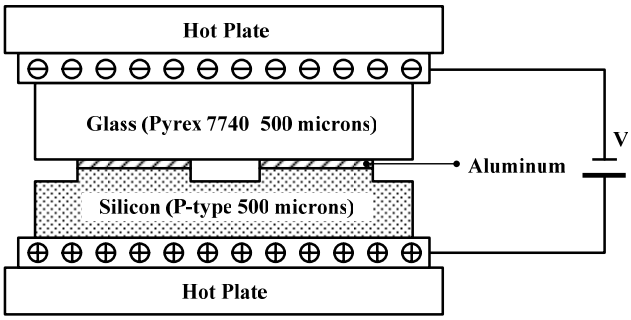

Figure 3. The schematic of specimen bonding configuration

The anodic bonding of these specimens was performed at the temperature range from 300°C to 375°C and at the voltage range from 150V to 500V for less than 30 minutes on an open (non-vacuum) bonding system. The bonding voltage was applied after the selected bonding temperature was reached. When the bonding was completed, the bonded sample was cooled to room temperature in 2 hours.

Before the upcoming tests, all specimens were examined under optical microscope. Some of the glasses were removed to expose the aluminum film for the SEM microanalysis with energy dispersive X-ray (EDX) and EBSD. The specimens were examined in a Sirion 400NC (FEI Field Emission Gun SEM) with the EBSD system (INCA Energy and Crystal System of Oxford).

2.2. Transmission electron microscopy

To prepare TEM test, the bonded samples were cut into small bars with a cross-section of 1.5mm×1.5mm (perpendicular to the interface). These small bars were individually glued into 3mm diameter copper tubes with an inner diameter of 2.2 mm. After the glue was cured on the Nuova II curing stage, these copper tubes were sectioned into slices approximately 750 μm thick, and then ground down to a thickness of about 40 μm and dimpled at the interface. Before argon-ion milling, these foils were attached to molybdenum support rings with an inner diameter of 1 mm. Specimens

were ion milled to electron transparency at room temperature by a Gatan Model 691 precision ion polishing system (PIPS). All TEM specimens were examined in a 300 kV Tecnai F30 (FEI Field Emission Gun TEM with LaB6 filament). STEM and energy dispersive X-ray (EDX) spectroscopy microanalysis were used for chemical analysis.

2.3. Tensile experiment under quasi-static loading

In order to characterize the bonding strength, each bonded chip was diced into 4 mm × 4 mm specimens by an automated dicing saw. Before the tensile test, all samples for tensile tests were examined under an optical microscope with 50× objective lens to exclude defective ones. The specimens were attached to aluminum jigs with glue for the tensile test. The bonding strength was measured by a tensile pulling machine (GATAN Microtest 2000) and the specimen under test was pulled perpendicular to the bonding interface until its rupture. The test pulling speed was 1 mm/min, and the pulling speed and the data acquisition were controlled by a personal computer. In these pulling tests, it was found that the maximum failure loads of these specimens were less than 5 N, and the specimens were easily damaged when they were fixed to rigid fixtures of the test machine. The alignment of the test studs is of critical importance because small deviations will induce bending moments which can cause premature failure of the test sample [13]. To improve the alignment of test samples and to avoid the early failure caused by the force from sample installation, a special fixture was designed with flexible steel wire strand, as shown in Figure 4.

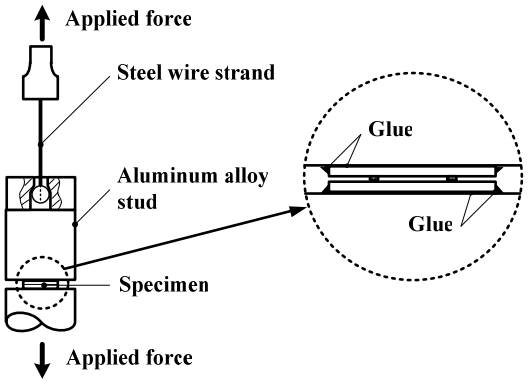

Figure 4. Schematic of fixture for tensile tests

3. Results and discussion

3.1. Fractures in bonded specimens

When all the bonding specimens were examined under optical microscope, fractures were found in some of the specimens, as indicated by white arrows in Figure 5. The fractures occurred in the glass side at the corner of the mesas, and many of them were found in the samples anodically bonded at higher bonding temperature. During the process of anodic bonding, when the bonding temperature was larger than 350°C, the fractures of this type were easily found in some specimens. This kind of fractures seldom occurred in the specimens bonded at the temperature of no more than 350°C. The reason for the occurrence of these fractures is the different thermal expansion coefficient with Pyrex

7740 glass and silicon. The higher the bonding temperature was, the larger the difference of thermal expansion coefficient between the glass and silicon, that is, the larger the residual stress was. The residual stress results in these fractures.

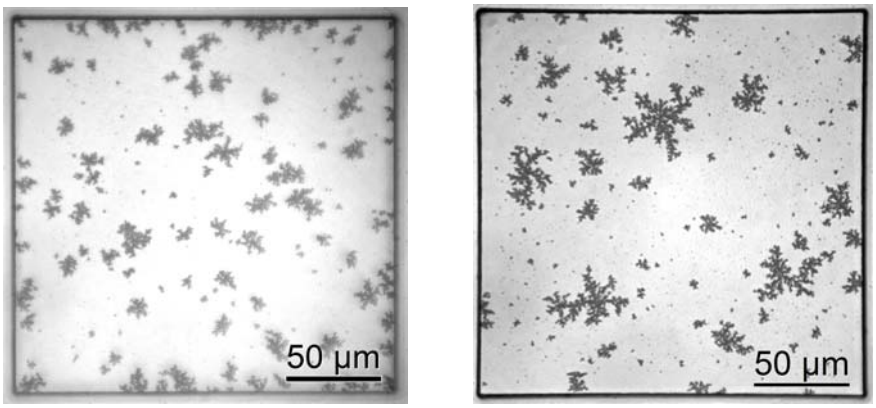
Figure 5. The typical fractures in the samples with Al film of 950 Å

3.2. Fractal patterns and dendritic nanostructures

3.2.1. Fractal patterns

With the optical microscope, many fractal patterns were found in the intermediate aluminum film, as shown in Figure 6. The size of the patterns decreases with the thickness of Al film and increases with the bonding temperature. The fractal patterns in the aluminum film have the characteristics of two-dimensional Diffusion-Limited Aggregation (DLA) model [14, 15]. The fractal dimensions of the typical fractal patterns are calculated by sand-box method [16, 17].



(a) 350 °C (b) 375 °C

Figure 6. Fractal patterns distribution in 500 Å thick Al film at different bonding temperatures

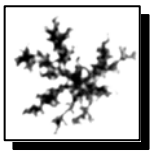
The fractal patterns in the intermediate aluminum film have the typical dimension of 2-D DLA process, and their fractal dimension is around 1.7, as listed in Some fractal patterns were analyzed with the EDX and EBSD systems of INCA. The microanalyses show that the fractal patterns contain the crystalline grains of Aluminum and Silicon. These fractal patterns were formed in the process of anodic bonding due to the limited diffusion and aggregation of Si atoms in the Al film.

These diffused Si atoms mainly originate from the following chemical reaction, $4Al + 3SiO_2 = 2Al_2O_3 + 3Si$. When the temperature is above 300°C, there exists a chemical reaction between the Al and SiO_2 [18]. The silicon dioxides come from the slightly oxidizing of silicon wafer on its exposed surface before the aluminum sputtering process of these silicon wafers.

Table 2.

Some fractal patterns were analyzed with the EDX and EBSD systems of INCA. The microanalyses show that the fractal patterns contain the crystalline grains of Aluminum and Silicon. These fractal patterns were formed in the process of anodic bonding due to the limited diffusion and aggregation of Si atoms in the Al film. These diffused Si atoms mainly originate from the following chemical reaction, $4Al + 3SiO_2 = 2Al_2O_3 + 3Si$. When the temperature is above 300°C, there exists a chemical reaction between the Al and SiO_2 [18]. The silicon dioxides come from the slightly oxidizing of silicon wafer on its exposed surface before the aluminum sputtering process of these silicon wafers.

Table 2. The typical fractal dimensions of the fractal patterns in the Al films[19]

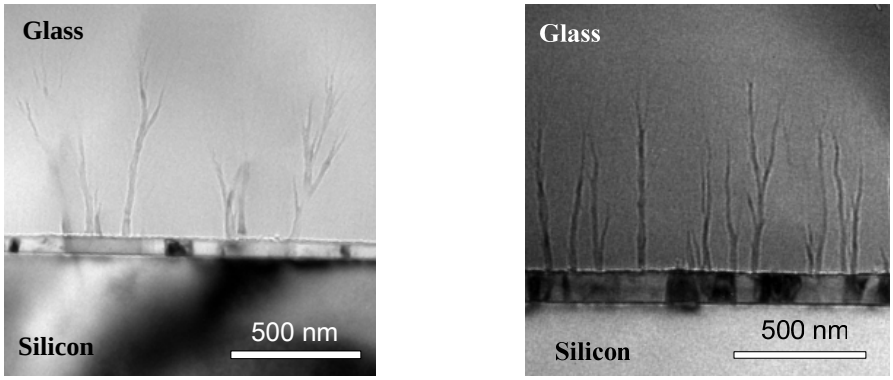
					


$D_B = 1.702$	$D_B = 1.695$	$D_B = 1.681$	$D_B = 1.696$	$D_B = 1.700$	$D_B = 1.727$

When the Al film is thin enough, the fractal patterns run through the span of the whole thickness of the film, and bond with the substrate and glass. The strength of chemical bond is 799.6±13.4 kcal/mol for Si-O, 511±3 kcal/mol for Al-O, and 325±7 kcal/mol for Si-Si [20]. Therefore, the fractal pattern improves the bonding strength between the Pyrex glass and the aluminum thin film coated on the silicon substrate.

3.2.2. Dendritic nanostructures

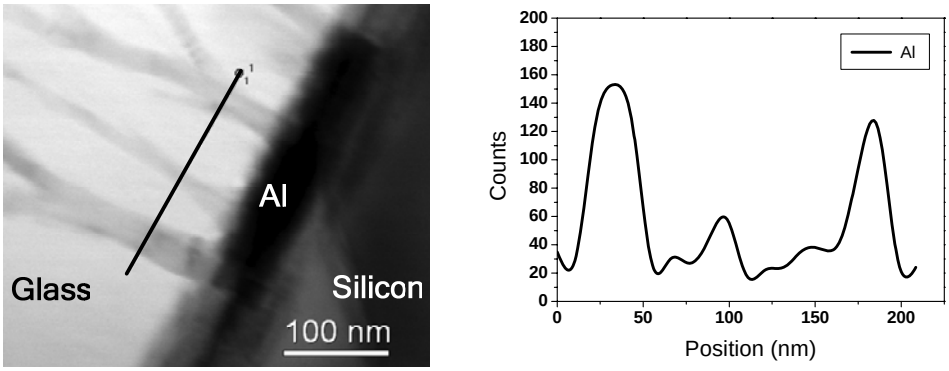
In all anodically-bonded samples, dendritic nanostructures were found in the Pyrex glass near the Al/glass interface, as shown in Figure 7. The dendritic nanostructures, which are seen over the whole thin area, exhibit a similar maximum height of 600-650 nm in the specimens bonded at 350°C, 400 V. These three-dimensional treelike structures have a trunk of tens nanometers in diameter (less than 40 nm). TEM cannot show all the small branches of these 3-D dendritic nanostructures.



(a) 50 nm aluminum film (b) 95 nm aluminum film

Figure 7. Dendritic nanostructures of specimens at 350°C and 400 V

Figure 8 illustrates the EDX analysis position and element analysis result of the nano dendritic structures under STEM mode. The electron beam scanning path is marked with a black thick line across three trunks of the dendritic structures, as shown in Figure 8(a). Element analysis indicates that the dendritic nanostructures are aluminum enriched, as shown in Figure 8(b). STEM/EDX microanalysis provides enough evidence of diffusion of aluminum into the Pyrex glass during anodic bonding. Examined by EDX, the trunks exhibit lesser counts of silicon and oxygen while the aluminum counts are conspicuously increased.

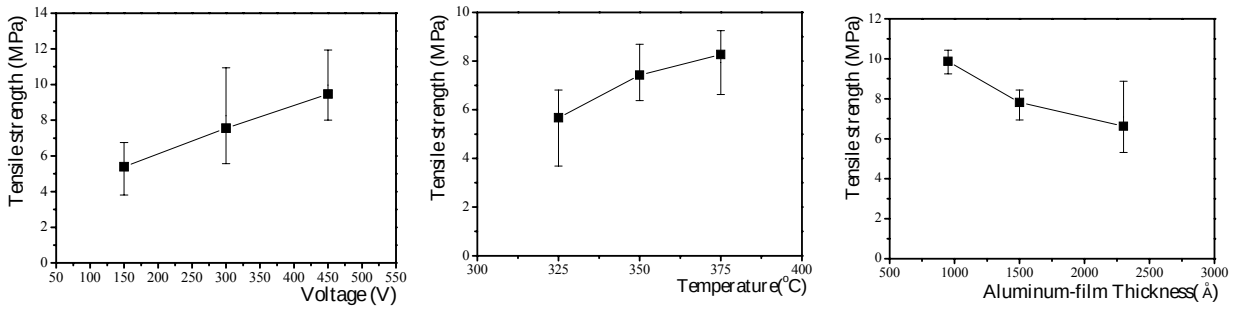


(a) Scanning position (b) Element counting

Figure 8. Scanning position and element counting for EDX analysis

3.2. Bonding strength

The mean bonding tensile strength are shown in Figure 9. Bonding tensile strength, which is averaged from the results of five or more specimens. The measured bonding strength values exhibit a rather large variance around a mean value. This can be attributed to several aspects, such as the misalignment of specimens, the characteristics of bonding behavior [21], the micro defects due to residual stress, and etc. All the specimens pulled apart were also examined with the optical microscope and scanning electron microscope (SEM), and some parts of the aluminum film and the Pyrex glass were residual on the opposite side.



(a) Voltage (b) Temperature (c) Thickness

Figure 9. Bonding tensile strength

Figure 9(a) shows the tensile strength increases with the bonding voltage ranged from 150 to 450 V. The specimens in Figure 9(a) were bonded with 700 μm thick Pyrex 7740 glass wafer at 300°C, and their aluminum film is 1300 Å thick. In the process of anodic bonding, the higher bonding voltage means the larger force produced by the electrostatic field across the bonding interface, and brings about much larger and more intimate contact area between the bonding pairs, that is, more chemical bonds generated at the bonding interface and an enhancement of the bonding strength. On the other hand, the higher the bonding voltage is, the more amounts of movable ions will be produced in the glass and then the more anions, mainly O^{2-}, will accumulate in the bonding glass adjacent to the interface of glass/Al, which provides more opportunities to form the chemical bonds between oxygen and aluminum. Unfortunately, a high bonding voltage will introduce a risk of electric breakdown, and the maximum bonding voltage is limited mainly by the breakdown voltage over the depleted layer.

The tensile test results tell that the maximum failure loads also increases with the bonding temperature from 325 to 375°C, as shown in Figure 9(b). The specimens used in Figure 9(b) were bonded with 500 μm thick Pyrex 7740 glass wafer, and the thickness of aluminum film is 500 Å. Pyrex 7740 glass has a complicated chemical composition and contains some important alkali elements, which are responsible for the ionic current in the glass during the anodic bonding process. The increasing of bonding temperature gives rise to more amounts of the cations, and correspondingly induces a large number of anions to accumulate near the bonding interface, which also provides more opportunities to produce chemical bonds with aluminum in anode and then improves the bonding strength. But a high bonding temperature not only will lead to the degradation of metal leads and integrated circuits in MEMS device, but also will induce large thermal stress. In the high temperature bonding tests, cracks were found in the glass of some specimens due to thermal stress, as shown in Figure 5.

When comparing the tensile failure loads from the specimens which were bonded under the same temperature, voltage, and duration time but with the different thicknesses of aluminum film, we find that their bonding tensile strength increases with the decrease of aluminum film thickness in our tested range, as shown in Figure 9(c). All the tested samples in Figure 9(c) were anodically bonded under 300°C and 400 V. The mean tensile strength increases from 6.6 to 9.9 MPa, while the Al film thickness decreases from 2300 to 950 Å, which indicate a fact that the experimental results show the remarkable size effect. The bonding strength is affected by the thickness of Al film within the tested range of Al thickness.

4. Summary

In summary, the tensile specimens were anodically bonded at the relatively low temperature and voltage, using Pyrex 7740 glass and patterned crystalline silicon chips coated with Al film. To investigate the mechanical behavior of anodically bonded interlayer of Pyrex Glass/Al/Si, the tensile experiments were completed with the newly designed flexible fixtures, and the analysis for the anodically bonded intermediate layer were also made with SEM and TEM.

The formation of the fractal patterns in the process of anodic bonding is due to the limited diffusion, aggregation, and crystallization of Si and Al atoms in the intermediate Al film. These fractal patterns have the fractal dimension of 2-D DLA process, and their fractal dimension is around 1.7.

These fractal patterns in the intermediate Al film consist of Al and Si crystalline grains.The fractal patterns improves the bonding strength between the Pyrex 7740 glass and the Al intermediate layer coated on the crystal silicon substrate.

The formation of the dendritic nanostructures is due to the diffusion and reaction near the glass/Al interface under a non-equilibrium condition during the anodic bonding process. These nanostructures might reveal helpful clues in improving the bonding quality. The dendritic nano-crystalline structures are shown to be one of the key structures for the improvement of strength in anodic bonding.

Test results demonstrated that, the bonding strength increases with the bonding temperature and voltage. This is in agreement with earlier results reported in the literature. But the experiments exhibit that the tensile strength decreases with the increase of the thickness of Al intermediate layer. Although the measured bonding strength values exhibit a rather large variance around a mean value, the experimental results can be referenced qualitatively. With the dimensions of MEMS devices downward, the scale effect in anodically bonded micro anchors should be considerable during the process of device design.

Abstract Carbon-carbon (C/C) composites, in which a carbon matrix is reinforced by carbon fibers, are mainly used as thermo-structural protections in the aerospace engineering. The ablation of C/C composites at high-temperature causes mass loss, which is dominated by coupling effect of physical, chemical and mechanical factors. This paper classified the C/C ablation into three types according to the ablation mechanism: linear-rate reaction, parabolic-rate reaction and logarithmic-rate reaction. In this work, a micromechanical model of C/C composite with high-temperature heat conduction was established. A linear heat-transfer finite element analysis was carried out for revealing the damage morphology of C/C composites at an ultra high temperature.

Keywords C/C composites, ablation, surface recession, thermal damage

1. Introduction

Thermal protection materials, which are highly required in advanced thermal protection systems and envisioned for use on future hypersonic and space craft, will inevitably be subjected to utmost high temperature and strong oxidizing environment, such as the intercontinental ballistic missile nose cap often suffer an ultra high temperature of 7000~8000K atmosphere, dozens of megawatt heat flow density, unexpected high erosion of particle cloud and nuclear radiation in reentry [1]. Ablation phenomenon is frequent occurrence on the re-entry progress of space shuttle or rocket caused by aerodynamic heating, which can heat the surface of spacecraft up to a extremely high temperature in seconds. The thermal energy may lead to solid surface melting, evaporation, sublimation or decomposition of solid surface in the ultra temperature environment. Therefore, it is important for protecting the inner structure and astronauts from high temperature thermal damage.

Carbon-carbon(C/C) composites consist of carbon matrix and reinforced carbon fibers[2] and possess a series of excellent mechanical properties, such as high temperature resistance, low density, high specific modulus, high specific strength, small coefficient of thermal expansion, high ablation resistance and high temperature resistant. Therefore, C/C composites are widely used in technological applications as excellent ablation resistance and thermal protection materials, e.g. solid rocket motor (SRM) nozzle throats, reentry rocket nose cone, missile nose-tips and leading edges [3,4]. In the ablation process, the sublimation or decomposition of C/C composites will take away lots of heat and the surface temperature of aerospace craft will be effectually lowered down. Consequently, the ablation resistance of C/C composites is directly related to the strengths of astrovehicle, determining the achievement of task scheduled. Hence, the research on the ablation of C/C composites has a great significance.

In generally, researchers investigate the ablation mechanism of C/C composites in high temperature environment from two aspects: experiment research and numerical simulation research. The experiment is an effective method to understand the ablation mechanism of C/C composites. Unfortunately, the experimental simulation is extremely expensive because of the complexity of the extreme environmental conditions. Therefore, computer-based numerical simulation, which can predict the thermo-mechanical response of these composite heat shields, have become an effective method for analyzing the ablation behavior of C/C composites. Ultimately, it will achieve the design

purpose of C/C thermal protective materials based on the ablation research and simulation

In recent study, Aspa et al.[5] carried out a one-dimensional diffusion model to describe the effective surface ablation recession. Their analysis focused on the ablation of diffuse-controlled reaction. Vignoles et al.[6,7] investigated surface roughness of C/C composites by SEM. They discovered that fibers, matrices and interphase have different ablation resistance, which usually leads to typical surface roughness feature. In their work, a three-dimensional reaction-diffusion local model was set up to simulate the formation of the typical needle shape of the carbon fibers during ablation. Laborde et al.[8] established a damage model for carbon-carbon orthotropic composite materials with a special attention to the thermo-mechanical effects. They performed a numerical solution using an implicit incremental scheme implemented in ABAQUS.

The origanization of the paper is as follows. In the section 2, a brief introduction is given of ablation mechanism of C/C composites. Section 3 is devoted to classify the C/C ablation recession into three types according to the ablation mechanism. In section 4, a mesoscopic analytical model of C/C composite with high temperature heat conduction was established. The analysis used a heat-transfer finite element in ABAQUS to simulate the ablation morphology of C/C composites at ultra high temperature. The last section is the summary of the main conclusion resulted from the present work.

2. Ablation mechanism of C/C composites

There are mainly two types of carbon-oxygen (C/O) reaction for C/C composites in oxidation atmosphere: $C+O_2=CO_2$ and$2C+O_2=2CO$.
In the ablation process, the surrounding oxygen is transferred to the surface of the C/C composites. Ablation reaction primarily occurred on the surface of those materials, which resulted in mass loss with melting, sublimation and particle erosion. Then with the inward diffusion of oxygen in the surface microcracks and pores of C/C structure, further oxidation occurred. During the reaction process, fiber and matrix are oxidized simultaneously. Whereas the reaction rate of fibers is lower than the matrix. That means, along with the aggravation of ablation, the first melted interface layers separate the fibers and matrix. Ultimately, the fibers are burned into needle shape, while the around matrix are eroded into cylindrical shell. Fig.1 shows the ablation process of a C/C composite.

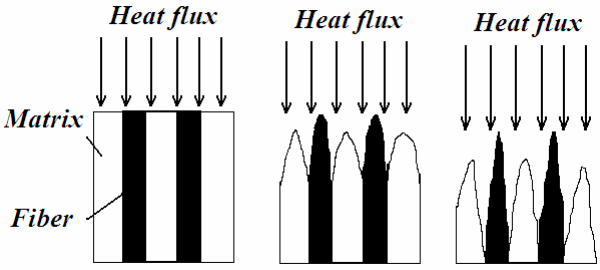

Figure 1. The ablation of the C/C composites

3. Ablation reaction rate of C/C composites

The oxidation reaction of C/C composites without high-temperature oxidation resistant coating is time-independent, and is mainly controlled by gas/solid interface reaction rate. In this case, the mass loss rate of C/C composites is linear with response time, as shown in Equation 1.

$$\frac{\Delta m}{A} = k_l t \tag{1}$$

where $\frac{\Delta m}{A}$ is the mass loss of C/C composites per unit area; k_l denotes coefficient of linearity

relation, which is determined by experiment; and *t* is the reaction time. Fig.2 shows the recession location of the ablation surface during the ablation process.

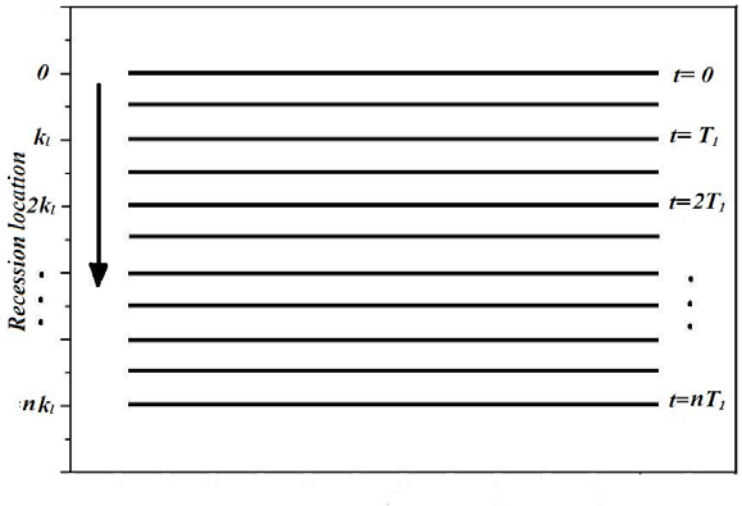

Figure 2. Recession location of the ablation surface

The ablation reaction of C/C composites with high-temperature oxidation resistant coating follows the parabolic-rate law, and the reaction rate is inversely proportional to the square root of time, which is determined by the diffusion rate of oxygen in the inner material, as shown in Equation 2.

$$\left(\frac{\Delta m}{A}\right)^2 = k_p t \tag{2}$$

where k_p is the parabolic rate constant or diffusion constant, which is derived from Arrhenius law as shown in Equation 3.

$$k_p = k_0 \, exp\left(-\frac{Q}{RT}\right) \tag{3}$$

where k_0 is the constant obtained by experiment; Q is the activation energy of oxidation; and R presents gas constant; T is the reaction temperature.

Logarithmic rate reaction is suitable for C/C composites with silicon elements. Early in the reaction process of ablation, the oxidation of silicon elements is rapidly, and silicon oxide produced from the oxidation between silicon and oxygen can generate a compact oxide layer covering the surface of C/C composites. The generated SiO_2 layer will prevent further diffusion of the oxygen and then increase the ablation resistance of the C/C. With the exacerbated of oxidation, the ablation of C/C composites will become severe and accompany with mass loss. Hence, the logarithmic-rate reaction mechanism is only appropriate for representing the early reaction of the C/C composites with silicon in lower high temperature.

3. Analytical model

C/C composite is a homogeneous multi-scale material. In microstructure, the “skeleton” of the composite consists of unidirectional bundles made of several thousands of fibers which are linked together by a pitch-based matrix. The formation of the typical roughness patterns of C/C composites in ablation process depends on the unidirectional fibers perpendicular to material surface. Due to the different ablation rates between carbon matrix and carbon fibers, the unidirectional fibers perpendicular to material surface will separate from the carbon base, expose to the external

oxidation environment, and take the shape of “needle clusters”. This paper focuses on the unit cell model of C/C composites in micromechanical structure, analyzing the change laws of C/C composites in high temperature thermal radiation and predicting the ablation morphology change.

There are two basic kinds of unit cell model of C/C composites. The first model, as shown in figure 3, is a hexahedron representative volume element (RVE), in which matrix and fibers are assumed homogeneous and isotropic, and the internal pores are negligible. The second model is a cylinder RVE, in which the fiber bundles are fit together into a 3D C/C structure. This meso-structure forms a network of meso-scale pores, as shown in figure 4.

In the finite element software of Abaqus, the thermal radiation analysis can be conducted according to the following steps: (ⅰ)modeling, (ⅱ) defining the materials property, (ⅲ) assembly model, (ⅳ) creating heat conduction steps and interaction, (ⅴ) applying boundary condition and load, (ⅵ) meshing and selecting element type, (ⅶ) creating analysis job, (ⅷ) results visualization.

The physical properties of C/C composite in the two models are listed in table 1. In the thermal radiation analysis, the physical constants of absolute zero temperature and Stefan-Boltzmann constants are -273.15 ℃ and 5.67E-8 W/(m^2 • k^4).

Table 1. Physical properties of C/C composites in the simulation models

Characteristic	Density	Elastic modulus	Poission’s ratio	Thermal conductivity	Specific heat
Unit	kg/m^3	GPa	--	W/(m • ℃)	J/(Kg • ℃)
Fiber	2000	230	0.22	1.15	5000
Matrix	1600	4.07	0.25	10.38	1000

Both of the two models use standard linear heat transfer element type DCC3D8 to analyze the thermal radiation. We assume the heat transfer is a transient state. It is subjected to surface radiation with ambient temperature of 2000℃ on top of the RVE and predefined temperature field of 300℃. We ignore the mass diffusion during the ablation process. The governing equation is

$$[C]\{\dot{T}\}+[K]\{T\}=\{F_q\}+\{F_r\},$$

where [C] is the element capacitance matrix, [K] is the sum conductivity matrix of heat conduction and thermal radiation. {F_q } and { F_r} are the load vectors due to applied heat flux and radiation respectively. We can obtain the temperature distribution in the C/C composite, and then calculate the heat flux by the following rule:

$$q = A((T-T^Z)^4-(T^0-T^Z)^4)$$

where A is the radiation constant , which was set to be one emissivity times the Stefan-Boltzmann constant; T^Z is the value of absolute zero on the temperature scale being used.

4. Numerical results

Damage analysis of hexahedron RVE in the ablation process was carried out first. The numerical example was presented to bring out for analyzing the potential ablation damage location. The finite element model was implemented in ABAQUS using a heat transfer element to analyze the ablation property of C/C composites during high temperature radiation of 2000℃. Figure 5 shows the heat flux distribution in a time of 0.13 seconds. The thermal flux magnitude of the 14 nodes along the circumscribed circle radius of the hexahedron is shown in figure 6.

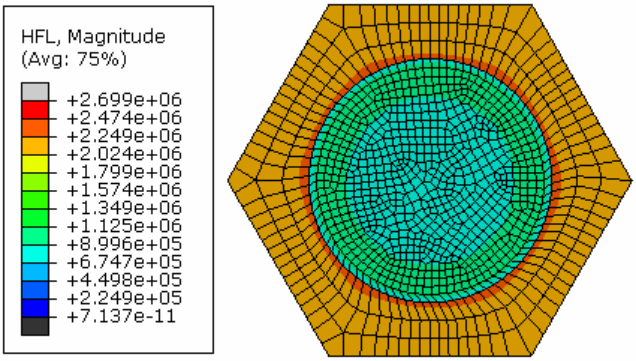

Figure 5. Heat flux distribution in micromechanical structure at 0.13seconds

The simulation result indicated that the heat flux at the interface between fiber and matrix is maximum, which make the interface damage easily, as shown in red colored area in figure 5. The result in figure 6 demonstrated that because of the mismatch between fibers and matrix, the thermal flux at the interface jumps to a higher value than the values inside the fiber, implying the debonding between fibers and matrix may happen during the ablation process.

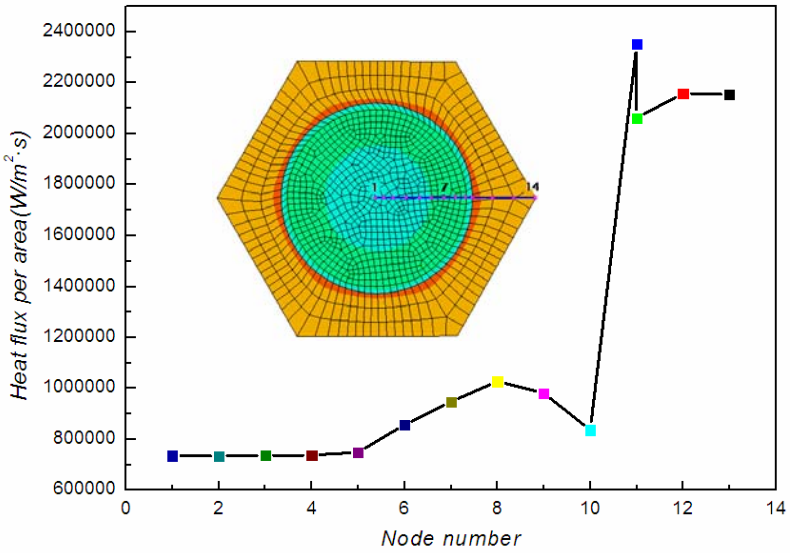

Figure 6. Variation of heat flux of selected nodes

Next, the damage analysis of Cylinder RVE in the ablation process was conducted. The numerical simulation focused on the temperature rise period of cylinder RVE in ultra thermal radiation environment. According to the symmetry of the cylinder RVE of C/C composites, a 3D axisymmetric model was established in software ABAQUS. The heat-transfer element was used to simulation the progress of temperature rising up during the ultra thermal radiation. It was subjected to specified surface radiation interaction with a temperature of 2000℃on the surfaces except the

bottom one. Both matrix and fibers are assumed homogeneous and isotropic. Figure 7 (a) illustrates the axisymmetric model of cylinder RVE, and the mark numbers of selected nodes are shown in meshed model in Figure 7(b).

The ablation morphology of C/C composites is determined by the temperature when the oxidation is adequate. As shown in Figure 8, it was indicated that the carbon fiber presented a cone head, and the carbon fibers took the shape of needles after ablation processes. The total ablation time was about 50 seconds. In the ablation process, the temperature of the material came to balance in 40s. The results indicate that the ablation morphology of C/C takes the shape of typically “needle clusters” due to the mismatch of the thermal property of the carbon fibers and matrixes.

The analysis result is consistent with experimental results in Ref.9. Figure 9 illustrates that the temperature gradient of material surface exposed to the external environment changes greatly, which will increase the incidence of material surface damage.

5. Conclusion

In this paper, the ablation damage of C/C composites in high temperature radiation environment was investigated. The conclusions can be remarked as follows.

(1) The mismatch of ablation rate between fiber and matrix leads to a high heat flux and damage at the interface during thermal radiation.

(2) The ablation morphology of C/C composites takes the shape of typical “needle clusters” due to the mismatch of the thermal property of the carbon fibers and matrixes.
