For origin dislocation densities below $10^{12}m^{-2}$ (an undeformed material) the yield stress is high and it is almost unchanged with the dislocation density decrease. One can see that there is an "optimal" dislocation density which corresponds to the lowest shear stress. It is proportional to the strain rate according to Orowan equation (11). Further increasing of the origin dislocation density results in the increase of the yield strength according to the Taylor hardening low (1). Increasing of the dislocation density during the deformation is almost absent if the origin dislocation density exceeds $10^{14}m^{-2}$, as it was demonstrated by our calculations with use of the Eq.(6) for dislocations kinetics.

4.2 An inverse Hall-Petch relation in ultrafine crystalline copper

Figure 3 presents dependence of the dynamical yield stress on the grain size (in the Hall-Petch coordinates) at strain rates from $2.4\cdot10^{8}s^{-1}$ to $3.5\cdot10^{8}s^{-1}$ with «not optimal» origin dislocation densities. In the coarse grained materials (grain size above 300μm) the Hall-Petch relation is observed.

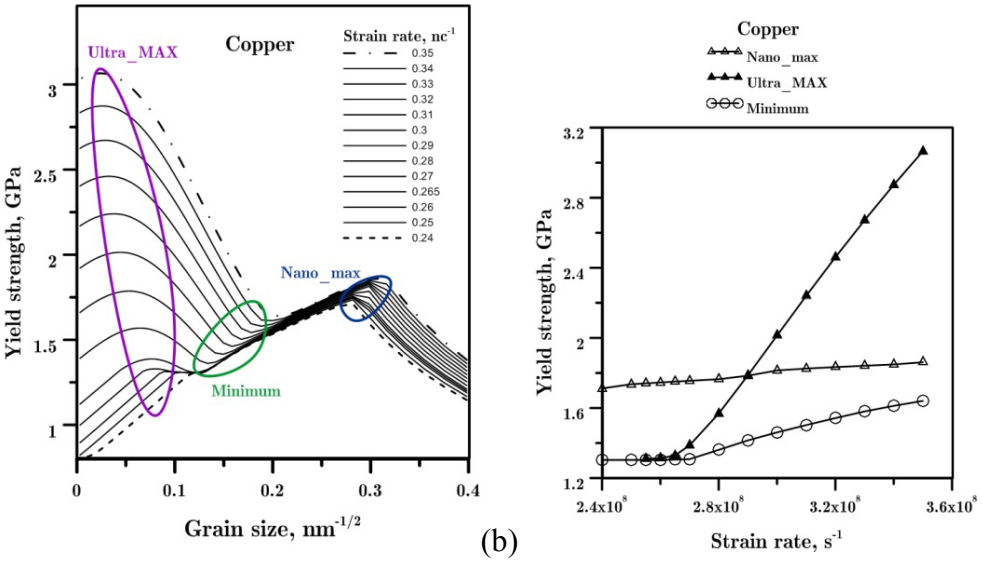

Figure 3 The dependence of the dynamic yield stress on the grain size at different strain rate (a) and on the strain rate at different grain size (b) for copper at extremely high strain rate.

The well-known inverse Hall-Petch relation is also observed for the grain size range <12 nm ($d^{-1/2}$~0.3). But the second maximum of the dynamic yield strength corresponding to the grain sizes of about of hundreds of nanometers appears in this situation. Our calculations demonstrate that at the strain rate above $10^{7}s^{-1}$, the ultrafine-grained copper is stronger to shifting than the nanocrystalline copper. Existence of additional maximum in the ultrafine-grain material is explained by the beginning of the grain boundary sliding and by its contribution into the plastic deformation rate. Figure 3(b) demonstrates a linear growth of the yield strength with increasing of the strain rate. Growth rate is maximal for the ultrafine crystalline metals.

4.3 Yield strength limitations

For all high strain rates the yield strength increases with the strain rate increase. But there are several mechanisms limiting this growth. The homogeneous nucleation dislocation must solve the problem of the dislocation starvation. It can be included as an additional dislocation source in the dislocation kinetics equation (6):

$$\frac{d\rho_D^G}{dt} = 2\pi c_t N, \quad \dot{N} = J_{GD} - \frac{N}{c_s\sqrt{\rho_D}}, \tag{12}$$

where N is a number of homogeneously nucleated dislocation per unit volume. We supposed here that the homogeneously nucleated dislocation loop becomes an ordinary dislocation if its diameter grows up to the mean distance between the dislocations. The nucleation rate of the dislocations per unit volume is equal to [34]:

$$J_{GD} = J_{GD}^0 \exp\left(-\frac{U_{GD} - \sigma_\tau V_{GD}}{kT} \right) \tag{13}$$

For copper activation volume $V_{GD} = 2.7 \cdot 10^{-28}$ m^3 , activation energy $U_{GD} = 4.67$ eV and the constant $J_{GD}^0 = 10^{14}$ s^{-1} [34]. Figure 4 demonstrates the dependence of the dynamic yield stress on the strain rate for different dislocation densities. One can see that homogeneously nucleation of dislocation effective for strain rate 10^8s^{-1}-10^9s^{-1}. After that efficiency of dislocation gliding mechanism achieve its theoretical limit.

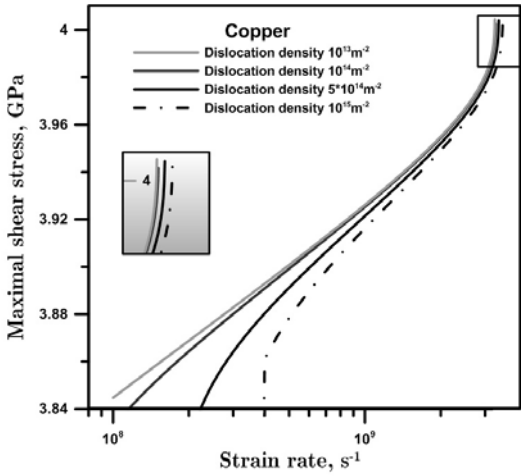

Figure 4 the dependence of the dynamic yield stress on the strain rate for different dislocation densities.

The twinning, as an additional mechanism of plasticity, has to limit the yield strength at extremely high-rate deformations. But our estimates show that efficiency of twinning mechanism is only a few times more than the efficiency of the dislocation plasticity. Therefore, it also decreases stresses in only limited range of the strain rates – less than 10^{10}s^{-1}.

4. Summary

The yield strength at low strain rate is limited and can be sufficiently increasing to theoretical tensile strength only by the way of impurities introduction. At the strain rates above 10^6s^{-1}, the ultrafine-grained metals have the maximum dynamical yield strength (instead of the nanocrystalline metals at the low strain rates). Abnormal and inverse Hall-Patch relations in the ultrafine grained copper were demonstrated by numerical simulations; dislocation starvation effect is related for its explanation. Analogous effect was detected experimentally in tantalum [35] and copper [36]. Mechanisms of the homogeneous nucleation of dislocation and the mechanical twinning effectively decrease the dynamical yield strength at the strain rates 10^8s^{-1}-10^9s^{-1}.

Abstract We have investigated numerically an evolution of initial perturbations of temperature or dislocation density in metals at high-rate deformation and its influence on the localization of plastic flow. A high-rate simple shear of micro-samples of pure metals and alloys, coarse-grained as well as nano-crystalline, has been simulated in two-dimensional geometry with use of the continuum mechanics supplemented by the dislocation plasticity and the grain-boundary sliding models. Perturbations of the temperature or dislocation density lead to restricted localization of the plastic deformation, but they can not initiate instability of the plastic flow as a self-sustained and increasing process. A more effective reason of the localization is the stress concentration, caused, for example, by boundary conditions. Rate of the plastic deformation is maximal in areas of the shear stress localization and it can be close to zero outside these areas. Heterogeneity of the grain sizes distribution through the sample can also lead to substantial localization of the plastic flow due to the grain size dependence of the dynamic yield strength.

Keywords High-rate plasticity, Localization, Temperature perturbation, Dislocations, Metals

1. Introduction

Localization of macroscopic plastic deformation is a widespread phenomenon in metals. It can be provoked by decrease of the material temperature, by increase of deformation rate or by decrease of grain size in polycrystalline metals. Localization of the plastic flow manifests themselves as an appearance of local areas with high plastic deformation values - up to several tens. This phenomenon is being researched intensively [1-6]. Heterogeneities in form of narrow bands arising at the high rate deformation are known as adiabatic shear bands. They are two-dimensional and almost flat formations, which boundaries are displaced, one relative to another, like in cracks of the 2nd or 3rd type, but material between the boundaries remains continuous. Thickness of the bands usually varies from ten to several hundreds of micrometers, while an extent of the bands varies from several millimeters up to several centimeters. Up to 90% of the whole plastic deformation of the material can be concentrated in the shear bands, as well as high shear deformation is observed in the neighborhood of the bands [3]. Shear bands have a complex structure of highly deformed material and can contain dislocation arrangements and nanocrystalline grains inside themselves [7]. Such bands were observed in metallurgical processes for a long time and were described first by H. Tresca [8]. A hard striker breaking through the metallic barrier is another example of practically important process, in which localization is well defined and it was observed rather long ago [9,10]. Localization substantially effects on the material strength as a whole relative to shear deformation.

First important point in explanation of the shear bands formation was made by C. Zener and J.H. Hollomon [11], which had proposed that a local temperature rise during the deformation leads to softening of the material, and that competition between the temperature softening and a strain hardening results in instability of the plastic flow (thermoplastic instability) and in the localization [1,3]. This viewpoint had been supported by many authors and until recently it often was seen as only one possible. But in a large number of materials revealing the localization, the plastic deformation results in inessential temperature increase, which is not enough for a substantial

softening of a uniformly deformed material [12,13]. High-speed infrared photography have shown, that even in the areas of the plastic flow localization the temperature rise does not exceed 10 K in iron [14], while in titanium it is about 100 K [15]. Therefore, the thermoplastic instability could not be a universal mechanism of the localization.

At high-rate deformation of pure metals (at the strain rates about 10^5-10^6 s^{-1} or higher) a temperature hardening came in the stead of the temperature softening [16,17]. It is caused by an increase with temperature of friction force, which acts on moving dislocation [17,18]. Dislocations move in an over-barrier mode in the pure metals at such strain rates, and the dynamic yield stress is determined by the friction force and by the dislocation density. The transition to the over-barrier mode, revealing in the temperature hardening, can by expected in alloys as well but at the even more high strain rates. In conditions of the temperature hardening the thermoplastic instability scenario can not be truth. It also puts a question about place of the temperature perturbations and other factors in initiation of the localization.

Localization is often attended by a substantial change of defects substructure [7]. While the thermoplastic instability is theoretically well described, an influence of the defect substructure on the localization process is investigated on the level of estimations only. Objective of the present work was to investigate possible instabilities of plastic flow with respect to initial perturbations of temperature or dislocations density or the grain size in polycrystalline metals. We numerically studded a simple shear of pure monocrystalline aluminum, nanocrystalline aluminum and aluminum alloy. It is known that the pure aluminum is not inclined to the localization [19], while the aluminum alloys reveal it [20,21]. The obtained results, at first, seemed to be strange, but, in truth, fully explainable.

2. Model and formulation of problem

Total plastic deformation of the polycrystalline metals is supposed to be a result of the combined action of two competing effects, namely, the dislocation motion and the sliding along the grain boundaries. According to this viewpoint, the plastic deformation tensor w_{ik} is represented by the sum $w_{ik} = w_{ik}^{\mathrm{D}} + w_{ik}^{\mathrm{gb}}$, where w_{ik}^{D} is the part of plastic deformation caused by the dislocation motion, and w_{ik}^{gb} is the part caused by the grain boundary sliding. The dislocation plasticity [22,23] and the grain boundary sliding [24-26] models are generalized on the two-dimensional Cartesian case (2D) and used here for determination of w_{ik}^{D} and w_{ik}^{gb} correspondently. Full model consists of continuum mechanics equations supplemented by the equations for dynamics and kinetics of dislocations and by the equations for time derivatives of w_{ik}^{D} and w_{ik}^{gb}.

2.1. Equations system

Here we write down the equations system to be solved numerically below:

$$\frac{1}{\rho}\frac{d\rho}{dt} = -\frac{\partial v_k}{\partial x_k}, \tag{1}$$

$$\rho\frac{dv_i}{dt} = \frac{\partial}{\partial x_k}\left(-P\cdot\delta_{ik} + S_{ik}\right), \tag{2}$$

$$\rho\frac{dU}{dt} = \left(P + \frac{S_{ik}^2}{4G} + \varepsilon_D\rho_D\right)\frac{1}{\rho}\frac{d\rho}{dt} + \frac{\partial}{\partial x_l}\left(\kappa\frac{\partial T}{\partial x_l}\right) + S_{ik}\frac{dw_{ik}}{dt} - \varepsilon_{\mathrm{D}}\frac{d\rho_{\mathrm{D}}}{dt}, \tag{3}$$

$$S_{ik} = 2G\left[u_{ik} - \frac{1}{3}u_{ll}\cdot\delta_{ik} - w_{ik} \right], \tag{4}$$

$$\frac{du_{ik}}{dt} = \frac{1}{2}\left[\frac{\partial v_i}{\partial x_k} + \frac{\partial v_k}{\partial x_i} \right] + \Omega_{ik}, \tag{5}$$

$$\frac{dw_{ik}^{\mathrm{D}}}{dt} = -\sum_{\beta} \frac{1}{2}\left(b_i^{\beta} n_k^{\beta} + b_k^{\beta} n_i^{\beta} \right) V_{\mathrm{D}}^{\beta} \rho_{\mathrm{D}}^{\beta} + \omega_{ik}, \tag{6}$$

$$\frac{m_0}{\left[1-\left(V_{\mathrm{D}}^{\beta}/c_{\mathrm{t}}\right)^2\right]^{3/2}} \frac{dV_{\mathrm{D}}^{\beta}}{dt} = \left(S_{ik} b_i^{\beta} n_k^{\beta} - \frac{bY}{2}\cdot \mathrm{sign}\left(S_{ik} b_i^{\beta} n_k^{\beta} \right) \right) - \frac{B\cdot V_{\mathrm{D}}^{\beta}}{\left[1-\left(V_{\mathrm{D}}^{\beta}/c_{\mathrm{t}}\right)^2\right]^{3/2}}, \tag{7}$$

$$\frac{d\rho_{\mathrm{D}}^{\beta}}{dt} = \frac{0.1}{\varepsilon_{\mathrm{D}}} \left\{ \frac{B\cdot\left(V_{\mathrm{D}}^{\beta}\right)^2}{\left[1-\left(V_{\mathrm{D}}^{\beta}/c_{\mathrm{t}}\right)^2\right]^{3/2}} + b\cdot Y\cdot\left|V_{\mathrm{D}}^{\beta}\right| \right\} \cdot \rho_D^{\beta} - k_a b\cdot\left|V_{\mathrm{D}}^{\beta}\right|\cdot\left(\rho_{\mathrm{D}}^{\beta}\right)^2, \tag{8}$$

$$\frac{dw_{ik}^{\mathrm{gb}}}{dt} = \frac{1}{2G\,\mathrm{T}} \sum_{\alpha} \tau_i^{\alpha} n_k^{\alpha} \left(S_{lm}\cdot\tau_l^{\alpha} n_m^{\alpha} - y_b \right) + \omega_{ik}^{\mathrm{gb}}. \tag{9}$$

where Eq. (1) is the continuity equation [27], Eq. (2) is the equation of motion, Eq. (3) is the energy conservation law, Eq. (4) is the generalized Hooke law [28] with accounting of the plastic strains w_{ik}, Eq. (5) is the equation for geometrical deformation u_{ik}, induced by a macroscopic motion of substance, Eq. (6) is the generalized Orowan equation [29] for the plastic strain w_{ik}^{D}, Eq. (7) and Eq. (8) are equations of dynamics and kinetics of dislocations [22]. Eq. (9) describes the grain boundary sliding [24-26], where T - relaxation time and y_b - threshold stress for sliding.

In the Eq. (1) – Eq. (9): ρ is substance density; $v_i = \{v_x, v_y, 0\}$ is velocity vector; $x_i = \{x, y, 0\}$ are the Cartesian coordinates; P is the pressure, which is determined from a wide-range equation of state $P = P(\rho, U)$ [30,31]; S_{ik} is the tensor of stress deviators, which characterizes the shear stresses; U is the part of internal energy, which corresponds to the state with zero stress deviators $S_{ik} = 0$ and with zero dislocation density $\rho_{\mathrm{D}} = 0$; T is the substance temperature, which also can be found from the wide-range equation of state $T = T(\rho, U)$; G is the shear modulus; κ is the heat conductivity coefficient; $\varepsilon_{\mathrm{D}} \approx 8\ \mathrm{eV}/b$ is the dislocation formation energy per unit length, where b is modulus of the Burgers vector of dislocation.

Tensors Ω_{ik}, ω_{ik}^{D} and $\omega_{ik}^{\mathrm{gb}}$ take into account the change of u_{ik}, w_{ik}^{D} and w_{ik}^{gb} correspondently due to substance rotation [32]. Indexes i,k,l,m numerate the space directions and run from 1 to 3; the summation rule is valid for dummy indexes; δ_{ik} is the bivalent mixed tensor. Index β numerates possible slip systems of dislocations, which is characterized by the Burgers vector b_i^{β} and by the normal to the slip plane n_i^{β}. Dislocation density in the corresponding slip system is designated as $\rho_{\mathrm{D}}^{\beta}$, velocity of these dislocations - V_{D}^{β}. Total density of dislocations can be obtained by summation $\rho_{\mathrm{D}} = \sum_{\beta} \rho_{\mathrm{D}}^{\beta}$. In the Eq. (7), Eq. (8): $c_{\mathrm{t}} = \sqrt{G/\rho}$ is the transverse sound speed of the material; $m_0 \approx 10^{-16}$ kg/m is the rest mass of the dislocations; Y is the static yield stress; k_a is the annihilation factor; B is the coefficient of phonon friction, it describes the

resistance to the dislocation motion. Index α numerates possible planes of grains sliding, which are characterized by the normal n_i^α; τ_i^α is the direction of maximal shear stresses in the α-plane.

Eqs (1)-(8) were solved numerically with use of the computer program CRS, written by A.E. Mayer. Sub-problem of the substance dynamics (Eqs (1)-(3)) were solved by a modification of the numerical method proposed by A.P. Yalovets [33]. All other equations were solved by Euler method with a varied time step.

2.2. Problem statement

Simple shear of 2D metallic sample with square cross-section is simulated (Fig. 1). One face of the sample ("lower" face, $y = 0$) is at rest $\vec{v}(y = 0) = 0$, while the opposite face ("upper" face, $y = L$) moves along the "lower" face with constant velocity $v_x(y = L) = L \cdot \dot{\varepsilon}$ and $v_y(y = L) = 0$, where L is a lateral length of the square, $\dot{\varepsilon}$ is a shear deformation rate. The length L must be chosen small enough to provide disturbance propagation through the sample during a characteristic time of deformation (an inverse value to $\dot{\varepsilon}$), therefore, inequality $L \le 10^{-2} \cdot c_t / \dot{\varepsilon}$ was required.

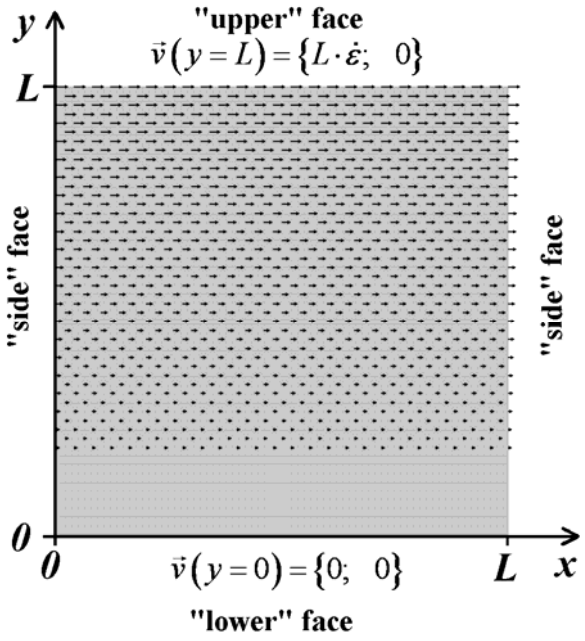

Figure 1. Initial state of the investigated 2D sample (initial velocity field is shown by little arrows).

Initial velocity was set linearly increasing from the "lower" face to the "upper" face: $v_x(x, y) = y \cdot \dot{\varepsilon}$, $v_y(x, y) = 0$, which corresponds to a uniform simple shear, thus, an initial shear rate was uniform along the sample. Two different problems were determined by boundary conditions on the "side" faces: constrained shear – at the forced movement of the "side" faces with velocity $v_x = y \cdot \dot{\varepsilon}$, $v_y = 0$; and free shear – at free surface condition on it.

Pure aluminum, aluminum-copper alloy and ultra-fine-grained aluminum were studied. The pure aluminum was characterized by the next expression for the static yield stress $Y_{\mathrm{Al}} = 2.2 \cdot 10^7 + 0.4Gb\sqrt{\rho_{\mathrm{D}}}$. This expression takes into account the strain hardening (second term in the right-hand part) in a Taylor relation form [34]. The aluminum-copper alloy was characterized by

another expression for the static yield stress $Y_{\mathrm{Al+Cu}} = 28.625 \cdot 10^7 - 2.425 \cdot 10^5 \cdot T + 0.4Gb\sqrt{\rho_{\mathrm{D}}}$. First and second terms of the last expression represent a critical stress, which is necessary for dislocation detachment from inclusion. This critical stress depends on temperature; presented expression was obtained from molecular-dynamics simulations by A. Kuksin and A. Yanilkin [34]. The main differences between the pure aluminum and the aluminum-copper alloy in our study were the higher value of $Y_{\mathrm{Al+Cu}}$ in comparison with Y_{Al}, and the decrease of $Y_{\mathrm{Al+Cu}}$ with temperature. All other parameters (equation of state, friction coefficient of dislocation movement) were supposed to be the same for both materials. For the ultra-fine-grained and nanocrystalline aluminum the yield stress was chosen in the next form: $Y_{\mathrm{Al}} = 2.2 \cdot 10^7 + 0.4Gb\sqrt{\rho_{\mathrm{D}}} + H/\sqrt{d}$, where d is the grain size, $H \approx 4.2\ \mathrm{GPa} \cdot \mathrm{nm}^{1/2}$ is the Hall-Petch coefficient for aluminum.

Plastic strain intensity W was used as indicator of the state of plastic strain. In the 2D case it can be written as, $W = \sqrt{(4/3) \cdot \left(w_{xx}^2 + w_{yy}^2 + w_{xx} \cdot w_{yy} + w_{xy}^2 \right)}$. Average value is determined as $\langle W \rangle = A^{-1} \int_A W \cdot dA$, where A is a cross-section of the sample (approximately $A \approx L^2$ during the shear). Deviation of the plastic deformation from its average value is numerically characterized by the root-mean-square deviation $\Delta W = \sqrt{A^{-1} \int_A \left(W - \langle W \rangle \right)^2 \cdot dA}$.

The considered strain rate was equal to $\dot{\varepsilon} = 10^5\ \mathrm{s}^{-1}$, which value is typical for the high-speed impact experiments [17]. The sample size L was chosen equal to $L = 100\ \mu\mathrm{m}$; the computational grid was 50x50 nodes. Initial perturbations were set in form of a narrow stripe ($4\ \mu\mathrm{m}$ width-way) parallel to *Ox* axis, which crosses the sample in its middle. In this stripe, either the initial temperature of substance was raised on ΔT, or the initial dislocation density was multiplied on factor $\left(1 + \Delta\rho_{\mathrm{D}} / \rho_{\mathrm{D}}\right)$, where ρ_{D} is an unperturbed value of the dislocation density, $\Delta\rho_{\mathrm{D}}$ is its perturbation; the value $\rho_{\mathrm{D}} = 10^7\ \mathrm{cm}^{-2}$ was used in calculations below. In nanocrystalline aluminum perturbation of the grain size was also investigated – grain size inside the stripe was set equal to d_1, which value is different from the grain size outside the stripe d.

3. Results and discussion

It was supposed, that if the specified perturbation is appropriate and enough for localization of plastic flow, then the upper half of the sample will plastically displace relative to the lower half at the free shear. But numerical experiments have shown that the initial perturbations of temperature or dislocation density influence on the localization of plastic flow only at the constrained shear mode. Therefore, we will consider results of the constrained shear at first.

Fig. 2 shows typical distributions of the plastic strain intensity for alloy and pure aluminum with initially perturbed temperature field. Raise of temperature in the alloy leads to decrease of the yield stress, and plastic deformation tends to be localized in the hot stripe (Fig. 2(a)). Constrained movement of the "side" faces suppresses total plastic shear along this stripe, therefore, the plastic deformation redistributes around the stripe, which, particularly, cause formation of arrowhead-like structures. Plastic deformation in vicinity of the hot stripe (aside from the arrowhead-like areas) is lower then the plastic deformation near the "upper" and "lower" faces. An inverse situation takes place for the pure aluminum (Fig. 2(b)). Rise of temperature increases the resistance to dislocations

motion and suppresses the plastic deformation inside of the hot stripe. For compensation of this effect, a more intensive plastic flow occurs in its vicinity. It can be treated as localization as well, not in the hot stripe, but around the stripe (around the perturbed area).

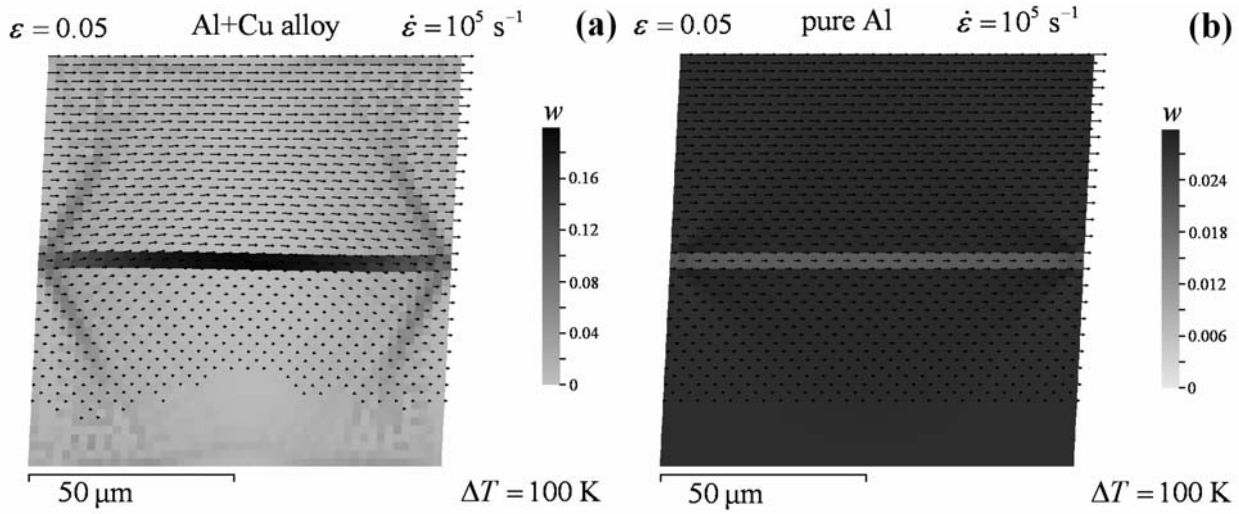

Figure 2. Distributions of the plastic strain intensity w in the aluminum-copper alloy (a) and in the pure aluminum (b) samples at the total deformation $\varepsilon = 0.05$. Initial temperature field was perturbed by narrow (4 μm) stripe with temperature raised on $\Delta T = 100$ K ; constrained shear.

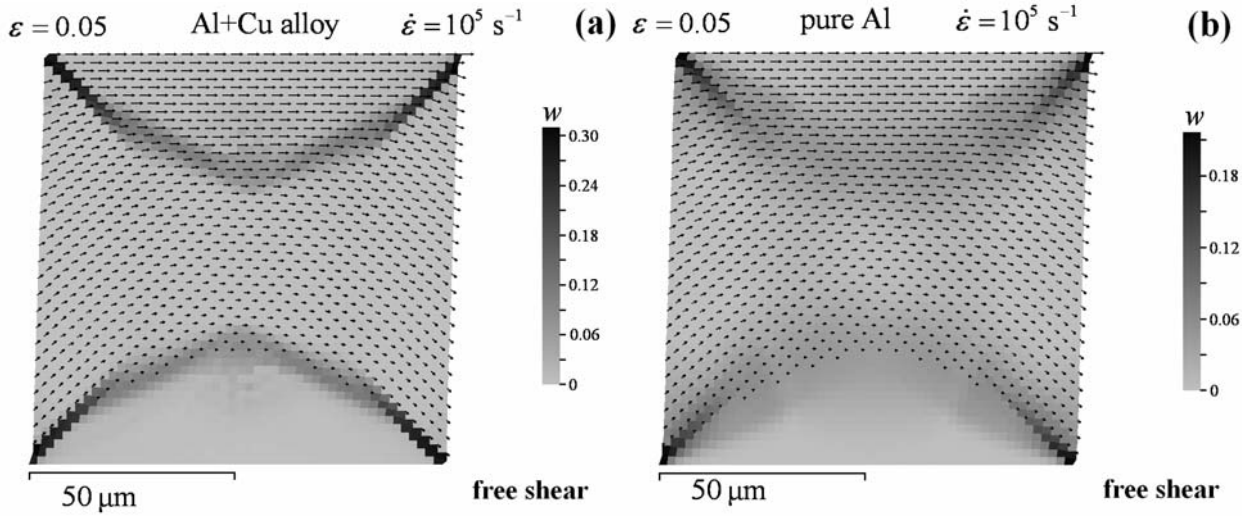

Figure 3. Distribution of the plastic strain intensity w in the aluminum-copper alloy (a) and in the pure aluminum (b) at the free shear are presented at the shear deformation $\varepsilon = 0.05$. Both in alloy and in the pure metal, localization begins along diagonals of the square.

Calculations show that substantial localization takes place only at ΔT above several tens or hundreds of K, while the plastic flow causes an increase of temperature on only about several K. These facts indicate that any random disturbance in temperature can not of itself lead to a self-sustained process of the connected temperature rise and temperature softening of the material. In other words, temperature perturbation can not initiate instability of plastic flow even in alloys. But pre-existing areas with substantially different temperature can in some degree localize the plastic flow around themselves both in alloys and in pure metals. The degree of localization in the pure metal is on an order of magnitude less than that in the alloy.

Increase of the initial dislocation density leads to a temporary softening of pure metal at dynamic

deformation, therefore, plastic deformation is higher in the perturbed stripe with the higher initial dislocation density and it is lower in the attached areas. This is a temporary effect, and it becomes lower with the increase of total deformation. It is explained by the fact that the dislocation density grows up, and the softening (a dynamical effect) is replaced by an increase of the yield stress with dislocation density (a strain hardening). In the case of alloy, the higher value of the yield strength causes an earlier transition to the strain hardening. As opposed to the temperature, the dislocation density changes substantially during the plastic flow. But it seems that the plastic flow instability can not be provoked by the dislocation density perturbation as well as in the temperature perturbation case. At the dislocation-induced softening the dislocation density growth diminishes the softening effect. At the strain hardening the "inverse" localization takes place, but more intensive plastic deformation around the perturbed area increases the dislocation density in this surroundings. It leads to an equalizing of the dislocation density and to a broadening of the involved area, it means, to delocalization. Meanwhile, an irregularity in the dislocations distribution leads to some localization of the plastic deformation, but this localization is restricted.

Much more localization takes place at the free shear (Fig. 3). Both in alloy and in the pure metal, localization begins along diagonals of the square. Region at rest near the "lower" face, region moving with constant velocity $\dot{L}$ near the "upper" face and a flowing central region appear as a result of development and intersection of the localization bands. In the alloy localization is stronger than in the pure metal. It must be emphasized, that the localization at free shear arises without any initial perturbation of the initial parameters. Moreover, any perturbation of temperature or dislocation density does not effect in this case.

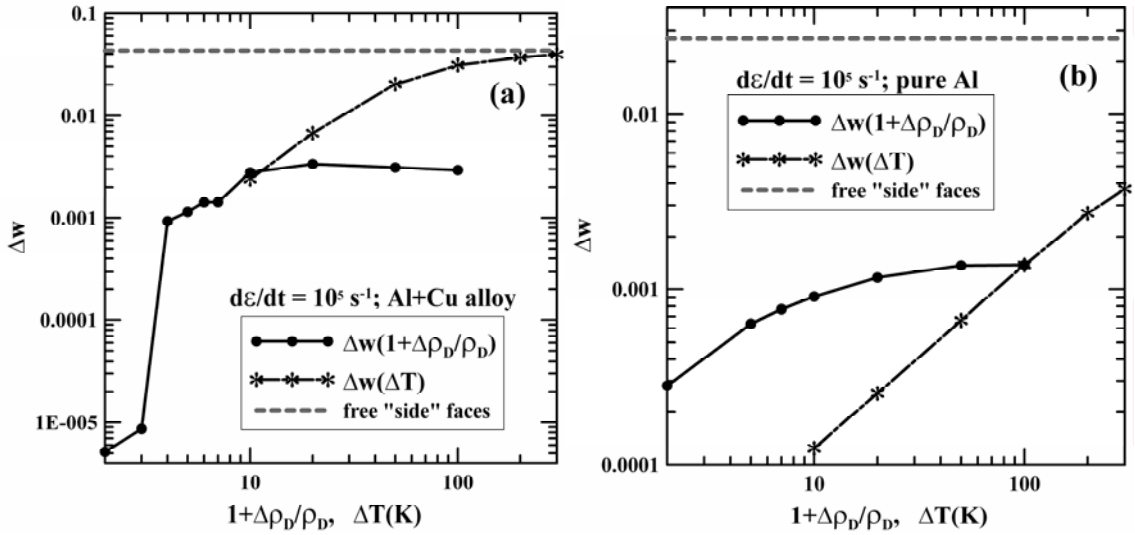

Figure 4. Comparison of the plastic flow localization degree in different situations. Aluminum-copper alloy (a) and pure aluminum (b), total strain is $\varepsilon = 0.05$. At the free shear the value of ΔW is constant.

Fig. 4 presents a comparison of the plastic flow localization degree produced by various initial perturbations of dislocation density or temperature at the constrained shear and the localization at the free shear. In the alloy, the temperature perturbations with $\Delta T > 10\,\mathrm{K}$ are substantially more effective than the dislocation density perturbation (Fig. 4(a)). At the temperature increase on $\Delta T \approx 300\,\mathrm{K}$ the degree of localization tents from bellow to the localization degree at the free shear. But it seems hardly probable that such high temperature drop can initially exist in the material. In the pure aluminum, the dislocation density perturbation is more effective from the viewpoint of the localization excitation than the temperature increase with $\Delta T < 100\,\mathrm{K}$ (Fig. 4(b)); but the free shear is much more effective than the both types of perturbations.

Perturbation of the grain size in ultra-fine-grained or nano-crystalline aluminum leads to substantial localization of the plastic flow at the "constrained" shear due to difference in the dynamical yield strength. Localization degree in nano-materials with the grain size $d < 100$ nm depends weakly on the perturbation value d_1 / d, therefore, localization in such materials has to arise at any arbitrary size distribution of the grains. But the localization degree is all the same less than it at the "free" shear; they become comparable only at the grain size $d < 10$ nm.

4. Conclusions

Summarizing, one can conclude that perturbation of both the temperature and the dislocation distribution, as well as of the grain size, can lead to restricted localization of the plastic flow. But they can not initiate the self-sustained process of the joint increase of corresponding parameter and of the localization degree, it means, they can not initiate the instability of plastic flow. Nonuniformity of acting stresses is the dominant factor of the localization of the plastic deformation. Therefore, the process of localization must substantially depend on the loading conditions and on the internal structure of the material (on the presence of inhomogeneities, pores, inclusions).

Abstract

The application of Mg alloys is greatly restricted because of their poor plasticity, which is closely related with the texture formed during hot forming. In this paper, the texture evolutions in Mg-Al and Mg-RE alloy during extrusion have been investigated. The results suggested that the texture of Mg alloy extrusion bar and tubes could be weakened by Ce addition with small content, but it does not work when Al is also exists. Thus, the Mg-RE alloys exhibit much higher tensile elongation and good yield symmetry. The mechanism of texture weakening by RE addition is due to the solute effect, which could surpass the twinning and activated non-basal slip.

Keywords: Texture, Mg-Al alloy, Mg-RE alloy, extrusion

1. Introduction

Deformation structures produced during high temperature extrusion of Mg rods recrystallize to produce a ring fiber texture with the c-axes of the grains perpendicular to the extrusion direction (ED) [1-2]. Such extrusions exhibit poor ductility and strong anisotropy [3] in their mechanical properties. Texture weakening or randomization is a desirable approach to get high ductility Mg alloys and a number of cases of weak or non-basal textures have been reported recently for Mg alloy sheets and extrusions [3-7]. Various authors have suggested that texture could be weakened via dynamical recrystallization during the processing with addition of Y, Ce and other rare earth elements. Mishra et. al [5] have shown that tensile ductility of extruded Mg-0.2wt% Ce is significantly enhanced due to texture randomization where the basal planes get oriented at 40~50° to the extrusion direction (ED) in the recrystallized microstructure.

Texture weakening in Mg alloy have been associated with various phenomena, including abnormal grain growth [8-9], particle-stimulated nucleation (PSN) [3, 6], particle pinning [10], solute drag [4], dynamic strain aging [11] and heterogeneous deformation leading to ease of shear band formation [6-7]. To clarify the effect of RE-element addition on the recrystallization texture after extrusion and to optimize the processing conditions for producing random texture in the Mg alloy extrusions, the microstructures of Mg-Ce and Mg-Al-Ce alloy tubes or rods have been investigated in this study. The approach for developing wrought Mg alloys with texture randomization and strengthening via alloying is discussed on the basis of the results.

2. Experimental

The materials studied in this work include nominally pure Mg (baseline), Mg-Ce, Mg-Al, and Mg-Al-Ce alloys. Unalloyed Mg and Mg alloy melts of about 100kg were prepared using commercially pure Mg ingots, pure aluminum and Mg-20%Ce master alloy in a steel crucible with SF6/CO2 protective cover gas. Billets of 75mm diameter and 230mm length were cast at about 700ºC into a permanent mold. The billets were preheated to 400 ºC for two hours and extruded in a Wellman Enefco™ 500-ton multipurpose vertical hydraulic press fitted with a circular die. Solid rods, approximately 15mm in diameter corresponding to an extrusion ratio (ER) of 25 were extruded using boron nitride lubricant at a billet speed of 10mm s^{-1} and air cooled.

Metallographic samples were prepared by standard methods, and the polished samples were etched in a solution containing 20ml glacial acetic acid, 50ml picric acid, 10ml methanol and 10ml deionized water. The polished samples were examined by the scanning electron microscope (SEM) and electron backscattered diffraction (EBSD) in a LEO™ 1450 SEM operating at 20kV fitted with a TSL™ EBSD camera [5]. The compositions of the particles in the Mg alloys were analyzed by electron probe microanalysis (EPMA). EBSD scans were obtained using beam step size of 2mm and a camera length of 18cm from an area approximately 1mm x 1mm and at least three different scans from the same sample were collected to ascertain the repeatability of the results. The inverse pole figure (IPF) map, image quality map with the twin boundaries outlined, and the (0001), (10-10), and (1-210) pole figures were processed with TSL OIM commercial software.

3. Results

The original microstructure including of AZ31 and AM30 alloy tubes are showed in Fig. 1, the IPF map in Fig. 1a and 1b show crystallization occurred during extrusion and the grain boundaries among majority grains are high angle grain boundaries with their misorientation higher than 15°, and average grain size is 50mm for AZ31 and 30mm for AM30. Pole figure shows ring basal texture with their c-axes perpendicular to extrusion direction(ED) in the two samples, but the majority grain orientations can be divided into two groups: one with their c-axes approximately parallel to the radial direction (Called the RD component) and the other with their c-axes approximately parallel to the tangential direction (Called the TD component), which is the typical extruded tube texture. And the max texture intensity is 5.704 and 5.051 for AZ31 and AM30, respectively.

The EBSD inverse pole figure (IPF) maps and corresponding (0001), (10-10), and (11-20) texture plots from as-extruded tubes of Mg-0.2Ce are shown in Figures 2(a) and (b). The differences in the texture between Mg-0.2Ce and AZ31, AM30 are evident from these figures. In the case of the Mg-0.2Ce tubes, the c-axes of the grains are not normal to the extrusion axis but make an angle about 45° to the extrusion axis, as is evident from the texture plot in Figure 2(b). This is similar to what has been reported in Mg-0.2Ce rods [10]. As the RD component shows clearly, the TD component seems to be very weak. Besides, the tensile curve of as-extruded tubes of Mg-0.2Ce tube is shown in Fig.2(c) compared with that of pure-Mg. It can be seen clearly that with the addition of 0.2%Ce the ductility enhances a lot.

With the addition of Ce and Al, the formability of the tubes and the macroscope of the tube are enhanced as showed in Fig. 3a. However, the deflection of the main texture seen in Mg-0.2Ce alloy did not occur in the case of Mg-3Al-0.5Ce alloy tube which can be seen in Fig.3 (b). The texture of Mg-3Al-0.5Ce is similar to that of AZ31. The tension and compression mechanical property are shown in Fig.3 (c). It can be seen that the strength of alloy increased a lot compared with Mg-0.2Ce but also exhibited the obvious yield asymmetry which can be seen widely in textured Mg alloys. And the elongation of Mg-3Al-0.5Ce alloy is about 20% which is lower than that of Mg-0.2Ce alloy.

The effects of RE addition on the texture of extrusion rod were also investigated in this study. The texture of pure-Mg, Mg-0.2Ce and Mg-3Al-0.2Ce alloy rods are shown in Fig.4 in a same reference frame to get a flagrant contrast. For the Mg-0.2%Ce alloy, the texture altered from typical

ring basal texture as showed in Fig. 4a, but for the Mg-3%Al-0.2%Ce alloy rod, the texture is similar with that in AZ31 or pure Mg rod.

Fig. 5 shows the backscattered electron micrographs along with the electron probe composition maps. The samples were taken from the longitudinal section (extrusion axis parallel to the sample plane). The results show that some particles in Mg-3%Al-0.2%Ce alloy have a composition close to $Mg_{17}Al_{12}$ phase an others with a composition close to $Al_{11}Ce_3$ are seen aligned along the ED [13]. By contrast, small intermetallic $Mg_{12}Ce$ phase particles [12] are distributed homogeneously in the Mg-0.2Ce alloy. In addition, the electron probe maps of individual element compositions in Fig. 5 suggest that, in the Mg-0.2Ce, the solute Ce is distributed in the matrix while there is no measurable solute Ce present in the matrix of the Mg-3%Al-0.2%Ce sample.

4. Discussion

Deformed Mg acquires a preferred orientation or texture because deformation occurs on the most favorably orientated slip or twinning systems that reorient the grains [14]. The ring basal texture and rolling basal texture are almost universal in extruded Mg rod [2, 4, 15] and rolled Mg sheet [15-17], respectively, because of the basal slip and {10-12}extension twinning [18-19] dominating the deformation process. Fig. 6 shows IPF and PF maps of AZ31 tube compressed at room temperature to true strain of: (a) 0.01 (b)0.09 (C) 0.18. The figure shows that the {10-12} extension twinning resulted in the orientation altered during compression, in which the [0001] of twins is parallel to compression axis. That is the reason why the textures in AZ31 and AM30 tubes show TD and RD component as showed in Fig. 1. These textures are retained through the recrystallization stage. In this study, the Mg-0.2 wt.% Ce alloy tube and rod exhibited non-basal texture after hot extrusion, e.g. the basal poles were rotated ~45° towards the extrusion direction (ED). A postulate is an idea that the deformation mechanism in Mg-0.2 wt.% Ce is different from that in pure Mg and AZ31, e.g. there is few twinning and more non-basal slip in Mg-Ce alloy system.

In earlier studies of relationship between particle simulated nucleation (PSN) and recrystallization texture in Mg alloys, the weakening of the texture of WE54 alloy[3, 6] with 4wt% RE was ascribed to particle simulated nucleation or PSN. More recent studies [4] of Mg-1 wt.% Y alloy have showed significant texture-randomization even though this alloy is expected to contain very few particles [20]. Increasing the Mn content (i.e. particle) in AZ31 does not lead to changes in the sheet texture [21]. PSN alone cannot explain the different texture in AZ31 and ME10 alloy although both alloys contain particles [22]. In this study, weak or non-basal texture in the Mg alloy with 0.2 wt.% Ce, addition, and typical ring basal texture in the Mg-3 wt.%-0.2 wt.% Ce alloys are observed. Microprobe analysis for those samples (Fig. 5) indicated that there are many particles in Mg-0.2 wt.% Ce and Mg-3 wt.%Al-0.2 wt.% Ce alloys. The results suggest that particles are not necessary for the texture randomization in magnesium.

Comparing the solute (Ce and Al) distribution in the Mg-0.2 wt.% Ce and Mg-3 wt.% Al-0.2 wt.% Ce (Fig. 5), Solute Ce is distributed in the magnesium matrix in Mg-0.2 wt.% Ce alloy, but Ce is exhausted by the $Al_{11}Ce_3$ particles and no solute Ce is found in the matrix in Mg-3 wt.%-0.2 wt.% Ce alloy. The difference suggests that Ce solute in the magnesium may be necessary for the texture randomization for the Mg-Ce alloys. Al solute does not affect the texture according to the microstructure in AZ31 alloy presented in Fig.1. The above results point to the fact that Mg alloys, which are solute-strengthened by Al addition will not benefit from texture modification for ductility enhancement but such addition can influence grain refinement in lean Al alloys when Al content is below solubility limit. Concurrent strengthening and texture modification in Mg alloys have been reported in Mg-Zn-Ce alloys where Zn-Ce intermetallics have not been reported [7, 24].

Solute drag is known to influence both the grain boundary mobility of different grain boundary or ientations [14] and the recrystallization kinetics [23]. In this study, the grain structures in Fig.2 show more equiaxed grains and higher grain aspect ratio in the alloys with Ce in solution. This is consistent with Ce solutes influencing the boundary mobility due to solute drag to influence texture. Al solutes in magnesium do not affect the texture evolution during the hot extrusion as solute drag effect could be

absent at the temperature/strain rate combination present during extrusion. In Mg-3 wt.%-0.2 wt.% Ce alloy, the Ce and Al are tied up in $Al_{11}Ce_3$ phase and no Ce solute is present in the alloy, leading to th e ring basal texture. The solute drag effect in Mg-RE alloy is discussed broadly however how the solut e RE works on the deformation modes or recrystallization behavior is still confusion.

5. Summary

The texture evolutions in Mg-Al and Mg-RE alloy during extrusion have been investigated. The results suggested that the texture of Mg alloy extrusion bar and tubes could be weakened by Ce addition with small content, but it does not work when Al also exists. Thus, the Mg-RE alloys exhibit much higher tensile elongation and good yield symmetry. The mechanism of texture weakening by RE addition is due to the solute effect, which could surpass the twinning and activated non-basal slip.

Abstract In the process of inelastic deformation, cyclic accumulation of heat flux transferred from plastic work under cyclic loading results in an increased work temperature. The heat softening effects of material properties and external heat source will produce more plastic work. The fraction between plastic work and heat generation per unit volume can be introduced as a coupled source for thermal-mechanical analysis. Such coupling might be important in a simulation in which extensive inelastic deformation is accumulated fairly rapidly under cyclic loading and the mechanical properties are temperature dependent. To investigate the couple effect among temperature, stress and deformation under cyclic loading, a coupled thermo-mechanically cyclic plasticity model combined nonlinear isotropic hardening and kinematic hardening was established firstly in thermodynamics frame at large deformations. And then, the proposed model was implemented into finite element code ABAQUS by combining the user subroutine UMAT and UMATHT. Finally, some numerical results show the proposed model can capture thermal-induced necking in tensile loading, and the isotropic and kinematic hardening and thermal softening under cyclic loadings.

Keywords Inelastic heat generation, ratchetting, thermal softening, cyclic loading

1. Introduction

Elastic-plastic deformation behavior under cyclic loading has been investigated for some decades. Material models which describing macroscopic ratcheting response can be obtained within the framework of plasticity by combining the von Mises yield criterion with nonlinear kinematic hardening rules, e.g., the Armstrong-Frederick rule [1]. Some extended constitutive models of cyclic plasticity have been proposed to reasonably predict cyclic deformation behaviours of metal materials [2-6]. As a matter of fact, in the process of inelastic deformation, cyclic accumulation of heat flux transferred from plastic work under cyclic loading results in an increased work temperature. The thermal softening effect of material properties and external heat source will produce more plastic work The fraction between plastic work and heat generation per unit volume can be introduced as a source of coupling for thermal-mechanical analysis. However, the thermal effect induced by inelastic heat generation and its coupling with deformation were neglected in most ratcheting models. It is a reason that all the above-mentioned ratcheting models concern ratcheting in the context of small strains, the inelastic heat generation is neglectful small.

Recent experimental observation found that the ratchetting strain is up to 50% in the low-cycle fatigue [7], and thermo-elastic-plasticity coupling analysis in actual engineering application has attract attention [8]. So ratcheting problem without shakedown needs to be addressed on a consistent thermodynamic and large deformation frame. The thermo-mechanically coupled effect only in monotonic loading case has been modeled by the thermo-mechanically coupling constitutive models [9-16]. Therefore, a thermo-mechanically coupling cyclic plasticity constitutive model

needs to be established and make it available in commercial finite element packages, such as Abaqus for structural analysis.

In this work, a thermo-mechanically coupled cyclic plasticity model combined nonlinear isotropic hardening and kinematic hardening was established firstly in thermodynamics frame at large deformations. Further, the proposed model was implemented into finite element code ABAQUS by combining the user subroutine UMAT and UMATHT. Some numerical results were provided to validate the proposed model by simulating coupling thermo-mechanically behaviours under monotonic and cyclic loadings.

2. Thermo-elastic-plastic constitutive model

2.1. Deformation gradients

If the total deformation of materials is enough small, the thermal effect deriving from inelastic thermal generation is not significant. Therefore, the proposed model is derived at large deformation based on the hypoelastic-plastic theory. To separate recoverable and plastic contributions of the deformation gradient, the multiplicative decomposition of the deformation gradient is used [17]

$$\mathbf{F} = \mathbf{F}^r \mathbf{F}^p, \quad \mathbf{F}^r = \mathbf{F}^e \mathbf{F}^T \tag{1}$$

where $\mathbf{F}^r$ and $\mathbf{F}^p$ represents the thermo-elastic recoverable contribution and the plastic contribution of the total deformation gradient, respectively [18]. For metal materials, $\mathbf{F}^r$ describes the reversible distortion of the crystal, $\mathbf{F}^p$ describes irrecoverable deformation, for instance dislocation movements. Moreover, $\mathbf{F}^e$ and $\mathbf{F}^T$ are the elastic and thermal parts of the deformation gradient, respectively. For most metal materials, the elastic and thermal strains are small, and the multiplicative decomposition may be approximated by an additive decomposition of velocity gradient tensor $\mathbf{L}$ [16]

$$\mathbf{L} = \mathbf{L}^e + \mathbf{L}^T + \mathbf{L}^p \tag{2}$$

The rate of deformation tensor is the symmetrical part of velocity gradient tensor $\mathbf{L}$

$$\mathbf{D} = \frac{1}{2}(\mathbf{L} + \mathbf{L}^T) \tag{3}$$

2.2. Constitutive equations

Using the symmetric part of velocity gradient tensor in Eq. (2), the additive decomposition of the total rate of deformation tensor is expressed as

$$\mathbf{D} = \mathbf{D}^e + \mathbf{D}^p + \mathbf{D}^T \tag{4}$$

When we use the symmetric part of the velocity gradient with respect to current position and when the total elastic strain is always small compared to one. The rate of deformation decomposition is used in the form in almost all the inelastic constitutive models in finite element codes.

If only isotropic materials are considered, the elastic part of deformation rate can be given as

$$\mathbf{D}^e = \frac{1}{2G}\overset{\circ}{\tau} - \frac{v}{E}(tr\overset{\circ}{\tau})I \tag{5}$$

The thermal part of the rate of deformation tensor for isotropic materials can be expressed as

$$\mathbf{D}^T = \alpha \dot{T} \mathbf{I} \tag{6}$$

where α is thermal expansion coefficient and $\mathbf{I}$ is unit second order tensor.

At large deformation, an objective rate must be provided to state the objectivity of constitutive equations. The elastic stress-strain relation based on Jaumann objective rate can be written as

$$\overset{\circ}{\boldsymbol{\sigma}} = \mathbf{C}^e : \mathbf{D}^e = \mathbf{C}^e : (\mathbf{D} - \mathbf{D}^p - \mathbf{D}^T) \tag{7}$$

where $\overset{\circ}{\boldsymbol{\sigma}}$ is Jaumann rate of Cauchy stress, $\mathbf{C}^e$ is four order elastic tensor. Considering von Mises plasticity combined isotropic hardening and kinematic hardening and temperature dependent material properties, the yield function is expressed as a function of stress, temperature and equivalent plastic strain:

$$f = \bar{\sigma} - \sigma_y(\bar{\varepsilon}^p, T) \tag{8}$$

The equivalent stress can be defined as

$$\bar{\sigma} = \sqrt{1.5(\mathbf{s} - \boldsymbol{\alpha}) : (\mathbf{s} - \boldsymbol{\alpha})} \tag{9}$$

where $\boldsymbol{\alpha}$ is deviatoric back stress and the deviatoric part of stress tensor $\mathbf{s}$ is defined as

$$\mathbf{s} = \boldsymbol{\sigma} - \frac{1}{3} tr(\boldsymbol{\sigma}) \mathbf{I} \tag{10}$$

Associated plastic flow is used to derive the plastic part of deformation rate:

$$\mathbf{D}^p = \frac{\partial f(\mathbf{s} - \boldsymbol{\alpha})}{\partial \boldsymbol{\sigma}} \dot{\bar{\varepsilon}}^p = \dot{\bar{\varepsilon}}^p \mathbf{N} \tag{11}$$

where $\mathbf{N}$ is flow tensor of plastic strain and $\dot{\bar{\boldsymbol{\varepsilon}}}^p$ is the equivalent plastic rate defined as

$$\dot{\bar{\varepsilon}}^p = \sqrt{\frac{2}{3} \mathbf{D}^p : \mathbf{D}^p} \tag{12}$$

The isotropic hardening can be regarded as an increasing size in yield surface. In general, an exponential hardening is adopted to describe isotropic hardening with a threshold value as follows

$$\sigma_y(T) = \sigma_{y0}(T) + Q_{sa}(T)(1 - \exp(-b(T)\bar{\varepsilon}^p)) \tag{13}$$

where σ_{y0} is initial yield stress in the uniaxial loading at a reference temperature. The isotropic hardening parameters b and Q_{sa} are temperature dependent and can easily be calibrated by the uniaxial strain cycling at different temperatures.

A successful and popular approach is to introduce several back-stresses, where each back-stress is governed by the Armstrong-Frederick type of hardening rule. These models can be united in the following form:

$$\boldsymbol{\alpha}_i = \frac{2}{3} k_{1i}(T) \mathbf{D}^p - k_{2i}(T) \boldsymbol{\alpha}_i \dot{p}\,, \quad \boldsymbol{\alpha} = \sum_{i=1}^{M} \boldsymbol{\alpha}_i \tag{14}$$

where k_{1i} and k_{2i} are linear kinematic hardening coefficient and dynamics recovery coefficient for superposed M back stress components, respectively. Difference in Armstrong-Frederick typed models causes by different expressions in k_{1i} and k_{2i}. The accumulated plastic strain rate $\dot{p}$ is

equal to the equivalent plastic rate $\dot{\bar{\varepsilon}}^p$ according to J_2 plasticity.

According to the consistency condition, the differential form of Eq. (8) gives:

$$\dot{f} = \frac{\partial f}{\partial(\mathbf{s}-\boldsymbol{\alpha})} : \dot{\boldsymbol{\sigma}} - \frac{\partial f}{\partial(\mathbf{s}-\boldsymbol{\alpha})} : \dot{\boldsymbol{\alpha}} + \frac{\partial f}{\partial T}\dot{T} \tag{15}$$

Combining Eqs. (7), (11) and (15), the accumulated plastic strain rate can be obtained as:

$$\dot{p} = \frac{2G}{H(T)}\mathbf{N}:\mathbf{D} - \frac{1}{H(T)}(2G\alpha\mathbf{N}:\mathbf{I} + \frac{\partial\sigma_y(T)}{\partial T})\dot{T} \tag{15}$$

where G is shear modulus, H is defined as

$$H = 3G + k_{iso} + k_{kin} \tag{16}$$

where k_{iso} and k_{kin} represent isotropic hardening and kinematic hardening behaviours, respectively, and can be given as

$$k_{iso} = \frac{\partial\sigma_y(T)}{\partial\bar{\varepsilon}^p} \tag{17a}$$

$$k_{kin} = k_{1i}(T) - k_{2i}(T)\mathbf{N}:\boldsymbol{\alpha} \tag{17b}$$

Substituting Eq. (15) into Eq. (7) yields

$$\overset{\circ}{\boldsymbol{\sigma}} = \mathbf{C}^{ep} : (\mathbf{D} - \mathbf{I}\alpha\dot{T}) + \mathbf{C}^{e} : \mathbf{N}\frac{\partial\sigma_y(T)}{H(T)\partial T}\dot{T} \tag{18}$$

where $\mathbf{C}^{ep}$ is elasto-plastic modulus of continuum solids and defined as follows

$$\mathbf{C}^{ep} = \mathbf{C}^{e} - \frac{4G^2}{H}\mathbf{N}\otimes\mathbf{N} \tag{19}$$

2.3. Equation of energy balance

The material system must be in thermodynamic equilibrium. The local form of the first law of thermodynamics can be expressed as

$$\rho c_p\dot{T} = W^{pd} + \rho r - J\cdot div(\mathbf{q}) \tag{20}$$

where $J = \det\mathbf{F}$, c_p is specific heat and it is temperature dependent material parameter. $\mathbf{q}$ is thermal flux tensor, r is the internal thermal source, T is temperature. W^{pd} is the plastic dissipation term.

The latent stored energy for cold worked mild steel and copper was measured [18], which was assumed that the stored energy was a constant fraction of plastic work. However, subsequent experiment [19, 20] show it is dependent on the accumulated strain. Therefore, the heat generation is assumed as the rate of the plastic work multiplied by a function $\eta(p)$ related to calculated plastic strain:

$$W^{pd} = \eta(p)\cdot\boldsymbol{\sigma}:\mathbf{D}^p \tag{21}$$

According to Fourier's law, the heat conduction in the isotropic material can be expressed as

$$\mathbf{q} = -\mathbf{k}\partial_x T \tag{22}$$

The conductivity tensor $\mathbf{k}$ is assumed to be an isotropic tensor, that is related to a scalar material parameter K and $\mathbf{k} = K\mathbf{I}$.

Combining Eqs. (20), (21) and (22), the energy balance equation can be rewritten as

$$\rho c_p \dot{T} = \eta(p) \cdot \boldsymbol{\tau} : \mathbf{D}^p + \rho r + J \cdot div(\mathbf{q}) \tag{23}$$

The general form of three-type thermal boundary conditions are expressed as

$$\mathbf{q} : \mathbf{n} = -q_s\big|_{s1} + h(T_s - T_0)\big|_{s2} \tag{24}$$

$$T\big|_{s3} = T_s \tag{25}$$

These boundary conditions represent specified flux, convection and specified temperature on the respective parts of boundary, s_1-s_3. Here, h is the convection coefficient and $\mathbf{n}$ is the surface normal tensor.

2.4. Solution method

To solve thermo-mechanically coupling problem, coupled method and staggered method can be selected. The coupled method is more realistic even though it is computationally expensive due to involving handling of a large system of equations at every increment, which is necessary when a very large temperature gradient appears in an increment step. The staggered method have been improved to solve thermo-elasto-plastic problem [21], it is numerically convenient because it reduces the computational efforts significantly. In the work, the numerical treatment of coupled finite element analysis is based on the staggered solution scheme. The temperate fields are solved and as a known deformation field to apply in the deformation field, the temperature is updated as a common variable after iterating the two solutions until convergence. Moreover, a finite element implementation into finite element code, i.e., Abaqus, is also necessary for considering the thermal exchange with the around environment in thermo-mechanically coupled structural analysis. Based this purpose, the proposed model is implemented into Abaqus by combining user subroutine UMAT and UMATHT. The heat generation from plastic work is given by the heat generation rate RPL, which is related to plastic work and heat exchange factor η. The deformation and temperature fields are solved simultaneously at a reference temperature.

It is well known that the work done in a close loop is not exactly zero based on the hypoelastic-plastic frame. The stabilization with dissipated energy fraction option in the transient coupled temp-displacement analysis should be used to improve the convergence.

3. Numerical examples

3.1. Uniaxial tension

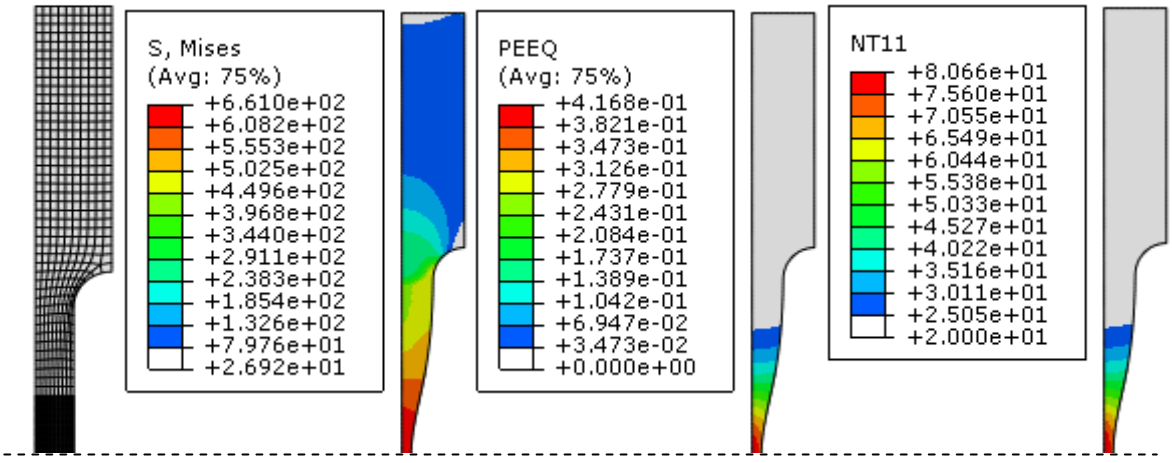
In this section, a numerical example was provided to simulate typical thermo-mechanically coupling effect. Thermally triggered necking of solid bar has been studied in literature [22], which is considered as a consequence of thermo-mechanically coupling. A 4-node axisymmetric thermally coupled quadrilateral element CAX4HT is used for coupled temperature-displacement analysis, the

finite element mesh is shown in Figure 1(a). To capture the necking process more accurately, a dense mesh is used nearby central section the specimen and ALE mesh technique is applied in the same place. The total length of the bar is 60mm, the length of work segment is 30mm, the radius of transition circular arc is 4mm and the radius of work segment is 4mm. Convection is applied on all free surfaces for a physically realistic simulation, the h is chosen to be 20000Wm^2/^{o}C, which is a generally used value [16]. For rail steel used here [24], the heat exchange factor η and its relation with accumulated plastic strain is not known. And then the factor η is simplified to be a constant value 0.9. For isotropic hardening, b and Q_{sa} are set to 0.25 and 100MPa. The upper end is fixed all freedoms and tensile velocity of 1mm/s is applied in the symmetrical plane. The surrounding temperature is assumed as room temperature 20^{o}C. The maximum allowable temperature change per increment is set to 10^{o}C. Total time 0.4s is used in the simulation and the automatic incrementation is used, the whole solution consist of 314 increment steps. Thermal-mechanical properties of the rail steel for the simulated specimen are given in Table 1. In the most quasi-static tension simulations, the increased temperature generated from plastic work is less than 100^{o}C, and then only part parameters are present here.

The equivalent stress, equivalent plastic strain and temperature were shown in Figure 1 (b), (c) and (d), respectively. It is found that necking can be reproduced successfully without any initial geometrical defect. Moreover, the temperature distribution is consistent with the equivalent plastic strain one, which shows that the temperature change causes by the plastic work. It must be noted that the isothermal analysis gives rise to a classical bifurcation problem, an initial defect must be introduced to trigger necking. However, the thermo-mechanically coupled problem is not a bifurcation problem, since inelastic heat generation gives rise to an increased temperature in the specimen and convection results in the non-homogeneous temperature distribution, which in combination with the thermal softening, triggers necking [23].

Table 1. Thermo-mechanical properties used in simulations [24]

T (℃)	E (GPa)	σ_y (MPa)	v	k_1 (GPa)	k_2	T (℃)	C_p (W/m-℃)	K (J/(Kg.C))	T(℃)	α (1e-6)
24	213	483	0.295	22.7	200	0	59.71	420	0	9.89
230	201	465.1	0.307	21.9	200	350	40.88	630	90	11.3



(a) (b) (c) (d)

Figure 1. Finite element simulations for necking of a circular bar with kinematic hardening model at time 0.4s: (a) the axisymmetrical finite element model with a symmetry plane (dot line); (b) the distribution of

equivalent von Mises stress; (c) the distribution of equivalent plastic strain; (d) the distribution of temperature

The thermo-mechanical coupling effect results in a significant thermal softening effect as shown in Figure 2. The load decreases with an increasing displacement when thermal-induced necking occurs. It is noted from Table 1 that the rail steel used in the simulation has a relative hardening parameter, which results in a flat plastic flow when applied displacement is less than 2mm.

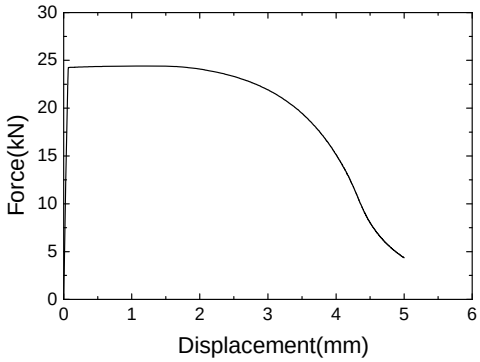


Figure 2. Force-displacement curve

3.2. Cyclic loading

In this example, thermo-mechanically coupling effect is investigated under cyclic stressing. An unsymmetrical stress cycling is applied in the symmetrical plane shown in Figure 1(a) and a total of 30 cycles were calculated. Figures 3(a) and (b) show the stress-strain curves located inside and outside nodes of central section of specimen, respectively. S22 and LE22 are Cauchy stress and logarithmic strain along Y direction, respectively. It is shown that the strain inside node of central section is much more than strain in outside node, which results in a large hysteresis loop in inside node of central section, i.e., more plastic work is done.

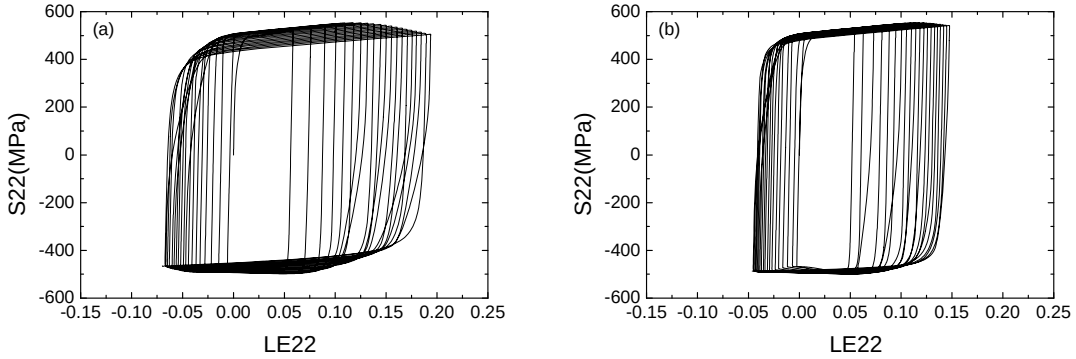

Figure 3. Stress-strain curves along loading direction: (a) inside node in central section; (b) outside node in central section.

Figures 4(a) and (b) show the accumulated plastic strain and temperature for inside and outside nodes in central section, respectively. It is found that more accumulated plastic strain appears in inside than outside nodes of central section. Corresponding, the temperature is higher for inside

node in central section due to conduction and convection. More accumulated plastic strain results in more inelastic heat generation; higher temperature result in more plastic strain due to thermal softening. It is the result the coupling among stress, deformation and temperature.

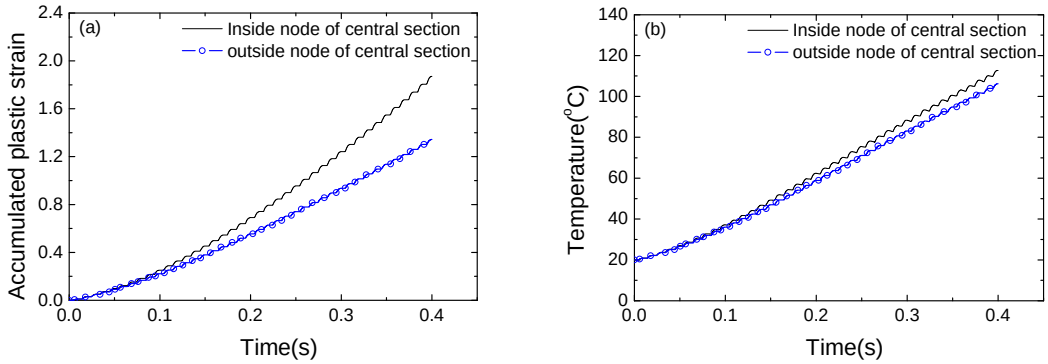

Figure 4. (a) accumulated plastic strain versus time and (b) temperature versus time located in different points.

For rail steel used here [24], the heat exchange factor η and its relation with accumulated plastic strain are not known. However, the influence of the heat exchange factor η on temperature field can be discussed by change the constant value of η, as shown in Figure 5. The total simulated time is limited within 0.1s. It is shown that isotropic hardening contributes more large thermal effect than isotropic hardening when the heat exchange factor η is fixed as 0.9. If only kinematic hardening is considered, the more temperature change occurs with the increased the heat exchange factor η at a fixed time. More important is that the temperature is accumulated with the increased loading cycle. It implies that the inelastic thermal generation can be neglected at a large cyclic number, e.g., low-cycle fatigue, even though the plastic strain is not significantly large.

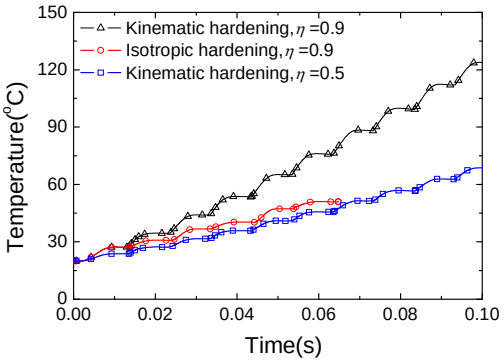

Figure 5. The curves of temperature versus time for isotropic hardening and kinematic hardening with different factors η

4. Conclusions

In the work, a thermo-mechanically coupling cyclic plasticity model with nonlinear isotropic and kinematic hardening was established at large deformations based on hypoelastic-plastic theory. The contribution of plastic dissipation to internal heat generation of materials was also addressed. The temperature dependent mechanical properties are employed. And then, the proposed model is

implemented into Abaqus by combining user subroutine UMAT and UMATHT. Transient coupled temperature-displacement finite element analysis was carried out to investigate thermo-mechanically coupled behaviours under monotonic and cyclic loadings. The thermally induced necking was reproduced without introducing any initial geometrical defect. The inelastic heat generation and, consequently, temperature are accumulated with an increased cyclic number, the interaction between deformation and thermal softening can be neglected, which should be addressed to constructing a more accurate model for predicting ratchetting at large cycles.

Abstract The metal foils indicate low level fracture strain compared with metal sheet. In this study, the free surface roughening is focused on to clarify the mechanism of ductile fracture for metal foils, since the ratio of surface roughness to thickness becomes larger compared with metal sheets. Materials used are pure copper and pure titanium foils and sheets with thickness of 0.05, 0.1, 0.3 and 0.5mm respectively. Free surface roughening and ductile fracture behavior are measured and observed under uni-axial tensile state. As a result, the surface roughening to thickness of metal foils with thickness of 0.05 and 0.1mm was larger than that of metal sheets with thickness of 0.3 and 0.5mm. To investigate the fracture behavior of metal foils, the fracture surface is observed by scanning electron microscope. For pure copper foils with thickness of 0.05 and 0.1mm, dimple pattern cannot be observed, while some dimples for metal sheets such as pure copper and pure titanium sheets with thickness of 0.3, 0.5mm and pure titanium foils with 0.05 and 0.1mm can be observed. As a result, the fracture type of metal foils divides broadly into two categories: existence dimple type for pure titanium and non-existence dimple for pure copper on fracture surface. In addition, the magnitude relation between the increase in ratio of surface roughness to thickness and strain hardening exponent *n* value would affect fracture strain level and existence or non-existence of dimple pattern on fracture surface.

Keywords Metal foil, Free surface roughening, Ductile fracture, Thickness

1. Introduction

Recently, micro metal forming process using metal foils is one of the promising approaches to fabricate micro stamping products such as micro shim, micro gasket, ultra thin valve for micro pump and parts for electric and medical devices. However, it is well known that the micro metal forming for metal foil with ultra thin thickness has problems on size effect. For example of the size effect, Fu reported that fracture strain decreases with decreasing thickness of specimen in uni-axial tensile test [1]. Thus, the metal foils in micro scale indicate different fracture behavior from metal sheet in macro scale. To clarify the fracture mechanism and to predict forming limit of metal foils are absolutely imperative for further development of micro metal forming.

In our previous report, we focused on free surface roughening phenomenon as one of factors related to fracture mechanism of metal foils. It is well known that surface roughness on free surface with non-contact tool situation increases with plastic deformation during metal forming process. An inhomogeneous model has been suggested for prediction of free surface roughening [2, 3]. Our experimental works reported that the ratio of surface roughness to thickness of copper foils with ultra thin thickness becomes large compared with that of conventional sheets [4]. Thus, the free surface roughening of copper foils may affect not only local problem such as accuracy of products and frictional condition but also global deformation behavior such as necking behavior which is onset of fracture. Furthermore, we reported that the forming limit of copper foils in stretching forming cannot be predicted by conventional ductile fracture criterion [5]. Moreover, unlike general metal sheets, dimple pattern on fracture surface cannot be observed of the copper foil. However, the previous reports dealt with limited materials such as copper alloy. The discussion about fracture

mechanism of metal foils was not insufficient.

In this study, we investigated the ductile fracture behavior and free surface roughening for not only pure copper foils but also various metal foils such as pure titanium foils. Influence of free surface roughening on ductile fracture behavior under uni-axial tensile state for metal foils was discussed experimentally.

2. Materials and experiment

Pure copper C1020-O and pure titanium TR270C-O foils and sheets with thickness t_0 of 0.05, 0.1, 0.3 and 0.5mm were used. The tensile test specimens were cut along the 0° to the rolling direction. In uni-axial tensile test, gage length was 10mm. A commercial tensile test machine was used for the tensile tests. Since a contact extensometer cannot be pasted for the metal foil, elongation was measured optically by using a video type non-contact extensometer. Tensile tests were conducted at room temperature and a strain rate of 1.6×10^{-3} /s. To get repeatability of experimental result, tensile tests were performed 3 times. After tensile test, fracture surface was observed by scanning electron microscope (SEM). To investigate effect of free surface roughening on ductile fracture behavior, the surface roughness was measured by confocal laser microscope. Until material fractures, surface roughness is measured at same area in five stages.

3. Results and discussion

3.1. Effect of thickness on fracture strain and free surface roughening behavior

Fig. 1 shows the effect of thickness on fracture strain obtained from uni-axial tensile test. Fracture strain decreases with decreasing thickness for all materials used as is the case in previous report [1]. In particular, the fracture strain of pure copper and pure titanium dramatically decrease from thickness of 0.3mm to 0.1mm. Thus, it is found that the thickness strongly affects fracture strain.

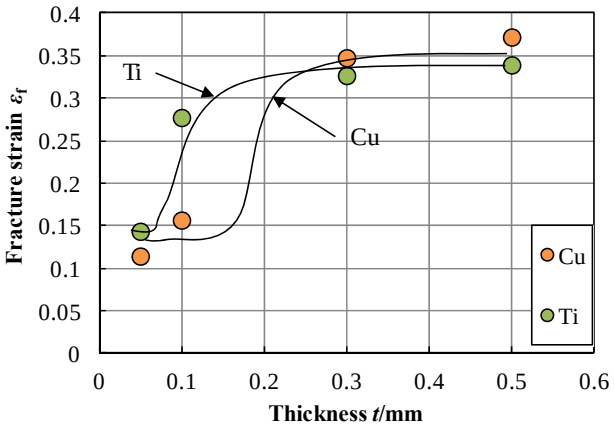

Figure 1. Effect of thickness on fracture strain in uni-axial tensile test

To clarify why the fracture strain significantly decrease with decreasing thickness, the free surface roughening on specimen surface during uni-axial tensile test was investigated. Here, we used ratio of maximum surface roughness to thickness Rz/t, because it is not always true that the surface roughness similarly decreases with decreasing thickness. The thickness t during deformation is calculated by assumption of volume constancy law and isotropic material. Fig. 2 shows the ratio of surface roughness to thickness Rz/t during uni-axial tensile test. The ratio of surface roughness to

thickness for each material linearly increases with increasing plastic strain. In addition, most important part is that the slope of ratio of surface roughness to thickness *Rz*/*t* is completely different between sheets (*t*=0.3 and 0.5mm) and foil (*t*=0.05 and 0.1mm). Particularly, the slope of evolution of *Rz*/*t* is changing significantly from thickness 0.3 to 0.1mm. As a result, it is supposed that the decrease in fracture strain has some connections with slope of relative free surface roughening *Rz*/*t*.

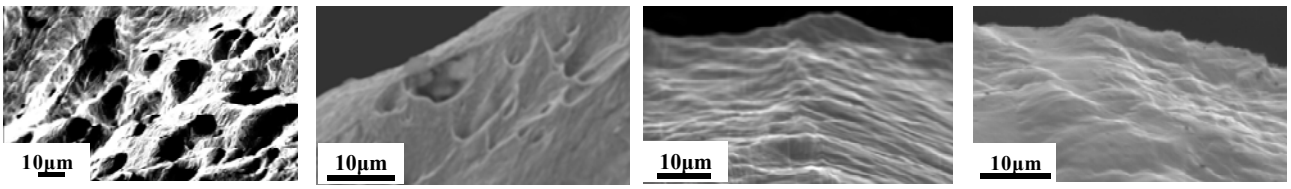
(b) Pure titanium

Figure 2. Evolution of ratio of surface roughness to thickness during uni-axial tensile deformation

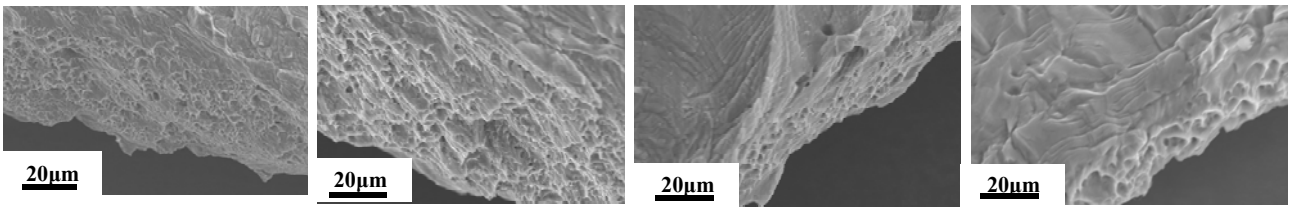
3.2. Fracture surface observation

To clarify the reason why the fracture strain changes significantly between thicknesses of 0.1 and 0.3mm, the difference in fracture mode was investigated by observing fracture surface by SEM. Figs. 3 and 4 show the SEM images of fracture surface for pure copper and pure titanium foils and sheets.



(a) *t*=0.5mm (b) *t*=0.3mm (c) *t*=0.1mm (d) *t*=0.05mm

Figure 3. SEM photographs of fracture surface for pure copper



(a) t=0.5mm (b) t=0.3mm (c) t=0.1mm (d) t=0.05mm

Figure 4. SEM photographs of fracture surface for pure titanium

In Fig. 3, some dimples on the fracture surface can be observed for pure copper sheets with thicknesses of 0.3 and 0.5mm. Meanwhile, non-dimples were on fracture surface of copper foils with thicknesses of 0.05 and 0.1mm. Generally, it is known that nucleation and growth of voids during plastic deformation causes dimple pattern on the fracture surface. Therefore, for metal sheets with relatively thicker thickness of 0.3 and 0.5mm, ductile fracture is caused by nucleation and growth of voids. On the contrary, it can be guessed that the metal foils with relatively thinner thickness of 0.05 and 0.1mm were fractured by other mechanism except nucleation and growth of voids because of non-dimple pattern on the fracture surface. These results about the existence or non-existence of dimple pattern on fracture surface between metal foils and metal sheets had some connections with significantly change in fracture strain in Fig. 1 and free surface roughening in Fig. 2. In the previous study, it was confirmed that the deep depth of surface defect purposely fabricated on the tensile specimen causes fracture at early tensile deformation stage [6]. Therefore, it would be considered that the evolution of free surface roughness causes similar effect of surface defect on the specimen. Thus, the fracture would be due to free surface roughening rather than nucleation and growth of voids inside the material.

Meanwhile, the dimple pattern can be observed for pure titanium foils and sheets with thickness of 0.05, 0.1, 0.3 and 0.5mm as shown in Fig. 4. The difference in fracture surface for pure titanium between foil and sheet cannot be confirmed seen in pure copper. Thus, it is guessed that origination of ductile fracture is not generated by free surface roughening but void nucleation and growth cause ductile fracture for pure titanium foils similar to general metal sheet, regardless the slope of relative free surface roughening is large for pure titanium foils as shown in Fig. 2. From these results, there are two fracture type of metal foils: pure titanium type with dimple pattern and pure copper type with non-dimple pattern on fracture surface.

3.3. Discussion on ductile fracture mechanism of metal foils

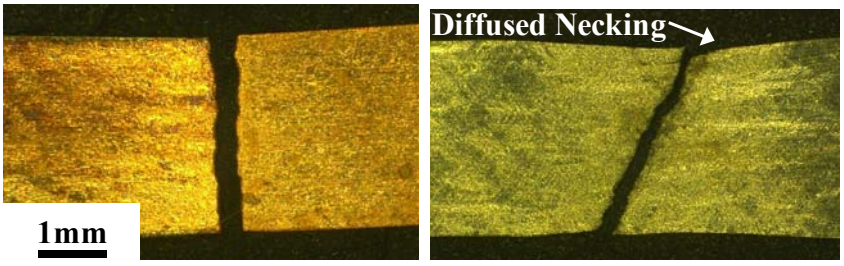
As described in section 3.1 and 3.2, it is found that the fracture type of metal foils divides broadly into two categories: existence dimple type for pure titanium and non-existence dimple for pure copper on fracture surface. To consider difference between both fracture types occurs for metal foils, we are focusing on not only the relative free surface roughening behavior and fracture surface observation described above but also basic material properties obtained from uni-axial tensile test as shown in Table 1. Material properties such as strain hardening n, K, ε_0 for each material were obtained from swift type flow stress curve as shown in Eq. (1).

$$\sigma = K(\varepsilon_0 + \varepsilon)^n \tag{1}$$

In addition, we discuss necking behavior near fracture area as shown in Fig. 5. Generally, the occurrence of necking behavior is strongly related to strain hardening exponent n [7]. it is well known that the larger n value, the larger necking strain.

Table 1. Material properties obtained from uni-axial tensile test

Material	Thickness t [mm]	n	K [MPa]	ε_0
Pure copper	0.05	0.56	671.2	0.022
	0.1	0.54	602.6	0.026
	0.3	0.46	524	0.014
	0.5	0.44	509.6	0.012
Pure titanium	0.05	0.085	533	0.015
	0.1	0.16	521.7	0.0063
	0.3	0.38	616.8	0.07
	0.5	0.33	604.1	0.05



(a) Pure copper (b) Pure titanium

Figure 5. Photographs of necking area after uni-axial tensile test

The strain hardening exponent n value of pure copper foil with thickness of 0.05mm in Table 1 was 0.56, respectively, but n value of pure titanium foil with thickness of 0.05mm was 0.085. Thus, n value of pure titanium foil is smaller than that of pure copper foil. The fracture strain of pure copper foil with thickness of 0.05mm indicates very low value as shown in Fig. 1 in spite of large n value 0.56. Additionally, it can be observed that the tensile test specimen of pure copper foil was fractured vertically to the tensile direction without diffused necking as shown in Fig. 5 (a). From these result, it is considered that the increase in the ratio of surface roughness to thickness causes inhomogeneous thickness distribution, which would lead to origination of fracture as a fracture mechanism of metal foil with non-dimple type such as pure copper. Originally, the pure copper foil with thickness of 0.05mm is supposed to indicate large fracture strain due to large n value, but fracture occurred before diffused necking because of increasing the ratio of surface roughness to thickness during deformation. Thus, it is considered that the void nucleated by occurrence of diffused necking is not growing in the specimen, and then the dimple pattern on fracture surface of pure copper foils with thickness of 0.05 and 0.1mm cannot be observed.

Meanwhile, n value of pure titanium foil with thickness of 0.05mm is extremely low value of 0.085 as shown in Table 1. Thus, it is confirmed that the necking strain indicates low level and the fracture occurs obliquely to the tensile direction as shown in Fig. 5 (b) after diffused necking. As shown in Fig. 2, the relative free surface roughening of pure titanium foils with thickness of 0.05 and 0.1mm is large as well as that of pure copper foils. However, in case of pure titanium foils with lower n value, it is supposed that the fracture occurs by necking along with metal sheet before effect of free surface roughening becomes marked. As a fracture mechanism of pure titanium foil, the occurrence of necking with lower n value is initiative of fracture of foils compared with relative free surface roughening. Therefore, the dimple pattern on fracture surface which is generated by nucleation and growing of voids after necking of pure titanium foil can be observed.

From these results, fracture mechanism of metal foil can divide broadly into two categories by the magnitude relation between the increase in ratio of surface roughness to thickness and strain hardening exponent *n* value, which would affect fracture strain level and existence or non-existence of dimple pattern on fracture surface.

4. Conclusion

In this study, the ductile fracture behavior and free surface roughening for various metal foils such as pure copper and pure titanium foils was investigated experimentally to clarify the general fracture mechanism of metal foils. As a result, the fracture type of metal foils divides broadly into two categories: existence dimple type for pure titanium and non-existence dimple type for pure copper on fracture surface. In addition, the magnitude relation between the increase in ratio of surface roughness to thickness and strain hardening exponent *n* value would affect fracture strain level and existence or non-existence of dimple pattern on fracture surface.

Abstract Engineering a bimodal grain size distribution in nanostructured materials has been proved to effectively achieve both higher strength and higher ductility. In these materials, large grains provide hardening ability and small grains provide larger yield stress. Accounting for the contributions of microcracks which nucleate in the nano/ultrafine grained phase and stop at the boundary of large grains during the plastic deformation, a mechanism-based plastic model is developed to describe the strength and ductility of the bimodal metals. The strain-based Weibull probability distribution function is utilized to predict the failure behavior of the bimodal metals. With the aid of the modified mean field approach, the stress–strain relationship can be derived by combining the constitutive relations of the nano/ultrafine grained phase and the coarse grained phase. Numerical results show that the proposed model can completely describe the mechanical properties of the bimodal metals, including yield strength, strain hardening and uniform elongation. The predictions are in good agreement with the experimental results. These results will benefit the optimization of both strength and ductility by controlling constituent fractions and the size of the microstructures in materials.

Keywords Bimodal grain size distribution, Strength, Strain hardening; Ductility, Weibull distribution

1. Introduction

Nanostructured and ultrafine-grained metallic materials have been observed to perform outstanding physical and mechanical properties. One of the most remarkable improvement is the superior mechanical strength compared to those of corresponding coarse-grained counterparts [1]. Therefore, these materials have been of significant interest and the key importance in designing lighter and stronger structures. So far, there have been several strategies to obtain the higher strengthening materials, including refining grain size, solid solution alloying and plastic straining [2], but these materials perform the disappointingly low tensile ductility. Due to this fact, the simultaneously higher strength and ductility in metals and alloys are expected and have emerged as the essentially challenging issue in the application of the nanostructured metals. In the past ten years, several alternative approaches are addressed to achieve the higher strength with keeping the high ductility, such as by generating the internal boundaries such as nanotwins in polycrystalline metals [3], or mixing the various sizes of microstructures in nanostructured materials [4-5].

The bimodal grain size distributions in nanostructured metals/alloys, which is considered as an effective approach to obtain the higher strength with good ductility, were first studied experimentally by Wang et al [4] and Tellkamp et al. [6] respectively. Their observations showed that such kind of nanostructured metals/alloys have higher strength and high ductility simultaneously. After these pioneering works, the subsequent various experiments and theoretical studies are carried out to investigate the mechanical performance in bimodal nanostructured metals and alloys [7-9]. These experiments demonstrated that the nanograins or ultrafine grains contribute

to the higher strength and the higher ductility is attributed to the coarse grains. For the fracture in bimodal metals/alloys, there exist some explanations to shed some lights into the possible mechanism of failure. The cavitations in nanograin/ultrafine phase, necking in coarse grains and shear localization are responsible for the fracture in bimodal metals [10-12]. Besides of that, the cavitations and microcracks play an important role in the improved ductility of the bimodal metals/alloys, which have been indentified further by the recent experiments [13]. The predictions of mechanical behaviors in bimodal metals/alloys have become a key issue to optimize the grain size distribution and the volume fraction of continents in bimodal metals/alloys for desiring the high strength and high ductility. So far, there are several works to develop the theoretical model for predicting the constitutive behavior and the failure properties of bimodal metals/alloys [14-15].

It has been demonstrated in experimental observations of tensile deformation in bimodal materials that the nanoscale voids or nano/microcracks lead to the modification of stress and strain for the plastic deformation. The objective of the present paper is to introduce the mechanism-based plastic model for bimodal metals in which the impacts of the microcracks generated during plastic deformation in bimodal materials on the mechanical properties are accounted for [16]. The bimodal copper is selected as an example to predict the corresponding mechanical behavior of bimodal metals. The weibull probability distribution of nan/microcracks is analyzed in the simulations. Numerical results show that the developed plastic model of bimodal metals can describe the mechanical properties of bimodal copper completely.

2. A Set Up of Model

The nanostructured metal with bimodal grain size distribution is considered as the composite metals consisting of the nanograined matrix phase and the course grained phase, as shown in Fig. 1. Since the grain boundaries have great contribution on the mechanical properties of nanocrystalline materials, the strain gradient in GBDPZs are involved in the proposed model to capture the effects of grain boundaries on the plastic deformation. Therefore, the mechanism-based strain gradient plasticity [17] is adopted here to describe the stress-strain response in each constituent of bimodal metals. A summary of the formulation is provided in the following. The strain rate $\dot{\boldsymbol{\varepsilon}}$ can be decomposed into its elastic and plastic parts,

$$\dot{\boldsymbol{\varepsilon}} = \dot{\boldsymbol{\varepsilon}}^{\mathrm{e}} + \dot{\boldsymbol{\varepsilon}}^{\mathrm{p}} \tag{1}$$

The elastic strain rate is obtained from the stress rate in the linear elastic relation as

$$\dot{\boldsymbol{\varepsilon}}^{\mathrm{e}} = \mathbf{M} : \dot{\boldsymbol{\sigma}} \tag{2}$$

where $\mathbf{M}$ is the elastic compliance tensor. The plastic strain rate is proportional to the deviatoric stress $\boldsymbol{\sigma}'$ based on the conventional J2-flow theory of plasticity, given as

$$\dot{\boldsymbol{\varepsilon}}^{\mathrm{p}} = \frac{3\dot{\varepsilon}^{\mathrm{p}}}{2\sigma_{\mathrm{e}}}\boldsymbol{\sigma}' \tag{3}$$

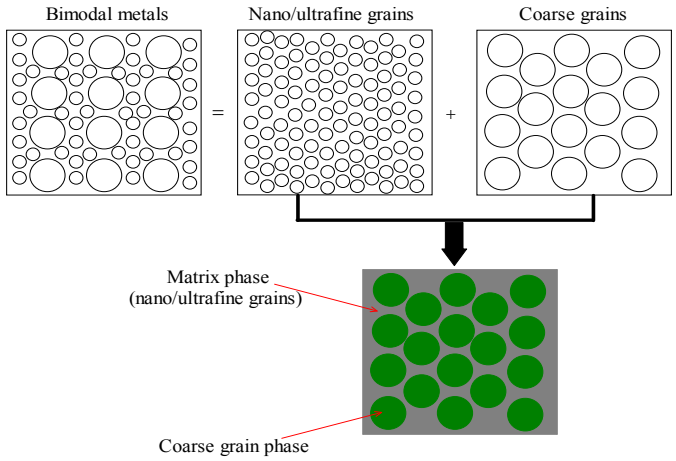

Fig. 1 Schematic drawings of bimodal grain size distributions in polycrystalline materials with assumption of the composite mixture model.

Here, $\sigma'_{ij} = \sigma_{ij} - \sigma_{kk}\delta_{ij}/3$ and $\sigma_e = \sqrt{3\sigma'_{ij}\sigma'_{ij}/2}$ is the von Mises equivalent stress. $\dot{\varepsilon}^p$ is the equivalent plastic strain rate which is determined by

$$\dot{\varepsilon}^p = \dot{\varepsilon}\left[\frac{\sigma_e}{\sigma_{flow}}\right]^{m_0} \tag{4}$$

in which $\dot{\varepsilon} = \sqrt{2\dot{\varepsilon}'_{ij}\dot{\varepsilon}'_{ij}/3}$ is the equivalent strain rate and $\dot{\varepsilon}'_{ij} = \dot{\varepsilon}_{ij} - \dot{\varepsilon}_{kk}\delta_{ij}/3$. m_0 is the rate-sensitivity exponent and σ_{flow} is the flow stress which will be addressed in the coming subsections for coarse grain and nano/ultrafine grains respectively. Eqs. (2)-(4) then establish the triaxial constitutive relation for the constituents in bimodal metals.

In the coarse grains, the surface-to-volume ratio of the grain boundaries is low enough to neglect its contribution on the plastic deformation. The primate deformation mechanism is dominated by the intragrain dislocation-mediated interaction which can be described by the Taylor evolution law. Thus the flow stress of the coarse grain can be expressed as

$$\sigma_{flow} = \sigma_0 + M\alpha\mu b\sqrt{\rho} + \sigma_b \tag{5}$$

Here, α, μ and M are the empirical constant, the shear modulus and the Taylor factor, respectively. σ_0 is the lattice friction stress and σ_b represents the back stress . ρ denotes the density of dislocations in grains which can be determined by the Kocks-Mecking's model [40]. According to Kocks and Mecking's model, the density of dislocations in the crystal interior obeys the evolution law with plastic strain, which allows for competition between accumulation and annihilation by dynamic recovery [18].

For the flow stress in the nano/ultrafined grains phase, the isotropic strain hardening is involved in the flow stress that is in consistency with the one in coarse grains described by Kocks-Mecking model, while the back stress with respect to the kinematic strain hardening is excluded in the nano/ultrafine grains phase. Then, the flow stress of the matrix phase can be expressed by

$$\sigma_{flow} = \sigma_0 + M\alpha\mu b\sqrt{\rho_I + \rho_{GB}} \tag{6}$$

in which the Taylor term in the flow stress is relevant to the dislocation densities in crystal interior and the GBDPZ. The density of dislocations in the GBDPZ can be expressed by

$$\rho_{GB} = \frac{n^{GB}\lambda^{GB}}{V_{Cell}} = k^{GB}\frac{\eta^{GB}}{b} \tag{7}$$

Here, $k^{GB} = 6d_{GBDPZ}/\phi^{GB}d_G$.

2.1. Impact of nano/microcracks

As the appearance of microcracks indicates, the number of dislocations stopped at the grain boundaries or around the cracks is increased. These dislocations pile up along the grain boundaries, impeding the movement of dislocations and ultimately resulting in back stress effects that must be taken into account during the plastic deformation in the nano/ultrafine-grained phase. Thus, the constitutive relation of the nano-grained phase will involve the back stress term in the flow stress expression. The flow stress in this phase is rewritten as

$$\sigma_{flow} = \sigma_0 + M\alpha\mu b\sqrt{\rho_I + \rho_{GB}} + \sigma_b^*, \tag{8}$$

where σ_b^* is the microcrack-induced back stress. The microcrack-matrix-effective-medium approach is utilized here to model the overall stress and strain in the nano/ultrafine-grained phase of the bimodal metals. The representative volume element (RVE) is often applied to account for the crack orientation statistics in the composite mechanics. The RVE boundary is subjected to tractions in equilibrium with a uniform overall stress of σ^∞ and the average strain in a solid with microcracks is consistent with regular and singular parts as

$$\overline{\boldsymbol{\varepsilon}} = \overline{\boldsymbol{\varepsilon}}^{\mathbf{m}} + \overline{\boldsymbol{\varepsilon}}^{\mathbf{c}}, \tag{9}$$

where $\overline{\boldsymbol{\varepsilon}}^{\mathbf{m}}$ and $\overline{\boldsymbol{\varepsilon}}^{\mathbf{c}}$ denote the matrix strain averaged over the RVE and the microcrack-induced variations in the overall average strain, respectively. If the matrix satisfies to be linear elastic, the matrix strain can be written as $\overline{\boldsymbol{\varepsilon}}^{\mathbf{m}} = \mathbf{M}^{\mathbf{m}} : \boldsymbol{\sigma}^\infty$. Because the microcracks generated during the plastic deformation of the bimodal metals are supposed to be parallel, the corresponding effective moduli are as follows:

$$E_1 = E_0[1 + \frac{16(1-v_0^2)}{3}\rho]^{-1}; G_{12} = G_0[1 + \frac{8(1+v_0)}{3(1-v_0/2)}\rho]^{-1}. \tag{10}$$

Please note from Eq.(15) that the effective moduli of the bimodal metals are associated with the density of microcracks in the materials. Experiments have revealed that the number of microcracks in the bimodal metals increased during the plastic deformation, suggesting that the density of microcracks in the bimodal metals is sensitive to the applied stress or strain. From this perspective, the strain-based Weibull distribution function with respect to the plastic strain is adopted here to character the number of microcracks. Thus the density of microcracks can be expressed as following

$$\rho = \rho_0 P(f_W) = \rho_0(1 - f_W(\varepsilon_p)) \tag{11}$$

Here, ρ_0 is a constant; $f_W(\varepsilon_p) = \exp(-(\varepsilon_p/\varepsilon_0)^m)$ is the strain-based Weibull distribution function in which ε_0 is the reference strain and m is the Weibull modulus.

2.2. Composite model

The composite model derived from the modified mean-field approach involves the Hill's recognition of a weakening constraint power for plastic deformation [19]. However, the flow stress in the following derivation is substituted by those in the nano/ultrafine-grained phase and the coarse-grained phase, respectively, both of which will be derived in the next section. Thus, the secant Young's modulus and secant Poisson ratio of the *i*th phase can be expressed by

$$E^{S(i)}=\frac{E^{(i)}}{1+\frac{E^{(i)}\varepsilon^{(i)}}{\sigma_{flow}^{(i)}}(\frac{\sigma_{11}^{(i)}}{\sigma_{flow}^{(i)}})^{\mathrm{m}_0-1}},\nu^{S(i)}=\frac{1}{2}-(\frac{1}{2}-\nu^{(i)}\frac{E^{S(i)}}{E^{(i)}}) \quad , \tag{12}$$

Throughout this paper the matrix will be indicated as phase 0 and coarse grains as phase 1. $E^{(i)}$ and $\nu^{(i)}$ denote the Young's modulus and the Poisson's ratio of the *i*th phase, respectively. The corresponding secant bulk and shear moduli of the *i*th phase are taken to satisfy the isotropic relations as $k^{S(i)}=E^{S(i)}/[3(1-2\nu^{S(i)})],\mu^{S(i)}=E^{S(i)}/[2(1+\nu^{S(i)})]$, respectively. Suppose that the composite is subjected to a boundary-displacement with a uniform strain $\overline{\boldsymbol{\varepsilon}}$, the relationship between the hydrostatic and deviatoric strains of the constituent phases and those of the composite are as follows [19]:

$$\begin{aligned}
&\varepsilon_{kk}^{(0)}=\frac{\alpha_0^s(\kappa_1-\kappa_0)+\kappa_0}{c_0\alpha_0^s(\kappa_1-\kappa_0)+\kappa_0}\overline{\varepsilon}_{kk},\varepsilon_{ij}^{(0)\prime}=\frac{\beta_0^s(\mu_1-\mu_0^s)}{c_0\beta_0^s(\mu_1-\mu_0^s)+\mu_0^s}\overline{\varepsilon}_{ij}^{\prime}-\frac{c_1\beta_0^s\mu_1}{c_0\beta_0^s(\mu_1-\mu_0^s)+\mu_0^s}\varepsilon_{ij}^{p(1)}\\
&\varepsilon_{kk}^{(1)}=\frac{\kappa_0}{c_0\alpha_0^s(\kappa_1-\kappa_0)+\kappa_0}\overline{\varepsilon}_{kk},\varepsilon_{ij}^{(1)\prime}=\frac{\mu_0^s}{c_0\beta_0^s(\mu_1-\mu_0^s)+\mu_0^s}\overline{\varepsilon}_{ij}^{\prime}+\frac{c_0\beta_0^s\mu_1}{c_0\beta_0^s(\mu_1-\mu_0^s)+\mu_0^s}\varepsilon_{ij}^{p(1)}
\end{aligned}, \tag{13}$$

where the mean stress components of the matrix phase and inclusions are given by

$$\begin{aligned}
&\sigma_{kk}^{(1)}=3\kappa_0\frac{\kappa_1}{c_0\alpha_0^s(\kappa_1-\kappa_0)+\kappa_0}\overline{\varepsilon}_{kk},\sigma_{ij}^{(1)\prime}=\frac{2\mu_0^s\mu_1[\overline{\varepsilon}_{ij}^{\prime}-(1-c_0\beta_0^s)\varepsilon_{ij}^{p(1)}]}{c_0\beta_0^s(\mu_1-\mu_0^s)+\mu_0^s}\\
&\sigma_{kk}^{(0)}=3\kappa_0\frac{\alpha_0^s(\kappa_1-\kappa_0)+\kappa_0}{c_0\alpha_0^s(\kappa_1-\kappa_0)+\kappa_0}\overline{\varepsilon}_{kk},\sigma_{ij}^{(0)\prime}=\frac{2\mu_0^s\{[\beta_0^s(\mu_1-\mu_0^s)+\mu_0^s]\overline{\varepsilon}_{ij}^{\prime}-c_1\beta_0^s\mu_1\varepsilon_{ij}^{p(1)}\}}{c_0\beta_0^s(\mu_1-\mu_0^s)+\mu_0^s}
\end{aligned}. \tag{14}$$

Here, f_i is the volume fraction of the *i*th phase and α and β are the components of Eshelby's tensor for spherical inclusions, as follows:

$$S_0^s=(\alpha_0^s,\beta_0^s),with\ \alpha_0^s=\frac{1+\nu_0^s}{3(1-\nu_0^s)},\beta_0^s=\frac{2(4-5\nu_0^s)}{15(1-\nu_0^s)}. \tag{15}$$

Therefore, the dilatational and deviatoric stresses and strains of the composite are connected by

$$\begin{aligned}
&\overline{\sigma}_{kk}=3\kappa_0\left[1+\frac{c_1(\kappa_1-\kappa_0)}{c_0\alpha_0^s(\kappa_1-\kappa_0)+\kappa_0}\right]\overline{\varepsilon}_{kk},\\
&\overline{\sigma}_{ij}^{\prime}=2\mu_0^s\left\{\left[1+\frac{c_1(\mu_1-\mu_0^s)}{c_0\beta_0^s(\mu_1-\mu_0^s)+\mu_0^s}\right]\overline{\varepsilon}_{ij}^{\prime}-\frac{c_1\mu_1}{c_0\beta_0^s(\mu_1-\mu_0^s)+\mu_0^s}\varepsilon_{ij}^{p(1)}\right\}
\end{aligned}. \tag{16}$$

To get an accurate description of the grain size-dependent local interaction and behavior in each phase, the grain size statistical distribution is frequently used to characterize the grain size distribution. Here, the grain size distribution in each phase is supposed to follow a Rayleigh

distribution with one parameter, instead of the log-normal distribution, for simplicity [20].

3. Numerical results and discussion

We now apply the developed models to predict the mechanical and failure behaviors of bimodal coppers, and then make comparisons with experimental results of bimodal coppers [4]. In the proposed composite mixture model, the matrix phase and coarse grain phase have equal elastic properties. These and other material parameters used in calculation are adopted in Ref [21]. For the sake of predicting the stress-strain relation of bimodal copper, the constitutive behavior in the matrix phase and coarse grain phase must be captured firstly. With the aid of the proposed constitutive relations, the stress-strain curves of matrix phase with average grain size as 300nm and coarse grain phase with mean grain size as 2μm are given in Fig.2a and Fig.2b respectively, by adopting the corresponding parameters. The corresponding experimental results are also plotted in Fig.2. Due to that the strain gradient is involved in the ultrafine or nanograins phase to describe the contribution of grain boundaries on the deformation mechanism, a reasonable value of strain gradient is provided to fit the experimental data. Note that the prediction can be in good accord with the measurements shown as in Fig.2a. For the coarse grain phase, the isotropic and kinetic strain hardening are both taken into account in the proposed constitutive relation and the calculated results can be agreeable very well with the experimental results (Seen in Fig.2b). After indentifying the constitutive relation in matrix phase and coarse grain phase, we then can simulate the stress-strain response in the framework of the proposed composite model involving the contributions of the microcracks. Fig.3 plots the predicted results based on the proposed model and the experimental data for bimodal copper are also reproduced in the figure. Here, the initial crack density ρ_0 is given as 0.04 and the Weibull modulus m as 10. It can be clearly noticed that the proposed model can capture very well the mechanical behavior in bimodal copper, the agreement between the simulations and the experiments is quite good not only in the yield stress but also in the strain hardening and the elongation at the ultimate strength.

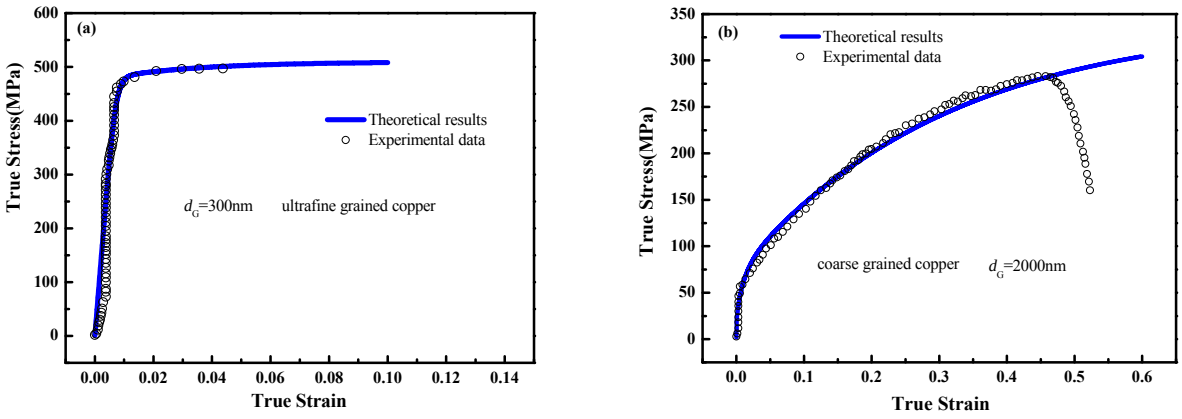

Fig. 2 Comparison of the stress-strain relationship between the experiments and theoretical results of coppers for the ultrafine/nanograins and the coarse grains

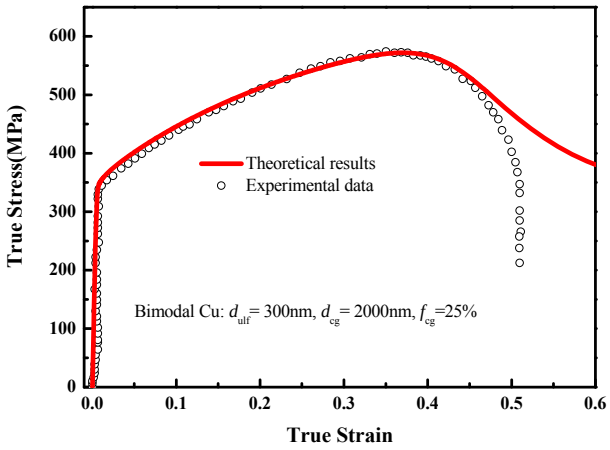

Fig. 3 Comparison of the stress-strain relationship between theoretical results and experiments for the bimodal Cu[8]

Owing to that the matrix grain dominates the high strength of the bimodal coppers and the inhomogeneous microstructures induces various mechanisms of strain hardening, we then further examined the dependence of the volume fraction of coarse grains on the mechanical response in bimodal copper. we plot the strength vs. uniform elongation with dependence of the volume fraction of coarse grains for the Weibull modulus as 3, 6 and 12 in Fig.4. It is worth to note from the figure that the strengths, including yield strength and ultimate strength, is weakened while the ductility is improved with the increment of the volume fraction of coarse grains. For the various Weibull modulus, the ductility increases with the increment of the Weibull modulus, and the slope of the curves for three different Weibull modulus are quite different with each other. It is also interesting to find from Fig.8 that the yield strength is independent on the Weibull modulus while the ultimate strength becomes smaller with decreasing the Weibull modulus.

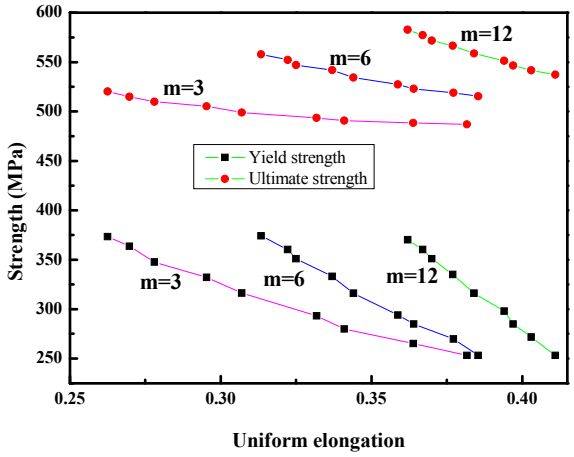

Fig. 4 Relationship between the strength and uniform elongation with different Weibull modulus for bimodal copper (d_{ulf}= 300nm, d_{cg}= 2000nm)

We further plot the curves of failure probability varied with the failure strain from the strain-based Weibull distribution function for the nanograined copper, coarse grained copper as well as bimodal coppers in Fig.5a. Inspired by the experimental observations, the characteristic strain ε_0 is adopted approximately as the measured uniform elongation. The Weibull modulus for the coarse grains and nano grains are determined by fitting the experimental results and the ones for bimodal cases are obtained by comparing with experiments. It can be found from the figure that the curves of bimodal cases are all located in the region surrounded by the curves of nanograins and coarse grains. The curves of bimodal copper with volume fraction of coarse grain as 45% and 83% in Li's measurements [9] are close to the one of the nano grains. It means that the failure properties of these two cases perform in an obvious brittleness comparable with nanocrystalline metals. The curve of the bimodal copper achieved by Wang et al [4], however, approaches the one of the coarse grains as well as the one with coarse grain fractions as 98% [9]. Under the same reference strain, the variability of the failure strain with a large Weibull modulus is less than the one with a small Weibull modulus, as shown in Fig. 9b. It means that, suppose the reference strain in the bimodal metal of $f_c = 0.45$ to be 30%, the limited measurements of corresponding case in Ref.[9] can be included in the reasonable failure probability which is determined by the sufficient data of measured samples.

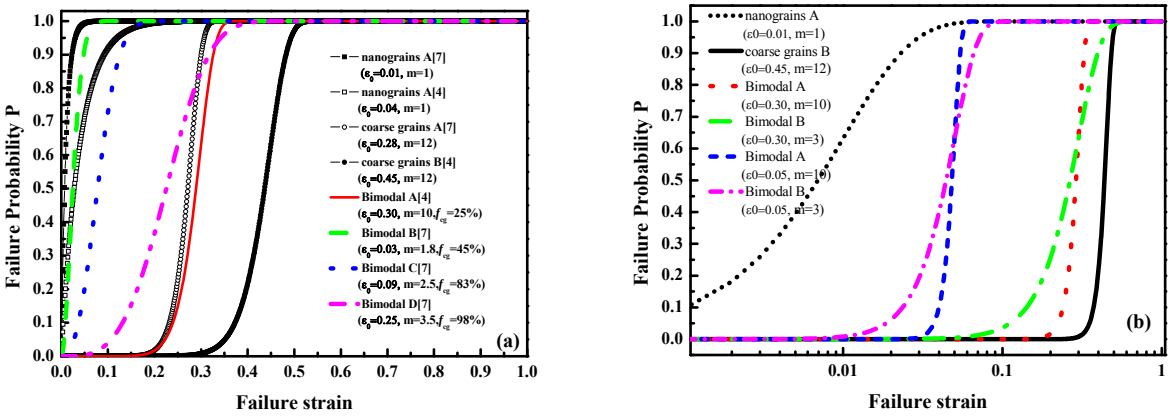

Fig. 5 The failure probability varied with failure strain with different Weibull modulus and a given volume fraction of coarse grain in bimodal copper.

4. Conclusion

In this paper, a micromechanics-based model, which has been developed in the previous authors' work, is introduced to investigate the mechanical behaviors of polycrystalline coppers with bimodal grain size distribution, accounting for the microcracks generated during plastic deformation.. Because of the appearance of the microcracks in the bimodal metals, the local mechanical properties are modified completely. After indentifying the related parameters in the developed model, the stress-strain response of the bimodal copper are predicted to make a comparison with the corresponding experimental results. The present numerical results reveal that the proposed micromechanical model can be utilized to describe the mechanical behavior of bimodal metals completely and successfully and to be expected to predict the mechanical properties such as the

yield stress and ductility. The predictions based on the proposed model are agreeable very well with the experimental data of bimodal copper. The results with respect to the Weibull modulus of microcrack density suggest that the bimodal metals will have good ductility with higher Weibull modulus which can be considered to be associated with the microstructures in the materials. The results in this paper will shed some lights on optimizing the distribution of microstructures and the grain size in polycrystalline materials to promise the achievement of higher strength and higher ductility in polycrstal metals or alloys.

Abstract Suppose the particles in with volume fraction c in an RVE of a particulate composite are separated into two groups, with volume fractions $(1-\lambda^{-1})c$ and c/λ over the RVE, respectively, a combined self-consistent and Mori-Tanaka approach is proposed for the evaluation of the effective elastoplastic property of particulate composites. The particles in Group I and the original matrix form a fictitious matrix, and its mechanical property is determined with the self-consistent scheme. The RVE of the composite consists of the fictitious matrix and Group of particles, and its mechanical property is determined with the Mori-Tanaka scheme. The conventional Mori-Tanaka scheme and self-consistent scheme can be obtained as the two limit cases as λ =1 and λ =∞, respectively. The constitutive behavior of the particles in Group I is identical with that in Group II. The effective elastoplastic behavior of some typical particulate composites is evaluated, and the comparison with the experimental results demonstrates the validity of the proposed approach. The induced λ can serve as a parameter related to the actual property of composites and identified by experiment, for a more accurate evaluation of the effective elastoplastic property of particulate composites.

Keywords Particulate composite, Elastoplasticity, Effective property, Mean-field approach

1. Introduction

The overall property of a composite is governed by the properties of their constituents and the microstructures. In order to achieve the desired property of a composite, an appropriate approach for the evaluation of the overall property of the composites is essential. Many micromechanics approaches have been developed [1-8] and extensively used to evaluate the effective properties of composites. The homogenization approaches have also been developed for the evaluation of the elastoplastic or elastoviscoplastic properties of composites [9-11].

It has been shown that there might be a big gap between the effective properties of a composite obtained respectively with the conventional Mori-Tanaka scheme and the conventional self-consistent scheme [12]. Since both schemes are extensively used in the evaluation of the effective property of composites, a question one may ask is whether one can evaluate more accurately the effective property of a composite with the combination of these two schemes. A combined self-consistent and Mori-Tanaka approach was proposed by Peng et al [13] for the evaluation of the effective elastic property of particulate composites. It was shown that the conventional Mori-Tanaka scheme and self-consistent scheme can be obtained as the two limit cases of the approach. The effective elastic properties of some typical particulate composites were evaluated and compared with experimental results, and the satisfactory agreement between the computed and the experimental results demonstrates the validity of the proposed approach.

In this article, the combined self-consistent and Mori-Tanaka approach [13] is extended to the evaluation of elastoplastic properties of particulate composites. The effective elastoplastic responses of some typical particulate composites are analyzed and compared with experimental results.

2. Extension of Combined Self-consistent and Mori-Tanaka Approach

An RVE of a particulate composite consists of the matrix of mechanical property $\mathbf{L}^m$ and particles of mechanical property $\mathbf{L}^c$ with total volume fraction c. The particles are separated into two groups by introducing a parameter λ ($\lambda \geq 1$): Group I contains particles with total volume fraction $(1-\lambda^{-1})c$ over the RVE, and Group II contains particles with total volume fraction c/λ over the RVE. The effective elastoplastic property of the composite can be determined by two steps: in the first step, the particles in Group I are embedded in the original matrix to form the fictitious matrix (with equivalent particle volume fraction $\hat{c}$), and the elastoplastic property of the fictitious matrix, $\hat{\mathbf{L}}^m$, is determined with the self-consistent scheme; and in the second step, the particles in Group II are further distributed randomly in the fictitious matrix to form the RVE, and the effective elastoplastic property of the composite, $\bar{\mathbf{L}}$, is determined with the Mori-Tanaka scheme, the particle inclusions in Group II should be necessarily sufficient to meet the requirement of the application of the Mori-Tanaka scheme.

Suppose the volume of the RVE is V, the volume of the original matrix is $V_m = (1-c)V$ and the volume of the particle inclusions in Group I is $(1-\lambda^{-1})cV$, the volume of the fictitious matrix is $\hat{V}_m = V_m + (1-\frac{1}{\lambda})cV = (1-\frac{c}{\lambda})V$, and the equivalent volume fraction of the particles in the fictitious matrix is

$$\hat{c} = (1-\frac{1}{\lambda})cV \Big/ \left[(1-\frac{1}{\lambda})cV + (1-c)V\right] = \frac{\lambda-1}{\lambda-c}c\,. \tag{1}$$

In the first step, making use of the Hill's self-consistent scheme, the elastoplastic tensor of the fictitious matrix can be determined as follows by averaging the stress rate field over $\hat{V}_m$, i.e.,

$$\hat{\mathbf{L}}^m = (1-\hat{c})\mathbf{L}^m \cdot \mathbf{A}^m + \hat{c}\mathbf{L}^c \cdot \mathbf{A}^c\,, \tag{2}$$

where
$$\mathbf{A}^c = [\mathbf{L}^* + \mathbf{L}^c]^{-1} : [\mathbf{L}^* + \hat{\mathbf{L}}^m], \qquad \mathbf{A}^m = [\mathbf{L}^* + \mathbf{L}^m]^{-1} : [\mathbf{L}^* + \hat{\mathbf{L}}^m], \tag{3}$$

and
$$\mathbf{L}^* = \hat{\mathbf{L}}^m : \left(\mathbf{S}^{-1} - \mathbf{I}_4\right). \tag{4}$$

$\hat{\mathbf{L}}^m$ relates the stress rate $\dot{\hat{\boldsymbol{\sigma}}}^m$ and the strain rate $\dot{\hat{\boldsymbol{\varepsilon}}}^m$ of the fictitious matrix by

$$\dot{\hat{\boldsymbol{\sigma}}}^m = \hat{\mathbf{L}}^m : \dot{\hat{\boldsymbol{\varepsilon}}}^m\,, \tag{5}$$

and the stress rate and the strain rate in the original matrix and the particles are determined with

$$\begin{aligned} \dot{\boldsymbol{\varepsilon}}^c &= \mathbf{A}^c : \dot{\hat{\boldsymbol{\varepsilon}}}^m, & \dot{\boldsymbol{\sigma}}^c &= \mathbf{L}^c : \dot{\boldsymbol{\varepsilon}}^c, \\ \dot{\boldsymbol{\varepsilon}}^m &= \mathbf{A}^m : \dot{\hat{\boldsymbol{\varepsilon}}}^m, & \dot{\boldsymbol{\sigma}}^m &= \mathbf{L}^m : \dot{\boldsymbol{\varepsilon}}^m.\end{aligned}\,' \tag{6}$$

In the second step, making use of the Mori-Tanaka scheme and keeping in mind that the RVE of the material is composed of the fictitious matrix and the particle inclusions in Group II (with total volume fraction c/λ) and the domain for averaging strain (or stress) is $\hat{V}^m + \frac{c}{\lambda}V = V$, the

corresponding expression can easily be obtained as

$$\dot{\boldsymbol{\varepsilon}}^c = \tilde{\mathbf{A}}^c : \hat{\dot{\boldsymbol{\varepsilon}}}^m, \qquad \dot{\boldsymbol{\sigma}}^c = \mathbf{L}^c : \dot{\boldsymbol{\varepsilon}}^c, \tag{7}$$

where $$\tilde{\mathbf{A}}^c = [\tilde{\mathbf{L}}^* + \mathbf{L}^c]^{-1} : [\tilde{\mathbf{L}}^* + \hat{\mathbf{L}}^m], \quad \text{with} \quad \tilde{\mathbf{L}}^* = \hat{\mathbf{L}}^m : (\mathbf{S}^{-1} - \mathbf{I}_4), \tag{8}$$

$$\bar{\mathbf{L}} = \hat{\mathbf{L}}^m + \frac{c}{\lambda}\left(\mathbf{L}^c - \hat{\mathbf{L}}^m\right) : \tilde{\mathbf{A}}^c : \left[\left(1 - \frac{c}{\lambda}\right)\mathbf{I} + \frac{c}{\lambda}\tilde{\mathbf{A}}^c\right]^{-1}, \tag{9}$$

$$\bar{\dot{\boldsymbol{\sigma}}} = \bar{\mathbf{L}} : \bar{\dot{\boldsymbol{\varepsilon}}}, \tag{10}$$

$$\hat{\dot{\boldsymbol{\varepsilon}}}^m = \left[\left(1 - \frac{c}{\lambda}\right)\mathbf{I} + \frac{c}{\lambda}\tilde{\mathbf{A}}^c\right]^{-1} : \bar{\dot{\boldsymbol{\varepsilon}}}. \tag{11}$$

It can be seen easily by comparing Eq. (8) with Eqs. (3) and (4) that $\tilde{\mathbf{L}}^* = \mathbf{L}^*$ so that $\tilde{\mathbf{A}}^c = \mathbf{A}^c$, indicating that the response of the particles in Group I given by Eq. (6) is identical with that of the particles in Group II given by Eq. (7). This fact, on one hand, implies the consistency of the constitutive behavior of the two parts of the particles in the extended approach, and on the other hand, brings convenience to the corresponding analysis.

Eqs. (9) and (11) can be reduced to the results of the conventional Mori-Tanaka scheme if λ =1 (noticing that if λ=1, there would be no particles in the fictitious matrix), $\hat{\mathbf{L}}^m = \mathbf{L}^m$. If λ is sufficiently large so that $c/\lambda \to 0$ (implying that there would be no particles in Group II), one obtains $\bar{\mathbf{L}} = \hat{\mathbf{L}}^m$ (Eq. (9)), $\hat{\dot{\boldsymbol{\varepsilon}}}^m = \bar{\dot{\boldsymbol{\varepsilon}}}$ (Eq. (11)), so that $\hat{\dot{\boldsymbol{\sigma}}}^m = \bar{\dot{\boldsymbol{\sigma}}}$ (Eqs. (10) and (5), noticing that $\bar{\dot{\boldsymbol{\sigma}}} = \dot{\boldsymbol{\sigma}}^0$ in the Mori-Tanaka scheme), the extended approach is reduced to the conventional self-consistent scheme.

Thus, it is known that the conventional Mori-Tanaka scheme and the conventional self-consistent scheme can be obtained as the two limit cases of the proposed approach as λ=1 and λ=∞, and the variation of λ may provide the evaluation of the elastoplastic property varying between the result given by the Mori-Tanaka scheme and that given by the self-consistent scheme. In practical application, the introduced λ may serve reasonably as an adjustable parameter that can be associated with the actual properties of composites and determined by experiment. This is important because the mechanical properties of composites are affected by many factors such as compositions, microstructures, internal constraints, etc., and the fabrication of composites may inevitably involve various unexpected factors that also strongly affect the overall property of the composites. The effects of these factors could be comprehensively considered with λ.

3. Constitutive Model and Numerical Algorithm

3.1. Elastoplastic constitutive equation

Assuming both constituents of a composite are initially isotropic and plastically incompressible, in the case of isothermal and small deformation, the following incremental form of the elastoplastic relationship can be obtained [14]

$$\Delta\mathbf{s}(z) = A\Delta\mathbf{e}^p + \mathbf{B}(z_n)\Delta z \tag{12}$$

where **s** and $\mathbf{e}^p$ are deviatoric stress and plastic strain, respectively,

$$A = \sum_{r=1}^{3} k_r C_r \qquad \mathbf{B}(z_n) = -\sum_{r=1}^{3} k_r \alpha_r \mathbf{s}^{(r)}(z_n), \tag{13}$$

$$\Delta\mathbf{s}^{(r)}(z) = k_r(C_r\Delta\mathbf{e}^p - \alpha_r\mathbf{s}^{(r)}(z_n))\Delta z, \quad k_r = \frac{1-e^{-\alpha_r\Delta z}}{\alpha_r\Delta z}, \qquad z = z_n + \Delta z, \tag{14}$$

z is generalized time that is non-negative and increases monotonically during any plastic deformation in terms of the following definition

$$\Delta z = \frac{\Delta\zeta}{f(z)}, \qquad \Delta\zeta^2 = \Delta\mathbf{e}^p : \Delta\mathbf{e}^p, \tag{15}$$

$f(z)$ is a hardening function, C_r and α_r (r =1,2,3) are material constants. The deviatoric elastic relation is

$$\Delta\mathbf{e} - \Delta\mathbf{e}^p = \frac{\Delta\mathbf{s}}{2G} \tag{16}$$

where **e** is deviatoric strain tensor and G is shear modulus. The volumetric constitutive relation can be expressed as

$$tr(\boldsymbol{\sigma}) = 3Ktr(\boldsymbol{\varepsilon}) \qquad \text{or} \qquad tr(\Delta\boldsymbol{\sigma}) = 3Ktr(\Delta\boldsymbol{\varepsilon}), \tag{17}$$

where $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$ are stress and strain tensors, respectively, and K is bulk modulus. Rewriting Eq. (15) as

$$\Delta z = \frac{\Delta\mathbf{e}^p}{f^2\Delta z} : \Delta\mathbf{e}^p \tag{18}$$

and making use of the following relationships

$$\Delta\mathbf{s} = \Delta\boldsymbol{\sigma} - \frac{1}{3}tr(\Delta\boldsymbol{\sigma})\mathbf{I}_2 \qquad \Delta\mathbf{e} = \Delta\boldsymbol{\varepsilon} - \frac{1}{3}tr(\Delta\boldsymbol{\varepsilon})\mathbf{I}_2, \tag{19}$$

where $\mathbf{I}_2$ is the identity tensor of rank two, the incremental constitutive equation can be derived from Eqs. (12), (16) and (17) as [14]

$$\Delta\boldsymbol{\sigma} = \mathbf{L} : \Delta\boldsymbol{\varepsilon}, \tag{20}$$

where

$$\mathbf{L} = 2G_p\mathbf{I}_4 + \left\{K - \frac{2}{3}G_p\right\}\mathbf{I}_2 \otimes \mathbf{I}_2 + \frac{(2G)^2}{(2G+A)^2 f^2(z)}\frac{1}{a}\mathbf{B}\otimes\frac{\Delta\mathbf{e}^p}{\Delta z}, \tag{21}$$

with $$G_p = \frac{GA}{2G + A}, \qquad a = 1 + \frac{\mathbf{B} : \Delta\mathbf{e}^p}{(A + 2G) f^2 \Delta z}. \tag{22}$$

If the particles are assumed linearly elastic, the constitutive relationship of the particles can easily be obtained as follows by ignoring the terms related to plastic deformation and noticing that for elastic material, A is sufficiently large and G_p tends to G (Eqs. (22) and (21))

$$\mathbf{L} = 2G\mathbf{I}_4 + \left\{K - \frac{2}{3}G\right\}\mathbf{I}_2 \otimes \mathbf{I}_2. \tag{23}$$

Eq. (20) can be specified as follows for the matrix and the particles in a particulate composite

$$\Delta\boldsymbol{\sigma}^m = \mathbf{L}^m : \Delta\boldsymbol{\varepsilon}^m \qquad \text{and} \qquad \Delta\boldsymbol{\sigma}^c = \mathbf{L}^c : \Delta\boldsymbol{\varepsilon}^c \tag{24}$$

3.2. Numerical Algorithm

For simplicity, we assume in the analysis that the particles are of spheres with identical size, if we further ignore the minor difference between the result obtained with anisotropic Eshelby tensor and that obtained with isotropic Eshelby tensor provided the plastic deformation is moderate [15], both the original matrix and the fictitious matrix can be approximated as overall isotropic, then the following Eshelby tensor for isotropic media is adopted in the analysis [10],

$$\mathbf{S} = a\,\mathbf{I}_2 \otimes \mathbf{I}_2 + b[\mathbf{I}_4 - \mathbf{I}_2 \otimes \mathbf{I}_2], \tag{25}$$

with $$b = \frac{2(4 - 5\nu)}{15(1 - \nu)}, \qquad a = 1 - b. \tag{26}$$

The analysis of the response of a composite material involves the constitutive behavior of the original matrix and that of the particles, which are determined with Eq. (6). For a stress-controlled process, the numerical algorithm for the analysis of the elastoplastic response of a two-constituent composite is stated as follows: For the prescribed particle volume fraction c and the parameter λ, $\hat{c}$ can be calculated with Eq. (1), and with the results obtained in the k-th iteration of the l-th increment of loading, such as $(\Delta\bar{\boldsymbol{\varepsilon}})_{(l)}^{(k)}$ and of the composite, $(\hat{\mathbf{L}}^m)_{(l)}^{(k)}$ of the fictitious matrix, $(\Delta\boldsymbol{\varepsilon}^m)_{(l)}^{(k)}$, $(\Delta\boldsymbol{\sigma}^m)_{(l)}^{(k)}$ and $(\mathbf{L}^m)_{(l)}^{(k)}$ of the matrix, and $(\Delta\boldsymbol{\varepsilon}^c)_{(l)}^{(k)}$, $(\Delta\boldsymbol{\sigma}^c)_{(l)}^{(k)}$ and $(\mathbf{L}^c)_{(l)}^{(k)}$ of the particles, in the following (k+1)th iteration, $(\mathbf{L}^*)_{(l)}^{(k+1)}$, $(\mathbf{A}^c)_{(l)}^{(k+1)}$ and $(\mathbf{A}^m)_{(l)}^{(k+1)}$ can be calculated with Eqs. (4) and (3) respectively, and then, keeping in mind $\tilde{\mathbf{A}}^c = \mathbf{A}^c$, $\bar{\mathbf{L}}_{(l)}^{(k+1)}$ of the composite can be immediately obtained with Eq. (9). Given the l-th increment of stress $(\Delta\boldsymbol{\sigma}^0)_{(l)}$, $(\Delta\bar{\boldsymbol{\varepsilon}})_{(l)}^{(k+1)}$ can be solved from Eq. (10), and $(\Delta\hat{\boldsymbol{\varepsilon}}^m)_{(l)}^{(k+1)}$ with Eq.(11), then $(\Delta\boldsymbol{\varepsilon}^m)_{(l)}^{(k+1)}$, $(\Delta\boldsymbol{\sigma}^m)_{(l)}^{(k+1)}$, $(\Delta\boldsymbol{\varepsilon}^c)_{(l)}^{(k+1)}$ and $(\Delta\boldsymbol{\sigma}^c)_{(l)}^{(k+1)}$ can be obtained with Eq. (6), the mechanical property of the matrix $(\mathbf{L}^m)_{(l)}^{(k+1)}$ and that of particles $(\mathbf{L}^c)_{(l)}^{(k+1)}$ can be updated with Eqs. (21) and (23), respectively, than the mechanical property of the fictitious matrix, $(\hat{\mathbf{L}}^m)_{(l)}^{(k+1)}$, can be calculated with Eq. (2). The iterative process continues until the following inequality is satisfied,

$$\delta = \frac{\left\| \Delta \bar{\boldsymbol{\varepsilon}}_{(l)}^{(k+1)} - \Delta \bar{\boldsymbol{\varepsilon}}_{(l)}^{(k)} \right\|}{\left\| \Delta \bar{\boldsymbol{\varepsilon}}_{(l)}^{(k+1)} \right\|} \le \delta_0 , \tag{27}$$

where δ_0 is the tolerant error and δ_0=0.0001 is used in computation. After superimposing the derived increments on the corresponding quantities up to that after the (l-1)th increment of loading, one obtains $(\boldsymbol{\sigma}^0)_{(l)}$ and $(\bar{\boldsymbol{\varepsilon}})_{(l)}$ of the composite, and then starts the computation for the next increment of loading.

3. Numerical Examples and Verification

The elastoplastic behavior of some typical particulate composite materials subjected to tensile/compressive loading is computed and compared with experimental results.

The material constants involved in the proposed approach includes elastic/elastoplastic material constants of each constituent and λ. For the composites consisting of purely elastic particles and elastoplastic matrix, the elastic property of each constituent is usually provided by material suppliers or can be determined with conventional test; and the plastic constants of the matrix can be identified with simple test (e.g., tensile test) of pure matrix; λ can then be identified by fitting simple testing result (e.g., σ-ε curve) of the composite.

The variation of the tensile response of an Al/Al_2O_3 composite with respect to the volume fraction of Al_2O_3 particles is computed and shown in Fig. 1. The material constants adopted are given in Table 1, in which the Al matrix is assumed elastoplastic and the Al_2O_3 particles are purely elastic. The elastic constants are adopted from [16]. The plastic constants of the matrix are identified with the empirical relation $\sigma = 130 \times \left[1 + \left(\varepsilon^p \right)^{0.2} \right]$ [16], and the hardening function $f(z)$ (in Eq.(15)) takes the following form

$$f(z) = d - (d-1)e^{-\beta z} \tag{28}$$

where d and β are material constants. It can be seen in Fig. 1 that the σ - ε curve of the Al matrix (c=0) computed with the obtained material constants can reasonably replicate the empirical σ-ε curve. The ultimate strength of the composite, σ_u, increases with the increase of c.

Table 1 Material constants of Al/Al_2O_3

Constituent	E (GPa)	ν	C_1/α_1, C_2/α_2, C_3/α_3 (MPa)	$\alpha_1, \alpha_2, \alpha_3$	d, β
Al	69	0.345	112, 25, 17.5	2500, 800, 200	1.25, 16
Al_2O_3	400	0.25	----------	----------	---------

The effective σ - ε curves of c=0.34 corresponding to different λ is shown in Fig.2(a), where the σ-ε curve is hoisted with the increase of λ, but all the curves lie between the two bounds determined respectively by λ=1 and $\lambda \to \square$. There is a remarkable gap between the σ-ε curves evaluated respectively with λ=1 and $\lambda \to \square$. The variation of σ_u against λ for c=0.34 is shown in Fig. 2(b), where the results given by the conventional Mori-Tanaka scheme and the conventional self-consistent scheme are independent of λ and serve as the lower and the upper bounds, respectively. The results given by the combined self-consistent and Mori-Tanaka approach starts from that obtained with Mori-Tanaka scheme, increases with λ, and approaches the asymptotic

value determined with self-consistent scheme. It can be seen that the experimental result also lies in the region bounded by the curve with λ=1 and that with λ=∞. It can be found that the σ-ε curve with λ=8 can well fit the experimental result. All the curves in Fig. 1 are computed with λ=8, the obtained results fit well the empirical results at c=0 and experimental results at c=0.34, and the curves obtained at different c seems reasonable.

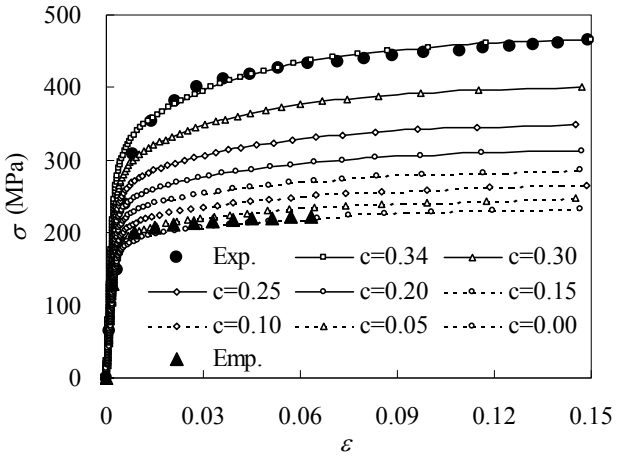

Fig. 1 Experimental and computational σ-ε curves of Al/Al_2O_3 composite

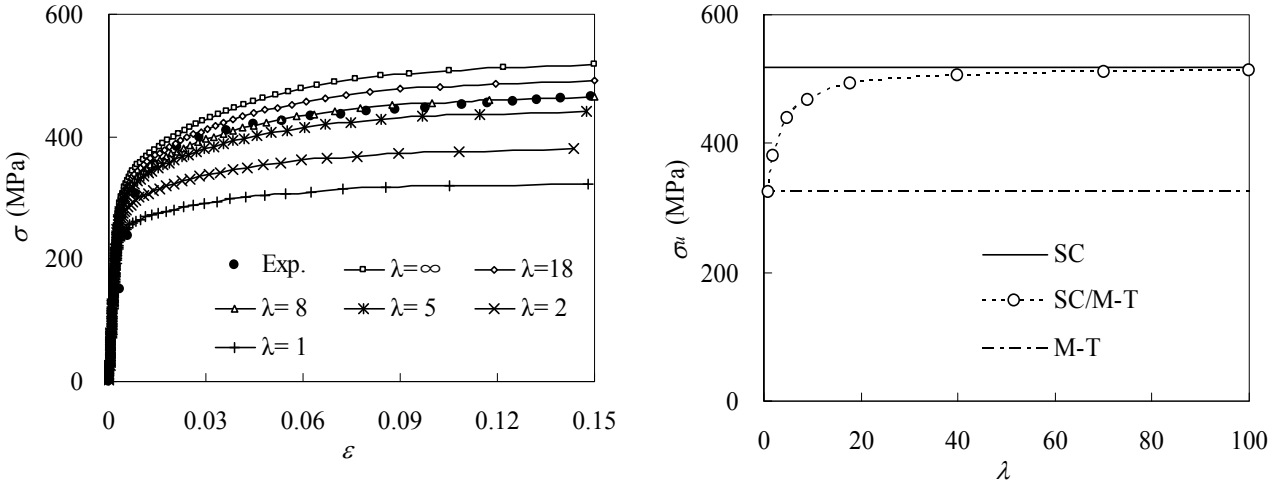

(a) Effective σ-ε curves of Al/Al_2O_3 composite using different λ (c=0.34)

(b) Variation of ultimate strength against λ (c=0.34)

Fig. 2 Effect of λ on σ-ε curves of Al/Al_2O_3 composite

It can be found in Fig. 2 that λ strongly affects the evaluated effective property of the composite. If λ changes between 1 and infinite, the evaluated effective property of the composite will change between the result determined by the Mori-Tanaka scheme and that by the self-consistent scheme, with the tendency definitely identical to that caused by the decrease of particle size, which was reported frequently and investigated extensively by many researchers [17-20]. It implies the possibility for the extended approach to describe implicitly and phenomenologically the size-effect of particulate composites. Suppose the volume of a RVE is fixed, given particle volume fraction c, the number of particle inclusions in the RVE, N, should reflect the size information of the particles. For instance, N should be a smaller value for larger particles, and vice versa. Suppose the particle volume fraction c is fixed in both Composite 1 and Composite 2, and the particles are of identical

spheres of diameter φ_1 in Composite 1 and diameter φ_2 in Composite 2, letting $N_1=\lambda_1 m$ for Composite 1 and $N_2=\lambda_2 m$ for Composite 2, where m is a constant related to the volume of RVE and the minimal number of particles required by the application of the Mori-Tanaka scheme, one can easily obtain the relation between λ_1 and λ_2 of the two composites as $\lambda_2=\left(\varphi_1/\varphi_2\right)^3\lambda_1$. It indicates that if λ_1 for the evaluation of the effective property of Composite 1 is fixed or fitted from experimental data, λ_2 for that of Composite 2 can be approximately estimated with the above relationship without necessity of being identified individually.

Fig. 3 shows the capability of the present approach in the description of the effective σ-ε relation of the composite consisting of Al356 (T4) matrix and 15% SiC particles. The material constants adopted are listed in Table 2, where it is assumed that the Al356 (T4) matrix is elastoplastic and the SiC particles are purely elastic. The elastic constants of the two constituents are the same as those used by Lloyd [17]. The plastic constants of the matrix are identified by fitting the empirical relation $\sigma=86+141.7\left(\varepsilon^p\right)^{0.365}$ given in [17]. It can be seen in Fig. 3 that the σ-ε curve of the matrix obtained by the extended approach (with c=0) agrees reasonably with that given by the empirical relation [17]. For c=0.15 and φ=16 μm, the effective σ-ε curve obtained with the extended approach using λ_{16} =1, corresponding to the result using the Mori-Tanaka scheme, can reasonably fit the experimental result. Experimental results show that, even if the volume fraction of particles keeps unchanged, the composite with smaller SiC particle inclusions (e.g., φ=7.5 μm) exhibits larger resistance against irreversible deformation. The effective σ-ε curve of the composites using $\lambda=\left(16/7.5\right)^3\lambda_{16}\approx 9.71$ is shown in Fig. 3 with solid line, which agrees reasonably with the experimental effective σ-ε curve. The effective σ-ε curve computed with the self-consistent scheme is also shown in Fig. 3 for comparison.

5. Conclusion and discussion

The combined self-consistent and Mori-Tanaka approach for the evaluation of the elastic

property of particulate composites [13] is extended to the evaluation of the elastoplastic property of particulate composites. Several examples are exhibited and compared with the experimental results. The following conclusion can be drown from the analysis:

(1) The comparison between the computed and the experimental results shows that the effective elastoplastic property of the composites can be satisfactorily evaluated with the extended approach by properly choosing the parameter λ, demonstrating the validity of the extended approach.

(2) The results given by the Mori-Tanaka scheme and the self-consistent scheme can be obtained as two bounds of that by the extended approach as the λ=1 and λ=∞, respectively, and the variation of λ between λ=1 and λ=∞ yields the results lying between the two bounds.

(3) The constitutive behavior of the particles outside of the introduced fictitious matrix is identical with that of the particles inside the fictitious matrix, indicating the consistency of the particle behavior in the combined approach.

(4) The introduced parameter λ can take into account comprehensively the effects of the factors such as microstructures (e.g., the size and shape of the inclusions), internal constraints (e.g., interfacial condition between different constituents), etc., as well as various unexpected factors during the fabrication of composites, which may strongly affect the overall property of the composites. In other words, λ can be associated with the actual property of composites and identified with experiment for a more accurate evaluation of the effective property of composites.

(5) The approach can describe implicitly the effect of particle size on the elastoplastic property of composites. With the help of the baseline experimental data of a composite with the particles of a specified size, the mechanical properties of composites with the same constituents but different size of particles could be estimated approximately with the proposed approach.

In this article we like to suggest a method parallel with the conventional mean-field schemes. In order to show more clearly the capability of the approach, we do not introduce other influencing factors, for example, higher-order gradients of deformation or isotropisation of tangent stiffness tensor, etc., to avoid blurring the advantages of the proposed approach.

It should be mentioned that, in the proposed approach with the increase of λ, the obtained effective elastoplastic response exhibits the tendency definitely identical with the size-effect phenomenon. Although it is known that “such effects cannot be included in the conventional inclusion-infinite matrix based Eshelby problem” [21], we are still interested in this capability. It can be accounted for with the difference between the assumptions used in the Mori-Tanaka scheme and in the self-consistent scheme. It is known that, although the Mori-Tanaka scheme involves the interaction between mediums, when any particle is added, the matrix is always considered as the original one without taking into account the existing reinforcement by other particles. Thus, in mathematics, the particles in an RVE can be assumed necessarily sufficient and randomly distributed, which implies relatively large size of the particle inclusions. However, in the conventional self-consistent scheme, the property of the matrix is assumed to be that after all the particle inclusions are added, which implies sufficiently large number of sufficiently small inclusions in the RVE. Since the proposed approach could adjust the property of the fictitious matrix (from that of the original matrix to that of the matrix with all particle inclusions being added) by adjusting λ, it should be able to describe the particle size effect to some extend. The introduced parameter λ can, on one hand, take into account averagely the enforcement in the fictitious matrix, and on the other hand, related to the ratio of the particle size to the reference particle size, which account for why it possesses the capability of

describing the relative “size-effect” of particulate composites.

Abstract The effect of nanoparticle modification on the interlaminar shear fracture behavior of carbon fibre/ epoxy laminates were studied by the End Notched Flexure (ENF) tests. The mode II fracture toughness was improved in the presence of these nanoparticles although nano-rubber was more effective compared to nano -silica. Examination of the fracture surfaces of composite laminates by scanning electron microscopy showed no debonding of nano-silica particles but some evidence of nano-rubber cavitation. Anti-Symmetric Four-Point Bending (ASFPB) tests of the nanoparticles modified epoxies was conducted and the results indicated that nano-silica was more effective in toughening bulk epoxy, but this high toughness could not be effectively transferred to mode II delamination in the composite laminates. Finite element analysis was performed to confirm the predominant Mode II stress state of the ASFPB test.

Keywords: Mode II delamination; carbon fibre composite; silica nanoparticles; rubber nanoparticles.

1. Introduction

Fiber laminates are widely used today for their outstanding strength-to-weight ratio. However, their interlaminar weakness is a major problem limiting their service applications. Hence, many past efforts have focused on increasing the interlaminar fracture resistance. Recently, nano-sized particles are found to improve the toughness of bulk epoxies [1-4] and this has stimulated many new research activities on the potential of incorporating these nanoparticles to increase the fracture toughness of composite laminates. Thus, previous studies on mode I double-cantilever-beam (DCB) delamination tests [5-6] showed that, with nanoparticle modification of the epoxy matrix, the mode I interlaminar fracture toughness of carbon fibre composites can be improved up to 150% and 27% by rubber and silica nanoparticles, respectively [6]. But in most practical situations, delamination often happens in a mixed mode I and mode II fracture. Hence, before studying the mixed mode problem, it is important to investigate whether the nanoparticles can also increase the mode II fracture resistance.

In this paper, we present recent findings on mode II toughness of carbon fibre/epoxy laminates and corresponding bulk epoxies, which are modified by different nanoparticles: (a) nano-silica and (b) nano-rubber. End Notched Flexure (ENF) tests [7] were conducted on these composite systems and their interlaminar toughness values, G_{IIC}, were evaluated. Corresponding bulk materials without carbon fibers were investigated by the Anti-Symmetric Four-Point Bending (ASFPB) test. Finite element analysis was applied to evaluate the stress state at the crack-tip based on the ASFPB experiments. Fracture surfaces of both ENF and ASFPB samples of different material systems were studied by Scanning Electron Microscopy (SEM) to examine their toughening mechanisms and possible interactions between fibers and nanoparticles. Comparison of mode I [6] and mode II toughness was made to quantitatively study the overall delamination resistance of the fiber laminates with different matrix formulations.

2 Experimental Method

2.1 Sample preparation

The processing of the composite laminates with different matrix systems (see Table 1) for mode II testing was identical to that used in our previous work on mode I delamination [6]. The composite laminates were fabricated from plain woven carbon fibres (168058ITL supplied by Inter-Turbine Advanced Logistics Pty Ltd, Australia) with a planar density of 203 g/m^2. The epoxy resin system included Araldite-F (diglycidyl ether of bisphenol A, DGEBA) and piperidine, both supplied by Sigma-Aldrich, where the piperidine was applied as a curing agent by the weight ratio of 100:5. Two types of nanoparticles were used: 40 wt% sol-gel nano-silica (Nanopox F400, Nanoresins AG, Germany) with ~20 nm SiO_2, and nano-rubber/bisphenol A (Kaneka Corporation, Japan) with 25 wt % of ~100 nm core-shell rubber in master batches.

Eighteen-ply laminates of ~270 mm^2 were prepared by the hand lay-up method. Precautions were taken to keep the fabrics well aligned and flat. A 0.2 mm thickness Kapton® polyimide film was inserted in the mid-plane of the laminates to act as the initial crack. The laminates were wrapped with bleeders and release film within a vacuum bag, and first vacuumed in a chamber for 20 min followed by curing in a hot-press at 120 ºC for 16 h. High curing temperature excursions for long durations were applied to ensure the resin was fully cured. A pressure of 250 kPa was applied during curing to maintain a uniform laminate thickness and a constant fiber volume fraction, which were 0.19 mm and 60±1%, respectively. 120x20 mm^2 ENF samples were finally cut from the square panels by a wet diamond saw.

The bulk materials prepared for ASFPB testing were the same as the matrices of the laminates. Material formulations were prepared by mixing plain DGEBA resin with required amounts of nano-silica or nano-rubber master batch. After adding the curing agent to the blend, the mixture was poured into a preheated mould for curing at 120 °C for 16 h identical to the laminates. A pre-crack was made under the requirements of the test on the middle of each specimen with a sharp blade.

Table 1 Matrix formulation of carbon fibre laminates

Material Code	Matrix Formulation by Weight Percentage (%)		
	Epoxy	Silica	Rubber
E* (control)	100	--	--
S6	94	6	--

2.2 Fracture toughness measurements

Three-point ENF tests

Standard 3-point ENF tests were performed in an Instron 5567 machine according to the Protocol for Interlaminar Fracture Testing No. 2 (1992) [7]. Fig. 1 shows the geometry and dimensions of the ENF sample. The initial crack length a is 25 mm and a/L = 0.5. The crack mouth opening displacement rate was 0.5 mm/min. 5 samples were tested for each matrix system and their load-displacement curves were recorded. The interlaminar toughness, G_{IIC}, was calculated according to

the protocol [7] by:

$$G_{IIC} = \frac{9a^2\delta P}{2b(2L^3+3a^3)} \cdot \frac{1-0.6099\times\left(\delta/L\right)^2}{1+0.3766\times\left(\delta/L\right)^2} \tag{1}$$

where δ and P are displacement and maximum force recorded at the load-point at fracture.

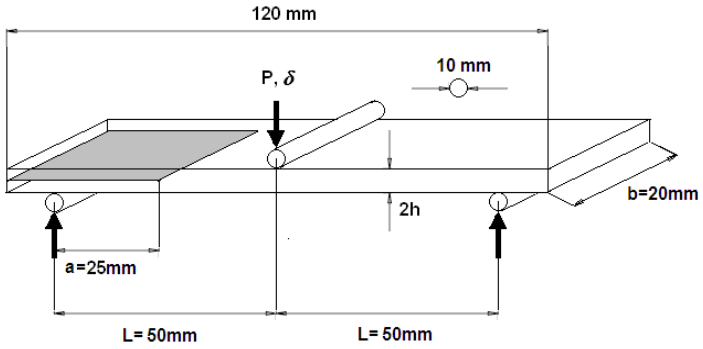

Figure 1. Dimensions of ENF specimen.

Four-point ASFPB tests

ASFPB tests were conducted on bulk materials with pre-cracked specimens, 90(L)x6(B)x16(W) mm^3, as shown in Fig. 2. The loading distance S_2/W = 0.75; S/W=3 was chosen and the pre-crack length was strictly limited to within $0.53 \le a/W \le 0.75$ based on previous studies [8-10] in order to provide a pure in-plane shear stress field around the crack-tip which would induce a high K_{II}/K_I ratio (over 20) [8]. Thus, it is reasonable to consider the ASFPB test as pure mode II fracture under such a geometric configuration since mode I fracture can be essentially neglected. Hence, according to [10], the mode II stress intensity factor can be calculated from:

$$K_{II} = F_{II}\tau_0\sqrt{\pi a} \tag{2}$$

where

$$F_{II} = -0.2915 + 6.33229\frac{a}{W} - 9.1199\left(\frac{a}{W}\right)^2 + 6.0570\left(\frac{a}{W}\right)^3$$

$$\tau_0 = \frac{P_1 - P_2}{WB} \quad P_1 = \frac{S_1}{S}P\,; \quad P_2 = \frac{S_2}{S}P$$

We assume $K_{IIC} \approx K_{II}$ when P is substituted with the maximum load at fracture. The tests were conducted on an Instron 5567 at a speed of 0.5 mm/min at the load-point.

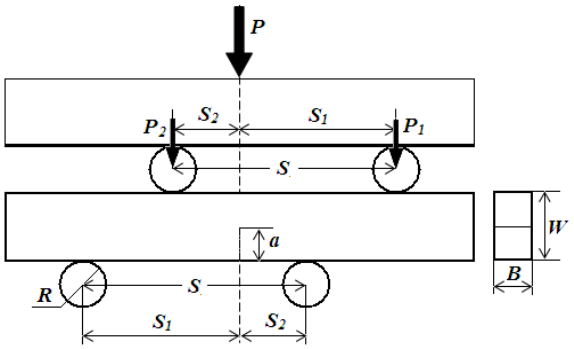

Figure 2. Dimensions of ASFPB specimen.

2.3 Finite Element Analysis (FEA)

The stress state for the mode II ASFPB test was simulated using ABAQUS. The geometry of the model is the same as the test sample, which is 90(L)x6(B)x16(W) mm^3. Since the ASFPB sample is symmetric to the central crack line, two parts were built and partially tied together to form a 10 mm crack. The loads, P_1 and P_2, were applied over contact areas, 2x6 mm^2 and 1x6 mm^2, respectively, aligned with the impressions left on the sample after the test. Young's modulus was chosen as 2.6 GPa to simulate the stress distribution, which was found insensitive to modulus verification within a small range (~10%) due to the plane strain feature of the FEA model. The average maximum load at fracture during the experiments (1200 N) was applied in the simulation study. Hence, the resultant stress distribution obtained in FEA should show the stress state at fracture initiation.

2.4 Microstructure analysis

The fracture surfaces of the fibre composites and the bulk samples were coated with a thin gold layer and examined by SEM (Zeiss ULTRA Plus SEM) at an accelerated voltage of 2 kV.

3 Results and Discussion

3.1 Carbon fiber laminates

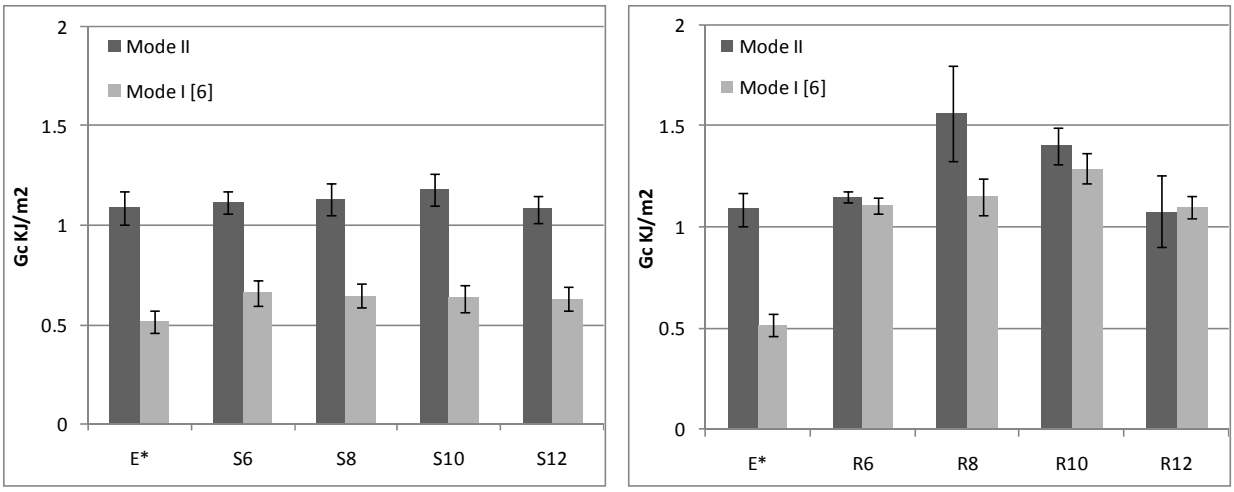
Load-displacement curves of the ENF tests were recorded with an Instron 5567. The maximum load P and corresponding displacement δ from each load-displacement curve were substituted into Eq. (1) with the initial crack length a to obtain G_{IIC} for each specimen. According to the protocol [7], the crack length a is measured after the test by opening the sample. The average value of 4 samples was reported as the mode II fracture toughness of the corresponding material system.
In Fig. 3, calculated G_{IIC} values with standard deviations of nano-silica and nano-rubber modified fiber laminates are compared with their G_{IC} values [6]. In mode II fracture, the silica nano-particles are not as effective as they are in mode I, Fig. 3(a). G_{IIC} increases with increasing nano-silica loading until it reaches a maximum at 10 wt% silica, which is ~8% higher than the control. Further increase of silica loading lowers G_{IIC}. This trend is similar to the mode I results [6]. Mode II fracture toughness of nano-rubber modified fiber laminates are shown in Fig. 3 (b). Unlike silica, nano-rubber particles can improve G_{IIC} by as much as 43% higher than the control at 8 wt%. Again, higher nano-rubber loading cannot improve G_{IIC}; and at 12 wt%, G_{IIC} is even lower than the control. These results should be viewed with caution since at 12 wt% of nano-rubber or nano-silica uniform dispersion of these particles was difficult to achieve, which would lead to reduced toughness values. It is further noted that with pure epoxy matrix, G_{IC} of the composite laminates is ~54% lower than G_{IIC}. For silica modified epoxy matrix, the mode I delamination resistance G_{IC} is ~48-50% of the mode II delamination, G_{IIC}. However, the differences between G_{IC} and G_{IIC} of nano-rubber filled composites, R6, R10 and R12, are less than 10%. Indeed, G_{IC} of R12 is even slightly higher than G_{IIC}. Hence, nano-rubber modified composite laminates can provide superior mode I and mode II toughness, e.g., R8 and R10, which is not possible in nano-silica laminates.

3.2 Bulk materials

The mode II fracture toughness, G_{IIC}, of the bulk materials, which are the same as the matrix of the composites, was determined by the ASFPB tests. The results are listed in Table 2 with ±1standard deviation, where the K_{IIC} values were calculated using Eq. (2). To compare to the toughness of the corresponding fiber composites, the critical stress intensity factors K_{IIC} of bulk materials are converted to the fracture energy G_{IIC} (see Table 2) by:

$$G_{IIC} = \frac{(1-\mu^2)K_{IIC}^2}{E} \tag{3}$$

where μ is Poisson's ratio and E is Young's modulus. In the calculations, the values of Poisson's ratio of different material systems were obtained by the simple rule of mixture based on the density, Poisson's ratio and volume percentage of the epoxy and particles [4]. Note that the ratio of K_I/K_{II} at fracture is less than 4%, indicating that the ASFPS geometry is suitable for mode II toughness evaluation.



(a) Nano-silica modified system (b)Nano-rubber modified system

Figure 3 Comparisons between G_{IIC} and G_{IC} [taken from [6]] of nanoparticles modified composites.

Table 2. Mode II fracture toughness of the bulk material.

Material Code	K_{IIC} (MPa $\sqrt{m}$)	K_I/K_{II}	E (GPa) [4]	G_{IIC} (kJ/m^2)
E*	3.53 (±0.23)	0.031	2.86	3.82
S10	4.18 (±0.21)	0.044	3.14	4.88
R10	2.78 (±0.21)	0.035	2.30	2.95

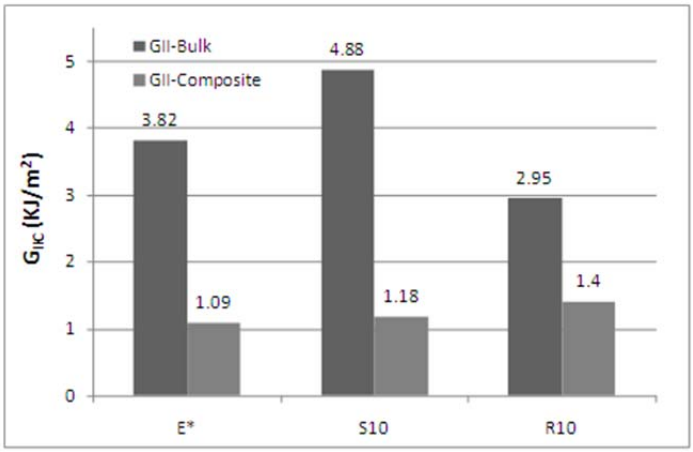


Figure 4. Comparison of G_{IIC} of bulk and composite laminates.

Figure 4 compares the mode II fracture toughness G_{IIC} of the bulk materials (neat epoxy and nanoparticle modified epoxy) and their fibre composite laminates. Notably, the fracture energy is improved by nano-silica modification in S10 as bulk; however, G_{IIC} of the S10 composite laminate is 76% less than that of the corresponding bulk materials. Thus, the toughness transfer efficiency in mode II of S10 is much lower than that in mode I [6], where the G_{IC} of fibre composite is more than 94% of the corresponding bulk. The nano-rubber filled epoxy has a higher transfer efficiency of ~50% from bulk to composite laminate, but the incorporation of rubber particles decreases the bulk G_{IIC} when compared to pure epoxy.

FEA was applied to understand the stress state of mode II ASFPB test. Figures 5(a)-(c) show the distributions of normal stresses, σ_x and σ_y, and shear stress, τ_{xy}, respectively. The crack tip stresses have been discussed in [11]. At fracture initiation, the crack-tip is subjected to a local tensile stress σ_x of ~5 MPa, (see Figure 5(a)), but the shear stress τ_{xy} is most dominant, which is ~30 MPa. The FEA results confirm that the samples failed primarily due to mode II fracture.

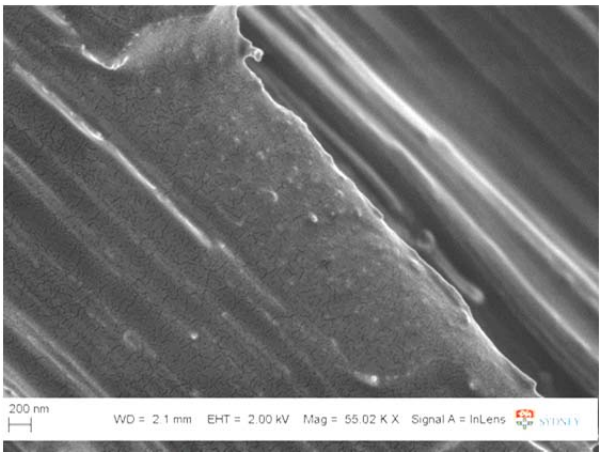
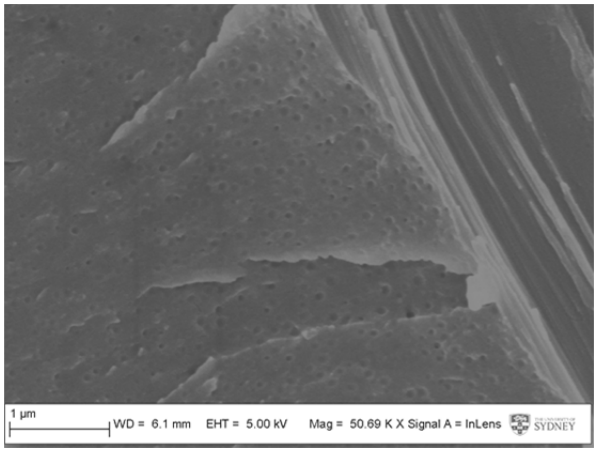
3.3 Fractograph study

Two matrix formulations were chosen to study the effects of nanoparticles on ENF tests: 10 wt% silica (S10) and 10 wt% rubber in epoxy (R10), in comparison with the control laminate (E*). In mode II fracture, there is good bonding observed between fiber and matrix for all composites and no separations can be seen in Figs. 6(a)-(c). However, obvious debonding between fibers and rubber modified matrix was observed in our previous study on mode I delamination [6] possibly due to the different fracture mode. Since the cracks are not open in mode II, fiber pullout from the matrix is difficult. Fig. 6(a) shows the fracture surface of the composite laminates, where silica nanoparticles

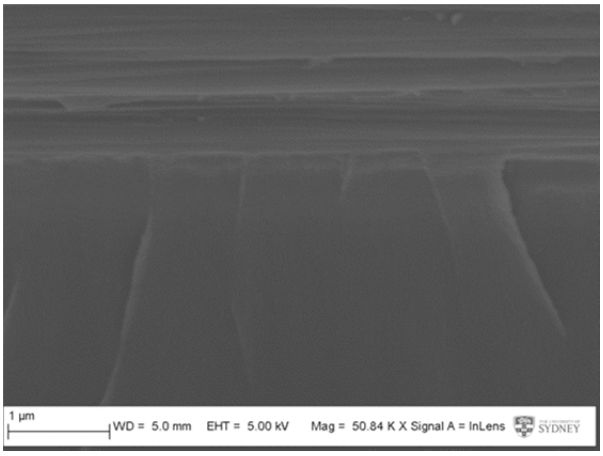
are evenly dispersed in the matrix. No particle debonding or pullout can be found in Fig. 6(a), where the nano-silica particles are well covered by epoxy. Since silica nanoparticle debonding is the major toughening mechanism in mode I [4-6], Fig. 6(a) therefore explains why the improvement of fracture toughness of these composites in mode II is not as remarkable when compared to the laminates with unmodified epoxy matrix. In contrast, nano-rubber particles in mode II fracture surface are observed to be well-dispersed in epoxy in Fig. 6(b). However, it is difficult to ascertain if the nano-rubber particles are cavitated, though some evidence exists when examined on much higher magnification. Another possible reason for the increase in toughness of R10 is the micro-voids introduced during processing of the laminates. When the rubber particles were added to epoxy, the viscosity of the resin was increased which made the resin flow between the fibres more difficult. More air bubbles and voids might form in the laminates. During delamination propagation, these voids may reduce the stress intensity at the crack tip and delay the delamination growth. However, further examination on the composite microstructure before and after testing are needed to prove the above hypothesis.



(a) Fracture surface of carbon fiber/S10 composite.



(b) Fracture surface of carbon fibre/R10 composite.



(c) Fracture surface of carbon fibre/E* composite.

Figure 6. Fractographs of ENF mode II specimens.

Figs. 7(a)-(c) show fracture surfaces of mode II ASFPB specimens of pure epoxy (E*), nano-rubber and nano-silica modified epoxies (R10 and S10) by optical microscopy under low magnification (x6) on the left side and high magnification (x750) by SEM on the right side. Pure epoxy shows typical brittle fracture characteristics in Fig. 7(a). Silica modified bulk epoxy shows the roughest surface; however, no typical silica debonding is observed in Fig. 7(b) even at higher resolution. In Fig. 7(c),

the rubber modified sample shows clear stress-whitened area in the center of the crack tip, indicating plastic deformation occurred during mode II fracture. R10 also possesses the smoothest near crack-tip region, which agrees with the test results where rubber modified epoxy shows the lowest G_{IIC}.

4 Conclusion

Mode II fracture behaviors of nanoparticles modified carbon fibre laminates have been studied by the ENF tests. Additional mode II ASFPB tests were also conducted on the nanoparticles modified bulk epoxies. From the results obtained we can conclude below:

(a) Nano-rubber modified epoxy is effective in enhancing the mode II toughness, G_{IIC}, of composite laminates depending on the particle loading. For example, R8 increases G_{IIC} by over 40% compared

to E*. By contrast, nano-silica modified epoxies are not as effective and only less than 8% improvement on G_{IIC} can be achieved.
(b) Mode II toughness G_{IIC} of nano-silica modified epoxy composite laminates are approximately twice the mode I toughness G_{IC} independent of the particle loading. The ratio of G_{IIC}/G_{IC} for nano-rubber modified epoxy composite laminates is much less.
(c) Nano-silica particles increase significantly G_{IIC} of the bulk epoxy; but this high toughness cannot be effectively transferred to the delamination toughness of the nano-silica modified epoxy composite laminates.
(d) Regarding the toughening mechanisms, silica particle debonding and rubber cavitation are not clearly shown by the SEM photos of mode II fracture surfaces, although thyeare the major toughening mechanisms in Mode I fracture of nanoparticle modified epoxy [6] and their fibre composites [4]. Further study will be conducted to identify the main reasons for the increase of G_{IIC} in S10 (bulk) and R10 (composites laminates).

Abstract CFRP plates were subjected to impact loading by a drop-weight impact testing machine. Stacking sequence of the plates was [cloth/0°/90°/0°/90°/0°/cloth]. Dimension of the plates was 60 mm in length and width and 2mm in thickness. Then thermal conductivity of the plates in the thickness direction was measured by the static comparison method. Although it is difficult to measure the absolute value of thermal conductivity in general, reproducibility of the measurement was improved and variation from the initial value was discussed in the present paper. Distribution of the thermal conductivity due to impact damage on the plane was clarified as a function of distance from the impact point. On the other hand, the CFRP plates were cut by diamond saw and cross sections of the plates were observed by an optical microscope. Then length and number of delamination and transverse cracks were measured respectively on the photomicrographs. Distribution of damage such as delamination and transverse cracks on the plane was also clarified as a function of distance from the impact point. Finally, the relationship between variation in thermal conductivity and impact damage was clarified experimentally on the basis of the experimental measurements.

Keywords CFRP, Impact damage, Thermal conductivity, Delamination, Transverse crack

1. Introduction

Carbon fiber reinforced plastics (CFRP) have remarkable properties such as high strength-to-density ratio, tailor-made strength, etc. as well as advantages of polymers. Using the advanced properties, CFRP are utilized for many engineering structures and products of daily use. Especially, usage of CFRP for airplanes is increased recently from the viewpoint of weight reduction in order to save fuel consumption.

Considering the usage of CFRP in airplanes and automobiles, impact loading is unavoidable in their operations. For instance, bird strikes during flight, drop of tools during maintenance and collision during driving. Delamination, transverse cracks and debonding between matrix and fibers are well-known as internal damage of CFRP due to applied loading. When CFRP is fabricated by laminating prepreg sheets, impact loading causes internal damage such as delamination. Since internal damage causes reduction of mechanical properties and residual life, development of non-destructive inspections for CFRP [1–6] is important to guarantee reliability for structures.

Hammering tests among non-destructive inspections are often used practically for large-scale structures. The method of hammering tests is very simple and necessary tools are only hammers. However, the test results depend on experience of inspectors and only qualitative results are obtained. On the other hand, since X-ray inspections [3] and ultrasonic inspections [3] are precise methods, expensive equipments and special techniques are necessary and testing places are restricted. Non-destructive tests by infrared pulse thermography [4–6] are simple method, however, resolution to inspect internal damage is not so high.

Internal damage causes variation in material properties [7], so that internal damage can be inspected from the variation in material properties inversely. In practice, distribution of temperature is measured in non-destructive tests by infrared pulse thermography, and the distribution is caused by variation in thermal conductivity due to internal damage [8, 9]. In the present research, in order to

improve the resolution to inspect internal damage by infrared pulse thermography, assistance by numerical simulation is considered. Namely, if distribution of temperature in CFRP plates due to internal damage can be simulated, the internal damage could be predicted from the distribution of temperature by inverse analyses. For the numerical simulation, the relationship between thermal conductivity and internal damage is necessary. Accordingly, in the present paper, in order to investigate the relationship as a first step, CFRP plates are subjected to impact loading by a drop-weight impact testing machine, and variation in thermal conductivity from the initial value and internal damage such as delamination and transverse cracks are evaluated. Then the relationship between thermal conductivity and internal damage is clarified.

2. Experimental Methods

2.1. Drop-weight impact test

CFRP plates are used as specimens. Dimension of the plates is 60 mm in length and width and 2mm in thickness, and the stacking sequence is [cloth/0^o/90^o/0^o/90^o/0^o/cloth]. The CFRP plates are fixed in a drop-weight impact testing machine (Instron, CEAST9310) by the plate with a hole 40 mm across. A hemispherical tup falls on the center of specimens inside of the hole. Diameter of the tup is 12.6 mm. Three levels of impact energy are applied to specimens, and they are 5.1, 9.9 and 21.0 J. In the tests, drop height is fixed to 0.7 m and mass of weight is changed.

2.2. Measurement of thermal conductivity

Thermal conductivity of CFRP plates in the thickness direction is measured by the static comparison method [10]. Fig. 1 shows schematic diagram of the method. Self-making apparatus is used. In the static comparison method, a specimen and a reference sample whose thermal conductivity is known are placed in series. Then heat flow is given to the reference sample and specimen in series by a heater, and the difference in temperature ΔT_1 and ΔT_2 between both ends of specimen and sample is measured by thermocouples, respectively. The thermal conductivity of the specimen λ is evaluated relatively from the thermal conductivity of the reference sample λ_{ref} by using the ratio of the difference in temperature ΔT_1 and ΔT_2 and dimensions of specimen and sample [10].

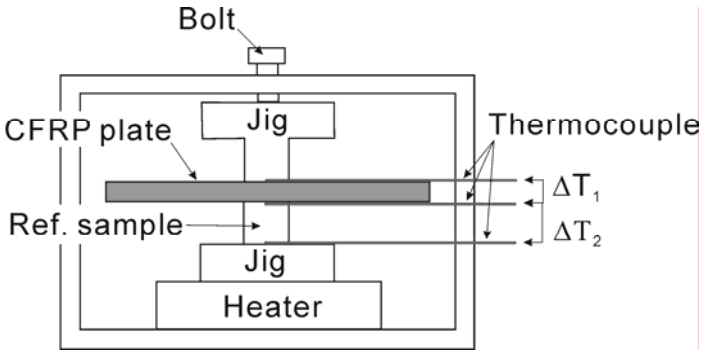

Figure 1. Schematic diagram of the static comparison method to measure thermal conductivity in the thickness direction of CFRP plates.

In order to improve reproducibility of measurement, the measurement is carried out in a vacuum vessel. The reference sample is selected so that thermal conductivity of the sample λ_{ref} is close to that of specimens. In the present paper, type 304 stainless steel (SUS304) is used as the reference

sample. The measurement is carried out in two cases. Namely, heat flow is given to specimen through reference sample, and heat flow is given to reference sample through specimen. The order of sequence for specimen and reference sample is changed. In the calculation of thermal conductivity λ, difference in temperature is necessary. However, if gradient of the relationship between difference in temperature and input electric power of heater is used instead of the difference in temperature, the reproducibility of measurement is improved [10].

Although it is difficult to measure the absolute value of thermal conductivity in general, reproducibility of the measurement could be improved. Since objectives of the present research are non-destructive inspection based on variation in material properties, the reproducibility is important because variation in material properties from their initial values is measured and discussed.

Fig. 2 shows positions of measuring thermal conductivity in specimens. Impact loading is applied to the center of specimens and the loading point is numbered 1. Thermal conductivity is measured at nine points (No. 1 through 9) as shown in the figure.

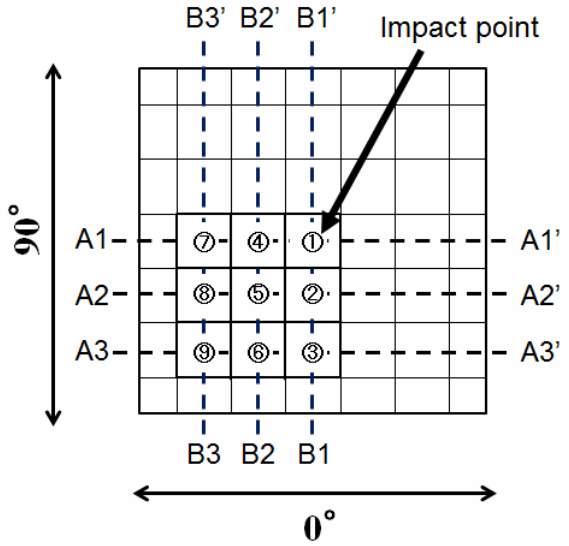

Figure 2. Positions of measuring thermal conductivity and observing cross sections.

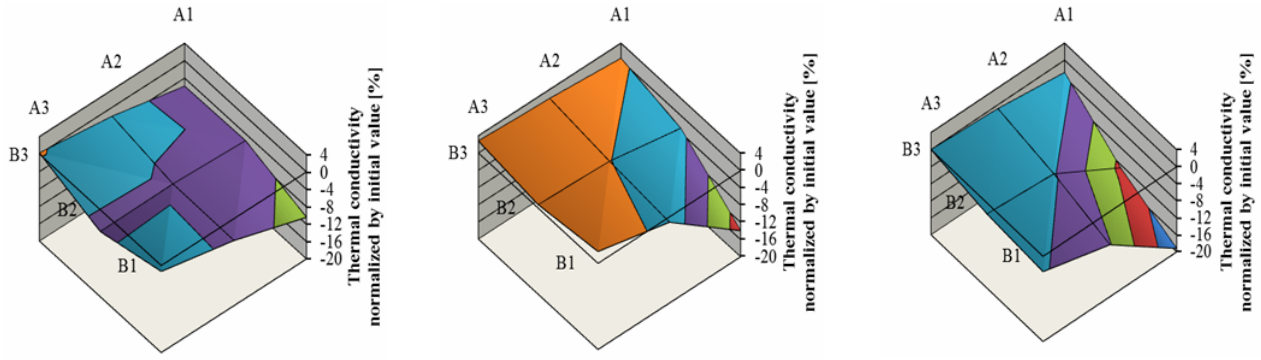
2.3. Evaluation of internal damage

Specimens are cut in two directions as shown in Fig. 2. They are named A-direction and B-direction. A-direction coincides with 0^o which is orientation of fiber alignment directly under cloth layer. Three cross sections in each direction (for instance, A1-A1', A2-A2' and A3-A3' in A-direction) are observed by an optical microscope. Specimens are embedded in resin and they are cut by diamond saw for the observation. After cutting, cross sections are polished. A couple of specimens subjected to the same impact loading are prepared for observation in A-direction and B-direction. In order to evaluate internal damage due to impact loading, photographs of cross sections are captured into a personal computer, and length and number of delamination and transverse cracks are evaluated.

3. Experimental Results

Figs. 3 show distribution of thermal conductivity in a quarter of specimen subjected to impact energy of (a) 5.1J, (b) 9.9 J and (c) 21.0 J. Thermal conductivity is normalized by the initial value. Coordinate point of A1 and B1 is a position of impact loading. As shown in the figures, reduction of

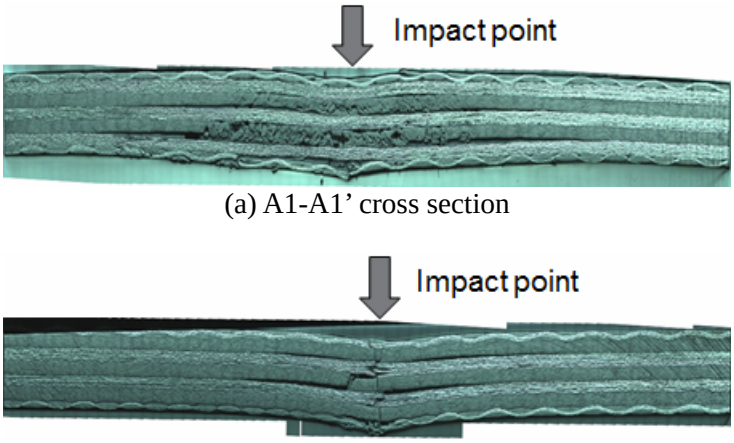
thermal conductivity is the largest at the position of impact loading. Reduction of thermal conductivity in A-direction (measuring points of No. 4 and 7) is larger than that in B-direction (those of No. 2 and 3). They are caused by anisotropy of specimens. Stacking sequence of specimens is [cloth/0°/90°/0°/90°/0°/cloth] and internal damage is more significant at opposite side of impact point. The layer directly under cloth layer is important for damage development and anisotropy is caused by the orientation of fiber alignment in the layer.



(a) 5.1 J (b) 9.9 J (c) 21.0 J

Figure 3. Distribution of thermal conductivity in a quarter of specimen subjected to impact energy of (a) 5.1J, (b) 9.9 J and (c) 21.0 J. Thermal conductivity is normalized by the initial value. The A1-B1 point is a position of impact loading.

Figs. 4 show photomicrographs of cross sections for specimens subjected to impact energy 21.0 J on (a) A1-A1' cross section and (b) B1-B1' cross section. As shown in the figures, delamination and transverse cracks are observed on the cross sections. Internal damage expands from impact point and it is significant near opposite side of impact point. By comparing both photomicrographs, anisotropy on internal damage is found clearly.



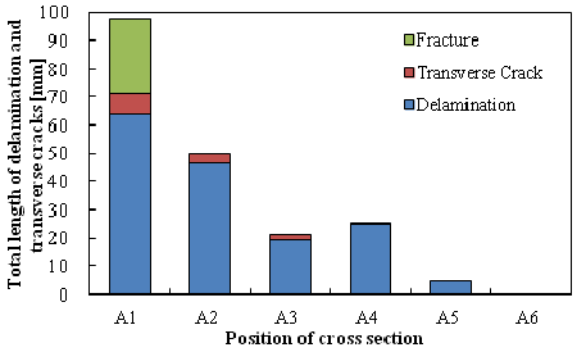
(a) A1-A1' cross section

(b) B1-B1' cross section

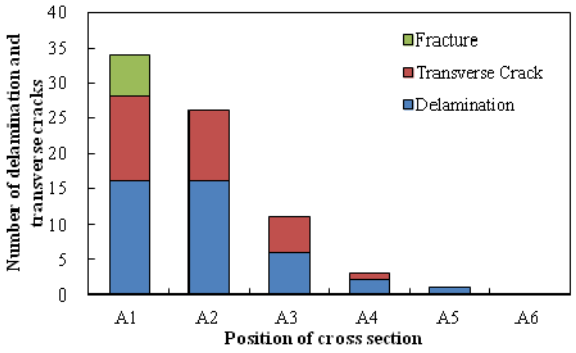
Figure 4. Photomicrographs of cross sections for specimens subjected to impact energy 21.0 J on (a) A1-A1' cross section and (b) B1-B1' cross section.

On the basis of photomicrographs, length and number of delamination and transverse cracks were measured. Figs. 5 show internal damage on each cross section of specimen subjected to impact energy of 21.0 J. Fig. 5(a) shows total length of delamination and transverse cracks plotted as internal damage, and Fig. 5(b) shows number of delamination and transverse cracks plotted as internal damage. In the figures, "fracture" means that damage is significant and it is difficult to

distinguish between delamination and transverse cracks. Internal damage reduces as position is apart from impact point, and internal damage in A-direction is larger than that in B-direction. It is also found that ratio of delamination to transverse cracks with respect to total length in Fig. 5(a) is about 9 to 1 at any positions while the ratio with respect to number in Fig. 5(b) is about 6 to 4.



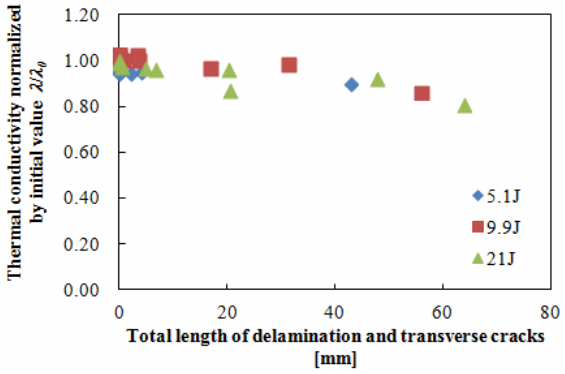
(a) Total length of delamination and transverse cracks



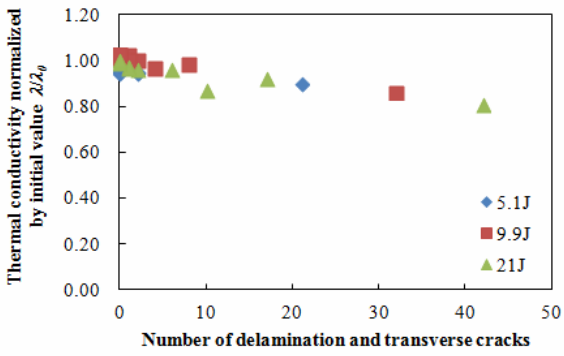
(b) Number of delamination and transverse cracks

Figure 5. Internal damage on each cross section of specimen subjected to impact energy of 21.0 J. (a) Total length and (b) number of delamination and transverse cracks are plotted as internal damage.

Figs. 6 show the relationship between thermal conductivity and internal damage. Thermal conductivity is normalized by the initial value. Total length and number of delamination and transverse cracks are adopted as internal damage. The total length and number of delamination and transverse cracks are summation of those in A-direction and B-direction, and the summation is carried out on the same area as thermal conductivity is measured. As shown in the figures, thermal conductivity reduces as internal damage increases. The relationship was clarified experimentally in the present research.



(a) Total length of delamination and transverse cracks



(b) Number of delamination and transverse cracks

Figure 6. Relationship between thermal conductivity and internal damage. (a) Total length and (b) number of delamination and transverse cracks are adopted as internal damage.

4. Concluding Remarks

The objectives of the present research are to improve the resolution of non-destructive inspection for CFRP by infrared pulse thermography. For the purpose of the improvement, assistance of numerical simulation is necessary. Therefore, in the present paper, in order to simulate distribution

of temperature due to variation in thermal conductivity on CFRP plates including internal damage, the relationship between thermal conductivity and internal damage due to impact loading was investigated experimentally.

Conclusions of the present paper are summarized briefly as follows:

(1) Distribution of thermal conductivity in the thickness direction on CFRP plates including impact damage was clarified, and it was indicated that the distribution depends on the level of impact energy.
(2) By observation of cross sections of CFRP plates, length and number of delamination and transverse cracks were measured as internal damage. The internal damage has anisotropy with respect to the fiber orientation directly under cloth layer, and it was found that the ratio of delamination to transverse cracks has constant value.
(3) By combining results of measurement for thermal conductivity with results of evaluation for internal damage such as length and number of delamination and transverse cracks, the relationship between thermal conductivity and internal damage was clarified experimentally.

As next steps, internal damage is described by a damage variable on the basis of the continuum damage mechanics [9, 11], and development of internal damage is formulated as an evolution equation of the damage variable as a function of impact energy and distance from impact point. Using the relationship between thermal conductivity and internal damage, variation in thermal conductivity is calculated by the damage variable and distribution of temperature is simulated by taking into account the development of internal damage. By utilizing inverse analyses, internal damage could be predicted inversely from distribution of temperature which is measured by infrared pulse thermography, in future.

Abstract

This paper aims to investigate the influence of particle clustering on the tensile behavior of particle-reinforced composites composed of aluminum matrix and ceramic particles. Matrix was allowed to deform plastically, yet particles had only elastic deformation in a damage free process. By assuming a periodic microstructure, finite element simulations of a unit cell were carried out. The unit cells were modeled with different cluster densities as well as different particle aspect ratios. All particles were assumed to be oblate ellipsoids which were arranged linearly along the loading direction. Uniaxial stress-strain curves were gained through imposing gradual incremental displacements on the surface of the unit cell to the overall far-field strain of four percent. It was shown that clustering increases the plastic strain within ligaments between particles and promotes the strain hardening in the clustered region. Eventually, it causes a considerable increase in the level of the maximum principal stress in particles. The differences in stress-strain behavior among various composite models in macroscopic level were negligible.

Keywords: Particle-reinforced composites, Clustering, Finite Element Method (FEM)

1. Introduction

Dual-phase alloys and particle-reinforced composites are widely used in numerous areas such as automotive and aerospace industries. Dispersed particles improve mechanical properties of the matrix and lead to high strength composites. Several modelling methods have been proposed recently in order to predict mechanical behaviors of these composites. These modelling techniques can be split into two categories: analytical and finite elements methods. In general, analytical methods rely upon the equivalent inclusion method of Eshelby [1] and on their mean-field extensions [2]. There are a number of analytical modelling approaches proposed, such as the tangent-based [3] and secant-based [4] homogenization approaches, which have been relatively successful in terms of predicting non-linear behavior of composite materials. However, in terms of micro-structural details such as stress state within the particles, analytical approaches are not sufficiently accurate [5], because their formulations are based on different simplifying assumptions such as a homogeneous distribution of particles in the matrix [6]. Unlike the analytical approaches, FE techniques enable us to distinguish the influence of heterogeneous particle distribution, which is much more realistic than homogeneous particle distribution [7].

In the study conducted by Abedini et al. [8], the influence of particle clustering on mechanical behavior of particle-reinforced composites has been investigated quantitatively by using the method introduced by Thomson et al. [9] for multi-particle unit cells. Composite material is assumed to be composed of repeated multi-particle unit cells containing spherical particles. Morphology of different types of particle clustering has been investigated so that useful comparisons between different cluster severities and geometries can be made. This method has provided a good understanding of local stress state within particles in a cluster. Local stresses

within clusters have a significant role for the initiation of microvoids which can result in the earlier onset of damage. By taking advantage of the periodic symmetry, the particle field has been reduced to a single unit cell. Based upon FE analysis, Abedini et al. [8] has concluded that as the degree of clustering increases, the flow stress of the composite exhibits a slight increase. The objective of the present article is to perform a quantitative analysis of linear cluster arrangement within unit cell in uniaxial tension. According to Abedini et al.'s work [8], linear cluster morphology was highlighted among other morphologies as the most sensitive cluster type to various stress conditions. Unlike Abedini et al. [8], in the present study, ellipsoidal particles are modeled instead of spherical ones since based on Chawla and Chawla's [6] results, ellipsoidal particles simulate more realistic geometry comparing to spherical particles .

2. Model Description

2.1. Cluster Geometry

Due to the high sensitivity it indicates [8], linear cluster morphology has been considered. Figure 1 shows one-eighth of a single particle unit cell along with a linear particle arrangement in the cluster. Ellipsoidal particles aligned with loading axis were modeled in clusters with a variety of densities. Here in Figure 1 particles are not depicted in their spots , for the morphology is clearer in this way. Due to the symmetry, only one eighth of each unit cell has been modeled. Each unit cell of the cluster model contains three ellipsoidal particles within it.

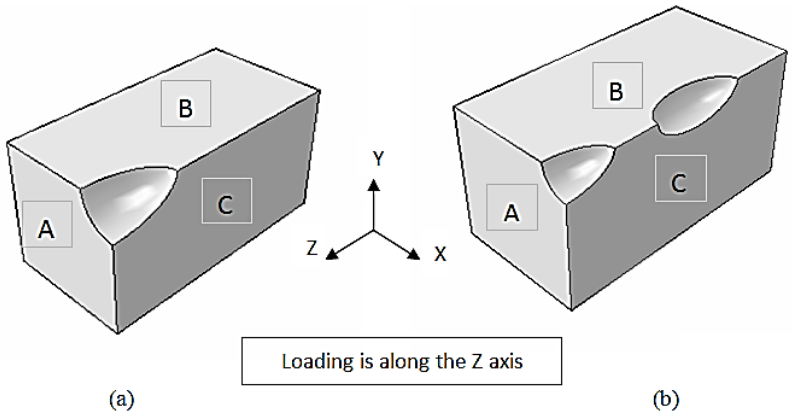

Figure 1- One eighth of unit cell for: (a) Single particle, (b) Linear cluster.

As displayed in Eq. 1, severity of a cluster is quantified through the variable *K* which is equal to the inter cluster spacing, *D*, relative to the inter particle spacing, *d*. The larger the value of *K*, the denser particle clustering is achieved.

$$K = \frac{D}{d} \tag{1}$$

Cluster densities of K = 18, 10, 6 and 3 were investigated along with aspect ratios of AR=2,3 for ellipsoids. The aspect ratio of the unit cell $\frac{L_1}{L_2}$ was assumed to be equal to the aspect ratio of the particles.

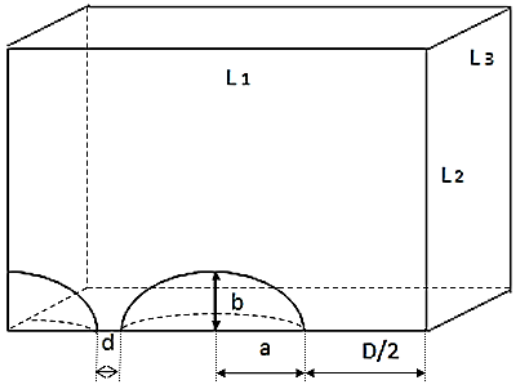

Figure 2 – One eighth of a unit cell along with symbol definitions, $AR = \frac{a}{b}$.

2.2. Boundary Conditions and Material Properties

In order to ensure that the periodic microstructure assumption is still valid, all of the planes of the unit cell are considered to remain planar and to maintain their initial orientation. Displacements along normal directions as well as rotations around all axes are restricted for all three planes of symmetry (planes A, B and C in Figure 1). Uniaxial tension was gained through imposing gradual incremental displacements on the side surface along the z axis to the overall strain of four percent. The small level of overall strain was chosen to support the assumption of damage free composite.

Three-dimensional FE models of particle-reinforced composite were simulated in order to predict the overall uniaxial tensile stress-strain response, local stress fields and local strain fields. Commercial FE software, ABAQUS, was used to perform the simulation. A typical FE mesh with eight-node linear brick elements was used, as is depicted in Figure 3. Each series of meshing was checked for mesh sensitivity, and distortion, which was pointed out through the ABAQUS mesh verification tool, which was found adequately negligible with a sufficiently refined mesh. All simulated particle-reinforced composites were composed of an aluminum matrix and ceramic particles.

It was assumed that the elastic-plastic matrix obeys the hardening rule represented in Eq. 2 :

$$\sigma = \sigma_y + K\varepsilon_p^n \tag{2}$$

Where ε_p and σ_y are the accumulated plastic strain and the initial yield stress, respectively and the values of constants, K and n, are shown in Table 1 along with other mechanical properties of the constituents.

The bonding between the matrix and particles was assumed to be perfect, and thermal residual stresses were not taken into account. Furthermore, the nucleation of voids by particle cracking or

interface separation was also not considered as the objective of this study is to investigate the influence of particle clustering on the material response before the onset of damage.

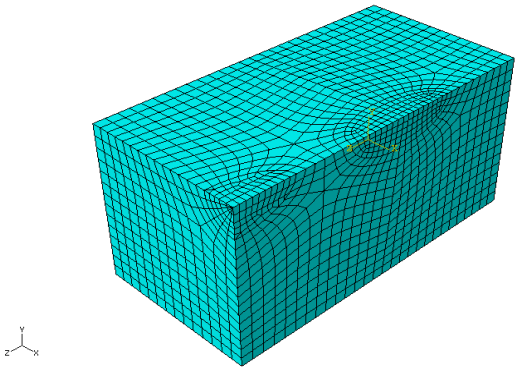

Figure 3- A typical FE mesh for the linear cluster model with *AR*=2 and *K*=3.

Table 1 – Material properties of each of the phases.

	E (GPa)	*Poisson's ratio*	σ_y (MPa)	*K* (MPa)	*n*
Aluminum	75	0.3	75	416	0.39
Ceramic	400	0.2	-	-	

3. Results and Discussion

3.1. Macroscopic Response

Overall mechanical behavior of the unit cells under uniaxial tension is reported in this section. Linear clusters containing ellipsoidal particles with different aspect ratios and levels of cluster densities have been studied and compared over the particle volume fraction of 0.01. These results are based on volumetrically averaged, macro stress values with respect to macro strain. Figures 5 and 6 indicate that as *K* increases (i.e., the cluster becomes denser), the flow stress in the unit cell increases slightly. However, these graphs represent almost the same behaviors in the elastic regime. Moreover, the difference between the largest and the smallest flow stress is so small (around 0.6%) that makes the effect of particle clustering on overall behavior of the unit cells negligible. Therefore, it is concluded that the higher particle clustering increases the work hardening to a very limited degree in the macroscopic scale. All FE results are in qualitative agreement with the results obtained by Abedini et al. [8] for spherical particles.

Another comparison also has been made to analyze clusters with the same clustering density but different particle aspect ratios. According to the definition of aspect ratio presented in Figure 2, spherical particles acquire *AR*=1. This comparison illustrates the influence of particle aspect ratio on the overall response of the composite. The results for ellipsoidal particles (with *AR*=2 and 3) are compared to the corresponding curves for spherical particles (*AR*=1) reproduced from Abedini et al [8]. Figures 7-9 depict overlapping curves of the same cluster density with different aspect ratios of particles. These diagrams show nearly identical curves in the elastic regime and a very limited scatter when plastic deformation becomes dominant. However, in all cases, it is observed that the stress-strain curves with greater particle aspect ratios lie slightly above other curves. It implies that longer oblate ellipsoidal particles make the composite slightly stronger.

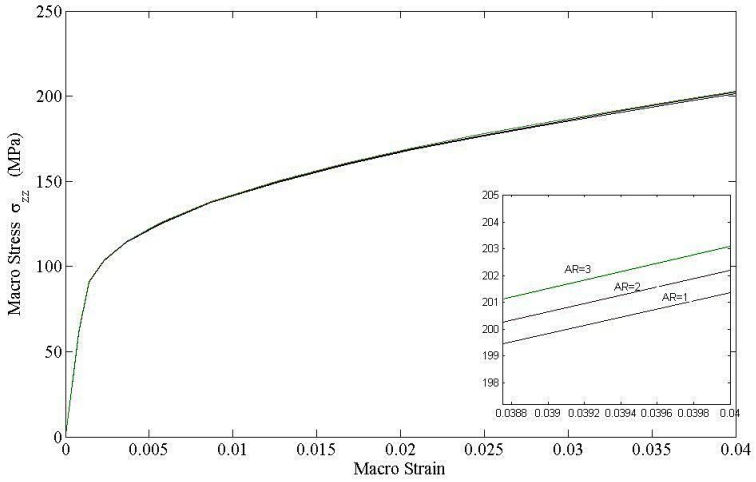

Figure 8- Overall behavior of composites for *AR*= 1,2,3 with a cluster ratio of *K*=10.

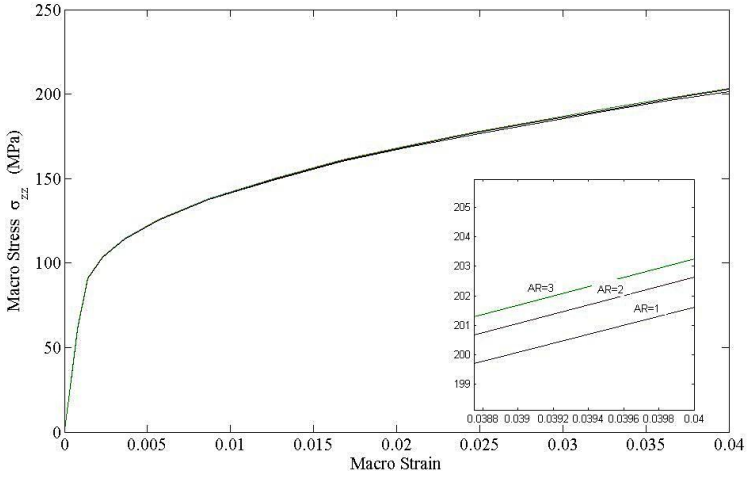

Figure 9- Overall behavior of composites for *AR*= 1,2,3 with a cluster ratio of *K*=18.

3.2. Microscopic Response

Although macroscopic response for the composite is important, it does not fully reveal why and how failure occurs in the heterogeneous material. Hence, microscopic response should be investigated since failure begins as a local event. Figures 10 and 11 show the results for volume averaged principal stress in the middle particle of the linear cluster model with respect to far-field strain. Unlike macroscopic responses that were not substantially influenced by cluster densities, Figures 10 and 11 evidently show a significant increase of the principal stress within the particle with increasing the particle clustering density. In other words, the smaller the space between particles, the greater stress is present in the particle. Also, single particle models show the smallest level of stress in comparison with all multi-particle cluster models. As expected, these trends are totally in agreement with the results for spherical particle(s) [8].

After the evaluation of the influence of the cluster density on averaged principal stress in the middle particle, the volumetrically averaged maximum principal stress in the middle particle of the linear cluster model with respect to far-field strain was investigated for models of the same cluster densities (K) and different ARs. Figures 12 and 13 depict the results. Curves representing the behavior of spherical particles (AR=1) are taken from Abedini et al.'s work [8]. According to Figures 12 and 13, as the aspect ratio increases in the composite, the larger maximum principal stress is imposed on the middle particle. Furthermore, the amount of stress experienced by the particle increases as the cluster density increases and this increase is more significant for the cluster models with higher aspect ratio particles.

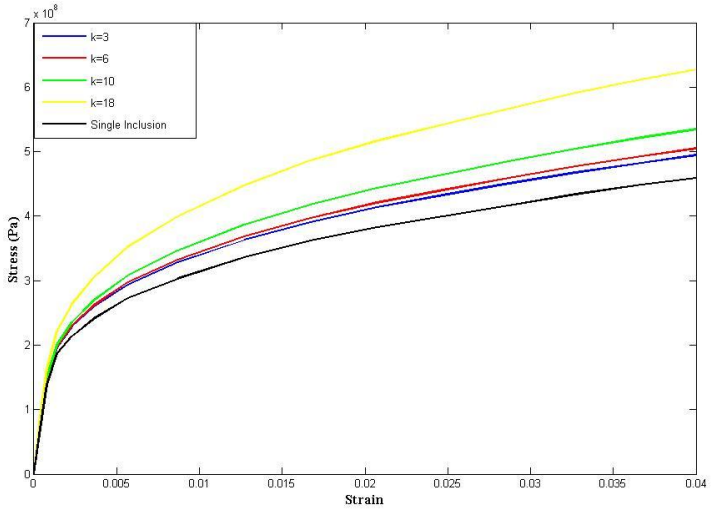

Figure 10- Microscopic behavior of middle ellipsoidal particle for linear cluster with AR=2 and different values of K.

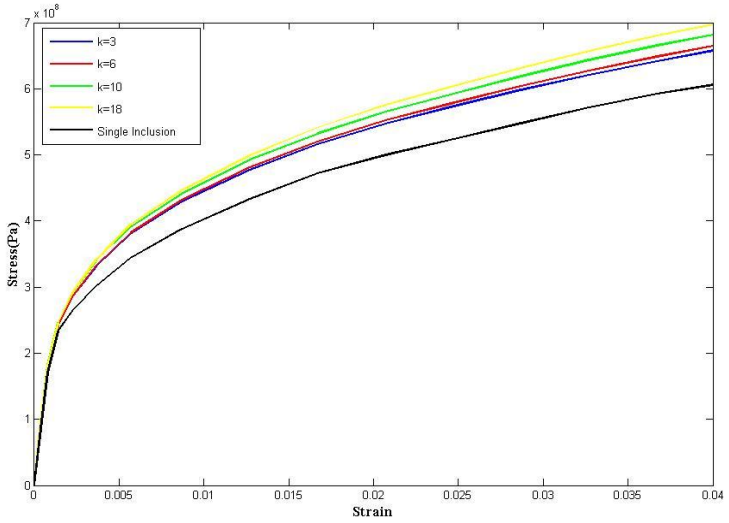

Figure 11- Microscopic behavior of middle ellipsoidal particle for linear cluster with *AR*=3 and different values of *K*.

The equivalent plastic strain is a direct measure of the level of plastic flow in the matrix. Higher plastic strain in a region causes more hardening, and, consequently, greater stress is transferred into the particles in the region. As Figure 14 indicates, the maximum equivalent plastic strain occurs in the space between particles. Since the maximum plastic strain takes place within clusters, it can be predicted that particle fracture (and consequently damage) is initiated from the clustered area which is in total agreement with experimental results available in the literature [9].

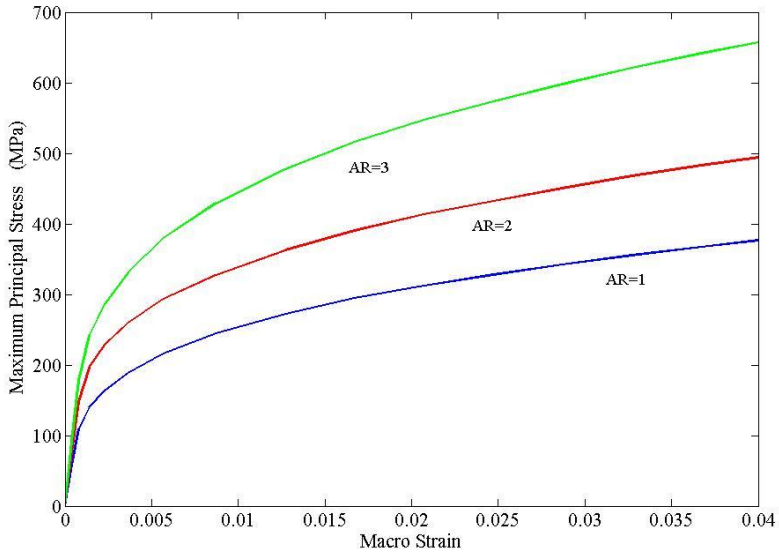

Figure 12- Mechanical behavior of the middle particle in linear cluster model of the composites with *AR*= 1,2,3 and *K*=3.

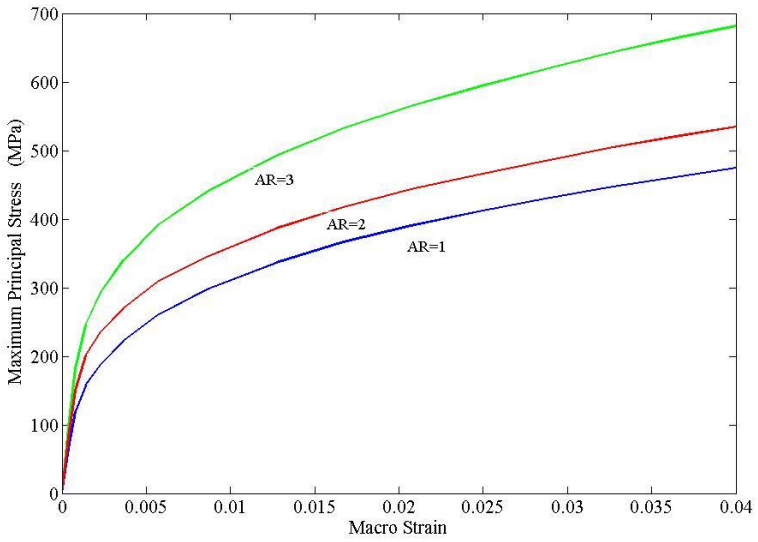

Figure 13- Mechanical behavior of the middle particle in linear cluster model of the composites with *AR*= 1,2,3 and *K*=10.

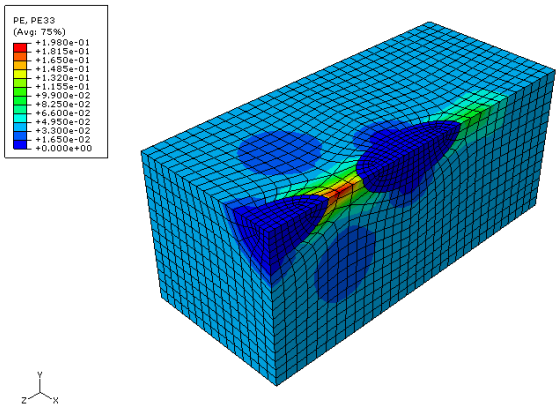

Figure 14-Contour plot of the maximum principal plastic strain in the FE model.

4. Conclusions

The traditional analytical and numerical approaches to predict the mechanical behavior of particle-reinforced composites are based on assuming homogeneous distribution of particles within the matrix; however, this assumption is not compatible with real composites. Finite elements simulation of uniaxial tension has been conducted considering particle clusters with different aspect ratios of the particles within the matrix and different densities of clusters. In the work conducted by Abedini et al. [8], linear cluster models were found to be the most sensitive particle clustering arrangement to cluster density variation compared to other cluster geometries. The current study was focused on the effect of linear clusters consisting of ellipsoidal particles on the mechanical behavior of particle-reinforced composites.

In both macro and micro scales, it was evident that increasing the cluster density leads to higher level of average stress experienced by the whole composite and the middle particle. However,

differences in macroscopic stress among different cluster densities were negligible for the same particle volume fraction. Furthermore, influence of particle aspect ratio was evaluated for models with same cluster densities (K), in macro and microscopic level. Models with higher aspect ratios demonstrated greater levels of stresses within individual particles, implying that a higher load is being transferred to the particles.

Results obtained from this research indicate that as cluster density increases, so does plastic strain in the ligament and this increase is more significant for the clusters with oblate particles. Therefore, it clearly justifies how an increase in cluster density and particle aspect ratio eventually increases stress both in micro and microscopic scale. All results obtained in this study are in good agreement with experimental and FE results available in the literature.

The Effect of Nano- and Micro-Fillers on the Strength and Toughness of PIR Foams Obtained From Renewable Resources

Janis Andersons[1,*], Ugis Cabulis[2], Uldis Stirna[2]

[1] Institute of Polymer Mechanics, University of Latvia, Riga LV-1006, Latvia

Abstract Low-density rigid polyisocyanurate (PIR) foams obtained from renewable resources (with the polyol system comprising up to 80% of rapeseed oil esters) have been produced and tested for strength and fracture toughness in a range of foam density of importance for practical applications. In order to enhance the mechanical characteristics of the foams, the effect of several nano- and micro-fillers has been investigated experimentally. It is demonstrated that nano-fillers, such as organically modified nanoclays, carbon nanotubes, ZnO nanoparticles, increase both the strength and toughness of the foams whereas such micro-fillers as milled carbon fibers, while providing substantial increase in stiffness, have little effect on foam strength and toughness. Scaling models relating filled solid polymer properties to those of the filled foams have been considered and shown to have a predictive potential.

Keywords polymer foams, strength, toughness, nanoclay, carbon fibers

1. Introduction

Currently there is an increasing worldwide interest in modern technologies based on renewable raw materials. The introduction of plant components into polyurethane (PUR) systems meets all the aims of sustainable development and is an important challenge for chemical companies. Polyisocyanurates (PIRs) are synthesized using two basic components: polyols and isocyanates. In recent years, increasing interest from industry concerning polyols derived from renewable sources (different natural oils, such as rapeseed oil (RO), castor, soya, palm, sunflower oils, etc.) has been perceived. These natural ingredients can be successfully used to obtain different PIRs including porous composites. Moreover, the anticipated effects of progress in polymer materials should lead to the improvement of their properties and the reduction of their manufacturing cost. This is one of the reasons to carry on the research in the field of porous composites with the use of nano- and micro-fillers [1].

Rigid low-density closed-cell PIR foams are used primarily as a thermal insulation material in building construction and in the global appliances (refrigerators, freezers, etc.) industry, as well as in aerospace industry. Although not expected to bear load, low-density foams still have to exhibit strength and toughness adequate for loading conditions in the intended applications. Various high-stiffness nano- and microfillers such as organically modified clay, carbon nanotubes, and metal oxides [[1]-[4]], as well as carbon microfibers [[5]] have been shown to improve considerably the mechanical response of PUR and PIR foams at relatively low filler loadings. Prediction of strength of foam materials based on micromechanical considerations is complicated due to large variability in foam morphology. However, scaling relations linking foam strength and toughness to density and morphological parameters of the foams and deformability or strength characteristics of the foam struts have been derived and verified experimentally, see e.g. [[6], [7]]. The present study aims at

experimental evaluation of the effect of commercially available fillers on the strength and toughness of RO PIR foams and their relation to the strength of filled solid polymers.

2. Materials

2.1. Polyol synthesis

Polyols on the basis of renewable natural oils, suitable for obtaining PUR and/or PIR, can be obtained by different methods. Most often the esterification or epoxidation of oils is applied. In the present work, for producing of PUR, polyol obtained by amidization of RO with diethanolamine was used. Temperature: 140˚C, catalyst: zinc acetate. The RO / diethanolamine molar ratio was 2.9 / 1.0. RO obtained from the company *Iecavnieks* (Latvia) was used for the synthesis of polyols. Firstly, optimum synthesis conditions of polyols suitable for obtaining PUR were determined. The synthesis process was controlled from the diethanolamine (acid value and NH value) conversion degree. The structure of polyol was characterized from FTIR spectroscopy data.

2.2. Fillers

Four different nanoclays or organically modified montmorillonites (MMT): Cloisite® 15A, Cloisite® 30B, Cloisite® 93A (produced by *Southern Clay Products, Inc.*) and Dellite® 43B (produced by *Laviosa Chimica Mineraria S.p.A.*) were used as fillers of RO PIR foams. The clays are purified natural montmorillonites modified as follows: Cloisite® 15A is modified with a dimethyl dehydrogenated tallow quaternary ammonium having a cation exchange capacity of 125 mequiv/100 g, 30B - modified by methyl tallow bis-2-hydroxyethyl ammonium with a concentration of 90 meq/100 g clay, 93A - modified with a quaternary ammonium salt (methyl, dihydrogenated tallow ammonium) in a concentration of 90 mequiv/100 g of clay, and Dellite® 43B is modified by dimethyl benzylhydrogenated tallow ammonium. Multi-wall carbon nanotubes Nanocyl® NC7000 (produced by *Nanocyl s.a.*) with average diameter of 9.5 nm and average length of 1.5 μm (according to manufacturer's data), as well as zinc oxide nanoparticles Zano® 20 (produced by *Umicore Zinc Chemicals*) with the size of ca. 30 nm were also used for filling the foams.

Carbon-fiber-filled foams were manufactured using Tenax-A milled carbon fibers, with 7 μm diameter, of two types. Type 383 fibers had length within 50-150 μm range with the average length of 100 μm, whereas Type 385 fiber length was in the 40-70 μm range having the average length of 60 μm. The bulk density of the fibers amounted to 350 kg/m^3 and 550 kg/m^3, respectively.

2.3. Foam production

The formulations used in this study were polyols from RO, and a higher functional polyether polyol based on sorbitol Lupranol 3422 (it contains only secondary hydroxyl groups, OH Number 490 mg KOH/g) - from *BASF*. As additives, surfactant NIAX Silicone L6915LV, from *Momentive Performance Materials* and catalyst Polycat 5 from *Air Products* were used. Tris-chloropropyl phosphate (TCPP), used as a flame retardant, was supplied by *Albemarle* and as blowing agent, a

mix of water and cyclo-pentane was used. As an isocyanate, polymeric diphenylmethane diisocyanate - IsoPMDI 92140, supplied by *BASF*, was used.

PIR samples were obtained by mechanically mixing appropriate amounts of IsoPMDI 92140 and the polyol system (polyols, surfactant, catalysts, and blowing agent) for 10-15 s. The unreacted mixture was poured into a plastic mould (20 x 30 x 10 cm) for free foaming. The polymerization reaction took place at room temperature for all the obtained samples and was completed in about 3-5 min. The foam samples were conditioned before tests for at least 24 h.

Nanoclay loadings in the range of 1% to 5% by weight were considered. The exfoliation of MMT nanoclays in RO polyol was performed by MRC Ultrasonic Cell Crusher. The same procedure was applied also for mixing Zano 20 and Nanocyl NC7000 fillers in RO polyol at 1 % wt. When producing microfiber-filled foams, carbon fibers of the selected type were mixed into the polyol system. After stirring, the fiber suspension in polyol was degassed, the foaming agent added, the mixture stirred and foamed. Three different fiber loadings were obtained: 2%, 4% and 6% by weight. Good dispersion was achieved, as suggested by the change in viscosity of the filled polymer for nano- and by optical microscopy for micro-fillers. The content of different fillers in the foams was calculated on the basis of initial weights.

For characterization of the mechanical properties of solid, monolithic unfilled and nanofilled polymers, the mixture prepared as described above was poured in plastic ampoules of ca. 14 mm diameter and 80 mm length. The ampoules were subjected to centrifuging to eliminate bubbles.

3. Characterization of mechanical properties

3.1. Strength

For mechanical testing, specimens were produced from slices of the foam blocks cut along the rise direction of the foams (for illustration of the free foaming , see Fig. 1) . The specimens for tension

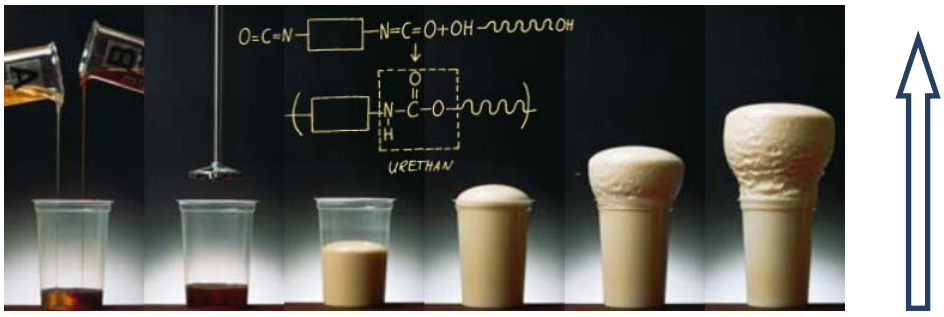

Fig. 1. Illustration of the free foaming process. The arrow shows the foam rise direction.

tests were machined to a dog-bone shape, with a rectangular test section of 85 mm length, 22 mm width, and 20 mm thickness. The specimen orientation was chosen so that the mechanical response in the direction normal to foam rise could be characterized. An extensometer with 50 mm base

length was used for strain measurement in the loading direction. For gripping, metallic plates with hooks were glued to the ends of the specimens. Tensile tests were carried out by stroke control, at a displacement rate of 8 mm/min. For compressive tests, rectangular specimens of dimensions 80 x 30 x 30 mm were cut from the foam slices and loaded at a rate of 10 %/min. Thus comparable specimen gauge length and loading rate was ensured for both, tensile and compressive tests normal to the foam rise direction. Thin Teflon films were put between the top and bottom ends of specimens and the plates of the testing machine to reduce the friction in compression tests.

Apparent density of each of the foam specimens was determined before the tests. The variation of density with filler loading is shown in Figs. 2 and 3 for MMT fillers and in Fig. 4 for carbon fiber fillers (foams with different initial densities in 34 to 50 kg/m^3 range were filled, as seen in Figs. 2-4). Note that the markers in Figs. 2 and 4 have been slightly offset with respect to the correct filler content values for better legibility. The presence of fillers apparently had larger effect on foam density when the initial, neat foam density was lower. Addition of Zano 20 at 1 % wt. increased foam density from ca. 34 for neat foams to 45 kg/m^3, whereas filling by Nanocyl at the same loading produced foams with 55 kg/m^3 density.

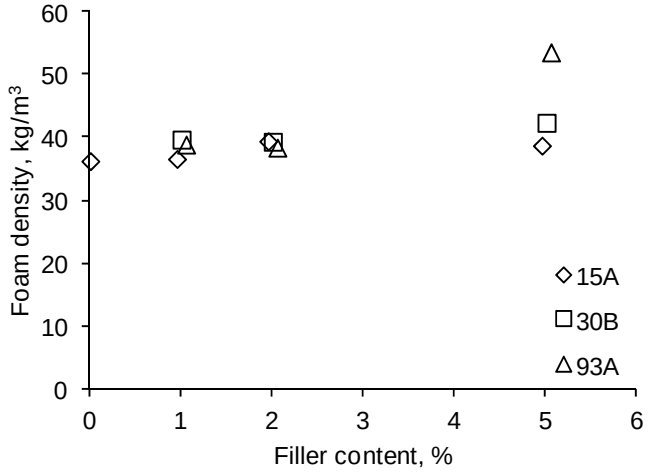

Fig. 2. Foam density vs. Cloisite content

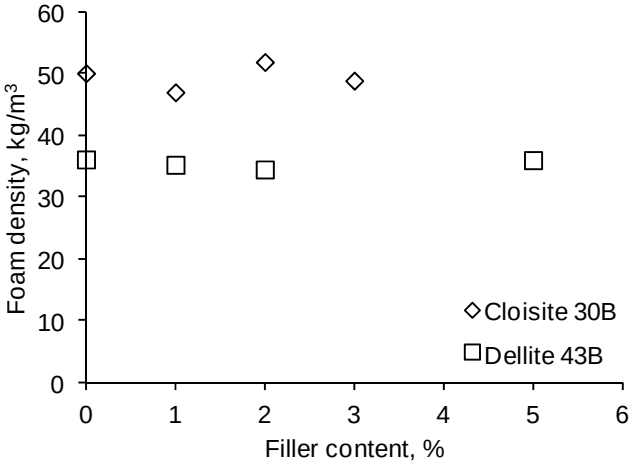

Fig. 3. Foam density vs. MMT content

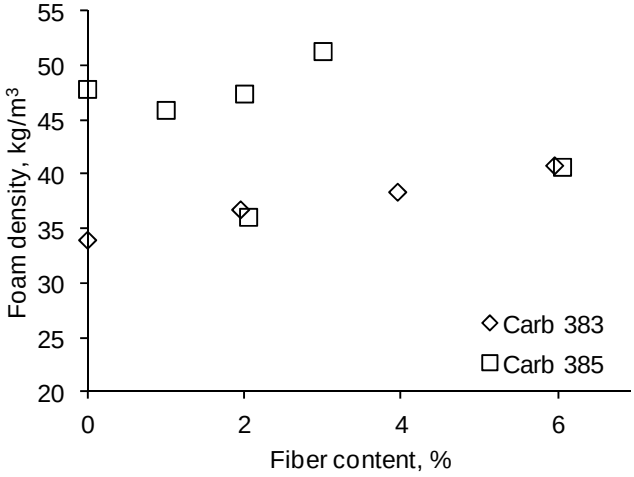

Fig. 4. Foam density vs. carbon fiber content

The solid polymer samples were removed from ampoules upon setting of the polymer, and

cylindrical dog-bone shaped specimens were manufactured by turning. The length of the test section of the specimens amounted to ca. 28 mm and diameter to 5.5 mm. Specimen ends were glued into tubular aluminum tabs. Tensile tests were carried out by stroke control with the displacement rate of 1 mm/min. Young's modulus was determined from the initial, linear part of the stress-strain diagram, while the maximum stress before failure was taken as the tensile strength [[3]].

3.2. Toughness

Fracture toughness of the foams for crack propagation in mode I in the foam rise direction was determined according to ASTM Standard D5045-99. Compact tension specimens with the height and width equal to 65 mm and 20-mm thickness were used. Detailed description of the test procedure and results for neat foams is provided in [[8]].

4. Results and discussion

4.1. Strength of neat polymer foams

By varying the amount of blowing agent, rigid neat RO PIR foams with apparent density in the range from 30 to 60 kg/m^3 were obtained. The dependence of foam strength on density is shown in Fig. 5 for tensile and in Fig. 6 for compressive loading normal to the foam rise direction. It is seen in the graphs that the compressive strength appears to be slightly more affected by foam density than the tensile strength.

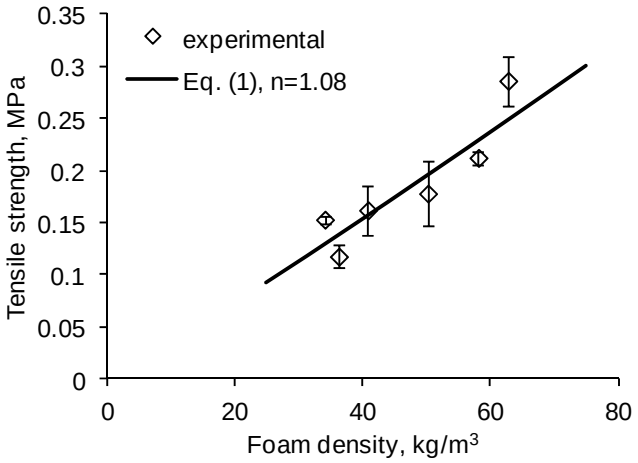

Fig. 5. Tensile strength vs. neat foam density

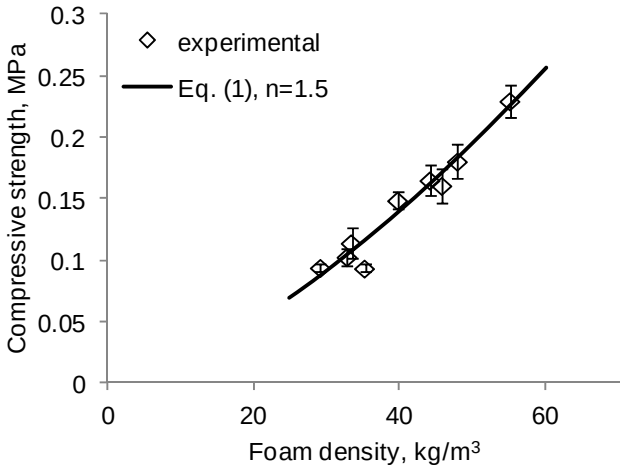

Fig. 6. Compressive strength vs. neat foam density

Assuming a particular geometry of foam cells, a power-low relationship for foam strength σ_f as a function of density ρ_f has been derived in [[6]]

$$\sigma_f = C\rho_f^n \tag{1}$$

where the factor C is related to properties of the cell wall material. For tensile strength of brittle foams, $C = c_8 \sigma_s / \rho_s^n$ where c_8 is a numerical prefactor, σ_s designates tensile strength of the solid cell-wall material and ρ_s - its density. Approximating the respective strength data with Eq.

(1), the value of n = 1.08 was obtained for tensile and n = 1.5 for compressive strength. The agreement of Eq. (1) with the experimental data is reasonably good as seen in Figs. 5 and 6.

4.2. Tensile strength of nanoparticle-filled polymer foams

The presence of nanofiller in a polymer may affect its mechanical characteristics as well as the density and morphology of polymer foams. The scaling relation Eq. (1) should equally apply to filled polymer foams. Hence, the tensile strength of filled polymer foams should scale with solid polymer strength as follows

$$\sigma_f\left(c_{fil}\right) = c_8\left(\frac{\rho_f\left(c_{fil}\right)}{\rho_s\left(c_{fil}\right)}\right)^n \sigma_s\left(c_{fil}\right) \tag{2}$$

where c_{fil} designates filler loading. For low filler concentrations of practical interest, its effect on density of the solid polymer can be neglected, $\rho_s\left(c_{fil}\right) \approx \rho_s(0)$, and polymer strength approximated by a linear function of filler concentration

$$\sigma_s\left(c_{fil}\right) = \sigma_s(0)\left(1 + \mu c_{fil}\right) \tag{3}$$

with μ denoting the reinforcement efficiency factor. It is convenient to introduce the reduced foam strength as follows

$$\sigma_f^*\left(c_{fil}\right) = \sigma_f\left(c_{fil}\right)\left[\rho_f(0)/\rho_f\left(c_{fil}\right)\right]^n \tag{4}$$

(Note that a similar reduction method for foam strength has been introduced in [[9]].) Then, by combining Eqs. (1) – (4), the reduced strength can be expressed via neat foam strength and filler content as follows

$$\sigma_f^*\left(c_{fil}\right) = \sigma_f(0)\left(1 + \mu c_{fil}\right) \tag{5}$$

In order to determine the reinforcement efficiency factor experimentally, the strength of neat and filled foam cell wall material, e.g. struts, should be measured. Such tests are, however, prohibitively complicated even for strut stiffness, due to small dimensions and non-uniform shape of the struts. Macroscopic samples of monolithic polymer are likely to yield only a lower bound for strut strength due to differing flaw structure, with more severe flaws likely to be introduced in polymer samples during manufacture compared to the flaws in microscopic struts arising during rise of the foams. However, μ characterizes the ratio of neat and filled strut strength as seen in Eq. (3) rather than the absolute strength values. Since the flaw distribution in neat and filled polymer samples, prepared following the same procedure, should be comparable, the difference in their strength should reflect variation in intrinsic strength due to the presence of a filler. Hence, as a first approximation, an estimate of μ can be obtained using the ratio of strength of neat and filled polymer samples.

Tensile strength of monolithic neat and filled RO PIR samples is presented in Table 1. Filler content

in the filled solid polymers amounted to 1 % wt. Solving Eq. (3) for μ, expressing c_{fil} in weight percent, and using the average strength data from Table 1, estimates of μ were obtained and presented in Table 1.

Table 1. The effect of filler at 1 wt. % on polymer strength

Filler	no filler	Zano 20	Nanocyl	Cloisite 30B	Dellite 43B
Mean strength, MPa	58.5	65.4	64.9	65.1	60.5
Standard deviation, MPa	6.1	2.7	1.5	2.9	0.7
Number of tests	10	4	4	4	3
μ, 1/%	-	0.119	0.111	0.114	0.034

The reduced tensile strength of foams as a function of nanoclay concentration is shown in Figs. 7 – 9. It is seen that the strength varies almost linearly with filler loading for low concentrations, up to 3 % wt., in qualitative agreement with Eq. (5). At the highest concentration of 5 % wt. considered, the reinforcement efficiency appears to drop, with foam strength being comparable or lower than that at 2 % wt. loading as seen in Figs. 7 and 9.

The strength of low density foams filled with three differently modified Cloisite nanoclays is shown in Fig. 7 as a function of clay loading. It is seen that the strength of all three foams appear to be quite close at the filler concentrations of 1 and 2 % wt., with overlapping scatter bands. The variation of foam strength with filler content, predicted by Eq. (5) using the value of reinforcement efficiency factor μ determined for Cloisite 30B, is in good agreement with test results for the lower fiber loadings. Reasonable agreement of Eq. (5) with strength data is seen also for higher density foams, Fig. 8. However, for low density foams filled with Dellite 43B nanoclay, Eq. (5) using the respective μ value from Table 1 appears to underpredict foam strength shown in Fig. 9.

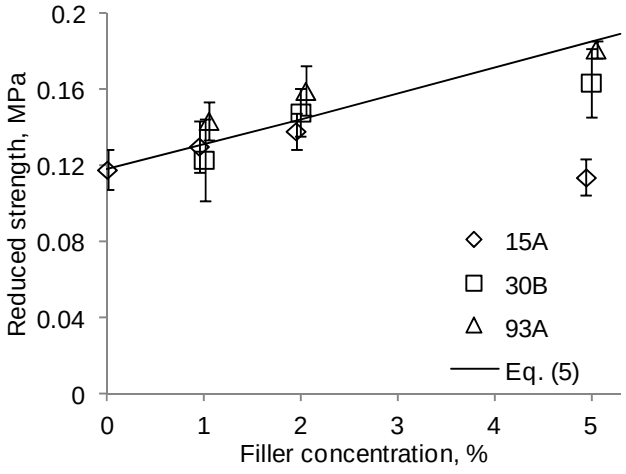

Fig. 7. Reduced tensile strength as a function of nanoclay loading for three Cloisite clays

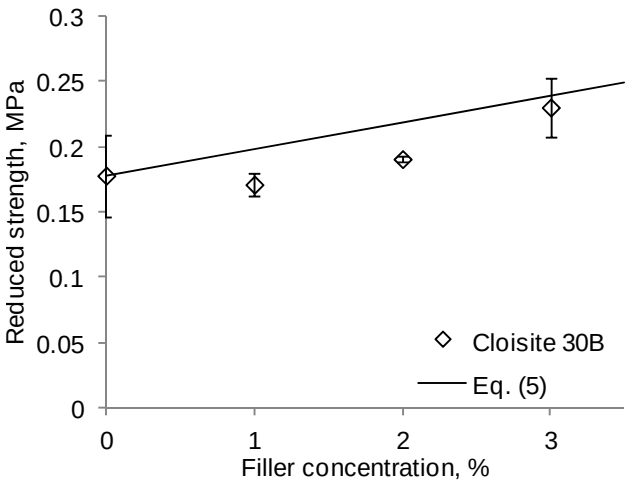

Fig. 8. Reduced tensile strength as a function of Cloisite 30B nanoclay loading

At a given filler loading, the theoretical dependence of tensile strength on foam density can be easily show to have the form

$$\sigma_f\left(c_{fil}\right)=C\rho_f^n\left(1+\mu c_{fil}\right) \tag{6}$$

with the parameter C and n values as determined for neat foams. It is seen in Table 1 that the μ values for ZnO, carbon nanotube, and Cloisite 30B filled polymers are very close, with the average of μ = 0.114. The strength of foams with the fillers mentioned above at 1% wt. is plotted as a function of the filled foam density in Fig. 10. A reasonable agreement with the prediction by Eq. (6) using the average μ value is seen.

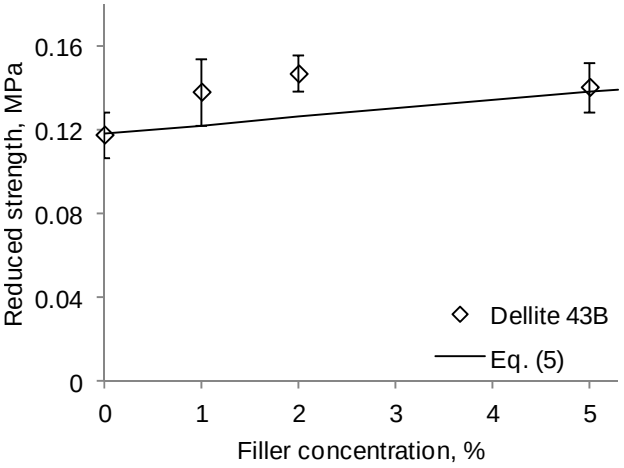

Fig. 9. Reduced tensile strength as a function of Dellite 43B nanoclay loading

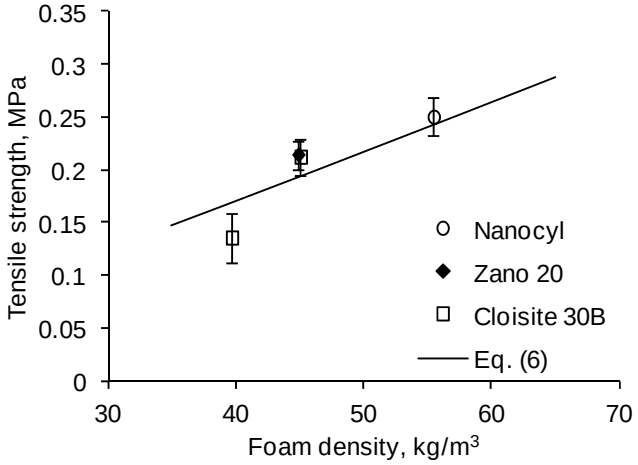

Fig. 10. Tensile strength vs. foam density of filled foams containing 1 % wt. of nanoparticles

4.3. Strength of carbon fiber-filled polymer foams

The reduced tensile strength of foams filled with milled carbon fibers is shown in Fig. 11 as a function of filler content. No apparent effect on the strength is observed for either of the fiber types differing in average length by a factor of ca. 1.7. The reduced compressive strength of foams with two different densities, shown in Fig. 12, was also barely affected by the presence of fiber filler. For ease of comparison, the strength of unfilled foams is indicted by dashed lines in Figs. 11 and 12.

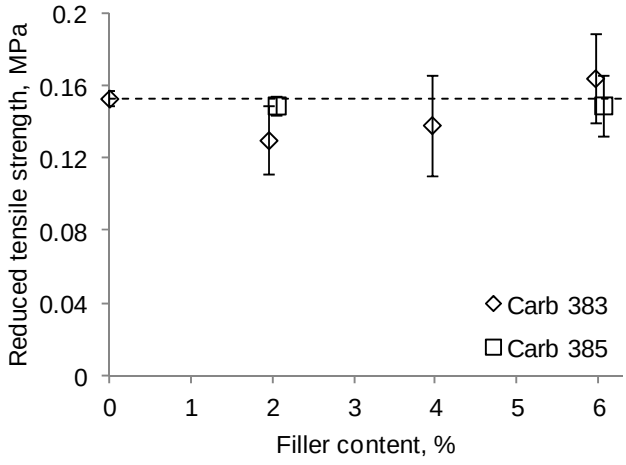

Fig. 11. Reduced tensile strength vs. carbon fiber content

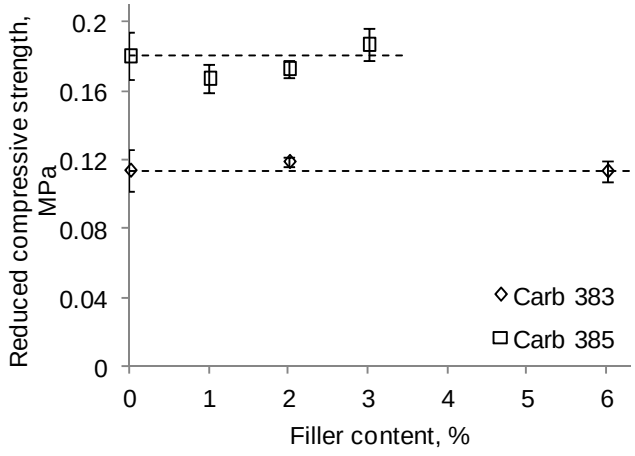

Fig. 12. Reduced compressive strength vs. carbon fiber content

SEM and optical microscopy revealed that the carbon fibers were located within the cell wall

material, in cell struts and nodes, which resulted in appreciable increase in foam stiffness [[5], [10]]. However, polymer struts containing no fibers were also observed even at the highest fiber loading, which might have served as the sites of failure initiation, thus negating any increase in strength of the fiber-reinforced struts.

4.4. Fracture toughness of filled polymer foams

For the range of RO PIR foam density considered, mode I fracture toughness for crack propagation along the foam rise direction was found to vary approximately linearly with foam density [[8]]

$$K_{Icf} = C_k \rho_f \tag{7}$$

Relation Eq. (7) is plotted in Fig. 13 by a solid line together with the experimental toughness values of foams with nano- and microfillers at 1 wt. % loading. It is seen that the presence of carbon microfibers apparently fails to enhance foam resistance to cracking, since the toughness of carbon 385 fiber filled foams agrees within experimental scatter with that of neat foams of comparable density.

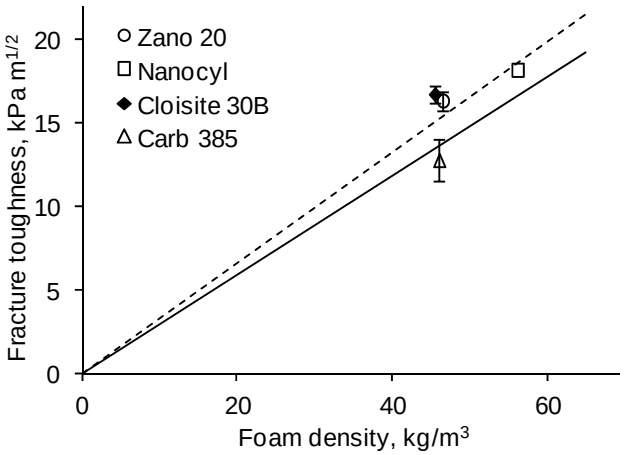

Fig. 13. Fracture toughness of filled foams at 1 wt. % loading. Solid line corresponds to neat foam toughness, dashed line plots prediction by Eq. (9)

Scaling relations derived in [[6], [7]] for foam toughness have the form

$$K_{Icf} = C_k \rho_f^n \tag{8}$$

where $C_k \sim \sigma_s \sqrt{l_s} \big/ \rho_s^n$ with l_s designating strut length and the exponent estimates ranging from n = 1 [[7]] to 1.5 [[6]]. Combining Eqs. (3), (7), and (8) (with n = 1), we obtain for filled foam toughness

$$K_{Icf}\left(c_{fil}\right) = C_k \rho_f \left(1 + \mu c_{fil}\right) \tag{9}$$

with the parameter C_k value as determined for neat foams. The prediction according to Eq. (9) is plotted in Fig. 13 by dashed line, using the average μ value for ZnO, carbon nanotube, and Cloisite 30B filled polymers. It is seen that Eq. (9) reasonably accurately reflects the observed increase of

nanofilled foam toughness with respect to that of neat foams. However, the strut length factor, neglected in Eqs. (7) and (9), should be explicitly incorporated in the toughness relations since the variation of strut length with foam density may differ for neat and filled foams.

5. Conclusions

Production technology of rigid low-density polyisocyanurate foams obtained from renewable resources, with the polyol system comprising up to 80% of rapeseed oil-derived esters, has been developed. The production process is energy-saving and environmental friendly. The effect of nano-scale (organically modified MMTs, carbon nanotubes, ZnO particles) and micro-scale (milled carbon fibers) fillers on the strength and toughness of RO PIR foams has been experimentally evaluated. Taking into account the increase in foam density due to the presence of filler, carbon microfibers yielded negligible effect on the tensile and compressive strength and fracture toughness of foams in the 2 to 6 % wt. loadings studied. By contrast, nanofillers at 1 to 3 % wt. loading increased both strength and toughness of the foams. The reinforcement efficiency of the nanofillers can be roughly estimated by strength tests of filled solid polymers.

Abstract A recent development of carbon nanotubes (CNTs) based structural composite materials is to grow CNTs radially on micro-fibres and to use these hybrid fibres to develop superior 3D composites. Due to the extremely high tensile strength and stiffness of CNTs and the increased interfacial areas, it is expected that the fracture toughness of the new composites will be increased substantially. To evaluate the bridging effect of this new hybrid fibre, a finite element model was developed to simulate the pullout of a carbon fibre with radially grown carbon nanotubes. The physical multi-length scale problem is treated at the single macroscopic scale by using equivalent spring elements to simulate the bridging effect from CNTs. The nonlinear properties of the spring elements are obtained from the finite element simulation of a single CNT pullout, where the CNT is simulated by using membrane elements. The bonding and debonding behaviours between the carbon fibre-matrix interface and CNT-matrix interface are described by cohesive laws. The cohesive law for the carbon fibre-matrix interface was calibrated from macroscopic single fibre pullout experimental curves. The cohesive law for the CNT-matrix interface was calibrated from published experimental data on single CNT pullout. The numerical results indicate that the effect of growth CNTs on the carbon fibre is significant. The pullout force of the hybrid fibre has a significant increase at the elastic stage before interfacial debonding, which leads to a higher specific pullout energy.

Keywords carbon nanotube, composite, pullout, cohesive law, finite element

1. Introduction

Carbon fibre, which contains at least 92% carbon [1], has been used in broad fields such as aircraft, marine, energy, biomedical and recreational applications due to its high specific stiffness, specific strength, and low thermal expansion characteristics. Carbon nanotubes (CNTs) are the finest and strongest fibres with tube diameter on the nanoscale and lengths from micro to millimetres (up to 18mm) [2]. They are considered as the new generation of reinforcing phase in fabricating nanocomposite materials. Adding 1wt% of CNTs to matrix material, the stiffness of the composite can increase up to 42% [3]. A recent development of carbon nanotubes (CNTs) based structural composite materials is to grow CNTs radially on micro-fibres and to use these hybrid fibres to develop superior 3D composites, carbon nanotube (CNT)/carbon fibre (CF) hybrid composites, which take the advantages of carbon fibres and carbon nanotubes. The traditional fibres only provide the in-plane (x and y directions in Cartesian coordinates) reinforcement. The delamination always occurs in these traditional laminated composites since there is no reinforcement in the direction of the coordinate z (through-thickness direction) to resist the crack initiation and propagation. Since the CNTs align in multi-directions in the matrix, they can provide the reinforcement to the matrix in different directions as 3D reinforcement.

Due to the extremely high tensile strength and stiffness of CNTs and the increased interface areas, it is expected that the fracture toughness of the new composites will be increased substantially. In recent years, some researchers have grown CNTs on the surfaces of carbon fibres to improve the interfacial strength between the fibres and matrix [4-8]. A single fibre pullout test is one of the most widely used techniques to quantify the interfacial strength. In the past few years, only few researches have been carried out to understand the mechanical performance of CNTs reinforced composites using the single fibre pullout test. For example, Qian, et al. [9] examined the interfacial shear strength of CNT-grafted fibres using both the single fibre pullout and push out test. The

experiment results of the CNT-grafted fibres pullout test showed that the interfacial shear strength have a significant increase (from 75 to 118MPa).

Due to the extremely small size, the role of using this hybrid fibre in composite fracture is still unclear. Thus it is essential to use theoretical and numerical analysis to examine the pullout of this new hybrid fibre from the polymer matrix. Several numerical studies have been carried out on the CNT pullout, but no numerical study on CNT/CF hybrid fibre pullout has been reported. Kulkarni et al. [10] and Nie et al. [11] developed two similar multiscale models to evaluate the effect of interfacial strength on the elastic modulus of CNT/CF fibre reinforced polymer composites. In their simulation, they firstly modelled a nanocomposite formed by a single CNT embedded in the epoxy matrix (CNT/matrix) and numerically predicted the overall mechanical properties of the nanocomposite. The second step is to consider the nanocomposite as an equivalent matrix and use it to form a single carbon fibre nanoreinforced laminated composite.

Cohesive zone modelling is a commonly used technique to investigate the failure governed by crack or debonding propagation. It establishes the traction-separation relation for the interface and bridges the gap between the stress- and energy-based approaches [12]. Many studies have been carried out on the interfacial behaviours of fibre-reinforced polymer (FRP) and concrete under mode II conditions [13, 14] by using cohesive zone modelling. However, very little attention has been paid to use cohesive zone modelling to numerically simulate the CNT/CF hybrid fibre pullout.

The purpose of this paper is to investigate the single CNT/CF hybrid fibre pullout test through coupling the single carbon fibre pullout and CNT pullout. The physical multi-length scale problem is treated at the single macroscopic scale by using equivalent spring elements to simulate the bridging effect from CNTs. The bonding and debonding behaviours between the carbon fibre-matrix interface and between the CNT-matrix interface are described by cohesive laws. In this paper, a finite element model of CNT/CF hybrid fibre pullout is firstly presented. Secondly the single carbon fibre pullout and the single CNT pullout are studied by using cohesive zone modelling. The two different cohesive laws for the carbon fibre-matrix interface and CNT-matrix interface are calibrated from macroscopic single carbon fibre pullout experimental curves and published experimental data on single CNT pullout, respectively. The single CNT/CF hybrid fibre pullout test is investigated by using a cohesive finite element model in which the two pullout processes at different scales are coupled. The effect of CNTs on debonding force and specific pullout energy are investigated.

2. Numerical Model

CNTs can be radially grown on the surface of carbon fibres using chemical vapour deposition (CVD). Fig. 1 shows Scanning Electron Microscope (SEM) image of carbon fibre after CNT growth [15]. These hybrid fibres are then embedded in an epoxy matrix to produce CNT/CF hybrid fibre reinforced composites. The diameter and interfacial area of the fibre are significantly increased by growth CNTs which can improve the fracture toughness of traditional fibre-matrix composites.

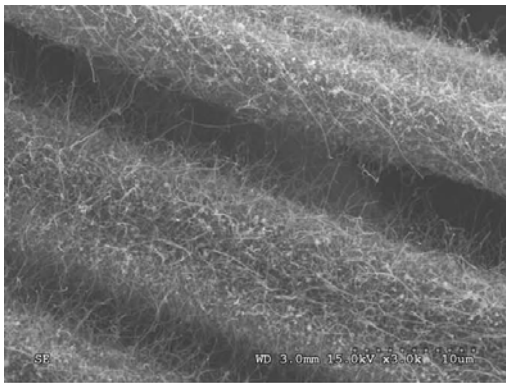

Figure 1. SEM image of a hybrid fiber with CNTs [15]

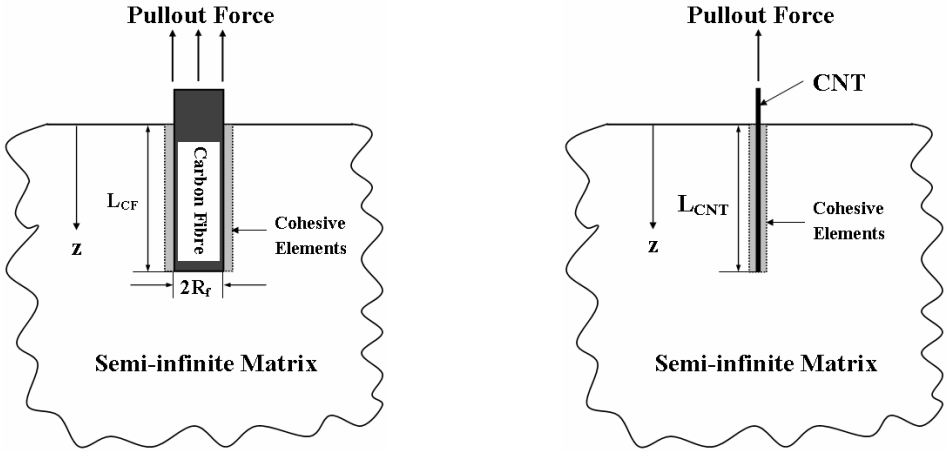
In a typical single fibre pullout test, there are three stages during the pullout process, including elastic deformation stage before debonding, debonding stage and sliding stage. In the first stage, the fibre and the matrix are well bonded. As the pullout force increases, a crack initiates and propagates along the interface between the fibre and the matrix, leading to a complete debonding, which is the debonding stage. In the last stage, the fibre slides out from the matrix, with friction acting between the two newly formed surfaces. One condition of pullout test is that the length of fibre embedded in the matrix must be less than the critical embedded length for debonding. Otherwise the fibre will break before the debonding occurs.



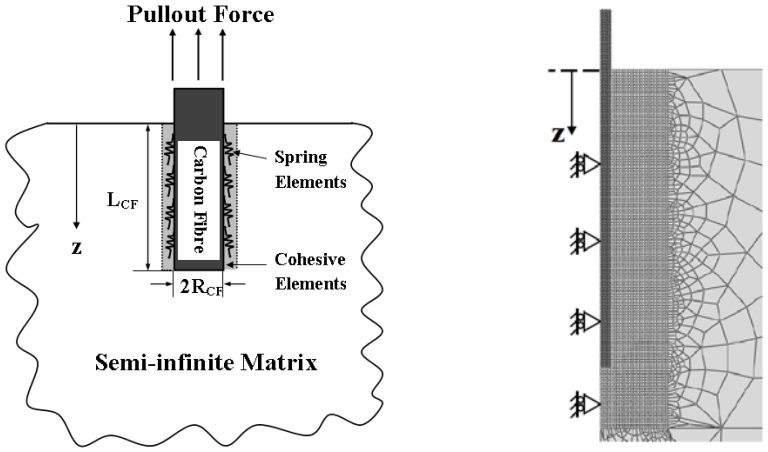
(a) (b)

Figure 2. (a) A schematic diagram of a single carbon fibre pullout model; (b) A schematic diagram of a single CNT pullout model

In this study, the CNT/CF hybrid fibre pullout was simulated through coupling of the single carbon fibre pullout and single CNT pullout. In the single carbon fibre pullout, a pullout displacement was applied uniformly on the top surface of the cylindrical fibre embedded in a semi-infinite matrix in the axial direction as shown in Fig. 2(a). The commercial finite element package Abaqus was used to investigate the carbon fibre pullout problem. A two-dimensional axisymmetric model was constructed with a very fine mesh (element type CAX4 and size 1μm ×1μm) in the area around the interface between the fibre and the matrix to ensure the accuracy of the numerical results. A small number of four-node, axisymmetric cohesive elements (COHAX4) were used to define the cohesive zone [16]. In the single CNT pullout, another two-dimensional axisymmetric model was developed using a single cylindrical CNT embedded in a semi-infinite matrix. A pullout displacement was also applied on the top of the CNT in the axial direction as shown in Fig. 2(b). L_{CNT} is the total embedded CNT length. Due to its extreme small size (in nanoscale), membrane elements (MAX1)

were used to represent the CNT. The membrane element can be used to represent the thin surface which offers strength in the plane of the element without bending stiffness [17]. The axisymmetric cohesive elements (COHAX4) were also used to define the cohesive zone between the interface of CNT and matrix.

The physical problem of the CNT/CF hybrid fibre pullout was treated as a cylindrical carbon fibre attached with spring elements which perform the bridging effect of CNTs embedded in a semi-infinite matrix, as shown in Fig. 3(a). Spring element is defined as a deformable member which is subjected to tensile or compressive loads in the axial direction. In the pullout simulation, the spring elements are elongated and the spring forces resist the fibre to be pulled out [18, 19]. The parameters involved to define the nonlinear spring elements were obtained based on the numerical results from the single CNT pullout. The radius of the fibre is denoted as R_{CF} and L_{CF} is the total embedded fibre length. As the model developed in carbon fibre pullout [16], a pullout displacement will be applied uniformly on the top surface of the fibre in the axial direction. Since the spring elements are used to simulate the force of CNTs applied on the carbon fibre during the pullout, the debonding of CNT-matrix interface will not be explicitly simulated in the hybrid fibre pullout model. Therefore the debonding only occurs between the carbon fibre and matrix interface, which is assumed to initiate at the carbon fibre-matrix interface and propagate longitudinally along the carbon fibre. It is also assumed that the normal stress along the carbon fibre does not exceed its material ultimate strength, so the carbon fibre will not break before it is pulled out. The plastic behaviour is not considered in this paper.



(a) (b)

Figure 3. (a) A schematic diagram of the CNT/CF hybrid fibre pullout model using spring element to perform the CNT; (b) Axisymmetric finite element model for a single CNT/CF hybrid fibre pullout with a fine mesh around the interface

Due to the symmetry of this problem, a two-dimensional axisymmetric model was constructed in this finite element analysis. The radius and depth of the matrix are much larger than the dimensions of the fibre in the numerical models so as to simulate a semi-infinite matrix body. The bottom of the model is constrained in both the radial and axial directions. The vertical side along the axisymmetric axis is constrained only in the radial direction. The model contains a total of 5149 four-node quadrilateral elements. A very fine mesh with the smallest elements (CAX4) of 1μm ×1μm were used in the area around the interface as shown in Fig. 3(b). A small number of four-node, axisymmetric cohesive elements (COHAX4) were used to define the cohesive zone. Nonlinear spring elements (SPRING1) were used to model the bridging effect of CNTs in the CNT/CF hybrid fibre pullout. In reality, the CNTs grown on the carbon fibre surface should be

considered as the CNTs embedded in the matrix at an inclination angle of 90º with respect to pullout direction. For this case, the CNT should be considered as a flexible string passing over a frictional pulley, and a snubbing friction model can be derived to relate the pullout force to the fiber inclination angle [20]. Therefore, a frictional pulley model for pullout force of the single inclined CNT was firstly introduced

$$F_{CNT(\Phi)} = F_{CNT(\Phi=0)} e^{f\Phi} \tag{1}$$

where $F_{CNT(\Phi)}$ is the pullout force of inclined CNT with the pullout direction Φ. f is the snubbing friction coefficient which is assumed as 0.1 in this study. Secondly, the pullout force of the single CNT obtained in FE simulation with pulley effect was applied to define the nonlinear properties of the spring elements.

In addition, two cohesive zones were defined between the carbon fibre-matrix interface and CNT-matrix interface in this study. In the single carbon fibre pullout simulation, a bilinear cohesive law was implemented [16]. In the single CNT pullout simulation, the cohesive zone model was adopted from Tvergaard [21] and Chaboche et al. [22]. The interfacial debonding during a fibre pullout test is a pure mode II fracture problem. Therefore the mode II cohesive law [22] can be simplified as

$$T_t = \left(\frac{27u_t^3}{4\delta_t^3} - \frac{27u_t^2}{2\delta_t^2} + \frac{27u_t}{4\delta_t} \right) \tau_{\max} \tag{2}$$

where u_t is the tangential separation and δ_t is the complete tangential separation. $\tau_{\max}$ is the interfacial crack initiation stress under shear loading condition. Correlating to energy-based fracture mechanics, the fracture energy G_{IIc} is the area under traction-separation curve.

3. Results and Discussion

3.1 Single Carbon Fibre Pullout Simulation

A comparison study between a finite element simulation and an experimental pullout test was first carried out as shown in Fig. 4 [16]. A 7μm diameter HTA-7-6K carbon fibre is embedded in an Epilox epoxy matrix with the embedded length L_{CF} = 100μm, which is consistent with the experiment by Bogoeva-Gaceva et al. [23]. The residual thermal stresses were considered on the assumption of ΔT = -95°C.

From Fig. 4, it can be seen that the simulated pullout curve agrees overall very well with the experimental curve from Bogoeva-Gaceva et al. [23] with these fitted parameters $\tau_{\max(CF)}$ = 45MPa, separation displacement of crack initiation $\delta_{d(CF)}$ = 21.86μm, and the complete separation displacement $\delta_{t(CF)}$ = 25μm. These calibrated parameters of cohesive zone are used to simulate CNT/CF hybrid fibre pullout in the following section.

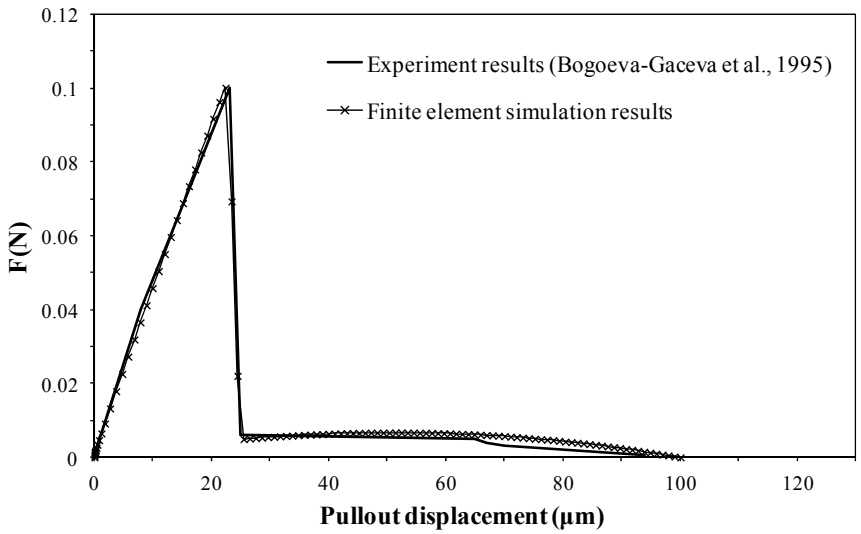


Figure 4. Comparison between experiment and FE simulation for single carbon fibre pullout curve

3.2. Single CNT Pullout Simulation and Validation

Similarly, another comparison study between a finite element simulation and an experimental single CNT pullout test was carried out. In this study, a 24nm diameter multiwalled-carbon nanotube (MWNT) is embedded in an epoxy matrix with the embedded length L_{CNT} = 2.6μm, which is consistent with the experiment by Cooper et al. [24].

Fig. 5 shows the simulated single CNT pullout curve. The numerical results were compared with the experimental results as shown in Table 1. W_{CNT} is the total CNT pullout energy, which is the total area under the pullout force-displacement curve. It can be seen that the numerical results agrees overall very well with the experimental results listed by Cooper et al. [24] with these fitted parameters $\tau_{\max(CNT)}$ = 36MPa, $\delta_{d(CNT)}$ = 140nm, $\delta_{t(CNT)}$ = 410nm which are used to define the nonlinear properties of spring elements in the following section.

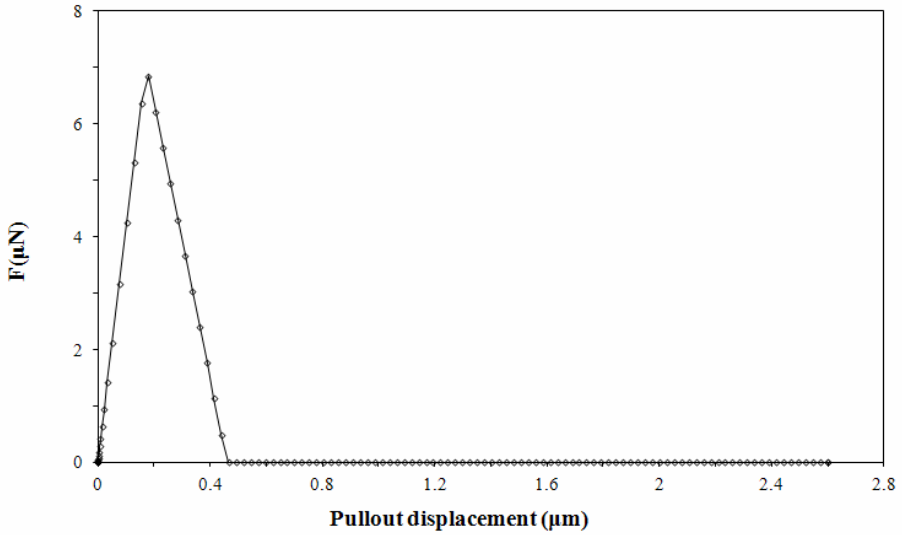

Figure 5. FE simulation for single CNT pullout curve

Table 1. Comparison between experiment and FE simulation for single CNT pullout

	FE simulation	Cooper et al. [24]
Maximum pullout force $F_{\max(CNT)}$ (μN)	6.845	6.8±1.7
Total CNT pullout energy W_{CNT} (J)	1.63×10^{-12}	1.6×10^{-12}

3.3. CNT/CF Hybrid Fibre Pullout

3.3.1. Estimation of length and number of CNT grown carbon fibre

To simulate a single CNT/CF hybrid fibre pullout, the length and number of CNT radially grown on the single carbon fibre should be identified. In this study, the length and number of CNTs were estimated based on the experimental results obtained by Zhang et al. [25]. In their experiment, carbon nanotubes were successully grown on the surface of a 7μm diameter carbon fibre T650 by chemical vapor deposition. The diameter of the CNT/CF hybrid fibre measured was appoximately 20μm. Therefore, the length of CNTs (L_{CNT}) grown on the carbon fibre surface can be estimated as 6.5μm.

The number of CNTs grown on the carbon fibre surface was calculated based on the CNT population density estimated from the experiment. The CNT population density at the carbon fibre surface was estimated as high as 8×10^9 tubes/cm^2 [25]. In this study, it is assumed that CNTs are uniformly grown on the carbon fibre surface. The number of CNTs grown on the carbon fibre surface per unit length can be calculated as 1760 tubes/μm. It is also assumed that there are 100 layers of CNTs uniformly distributed along the carbon fibre-matrix interface (L_{CF} = 100μm with element size 1μm ×1μm). Therefore, the total number of CNTs distributed on each layer was estimated as 1760 tubes. In addition, 99 layers of CNTs were used to joint with the carbon fibre in the hybrid fibre simulation which excluded the bottom layer of CNTs.

3.3.2. CNT/CF hybrid fibre pullout force

The maximum pullout force of hybrid fibre ($F_{\max(H)}$), is one of the most important parameters recorded from a pullout test, which is used to calculate the average interfacial strength. Fig. 6 showed the case of CNTs completely pulled out with the single carbon fibre. It can be seen that the magnitude of the maximum pullout force for CNT/CF hybrid fibre ($F_{\max(H)}$ = 0.39N) is much higher than the carbon fibre pullout ($F_{\max(CF)}$ = 0.1N). The maximum pullout force of the hybrid fibre has a significant increase by 290%. The increased pullout force was observed in the early stage of elastic deformation before the interfacial debonding occurred in carbon fibre. An et al. [26] performed an experiment of the CNT/CF hybrid fiber pullout to confirm that the maximum pullout force of hybrid fibre had a significant increase up to 120%. The difference probably is due to the different number of CNTs and carbon fibre embedded length used in this study.

The interfacial shear strength (IFSS), which is traditionally used to evaluate the interfacial bonding, is normally calculated from the load-displacement curve of a fibre pullout test. It can be defined as [27]

$$\tau_s = \frac{F_{\max}}{2\pi R_{CF} L_{CF}} \tag{3}$$

The IFSS increases from about 45.5MPa to 177MPa. This improvement of the interfacial shear strength is due to the increased interfacial area and roughness, which can provide a stronger interfacial bonding between the CNTs, carbon fibre and the matrix. A significant improvement in the IFSS was also observed in the experiment studies [7, 9, 26, 28]. This study indicates that the effect of growth of CNTs on the carbon fibre surface is significant, which can enhance the adhesion between the fibre-matrix and thus improve the delamination resistance of the composite.

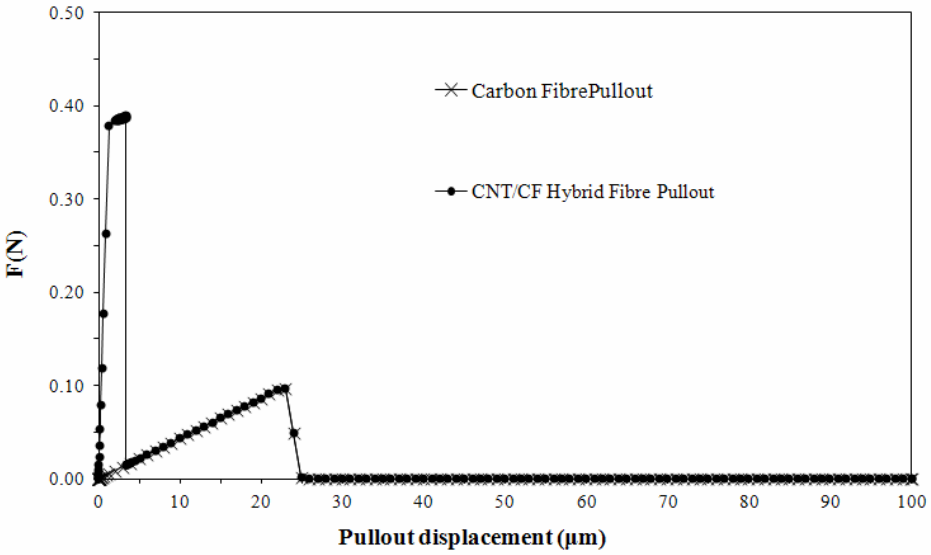

Figure 6. Comparison between the single carbon fibre pullout and the single CNT/CF hybrid fibre completed pullout curve.

3.3.3. Specific pullout energy

The specific pullout energy can be well used to quantify the beneficial effect of growth of CNTs on the bridging resistance of fibres in composites, which is first introduced in this paper. The specific pullout energy ω is defined as

$$\omega = \frac{W}{2\pi R_{CF} L_{CF}} \tag{4}$$

where W is the total fibre pullout energy, which is the total area under the pullout force-displacement curve. Specific pullout energy can be used to quantify the fibre bridging effect in a composite failure analysis. Fibre bridging appears behind a major crack tip in an intralaminar fracture, which enhances the fracture resistance of fibre reinforced composite. According to the calculated results, it can be seen that the influence of growth of CNTs on the specific pullout energy is significant. The magnitude of the specific pullout energy of CNT/CF hybrid fibre (ω_H = 1032J/m^2) is much higher than the carbon fibre (ω_{CF} = 565J/m^2). The specific pullout energy of the CNT/CF hybrid fibre increases by 83%. This is due to the large resistance induced by the carbon nanotubes, which requires more energy to pullout the fibre.

4. Conclusion

A finite element model was developed to simulate the pullout of a carbon fibre with radially grown carbon nanotubes. The bonding and debonding behaviours between the carbon fibre-matrix

interface and CNT-matrix interface were described by cohesive laws. Equivalent nonlinear spring elements were used to simulate the force of CNTs applied on the carbon fibre during the pullout. The numerical results of the CNT/CF hybrid fibre pullout from a case study show that the growth of CNTs on the carbon fibre surface has a significant effect on the maximum pullout force, and they increase the resistance in fibre at the elastic deformation stage before interfacial debonding. There also a signification improvement in the interfacial shear strength, which indicates that growth of CNTs can provide a stronger interfacial bonding between the CNTs, carbon fibre and the matrix. The beneficial effect of growth of CNTs on the bridging resistance of fibres in composites can be well quantified by the specific pullout energy. The increased specific pullout energy of the hybrid fibre indicates that growth of CNTs can enhance the fracture resistance of fibre reinforced composites.

Abstract This study aims to examine the adhesion work of electrospun polymer nano- and micro-fibers. The adhesion energy at the interface of electrospun membrane and a rigid substrate is characterized by a shaft-loaded blister test (SLBT). By controlling the processing parameters, polyvinylidene fluoride (PVDF) fibrous membranes are prepared with fiber diameters ranging from 201 ± 86 nm to 2,724 ± 587 nm. The adhesion energy between electrospun membrane and rigid substrate increases from 8.1 ± 0.7 mJ/m^2 to 258.8 ± 43.5 mJ/m^2 by use of smaller fiber diameters. Adhesion energies between electrospun PVDF membranes and SiC substrates made of different grain sizes are evaluated. Fibrous membrane produces an adhesion energy as high as 420.1 ± 62.9 mJ/m^2 in contact with SiC substrate with a 68 μm grit size. The SLBT methodology is extended to understand the adhesion energy between electrospun membranes. The increase in adhesion work is attributed to an increased area between fiber delaminated surfaces and surface asperities.
Keywords Adhesion energy, Electrospinning, Fiber diameter

1. Introduction

Hierarchical structures are usually evolved by insects and geckos on feet to produce extraordinarily strong adhesion for bodyweight support [1-3]. This phenomenon inspires researchers to use artificial polymer fibrillars in producing film-like adhesives [4-6]. Recently, thin membrane composed by ultrafine fibers is fabricated by electrospinning from polymer melt or solution [7-12] in a very simple process. The obtained electrospun membrane initiates a unique way to produce strong film-like adhesives. It requires a suitable characterization method is produced to evaluate the adhesion property of electrospun membranes.

In our previous an effective Shaft Loaded Blaster Test (SLBT) is reported to measure adhesion energy between electrospun membrane and rigid substrate [13]. As shown in Figure 1, SLBT consists of three main parts including stiff shaft, central holed rigid substrate and electrospun membrane. During SLBT, mechanical load is applied by through the stiff shaft on the center of electrospun membrane to form an axisymmetric conical delamination at membrane-substrate interface. The interrelationship of P-w_0-a between the measureable quantities, is governed by

$$P = \frac{\pi}{4}\left(\frac{Eh}{a^2}\right) w_0^{\,3} \tag{1}$$

Where P is the exterior force; E and h are elastic modulus and thickness of the membrane respectively; a and w_0 respectively refers to debonding radius and central deflection. In SLBT, mechanical equilibrium is exhibited [14-17], that is, the strain energy release rate, G, equals the work of adhesion, W, provided the entire membrane is linear elastic response. The equation is presented as

$$G = W = \frac{1}{4}\left(\frac{P\, w_0}{\pi\ a^2}\right) = \frac{1}{4\pi}\left(\frac{P}{w_0}\right)\cdot\left(\frac{w_0}{a}\right)^2 \tag{2}$$

By understanding of the principle [14-16] and process [13] of SLBT, in this paper we develop a research to discuss the adhesion work of electrospun polymer nano- and micro-fibers. Fiber

diameter is systematically examined to characterize size effect of electrospun fibers on adhesion energy. Surface asperity of rigid substrate is also discussed in detail to show the condition of high adhesion energy between electrospun membrane and rigid substrate.

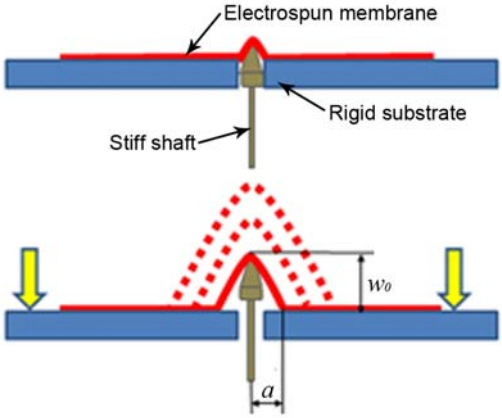

Figure 1. Schematic of shaft loaded blister test

2. Experimental Works

2.1. Materials

PVDF (Kynar 761) is purchased from Arkema Incorporation. N,N-Dimethylformamide (DMF) and acetone are purchase from Fisher Scieare at reagent grade.

2.2. Preparation of electrospun membranes

PVDF membranes for adhesion tests are fabricated by electrospinning. PVDF powder is dissolved in a solvent mixture of DMF and acetone to form PVDF solution. The concentration of PVDF solution is controlled at 0.15-0.20 g/mL. The volume ratio of DMF and acetone is selected as 7:3 and 5:5. Electrospinning is conducted at ambient temperature, solution feed rate 0.3 mL/h under applied voltage at 10 kV. Electrospinning process is proceeded ~10 h to fabricate a 10 μm thick fibrous membrane. Then electrospun PVDF membrane was dried in vacuum oven at 50 ºC for 12 h before used in SLBT.

2.3. Characterization of fiber mophology

Fiber morphology of electrospun membranes is characterized by scanning electron microscopy (JEOL JSM-6510LV). Before imaging, samples are coated with silver by sputter coater (K575x, Emitech) for 1.5 min at 55 mA. Average fiber diameter and fiber density are determined from SEM micrographs by use of the software ImageJ 1.45s. For each sample, five images are used for calculation and total 100 fibers are measured for average diameter calculation. Fiber density is also calculated by measuring the total area occupied by fibers in SEM micrographs.

2.4. Operation of SLBT

PVDF membrane is cut into a square of 30 mm by 30 mm for SLBT. The rigid substrate is prepared from cardboard with inorganic coating (detailed information of the substrate is exhibited in our previous work [13]). The arithmetic average roughness (R_a) of the substrate is approximately 128 nm. In order to make good contact, a lightweight plastic roller (~100 g) was used to roll over the membrane onto the substrate to squeeze air bubbles between membrane and substrate. Figure 1 shows a schematic of SLBT. Electrospun membrane is self-adhered onto the

top surface of rigid substrate. A rigid shaft with spherical cap (R=0.35mm) is used to apply force P to the electrospun membrane. In SLBT, the test speed is consistent at 20 mm/min. Before the test, the shaft is set to just contact with electrospun PVDF membrane, but no debonding between the membrane and substrate happens. During the test, initial vertical displacement leads to a blister debonding of the local area on the membrane close to the shaft end.

In SLBT, P is recorded by a 1 N load cell (Futek Advanced Sensor Tech). The whole test is monitored by 7X-45X Simul-Focal Trinocular Boom Microscope and recorded by a 3M camera (AMscope). Video captures are analyzed by ImageJ 1.45s to obtain in-situ deformation profile. Therefore, the relationship between delamination radius (a) and central deflection (w_0) can be obtained.

Silicon carbide (SiC) substrates with different surface asperities are also used to do the SLBT to evaluate adhesion energy between electrospun membrane and rigid substrate. After the test, adhesion energy is calculated by equation (2).

3. Results and Discussion

3.1. Morphology of Electrospun Membranes

SEM images and fiber diameter of electrospun PVDF membranes are shown in Figure 2. All the electrospun membranes show uniform fibers without bead. Fiber diameter distribution is exhibited

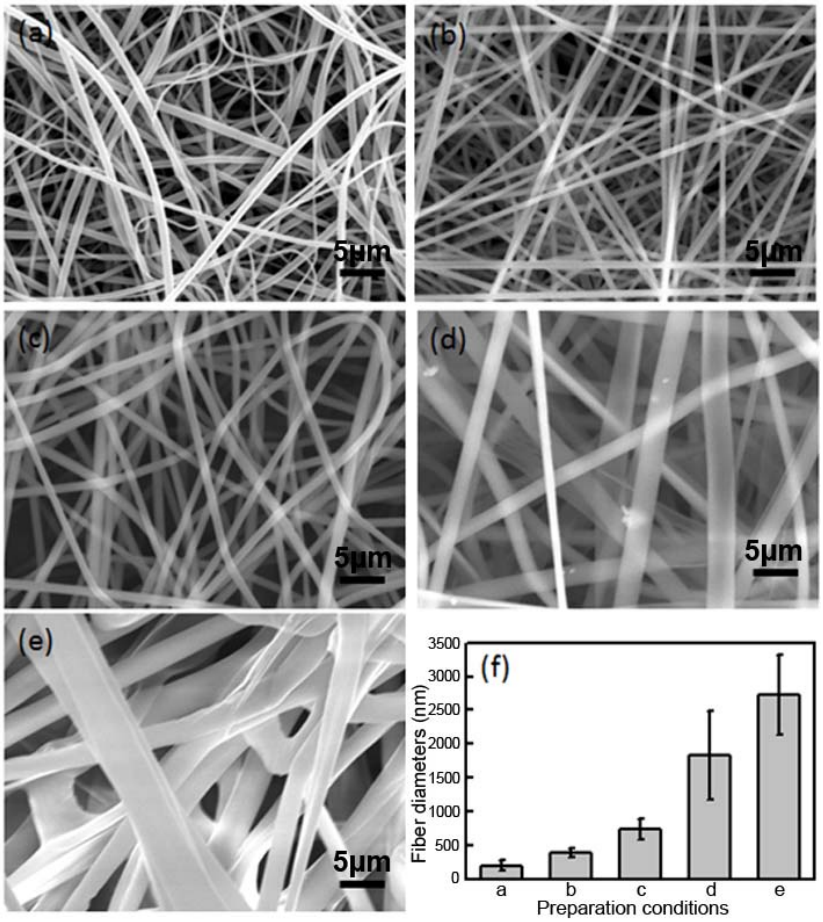

Figure 2. SEM images of electrospun PVDF membrane prepared at conditions of solution concentration and DMF/acetone (a) 0.15 g/mL, 7:3, (b) 0.17 g/mL, 7:3, (c) 0.15 g/mL, 5:5, (d) 0.17 g/mL, 5:5, (e) 0.20 g/mL, 7:3, respectively. Average fiber diameters of (a-e) is summarized at (f).

in Figure 2(f) with a trend of increase from 201 ± 86 nm to 2724 ± 587 nm. The increase of fiber diameter is attributed to high concentration of electrospun PVDF solution and large percentage of high boiling point solvent (DMF). Until today, this phenomenon is clearly recognized as the basically theory of electrospinning supported by a great deal of references [17-22]. Fiber densities of electrospun membranes are summarized in Table 1. Different fiber diameter doesn't result in different fiber density. From Table 1, fiber densities are from 77.81 % to 84.69 % without significant difference.

Table 1 Diameter, fiber density and adhesion energy of electrospun membranes

Preparation conditions	Fiber diameter (nm)	Fiber Density (%)	Adhesion Energy (mJ/m^2)
(a) 0.15 g/mL, 7:3	201 ± 86	84.7 ± 2.3	258.8 ± 43.5
(b) 0.17 g/mL, 7:3	387± 65	77.8 ± 2.8	196.3 ± 23.4
(c) 0.15 g/mL, 5:5	733 ± 154	79.2 ± 1.0	157.0 ± 37.5
(d) 0.17 g/mL, 5:5	1835 ± 653	84.7 ± 5.8	77.0 ± 8.8
(e) 0.20 g/mL, 7:3	2724 ± 587	83.3 ± 6.4	8.1 ± 0.7

3.2. The work of adhesion

The work of adhesion between electrospun membrane and rigid substrate in SLBT is calculated by equation (2) and recorded in Table 1. With the increase of fiber diameter, it shows an obvious decrease in adhesion energy. When the diameter of electrospun PVDF fibers is about 201 ± 86 nm, the adhesion energy is up to 258.8 ± 43.5 mJ/m^2. But, fiber diameter increases to 2724 ± 587 nm leading to 32-fold decrease in adhesion energy to only 8.1 ± 0.7 mJ/m^2. In SLBT, the rigid substrate has an inorganic coating on the surface indicating an arithmetic average roughness (R_a) of ~128 nm. It must form some rough area with several hundred nanometers fluctuant change on height. Because of the nano- and micro-size of electrospun PVDF fibers, they are usually very flexible with the ability to be crushed into the empty space of topographical rough area of the rigid substrate. Thin fiber is easier to produce larger effective contact with the surface of the rigid substrate. It will initiate higher work of adhesion during SLBT. On the contrary, thick fibers with the diameter of 2724 ± 587 nm are too large to be crushed into the small empty space on the topographical rough area at the surface of the rigid substrate. The contact area between electrospun membrane and rigid substrate should be very low. Low adhesion energy can be observed in SLBT.

Adhesion energy between electrospun PVDF membrane and rigid substrate is also enhanced by interlocking effect. Interlocking refers to the multi-point contact between electrospun fibers and rigid substrate. Thin fiber is no doubt flexible and easy to bend to contact many points of rigid substrate surface at the same time. The thinner electrospun PVDF fiber is, the easier the fiber forms effective contact with rigid substrate. In fact, SLBT debonding is a crack propagation process between the electrospun PVDF membrane and the rigid substrate. Formation of interlocking could increase the difficulty of crack propagation resulting in sharp increase of adhesion energy. Stein and co-workers [23] reported the sharp increase in interfacial toughness from 8 J/m^2 to 145 J/m^2 of two immiscible polymer plates by scribing grooves at the interface of plates to induce interlocking effect. By considering the flexibility of electrospun fibers and the principle of interlocking effect, it is concluded that reducing the fiber diameter of electrospun PVDF fibers is one of critical factors for significantly increases in adhesion energy between electrospun membrane and rigid substrate.

3.3. Surface roughness of rigid substrate

In order to understand the relation between adhesion energy and surface roughness of rigid substrate,

a series of SiC substrates with different surface asperities is applied in SLBT to characterize adhesion energy. Figure 3 exhibits the surface morphology and surface profile of SiC substrates. All of the SiC substrates show uniform grit distribution with different grit size [see left side of Figure 3]. The smallest size of grit is 5 μm showing a height fluctuation of ~3 μm on the surface. SiC substrate also exhibits large size of grit at 68 μm with ~30 μm fluctuation on height.

Electrospun PVDF membrane with fiber diameter of 387± 65 nm is used to test the adhesion energy with SiC substrates. By increasing of the grit size on surface of SiC substrates, it shows an increase trend of adhesion energy. When the grit size is lower than 15.3 μm, the adhesion energy is below 150 mJ/m^2. By use of large grit size SiC substrate, the adhesion energy reaches over 400 mJ/m^2. At the grit size of 68 μm, it shows the highest adhesion energy at 420.1 ± 62.9 mJ/m^2.

Large size of grid produces larger empty space between the SiC grids. Electrospun PVDF fibers can

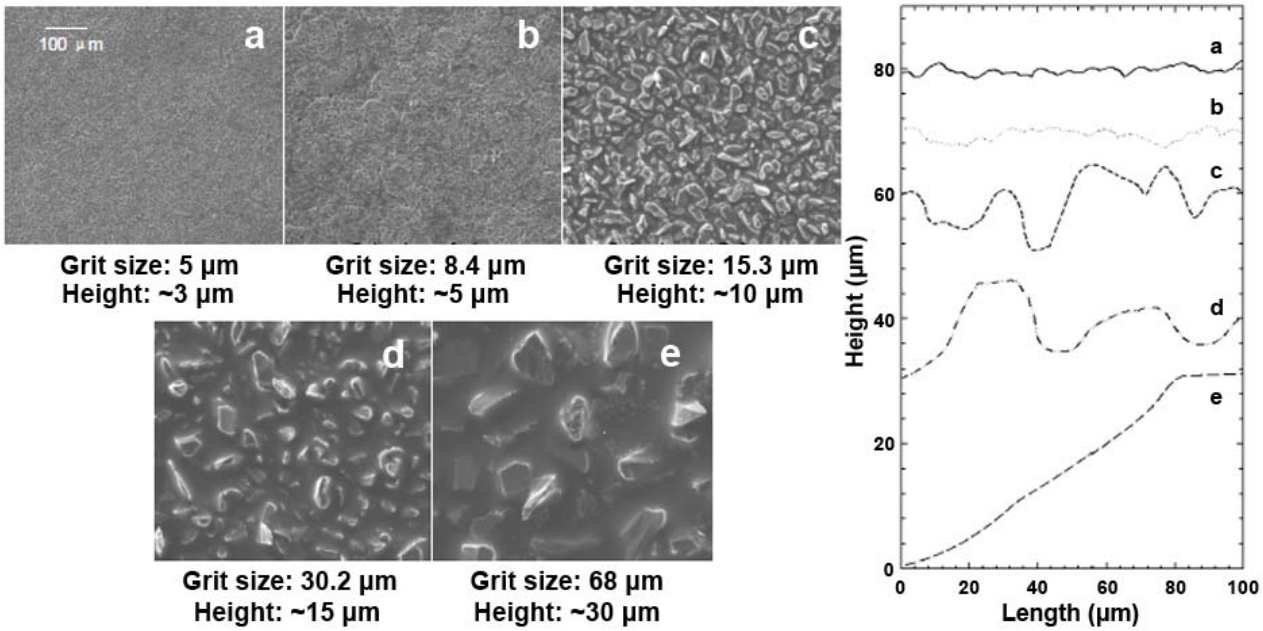

Figure 3. Surface morphology of SiC substrates.SEM images of SiC substrates (a-e) with different grit size are exhibited in left side. Surface scans of the substrate are included in right side.

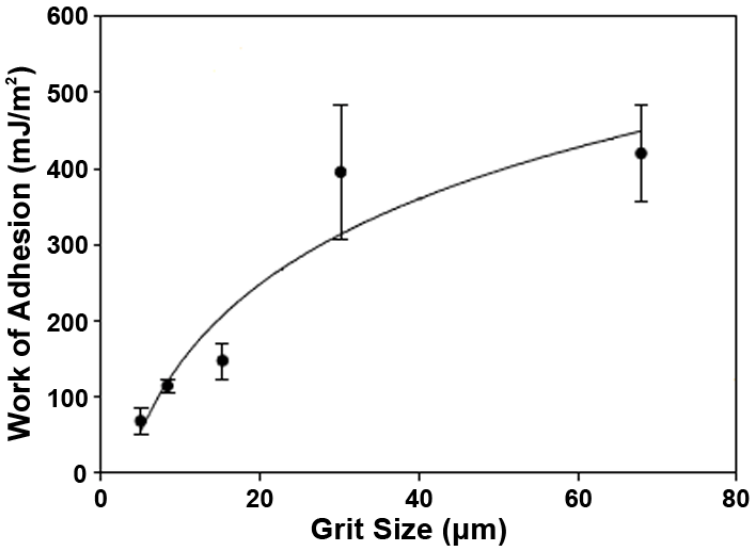

Figure 4. Adhesion energy between electrospun PVDF membrane and SiC substrate.

be easily crushed into the space to produce the high effective contact with substrate surface. When the space is large enough, many fibers can be crushed into the same area. Strong interlocking effect is initiated. As a result, higher work of adhesion can be produced in SLBT. However, when the grid size exceeds a critical value, the space between SiC grids is much larger the diameter of electrospun PVDF fibers. The increase of fiber amount will not produce an obvious increase in surface contact and interlocking effect. In our experiment, there is no large difference shown in adhesion energy between the grid sizes of SiC at 30.2 μm and 68 μm. Only 20 mJ/m^2 difference of adhesion energy is detected by use of the two SiC substrates. The surface asperity also plays an important role to the adhesion energy between electrospun membrane and rigid substrate.

4. Conclusions

SLBT methodology for testing the adhesion energy is conducted to determine the work of adhesion between PVDF membrane and rigid substrate. Electrospun PVDF membranes with increased fibers diameter show an obvious decrease in adhesion energy. The adhesion energy between electrospun membrane and rigid substrate can drop from 258.8 ± 43.5 mJ/m^2 to 8.1 ± 0.7 mJ/m^2 by increasing the fiber diameter from 201 ± 86 nm to 2,724 ± 587 nm. The surface asperity is also a critical factor for adhesion energy. The work of adhesion up to 420.1 ± 62.9 mJ/m^2 is detected between electrospun PVDF membrane and SiC substrate with a 68 μm grit size in SLBT.

Abstract
The tensile and shear failure behavior dependence on chain length and temperature in amorphous polymers are scrutinized using molecular dynamics simulations. A wide range chain length of alkane is tested under tension and shear with various temperatures. We find that the broken rate (the broken bond number to all polymer chain number ratios) under tension and shear increases with increasing chain length and temperature. For a given chain length and temperature, the broken rates under shear are always higher than those under tension at a same large strain. For a given chain length, the tensile and shear stresses decrease with increasing temperature. We propose three typical fracture mechanisms to effectively elucidate the ductile fracture response based on the predominance of chain scission process.

Keywords Failure, Chain length, Linear polymers, Molecular dynamics.

1. Introduction

Amorphous polymers are one of the most fundamental polymer molecular shapes that have widely been investigated by many researchers due to the important physical and chemical properties [1,2]. Glass forming polymers ($T<T_g$, T_g is the glass-transition temperature) are of great industrial importance and scientific interest. Their unique mechanical properties arise from the connectivity and random-walk-like structure of the constituent chains [3]. At very small strains, the response is elastic. At slightly larger strains, yielding occurs when intermolecular barriers to segmental rearrangements are overcome. Following yield, the material may exhibit strain softening, a reduction in stress to a level corresponding to plastic flow. At higher strains, the stress increases as the chain molecules orient, in a process known as strain hardening. Strain hardening suppresses strain localization (crazing, necking, shear banding) and is critical in determining material properties such as toughness and wear resistance [4,5]. In the other hand, the yield point of the polymers disappears after $T>T_g$. Recently, we have found that the chain length (CL) and temperature have a large effect on the thermomechanical properties of linear polymers [6-8] based on united-atom (UA) and coarse-grained (CG) molecular dynamics (MD) simulations. Since the UA and CG potentials limitations, the effect of the CL and temperature on the failure behavior is not understood well yet. Especially, the failure behavior under shear has been scarcely reported in previous work. Therefore, understanding the molecular origins of macroscopic fracture behavior such as fracture energy is a fundamental scientific challenge [5,9].

In this paper, the tensile and shear failure behavior dependence on CL and temperature in linear polymers are scrutinized using MD simulations. A wide range chain length of alkane is tested under tension and shear with various temperatures. The fracture mechanism is proposed based on the detailed analysis of the fracture response.

2. Simulations details

The bulk structure of linear polymers can be modeled using the semicrystalline lattice method [10], which utilizes the face-centered cubic (*fcc*) diamond structure as a template to carbon backbones of entangled polymers. The detailed process was detailedly described in our previous work [6]. The total number of beads in the initial structure is kept constant 180000 from CL=9 to CL=1200, in which the number of chains changes accordingly from 20000 (CL=9) to 150 (CL=1200). Since our aim does not simulate a specific polymer, we use a bead-spring polymer model derived from the one suggested by Kremer and Grest [11]. A finitely extendable nonlinear elastic (FENE) backbond potential is applied along the polymer chain

$$U(r) = -\frac{k}{2} R_0^2 \ln\left[1 - \left(\frac{r}{R_0}\right)^2\right], \tag{1}$$

where k=30 and R_0=1.5 to guarantee a certain stiffness of the bonds while avoiding high frequency modes (which would require a rather small time step for the integration) and chain crossing [12]. The beads interact through a truncated Lennard-Jones (LJ) potential of the form

$$\begin{cases} U_{LJ}(r) = 4\in\left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6} - \left(\frac{\sigma}{r_c}\right)^{12} + \left(\frac{\sigma}{r_c}\right)^{6}\right], r < r_c = 1.5\sigma \\ U_{LJ}(r) = 0, r > r_c \end{cases}, \tag{2}$$

where ε and σ are the characteristic energy and distance parameters that define the shape of the energy distance curve, while r_c is the cutoff distance for the potential. The LJ potential provides a smooth transition to zero values at the cutoff distance. In this work, we adopt the reduced units formalism and all physical quantities are expressed as multiples of m (bead mass), ε, σ and k_b (Boltzmann constant) while these parameters are set equal to one in our computation [13]. The bond is broken as r>1.15σ and the corresponding interaction is shut off, while a non-bonded LJ interaction is introduced between the two beads.

Each generated initial three-dimensional structure is annealed for 1×10^6 steps until the pressure and energy of the system is stable, keeping both the temperature T=1.3ε/k_b and the pressure P=1 (the time step dt=0.002) in the *NPT* ensemble controlled by the Nose-Hoover's thermostat [14]. Then, the system is cooled down to be the given temperature by the same *NPT* ensemble and the density of the system is monitored while cooling step-wise at an effective rate of $1/(1\times10^6$ steps). The system is then kept at the constant temperature (the given temperature) for 1×10^6 steps in the same *NPT* ensemble. The obtained structures are subjected to the uniaxial tension and compression and performed to obtain stress–strain response with different CL and temperature in the non-equilibrium MD simulations [15]. Periodic boundary conditions are applied in all directions. All the MD simulations have been performed using LAMMPS software [16].

3. Results and discussion

3.1 Failure behavior under uniaxial tension

Fig. 1 shows the stress-strain curves with different CL for two different temperature T=0.1 and T=0.3. The typical process (elastic, yielding, softening and hardening) is displayed in Fig. 1, while the hardening process is not evident when CL≤18 and the difference among the nonlinear parts of the stress-strain curves is also not large when CL≤144. The main reason is that the density and entanglement of short CL is lower than those of longer chain, which results in that

the bond number per unit volume in short CL is lower than those in longer CL. So the required external work for the shorter CL is lower than that for the longer CL. That is to say, the stiffness of the shorter CL is lower than that of longer CL. Since the density almost tends to a constant when CL≥140 [6], the effect is not evident in the range of CL≥140. Fig. 2 shows bond broken rate (the number of broken bond / the number of total chains) with different tensile strain for different CL and two temperatures T=0.1 and T=0.3, in which the broke rate increases with increasing CL.

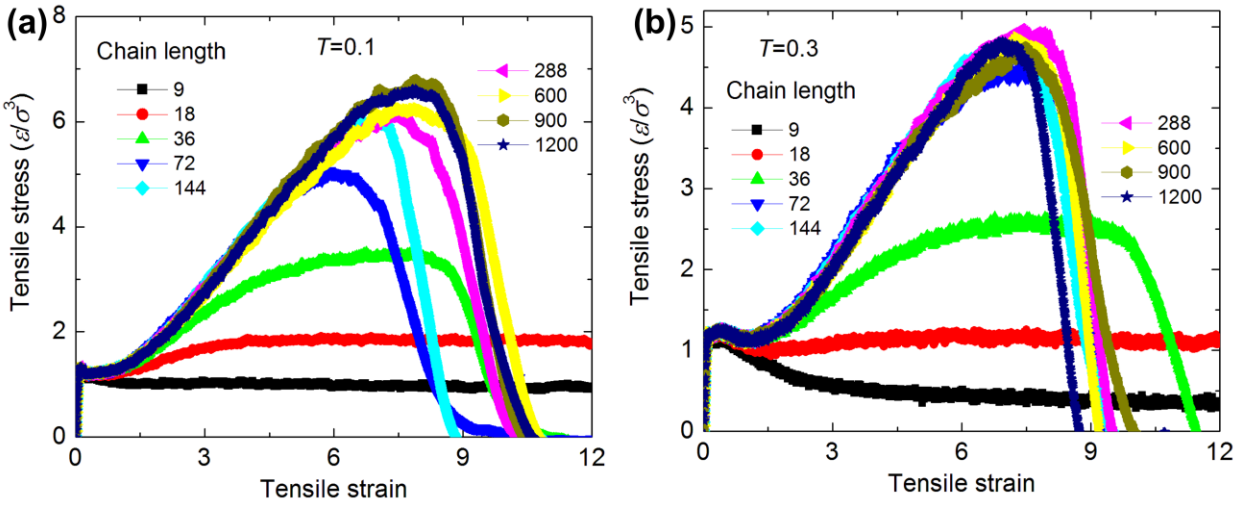

Fig. 1 The tensile stress-strain curves with different chain length for two different temperatures. (a) T=0.1; (b) T=0.3.

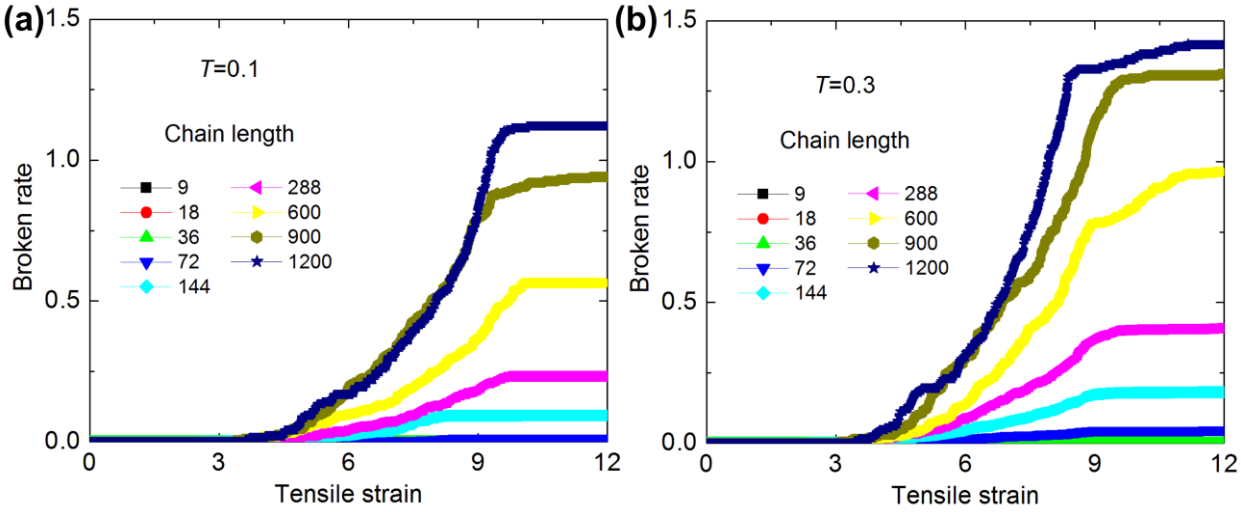

Fig. 2 The broken rate-strain curves with different chain length for two different temperatures. (a) T=0.1; (b) T=0.3.

We also find that the first broken bond is occurred at strain>3 and the stress is still hardening with increasing strain by comparison with Fig. 1 and Fig. 2. After strain>9, the stress decreases and the number of the total broken bonds tends to a constant. Fig. 3 shows the stress-strain curves and broken rate for CL=288 with different temperature. The stress decreases and the

broken rate increases with increasing temperature for same strain. For high temperature (T=0.5 and 0.7), the number of broken bond always increases with increasing strain even if the strain is higher than 12. The possible reason is that the temperature is higher than the glass-transition temperature T_g=0.35 (here) when T=0.5 and 0.7, in which the creep and high-elastic property is more evident in the high temperature and the yield point disappears. To interpret these MD simulations and obtain insight into the difference in fracture behavior of different CL and temperature, we plot the atomic strain distribution in the deformed configuration of the polymer models in Fig. 4 and Fig. 5. The ultimate fracture strain increases with increasing temperature in Fig. 4, which gives a good explanation of the above analysis. In Fig. 5, no void or atomic strain concentration for CL=18 can be found even at strain=12, which validates no broken bond in Fig. 2a. The ultimate fracture strain almost increases with increasing CL when CL≥72, which is also validated from Fig. 2a.

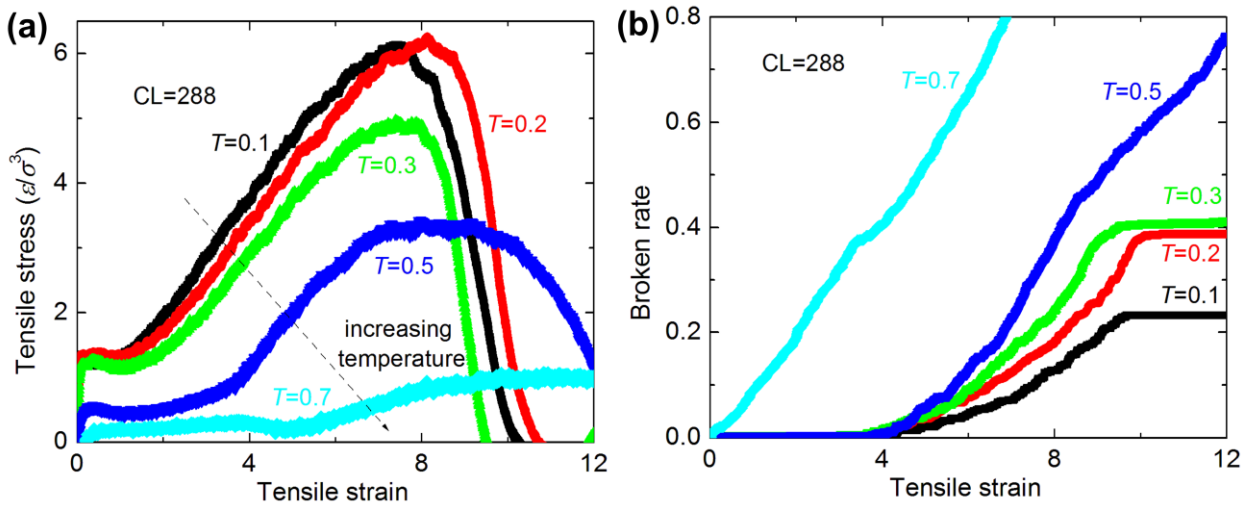

Fig. 3 The tensile stress-strain and broken rate-strain curves with different temperature for CL=288. (a) Stress-strain curves; (b) Broken rate-strain curves.

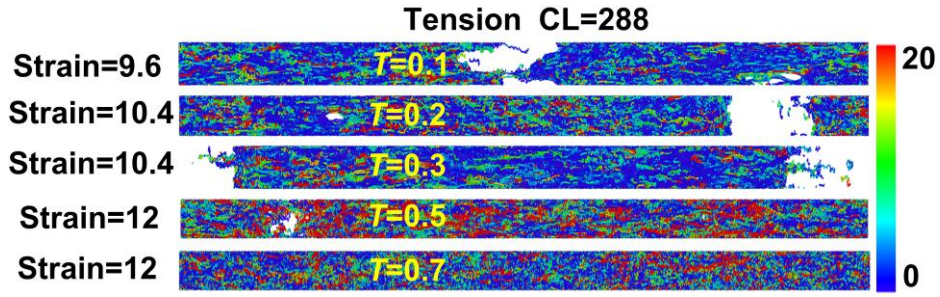

Fig. 4 The atomic strain (along the tensile direction) distribution for CL=288 at different temperature.

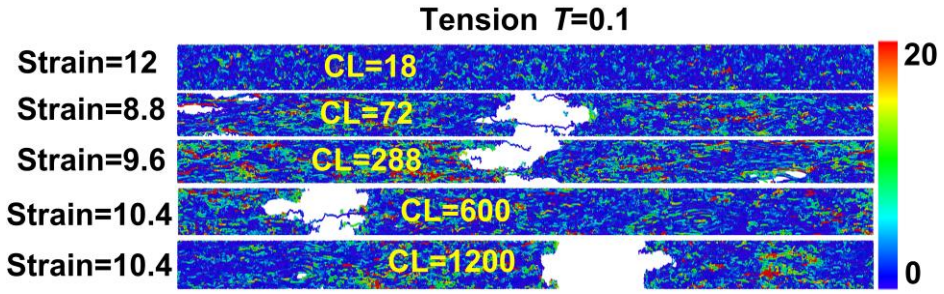

Fig. 5 The atomic strain (along the tensile direction) distribution for different CL at T=0.1.

Three typical mechanisms of the fracture behavior under uniaxial tension are plotted in Fig. 6. Fig. 6a represents the covalent bond broken phenomenon, which requires very high external loading (about 15000 MPa for linear polymers). Fig. 6b represents the polymer chain slipping with each other (about 5000 MPa). Fig. 6c represents the separation between any two polymer chains, which is mainly dominated by van der Waals interactions (about 100 MPa). For short CL, the fracture behavior is mainly determined by the chain slipping and separation. For longer CL, the fracture behavior is dominated by the competition between the chain slipping and bond broken mechanisms, in which the bond broken mechanism increases with increasing CL since the entanglement density increases with increasing CL. For very long CL, the bond broken mechanism mainly dominates the fracture behavior. The three mechanisms provide a good explanation of the MD results from Fig. 1 to Fig. 5.

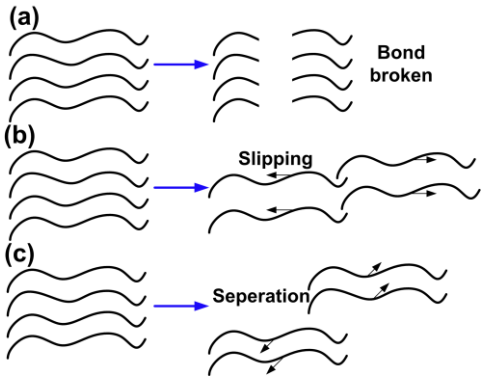

Fig. 6 Three typical mechanisms of microstructural evolution under uniaxial tension in linear polymers.

3.2 Failure behavior under shear

Fig. 7 shows the shear stress-strain curves with different CL for two different temperatures T=0.1 and T=0.3. The typical process (elastic, yielding, softening and hardening) is also displayed in Fig. 7. Unlike tension, the hardening process is also evident even for very short CL. The stress strength (the peak point of the stress) and strain strength (the strain at the stress strength point) both increase with increasing CL when CL≤144. The possible reason is that the polymer chains mainly keep the slipping process even in the hardening stage under shear, while the polymer chains are mainly stretching process after elastic stage under tension.

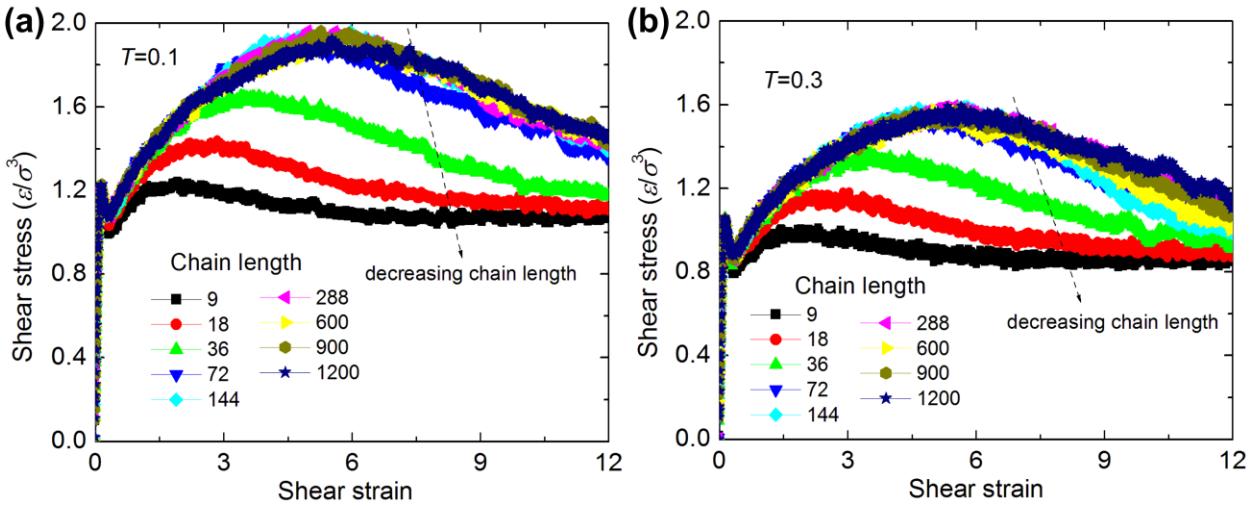

Fig. 7 The shear stress-strain curves with different chain length for two different temperatures. (a) T=0.1; (b) T=0.3.

Fig. 8 shows the corresponding broken rate with different CL for two different temperatures of Fig. 7. Similar to tension, the shear broken rate also increases with increasing CL. Unlike tension, the broke rate always increases with increasing shear strain even strain>12. Fig. 9 shows the ratio of tensile broken rate to shear broken rate with different strain. The ratio is always smaller than 1. In other words, for a given chain length and temperature, the broken rates under shear are always higher than those under tension for a same large strain. The possible reason is that the slipping and separation process mainly dominate the forward stage of the fracture behavior under shear, while the coupling slipping and broken mechanisms determine the fracture behavior under uniaxial tension. The r_c=1.5 of LJ potential is higher than the broken distance of r_{broken}=1.15 (see section 2), which leads to the higher ultimate fracture strain (that is, the structure is broken as two parts) under shear.

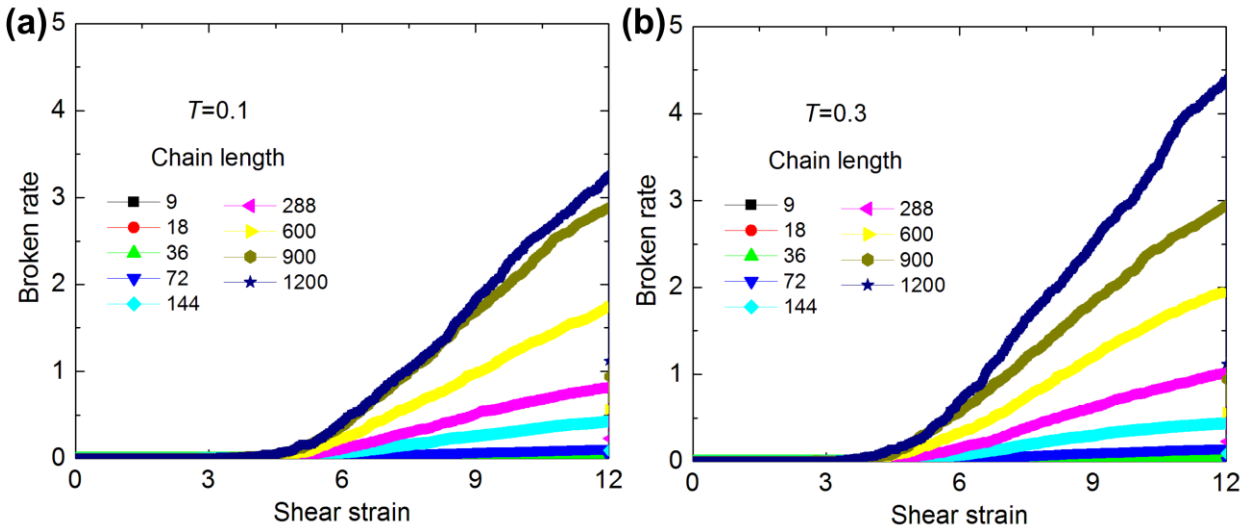

Fig. 8 The shear broken rate-strain curves with different chain length for two different temperature. (a) T=0.1; (b) T=0.3.

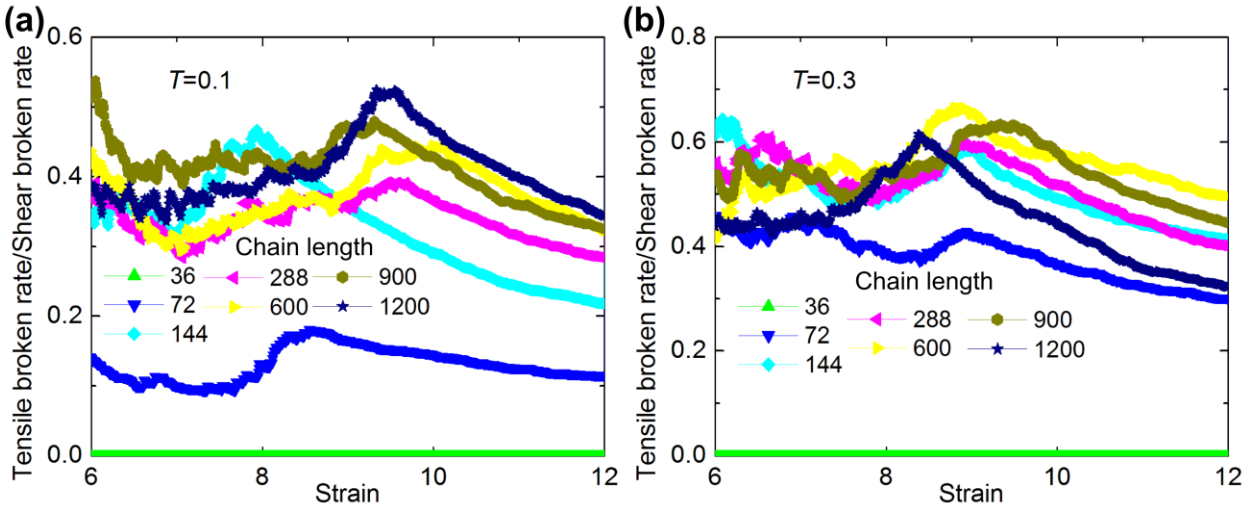

Fig. 9 The tensile broken rate/shear broken rate with different chain length for different temperature. (a) T=0.1; (b) T=0.3.

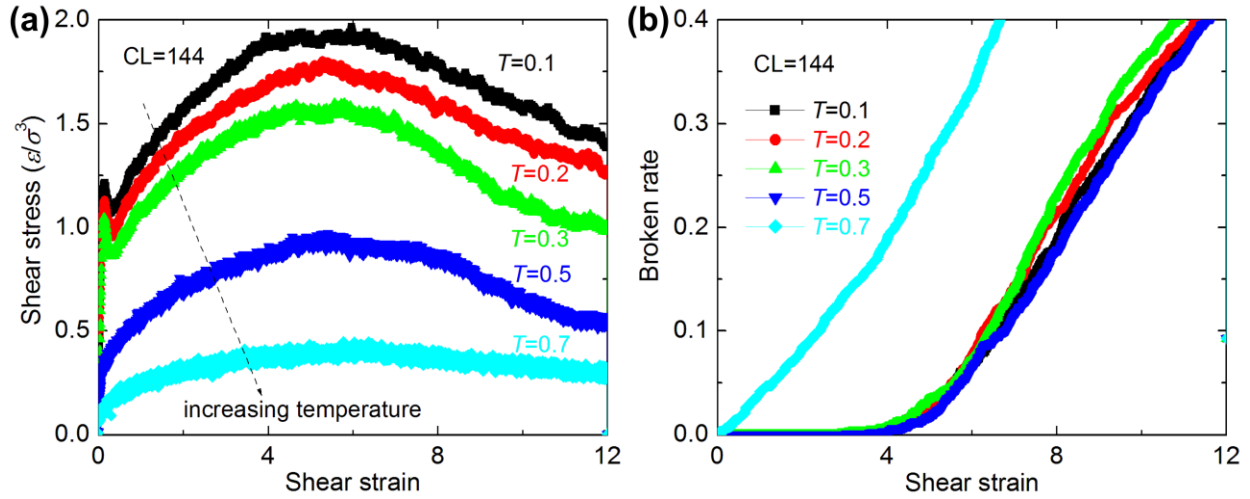

Fig. 10 The shear stress-strain and broken rate-strain curves with different temperature for CL=144. (a) Stress-strain curves; (b) Broken rate-strain curves.

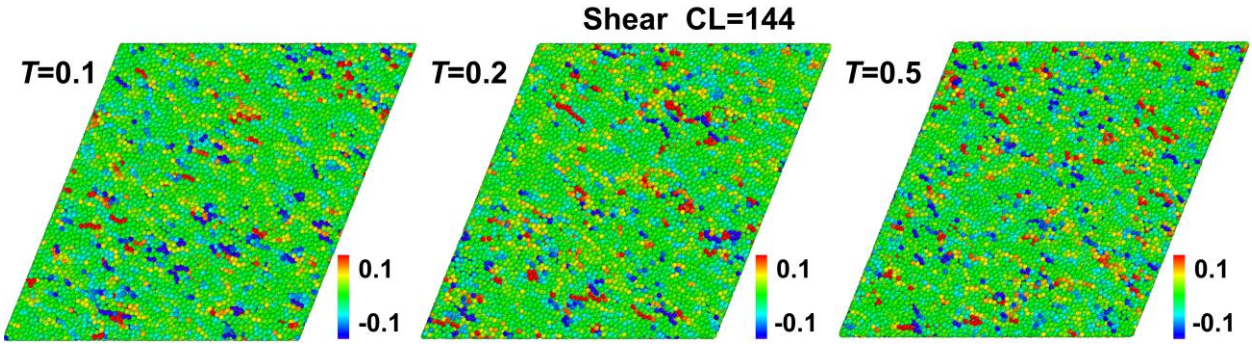

Fig. 11 The atomic strain (along the shear direction) distribution for CL=144 at different temperature under shear strain=58%.

Fig. 10 shows the shear stress-strain curves and broken rate for CL=144 with different temperature. The shear stress decreases with increasing temperature for same strain. For high temperature (T=0.5 and 0.7), no evident yield point can be also seen in Fig. 10a, which is same with tension. The difference of shear broken rate for different temperature is not large as T<0.7. To further understand the response, we plot the atomic strain (along the shear direction) distribution under shear strain (58%) for different temperatures and CL in the deformed configuration of the polymer models in Fig. 11 and Fig. 12. For CL=144 under same shear strain, the difference of the atomic strain distribution with different temperature is not evident in Fig. 11. For T=0.1, the atomic strain concentration increases with increasing CL in Fig. 12. The possible reason is that more entanglements are in large CL, which leads to the atomic stress concentration at these positions.

From above analysis, the ultimate fracture strain increases with increasing temperature under uniaxial tension. Under uniaxial tension, the fracture behavior is mainly determined by the chain slipping and separation for short CL. For longer CL, the fracture behavior is dominated by the competition between the chain slipping and bond broken mechanisms, in which the bond broken mechanism increases with increasing CL since the entanglement density increases with increasing CL. For very long CL, the bond broken mechanism mainly dominates the fracture behavior. Under shear, the atomic strain concentration increases with increasing CL for a given temperature. The shear broken rate is always higher than that under tension for same CL in the same large strain. The possible reason is that the slipping and separation process mainly dominate the forward stage of the fracture behavior under shear, while the coupling slipping and broken mechanisms determine the fracture behavior under uniaxial tension. The r_c=1.5 of LJ potential is higher than the broken distance of r_{broken}=1.15 (see section 2), which leads to the higher ultimate fracture strain (that is, the structure is broken as two parts) under shear.

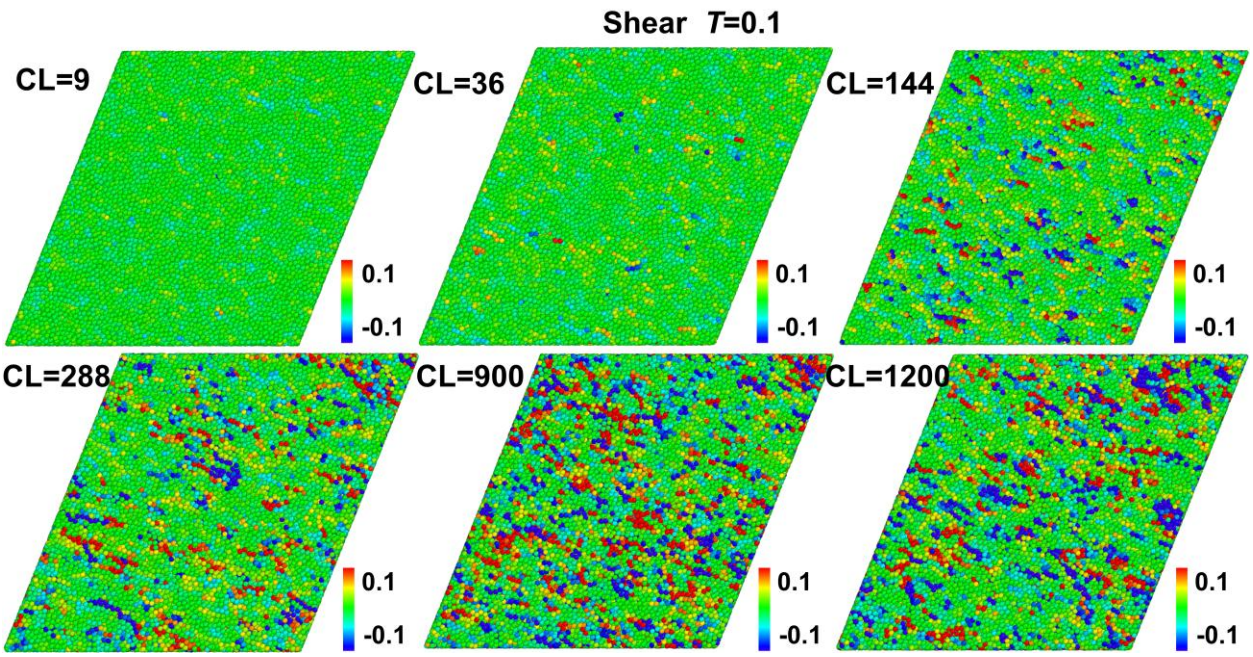

Fig. 12 The atomic strain (along the shear direction) distribution for different CL under shear strain=58% at T=0.1.

4. Concluding remarks

In summary, the tensile and shear failure behavior dependence on chain length and temperature in linear polymers are investigated using molecular dynamics simulations. A wide range chain length of alkane is tested under tension and shear with various temperatures. We find that the broken rate (the broken bond number to all polymer chain number ratios) under tension and shear increases with increasing chain length and temperature. For a given chain length and temperature, the broken rates under shear are always higher than those under tension at a same large strain. For a given chain length, the tensile and shear stresses decrease with increasing temperature. Under uniaxial tension, the fracture behavior is mainly determined by the chain slipping and separation for short CL. For longer CL, the fracture behavior is dominated by the competition between the chain slipping and bond broken mechanisms, in which the bond broken mechanism increases with increasing CL. For very long CL, the bond broken mechanism mainly dominates the fracture behavior. The slipping and separation process mainly dominate the forward stage of the fracture behavior under shear. The r_c=1.5 of LJ potential is higher than r_F=1.15 bond broken, which leads to the higher ultimate fracture strain under shear than that under uniaxial tension.

Assessment of Damage and Long-Term Strength of Polyethylene

P-Y Ben Jar

Department of Mechanical Engineering, University of Alberta, Edmonton, AB, T6G 2G8, Canada
ben.jar@ualberta.ca

Abstract Tensile strength of polyethylene is examined at various crosshead speeds using cylindrical specimens of 20 mm in gauge length. Through monotonic stretch with intermittent halt for load relaxation, the study shows that long-term tensile strength of polyethylene should be around half of the short-term strength determined in the standard test conditions. The study discovers a transition in the localized deformation (commonly known as necking), of which the appearance changes from opaque white to translucent when the crosshead speed is reduced from 0.05 to 0.01 mm/min, possibly due to the suppression of cavitation damage at the low crosshead speed. At a sufficiently high crosshead speed, damage generation can occur at a threshold strain as low as 4% which is way below the yield strain of the material. It is therefore concluded that determining long-term tensile strength of polyethylene needs to consider accumulation of the damage. Since this type of damage is not quantified in any of current standard methods, the study suggests that results from those tests need to be analyzed carefully to ascertain their validity for characterizing long-term performance of polyethylene products.

Keywords Long-term strength, polyethylene, damage, neck

1. Introduction

Polyethylene (PE) is known for its excellent ductility, superb corrosion resistance and strong strain hardening ability [1]. Its reliable performance has expanded the applications to products such as pipes for natural gas transportation that requires service lifetime for more than 50 years. Although standard methods, e.g. ASTM D1598 and D2837, are available to assess serviceability of PE pipes for this purpose, accuracy of the assessment is hindered by uncertainty in the resistance to a fracture behaviour known as slow crack growth (SCG) [2].

SCG development was discovered from early tests on full-sized pipe specimens subjected to internal hydrostatic pressure [3-5]. Results show a transition on the trend line of hoop stress versus time to failure, which yields a much steeper change of stress drop with increase of time to failure after the transition than before, with the former showing crack growth in much more brittle manner than the latter. Therefore, evaluating performance of PE pipes in service requires testing that takes at least one year for each specimen to ensure that the failure behaviour after the transition does not occur in service. In view of the lengthy time required for such tests, many studies have turned to accelerating tests that use small coupon specimens with sharp notches to shorten the time to initiate the crack growth [6, 7]. Although the use of sharp notches prevents the tests from determining the critical stress level for the transition to the SCG development, the results show a trend line that bears some similarity to the transition observed in full-sized pipe tests. As a result, the accelerating test becomes very popular for materials comparison, and is standardized as ASTM F1473.

Fracture generated in the notched specimens is known to be governed by shear deformation, and the transition is due to the change of shear deformation from the macroscopic scale (i.e. in a ductile manner) to the microscopic scale (in a brittle manner) [8, 9]. The latter is also known as craze that contains fibrils in a constrained space in front of the notch tip [10]. Based on results from the accelerating tests, formation of crazes is suggested to be the dominant mechanism for the SCG

development [11]. An extensive testing program has shown that the test method can generate a transition of the trend line for a wide range of PE materials [6].

Results from the above accelerating test are always analyzed as a function of the applied load, in terms of stress without the notch or stress intensity factor [11]. Since the applied load remains constant during the test, it is perceived that loading rate does not play any role on the deformation and fracture behaviour. However, the applied load needs to increase to the targeted level at the beginning of the test, for which the duration is relatively short. At the notch tip, rate of the initial stress increase should be pretty high. If the high loading rate generates damage that leads to different fracture behaviour from that occurs during the SCG development, results from the accelerating test should not be used to evaluate the SCG resistance. To my knowledge, such a scenario has never been seriously considered for the development of the accelerating test.

Work by O'Connell et al. [12] shows a transition from ductile to brittle fracture by testing notched specimens at an extreme combination of low loading rate and high temperature, that is, at a crosshead speed of 0.005 mm/min and temperature of 110^{o}C. The transition is opposite to the effect of loading rate and temperature commonly known for deformation and fracture behaviour of polymers. Fracture surfaces generated in such an extreme condition are featureless and without any indication of whitening. Note that this type of fracture behaviour is different from that shown in the work by Lu et al. [13] using a similar specimen design but subjected to a higher initial loading rate at a lower temperature. The latter always contains a thin but distinct whitening zone adjacent to the fracture surface. Unfortunately, due to the presence of sharp notches, difference of the true loading rates at the notch tips of those specimens cannot be quantified.

Some studies on the accelerating test have adopted notch-free specimens so that the loading rate (in terms of rate of strain increase) and its effect on the deformation behaviour can be quantified. Most of this type of studies applied a strain rate above 10^{-3} s^{-1} [e.g. 14-16], which is equivalent to a test speed about 1.2 mm/min for a gauge length of 20 mm. At the moment when this manuscript is prepared, the lowest strain rate that can be found in the literature is in the order of 10^{-5} s^{-1} [17].

A strain rate of lower than 10^{-5} s^{-1} is used in the work described in this paper to introduce a deformation transition that changes the neck appearance from opaque white to translucent. Based on the observed deformation transition, this paper investigates effects of loading rate on the necking phenomenon of notch-free PE specimens. In addition to the reduction of the crosshead speed, a special loading scheme is used to determine the stress-elongation curve of PE, in order to determine the long-term strength and its change caused by different initial loading rate.

2. Experimental

2.1. Materials

Specimens used for the mechanical testing are prepared from PE plates of 10 mm thick, provided by NOVA Chemicals, of which molecular weight, molecular weight distribution, and density are given in Table 1. The plates were compression-molded from pellets to ensure isotropy of the mechanical properties. Cylindrical specimens with geometry same as those used in ref. [18] were machined from those plates, with dimensions shown in Figure 1. To ensure that necking was always initiated in the middle of the gauge section where an extensometer was placed to monitor the change of cross-sectional dimensions, a small imperfection was introduced there to reduce the diameter by less than 2%. Note that despite the presence of such an imperfection, all specimens could show full neck development in the whole gauge section prior to the final fracture.

Table 1. Material characteristics of PE used in this study [19].

Weight-average molecular weight (M_w) (g/mol)	Number-average molecular weight (M_n) (g/mol)	Branches per 1000 C	Density, ρ (g/cm^{-3})	Crystallinity (%)	Tensile yield strength (MPa)
73,074	30,391	3.4–4.2	0.941	63.6	20.2

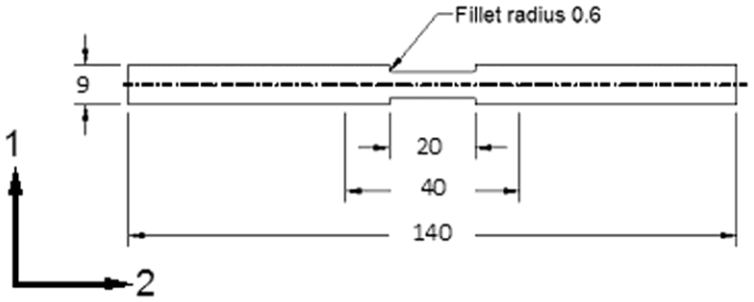

Figure 1. Dimensions of cylindrical specimen used in the study.

2.2. Mechanical Testing

All tests were conducted using a universal testing machine (QUASAR 100) at room temperature. Eight crosshead speeds between 0.001 and 5mm/min were selected for the testing, corresponding to the initial straining rate between $8x10^{-7}$ and $4x10^{-3}$ sec^{-1}. Two types of tensile tests were used. One, named simple tensile test here, applies a constant crosshead speed in the range between 5 and 0.001 mm/min until the stroke reaches a pre-set value. The other, named relaxation test, applies a constant crosshead speed of 1 or 0.001 mm/min, to reach a preset stroke and then, holds the stroke for 100,000 seconds (about 28 hours) while change of the load is recorded. For both types of tests, stress and area strain were calculated. The latter was defined as $ln\ (A_o/A)$ where A_o is the original cross-sectional area and A the cross-sectional area at the moment of measurement.

3. Results and Discussion

3.1. Simple Tensile Test

Figure 1 shows the summary of engineering stress versus stroke from simple tensile tests. As expected, peak stress decreases with the decrease of crosshead speed. In addition, profile around the peak load changes with the crosshead speed. In particular, the curve section around the maximum stress changes from single-peak to double-peak, with the two peaks separating further away with the decrease of the crosshead speed. The post-tested specimens also show a transition with the decrease of the crosshead speed. As shown in Figure 3, by decreasing the crosshead speed, noticeably from 0.05 to 0.01 mm/min, the neck appearance changes from opaque white to translucent. The latter has a similar color of the original specimen.

Figure 4 summaries maximum engineering stress as a function of crosshead speed, in logarithmic scale in Figure 4(a) and linear scale in Figure 4(b). Insert in Figure 4(b) depicts change of the maximum engineering stress at crosshead speeds below 0.01 mm/min. Both figures suggest that

around the lowest crosshead speed used in the study, 0.001 mm/min, the maximum engineering stress does not show any tendency of reaching a plateau value, but prediction from the two figures for the maximum engineering stress at zero crosshead speed is very different. Figure 4(a) suggests that the value could be way below 10 MPa; while Figure 4(b) based on specimens with translucent neck appearance (for crosshead speeds at and below 0.01 mm/min), the value should be about 10.5 MPa.

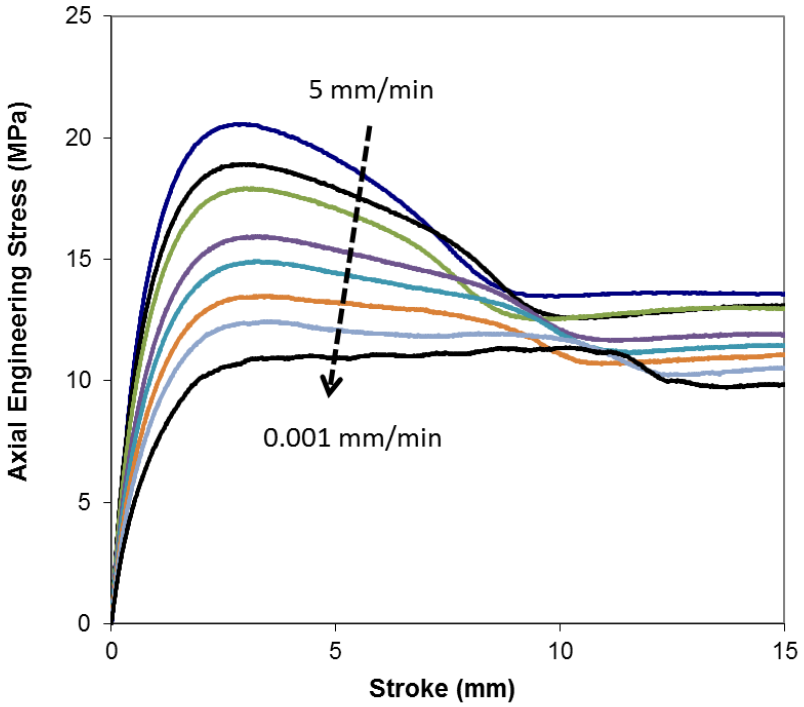

Figure 2. Engineering stress-stroke curves for crosshead speeds from 5 to 0.001 mm/min.

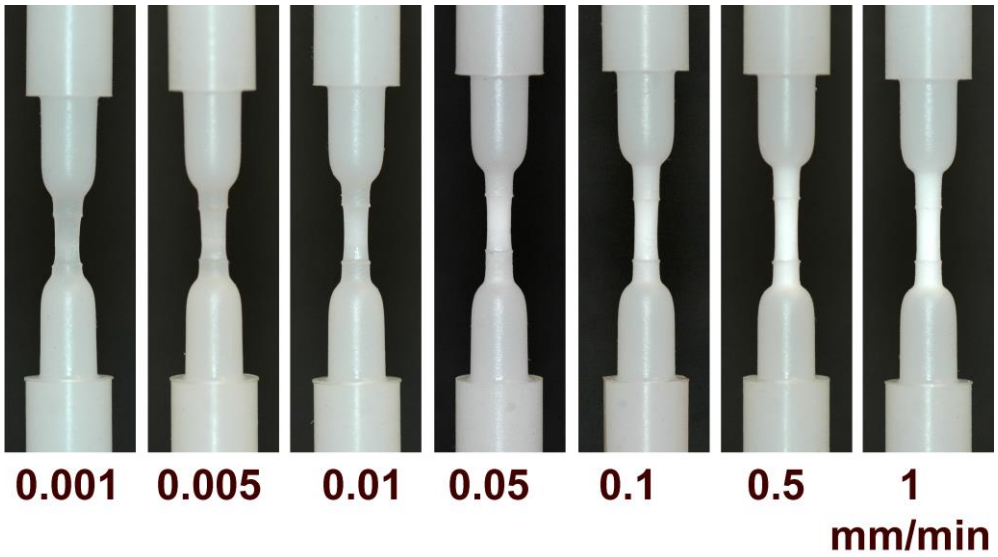

Figure 3. Transition of specimen deformation by changing the crosshead speed from 1 to 0.001 mm/min.

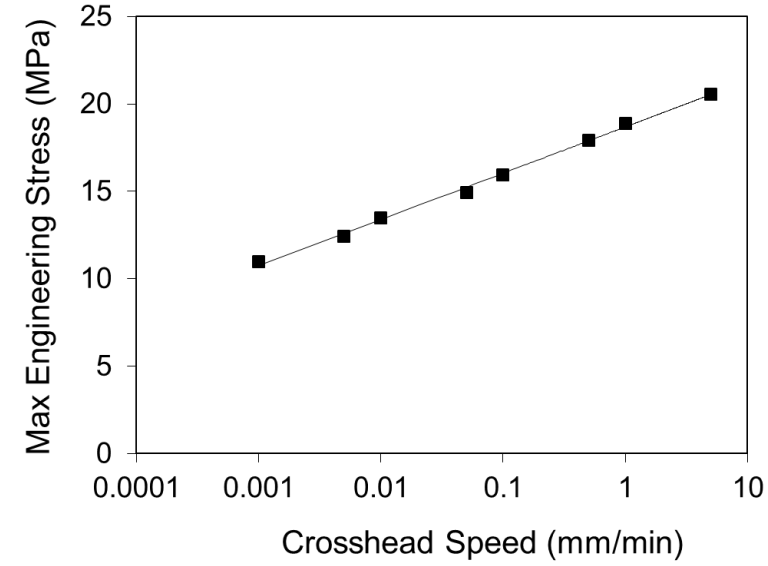
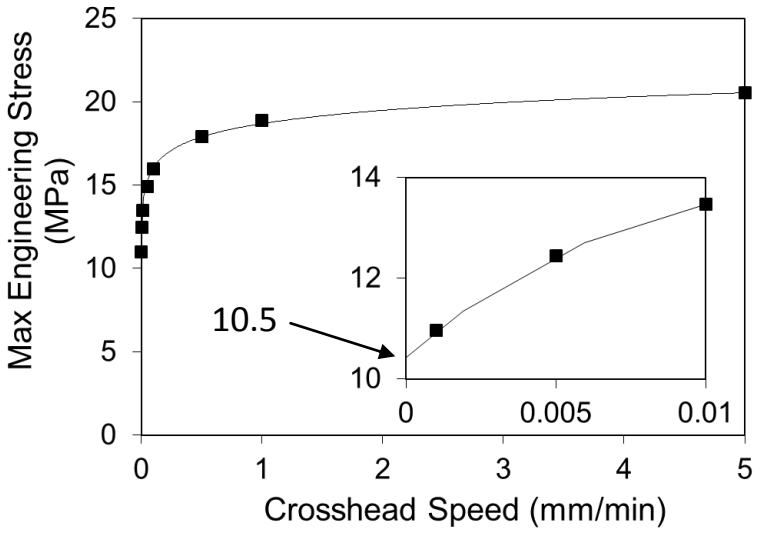


(a)



(b)

Figure 4. Maximum engineering stress versus crosshead speed in (a) logarithmic scale and (b) linear scale.

In view of the uncertainty in predicting the strength at zero crosshead speed (regarded as the long-term strength here), another test (named intermittent tensile test) was conducted, at the lowest crosshead speed that is provided by the test machine, 0.001 mm/min. Instead of applying a monotonic increase of stroke, stroke for the intermittent tensile test was programed to reach a pre-set value at 0.001 mm/min and then, the load was allowed to relax for 100,000 seconds. This time period was chosen based on some preliminary tests which suggest that the load maintained at a fairly constant level after 100,000 seconds, after which the further load decrease within the same period is within two times of the load cell resolution (± 0.5N). An example of the engineering stress-stroke curve from the intermittent tensile test is shown in Figure 5, in which the pre-set stroke values range from 0.8 mm to 6 mm. The corresponding long-term stress values at those strokes are then connected to form the long-term stress-stroke curve, also shown in Figure 5. Peak value of the long-term stress-stroke curve is 9.9 MPa, which is very close to that predicted from Figure 4(b), using values from three lowest crosshead speeds, from specimens with translucent neck appearance.

Note that the above pre-set stroke values cannot be applied to intermittent tensile test at a crosshead

speed of 1 mm/min. This is because after the relaxation, the stroke required to resume the tensile loading is much longer than the pre-set increment of the stroke values. As a result, individual relaxation tests, as presented below, are used to compare the long-term stress-stroke curves between two crosshead speeds, 1 and 0.001 mm/min.

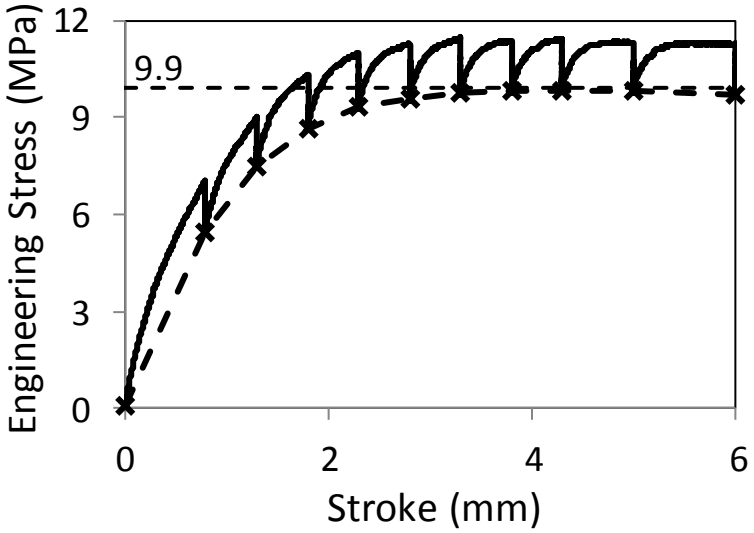


Figure 5. Engineering stress-stroke curves from an intermittent tensile test at crosshead speed of 0.001 mm/min, showing a long-term strength of 9.9 MPa, at a stroke between 3.8 and 4.3 mm.

3.2. Relaxation Test

Relaxation tests for the same period of 100,000 seconds were conducted at pre-selected strokes to establish long-term stress-stroke curves at crosshead speeds of 1 and 0.001 mm/min. Note that for the relaxation tests, each specimen is used only for one pre-set stroke.

Figure 6 summarizes results from the relaxation tests. The overall curve profile at 0.001 mm/min is similar to that shown in Figure 5 with peak stress at 9.9 MPa, and is distinctively above the curve from 1 mm/min. Peak stress for the latter is 8.9 MPa, suggesting that by increasing the crosshead speed from 0.001 to 1 mm/min, the long-term tensile strength of PE is reduced by about 10%. Figure 6 also suggests that with the increase of the stroke, difference of the long-term stress between curves at the two crosshead speeds increases, and the difference exists even at the smallest stroke of 0.8 mm which corresponds to an area strain of 3.6%. The stress decrease by increasing the crosshead speed is an indication of damage introduced by the deformation. Therefore, Figure 6 suggests that damage must have been generated at a very early stage of the deformation process.

Figure 7 depicts the post-test specimens with different strokes at the crosshead speed of 1 mm/min. For strokes below 6 mm, there is no clear neck formation. Therefore, only 1 photograph, taken from a specimen with stroke of 1.3 mm, is shown in the figure. Similar behaviour was found from specimens tested at 0.001 mm/min, except that the neck appears to be translucent, instead of opaque white.

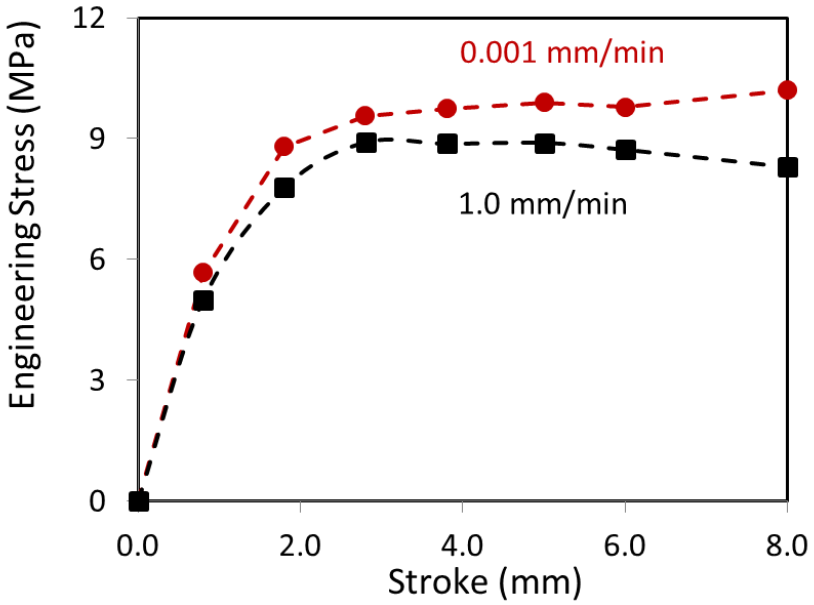

Figure 6. Engineering stress versus stroke from relaxation tests at 2 different crosshead speeds.

Further evidence for the damage generated by a high crosshead speed of 1 mm/min is shown in Figure 8 which contains three engineering stress-stroke curves, all from simple tensile test to a preset stroke of 1.8 mm at a crosshead speed of 0.001 mm/min. The three curves are from a virgin specimen, labeled "As is," and after stretch to 1.8 mm at two crosshead speeds, as labeled by "After 1 mm/min" and "After 0.001 mm/min," respectively. The figure suggests that the prior stretch at 0.001 mm/min does not change much of the stress increase with time, but the prior stretch at 1 mm/min has decreased the stress response. Therefore, even at a crosshead speed of 1 mm/min, corresponding to an initial strain rate of around 8×10^{-4} s^{-1}, damage is introduced way before the yield point. This phenomenon has also been observed by similar tests at other pre-set stroke values of less than 5 mm.

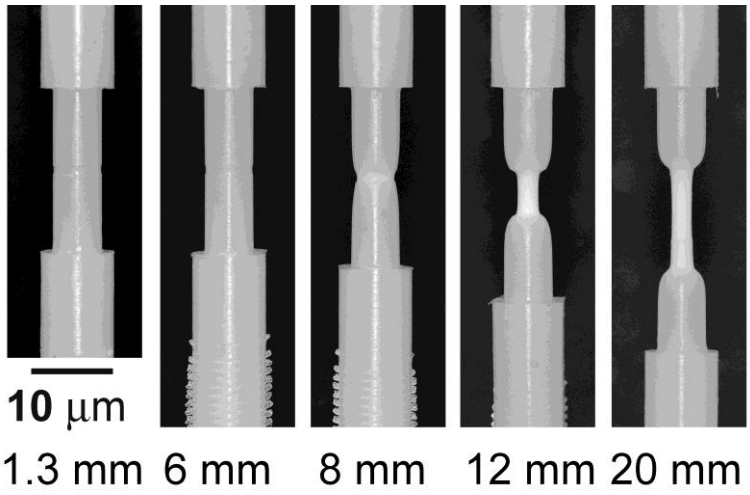

Figure 7. Specimens after being tested at 1 mm/min for different pre-set strokes (given under each photograph). Specimens tested at 0.001 mm/min have similar dimensional changes but do not show any whitening.

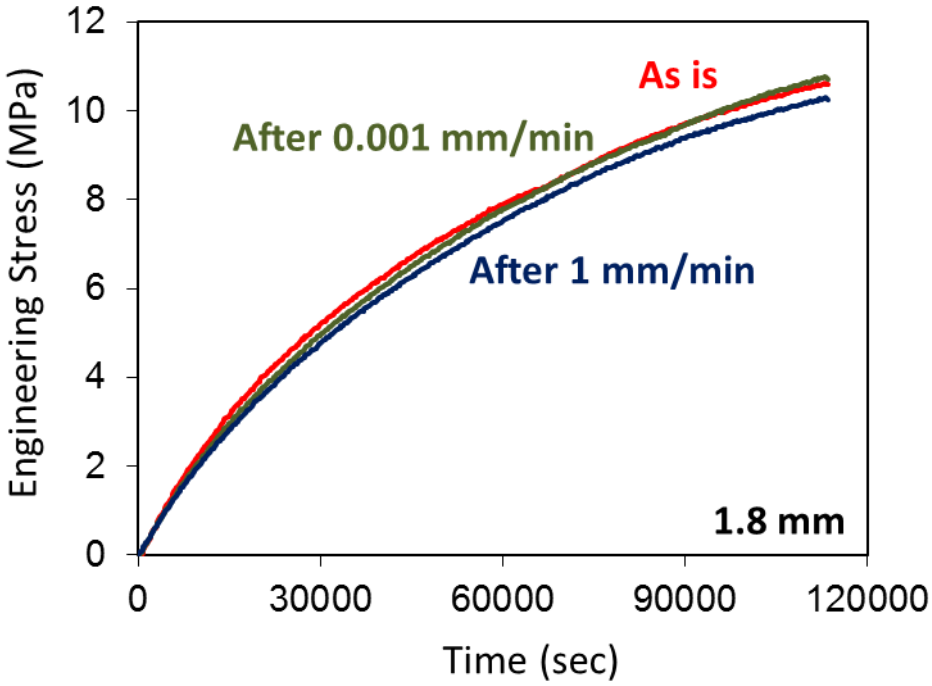

Figure 8. Comparison of engineering stress response with different loading history: as is, after stretch of 1.8 mm at 1 and 0.001 mm/min, respectively.

4. Conclusions

This paper presents an experimental study to assess long-term strength of PE and influence of loading rate on the damage generation. The study is based on a newly discovered "deformation transition" in notch-free specimens which generates translucent neck instead of the common opaque white. The discovery leads to development of a short-term test that uses coupon specimen to quantify the long-term strength of virgin PE. The results suggest that long-term strength of virgin PE is about 50% of its strength determined from the standard test.

The study also shows that long-term strength of virgin PE only represents the upper limit of the strength for PE pipe, as damage generated during the pipe transportation and installation may further reduce the strength. The results indicate that even under a loading rate of 1 mm/min, corresponding to a strain rate around $8x10^{-4}$ s^{-1}, damage can be generated in polyethylene at a strain level less than 4%. Therefore, long-term damage resistance of polyethylene pipes can be very different from the short-term test results that are often determined from virgin material.

The results suggest that assessment of long-term performance of PE pipe should include the damage assessment which may be generated during installation and service. Since such damage assessment is not considered at present, a new methodology is needed to quantify and monitor the damage evolvement in a plastic pipe and to quantify its effect on PE's long-term performance.

Acknowledgements

The work was supported by Natural Sciences and Engineering Research Council of Canada (NSERC). Sincere appreciation is due to Campbell, Waege and Bubenko for specimen preparation and Faulkner for fabrication of the extensometer used in the testing.

Abstract Fracture in ductile glassy polymers is usually preceded by noticeable and extensive plastic deformation, as shear yielding takes place in the form of shear bands that are limited by progressive hardening of materials at continuous deformation. In the case of a notched specimen, this induces a noticeable crack blunting before the failure. We use a constitutive law that captures realistically the stress-strain fields of solid glassy polymers. In particular, we account for a rate dependent yield stress followed by intrinsic softening and progressive hardening at continued deformation. We analyzed the 3D crack tip fields around a blunted notch loaded under mode I. With an increasing ratio between thickness versus notch tip radius, the shape of crack tip area evolves from a flame like zone characteristic of plane stress conditions to slip lines when plan strain conditions prevail. For a constitutive law representing the response of polycarbonate, we identified a critical thickness vs notch radius value that indicates the transition between plane stress to plane strain dominant loading conditions. The implication for the geometry necessary to derive material toughness experimentally is pointed out and an examination of the mean stress constraint related to the onset of failure by crazing is reported.

Keywords crack tip plasticity, fracture, glassy polymers, 3D effects

1. Introduction

Fracture in glassy polymer involves the competition between two localized plastic deformation: shear yielding and crazing. Shear yielding is related to the material's mechanical response with the localization of plastic deformation upon yielding followed by progressive hardening that controls the shear bands thickness. Crazing is the mechanism underlying failure that involves also localized plasticity, although at a much smaller scale. In glassy polymers, the crack tip fields around a notch loaded under mode I have been analyzed in a seminal paper by Lai and Van der Giessen [1] for 2D plane strain condition. These authors showed that the specific plastic zone made of a collection of shear bands similar to Hill's slip lines is related to the material's constitutive law with softening trigeering the formation of shear bands of which development is arrested by progressive hardening at continued deformation. This latter feature acts as a shear bands lock that promotes the nucleation of new shear bands to form a specific plastic zone; in the case of thin polymer films, when plane stress conditions prevail, a flame like plastic zone is observed, for instance in tests by the essential work of fracture (EWF) tests [2]. In ductile polymer fracture, when the onset of failure is preceded by noticeable plastic deformation as in polycarbonate, to determine the geometry for which plane strain conditions prevail remains heuristic from an experimental point of view. For instance, Parvin and Williams [3] observed that a ductile to brittle fracture transition takes place in a SENT polycarbonate specimen with increasing the sample's thickness. They ascribed this transition to a critical thickness (t) versus size of the plastic zone (r_p) as t/r_p, with r_p the extent of plastic zone under plane stress condition. By taking K_{c1} the toughness measured for thick samples and K_{c2} that for thin samples, they proposed a empirical relationship that captures the variation on the toughness with the specimen's thickness. More recently, Tvergaard and Needleman [4] investigated the

thickness effects in Izod fracture tests used in polymer samples and pointed out differences in the crack tip fields. For the thicker specimens, the predicted maximum mean stress appears much higher in the midsection than on the free surface. For thin specimens, a similar mean stress constraint is observed across the material's thickness, which indicates that plane stress conditions prevail. For the measure of the material's toughness, one wished to ensure that plane strain conditions prevail and if not, to estimate whether plane stress or a combination between plane stress and plane strain conditions is met. We present an analysis of the crack tip fields along the spirit of Lai and Van der Giessen [1] but within a 3D framework. The results presented here show that the shape of the predicted plastic zone can be used as an indicator of the plane stress/ plane strain condition and a geometrical criterion is proposed for the estimation of the thickness large enough to ensure plane strain conditions.

The paper is organized as follows. We first present the materials constitutive law and report the parameters identified for the polycarbonate under consideration. Then we present the 3D notched configuration and related problem formulation. For identical loading conditions, the influence of the thickness on the predicted crack tip fields in terms of cumulated plastic deformation is reported. The analysis of the variation of the mean stress with thickness, and its comparison with 2D calculations performed for plane stress and plane strain conditions are presented and used for proposing a criterion indicating when plane strain conditions prevail.

2. Material model and parameters identification

2.1. Constitutive Law

The constitutive law used to model the large strain plastic behavior is based on original ideas due to Boyce et al. [5] with some modifications introduced later by Wu and Van der Giessen [6] for the hardening part. In this section, we report the governing equations and materials parameters to be identified to represent the bulk, craze-free, response. The reader is referred to [7] for details on the computational aspects. The 3D constitutive model has been implemented in abaqus [8] within a User Material routine. The mechanics of fully three-dimensional large strain deformation involves the deformation gradient tensor $\boldsymbol{F}$, which maps a material point of the reference configuration into the current configuration. The deformation gradient is multiplicatively decomposed as $\boldsymbol{F} = \boldsymbol{F}^{\mathrm{e}}\boldsymbol{F}^{\mathrm{p}}$, in which $\boldsymbol{F}^{\mathrm{p}}$ describes the deformation from the initial to an intermediate, "relaxed" or "natural" configuration, followed by an elastic transformation $\boldsymbol{F}^{\mathrm{e}}$ up to the final deformation $\boldsymbol{F}$. The velocity gradient in the current configuration is $\boldsymbol{L} = \dot{\boldsymbol{F}}\boldsymbol{F}^{-1} = \dot{\boldsymbol{F}}^{\mathrm{e}}\boldsymbol{F}^{-\mathrm{e}} + \boldsymbol{F}^{\mathrm{e}}\dot{\boldsymbol{F}}^{\mathrm{p}}\boldsymbol{F}^{-\mathrm{p}}\boldsymbol{F}^{-\mathrm{e}}$ of which symmetric and anti-symmetric part correspond to the strain rate and spin tensor, $\boldsymbol{D}$ and $\boldsymbol{W}$ respectively. When the elastic part $\boldsymbol{F}^{\mathrm{e}}$ of the deformation gradient is small compared to the plastic one $\boldsymbol{F}^{\mathrm{p}}$ (i.e. $\boldsymbol{F}^{\mathrm{e}} \approx \mathrm{I}$), the velocity gradient reduces to $\boldsymbol{L} = \boldsymbol{L}^{\mathrm{e}} + \boldsymbol{L}^{\mathrm{p}}$ so that the total strain rate $\boldsymbol{D}$ becomes the sum of the elastic and plastic parts as $\boldsymbol{D} = \boldsymbol{D}^{\mathrm{e}} + \boldsymbol{D}^{\mathrm{p}}$.

Prior to the yield stress, amorphous glassy polymers exhibit a non linear stress strain response due to small viscoelastic effects. These are not considered explicitly but their effect on the mechanical response is accounted for by using a secant Young modulus instead of that derived from ultra-sonic wave velocities. In view of these approximations, the hypo-elastic law is used to express the bulk mechanical response as

$$\overset{\nabla}{\boldsymbol{\sigma}} = \boldsymbol{L}_{\mathrm{e}}\boldsymbol{D}^{\mathrm{e}}, \qquad (1)$$

where $\overset{\nabla}{\boldsymbol{\sigma}}$ is the Jaumann rate of the Cauchy stress, $\boldsymbol{L}_{\mathrm{e}}$ the fourth-order isotropic elastic tensor in terms of secant Young modulus E^{SECANT} and Poisson's ratio ν, which is in Cartesian components $\boldsymbol{L}_{ijkl} = \frac{E}{2(1+\nu)}\left[(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}) + \frac{2\nu}{1-2\nu}\delta_{ij}\delta_{kl}\right]$.

Within the elastic-viscoplastic framework used here, the plastic strain rate is

$$\boldsymbol{D}^{p} = \dot{\gamma}^{p}\frac{\overline{\boldsymbol{\sigma}}'}{\sqrt{2}\tau}, \text{ with } \tau = \sqrt{\frac{1}{2}\overline{\sigma}' \cdot \overline{\sigma}'} \tag{2}$$

being the equivalent shear stress and $\overline{\boldsymbol{\sigma}}$ the deviatoric part of the driving stress. The driving stress itself is defined by $\overline{\boldsymbol{\sigma}} = \boldsymbol{\sigma} - \boldsymbol{b}$. The back stress $\boldsymbol{b}$ responsible for the hardening is due to the entropic back forces generated by the deformation of the polymer chains during the plastic deformation, and will be defined later. The equivalent plastic shear rate $\dot{\gamma}^{p}$ is taken according to Argon's [9] expression

$$\dot{\gamma}^{p} = \dot{\gamma}_{0}^{p} \exp[-\frac{A(s_0 + \alpha p)}{T}(1 - (\frac{\tau}{s_0 + \alpha p})^{5/6})], \tag{3}$$

where $\dot{\gamma}_{0}^{p}$ and A are material parameters and T is the absolute temperature. Following Boyce et al. [5], intrinsic softening is accounted for with the definition of an internal variable s which varies from s_0 to s_{ss} at continued plastic deformation. The internal law

$$\dot{s} = h(1 - s / s_{ss})\dot{\gamma}^{p} \tag{4}$$

governs its variation during deformation, with h a parameter controlling the rate of softening and s_{ss} the value of s in a steady state regime. Furthermore, Equation (3) is modified in order to account for the pressure dependence by using $s + \alpha p$ instead of s_0 in (3), where $-\mathrm{p} = 1/3\mathrm{tr}\sigma$ is the mean (or hydrostatic) stress. The coefficient α represents the pressure sensitivity of the polymer which results in an asymmetric yield stress in tension and compression, for instance.

The description for back stress tensor $\boldsymbol{b}$ is based on ideas borrowed from theories for rubber elasticity with the cross-links of the rubbers considered as "entanglements" in the case of glassy polymers. The deformation of the resulting network is assumed to derive from the cumulated plastic stretch so that the principal back stress components b_α are functions of the principal plastic stretches λ_β as

$$b = \sum_{\alpha} b_{\alpha}\left(e_{\alpha}^{\mathrm{p}} \otimes e_{\alpha}^{\mathrm{p}}\right) , \tag{6}$$

in which $\boldsymbol{e}_{\alpha}^{\mathrm{p}}$ are the principal directions of the plastic stretch. In a description of the fully three-dimensional orientation distribution of non-Gaussian molecular chains in a network, Wu and Van der Giessen [10] showed that $\boldsymbol{b}$ can be estimated accurately with the following combination of the classical three-chain model and the eight-chain description of Arruda and Boyce [11]

$$b = (1-\rho)b^{3-\mathrm{ch}} + \rho b^{8-\mathrm{ch}}, \tag{7}$$

where the fraction $\rho = 0.85\bar{\lambda}/\sqrt{N}$ is based on the maximum plastic stretch $\bar{\lambda} = \max(\lambda_1, \lambda_2, \lambda_3)$ and on N, the number of segments between entanglements. The use of Langevin statistics for calculating b_α

implies a limit stretch of $\sqrt{N}$. The expressions for the principal components of b^{3-ch} and b^{8-ch} contain a second material parameter: the initial shear modulus $C^{R} = nk_{B}T$, in which n is the volume density of entanglements (k_B is the Boltzmann constant).

2.2. Parameters identification

In order to obtain a set of material parameters for the description of the finite strain visco-plastic response of the polycarbonate under consideration, experimental data of the stress-strain response for various strain rates are necessary. In compression, crazing is suppressed and uniaxial experiments are carried out on cylindrical specimens. In order to prevent any buckling, the diameter and the height of the specimen are 10 mm and 6 mm respectively. Low friction along the contact surface between the faces of the cylinder and the plates of the machine is ensured by using a hexagonal boron nitride powder (BN). Therefore, lateral displacement with respect to the direction of compression is allowed so that a uniform stress state prevails along the whole specimen. In order to characterize the rate dependency of the yield stress, a series of strain rates from 1×10^{-5}/s to 1×10^{-1}/s are investigated (see Fig. 1(a)). Following the identification procedure detailed in Saad et al., [12], the parameters are extracted from the uniaxial compression data and are reported in Table 1. The corresponding predictions are presented in Fig. 1(b).

Table 1. Material parameters for Polycarbonate

E^{sec}(MPa)	ν	s_0(MPa)	s_{ss}(MPa)	α	A(K/MPa)	h(MPa)	$\dot{\gamma}_0(s^{-1})$	C^R(MPa)	N

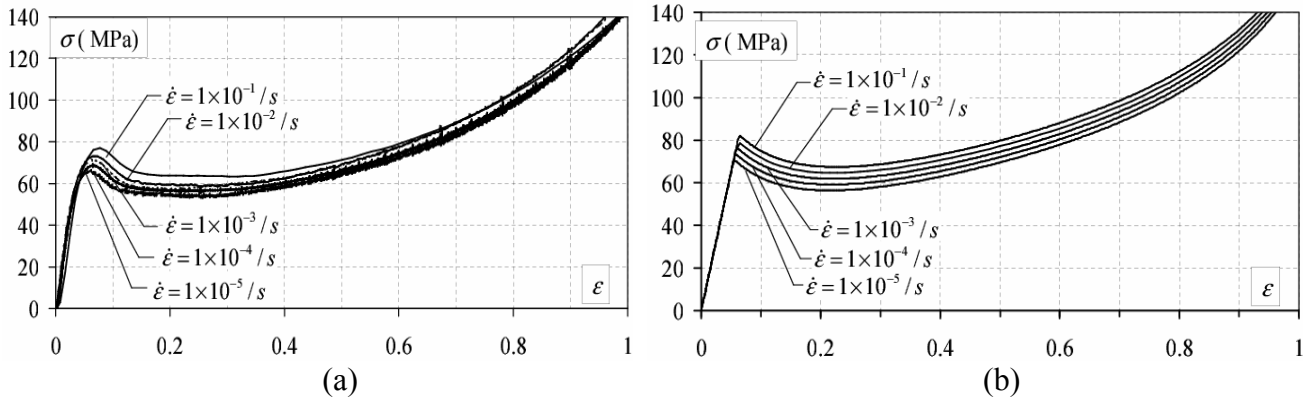

Figure 1.(a)Experimental cylinder compression stress-strain curves at strain rates varying from 1×10^{-5}/s to 1×10^{-1}/s (b) Predicted stress-strain response with the parameters identified in Table 1.

3. Problem formulation

In this section, we present the geometry of the specimen under consideration and the mesh used for the finite element analysis.

3.1. 3D analysis of a notched specimen under tension

The full 3D geometry of standard specimen loaded under mode I has dimension of h= 40 mm, w=20mm and a=10 mm , with a variable thickness B(see Fig. 2, left side). A blunted notch of radii R=0.25mm is considered. We use a blunted notch that would correspond to the blunting of a sharp crack up to this magnitude. It is also motivated by experimental issues in which practically machining a sharp notch is difficult if not impossible experimentally. The preparation of a blunted notch is preferred for the fracture measurements to be reproducible. The constitutive law described in section 2 is implemented in a UMAT subroutine in abaqus 6.10-2 [8] and used.

3.2. Description of the mesh

The geometry and the mesh are presented in Fig. 2. Refined elements are used around the notch to capture the stress-strain fields. In the region remote to the notch area coarser elements are used. The elements consist in C3D20R, which is a 20-node quadratic brick, with reduced integration. The amount of elements across the thickness is increased with the thickness increasing, their dimension remaining identical. For instance with R=0.25 mm and thickness t=1 mm, the mesh comprises of 12 layers of elements through the thickness of the specimen; a total number of 15558 quadratic elements and 70574 nodes are employed. The smallest element has an edge of 0.0027mm. A constant displacement rate $\dot{u}$=5 mm/s is prescribed on the top surface to mimic a Single Edge Notch Tension for all calculations.

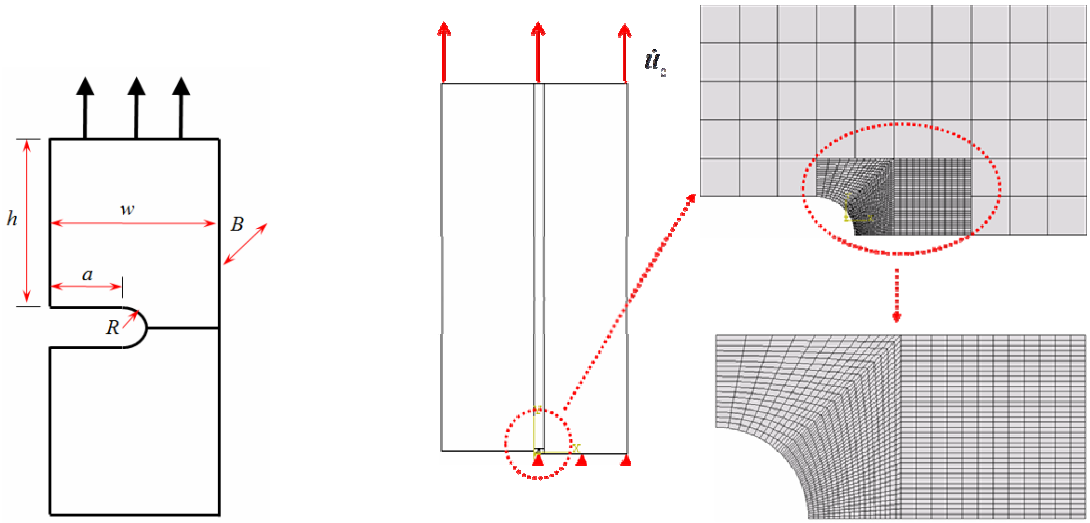

Figure 2. Geometry and mesh description for the Single Edge Notch Tension configuration

4. Results

In this section, we investigate the influence of the thickness on crack tip fields of blunt-notched specimens (see section 4.1.), with notch radius R=0.25mm. During the loading, plasticity initiates at the notch tip and extends on the notch region. The distribution of accumulated plastic shear strain around the notch is reported in Fig. 3. The variation of the maximum mean stress with the loading history represented by the overall axial strain $E_{axial}=u/2h$ is presented next.

4.1. Influence of the thickness on crack tip plasticity

Three sets of plastic shear strain distributions, and related contours, are reported in Fig. 5(a)-(i) at various load levels in terms of axial strain E_{axial} , for specimen thickness t=0.25 mm,1 mm and 4 mm, respectively.

For the thickness t=0.25 mm (t/R=1), we present in Fig. 3(a-c) the plastic shear strain distribution at the onset of plasticity(see Fig. 3(a)) and continued deformation(see Fig. 3(b) and 3(c))on the surface as well as at the center of the specimen. Far from the notch, no plasticity takes place and the response is elastic. Around the notch, we observe that the plastic zone initiates and grows simultaneously at the surface and in the center of the specimen, but the shape of the plastic zone is different. At E_{axial}= 0.75% it is seen that certain amount of plasticity arises around notch tip(see Fig. 3(a)). A homogeneous plastic zone inclined −30° from the equator is observed at the center, whereas a bifurcated plastic zone appears on the surface. With ongoing deformation, plastic zones both inside and outward expand rapidly. In Fig. 3(b), as E_{axial} equals to 0.875%, the plastic zone at the center gets a flame-like profile. At the surface, the plastic zone expands into a flame-like elongated plastic zone as well, which grows nearly parallel to the equator. Finally, as indicated in Fig. 3(c), a larger elongated plastic zone along the equator is observed at the center, whereas a similar elongated plastic zone appears parallel to the equator on the surface. For the configuration with thickness t=1 mm(t/R =4), at E_{axial}= 0.75%, plasticity initiates with very small amount of plasticity on the surface, and in the form of tiny shear bands at the center(see Fig. 3(d)). For E_{axial} about 0.875%, plasticity areas do not proceed much both inside and outward(see Fig. 3(e)), as compared with Fig. 3(b). Finally, instead of forming a flame-like elongated plastic zone as the t/R=1 case, a circular-arc shaped plastic zone concentrated near the crack tip at the center(see Fig. 3(f)). Thus, the plastic zone appears different for t/R=1 and t/R=4 till now. If the thickness of specimen is further increased to t=4 mm(t/R=16), in Fig. 3(g), when plasticity initiates at E_{axial}=0.75% , clear shear bands arise around the notch in the center, whereas on the surface only a tiny area of plasticity is observed. As E_{axial}=0.875%, shear bands continued to widen and diffuse at the mid-thickness, on the other hand, still tiny amount of plasticity exists on the surface (see Fig. 3(h)). With E_{axial} up to 1.125%, plastic deformation on the surface is still confined in a tiny region, whereas shear bands at the center enlarge a lot within a circular-arc, as shown in Fig. 3(i). This observation is similar to the plastic zone reported by Lai and Van der Giessen [1].

For the thinner specimen considered with thickness t=1mm(t/R=1), we observe that the magnitude of plastic zone at the center is comparable to that on the surface, which rationalize the fact that the plane stress conditions prevail. In the case of t/R=4, the plastic zones appear significantly less elongated when compared to the case with t/R=1, both in the middle of the thickness and at the

surface for the same overall deformation. Besides, the plastic strain distribution at the center is no longer comparable to that on the surface as in Fig. 3(a)-(c). This phenomena that plasticity on the surface failed to proceed as much as that at the center(see Fig. 3(d)-(f)) represents a transition from plane stress to plane strain conditions within the material. Finally, for the thick specimen with t/R=16 (thickness of 4mm), the apparent discrepancy in the shape of locally deformed area at the mid-thickness and on the surface indicates that plane strain condition dominates in the specimen.

The shape of the plastic zone corresponding to a flame-like profile under plane stress condition(see Fig. 3(c)), is found to agree well with Hashemi's [2] observations of the plastic zone in thin polymer films tests in EWF method. As the thickness over notch radius ratio $t/R \geqslant 4$, we observe at the center of the specimen the development of shear bands similar to those predicted by Lai and Van der Giessen [1] who performed 2D plane strain calculations, for a mode I load. These observations can be used to estimate the region where plane stress and plane strain prevail. In particular, it can be used as an indicator to assess whether or not plane strain conditions are dominant. Actually, for the case with t/R=16(4mm thickness specimen), plane strain conditions with characteristic shear bands are observed, similarly to those predicted by Lai and Van der Giessen [1] and observed experimentally (Ishikawa et al. [13] for instance). For this series of calculations, plane stress conditions prevail for t/R<4, plane strain effects emerge for t/R=4 and these conditions become dominant when t/R> 4, as shown for the case with t/R=16.

On the other hand, the case corresponding to plane strain conditions exhibits the largest magnitude of the maximum mean stress for a given loading. This case is investigated in detail in Lai and Van der Giessen [1] who evidenced that the location of the maximum mean stress coincides with the intersection of well defined shear bands that enhance its magnitude. The plots of the maximum mean stress with loading of the 3D calculations are bounded by those corresponding to the 2D planes stress and 2D plane strain cases. The calculations with thickness t=1mm (t/R=1) results in a plot of the maximum mean stress with loading close to that of the 2D plane stress case. As the thickness increases, the maximum mean stress-loading curve moves from the 2D plane stress to the 2D plane strain case. The shift is clear when carrying from 1mm to 4 mm in thickness and its variations becomes modest for larger thicknesses. The plots reported in Fig. 4 provide insights on whether plane stress or plan strain condition is dominant, for a given thickness to notch radius ratio. The foregoing observation that plane strain conditions become dominant at about t/R=16 is confirmed by the analysis of the maximum mean stress during loading. This somehow confirms the qualitative analysis based on the shape of the plastic zone presented in the previous section and evidences the influence of the thickness mean stress constraint in the notch region.

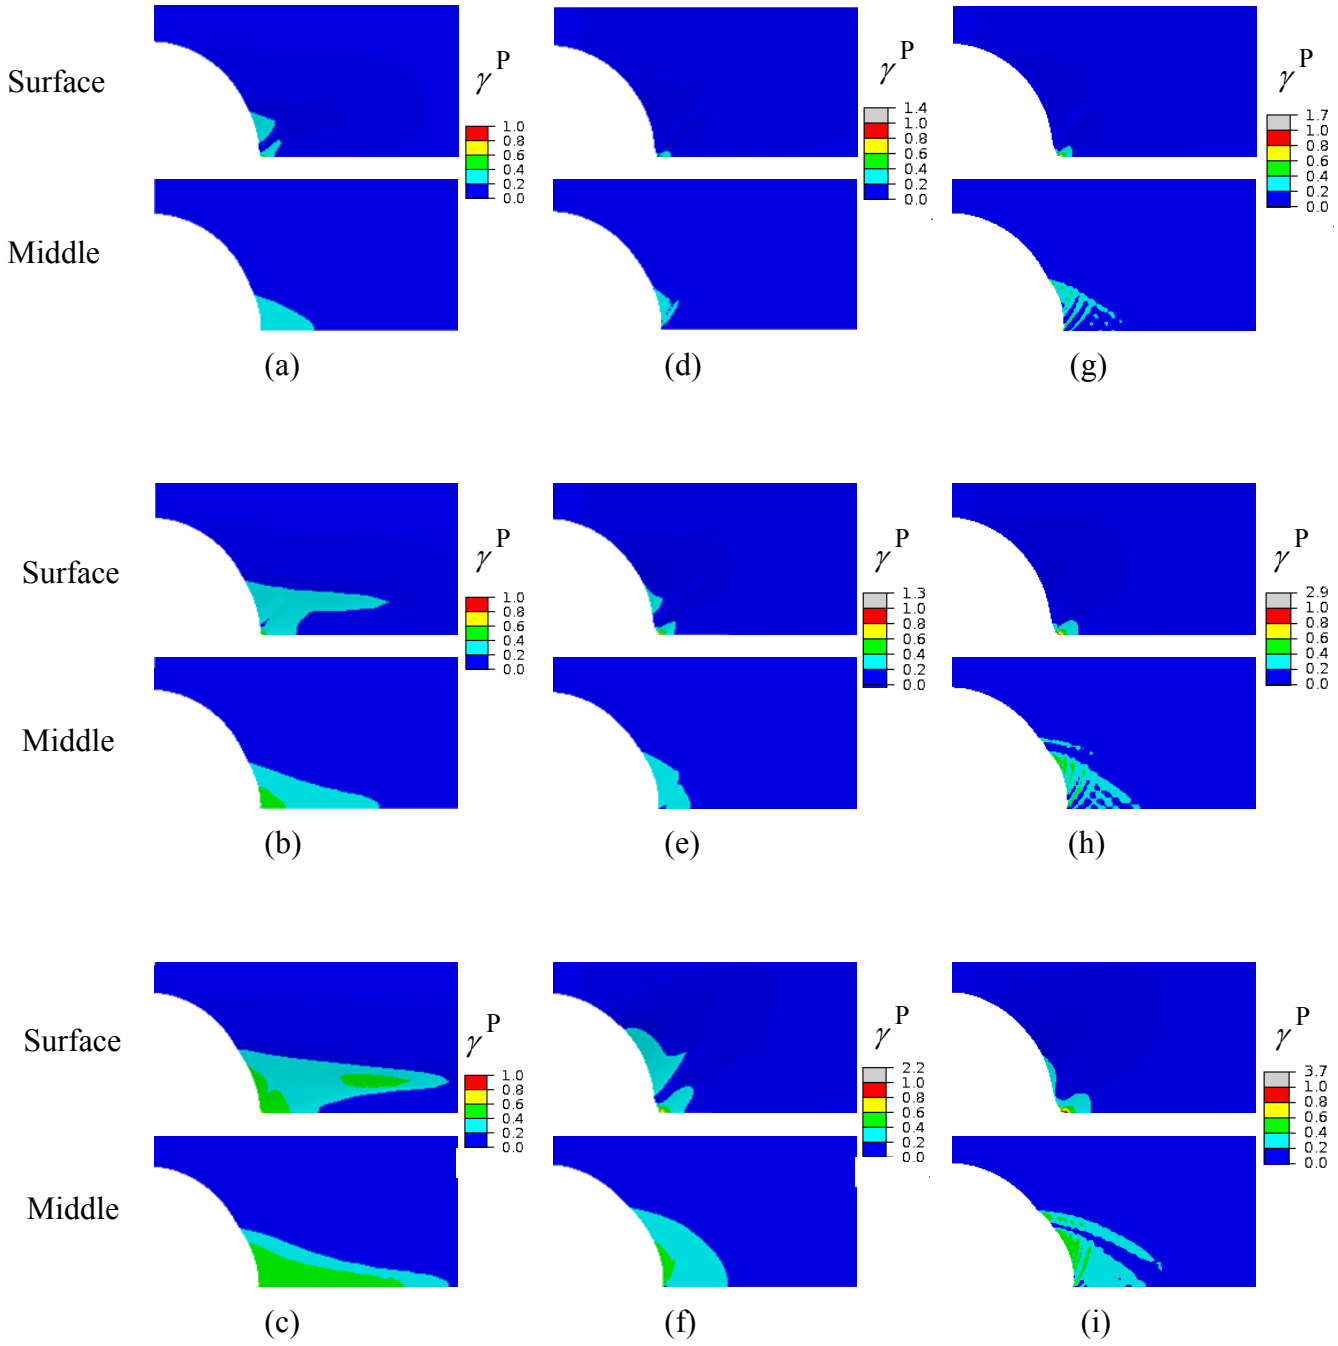

Figure 3. Plastic shear strain distribution at the surface and the mid-thickness, for R=0.25mm, at E_{axial}=0.75%, 0.875% and 1.125%, (a-c) for t=0.25mm; (d-f) for t=1mm; (g-i) for t=4mm.

4. Discussion and conclusion

The calculations performed in present work allow to compare the plastic zone at the center as well as on the surface of specimens. Plastic shear strain distribution of blunt-notched polymer bulks are reported, corresponding to specimens with various thicknesses and an initial blunted notch R=0.25mm.

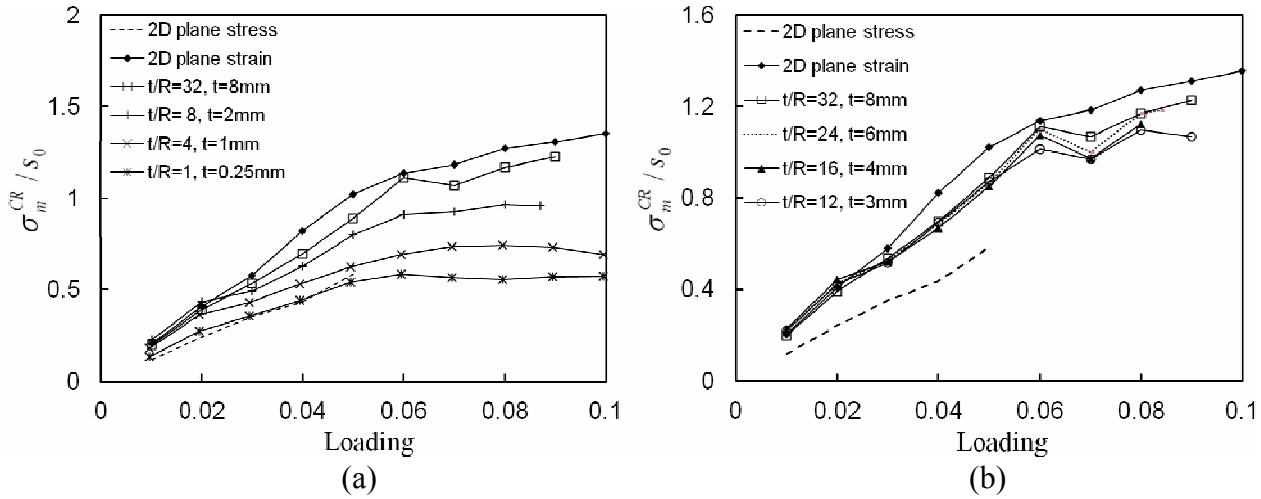

Figure 4. Variation of the maximum mean stress with loading for the 3D specimens of various thicknesses and 2D configurations under plane stress and plane strain conditions (R=0.25mm)

The shape of the plastic zone is shown useful as a marker for identifying if plane stress or plane strain conditions prevail. For the mode I under consideration here, a flame-like plastic contour is observed where plane stress conditions are met, for a small thickness and a ratio $t/R\leq$ □?4(thickness/notch radius). The shape of flame-like elongated plastic zone for the specimen with t/R=1 is in agreement with Hashemi's observations reported in [2]. By increasing the thickness and the ratio t/R, the shape of the plastic zone evolves from the flame-like to a plastic strain distribution. As for specimens with t/R=16, typical shear bands appear at the center of polymer, which are similar to that observed in Hill's slip line field and comparable to that reported by Lai and Van der Giessen[1]. The onset of a transition from plane stress or plane strain condition is observed as soon as the ratio thickness/notch radius t/R= 4. This observation is consistent with that reported by Parvin and Williams [3], if one considers the radius of the blunt crack $R_p\approx$ R is ductile polymer with a blunt notch. Thus, we propose a criterion to distinguish between plane stress and plane strain conditions. Although the criterion $t/R>$ 4 for plane strain conditions to emerge is established to R=0.25mm, we have investigated samples with a smaller (0.1mm) and a larger (0.5mm) notch radius. The variations of the plastic zone shape with the ratios t/R reported in Fig. 3 are also observed for R=0.1mm and R=0.5mm. This observation appears valuable when one considers an initial blunt notch.

For the configuration with an initial sharp crack, the onset of failure is usually taken from a Crack Tip Opening Displacement that is measurable experimentally. The CTOD is the characteristic of the material under consideration and its magnitude could be used as the value of the blunted notch radius and compare to the thickness in order to evaluate the minimum thickness for plane strain conditions. This information is valuable for one concerns with experimental polymer fracture and the issue of the size requirements for the estimation of the material's toughness. The present predictions need to be compared to experimental results. This is currently under progress and some preliminary results can already be reported. We have prepared the samples depicted in Figure 2 and performed some SENT fracture tests. In figure 5, we report the variation of the stress at rupture with the thickness. All samples have the same geometry in terms of crack length versus specimen width and the same height. In Fig. 5, we observe that the stress at rupture decreases with the thickness increasing with a plateau being reached for t/R=16. These first results are consistent with the predictions found here as the lowest stress at fracture is found for a specimen thickness larger than 4mm. A more detailed experimental investigation is under progress and will be addressed in a forthcoming paper.

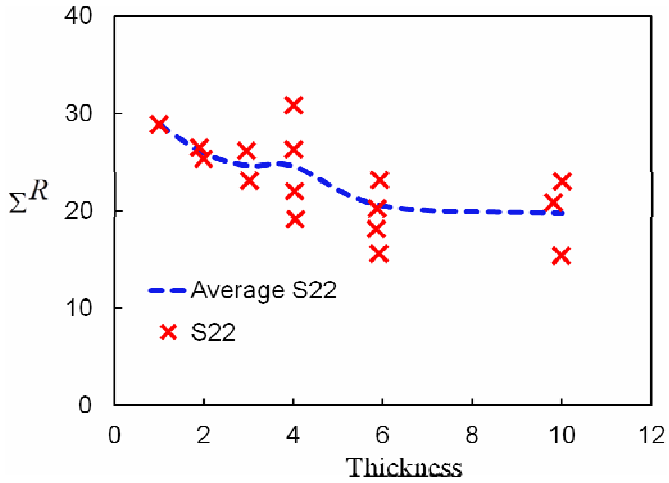

Figure 5. Experimental investigation of the stress at rupture from SENT specimen identical to those depicted in Fig. 2

A Damage Model for Sandwich Plate with Viscoelastic Core in three-Points Bending Fatigue Experiments

Xue QiChao[1], Zou GuangPing, Xiong Hailin

Department of Aerospace and Civil Engineering, Harbin Engineering University, Harbin, 150001, China

Abstract In three-points bending fatigue experiments of sandwich plate with visoelastic core and steel facplates, recovering effects of fatigue life are found for its viscoelastic properties of the core. If the fatigue experiment is interrupted and rest for some time before reloading, there will appear a phenomenon that the deflection doesn't reach the former value immediately but after a specific time or cycles. From defining the damage variable *D* as the ratio between the differences of maximum allowable bending deflection and processing deflection in experiments, the fatigue damage equation are established. To considering the recovering effects, a formula which is similar with deflection of isotropic viscoelatic beam under concentrated load in midspan is introduced in damage equation. The experiments result shows that this damage model considering recovering effects can demonstrate the damage very well for sandwich plate with viscoelastic core. And the existing of viscoelastic core can increase the fatigue life of sandwich beam specimen.

Keywords Sandwich, Viscoelastic Core, Fatigue, Damage Model

1. Introduction

Sandwich plate with viscoelastic core is widely used in civil engineering and shipbuilding fields [1]-[3] for weight reduction, rapid reparation, vibration isolation, noise reduction and resisting impact. It also has better fatigue resistance characteristic than ordinary steel structures. From the fatigue experiment, it is found that the existing of recovering effects by intermittent loading have influences on the fatigue life. Based on damage theory, a fatigue damage model is proposed to elaborate the damage of specimen considering recovering effect. From intermittent test, the recovering effect is affirmed and damage model is verified that it have a certain accuracy.

2.Fatigue experiment phenomenon

In the fatigue experiment process of practical engineering, structural fatigue load applied on structure load is often not continuous, but intermittent. For the exiting of viscoelastic core in sandwich plate, it makes the responses of sandwich beam specimen under three-points bending fatigue load different from ordinary sandwich plate's responses. From the three-points bending fatigue experiment process, the following phenomenon are found:

(1) Under pressure-pressure fatigue load to three-points bending specimen, along with increasing of cycle number, vertical deflection is also increased, for specimens with smaller interlayer cohesive force, the first crack appears in one end and gradually propagates as cycles increasing. When the vertical displacement reaches a certain level, there doesn't appear fracture or crushing phenomenon. But there will be propagation of the crack or tearing of core.

(2) When fatigue loading is intermittent, that is, interrupt fatigue load and unload, after a long time (such as a few hours), fatigue loading is applied once again. Then it is found that the vertical

[1] Xue1736@163.com

displacement cannot directly reach the previous loading position under the same load, but after a certain time or cycles before reaching the former position.

In the entire loading-stop-reloading process, overall fatigue life will increase than under continuous fatigue load. As shown in Figure.1, the curve of ‘a’ is the first load curve. When the loading process reaches a certain positions (at‘d’ or ‘e’), stop and unload for a while, then reload. The cure will follow the curve ‘b’ or curve ‘c’ before reaches the intersection point superimposed with the original curve ‘a’, rather than a direct continuation of load curve ‘a’. In this process, the number of cycles corresponding to the portion shown in the dashed line means the additional growth of fatigue life. The following attempts to establish a fatigue damage model to describe this phenomenon.

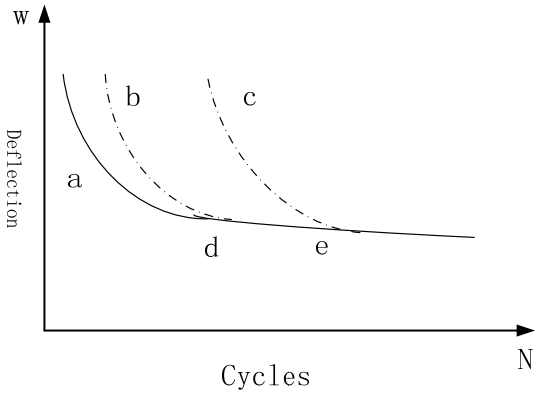

Fig.1 Loading-stop-reloading process

3. The fatigue damage model considering intermittent effects

Substantially the first few cycles of all fatigue tests exist nonlinear characteristic. For the metal material, these cycles does not exceed 100 before reach stable stage, but for the polyurethane elastomer sandwich panel, the presence of viscoelastic core make the initial cyclic loading can last a long time. When the load level is low, the number of cycles can even reach thousands of times. For the whole fatigue life of material, it cannot be ignored. Here according to the classical linear fatigue damage theory [], fatigue damage model will be established to consider the intermittent effect.

In a one-dimensional fatigue damage theory, the damage of the material can be represented by the damage variable *D*, it is usually a function of load cycles:

$$D=f\left(\Delta\sigma,\overline{\sigma},N,\cdots\right) \tag{1}$$

In which $\Delta\sigma$ is the stress amplitude, $\overline{\sigma}$ is stress mean, *N* is the cycles. Then the material damage can be defined by the damage variable:

$$\begin{aligned} D&=0, \quad N=0 \\ D&=1, \quad N=N_{\max} \end{aligned} \tag{2}$$

In order to describe the influences of the recovering effect, here introduce the damage variable D_{eff}, which is defined as the effective damage. When the variable is equal to 1, the material is destructive. It can be obtained by uninterrupted fatigue loading process. It also can be gotten by analysis the curve shown in Fig.1, the solid line corresponds to the effective fatigue life. The dashed parts of the curve can be considered to be invalid damage, but it need to be included in the whole fatigue life.

Suppose it is piecewise loading throughout the cycling loading process, and the loading frequencies are the same. Define the degree of recovery function $N_b\left(t,\Delta\sigma,\overline{\sigma}\right)$, if the stop time is t_{n-1} before the *n-th* loading, after reloading *N* cycles, the damage of reloading can be written as

$$D_{eff,n}=\Delta D_n=\begin{cases}0 & \mathrm{N}_n \le \mathrm{N}_b \\ f((\mathrm{N}-\mathrm{N}_b),\Delta\sigma_n,\overline{\sigma_n}) & \end{cases} \tag{3}$$

In which $D_{eff,n}$ is the damage of *nth* loading, and N_n represents the cycles of *n-th* loading. $f((N-N_b),\Delta\sigma_n,\overline{\sigma_n})$ is the function to calculate cumulated damage. Then whole damage of specimen can be written as:

$$D_{eff,n}=\sum_{n=1}^{n}\Delta D_n \tag{4}$$

Whole loading cycles is:

$$N_{total}=\sum_{n=1}^{n}\mathrm{N}_n \tag{5}$$

Cycles corresponding effective damage is

$$N_{eff}=\sum_{m=1}^{m}N_m\text{-}mN_b \tag{6}$$

In which *m* are times of stop-reload. To identify fatigue damage model considering the effect of recovering, most important thing is to define recover degree of function, it depend on theoretical analysis or experiments.

In order to simplify the analysis, the damage function uses linear cumulative damage model, based on the analysis of the Miner [4], damage parameters is related with the number of cycles, and has nothing to do with the load order. The analysis here supposes the damage is only related with the previous loading:

$$D(n)=\frac{n-n_{if}}{N_f-n_{if}}\quad n\ge n_{if} \tag{7}$$

n_{if} is the threshold of recover degree of function, and *n* is the loading cycles. For constant amplitude fatigue tests, the fatigue damage after load *N* times should be modified as follows:

$$D(N)=\frac{\sum_{m=1}^{m}N_m\text{-}mN_b}{N_{eff}\text{-}N_b}\quad N\ge N_b \tag{8}$$

4. Recover degree function N_b

The Recover degree function is generally determined by the experiment, for the sandwich beam with viscoelastic core it can be roughly determined the by theoretical analysis. For no obvious or small plastic deformation case, the loading loop is stable, and the average displacement can be calculated by followings:

$$w_{2n}^{middle}=\frac{1}{2}(w^{n\to\infty}_{(2n)t_1^+}+w^{n\to\infty}_{(2n)t_1^-})=\frac{Q_1+Q_2}{2}\frac{l^3}{48E_fI_f}+\frac{1}{E_0}\frac{l(1+\mu_c)}{2(A_c)}\frac{1}{1+e^{\frac{E_0}{\eta_0}t_1}}(Q_1+e^{\frac{E_0}{\eta_0}t_1}Q_2)$$
$$w_{2n+1}^{middle}=\frac{1}{2}(w^{n\to\infty}_{(2n)t_1^+}+w^{n\to\infty}_{(2n)t_1^-})=\frac{Q_1+Q_2}{2}\frac{l^3}{48E_fI_f}+\frac{1}{E_0}\frac{l(1+\mu_c)}{2(A_c)}\frac{1}{1+e^{\frac{E_0}{\eta_0}t_1}}(Q_2+e^{\frac{E_0}{\eta_0}t_1}Q_1) \quad (9)$$

In which w_{2n}^{middle} and w_{2n+1}^{middle} are the means of displacements when cycles are equal to *2n* and *2n+1* respectively. E_f is modulus of elasticity, I_f is moment on inertia of specimen; *b* is the width; *l* is the gauge length; A_c is section area of core. E_0, μ_c and η_0 are viscoelastic parameters of core; Q_1 and Q_2 are maximum pressure load and minimum pressure. When the specimen is reloaded after loading a certain cycles, it is equivalent to load a reverse static effect (Q_0) based on former deformation, so the displacement of unload can be obtained by subtracting the two displacements. Here take the mean of deflection of when cycles are equal to *2n*:

$$\begin{aligned}w_{2n}^{unload}&=w_{2n}^{middle}-w(t)\\&=(\frac{(Q_1+Q_2)}{2}-Q_0)\frac{Q_0l^3}{48E_fI_f}+\frac{1}{E_0}\frac{l(1+\mu_c)}{2(A_c)}\frac{1}{1+e^{\frac{E_0}{\eta_0}t_1}}(Q_1+e^{\frac{E_0}{\eta_0}t_1}Q_2)-\frac{Q_0l(1+\mu_c)}{2(A_c)}\frac{1}{E_0}(1-e^{-\frac{E_0t}{\eta_0}})\\&=(\frac{(Q_1+Q_2)}{2}-Q_0)\frac{Q_0l^3}{48E_fI_f}+\frac{1}{E_0}\frac{l(1+\mu_c)}{2(A_c)}\left[\frac{1}{1+e^{\frac{E_0}{\eta_0}t_1}}(Q_1+e^{\frac{E_0}{\eta_0}t_1}Q_2)-Q_0(1-e^{-\frac{E_0t}{\eta_0}})\right]\end{aligned} \quad (10)$$

After stop a certain time t_0, reload the specimen for *k* cycles, Specimen displacement w_{2n}^{reload} can be written as:

$$\begin{aligned}w_{2k}^{reload}&=w_{(2k)t_1^+}+w_{2n}^{unload}\Big|_{t=t_0}\\&=Q_1\frac{l^3}{48E_fI_f}+\frac{1-e^{-\frac{E_0}{\eta_0}2kt_1}}{1+e^{\frac{E_0}{\eta_0}t_1}}\frac{1}{E_0}Q_1\frac{l(1+\mu_c)}{2(A_c)}+\frac{e^{\frac{E_0}{\eta_0}t_1}(1-e^{-\frac{E_0}{\eta_0}(2k+2)t_1})}{1+e^{\frac{E_0}{\eta_0}t_1}}\frac{1}{E_0}Q_2\frac{l(1+\mu_c)}{2(A_c)}\\&+(\frac{(Q_1+Q_2)}{2}-Q_0)\frac{Q_0l^3}{48E_fI_f}+\frac{1}{E_0}\frac{l(1+\mu_c)}{2(A_c)}\left[\frac{1}{1+e^{\frac{E_0}{\eta_0}t_1}}(Q_1+e^{\frac{E_0}{\eta_0}t_1}Q_2)-Q_0(1-e^{-\frac{E_0t_0}{\eta_0}})\right]\end{aligned} \quad (11)$$

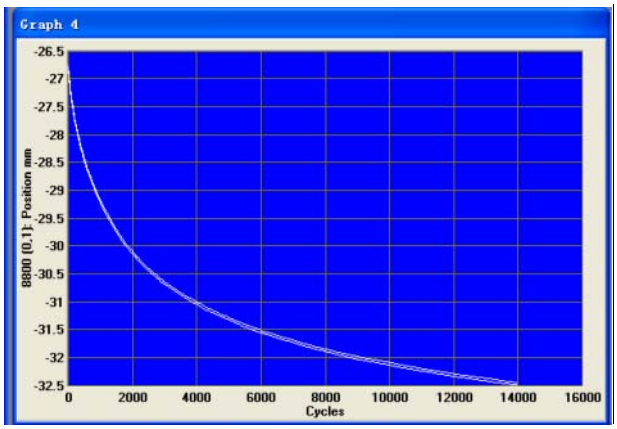
Make $w_{2k}^{reload}=w_{2n}^{middle}$, loading times *k* can be approximated solved, which is the extra fatigue life from the reload. When recovering function is determined, we can calculate the extra fatigue life of intermittent fatigue loadings.

5 Intermittent fatigue experiment

In order to verify the proposed fatigue damage model considering intermittent loading, intermittent fatigue experiments are carried out and the theoretical result are also calculated by using of equation (11). Specimens are tested which is shown in Figure. 2 and the loading level is equal to 0.7; ratio of stress is equal to 0.9. The loading frequency is 2Hz, after loading 14000 times, the response of specimen is stable, then unloading and resting for 1 hour, the cycles-deflection curve are shown in fig.2

In the first time loading process, the deflection of specimen is about 10.31mm. Reloading after 1hour, when the deflection reached 10.31mm again, the corresponding cycles is about 2100. If

taking deflection as damage value, it means the extra fatigue life from the rest. The results calculate by using of equation(11) are shown in Fig3, the rising curve of the graph presents the data of w_{2k}^{reload} - w_{2n}^{middle} specimen after resting for 1hour. The straight line presents the coordinate value which is equal to 0. From the Fig3a, the rising curve is infinitely close the straight line, which means in ideal state, the reloading curve is approaching to the straight line of steady state. But in actual experimental conditions, the steady line is an oblique line which declines with cycles increase. So we consider it intersected when the gap between two curves is 0.01mm. In this case, the corresponding cycles of Fig.3a is about 1580. Comparing Fig.2 and Fig.3, a certain error exists which is about 24.7%. One reason is viscoelastic model of polyurethane core is simplified to Kelvin model, another reason is theoretical calculation doesn't consider the plastic deformation of specimen in cyclic loads. According to theoretical analysis, if the rest time is long enough, each rest has same recovering fatigue life. But from the experimental result, the recover fatigue lives are different for multiple reloading. From Fig.2c and Fig.2d, the recover life of third reloading is 1300 cycles, and at the ninth reloading, recover life is 650 cycles. This means in multiple reloading processes, there are damages in the specimen, which cause the decrease of recover fatigue life.



a 1st loading 14000 cycles

a Rest for 1 hour（60min） b Rest for 6min

Fig.3 Recovering fatigue life curve

Fig.4 is the recover fatigue life calculation results obtained in different rest time by using of formula (11) in ideal state. As can be seen from the graph, the rest time of specimen need is very short. After rest for 750s the specimen can reach a stable state. And the corresponding recover fatigue life is approximately 1580 times, it is same to Fig.2a.

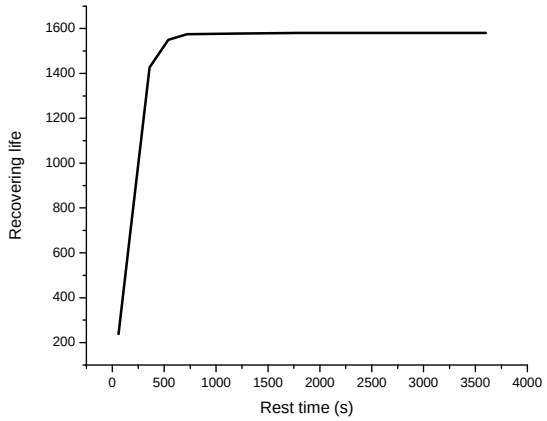

Fig.4 Recovering fatigue life for different rest time

Table.1 Experimental results for single specimen

Rload No.	Rest time（hour）	vertical deflection (mm)	Recover fatigue life	Cycles before rest	Damage
1	1	10.31	2100	14000	0.080
2	1	10.84	2060	7000	0.040
3	2	10.84	1790	2060	0
4	1	10.88	1680	2100	0
5	1	10.88	1360	1680	0
6	16	10.88	1140	1360	0
7	1	10.88	890	1040	0
8	1	10.88	710	890	0
9	1	10.88	600	710	0
10	1	15.03	2230	32700	0.188

11	14	20.1	2140	37300	0.214
12	15	25.3	2210	40700	0.234
13	14	30		41900	0.241
Total				187440	1

Table.1 is intermittent experimental results for single specimen, and it is also found that after multiple times reloading, if the deflection of last reloading is surpass the former loading, the recover fatigue life will increase. This is can be explained by damage viewpoint, that is because the new plastic deflection make the damage-resistance refreshed.

Equivalent damage of each reloading is also calculated by former method and listed in Table.1. Fatigue life result of each experiment is listed too. From Table, the total fatigue life is 187440, in which effective damage cycles is 173600. The recover fatigue life increases about 5.36% than specimen without rest and stop.

6 Conclusion

Recovering effects for sandwich beam with viscoelastic core are found in three-pionts bending fatigue test. A fatigue damage model considering recovering effects and recovering degree function of sandwich beam are proposed here. The intermittent fatigue experiment is carried out and the results show that the recovering fatigue life of specimen should not be ignored in loading-rest-reloading test and the damage model proposed here can describe the fatigue damage considering intermittent effects in certain accuracy.

Abstract Many fundamental as well as technical issues with PENT (ASTM F2136) are identified, for instance the inability of separating crack growth from crack initiation, too long duration of the test for new generation of PE, outdated test conditions unchanged since the original formulation designed for old PE materials, etc. Therefore, there is a quest for a new accelerated test method. Recently, a circular notched specimen (CNS) has been proposed as an accelerated fatigue testing. However, formation of an asymmetric crack in CNS and early transition to a ductile failure limit the applicability of CNS test for studies of SCG. There are several factors responsible for the asymmetry of SCG. Especially, geometric misalignments of CNS are the most common practical weakness of the test. The present paper reports the observation of asymmetric SCG in CNS under fatigue conditions and analysis by finite element method (FEM) of the CNS misalignments effect on the crack growth asymmetry. Root causes of the asymmetric crack growth and its effect on the time to failure (fatigue lifetime) are discussed.

1. Introduction

Plastic pipes have become popular in the pipe industry owing to their distinct advantages, which include low cost, low weight, good impact resistance, flexibility, and chemical resistance. However, it is known that plastic gas pipes such as polyethylene (PE) pipes do not have enough crack growth resistance to both ductile and brittle fracture as compared to metal gas pipes. To solve these critical problems, the plastic industry has dedicated a lot of effort to improving the crack growth resistance of pipe-grade PE to both ductile and brittle fracture. As a result, PE100/PE125-grade PE gas pipe resin has been developed by several PE resin manufacturers. However, current test standards for characterizing the crack growth resistance of PE are inadequate owing to the unique crack growth characteristics of PE. The American Society for Testing and Materials (ASTM) and the International Organization for Standardization (ISO) have proposed a few standard test methods for quantifying the resistance to slow crack growth of commercial pipe-grade polymeric materials such as PE [1].

However, since current test methods only suggest the recording of the time to failure, it is impossible to observe the response of the deformation and/or the crack growth behavior of the sample during tests. Consequently, most current test standards cannot distinguish between crack initiation and crack growth, which necessitates a new experimental method. The PENT test is suggested in ASTM as a standard test method for evaluating slow crack growth in PE materials [1], but this test lacks the capability to separate the crack propagation and crack initiation characteristics. Moreover, this test is designed only for a single stress level (2.4 MPa) based on old PE material and, therefore, there has been some criticism surrounding this standard. In stage II, it may be important to understand the crack initiation and crack propagation, and these should be addressed separately. In cases of crack propagation determining brittle fracture, there have been many experimental and analytical results, and the crack layer theory [2,3,4] is promising in predicting the complex continuous/discontinuous crack propagation observed in polyethylene. Meanwhile, studies of crack

initiation are relatively scarce due to uncertainty of its mechanism [5]. To solve these problems, some researchers have recently developed a new test that uses a circular notched specimen (CNS) (Fig. 1) to characterize the crack growth resistance and rank PE materials. Numerical investigation of the distribution of the stress intensity factors (SIFs) in CNS has been conducted in [6]. The advantage of the CNS is its moderate processing cost and the ease of fabricating the precrack. The front of the circular notch in the CNS is under triaxial stress conditions, making it possible to generate the highest effective stress, so accelerated tests can therefore be performed under any loading conditions. As a result, research of crack initiation and propagation using CNS is in progress [7,8,9]. However, it is also known that CNS create a problem for characterizing the crack growth behavior of brittle materials, because the crack growth is seldom axisymmetric [10]. In Fig. 2, experimentally observed cases of practically symmetric and typically asymmetric crack growth of PE in CNB specimens are shown [10]. Zhao et al. [10] reported that even initial imperfections in material or specimen geometry may strongly affect final time to failure, and asymmetrical fatigue crack propagation is easily changed in a severely distorted asymmetric manner. This can be critical as once asymmetric crack propagation takes place, recorded time to failure is shorter than that of symmetrical crack growth with all other parameters being the same. Moreover, as described above, the degree of asymmetry increases with crack propagation. As a result, the observed slope of S-N curve for time to failure may not represent the true fatigue behavior of the material, as it depends on specimen geometry imperfections. In other words, the crack growth process is highly sensitive to the variations of specimen geometry. In contrast with that, the crack initiation time is much less sensitive to geometry, except for notch depth variation Therefore it is more reasonable to use CNS testing for ranking materials with respect to the fatigue crack initiation resistance.

(a) Symmetric fatigue crack growth (b) Asymmetric fatigue crack growth

Fig. 2 Two typical types of fatigue crack growth in CNS

Many technical issues such as the notch sensitivity (brittleness), the anisotropy of the specimen, the initial notch geometry, and the geometric alignment of the centerline of the specimen and the notch should be considered in the interpretation of experimental data for asymmetric crack formation [11].

The effects of two types of noncircular initial notch geometries of a CNB specimen, i.e., the misalignment of the centerlines of the specimen and the notch, and the ellipticity of the notch—on the crack growth behavior have been previously studied by the authors [11]. In addition, the geometric misalignment of the CNB specimen in the experimental setup is also a critical issue. There are two types of geometric misalignment:concentric and angular misalignments as well as a combination of two.— The individual effects of concentric and angular misalignments on the crack growth behavior were considered. The effect of the geometric misalignments of PE on crack growth behavior at the early stage is not very significant, but an asymmetric crack gradually develops as the crack grows.

In this study, the effects of various geometric misalignments of CNB specimens on the fatigue crack growth behavior of pipe-grade PE were investigated by three-dimensional (3D) numerical analyses. Combined misalignments (concentric and angular misalignments) and the effect of the direction of the angular misalignments (0, π/2, π, and 3π/2) of a CNB specimen were considered within the limitations of the practical difficulties created by test conditions. The variation of the SIFs with the progress of a two-dimensional (2D) crack under fatigue loading conditions based on the conventional Paris' equation was studied using 3D finite element analysis (FEA). In addition, the experimental observations of the asymmetric fatigue crack growth were compared with the 3D FEA results. Moreover, the effect of the asymmetric crack growth resulting from combined initial geometric misalignment on the lifetime to failure of the CNB specimen is also discussed.

2. Finite Element Analysis

The combined misalignment of the CNB specimen was studied by 3D FEA. The geometric misalignment,concentric, angular and their combination—were considered. The normalized concentric misalignment (e/R) was varied as 0, 0.004, 0.012, and 0.020, using CNB specimens of radius (R) 5 mm. At the same time, the angular misalignment (e_θ) was varied as 0, 0.1, 0.2, and 0.4. The directions of the angular misalignments were 0, π/2, π, and 3π/2. Combined misalignment is the combination of concentric and angular misalignments. The three types of misalignments—i.e., concentric, angular, and combined—are shown in Fig. 3(a). Fig. 3(b) shows the directions of the angular misalignments (0, π/2, π, and 3π/2). The misalignment conditions of this study are summarized in Table 1.

Table 1 Summary of misalignment conditions

	e/R	e_θ
Concentric misalignment	0.004, 0.012, 0.020	0
Angular misalignment	0	0.1, 0.2, 0.4
Combined misalignment	0.004, 0.012, 0.020	0.1, 0.2, 0.4

A commercial FEA program, ABAQUS, were used for the FEA of a 3D model of the CNB specimens in this study. All the crack tips were remeshed for each calculation of the SIFs by considering their singularities. The element was of type C3D20 (a 20-node quadratic brick), and there were 60,000 elements and 250,000 nodes for each specimen. The physical properties of the material of the FEA are listed in Table 2.

The SIFs were calculated from 16 node points of the circular (notch) crack contour—at 0, π/8, π/4, 3π/8, π/2, 5π/8, 3π/4, 7π/8, π , 9π/8, 10π/8, 11π /8, 3π/2, 13π/8, 7π/4, 15π/8, and 2π. Based on the

calculated SIF at each node, the amount of crack growth for each node was defined using the conventional Paris equation with constants C = 1 x $10^{-11.6}$ and m = 4 [4], as shown in Table 2, with the assumption of a fatigue interval of 10^5 cycles.

The critical SIF (K_c) was 75.7 MPa·$mm^{1/2}$, which was obtained from the experimental results of fractured CNB spec-imens with symmetric crack growths [19]. The lifetime to failure (termination of the crack-growth simulation) was determined when the SIF of any node point of the circular (notch) crack contour reached the critical SIF. The direc-tion of the crack growth was determined as the normal to the tangent to the circular crack (notch) contour based on the maximum tangential stress (MTS) criterion [20], as shown in Fig. 4.

3. Results and Discussions

The accuracy of the FEA was confirmed by comparing the SIFs calculated using FEA for a symmetric crack with those calculated using an analytical solution. The analytical expression of the SIFs of a CNB specimen was as expressed as below.

$$K = \frac{1}{2}\sigma_{net}\sqrt{\frac{\pi a d}{D}}\left(1+\frac{1}{2}\lambda+\frac{3}{8}\lambda^2-0.363\lambda^3+0.731\lambda^4\right)\cdot\left(1+0.1\sqrt{\frac{2a}{D}}\left(1-\frac{2a}{D}\right)\right), \quad (1)$$

where, σ_{net} is the net section stress, and a and D are respectively the crack length and diameter (d = D - 2a, λ = d/D). It was observed that the SIFs obtained from the FEA and the analytical solution were almost identical.

Combined misalignment (concentric and angular misalignments) and the effect of the directions of the angular mis-alignments (0, π/2, π, and 3π/2) of the CNS specimens were considered within the limitations of the practical difficulties of test conditions.

Fig. 5 shows the FEA results of the variation of the SIFs around the crack contour with a concentric misalignment (e/R) of 0.004-0.020 and angular misalignment (e_θ) of 0.1 and 0.4. For all cases, the direction of the angular misalignment was 0. There were only little differences in the initial SIFs, but the difference between the maximum and minimum SIF values rose as the crack grew. As expected, the maximum SIF was observed at $\theta = \pi$ and the minimum was observed at $\theta = 0$. It was also observed that when the directions of the concentric and angular misalignments were opposite, their effects neutralized each other and the normalized time to failure at high speeds decreased as

the angular misalignment increased. This means that when the direction of the angular misalignment was 0, the directions of the concentric and angular misalignments were actually opposite to each other. However, when the concentric misalignment was small, the two cases of angular misalignments of 0.1 and 0.4 early during the crack propagation had small differences between the maximum and minimum SIF values. However, as the misalignment became noticeable, the difference increased and exceeded those of other cases of the crack propagation. It could be concluded that these large differences at the early stage accelerated the crack propagation and decreased the lifetime.

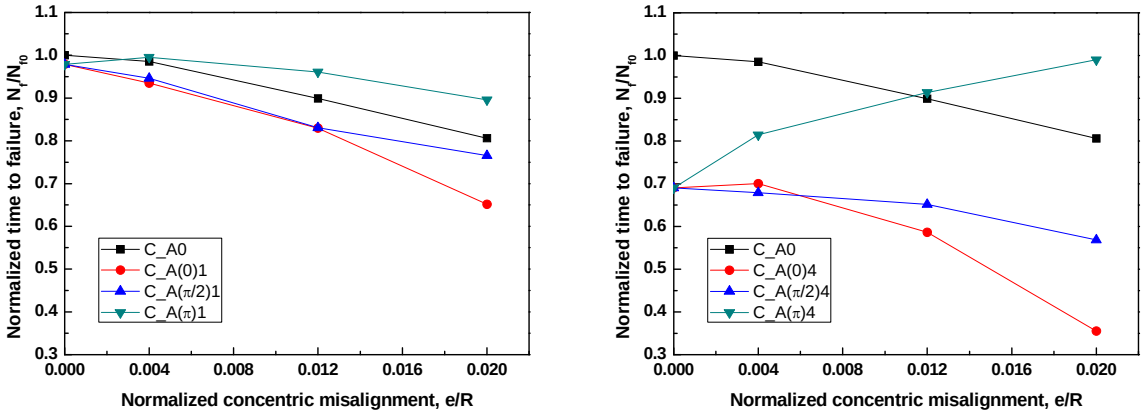
Fig. 7 The variation of normalized SIFs at the circular crack contour for 'π/2' angular direction

Fig. 6 shows the FEA results of the variation of the SIFs around the crack contour for various concentric misalignments (e/R) ranging from 0.004 to 0.200, angular misalignments (e_θ) ranging from 0.1 and 0.4, and angular misalignment direction of π. The angular misalignment direction of π

means that the concentric and angular misalignments were in the same direction. As the concentric misalignment increased, the stress distribution of the angular misalignment showed a different tendency. Although the angular misalignment was 0.1, the difference between the maximum and minimum SIF values was still small. Nevertheless, the asymmetric crack growth developed gradually as the concentric misalignment increased (see Figs. 6(a), 6(c), and 6(e)). It was also observed that as the concentric misalignment increased, the top positions of the maximum and minimum SIFs became upside down. However, when the angular misalignment was 0.4, the difference between the maximum and minimum SIF values was large at the early stage, and then gradually decreased as the concentric misalignment increased (see Figs. 6(b), 6(d), and 6(f)). Moreover, although the concentric misalignment increased, the top positions of the maximum and minimum values were not upside down; only their difference decreased. Based on these results, it can be understood that if the angular misalignment increased beyond 0.4, K/K_c became 1, after which the positions of the maximum and minimum SIF values were reversed and their difference further increased. From this result, it can be deduced that eθ rather than e/R influences the crack growth rate.

Fig. 7 shows the FEA results of the variation of the SIFs around the crack contour for various concentric misalignments (e/R) ranging from 0.004 to 0.020 and angular misalignments (e_θ) ranging from 0.1 and 0.4 when the direction of the angular misalignment was π/2. The angular misalignment direction of π/2 means that the concentric and angular misalignments were perpendicular to each other. It could be observed that the distribution of the SIFs around the crack contour shifted from the previous combination of misalignments. When the angular misalignment was 0.1, the SIFs around the crack contour did not change significantly (see Figs. 7(a), 7(c), and 7(e)). However, the distribution of the SIF around the crack contour varied more significantly. It could thus be deduced that the lifetime to failure varied somewhat as the direction of the angular misalignment changed. The distribution of the SIFs and the lifetime to failure were determined by the two misalignments. In other words, the direction of the misalignments could be critical to the reliability of the test results when using CNB specimens.



(a) e_θ=0.1 (b) e_θ=0.4

Fig. 8 Variation of the normalized time to failure under combined misalignments

Fig. 8 shows the variation of the normalized time to failure under combined misalignments. When the direction of the angular misalignment was 0, the lifetime to failure decreased regardless of the misalignment conditions. However, when the direction of the angular misalignment was π, the lifetime to failure increased up to a certain level for concentric misalignment. These results were because the concentric and angular misalignments simultaneously determined the distribution of the SIFs of the crack contour. The contributions of the two misalignments can therefore be varied. For example, when the direction of the angular misalignment was π, the shape of the asymmetric crack

growth for the concentric misalignment was opposite to that for the angular misalignment. Several other factors, such as the notch sensitivity (brittleness), anisotropy of the specimen, and notch geometry can also affect the lifetime to failure and the asymmetric crack growth of CNB specimens. However, it is clear that geo-metric misalignments of CNB specimens can significantly affect the crack growth behavior and the lifetime to failure. Therefore, it can be noticed that the installer should be careful to avoid any unintentional misalignment of the CNB specimen in order to produce reliable test results.

3. Conclusions

In this study we investigated the effects of various geometric misalignments of CNB specimens on the fatigue crack growth behavior of pipe-grade PE by means of three-dimensional (3D) numerical analyses. Combined misalignments (concentric and angular misalignments) and the effect of the direction of the angular misalignments (0, $\pi/2$, π, and $3\pi/2$) of a CNB specimen were considered within the limitations of the practical difficulties created by test conditions.

The distribution of the SIF changed with a change in the direction of the misalignments, so the lifetime to failure under combined misalignments could be varied depending on the status of the combined misalignment. For example, the time to failure increases as the angular misalignment in the direction of π increases, for up to 2% concentric misalignment of the radius of the CNB specimen It is not clear. On the contrary, the normalized time to failure for a combination of 2% concentric misalignment and 0.4 angular misalignment decreased by almost 65% compared to that without any misalignment.

Several other factors, such as notch sensitivity (brittleness), anisotropy of the specimen, and notch geometry can also affect the lifetime to failure and asymmetric crack growth in CNB specimens. However, it is clear that geometric misalignments of the specimens significantly affect the crack growth behavior and the lifetime to failure. Such sensitivity of the test results to various misalignments limit the potential of considering this test as a standard.

The interface debond analysis for sandwich beam with viscoelastic core and steel faceplates

Zou GuangPing, Xue QiChao, Chang ZhongLiang

Department of Aerospace and Civil Engineering, Harbin Engineering University, Harbin, 150001, China

Abstract a interface debond phenomenon appeared between viscoelastic core and steel faceplates when unloading in large deflection 3-point bending experiments for sandwich beam. From analysis of loading and unloading process, a reason of debond is found that it is the large deflection cause the debonding of interface firstly under the effect of shear stress. After unloading, local plastic rotation in the middle of beam lead to residual moment between upper faceplate and bottom faceplate. And the shear stress effect at interfaces is also transformed to tension stress. By double cantilever beam and single cantilever beam experimental results, a calculation method of critical deformation are given to calculate the critical strain energy release rate. then the critical crack length values of different types of the specimen are obtained.

Keywords Sandwich, Viscoelastic Core, Debond , Interfacial crack

1. Introduction

The sandwich plate structure with viscoelastic core is often used as bending components, and more and more applied in practical engineering. Characteristics of crack in viscoelastic plate is widespread concerned[1]-[3]. In this paper, the steel sandwich faceplate specimen with polyurethane viscoelastic elastomer core is tested by using of three-points bending experiments and found that due to the interface material property differences between the faceplate and the core, when the specimen is loaded in large deflection and then unloaded, it leads to delay debond phenomenon of crack for lower interfacial strength specimen. By double cantilever beam and single cantilever beam experimental results, a calculation method of critical deformation are given to evaluate the specimen damage, and determine the critical failure condition of specimen.

2. Three-points bending test

The three-points bending test for polyurethane elastomer steel sandwich plate structure is carried out according with the specification "Sandwich Plate Bending Experiments Norms". Bending strength, shear strength, bending rigidity and shear rigidity of the sandwich structure can be determined through three-points bending test. Thereby the modulus of elasticity and the shear modulus of core can be determined too. The shape of cross-section of specimen is rectangular, the thickness of sandwich core is about 11mm, and the faceplates have a thickness of 2 mm, which is shown in Figure 1.

Four different types of specimen are selected by different preparation methods and hardness of the core, which is numbered as No. 1 to No. 4 respectively. Preparation method of No. 1, 2 and 4 is directly pouring, and No. 3 specimen is the one prepare the elastomer core first, then use a strong glue to paste the faceplate and core together. Fig.2 is deflection-load curve of three-points bending experiments of sandwich plate specimen.

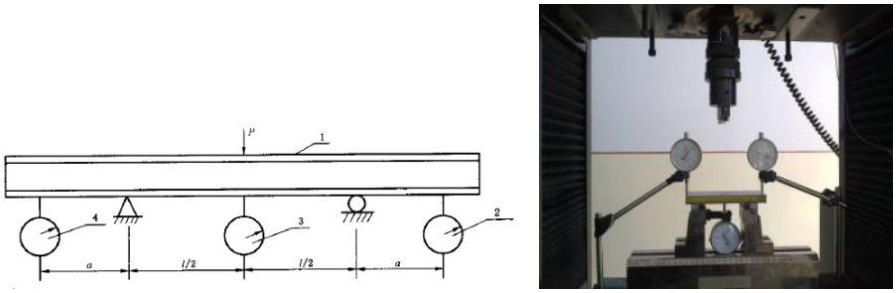

Fig.1 Three-points bending test

Table.1 Parameters and results for three-points bending tests

Specimen No. Item	1	2	3	4
Weight（g）	364.80	385.40	384.50	386.60
Hardness（D）	29	47	51	48
length（mm）	149.84	149.9	150.20	149.90
width（mm）	59.90	59.84	60.60	59.92
Thickness（mm）	13.86	15.64	16.04	14.52

Maximum stress (MPa)	26. 27	28. 00	60. 44	36. 90

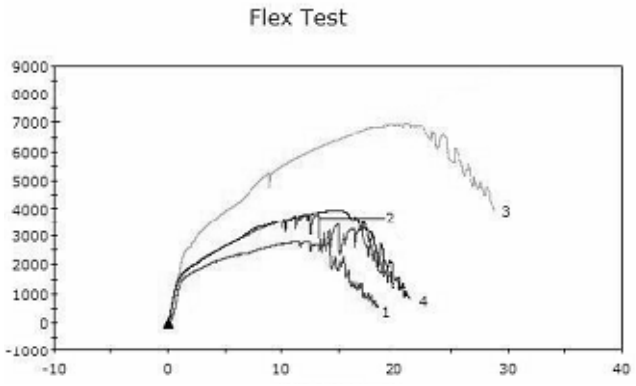

Fig.2 Deflection-load curve for sandwich plate

Observing the whole loading process of three-points bending test of Fig.2, it can be found that the destruction process can be roughly divided into three stages:

1) elastic deformation stage.

In the initial stage of loading, the faceplates and an elastomer core are in the elastic deformation, the internal stress of faceplates distributes uniformly. The faceplates bear the main bending effect, while the core is mainly responsible for shearing effect.

2) Strengthening stage.

When bending stress of faceplates reach the yield limit of the material, plastic hinge appears at the position where the crosshead contact with specimen, and the faceplates rotate around the hinge. In this stage, load-displacement curves rise slowly, on the one hand, this is because the plastic deformation of faceplate, on the other hand, it is because the specimen is constrained by horizontal reaction force at the supports due to deformation increases.

3) Failure stage.

Downward burr will appear on the load-displacement curve when the strengthening phase to a certain extent. As the increasing of load, the more burrs appears. This is because of the phenomenon of debonding between the faceplate and the core. If shear strength between the core and faceplate is smaller, there will be cracked firstly at the corner of the end position. The load curve gradually become horizontal, and great deformation of the faceplates appear along the central plastic hinge zone.

From the breakage of pouring specimen, it can be seen that the failure models of sandwich beam are large bending deformation destruction and shear failure of the interface between the steel faceplate and the polyurethane elastomer core. Such damage often occurs on the upper faceplate, but not obvious when loading. Delayed cracking phenomenon appears when unload. The so-called delayed fracture phenomenon is when the loading displacement reaches a certain limit then unloads, there is no obvious crack propagation at the beginning, but after a while, the crack propagates. For the specimens with weak bonding strength, debonding phenomenon on the upper faceplate will appear; and for the specimens with strong bonding strength, tears of the core occurs at the position of 1/3 length from the edge of the specimen. This is because a large plastic deformation of faceplates causes differences between two faceplates. When unload the specimen, the rebound effect from difference rotate angle between two faceplates make tension stress on the crack surface. When the stress is big enough, and the crack length is reach a certain value, the crack will propagate. For the viscoelasticity of polyurethane core, the crack will not propagate immediately, but for a certain time.

3 strain release rate calculation method of crack when unloading

In three-points bending test, the shearing of the vertical load result in the generation of initial crack in the edge, the bending moment when unloading is the main factors of generate crack propagating. Since the core is viscoelastic material, the crack propagation in the interface of sandwich plate

faceplate having a certain rate, and it sustain for a period of time with energy release in whole process. For isotropic viscoelastic material crack growth studies have been carried out [4], but in most cases of interface viscoelastic crack with different material, corresponding principle is no longer suitable for use. For the complexity from the singularity of the stress field of viscoelastic material interface crack, there is no effective method to solve the problem[5]. The method of this paper is constructed on the simplifications on the followings:

1) Using the critical strain energy release rate of crack to describe the debonding propagation.

2) Type I and II crack critical is obtained in case of not considering the viscoelasticity of the core material. In order to avoid the viscoelastic effect, the experimental process will last a long time. Due to the polyurethane elastomeric material is typical Kelvin solid, so there must be a limit for crack propagation, when the stress or strain energy release rate is less than this limit, the crack does not propagate; when it is greater than this limit, no matter how long the time last, cracks will propagate inevitable.

3) Through observation, crack tip was found that, because the big difference on the elastic modulus between faceplate material and viscoelastic core, when the crack propagate, there is local deformation of interface crack. The crack morphology is shown in Fig. 3a, and we simplify the deformation curve as a straight line shown in Fig. 3b.

4) Because the modulus of elasticity of the core material is low, but the deformation is large, so the stress along the direction of sandwich thickness of core is assumed uniform distribution.

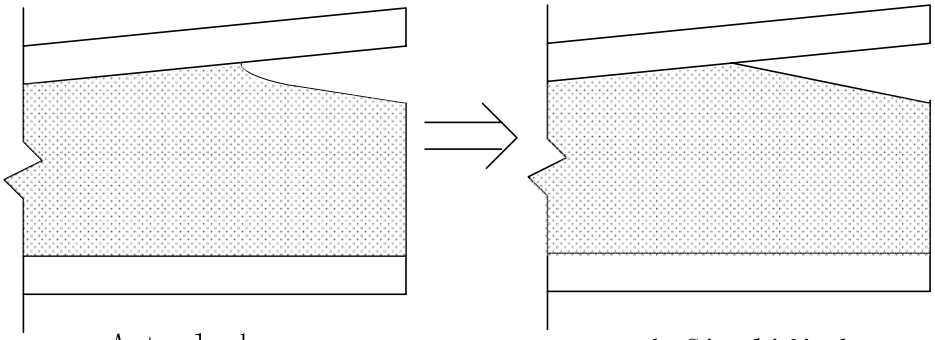

Fig.3 The simplified crack

Crack strain energy release rate can be written as:

$$G = \frac{1}{b}\left(\frac{dU_e}{da} - \frac{dU_s}{da} \right) \tag{1}$$

G is crack strain energy release rate, b is the specimen width, a is the crack length, U_e and U_s are stored strain energy and external forces work done. As shown in Figure 4， the cracking process is assumed that crack opening angle is constant in the interface crack growth, corresponding extended strain energy release rate is the critical strain energy release rate. The classical fracture mechanics

has proven the crack opening displacement and strain energy release rate are equivalent, and here we make this assumption too. Simplification of the crack propagation process is shown in Figure 4:

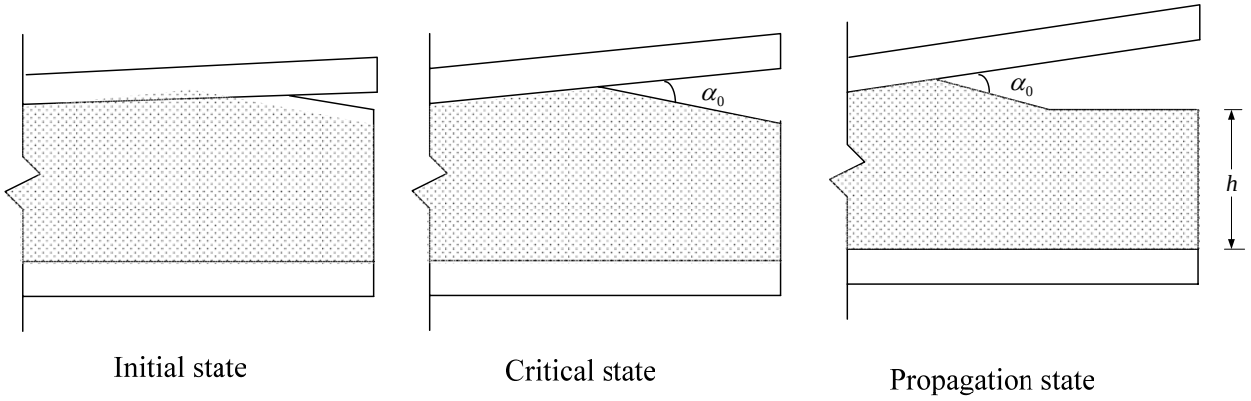

Fig.4 The simplified crack of propagation

For the initial open stage, the crack open angle gradually becomes larger and larger. In the critical state of crack, the core on the right of crack gradually unloaded to the original state, in which the internal stress is 0. In the propagation state of the crack, the crack tip angle unchanged, the right part of crack is not affected by the crack. Only core material of oblique line part is affected. Flat part unloads completely with no stress.

Take the critical state of the cracks to analyze, when crack propagate the length of δa, the corresponding angle of the upper faceplate is β_0, which increase the $\Delta\beta$. Its geometry is shown in Figure 6. When crack extended forward, the flat segment is negligible. Shaded part in Figure 5 is the sandwich viscoelastic core material, the crack extended to point *B2* from point *B1* , crack propagation angle remains unchanged, that is $\angle AB1A1 = \angle AB2A2$,*CA2=B1A1*.

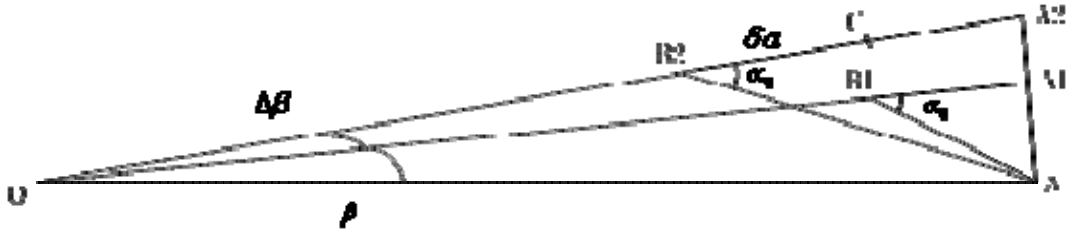

Fig.5 Geometrical relationship of crack propagation

Calculation parameters of the Figure 5, where: the length of *AA2* is $b\sin\left(\frac{\beta+\Delta\beta}{2}\right)$, the length of *AA1* is $b\sin\left(\frac{\beta}{2}\right)$, With the law of sines, we can get length of *B1A1* is $b\sin\frac{\beta}{2}\cos\left(\alpha_0-\frac{\beta}{2}\right)l\sin\alpha_0$, which is also the initial length of the crack:

$$a = l\cdot\sin\frac{\beta}{2}\cos\left(\alpha_0-\frac{\beta}{2}\right)\cdot l\sin\alpha_0 \tag{2}$$

To calculate the variation availables on both sides of the equation, we can get:

$$\delta\beta = \frac{2\sin\alpha_0}{l\cos(\beta - \alpha_0)}\delta a \tag{3}$$

If recover moment can be seen as external forces, external work done is:

$$U_s = M\Delta\beta \tag{4}$$

So the length of *A2B2*:

$$l\sin\frac{\beta}{2}\cos\left(\alpha_0 - \frac{\beta}{2}\right) l\sin\alpha_0 + \delta a \tag{5}$$

Also relationship between crack propagation length and angle changes can also be obtained from the law of sines:

$$\delta a = \frac{l\cos\left(\alpha_0 - \frac{\beta+\Delta\beta}{2}\right)\sin\frac{\beta+\Delta\beta}{2} - b\sin\frac{\beta}{2}\cos\left(\alpha_0 - \frac{\beta}{2}\right)}{\sin\alpha_0} \tag{6}$$

The change of internal energy can be embodied by calculating shaded area differences of bond stress:

$$U_e = \frac{l}{4}b\sigma_{bs}\left[\left(\frac{l}{2} - \delta a - a\right)\sin(\beta+\Delta\beta) - \left(\frac{l}{2} - a\right)\sin\beta\right] \tag{7}$$

Substituting the above formula into the crack strain energy release rate of the formulas (1), critical strain energy release rate can be calculated according to the crack propagation angle:

$$G = \frac{1}{b}\left(\frac{dU_e}{da} - \frac{dU_s}{da}\right) = \frac{1}{b}\left[\frac{1}{4}b\sigma_i\sin\beta - \frac{2M\sin\alpha_0}{l\cos(\beta - \alpha_0)}\right] \tag{8}$$

If internal parameter of formula is known, it can be approximated to the calculated strain energy release rate of the crack.

4 Cracking strain energy release rate calculation example

In order to verify the correctness of the former derivation, we need to determine the strain energy release rate of interface crack between the steel plate and the core. Literature [6] prefabricated interface crack by embedding PVC film before pouring the core. DCB experiment and SLB experiments are carried out to determine the critical strain energy release rate of I type crack for specimens with the soft hard core separately. The measured type I crack strain energy release rates are shown in table 2.

Table 2 Strain energy release rate of sandwich plate

Experiment name	The type of specimen	Energy release rate （N/m^{-1}）

Soft core	G_f	526
Hard core	G_f	1783

Combined with equation (8), at the beginning of propagation, $\beta = 0$, strain energy release rate can be calculate by the following formula:

$$G = \frac{2E_f I_f \theta}{bl\left(\frac{L_0}{2} - a\right)} \tan\alpha_0 \tag{9}$$

In which E_f is modulus of elasticity, I_f is moment on inertia of specimen; b is the width, L_0 is the actual length of specimen after large deflection; l is the gauge length; a is the crack length. When crack propagation angle α_0 and the critical strain energy release rate are determined, we can calculate the critical crack length based on the previous formulas. Since θ is a function of the bending load Q and the plastic rotation angle φ, through the analysis the formula can be obtained as followings:

$$\theta = \frac{Q\sqrt[4]{\frac{1}{4E_f I_f k^3}}}{\frac{l}{\cos\phi} - 2r} \tag{10}$$

In which $k=k_0 b$, k_0 is foundation modulus; r is the radius of supported roll shaft. Bending load Q and the rotation angle φ can be obtained from fitting the experimental load-displacement curve. Based on the former three-points bending experiment, we fit the relationship by bilinear model:

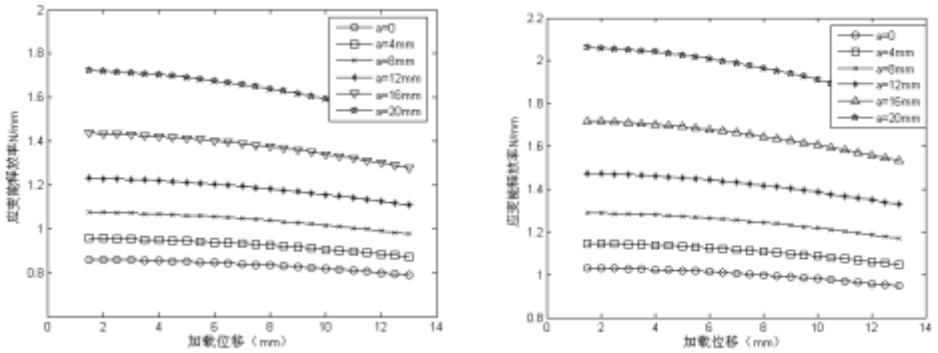
$$\text{Hard core: } Q = 1780 + (\lambda - 1.3)\tan 26.6°$$

$$\text{Soft core: } Q = 1480 + (\lambda - 1.3)\tan 16.0° \tag{11}$$

In the formula, λ is loading displacement. Combined with the crack propagation angle α_0 determined from DCB and SLB experiments, the strain energy release rate corresponding to different crack lengths can be calculated, as shown in Figure 6.

From Figure 6, corresponding to different crack length values, strain energy release rate curve is substantially parallel, and slightly decreased. The larger the crack length is, the higher the strain energy release rates are. If strain energy release rate is larger than critical value, crack propagation occurs. Variation trend (Fig. 6b) of strain energy release rate with loading displacement is similar to Fig. 6a, the error is due to the ideal elastoplastic assumptions for faceplates material. Comparing the results of soft core and hard core, difference of strain energy release rate is not very large. The

critical interface strain energy release rate of soft core and hard core is different, the hard core's critical strain energy release rate is 1.783N/mm, corresponding allowable critical crack length for specimen in this paper is 16mm; the soft core's critical strain energy release rate is 0.525 N/mm, which is less than the value of strain energy release rate at position *a=0*, This means that as long as specimen reach the yield limit, damage will be in the form of inter-layer cracking.



a Soft core specimen b Hard core specimen

Fig.6 Strain energy for different cores of specimen

5 Conclusion

Based on three-point bending experiments for sandwich plate with polyurethane elastomer core, it is found that specimens with different bond strength and core hardness have different failure modes. Here proposed a method of calculating the critical strain energy release rate to obtain the critical crack length values of different types of the specimen. Although there are some errors, but it can be substantially obtained the strain energy release rate and describe the propagation of interfacial crack.

Abstract Since the use of rubbers has been widespread in many industrial applications these last decades, the structures integrity including rubber parts requires the mechanical capabilities of such materials to be known and mastered. To prevent failure in the designing process, it is necessary to provide strong criteria taking into account not only their highly extensible capability but also the complex multiaxial loadings to which they could be subjected. In this work, the intrinsic defect concept is introduced and coupled in the fracture mechanics framework with the *J* integral in order to derive a multiaxial fracture criterion. Mechanical tests up to failure on rubber specimens subjected to monotonic biaxial loading paths were achieved on two materials. The fracture criterion requires as an input the critical value of the *J* integral which was also experimentally measured on CCT specimen. A generalized expression of the *J* integral under biaxial loading is proposed on the basis of finite element calculations on a representative volume element containing a small circular defect. The estimated failure elongations were found in very nice agreement with experimental data on the two kinds of rubber materials. Moreover, we have also outlined the predicting capability of this approach when applied to thermoplastic elastomers.

Keywords Rubber, *J* integral, fracture criterion, intrinsic defect.

1. Introduction

The fracture mechanics approach [1, 2], and its extension to rubbers [3-11], has shown its capability when dealing with crack problems. Nevertheless, if the material contains no visible crack or defect, this approach can be adapted assuming that all materials generally contain defects. These defects originated from material process can grow when subjected to mechanical loading and provoke failure of the component. When dealing with rubbers, these defects may be due to the reinforcing particles added to the neat matrix. Even the filler size is generally very small (less than 100 nm) but it can form aggregates, the size of which can have strong effects on the strength [12, 13] or the fatigue life properties [14-16]. In this work, an attempt to predict the fracture of specimen containing no cracks, but assumed to contain intrinsic flaws, by using the fracture mechanics approach is explored. The main assumption which is made is that these intrinsic flaws, as classical cracks, act as potential stress concentrators which are responsible of the fracture. This analysis uses experimental data obtained from mechanical tests under different biaxial loading paths [17, 18].

2. Experimental study

2.1. Materials and experiments

Two materials are used in this study: a Natural Rubber (NR) and a Styrene Butadiene rubber (SBR).

Different loading paths are used: uniaxial tension, pure shear, equal biaxial tension and biaxial tension with three biaxiality ratios. The biaxial loading was obtained by inflating a membrane (elliptical for biaxial loading and circular for equal biaxial loading) up to failure [17, 18]. For each test, the stretches λ_i (defined as the ratio of the actual length over the initial length in the *i* principal direction) in the two loading directions are measured up to complete failure giving the critical values. In the thickness direction λ_3 is estimated by using the incompressibility assumption:

$$\det \mathbf{F} = \lambda_1 \lambda_2 \lambda_3 = 1, \tag{1}$$

where $\mathbf{F}$ is the deformation gradient tensor. The critical *J* integral J_c was measured on center-cracked tension (CCT) specimens [11] for the two hyperelastic materials. The J_c average values were 21 kJ/m² and 13 kJ/m² for SBR and NR, respectively.

2.2. Constitutive laws

Th above mentioned tests were used to identify the parameters of the constitutive laws [17, 18]. For the NR material, it was found the best fitting of the experimental data is given by the Yeoh strain energy density (SED) function [19] while for the NR material a second order Ogden function was preferred [20]. The two SED functions are given by equations (2) and (3) respectively:

$$W = C_{10}\left(I_1 - 3\right) + C_{20}\left(I_1 - 3\right)^2 + C_{30}\left(I_1 - 3\right)^3, \tag{2}$$

$$W = \frac{\mu_1}{\alpha_1}\left(\lambda_1^{\alpha_1} + \lambda_2^{\alpha_1} + \lambda_3^{\alpha_1} - 3\right) + \frac{\mu_2}{\alpha_2}\left(\lambda_1^{\alpha_2} + \lambda_2^{\alpha_2} + \lambda_3^{\alpha_2} - 3\right), \tag{3}$$

where *W* is the SED, I_1 is the first invariant of the right Cauchy-Green strain tensor, λ_i are the principal stretches and C_{ij}, μ_i and α_i are material constants to be determined using a least square method. Table 1 reminds the values of all the material constants.

Table 1. Material constants for the NR and SBR materials.

	C_{10} (MPa)	C_{20} (MPa)	C_{30} (MPa)	
NR	0.298	0.014	0.00016	
	μ_1 (MPa)	α_1	μ_2 (MPa)	α_2
SBR	0.638	3.03	-0.025	-2.35

2.3. Intrinsic flaw size

To determine the intrinsic defect size, the formulation given by Rivlin and Thomas [3] can be used. For plates containing a crack of length *a* and submitted to tensile loading, these authors expressed the tearing energy *T*, equivalent to the *J* integral, as follows:

$$J = T = 2k\left(\lambda\right)Wa, \tag{4}$$

where k is a proportionality factor depending on the stretch ratio, which can be expressed for single edge cracked specimen (SENT) specimens, according to Lindley [21] in the following form:

$$k = \frac{2.95 - 0.08(1-\lambda)}{\sqrt{\lambda}}, \tag{5}$$

For CCT specimens, the expression proposed by Lake [22] is slightly different:

$$k = \frac{\pi}{\sqrt{\lambda}}, \tag{6}$$

Therefore, the intrinsic defect size can be estimated using equation (4). It comes:

$$a_{th} = \frac{J_c}{2k(\lambda_c)W_c}, \tag{7}$$

in which J_c is the critical value of J mentioned earlier in section 2.1, W_c corresponds to the SED at break of a smooth specimen loaded in uniaxial tension which can be computed using equations (2) and (3) and λ_c is the stretch at break under uniaxial tension. Since the intrinsic flaw is supposed embedded in the bulk, the flaw is taken centered in this investigation and equation (6) is used to calculate the k factor. Using equation (7) the size was found equal to 120 μm for NR while for SBR the size is 160 μm.

3. Finite element analyses

3.1. Representative volume element

Assuming a circular defect in order to avoid preferential propagation direction under biaxial loading, a representative volume element (RVE) was introduced to achieve finite element calculations. Since the defect size is estimated from uniaxial tension tests, the size of the square shape RVE was fixed equal to the width of the tensile specimen which is 10 mm as schematically shown in figure 1.

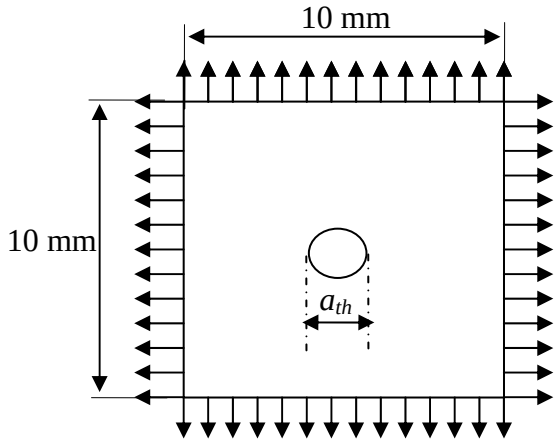

Figure 1. Reference volume element containing a circular defect.

Due to the symmetries of the RVE, only a quarter of the specimen (the shaded part) is modeled in

the finite element program. Such a modeling allows getting uniaxial tension, pure shear and different biaxial loadings by varying the ratio in the assigned displacements respectively in the horizontal and vertical directions.

3.2. *J* integral determination

The numerical analysis is performed under plane stress and finite strain conditions using a total Lagrange framework, the constitutive laws being an input given by SED functions previously introduced in equations (2) and (3). The FE program was Marc MS software.
To calculate *J*, the Begley-Landes method [23] based upon the energy interpretation of *J* was used. which allows to express *J* in the following form:

$$J = -\frac{\partial U}{\partial A}, \tag{8}$$

where U is the stored elastic energy and A is the crack (defect) area. This method requires to estimate the potential energy for varying crack lengths and to plot the energy per unit thickness function of the crack area for a given displacement. The evolution is fitted by straight lines the slope of which gives the *J* value. In this work, for each material, seven defect sizes close to the reference value (i.e. that calculated by using equation (7)) were used to estimate *J*. In order to verify the validity of the Begley-Landes method, preliminary calculations on a RVE containing a sharp crack were achieved. The values obtained were compared to the direct calculation of the *J* integral available on the software. The results, shown in figure 2 for uniaxial tension, highlight the validity of this method, especially for high level of strain.

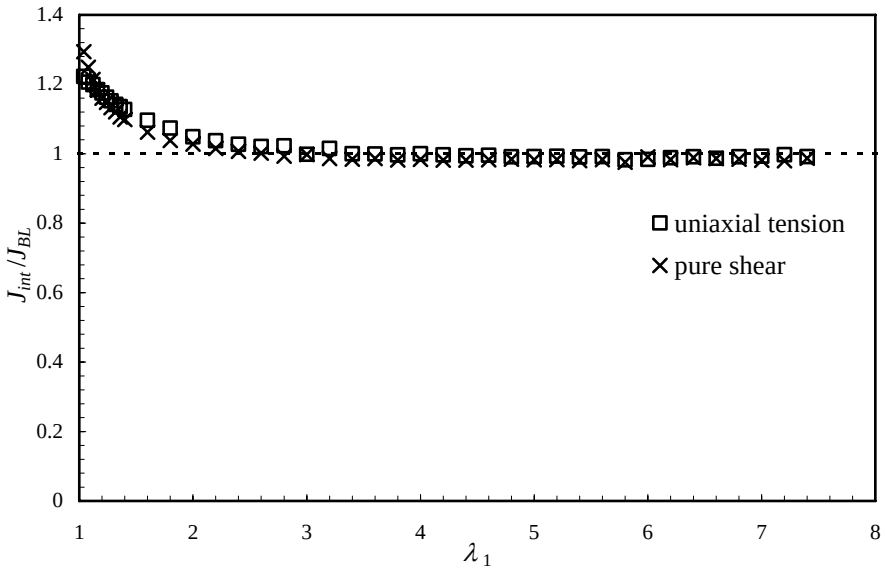

Figure 2. Evolution of the ratio J_{int}/J_{BL} as a function of the principal stretch λ_1 (SBR material).

3.3. *k* factor evolution

Finite element simulations were achieved for uniaxial tension, pure shear and four biaxiality ratios *b* defined as:

$$b = \frac{\lambda_2}{\lambda_1}. \tag{9}$$

The k factor was then computed using equation (4). Figure 3 shows the evolution of this factor as function of the equivalent stretch expressed as follows:

$$\lambda_{eq} = \sqrt{\frac{I_1}{3}}, \tag{10}$$

where I_1 is the first invariant of the right Cauchy-Green strain tensor.
The influence of the loading path is clearly highlighted on this figure. Moreover, we have not found any effect of the kind of material.

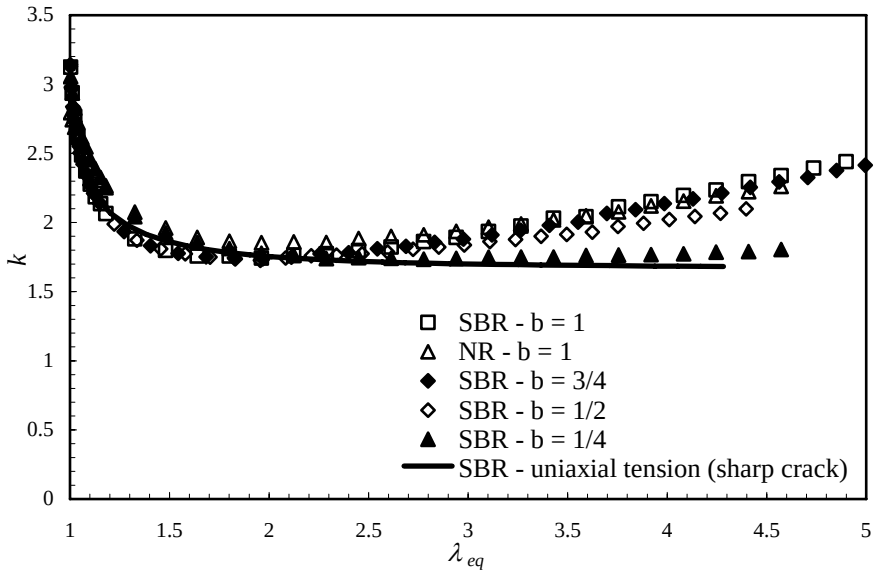

Figure 3. *k* factor as a function of the equivalent stretch λ_{eq} (circular defect, a = 0.06 mm).

4. Results

4.1. A new unified expression of *J*

Since a strong dependence of *k* on the biaxiality ratio is pointed out, the calculation of *J* using equation (4) requires to analytically express the *k* factor for every value of *b*. Another idea is to try to unify these results leading to rewrite *J* in the following form:

$$J = 2 f\left(\lambda_{eq}\right) W a, \tag{11}$$

where *f* is a function of the equivalent stretch which can be expressed in a multiplicative form as follows [24]:

$$f\left(\lambda_{eq}\right) = \left(\lambda_{eq}\right)^{\gamma} g\left(\lambda_{eq}\right), \tag{12}$$

where *g* is another function of the equivalent stretch and γ is an exponent depending on the biaxiality ratio [24] and varying from 1.05 for uniaxial tension to 1.35 for equibiaxial tension. Equation (11) therefore becomes:

$$J = 2\lambda_{eq}^{\gamma} g\left(\lambda_{eq}\right) W a. \tag{13}$$

In this case, as shown in figure 4, all the data can be shifted to get a master curve and the evolution of g can be written in a polynomial form as follows:

$$g\left(\lambda_{eq}\right) = 0.255 + \frac{2.837}{\lambda_{eq}^2} - \frac{2.888}{\lambda_{eq}^4} + \frac{2.507}{\lambda_{eq}^6}, \tag{14}$$

As shown on figure 4 all the data (dots) are well fitted by equation (14) represented by the continuous line.

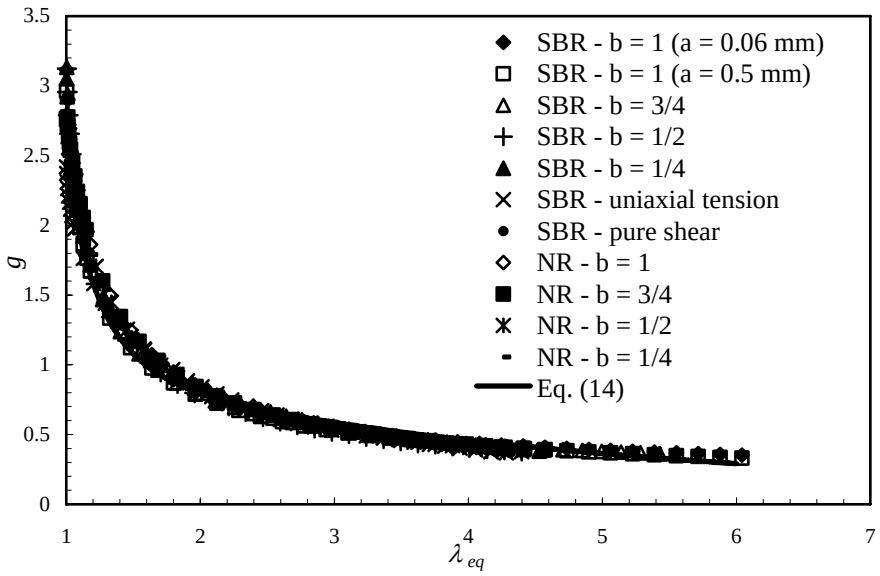

Figure 4. g as a function of the equivalent stretch λ_{eq} (a = 0.06 mm if not reported).

Figure 5 shows the validity of equation (11) to estimate the J integral. Indeed, the values obtained from equation (11) are compared to the data issued from the Begley-Landes method in the case of biaxial loadings.

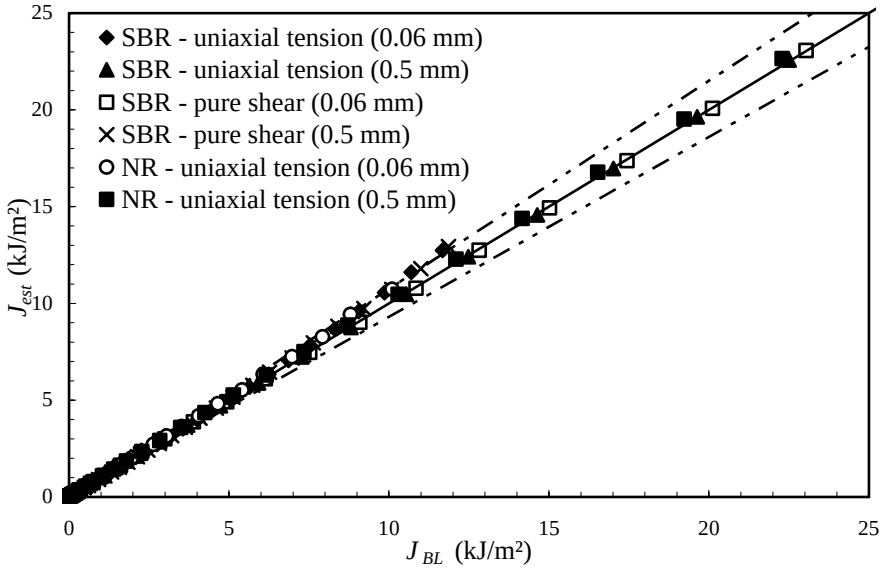

Figure 5. Comparison between J calculated from equation (11) and J_{BL} issued from the Begley-Landes method for biaxial loadings.

The maximum deviation observed is less than 5% (dashed lines). Note, even not reported on the figure, that the accuracy for uniaxial tension and pure shear is improved.

4.2. Fracture criterion

At crack initiation J takes its critical value expressed as follows:

$$J_c = 2\lambda_{eq_c}^{\gamma}\left(0.255+\frac{2.837}{\lambda_{eq}^2}-\frac{2.888}{\lambda_{eq}^4}+\frac{2.507}{\lambda_{eq}^6}\right)W_{0_c}a_c\,, \tag{15}$$

where the subscript c denotes the critical value reached at crack initiation. From equation (15) the critical stretches can be therefore derived for any loading path.

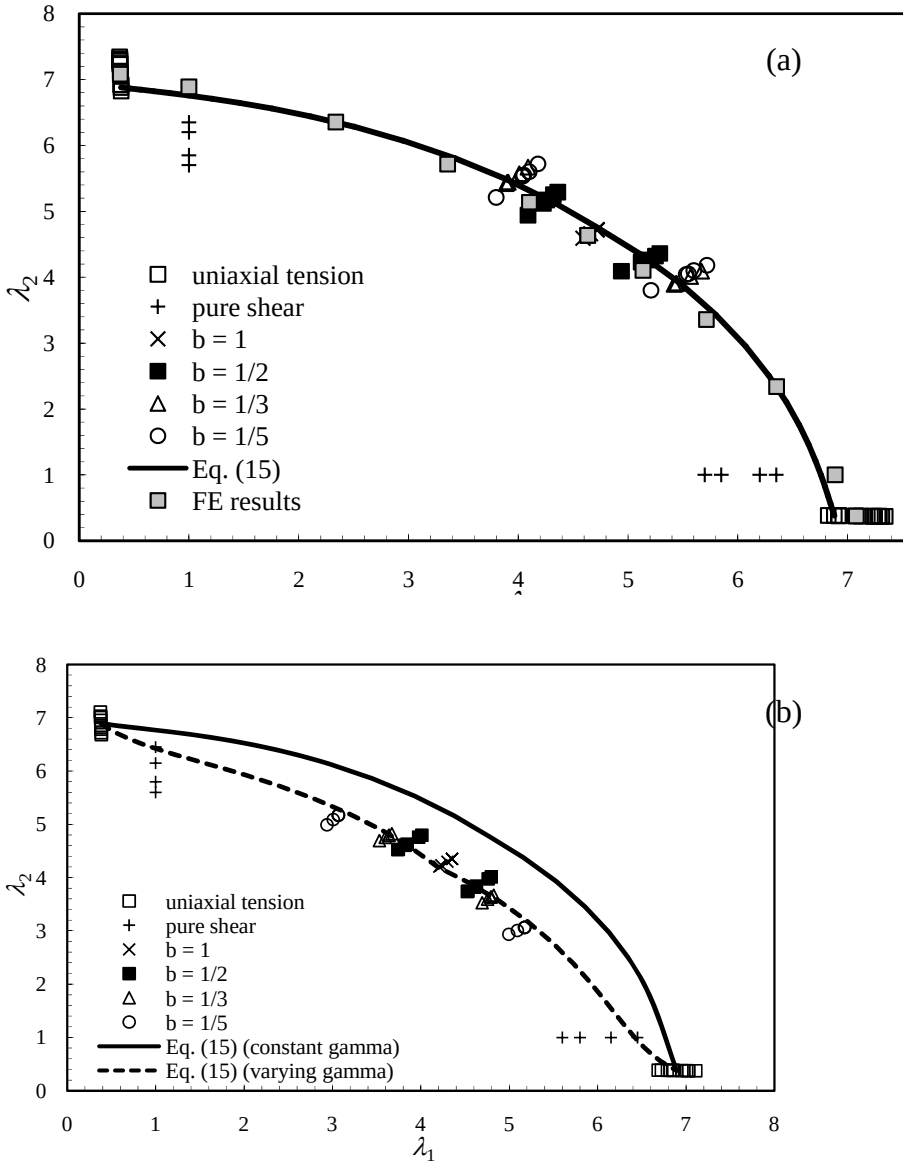

Figure 6. Failure envelopes for (a) NR and (b) SBR.

Figure 6 shows the predictive capability of the proposed approach. The failure envelope in terms of principal stretches is well predicted when using the intrinsic defect concept coupled with fracture mechanics. For NR, the exponent γ can be taken constant while for SBR it is necessary to introduce a slight variation with the biaxiality ratio.

5. Conclusion

A fracture criterion based upon the intrinsic defect concept is an original way to predict the critical stretches at failure when dealing with rubbers. The methodology we have proposed is quite easy to use and only requires two data: the stretch at break under uniaxial tension and the fracture toughness in terms of J_c. The constitutive law of the material is also an input which is necessary. We have also developed a general formulation of J which can be used, whatever the loading path in 2D conditions.

Abstract

For rapid crack propagations, two kinds of material behavior have been observed. Typically, most materials show an increase of the fracture energy with the crack tip velocity. However, there do exist a few materials for which the fracture energy tends to decrease with the velocity [1, 2]. They are viscoplastic blend materials like polymers such as rubber toughened polymethylmethacrylate (RT-PMMA). For these materials, crack tips are seen to propagate at the same velocity whatever the loading rate is (or strain energy release rate). This critical velocity has been shown to be the crack branching velocity, at least at a macroscopic scale. Our study shows that the classical approach which considers that the amount of created surface during the propagation can be approximated as the sample thickness multiplied by the crack length is not appropriate. Indeed, this study shows that the exact fracture surface roughness has to be included in the amount of created surface in order to establish an intrinsic material fracture energy G_{ID}. As the fracture surface roughness depends on the scale at which the sample is observed, a self-affine model widely used for fracture surfaces is introduced [3, 4]. This statistical geometrical model of the fracture surface with two parameters, a Hurst exponent and a topothesy is shown to be effective and provides a better estimate of the intrinsic surface fracture energy.

Keywords Dynamic fracture, rapid crack propagation, polymers, energy release rate, self-affine analysis, Hurst exponent.

1. Introduction

Considering rapid crack propagation, two kinds of material behavior have been observed. On the one hand, there are materials for which the fracture energy increases with the crack tip velocity. Fracture velocity changes during the crack propagation when the released energy varies, i.e. the dynamic energy release rate G_{ID}. Practically, a difference of velocity before and after branching is observed and, for instance, the main crack propagates faster than the secondary cracks after branching [5-7]. On the other hand, there are materials for which the fracture energy tends to decrease with velocity. They are viscoplastic blend materials and typically polymers such as rubber toughened polymethylmethacrylate (RT-PMMA) or many semi-crystalline polymers. In these materials, crack tips are seen to propagate at the same macroscopic velocity whatever the macroscopic fracture energy in mode I solicitation [1, 8, 9]. This velocity corresponds to the crack branching velocity, typically $0.6C_r$, where C_r is the Rayleigh wave speed. In the case of rapid crack propagations, as observed in [1], to maintain the propagation at the same macroscopic crack branching speed, the surface roughness evolves as a function of the available energy release rate G_{ID}. Below a minimal value of $G_{ID,}$ cracks stop without any decrease of the crack tip velocity contrarily to the first kinds of materials. Crack arrest phases correspond to relatively smooth fracture surfaces and fracture surface roughness is seen to increase with the value of fracture energy at constant velocity. These observations confirm the aim of this study to explore the roughness of fracture surfaces as a function of the energy release rate G_{ID}. Moreover, classical consideration of the created surface such as the sample thickness times the crack length is not appropriate since several values can be obtained for the fracture energy at constant crack tip velocity. Evaluating the quantity of created surface is not simple since the surface roughness is correlated with the scale at which the sample is observed. Hence, validating the self-affine geometrical model would be of great

interest. The concept of self-affinity [10] of surface roughness has been described for many natural surfaces including fracture surfaces. This concept allows the introduction of the existence of a roughness exponent called the Hurst exponent [11] which is known to be unique and universal between 0.78 and 0.80 for many materials such as rocks [3, 4, 12] wood [13-15], steel [16-18] or polymers [19-21]. This study shows the interest of the self-affine geometrical model of fracture surface, with two parameters being the Hurst exponent and the topothesy.

2. Materials and methods

The general principle of Rubber Toughened (RT) reinforcement is to dissipate energy throughout the material through elastomer particles in contrast to pure amorphous polymers for which the energy dissipation is smaller and only located at the crack tip [22-31]. RT-PMMA consists of a PMMA matrix containing a volume fraction of approximately 20% of spherical elastomer particles of about 200nm in diameter. The elastomer particles are prepared separately and then mixed with PMMA in a fluid state at high temperatures. The glass transition temperature T_g of the matrix is 105°C while that of the elastomer particles is about -30°C. Fig. 1 presents sample characteristics for rapid crack propagation (RCP) tests.

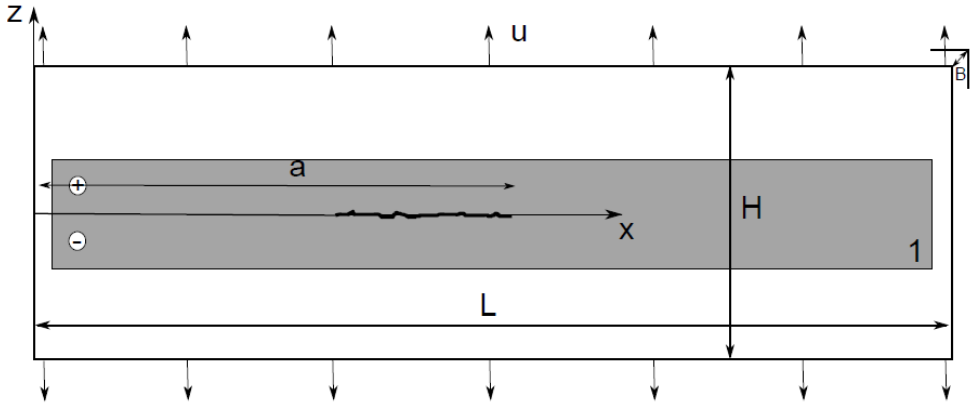

Figure 1. Schematic representation of the strip band geometry (L≈200mm, 25mm<H<45mm, B≈2mm) uniformly loaded with imposed displacements *u* in mode I. A conducting layer (1-an Ag layer of approximately 10 µm is spread on the sample) used to record the crack tip position during propagation.

A conductive layer is sprayed onto the sample and the resistance evolution is recorded during the fracture, with a National Instrument USB-6351 data acquisition which ensures a 1.25 $MS.s^{-1}$ sampling rate. After calibration, fracture tip velocities are measured**.**

The strip band geometry allows a relatively simple mechanical analysis of the structure [32]. Samples are initially preloaded in tension using an Instron tensile testing machine equipped with a 150 kN force cell. A notch $a_0 \approx 5/2.H$ is machined in the sample before loading. Crack propagation is then initiated by an impact of a razor blade at the tip of the notch. The entire test is performed at a quasi-constant temperature of 23°C.

An opto-mechanical stylus profilometer was used to characterize the *post-mortem* fracture surface of the RT-PMMA. A mechanical arm carrying a stylus is moved horizontally at constant speed (about 1 $mm.s^{-1}$) and subjected to a gravity force ensuring that the sapphire tip (φ = 5µm) keeps in contact with the surface. Measurements are discretized along a grid (N_x, N_y) with a mesh (Δ_x, Δ_y). This technique is compatible with surface transparency which prevents the direct use of optical techniques. The present profilometer cumulates optical precision of the height measurement and mechanical description of the air/RT-PMMA interface (no penetration).

First of all, height measurements Z(X,Y) are used to build the topography of fracture surfaces. The chosen mesh grid is: $\Delta_x=\Delta_y=10\mu m$ with a resolution of 2µm. Fracture maps show the surface

roughness during crack propagation, in particular during branching or crack arrest (see Fig. 2-3). Note that for RT-PMMA macroscopic fracture speed is observed to be constant even if the roughness changes [1]. Fig. 2 shows a perspective view of the fracture topography, before a branching zone.

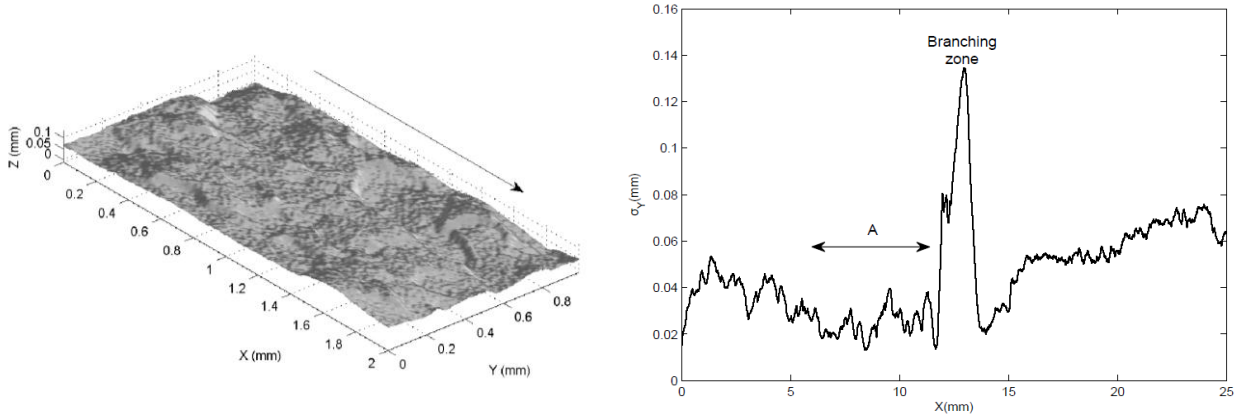

Figure 2. Topography of a fracture surface of RT-PMMA before a branching zone and standard deviation $\sigma_y(x)$ of the height along the Y axis in function of the X axis which defines the stationary state (A) just before a branching zone.

This study also addresses the surface topography decrease just before a crack arrest in a sample of RT-PMMA (Fig. 3) when the fracture energy becomes too low for the crack to continue. A small cut is made to the samples in order to access crack arrests zones. To illustrate the variation of the surface roughness during crack propagation, the standard deviation σ_y (Eq. 1) of the height Z(X,Y) along the Y axis is calculated as a function of the X axis. The amplitude variation of σ_y is used to make the difference between stationary and non-stationary regimes. A stationary regime corresponds to quasi-constant fluctuations of σ_y. Fig. 2 and Fig. 3 show two stationary states before branching (A) and after branching (B):

- Regime A: σ_y amplitudes seem relatively constant just before a branching zone.
- Regime B: σ_y amplitudes seem relatively constant just before a crack arrest.

$$\sigma_y^2 = \frac{1}{N}\sum (h - \bar{h})^2 , \quad (1)$$

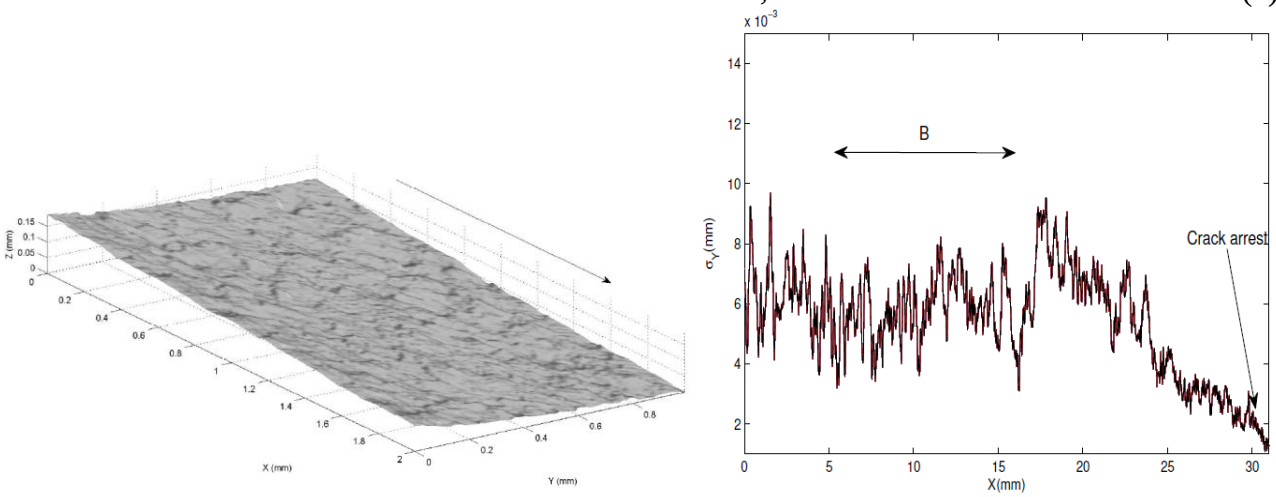

Figure 3. Topography of a fracture surface of RT-PMMA just before a crack arrest and standard deviation $\sigma_y(x)$ of the height along the Y axis in function of the X axis which defines the stationary state (B) just before a crack arrest phase.

In order to estimate fracture surfaces a routine in Fortran was created with two estimating methods. The first method called "spherical convolution" consists to probe the experimental surface with an imaginary profilometer having a variable needle radius R_p. The second method called "sampling" consists in undersampling data, i.e. to keep a point every R_p (Fig. 4). Finally, this program computes the amount of developed fracture surface $\mathcal{A}$ and developed lengths respectively along X and Y axis (l_x, l_y).

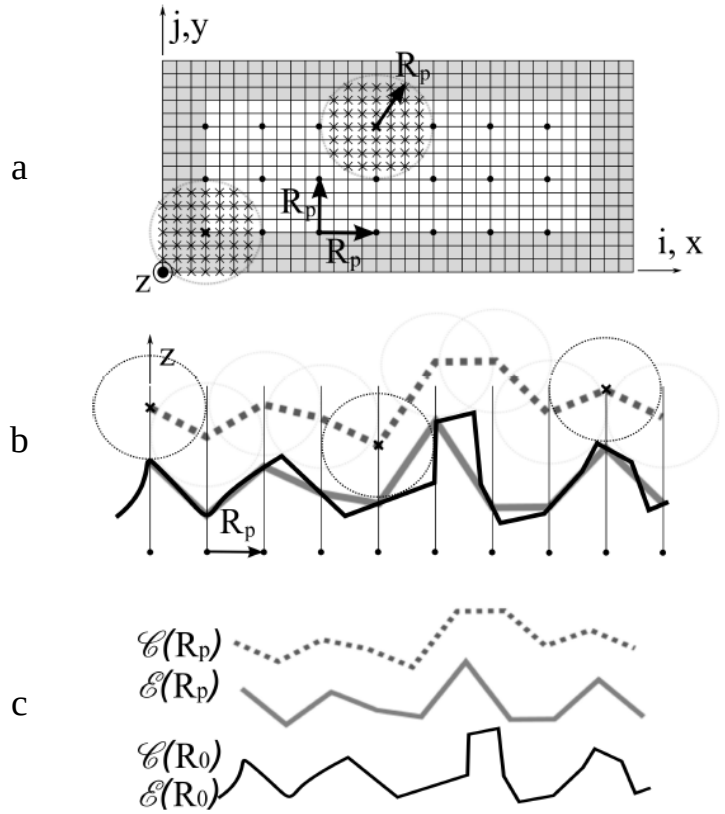

Figure 4. a-Top view of the synthetic profile b- "Spherical convolution" method and "sampling" method c-Profile of fracture surface obtained with the help of "spherical convolution" method or "sampling" method.

Finally, the concept of self-affinity introduced by Mandelbrot [10] is used to describe the roughness of fracture surfaces of RT-PMMA. It applies to surfaces that are statistically invariant under an affine transformation, such as: $X \rightarrow \lambda_x.X$; $Y \rightarrow \lambda_y.Y$; $Z \rightarrow \lambda_z.Z$ with $\lambda_x = \lambda_y$; $\lambda_z = \lambda_x^{\chi}$ with χ, the roughness exponent, or the Hurst exponent ($0<\chi<1$). Today, there are various analytical techniques to analyze stationary and transient self-affinity. Root Mean Square (RMS), Maximum-Minimum (MM), Fourrier Power Spectrum (FPS) and Averaged Wavelet Coefficient (AWC) methods which are used in this study are described in [4, 33-35]. The aim is to determine a self-affine geometrical model of the fracture surface from the estimates of the Hurst exponent and the topothesy l_r or the pre-factor *C*. The topothesy [35-38] which corresponds to the theoretical length scale over which the surface roughness has an average slope of 45° ($\sigma(l_r)=l_r$) is calculated using the RMS method (Eq. 2):

$$\sigma(\Delta x)=C.\Delta x^{\chi} \text{ with } C=l_r^{(1-\chi)}, \quad (2)$$

The energy release rate G_{Id} (Eq. 3) is computed assuming a classical Griffith energy balance accounting for inertial effects such as:

$$G_{Id} = \frac{\Delta W_{ext} - \Delta W_{ela} - \Delta K_{cin} - \Delta W_{dis}}{B\Delta a}, \quad (3)$$

where B is the thickness of the sample, Δa the crack length, W_{ela} the strain elastic energy, K_{cin} the kinetic energy, W_{ext} the work done by external forces and W_{dis} the bulk dissipated energy integrated over the entire structure. It has been largely assessed with optical techniques that Linear Elastic Fracture Mechanics (L.E.F.M.) formalism is valid for the dynamic fracture of amorphous polymers since the process zone is sufficiently confined [39, 40]. When the crack tip position $a(t)$ during propagation and the initial stress state are known, the energy release rate G_{ID} may be calculated between two tip positions a and $a+\Delta a$ by means of a transient dynamic finite element procedure, using the CAST3M software [41]. Dissipated energy, such as damping, does not involve nonlinear behavior in the process zone but only outside the process zone. Indeed, assuming L.E.F.M, the fracture toughness G_{Idc} accounts for non linearities in the process zone by setting $G_{Idc} = G_{Id}$ for crack length increase. Since it has been shown that viscoelasticty is negligible for these experiments, $W_{dis} = 0$ [42].

3. Results

During rapid crack propagation (RCP) tests, the macroscopic crack speed is quasi constant for a given specimen at a given temperature, whether branching occurs or not (Fig. 5). However, for a quasi-constant crack speed, several values of energy released rates have been recorded. The information given in the Table 1 highlights a striking difference of $<G_{ID}>$ for a measured same crack speed.

Table 1. Mean dynamic fracture energy values for cracks which branch ($<G_{ID}>_{max}$) and stop ($<G_{ID}>_{min}$).

$<G_{ID}>_{min}(kJ/m^2)$	$<G_{ID}>_{max}(kJ/m^2)$	$<G_{ID}>_{max}/<G_{ID}>_{min}$
0.58±0.2	1.70±0.2	3.0±0.2

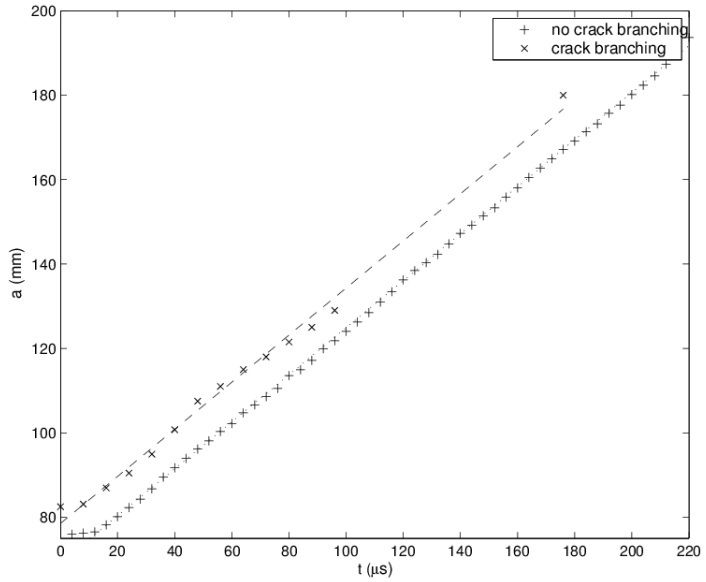

Figure 5. Crack lengths versus time in the case of crack branching and in the case of no macroscopic crack branching.

To quantify the differences of magnitudes of fracture surfaces between stationary states (A) and (B),

pre-factors are compared (Table 2). A significant difference of roughness is highlighted between the roughest and the smoothest surfaces observed on RT-PMMA samples.

Table 2. Pre-factors and topothesy calculated with RMS method before a branching zone (A) and a crack arrest (B).

	Pre-factor C (mm)	Topothesy l_r (mm)	C(A)/C(B)
A	$10^{-1.84}$	1.10^{-4}	2.4±0.2
B	$10^{-2.22}$	9.10^{-6}	

Pre-factors and topothesy are calculated for each regime (A) and (B) for 10 samples of RT-PMMA. The ratio of *C(A)* to *C(B)* is equal to 2.4 ± 0.2. The self-affine geometrical model for stationary states (A) and (B) is defined with two parameters: the Hurst exponent and the topothesy. The results obtained by the two methods (RMS and MM) are shown in Fig. 6.

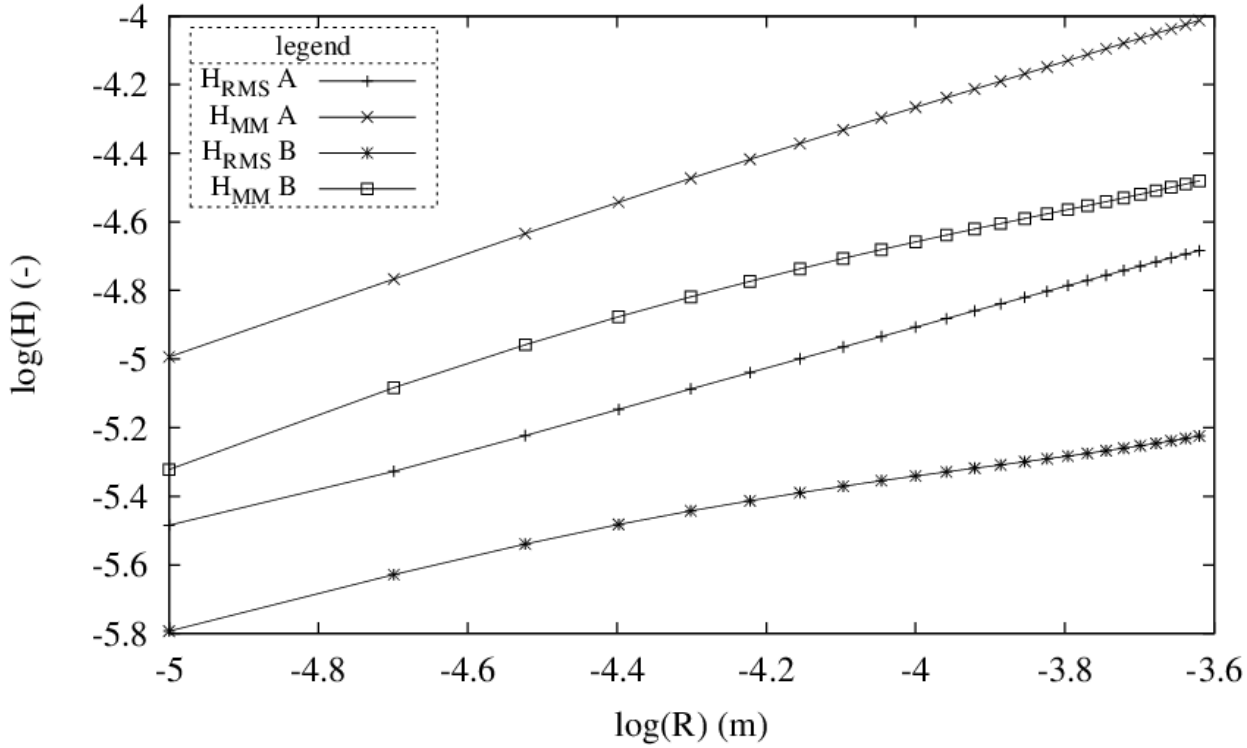

Figure 6. Statistical data analysis (RMS and MM) obtained by the characterization of RT-PMMA fracture surfaces (A and B).

The Hurst exponent is obtained from the average slope β of each curve in a log-log diagram with $\beta=\chi$ for RMS and MM methods. All values of Hurst exponent which have been obtained are summarized in Table 3. The main observation is that the surface roughness of RT-PMMA follows a self-affine model in stationary regimes. In suggested stationary regimes (A and B) the self-affine model stays stable along the crack propagation with$\langle\chi\rangle=0.61 \pm 0.05$. The average value of the Hurst exponent $\langle\chi\rangle$ was calculated using the analysis of 10 profiles.

Table 3. Roughness exponent of RT-PMMA fracture surfaces for stationary states A and B.

Methods	RMS	MM
$\chi(A)$	0.54	0.60
$\chi(B)$	0.56	0.62

Furthermore, a decrease of the prefactor and the topothesy was observed between A and B states (Table 2). This corresponds to a significant decrease of surface roughness. Contrary to the pre-factor and the topothesy, the Hurst exponent stays stable between the two stationary regimes. The interest of analyzing the pre-factor and the topothesy provides an estimate of the difference of fracture surfaces between the two domains. Fig. 7 presents the quantity of developed surface for "spherical convolution" and "sampling" methods for stationary regimes (A) and (B). The amount of developed surface in domain (B) is significantly lower than the amount of developed surface in domain (A).

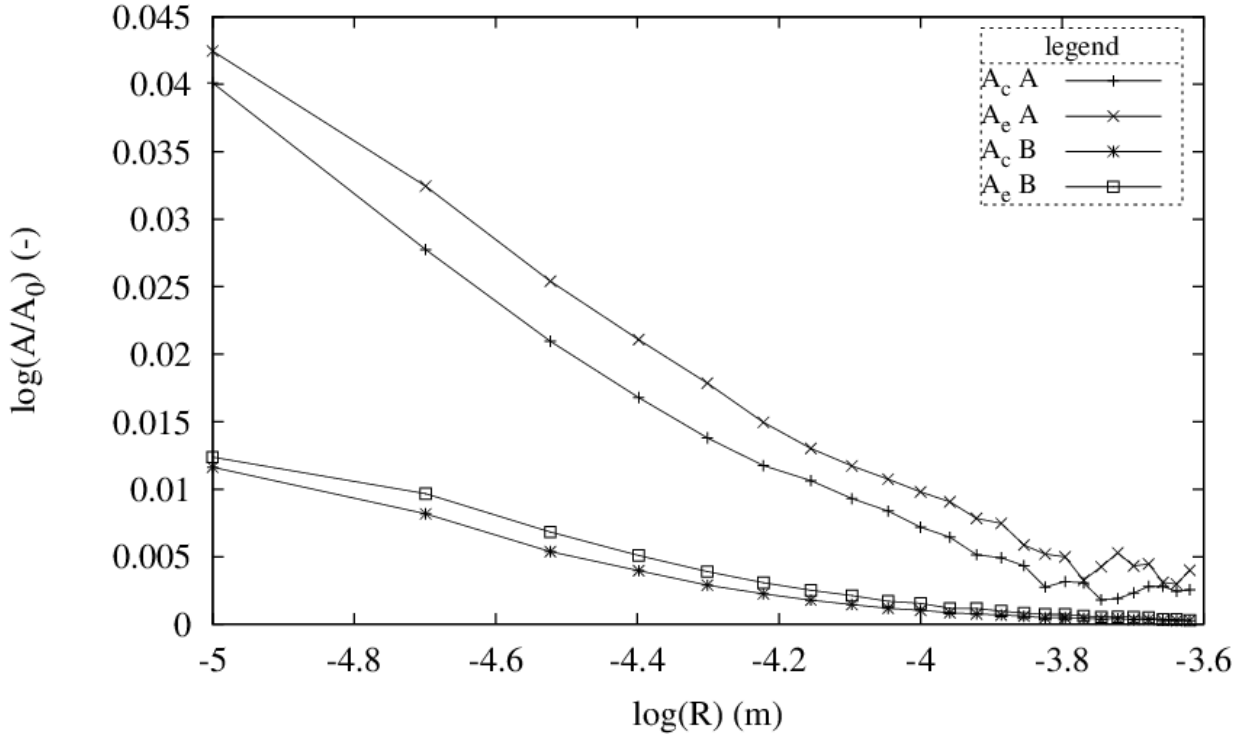

Figure 7. Total fracture surface for "spherical convolution" method ($_c$) or "sampling" method ($_e$) for stationary regimes (A) and (B).

Whatever the method, "spherical convolution" or "sampling", the amount of developed surface which are calculated is relatively similar. The choice of the method thus is indifferent on the result.

4. Discussion and conclusions

Using an dynamic L.E.F.M. approach, RT-PMMA samples have revealed a "loss" of G_{ID} unicity which is related to $B\Delta a$ (Eq. 3) at a crack tip velocity of approximately $0.6C_r$. Indeed, maximum values of fracture energy have been shown to vary up to 3.0 ± 0.2 times the minimum. The results suggest that differences of G_{ID} exist and are associated to the RMS of the fracture surface σ_y. In this article the roughness of fracture surfaces obtained from the analysis of *post-mortem* surfaces, has been quantified with Hurst exponents and pre-factors ratios during stationary regimes (A and B) before and after branching. Surfaces considered as inaccessible, either because of the profilometric technique (5µm sapphire radius tip) or because of local branches (sub-surfaces), are neglected in this study. However it is observed that the amount of fracture of inaccessible surface seems

negligible compared to the accessible surface. It is shown that a crack creates 2.4±0.2 times more surfaces before a branching zone than before a crack arrest. In addition, the self-affine model allows one to say that the surface roughness could be considered as statistically invariant under an affine transformation. Evidently the model could lose its validity below the micrometric scale, i.e. resolution scale. The "loss" of G_{ID} unicity at approximately $0.6C_r$ can therefore be associated with the amount of created fracture surface even if the quantification of $\mathcal{A}$ is practically fastidious. G_{ID} is calculated as a function of the created projected fracture surface ($B\Delta a$) on the average fracture plane. In the case of rubber toughened polymer, and most probably semi-crystallines, experiments thus show that it would be pertinent to correct the real area of the crack surface $\Delta\mathcal{A}/\Delta\mathcal{A}_0$ with $\Delta\mathcal{A}_0 = B\Delta a$ the projected area and $\Delta\mathcal{A}$ the real surface. For these kinds of materials it would be necessary to multiply G_{ID} by $\Delta\mathcal{A}/\Delta\mathcal{A}_0$. Finally, the determination of the Hurst exponent ($\chi=0.61 \pm 0.05$) independently of the fracture domain (A or B) supports the universality of the self-affine scaling of fracture surface for quasi-2D sample geometries. The self-affine geometrical model with two parameters (Hurst exponent and pre-factor or topothesy), shows its effectiveness in this type of study. However, the single Hurst exponent is no longer sufficient, by itself, to describe all the regimes encountered and, more precisely, with these kinds of rubber toughened polymers.

Abstract Notch sharpening of polymeric fracture samples is still an unsolved problem. The existing methodologies for the evaluation of the fracture toughness of polymers recommend the use of contact techniques such as razor sharpening which, in some cases, can induce high scatter in toughness results or even overestimated values.

The present work analyzes the effect of crack sharpness on the fracture toughness of epoxy resins. Three-point bending tests were carried out on specimens with a wide range of tip radii, going from the size of natural cracks, ~ 0.1 μm, to 2 mm. The behavior of the fracture toughness versus the crack tip radius has been modeled using a two criterion elastic model, a length and a stress, to estimate the overestimated toughness values with the crack tip radius and the effect of blunting arising from plastic deformation.

Keywords fracture toughness, crack sharpness, epoxy resins

1. Introduction

The influence of crack sharpness on the fracture toughness values of polymeric materials has recently caught the attention of the scientific community. Several works have appeared in the literature highlighting the role of the notch sharpening technique on the fracture parameters of either semi crystalline heterogeneous polymeric materials such as ethylene-propylene block copolymers [1-3] or amorphous polymers such as polycarbonate [4]. In all these studies, the values of the fracture toughness obtained using different approaches were determined from samples sharpened via two procedures: a non contact technique based on the femtosecond laser ablation and the traditional contact technique using a razor blade. Independently of the material under study, the results always followed the same trend. The fracture toughness determined from the samples sharpened via the femtosecond laser ablation technique showed lower values than those obtained from the specimens sharpened via the traditional razor blade technique. The reason is that the femtosecond pulsed laser ablation is characterized by very rapid creation of vapor and plasma phases, negligible heat conduction and the absence of liquid phase [5-6]. Thus, this technique can remove the material of the notch tip by ablating it with almost no heat dissipation, preventing melting and thermal deformations of the surrounding area. However, the specimens sharpened using the razor blade always showed damage ahead of the crack tip in form of plastic deformation which seems to be the reason of the higher fracture toughness values.

All these discoveries have aroused some questions concerning the well established criteria of the quality of the notch. Both ESIS (European Structural Integrity Society) [7-9] and ASTM (American Society for Testing and Materials) [10-11] indicate that when a natural crack cannot be generated in

polymers by either fatigue cracking, due to hysteretic heating, or by tapping on a new razor blade placed in the notch, the sharpening can be achieved by sliding a new razor blade into the root of the machined notch. The resulting crack tip radius must be lower than 20 μm.

In the light of the previous results, the aim of the present work is to investigate more deeply the effect of the crack tip radius on the fracture parameters of a brittle polymer such as an epoxy resin. Special attention will be paid to the reasons of the overestimated values in the fracture toughness with the crack tip radius and the influence of blunting will be analyzed using an elastic model modified for blunt cracks [12].

2. Theoretical background

Kinloch and Williams [13] showed that in brittle polymers such as epoxy resins, the localized plastic deformation that occurs at the crack tip prior to crack propagation is a controlling factor and thus emphasising the role of crack tip blunting at the instant of fracture. A model based on the elastic solution for the stresses around the tip of an elliptical hole when subjected to a remote tension, σ, normal to the semi-major axis, a, is used to analyze the fracture toughness of specimens with blunt cracks [12]. During loading a specimen with an initial crack tip radius, R_0, the plastic deformation occurring at the crack tip front with length r_C and stress σ_C induces further crack tip blunting resulting in an increase in the crack tip radius, R_C (Figure 1).

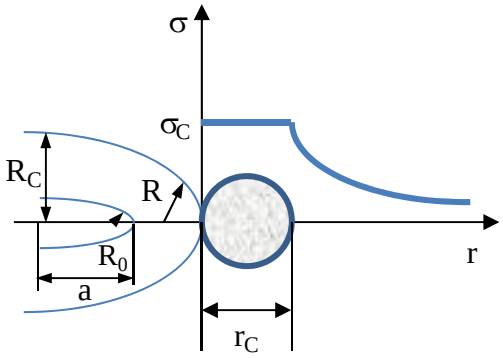

Figure 1. Crack tip front at the instant of fracture of specimens with blunt cracks

The stress σ_C at a distance r_C from the notch tip may be written in terms of the tip radius at the instant of fracture, R, and the remote applied tension σ as [14]:

$$\frac{\sigma_C}{\sigma} = \frac{2\sqrt{a}\left(R + r_C\right)}{\left(R + 2r_C\right)^{3/2}} \tag{1}$$

For a perfectly sharp crack, R=0, we have:

$$\frac{\sigma_C}{\sigma} = \sqrt{\frac{a}{2r_C}} \tag{2}$$

and thus, the fracture toughness of a sharp crack, K_{IC}, can be expressed as a function of either the remote applied tension σ and the crack length a or the near field tension at the crack tip σ_C and length factor at the crack front through:

$$K_{IC} = \sigma\sqrt{\pi a} = \sigma_C\sqrt{2\pi r_C} \tag{3}$$

For blunt cracks, the high level of stress developed at the crack tip implies the use of an apparent fracture toughness, K_b, that is, the fracture toughness of an equivalent sharp crack specimen with a stress distribution at the instant of fracture identical to that of a specimen with a blunt crack. This apparent fracture toughness, K_b, is related to the fracture toughness of the material, K_{IC}, via:

$$\frac{K_b}{K_{IC}} = \frac{\left(1+\frac{R}{2r_C}\right)^{3/2}}{\left(1+\frac{R}{r_C}\right)} \tag{4}$$

Since we are using the elastic field, the contained yielding may be modelled using a line zone with a stress identical to the yield stress, σ_Y, giving a crack opening displacement, δ:

$$\delta = \frac{K_b^2}{E\sigma_Y} \tag{5}$$

For a crack of original radius R_0, the plastic deformation characterized by δ will further blunt the tip and assuming smooth blunting, then:

$$R = R_0 + R_C = R_0 + \frac{\delta}{2} \tag{6}$$

So, the increase in the crack tip radius at the instant of fracture is equal to half the crack opening displacement. On the other hand, the crack tip radius at the instant of fracture, R, can be also expressed as function of the R_0 and R_C through the expression:

$$\sqrt{\frac{R}{r_C}} = \sqrt{\frac{R_0}{r_C}} + \sqrt{\frac{R_C}{r_C}}\left(\frac{K_b}{K_{IC}}\right) \tag{7}$$

Thus, the fracture for blunt cracks is going to be defined in terms of σ_C and r_C, which is also compatible for sharp cracks. For blunt cracks, it is the comparison of R and the length factor r_C which determines the influence of the crack tip radius.

The apparent fracture toughness, K_b, can be obtained from the experimental fracture toughness values, K_I, through the equation:

$$K_b = \frac{2}{\pi}\hat{K}\left[\ln\left(\sec\left(\frac{\pi}{2}\frac{K_I}{\hat{K}}\right)\right)^2\right]^{1/2} \tag{8}$$

where $\hat{K}$ is the plastic fracture toughness, that is, a plastic collapse condition of the uncracked specimen ligament (the width effect [13]) is to be taken into account as the stress level at failure increases with the initial crack tip radius, R_0. $\hat{K}$ has been calculated following the guidelines

given in [12].

Finally, combining equations (4) and (7), we have

$$K_I \approx K_{IC}\left[\frac{1}{2\left(1-\sqrt{\frac{R_C}{8r_C}}\right)}+\frac{\frac{R_0}{8r_C}}{\left(1-\sqrt{\frac{R_C}{8r_C}}\right)^2}\right]^{1/2} \quad (9)$$

For $\frac{R_0}{8r_C}$ too many greater than one, equation (9) reduces to:

$$K_I \to K_{IC}\sqrt{\frac{R_0}{8r_C}} \quad (10)$$

Replacing K_{IC} by the equation (3), equation (10) may be written by

$$K_I \to \sigma_C \frac{\sqrt{\pi}}{2}\sqrt{R_0} \quad (11)$$

From this analysis, it is suggested that K_I will be larger, i.e. ductile behaviour, and the criterion for this condition can be written as

$$\frac{\pi}{8}\frac{\sigma_C^2}{E\sigma_Y}=1 \quad (12)$$

where E is the Young´s modulus of the material.

3. Experimental procedure

The material under study was a commercial diglycidyl ether of bisphenol A (DGEBA) epoxy resin with a Young´s modulus of 2.65 GPa and a yield stress of 85 MPa. The chosen configuration for the fracture toughness tests was the Single Edge Notch Bend specimen (SENB) with overall dimensions of 6x12x54 mm^3. The initial crack length after sharpening to width ratio was 0.5.

All the fracture specimens presented an initial V-machined notch. Different notches were introduced in the materials which can be mainly divided into two groups: samples with sharp cracks and those with blunt notches. The sharp cracks were obtained by two procedures: the traditional contact technique for brittle polymers as tapping and a non-contact technique as the use of a femtosecond pulsed laser ablation or femtolaser. For the contact procedure, a light hammer was used to tap a razor blade placed into the root of the machined notch till a natural crack was attained. The natural crack was inserted with the razor blade at room temperature and frozen at liquid nitrogen temperature. In case of the non-contact technique, the sharpening of the notch was produced through a Femtolaser [5-6], using a commercial Ti:sapphire oscillator (Tsunami, Spectra Physics) plus a regenerative amplifier system (Spitfire, Spectra Physics) based on chirped pulse amplification (CPA) technique. For the epoxy, 120-fs pulses at 395 nm with a repetition rate of 1

kHz were utilized. The scanning speed was 130 μm/s and 4 passes were carried out with pulse energy of 0.008 mJ. The sharp length inserted by the femtolaser was of 500 μm.

For the blunt notched samples, different techniques were used to achieve different crack tip radii which can be divided into three groups depending on the dimensions. To introduce notches with 0.01, 0.02, 0.05, 0.07 and 0.1 mm in diameter, razor blades produced at the Imperial College with different crack tip radii were employed. The razor blade was slid gently across the root of the notch trying to remove the material without pressing.

To introduce notches bigger in size, that is, with diameters of 0.4, 0.6, 0.8, 1, 1.5, 2, 2.5 and 3 mm, a drilling technique was employed using drills with different radii mounted on a high speed drilling machine.

Finally specimens with up to 4 and 7 mm in notch diameters were analyzed and for the insertion of such huge notches a milling machine was used.

Prior to testing, the surfaces of every single specimen were analyzed via optical microscopes and scanning electron microscopy to check the crack tip front and measure the crack tip radius. The samples which presented any type of damage in form of microcracks or areas with different colour or texture were discarded.

The tests were carried out in an electromechanical testing machine (Instron 3365) at room temperature under displacement control at a cross-head rate of 10 mm/min. A three point bending fixture was used with a loading span four times de width. A load cell of ± 1 kN and an extensometer were used to measure the load and load displacement line, respectively. The methodology employed to obtain the fracture toughness and the energy release rate was the ESIS TC4 protocol entitled "K_C and G_C at slow speeds for polymers" [7].

After the tests, the morphology of the fracture surfaces was inspected via optical microscopes.

4. Results and discussion

4.1. Experimental results

Figure 2 shows the experimental fracture toughness values, K_I, as a function of the initial crack tip radius, R_0. As expected, the fracture toughness increases with the notch tip radius. The fracture toughness of the specimens with a natural crack obtained by tapping presented the lowest fracture toughness values, ~0.5 MPa·$m^{1/2}$, and of course the smallest crack tip radii, of 0.2 μm. It is worth mentioning that a small increase in the crack tip radius implies a huge increase in the fracture toughness. For example, even the specimens with sharp cracks sharpened via femtolaser presented values of the fracture toughness almost twice the value obtained from specimens with a natural crack, as the crack tip radius of the former was 0.8 μm, four times bigger.

The rapid increase of the fracture toughness with the crack tip radius is due to blunting as the fractographic analysis reveals. There is a marked change in the morphology of the fracture surfaces as the crack tip radius increases. Figure 3 shows a characteristic fracture surface of a specimen with a sharp crack. As shown, the fracture surface is plain and smooth without any remarkable characteristic.

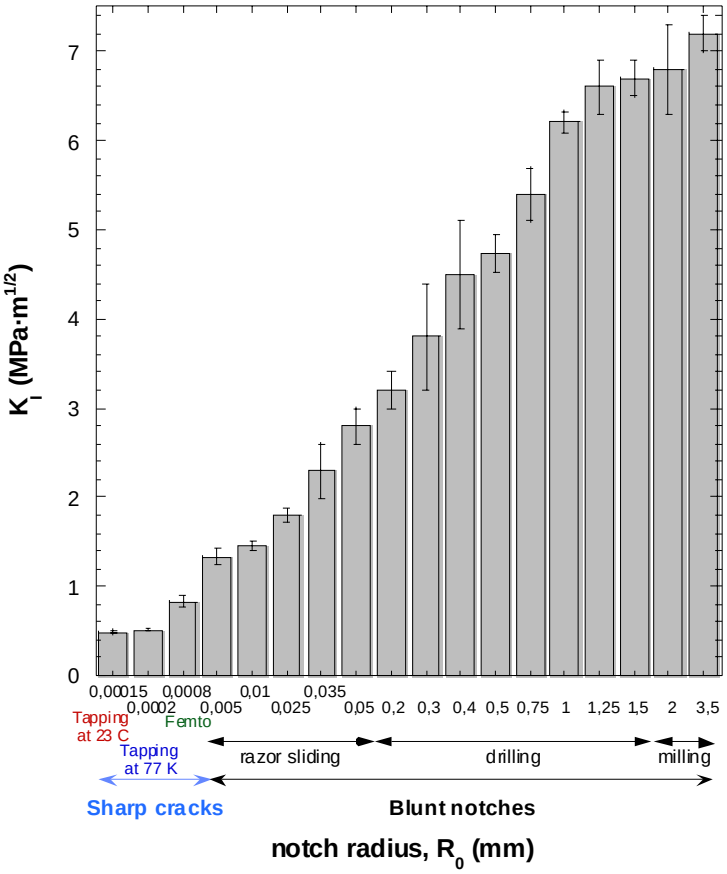

Figure 2. Experimental fracture toughness, K_I, versus the original initial crack tip radius, R_0.

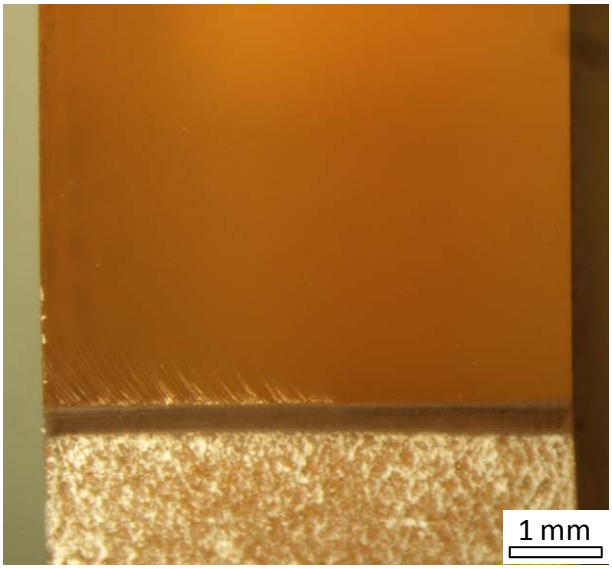

Figure 3. Characteristic fracture surface of a specimen with a sharp crack (specimen sharpened using a femtolaser)

On the other hand, Figure 4 displays the characteristic morphology of the fracture surface of a specimen with a blunt crack introduced via razor sliding. The surface is mainly plain and smooth as in the case of specimens with sharp cracks but some river markings appear close to the notch and become larger and more accentuated as the notch radius is higher.

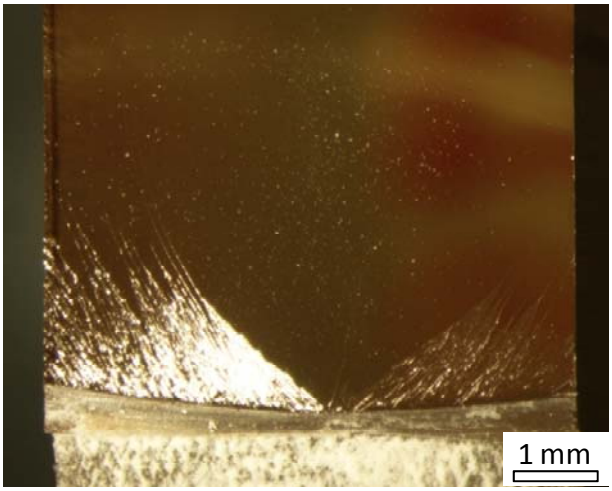

Figure 4. Characteristic fracture surface with a blunt notch introduced via razor sliding (initial crack tip radius of 25 μm)

The morphology of the fracture surfaces of the specimens with blunt notches inserted via drilling or milling changes drastically (Figure 5). The river markings are not longer limited to a tiny area close to the notch but they are spread all over the surface and the roughness is increased with the crack tip radius. Looking more closely to the surface, there is a more or less rounded region from where the unstable crack propagation seems to emerge. This type of morphology is caused by blunting.

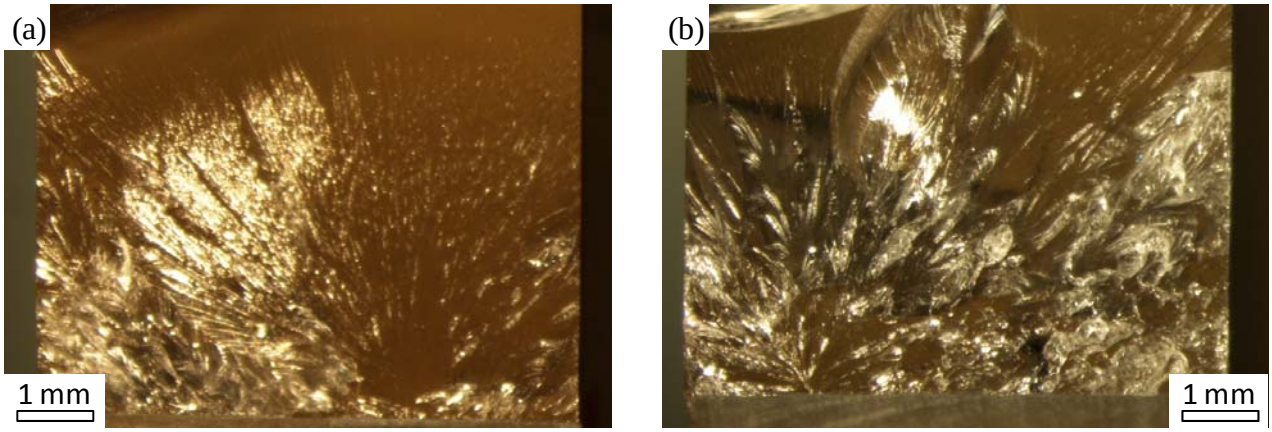

Figure 5. Fracture surfaces of the specimens with blunt notches inserted via (a) drilling (initial crack tip radius of 300 μm) and (b) milling (initial crack tip radius of 1.5 mm)

4.2. Modelling

The model described in the theoretical background was applied to the experimental data presented here to find out the role of blunting on the high values of the fracture values with the increase in the crack tip radius through the parameters σ_C and r_C. Figure 6 shows the apparent fracture toughness, K_b, against the square root of the initial crack tip radius, $\sqrt{R_0}$. Each colour groups the fracture values of specimens with notches introduced via a specific notching technique. In general and independently of the notching procedure, the true fracture toughness increases monotonically with the crack tip radius although some slightly deviations are to be pointed out. First of all, the values obtained from specimens with blunt notches introduced by razor sliding slightly divert from the general trend. These values are higher than expected and the microscopic analysis of the virgin specimens reveals the reason (Figure 7). There is a tiny region ahead of the crack tip with different texture corresponding to some damage caused during the notching process (outlined with a red dotted line). Secondly, from $K_b \approx 7$ MPa·m$^{1/2}$, the increase in the true fracture toughness with the

crack tip radius is not so marked and it seems that from there on the values are tending to a horizontal asymptote.

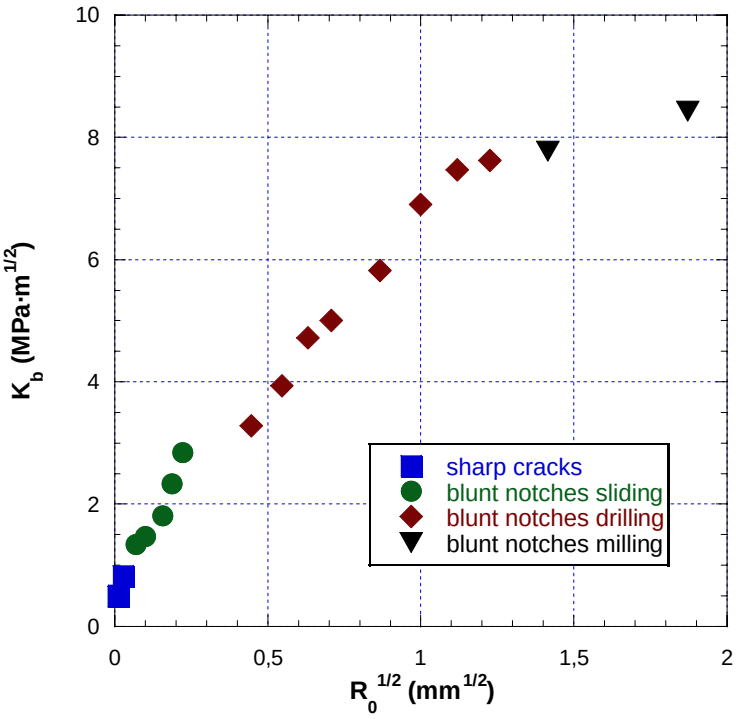

Figure 6. Apparent fracture toughness as a function of the initial crack tip radius

Figure 7. Crack tip front of a specimen with a notch introduced via razor sliding where some damage can be observed ahead of the crack front (initial crack tip radius of 35 µm)

Figure 8 shows K_b vs $R_0^{1/2}$ together with the fitting to equation (9) and table 1 gives the parameters of the model. The fracture toughness resulting from the fitting of the data to equation (9) gives a value of 0.89 MPa·m$^{1/2}$, which is higher than the experimental fracture toughness obtained from specimens with sharp cracks (0.49-0.83) MPa·m$^{1/2}$ but lower than the fracture toughness obtained from samples with blunt notches introduced via razor sliding (1.34-2.80) MPa·m$^{1/2}$ (Figure 2).

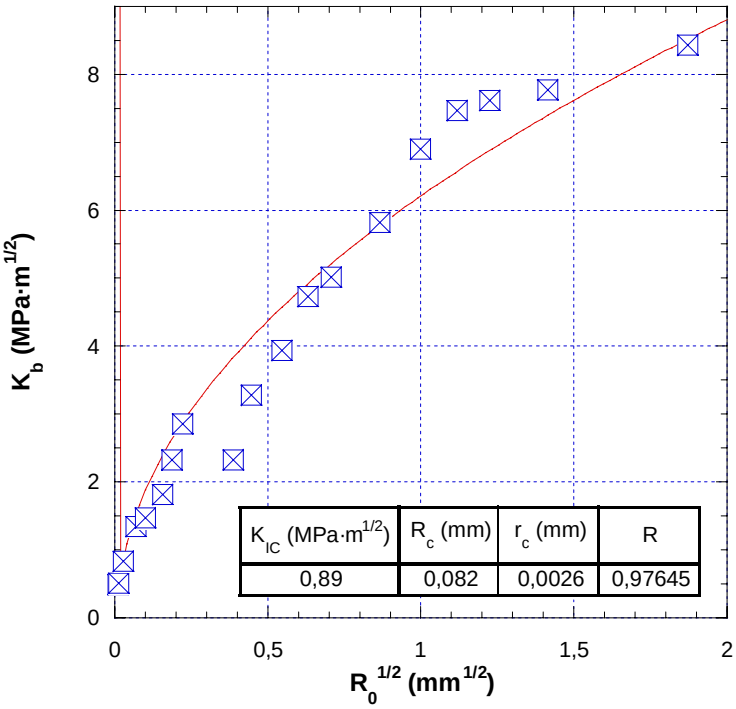

Figure 8. True fracture toughness versus the initial crack tip radius. Line is fitted from equation (9).

Concerning the parameters related to the fracture process, r_C and σ_C describe the critical length and the cohesive stress, respectively. The values of r_C= 2.6 μm and σ_C= 220 MPa are comparable to those found in the literature for similar epoxy resins [13]. It is interesting to note that the value of the plastic condition given by the equation (12) is far away from the unity, so the degree of ductility is relatively small. Finally, the value of the increase in the crack tip radius at the instant of fracture due to blunting, R_C, is 74 μm.

Table 1. Parameters of the model resulting from the data fitting to equation (9)

K_{IC} (MPa·m$^{1/2}$)	R_C (μm)	r_C (μm)	σ_C (MPa)	$\frac{\sigma_C}{\sigma_Y}$	$\frac{\pi}{8}\frac{\sigma_C^2}{E\sigma_Y}$
0.89	82	2.6	220	2.6	0.08

5. Conclusions

This work analyzes the influence of the crack tip radius on the fracture toughness on a brittle polymer such an epoxy resin. Different sharpening techniques were employed to attain different crack tip radii. To introduce sharp cracks, the traditional contact technique such as tapping a razor blade placed into the root of a machined notch and the more sophisticated non-contact procedure as the used of the femtosecond pulsed laser ablation were used. For the blunt notches, the procedures of razor sliding, drilling and milling were utilized to get different crack tip radii. The lowest values of the fracture toughness were obtained for the specimens with sharp cracks, in particular for those with cracks inserted via tapping. The fracture toughness increased rapidly with crack tip radius and the microscopic analysis of the fracture surface indicated that blunting was the reason of the steady increase.

A model based on the line zone model was applied to the experimental data to achieve a useful insight into the crack tip sharpness effects. The parameters obtained from the model denote that the

degree of ductility reached during the fracture process is not large and the plastic length and stresses developed in the crack tip front before the unstable crack propagation are comparable to the critical length and cohesive stress.

Abstract Trouser tear testing has been concerned in this research work. A polypropylene film and a low density polyethylene film used in the packaging industry are considered. The experimental trouser tear tests showed different results for both materials when they were subjected to load in different material directions. Therefore the hypothesis was verified, that the in-plane material orientation/alignment induced during manufacturing, hence creating anisotropic in-plane mechanical properties, also affects the tearing behavior. A brittle-like failure was shown in the polypropylene film while the low density polyethylene presented a highly ductile behavior. The two polymer films can be classified as one low-extensible and one high-extensible material according to the test method utilized. Material parameters in the principal material directions i.e. manufacturing direction and cross direction were extracted from the experimental tests for further numerical studies. Scanning electron microscope was used for micromechanical and fractographical analysis of the crack tip and crack surfaces created during the tests. The methods discussed will help classify different groups of materials and can be used as a predictive tool for the crack initiation and crack propagation path in packaging material, especially thin polymer films.

Keywords Anisotropic, thin polymer film, crack propagation, fracture mechanics, SEM

1. Introduction

Polymer films are extensively used in food packaging industry due to their beneficial mechanical properties, i.e. the combination of stiffness, strength and ductility. During transportation, handling and usage of packages, polymer films are exerted to different loading conditions. Polymers and rubber-like materials have previously been extensively studied experimentally in various fracture modes [1-3]. For the case of tearing, the experimental and theoretical analysis has been performed in [4-8]. This work will focus and extend the analysis on the experimental trouser tear tests in three different material directions for two types of polymer films used in packaging industry.

Fracture properties related to the specific material parameters such as critical fracture toughness, energy release rate, fracture energy and crack propagation resistance can be determined using a fracture mechanical test method. In brittle material this procedure is well known but for ductile material it is less developed. The two important fracture modes involved in the trouser tear test, mode I – in-plane opening mode and mode III – anti-plane shearing mode together with the mixed mode - trouser tear test are depicted in Fig. 1.

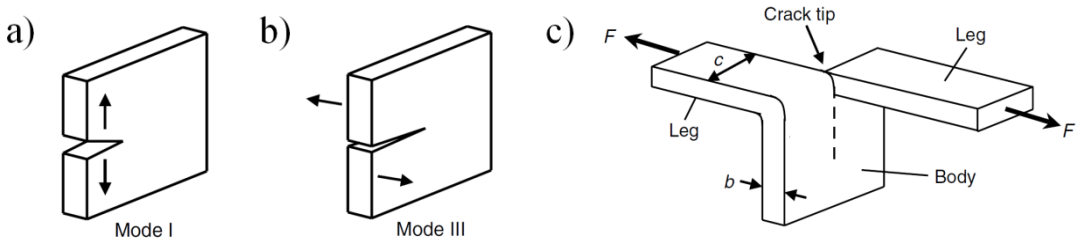

Figure 1. Three loading modes of cracked specimens: a) mode I b) mode III and c) mixed mode trouser tear test [9]

2. Materials

Two types of polymer films with different mechanical behavior were tested and analyzed in this work. One oriented polypropylene (PP) film and one low density polyethylene (LDPE) film were experimentally tested. The mechanical in-plane material properties for these two thin packaging materials have thoroughly been examined in previous works with slightly different scopes and interests [6-7,10-13]. In-plane elastic anisotropic material behavior is shown in the PP film according to (Table 1). To be able to distinguish the principal material directions a naming convention is used i.e. manufacturing direction (MD), cross direction (CD), and 45 degrees to the manufacturing direction (45). These abbreviations are further on used to indicate in which direction the load has been applied. In-plane material properties for the PP and LDPE are presented in (Table 1). In-plane material properties primarily dominate the mechanical behavior in the two polymer films studied. This is due to the thin thickness of the polymer films, hence plane stress assumption is valid. Therefore, out of plane properties are disregarded in this work.

Table 1. In-plane mechanical material properties for thin polymer films [10], [13]

Material	Thickness [μm]	Material orientation [-]	Young's modulus [MPa]	Yield strength [MPa]	Poisson's ratio [–]
PP	18	CD	5100	29	0.43
		MD	2200	28	0.25
		45	2800	28	0.30
LDPE	27	CD	140	5.1	0.4
		MD	140	5.1	0.4
		45	140	5.1	0.4

Manufacturing of polymer films involves several processing steps. During these different steps, polymer chains are aligned or enforced to orient in the manufacturing/rolling direction (MD) or stretching direction (MD or CD). The degree of orientation in the polymer chains vary in different polymer types and mixture of polymers. Temperature, thickness, chemical structure, polymer chain lengths, number of cross-links, entanglements and rate of crystallinity are all parameters affecting the final mechanical properties in the material. Anisotropy, different mechanical behavior in different directions, is therefore most often the case for many polymers. Due to anisotropy, polymer films tend to follow different preferred crack directions and find the lowest resistance path for crack propagation. Initial direction of crack extension depends of loading scheme and type of material. Brittle materials, as PP in this study, usually fracture by mode III defined in Fig. 1. Ductile materials, as LDPE in this study, usually fracture by mode I and mode III defined in Fig. 1 when exerted to a trouser tear test. If a crack is introduced into a specimen, such as in the trouser tear test, the stress distribution is no longer constant and homogenous within the material. The stress will vary and this variation is due to size and shape of crack and geometry of specimen. In fact, the geometry and the type of loading also have a significant influence on the crack propagation behavior. In brittle materials the process zone will be very local and in the vicinity of the crack tip, all the energy dissipates and new crack surfaces are created. On the other hand in a ductile material where a lot of plastic deformation occurs the process zone and active zone is a rather large area surrounding the crack tip. In this case a lot of energy is consumed in the plastic flow and for the trouser tear test in substantial leg deformation.

3. Experimental Procedure

Preparation and cutting of specimens were performed after pre-conditioning of the materials at 23°C and 50% RH for 40 hours prior to test in accordance with the test procedure defined in the standard ASTM D618-08 [16]. Sample cutting of the two types of polymer films were done with a sharp medical knife and it is recommended to frequently change blades. To minimize uncontrolled errors, such as edge effects, the specimens were cut in the same way every time with the same operator. Mounting and handling of the polymer film was carefully done in order to not damage the material and edges. Trouser tear test specimen geometry and dimensions are shown in Fig. 2. When the specimen is mounted in the tensile test equipment it looks like a pair of trousers, which explains the name of the test method. The 'legs' of the trouser specimen are then pulled in opposite directions to create tearing action. One of the grips in the tensile test machine, holding the specimen, is fixed and the other one is moved at a constant rate (10mm/min) during the test. Specimen extension is measured by grip separation. The test method utilized in this work, the American standard ASTM 1938-08 [15], was used for calculation of the tear resistance and is similar to the European standard ISO 6383-1:1983 [17]. These two methods calculate the force necessary to propagate a crack in a trouser tear test in plastic/polymer films with a thickness less than 250 μm. Several experimental tests, minimum five for each material direction, were performed for each test setup to characterize the mechanical behavior of each material and for different material orientations.

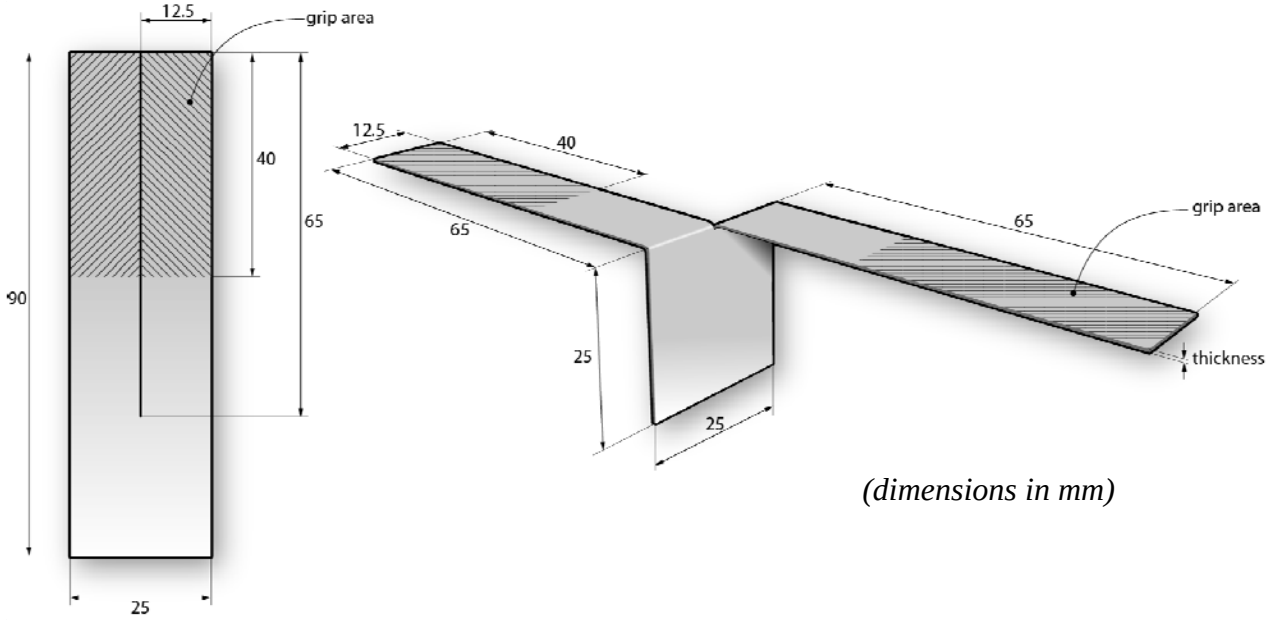

Figure 2. Trouser tear test specimen geometry, illustration by Carl Nordenskjöld

According to Fig. 2 a pre-made crack is introduced in each specimen before mounting in the experimental equipment. During the test, when the legs are separated and thus extended, the pre-made crack will continue to grow. In the figure the grip area is marked (hatched) and the one-color area is the material subjected to load, where the tearing action takes place. PP is brittle and sensitive to stress and to avoid crack initiation prior to the test a small slack (2 mm) was introduced when mounting. The registered forces in the experimental tests are low and therefore it is important that the grippers are rigid and unable to move during the tests. Even a small vibration can cause significant deviation in results and this external noise has to be controlled and minimized. Hence the gripping equipment was adjusted to be ultimately stiff to prohibit any movement of the clamps in the other directions than the stretching direction.

4. Experimental trouser tear testing results

In the test method, ASTM D1938-08, [15] two different types of behavior is classified; in this study PP is a low extensible or non-extensible film and LDPE is a highly extensible film. The generic response graphs from trouser tear tests, for the two different classes of materials are displayed in Fig. 3. Low extensible films, i.e. PP, exhibit a constant load during trouser testing. For highly extensible films, i.e. LDPE, the deformation energy of the specimen legs is significantly higher than the tearing energy. Tearing of highly extensible films is accompanied by significant plastic deformation.

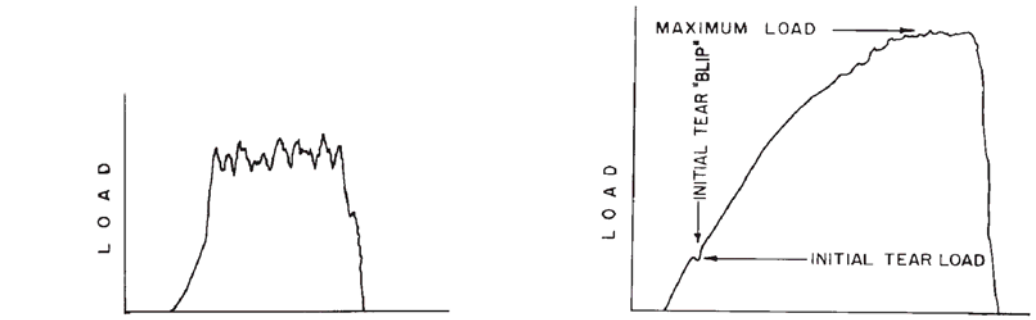

Figure 3. Load vs. time for trouser tear tests in a) low-extensible and b) highly-extensible polymer film, [15]

The force needed to propagate the pre-made crack in a polymer film specimen was experimentally measured in the laboratory at Tetra Pak in Lund. The utilized test method can be used for rating the tear propagation resistance of various plastic/polymer films of comparable thickness. Force and extension were recorded during loading and tearing of the specimens. The results are shown in Fig.4 for PP and in Fig.5 for LDPE. Five different specimens for each direction were studied to get an idea of mechanical behavior and statistical variation in the two types of polymer films. The force registered in the PP-film, as shown in Fig. 4, was low (note the unit mN on the y-axis). There was a significant difference of registered force in all the three material directions.

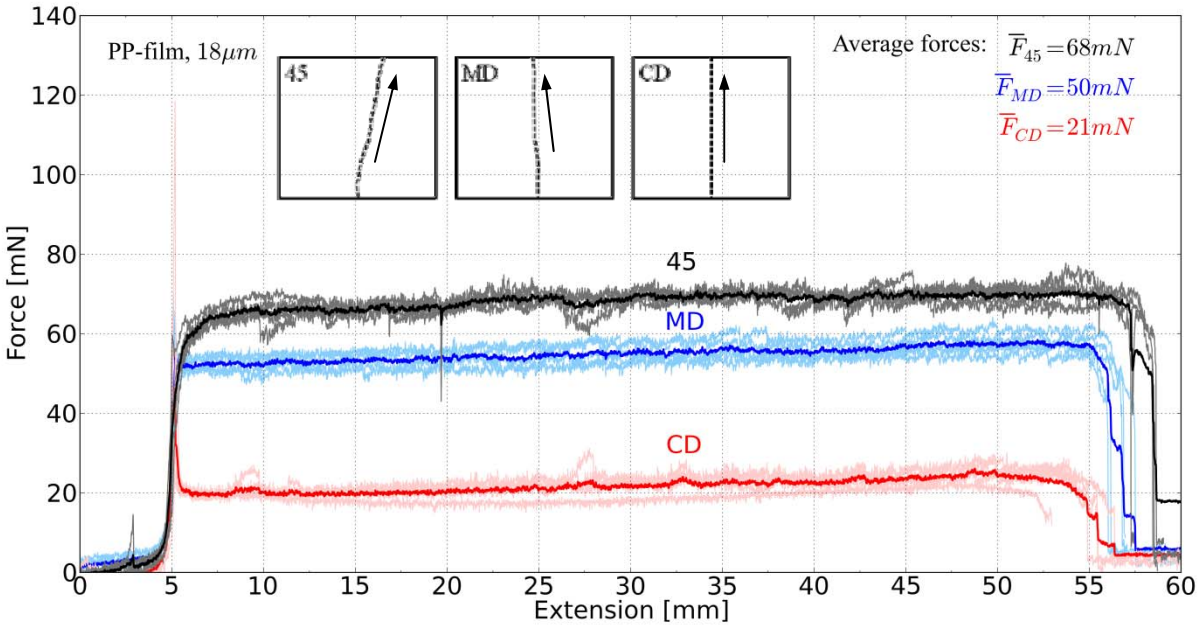

Figure 4. Trouser tear test in material direction 45°, MD and CD for PP-film, force vs. extension. Bold lines represent mean curves for each material direction.

For PP it is possible to clearly distinguish the three different material orientations as shown in Fig. 4. A noticeable high peak is shown in the PP-CD samples which probably indicates the breakage of chemical bonds in-between the polymer chains or the crystallites. The force is significantly higher than the average force for the continuous crack propagation when the material has found the lowest energy crack path direction. Lowest tearing resistance path for PP-45 is along the material alignment in CD, therefore the crack path is not orthogonal to the stretching direction. This means that the highest force is registered in these specimens. The experimental trouser tear test results for PP is depicted in Appendix A at different loading stages. In Appendix A is the three different crack propagation paths noticeable as depicted above in Fig. 4. It is important to note that the small fluctuations in the force values during tearing, present in all PP-graphs in Fig. 4, are not noise from the experimental equipment but rather due to the "stick-slip" behavior observed during fracture in many polymers [8]. The frequency and amplitude of these small fluctuations most probably relates to the morphology and micro mechanism of the polymer material, such as the polymer chain alignment, arrangement of crystallites, and distribution of crystalline and amorphous phases. However, systematic micro structural and fractographical characterization is needed to fully understand the "stick-slip" behavior. The LDPE-specimens don't show these small fluctuations in the force values during tests as shown in Fig. 5. The experimental trouser tear test results for LDPE is depicted in Appendix B at different loading stages.

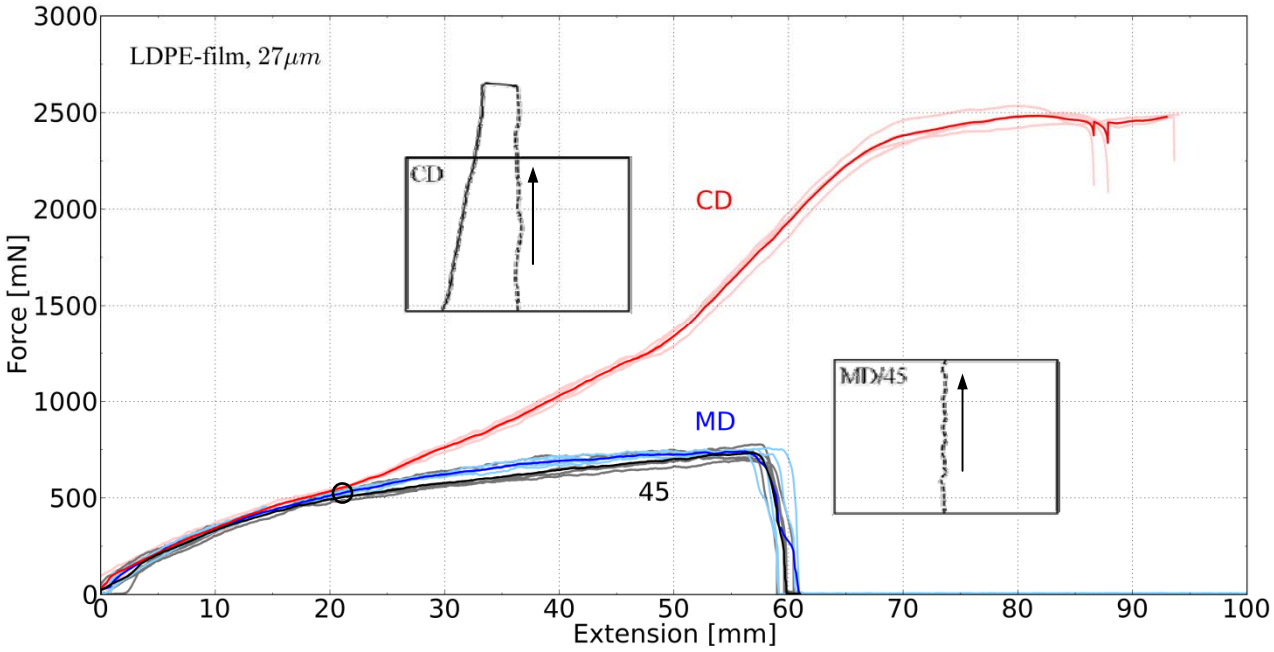

Figure 5. Trouser tear test in material direction CD, MD and 45° for LDPE-film.
Bold lines represent mean curves for each material direction.

For LDPE the total extension of the trouser test is 90 mm in CD and 60 mm in MD and 45. The total extension from tearing is only 50 mm, hence a significant part of the LDPE extension is elongation of the two legs. The un-bundled polymer chains, with the majority oriented in MD, enable a significant stretching in CD. Therefore a lot of energy is dissipated in material rearrangement, plastic work, elongation of the legs and heat generation. However, the initial part, until the circle shown in Fig. 5, similar behavior is presented in all three material directions CD, MD and 45 in LDPE. For low extensible films such as PP on the contrary, there is no deformation of the legs and the total extension is therefore 50 mm, the same length as the minimum possible tearing distance. Test results for highly extensible films, i.e. LDPE is depicted visually in Appendix B, and for low extensible films, i.e. PP in Appendix A.

In addition to the well known fracture mechanical parameters, such as stress intensity factor and J-integral defined in [14], Rivlin and Thomas defined the critical fracture energy from a trouser tear test. This quantity is also known as tearing energy, which is the energy spent per unit thickness per unit increase in crack length. Tearing energy includes surface energy, energy dissipated in plastic flow processes, and energy dissipated irreversibly in viscoelastic processes [1]. The equations described below are derived from the trouser tear test based on theoretical analysis of crack growth behavior [5]. This can simplify the description of the tearing energy from the experimental results. The equation for calculation of tearing energy was derived with experimental test of rubber-like materials and is also applicable for polymers. The tear strength equation to calculate the critical tear energy, T_C, of a propagated crack in LDPE in this study is

$$T_C = \frac{2F\lambda}{t} - wE \tag{1}$$

F is the tear propagation force, w is the initial width of specimen, t is the thickness of specimen, E is the strain energy density. For LDPE the strain energy density can be calculated using the area under stress-strain curve from an ordinary tensile test. It was found that the strain energy for LDPE is, $E_{LDPE} = 2.8\ N/m^2$. λ is the extension ratio of the legs, current length of specimen divided by initial length, which is normally 1 except for some materials which have high extension of legs as LDPE-CD ($\lambda = 1.8$). In case where high stretching of legs is visible, then Eq. 1 will be used to calculate the critical tear energy. Strain energy density, E, becomes zero in materials with no leg extension, in this study for PP, resulting in the general equation used widely for calculation of critical tearing energy in brittle materials,

$$T_C = \frac{2F}{t} \tag{2}$$

The relationship between rate of tearing and strain energy release rate is a material characteristic that is independent of test specimen geometry, when tested low extensible materials [4]. The extension in the specimen legs is negligible and ignored for such cases. It can be confirmed from Eq. 2 that the critical tearing energy is independent of the initial sample geometry and crack length. This assumption is valid only if the specimen undergoes mode III dominated failure. Critical tear energy for the PP & LDPE is calculated using the above equation. Crack propagation for PP is a completely mode III phenomenon so its crack propagation is a complete tearing process, while LDPE has plastic flow and deformation of legs in addition to tearing which is generating a mixed mode I and mode III failure. Tearing or crack propagation force, tearing work, tearing energy & tear extension for PP and LDPE are summarized in (Table 2).

Table 2. Trouser tear test results for two thin polymer films; PP and LDPE

Material	Thickness [μm]	Material orientation [-]	Tearing Force [mN]	Critical Tearing energy [N/m]
PP	18	CD	21	2330
		MD	50	5560
		45	68	7560
LDPE	27	CD	2500	333330
		MD	750	55560
		45	750	55560

The force applied in a trouser tear test for PP and LDPE is plotted versus extension of the clamps in Fig. 6. Both loading and un-loading is presented in the graphs. Arrow 1 indicates the initial extension to start a tear, overcome the threshold value of force needed to start the pre-made crack growing, point F indicates the initial force required to start a crack (crack-initiation), arrow 2 indicates the force needed to propagate the crack which is constant for PP and increasingly non-linear for LDPE. Arrow 3 indicates the final retraction of specimen as applied force is removed. Area below arrow 1 indicates the strain energy stored in specimen before crack growth (energy required to start a crack), area below arrow 2 indicates the energy released during crack extension Arrow 3 indicates the stored energy in the legs at the end of test. The non-linear segments of the curves, prior to tearing and during unloading, correspond to stored strain energy in the legs of the specimen.

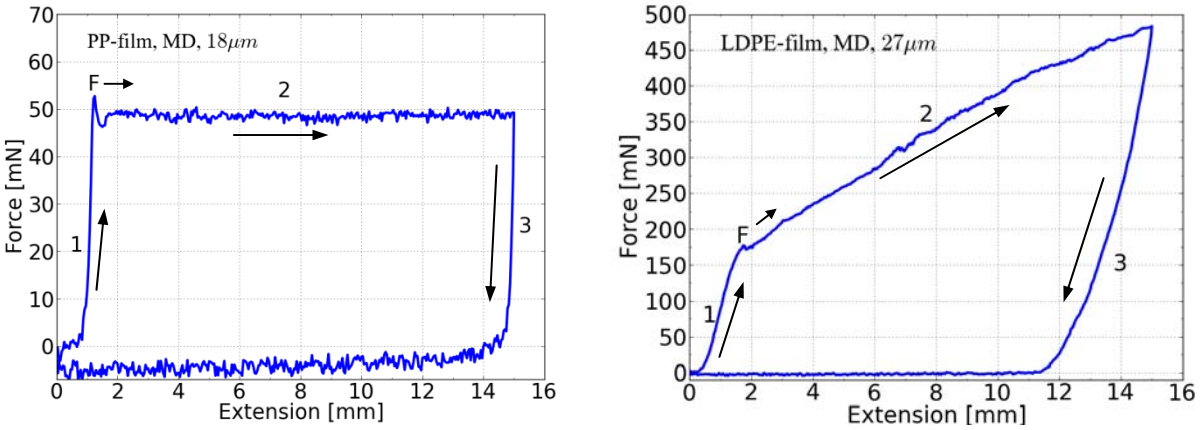

Figure 6. Trouser tear test, loading and unloading for PP and LDPE-film in MD.

From the fracture surfaces shown in Fig. 7 for PP and LDPE it is evident that the fracture mechanical behavior and processes are different in the two materials. Substantial plastic deformation is developed in the LDPE material leading to localized thinning of the cross section. PP material has no plastic deformation in the crack tip for tearing fracture. Fracture edges are presenting a wavy shaped geometry in the LDPE and representing a straight line in PP. This is an area that needs more thorough understanding and knowledge for future studies. The mechanical behavior and also the fracture mechanical behavior are strongly coupled to the manufacturing technology and process settings, what polymers that are used and also the morphology and chemical composition. This subject has to be addressed separately and finding technologies to be able to increase the knowledge and understanding of the micro mechanical behavior is important.

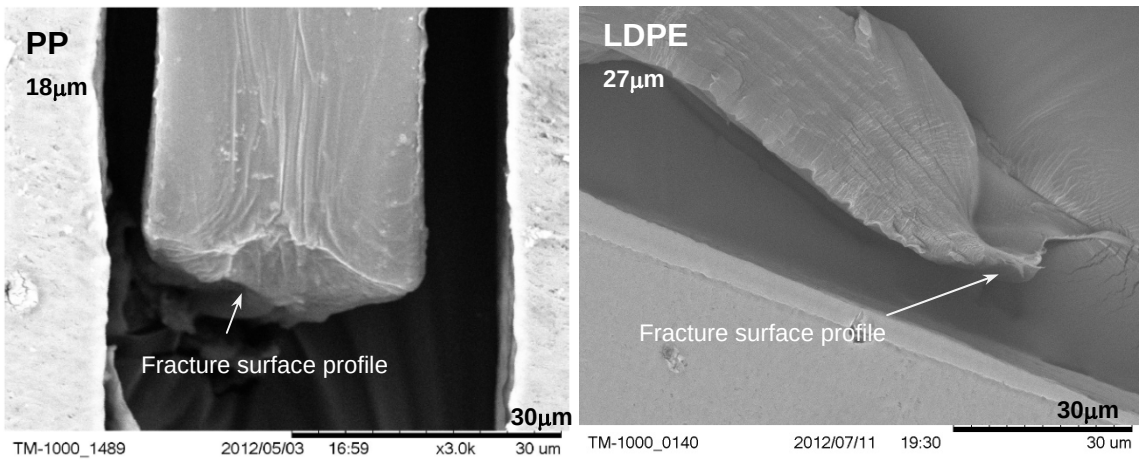

Figure 7. SEM pictures of the fracture surface profile in PP and LDPE.

5. Conclusions and discussion

Experimental trouser tear tests were performed in this research work according to the American standard ASTM 1938-08 [15]. Two polymer films with different fracture mechanisms and micro structural composition were studied, PP and LDPE. Repeatable and reproducible experimental results were obtained after adjustments of the experimental equipment. Non-compliant test equipment was used due to the low forces registered in the tests. For both materials different responses were measured in the three material directions MD, CD and 45.

Trouser tear test results for the highly extensible polymer film, LDPE in this study, show:
- Fracture is governed by a mixed mode material behavior (mode I and mode III).
- The tearing energy is directly proportional to the deformation of the plastic yielded zone at the fracture edge, hence creating increasing deformation zone with increasing force. Thus deformation and strain energy rate is continuously increasing showing higher tearing energy.
- One of the legs elongates when the crack tip exhibit both mode I and mode III failure, which is clearly shown in the case of loading in CD material direction.

Trouser tear test results for the low extensible polymer film, PP in this study, show:
- Fracture is solely governed by mode III material behavior.
- There is no pronounced yielded zone, hence all strain energy is consumed and dissipated into local plastic flow, crack tip growth, polymer chain orientation and heat generation.
- Low covalent bonding forces and voids present in the material gives a knotty or shaky tear graph. Knotty tear is due to that the crack path follows these small voids which result in small variation in forces.

It was found that, the low-extensible PP film requires only a small force to fracture, almost negligible compare to the highly-extensible film, LDPE. If the material fractures in a brittle fashion, PP in this case, the result is independent of the shape of the test specimen and the manner in which the deformation is applied. An almost constant tearing force is needed in brittle materials to propagate the crack in different material directions. In this type of material the local deformation in the surroundings of the crack tip is determining the global response. However, if the material is ductile the behavior is much more complicated. The plastic flow at the crack tip is not directly involved in the fracture process and hence the deformation doesn’t only take place locally in the vicinity of the crack tip. The test specimen size and geometry influence the result and therefore it is hard to find a material parameter governing ductile tearing. To separate the leg extension, the plastic flow and the actual tearing force is therefore challenging. It should be noticed that tearing force is also influenced to a large extent by type of polymer, temperature, material anisotropy and loading rate which has not been tested/discussed in this work. Finally, as seen in the SEM pictures, it is possible to distinguish a low-extensible and a highly extensible material by studying at the fracture surfaces in samples. In the highly extensible material the fractured surface is presenting a wave-shaped geometry. Low-extensible material shows a very sharp crack surface and hence a straight line is created during the trouser tear tests.

Abstract:

Poly dimethyl siloxane (PDMS) is a highly flexible inorganic polymer currently widely used in soft lithography and microfluidics applications due to its optical transparency, biocompatibility, and gas permeability in addition to the simplicity in fabrication process and ease of controlling the mechanical properties. Recent work has explored phenomenological and structure based entanglement models for a better understanding of entropic mechanisms in elastomers and to address limitations in classical rubber elasticity theory vis-à-vis the topological interaction arising due to chain crossing and their finite extensibility. To quantify the individual effects of physical entanglements and chemical crosslinking on the network structure-property relationships, we prepared two differently crosslinked PDMS elastomers and used swelling of the polymer in xylene to obtain variable microstructures. Highly crosslinked PDMS networks show isotropic swelling in xylene and high values of storage modulus as compared to PDMS obtained using low amounts of crosslinker. Uniaxial tension and biaxial experiments show that an increase in crosslinker leads to a higher modulus of the elastomers. Biaxial mechanical experiments show that the slip link model best fits our experimental data obtained using equibiaxial and nonequibiaxial tests that add constraints to the chain deformations. Dynamic mechanical analysis (DMA) studies show the dynamic variations in the chemical crosslinks and physical entanglements on the properties of the elastomer networks. Such studies relate structure-property relationships in PDMS networks that may be useful in microfluidics, mechanobiology studies to assess effects of substrate stiffness on cellular responses and biosensor applications.

Keywords Polydimethysiloxane, Swelling, Entanglement, Crosslinking

1. Introduction

Poly (dimethylsiloxane) (PDMS) is one of the most flexible known inorganic polymers and is a widely used as adhesives, dampers, and in microelectronics and biomedical devices [1]. PDMS is obtained through differential crosslinking of a base polymer to form tailored networks that can be used to produce dramatic changes the material properties of the crosslinked elastomer. Network properties are dependent on the amount of chemical crosslinking coupled with a high number of physical entanglements produced while keeping all other processing variables constant. Classical rubber elasticity models, obtained using the Gaussian description of the networks, show that the molecular weight of crosslinked polymer networks is directly proportional to the measured shear modulus. Recent investigations have focused on the individual contributions of the chemical

crosslinks and physical entanglements to the mechanical properties of elastomers using phenomenological and microstructure based models for the total strain energy [2, 3]. Of these, the Edward-Vilgis tube model, also referred to as the slip link model [4], and the Arruda-Boyce model [5] are promising models to describe mechanics of crosslinked networks.

Recent investigations in our lab show that the SL model describes the network properties of PDMS networks, crosslinked using differential amounts, to produce PDMS networks with varying network topography of individual chains. The goals of this study are to investigate the effects of varying physical entanglements on the mechanical properties of the PDMS elastomers that are hypothesized to produce a measurable difference in the material properties of the networks. We prepare PDMS elastomers by varying the crosslinking compound to produce two different network compositions and use swelling of the elastomers in xylene to alter the physical entanglements in the structure. Because swelling in solvents may cause removal of the uncrosslinked sol fraction of the polymers comprised of unreacted PDMS and star molecules [6], we use dynamic mechanical analysis (DMA) methods to distinguish between the properties of the prepared elastomers using a linear viscoelasticity framework. Further, to clearly distinguish between the entanglements and crosslinks, we use methods to swell the elastomers and assess changes in network microstructures using DMA measurements. The dynamics of the elastically active networks can be individually tested to quantify the elastic and viscous contributions to the mechanical properties of PDMS and investigate the effects of stoichiometric imbalance caused by differential chemical crosslinking and physical entanglements on the network properties.

2.Materials and Methods

Poly (dimethylsiloxane) was prepared by mixing base silicone elastomer with crosslinker (PDMS, Sylgard®184, Dow Corning) in weight ratios of 10:1 and 40: 1, represented as P10 and P40, in this study. The mixture was degassed to remove air bubbles and cured at 40 ^{0}C for 8 hours to obtain the silicone specimens for the mechanical experiments.

2.1 Swelling behavior

PDMS elastomers were completely immersed in xylene at room temperature for 24 hours and the swollen sample dimensions in the three directions were recorded using a digital camera (n=3). The images were processed to quantify three dimensional changes following swelling. Further, sample weights were obtained to characterize the swelling ratios at various time intervals. Swelling of elastomers in organic solvents is designed to produce alterations to the network conformations whose effects must be quantified using mechanical experiments. Finally, swollen specimens were air dried for 24 hours and tested to delineate differences in chemical crosslinks and physical entanglements on the measured mechanical properties.

2.2 Mechanical characterization

To characterize mechanical properties of PDMS elastomers prepared using differing crosslinking

ratios, monotonic compression and tension experiments were used. Because uniaxial experiments are insufficient to quantify the constitutive properties of elastomers, we also use planar biaxial experiments using variable stretches in two orthogonal directions to produce a wide range of deformations in parameter space. Such data, although scarce in literature, are necessary to quantify the differences in material behaviors and obtain a suitable strain energy function to describe the material. Finally, we use dynamic mechanical analysis (DMA) experiments to quantify changes in specimen microstructure caused due to swelling in xylene.

Uniaxial and biaxial tensile mechanical tests were performed using a custom planar biaxial instrument (Bangalore Integrated System Solutions (P) Ltd, India) details of which are published elsewhere [7]. Dumbbell (ASTM D412–06) shaped samples of P10 and P40 were cut from prepared PDMS sheets using a punching machine with die for uniaxial mechanical experiments. Specimens were clamped between two stretcher arms, preloaded to 20 gram force, and stretched uniaxially under force control (5 gm/sec). Marker points, placed 14 mm apart in the gauge region, were imaged using a video extensometry system, their displacements measured using centroid tracking with a custom MATLAB (v7.8.0.347 (R2009a)) programs which were finally used to quantify strains in the sample. Stretch (λ) at any point of elongation was calculated using a direct method obtained as a ratio of change in length during deformation to the original length. Loads in the specimen during deformation were continuously recorded and converted to engineering stresses using the cross sectional dimensions following prior to the experiment. Young's modulus was calculated using the linear portion of the stress-strain plot which corresponded to about 10% stretch. Biaxial and nonequibiaxial experiments were performed on flat P10 and P40 sample of dimensions 40 mm x 40 mm with thickness ranging from 1-1.6 mm. In this protocol, the elastomer sample was preloaded to 20 grams and stretched in the two orthogonal directions in various load ratios of 4.3:1.7, 3.3:5, 1:2, 2.3:3.3 and 1:1 at a rate of 2 gram/sec.

Monotonic compression test was done using Zwick/RoellZ005 Universal Testing Machine, GmbH Germany. Cylindrical samples (n=3) of PDMS of length 13 mm and diameter 30 mm were prepared and the specimens were compressed at a rate of 0.5 mm/sec, following a preload of 20 gm.

DMA experiments were carried out using P10 and P40 PDMS samples (n=3) of dimensions 40 mm length, 10 mm width and 4-5 mm thickness prepared using the two crosslinking ratios as described earlier. A Bose Electroforce® 3200 instrument (Bose Corp. USA) was used to preload PDMS samples to 0.1 N load followed by sinusoidal cyclic displacement of amplitude 1.5mm over a frequency range from 0.5 to 80 Hz. Discrete Fourier transforms of the analog force and displacement traces were calculated using custom MATLAB programs and the phase difference between these traces, δ, were used to compute the storage (E'), loss moduli (E'') and loss tangent ($\tan\delta$) defined as

$$E' = \mathrm{E}\cos\delta,\ E'' = \mathrm{E}\sin\delta,\ \tan\delta = \frac{E'}{E''} \tag{1}$$

where E is Youngs modulus.

3. Results and discussion

3.1. Effects of swelling on PDMS samples

Weight ratio of swollen PDMS samples, calculated as

$$\%\ Swelling\ Ratio = \frac{W_s - W_u}{W_u} * 100 \quad (2)$$

W_u and W_s in equation (2) are the weights of unswollen and swollen sample respectively. Swelling ratio for P40 and P10 are plotted for various time intervals (Figure 1). These results clearly show that swelling ratio for P40 specimens is significantly higher than that for P10 group at each time interval. Further, specimens from both groups reach equilibrium swelling by 24 hours. Specimens swollen in xylene for 4 and 24 hours were air dried for one day to remove residual xylene and obtain an altered polymer microstructure produced by changes to the physical entanglements in the polymer networks.

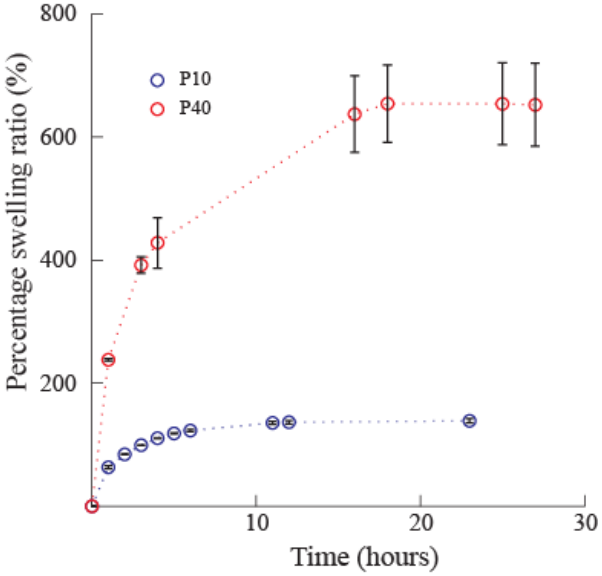

Figure 1. Variations in swelling ratio of P10 and P40 specimens swollen in xylene over a 28 hour period. At each time interval, P40 samples have a higher swelling ratio as compared to P10 specimens.

Table 2 shows corresponding changes in specimen length, width, and thickness following swelling in xylene for 4 hours calculated based on initial sample dimensions before swelling.

	Length (%)	Width (%)	Thickness (%)	
			Before drying	After 24 drying
P10	34.27± 6.02	33.70± 8.88	49.56±12.74	-0.84±0.85
P40	71.62±3.36	63.55±8.61	75.71±2.81	-10.82±3.93

Differences in the swollen weights of P10 and P40 samples correlate with changes in the sample dimensions. All samples swell isotropically in the three dimensions albeit the changes in P40 specimens were significantly higher than P10 samples respectively. We dried the samples in air for 24 hours to investigate possible changes in weight and thickness. Our results show that dried P40

samples have significantly lower weight (-17.03±9.73 %) as compared to control unswollen samples. However, there were no differences in the corresponding dry weights for the P10 specimens (-3.80±0.07%). These differences in specimen weights correlated with a decreased thickness of P40 samples by about -10.82±3.93%. that suggest removal of uncrosslinked PDMS polymer, commonly referred to as sol, from the network structure due to swelling in xylene [5, 8]. Spectroscopic methods, among others, may be useful to investigate such effects and will be used in the future to quantify the effects of xylene treatment on PDMS elastomers. These results are similar to those seen by others to investigate the effects of swelling of different solvents, including xylene, on solubility of PDMS [9].

3.2. Mechanical Characterization

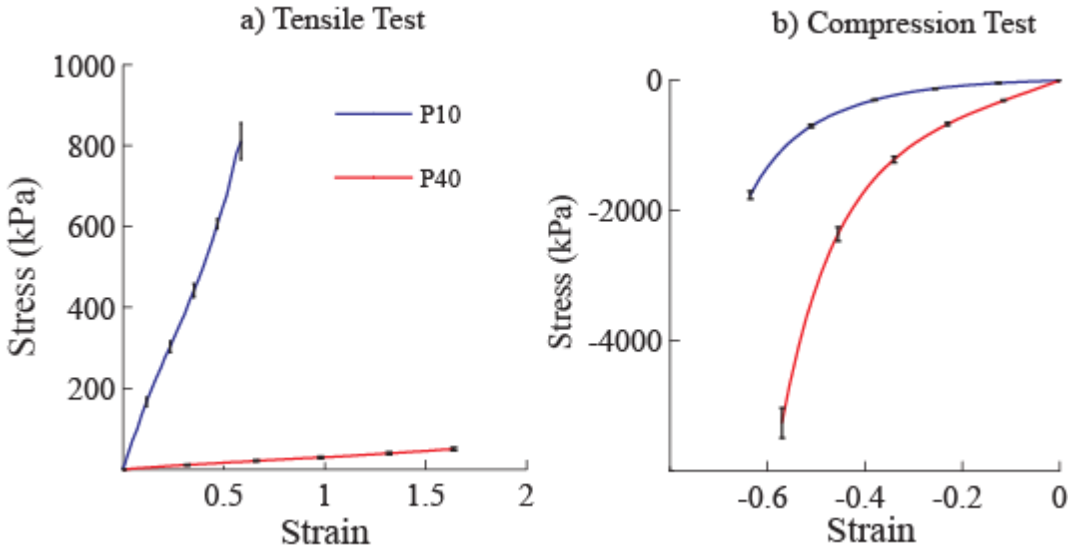

Figure 2. Uniaxial tension (a) and compression (b) results for P10 and P40 samples.

Uniaxial tensile tests in compression and tension were performed on the P10 and P40 specimens (n=2) and the average values of the stress corresponding to each strain value are represented in Figure 2a,b. Tensile moduli were obtained using the slope of stress-strain curves corresponding to strains of about 10%. Results show that P10 samples have a significantly higher modulus ($p<0.05$) of 1400.02±15.84 kPa as compared to P40 specimens (39.46±4.34 kPa). Hence, a decrease in chemical crosslinking amounts causes dramatic differences in the mechanical properties of PDMS. We note a corresponding trend in results from compression experiments with a modulus of 2687±75.65 kPa and 300.48±9.15 kPa for P10 and P40 respectively.

Although uniaxial tests are useful to provide comparisons between the stiffness between groups, they are insufficient to be used to obtain a strain energy function to describe the microstructural properties of elastomers. We must instead rely on comprehensive biaxial tests performed using constraints in two orthogonal directions to obtain a parameter space of deformations. We performed nonequibiaxial and equibiaxial experiments on P10 and P40 samples to explore the contributions caused by strain induced topological adaptations in network structure due to loading in the two orthogonal directions (Figure 3). Equibiaxial experiments confirm that P10 sample has stiffer

response as compared to the P40 specimen.

We use results from biaxial experiments to evaluate phenomenological and microstructural based strain energy models to describe the PDMS networks. These investigations show that the slip link model [10], which considers individual contributions of physical entanglements and chemical crosslinks on microstructural mechanics of elastomer networks, fit the biaxial and uniaxial experimental results better (r^2 =0.958) than Mooney Rivlin model, Arruda-Boyce, and the neo-Hookean models. However comparisons between the model fits to the P40 and P10 samples shows that in highly crosslinked P10 stress-strain behavior have contributions from physical entanglements.

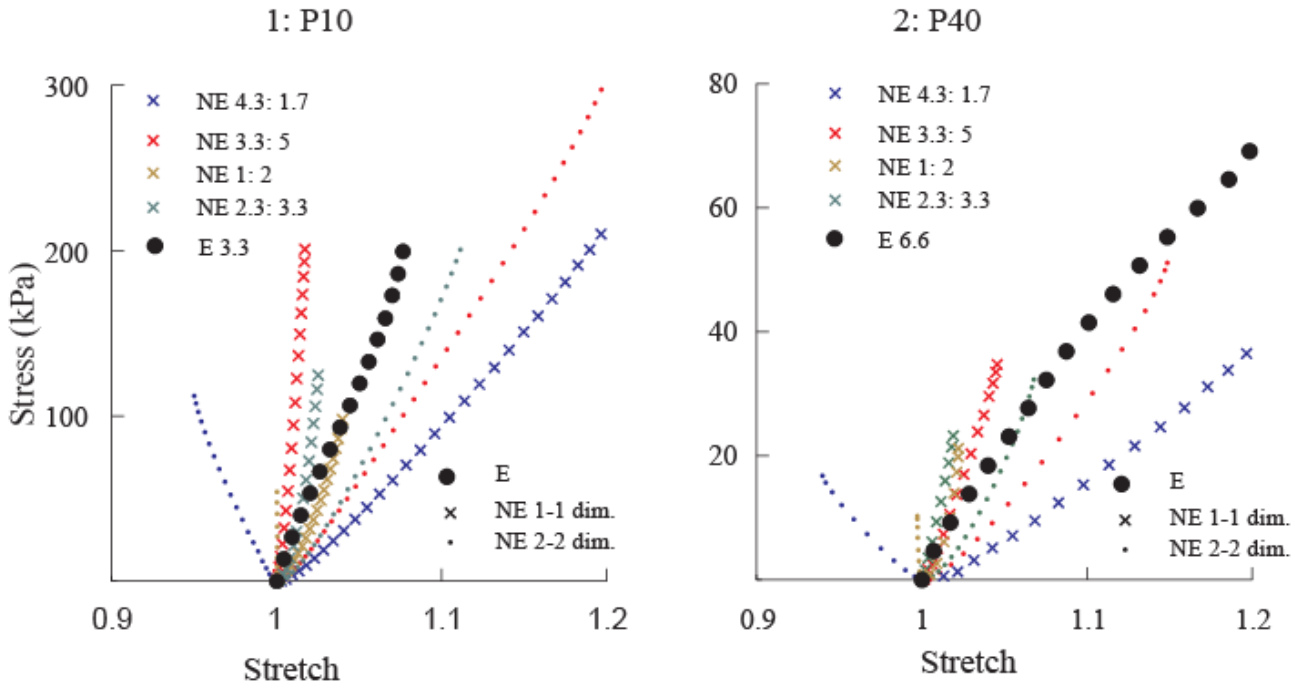

Figure 3. Equibiaxial (E) and nonequibiaxial (NE) stress-stretch results for P10 and P40 samples [10] obtained by differential stretching of samples in two orthogonal directions denoted 1-1 and 2-2 in the figure. The maximum load in the P10 sample was 600 gram whereas that in the P40 was 60 gram. The different ratios in NE experiments were normalized with respect to these maximum loads.

To clearly distinguish between the entanglements and crosslinks, we use methods to swell the elastomers and assess changes in network microstructures using DMA measurements. P10 and P40 samples in the unswollen state and that obtained by swelling and drying the elastomers were subjected to cyclic sinusoidal loading as described earlier (Figure 4).

Higher values of E' as compared to E'' with corresponding low values for tanδ demonstrate the dominance of elastic behavior contributing to the measured viscoelastic property of P10 and P40 samples. In general, E' and E'' for PDMS increases with an increase in frequency. Although entangled chains can slide freely at low frequencies, they are unable to loosen at higher frequencies that result in restriction in the motion of the polymer chains and a corresponding increase in

modulus. The trend of frequency dependent response of storage and loss modulus of swollen P10 is however different as compared to that of unswollen specimen due to the presence of xylene. A similar frequency dependent response for dried samples following swelling and unswollen P10 specimens suggests that the chemical crosslinking of networks was not altered due to swelling. In contrast, there is a large variation in the storage modulus of unswollen and swollen, dried specimen for P40 specimens. Thes differences may arise due to the presence of trapped entanglements in the highly crosslinked P10 samples leading to lower rearrangements in the entanglements during swelling as compared to P40 specimens that also shows loss of sol fraction of uncrosslinked material and a corresponding lower molecular weight. The rate of increase in E' for the P40 specimens with respect to increase in frequency was however high compared to P10 specimens.

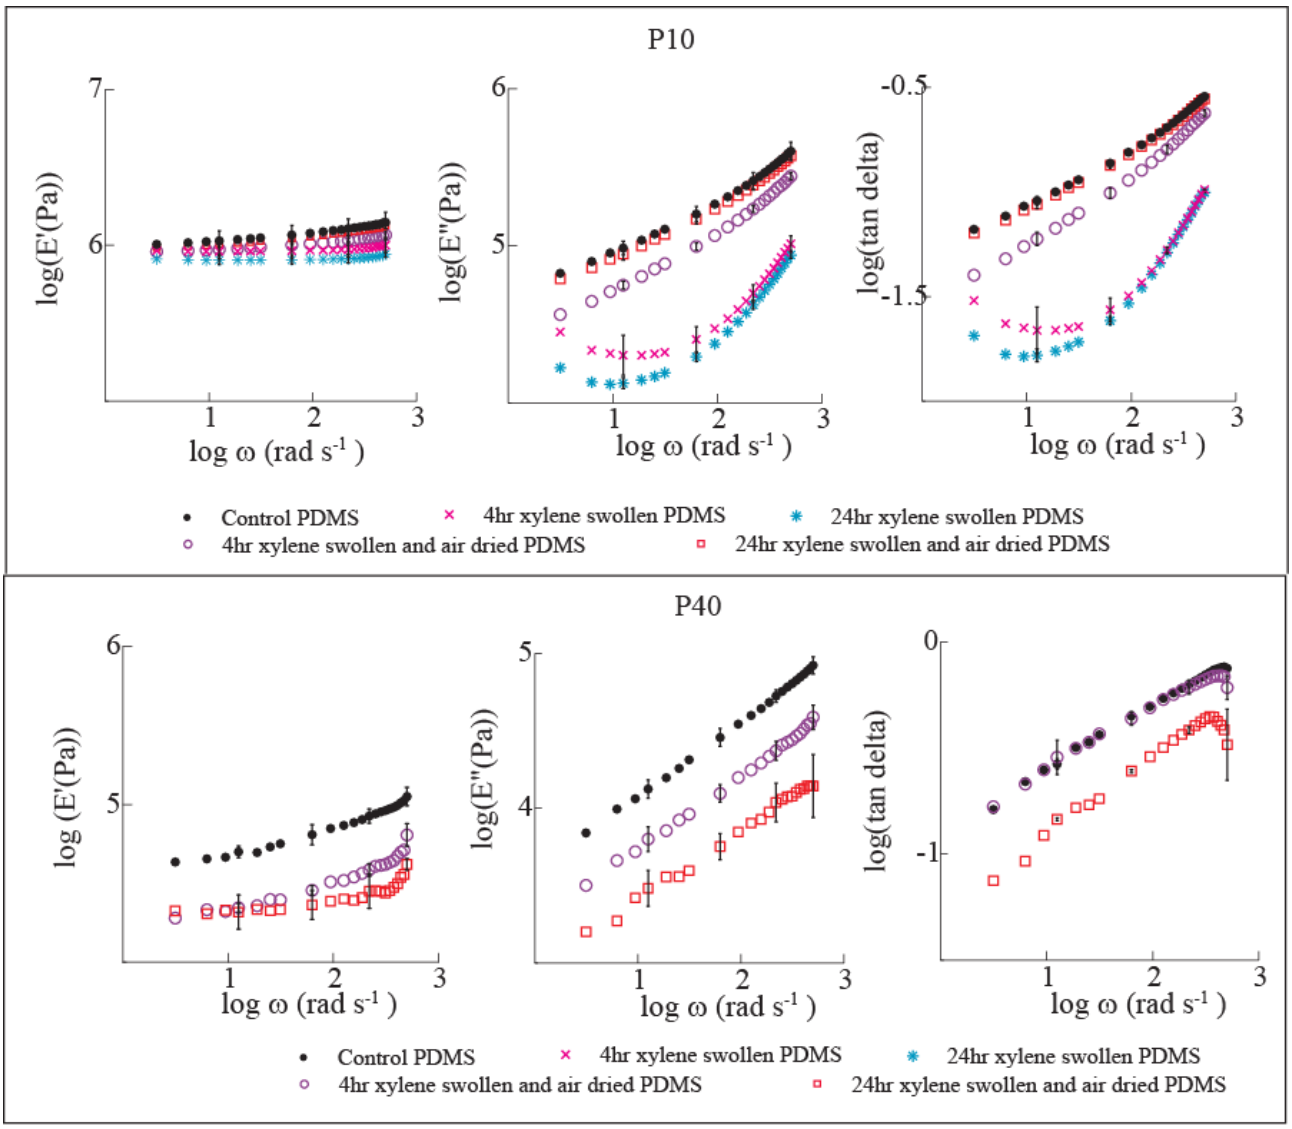

Figure 4. Effect of swelling in xylene on storage modulus (E'), loss modulus (E'') and damping factor (tan δ) for (a) P10 and (b) P40 specimen.

Table 3. Percentage increase E' of P10 and P40 when frequency varies from 1to 80Hz

	Control	Xylene for 4hr, drying	Xylene for 24hr, drying	Xylene for 24hr	Xylene for 4hr
P10	38.09±0.85	28.05±1.39	39.10±1.31	8.15±1.48	7.87±0.01
P40	159.60±10.29	239.35±71.02	103.42±18.62		

4. Conclusions

To study the effect of entanglements and crosslinks in the macroscopic behavior we performed swelling measurements and mechanical characterization of PDMS prepared with different weight ratios of base polymer to crosslinker, denoted as P10 and P40, in this study. Tensile, compression and biaxial mechanical tests show that P10 specimens demonstrate a stiffer response as compared to P40 specimens. Results from biaxial experiments were fit to the Edward-Vilgis slip link model using a nonlinear least squares fit method. Our results show that the mechanical response of elastomers demonstrate individual contributions from chemical crosslinks and physical entanglements. To delineate the effect of crosslinking and entanglements we performed DMA measurements on unswollen control material and those swollen in xylene, and dried in air for the P10 and P40 samples in the study. Our study shows that the P10 specimens have higher values of Young's modulus and storage modulus and a corresponding low swelling ratio due to the higher degree of crosslinking and hence presence of trapped entanglements. In contrast, a low degree of crosslinking in P40 samples demonstrated a higher viscous contribution as compared to the elastic behavior of the P10 elastomers. Our results also show that both P10 and P40 exhibit an increase in rigidity and loss modulus at high frequencies. Dynamic mechanical experiments also show that the elastic and loss moduli decrease due removing of uncrosslinked polymer and locking the chains in different configurations produced by swelling. Ongoing stress relaxation experiments are envisaged to characterize the effects of swelling on the mechanical properties that will lead to a better understanding of the effects of entanglement in the on viscous properties of PDMS.

Abstract Shear thickening fluids (STFs) classified as Non-Newtonian fluids are fluidic composites of dense suspensions. These fluids display unusual phase transitions between liquid and "solid" phases due to recoverable changes in viscosity at a critical rate of shear. This study characterizes the fracture behavior of a STF with 58 vol.% dispersion of styrene/acrylate particles in ethylene glycol. Double cantilever beam (DCB) specimens with the STF as adhesive layer were utilized to investigate the Mode-I fracture energy of the STF. The fracture behavior of the STF of different thickness was evaluated in detail at different crack opening displacement rates, varying from 1 mm/s to 50 mm/s. The results indicate that the fracture behavior of the STF is very rate-sensitive. However, before the opening displacement rate reaches 5 mm/s, the STF is not showing any "solid" like behavior. The average Mode-I fracture energy of the STF increases with an increase in the opening displacement rate up to 30 mm/s, after that the values are plateaued and almost constant at 240 J/m^2. This is comparable to the fracture toughness of a typical epoxy. The fracture energy of the STF also shows an inverse dependence on the thickness of the STF at low opening displacement rates, but at high rates such dependence was not observed.

Keywords Fracture energy, Shear thickening fluid (STF), Rate effect, Double cantilever beam (DCB), Adhesive thickness

1. Introduction

The ability to divert or dissipate dynamic energy during impact has many engineering challenges in industrial, biomedical and military applications. Shear thickening fluids (STFs) can play a vital role in engineering designs as energy shunting materials. STFs are mostly fluidic composites of dense suspensions that exhibit reversible shear thickening behavior, and STFs are non-Newtonian fluids, which can sometime display intriguing phase transitions between liquid and "solid" phases due to the recoverable changes in viscosity at a critical shear rate [1]. The use of STFs opens up many opportunities in developing new passive, energy-absorbing systems in applications including liquid dampers/brakes, liquid armor, etc.

Over the last few decades, the shear thickening behavior of concentrated dispersions has been a major topic of interest for rheologists owing to their immense importance in industry [1-4]. Shear thickening was initially believed to be a severe problem, because it leads to such issues as failure of mixer motors due to overloading, damage mixer blade and other processing equipment, and induce dramatic changes in suspension microstructure, such as particle aggregation, which results in poor fluid and coating qualities [1]. The early investigations of shear thickening behavior were to mitigate damage on processing equipment caused by the shear thickening transition [5, 6]. Later STFs have become attractive due to their unique property that makes them ideal for energy absorption applications. When subjected to an impact, this shear rate-activated fluid converts from a low viscous to a high viscous state almost instantaneously, and it can absorb some of impact energy while helping to dissipate the remaining energy. Many studies have been done on the energy absorption applications of STFs. For the personal protection with application of STFs as 'liquid armor', it has attracted many efforts in research [1, 7-9], and STFs-treated fabrics showed not only

the enhanced ballistic resistance but also higher flexibility and light weight [10-17] than the untreated ones. STFs have been also used in several other specific applications, especially in ski boot cushioning, liquid couplings, shock absorber fillings, rotary speed limiters, damping and control devices [18, 19].

The previous studies clearly highlight the strong potential of STFs for various industrial applications as new adaptive energy-absorbing materials, owing to their unique mechanism of recoverable liquid-"solid" transitions. The performance of the STF-based systems is greatly dependent on the behavior of STFs near the shear thickening transition as well as their properties after the shear thickening transition in particular. Most existing research has focused on the characterization of STFs using classic rheological methodology. Previous research primarily dealt with examining the response of shear thickening systems, especially in the identification of critical transition which indicates shear thickening occurrence. However, the properties of STFs after the shear thickening transition cannot be captured because of the limitations of conventional rheometers.

In this study the fracture behavior of a STF composed of 58 vol.% dispersion of styrene/acrylate particles in ethylene glycol [20] was investigated to quantitatively evaluate the dilatant ability of STF to shunt energy after shear thickening transition. Virtually for all applications fracture toughness or fracture energy is one of the most important material properties for characterizing energy dissipation capability; and it can be dependent on several factors, such as the type of loading (e.g. tensile and shear), the environmental conditions (e.g. temperature and moisture), the loading rate. Fracture tests were performed using a double cantilever beam (DCB) specimen with STF as adhesive layer to investigate the effect of displacement rate and adhesive layer thickness. A high speed digital (HSD) camera was used to carefully examine the fracture behavior of STF.

2. Experimental

2.1. Material

The STF used in this research work is a water soluble fluid composed of 58 vol.% dispersion of styrene/acrylate particles in ethylene glycol, supplied by BASF AG (Germany). The spatial distribution and the geometry of particles have been examined previously using a Zeiss 902 transmission electron microscope (TEM) and a scanning electron microscope (SEM) [20], and the shape of particles is near-spherical with an average size of about 300 nm; the particles were well dispersed in the ethylene glycol with the existence of micro-sized flocculation.

2.2. Specimen Configuration

There is no standard method to measure the Mode-I fracture energy of STFs. In this work, double cantilever beam (DCB) specimens with the STF as the adhesive layer were adopted in such an approach. The upper and lower beams of DCB specimens were carbon fiber-epoxy (CF/EP) plain woven composite beams, which were selected owing to their high stiffness, lightweight and smooth surface properties. The CF/EP beam was 200 mm long with 30 mm in width and 1.7 mm in thickness. Two aluminium (Al) loading blocks were bonded on the upper and lower surface of CF/EP beams at one end using a high strength adhesive, as shown in Fig. 1.

Before applying the STF, the surfaces of CF/EP beams were cleaned by rinsing with water. After water rinsing and complete drying, STF was uniformly distributed between two beams with a folded Al foil of 0.02 mm in thickness, which replicates a single entity of a start-crack (Fig. 1). The

length of the start-crack amounted to 50 mm. The folded Al foil was chosen to form the start-crack due to its flexibility, thin and smooth surface features. To maintain the uniform thickness of the adhesive layer without voids in it, sufficient STF needs to be applied to allow a continuous spreading of the STF from the center of the specimen to the edges by squeezing flow. Different adhesive layer thicknesses, ranging from 0.2 mm to 2.05 mm, were obtained for the Mode-I fracture experiments.

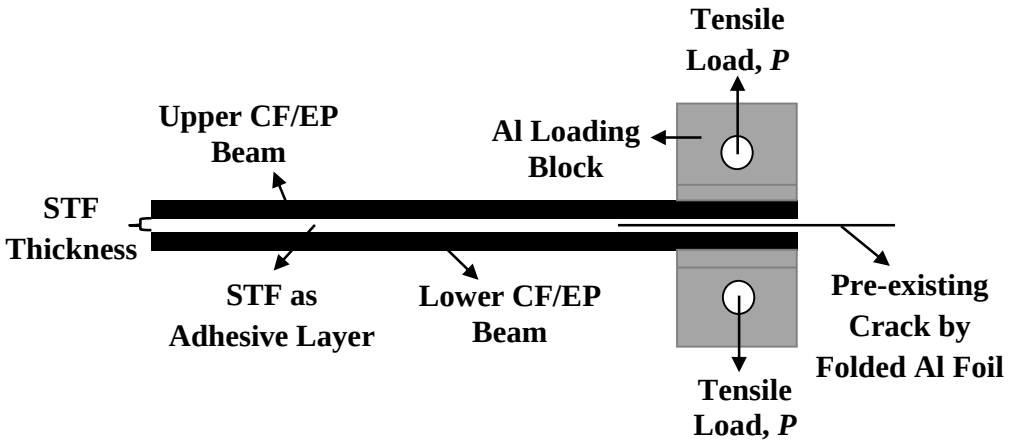

Figure 1. Schematic diagram of a DCB specimen with STF as adhesive layer and Al foil as a pre-existing crack

2.3. Mode-I Fracture Test Procedure

An Instron 8501 servo-hydraulic machine configured with a data acquisition system was utilized to conduct experiments in a displacement-controlled mode. The load experienced throughout the experimental duration with respect to the crack opening displacement was monitored and recorded through the load cell by a digital data acquisition unit at a sampling rate of 1000 Hz. Experiments were performed under various stroke speeds, ranging from 1 to 50 mm/s for the DCB specimens with different STF thickness, while holding all other variables constant. Stroke speeds chosen for experiments were 1, 5, 10, 20, 30, 40, and 50 mm/s, and all tests were undertaken under ambient conditions. Up to 50 experiments were conducted at each displacement rate with different STF thickness.

2.4. High-Speed Photography

Video recording was performed during each experiment using a high speed digital (HSD) camera with a frame rate of 500 frames/sec (fps) at a resolution of 512 ×240 pixels per image, in order to capture the specimen's physical movement. It helped to calibrate the actual displacement, and it also helped to observe the crack opening and crack propagation. With the help of a software program, the fracture behavior of STF in different stages of loading could be evaluated in detail.

2.5. Fracture Energy

The fracture energy of the STF to resist opening separation can be established by accessing the raw data obtained from the experiments. Continuous records of HSD image, load and corresponding opening deflection of CF/EP beams were used for determination of the fracture energy of STF in a DCB specimen. The data reduction scheme to determine the fracture energy for the DCB specimen with an adhesive layer of STF is the 'Modified Beam Theory (MBT) Method' [21] which quantifies the strain energy release rate at the crack initiation and propagation. The fracture energy or the critical energy release of a DCB specimen [22] is expressed as:

$$G_I = \frac{3P_c\delta_c}{2ba} \quad (1)$$

where, P_c = the critical load for crack growth, δ_c = the opening displacement at the critical load P_c, b = the specimen width, and a = the start-crack length.

3. Results and Discussion

3.1. Fracture Load

The response of the STF undergoing DCB fracture test was quantitatively assessed by synchronizing the load experienced by DCB specimen against its opening deflection in conjunction with the records of the HSD camera. Fig. 2 shows the typical load-displacement curve at a displacement rate of 40 mm/s. At point O_1, a local hike in load can be observed, but no crack growth was clearly visible in the specimen, Fig. 3(a). When the load was further increased, reaching its peak, point O_2, a white spot was observed in the STF layer at the tip of the start-crack, Fig. 3(b), showing the initiation of crack growth. After the peak, point O_2, the load started to drop continuously, accompanied by crack propagation in the specimen, Fig. 3(c).

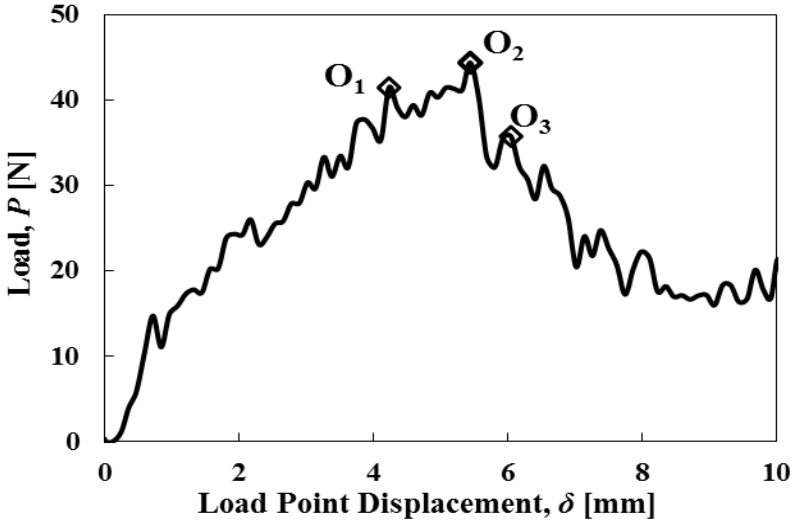

Figure 2. Load-displacement curve of a DCB specimen at a displacement rate of 40 mm/s

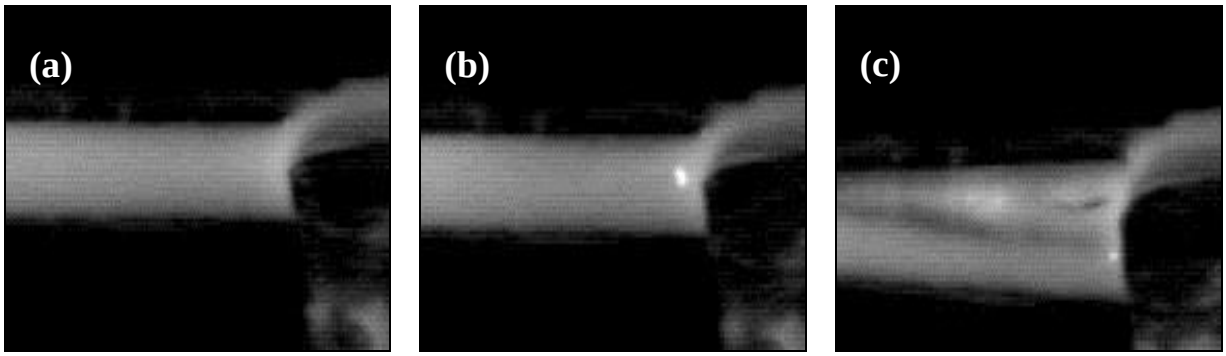

Figure 3. Fracture of STF was observed by HSD camera at dissected points of load-displacement curve in Fig. 2

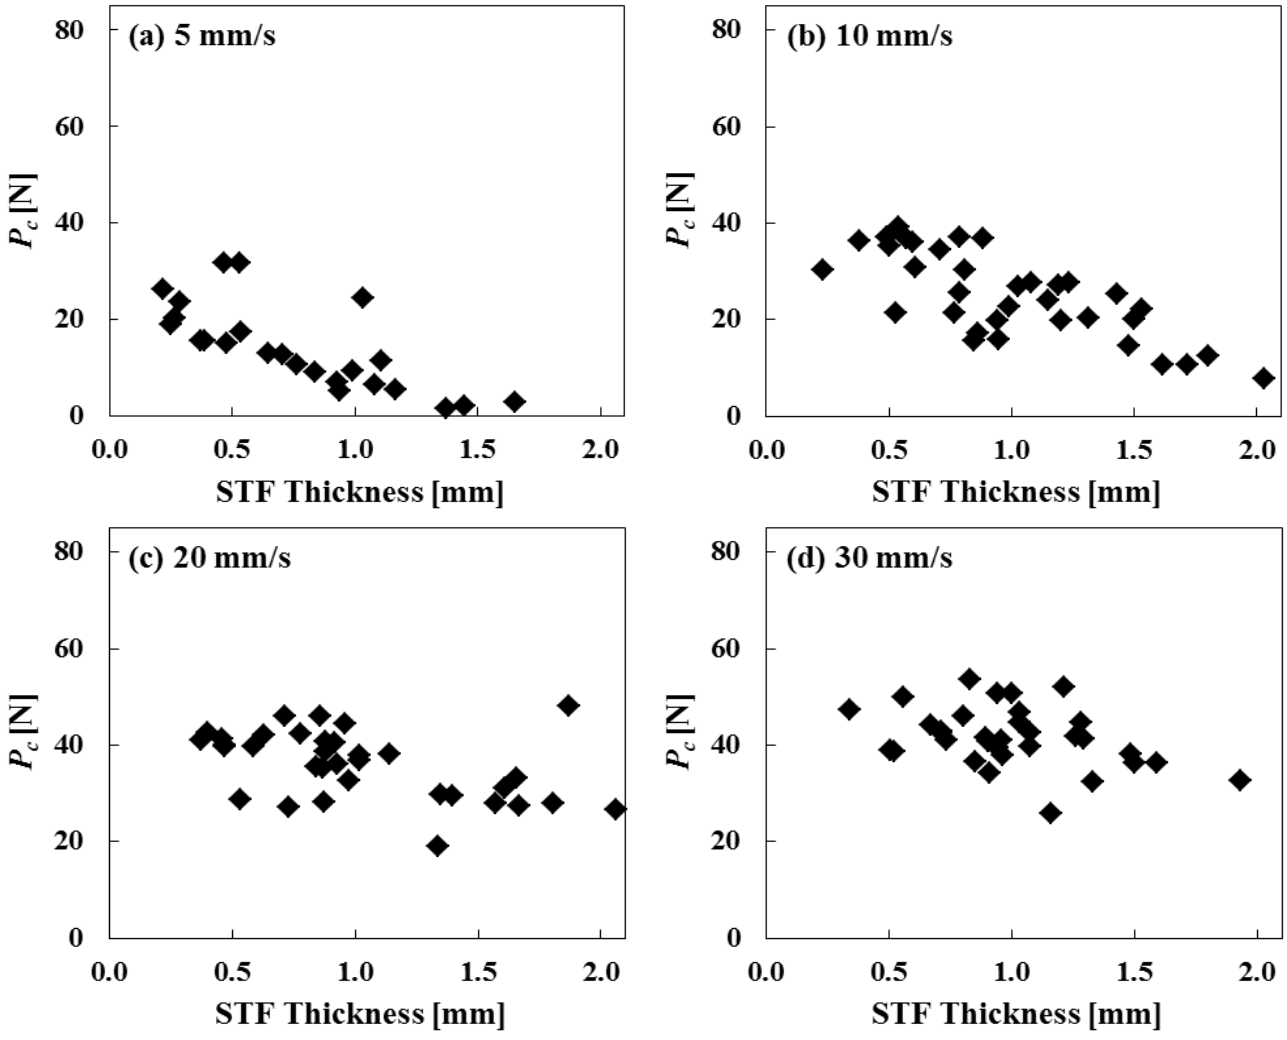
By comparing the load-displacement curve of each specimen with corresponding video images, the critical load and the corresponding opening displacement for calculating the Mode-I fracture energy of the shear thickening fluid were defined. It was observed that not all DCB specimens showed the fracture behavior as a conventional solid. In particular, specimens tested at low displacement rates or with a thick layer of STF, exhibited an opening during which stretching of the STF with less

bending of the two CF/EP beams occurred. Additional calculation was done to get the effective Young's modulus of the CF/EP beams using the load-displacement curve and following the simple cantilever beam theory. For those DCB specimens, for which the effective Young's modulus of the CF/EP beam was clearly lower than that measured (using the same CF/EP laminate beam under three-point bending and following the procedure of ASTM D7264), the fracture energies calculated using Eq. (1) were excluded from the further discussion.

3.2. Effect of STF Thickness

It was expected that the STF layer thickness is a critical parameter, since the shear thickening phenomenon occurs only in localized regions where the shear rate goes beyond the critical shear rate, which is around 5/s [20]. Therefore the shear thickening effectiveness can disappear with increasing volume of the STF, especially at a reduced shear rate. The relation between the critical load to split the STF and the STF thickness is discerned in Fig. 4, with the STF thickness in a range from 0.2 mm to 2.05 mm. By arranging the maximum forces with respect to the STF thickness, it can be seen that a small STF thickness requires a greater load to split the STF in a DCB specimen, and vice versa. The greater the fluid thickness, the less aggregation or jamming of particles occurs, hence resulting in a lower critical load to split the specimen. However this relation is more obvious for low displacement rates (e.g., Fig. 4(a) for 5 mm/s and Fig. 4(b) for 10 mm/s). With increasing the displacement rate, the effect of the STF thickness on the critical load reduces. For displacement rates from 40 mm/s to 50 mm/s the critical load does not display any significant dependence on the STF thickness, Fig. 4(e) and Fig. 4(f).



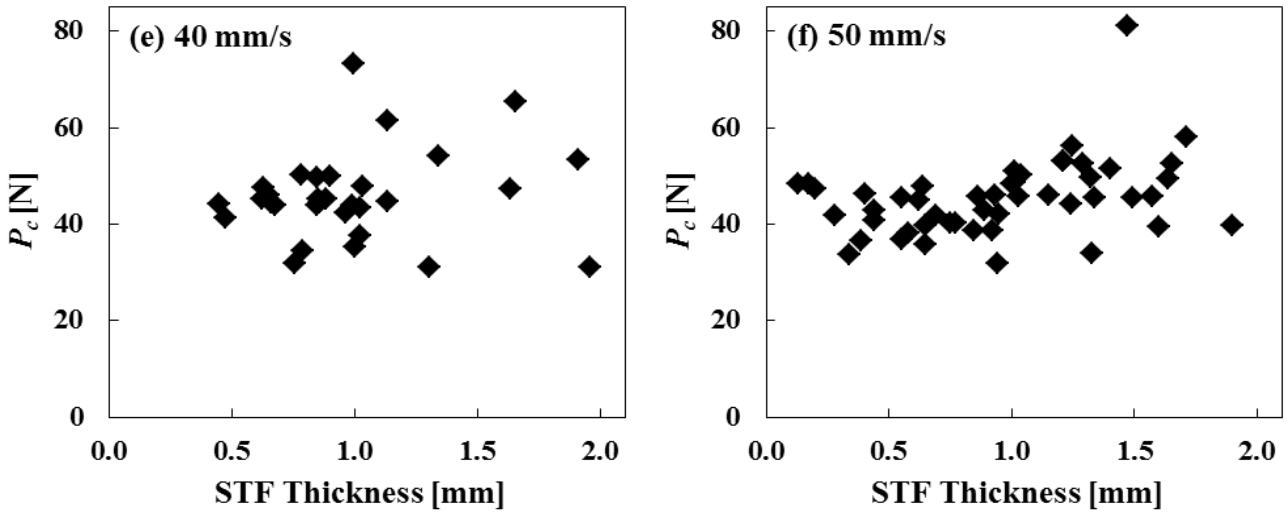


Figure 4. Effect of STF thickness on critical load at different displacement rates

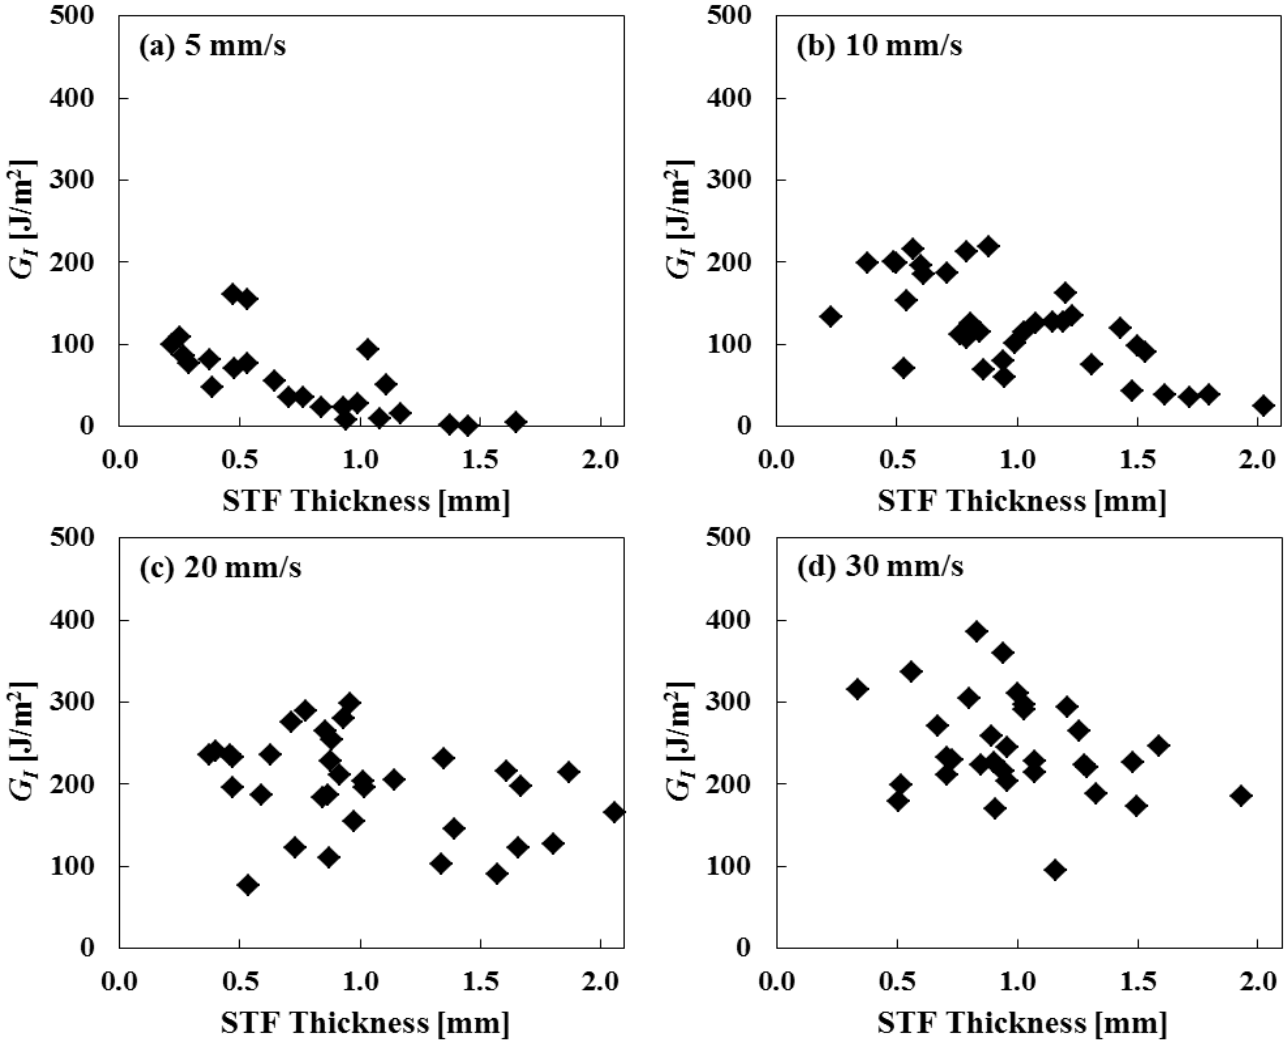
Eq. (1) shows that the Mode-I fracture energy of STF is directly proportional to the critical load, and therefore, it is expected that a similar tread of Mode-I fracture energy in relation to the STF thickness exists. The Mode-I fracture energy versus the STF thickness is plotted for different displacement rates in Fig. 5.



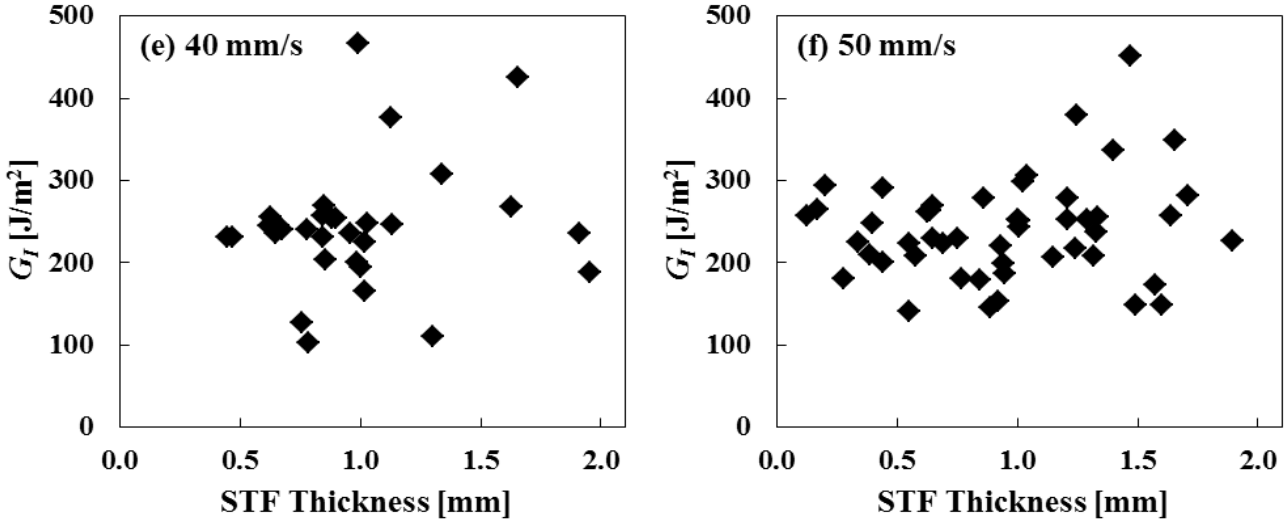


Figure 5. Effect of STF thickness on Mode-I fracture energy at different stroke rates

Up to a displacement rate of 20 mm/s, a reduced fracture energy with increased STF thickness is visible. This means, a larger STF thickness certainly results in a decreasing efficiency of the STF to absorb energy. However, with increasing the displacement rate this inverse relation cannot be observed anymore. For displacement rates from 30 to 50 mm/s, the Mode-I fracture energy does not show any significant relation with the STF thickness, in particular not at 50 mm/s.

3.3. Effect of Loading Rate

The loading or displacement rate is one of the most prominent parameters for examining the fracture behavior of STFs. The rates used here for the DCB fracture experiments were 1, 5, 10, 20, 30, 40, and 50 mm/s. The maximum of 50 mm/s was limited by the capacity of the Instron 8501 testing machine. The actual displacement rate was validated using the synchronized HSD images as well as the calculation from the time and displacement data. It was found that the actual displacement rates were very close to the preset ones in the testing range chosen. Existing differences were small, with a maximum being about ±4% of the preset ones.

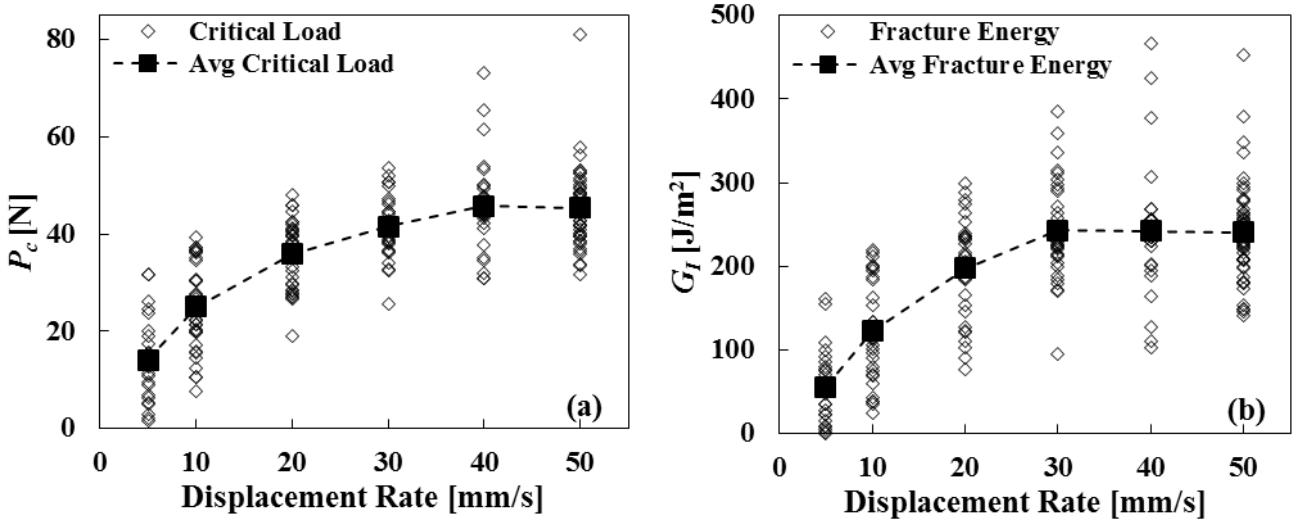

Figure 6. Effect of stroke speed on (a) critical load and (b) fracture energy of STF with different thickness

At a low displacement rate of 1 mm/s, STF is able to flow as an ordinary fluid, and the load cell did not measure any clear load with respect to the opening displacement, indicating such a

displacement rate is not enough for STF to have the transition from liquid to "solid". The HSD camera also shows there is no clear shear thickening effect of STF at this rate. In fact, before the displacement rate reaches 5 mm/s, STF did not show any "solid" like behavior, therefore no "fracture" was visible.

The effects of displacement rate on the critical load and fracture energy of the STF are graphically represented in Fig. 6, showing the results for each individual specimen. Fig. 6(a) presents the critical load with respect to displacement rate from 5 mm/s to 50 mm/s. With increasing deformation rate, the viscosity of the STF at the crack tip sharply increased, thus suppressing flow of the STF; instead it stiffens greatly and is capable of resisting an opening displacement more efficiently, causing a higher load. The increasing trend is supported by studies in the literature, which acknowledge a positive correlation between the STF's viscosity and the rate of deformation. The critical load varies with a substantial scatter for all displacement rates, because of the effect of STF thickness, articulated in the previous section. Other factors may also contribute to the scatter, such as voids or the uneven STF thickness because of leak of STF before the start of a test. However, the mean value of the critical load clearly increases with an increase in displacement rate up to 40 mm/s. A further increase in the displacement rate shows that the average critical load remains almost on a steady value. The mean values as well as the standard deviations of critical loads for different displacement rates are presented in Table 1.

Table 1. Means and standard deviations of critical load and fracture energy at different displacement rates

Displacement Rate [mm/s]	**Critical Load, P_c (Mean ± SD) [N]**	**Fracture Energy, G_I (Mean ± SD) [J/m^2]**
5	14 ± 9	56 ± 46
10	25 ± 9	123 ± 58
20	36 ± 7	198 ± 59
30	42 ± 6	243 ± 60
40	46 ± 9	242 ± 76
50	45 ± 8	240 ± 61

Almost a similar trend is observed for the Mode-I fracture energy of STF for different opening displacement rates in Fig. 6(b). As the critical load values, the fracture energy also shows a clear scatter in the values at each displacement rate, attributed to the effect of STF thickness. Also here, the average values and the standard deviations of fracture energy were calculated and summarized in Table 1. With an increase in the opening displacement rate, a positive relation is found between the fracture energy up to a displacement rate of 30 mm/s. At a low rate of 5 mm/s, the STF is able to absorb a small amount of energy while acting as a viscous "solid", though its actual value may be arguable. After the displacement rate reaches 30 mm/s the average fracture energy of STF is plateaued and remains almost constant with an averaged value about 240 J/m^2. This value indicates that the STF is capable of absorbing a certain amount of fracture energy, being comparable to a low cross-linked epoxy [23]. It seems the average value of Mode-I fracture energy of STF peaks at 30 mm/s, and it tends to reduce slightly after the displacement rate of 30 mm/s. However, such a tendency needs the careful evaluation of further studies, especially with facilities allowing higher displacement rates.

4. Conclusion

In this study, DCB specimens were used to characterize the fracture behavior and Mode-I fracture

energy of a shear thickening fluid (STF), containing 58 vol.% dispersion of styrene/acrylate particles in ethylene glycol. Effects of displacement rate (up to 50 mm/s) and STF thickness in the range of 0.2 to 2.05 mm were evaluated in detail.

The results reveal that as the displacement rate increases, the local shear rate at the crack-tip increases, sharply increasing the viscosity of the STF, thus suppressing the flow of the latter. It stiffens greatly and is capable of resisting an opening displacement efficiently, causing a higher load. Confirmed by the high speed camera images, STF clearly shows a "solid" behavior, fracturing with crack growth, when the opening displacement rate is higher than 20 mm/s. The Mode-I fracture energy of the STF increases with an increase in the displacement rate until 30 mm/s. In addition, the STF thickness was found to have a significant influence on the value of Mode-I fracture energy, attributed to the shear-thickening mechanism.

The most interesting result is that the STF adopted in this study shows almost a constant average value of fracture energy of 240 J/m^2 after the displacement rate is higher than 30 mm/s. This value indicates that the STF is capable of absorbing a certain amount of fracture energy, being comparable to a low cross-linked epoxy.

Future studies will be conducted at higher displacement rates. Such a more comprehensive characterization of the fracture behavior of STFs will certainly aid the development of energy absorbing devices using various STFs.

Abstract The failure can be caused in polymers by thermal stress and vapor pressure during reflow process. A profound view on dynamic growth of voids during reflow process is provided in this paper. The mechanical model is analyzed at first. Then the dynamic equation is derived via the energy method. Furthermore, we apply the method to numerically solve the dynamic increase of void volume fraction under the linear-elastic model. Also, the increase proceeding under different Young's Modulus is compared. It is interesting that the final void volume fraction remain constant when the Young's Modulus keeps unchanged during the reflow process. At last, the dynamic growth curves on the assumption of super-elastic constitution under different initial void volume fraction are compared. It is notable that the initial void volume fraction is extraordinarily significant for the eventual deformation.

Keywords Polymers, dynamic growth, vapor pressure, electronic packaging

1. Introduction

Polymer materials have wide applications in industry such as being adhesive film in the microelectronic packaging. However, polymers are of high porosity which influences the reliability of electronic packing. Besides, most of polymers are hydrophilic materials which are capable of absorbing a large number of moisture in ambient environment. According to the requirement of electronic packaging, electronic devices would experience a reflow process which is completed within a few minutes. The peak temperature of devices during this process typically ranges from 220℃ and 260℃, consequently moisture stored in polymer materials vaporizes and becomes vapor pressure which also pose serious threat on the reliability of package[1-3]. With regard to instable growth of micro-voids, there are a large number of works related to the field. Ball[4] investigated discontinuous equilibrium solutions of cavitations in the year of 1982. Based upon Ball's theory, Lopez-Pamies et al. [5-6] put forward the defect-growth theory. As to the failure of cavitations caused by vapor pressure, Fan et al. [7] derived a micromechanics based vapor pressure model, Huang et al. [8-9] studied cavitations' instabilities of a central hole in an infinite plate subjected to distributing pressure. And then, Guo et al. [10-12] investigated instabilities of micro-voids subjected pressure on the inner boundary and thermal stress on the outer boundary. Also, there are some literature investigating the cavitation instability in different packaging materials[13-15].However, the former work mainly focuses on the critical load of instable growth of micro-voids. Actually, it is also significant to produce a profound understanding of the dynamic growth process of voids, which will be beneficial to the industrial design. In the industry of electronic packaging, we can control the temperature to optimal processing when electronic devices are manufactured. Therefore, it is of great importance to acquire the responding increase of micro-voids with respect to time.

The outline of the paper is organized as follows: In Section 2, the mechanical model is built up. In Section 3 the energy principle is introduced to derive the transient growth equation of micro-voids to help further the discussion in the next section. In Section3, we utilize the equations in Section 3 to obtain the curve of growth of micro-voids as the time increases under the elastic and super-elastic models, respectively. In the end, the results obtained are compared, and some intriguing phenomena appear through our analysis. This paper will present a good understanding on how the void growth

during reflow process, and will benefit the engineer's design of polymer materials in this industry.

2 Formulation of Mechanical Model

The moisture absorbed by the electronic materials is trapped in numerous pores (or micro-voids). During reflow process, the temperature of the package is raised to about 220℃ or more, which induce the evaporation of moisture in micro-voids. Thus, the micro-voids are subjected to internal vapor pressure p and remote stress σ_r^A, which denotes the thermal stress due to the increased temperature . For the purpose of analysis, it is convenient to consider a spherical volume of material containing a micro-void of spherical shape with initial inner radius R_1 and outer radius R_2. We assume that the matrix material is incompressible. And the micro-void will enlarge when it subjected to the combined effort of vapor pressure p and thermal stress σ_r^A. Therefore, we assume the r_1 and r_2 as the inner and outer radius after deformation. The mechanical model is displayed in Fig. 1.

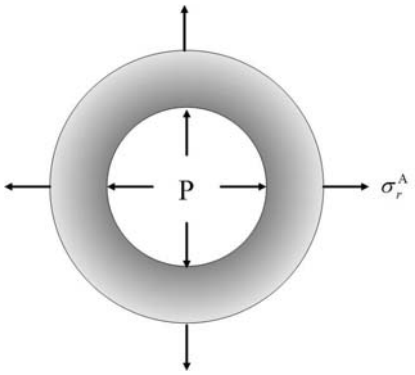

Fig. 1 The mechanical model of micro-voids under the action of vapor pressure and thermal stress

The micro-void is geometrically characterized by the initial and current void volume fractions f_0 and f:

$$f_0 = (\frac{R_1}{R_2})^3 \qquad f = (\frac{r_1}{r_2})^3$$

,

There are numerous vapor pressure models based on various theories. vapor pressure p satisfies the ideal gas law, then the vapor pressure model we use is shown as follows[16]:

$$P = P_0 \frac{T}{T_0} \frac{f_0}{f} \frac{1-f}{1-f_0} \mathrm{e}^{-3\alpha\Delta T} \tag{1}$$

Where p_0 is the initial pressure at room temperature, T represents current temperature, T_0 denotes initial temperature, α represents coefficient of heat expansion, $\Delta T = T - T_0$. During the reflow process in electronic packaging , temperature loading mode will reach the peak temperature more than 220℃, and temperature variation could be represented as the function of time t. Fig.2 displays a kind of temperature loading process with respect to the time.

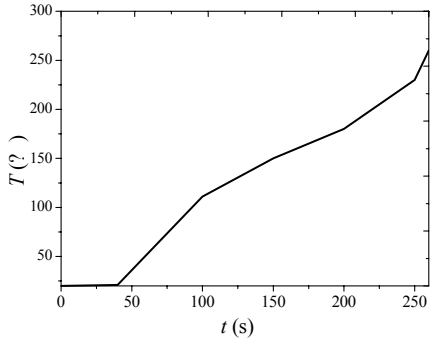

Fig.2 A typical temperature loading

How to utilize the variational principle to derive the growth function of micro-void? Firstly, we describe an arbitrary point(R, Θ, Φ) in the spherical coordinates in the initial configuration, and (r, θ, φ) represents the corresponding coordinates in the deformed micro-voids. It is notable that the deformation is spherically symmetric, therefore

$$\mathrm{r}=r(R),\theta=\Theta,\ \varphi=\Phi \tag{2}$$

Therefore, the domain before deformation is

$$D_0=\{(R,\Theta,\Phi)\,|\,0\le R_1\le R_0<R_2,0<\Theta\le 2\pi,0\le\Phi\le\pi\}$$

According to spherically symmetry, domain after deformation is

$$D=\{(r,\theta,\varphi)\,|\,r=(R)\ge 0,\ \ R_1\le R\le R_2,\Theta=\theta,\Phi=\varphi\}$$

Because of the condition of incompressibility, the volume relation below can be obtained:

$$r^3-r_1^3=R^3-R_1^3 \tag{3}$$

In terms of Eq. (2), the current void volume fraction can be displayed as

$$f=\frac{f_0a^3}{1-f_0+f_0a^3} \tag{4}$$

Where $a=r_1/R_1$ denotes the growth ratio of the micro-void.

3 Derivation of Governing Equation

In the section above, the geometrical configuration has been described. In this section, the fundamental formulation will be discussed in detail. We denote W as the strain energy function of the electronic packages. As to the linearly elastic material, the function is well-known for us[17]. When the ambient temperature is relatively higher or the materials themselves are soft, the super-elastic model should be taken into account. There are a vast amount of super-elastic models. In this paper, the neo-Hookean strain energy function will be introduced when the super-elastic analysis is conducted. The function of neo-Hookean material can be written as

$$W=\frac{\mu}{2}(\lambda_r^2+\lambda_\theta^2+\lambda_\phi^2-3) \tag{5}$$

Where, λ_r, λ_θ, λ_ϕ represent the principal stretches in the respective directions, respectively. Cauchy stress components in spherical coordinate system (r, θ, φ) corresponding to neo-Hookean materials are shown below:

$$\sigma_r=\lambda_r\frac{\partial W}{\partial\lambda_r},\qquad \sigma_\theta=\sigma_\phi=\lambda_\theta\frac{\partial W}{\partial\lambda_\theta} \tag{6}$$

Also, the principal stretches in the respective directions can also be described as:

$$\lambda_r=\frac{dr}{dR}=r'(R),\qquad \lambda_\theta=\lambda_\phi=\frac{r(R)}{R} \tag{7}$$

The total potential energy can be expressed as follows:

$$E=\int_{R_1}^{R_2}4\pi R^2W(\lambda_r,\lambda_\theta,\lambda_\phi)dR-\int_{R_1}^{r_1}4\pi R^2p\left(R\right)dR+\int_{R_2}^{r_2}4\pi R^2\sigma_r^A dR \tag{8}$$

According to the principle of least potential energy, we can obtain the governing equation from the first term in total potential energy after variation. Taking the Eq. (4)-(6) into the newly obtained variatianal equation, the governing function of dynamic growth of micro-void can be formulated.

4 Results and Discuss

In the last section, the derivation of governing function is discussed. In this section, we apply the method discussd above to predict that how void volume fraction f increase with respect to the time.

If we assume the material is linearly elastic, the governing function is shown as follows:

$$\frac{df}{dt}=\frac{9p_0f_0(f_0-f)f(1-f)(1-3\alpha T)\dfrac{dT}{dt}}{4ET_0(1-f_0)f^2e^{3\alpha\Delta T}[\dfrac{f_0}{f}\ln\dfrac{f_0}{f}\dfrac{1-f}{1-f_0}-\ln\dfrac{1-f}{1-f_0}]+9p_0f_0(f_0-f)T} \tag{9}$$

Where E is the Young's modulus of polymer materials applied in electronic devices. Due to the limited influence of thermal loading,thermal stress can be ignored, which means that the vapor pressure plays the major part on the growth of micro-voids on the proceeding of reflow. It is obvious that Eq. (9) is a IVP which can be solved numerically. The initial condition is that when t=0, f= f_0.Another problem is that as the loading temperature increases, the polymer materials will undoubtedly become softer and softer. As a result, the Young's modulus will decrease sharply. Hence, we compare three types of Young's modulus: 1GPa, 0.1GPa and linear decrease from 1GPa to 0.1GPa. The other parameters are selected as follows : f_0=1%, P_0=0.1MPa, T=0.94t+T_0, T_0=25℃， $\alpha=1.5\times10^{-4}$ .The growth of f as the time goes on is demonstrated in Fig. 3.

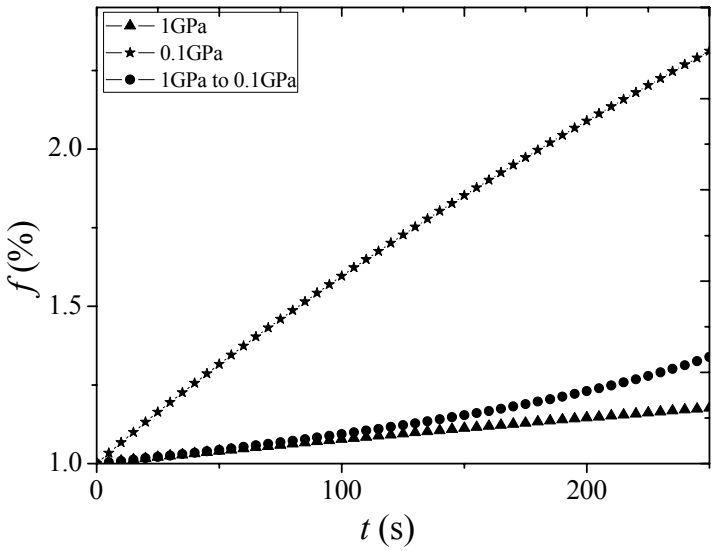

Fig.3 Dynamic growth of micro-void under different Young's Modulus

As it shown in Fig. 3, it is clearly to see the growth of cavitation during reflow process .and it is also notable that the soften the material are , the larger the deformation of micro-void is . In the electronic industry, it is not difficult for us to measure the Young's modulus of polymer materials with regards to different temperature. Thereby, we can accurately simulate the dynamic growth of micro-void regarding to variation of Young's modulus. In addition, the method of temperature loading also influences the transient growth of micro-voids. If the temperature T is non-linearly dependent with time t, the whole increase of void volume fraction will be different from the result in Fig. 3. Fig. 4 depicts the compassion between the linear temperature loading and quadratic temperature loading (T=0.003t^2+0.19t+T_0). We can see that when the temperature loading change, the void will increase in another way. However, it is intriguing to find that the final void volume fraction after the reflow process is the same no matter how matter the temperature is loaded in linear form or quadratic form if the Young's modulus remains unchanged with increasing temperature. However, if Young's modulus of materials varies with temperature, the fascinate

phenomenon will not appear.

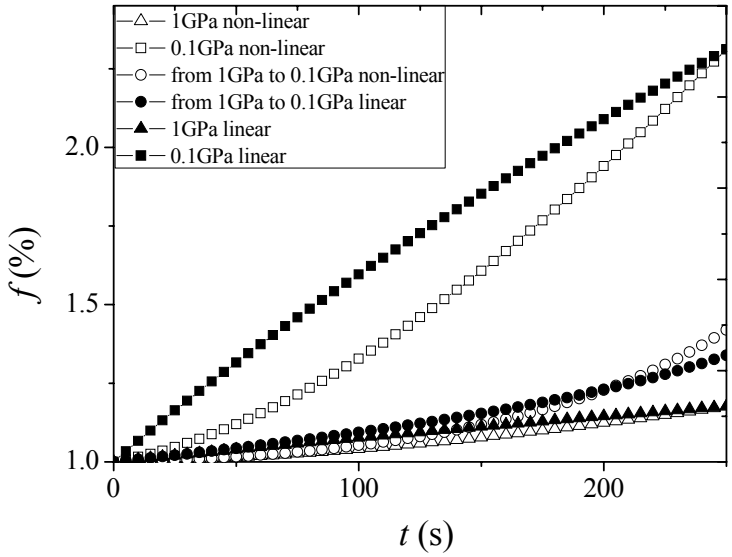

Fig. 4 Comparison between dynamic growth of micro-void under different temperature loadings

In reality, it is impossible for most of polymer materials to maintain the property of linear elasticity. In most of cases, polymers behave as super-elasticity even at the room temperature. The neo-Hookean model is one of the most common models applied in polymer materials. The dynamic growth equation can also be derived via the same method discussed above:

$$\frac{df}{dt}=\frac{P_0 f_0 f(1-f)(1-3\alpha T)\,dT/dt}{2\mu T_0(1-f_0)f^2 e^{3\alpha\Delta T}\{\frac{f_0}{f^2}[(\frac{f_0}{f}\frac{1-f}{1-f_0})^{-\frac{2}{3}}+(\frac{f_0}{f}\frac{1-f}{1-f_0})^{\frac{1}{3}}]-(\frac{1-f}{1-f_0})^{\frac{1}{3}}-(\frac{1-f}{1-f_0})^{-\frac{2}{3}}\}+P_0 f_0 T} \tag{10}$$

The shear modulus μ is set to 333 MPa ,and other variables is of the same value with that in the former discussion. The void growth is shown in Fig. 5. It is notable that the increase of void volume fraction is closely dependent on the value of initial void volume fraction.

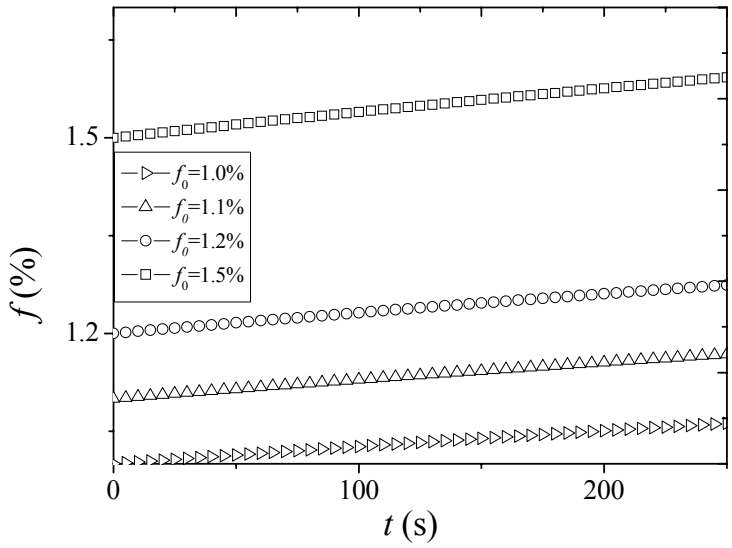

Fig.5 Dynamic growth of super- elastic micro-void under various initial void volume fraction

5 Conclusions

In this paper, theoretical results for dynamic growth of micro-voids are obtained with the context of finite deformation. The numerical method is applied to calculate the deformation of a void under the constitutional model of linear elasticity and super-elasticity. According to results acquired, it is notable that ways of growth are completely different when the temperature loadings are various. Secondly, when the Young's Modulus remains constant, the consequent that the final value of f will never change is fascinating. At last, the increase of void volume fraction is extremely dependent on the initial void volume fraction. Our investigation will provide a good understanding of mechanism of dynamic growth for engineers and researchers.

Abstract

In this paper, we used the eXtended Finite Element Method (XFEM), implemented in the software CAST3M developed by Commissariat à l'Energie Atomique (CEA), to simulate the fatigue crack growth of the contact wire in the railway catenary.

The material characteristics and parameters of the Paris law were identified thanks to experimental tests performed in a laboratory of Société Nationale des Chemins de Fer Français (SNCF). Specimens were cut directly from the contact wire. Two mean-stress levels were considered. The stress intensity factors were calculated by Finite Elements Method.

In order to validate the model and check its robustness, we performed a parametric analysis with different crack geometries. The numerical results showed a good agreement with the experimental observations in terms of the evolution of the crack shape and its growth rate. These results show that this numerical strategy is relevant and efficient to predict the critical size and the residual lifetime of the fatigue cracks detected by maintenance operations (Ultrasonic monitoring).

Keywords: fatigue crack growth, numerical simulation, eXtended Finite Element Method (XFEM), railway catenary.

1. Introduction

The role of the catenary system is to transmit the electrical energy from the energy supply point to trains (Fig. 1). To ensure a good current collection quality during a train passage, the pantograph applies a vertical force on the contact wire. This upward force causes a periodic bending stress. In addition to this periodic bending stress, the contact wire is subjected to a constant mechanical tensile force depending on the maximum speed of the line. The role of this tensile force is to avoid problems of dynamic instabilities in the contact wire. Moreover, the wear due to the pantograph passages reduces the cross section of the contact wire which leads to a higher tensile stress in the wire. These conditions accelerate the risk of fatigue fracture of the contact wire.

To predict the propagation of fatigue crack, different approaches could be considered. The most popular one is Finite Element Method (FEM). However, the conventional FEM using fixed meshes can only deal with this type of problem, either if the crack path travels through mesh nodes, or if we remove mesh elements [1]. This is an extremely important limitation in industrial applications.

In order to overcome the disadvantage of FEM, we used in this paper the eXtended Finite Element

Method (XFEM), implemented in the software CAST3M [4] developed by Commissariat à l'Energie Atomique (CEA), to simulate the fatigue crack growth of the contact wire. The identification of material parameters and the numerical modeling of the contact wire are described in the next sections. The numerical results are shown and discussed in the last section of the paper.

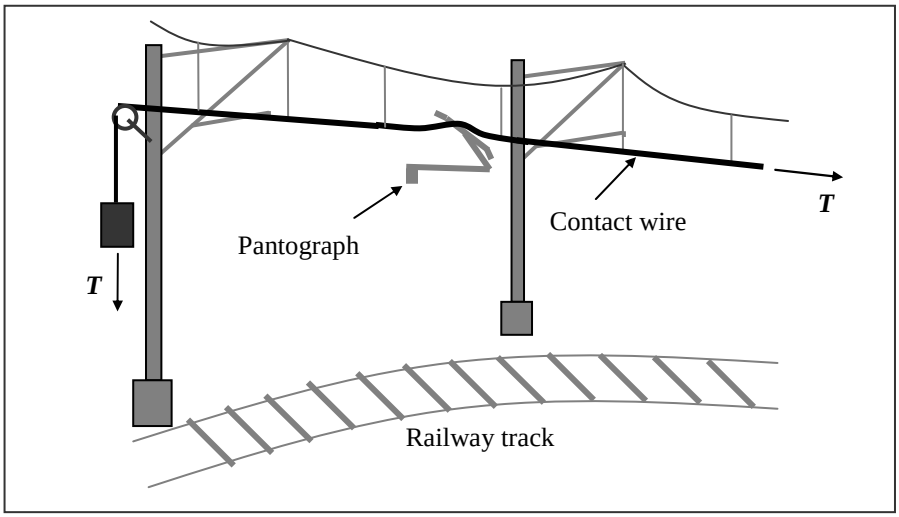

Figure 1. Railway Catenary

2. Fatigue Tests

2.1. Fatigue test specimen

In order to identify the mechanical characteristics and the fatigue crack growth law of copper contact wire, we had carried out fatigue tests with specimens cut directly from the contact wire (Fig. 2). An initial crack of 1mm depth was created on the contact size in the middle of the specimen.

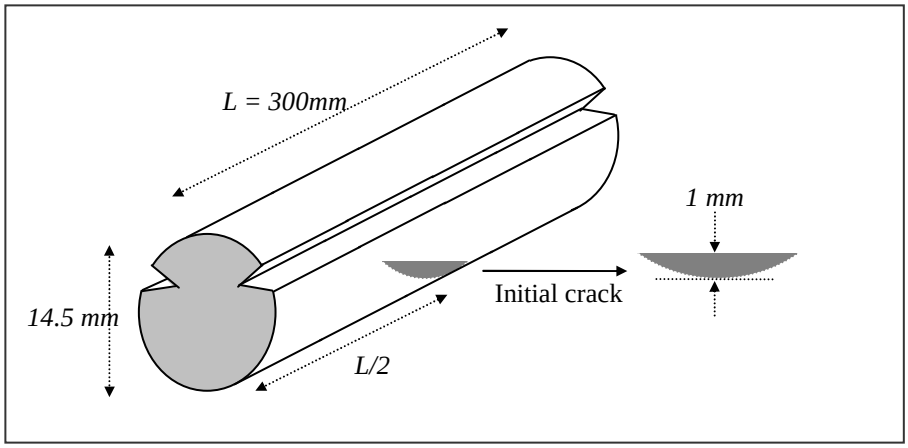

Figure 2. Specimen for fatigue tests (copper contact wire)

2.2. Fatigue crack growth test rig and conditions

The fatigue crack growth test rig is illustrated in Fig. 3. These tests were conducted in air at room temperature on a servo-hydraulic test machine having a load capacity of 50 tons with a frequency of 10 Hz under constant amplitude loading. These tests were conducted at different stress ratio R.

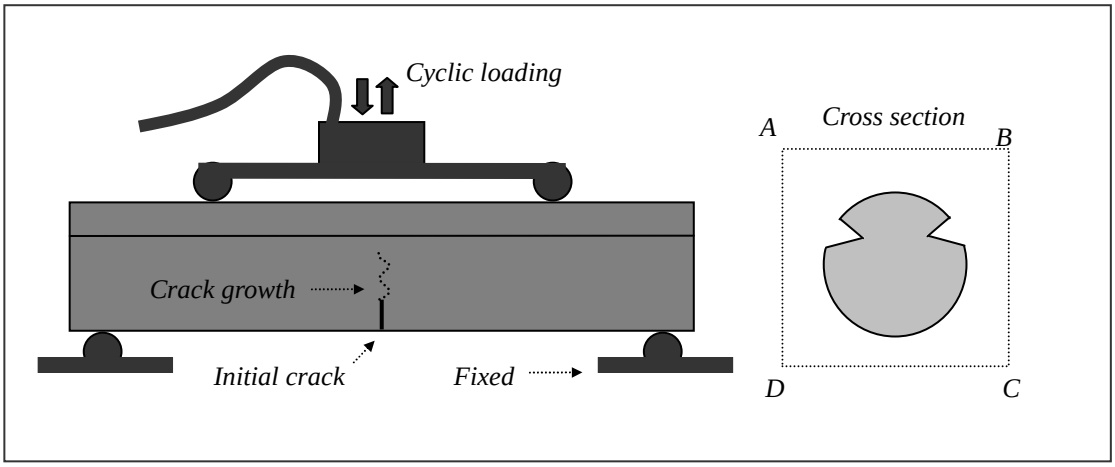

Figure 3. Fatigue crack growth test rig.

2.3. Test results

The test results are shown in the figure 4. Using the test results coupled with numerical calculations (FEM), we identified the parameters of Paris law (m, C) and the toughness (K_{1c}) of the copper material.

Paris law: $$\frac{da}{dN} = C.\Delta K^{m} \quad (1)$$

3. Modeling

3.1. XFEM Model

In this paper, we used the eXtended Finite Element Method for linear elastic fracture mechanics (LEFM), in which an enrichment basis is added to the classical finite element basis approximation. This is done using the partition of unity method developed in Babuska and Melenk [2]. The enriched basis shape functions are associated to new degrees of freedom and the displacement field can be written (see Moes *et al.* [1]):

$$U = \sum_{i \in \mathrm{N}} N_i(x) U_i + \sum_{i \in \mathrm{N}_{cut}} N_i(x) H(x) a_i + \sum_{i \in \mathrm{N}_{branch}} \sum_{\alpha} N_i(x) F_\alpha(x) b_{i,\alpha} \tag{2}$$

N is the set of the standard finite element nodes, N_{cut} the set of nodes which belong to elements completely cut by the crack and N_{branch} the set of nodes containing a crack front. N_i are the standard finite element shape functions, $H(x)$ is a Heaviside function which value is 1 if x is above the crack surface and -1 if x is under the crack surface. $[F_\alpha]$ is derived from the LEFM asymptotic displacement field:

$$[F_\alpha] = \left[\sqrt{r} \sin\left(\frac{\theta}{2}\right), \sqrt{r} \cos\left(\frac{\theta}{2}\right), \sqrt{r} \sin\left(\frac{\theta}{2}\right)\sin(\theta), \sqrt{r} \cos\left(\frac{\theta}{2}\right)\sin(\theta) \right] \tag{3}$$

3.2. Numerical algorithm

The eXtended Finite Element Method (XFEM), implemented in the software CAST3M developed by Commissariat à l'Energie Atomique (CEA), was used in this paper to simulate the fatigue crack growth of the contact wire.

In this XFEM model, the mesh of the structure (three dimensions) without crack is fixed during the crack growth. The position of the crack inside the structure is identified thanks to an independent crack mesh (two dimensions) which needs to be updated after each crack growth step.

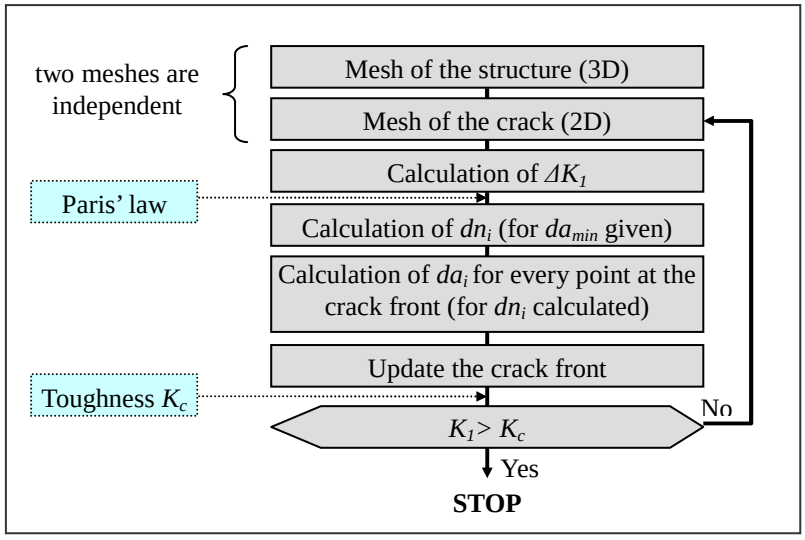

Figure 5: Numerical algorithm for fatigue crack growth simulation.

The numerical algorithm is shown in Fig. 5. The Paris' law and the toughness are material inputs which are identified in the previous section. The calculation of stress intensity factors K_i is done by using the domain integral method (J integral). The crack growth step da_{min} is a numerical input. A convergence study for this numerical input is necessary.

The simulation is stopped if the stress intensity factor K_1 is greater than the toughness K_c of copper material. Otherwise, the crack front is updated and a new crack mesh is constructed.

4. Numerical Results

4.1. Inputs

In this section, we study the fatigue crack growth of a contact wire in flexure using the XFEM presented in previous section.

The meshes of the structure (worn contact wire without crack) and the two initial cracks are shown in Fig. 6. In the cross section of the structure, QUAD elements are used. The final mesh (3D) of the structure is obtained by extrusion of the cross sectional profile. Special 3D XFEM elements are used in the crack zone. Whereas, the elements used to mesh the cracks are classical 2D triangular elements.

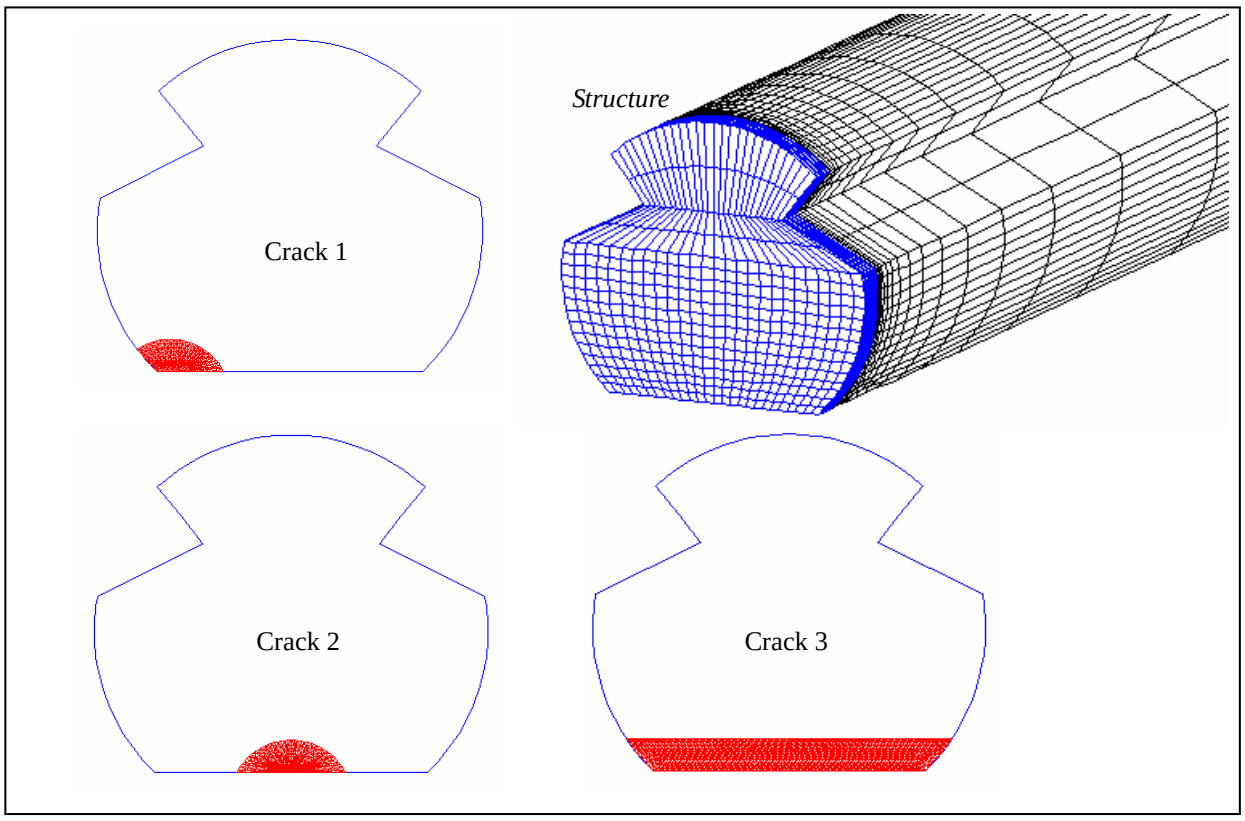

Figure 6: Meshes of the structure and initial cracks

The material parameters (Paris' law and toughness) are identified in the section 2 and the numerical model is presented in the section 3.

4.2. Results

Figure 7 shows the stress intensity factors calculated at the crack front for different types of initial crack. We can see from these results that the mode I is dominant ($K_2 \sim 0$ and $K_3 \sim 0$) in all cases. Thus, the Paris' law is applicable for our model.

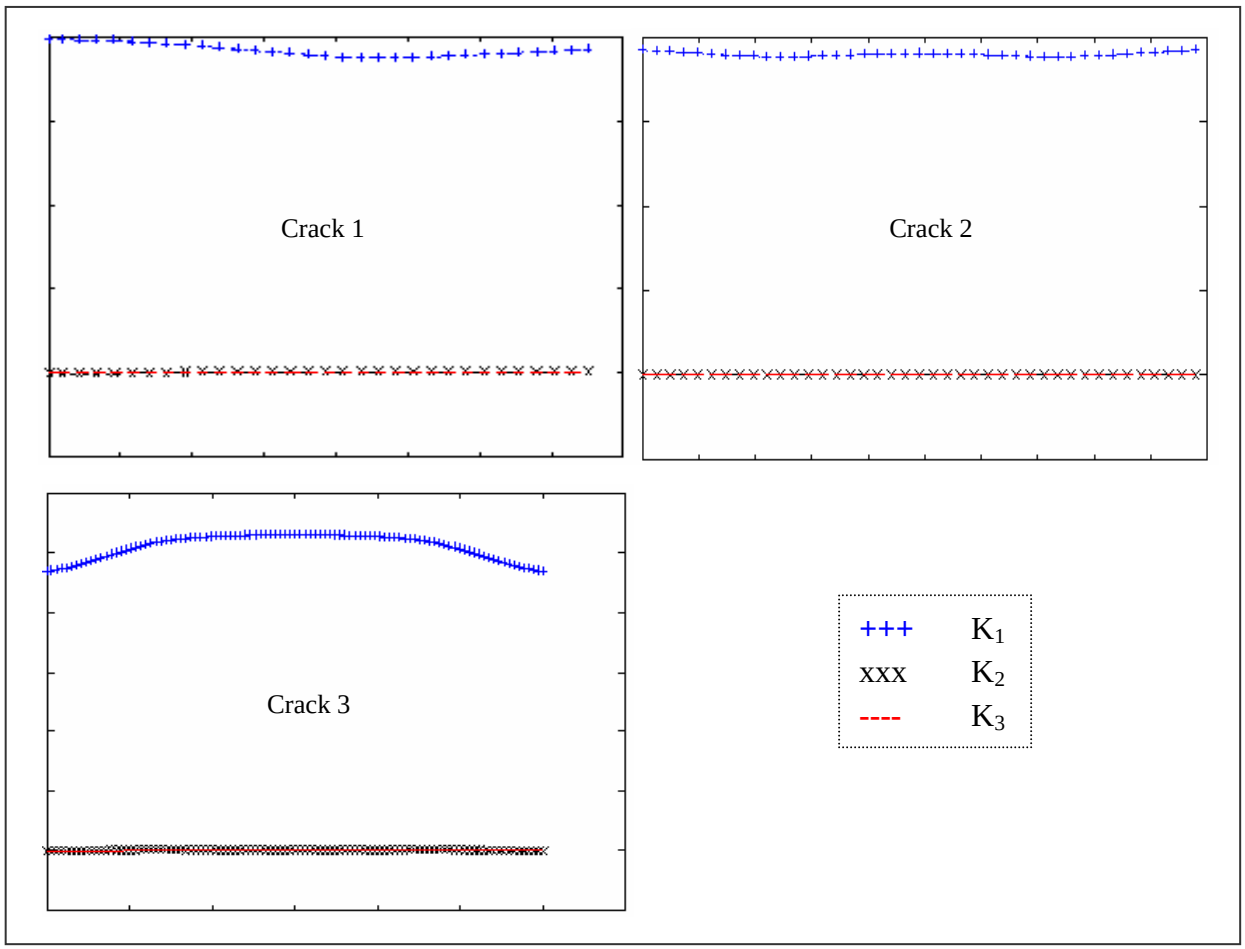

Figure 7: Stress intensity factors for three initial cracks

Using the XFEM model described above, we've performed different crack growth simulations. We can see in the figure 8 a comparison between the numerical simulation and the test result. The numerical results showed a good agreement with the experimental test in terms of the evolution of the crack shape and its growth rate.

In the figure 9, we show the crack growth simulated for three types of initial crack. Figure 10 shows the evolution of the crack depth in function of the loading cycles. This type of curve could be used in combination with the ultrasonic measurements to optimize the maintenance planning of the contact wire. For example, if we detect a crack of contact wire (point A) at the moment *t*, using the numerical curve (Fig. 10) we could estimate the action timescale before reaching the critical crack (point B). To follow the real crack growth, some additional measures could be performed between twos points A and B. If necessary, the critical point B could be modified after each measurement.

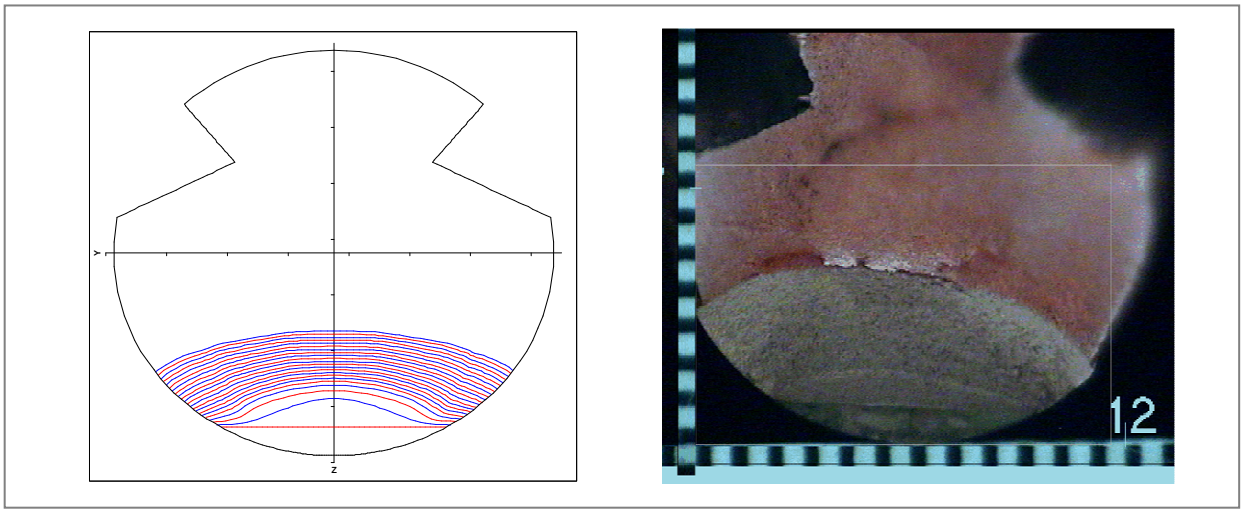

Figure 8: Comparison between the numerical simulation and the test result

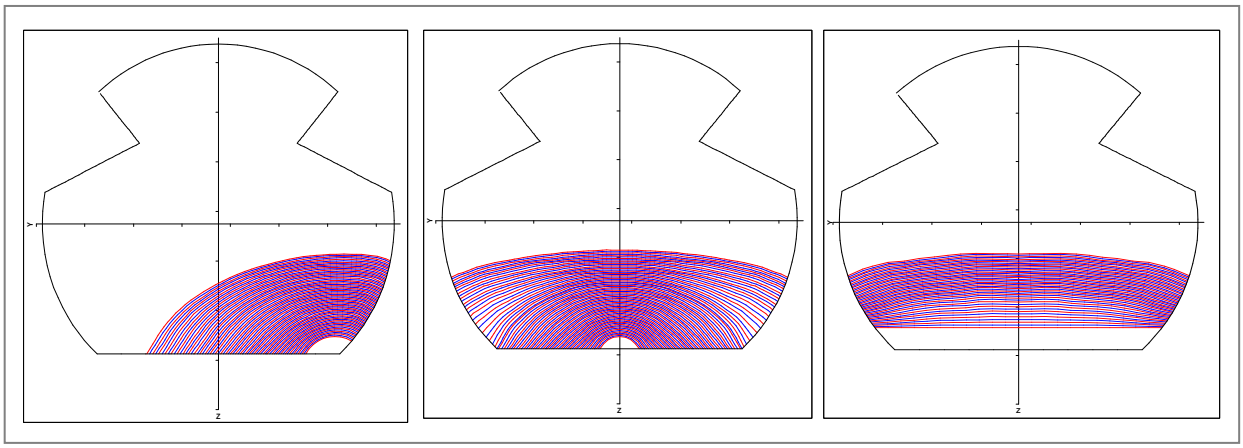

Figure 9: Crack growth for different initial cracks

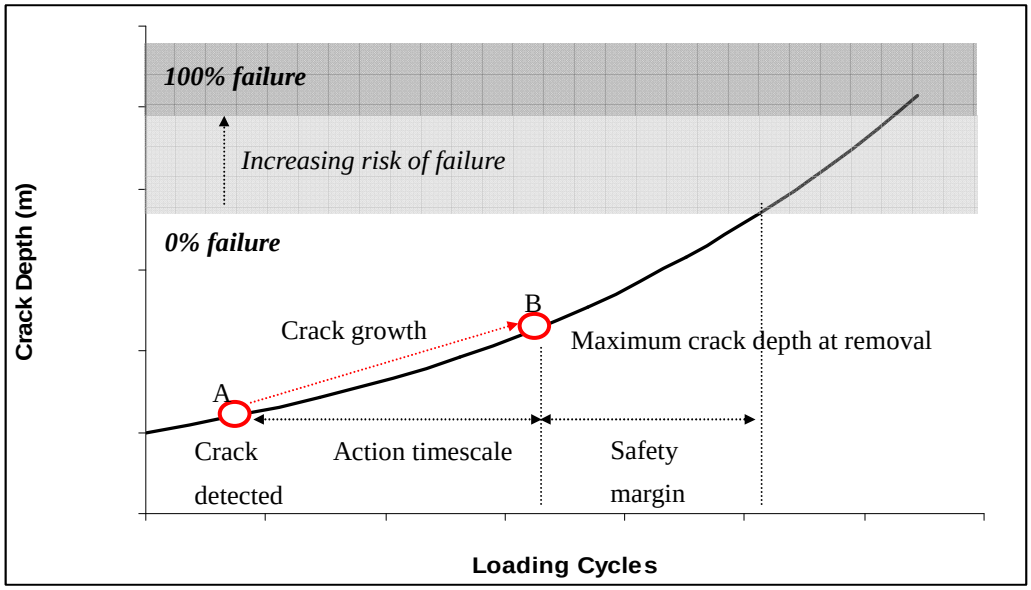

Figure 10: Evolution of the crack depth

5. Conclusion

In this paper, we used the eXtended Finite Element Method (XFEM), implemented in the software CAST3M developed by Commissariat à l'Energie Atomique (CEA), to simulate the fatigue crack growth of the contact wire.

The material characteristics were identified thanks to experimental tests performed in a laboratory of Société Nationale des Chemins de Fer Français (SNCF) with specimens cut directly from the contact wire.

Different geometries of crack were studied. The numerical results showed a good agreement with observation in term of the evolution of the crack shape and its growth rate. Theses preliminary results show that this numerical strategy can be used to predict the critical size and the residual life of fatigue cracks detected by maintenance operations.

A more detailed study on the real cracks detected in the contact wire will be the target of the next step.

Abstract With the development of new generations of CRH trains in China, one new fatigue integrated analysis method was proposed to evaluate high speed train carbody structure fatigue life and durability. The CRH train's carbody structure was used here as an example for study the interaction relation between vehicle dynamic characteristic and fatigue property running in BEIJING-TIANJIN intercity line. The detail method steps include: Firstly, MBS (Multi Body Simulation) technologies allowed the development of more detailed and accurate vehicle-rail rigid-flexible coupled dynamics model which can be used as input of stress distribution calculation. And The typical carbody structure's fatigue load spectrum and extrapolation were calculated here through quasi-static stress method according to field running condition for different radius curve (400-2500 m), which was random combination of Track irregularity, W/R profile and Cant deficiency. Secondly, Aluminum alloy structure FE (Finite Element) analysis technologies, such as modal analysis, substructure and stress calculation, were used to determine structure critical location and understand carbody structure nature frequencies and mode shapes influence. FM (Fracture Mechanics) assessment analysis for different load condition combination based on the structure stress distribution and stress/strain time histories results. Thirdly, carbody structure fatigue stress distributions in carbody selected dangerous regions were calculated in sub-model. And The analysis results were compared with the field dynamic stress test results. Finally, carbody fatigue life and durability analysis results were estimated based on aluminum material S-N curve with Palmgren-Miner damage cumulative theory. The critical structure fatigue failure influence can be taken into account in stress distribution used as input of FM. This work targets the capabilities of MBS and FEM (Finite Element Method) in the fatigue and durability design early stage and verification phase of the high speed train key structure, such as bogie structure, axle and wheel, etc. The results also illustrate that the proposed numerical simulation method can give an important contribution in terms of high speed train key structure component fatigue and durability evaluation.

Keywords Railway, Carbody, Fatigue life, Multibody Dynamics, FEM

1. Introduction

With the rapid development of high-speed railway in China, the CRH series train's vehicle key structure components fatigue design and analysis method are also facing the serious challenge of many technical difficult problems, such as running safety and ride comfort. Especially for the important structural components fatigue design and durability analysis method, there are many aspects worthy of consideration and study [1-2]. Despite the conventional railway vehicle structure fatigue design method had been applied in some structural components' durability during last years .But with the continuous improvement of vehicle speed, it has been revealed that dynamically loaded structure components' fatigue damage and structure destruction maybe become one of potential technical problems in future. Most of the recent research on the dynamic behaviors of vehicles /rail has been simulated by the need to understand the basically cause of practical service problems arising from the interaction between the vehicle and the track and to develop solutions or treatments for those problems.

With respect to structural fatigue problems, great deals of research have been done these years. During the more recent structure fatigue simulation techniques research, an integrated design methodology had been made use to evaluate structural fatigue (R.K.Luo,et al.1994, Stefan Dietz,1998).These procedures make use of multibody simulation packages (Schielen, 1990;kortum and sharp,1993) to determine the dynamic loads acting through the suspension onto the vehicle structure. Measured track data are generally used as excitation inputs. Using a finite element model of the structural a component on which the dynamic forces are acting, stress concentration locations

are identified and analyzed. Structure dynamic stress histories are determined under simulated loading and the fatigue life is determined using an appropriate fatigue theory. In reference [3], the author had systematically presented one hybrid simulation method to the carbody structure fatigue life assessment based on **MBS** (Multibody Simulation) and **FEM** (finite element method). In this paper, based on some typical literatures' achievements [4-7], one new fatigue life and durability evaluating method of high speed train carbody structure is proposed here to evaluate the carbody structure fatigue property and applied to the structure fatigue design. And one complex railway EMU carbody was used as an example to describe the detail method steps how to use in fatigue design development processes.

2. Structure Fatigue Numerical Calculation Method

There are three main factors, which affect the structure fatigue behavior: The S-N curve of structural components; the load time histories; and structural geometrical features. The carbody structure of railway vehicle is subjected to a very large number of variable amplitude stress cycles during their operational life. Large structural stress and complex load conditions are the main causes which lead to vehicle structural components' fatigue crack initiation and crack growth. And the weld structure manufacturing process of the structural components is one of the main factors which cause the structure destruction. Since this paper focuses on the structural fatigue damage caused by vehicle structural dynamic characteristics, so there will not be to evaluate the structure damage from the perspective of welded structural fatigue. Some weaknesses locations of the carbody structure are studied, such as the location of the secondary suspension, the traction or braking, the corners of the window, and so on.

This method considers the dynamic behavior of the full vehicle. It can greatly reduce the physical prototype test cost and design fault, while it can improve the accuracy of structural durability design and life prediction. Fatigue is one of the primary mechanisms causing deterioration of high speed train vehicle carbody structure during its lifetime. Straight track, tracking/ braking, curve passing, aerodynamics effect and other cyclic or alternating loads easily subject the carbody structure to huge numbers repeated stress over its life time. Cyclic loading causes fatigue cracks initiation, which causes cracks to form in the structure. These cracks grow longer with each stress cycle, degrading the carbody's structural strength and life. A crack initially grows slowly, but the rate accelerates as these cycles accumulate, to the point at which rapid crack growth results in a fracture. Thus, some durability design criteria for carbody are those can endure accumulated fatigue damage during service Life-Cycle to prevent structural failure.

A full vehicle's multibody dynamic model including carbody, bogies, the primary suspension and track are set up using the famous MBS software pack SIMPACK. The vehicle is described as rigid bodies interconnected via several different suspension systems. Several typical load cases, such as tangent line and curve passing, were performed in order to verify the accuracy of the dynamical model in reproducing the full vehicle dynamic behavior simulation. Carbody structure fatigue analysis puts a great demand on accuracy including MBS and FEM model .The quasi-static stress method was performed for carbody to obtain the stress histories. FEM model cannot be too complex since the dynamic analysis and fatigue assessment is time consuming. The finite element analysis method was used in software ANSYS. The load time histories are very important aspects since they are the actual source of fatigue failure prediction. Several complex loading conditions must be determined, either by analytical approaches or by dynamic stress tests. Due to the computational effort involved in dynamic simulations, only selections from the stress history can be used. Decisions as to what loads to apply must therefore be designed and selected analytically. Different types of railway vehicle operational conditions must be considered in additional to some extreme load cases generated from error operation.

A fatigue assessment method describes a sequence of steps to be taken in order to predict fatigue life from a given state of stress and strain. For carbody subjected to variable amplitude stochastic loading, the main steps include:

- Rain flow cycle counting;
- Damage calculation for each cycle;
- Fatigue damage accumulation.

The proposed new method for high speed train carbody structure is shown in Fig.1.

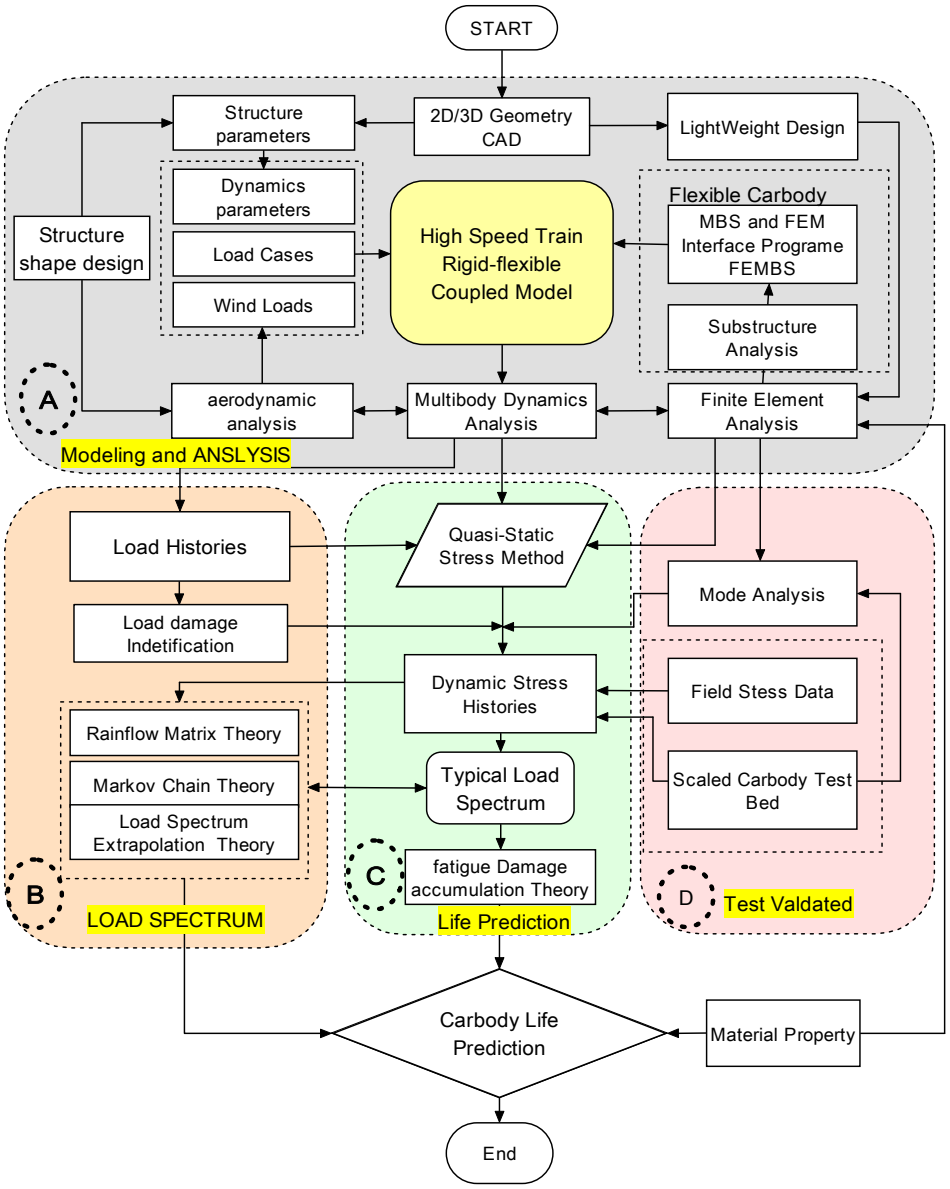

Fig. 1: New carbody structure fatigue life evaluation flowchart

Vehicle Dynamics Simulation with MBS. Dynamics analysis of the full vehicle can be used to obtain the load time histories for the carbody structure in typical running cases, such as the straight and curve lines. The CRH train vehicle was selected for this study to create the detailed multibody dynamics model, which was running between the Beijing-Tianjin intercity lines in China. The model has been substantially altered to accommodate more load cases and used to simulate railway vehicle dynamic behavior. The loads such as inertial loads and external loads derived using multibody dynamics analytical methods are mostly used for fatigue calculation [8].

The vehicle has been modelled with the aid of the MBS software SIMPACK library elements like rigid or flexible bodies, force elements and joints. The carbody was described as rigid body by each other. Several linear spring and damper elements describe the primary and secondary suspension

unites, the bump stops and viscous dampers are represented by nonlinear characteristics. The configuration and suspension characteristics of the system are included in the dynamic model. The full vehicle multibody dynamics model was shown in Fig.2.

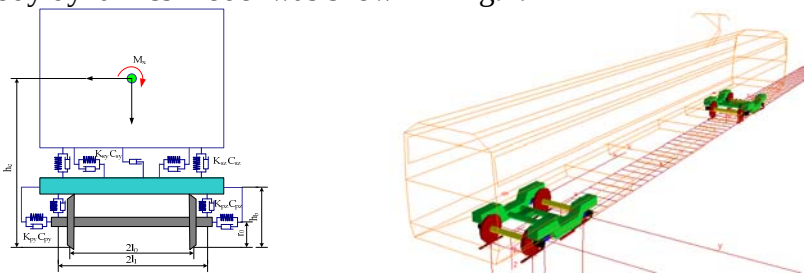

Fig.2: Dynamic model of carbody

The typical running case in operating condition has been designed to perform multibody dynamics simulation, which includes straight running, curve passing and traction/braking etc. The load histories have been calculated in MBS, which include forces, velocities, accelerate and angular velocities etc. And in order to take account of the influence of elastic carbody, the interface program FEMBS between finite element analysis codes and SIMPACK is used here to generate input data for flexible bodies to MBS simulation. The paper adopted the track irregularities is the real track excitation spectrum. They run on a straight railway in speed 200 km/h to 300km/h. Some dynamics simulation results are shown in Fig.3.

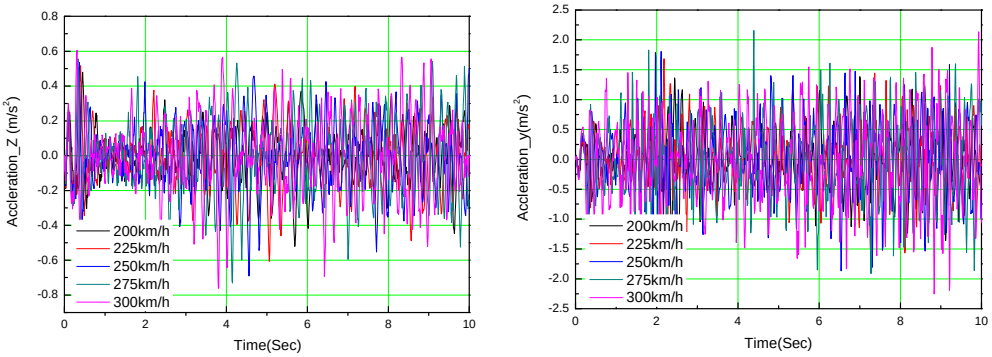

Fig.3: Vertical and lateral acceleration of carbody center

Finite Element Modeling of Carbody. The carbody structure fatigue damage is mainly caused by the vehicle dynamic response, which is usually expressed as stress or strain time history. Stress/Strain calculations for fatigue life estimation can be performed in the time domain or frequency domain. The quasi-static stress method was used to obtain the stress/strain time histories. The detail carbody stress analyses with ANSYS were performed based on MBS and FEM. And mode analysis is also performed here. The finite element model of the carbody is shown in Fig.4. Modal analysis is usually used to determine the natural frequencies and mode shapes of carbody structure. The modal analysis results are shown in Fig.5 and Table1.

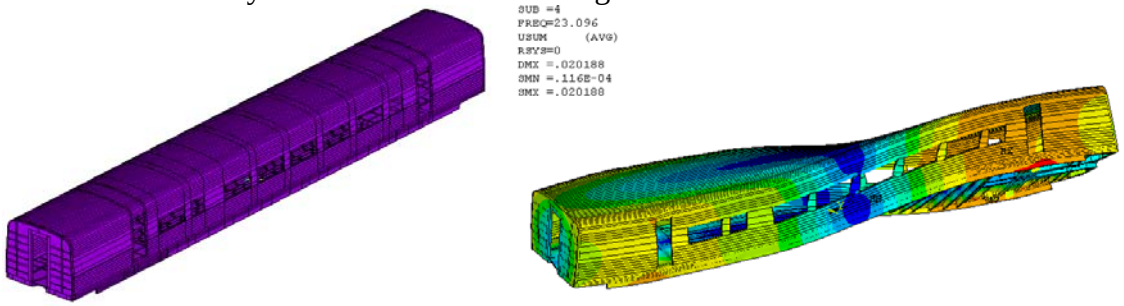

Fig.4: Carbody finite element model Fig.5: The 1st Torsion mode of Carbody structure

Table1.The results of the modal analysis

Fatigue Assessment of the Carbody Structure. The carbody structure fatigue life was predicted. and compared with the life calculated from the original test datum. The material used in the carbody was A6N01S-T5.The stress-Life(S-N) curve was created in software *Fe-Fatigue* according to the material fatigue design manual which is used in the fatigue life calculation. Based on the structure *S-N* curve and the Palmgren-Miner rule, the carbody structure fatigue life was evaluated. The results of the rain flow cycle counting are usually presented as a rain flow matrix giving the number of cycles occurring at various combinations of range and mean stress [9, 10]. Then the values of range and mean are rounded off to discrete values to give a matrix of manageable size. The calculation results for test point and node 70770 corresponded to the test points are shown in Fig.6.

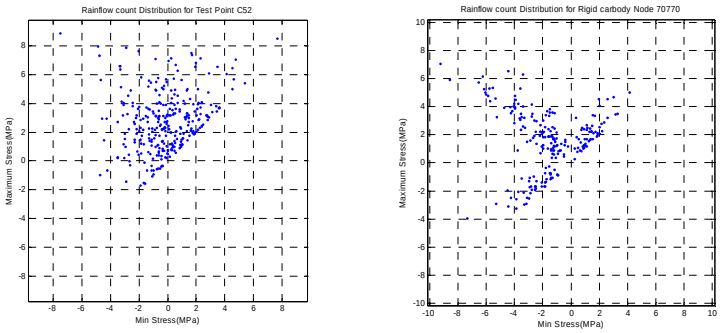

Fig. 6: Rainflow cycle count of C52 and Node 70770

3. Field Lines Dynamic Stress Test

In order to determine the accuracy of strain predicted from the simulation model, the field lines dynamic stress/strain test for carbody was performed to the carbody fatigue estimation. And fatigue life of carbody was calculated from the original field dynamic stress test data. The field dynamic stress/strain test points for the carbody and results for test point C52 are shown in Fig. 7.

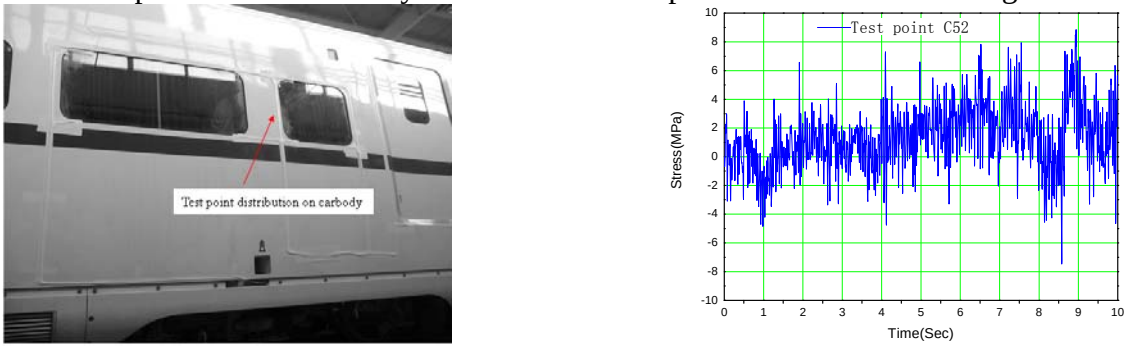

Fig.7 Dynamic stress/strain test and results for carbody

4. Results and Discussion

The primary goal of this paper is shown how to correctly evaluate the railway structure fatigue damage at the critical location of the carbody. It can show the relation mechanism between full vehicle's carbody dynamic characteristic and structure fatigue property. The safety factor analysis based on *S-N* method based stress was used to calculate the carbody damage distribution. Finally, according to rain flow matrix and Markov chain theory, material *S-N* curve, structure dynamic stress, and Palmgren-Miner damage summary theory, carbody structure fatigue life can be evaluated and compared with the field stress test results. Some carbody structure fatigue life calculation results are shown in Table2.And some fatigue analysis results are shown in Fig. 8.

Table 2. Fatigue life estimation comparison

Name	**Mean**(MPa)	**Min** (Mpa)	**Max**(Mpa)	**Range**(Mpa)	**Life repeats**
Test point c52	1.436	-5.814	9.522	15.336	2.694e6
Node 70774	-0.903	-9.253	7.045	16.298	2.278e6

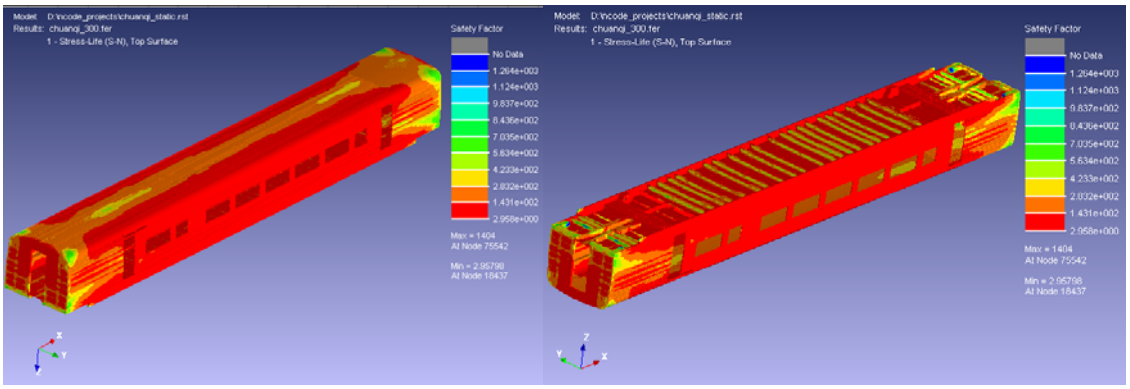

Fig.8: Safety factor analysis results

5. Conclusion

The new fatigue life and durability evaluating method of high speed train carbody structure based on MBS and FEM was proposed to evaluate the CRH vehicle carbody structure fatigue properties. This method can be used in early structure fatigue design in railway carbody structure new product development stage. Some simulation results are also shown and compared with the field dynamic stress test results to validate the method effective. The results also prove that the MBS-FEM simulation method can evaluate the carbody structure correctly. It is also beneficial to understand the influence for dynamic property to structure fatigue life prediction and satisfy with railway key structure component's durability design.

Safe Life and Damage Tolerance Concepts of Railway Axles

Abstract

On July 9, 2008 a high speed train derailed in Cologne main station, Germany at a low speed because an axle was broken. Fortunately, the derailment happened at a low speed so that nobody was injured. The reason for the broken axle was investigated and it turned out that most likely large inclusions located shortly underneath the surface in a T-transition were the origin of the final crack. Basing on that result, a systematic investigation on existing safety assessments of railway axles was performed. This results in an analysis of the production process of axles and in a critical review of existing of existing assessments. Improvements and future developments are outlined.

Keywords railway axles, derailment, service loading fatigue, inclusions, safety assessment

1. Introduction

A hollow axle of a German high speed train broke on 9 July 2008. Fortunately, the train derailed at low speed after change of running direction when crossing a Rhein bridge in Cologne. The failure occurred when the axle was in service 3.09 million kilometers which refers to 10^9 loading cycles. A more detailed report on the failure investigation is provided in [1]. Because the fracture surfaces were heavily destroyed no definite answer could be given to the question of the initiation site. However, non-metallic inclusions of unacceptable size were found nearby the crack origin. The investigators assume a similar inclusion to be responsible for fatigue crack initiation. Basing on this event, a critical review of state-of-the-art design is presented and the further development is basically revealed.

2. Safe Life and damage Tolerance Concepts: State-of-the-Art and Necessity of Improvements

2.1. Overview

The design and operation of railway axles are based on a two-stage safety concept comprising “safe life” and “damage tolerance” methods. Figure 1 schematically illustrates the state-of-the-art concept and extends it by further options which are presently under development or offer additional potential in the future. The figure is taken from an extended discussion on axle safe design which the authors of this paper and others presented in [2]. This shall not be repeated here in detail. Instead a number of selected issues shall be briefly discussed which, as the authors think, promise potential for further increasing the safety level of axles. These are:

(a) Limiting the projected lifetime as a consequence of features such as damage accumulation, potential very high cycle (VHCF) effects and corrosion. A specific concept is the “one-million miles axle” based on a worst case scenario including fatigue crack propagation;

(b) Taking into account the most common reasons for fatigue crack initiation, corrosion pits, damage due to flying ballast impacts and non-metallic inclusions in the material by advanced design

rules, and;

(c) Improving the reliability of non-destructive testing (NDT) with respect to its probability of detection (PoD)-crack size characteristics.

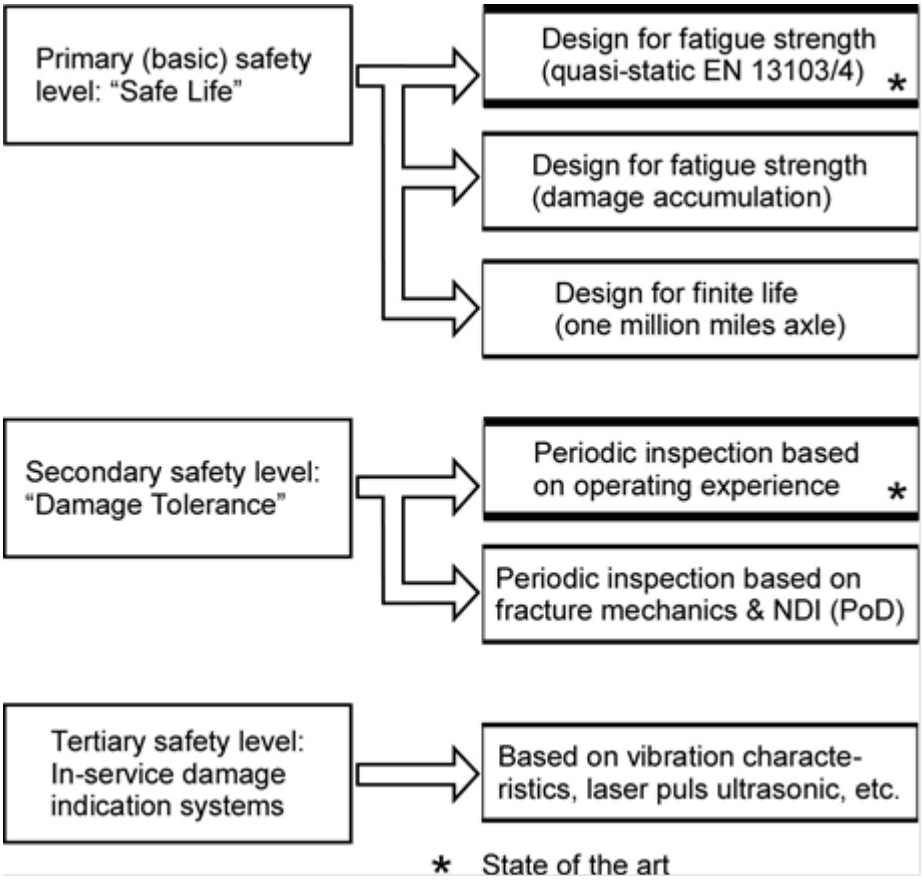

Figure 1: Components of a safety assessment of railway axles. All options not marked with a * refer to present or future development.

2.2 Limiting the Projected Lifetime?

Figure 2 gives a brief overview on the various options of fatigue strength and fatigue life design of railway axles.

Figure 2a: The approach followed by the present standards (in Europe EN 13103 [3] for trailing and EN 13104 [4] for driving axles) implicitly assumes a constant amplitude loading with the stress amplitude being conservatively estimated as superimposed maximum loading, i.e., different to reality all loads are assumed to act simultaneously. Unknowns, e.g., a potential reduction of the admissible stresses below the fatigue limit due to the very high cycle fatigue (VHCF) phenomenon (for a service time of 10^8 and more loading cycles) or other features are covered by ample safety margins. The maximum permissible stress in the axle is given by the fatigue limit of the material under consideration (EA1N carbon steel = C35, normalized and EA4T alloy steel = 25CrMo4, quenched and tempered) but it additionally depends on the type of axle (solid or hollow) and the axle section (away from or beneath the press fits, etc.). If the axle is exposed to corrosion some reduction of the permissible stress is required but no detailed rule is given in the standards cited above. However, EN 13261 ([5], Tab. 11), in such a case, specifies a value of 60% of the maximum

allowable stresses of EN 13103 and EN 13104. For all other cases, where the axles are not exposed to environmental corrosion, it is assumed that no reduction of the fatigue limit due to some kind of damage occurs during service which implicitly means that protection measures have to be taken which exclude such damage or the damage has to be removed soon after it appears in service.

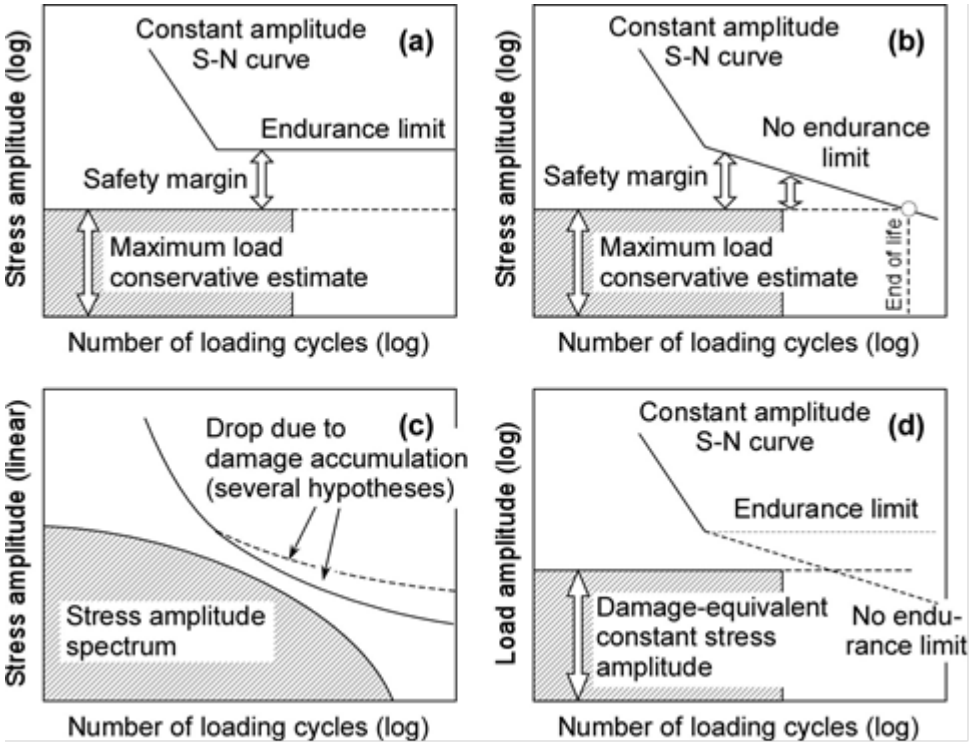

Figure 2: Potential concepts of fatigue strength analysis.

Figure 2b: As an alternative to the standard method, VHCF could be taken into account by replacing the fatigue limit by a sloping curve beyond the knee-point. Sonsino [6], based on the re-analysis of a large body of fatigue data proposes a modified fatigue life diagram with a decrease of 5% per decade loading cycles in logarithmic scales for steels. Note, however, that the author explicitly excludes from this rule cases where environmental or fretting corrosion is present (such as in axle press fits).

Figure 2c: A design stress spectrum, i.e., a histogram of the frequency of occurrence of different stress magnitudes, is compared with an S-N curve corrected for damage accumulation. This is obtained by a modified Palmgren-Miner rule according to one of several proposals. Note that, different to Figure 2b, the drop of the S-N curve beyond the knee-point is not caused by the VHCF effect but by damage accumulation. A special feature of variable amplitude loading is that loading cycles with stress amplitudes below the fatigue limit may contribute to fatigue damage when there is a mixture of stress amplitudes above and below this level. This is the case because the high stress amplitudes (above the fatigue limit), due to their damaging effect, cause subsequent lowering of the fatigue limit. Depending on the applied stress spectrum the drop in the S-N curve can be more pronounced than those caused by the VHCF effect because of which one could think about cases where it “covers” the latter in a conservative way.

Figure 2d: A damage accumulation analysis is used to obtain a damage-equivalent constant stress amplitude. This is then used like the maximum stress amplitude of Figure 2a but it actually describes variable amplitude loading. The fatigue strength analysis is performed as in Figure 2a or b

against the constant amplitude S-N curve.
The approaches according to Figures 2c and 2d have been proposed in some recently finished research projects on the safety of railway axles ([7], see also [8], [9]). Note that they require real stress amplitude spectra, e.g., from test runs. Although a number of those has been determined over the last decade (e.g. [7], [8], [9]) there is still need for generally accepted reference loading spectra for the various kinds of railway transportation (high speed, freight etc.) and different track quality (modern high speed and traditional track, significantly curved track, track with switches and crossovers, e.g., at stations, etc.). As long as generally accepted information of that kind is not available the damage accumulation based analyses are hardly an alternative to the fatigue limit based standards discussed at the beginning of this section. But, although it can be argued that these "cover" the damage accumulation effect by its ample safety margins, damage accumulation based approaches, in the opinion of the authors of this paper, point into the right direction for future development. Note, however, that they have to include further effects such as damage due to corrosion and ballast impacts during service (see Section 2.3).

2.3 In-service effects on Fatigue Life

Corrosion pits and notches due to flying ballast impacts develop during service which means that the fatigue strength is not a material and/or component property established once for all but can reduce during the lifetime of the component. Failures of axles in freight wagons are frequently caused by corrosion pits at the axle shafts. Besides the corrosion effect itself corrosion pits act as stress raisers.

With respect to flying ballast impacts a systematic screening has shown that the latter is a rather typical issue of high-speed traffic [10]. Whereas only on 5% of other axles showed impact notches 30% of the high-speed axles were affected. The reason for flying ballast is aerodynamic effects with respect to the high speed which make impact from debris more likely. On 9 February 2006 a passenger train derailed in New South Wales, Australia after an axle completely fractured at the radius relief area between the gear and wheel seats [11]. Whilst the crack initiation site could not be identified on this specific axle, twelve similar axles were found with fatigue cracks at identical axle sections. Five of these were closer examined. In each case the crack originated from small surface indentations with depths between 0.1 and 0.9 mm which, by means of chemical analyses of crystalline material embedded in the indentations, could be identified as the result of ballast impacts.

The average depth of the detected impact notches was 0.8 mm, i.e., significantly larger than that of typical corrosion pits [10]. The 95% upper bound depth of about 2 mm was close to earlier assumptions in [12]. Of course a ballast-induced notch is not a crack although there is some chance of sharp edges from which small fatigue cracks could easily develop. A systematic investigation on the typical and most dangerous impact notch geometry and its effect on the local stress concentration and small crack initiation and on the residual stress field generated by the impact is due in the future. Note, that impact damage also promotes stress corrosion crack initiation by local damage of the coating and the introduction of complex residual stresses.

2.4 Potential effect of on-metallic inclusions

Non-metallic inclusions originate from the steel manufacturing process such as illustrated in Figure 3. When, e.g., aluminium is added for deoxidisation, oxidic inclusions such as Al_2O_3 are formed, silicon oxides can be introduced form mould powder etc. Besides oxides there may also be sulfides such as MnS or other particles. The size of the inclusions is in the order of ten µm up to mm.

During forging or rolling the inclusions can be crushed, this way forming clusters or inclusion "chains". An example is shown in Figure 4 which belongs to the failure investigation on the German high speed train mentioned in the beginning of Section 1 (for details see [1]).

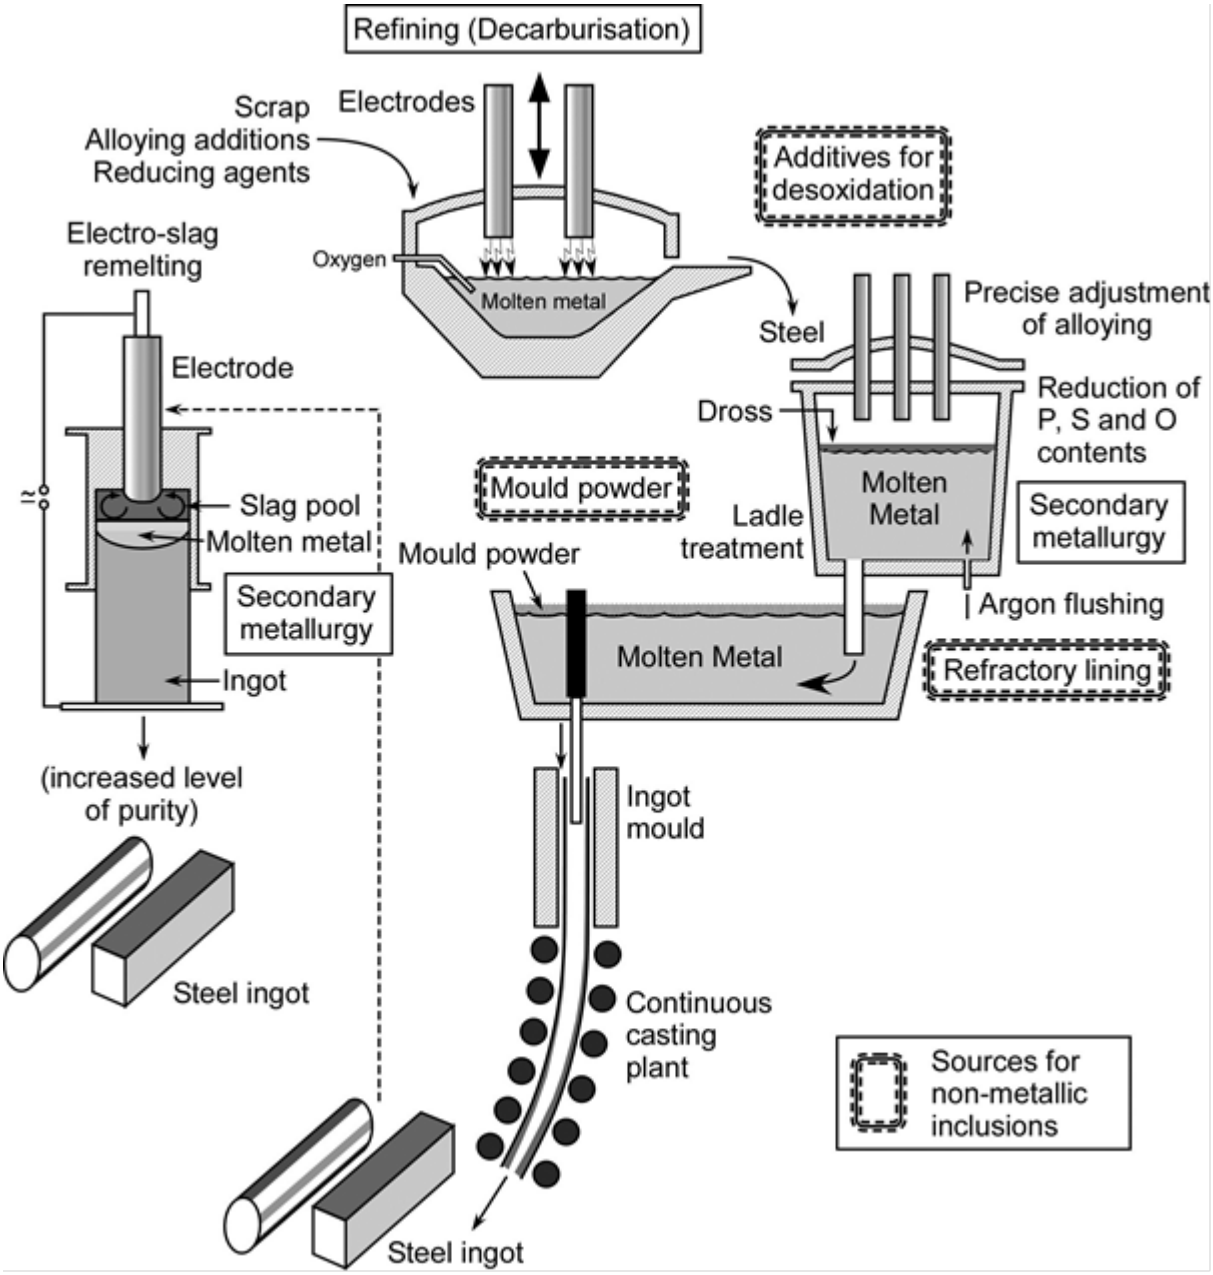

Figure 3: Sources for non-metallic inclusions during steel manufacturing.

In general, the lifetime of a crack consists in the initiation stage, where cracks are formed due to irreversible plastic deformation along slip bands, short crack propagation (up to a size of roughly 0.5 to 1 mm in engineering materials), long crack propagation (beyond that crack size) and final fracture. The effect of the non-metallic inclusions consists in a substantial shortening of the crack initiation stage leaving short crack propagation as the stage which controls lifetime. Inclusions differ from the matrix in several aspects: they have different elastic constants (stiffness mismatch), different strength and hardness properties (strength mismatch) and different thermal contraction coefficients (thermal contraction mismatch). Frequently, they show a square-edged shape which, in

combination with the difference in hardness between particle and matrix causes stress concentrations at the corners and, due to this, local damage in the adjacent matrix material when the component is subjected to applied loading. An example of the effect of inclusions on the lifetime of carbon steel is presented in Figure 5. Note that it is the defect area normal to the loading direction (which, in axles, is much smaller than that in axial direction) that correlates with the fatigue life (and strength).

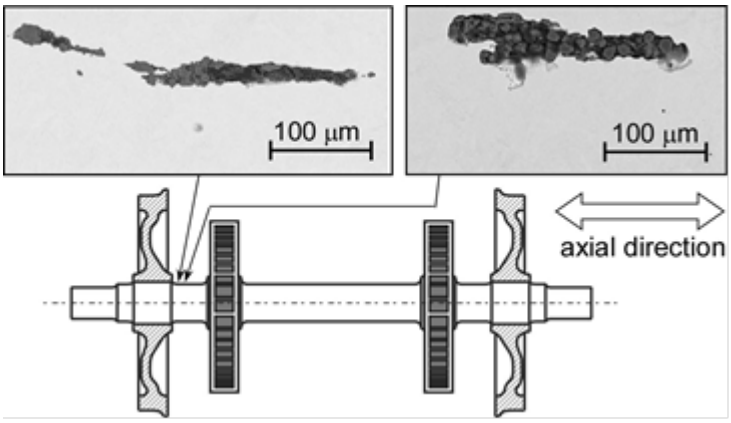

Figure 4: Nearly axially orientated non-metallic inclusions found in sections adjacent to the fracture surface very close to the crack origin in the broken axle of the German high speed train mentioned in Section 1 (according to [1]), axle type shown schematically.

In order to prevent large inclusions EN 13261 refers to the materials standard ISO 4967 which gives rules for maximum tolerable inclusion dimensions between 76 and 436 µm depending on the inclusion type (sulphide, aluminate and silicate globular oxide) and the category of steel quality (1 or 2). The absence of larger particles has to be proven by metallography at a limited (approximately 200 mm2) polished area parallel to the axial direction half-way between surface and centre in solid and between outer and inner surface in hollow axles at the section of the largest diameter (Figure 6). No guidance is given on the number of axles of a batch to be investigated. This is the more problematic as large inclusions at critical positions – which could act as fatigue crack initiation sites – have to be assumed to be very rare in reality; a statement which is obvious at the background of the relative small number of axle failures in reality. It is certainly not consistent to look for seldom events by a very limited sample. In addition, one could ask whether it is meaningful to look for large inclusions in the middle of the wall and not at the potentially critical locations in the axles such as the T notch or other geometric transitions or the press seats.

On one hand microscopic defects in the order of some ten or hundred micrometers which have to be detected by means of metallography based on a very limited sample, on the other hand the exclusion of much larger macroscopic defects in the order of millimetres by NDT screening of the whole component – and in between a gap, at least if one thinks about standard NDT methods.

What could be an alternative to these inconsistent requirements? In [2] the authors proposed to perform a more thorough investigation on a number of carefully chosen axles (e.g. by ultrasonic immersion technique or destructive methods) and to use the result for statistically specifying an upper-bound inclusion size which, by state-of-the-art quality control, will be found with high probability. Smaller defects which could escape its detection have then to be taken as existent even if the NDT record is “negative”. This limit defect size could then be used, in a worst case scenario, for the specification of a general reduction factor for the fatigue strength. The NDT technique has to be developed such that defect sizes larger than the limit are very probably be found by quality control measures which have to be exclusively based on a methodology allowing the complete

screening of the mechanically critical positions of the axles.

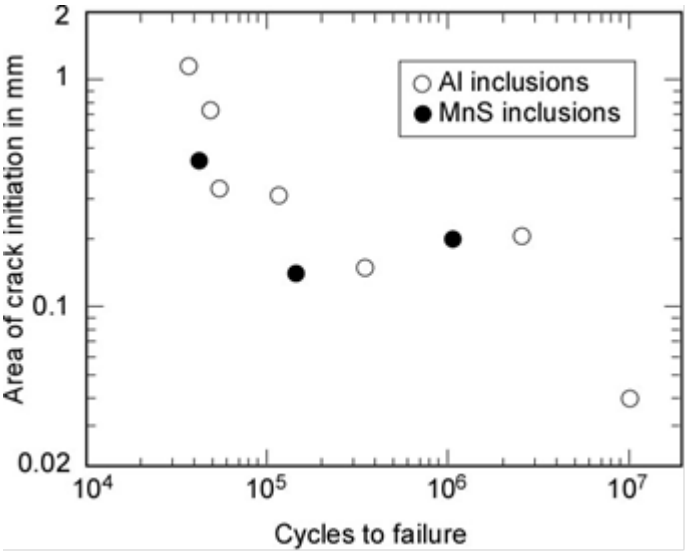

Figure 5: Effect of the defect area normal to the loading direction on the fatigue life of a hot rolled A537 carbon steel at a maximum stress of 260 MPa (according to Ma [13]).

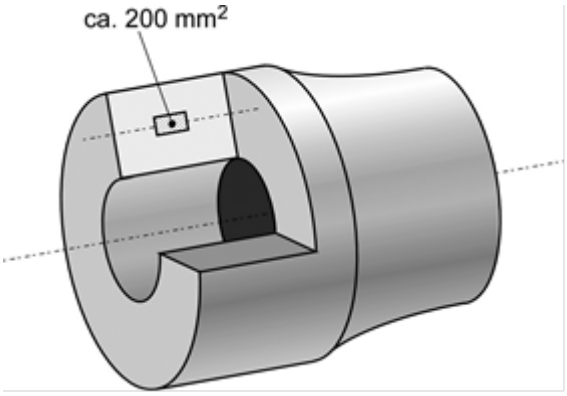

Figure 6: Location for the metallographic proof of the absence of inclusions larger than permissible with respect to ISO 4967 and EN 13261 (not in scale).

2.5 Reliability Issues of Non-destructive Testing (NDT)

A science-based inspection regime consists in two major elements: facture mechanics based residual lifetime and the probability of detecting (PoD) a crack of a certain size. Combining both types of information, the probability to find a potential crack in due time, i.e., before it becomes critical can be determined as a function of the inspection interval. No discussion on the fracture mechanics part shall be provided here, see, however the detailed discussions of the authors in [2].

Non-destructive testing is usually performed by ultrasonic (US) (shorter interval) and magnetic particle inspection (MPI) (larger interval). It seems likely, that MPI is the most cost-effective NDT technique for a bare axle (the wheels, bearings, brake discs etc. are removed) during its overhaul. Note, however, that there might be the risk of scratching during dismantling. Unfortunately fatigue cracks may be initiated and grow to failure in less time than needed to wear out the wheels. Therefore, costly and disruptive axle inspections in between overhauls have to be carried out which are usually based on US as a compromise between a limited intrusiveness, which disrupts train

service, and a lower PoD compared to MPI.

With respect to ultrasonic inspection it has to be distinguished between:

- far end scan (the axle is inspected from the end of the axle to mid-span or further) near end scan (the axle is inspected from the end of the axle to an adjacent seat) and high angle scan (the axle is inspected from the axle body across the seat),
- inspection from the outer surface in solid axles and from the bore in hollow axles,
- manual or automated testing, and
- standard or sophisticated test and analysis methods such as phase array, synthetic aperture focusing technique (SAFT) etc.

PoD-crack size curves for railway axles have first been determined by Benyon and Watson [14] in 2001 (see also the subsequent discussion in [15]). The by now most up-to-date and most systematic study of PoD on railway axles has been performed in the European WIDEM project [16]. In Figure 7 some of these data are shown along with the data of [14]. Note that none of the curves can be generalised because they belong to specific test setups.

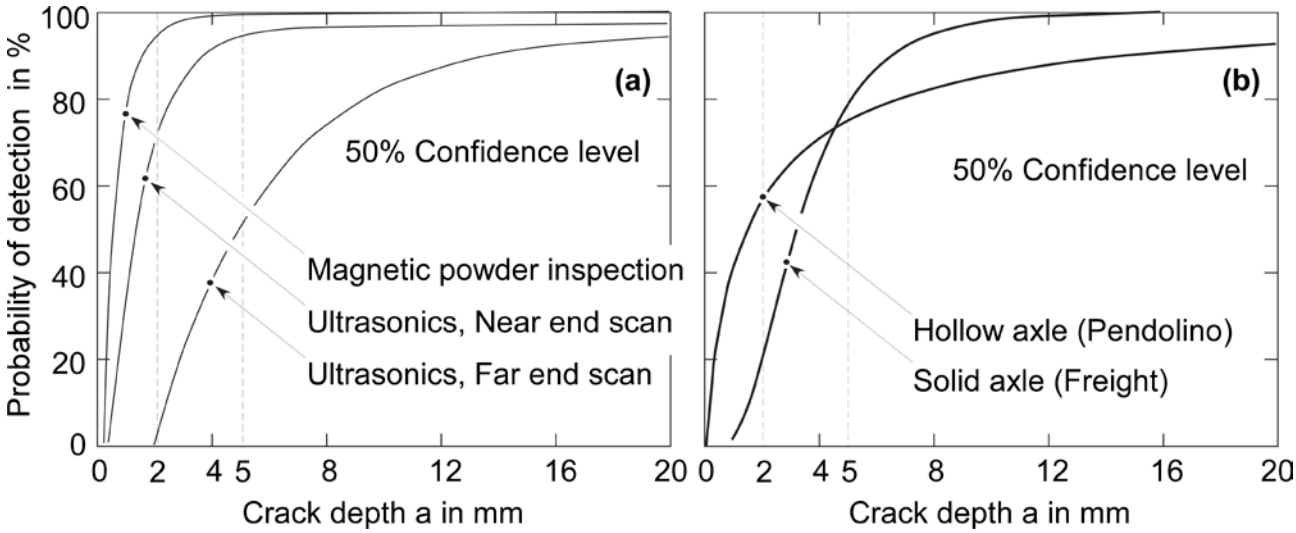

Figure 7: Probability of detection (PoD) of cracks as a function of crack depth. (a) Data obtained by magnetic particle inspection and ultrasonic techniques (according to [14]; 50% confidence level; solid axle); (b) Comparison between ultrasonic near end scan data for solid axles and ultrasonic data obtained from the bore of hollow axles (according to [16]; 50% confidence level).

The overall probability of non-detection (PoND) as the complement to the POD is identical with the probability that an axle with an initial crack of 2 or even more millimeters depth (such as assumed in the fracture mechanics analysis) fails because the crack was not found in due time. This has to be distinguished from the failure probability of an arbitrary axle in the fleet which is smaller by magnitudes since a pre-existing crack of that size is very unlikely.

Besides the fracture mechanics based residual lifetime the steepness of the PoD-crack size curve is the second key parameter for establishing inspection intervals. This is illustrated in Figure 8. The failure probability of the axle, i.e., the probability that the crack will not be found in due time, increases for a larger inspection interval but it significantly reduces for a shorter one, i.e., with any additional inspections before potential failure (Figure right). The PoD of a specific inspection

becomes larger when the crack is more extended and when the PoD-crack size curve is steeper (Figure 8 left). Therefore, measures for improving the PoD-crack size curve [in the figure from (1) to (2)] are of paramount importance for reaching an optimum between safety and cost-efficiency.

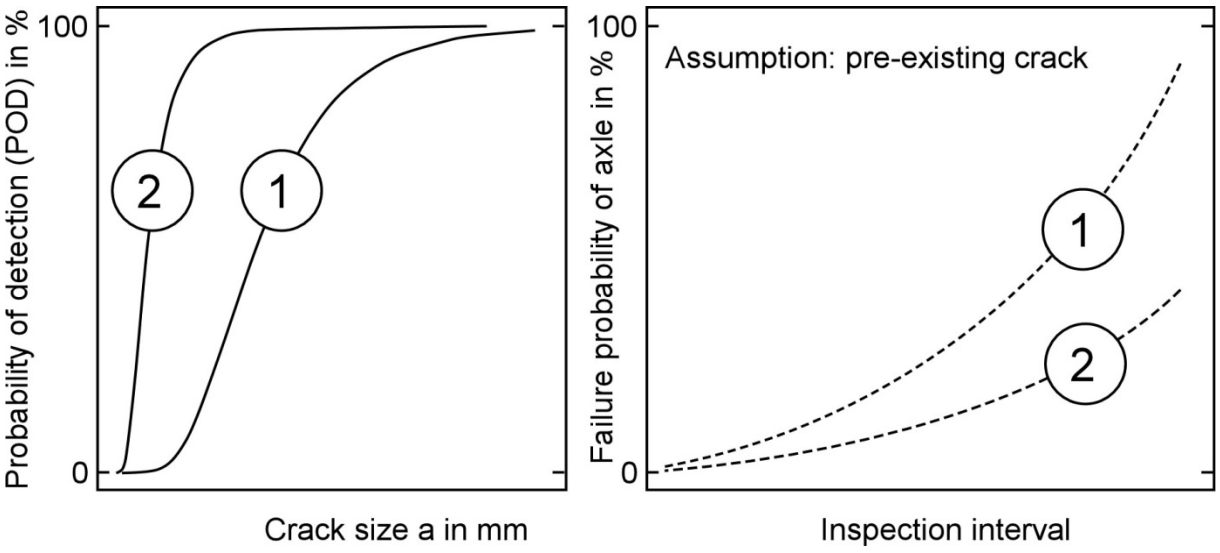

Figure 8: Schematic correlation between the PoD-crack size characteristics of a NDT method, the inspection interval and the failure probability of an axle with a pre-existing crack.

No detailed discussion on options for improving the PoD-crack size characteristics shall be given here because this is a subject of ongoing and future research activity, see however the remarks in [2]. Certainly increasing automation will lead to improvements in NDT quality since, this way, human factors such as the level of training and experience of the inspectors and others which significantly contribute to the variability in manual inspection results are eliminated. Another measure is the application of more sophisticated test and analysis methods, e.g., for US, the application of the phase array or synthetic aperture focusing technique (SAFT). Note, however, that the challenge is not just to have more reliable NDT methods but to optimize these for railway axles with respect to the inspection time needed such that cost-intensive intrusiveness, which disrupts train service, is kept as small as possible.

3. SUMMARY

Starting with an axle failure case and a failure statistics for Europe the paper gives a brief overview on selected issues of existing and potential innovative safe life and damage tolerance methods for railway axles which, as the authors think, promise some potential for further increasing the safety level of axles. The issues addressed comprise questions of limiting the projected lifetime as a consequence of features such as damage accumulation, the potential very high cycle fatigue effect and corrosion including the “one-million miles axle” concept and in-service effects on the fatigue life such as corrosion pits and flying ballast impact notches. Special attention is put on the potential effect of non-metallic inclusions on fatigue strength and lifetime. A gap in the existing quality regulations has been identified. As an alternative it is proposed to carry out a throughout investigation of the as-is state and to correct the design fatigue strength with respect to a limiting defect size which will not be found with acceptable probability in quality control. Defect sizes above this limit have to be found with high reliability by innovative NDT techniques. Finally, the improvement of the PoD-crack size characteristics of NDT has been identified and discussed as a paramount goal for reaching an optimum between safety and cost-efficiency.

Analysis of fatigue crack initiation and propagation in ship structures

Wengang Mao[1,*], Jonas W Ringsberg[1]

Abstract

Ships structures are subjected to various types of cyclic loads from waves, wind and cargo operations that cause fatigue damages in the structures. There exist rules to regulate the structural design with sufficient fatigue strength to survive their service period. However, fatigue cracks do occur earlier than expected in numerous locations of e.g. ocean-crossing container vessels. The presence of fatigue cracks greatly affects a ship's safety and serviceability. Managing how initiated cracks grow is an important task to ensure a safety and cost-effectiveness ship transportation. The objective of this study is to develop a robust method, which can be used to predict crack growth and crack maintenance in ship structures. A longitudinal stiffener of a 2800TEU container vessel with full-scale measurements of e.g. strain signals and operation conditions are used in the study. Firstly, a spectral *S*-*N* fatigue analysis is adopted to predict when the first crack occurs in the ship's most fatigue-critical region. Then the crack's growth characteristics are modeled by the code FRANC2D. Finally, the time needed for the crack initiation and growth are studied in terms of structural maintenance plan, i.e. crack growth management.

Keywords Fatigue crack, hydrodynamic loads, ship structure, spectral method and wave height.

1. Introduction

The size of ships has increased rapidly during the last decade as a result of the fast growth of the global shipping market and the developments of construction technologies that also makes the high-tensile steels widely used in ships. The increase of dimensions and high-tensile steel usage in ships made the ship structures more flexible when they are operated in waves. The wave (hydrodynamic) loads can cause continuously changing stresses and result in fatigue damages in ship structures, which challenges the ship's structural integrity and thereby its safety. Therefore, ship structures should be designed with sufficient fatigue strength based on the rules [1], where fatigue strength is assessed using stress-based approaches (the high-cycle fatigue analysis). In ship class rules, the stress range distribution is normally provided for the fatigue assessment. But for a novel ship design, the stress range distribution is not available and should be computed by a direct calculation method that demands huge computation powers to consider the ship's specific operation conditions and encountered wave environments. However, large uncertainties cannot be avoided in the above two fatigue design processes [2]. For example, a ship's real encountered wave environments may be different from that used and proposed in the fatigue design rules [3, 4]. The results from the hydrodynamic loads analysis can be large [5]. There are additional factors which are also often disregarded in the fatigue analysis of ship structures, such as analysis of the effects of redistribution of residual stresses from manufacturing, corrosion, weld defects, etc., and these factors contribute to even larger uncertainty in the fatigue assessment. The sum of all these factors may explain why fatigue cracks are found earlier than expected in many vessels. Repairing the entire minor to moderate cracks is expensive and it is seldom an alternative, due to the economic issues related to the maintenance process. Hence, the understanding if "initiated" and visible cracks are critical to the structure's integrity becomes an important issue. Tools and methods for maintenance plan based on

crack growth management should therefore be developed. In the literature, crack propagation under various sailing conditions has been investigated in e.g. [6]. A summary of the progresses of using fracture mechanics in the maritime industry is summarized in [7].

The objective with the current study is to present the derivation of a useful method that can be used to predict the fatigue crack growth in a ship structure. In the development, the special loading characteristics of ship structures are dealt with. It has been formulated to assist maintenance planning with respect to e.g. repair of fatigue cracks. A structural detail with an initiated crack in a 2800TEU container ship is used to demonstrate the approach using fatigue loads from a direct calculation. The results are compared with full-scale measurements made on the vessel. Finally, based on the operation conditions for the current case study vessel and the existing crack, the number of voyages the ship structure can undertake before final rupture is investigated.

2. A spectral method for ship fatigue assessment

For the ship fatigue assessment, the long-term structural stresses are divided into a series of short stationary signals [8]. A stationary process can last for from 20 minutes to several hours. The structural stress under a stationary sea state is caused by the wave loads applied on ships. The waves in a sea state is often described by the significant wave height, H_s, the wave period T_p, and a specific wave spectrum $S(H_s, T_p)$. In order to estimate a ship's fatigue damage under a sea state, its structural stress is often assumed to be Gaussian distributed [9]. Hence, both the hydrodynamic loads and the structural stresses can be computed by linear theories.

2.1. High-cycle fatigue analysis

Ship structures are designed to behave elastically during its design life of around 20 years. The fatigue strength is assessed by stress-based approaches, i.e. high-cycle fatigue design principles. In the analysis, the material behavior is characterized by a *S*-*N* curve, with a log-linear dependence between the number of cycles to failure N, and the stress cycle range S, $\log(N) = \alpha - m\log(S)$. Different *S*-*N* curves exist for different materials, geometries, welds, etc., the parameters a and m are usually categorized based on the properties of structural details in the class rules. The stress ranges, here denoted by S_i, ($i = 1,\ldots,n$), can be obtained by the rainflow counting method for each sea state. Finally, the accumulated damage is calculated using the linear Palmgren-Miner law as:

$$D = \sum_{i=1}^{n} \frac{S_i^m}{\alpha} \tag{1}$$

In order to estimate the fatigue damages accumulated in a sea state, it is necessary to get the total number and distribution of the stress ranges S_i. Since the stress is assumed to be Gaussian, it is sufficient to get the spectrum of structural stresses for the ship fatigue assessment.

2.2. Ship structural stresses in a sea state

The variability of structural stresses, denoted by $X(t)$ here, is mainly caused by the change of the wave loadings applied on ships. Hence, it is essential to get the correct wave (hydrodynamic) loads.

The structural stresses due to the wave loads can be computed by beam theory. To simulate and evaluate realistic ship operation conditions, the computation has to be done for many sea states, at various ship speeds, U, and different heading angles, θ. In general, a frequency domain analysis is used to first compute the Response Amplitude Operators (RAOs) of the hydrodynamic loads using linear potential strip theory [10]. Then, by means of beam theory, the transfer function of structural stresses $H_\sigma(\omega|U, \theta)$ is calculated using the section modulus of the structural detail of interest. Often, a stress concentration factor is added in the transfer function to get the local stresses. Thereafter, the stress spectrum under arbitrary sea states, $S_\sigma(\omega|H_s, T_p)$, can be computed as:

$$S_\sigma(\omega\,|\,U,\theta,H_s,T_p) = |\,H_\sigma(\omega\,|\,U,\theta)\,|^2 \cdot S_e(\omega\,|\,H_s,T_p), \tag{2}$$

where $S_e(\omega|H_s, T_p)$ is the encountered wave spectrum. It is not always explicitly derived for all wave frequencies, but the spectral moments are rather easy to obtain and of great interest in fatigue analysis. The n-th order spectral moments is calculated by:

$$\lambda_n = \int_0^\infty \left|\omega + \omega^2 U\cos\theta / g\right|^n H_\sigma^2(\omega\,|\,U,\theta) S(\omega\,|\,H_s,T_p)\,d\omega. \tag{3}$$

Let R denote the local maxima of the Gaussian stress signal X in a sea state. The distribution of R can be described by Rice's distribution function:

$$F_R(r) = \Phi\left(\frac{r}{\varepsilon\sigma_x}\right) - \sqrt{1-\varepsilon^2}\,\Phi\left(\frac{\sqrt{1-\varepsilon^2}}{\varepsilon}\frac{r}{\sigma_x}\right) e^{-\frac{1}{2}\left(\frac{r}{\sigma_x}\right)^2} \tag{4}$$

where Φ is the standard normal cumulative distribution function, σ_x is the standard deviation of X and $\sigma_x = \sqrt{\lambda_0}$, ε is the spectral width parameter. If $\varepsilon = 0$, Eq. (4) becomes Rayleigh distribution:

$$F_R(r) = 1 - e^{-\frac{r^2}{2\sigma_x^2}}, \text{where } R \geq 0 \tag{5}$$

For the narrow band Gaussian process, the number of local maxima can be computed through the zero-upcrossing frequency of the signal $X(t)$ as $f_z = \frac{1}{2\pi}\sqrt{\frac{\lambda_2}{\lambda_0}}$.

2.3. A spectral fatigue method

Since the waves in a stationary sea state are actually random processes, the stress cycle range S is also a random variable with the probability density function (pdf) denoted by $f_S(s)$. Then, the expected value of S^m is computed by $E[S^m] = \int_0^\infty s^m f_S(s)\,ds$. For a zero mean narrow band Gaussian stress $X(t)$, the stress cycle range S is approximated by two times the stress amplitude R, i.e. $S \approx 2R$. Subsequently, by means of Eq. (5), $E[S^m]$ can be computed by:

$$E[S^m] \approx \int_0^\infty (2r)^m f_R(r)\,dr = \left(2\sqrt{2}\sigma_x\right)^m \Gamma\left(\frac{m}{2}+1\right) \tag{6}$$

where $\Gamma(x)$ is the gamma function. The expected fatigue damage computed by Eq. (1) becomes:

$$E[D]=\frac{N_0}{\alpha}E\left[S^m\right]\approx\frac{N_0}{\alpha}\left(2\sqrt{2}\sigma_x\right)^m\Gamma\left(\frac{m}{2}+1\right) \tag{7}$$

where N_0 is the expected number of stress cycles and computed by $N_0 = T{:}f_z$ for $X(t)$, $t \in [0, T]$. Finally, the expected fatigue damage caused by the narrow band stress $X(t)$ denoted by D_T, is:

$$D_T = E[D]\approx\frac{T}{2\pi\alpha}\sqrt{\frac{\lambda_2}{\lambda_0}}\left(2\sqrt{2\lambda_0}\right)^m\Gamma\left(\frac{m}{2}+1\right) \tag{8}$$

Equation (8) is also known as the narrow band approximation and works quite well even for stress signal with spectral width parameter ε up to 0.5 [10].

3. Crack propagation analysis for ship structures

Ships follow specific inspection and maintenance plans based on rules and regulations. Because of large costs during the repair process [11], ship owners would like to repair ship defects and cracks during the ship's regular hull survey, which should be carried out from every 2 to 5 years depending on the type and age of the vessel. However, it is not practical or possible to repair all the cracks at once. Consequently, it is of great interest to study when fatigue cracks propagate and reach a critical length which requires immediate repairing. In the following, an efficient way for such an analysis is derived and it has been limited to Model I crack propagation according to linear elastic fracture mechanics principles.

3.1. Fatigue crack propagation analysis

The rate of fatigue crack propagation under cyclic loads can be described by the Paris' law [12] as:

$$\frac{da}{dN}=C\cdot\Delta K^k \tag{9}$$

where a is the crack length, N is the number of cycles, da/dN is the crack growth per load cycle, and C and k are material parameters from experiments. The ΔK is the range of the stress intensity factor during a load cycle, i.e. $\Delta K = K_{max}\text{-}K_{min}$, where the stress intensify factor K is defined as $K=\sigma f(a/w)\sqrt{\pi a}$, in which σ is the tensile stress perpendicular to the crack plane, $f(a/w)$ is the dimensionless parameter in terms of the crack geometry. The value of K can be difficult to describe analytically for ship structures due to their geometrical complexity. Alternatively, codes such as FRANC2D [13] can be used to compute K as a function of the crack length. Let $Y = f(a/w)\sqrt{\pi a}$. The stress intensity factor can be written as $K = \sigma Y$. For the computation of Y by Franc2D, the crack growth is treated as a series of stages, i.e. the crack grows from a_j, j = 0,1,..., M, corresponding to the value of Y_j, j = 0,1,..., M. Here, a_0 is the initial crack length and a_M represents the critical crack length defined for crack repair. Finally, the stress intensity factor range becomes $\Delta K = \Delta\sigma Y$.

3.2. Fatigue crack growth under a sea state

Following the reasons in Section 2.3, here the stress signal $X(t)$ is also assumed to be a zero mean narrow band Gaussian process. Further, it is assumed that the compressive stress does not contribute

to the crack propagation. Hence, the stress range $\Delta\sigma$ equals to the local maximum of $X(t)$, $\Delta\sigma = R$. Let T denote a sea state lasting period, say 30 minutes, and assume that Y is constant for a crack from a_j to a_{j+1}, i.e., $Y = Y_j$, which is computed by fracture mechanics codes such as the FRANC2D. The expected number of stress cycle N_0 is known from Section 2.3. Then the expected crack growth in the sea state can be computed by:

$$\Delta a_T = E\left[\sum_{i=1}^{n} C\Delta K_i^n\right] = CN_0 Y_j^k E[\Delta\sigma^k] = \frac{TC}{2\pi}\sqrt{\frac{\lambda_2}{\lambda_0}}\Gamma\left(\frac{k}{2}\right)\left(\sqrt{2\lambda_0}Y_j\right)^k \tag{10}$$

where λ_0 and λ_2 are the spectral moments of $X(t)$ in the sea state as Eq. (3). By means of Eq. (10), it is straightforward to compute how many sea states a ship can sail until the crack of interest reaches to a_M, which is the critical crack length that requires repair, cf. crack growth management.

3.3. Sailing wave environments and ship response

When a ship sails across the ocean, e.g. on the North Atlantic trade, the ship typically encounters one or two storms with high significant wave height H_s, see Fig. 1 (left) for an example. Depending on the weather forecast information, captains can choose different routes for safety and economics reasons. For the prediction of fatigue crack growth, it is of great interest to know the distribution of the wave environment a ship will encounter in a few years. A large amount of data is available, such as wave measurements from satellites, hindcast or buoys, which can be used for this purpose. There also exist statistical models built up based on the data, e.g. [14], which can be used to simulate the mean and covariance of wave environments along various ship routes.

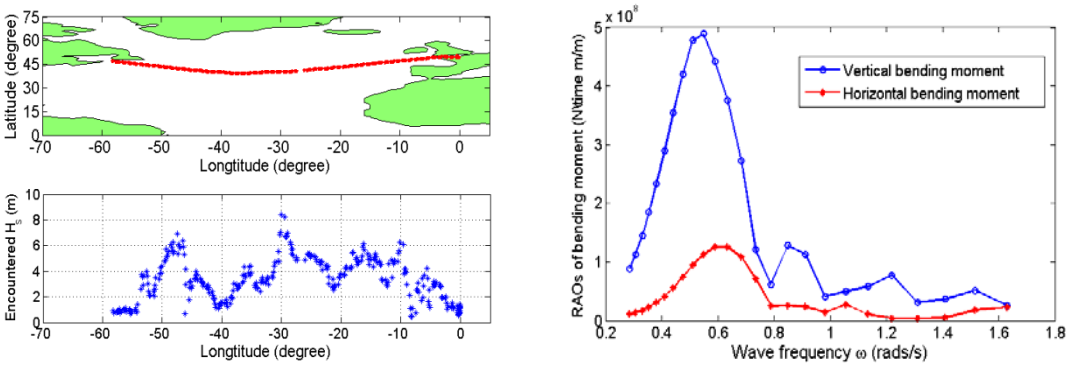

Figure 1. (Left) One voyage from Europe to North America with the significant wave height H_s for all the encountered sea states during the voyage; (Right) response amplitude operators of two bending moments for a ship operating with 10 m/s forward speed and heading angle 20 degrees.

For ship fatigue assessment, the structural response should be computed for all encountered sea states. In the maritime industry, the response is often described by the transfer function, $H_\sigma(\omega|U, \theta)$, which depend on the ship speed and the heading angle. When sailing in the North Atlantic Ocean from Europe to North America, ships usually have to go against waves with a heading angle to the wave encounter direction that varies between 20 to 50 degrees. As a result, the normal stress signal $X(t)$ is composed of stresses from the ship's vertical bending, horizontal bending and Vlasov Torsion. In the right plot of Fig. 2, an example of these two bending moments is depicted.

4. A case study: fatigue analysis of ship structures

A structural detail amidships (see Fig. 2) of a 2800TEU container ship is used to demonstrate the approaches for ship fatigue analysis presented in the previous sections, i.e. fatigue initiation in Section 2 and crack propagation in Section 3. The purpose of the analysis is to explain how the two analysis methods can be implemented to plan the maintenance of ship structures. The structural detail of interest was identified from reports, which stated that fatigue cracks were initiated after less than half of the vessel's fatigue design life. Hence, instruments were installed onboard to measure the time series of strains (stresses), significant wave height, heading angle and ship speed when crossing the North Atlantic. The measurement campaign includes 14 voyages where 7 go from Europe (EU) to North America (NA), while the other 7 go to EU from NA. For the following fatigue analysis, the parameters in the *S-N* curve [9] and the Paris' law [15] are listed in Table 1 .

Table 1. Material parameters in the *S-N* curve and in Paris law for the AH36 steel.

	S-N curve		Paris law	
Parameters	α	m	C	K
Values	$10^{12.76}$	3	1.45×10^{-11}	2.75

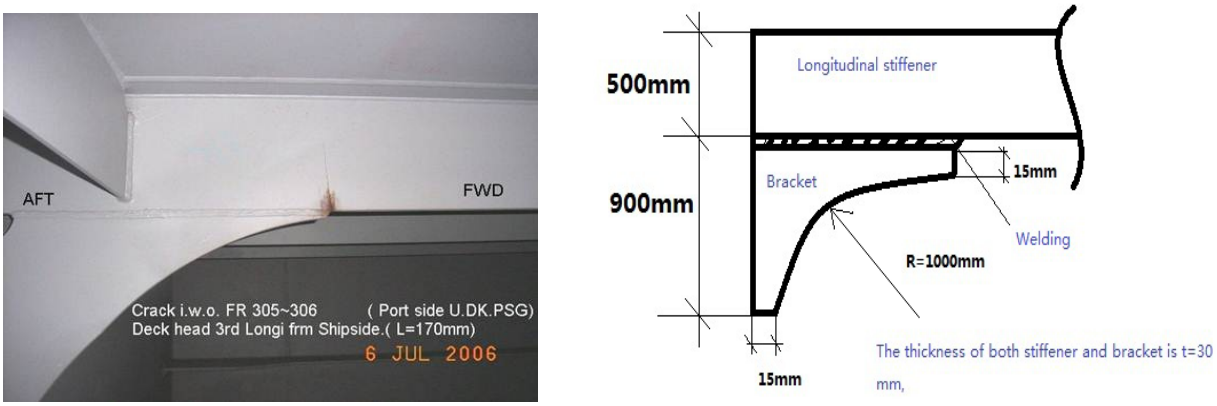

Figure 2. A fatigue crack in the case study vessel and the structural detail in the fracture analysis.

4.1. Fatigue crack initiation analysis

Firstly, by means of the measured stress signals, the fatigue damages accumulated during each individual voyage are computed by the rainflow counting method – they are denoted as the "observed" damages. Secondly, the transfer function of structural stress is computed by means of a 2D strip theory hydrodynamic analysis and the simple beam theory for structure analysis. Then, combining the transfer function with the wave measurements (H_s, T_p) for all encountered sea states, the fatigue damages are computed by the spectral method as Eq. (8). The results from both methods are presented in Fig. 3. It is of interest to focus the study of the fatigue damages during winter season voyages from Europe to North America where the ship were operated in the harshest conditions. For these voyages, the spectral method gives maximum 30% discrepancy from the observed damages, but in the long-term analysis, the spectral method works well in comparison with the rainflow method. The results also confirm the initiation of a fatigue crack observed

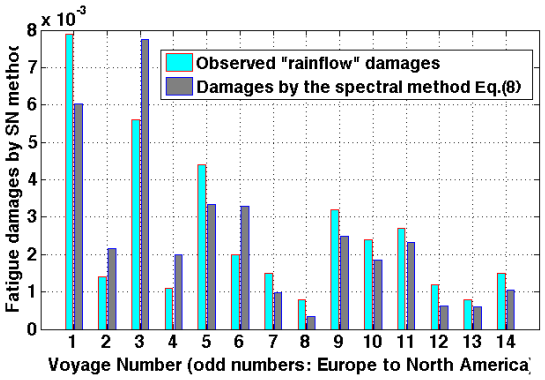

Figure 3. Observed fatigue damages and damages computed by the spectral method introduced in Section 2.3 for all measured voyages. Voyages 1-7 represent winter seasons, 8-14 represent summer seasons.

4.2. Crack propagation analysis and maintenance plan

A ship's structure integrity can be strongly affected by fatigue cracks depending on their locations. Sometimes, the cracks can lead to undesirable consequences, such as oil leakage and compartment flooding, or even structural failure of the entire ship. In principle, the deck plates and longitudinal stiffeners/girders have to undertake the ship's global strength. The cracks around these areas should be repaired well in time before they reach to a critical value. For this purpose, the crack propagation analysis is needed to plan the cracks maintenance. For the example container ship, the critical crack length is assumed to be 200 mm. The crack propagation analysis is performed using the approach presented in Section 3.2. It enables us to estimate how many voyages or sea states the ship can sail before the crack reaches to 200 mm. The initial and interval crack growth length is set to be 5 mm for the linear elastic fracture mechanics analysis. A strong beam is attached on the top of the stiffener to model the deck effect as shown in Fig. 2. A crack is initiated at the connection between the longitudinal stiffener and the associated bracket with high stress concentration. The crack growth path and corresponding stress intensity factors K_I are computed using FRANC2D [13]. For the current boundary and loading conditions, an analysis showed that crack propagation was governed by Mode I. The final stage of the crack propagation and K_I are presented in Fig. 4.

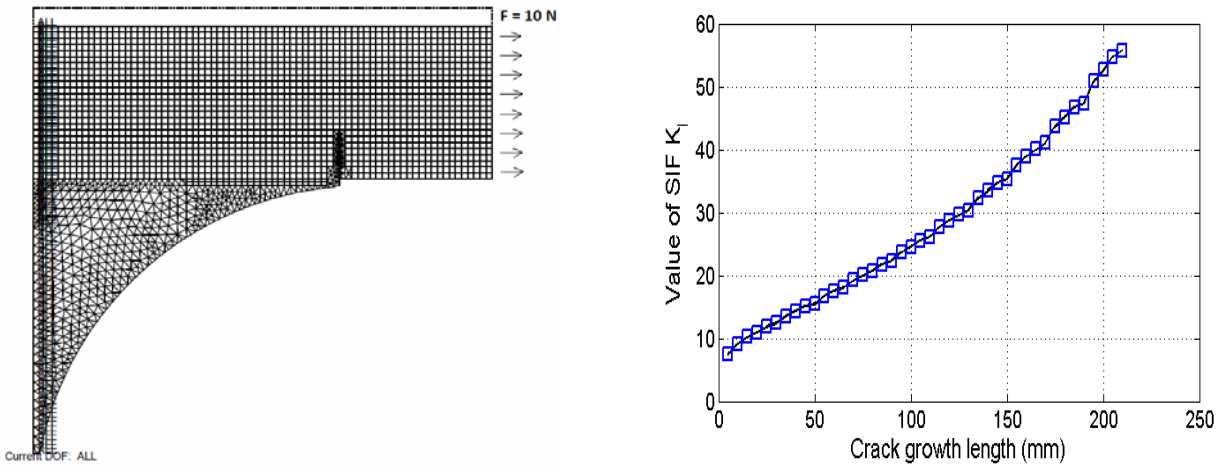

Figure 4. Fatigue crack growth path and stress intensity factors computed by FRANC2D, where the initial crack length is 5mm, the crack is propagated straight upwards, and the element is set to 20 mm.

In order to predict the fatigue crack growth, it is necessary to get the wave environments, which the ship will encounter in the future years' operation. In this study, the ship is assumed to sail along the same routes as the measured 14 voyages. Further, it is assumed that the ship is operated with the same speed and heading angle as the measured ones. The significant wave heights H_s along the measured routes are simulated using a spatio-temporal wave model presented in [14]. It contains the covariance structure of the ocean field in both time and space and enables us to simulate the value of H_s and their correlations for all locations (sea states) along the measured routes. Because of the natural variability of the wave environments, the value of H_s could change as in Fig. 5, together with the observed in one winter voyage. In the study, a stationary sea state is assumed to be 30 minutes and described by the Pierson-Moskowitz (P-M) power spectrum density which is expressed in terms of the significant wave height, H_s, and the wave period, T_p.

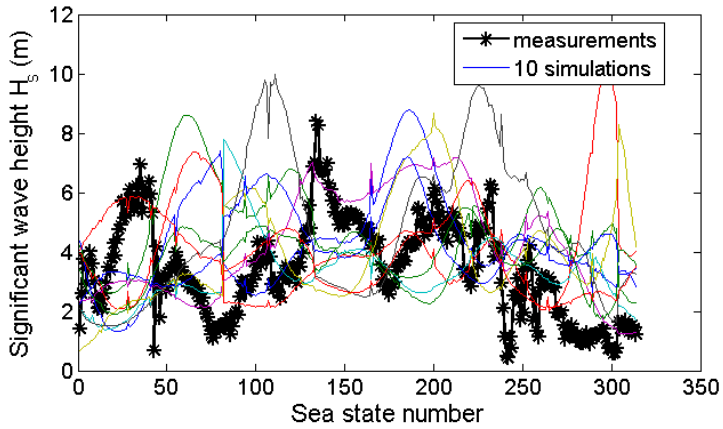

Figure 5. Significant wave heights along the route in Fig. 1 using the spatio-temporal model [14].

The crack propagation analysis is divided into various crack growth stages/intervals. For each stage, the crack increment is computed by Eq. (10) for the ship in a specific condition (H_s, T_p, U and θ). Subsequently, how many sea states the ship can sail for the crack growing from a_i to a_{i+1} can be also calculated. Finally, the repair time, i.e. when the crack reaches to the critical length 200 mm, can be easily predicted. Using the repeated simulations of encountered H_s as in Fig. 5, the mean and variance of the fatigue crack growth under a certain period can be estimated. Therefore, the variation of the total sailing time until the crack propagates to a specific length can be predicted.

Using the wave environments from the wave model simulation [14], the ship can sail for 2.53 years before the crack reaches 200 mm. If the waves are simulated many times from the other approach, the median value of such a period is 2.74 years, while the standard deviation of the period is 0.34 year. Within each interval, the expected number of sea states needed for the crack to grow 5 mm is shown in Fig. 6, as well as the standard deviation of the number. When the crack length is short, more sea states are needed for the crack to propagate 5 mm. It can grow very fast when the crack is close to its critical value. In this case, only a few sea states can cause the crack to propagate 5 mm. It should be noted that the number of sea states for the crack to grow 5 mm does not always decrease as the crack length increase, such as the crack grows to 25 mm, 50 mm etc. This is because the crack can grow slower when the ship meets more calm sea state, e.g. during summer, or/and sails with a better operation condition (speed and heading angles with respect to waves, and less

loadings etc.). These findings can be used in a ship fatigue routing plan, i.e. optimization of ship courses, ship speeds, heading angles and loading conditions. It has to be combined with the shipping schedule, structural ultimate safety, onboard weather forecast information and regular inspection to maximize the ship's serviceability before the regular inspection and maintenance. Further, the large standard deviation in Fig. 6 indicates that the ship has a potential to extend its repair time dramatically if the ship's operation is well planned.

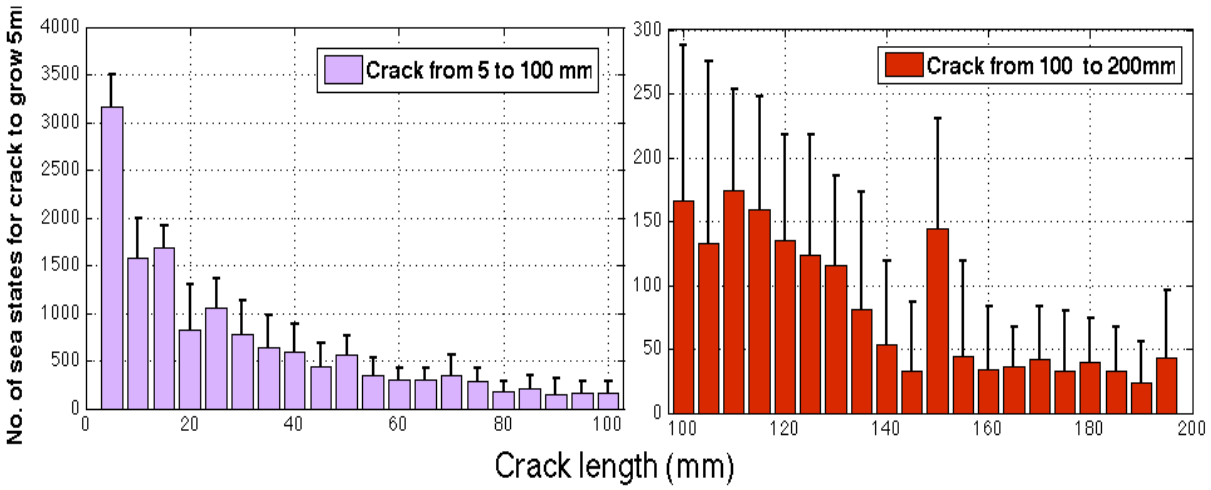

Figure 6. Median and standard deviation of the sailing periods (number of sea states) when the fatigue crack reaches 200 mm. Bars: median values of sea state number; lines: the standard deviation of sea state number needed for the crack to propagate 5 mm.

5. Discussion and conclusions

Conventional fatigue design of ship structures is carried out using high-cycle fatigue approaches, with stress ranges from either empirical data or direct calculations. Because of large uncertainties involved in the ship fatigue design process, such as the variation of encountered wave environments, computation of hydrodynamic fatigue loads and stress concentration factor, etc., fatigue cracks occur much earlier than expected. It is of great interest to study the crack propagation conditions in order to design and plan a maintenance strategy based on crack growth management, which ensures e.g. safety of the vessel. In this study, an efficient method for fatigue crack propagation analysis in ships was derived based on the narrow-band spectral fatigue method. The spectral method was validated by full-scale measurements on a 2800TEU container ship, to give accurate prediction of stress range distributions. In a crack propagation analysis, a case study using an example from reality of a structural detail prone to fatigue was used to demonstrate the application of the proposed method. The results show that depending on the encountered wave environments, the crack is critical and needs to be repaired within 2 to 3 years. During the crack propagation process, many sea states were required for the crack to grow 5 mm, but when the crack reached close to 200 mm, only a few sea states grew the crack 5 mm. It indicates the necessity to repair the crack in time since it can grow so fast that structural integrity and safety may be jeopardized.

Abstract During fatigue of metastable austenitic steels, local plasticity is linked with the formation of martensite. It was shown that cubic α´ martensite nucleates at slip band and ε martensite intersection sites ahead of growing fatigue cracks. Since such intersections require the operation of alternate slip systems, martensite formation was found only for shear-controlled single-slip crack propagation (mode II) prevailing during the early propagation phase of microstructurally short fatigue cracks. Surprisingly, cracks were found not to initiate within martensitically transformed grains but by a fraction of 70% along twin boundaries. The extent of martensite formation ahead of a propagating crack increases with increasing crack length and eventually, gives rise to transformation-induced crack-closure effects. The interaction between the crack tip plasticity and the local microstructure was quantitatively analysed by automated electron back-scatter diffraction (EBSD) in the scanning electron microscope (SEM) applied to the electro-polished surfaces of fatigue specimens. Following a geometrical model for martensitic transformation, further analysis of the relevant fatigue mechanism became possible aiming to both mechanism-based life prediction and tailoring fatigue resistant microstructures.

Keywords austenitic steels, martensitic transformation, fatigue crack propagation, short crack model

1. Introduction

Metastable austenitic stainless steels, e.g., AISI 304, may exhibit a transformation from fcc austenite into bcc martensite (α´ martensite) if a certain monotonic or cyclic plastic strain value is exceeded. This so-called TRIP effect (transformation-induced plasticity) is widely technically used, e.g., for work-hardened spring elements. From a thermodynamic point of view, at room temperature the Gibbs free energy difference ΔG between the fcc and the bcc phase is not large enough for spontaneous martensitic transformation to occur. However, this changes when sufficient plastic strain energy ΔG_{mech} is added, as it is schematically represented in Fig. 1a. Generally, the phase relationship between the parent fcc austenite and the martensite can be explained by the Bain relationship as shown in Fig. 1b [1]. From a microstructure point of view, plastic slip along the {111} slip planes of the fcc austenite cause the formation of extended stacking faults (due to the low stacking fault energy of the metastable austenitic steels), i.e., hexagonal ε martensite bands. The cubic α´ martensite nucleates at intersection points of the ε martensite bands (cf. [2,3]). Between the parent austenite and the transformed martensite, the Kurdjumov-Sachs relationship is fulfilled (cf. [4]):

$$\{111\}_{\gamma} \| \{101\}_{\alpha'} \quad \text{and} \quad <110>_{\gamma} \| <111>_{\alpha'} \quad . \tag{1}$$

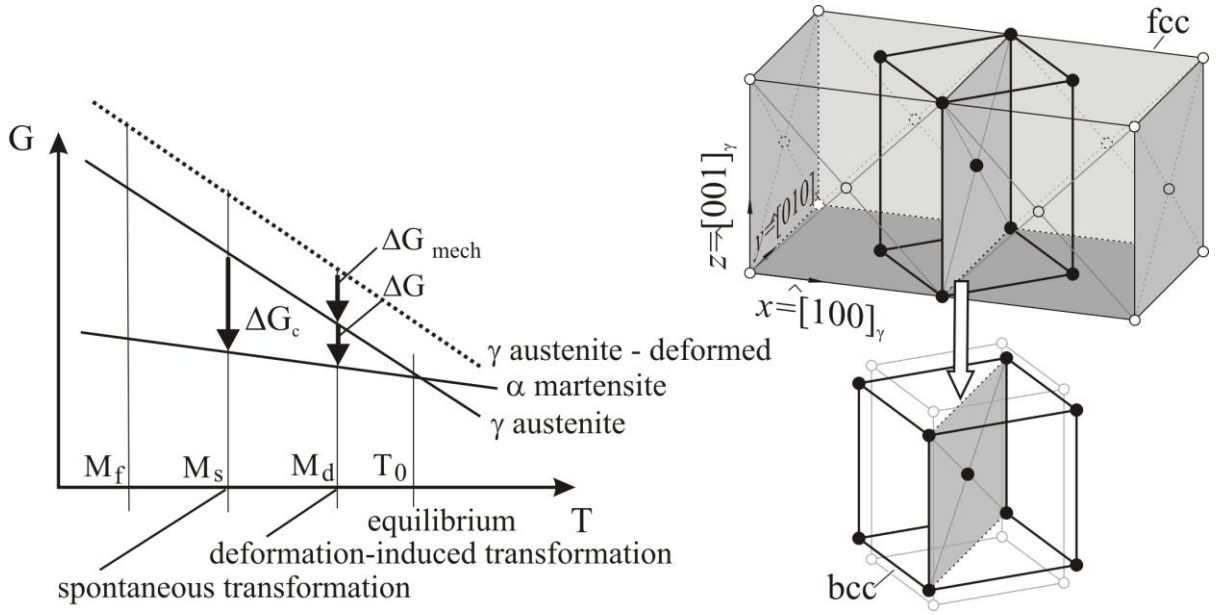

Figure 1. (a) Contribution of the mechanical strain energy ΔG_{mech} to the thermodynamic driving force for austenite-to-martensite transformation and (b) unit cell model of the martensitic transformation, according to Bain [1].

According to Olson and Cohen [3], the α´ martensite volume fraction $f_{\alpha'}$ can be calculated as a function of the plastic strain ε_{pl} by Eq. 2:

$$f_{\alpha'} = 1 - \exp\left(-\beta\left(1 - \exp\left(-\alpha\varepsilon_{pl}\right)\right)^n\right), \tag{2}$$

with n being a material-depending exponent, α a temperature-depending constant, and β accounting for the probability that martensite embryos are formed at shear-band intersections. While under monotonic loading conditions the α´ saturation level is reached at $f_\alpha \approx 0.9$, under cyclic loading conditions the transformation depends on the accumulative plastic strain $\varepsilon_{pl,\,cum}$ and sets in only when a critical threshold of $\Delta\varepsilon_{pl}/2 \approx 0.3$ is exceeded [5]. Under high-cycle fatigue (HCF) loading conditions and correspondingly very small $\Delta\varepsilon_{pl}$, plastic deformation is limited to grains of favorable orientation of the slip systems, with values of the Schmid factor $M_S \approx 0.5$. Smaga et al. [6] use the Olson-Cohen model to define a damage parameter that includes inhomogeneous cyclic hardening due to martensitic transformation. In very-high cycle fatigue (VHCF) Müller-Bollenhagen et al. [7] had shown that the onset of fatigue damage in form of local plasticity is stopped by martensite formation (self healing of defects); they concluded that metastable austenitic stainless steels exhibit a real fatigue limit. However, in the HCF regime short fatigue cracks may initiate without martensitic transformation. The propagation of such cracks cannot be shielded completely by the formation of martensite in the plastic zone ahead of the crack tip [4].

In order to understand and to predict the propagation behavior of microstructurally short fatigue cracks in metastable stainless steels, the geometrical model of Bogers and Burgers [8] was employed. It considers co-operative slip at two austenite slip systems as schematically represented in Fig. 2. Here, bcc α´ martensite nucleation is a product of partial dislocation displacement on every 2nd (T/2) and every 3rd (T/3) {111} slip plane, respectively.

$$\frac{T}{3} = \frac{1}{3}\cdot\frac{1}{6}a\left[211\right]_{fcc} \quad \text{and} \quad \frac{T}{2} = \frac{1}{2}\cdot\frac{1}{6}a\left[21\bar{1}\right]_{fcc} \quad . \tag{3}$$

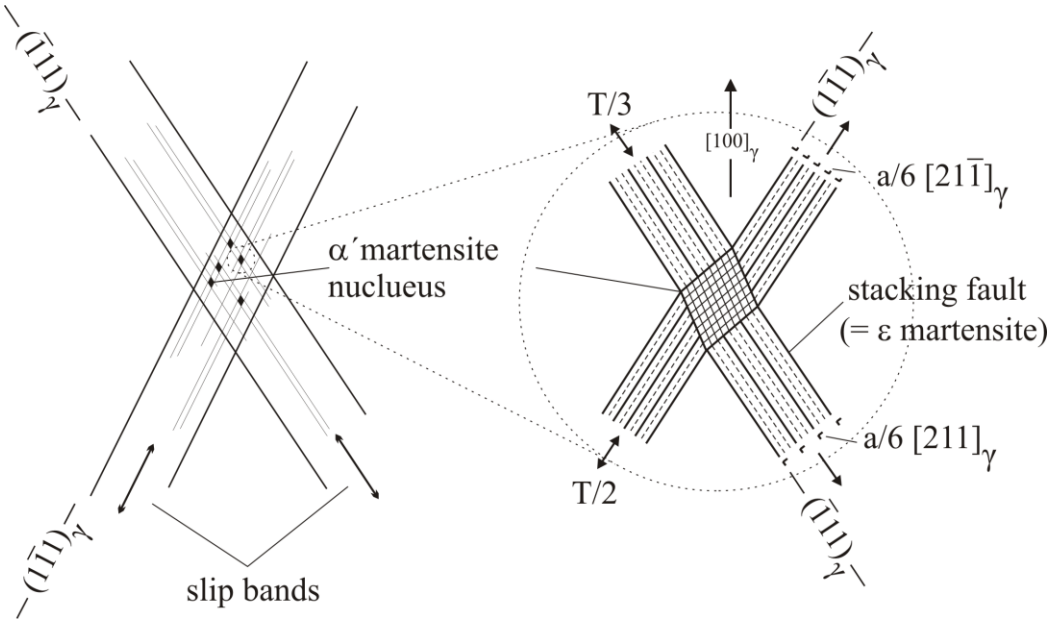

Figure 2. α´martensite nucleation at {111} slip-band intersection points, according to the model of Bogers and Burgers [8].

The Bogers-Burgers model for martensite formation at fcc shear band intersections has been proven experimentally in various studies and is the basis for the modeling concept introduced in section 4.

2. Experimental

The experiments were carried out on cylindrical specimens of the metastable austenitic stainless steel AISI 304L provided by Deutsche Edelstahlwerke Siegen, Germany, with the chemical composition given in Table 1. Prior fatigue testing, the specimen material was solution heat-treated for 1.5h at a temperature of 1050°C in order to homogenize the microstructure resulting in an average austenite grain size of 74µm. To analyze microstructurally short fatigue cracks within a limited area, two shallow notches were machined at 0° and 180° of the gauge length of the specimens (see Fig. 3). To apply electron channeling contrast (ECCI) and electron back-scatter diffraction (EBSD) within the scanning electron microscope (SEM), the surface of the specimens was electrolytically polished at T=-15°C/15V using perchloric acid (8%, cf. [9]).

Table 1. Chemical composition of the metastable austenitic steel used in this study (in wt. %).

alloy	Fe	C	Cr	Ni	Si	Mn	Cu	Mo
AISI 304L	Base	0.03	18.1	8.75	0.62	1.85	0.54	0.37

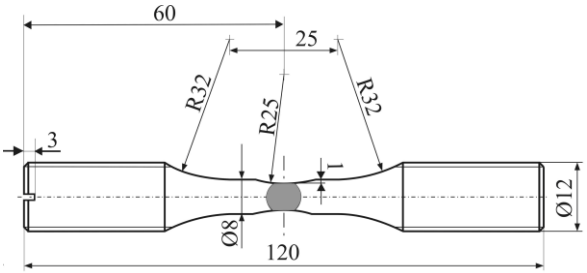

Figure 3. Shallow-notched specimens for microcrack characterization in a servohydraulic testing system.

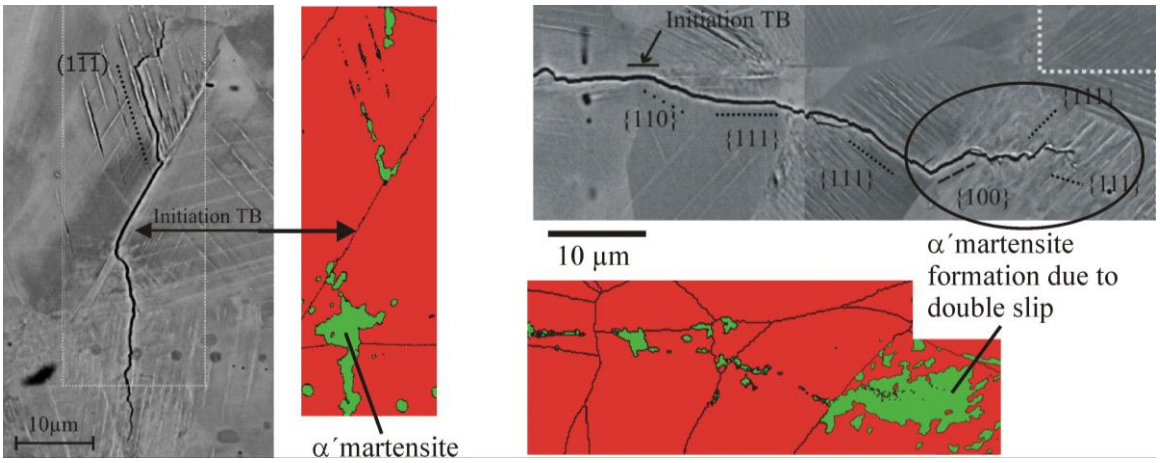
Fatigue cracks were followed using a MTS810 servohydraulic testing system under load control at a stress ratio of R=-1. Crack length analyses and measurements of the crystallographic orientation/phase distributions were done in the SEM by periodically removing the specimens from the testing machine. The fatigue limit was estimated by rotating bending tests following the staircase approach.

3. Results

The fatigue limit of the AISI 304L test material was found to lie in the range between $\Delta\sigma/2$=230MPa and $\Delta\sigma/2$=240MPa. It is worth mentioning that (i) above a number of cycles of $N\approx5\cdot10^5$ cycles no failure was observed at all and (ii) the fatigue limit is of the same order of magnitude than the 0.2%-offset yield strength of $R_{p0.2}$=237MPa. HCF microcrack propagation studies were carried out at a stress amplitude (fully reversed, R=-1) of $\Delta\sigma/2$=245MPa. After a few thousands of cycles, martensitic transformation occurred in favorable oriented grains of a high Schmid factor close to M_S=0.5. Furthermore, it is believed that the high elastic anisotropy of austenitic steel ($A=2C_{44}/(C_{11}-C_{12})$=3.81, cf. [10]) promotes the local transformation process, but obviously also crack initiation. About 70% of all crack initiation events (48 evaluated cracks) can be correlated with twin boundaries, which exhibit high anisotropy stresses, as it was analyzed in the studies of Heinz and Neumann [11] and Blochwitz and Tirschler [12]. Surprisingly, crack initiation cannot be correlated with martensitic transformation.
Figure 4a shows an example of crack initiation at a twin boundary. Only when the crack path leaves the twin boundary (above and below the twin boundary crack segment) and continues by alternating activation of various {111}<110>-type slip systems, martensite could be identified by means of EBSD phase analysis. Obviously, the slip intersections act as martensite nucleation sites, according to the theory of Olsen and Cohen [3] and Bogers and Burgers [8]. This observation is further supported by Fig. 4b. Again, the crack was initiated at a twin boundary segment. When following the right-hand branch of the crack, one may notice that propagation follows a {110} martensite plane. It is believed that the activation of alternate slip systems in the austenite ahead of the crack tip cause martensite formation. In the following, further crack propagation occurs within the martensite phase. In a more pronounced manner this was observed within the circle area in Fig. 2b. However, as long as fatigue crack propagation is driven by the activation of only one slip system, no martensite formation can be identified.

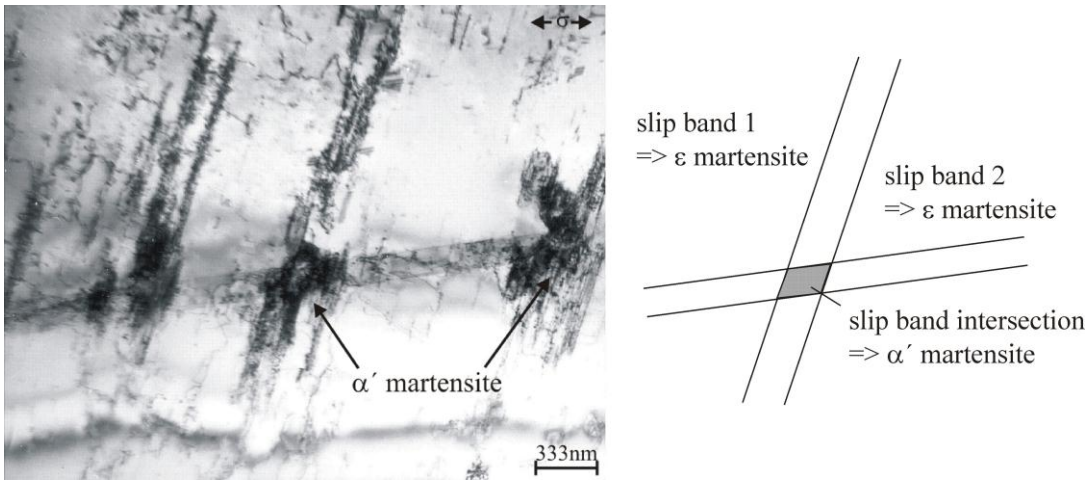


a b

Figure 4. Microstructurally short fatigue cracks: (a) crack initiation at a twin boundary without any martensite formation (see EBSD map beside) and (b) crack propagation operated by alternating slip in combination with massive martensite formation (see EBSD map below).

The Bogers-Burgers mechanism was identified by using transmission electron microscopy (TEM).

Figure 5 shows the intersection of {111} slip bands, which can be interpreted as stacking faults changing the stacking sequence from ABCABC with the fcc austenite to ABAB within the slip band. Such stacking faults correspond to ε martensite bands. Where these bands intersect bcc α´martensite is formed (see Fig. 5a).



a b

Figure 5. Deformation-induced α´ martensite formation during HCF loading of AISI 304L steel after N=10^5 cycles: (a) TEM micrograph and (b) schematic representation.

Analysis of the crack propagation rate as a function of the local microstructure revealed that the crack propagation rate decreases strongly, when (i) the propagation mode changes from single-slip propagation mode to double slip propagation mode, (ii) the crack propagates into transformation martensite, or when (iii) the crack tip approaches a grain boundary. Generally, the strong interactions between the plastic zone ahead of the crack tip and the local microstructural features give rise to an oscillating crack propagation rate, which was found at lower stress intensity ranges ΔK than the threshold value ΔK_{th}. The comparison of the propagation behavior of several microcracks with the one of a long crack is shown in Fig. 6.

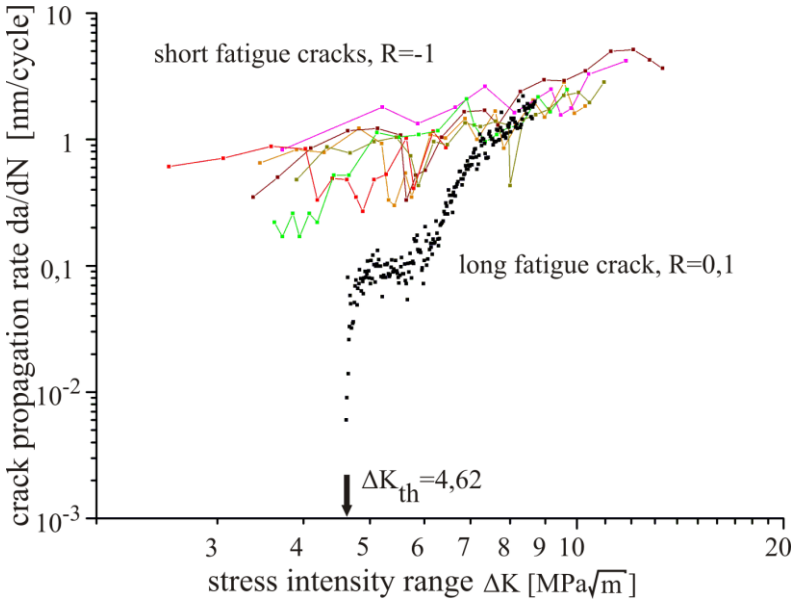


Figure 6. Propagation behavior of short (2a<400µm) and long fatigue cracks in metastable austenitic steel AISI 304L.

4. Modeling Concept and Discussion

It is the aim of the study to predict the complex propagation behavior of microstructurally short fatigue cracks, as presented in section 3. For this purpose a short crack model has been developed where the crack and its plastic zones are meshed by boundary elements (for details see [13,14]). The boundary elements represent shear displacements along individual slip planes and normal and shear displacements within the crack. Accounting for the boundary conditions that (i) within the crack the normal displacements must be positive and no shear stresses are present and (ii) the shear stress values within the slip bands are limited to the friction stress τ_{fr}, the equation system for the displacement distribution along crack and slip bands can be calculated. The crack propagation rate results from the cyclic crack tip slide displacement ΔCTSD as follows

$$\frac{da}{dN} = C \cdot \Delta CTSD\,, \tag{4}$$

where C represents the irreversible part of ΔCTSD that contributes to crack advance.
In order to account for the Bogers-Burgers mechanism of martensitic transformation (see section 1), the model has been extended to alternate slip ahead of the crack tip. Vector addition of the slip displacements b_{t1} and b_{t2} (see Fig. 7) give a resulting displacement b_R. The magnitude of these displacements determines the size of the corresponding martensitic transformation zone. The direction of the resulting displacement does not necessarily correspond to a slip direction of the martensite phase, the displacement b_R is projected onto the current crack propagation direction, eventually resulting in the crack tip displacement b_{RP} corresponding to CTSD within the crack propagation plane.

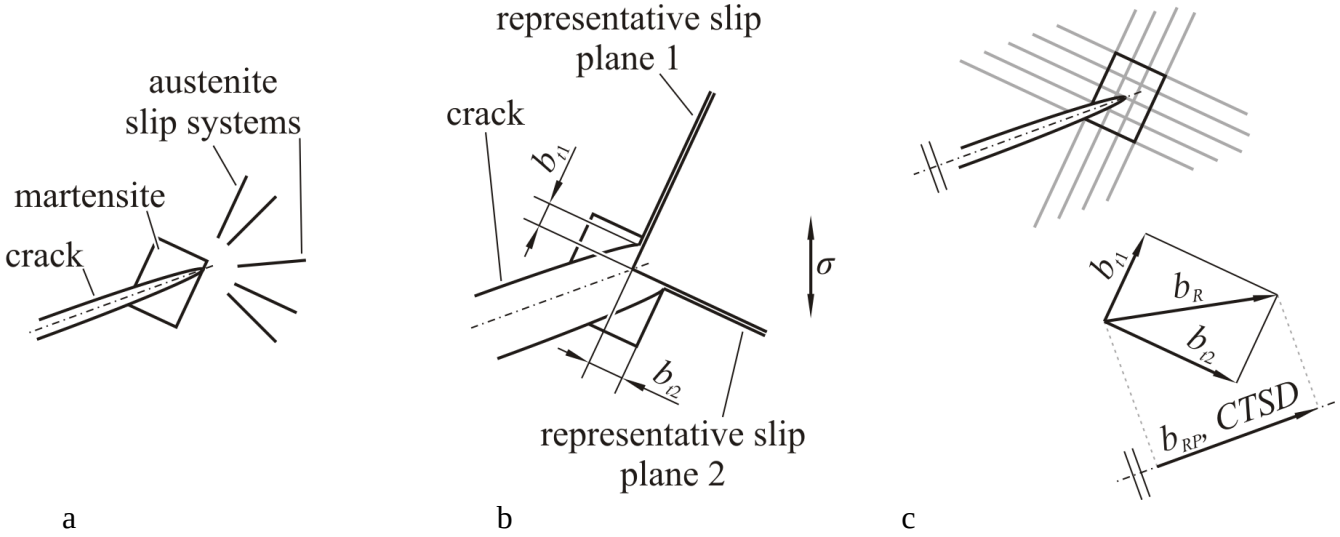

Figure 7. Modeling concept for strain-induced martensite formation ahead of a growing fatigue crack: (a) crack tip with martensite and the various austenite slip systems, (b) displacement at two representative slip planes, and (c) corresponding new martensite zone with the respective crack tip slide displacement.

As mentioned before, the austenite to martensite phase transformation results in a 2.57% volume increase. Therefore, a volume strain ε_m is implemented in the model. As schematically shown in Fig. 8, the martensite phase and the individual grain boundaries are meshed by boundary elements that describe absolute displacements of the boundaries. By superimposing the displacements within the plastic zone ahead of the crack tip (relative displacements) with those of the boundaries (accounting

for the individual elastic properties) and the volume strain within the transformation zone, one can predict crack propagation.

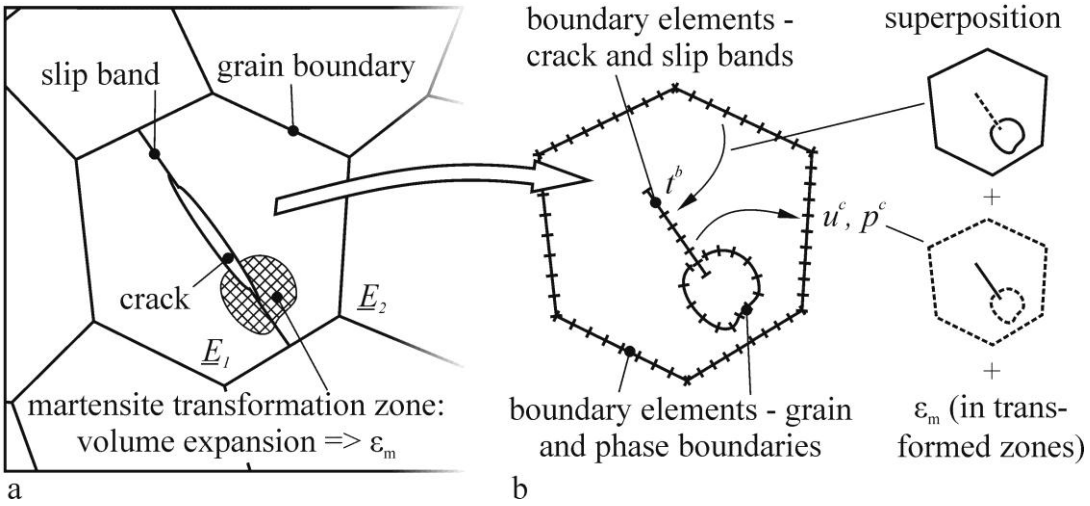

Figure 8: Schematic representation of the boundary element model: (a) crack with adjacent slip bands and martensite transformation zone in an individual grain of stiffness E_1 and (b) superimposition of crack-free grain, crack in an infinite plate and volume expansion strain ε_m.

Figure 9 shows the application of the model to a real microstructurally fatigue crack in AISI 304L. Certainly, the simulation shows a martensite distribution of much higher homogeneity than the experimental evaluation, but the predicted crack propagation rates are in reasonable agreement. Hence, one may conclude that the modeling concept represents the governing mechanisms in the right way, supporting the concept of Bogers and Burgers to be applicable to fatigue crack propagation in combination with martensitic transformation in metastable austenitic steels.

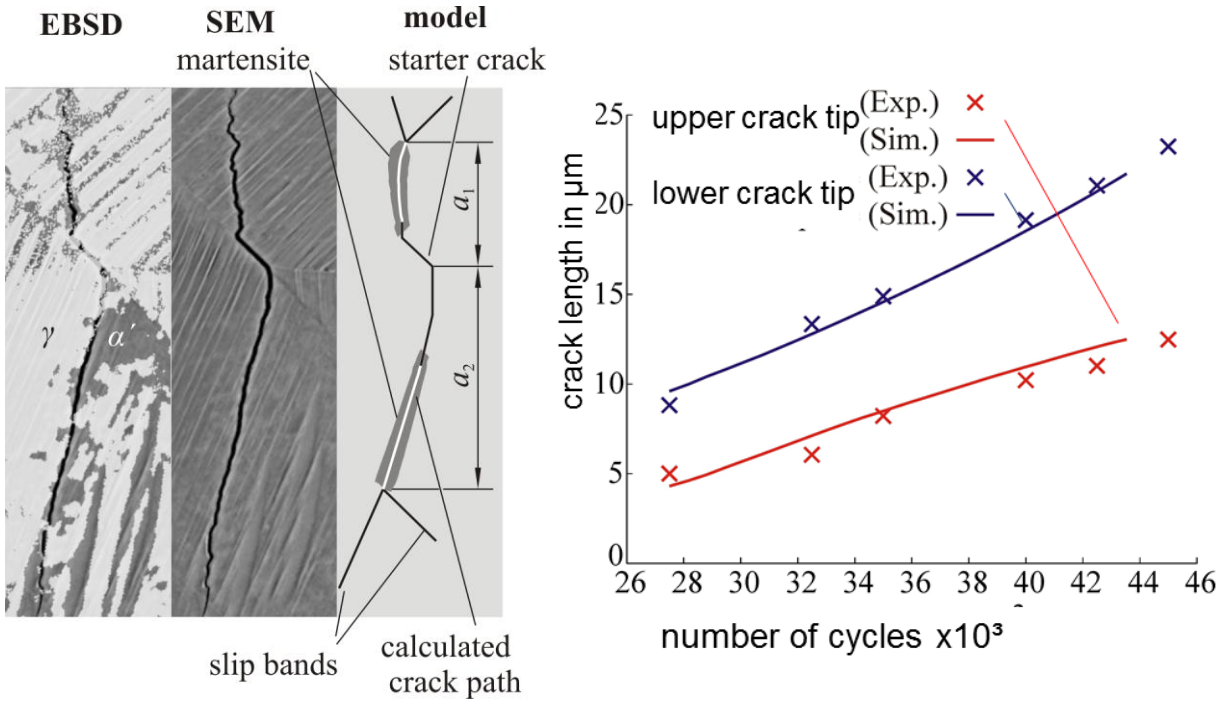

Figure 9. Microstructurally short fatigue crack in AISI 304L: (a) EBSD phase distribution, SEM micrograph and predicted strain induced martensite, (b) corresponding simulated vs. experimental fatigue crack propagation.

5. Conclusions

Crack propagation during high-cycle fatigue loading of metastable austenitic steel AISI 304L is not only governed by interactions with local microstructural features such as the alloy grain boundaries. Moreover, plastic slip ahead of the crack tip causes the formation of strain-induced α´ martensite. According to a geometrical model of Bogers and Burgers, the fcc austenite to bcc martensite phase transformation can be described by co-operative activation of partial dislocations on two intersecting {111} type slip bands. It was proven by scanning and transmission electron microscopy that martensite formation occurs only within areas of multiple slip activation. For crack initiation and propagation along single slip bands no martensite formation was identified. Depending on the local crystallographic orientation of the grains with respect to the remote stress axis and depending an the amount of martensite phase formation, the crack propagation rate is increased or decreased, respectively. This can be qualitatively predicted by computer simulation using a boundary element approach where the crack and the possible slip planes are described by boundary elements allowing for martensitic transformation according to the Bogers-Burgers model.

Abstract Fatigue strength of suspension springs in service life is subject to numerous influences. Besides the mechanical loading, determined by the kinematics of the suspension system, road conditions and driving maneuvers, fatigue strength of suspension springs is vitally affected by material properties, coating and environmental influences. Typical failure modes of suspension springs and their causes can be divided into several groups like static and cyclic loads, geometry and dimensions, manufacturing influences, mechanical defects of coating or steel surface, corrosion, fretting corrosion and imperfection of steel purity. This paper covers the influence of mechanical loading taking into account the influences of the kinematics of the suspension system, environmental conditions and steel purity. This leads to a comprehensive experimental validation strategy for suspension springs. Also statistical effects are discussed that have to be taken into account for a safe proof out.

Keywords Suspension springs, fatigue, corrosion, steel purity, testing

1. Introduction

Springs are used in many technical applications and play a vital role as elastic elements. In passenger cars, steel coil springs are used widely as suspension springs and as valve springs. Their durability in these cases is vital for the safety and reliability of the vehicle. Therefore, failure of suspension as well as of valve springs must be avoided with a high level of safety. For this, dedicated concepts for design and proof out are necessary.

In this paper, the relevant service loads acting on suspension springs of cars will be shown as well as pictures of typical failure modes. Besides a description of the failure modes leading to a defect of a suspension spring, a concept for proof out of suspension springs will be discussed, taking into account fatigue due to mechanical loading under corrosive media, contact and abrasive wear and damage due to grit impact. Finally, a concept for proof of steel purity is shown.

This paper is focused on coil springs used in passenger car suspensions. However, the methods may be used for evaluation of others springs in other applications with adaptions that take into account the differences in the respective application.

2. Material, Design and Conditions of Installation

Suspension springs of ground vehicles are subject to high static and cyclic loads. In order to realize the wanted stiffness characteristics within a minimum of designed space and mass, high strength steels like 52CrMoV4 or 54SiCr6 with a tensile strength of 1400 up to 2000 MPa are widely used. The local stresses acting in the springs are very high with a high frequency of occurrence. The sensitivity of steels to stress concentrations due to notches increases with increasing tensile strength and yield ratio. Therefore, springs made out of high strength steels will be sensitive to defects on the surface that may be caused by the production process, grit impact, abrasive wear or corrosion.

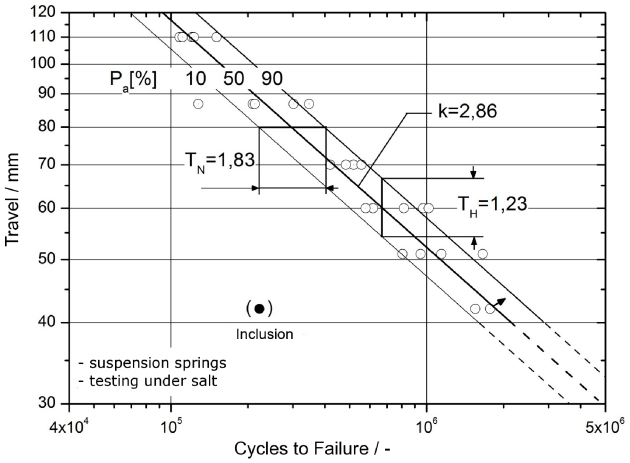

Figure 1. Failure caused by discontinuity of microstructure (inclusion) [2]

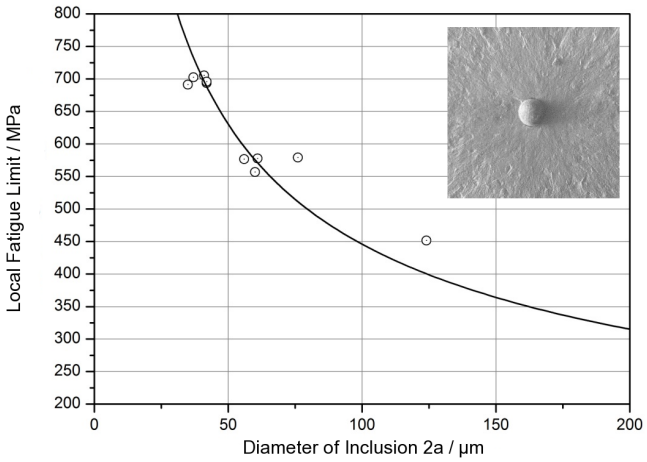

Figure 2. Influence of size of non-metallic inclusions on local fatigue limit [1]

Also, nonmetallic inclusions or other imperfections within the material may cause a failure, especially under high cycle fatigue loading. The combination of high local stresses and defect size may lead to stress concentrations above the threshold value for crack propagation. Hence, a material defect can act as an initial crack, propagating under cyclic loading and leading to a failure of the spring (see Fig. 1). In [1], the influence of nonmetallic inclusions in high strength steels was investigated in a comprehensive way yielding a correlation of the size of inclusion and upper boundary of possible fatigue limit (see Fig. 2). For the design of springs made from high strength steels, this means that the higher the used stress level and therefore the necessary strength level of the material, the more critical steel purity must be taken into consideration in testing for development, qualification and quality assurance. Since nonmetallic inclusions usually follow a different statistical distribution than the cyclic strength values of the base material, these have to be taken into consideration separately. Whether an impurity in the material will be critical for the endurance of a spring, does not only depend only on the size of the impurity but also on its location within the spring, since crack propagation will only occur, if there is a high local stress level at the location of the defect. This fact must be considered with respect to the critically stressed material volume and the statistical size effect. Detailed description on this can be found in [2].

With high strength steels in suspension springs of ground vehicles, special focus must be set on the risk of stress corrosion cracking. This effect may not necessarily depend on a higher tendency for corrosion of the used steel. It may also be caused by the high local stresses in combination with the notch sensitivity of the material. In order to decrease the risk of stress corrosion cracking, nowadays suspension springs are coated with specialized coating systems. Not only do these coatings prevent the spring from corrosion but also from other surface damages like grit impact.

The local stresses acting within a coil spring depend mainly on the geometrical design, the axle kinematics and the load applied. Also the local design, stiffness and surface properties of the spring attachments do influence the local stresses and the risk of abrasive wear and corrosion in the contact area of springs and spring attachments. While in a MacPherson strut, the upper and lower spring attachment will only move in a linear displacement (parallel deflection), in twin lever axle kinematics, also a lateral displacement as well as a rotation between the upper and lower spring attachments usually occur (circular deflection, see Fig. 3). Off course, this will yield different local stresses in the springs. The geometric design as well as the stiffness of the upper and the lower spring attachment as well as the geometric design of the first and last winding of the coil spring can significantly influence the local stresses in this critical area. These effects must be considered both

in the design as well as in the validation process of a spring. The design of the spring attachment does not only influence the local stresses within the spring in the contact area. It also influences the abrasive wear on the spring coating in the contact area, especially in the lower attachment. Especially under corrosive media, the contact area plays a vital role for the fatigue live of a coil spring. Springs that may be deflected up to block experience contact wear at the areas of contact. This also may damage the coating and enable corrosion on the spring.

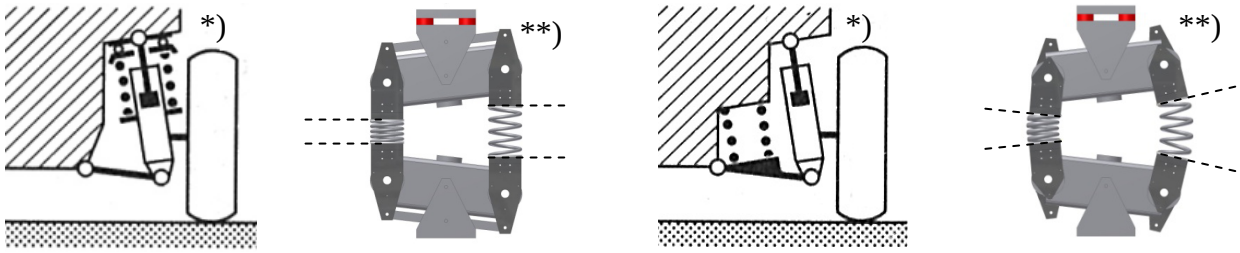

Figure 3. Kinematics of parallel and circular deflection in car suspension and test facility (* [3], ** IABG)

3. Service Loading

Besides geometry, material, production and conditions of installation, the loads and environmental conditions in service determine the service life of springs. The mechanical loads consist of a static preload and superposed cyclic loading. Fig. 4 gives a schematic overview of a typical load history of a suspension spring of its lifetime in a vehicle, beginning with its installation.

Maximum and minimum deflections are determined by the conditions of installation and the axle kinematics. The static preload consists of the preload due to mounting and the preload of the proportional weight of the car. This typically causes car springs to experience cyclic stresses with a high mean-stress. The cyclic loads are caused by driving maneuvers and surface roughness. A typical passenger car will only be moved for about 3% of its service life (counted in days rather than number of cycles). Hence, also effects acting during the 97% of time when the car is parked must be taken into account, since stress corrosion cracking may also act in these periods.

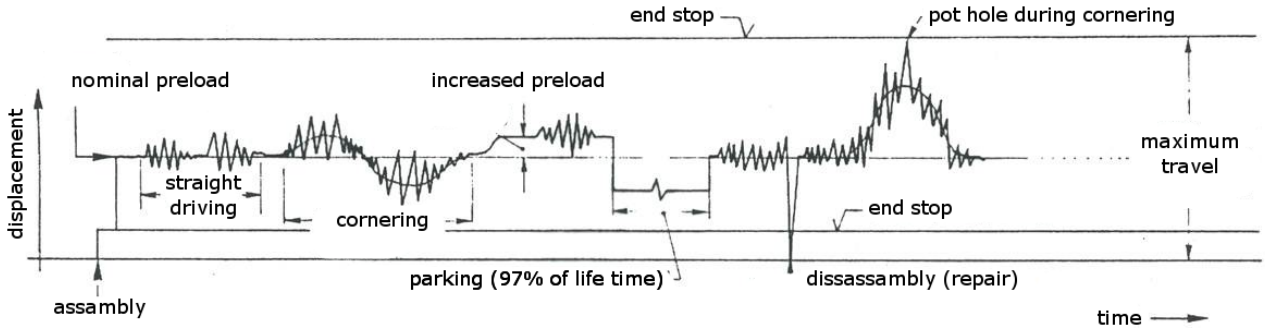

Figure 4. Schematic loading of suspension springs of passenger cars [4]

The cyclic loading of a spring consists of a variety of load cases (see Fig. 4). While cruising on paved roads will cause low to middle load amplitudes, driving on rough roads or off road, dynamic cornering and special incidents like driving through a pothole or over speed bumps will cause much higher loads that also have to be safely taken into account. Also, combinations of different maneuvers must be considered, such as high vertical dynamics due to rough road surface while taking a sharp corner at high speed. Thus, the full possible travel of the spring, from fully extended to fully compressed, usually is covered. For a safe and still economically sensible design and test strategy, both amplitudes as well as number of occurrence of the different load cases must be

investigated by means of extensive road load measurement, road data profiling, multi body simulations, statistical evaluation and extrapolation of the respective results (see also [5]).

Besides mechanical loading, suspension springs in ground vehicles are subject to environmental and service conditions that may influence the service life especially of high strength springs significantly [4]. In many regions, corrosive media are present on the roads at least temporarily. Anything from normal humidity over rain to salt water will be found during driving cars on roads all over the planet. Hence, corrosion can act on the springs if they are not covered by a durable coating. Especially during winter periods, grit that hits the springs may damage this coating making its protection void. Additionally, micro mechanical relative movement in the contact region between spring and spring seat will cause abrasive wear on the coating. This effect may be intensified, if abrasive media like grit or sand are cumulated in the lower spring seat. Due to the permanent static pre load due to assembly and car weight, springs are under a constant pre-stress, thus being subject to the threat of stress corrosion cracking. This threat is significantly higher under the conditions described.

The influences shown on the service life of suspension springs in ground vehicles under cyclic loading are not independent from each other. For example, the influence of corrosive media is much stronger, if the coating of the spring is damaged due to grit impact. Hence, the combination of load influences must be regarded as a complex load scenario in design and testing in order to cover the combined influences.

In commercial vehicles, especially in heavy trucks, leaf springs rather than coil springs usually are used in the suspension. Here, besides the influences described above additional effects may be important. Leaf springs usual front axles of commercial vehicles are subject to additional load cases such as torsional deformation due to vehicle roll and driving over single sided obstacles or S-shaped bending due to breaking moment [11, 12]. These have to be taken into consideration in design and testing.

4. Failure Modes

Coil Springs in passenger car suspensions show a number of typical failure modes, caused by material defects, the production process and complex service loading. Often, failures are caused by a combination of influences. Surface damage due to grit impact and abrasive wear together with corrosion may initiate crack propagation finally yielding a defect of the spring.

The most common failure mode of suspension springs of ground vehicles is the formation of fatigue cracks initiated from surface defects. The high strength steels used for these components are very sensitive to any geometrical or metallurgical discontinuity. In the sense of fracture mechanics, these can be interpreted as cracks. Making use of the potential of the high strength steels used for suspension springs, high local stresses will be allowed in the springs, yielding high stress intensity factors at these cracks. If the threshold value for crack propagation is exceeded, the cracks will propagate under the cyclic loading causing a failure of the component. Fig. 5 shows a typical failure of a suspension spring of a passenger car starting from a surface defect.

Another failure mode is shown in Fig. 6. Here, a fatigue crack started from a non-metallic inclusion below the surface of the spring. Since these internal defects will only lead to a propagating crack, if the threshold value for crack propagation is exceeded, they will only cause a failure, if they are located in a highly stressed volume of the spring. Hence, the frequency of occurrence of this failure

mode is smaller than the one of defects on the surface, where local stresses are naturally high due to the stress distribution over the cross-section under combined torsional and bending loading. Reports about failures due to internal defects can be found e.g. in [6] for coil springs and in [7] for leaf springs. These failures follow a different statistical distribution then failures due to surface defects (see Fig. 1). In component testing, this effect is difficult to cover because of the low probability of occurrence, hence special test methods and statistical evaluation should be used as described in [2].

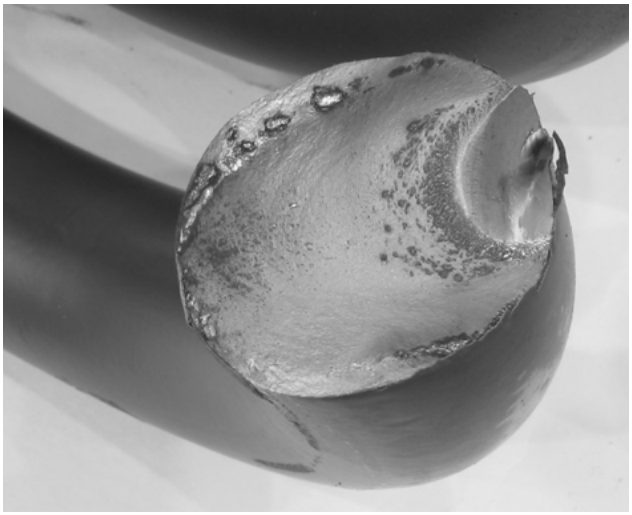

Figure 5: Fatigue fracture of suspension spring initiated at surface [8]

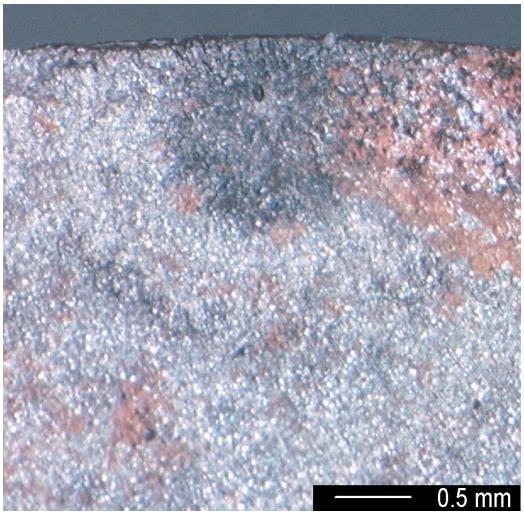

Figure 6. Fatigue fracture of coil spring initiated at non-metallic inclusion [IABG]

Harsh environmental conditions may decrease the cyclic strength of a spring considerably. Grit impact, abrasive wear and corrosive media can form defects acting as starting crack yielding a component failure. Fig. 7 shows a typical fracture surface of a suspension spring. The crack started from a surface defect under corrosion and propagated under cyclic loading. The significant influence of corrosion on the cyclic strength of high strength springs is shown in Fig. 8. Here, numerous springs where tested with constant amplitude cyclic loading in dry air and under a 5% NaCl-solution that was sprayed on the specimens intermittently. The test results were statistically evaluated. For a clearer picture and a better understanding, only the regression lines are shown.

Taking the S-N-curve of the test results under “dry” laboratory conditions as a reference, the influence of corrosion due to salt water can be seen for uncoated springs, coated springs without pre-damage and coated springs with pre-damage due to grit impact. All tests were performed on IABG Corrosion Spring Testing Machines (Fig. 9). The grit impact was generated with an IABG Grit Impact Simulator. The test parameters for grit impact as well as for corrosion were optimized in order to reproduce typical effects as can be seen on springs under service loading for longer periods. It is apparent that corrosion can decrease the cyclic strength of a high strength spring significantly. The effect can be reduced considerably by application of adequate surface coating, but cannot nearly be eliminated. If the surface coating is pre-damaged by grit impact, the better part of the positive effect is lost again. Also note that in all cases, up to $2 \cdot 10^6$ load cycles, no clear endurance limit can be found when testing in corrosive environmental conditions.

Taking into account these results, it is clear that for safe evaluation of the cyclic strength of suspension springs in ground vehicles, a combined test procedure must be defined and obeyed that covers all the effects described. Cyclic testing in dry laboratory conditions still may be very helpful for a first evaluation and optimization of geometry, material and production process. A final qualification test however must also contain grit impact, abrasive wear and corrosive media.

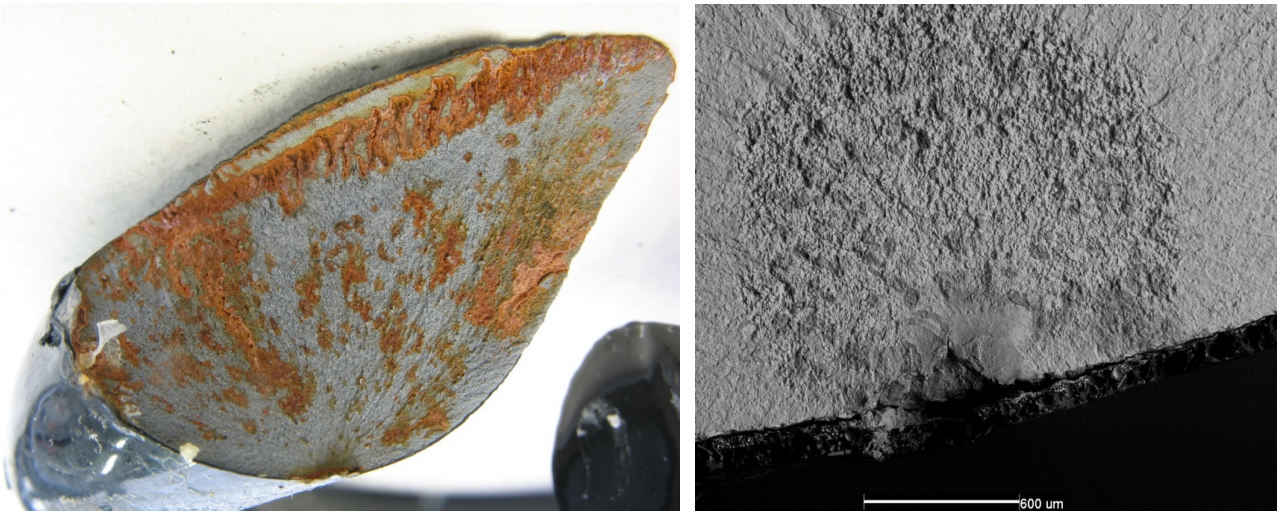

Figure 7. Fatigue fracture initiated by a corrosion pit [8]

Figure 9. Corrosion Spring Testing Machine [IABG]

5. Experimental Proof of Service Strength

A test concept for suspension springs of ground vehicles has to cover all failure modes with the required safety factors in order to limit the probability of failure to an acceptable minimum. Here, a separate definition of development and qualification tests may be reasonable. While development tests may be performed on specimens from the raw material or generic spring geometries in dry laboratory condition, the authors strongly recommend a comprehensive test program with the specific springs from the series production process for a final qualification test.

For evaluation of raw material and semi-manufactured products like the spring wire, the usual tests for static properties like yield strength and ultimate tensile strength etc. should be amended by tests for cyclic properties in order to securely assure the cyclic strength and the steel purity. Fig. 1 shows test results from a large test program where only 1 out of 120 springs failed due to a non-metallic inclusion at very low load amplitude. This is equivalent to a probability of failure of 1 out of 30 cars (usually having 4 springs each), which surely is not acceptable! These inclusions can very hardly be found with component tests. Due to the inhomogeneous stress distribution, only a small portion of the volume of a coil spring is loaded to local stress levels at which a crack will propagate starting from this inclusion. In order to investigate steel purity, special cyclic tests are recommended using

specimens with a high critically stressed volume in order to facilitate the finding of the largest size of inclusion with an affordable effort for testing [2].

To investigate the steel purity in an efficient and safe way, a test machine and test method was developed at IABG using dedicated specimens that cover the critically stressed volume of about 50 springs with only one test. This test does not depend on a specific geometry of a spring and is recommended as development and acceptance test for raw material and semi-manufactured parts like spring-wire. It is much more reliable than the commonly used method for determination of steel purity only based on the analysis of metallographic specimens [2].

To the authors' knowledge and believe, the fatigue strength of a high strength coil spring for use in the suspension of a ground vehicle can only be safely approved, if tests on series production parts are performed in realistic installation conditions (original spring seats and orientation). A simulation of the axle kinematics with special focus on the deviations and deflections of the spring seats in both limits of travel is mandatory. The environmental conditions consisting of corrosive and abrasive media have to be simulated. If the risk of grit impact cannot be eliminated during service life, testing of springs that have undergone a grit impact simulation prior to the fatigue test in corrosive environmental conditions is mandatory. Only with this combined test procedure, realistic results can be obtained that allow for a safe evaluation of the service strength in field use.

A complete simulation of the axle kinematics containing all boundary conditions may be performed in a front or rear axle test facility. However, installation and running costs of these test facilities are very high and a lot of car components are needed for the test that may not be available at the time of testing. Moreover, a specific variation of test parameters in order to investigate the influence of single parameters often is difficult or not possible. Therefore, Resonance Testing Machines are commonly used for testing of coil springs, since they combine extremely low energy consumption, high reliability and a minimum of effort for the single test setup. Using an adjustable axle geometry simulator, the kinematics of the real axle can be reproduced. Corrosive environmental conditions can be generated in a realistic way by a facility for supply and intermittent application of salt water. Abrasive wear can be simulated by application of abrasive media at the lower spring seat where the media would also accumulate in real field use. Hence, all influences that are relevant for the fatigue life of suspension springs under complex loading can be simulated in a precise, effective and cost saving way (see Figure 9).

The number of specimens to be tested as well as the test spectra and the parameters for pre damage, simulation of corrosion and abrasion must be determined in a way that the different types of field use are covered with a high level of certainty, yielding test results correlating well with field experience. To cover statistical effects, the number of tests, the selected test amplitudes and the method for statistical evaluation of the test results must be described precisely.

An example for a description of a qualification program for coil springs was defined by German OEMs in the working group for springs and stabilizer bars [10]. To avoid incidental failures from non-metallic inclusions, the authors additionally recommend a test of the raw material or the half manufactured product for steel purity as described in [2]. A continuous adaption of the test parameters to new information from field use should be performed in order to always keep the test procedure up to the level of technology. A comparison of tested samples with parts from field use can be used to scale and adapt the test parameters in order to generate test results correlating with field use in an optimized way.

Depending on the focus of investigation, research tests may be performed on generic test samples. 360°-sections from cylindrical coil springs have proven a good sample geometry since they can be reproduced with a minimum of manufacturing costs for the samples. With a special Resonance Testing Machine for single coils, specific influences of e.g. material, heat treatment and shot peening can be studied using generic specimens. Compared with tests on designed to specification coil springs, tests on generic test springs can be performed with identical geometry of test sample providing comparable test results over a very long period time. However, the different stress distributions in a single 360°-section and the spires in complete coil spring must be taken into consideration in definition of the tests and in interpretation of the test results.

6. Conclusion and Outlook

It has be shown that for safe qualification of fatigue strength of suspension springs in passenger cars, a test program must be specified and performed consisting of test of series production springs under cyclic loading with simulation of the axle kinematics, environmental conditions and pre-damage. Additional test on specimen for the proof of steel purity are recommended by the authors. This is especially important for springs made out of high strength steels in order to fully make use of the potential of high strength materials with a maximized reliability. For quality assurance, mechanical testing of samples for steel quality as well as testing of springs from series production is recommended.

Influence of different microstructures of the welding zone on the fatigue crack growth behaviour of HSLA steels

Abstract To meet the cost and weight reduction requirements in welded structures, high-strength low-alloy (HSLA) steels are increasingly used in all fields of mechanical engineering. However, in comparison to low-strength steels these materials are more susceptible to notches or initial cracks. Therefore, an extensive investigation of fatigue crack growth behaviour in the different microstructural zones of the heat-affected zone (HAZ) of the weld is necessary for an appropriate lifetime evaluation of welded joints.
For this purpose, fracture mechanics parameters like thresholds and crack growth rates in the different microstructural zones of the HAZ as well as in the base material are characterized by single edge notched bending (SENB) specimens. The different microstructures are reproduced with a Gleeble thermal simulator system using the same heating curves as measured previously during the welding process of a representative joint. The specimens feature the three characteristic microstructural zones of the HAZ (intercritical, fine-grained and coarse-grained zone). The effect of varying stress ratio R on the crack growth threshold and the crack growth curves is also assessed.

Keywords fatigue crack growth, HAZ, microstructures, HSLA

1. Introduction

For cost reduction reasons in mechanical engineering, especially in the field of welded constructions, the use of high-strength steels increases. Low-strength steels are uncomplicated in construction and usage due to notch insensitivity and good-natured crack propagation behaviour, whereas high-strength steels are much more challenging in construction and processing. With rising strength these steels are more susceptible to notches, pores or initial cracks, so the adequate dimensioning of welds made of such steels requires a high degree of knowledge of material-specific values. Although post-welding conditioning like high-impact treatment is common for such welds, the effects of these treatments have been investigated only phenomenologically so far. Especially the shift of the mean stress and its influence on the fatigue behaviour of the different microstructural zones in the heat affected zone of the weld has to be investigated. Whereas the effects of the weld toe can be described with classical stress-based approaches, the effects of pores or initial cracks require a more sophisticated fracture mechanic approach. In corresponding guidelines like the IIW recommendations [1] thresholds of only 2 MPa$\sqrt{m}$ are used, which lies below the effective threshold $\Delta K_{theff.}$. This leads to a high safety factor on one hand, but is in conflict with the principle of lightweight design on the other hand. Furthermore, only the crack propagation behaviour of the base material is well known, while the other microstructural zones of the weld are ignored. So the aim of this work is the investigation of the fatigue crack propagation behaviour in the different characteristic microstructural zones of the HAZ of a welded joint at different stress ratios.

2. Manufacturing of the different microstructural zones

The HAZ of a welded joint can be subdivided into three different zones, where the microstructure differs significantly from that of the base material (Fig. 1). The base material (BM) is a

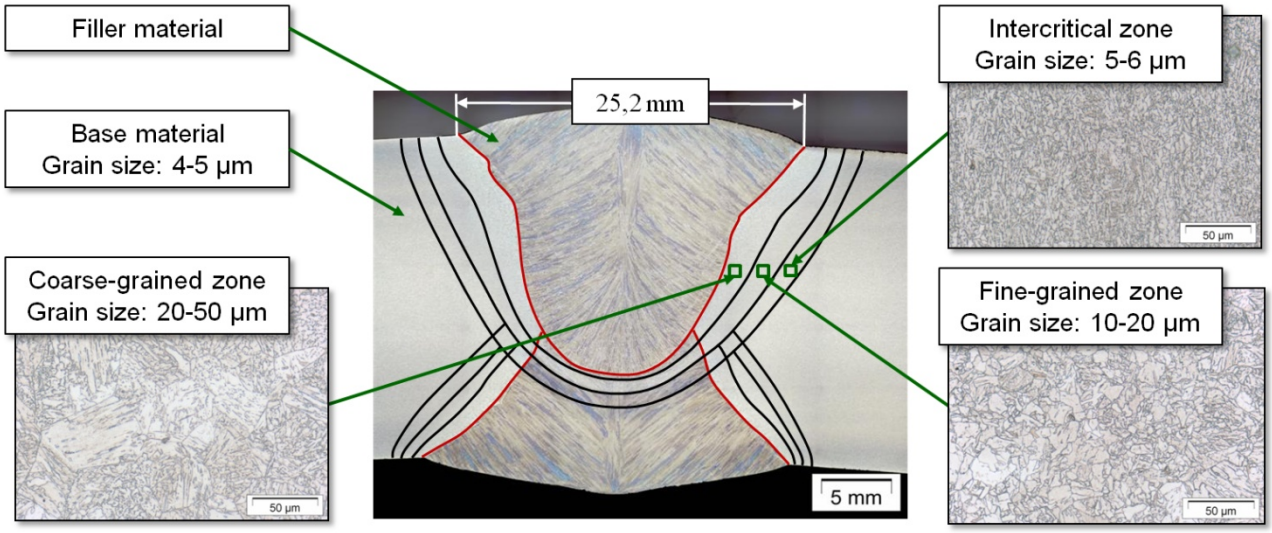

Figure 1. Characteristic microstructural zones of the HAZ of a double-submerged arc-welded joint [3]

thermomechanically rolled high-strength steel with an average grain size of 4-5 µm. The so-called intercritical zone (IZ) has a fine microstructure with an average grain size of about 5 to 6 µm, while in the fined-grained zone (FZ) an average grain size of about 10 to 20 µm was determined. The coarse-grained zone (CZ) shows an average grain size of up to 50 µm. The chemical composition of the base material is shown in Tab.1.

Before reproducing the microstructures it is necessary to get information about the local "heat treatment" due to the welding process for the formation of the characteristic zones of the HAZ. For this purpose metal sheets with a thickness of 20 mm are double-submerged arc-welded to represent the real welding process. For the appropriate measurement of the temperatures sensors are pinned onto the blank sheets in defined distances to the weld (Fig. 2, left). The gathered temperature curves (intercritical zone IZ, fine-grained zone FZ) are shown in Fig. 2 (right).

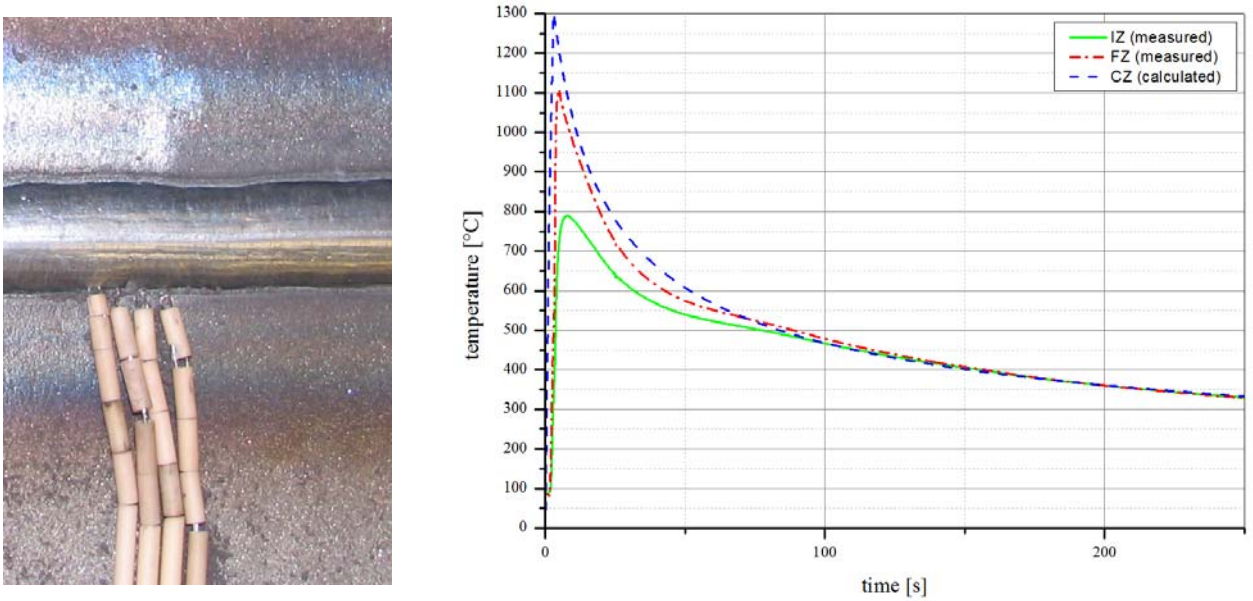

Figure 2. Positioning of the temperature sensors (left) and temperature curves for the heat treatment (right) [3]

Table 1. Chemical composition of the base material [%]

C	Si	Mn	P	S	Al	Cr	Ni	Mo	Cu	V	Nb	Ti
0.05	0.3	1.8	0.009	0.001	0.04	0.2	0.0	0.1	0.0	0.00	0.04	0.01

The temperature curve of the coarse-grained zone (CZ) was calculated according to SEW 088 [2] based on the other measured temperature curves. These heating curves, especially the cooling rates and peak temperatures, are the input for the heat treatment of metal blanks in a Gleeble thermal simulator. With this procedure, blanks with similar microstructures as found in the IZ, FZ and CZ are produced.

After producing these so-called Gleeble blanks, the homogeneity of the resulting microstructures has to be verified. After grinding, polishing and etching of the microsections of the three distinctive zones, they were investigated at different positions across the specimen cross section with optical microscopy and EBSD[1] captures. The results were compared with the results of the investigations of the HAZ of the laboratory weld. As a preliminary result, the microsections differ marginally in grain size, but show a good correlation along the width of the specimen. Additional information from hardness measurements with the Vickers method confirms the overall picture, that the Gleeble blanks exhibit a homogeneous microstructure in the areas of interest and no deviation of crack propagation and fatigue endurance limit due to differing microstructures should occur.

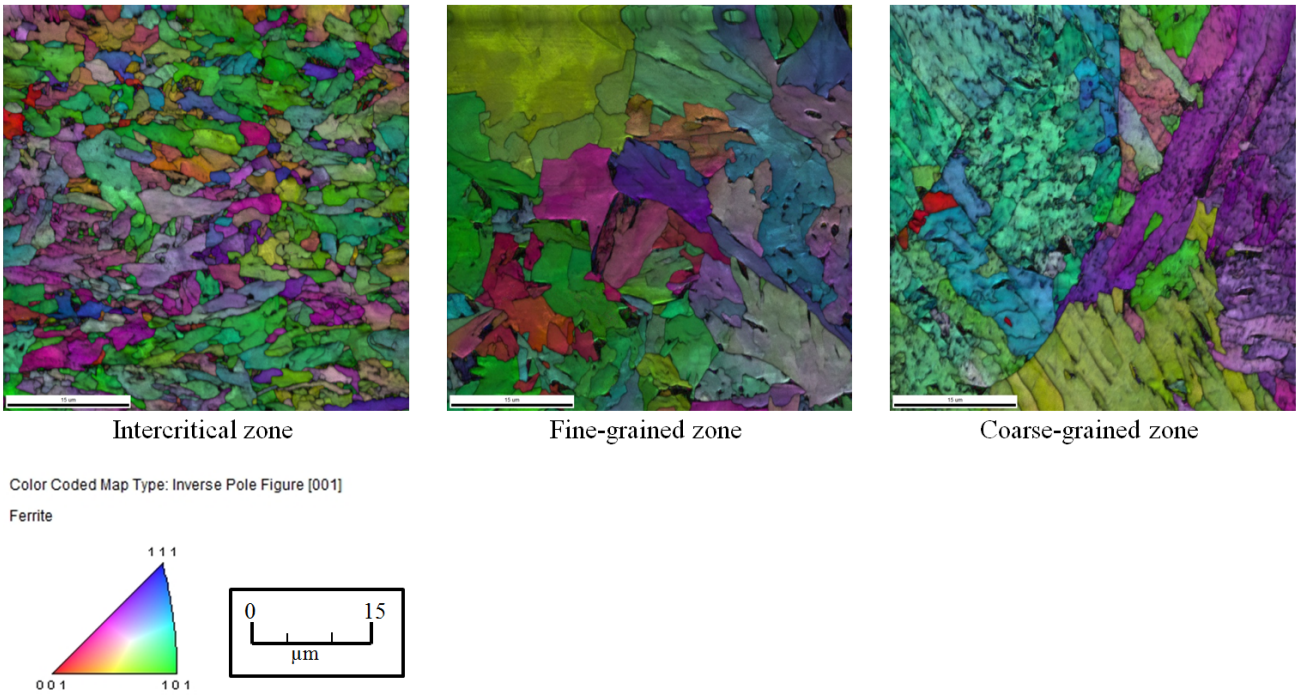

Figure 3. EBSD captures of the different zones

It was also found that due to thermomechanical rolling a distinctive texture orientation is established in the microstructure of the base material. This orientation can also be found in the intercritical zone. Because of the lower temperatures, no microstructural changes occur in this zone. Due to higher temperatures in the FZ and CZ a phase change takes place and the original orientation of the base material is eliminated; the evolution of orientation and average grain size can be seen from Fig. 3.

[1] Electron backscatter diffraction

3. Fatigue crack growth

For the investigation of the crack propagation behaviour, single-edge notched bending (SENB) specimens are used. The tests are performed on a RUMUL Cracktronic resonance testing rig. For crack length measurements a direct-current potential-drop (DCPD) measurement system developed in-house is used. For minimizing the effect of the plastic zone, the so called CPCA testing method is used. This method and its differences to the method according to ASTM [4] are well described in the literature [5]; for the sake of completeness, the general procedure will be described here. The specimens are initially compression pre-cracked for gathering a small plastic zone around the initial crack tip. After this, the specimen is loaded with an initial bending moment resulting in a stress intensity factor higher than the effective threshold ΔK_{theff} but lower than the long-crack threshold ΔK_{th}. The crack will start to grow and will stop after a certain distance due to crack closure effects. Now the bending moment is increased, the same procedure as described before will occur. This procedure is repeated until the stress intensity reaches the long-crack threshold. There the crack will not stop, and the fatigue crack growth curve (FCG) is obtained. For region I of the FCG curve a modified Klesnil-Lukas approach (Eq. 1) and for region II the classic Paris-Erdogan law (Eq. 2) is used. The findings of the different microstructures can be found in Tab. 2 (base material), Tab. 3 (intercritical zone), Tab. 4 (fine-grained zone) and Tab. 5 (coarse-grained zone). Due to missing K_{Ic}-Values fitting of region III has to be skipped. In the following figures the crack propagation curves are only extended without consideration of K_{Ic} until a stress intensity of 50 MPa√m is reached, and then truncated.

$$\frac{da}{dN} = C \cdot \Delta K^{m-p} \cdot \left(\Delta K^{p} - \Delta K_{th}^{p}\right), \tag{1}$$

$$\frac{da}{dN} = C \cdot \Delta K^{m}, \tag{2}$$

4. Comparison of the fatigue crack behaviour of the different microstructures

The tabular data of the different microstructures can be found in Tables 2-5; in the following discussion this data will be graphically formatted to demonstrate the differences. As expected the diagrams show a shift from lower thresholds at R=0.5 (Fig. 4) to higher ones at R=0.1 (Fig. 5) and R=-1 (Fig. 6). In general the following trend correlates through all stress ratios: the base material shows the lowest thresholds, followed by the coarse-grained and the fine-grained zone.

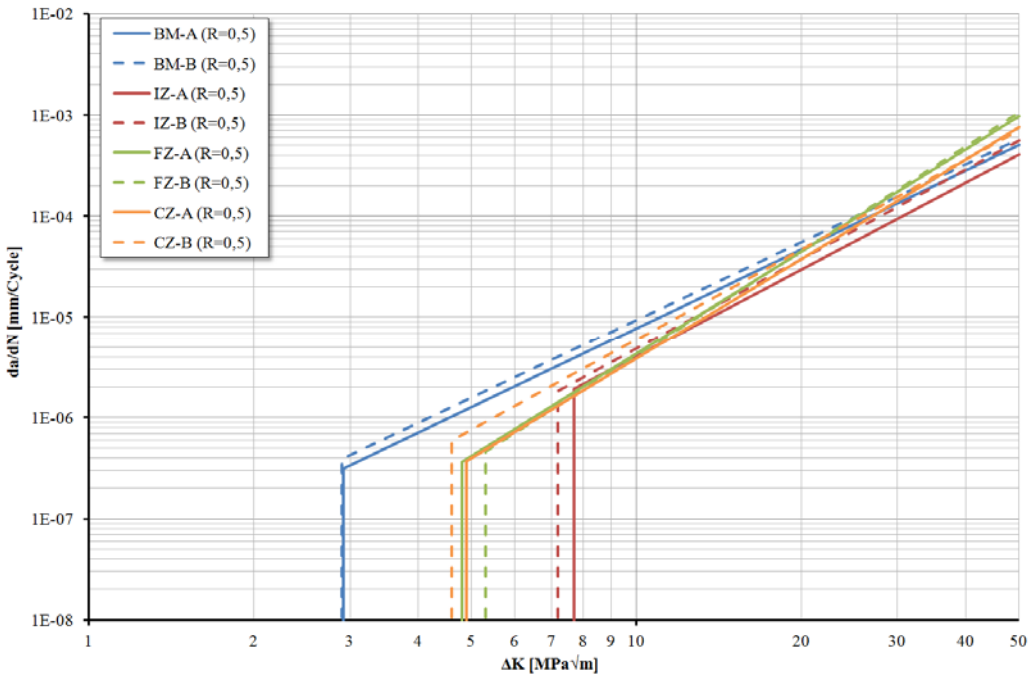

Figure 4. Comparison of the FCG behaviour of the different zones at R=0.5

The intercritical zone shows disproportionately high thresholds in comparison to the other zones, which is due to the long $t_{8/5}$-time of nearly 70 seconds resulting in a soft-annealing of the microstructure and leading to an increase in ductility. The slopes of the Paris-Erdogan regime show values between 2.56 and 4.88. Because of the setup of the crack measurement system (measurement of the potential drop by spring probes) especially the experiments with a stress ratio of R=-1 are hard to execute. The spring probes are losing the contact to the surface of the specimen, in particular at higher amplitudes. Therefore the scatter of the measured voltages increases, leading to a higher scatter of the thresholds and the crack propagation rates.

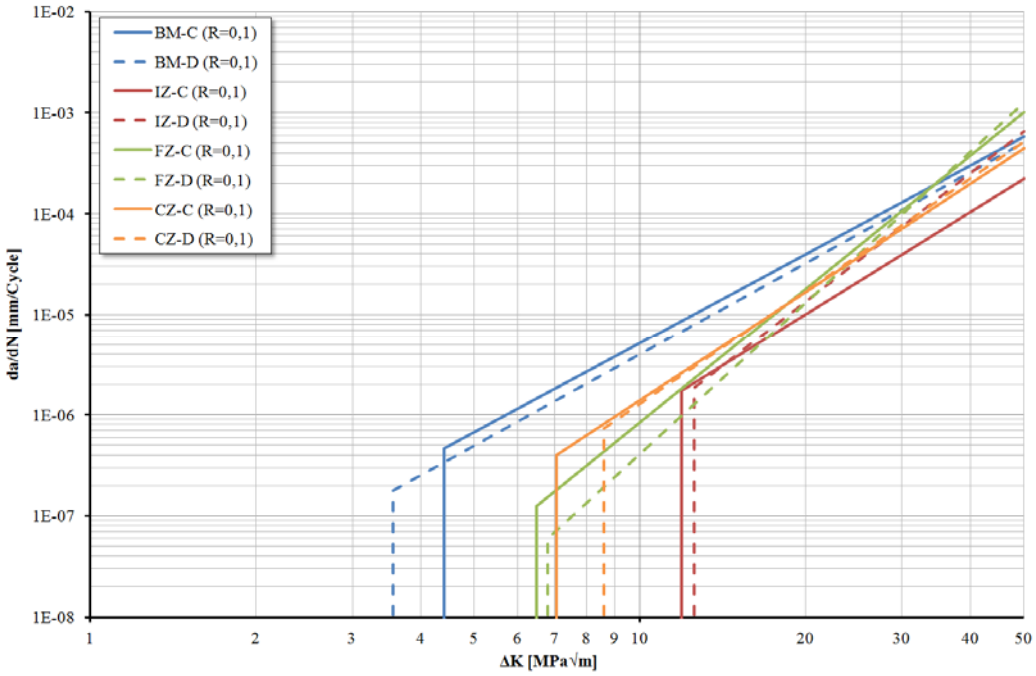

Figure 5. Comparison of the FCG behaviour of the different zones at R=0.1

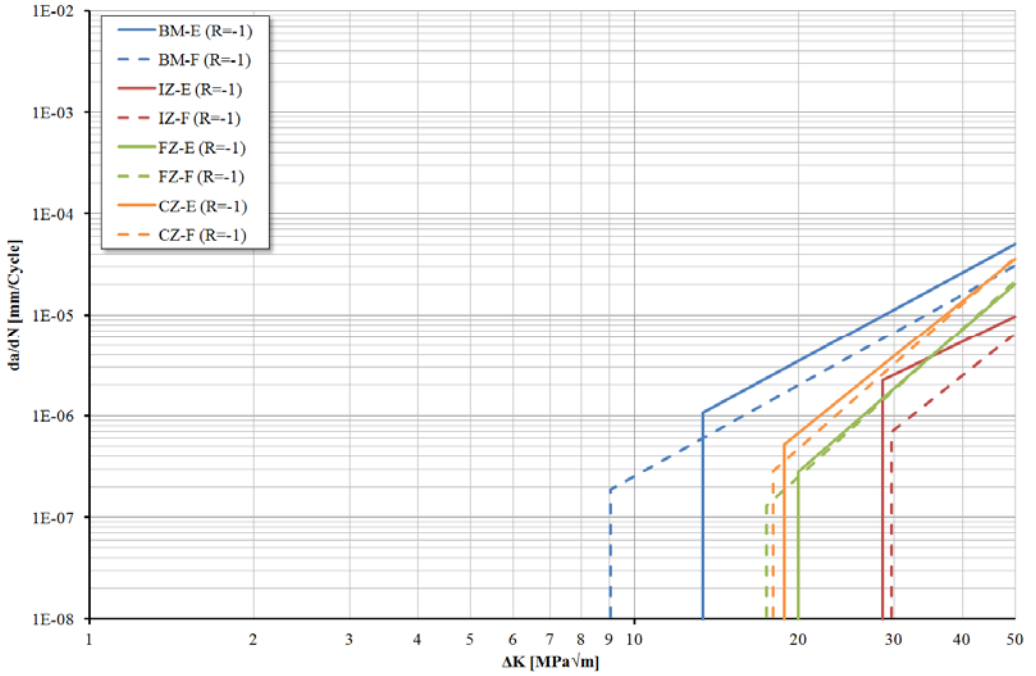

Figure 6. Comparison of the FCG behaviour of the different zones at R=-1

5. Conclusion

The results show that surprisingly, the base material has the lowest thresholds among all microstructures of the HAZ of the representative weld. This could presumably be due to the distinctive texture or the residual stresses in the metal blanks stemming from the rolling process. If no post-weld treatments like machining of the weld or impact treatments are performed, the geometric notch at the weld toe is the crack initiation point. Under cyclic loading, the conservative approach of the low thresholds of 2 MPa√m as a base of a fracture mechanics design approach in the studied case (double-submerged arc-welded with high $t_{8/5}$ times) only makes sense if the geometric notch has a low influence and crack initiation occurs in the base material. With these results it also can be shown how a shift of the stress ratio R influences the crack propagation thresholds within the HAZ. Further investigations concerning the residual stress state in the metal sheet blanks are necessary, however. This work represents an important preliminary contribution to a better understanding and interpretation of different effects due to manufacturing, machining and post-welding processes in the different regions of the HAZ and their influence on the fatigue crack propagation behaviour.

Abstract Several cases of undefined conditions during operation of steam turbines, such as shut down of the turbine or leaking of the condenser, can lead to a corrosive environment. If the concentration of oxygen and chloride exceeds a critical level, pitting corrosion can occur. Since corrosion pits increase the local stress field, the initiation of fatigue cracks is facilitated and – under adverse conditions – these cracks can lead to final failure.
In this work, the results of fatigue tests on 12% Cr martensitic stainless steel, which is a standard blade material in the low pressure part of a steam turbine, are presented. The influence of corrosion pits and environment on the fatigue limit is investigated. Pit-to-crack transition is studied by optical observation and fractographic examination. The test environments were air at 90 °C and an aqueous solution with defined content of chloride and oxygen. To simulate an aggressive environment in which corrosion pits can form, fatigue tests in aerated 6 ppm Cl^- solution at 90 °C are performed.

1. Introduction

Failure of steam turbines often takes place at the last stage of the low pressure blades where early condensate occurs. Although steam turbines were designed for a maximum operational time of 20 years, several turbines are in service since more than four decades. The turbine blades are loaded by different kinds of stresses. High mean stresses due to centrifugal forces and superimposed cyclic loading with low stress amplitudes induced by inhomogeneous steam flow with load frequencies of ca. 2 kHz are acting. Therefore, fatigue life data for high stress ratios in the very high cycle fatigue (VHCF) regime are important to predict fatigue life. Fatigue cracks were frequently observed to initiate at corrosion pits. During standard operational conditions the absence of impurities – such as chlorides – and oxygen prevents the material from corrosion. But shut down of the turbine or leaking of the condenser leads to undefined conditions where corrosion pitting may occur. Martensitic 12% Cr steel is a standard material for blades in the low pressure part of steam turbines. Extensive research was started already in the 1980s to simulate and understand the phenomenon of corrosion assisted fatigue of blading materials [1,2]. A project with the aim to develop a methodology for the prediction of corrosion fatigue life in steam turbine blades is still in progress [3] and several results were already presented [4-7].
In the present work, fatigue life test results are presented for smooth and pre-pitted specimens. The influence of stress range R and pit dimension is discussed for different environments. Fatigue tests were performed at 90 °C in air and aqueous solution. De-aerated 300 ppb Cl^- solution is often used to simulate service conditions in the low pressure part of steam turbines where early condensate occurs [8]. Since fatigue life tests in de-aerated solution and air lead to similar results [5], only the data determined in air are discussed in this work. To simulate a more aggressive environment in which corrosion pits may form, additional tests in aerated 6 ppm Cl^- solution at 90 °C were carried out. Crack initiation at corrosion pits was investigated by optical observation during fatigue loading. The fatigue crack growth rates (FCGRs) were determined and compared to measurements of long crack growth [7]. Fractographic examinations with scanning electron microscope (SEM) were performed in order to investigate crack initiation mechanisms.

2. Materials and experimental procedure

2.1. Material

The investigated material is a dual certified 403/410 martensitic 12% Cr steel. The material was hardened at 913 °C and tempered. The chemical compositions and the mechanical properties (provided by the supplier) are listed in Table 1 and 2. The mean grain size was 6 μm.

Table 1. Chemical composition of 403/410 SS (in weight %)

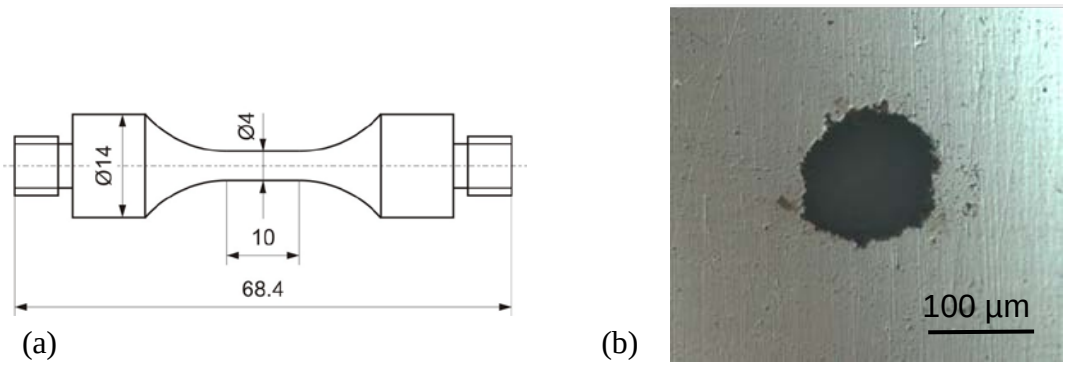
C	Cr	Mn	Si	Ni	Mo	Cu	S	P
0.13-0.14	11.79-11.8	0.41-0.49	0.18-0.26	0.28-0.33	0.13-0.18	0.07-0.10	<0.002	<0.020

Table 2. Mechanical Properties of 403/410 SS at room temperature

Tensile Strength (MPa)	Yield Strength (MPa)	Elongation (%)	Reduction of Area (%)
767	596	23	68

2.1. Test specimens

The shape of the test specimen for fatigue life tests is shown in Figure 1a. The specimens were machined, ground and polished with abrasive paper (up to grade #4000). The obtained mirror-like finish enabled observation of fatigue cracks that initiated at corrosion pits. To eliminate residual stresses, the specimens were stress-relief annealed in high vacuum (10^{-6} Pa). The stress relief procedure was: Heating from room temperature to 600 °C 1 h, holding for 2 h, cooling from 600 °C to 400 °C in 2 h and to room temperature in approx. 12 h. Additional specimens were produced with corrosion pits located in the gauge length of the specimen. A typical corrosion pit on the surface of a test specimen is shown in Figure 1b. The pre-pitting procedure was developed and arranged at the National Physical Laboratory and is described in more detail in [9]. Corrosion pits with depths of ca. 50, 100 and 250 μm were used. The actual depths were ±10% of the targeted value.



(a) (b)

Figure 1. Specimen shape for fatigue life tests (a) and corrosion pit in the gauge lengths of the specimen (b)

2.2. Fatigue testing method

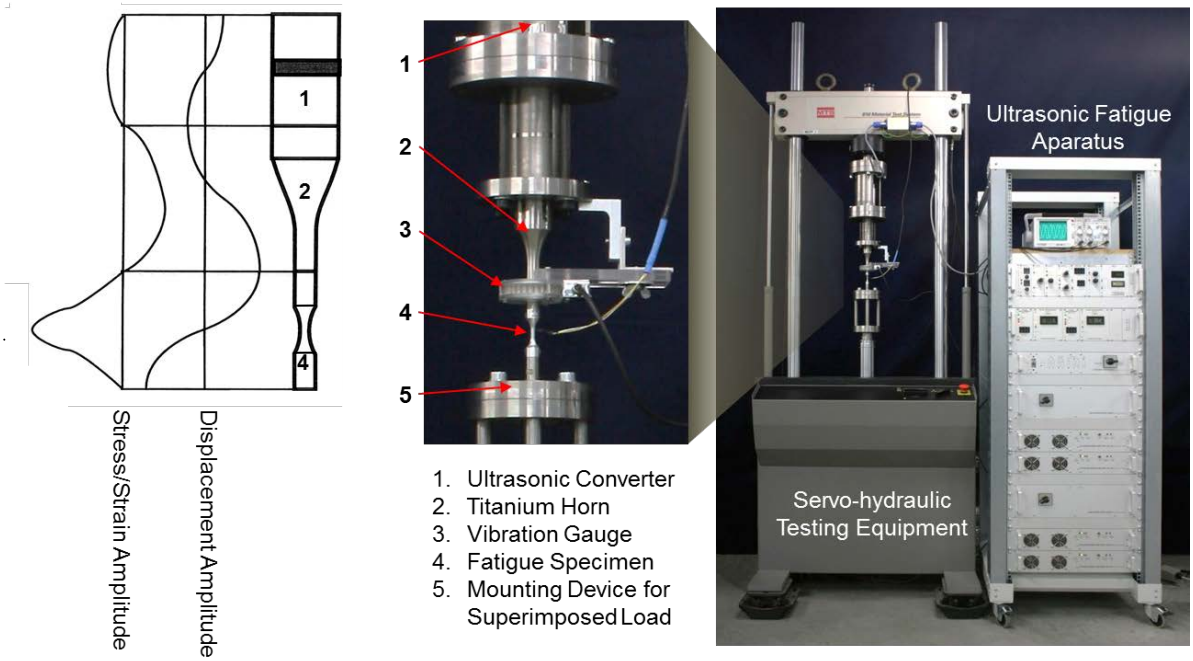


Figure 2. Ultrasonic fatigue test setup

The fatigue tests were conducted with an ultrasonic fatigue testing equipment. The ultrasonic converter is attached to a servo-hydraulic testing equipment which allows testing at higher stress ratios by superimposing static loads. The ultrasonic fatigue technique works by stimulating specimens to resonance vibration. The geometry of the resonance system – including the test specimen – is adjusted to achieve a resonance frequency of approximately 20 kHz. The failure location (region with maximum stress/strain amplitude) is stationary and therefore can be observed optically during fatigue testing. This is due to the absence of a vibration amplitude at the node of the standing wave during oscillation. An optical system with 250x magnification was used to detect crack elongations of less than 10 µm.

2.3. Aqueous solution circulation system

A water circulation loop with a 35-l-reservoir was used for measurements in aqueous environments. The set-up is shown schematically in Figure 3 and described in more detail in [7]. It allows testing in solutions with defined content of chloride and oxygen at constant temperature. Aeration was achieved by passing laboratory air with a diaphragm pump into the solution. Conductivity and oxygen level were detected during measurement. The flow rate of the liquid was 3 l/hour. The corrosion potential was measured using an Ag/AgCl reference electrode but the potentials quoted are referred to the saturated calomel electrode (SCE) at 25 °C. The corrosion potential during fatigue testing in aerated 6 ppm Cl^- solution was between -0.18 V(SCE) and 0.01 V(SCE).
Ultrapure water (initial conductivity of 0.06 µS/cm and AR grade NaCl) was used to prepare the solution. A new solution was used whenever the conductivity of the water increased by 10% of the initial value.

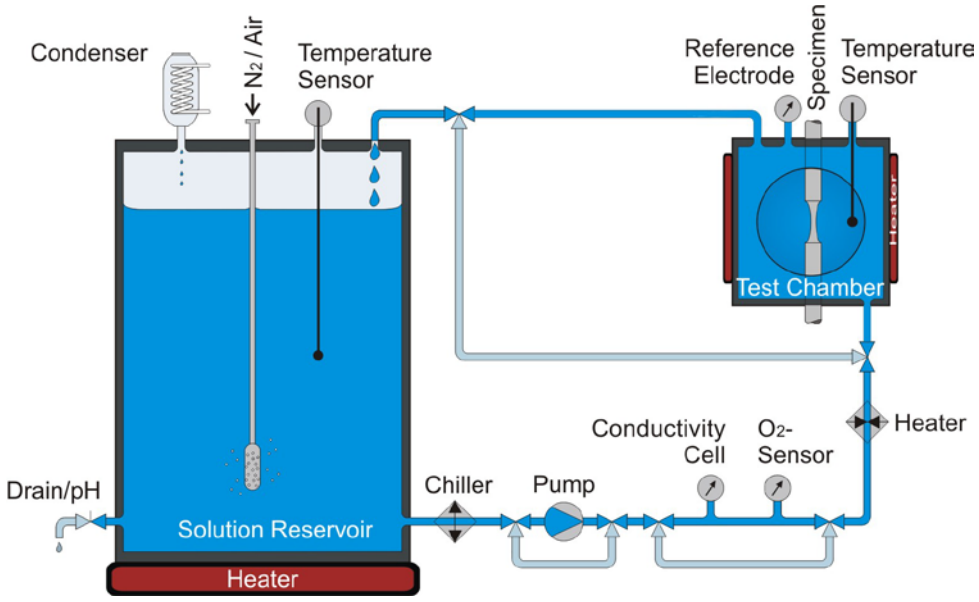

Figure 3. Schematic of the aqueous solution circulation system

3. Results

S-N tests were performed on smooth and pre-pitted specimens with pit depths of 50, 100 and 250 µm. The fatigue limit $\Delta\sigma_0$ was defined as the cyclic stress range where at least two specimens survived a minimum of 1×10^9 cycles. Specimens that did not fail – so called run-outs – are marked with arrows in the *S-N* plots. The fracture surfaces were observed by scanning electron microscopy (SEM).
The dimensions of the pits were determined from the fracture surface. The maximum variability in pit depth was defined to be ±10% of the proposed size. 55 pre-pitted specimens met that requirement and are plotted in *S-N* diagrams. To enable measurement of the run-out specimens with corrosion pits, they were loaded at higher stress ranges until failure occurred.

3.1. Fatigue lives in air at 90 °C

Results of the *S-N* tests in air at 90 °C are shown in Figure 4a. A significant decrease of the fatigue limit $\Delta\sigma_0$ with increasing stress ratio and pit size is obvious.
The determined fatigue limits $\Delta\sigma_0$ are plotted in a Haigh diagram where the stress amplitude $\Delta\sigma/2$ is plotted versus the mean stress σ_m, see Figure 4b. For both, smooth and pre-pitted specimens, the results can be fitted by Gerber parabolas:

$$\Delta\sigma_0 = \Delta\sigma_{0,R=-1} \cdot (1 - \sigma_m/\sigma_u)^2). \quad (1)$$

Since the fatigue limits at fully reversed loading ($R = -1$) $\Delta\sigma_{0,R=-1}$ (which is equivalent to the values at the ordinate in the Haigh diagram) were not determined, the values were obtained by extrapolation of the curves. Both the determined fatigue limits and the assumed values for $R = -1$ are summarised in Table 3.

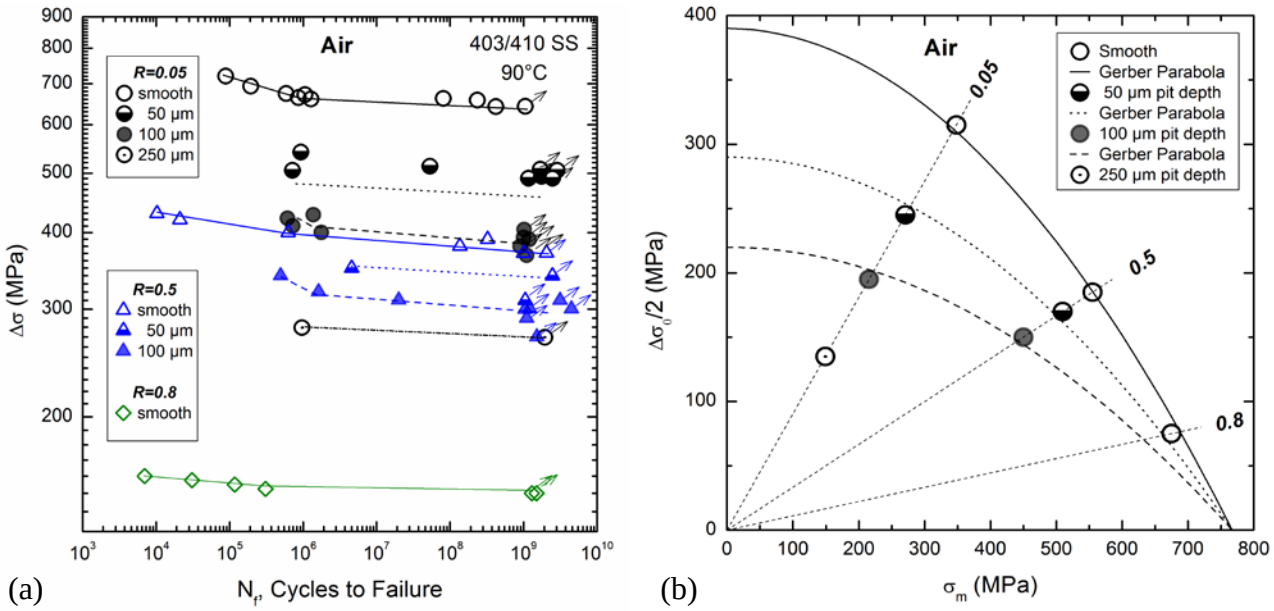

Figure 4. *S-N* plot (a) and Haigh diagram (b) for smooth and pre-pitted specimens in air at 90 °C

Table 3. Fatigue limits determined in air at 90 °C (in MPa)

Pit size	R = 0.05	R = 0.5	R = 0.8	R = −1*
Smooth	630	370	150	780
50 µm	490	~340	-	580
100 µm	390	300	-	580
250 µm	~270	-	-	-

* stress ranges for R = −1 obtained by extrapolation

3.2. Fatigue lives in aerated 6 ppm Cl^- solution at 90 °C

Results of the *S-N* tests in aerated 6 ppm Cl^- solution at 90 °C are shown in Figure 5a. The fatigue limits are again plotted in a Haigh diagram (Figure 5b) and summarised in Table 4. The Gerber parabola according to Eq. 1 fits well for smooth specimens. But for pre-pitted specimens, the deviation from the parabola is higher.

Table 4. Fatigue limits determined in aerated 6 ppm Cl^- solution at 90 °C (in MPa)

Pit size	R = 0.05	R = 0.5	R = 0.8	R = −1*
Smooth	530	330	145	600
100 µm	350	220	~130	320
250 µm	-	-	105	

* stress ranges for R = −1 obtained by extrapolation

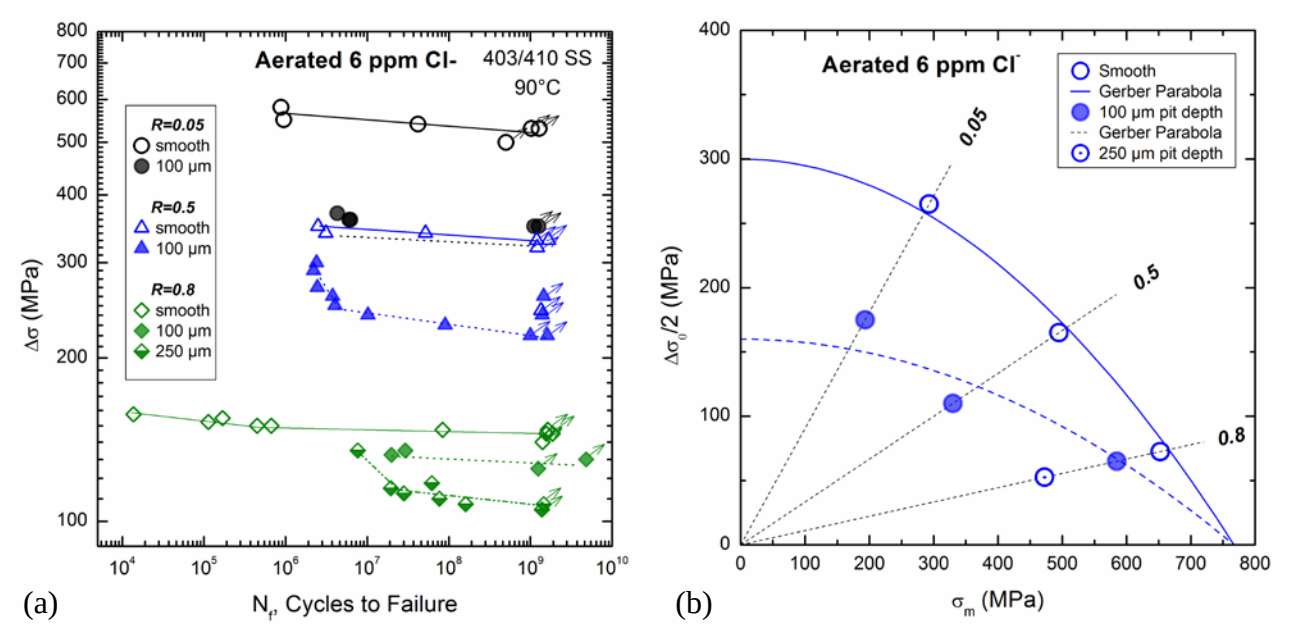

Figure 5. *S-N* plot (a) and Haigh diagram (b) for tests in 6 ppm Cl^- solution at 90 °C

3.3. Pit-to-crack transition

Pit-to-crack transition was observed by optical observation of the pit during fatigue loading. FCGRs were determined by measuring the crack extension during fatigue loading. The applied stress range was kept constant during testing which consequently increased the stress intensity factor range with crack elongation. Cracks were observed at stress ranges below the fatigue limit of pre-pitted specimens that initiated during fatigue loading but became non-propagating. The stress intensity factor range was calculated assuming a semi-circular crack shape. Figure 6a shows the FCGR curves for cracks emanating from pits with depths of 50 µm and 100 µm. For each pit size, the growth rates of a crack that caused final failure and one that became non-propagating are shown.

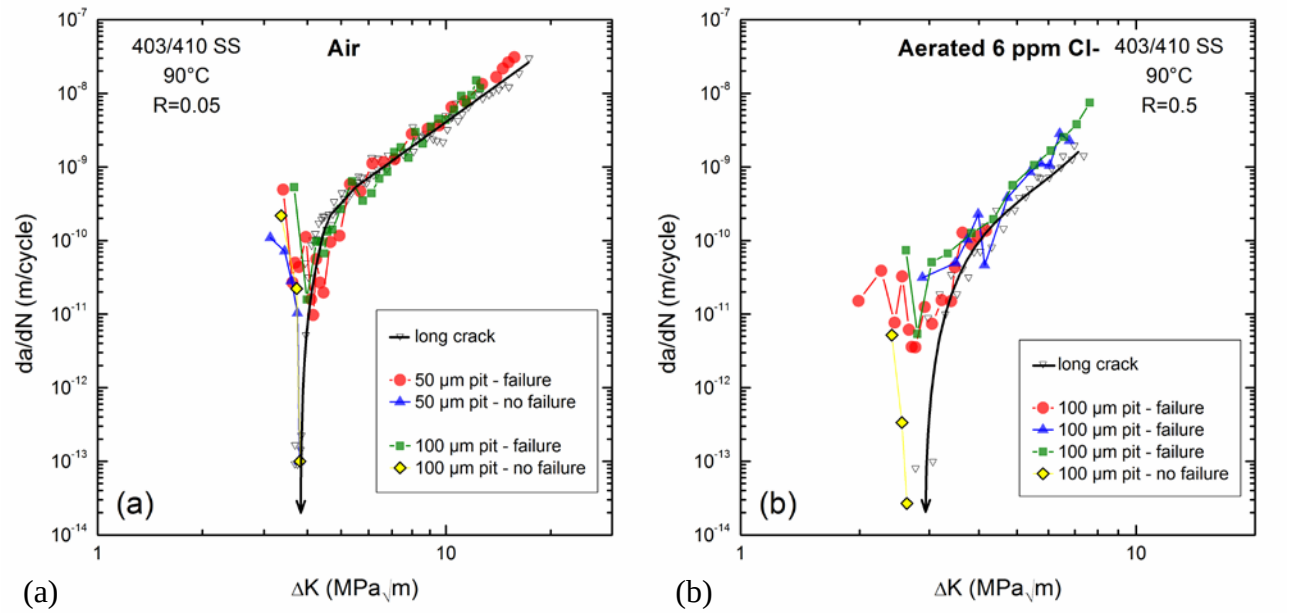

Figure 6.d*a*/d*N* vs. Δ*K* for cracks emanating from corrosion pits in: air (a) and aerated 6 ppm Cl^- solution (b)

The same is shown in Figure 6b for measurements in 6 ppm Cl^- solution. The FCGR curves are compared with long crack growth rate curves of the same material [3,7]. The cracks that initiated at the pits show the typical short-crack behaviour of crack elongation at stress intensities below the threshold. These cracks either arrest at microstructural barriers or progress and become long cracks. This behaviour was found for both environments as can be seen in Figure 6 although the calculated stress intensities for cracks that initiated at pits are only a rough estimation.

3.4. Fractography

3.4.1. Fatigue tests in air at 90 °C

Observation of the fracture surfaces with SEM and optical microscope gave information about crack initiation site and mechanisms. At $R = 0.05$, the smooth specimens failed from surface inclusions as shown in Figure 7a. Analysis with EDX identified these non-metallic inclusions with diameters of approx. 10 µm as Al_2O_3. Two specimens that failed during testing in air after 10^8 cycles failed from the interior. A so called fish-eye fracture was found. Crack initiation was in the matrix, and no inclusion could be detected.

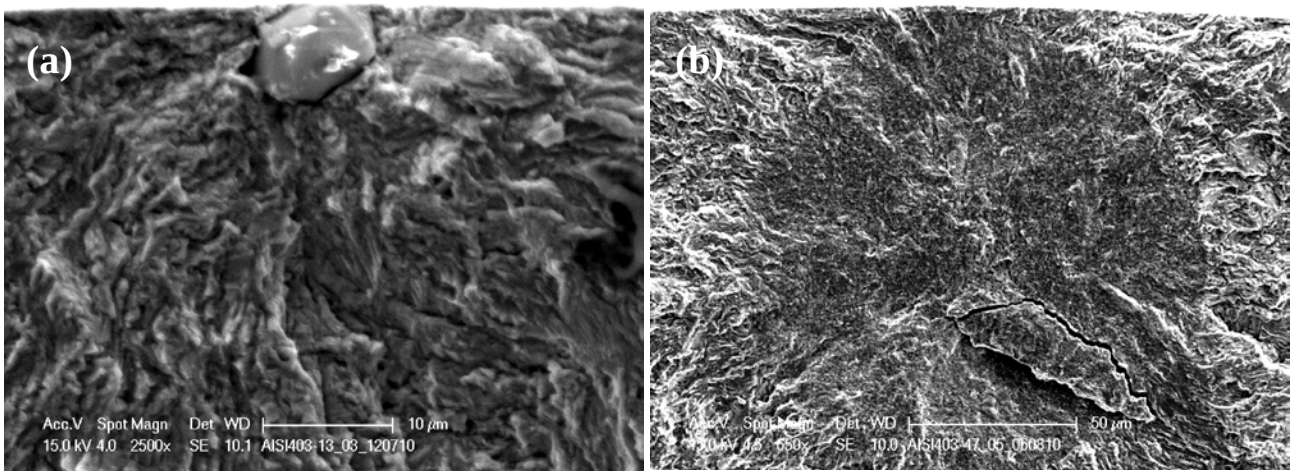

Figure 7. Fracture surfaces of smooth specimens tested at $R = 0.05$ in air at:
$\Delta\sigma = 672$ MPa ($N_f = 1.06 \times 10^6$) (a) and $\Delta\sigma = 642$ MPa ($N_f = 4.20 \times 10^8$) (b)

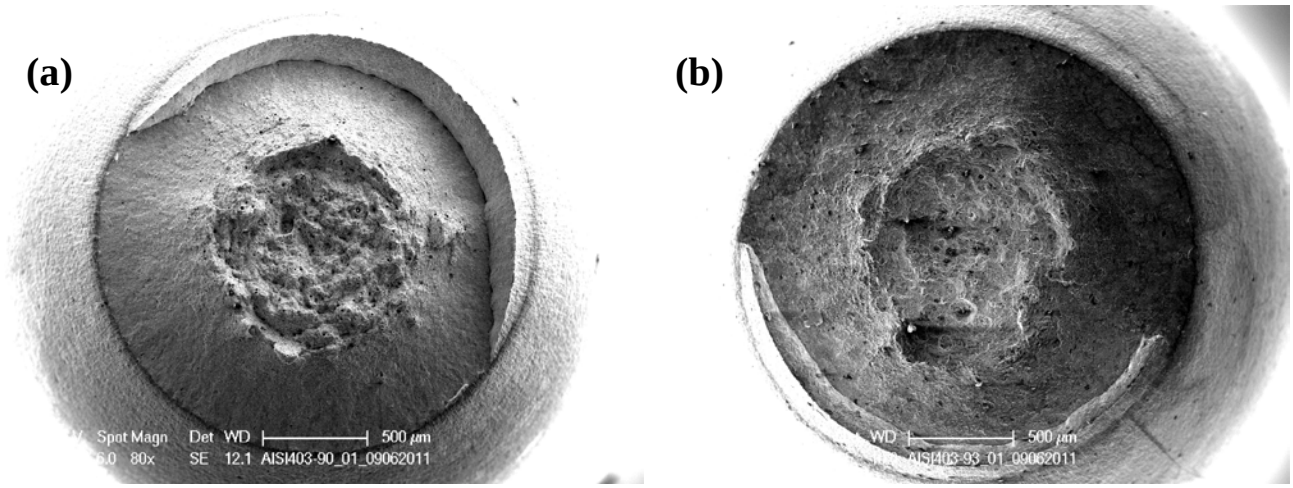

Figure 8. Fracture surfaces of smooth specimens tested at $R = 0.5$ in air at:
$\Delta\sigma = 380$ MPa ($N_f = 1.36 \times 10^8$) (a) and $\Delta\sigma = 400$ MPa ($N_f = 6.25 \times 10^5$) (b)

At $R = 0.5$ and $R = 0.8$, the crack initiation site for smooth specimens is not detectable since very high deformation at the fractured surface was observed. The cup-and-cone fracture as shown in Figure 8a and b was found for all smooth specimens. This kind of fracture surface is usually observed after tensile testing and suggests the dominance of cyclic creep due to the high maximum stress. Cyclic softening of the material during testing is supposed as reported by Kovacs et al. [10] for 12% Cr steel martensitic steel (X10CrNiMoV12-2-2). Nevertheless, failure occurred above 10^8 cycles.

For pre-pitted specimens tested at $R = 0.05$, crack initiation was always found at the pit. Figure 9 shows corrosion pits of different depths at the crack initiation sites. But at higher stress ratios, corrosion pits need not necessarily cause final failure. At $R = 0.5$, one of three pre-pitted specimens with a pit depth of ca. 50 µm showed high plastic deformation and a short crack after fatigue failure (Figure 10a). The corrosion pit was found some millimetres away from the fractured surface and the fracture was cup-and-cone like (Figure 10b). Similarly, short cracks were found at 100 µm deep pits when they were tested at $R = 0.8$ but none of these caused final failure. This means that there is a critical pit size depending on the stress ratio which may cause final failure. A greater pit size leads to a lower fatigue limit. Consequently, cyclic creep becomes an opposing mechanism when the maximum stress – i.e. the stress ratio – is higher. If the pit is rather small, high stresses are necessary to initiate a fatigue crack, and the material shows cyclic softening.

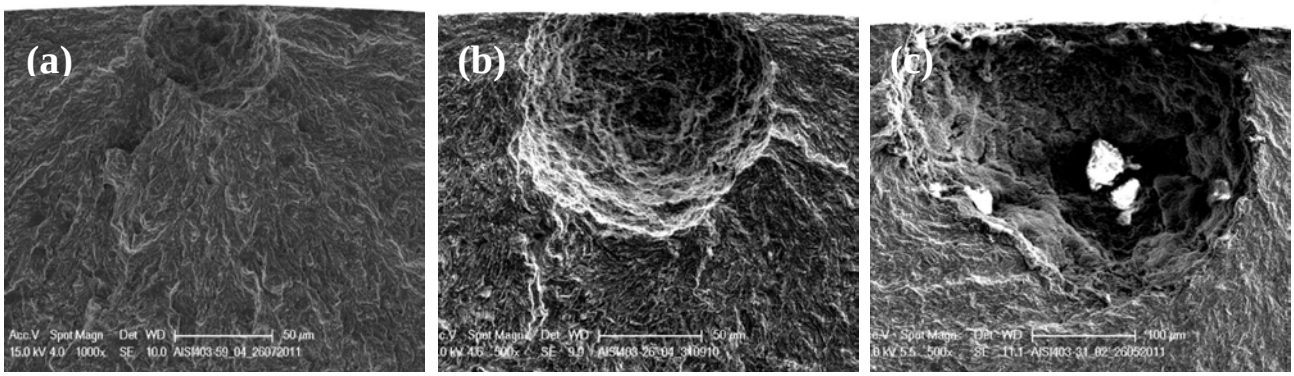

Figure 9. Fracture surfaces of pre-pitted specimens tested at $R = 0.05$ in air with a pit depth of: 50 µm ($\Delta\sigma = 507$ MPa, $N = 1.69 \times 10^9$) (a), 108 µm ($\Delta\sigma = 422$ MPa, $N_f = 6.11 \times 10^5$) (b) and 277 µm ($\Delta\sigma = 280$ MPa, $N_f = 9.65 \times 10^5$) (c)

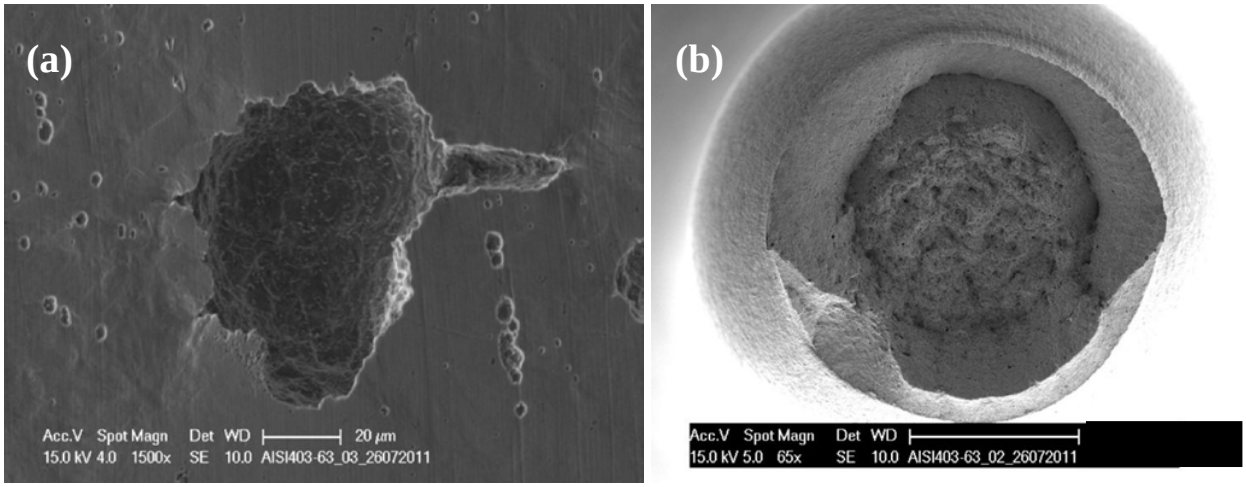

Figure 10. Corrosion pit with a depth of 48 µm (a) and fracture surface (b) of a specimen tested at $R = 0.5$ at $\Delta\sigma = 651$ MPa ($N_f = 2.38 \times 10^8$)

2.4.2. Fatigue tests in aerated 6 ppm C^- solution at 90 °C

S-N tests with smooth specimens showed a similar crack initiation behaviour like tests in air. Al_2O_3 inclusions were found again at the crack initiation site. Due to the decrease of the fatigue limit in the corrosive liquid, the cup-and-cone like fracture caused by cyclic creep was found only for tests at $R = 0.8$. Figure 11a shows a smooth specimen that was fatigue loaded at $R = 0.5$. An Al_2O_3 inclusion is located at the crack initiation site. Also the critical pit size for causing final failure at higher stress ratios is reduced. All pre-pitted specimens that were tested in the solution showed failure emanating from the pit. A corrosion pit with a depth of 100 µm is shown on the fracture surface of a specimen tested at $R = 0.8$ in Figure 11b.

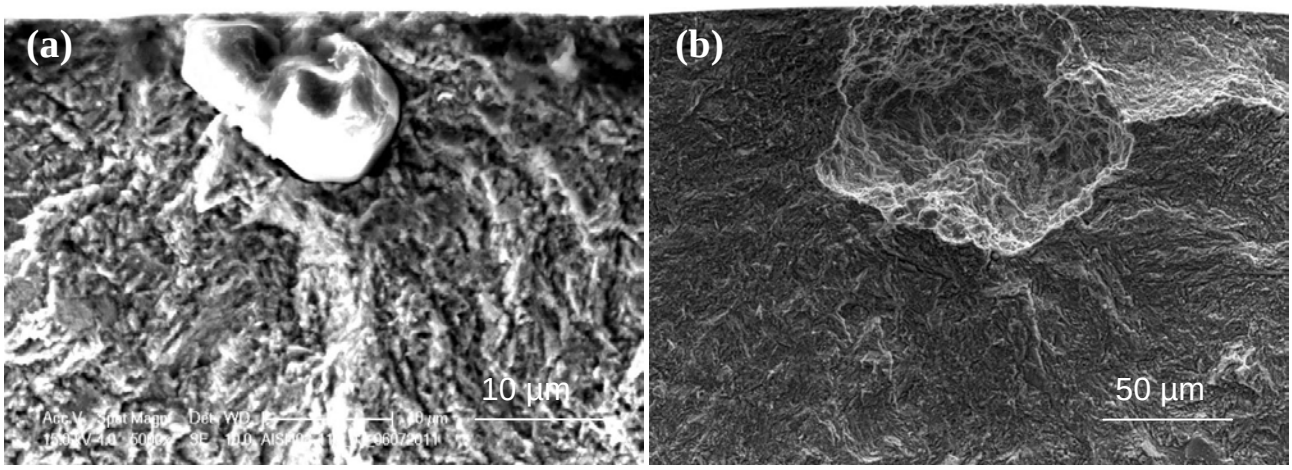

Figure 11. Fracture surfaces after testing in aerated 6 ppm Cl^- solution: smooth specimen at $R = 0.5$ ($\Delta\sigma = 340$ MPa. $N_f = 3.11 \times 10^6$) (a) and 101 µm deep pit at $R = 0.8$ ($\Delta\sigma = 135$ MPa, $N_f = 2.93 \times 10^7$) (b)

Acknowledgements

The presented results were achieved during a program to develop a methodology for the prediction of corrosion fatigue life in steam turbine blades, being conducted by the Electric Power Research Institute (EPRI) of Charlotte NC.

Abstract Fatigue crack growth and conventional fatigue tests have been carried out from different sampling locations within a wind turbine hub. S/N curves as well as fatigue crack propagation properties have been determined in dependency of the local microstructure. Subsequent fractographic analysis of the conventional fatigue tests showed micro-shrinkage to be the dominant reason for crack initiation. Statistical analysis of these micro-shrinkages showed a relationship between their size and the local solidification conditions. A model is proposed, linking the size of the shrinkages and the fatigue strength of nodular cast iron. Using this model, it is possible to describe the fatigue strength of nodular cast iron in dependence of the local solidification conditions or local microstructure, respectively.

Keywords Ductile Iron, fatigue, defects, micro-shrinkage

1. Introduction

Nodular cast iron is widely used for structural components of wind turbines due to its very good castability. Guidelines and codes dominate the design process of such components, which are rather conservative regarding the tolerable stresses [1,2]. Although these components can easily weigh up to several ten tons, their material properties are far from homogeneous. Large wall thicknesses and added chill irons result in different solidification conditions leading to different microstructures. Different material properties arise, depending on the local microstructure. Casting simulation tools are able to estimate local solidification conditions and the resulting local static material properties [3]. If the materials full potential should be used, the estimation of the dynamic material properties using empirical relationships between static and dynamic properties, which is common for guidelines, is not sufficiently accurate. In this paper, the Kitagawa Takahashi diagram [4] modified by El-Haddad [5] is used to describe the local cyclic material properties of nodular cast iron based on metallographic parameters. Therefore, fatigue crack growth experiments as well as conventional fatigue tests have been carried out using specimen with different characteristic microstructures. The Woehler experiments used for these investigations have already been published in [6]. The results of further investigations of the fractured specimen's surfaces, as well as the results of crack growth experiments are presented in this paper.

2. Experimental Procedure

A wind turbine hub made of EN-GJS-400-18U-LT standardized in [7] was used as base material for these investigations. The material has been taken from different sampling locations within the wind turbine hub in order to retrieve material with various solidification conditions and microstructures resulting in different material properties. The reader is referred to [6] for a detailed description of the sampling locations.
Fatigue crack growth experiments have been carried out according to [8] at room temperature and ambient air using the direct current potential drop method. The specimens have been subjected to four-point bending loads. For further information on the testing equipment refer to [9].

Single edge notched specimens have been used, their geometry is illustrated in Figure 1. To ensure a sound specimen surface, all the specimens have been grinded using a P320 sandpaper. The notch of the specimens has been pre-scratched.
Crack growth tests have been carried out using R-ratios of R=-1, R=0 und R=0.3. Only the threshold of the stress intensity factor K_{th} has been evaluated.

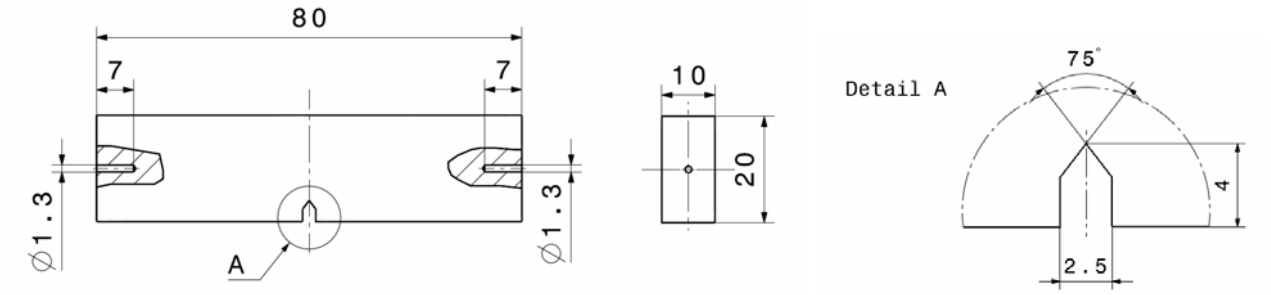

Figure 1: Geometry of the crack growth specimen

Constant amplitude Woehler experiments have been carried out at room temperature and ambient air. A resonance test rig Sincotec Exciting MAG was used to test the specimens up to 10^7 load cycles with a frequency of about 120Hz. All specimens have been tested under fully reversed loading (R=-1).
The finite life region was evaluated according to ASTM E739 [10]. The existence of a distinct fatigue limit is assumed according to [11], because the investigated material was fully ferritic and no retained austenite was found. The evaluation of the fatigue limit was carried out using the arcsin $\sqrt{p}$ transformation [12] with the estimator according to [13, 14].
Fractographic analysis of the fractured specimen surface has been carried out using a scanning electron microscope (Zeiss EVO MA15). Micro-shrinkages found in the fractured surfaces have been manually traced and two parameters (square root of particle area and maximum dimension) have been evaluated.

3. Crack Growth Experiments

At first, the specimens have been categorized using a qualitative measurement of the solidification rate depending on their sampling location (fast, medium, normal, slow). The number of tested specimen is available in Table 1.

Table 1: Test plan for the crack growth tests

Solidification speed	fast	medium	normal	slow	medium	slow	fast	medium	Slow
Stress-ratio R	0	0	0	0	0.3	0.3	-1	-1	-1
Number of samples	2	1	2	4	2	2	2	2	2

The results of the fatigue crack growth experiments are summarized in Figure 2. It is clearly visible, that the threshold K_{th} is decreasing with increasing stress ratio. Furthermore, the dependence of the microstructure becomes obvious, faster solidification (fine microstructure) leads to a lower threshold then slow solidification (coarse microstructure). The same trend has also been observed by Huebner et al. in [15] as well as Komber in [16] who also observed this trend for lamellar cast iron. She proposed a model to describe the threshold for crack initiation in dependence of microstructural parameters, namely the shape factor of the graphite nodules f and the mean distance between the graphite particles λ. This trend is contributed to the fact that the graphite particles act as crack stoppers. Huebner also observed lower crack growth rates in region II and a delayed transition to the region III for slower solidification rates in [15].

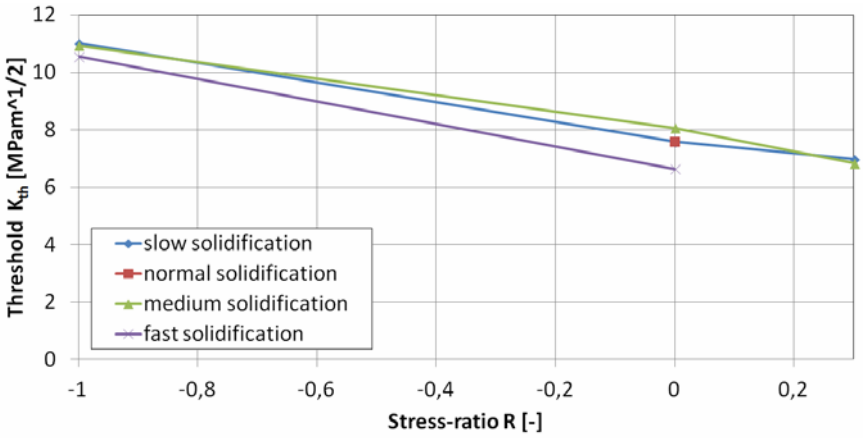

Figure 2: Threshold for crack propagation K_{th} in dependence of stress ratio and microstructure

To further quantify the solidification speed and to compare the results with those found in the literature, several metallographic parameters have been evaluated for each tested specimen. Therefore, the following parameters of the graphite particles from metallographic grindings made from each tested specimen have been evaluated:

- mean distance between the particles λ
- particle diameter d
- shape factor of the particle f
- number of particles per square millimeter n

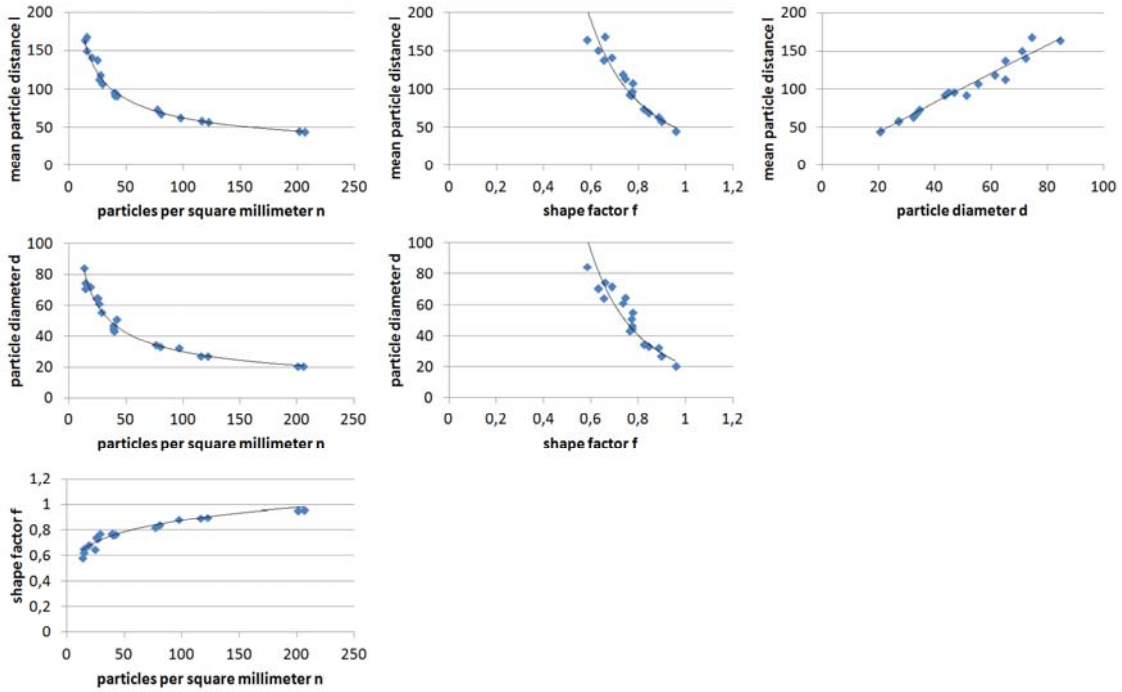

Figure 3: Comparison of the evaluated metallographic parameters (λ, d, f, n)

These four parameters have been plotted against each other in Figure 3. One can observe that all parameters are depending on each other. Slower solidification leads to larger mean distances λ, larger particle diameters d, smaller shape factors f (more degenerated graphite particles), a smaller number of particles n and vice verca. No distinct effect of the shape of the graphite nodules could be isolated. Therefore, describing the threshold K_{th} by more than one parameter, as Komber did in

[16] for different types of cast iron, is not necessary for nodular cast iron. The coefficient of determination illustrated in Figure 4 shows only a slight improvement compared to the fit using only the number of nodules per square millimeter. One can also see that the scatter of both empirical fits is very high, resulting in a quite low coefficient of determination. The fit parameters are summarized in Table 2.

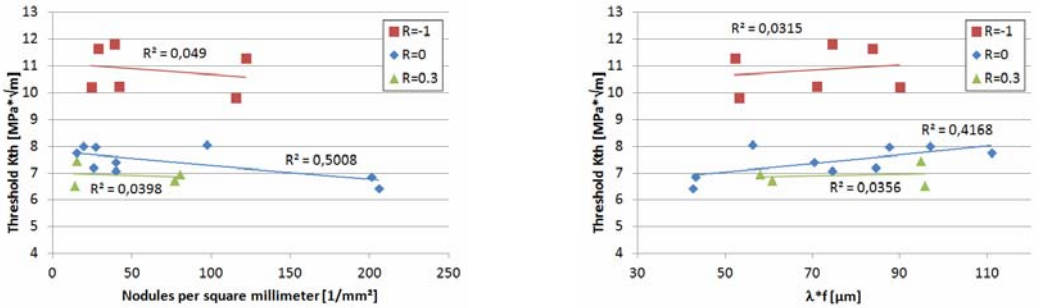

Figure 4: Threshold Kth in dependence of the number of particles per square millimeter (left) and the formalism used in [12,13] (right)

Table 2: Parameters of the empirical fit of the threshold K_{th}.

	Nodules/mm² [1/mm²]			λ*f [µm]		
	R=-1	**R=0**	**R=0.3**	**R=-1**	**R=0**	**R=0.3**
Slope	-0,0042	-0,0052	-0,0022	0,0097	0,0157	0,0037
y-intercept	11,11	7,82	7,01	10,16	6,27	6,63

Figure 5 shows a comparison of thresholds found in the literature [15,16,17]. As Zambrano already pointed out in [17], considerable differences are found in the resulting thresholds. The data presented in this paper shows good agreement with [15,16] for R=0 and R=0.3. Significant differences for the R=-1 tests have been found compared to [17]. It should be pointed out, that [15,16] used three-point bending specimen, [17] used edge cracked tension specimen and four point bending specimen have been used in the present investigations.

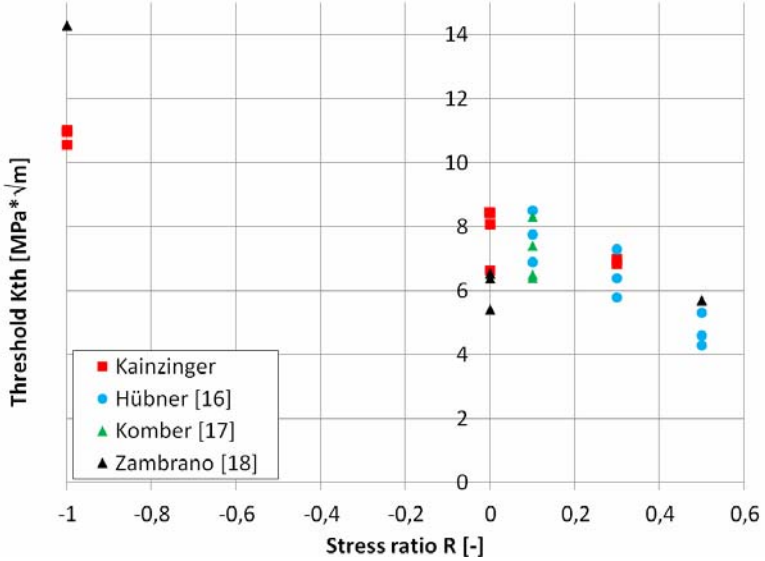

Figure 5: Comparison of thresholds found in the literature

4. Woehler Experiments

The Woehler experiments used for this paper have already been published in [6]. To improve the readability the results will be summarized shortly. For detailed information the reader is referred to the original paper.
Specimens have been taken from different sampling locations within the aforementioned wind turbine hub to cover a variety of different solidification conditions ranging from very slow solidification (coarse microstructure) in the center of a 100mm thick wall (position 1) to very fast solidification (fine microstructure) beneath chill irons (position 4). The results of these S/N curves are summarized in Figure 6. The fatigue strength increases with decreasing solidification time. In [6] an empirical model was proposed linking the parameters of the S/N curve with the local number of nodules per square millimeter. Good correlation was achieved between the model and the experiments. In the following part of this paper, a more physically based approach is proposed using the Kitagawa Takahashi diagram [4] modified by El Haddad [5].

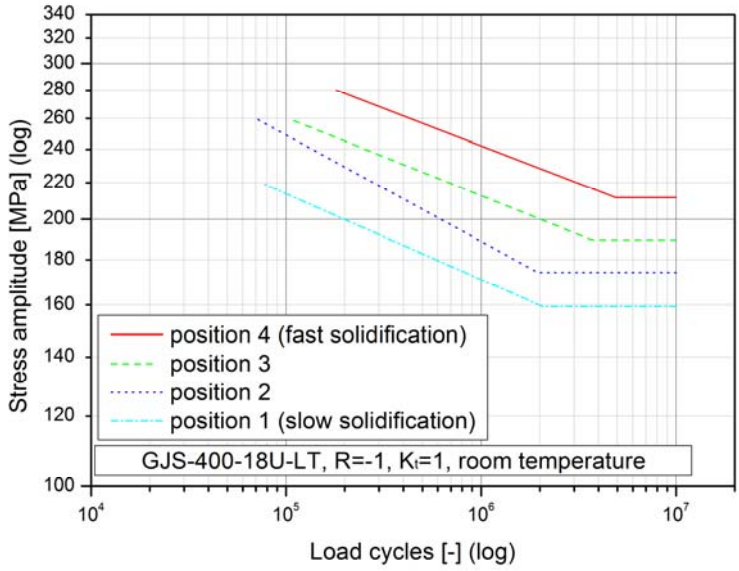

Figure 6: Results of the S/N curves from different sampling positions [8]

5. Fractographic Analysis

The fractured specimen surface has been analyzed using a scanning electron microscope. Micro-shrinkages have been found to be the dominant site of crack initiation (cf. Figure 7). This has also been confirmed by other authors, e.g. [18,19].

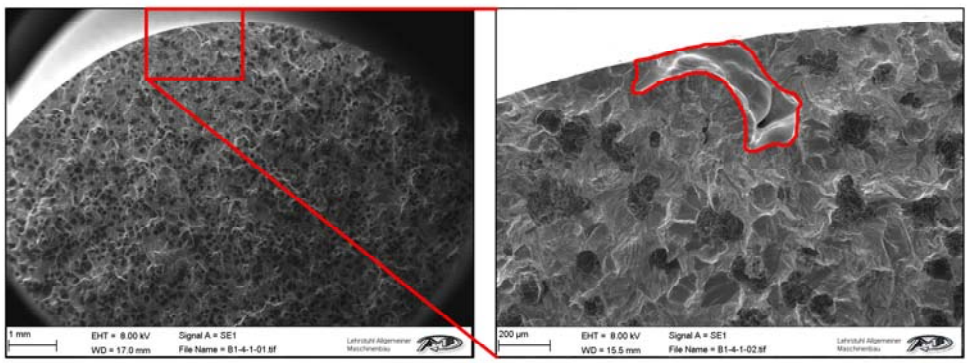

Figure 7: Micro-shinkages of different sizes found in the fractured specimen surface.

All micro-shrinkages were located at the specimen surface. Subsequent measurement of these micro-shrinkages has been carried out. The square root of the area [20] and the maximum dimension of the defects have been measured for all tested specimen. Some fracture surfaces revealed more than one micro-shrinkage, these specimens have not been evaluated due to the interaction effects of the micro-shrinkages.

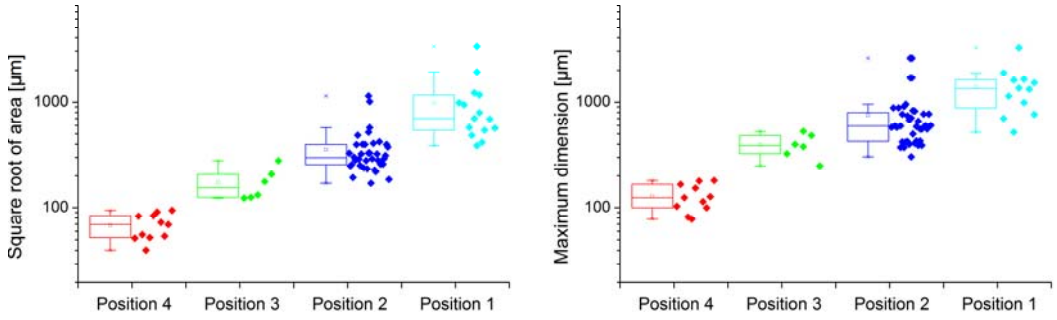

Figure 8: Box-plot of the size of the microshrinkages found in the fractured specimen surface. The square root of the area is displayed on the right side, the maximum dimenson on the left.

It has been observed that the size of the micro-shrinkages significantly decreases with decreasing solidification time (fine microstructure), which is illustrated by means of a box-plot in Figure 8. This trend is visible for both, the square root of the area as well as the maximum dimension.

6. Discussion

When considering both experimental results on their own, the observed trend is contradictory. The crack growth experiments indicate higher thresholds and lower crack growth rates (cf. [15]) for a coarse microstructure (slow solidification, respectively). This should result in better fatigue properties but the results of the fatigue tests show the exact opposite, a coarse microstructure leads to worse fatigue properties. The missing links are the micro-shrinkages of different sizes. Figure 8 shows the size of the shrinkages in dependence of the microstructure. Their mean values of the square root of their area ranges from 68µm for the fine microstructure up to 688µm for the coarse microstructure. This compensates the effect of the better crack growth properties of the coarse microstructure. The fatigue properties get worse, due to the disproportionally big size of the micro-shrinkages.

7. Local Fatigue Model

The Kitagawa Takahashi diagram modified by El Haddad, compensating the effects of short crack growth, will be used to describe the effect of micro-shrinkages on the fatigue behavior of ductile iron. The used equation is the following:

$$\sigma_a = \frac{\Delta K_{th}}{Y \cdot 2 \cdot \sqrt{\pi \cdot (a + a_0)}} \tag{1}$$

The threshold for crack propagation K_{th} is not constant throughout the material, it increases in case of a more coarse microstructure. For a better illustration of all sampling positions in a single diagram Eq. (1) has been normalized by being devided by the threshold:

$$\frac{\sigma_a \cdot 2}{\Delta K_{th}} = \frac{1}{Y \cdot \sqrt{\pi \cdot (a + a_0)}} \tag{2}$$

The corresponding threshold for the S/N curves from positions 1-4 have been calculated using the empirical fit using only the number of graphite nodules per square millimeter in Figure 4. A constant geometry factor of Y=0.65 has been used.
The El Haddad approach requires a fatigue limit of a defect free material to calculate the intrinsic crack length a_0. Since no defect free material was available for this research, the parameter a_0 was fitted to yield the best correlation between the estimated and the tested fatigue limits. A value of a_0=425µm led to the best results. This value of a_0 results in a theoretical fatigue limit of the defect free material of 212 to 231MPa, depending on the used threshold (10.1 and 11MPam^1/2, respectively). This defect free fatigue limit shows very good correlation with the empirical model proposed in [8].

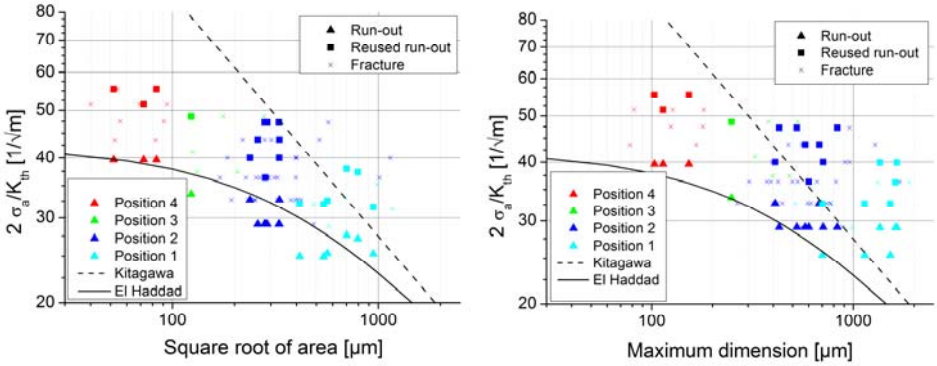

Figure 9: Normalized Kitagawa Takahashi diagram for all four sampling positions using the square root of the area (left) and the maximum dimension (right).

The Kitagawa Takahashi diagram using the square root of the area and the maximum dimension of the micro-shrinkage is illustrated in Figure 9. Using the square root of the area results in an overall good correlation, the use of the maximum dimension always led in conservative estimations of the fatigue limit. This is also emphasized in Figure 10, where the estimated fatigue limit is plotted against the experimental result. Therefore, the mean defect size (square root of area or maximum dimension, respectively) has been used to calculate the corresponding estimation using Eq. (1).

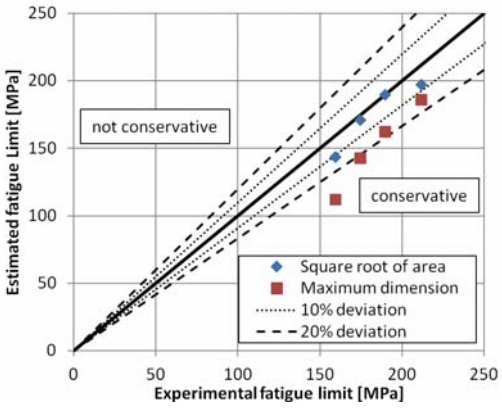

Figure 10: Comparison of the experimental and estimated fatigue limits.

8. Summary

- Fatigue crack growth as well as conventional fatigue tests have been carried out on specimens from different locations within a wind turbine hub. The sampling locations represent different solidification conditions which result in different microstructures.
- It has been found, that the fatigue crack propagation properties as well as the parameters of the S/N curve significantly depend on the local microstructure. The threshold for crack propagation K_{th} decreases with decreasing solidification time (fine microstructure), the fatigue properties increase with decreasing solidification time (resulting in a large number of particles per square millimeter).
- A contradictory trend has been found comparing the crack growth and conventional fatigue tests with different microstructures. Crack growth experiments show better fatigue properties for coarse microstructures, whereas conventional fatigue tests showed worse properties.
- Micro-shrinkages have been found to be the dominant site for crack initiation. The size of these micro-shrinkages compensates for the contradictory trend mentioned above.
- Subsequently, the local fatigue crack properties and the size of the micro-shrinkages are combined in the Kitagawa Takahashi diagram modified by El Haddad. Using the square root of the defect area leads to very good results. The maximum dimension always leads to conservative results.

Abstract The fatigue failure of compressor wheel rub is one of important failure modes of turbocharger for vehicle application. Because the operating state of turbocharger in the life cycle changes as the work condition of diesel engine changes, the compressor wheel rub of turbocharger is applied by the variable stress which can causes the fatigue failure. In this paper, the effect of centrifugal load, thermal load and aerodynamic load on the stress of compressor wheel rub is studied, and then the fatigue stress spectrum of compressor wheel rub is developed based on the endurance test profile of vehicle engine. In order to research the fatigue strength of compressor wheel rub, the fatigue specimen is designed and the relationship between the stress and fatigue life of compressor wheel rub is built. Then, utilizing the linear Miner cumulative damage rule and the first-order reliability method, the reliability model of compressor wheel rub with fatigue failure mode is derived, and the rule that the reliability of compressor wheel rub changes with life is studied. Based on the reliability model of compressor wheel rub with fatigue failure mode developed, the method for determining the reliable fatigue life of compressor rub of turbocharger is proposed. The result shows that with the method developed in this paper the fatigue life of compressor wheel rub for the given reliability can be predicted reasonably, and the reliability of compressor wheel rub can also be calculated for the given fatigue life.

Keywords Fatigue, Life prediction, Turbocharger, Compressor wheel, Reliability, Reliable life

1. Introduction

Turbocharger has been applied into all kinds of vehicle engines to improve the performance and reduce the emission in recent years [1-3]. The compressor wheel is one of the most key components of turbocharger, which can transform the mechanical energy recovered by the turbine to the energy of air and improve the intensity of inlet air of engine. For the turbochargers for vehicle application, because of the complex and variable operating section of vehicle engine, the running status of compressor wheel of turbocharger changes continuously and the compressor wheel is applied by the variable loading process, which can cause the fatigue failure of compressor wheel rub [4-5]. Once the fatigue failure happens in the compressor wheel, the turbocharger can not work normally. Thus, it is very important that analyze the reliability of compressor wheel rub with fatigue failure mode and predict its fatigue life scientifically.

Because the fatigue reliability and life of compressor wheel rub is related with the real operating profile of engine equipped with the turbocharger, it is very important that obtain the exact operating profile of engine in the process of analyzing the reliability and life of compressor wheel of turbocharger. However, in the development stage of turbocharger, it is hard to obtain the exact operating profile of engine or the turbocharger, especially for the engines for vehicle application, and in most cases it is very difficult to analyze the fatigue life and reliability of turbocharger compressor wheel.

In this paper, a new method for analyzing the fatigue reliability and predicting the life of compressor wheel rub of turbocharger is developed based on the endurance test profile of engine for vehicle application. The reliability model of compressor wheel rub with fatigue failure mode is derived, and the method for predicting the fatigue life of compressor wheel rub corresponding to the

different given reliability is proposed.

2. Stress Analysis of Compressor Wheel Rub with Fatigue Failure Mode

The sketch of compressor wheel of turbocharger and its critical locations of fatigue failure (namely, the maximal stress appearing areas) are shown as Figure 1, and it can be seen that the maximal stress of compress wheel generally appears in the rub for the normal operating cases of turbocharger.

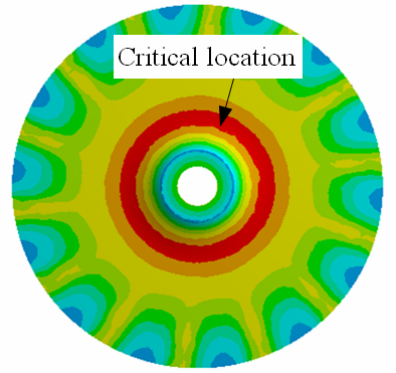

Figure 1. Critical locations of compressor wheel with fatigue failure mode

In the work process of turbocharger, the compressor wheel is applied by the centrifugal load, thermal load and aero dynamical load, simultaneously, and the stress value of compressor wheel rub is dependent on the running status parameters of compressor wheel of turbocharger, including the rotational speed, inlet and outlet temperature, inlet and outlet pressure, and so on.
Because in the development stage of turbocharger it is very hard to obtain the exact running status parameters of compressor wheel and the real operating profile of engine for vehicle application, in the following based on the endurance test profile of engine, the operating modes of engine which is composed of four main operating modes, is determined, and corresponding to different operating modes of engine the running status parameters of compressor wheel of turbocharger is studied. Further, according to the running status parameters of compressor wheel in different operating mode of engine, the stress of compressor wheel rub is calculated, shown as Table 1.

Table 1. Stress of compressor wheel rub corresponding to the operating modes of the endurance test profile of engine

Operating mode of engine	The running status parameters of compressor wheel of turbocharger						Stress of compressor wheel rub (MPa)
	Rotating Speed(r/min)	Inlet Temperature (K)	Outlet Temperature (K)	Inlet Pressure (Bar)	Outlet Pressure (Bar)	Flow (kg/s)	
1	104019	297	483	0.896	3.340	0.569	267
2	98735	297	479	0.894	3.216	0.548	223
3	95420	297	471	0.892	3.025	0.503	209
4	91984	297	468	0.891	2.873	0.476	195

According to the endurance test profile of engine and the stress of compressor wheel rub shown as Table. 1, the fatigue stress history of compressor wheel rub is built, shown as Figure 2.

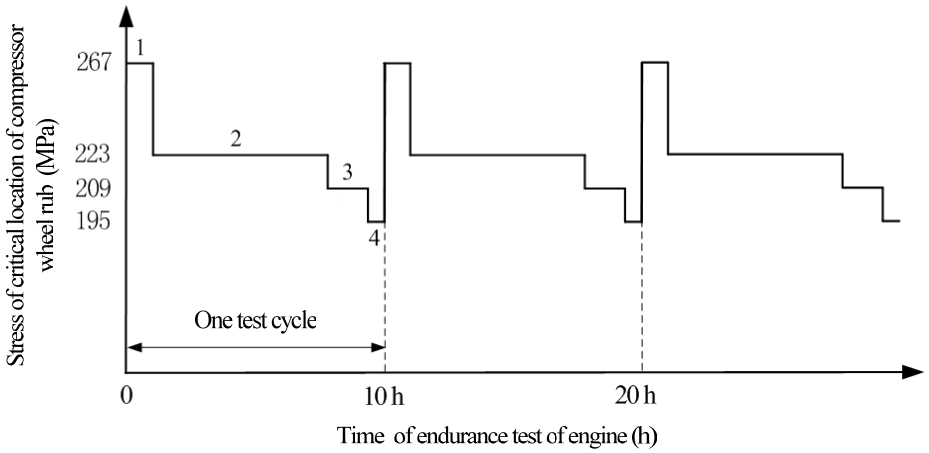

Figure 2. Fatigue stress history of compressor wheel rub corresponding to the endurance test profile of engine

3. Study on the strength of Compressor Wheel Rub with Fatigue Failure Mode

In order to study the fatigue strength of compressor wheel rub of turbocharger, the test specimen which can reflect the effect of structural characteristics and manufacturing process on the fatigue strength, is designed as Figure 3. Forty-five specimens of compressor wheel rub are manufactured and the fatigue test of these specimens is done at the fatigue-testing machine.

According to the results of fatigue test of compressor wheel rub specimen, the relationship between the fatigue life of compressor wheel rub and stress is subjected to the form of exponential function, namely,

$$Ne^{\alpha s} = C \tag{1}$$

And the relationship between the logarithm mean value $\mu_{\lg N}$ of fatigue life N of compressor wheel rub and stress s can be expressed as

$$\mu_{\lg N} + 0.02498\, s = 16.7535 \tag{2}$$

The relationship between the logarithm standard deviation value $\sigma_{\lg N}$ of fatigue life N of compressor wheel rub and stress s can be expressed as

$$\sigma_{\lg N} + 0.02522\, s = 13.5866 \tag{3}$$

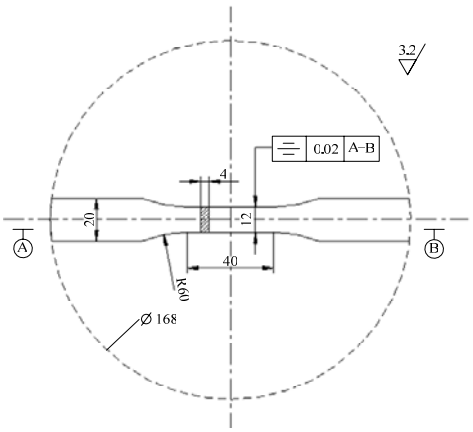

Figure 3. Fatigue test specimen of compressor wheel rub

4. Fatigue Reliability Modeling and Reliable Life Prediction of Compressor Wheel Rub

According to the linear Miner cumulative damage rule, the fatigue cumulative damage ΔD of compressor wheel rub corresponding to one cycle of endurance test of engine, can be expressed as

$$\Delta D = \frac{1}{N_1} + \frac{1}{N_2} + \frac{1}{N_3} + \frac{1}{N_4} = \sum_{i=1}^{4} \frac{1}{N_i} \tag{4}$$

Where, N_i is the fatigue life of compressor wheel rub corresponding to the stress s_i.

And the number of test cycles of engine endurance test to which the fatigue failure happened in the compressor wheel rub of turbocharger, can be derived as

$$n = \frac{1}{\Delta D} = \frac{1}{\sum_{i=1}^{4} \frac{1}{N_i}} \tag{5}$$

And the limit state function of compressor wheel rub with fatigue failure mode can be expressed as

$$Z = n\Delta D - 1 = n\sum_{i=1}^{4} \frac{1}{N_i} - 1 \tag{6}$$

When the fatigue life of compressor wheel rub is measured with the number of test cycles of endurance test of engine, the relationship between the fatigue reliability of compressor wheel rub of turbocharger and its life parameter can be developed as

$$R(n) = P\left(n\sum_{i=1}^{4} \frac{1}{N_i} - 1 < 0 \right) \tag{7}$$

Let $x_i = \log N_i$, and using the second moment method, the limit state function of compressor wheel rub with fatigue failure mode can be expressed as

$$\begin{aligned} Z &= n\sum_{i=1}^{4} 10^{-x_i} - 1 \\ &= n\sum_{i=1}^{4} 10^{-\mu_{x_i}} - 1 - n\ln 10 \sum_{i=1}^{4} 10^{-\mu_{x_i}} (x_i - \mu_{x_i}) \end{aligned} \tag{8}$$

And the mean value and standard deviation value of the limit state function of compressor wheel rub with fatigue failure mode can be expressed as

$$\mu_Z = n\sum_{i=1}^{4} 10^{-\mu_{x_i}} - 1 \tag{9}$$

$$\sigma_Z = n\ln 10 \sqrt{\sum_{i=1}^{4} \left(10^{-\mu_{x_i}} \sigma_{x_i} \right)^2} \tag{10}$$

With Eq. (2) and Eq. (3), the logarithm mean value and the logarithm standard deviation value of fatigue life of compressor wheel rub corresponding to the different stress shown as Tab. 1, can be calculated. and the result is substituted into Eq. (9) and Eq. (10), we have

$$\mu_Z = 9.0325 \times 10^{-11} n - 1 \tag{11}$$

$$\sigma_Z = 0.002772n \tag{12}$$

Further, according to Eq. (7), the reliability model of compressor wheel rub with fatigue failure mode can be developed as

$$R(n) = \Phi\left(-\frac{\mu_Z}{\sigma_Z} \right) = \Phi\left(\frac{1 - 9.0325 \times 10^{-11} n}{0.002772n} \right) \tag{13}$$

where, $\Phi(\cdot)$ denotes the cumulative distribution function of standard normal distribution.

The rule that the reliability of compressor wheel rub with fatigue failure mode changes as the number of test cycles of endurance test of engine can be obtained with Eq.(9), and it is shown as Figure 4.

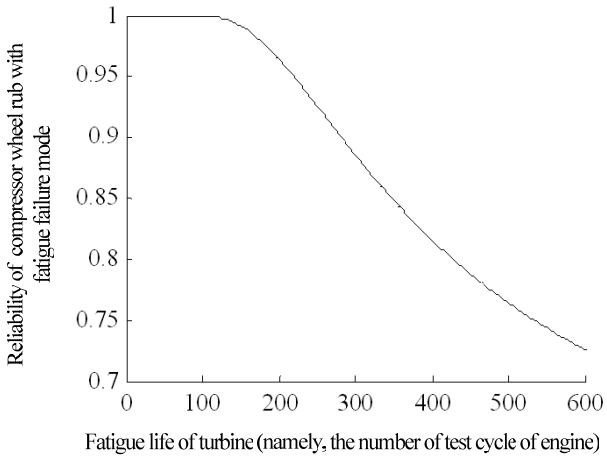

Figure 4. Reliability curve of compressor wheel rub with fatigue failure mode

From Figure 4, it can be concluded that the reliability of compressor wheel rub with fatigue failure mode decreases as the life parameter increases.

According to the relationship between the reliability of compressor wheel rub with fatigue failure mode and its life parameter, the reliable fatigue life of compressor wheel rub can be determined rationally. As shown in Fig. 5, when the reliability of compressor wheel rub with fatigue failure mode is 0.95, the reliable life $w_{0.95}$ is 220 cycles of endurance test of engine, and when the reliability is 0.9, the reliable life $w_{0.9}$ is 281 cycles of endurance test of engine.

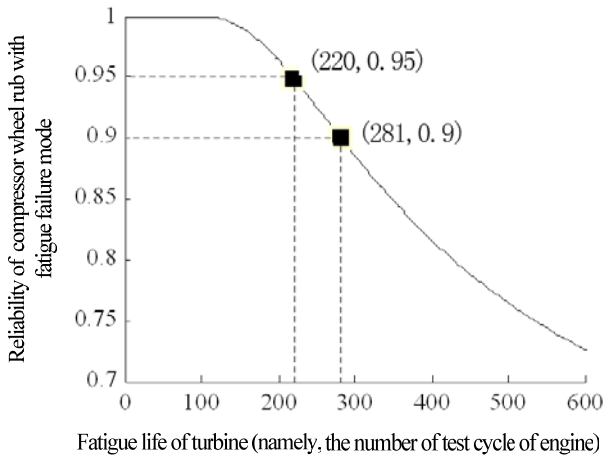

Figure 5. Reliable life of compressor wheel rub with fatigue failure mode corresponding to different reliability

5. Conclusions

The reliability and life of turbocharger compressor wheel rub with fatigue failure mode is studied in this paper. Based on the endurance test profile of vehicle engine, the running status of compressor wheel of turbocharger is analyzed when engine works in different operating modes, and the fatigue stress process of compressor wheel rub corresponding to the endurance test profile of engine is built. And the relationship between the fatigue life of compressor wheel rub and stress is developed

through the fatigue test of fatigue specimen. The reliability model of compressor wheel rub with fatigue failure mode is derived, and then the method for determining the reliable fatigue life of compressor wheel rub is proposed. The result shows that as the life parameter increases, the reliability of compressor wheel rub with fatigue failure mode decreases. When the reliability is given, the reliable fatigue life of compressor wheel rub can be predicted with the method proposed rationally.

A Software Tool for the Fatigue Growth Analysis of Multiple 3D Cracks from Fastener Holes

Yixiu Shu[1], Yazhi Li[1], Zhenxing Fan[1]
[1]School of Aeronautics, Northwestern Polytechnical University, Xi'an, 710072
* Corresponding author: shuyixiu@126.com

Abstract A software tool is developed to carry on automatic fatigue crack propagation analysis for the multiple three-dimensional (3D) cracks initiated from fastener holes. It is a computer code package being capable of handling the cases of multiple 3D cracks with quadratic curve fronts. The object-oriented programming language is used to develop user interfaces for the input of the initial data and output of the simulation results. To achieve life-span numerical simulation for the multiple 3D crack growth, ANSYS Parametric Design Language is used to create finite element model, conduct the stress analysis and regenerate finite element mesh for new crack configurations. Stress intensity factors of the cracks are determined using the crack opening displacements and incorporated into crack propagation laws to estimate the crack extension. An algorithm for the fast integration of crack growth equations is adopted to predict the fatigue crack growth life. As examples, two scenarios of corner cracks initiated from countersunk fastener hole in 2324-T39 alloy sheets are analyzed throughout their fatigue growth lives. The simulation results correlate well with the experimental ones.

Keywords Fastener hole, multiple 3D cracks, fatigue crack growth, numerical simulation, software tool

1. Introduction

Widespread fatigue damage (WFD) is one of the major concerns for the fleet of aging airplanes and significantly decreases the residual strength and residual fatigue life of the aircraft structures. The multiple site damage (MSD) is a kind of WFD happened in similar places of a single structure element and often appears as the multiple cracks initiated from the fastener holes of the aircraft panel structures. The link-up of these cracks is one of the critical conditions and probably leads to the final structure failure. Although most of the available studies are referring to the two-dimensional cracks [4-8], cracks in the panel structures usually initiate as three dimensional (3D), especially the corner cracks from fastener holes of thick panels. A cracks initiated from fastener hole side can be spotted from panel surface only if it has grown out of the area covered by fastener head, washer or nut, or penetrated the panel thickness. The period of the crack growth from initiation to visible takes a large proportion of its total life. Therefore, it is significant to study the behavior of multiple 3D crack growth from very beginning to final failure and achieve an adequate estimation of the crack growth life.

This paper deals with the fatigue growth analysis of multiple 3D cracks initiated from an array of countersunk holes, the scenario that is even more complicated than the kind of cracks from the regular through holes. There are two essentials to conduct such analysis. The first is to attain the stress intensity factors (SIFs) along the front curves of each crack. Because of the varying and complexity of the crack geometry, there is no closed form solution or data available for the SIF. The solution of the SIFs must be determined numerically, mainly by the finite element analysis, such as the calculations of Shen[9], Fawaz[10] and Park[11]. For the simulation of the scenario throughout the whole crack growth history, it is essential to develop a robust technique to take on the task of finite element modeling for given crack pattern and do remeshing over and over again for the various crack sizes and shapes relative to structure geometry during the crack growth. The second requirement is to apply an approach being able to make fast integration of crack growth equation and achieve consistent growth of the multiple cracks with error control, so as to attain adequate crack growth life prediction efficiently. The applicable approaches include the trial and error

method [15], variable optimization method [16] and load cycle segmentation method [11-13], etc., which have been used mainly for multiple 2D cracks. The reason of the more complexity of the present scenario over the multiple 2D crack issue is that the growth of every single 3D crack can be taken as that of several 2D cracks.

This paper describes the development of a computer tool based on commercial finite element software package, aiming to accomplish efficient and automatic simulation for the multiple 3D crack growth and life prediction. Design philosophy, analysis procedure and finite element modeling technique are described in detail. Examples are given to demonstrate the capability of the tool. Comparison is made between simulation results and the experimental ones.

2. Principal of multiple 3D crack growth analysis

2.1 Brief introduction of the tool

Although most of the present commercial finite element packages already have the function module to analyze fracture parameters, difficulty still remain in creating and updating finite element meshes for different crack patterns during crack growth, particularly for the situation of multiple site 3D cracks. So we decided to develop a tool to handle the analysis process of multiple 3D cracks over the whole fatigue growth life, without artificial intervention. The basic steps and module of performing such an analysis are shown in Fig. 1. The commercial software ANSYS are adopted as the computational engine, since the ANSYS Parametric Design Language (APDL) is easily edited and compiled to perform pre- and post- data processing, damage accumulation and result visualization during the analysis. The object-oriented language Visual Basic (VB) is used to develop user interfaces to facilitate operation and result representation.

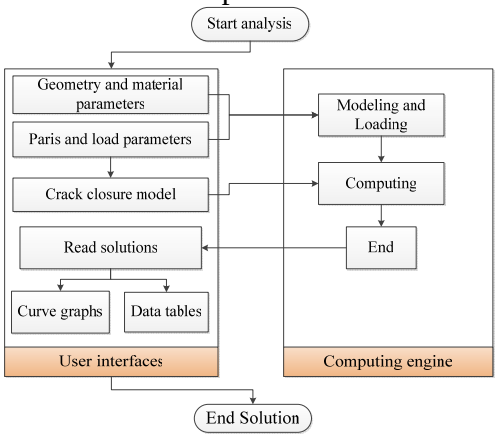

Figure 1. Flow chart of the tool

The tool has been tested under Windows XP and Windows 7 operation systems. It focuses on the sheet specimens with coplanar fastener holes (both countersunk and simple circular through ones) and multiple 3D cracks alongside them. The specimens are subject to constant amplitude loading and cracks may initiate from both sides of each fastener hole. Whole process of multiple crack growth can be simulated. Finite element modeling is parameterized, so as to adapt different geometries of structure and cracks. The parameters of geometry, material properties, loads and constraints are written to the file according to the APDL convention to parameter definition and passed to ANSYS. The analysis process is then running in background.

2.2 Philosophy of crack growth analysis

2.2.1 The fatigue crack growth model

3D cracks are supposed to propagate along the direction normal to their fronts. The Paris-form of crack growth rate equation is used [1]:

$$\frac{da}{dN} = C(\Delta K)^n \tag{1}$$

where ΔK is the stress intensity factor range.
Elber [2] discovered the phenomenon of fatigue crack closure and ΔK was replaced by its effective value

$$\Delta K_{eff} = K_{\max} - K_{open} = U\Delta K \tag{2}$$

where K_{open} is the value of stress intensity factor that causes crack opening during load cycling. U is crack closure function defined as the ratio of ΔK_{eff} to ΔK.

Elber carried out experiments on the Al-alloy 2024-T3 and found that for the stress ratio $R = -0.1$ to 0.7, U can be described as:

$$U = 0.5 + 0.4R \tag{3}$$

An improved function with a more realistic behavior for negative R-values was proposed by Schijve [3]:

$$U = 0.55 + 0.33R + 0.12R^2 \tag{4}$$

The crack growth life prediction program AFGROW [17, 18], developed by J. A. Harter uses a crack closure model in which a closure factor C_f is introduced.

$$K_{open} = C_f K_{\max} \quad ; \quad C_f = 1 - \left[\left(1 - C_{f0}\right)\left(1 + 0.6R\right)\left(1 - R\right)\right] \tag{5}$$

where C_{f0} is the value of C_f for $R = 0$. thus

$$\begin{aligned} \Delta K_{eff} &= K_{\max} - K_{open} = \frac{1 - C_f}{1 - R}\Delta K \quad \text{if } K_{open} \geq K_{\min} \\ \Delta K_{eff} &= K_{\max} - K_{\min} = \Delta K \quad \text{if } K_{open} < K_{\min} \end{aligned} \tag{6}$$

The Schijve model and the AFGROW model are implemented in our tool using APDL code.

2.2.2 Stress intensity determination

Stress intensity factors are determined by the finite element analysis of cracked structure as well as the crack tip opening displacement (CTOD) approach. As shown in Figure 8, for 2D crack case, K value at point *P* located on crack surface and close to crack tip can be calculated :

$$K_{IP} = \frac{2G}{1 + \kappa} \cdot \sqrt{\frac{2\pi}{r_P}} \cdot \left| v\left(r_P\right) \right| \quad \left(P = J, K\right) \tag{7}$$

where: $\kappa = \begin{cases} 3 - 4\upsilon & \text{plane strain} \\ \dfrac{3 - \upsilon}{1 + \upsilon} & \text{plane stress} \end{cases}$.

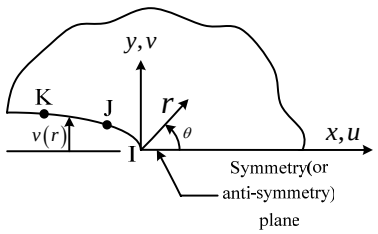

Figure 2. Normal section of a crack

Then the stress intensity factor at crack tip can be determined by displacement extrapolation techniques:

$$K_{\mathrm{I}} = \frac{c}{c-1} K_{\mathrm{I}J} - \frac{1}{c-1} K_{\mathrm{I}K} \tag{8}$$

where: $c = L_{\mathrm{K}} / L_J$, L_K and L_J are distances from the point *K*/*J* to the crack front respectively.

2.2.3 Denotation of different crack configurations

For the present 3D cracks, SIF at any point of a crack front curve is determined by taking Figure 2 as the plane passing that point and normal to the tangent of the curve. The crack front of a corner crack is assumed as a quadratic curve, as is shown in Figure 3. The crack growth is simulated stepwise using remeshing technique combining with fatigue crack growth model. In each analysis step, three sampling points are chosen on every crack front, one in the middle of the curve and two others are close to both ends of the curve. The increments of crack growth on these points are assumed along the directions normal to the crack front curve. We are not choosing both ends of the curve as the sampling points, since the curve may not be perpendicular to the free boundaries on its ends and this will bring error to the stress intensity determination. The crack front curve at the end of present step is updated as a new quadratic curve according to the new positions of the sampling points.

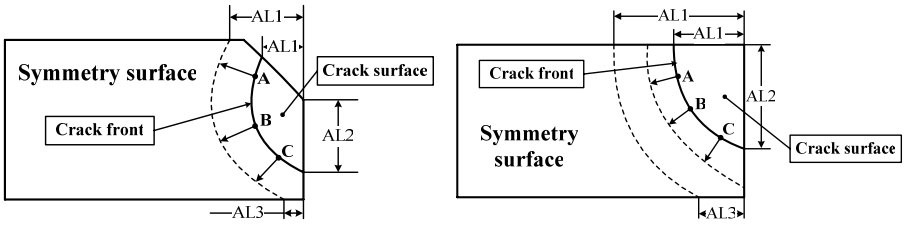

Figure 3. Crack shape and location of sampling points.

2.2.4 Criterion for the multiple crack growth

Fatigue cracks are growing cycle by cycle by their nature, but we cannot afford doing in this way in our simulation. It is possible to boost the calculation by splitting total number of load cycles into several steps. The number of cycles in each step is determined with error control. By this way the crack size increments are calculated stepwise. A criterion proposed by Zhang [11, 12] for multiple 2D crack case is adopted for the present multiple 3D cracks. All the sampling points on every crack front curve should meet the following criterion for crack size increment:

$$\Delta a_{ij} \le 2a_{ij}\left[\left(1-et\right)^{-\frac{1}{2n}} - 1\right] \tag{9}$$

where a_{ij} is the crack size at point *j* in computing step *i*, Δa_{ij} is the corresponding crack size increment, *n* is the exponent parameter in equation (1) and *et* is the error limit (normally as 0.01~0.1). Substituting equation (1) into equation (9), we obtain the upper bound of the number of load cycles:

$$\left(\Delta N\right)_{ij} = \frac{\Delta a_{ij}}{C \cdot \left(\Delta K_{ij,eff}\right)^n} \le \frac{2a_{ij}\left[\left(1-et\right)^{-\frac{1}{2n}} - 1\right]}{C \cdot \left(\Delta K_{ij,eff}\right)^n} \tag{10}$$

2.2.5 Failure criterion

The specimen is considered failing if any one of the following conditions is met: all cracks have separated its ligament (crack front approaches plate edge or the opposite hole edge or the distance between two approaching crack fronts is less than a small amount, such as 0.3mm (crack linking up)); or the average level of net section tensile stress has reached the yield strength of the material.

3. Finite element modeling technique.

3.1 FE model of fatigue crack growth

As the example to demonstrate the modeling technique of our software, consider a rectangular plate containing a central countersunk hole with both side corner cracks. As shown in Fig. 4, half-length model is used because of the symmetry of the specimen. The solid model is divided into three parts by two parallel cross sectional planes. The part including the hole is part 1 and the one next is part 2. Part 1 is re-divided into two blocks so that each crack belongs to a single block. Crack front curves are assumed quadratic. Two narrow volumes with rectangular cross section are created along each crack front (Fig. 5). A narrow volume is the crack front body used to build the mesh locally to the crack front.

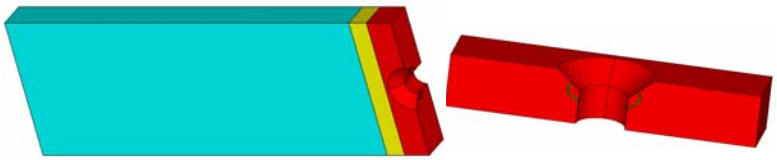

Figure 4. Model divisions

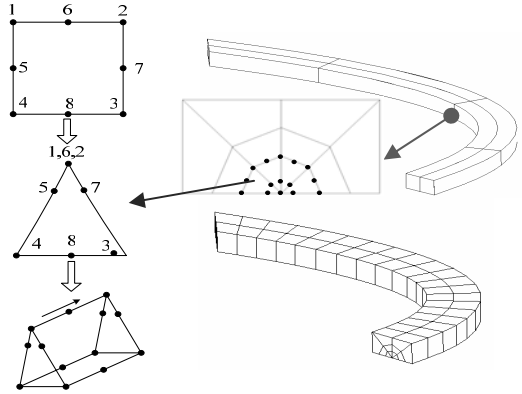

Figure 5. Finite element mesh for crack tip volumes

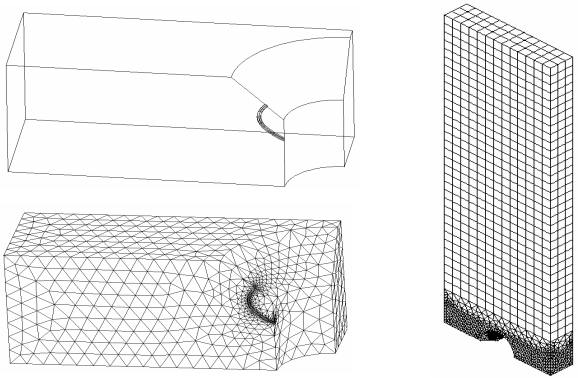

Figure 6. Finite element mesh

Cut each crack front body with three planes normal to the crack front curve, one in the middle and two others close to both ends of the body. We first mesh the cross sectional area created by the middle plane with eight-node isotropic 2D elements in which the four elements around crack tip are converted to the 8-node triangular elements by collapsing the three nodes on one of the four edges of each element to crack tip, and the mid nodes on the edges adjoining to crack tip have been moved toward crack tip to the quarter length position to produce crack tip singularity. We then sweep the area mesh both ways along the crack front to create the 3D mesh of the crack front body. The rest volume of part 1 is modeled by tetrahedron 3D elements. Part 3 is built with twenty nodes 3D elements. Part 2 is the transitional volume between part1 and part 3 and is modeled by tetrahedron 3D elements. Meshing details are shown in figure 5 and figure 6.

3.2 Considerations for the crack geometry change during remeshing

With the use of APDL language and the technique described in section 3.1, it is easy to accomplish

remeshing for the crack configuration shown in Figure 3. Nevertheless, the remeshing will fail when one of the crack front curve ends is moving across a vertex of the cross sectional area, because of the element distortion. So, “transitional zones” are specified around those vertexes for different crack scenarios, as shown in Figure 7. The radius of a transit zone is about 5~6 times of the crack tip element size (fixed as 0.2mm in our tool). If one of the crack front ends has just entered the transit zone, user defined crack front will be instead.

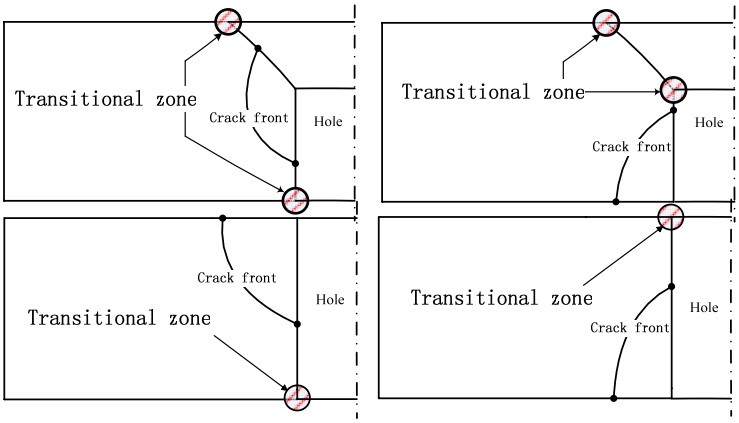

Figure 7. The transitional zones for different corner cracks from hole side

As example, corner cracks have initiated from a countersunk hole (Figure 8). There are two conditions for a crack front curve end moving across the vertex: before and after crossing. If a crack front curve end has moved in the transitional zone and has not cross the vertex, we bring the end back to the intersection point of the model boundary and the transitional zone. But the increment calculated in this step is stored and added to next step of calculation until the crack cross the vertex. In another condition that the end has passed the vertex but is still within the transitional zone, we move the end forward to the intersection point of the model boundary and the transitional zone. The two procedures make it possible to avoid element distortion and program crushing down. Simulation results shown in Figure 9 reveal that the procedures have only disturbed the form of a-n curve a little locally and not fundamentally affected the curve.

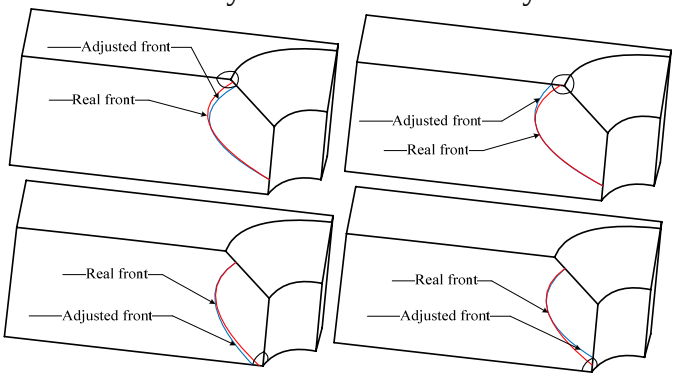

Figure 8. Crack adjustment when crossing a vertex.

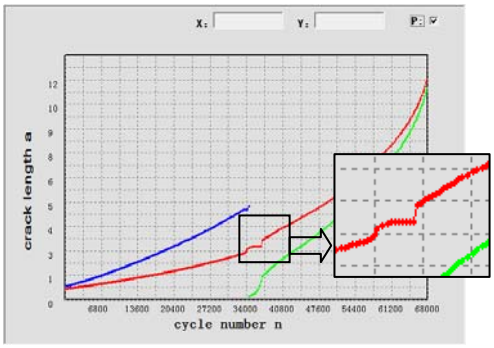

Figure 9. The effect of transitional zone treatment on a-n curves

4 User interfaces of the software.

4.1 Data preparation for the crack growth simulation.

Figure 10 shows the main interface of our software. There are two areas on the interface: the menu tree (area ①) and the operation area (area ②). Buttons for selecting models are listed on the menu tree on the left side of the interface and submenu belonging to each model can be unfolded by click on the corresponding button. The corresponding functions are then displayed on the operation area.

Parameters list on the operation area need to be input correctly. Explanations to the parameters are illstrated on the schematic diagrams at right hand side of the area.

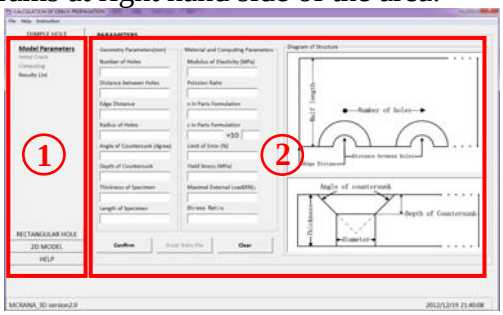

Figure 10. Main interface

Initial cracks are defined by inputing the parameterized sizes for each crack, as shown in Fig. 11. Two possible sites of crack initialization are indicated and each crack is quantified by three crack size parameters. For countersunk holes, crack located at countersink edge when the value of AL3(AR3) is zero and at the right angle edge when the value of AL1(AR1) is zero. Similarly, upper edge and bottom edge respectively for round through holes. All the three parameters for a crack are set to zero if it does not exist. Up to ten cracks are allowed in the software. A couple of crack growth equations are available. During execution, the real-time display of crack pattern can be observed on the computing window shown in Fig. 12.

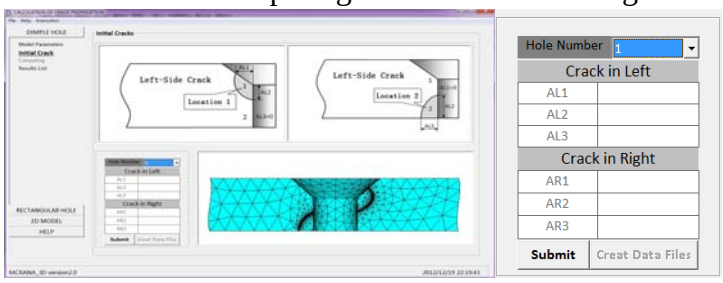

Figure 11. Interface for setting initial cracks.

Figure 12. Computing interface

4.2 Result Lists

Results are displayed in the form of data tables and curve graphs: data of parameterized crack sizes, stress intensity factors at sampling points, curves of crack sizes vs. load cycles and curves of stress intensity factors vs. crack sizes. All the data and curves can be saved as data files or image files. Figure 13 shows the examples of result display.

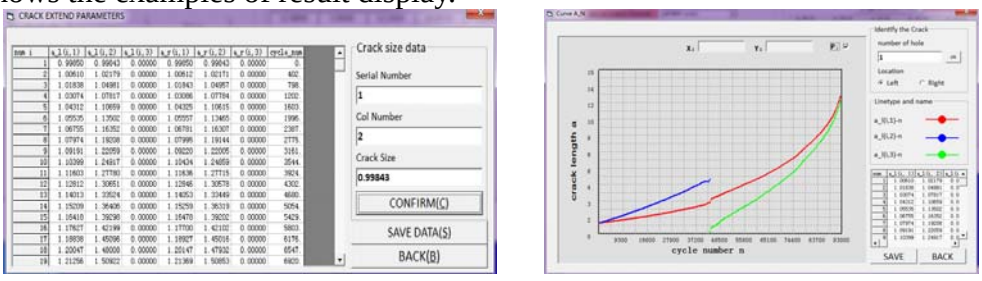

Figure 13. Two of the four interfaces of results representation

5. Simulation examples

5.1 Specimens.

Test has been carried out for the specimen with central countersunk hole, as shown in Fig. 14.

Material of the specimen is 2324-T39. The tensile strength is 8.6Mpa and the yield stress is 448MPa. The Paris law constants for 2324-T39 are $C = 2.74284\times10^{-7}$ and n=2.5269, with the units of ΔK in $\mathrm{MPa}\sqrt{\mathrm{mm}}$ and da/dN in mm/cycle.

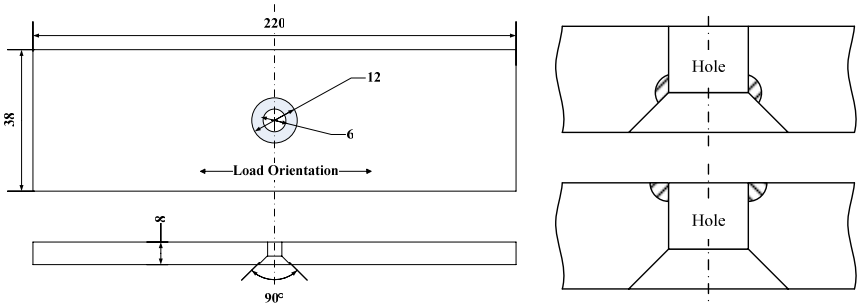

Figure 14. Specimen with a central hole and location of initial cracks.

There are two scenarios of initial cracks. Scenario 1 is double side sector-shape corner cracks from the edge of the countersunk and round through hole. Scenario 2 is the double side quarter disk corner cracks from the edge of the through-hole and back surface. The sizes of the initial cracks are listed in Table.1. The sizes of both side initial cracks are unequal for both scenarios.

Table.1 Sizes of initial cracks

Crack sizes	AL1	AL2	AL3	AR1	AR2	AR3
Model1	0.809	1.05	0	0．85	0.90	0
Model2	0	0.75	0.567	0	0.66	0.614

Constant amplitude tensile cyclic load was applied. The peak load is 26KN and the stress ratio is 0.06.

5.2 Simulation results.

Two crack growth models were used in simulation: Paris law and AFGROW model with $C_{f0} = 0.2$. Analysis was made throughout the total life of crack propagation: corner cracks - partially through the thickness cracks - fully through cracks - final failure. Figure 15 gives the testing and predicted crack growth curves for scenario 1. Figure 16 shows the images of crack growth for the scenario during the simulation. Similar results for the scenario 2 are given in Figures 17 and 18. Table 2 gives the test results and predictions for the fatigue crack growth lives. The results indicate that the software tool works well and the simulation of the Paris law is quite conservative, while the AFGROW model gives more satisfactory estimation.

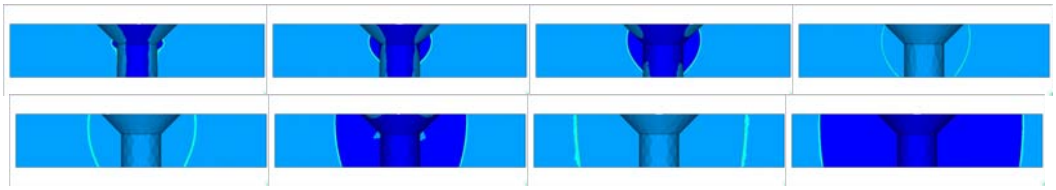

Figure 16. Images of crack growth of scenario 1

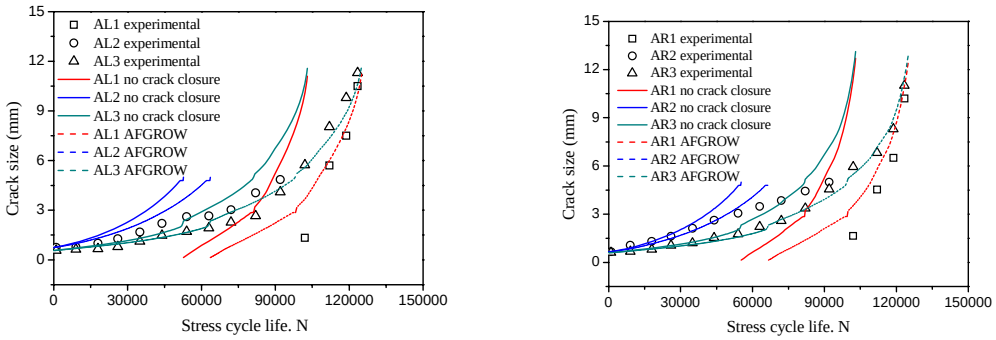

(b) (b)

Figure 17. Crack growth curves of scenario 2
(a). Left crack (b). Right crack

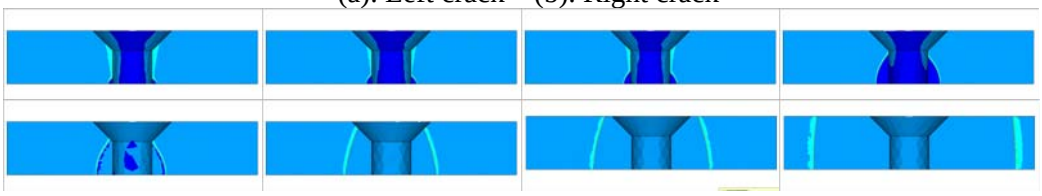

Figure 18. Images of crack growth of scenario 2

Table.2 Test and simulated results

	Crack location	Test life	No crack closure	AFGROW model
Scenario 1	countersunk side	85688	68587	81733
Scenario 2	rear side	123397	103027	125054

Further development of the tool involves extending the model type to the mechanically fastened joints through the consideration of fastener-hole contact.

6. Conclusions

A software tool has been developed using the ANSYS APDL and Visual Basic programming languages to simulate the multiple crack growth. This tool is capable of modeling metallic plate with coplanar countersunk holes or round through holes with different scenarios of multiple 3D cracks. 2D modeling function for through cracks is also available in our tool. Parameterized modeling is used to facilitate the pre-processing procedure. The Paris-form crack growth law and two crack closure models are included in the software. As the output of the execution, the lists of stress intensity factors and the curves of crack sizes vs. load cycles can be obtained. A useful function of our tool is the real-time visualization of the crack geometries during crack growth simulation. The results of example calculations indicate that the simulated crack growth behavior and fatigue growth lives agree well with the experimental results.

Residual Stresses Induced by Surface Enhancement Processes

Yukui Gao*, Zheng Zhong

Abstract The residual stress field caused by shot peening, hole cold expansion, laser shock peening and ultrosonic peening were presented and the influence of residual stresses on fatigue properties were investigated. The results show that shot peening can enhance the fatigue property, especially for high strength alloys. Moreover, hole cold expansion can increase the fatigue strength more than shot peening due to deeper residual compressive stress fields in surface strained layer and smoother surface. Laser shock peening and ultrasonic peening are the high intensity peening processes and can induce both the deeper residual compressive stress layer and the fine microstructure in surface strained layer, therefore they should have more important engineering applications in future.

Keywords residual stress, shot peening, hole cold expansion, laser shock peening, X-ray diffraction

1. Introduction

The weight objectives and aggressive performance are driving components made of advanced high strength materials and manufactured by some special surface enhancement processes to induce compressive residual stress. There are many surface enhancement processes that can introduce beneficial residual stress and improve fatigue property in localized, but critical areas. Shot peening is used on components of almost any shape due to its flexibility. Hole cold expansion is mainly employed to increase the fatigue strength and prolong fatigue life of parts with holes. Laser shock peening (also called as laser peening or shot peening) was originally developed in aeronautical industry to increase the resistance of foreign object damage (FOD) of blades, and then was employed to improve fatigue property of components with or without FOD and corrosion resistance of engine key parts (for example blisks and obturating ring). Ultrasonic peening was used to induce compressive residual stress and get fine microstructure in welded components.

Residual stress is stress present in a structure or component without any external load or any external moment and keeps itself balance. Residual compressive stress always occurs with residual tensile stress. The significance of residual stresses for fatigue is important in various practical problems. Unintentional tensile residual stress can have an adverse effect on fatigue performance, while beneficial compressive residual stress can significantly improve fatigue resistance.

Fatigue cracks generally starts at the free surfaces of components. As a consequence, the surface conditions are most significant for the fatigue behavior of a structure [1-4]. Surface enhancement to improve the fatigue resistance was developed a long time ago and now is still developing toward the high energy, deep surface layer, and complex treatments. Surface integrity is defined as surface conditions and functions for perfect or enhanced component surface and residual stress is the main aspect of surface integrity. Surface enhancement processes improve the fatigue property, stress corrosion cracking resistance and wear mainly by modifying surface integrity. Residual stress plays the important role in increase the resistance of fatigue and stress corrosion cracking.

There are many investigations on measurements and simulations of residual stresses and the role of residual stresses on fatigue crack initiation and propagation behaviors, while there are few quantitative studies on residual stress effects on fatigue strength/limits or fatigue life. Many scientific questions are not well answered and some phenomena cannot be reasonably explained. It is well known that fatigue crack usually starts subsurface where maximum tensile residual stress is for the surface enhanced specimens and fatigue strength is increased, then why can residual tensile stress improve fatigue resistance? Therefore, we should consider the influence of residual stresses on fatigue property in the view of both mechanics and materials science or other theories.

This paper focus on residual stress fields induced by surface enhancement processes and gives a brief review on the role of residual stress in the fatigue crack initiation and propagation behavior based on our many investigations.

2. Residual stress field characteristics and its effects on fatigue property for surface enhanced specimens

2.1. Residual stress field features induced by surface enhancement processes

It is important to obtain the residual stress field features before analyzing the effects of residual stress on fatigue performance. Many surface enhancement processes induce compressive residual stress in surface layer by elastic-plastic deformation, so the residual stress distribution in a material is often as a result of the retained strain of inhomogeneous plastic deformation. It should be pointed out residual stresses discussed here occur just on the macroscale. On a much smaller scale, another kind of residual stress can be present. It is well known that plastic deformation on a microscale is not a homogenous process and mainly induced by dislocation slips or twins or kinks which depend on deformation strain and strain rate as well as the tested material. Therefore, it is different from grain to grain, and even inside a single grain, the plastic deformation may be just concentrated into a few slip bands. The microresidual stresses are significant for explaining fatigue mechanism although it is not easy to obtain the precise and accurate values unless the deformation mechanism is clear. The characteristics of residual stress field induced by surface enhancement processes were briefly described as follows.

(1) Shot peening

Shot peening is a well-known process to introduce favorable residual stresses at the material surface of a component. This process plastically stretches the surface layer of a material and the elastic substrate material restrains this plastic deformed surface layer, therefore, residual stresses are induced. A typical residual stress field caused by shot peening is illustrated in Figure 1 and some parameters were proposed to analyze the characteristics of residual stress field by shot peening.

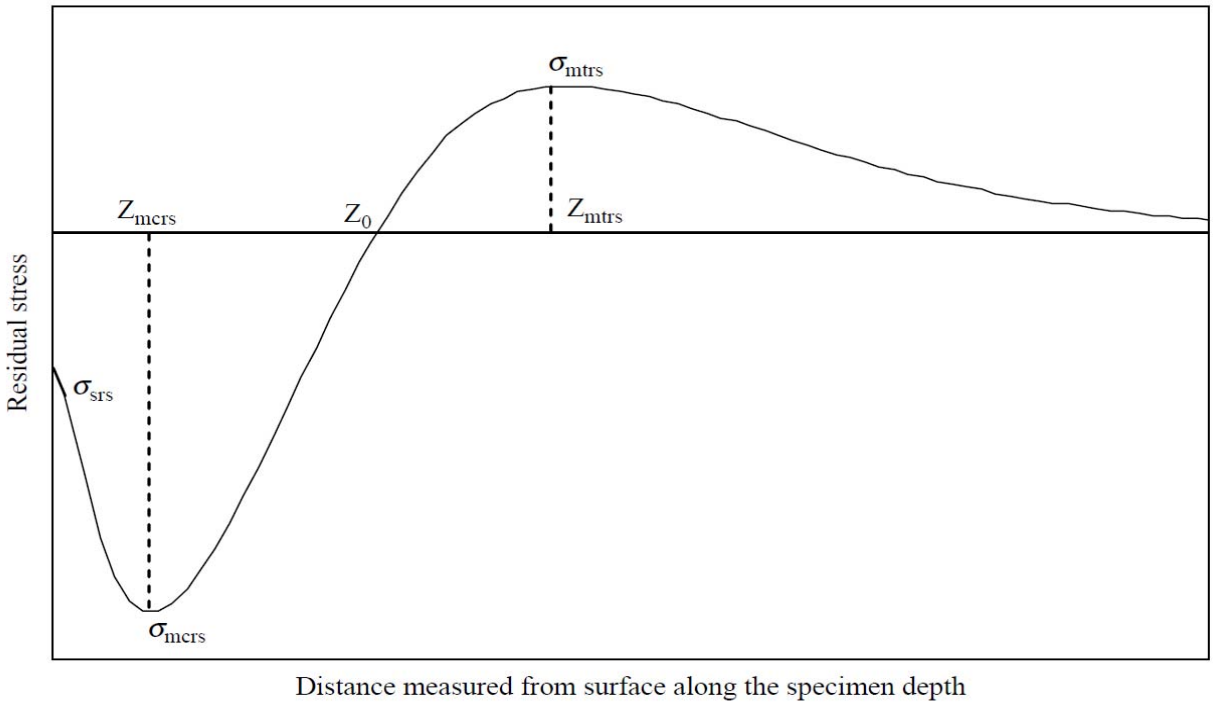

Fig. 1 Schematic residual stress field caused by shot peening

There are six parameters to show the residual stress distribution shown as in the Figure 1. σ_{srs} is the residual stress at the surface or call it as surface residual stress. σ_{mcrs} is the maximum compressive residual stress and its value is often more than half yield strength even in some cases near the yield strength for fcc crystalline metals but it is usually near the surface in the most cases. σ_{mtrs} is the maximum tensile residual stress its value is the order of tenth to half of the value of σ_{mcrs}, this

depends on the thickness of specimens. Z_{mcrs} is the distance from surface where compressive residual stress is the maximum. Z_0 is the depth where residual stress becomes zero and beneath where residual stress will change from compressive to tensile. Z_{mtrs} is the distance from surface where tensile stress is the maximum one. The values of these parameters are related to shot peening process parameters (such as shot peening intensity, surface coverage, shot's size and hardness etc.) and the peened material. The relationship of the values of these parameters to process parameters and material's property is given in the references [5, 6].

(2) Hole cold expansion

Hole cold expansion has been developed to increase fatigue resistance of components with holes. The hole is firstly drilled to a slightly undersized one which is a few percent smaller than the design size. Then a tapered pin or a split sleeve over a mandrel pulled through the hole to expand material around hole. As a result, plastic deformation occurs and the plastic zone has been stretched tangentially because it pushed outwards in the radial direction. The plastic zone has a larger diameter than before and the elastically strained material around this plastic zone will exert a pressure on the plastic zone, therefore tangential compressive stresses around the hole are introduced. The values of residual stress depend on the interference of hole to the tapered pin or the thickness of split sleeve over mandrel as well as the cold expanded material. A typical residual stress distribution along the cold expanded hole is given in Figure 2 [7].

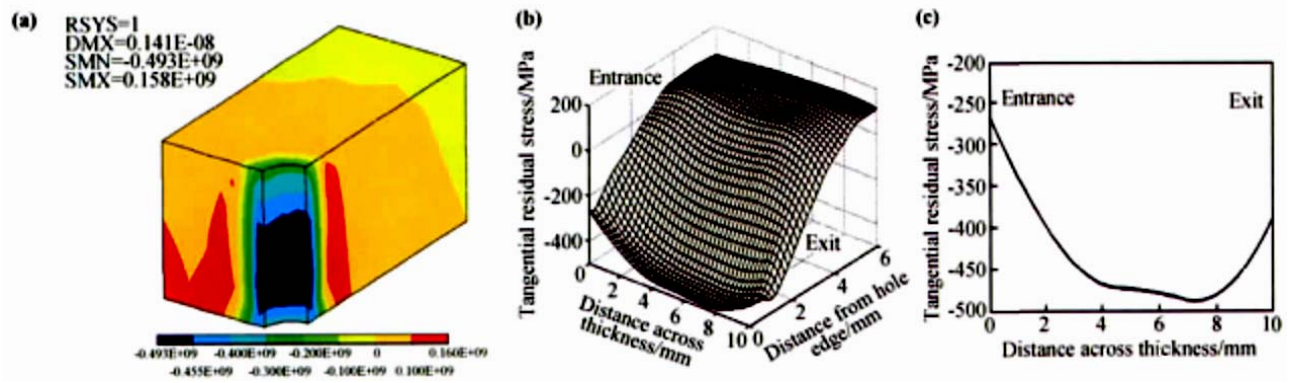

Fig.2 Tangential residual stress distribution of hole cold expanded 7050-T7451 aluminum alloy in (a) the whole component, (b) smallest cross-section plane and (c) hole edge along thickness [7]

The maximum compressive residual stress is not at the upper entrance surface or lower exit surface but the middle surface near exit surface. Moreover, the residual stress at entrance surface is less than one at the exit surface. Therefore, the 2-D residual stress could result in significantly under or overestimating fatigue life.

(3) Laser shock peening

Laser shock peening exposes the surface of a workpiece to laser pulses with pulse duration in the nanosecond range and obtains a modified surface layer on the order of millimeters. A typical residual stress distribution caused by laser shock peening is shown in Figure 3. The values of residual stresses depend on process parameters and peened material. The main parameters are pulsed energy, pulsed times and pulse duration. The mechanisms of deformation which occur in plastic shock wave deformation are highly dependent on the strain rate. It is well known that twin formation becomes particularly relevant as strain rate grows. Deformation is strongly determined by stacking fault energy, which constitutes a measure of the probability of cross slip of screw dislocations. Moreover, it is should be noted that any kind of thermal manipulation must be avoided; otherwise it will induce tensile residual stress. Consequently, the absorption layer must be thick enough to prevent thermal effects on the workpiece itself, and particularly in cases of overlapping irradiation, the absorbing layer should not have sustained damage that may result in thermal effects on the workpiece during the final irradiation. There are some differences in the values of residual stresses for different pulse times for easy plastic-deformation alloy as shown in Figure 3.

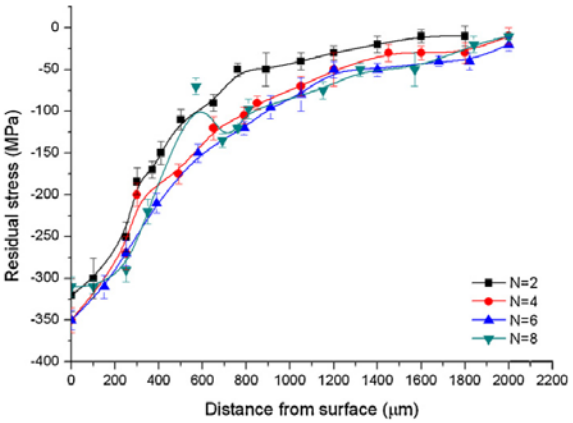

Fig.3 Residual stresses caused by laser shock peening in 7050-T7451 aluminum alloy [8]

(4) Ultrasonic peening

Ultrasonic peening induces deeper residual stress surface layer than conventional shot peening [9], as illustrated in Figure 4. Compared with shot peening, the value of surface residual stress for ultrasonic peened specimens is almost same as shot-peened one, while the maximum residual stresses of compressive and tensile are larger than shot-peened ones.

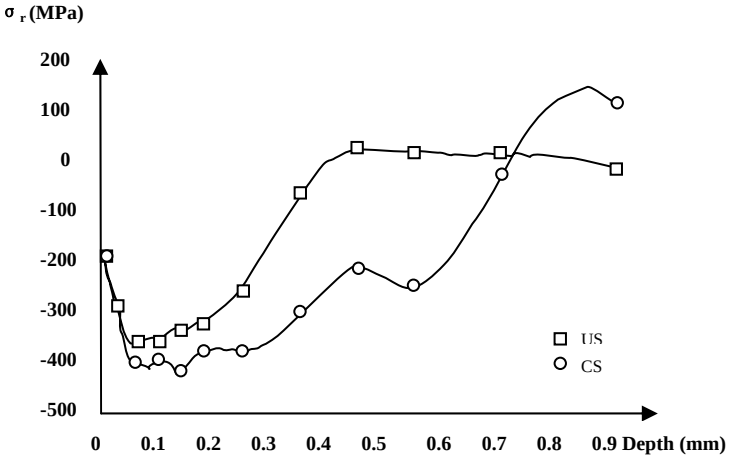

Fig.4 In-depth profile of residual stress in 2014-T6 aluminum alloy produced by conventional shot peening (CS) and ultrasonic peening (US) [9]

2.2. Effects of residual stress on fatigue crack initiation behavior

There are many investigations on residual stress on fatigue performance, and now we just provide some results of our studies. The rotating bending fatigue tests (stress ratio R=-1) were conducted for some aeronautical metallic materials including high strength steels, aluminum alloys, and titanium alloys. A total of 20 specimens were tested as a group to determine the fatigue strengths/limits for each alloy at 1×10^7 cycles by staircase method [10]. The experimental results are shown in Table 1. The apparent or nominal fatigue strength or limit, σ_{app}, is determined by the applied stress range, σ_a, for rotating bending fatigue tests. The local strength or limit, σ_{loc}, is calculated as the critical stress for fatigue crack initiation by combing the local applied stress, σ_{locapp}, with the local residual stress, σ_{locrs}, that is $\sigma_{loc} = \sigma_{locapp} + \sigma_{locrs}$. Moreover, the effect of surface enhancement is illustrated in the fatigue strengthens/limits increase of surface-enhanced specimens compared with unenhanced ones by as given in Table 1. The fatigue crack sources were determined by scanning electron microscope (SEM) and the locations of fatigue crack sources were determined by the distance from surface [11]. Some typical fatigue crack sources are shown in Figure 5. The fatigue crack sources always locate at the surface for unenhanced specimens, whereas for those surface-enhanced ones,

they are located beneath the surface-enhanced layer where residual stress is tensile.

Table 1 Rotating bending fatigue strengths/limits of high strength aeronautical structural materials

2.3. Influence of residual stress on fatigue crack propagation performance

The effect of shot peening on small crack growth was investigated in a 7475-T7351 aluminum alloy [12]. A single edge notch tensile specimen was employed and the notches were shot peened. Small crack growth fatigue testing was performed in an MTS fatigue tester using constant amplitude loading (stress ratio R=0.06 and maximum stress σ_{max} =160MPa) in a frequency of 10Hz at room temperature under laboratory air conditions. The plastic replica method was used to record small crack data at the notch root. To acquire accurate small crack lengths, acetyl cellulose plastic replicas (often called AC paper) were employed to monitor the small crack length as a function of the number of load cycles. Stress intensity factors for small cracks subjected both to external loads and to shot peening induced residual stresses were determined using weight function methods [12, 13]. The fatigue small crack growth rate was analyzed by FASTRAN software [14] and the crack propagation behavior of unpeened and shot-peened specimens is shown in Figure 6 and Figure 7, respectively.

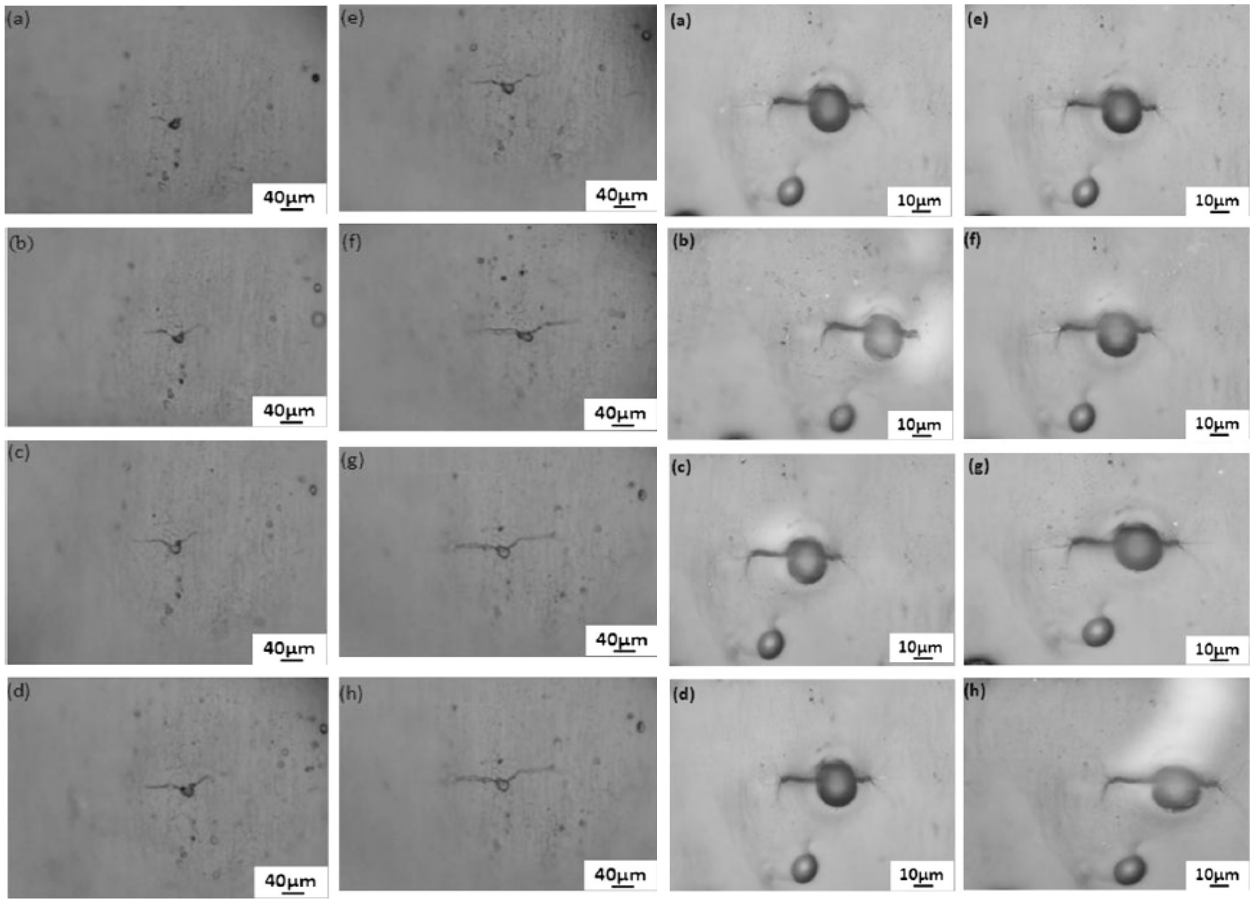

Fig.6 Replica SEM images showing small crack growth in an unpeened specimen of 7475-T7351 aluminum alloy for N cyles: (a) N=3000, (b)N= 6000, (c) N=9000, (d) N=10000, (e) N=11000, (f)N=13000, (g) N=15000, (h) N=18000. Finial failure occurred at 28000 cycles.

Fig.7 Replica SEM images showing small crack growth in an peened specimen of 7475-T7351 aluminum alloy for N cyles: (a) N=6000, (b)N= 7000, (c) N=8000, (d) N=10000, (e)N=12000,(f) N=14000, (g) N=16000, (h) N=19000. Finial failure occurred at 84000 cycles.

Compared with unpeened specimens, the small crack growth rates are very much lower for shot peened specimens. It is obvious that the small crack growth will show lower curves rate than large one if the residual stress effect is not considered, while it is normal rate if the effect of residual stress is considered, as shown in Figure 8. Therefore, the influence of residual stress on fatigue crack propagation behaviors or growth rates should be considered.

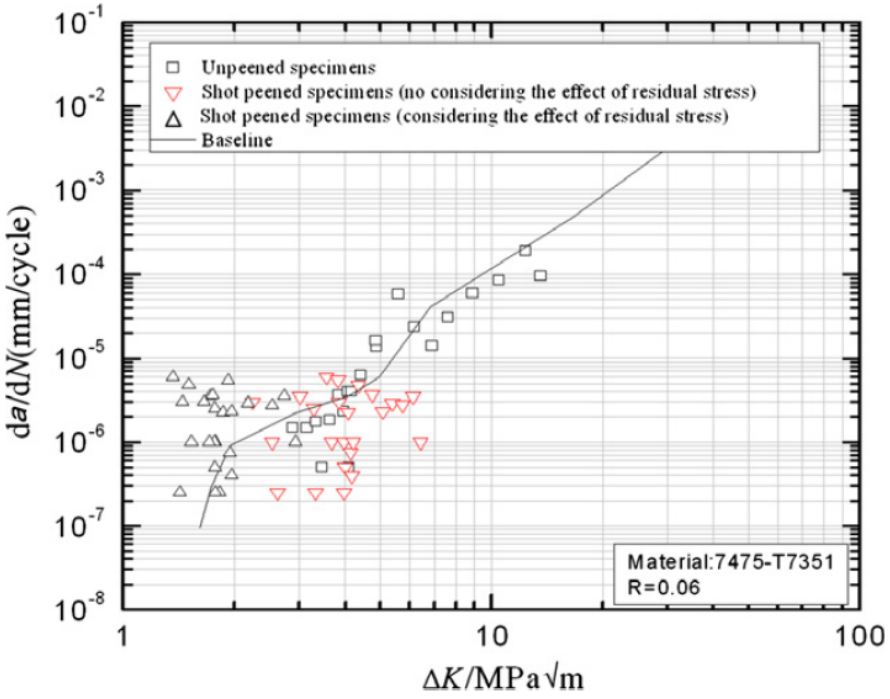

Fig.8 da/dN-△K curves for 7475-T7351 aluminum alloy

3. Conclusions and Recommendations

Residual stress has a significant effect on fatigue, stress corrosion cracking and other fracture performances. The residual stress distribution should be investigated quantitatively by experimental measurements or simulations and obtain the three dimensional characteristics.

(1) Surface enhancement processes introduce compressive residual stresses in surface layer and there are some parameters to describe the features of residual stress fields caused by surface enhancement treatments.

(2) Compressive residual stress can be measured by X-ray diffraction or neutron scatting and simulated by finite element methods or boundary element methods, therefore its effects on fatigue and fracture can be analyzed quantitatively.

(3) The fatigue crack can be initiated beneath compressive residual stress filed for surface enhanced specimens and the effect of residual stress should be considered both in the view of mechanics and materials science. Fatigue strengths/limits are increased by compressive residual stresses and surface cold worked layer for surface enhanced specimens.

(4) Fatigue crack growth rate is lower in the compressive residual stress filed for surface enhanced specimens compared to unenhanced ones; the effect of residual stress can be quantitatively analyzed by weight function methods and FASTRAN software.

Abstract This paper is devoted to the investigation of the shot-peening process using 3D finite element (FE) model of multiple impingement. In this analysis, we implement a novel ‘‘symmetry cell’’ approach to examine the impact effect of a large number of rigid and deformable shots on a high-strength steel target made from AISI 4340. Dynamic elasto-plastic simulations were conducted using a rate sensitive material model. A number of convergence tests, which account for element size and stiffness of contact elements, were carried out. In addition, efforts were devoted to determine the appropriate material damping parameters needed to dampen unwanted numerical oscillations associated with the explicit solver of LS-DYNA for this class of problems. The model was used to predict the effect of peening coverage upon the mechanically induced residual stress field for rate sensitive materials under multiple and repeated impacts.

Keywords Shot-peening, Multiple impacts, Residual stress, Finite elements, Rate sensitive

1. Introduction

Shot-peening is a cold-working process accomplished by bombarding the surface of the component with small spherical shots made of hardened cast-steel, conditioned cut-wire, glass or ceramic beads at a relatively high impingement velocity (40–70 m/s). It is used mainly to improve the fatigue life of metallic components [1]. During impingement, a plastic indentation surrounded by an elastic zone is formed. After contact between the shot and the target has ceased, the elastically stressed region tends to recover to the fully unloaded state, while the plastically deformed region sustains some permanent deformation. This inhomogeneous elasto-plastic deformation results in the development of a compressive residual stress field in the exposed upper most layers. To maintain equilibrium in the peened component, a tensile residual stress field is developed in the depth of the component. The mechanically induced surface compressive residual stresses have been found to be highly effective in enhancing the fatigue resistance of critical load bearing components.

The effectiveness of the peening treatment depends, to a large measure, on the peening intensity and the peening coverage. Peening intensity is a measure of the consistency of the treatment and of the plastic dissipation of the impinging shots. Peening coverage, on the other hand, is a measure of the obliteration of the original surface texture and can be defined as the ratio of the area covered by peening indentations to the total exposed surface area. Intensity and coverage depend on numerous variables, including work-piece characteristics, shot characteristics, flow conditions, stand-off distance and exposure time.

Direct residual stress measurements inside the compressed layer are expensive, time consuming, and requires the use of semi-destructive methods. Therefore, the modelling of the shot-peening process has received increasing attention from the scientific community. Several issues have emerged and received extensive investigations about modelling and simulations of multiple impact collisions. The first is concerned with the use of static or dynamic analysis to treat the peening process. Several contributions were made using quasi-static analysis [2-5]. However, some investigations [6-8] have shown that the indentation shape and residual stress distribution caused by static compression are different from those caused by dynamic impact. For example, according to

Kobayashi et al. [8], tensile residual stresses were developed at the centre of the indentation as a result of dynamic impact, while the residual stress caused by static compression is approximately zero at the centre of indentation. Therefore, more realistic approach must be considered to analyze the impact-related phenomena caused by shot-peening. The dynamic modelling of a single shot was initially conducted by Johnson [9] using a pseudodynamic approach, in which only the inertial properties of the shot was taken into account. More work used explicit solvers to model the dynamic process. This includes the contributions made by Klemenz et al. [10], Gariépy et al. [11] etc.

The second issue of simulation is how to model the shot-peening process that involves a large number of impact events. Some authors investigated single or twin shot impacts. For example, Edberg et al. [12] carried out dynamic FE analysis of a single shot on both viscoplastic and isotropic elasto-plastic targets. More and Kulkarni [13], Hong et al. [14] investigated the residual stress patterns from a single shot simulation. Meguid et al. [15,16] examined the effects of shot and target parameters upon the plastic zone development and induced residual stresses from both single and twin shot impacts. Despite the importance of the analysis of single and twin shot impacts to the understanding of the phenomena involved, modelling of the entire peening process should lead to more accurate results. Schiffner and Helling [17] used a simplified approach to model quasi-static target behaviour using time-dependent load functions obtained from the dynamic axisymmetric FE analysis of the impact of a single spherical shot. Their results showed that the influence of adjacent shots cannot be ignored. Meguid et al. [18] developed an enhanced symmetry cell to describe the high-density multiple impacts, and compared the predicted average residual stresses inside the target to experimental measurements using the holedrilling technique. Recently, Mylonas and Labeas [19], Sheng et al. [20] carried out 3D analysis implementing a large number of random shots. Kim et al. [21] investigated the residual stress for multiple shots at oblique impinging angles.

Another issue is to model the effect of the highly localized strain rates involved in the shot-peening process during impingement and rebounding of the jet stream. Some work modeled the target as rate insensitive materials [12,14,16]. However, for many real materials, dynamic analysis accounting for both inertia and rate effects would be essential. Meguid et al. [18] showed that using rate insensitive and rate sensitive material models would lead to different residual stress and plastic strain distributions. Strain rate dependent material was then used to model the target in the work by Kim el al. [21]. In this paper, we provide a 3D FE analysis of shot-peening process using a multiple impingement model for strain-rate sensitive targets and rigid shots. The residual stress distribution was analyzed and the effect of the peening coverage was investigated.

2. Finite element modelling

2.1. Configuration and boundary condition

The investigated situation is that a large number of identical shots impinge a metallic target at normal incidence. In this case, the effect of the boundary of the target can be considered negligible at the centre of the area examined. This has led us to the use of a symmetry cell, which would reduce the modelling considerably. The dimensions of the proposed symmetry cell are $C \times C \times H$, where C is the distance between adjacent shots in one row and H is the cell height, as outlined in Figure 1. The selected cell depth should be large enough to prevent interference from the boundary, while be small enough to maintain reasonable computational time. The single and twin shot impact

results published earlier in Refs. [14,16] indicate that a height no smaller than 4*R* is suitable for the different shot velocities examined in these papers. Here *R* is the shot radius taken as 1.0 mm. For the current multiple-indentation problem $H = 4R$. The distance *C* can be changed to get different peening intensity.

Symmetry boundary conditions were used at the four side faces of the cell. In addition, all displacements of the cell bottom were restrained. To provide a greater degree of accuracy, full eight-node integration was used. The mesh near the impinging locations was refined. All shots were identically modelled as rigid body discretized using eight-node brick elements with a coarser mesh density. Convergence tests were conducted using different meshes. The convergence test results indicated that the mesh depicted in Figure 1(b) was capable of representing the peening process in a cost-effective manner, as measured by the marginal difference in the maximum residual stress results. Accordingly, this mesh was used for the remainder of the study.

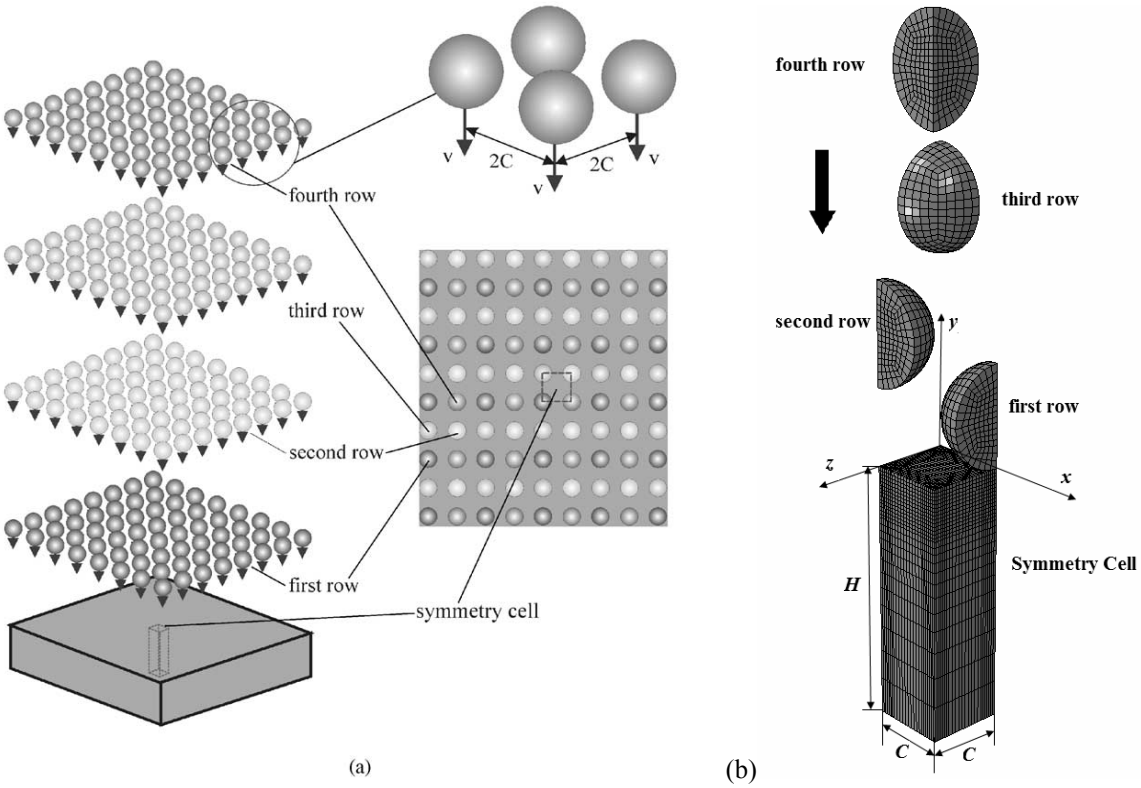

Figure 1. FE multiple impingement model: (a) full model, and (b) discretised symmetry cell.

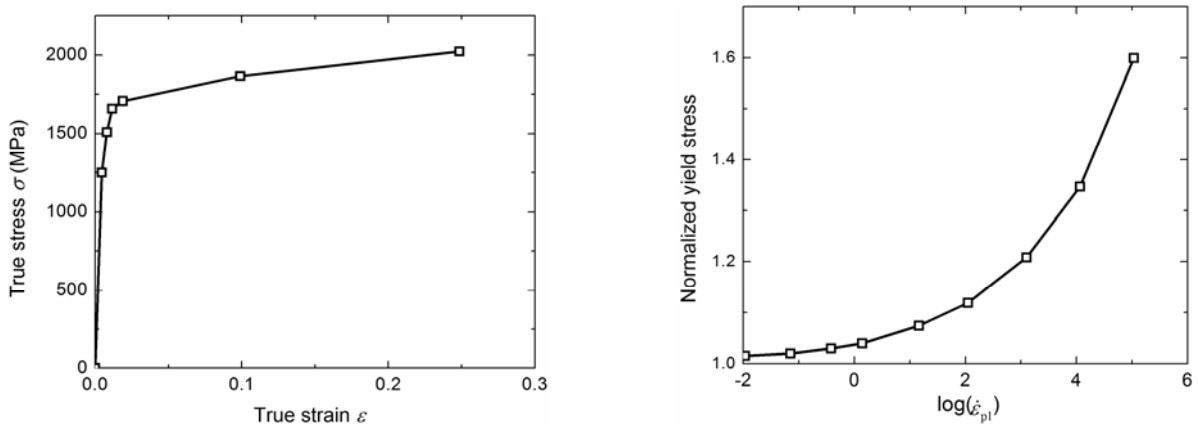
2.2. Material models

The material of the target was high-strength steel AISI 4340 with density of 7850 kg/m3, which is widely used for shot-peening applications [14,16,18]. A bilinear isotropic hardening elasto-plastic constitutive law was used to model AISI 4340 with Young's modulus of 205 GPa and Poisson's ratio of 0.25 [22]. The strain-rate sensitivity was accounted for by using the data developed by Premack and Douglas [22], since they appear to be more reliable and cover a wider range of strain-rate values which are comparable to those observed in shot-peening (up to 10^5 1/s). These data are incorporated in the FE model by scaling the quasi-static stress–strain curve for different strain rates according to [22]. The shots were made of high carbon steel with the density assumed as being 7850 kg/m3.



(a) (b)

Figure 2. Stress–strain relationship for AISI 4340 steel [22]: (a) quasi-static uniaxial stress–strain curve, and (b) the normalised effective yield stress accounting for strain-rate sensitivity.

2.3. Simulation procedure

The peening treatment of the cell was simulated by the impingement of rows of identical shots with a symmetric layout inside each row. These rows are further combined in series of four rows each. To achieve higher peening coverage, each subsequent row in the series is shifted laterally so that the shots in this row impinge different areas of the target symmetry cell as shown in Figure 1. To achieve higher peening intensity, several series of shot rows were used to impact the cell. A total of four series was used, which brings the total number of shot rows to 16.

The 16 shots were impinging to the target surface of the symmetry cell one by one as shown in Figure 1(b). The impinging velocity was unanimously chosen as 75 m/s in this study. A time interval of 10 ms was chosen between subsequent impacts. It is necessary to introduce material damping in order to prevent unnecessary long post-impact residual oscillations. If these oscillations are not reduced significantly prior to the following impingement taking place, they could accumulate leading to numerical instability. However, care must be taken so that the introduction of this damping should not disturb the solution. The material damping was introduced as being Eq. (1).

$$D = \alpha M + \beta K \,, \tag{1}$$

Where D, M and K are the damping, mass and stiffness matrices, respectively. As a result of a number of trial runs, it was determined that effective damping can be achieved using a stiffness proportional damping coefficient β = 2 x 10^{-9} s. To obtain reliable values of mass proportional damping α the following approach was adopted. For the given symmetry cell, the minimal modal frequency ω_0 could be estimated as in Eq. (2).

$$\omega_0 = \frac{1}{H}\sqrt{\frac{2E}{\rho}} \,, \tag{2}$$

Where E is the target Young's modulus, ρ is its density and H is the height of the symmetry cell. The mass proportional damping is then determined as in Eq. (3).

$$\alpha = 2\omega_0 \xi \,, \tag{3}$$

Where ξ is the corresponding modal damping parameter. In this study, ξ was selected as 0 during the impact stage and changed to 0.5 between subsequent shot impacts to decay the unwanted low-frequency oscillations.

3. Results

The FE model was developed using the explicit commercial finite element code ANSYS/LS-DYNA version 13. In contrast to the single shot impact, the current model is capable of modelling the effect of peening coverage. This was achieved by varying the separation distance C between adjacent shots. Figure 3 shows the residual stress distribution along the target depth direction. The residual stress σ_{xx} is plotted versus the target depth at three locations A–A, B–B and C–C as indicated in Figure 3(a). Three normalized separation distances were investigated as shown in Figures 3(a)–(c), respectively for C/R=1, 1.5 and 2. The corresponding stress distribution beneath the centre-line after repeated impact of four subsequent shots that hit the target in the same place is also provided for comparison. The results show that multiple shot impacts lead to interaction between the unloading residual stress fields resulting from individual impacts. This interaction effects lead to a much more uniform distribution of residual stresses along the target surface and subsurface regions than the results of single and twin shot impact models. As expected, the decrease in the separation distance leads to a more uniform residual stress distribution across the target as can be seen from the smaller distinction between the three curves of different locations. This is attributed to stronger interaction between individual shot impacts. The average depth of the compressed layer increases with the decrease in the normalized separation distance. However, the maximum values of the compressive residual stress are comparable for all the three cases examined. For separation distance $C/R \geq 2$, the residual stress distributions beneath the shot corresponding to the multiple impingement model are very close to those of the repeated impact sequence of four coincident shots.

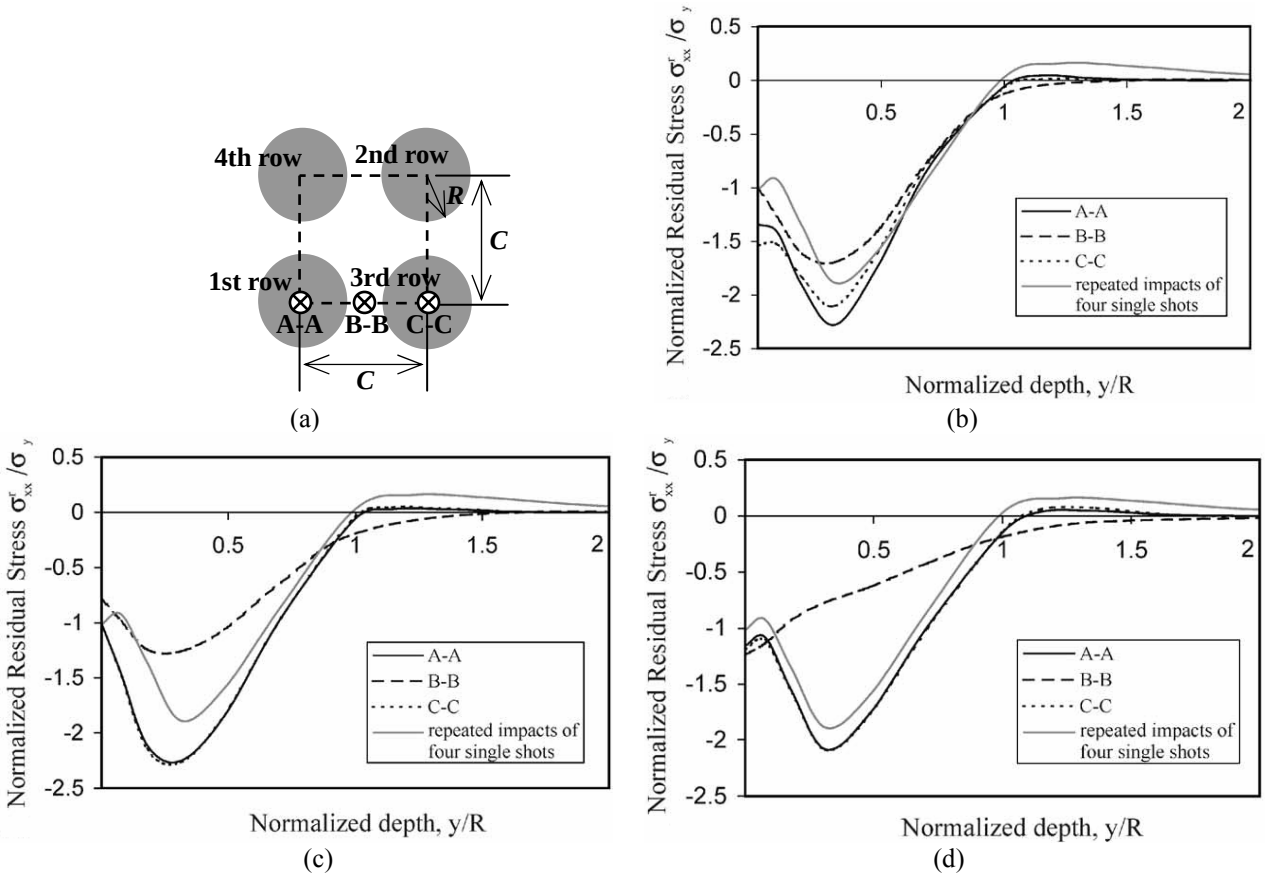


Figure 3. Effect of separation distance C/R upon residual stress distributions along target depth direction at three locations as indicated in (a) after rebound of fourth series (16 row) of shots: (b) C/R=1, (c) C/R=1.5, and (d) C/R=2. Also compared is the distribution along the center line for the case of four subsequent shots hitting the target at the same place.

4. Conclusions

A comprehensive 3D dynamic elasto-plastic finite element analysis was conducted to simulate the shot-peening process using rate sensitive targets, multiple and repeated impingements. The mechanically induced residual stress distributions were examined using a representative symmetry cell. It indicated that multiple shot impacts resulted in a more uniform residual stress at and immediately beneath the exposed surface layers compared to single and twin shot impacts. The separation distance between shots influences the residual stress field significantly. The decrease in separation distance leads to a more uniform residual stress distribution in the treated target. The average depth of the compressed layer increases with a decrease in the normalized separation distance C/R from 2 to 1. However, the maximum value of the compressive residual stress and plastic strain fields are comparable for all the three cases examined. For separation distances $C/R \geq 2$, the interaction between different shot impacts along the target surface are negligible.

Determination of Residual Stresses in Structural Elements Using Electron Speckle Interferometry Method

Leonid Lobanov*, Vyacheslav Pivtorak, Viktor Savitsky, Galina Tkachuk

E.O.Paton Electric Welding Institute, Kyiv, Ukraine
* Corresponding author: holo@paton.kiev.ua

Abstract Electron speckle-interferometry can be used in combination with hole drilling for an accurate determination of residual stresses (ESPI-HD method). Technology and compact equipment for efficient measurement of residual stresses based on ESPI-HD method have been described.

The computation method for calculation the values of stress tensor components based on surface displacements data has been suggested. Use of the ESPI-HD method allows increasing the accuracy of residual stress determination. High sensitivity of the instrumentation allows conducting investigations of the stressed state on a small base (0.5 mm) without loss of the experiment accuracy.

A special new approach to the conventional method of speckle-interferometry in order to investigate stress gradients over the surface of the test object has been added. The efficiency of application of the offered procedure for evaluation of the gradient of stresses is shown for investigation of residual stresses in welded structures.

Keywords residual stresses, electron speckle-inteferometry, hole-drilling method, welding

1. Introduction

In the production of the welded structures the high-strength steels and cast alloys find the more wide application. However, the serviceability and reliability of these materials depend greatly on the effect of residual stresses, the high level and the local gradient of which can lead to the initiation of cracks, reduction in corrosion resistance, etc. Therefore, the development of the reliable and informative methods of investigation of a stressed state in structures is important.

One of the most widely used methods for determination of residual stresses is the hole-drilling strain-gage method, in which a through-thickness or blind hole is made in the inspected point of the surface, and the strains, caused by unloading of the material volume during the residual stresses release, are measured in the vicinity of the hole. The values of these strains are subsequently used to calculate the main directions and appropriate values of the residual stresses.

The contactless methods, based on the laser interferometry for measuring the surface displacements, can overcome the difficulties, related to the bonding of the strain gauge arrays in the vicinity of the holes, and can also provide more information about the residual stress state of the object [1-3].

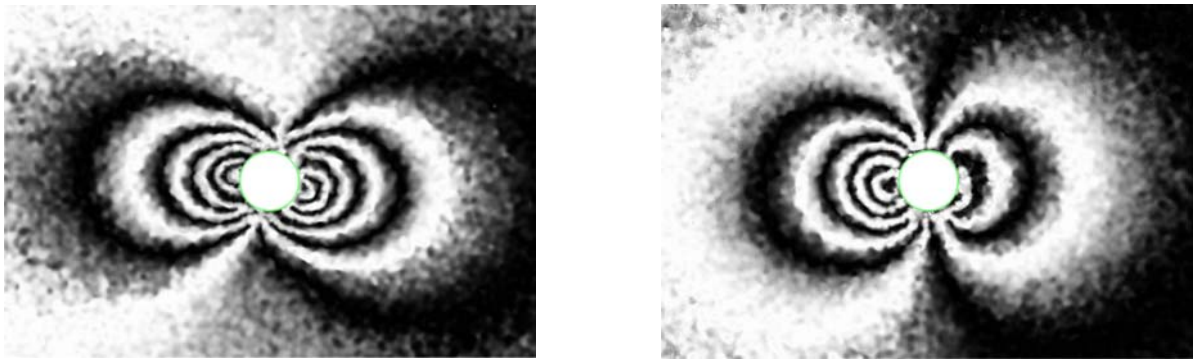
2. Determination of residual stresses by means of the ESPI-HD method

The electron speckle-interferometry (ESPI) in the combination with the hole-drilling can be used for fast and accurate determination of residual stresses [4, 5]. The speckle-interferometry method for determination of residual stresses is based on the application of the optical scheme of the interferometer in which the investigated section of the object is illuminated under the same angle

symmetrically from two directions, so that it is possible to determine the in-plane components of the displacement vector, which characterize the deformation of the object.

The displacements, caused by relaxation of residual stresses in the bulk material due to drilling of the blind holes, are measured using the ESPI method. The measurements are made in the following sequence [4]: the device is placed on the surface of the object. The reflected speckle-pattern, characterizing the initial condition before hole-drilling in the controlled section, is stored in the computer memory using a CCD-camera.

After unloading of the stresses due to drilling of a blind hole with the diameter and depth of approximately 0.4-1.0 mm, the reflected second speckle-pattern is also stored in the computer. After the computer processing of these two speckle-patterns, the monitor shows the interference fringes in the vicinity of the hole that contains the information about the displacements (Fig. 1).



a) b)

Figure 1. Typical fringe patterns in the vicinity of a drilled blind hole in a stressed material: a) symmetrical fringe pattern. The gradient of residual stresses over the surface on the base of the measurements is absent; b) non-symmetrical fringe pattern. The gradient of residual stresses over the surface is present

Based on the computer processing of the fringe patterns, the displacements in the irradiated area can be evaluated, as well as the residual stresses can be calculated.

The developed procedure provides the measurement with the help of the speckle-interferometry of a displacement component u_x at a constant distance from the hole center (for instance, $r = 2{,}5r_0$). In this case the dependence of the measured displacements u_x, resulting from relaxation of stresses σ_{xx}, σ_{yy} and τ_{xy} is expressed by the formula [3]:

$$u_x(\theta)=F(\theta)\,\sigma_{xx}+G(\theta)\,\sigma_{yy}+H(\theta)\,\tau_{xy} \qquad (1)$$

where $F(\theta)$, $G(\theta)$ and $H(\theta)$ are the functions, which depend on the mechanical properties of the material, the distance from the hole center and its diameter, angle θ determines the coordinates ($x = 2{,}5r_0\cos(\theta)$; $y = 2{,}5r_0\sin(\theta)$) of the point, where the displacement is measured.

Determination of residual stresses, using the offered procedure, is realized in the following stages:

- points at distance of $2.5r_0$ from the center of the drilled hole of the radius r_0 at the different angles θ relative to the axis of illumination are selected;
- displacements $u_x(\theta)$ at the chosen points are measured, using a speckle-interferometer;
- components σ_{xx}, σ_{yy} and τ_{xy} are calculated from Eq. 1, using the least squares method;
- values of principal stresses σ_1, σ_2 and principal angle are determined.

A small device, positioned directly on the surface of the investigated object (Fig. 2) has been designed for determination of residual stresses in the elements and sections of the structures. Software 'Fringe Editor' for automatic image processing has been developed (Fig. 3).

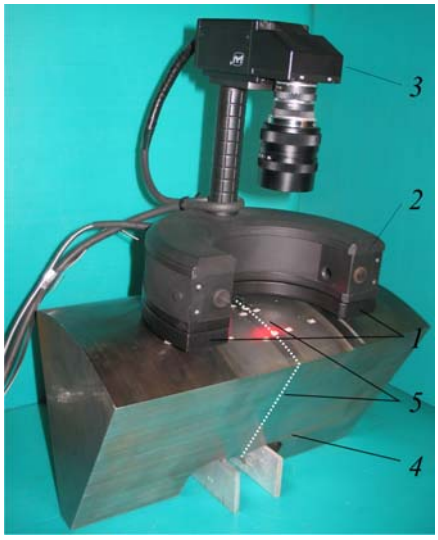


Figure 2. General view of the optical device, including: 1 – basement; 2 – removable module of speckle-interferometer; 3 – CCD-camera; 4 – sample of a welded joint; 5 – a weld seam

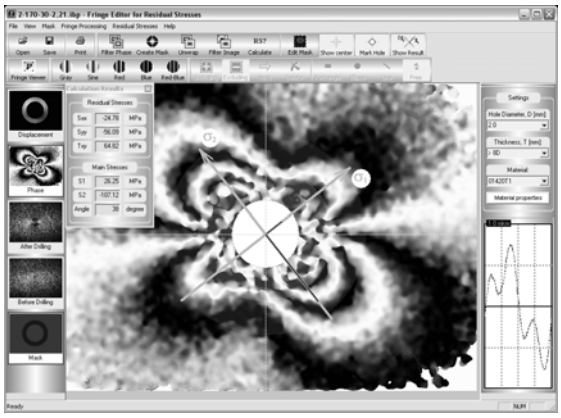

Figure 3. General view of the software user interface

The unit for determination of residual stresses, using the ESPI-HD method, includes a system of illumination and observation, which makes it possible to measure the displacements in the plane of the object examined. The unit consists of two parts: a basement 1 and a removable module 2, in which the optical system of the interferometer is assembled (Fig. 2). The basement is mounted on the sample examined and remains fixed while the measurements are being carried out for the point selected.

The solution of the well-known problem about the bending of a console beam with a fixed end by a force applied to a free end was used to evaluate the accuracy of the displacement measurements, using the developed small-sized speckle-interferometer and automated computer processing of speckle-patterns. The experiments have shown that the deviation of the values of stresses, which were determined by the ESPI-HD method, from the analytically estimated values, does not exceed 6 % of yield strength of the material tested [5].

3. Stress gradient over a surface

Determination of residual stresses on the basis of the hole-drilling methods assumes that stresses in the directions *x* and *y* are not changed. However, there is a non-homogeneous stressed state in the weld and HAZ, i.e. a gradient of residual stresses is present in those areas. (Fig. 4, 5). In this connection, it is suggested to use the drilling of the small-diameter holes at these areas to increase the accuracy of stress determination. It should be noted here, that the decrease of the holes' diameter leads to the reduction of the displacement measuring sensitivity and to the complication of the the process of drilling the holes in the high-strength metals and alloys.

It is known that the application of electron speckle-interferometry for determination of residual stresses makes it possible to gather more information about the residual stress state of the object compared with the data from the resistance strain gauges, that is achieved by calculating a significantly larger amount of values of the displacements caused by the hole-drilling.

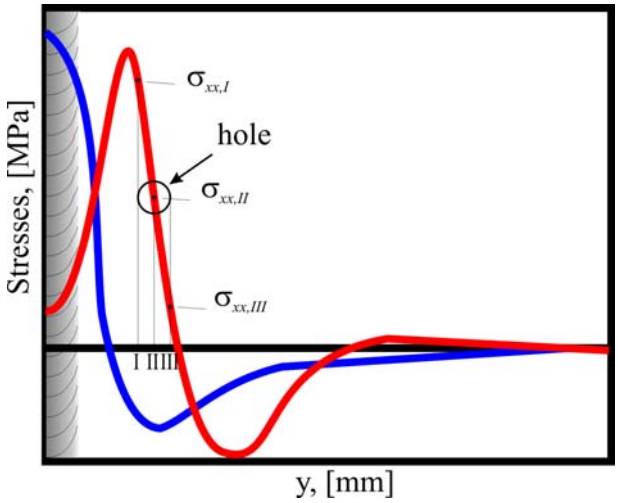

Figure 4. Typical distributions of longitudinal residual stresses versus distance from the weld center line

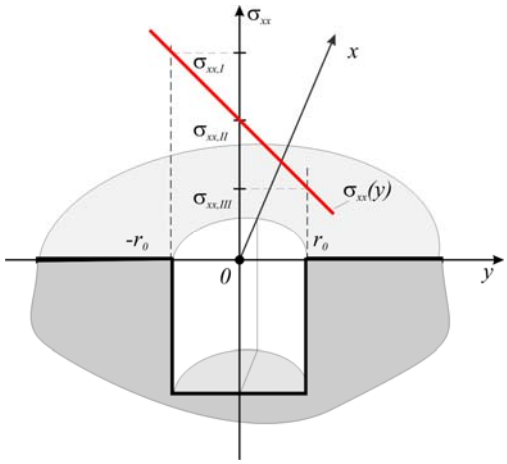

Figure 5. Local distribution of residual stresses across the hole

The ESPI-HD method for determination of residual stresses has been improved with a new approach for investigation of the stress gradient over the surface of the objects being examined. The principle of the approach will be briefly described below.

The area around the hole is divided into sectors. The displacements and their values, which are used for computing the stresses, are measured in those sectors (Fig. 6). The displacements data in the first and fourth circumference quadrants are used to determine the residual stresses for sector C_1, in the second and third quadrants – for sector C_2, the whole data about the displacement values along the circumference are used for determination of residual stresses corresponding to sector C_0 (Fig. 6).

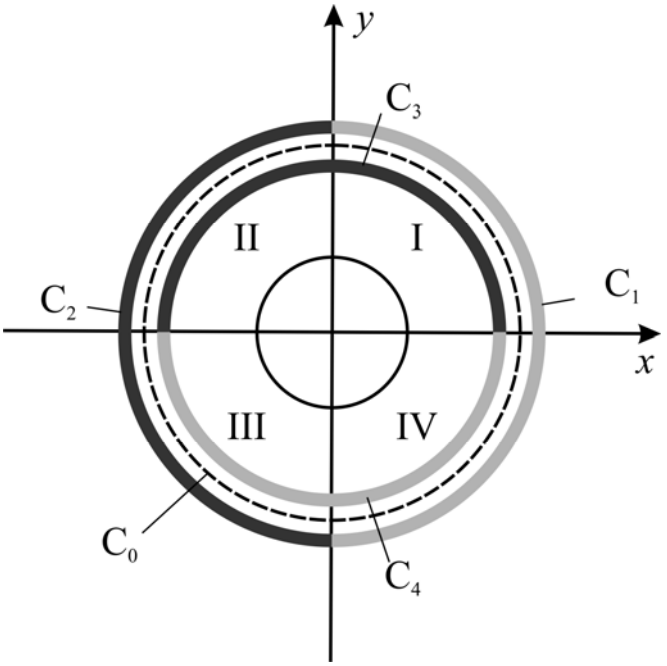

Figure 6: Scheme of an area division into sectors for investigation of the stresses' gradient in the hole zone

In order to assess the stress gradient it is necessary to determine stresses, using the data about displacements in the points both along the entire circumference around the drilled hole (Fig. 5) and in the points, located in the separated sectors around the drilled hole (compare Fig. 5). The computations, made with FEM, have shown that stresses, calculated from the data about displacements in all the points of the circumference (C_0), will have averaged values ($\sigma_{xx,avr}$) as compared with stresses from the measurements in the separated sectors (C_1 and C_2). The higher the stress gradient in the hole zone is, the larger the difference between the results of the stresses' calculation from displacements data in sectors C_1 and C_2. This gives the possibility to determine the direction of the stress gradient around the hole contour that allows to find the extreme values of residual stresses at a high accuracy.

To evaluate the gradient of stresses we have to plot the stress diagram. The data of the displacements, measured in the points along the circumference *2* (Fig. 7), located at a certain distance ($2.5r_0$) from the drilled hole center *1* (radius r_0), are used for determination of averaged residual stresses. If the stresses $\sigma_{xx,}$ calculated from the data from the different sections, are not equal, then the gradient of stresses over the object surface is present. In that case there is a dependence of stresses, being calculated on angle α (angle between radius-vector *b* and axis *OX*, Fig. 7). To assess the gradient of stresses in the hole vicinity, the diagram of the changes of stresses along the circumference is plotted on the base of the displacements data in the points of the sector 3 from angle α (the points of the sector 3 have polar coordinates within the range from $\alpha - \pi/2$ up to $\alpha + \pi/2$).

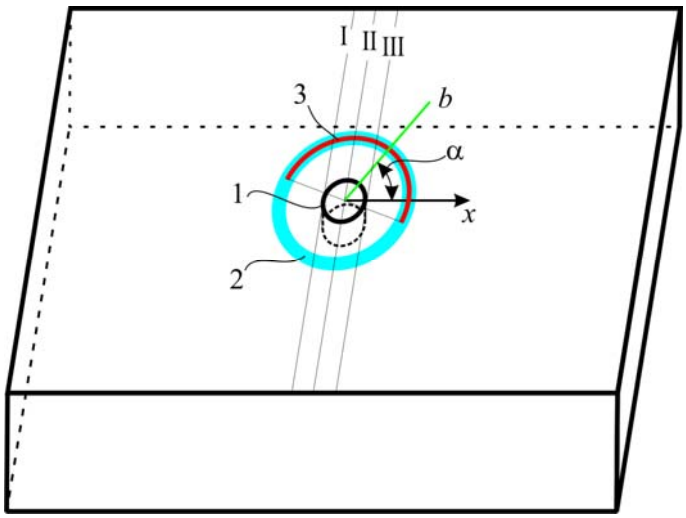

Figure 7. Scheme of the location of the points, in which the stresses are determined from the displacements data, where: 1 – hole; 2 – circumference, along which the displacements have been measured, used for calculation of stresses; 3 – circumference sector, in which the displacements are measured, used for determination of the stressed state when analyzing the stress gradient over the surface

An example of the calculated stress diagram is shown in Fig. 8. A conclusion about the presence of the residual stresses gradient can be drawn based on deviation of a curve of stresses from the circle with the radius, which is equal to the averaged value of stresses.

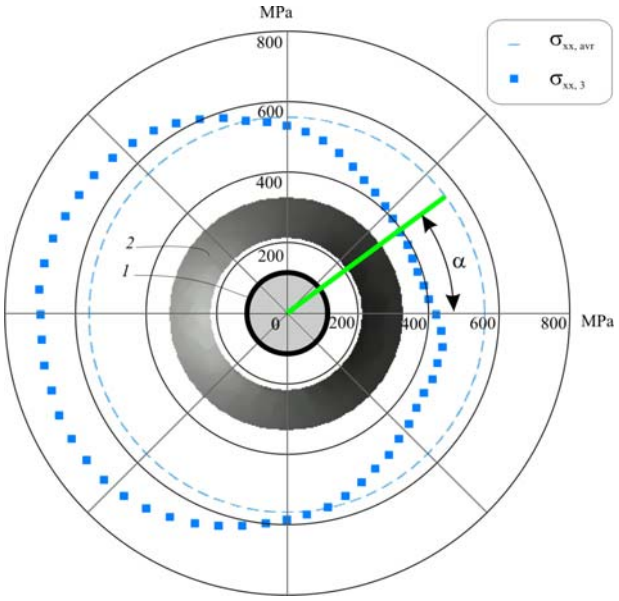

Figure 8. Graphical presentation of stresses σ_{xx} (square dots), with the use of the data about the displacements in the sector 3 (Fig. 7), illustrating deviations from the averaged values $\sigma_{xx,avr}$ and indicating the gradient of residual stresses over the surface. 1 – hole; 2 – measured displacements are presented in the form of a grayscale values

4. Application

The procedure of determination of residual stresses and the equipment, designed for this purpose, have been used for study of the stressed state in 1020 mm diameter welded gas and oil pipelines (Fig. 9). The ESPI-HD method has made it possible to determine residual stresses in the different areas of the welds. This technique does not require strong surface preparation. Drilling of holes with diameters and depths from 0.5 up to 1.0 mm provided high accuracy and relatively small damage.

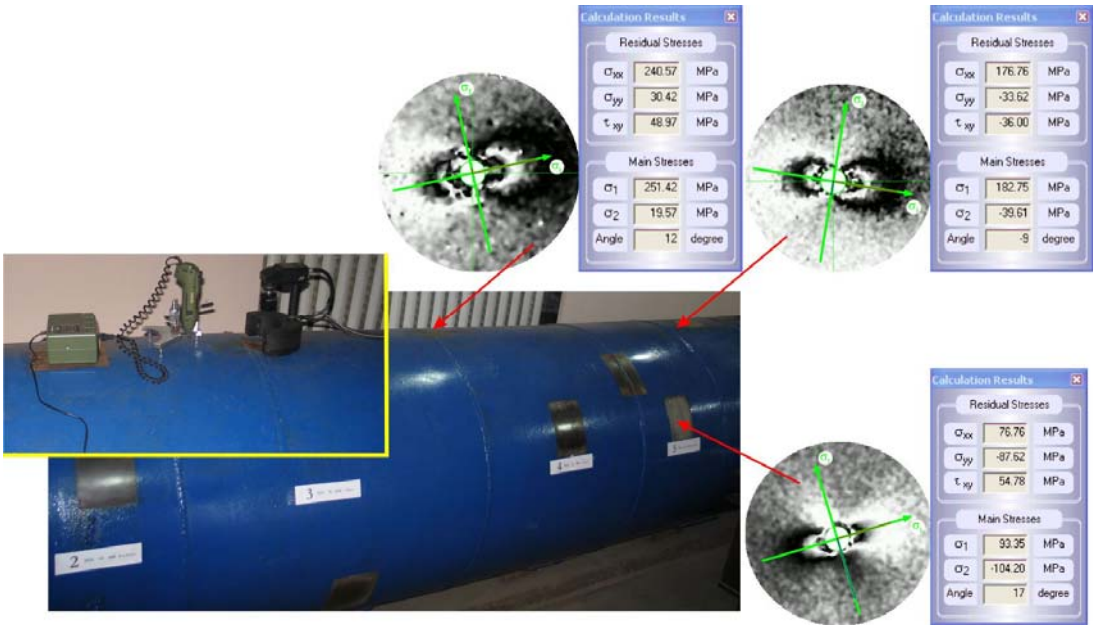

Figure 9. Determination of residual stresses in welded joints of gas and oil pipelines.

Another important advantage of the ESPI-HD method in comparison with the strain-gage hole-drilling method is that it does not require the removal of the weld reinforcement, which can lead to a redistribution of residual stresses.

Residual stresses have been determined in the Cr-Mo-V turbine element (Fig. 2). Typical distribution of circumferential residual stresses in the surface welded turbine rotor is presented at Fig. 10a, where compressive residual stresses are obtained due to phase transformation. However, the use of the proposed methodology for evaluating the stress gradient over the surface revealed two sharp peaks in HAZ, which have resulted from the martensitic transformations in the narrow zones of the width up to 2 mm (Fig. 10b). Thus, the use of the proposed techniques for the stress gradient analyses enabled to clarify the data about distribution of residual stresses and to identify a number of the important features.

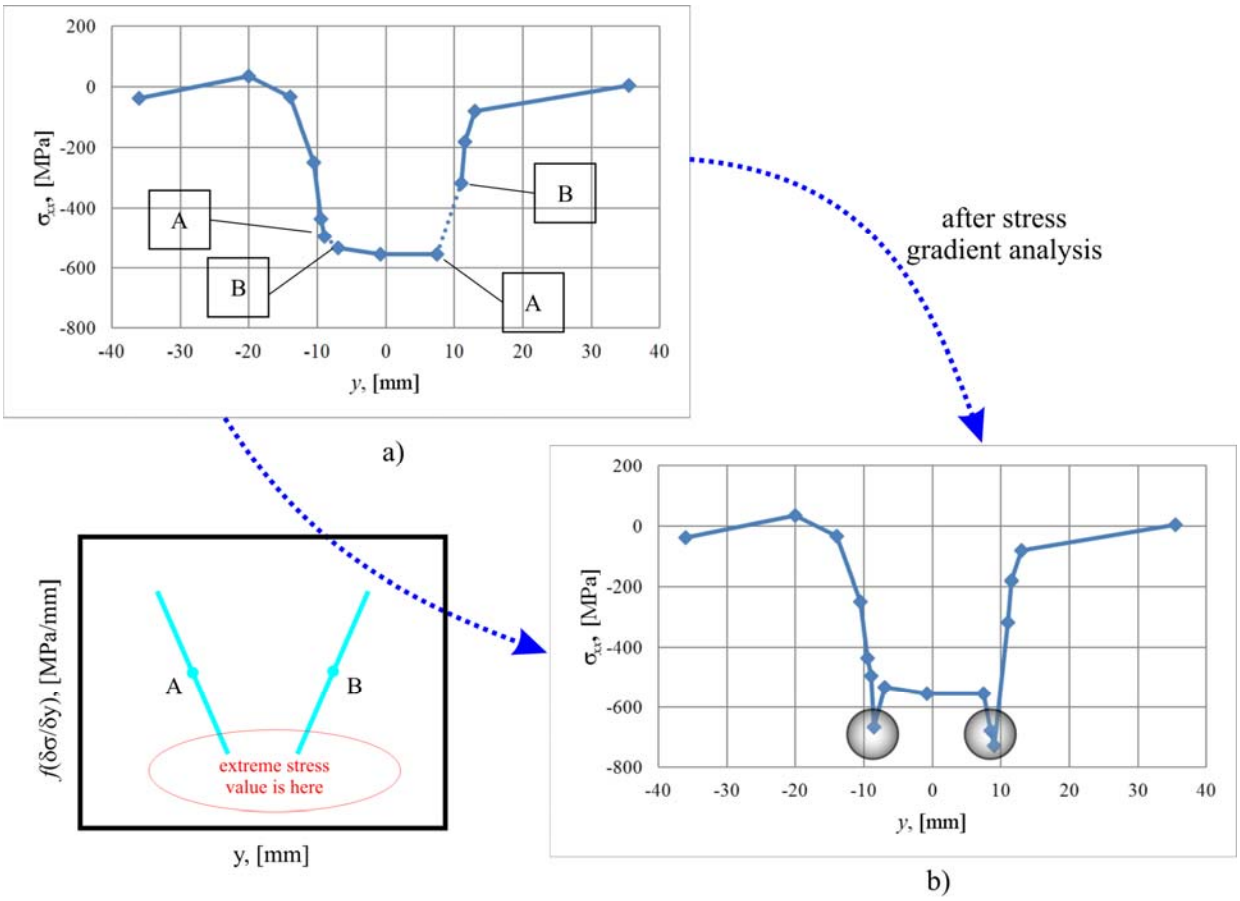

Figure 10. Distribution of circumferential residual stresses in the surface welded rotor obtained by: a) – conventional method of determination of residual stresses; b) – ESPI-HD – method with the technology of evaluating the stress gradient over the surface

5. Summary

Thus, the use of the ESPI-HD method makes it possible to increase the accuracy of residual stress determination and also gives an additional opportunity of the stress gradient assessment on the basis of the drilled out hole. The high sensitivity of the device enables to conduct the investigations of the stressed state on a small base (from 0.5 mm) without any loss of the experiment accuracy. The developed procedure of residual stress determination, compactness of the equipment and efficiency of the computer processing of the optical information open the new possibilities for examining the structures under the laboratory and industrial conditions.

The efficiency of the application of the offered procedure for evaluation of the stress gradient over the surface in order to investigate residual stresses in the welded structures has been shown.

Abstract The influence of high speed turning and tool wear on the microstructure and residual stresses of Inconel 718 was investigated. The turning was performed using whisker reinforced alumina ceramic inserts and a cutting fluid. By electron channelling contrast imaging in SEM, significant microstructural changes, including grain-refinement in a thin surface layer and heavily deformed microstructure to a certain depth, were observed in turning using a new tool. X-ray diffraction measurements also revealed a characteristic residual stress field with surface tensile stresses and subsurface compressive stresses. With the development of wear in the tool flank, mechanical forces and heat involved in the cutting operation increased, leading to a much larger cutting affected zone and more drastic changes in the surface integrity. High surface tensile residual stresses, up to 1500 MPa, and dissolution of reinforcing precipitates and recrystallization of the surface layer were induced by severe tool wear, both of which can significantly affect the fatigue strength of the machined part.

Keywords High speed machining, Surface integrity, Residual stress, Tool wear, Inconel 718

1. Introduction

Various machining operations such as turning, milling and drilling are widely employed to create designed shapes and dimensions of engineering parts with the help of cutting tools. During such a manufacturing process, material is removed from the surface of a part with the help of a cutting tool, causing severe localized plastic deformation and shearing. Because of the mechanical work done and friction between the cutting tool and both the newly formed workpiece surface and the chip, the temperature in the cutting zone is unavoidably raised. The nature of such a process involving localized plastic deformation and heating means structural development and thereby property changes in the surface as well as subsurface of the machined part. Plastic deformation, heat induced microstructural changes, hardness variations and residual stresses are frequently observed in the cutting affected zone [1-4]. Such changes may have a direct impact on the performance and reliability of machined parts and therefore are constantly a subject of interest in research.

The current project investigates the influence of high speed turning on the surface integrity of nickel based superalloy Inconel 718. Nickel based superalloys have good strength as well as excellent oxidation and corrosion resistance at elevated temperatures. They constitute a very important group of structural materials suitable for high temperature applications in the aerospace and energy conversion industries. However, the alloys are also known as hard-to-cut materials due to their high strain hardening rate, poor heat conductivity and high-temperature strength. The poor machinability not only contributes to a low material removal rate but also induces rapid tool wear [5] which changes the cutting geometry of the tool. For wear in the tool flank, the increased tool-workpiece contact area and vanished clearance angle lead to increased mechanical forces and heat generation during cutting [5]. As a result, machining influence on the surface integrity of the workpiece is enhanced [4]. Microstructure alterations and residual stresses in turning of Inconel 718 by worn tools were studied in a few publications. Sharman et al. through optical microscopy and microhardness testing revealed that tool wear during turning of Inconel 718 increased the plastic

deformation depth, and at the higher speed end of the studied range of 40–120 m/min it also enhanced strain hardening of the subsurface [5]. Analysis by high resolution imaging of electron channeling contrast (ECC) in backscatter detectors and electron backscatter diffraction (EBSD) revealed that recrystallization and partial recrystallization also occurred in an immediate subsurface layer of 200–300 nm at a cutting speed of 300 m/min [6]. In [7], tool wear was reported to promote the formation of a so called white layer, independent of the application of coolant. Cutting using a worn tool is often found to increase the surface tensile residual stresses. In turning of Inconel 718 at low cutting speed (40 m/min), high surface tensile residual stresses up to 1043 MPa were reported in a surface prepared using a worn tool and the surface tensile stresses was found to decrease with increasing cutting speed [8]. For face finishing turning of RR1000 alloy, residual stress profile measurements revealed that tool flank wear not only increased the surface tensile residual stresses but also extended the compressive peak stresses to a larger depth [9].

This paper presents results from studies on the evolution of microstructural changes and residual stresses with the development of tool wear for high speed turning of Inconel 718 at 200 m/min with a cutting fluid. The influence of tool wear on residual stresses for cutting using the same tooling conditions but without the application of cutting fluid can be found in [10]. In [6], research work on subsurface deformation and their correlation to tool wear for turning at higher speed was reported.

2. Experimental Details

2.1. Material and machining operations

The Inconel 718 used in the current investigation has a nominal composition of: 53.8% Ni, 18.1% Cr, 5.5% Nb, 2.9% Mo, 1% Ti, 0.55% Al, 0.25% C, 0.04% Si and balance Fe (in weight). Round bars of 70 mm diameter and 200 mm length were received in solution annealed and aged condition with a nominal bulk hardness of 45±1 HRC. The backscatter electron images in Fig. 1 reveals a microstructure of equiaxed γ grains of nickel solid solution strengthened by very fine intermetallic γ" (coherent body centered tetragonal Ni_3Nb) particles visible at higher magnification. Elongated δ (an incoherent orthorhombic Ni_3Nb) particles are observed at grain-boundaries with some of them penetrating deep into the grains.

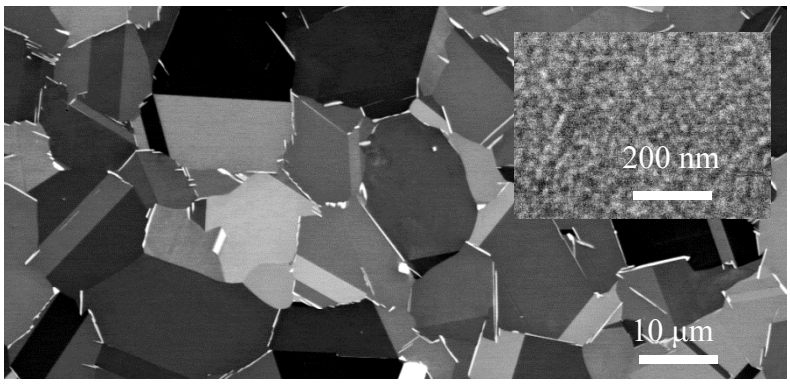

Fig. 1 Backscatter electron image of the as received alloy with a nickel base solid solution γ and reinforcing γ" precipitates (the inset). The elongated bright particles often located at grain boundaries are δ precipitates.

The as-received bars were machined down to 40 mm before further turning using whisker reinforced alumina ceramic (Al_2O_3+SiC_w) tools to prepare samples for the investigation. The cutting tool had a honed cutting edge and negative rake chamfer ($0.1x20^o$). The insert was mounted in a CDJNL3025P11 (ISO) type tool holder with a tool geometry of -6^o rake angle, 6^o clearance angle,

93^o edge major tool cutting and -6^o cutting edge inclination angle. To investigate the influence of tool wear on the machined surface quality, samples were also prepared with used tools of two degrees of flank wear, namely semi-worn tools (VB_{max} = 0.15 mm) and worn tools (VB_{max} = 0.3 mm). The cutting speed, feed rate, and cutting depth were 200 m/min, 0.2 mm/revolution, and 0.3 mm, respectively. All machining trials were conducted on a SMT500 CNC turning machine with a spindle speed up to 4000 rpm and a drive motor rated up 70kW. The cutting fluid was Sitala D 201-03 (Shell) containing 5% of semi-synthetic emulsion in solution and provided with 5 MPa at 40 l/min through an orifice 5 mm in diameter.

2.1. Surface integrity characterization

X-ray diffraction stress analysis is based on evaluating changes in the interplanar spacings of certain (hkl)-planes, namely the elastic strains, from which the residual stresses responsible for causing the changes are derived. Measurements in the current study were carried out in ψ-mode [11] on a Seifert X-ray diffractometer. With ψ being the angle of sample tilt around an axis passing through the goniometer center in the diffractometer plane, the commonly used $\sin^2\psi$-method [11] was employed to calculate residual stresses from the interplanar spacing measurements made in multiple ψ angles. To obtain a stress value, thirteen ψ-angles spreading in equal $\sin^2\psi$ interval between ($\psi = -50^o$) and ($\psi = 50^o$) were used. Diffraction peaks from the nickel γ-220 reflection were obtained using the Cr-K_α radiation and a pinhole collimator of 2 mm diameter. The peak positions and widths were determined by curve fitting with two pseudo-Voigt functions for $K_{\alpha1}$ and $K_{\alpha2}$, respectively. The X-ray diffraction elastic constant for nickel γ-(220) plane, needed for the stress calculation, is 4.65×10^{-6} MPa^{-1} [12]. To obtain depth profiles of residual stresses, stepwise electrolytic polishing was employed to expose the underlying material for diffraction measurements. The stress profiles presented in this paper are as measured results without any correction for possible stress relaxation due to the electrolytic polishing.

Small samples were cut from the machined bars. A surface encompassing both the cut and feed directions was then mechanically ground and polished following a procedure for preparing samples for electron backscatter diffraction (EBSD) analysis. The microstructural characterization was carried out in a Hitachi SU-70 FESEM scanning electron microscope. Annular solid state backscatter detectors from Hitachi were used to obtain images of electron channeling contrast (ECC) from the polished surface. The plastic deformation depth was also characterized by measuring the density of low angle grain boundary (LAGB) in EBSD using a Nordlys detector from Oxford Instruments. Scans with a step size of 0.5 μm were then performed along lines perpendicular to the cutting surface. The LAGB was defined as a misorientation of 1 to 10 degrees between two contiguous measurement positions along a scanned line. Its density at a particular sample depth was then calculated by averaging the number of lines containing a LAGB at the depth over the total number of scanned lines.

3. Results and Discussions

3.1 Microstructure of machining affected zone

As a reference state to illustrate the effect of dry cut, microstructure in the sample prepared using a new tool was briefly described in [10]. A more detailed analysis with regards to the cutting induced plastic deformation and temperature rise is given here. Fig. 2(a) presents an overview of microstructural alterations in the cutting affected zone. A plastic deformation gradient varying from surface towards depth is revealed by the ECC. Lattice distortions visible as contrast variations are seen at a depth up to about 60 μm. This zone, corresponding to the deformation depth indicated by

the LAGB density profile from EBSD line scans (Fig. 3(a)), is hereafter termed heavy deformation zone. Although slip bands related to cutting induced plastic deformation can be found in grains at a larger depth, the analysis here is limited to the zone of heavy deformation. Different microstructural features identified along the depth near the machined surface are shown in Fig. 2(b). In the outmost surface, Fig.2(c) discloses a discontinuous layer of less than 1 μm thick, distinguished from the material beneath by its very fine structure consisting of elongated grains lying in the cutting direction and some equiaxed grains. Such a layer with ultrafine or nano-sized grains has been reported in surfaces machined under certain cutting conditions [13,14] and is often attributed to severe plastic deformation with possible influence of a high temperature. In the current sample, deformation bands extended from the layer beneath are still recognizable and fragmented δ-particles are visible (Fig. 3(c)). These observations imply that severe plastic deformation is the main cause of the grain-refinement but the cutting heat may cause recovery and even partial recrystallization, producing the sharp boundary to the layer beneath.

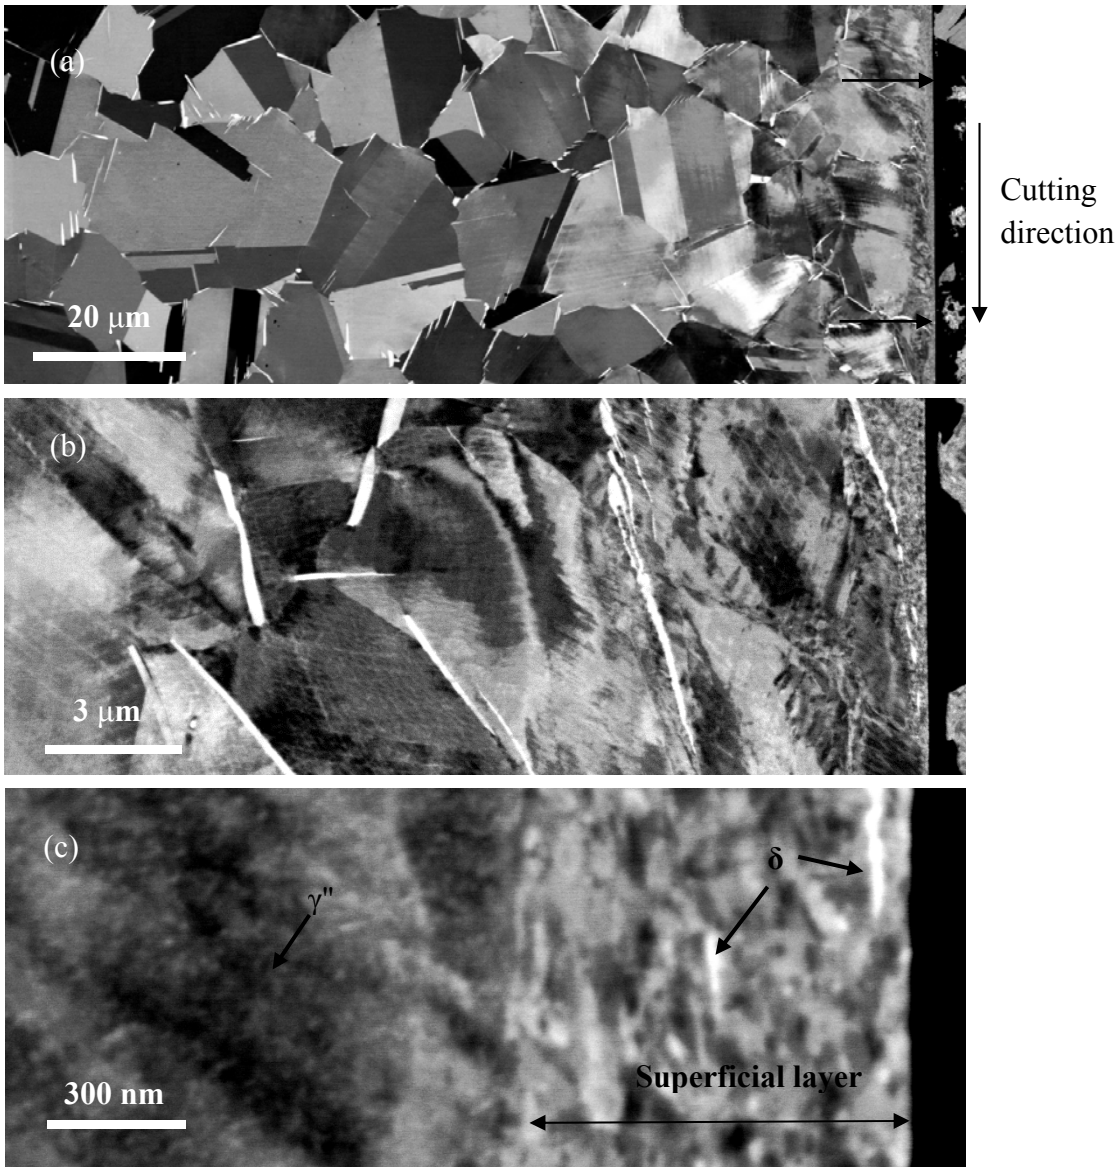

Fig. 2 Backscatter images showing microstructural alternations in machining affected zone of the sample prepared using a new tool. The machined surface is indicated by the arrows.

The next layer which extends to a depth of 10 to 25 μm contains severely deformed grains (Fig. 2(b)). In the literature, distorted grain boundaries and deformation bands are frequently reported from optical microscopic study on etched surfaces, see for example [7]. In comparison, the backscatter image in Fig. 2(b) reveals finer microstructural features such as fine slip bands and concentrated plastic strains in the vicinity of grain boundaries. As can be seen in the region close to the superficial layer, elongated grains inclining towards the cutting direction prevail. Stretching and rotation of the grains are accomplished by shear, leaving dense deformation bands extending over the grains. In many grains, the deformation bands tend to bend towards the cutting direction with rather abrupt change of the bands orientation. Fine slip bands are also observed in the regions between the deformation bands. In other grains which are less distorted, dislocation slip on multiple slip systems results in cell-like features. The δ-precipitates in this zone either deform following the grain boundaries and/or are sheared together with the deformation bands. It can be concluded from the above observations that heat from the cutting process has little effect on the already deformed structure; the forced cooling by cutting fluid and the poor thermal conductivity of the superalloy prevent a large amount of the cutting heat from penetrating into the depth. The retained strain hardening effect is expected to locally increase the hardness but at a cost of the ductility. Deeper in the sample, plastic deformation is less significant. The grains are characterized by cross-slip bands but the grain boundaries remain essentially undistorted (Fig. 2(a)).

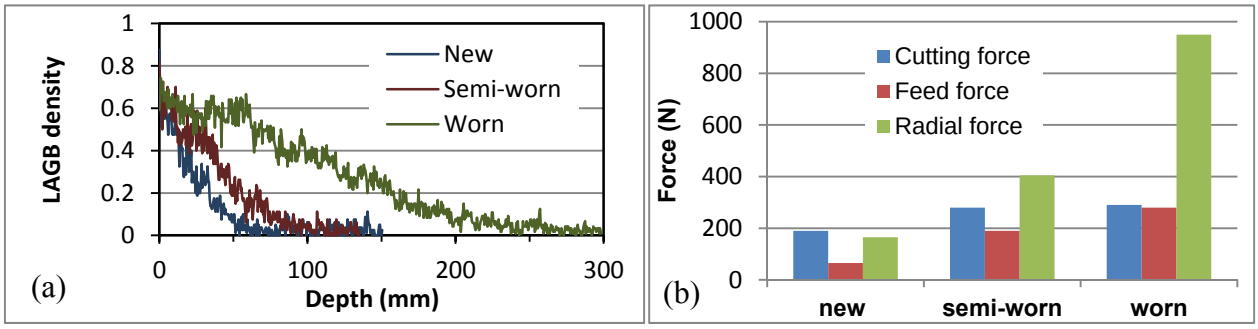

Fig. 3 Depth distribution of low angle grain boundary (a) and mechanical force components (b) for cutting under different tool conditions.

Cutting by a semi-worn tool with flank wear of VB_{max} = 0.15 mm leads to a larger cutting affected depth, as disclosed in Figs. 3(a) and 4(a). The depth of heavy plastic deformation shown in Fig. 4(a) is now slightly over 100 μm (Fig. 3(a)) and the severely deformed zone with distorted grains and grain boundaries extends to about 30 μm. The increased plastic deformation in association with tool wear is related to a higher cutting temperature and larger mechanical forces [5]. Wear in the tool flank results in a larger contact area between the tool and the sample surface as well as vanishing of the clearance angle. Subsequently, larger mechanical forces are required for material removal, as revealed by Fig. 3(b), leading to a larger deformation depth. Because of both the increased mechanical energy input and friction between the sample and tool, the cutting heat also increases which not only enhances plastic deformation by reducing the strength of the affected surface layer but also causes more significant microstructural changes. As can be seen in Fig 4(b), almost complete recrystallization occurs in the surface layer and partial recrystallization in some grain boundary regions beneath.

As a result of further increase in the mechanical forces (Fig. 3(b)) and heat, a much larger mechanical and temperature influence is found for cutting using a worn tool (VB_{max} = 0.3 mm). The heavy deformation depth reaches over 250 μm (Fig. 3(a)) with the severely deformed layer extending to about 60 μm below the surface (Fig. 5(a)). The fully recrystallized surface layer

containing equiaxed grains of over 100 nm in size and annealing twins becomes as thick as 3 μm (Figs. 5(b) and (c)). The strengthening γ'' particles completely disappeared from the layer, which may facilitate recrystallization of the layer. In some places, a very thin but extremely fine featured layer can be observed on top of the recrystallized zone, as can be seen in Fig. 5(c). This layer may form because of remelting by a high surface temperature [6] and quenching by the cutting fluid. Such changes in the microstructure greatly improves the surface ductility but at the cost of strength. In the depth between 2 to 10 μm, bands containing ultrafine, elongated or equiaxed grains or cell-structures associated with grain boundaries lie in a low angle to the cutting surface (Fig. 5(b)). It seems that as more cutting heat penetrates deeper into the material, the extremely distorted grain boundary regions may partly recrystallize. Between the heat affected grain boundaries are parallel short deformation bands and coarser cells formed by crossed slip bands. The rest of the heavy deformation zone shows similar microstructural feature to those in the samples prepared by the new tool and semi-worn tool.

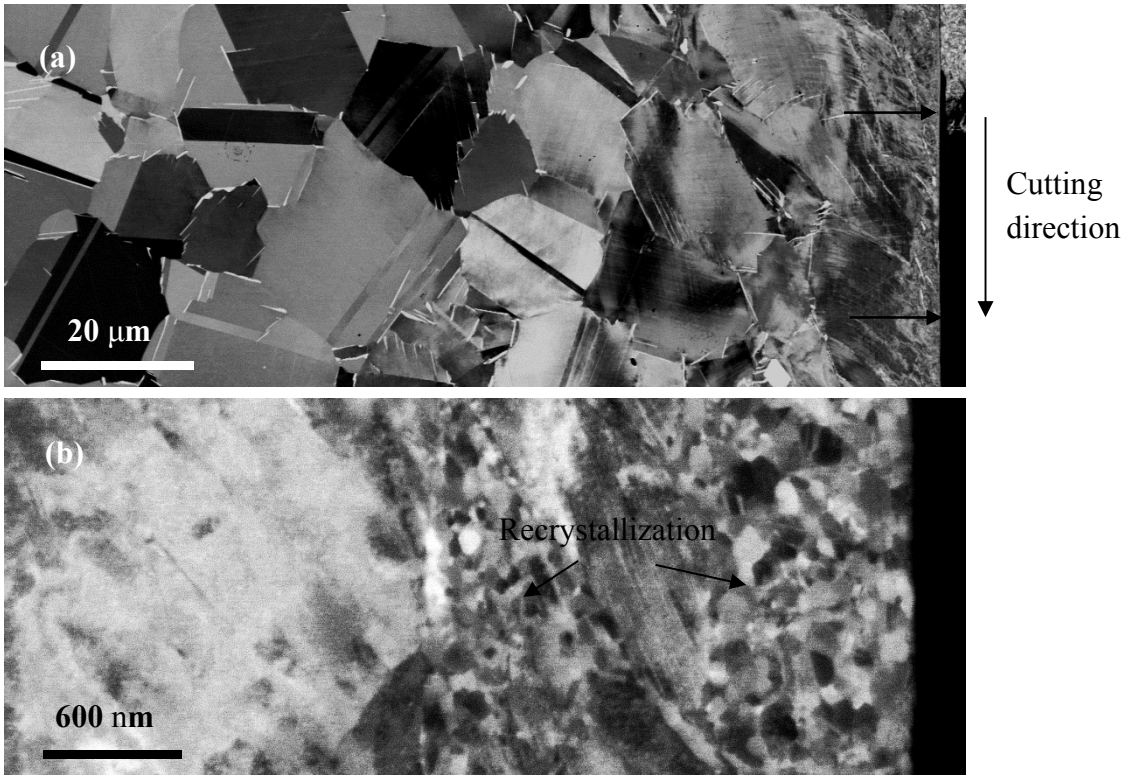

Fig. 4 Machining affected depth of the sample prepared by turning using a semi-worn tool.

3.2 Residual stresses

Residual stress profiles are presented in Fig. 6. As can be seen, tensile residual stresses are found in a thin surface layer and compressive stresses in the subsurface zone. The cutting tool condition affected both the extent of the tension and compression zones and the peak stress values. The diffraction peak width, given as full width at half maximum intensity (FWHM) in Fig. 6, is related to lattice distortion and grain size. Except for the surface layer containing ultrafine grains, the observed peak broadening can be attributed mainly to cutting induced plastic strains. The cutting affected depths indicated by the FWHM profiles are somewhat larger than that observed in Section 3.1 (Fig. 3(a)), indicating that X-ray diffraction is more sensitive for small plastic strains.

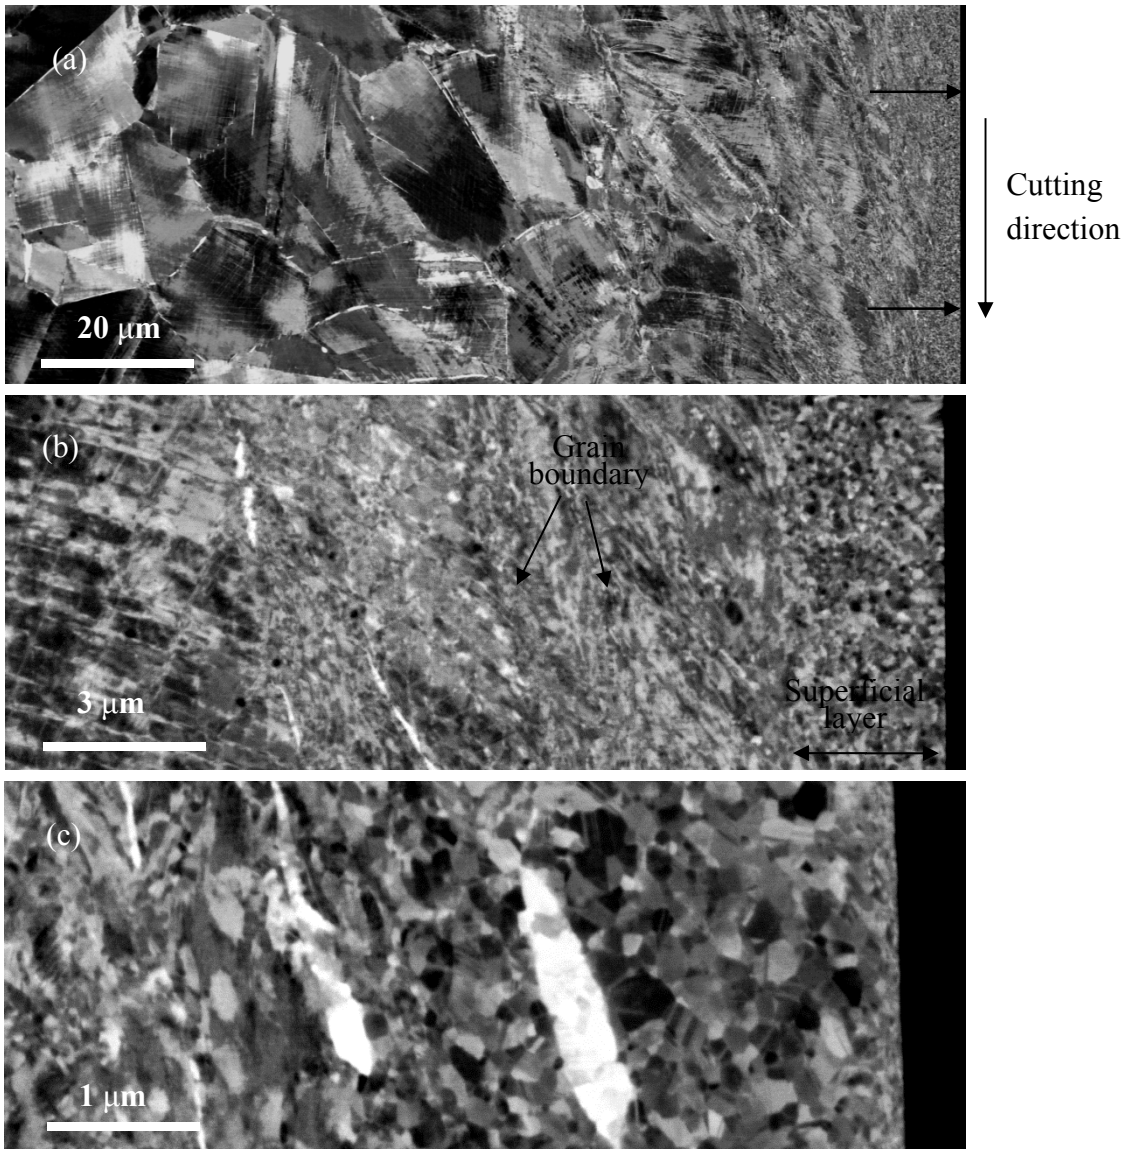

Fig. 5 Microstructure of the cutting affected depth prepared by a worn tool.

A 10 μm thick tensile zone with relatively low peak stresses is induced by cutting using the new tool, see Fig. 6(a). The residual stress field is slightly anisotropic, with a more rapidly decreasing stress in the feed direction. After reaching maximum compressive stresses at about 50 μm, both the stress components decrease, approaching zero at a depth of about 150 μm. The depth affected by plastic deformation reaches about 100 μm. A similar residual stress field with surface tensile stresses and subsurface compressive stresses has been reported for nickel-based alloys machined under different cutting conditions, for example, in the cutting speed range between 40 m/min and 120 m/min [8,15,16] and over 400 m/min [9,13,17]. Surface tensile stresses are often attributed to a dominant thermal effect from the cutting process [13,18]. When the contraction of a surface layer on cooling is hindered by the subsurface material of lower temperature, the surface layer will be put in tension and the subsurface layer in compression. On the other hand, plastic deformation involved in the cutting process which is mostly in-plane expansion has the opposite effect and will introduce compressive stresses in the surface layer [18]. Analogously, microstructural changes leading to a volume expansion of the surface layer will result in surface compression and subsurface tension. As analyzed in [10] for turning under the same cutting conditions but without the application of a cutting fluid, the observed stress field in Fig. 6(a) can be attributed to superposed mechanical and thermal effects: a somewhat anisotropic residual stress field with surface compression is induced by

surface plastic deformation and thermal stresses from cooling of a heated surface layer reverse the surface compression to tension.

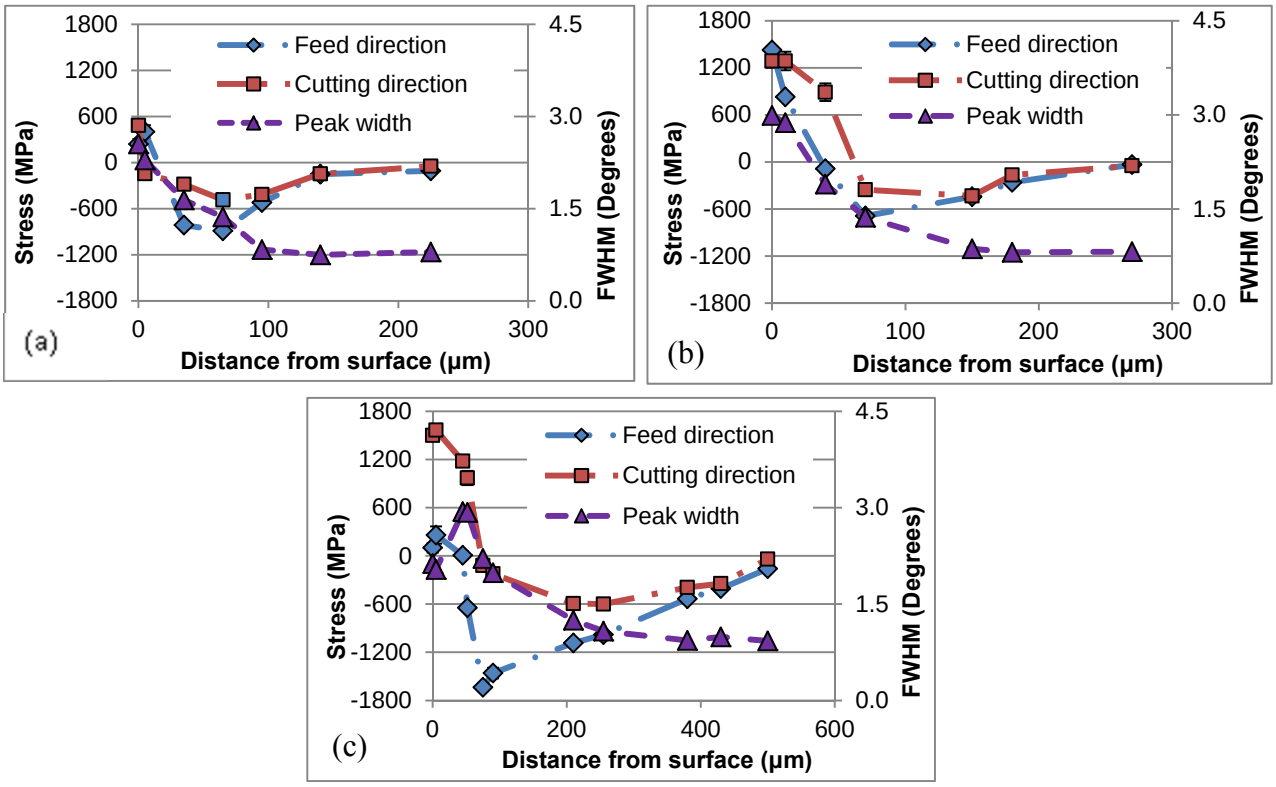

Fig. 6 Residual stresses and FWHM in the machining affected depth prepared using new tool (a), semi-worn tool (b) and worn-tool (c).

The higher cutting heat generated when using the semi-worn tool has a large influence on the surface tensile zone. The size of the zone is increased and the surface stresses are raised from about 240 MPa to 1400 MPa in the feed direction and 480 to 1300 MPa in the cutting direction (Fig. 6(b)). The higher mechanical forces (Fig. 3(b)) have little effect on the peak compressive stresses but enhance strain hardening in the near surface region, as revealed by the higher FWHM values, as well as expand the compression zone to a larger depth of 270 μm.

For the turning by the worn tool (VB_{max} = 0.3 mm), Fig. 6(c) reveals a surface tensile stress of 1500 MPa and a subsurface compressive peak of 600 MPa in the cutting direction. On the other hand, the surface tensile stress in the feed direction is reduced to 100 MPa, and at the same time the compressive stress peak is increased to about 1100 MPa. While the plastic deformation depth is further increased, to about 400 μm, recrystallization in the surface layer and partial recrystallization in the subsurface layer (Fig. 5) fully or partly removes the strain hardening effect, leading to low peak widths in the region (Fig. 6(c)). In spite of a stronger temperature effect on the microstructure, the observed residual stress anisotropy and the larger hardening depth suggest a more significant mechanical effect on the residual stress profiles in comparison with cutting using the semi-worn tool. The severe flank tool wear increases the feed and radial force components but has little effect on the cutting force component (Fig. 3(b)), which may result in a large difference between the two residual stress components. The recrystallization of the outer layer then relaxes the surface compressive stresses and residual stresses of tensile nature are generated later during cooling. It is interesting to compare the influence of tool wear with that of cutting speed for which increasing cutting speed also leads to a higher cutting temperature but lower mechanical forces [19] in contrast

to tool wear. Inspection of the results from face grooving of Inconel 718 published by Schlauer et al. [17] reveals that the increased thermal effect accompanying an increase in cutting speed from 410 m/min to 810 m/min enhances mainly surface tension and subsurface compression but has little influence on the stress anisotropy.

4. Conclusions

Electron channeling contrast imaging and X-ray diffraction were used to study machining induced microstructural changes and residual stresses, respectively, in Inconel 718 samples prepared by high speed turning under different cutting conditions. The following conclusions can be drawn from the investigation:

Mechanical forces and heat generated in the cutting process induced significant microstructural changes in the cutting affected zone. For cutting using a new tool, a surface layer of ultrafine grains formed because of local severe plastic deformation and high cutting heat. The layer beneath was heavily deformed, showing distorted grains and grain boundaries, deformation bands, and crossed slip bands; however, little influence of cutting temperature on the deformed microstructure was observed.

With the development of wear in the tool flank, the thicknesses of the fine-structured layer and the heavily deformed zone were increased as a result of increased mechanical forces and cutting heat. The temperature influence on the deformed microstructure was also enhanced. For turning using a worn tool, full recrystallization and dissolution of the strengthening γ" were observed in a surface layer up to several micrometer thick.

All the investigated samples showed a characteristic residual stress field with surface tensile stresses and subsurface compressive stresses, generated due to the localized plastic deformation and heating.

The increased cutting heat input and mechanical forces because of tool wear expanded both the tension and compression zones and resulted in much higher surface tensile stresses, up to 1500 MPa. When severe tool wear occurred, the residual stress field became strongly anisotropic, which could probably be ascribed to the different dependence of cutting force components on tool wear.

It has been shown that as tool wear progressed, surface damage in the form of microstructural alterations and tensile residual stresses increased. The level of tool wear is therefore crucial to the surface and subsurface quality of the machined part and severe tool wear may significantly affect its fatigue strength.

Abstract Weld residual stresses and microstructural changes show coupled effects on fatigue crack growth rates resulting in more difficulties and complexity in crack growth life analysis for weld joints. Uncoupling these effects is a desirable option for understanding the influence of each factor and establishing more accurate crack growth prediction methods. A method for isolating the contributions of residual stress and weld microstructure change to fatigue crack growth rates in welds is presented in this paper. The proposed method is based on the superposition rule in fracture mechanics. Example of fusion weld specimens of different configurations and subjected to different loading conditions are presented to demonstrate the procedure of the method. Factors that will influence the solution, such as the applied and residual stress intensity factors, effective stress intensity factor ratio, choice of crack growth laws etc. are assessed and discussed in details.

Keywords Fatigue crack growth rate, Weld, Residual stress, Microstructural change, Isolation

1. Introduction

The application of advanced welding technologies to fabricate aircraft structural components is recognized as one of the most promising methods to achieve further structure weight reduction and manufacture cost saving, which requires a step change in the structural integrity assessment and, consequently, sets new challenges to the damage tolerance evaluation for welded joints. Crack growth life estimation is one of the key tasks in damage tolerance assessment. Welding procedure will introduce micro-structural changes as well as weld residual stress (RS), both of which have shown significant effects on fatigue crack growth (FCG) rates. Significant amount of research has been conducted in the past 20 years to understand the crack growth behaviors in aerospace aluminum alloys joined by different advanced welding technologies, e.g. fusion, laser and friction stir welding (FSW), which have different characteristics in RS levels and microscopic texture [1-9].

Effects of microstructure and residual stress on FCG depend on the relative positions of the crack to the weld zone. Tests on specimens with crack parallel to the weld line indicate that the growth rate in the regime with low hardness is much slower and of higher threshold [10, 11], while it is not always the same for longitudinal welded specimen (crack propagates perpendicular to the weld line). Fratini et al. [4] presented similar results in the study on longitudinal welded 2024-T351 aluminum alloy showing changes in microstructure and hardness play a major role in the fusion zone (FZ) and residual stresses take the first place outside the FZ. Pouget et al. [9] predicted crack growth rate in longitudinal FSW 2050 aluminum alloy by finite element simulation showing that the material parameters in FZ could have significant effects on predicting results. Therefore, it is a common practice that only the primary influential factor is considered in crack growth analysis of welds. For example, studies [7, 12-14] have concluded that RS plays a major role on the FCG rates for crack propagation perpendicular to a weld, consequently, superposition rule is adopted in this case to account for the combined effects of residual and applied stresses on crack growth, microstructural changes effect, although present obviously in weld nugget, is ignored. For crack propagation within

and parallel to a weld, crack growth rates have been found to be considerably lower than that in the base material (BM) [11]; effect of microstructural and hardness changes on FCG rate is most important and hence must be considered in this circumstance. However, in most cases, both microstructural change and residual stresses contribute to the change in crack growth rate in welds compared with that in the BM, and the two contributions couple each other [4,9,10,15]; neglecting any of the two (to simplify the crack growth analysis procedure) will result in inaccurate analysis.

On the other hand, it is well-known that RS magnitude and distribution are different for different dimensions, but the weld metal (WM) microstructural change should be the same for the same welding process parameters even though the dimensions of the test coupon and component are different. If the coupled effects on FCG rate can be isolated, it will provide a more accurate analysis tool for predicting crack growth life, and have wider applicability.

A method for isolating the contributions of RS and weld micro-structure change to fatigue crack growth in welds is presented in this paper, which is based on the superposition rule in fracture mechanics. An example of VPPA (Variable Polarity Plasma Arc) welded specimens is presented to demonstrate the isolation procedure. The characteristic parameter, i.e. stress intensity factors due to residual and applied stresses, is calculated by finite element method. Factors which will influence the results, such as applied and residual stress intensity factors, effective stress intensity factor ratio, choice of crack growth laws, etc. are assessed and discussed in details.

2. Methodology for Isolating the Contributing Factors

2.1. Basic idea

The difference in the crack growth rate between the WM and the BM is:

$$\Delta = \left(da/dN\right)_w - \left(da/dN\right)_b \qquad \text{* MERGEFORMAT (1)}$$

where $\left(da/dN\right)_w$ and $\left(da/dN\right)_b$ are the crack growth rates in the WM and BM respectively.

The difference Δ is the summation of the two contributing parts; one arises from weld residual stresses, labeled as Δ_1, and the other is due to the microstructural change introduced by the welding process, marked as Δ_2. Fig. 1 shows schematically the changes in crack growth rate consisting of Δ_1 and Δ_2. These increments, Δ, Δ_1 and Δ_2, can be either positive or negative and may not be kept the same with the increase of the stress intensity factor range ΔK.

As mentioned, Δ_1, arising from the residual stress, is associated with the configuration of the weld component, and Δ_2 depends only on the weld process parameters. If Δ_1 and Δ_2 can be obtained respectively, the contributions of residual stress and microstructural change on crack growth can be isolated.

2.2. Method for determining Δ_1

Since Δ_1 arises from RS, it is reasonable to assume that a weld procedure introduces residual stress only without changing the microstructure. The crack growth rate in this case is:

$$\left(da/dN\right)_R = \left(da/dN\right)_b + \Delta_1 \qquad (2)$$

where $(da/dN)_b$ is the crack growth rate in the BM subjected to externally applied load, and can be correlated by stress intensity factor range ΔK, stress ratio R, and material property constants A_1, A_2, …, A_n. Commonly used correlation equations are the Paris, Walker, Forman, and NASGRO equations etc. [16]. A general form of these laws can be expressed by Eq. (3), where $(da/dN)_R$ is the crack growth rate due to the combined applied stress and RS. Because there is no material property change, the superposition rule [17] can be used reasonably, and $(da/dN)_R$ can be found by Eq. (4).

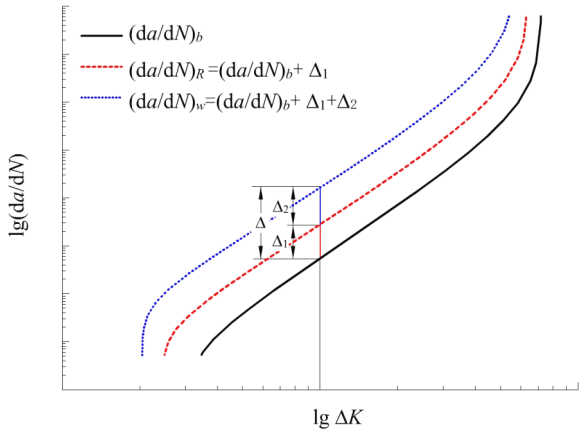

Fig. 1. Schematic of contribution of weld RS and material property change to FCG rate in WM

$$\left(da/dN\right)_b = f\left(\Delta K_{app}, R_{app}, A_1, \cdots, A_n\right) \tag{3}$$

$$\left(da/dN\right)_R = f\left(\Delta K_{tot}, R_{eff}, A_1, \cdots, A_n\right) \tag{4}$$

where ΔK_{app} and ΔK_{tot} are the stress intensity factor range due to the applied and total (applied + residual) stresses, respectively. R_{app} and R_{eff} are the stress intensity factor ratios due to the applied and total stress, respectively.

$$\Delta K_{tot} = K_{tot\max} - K_{tot\min} = \left(K_{app\max} + K_{res}\right) - \left(K_{app\min} + K_{res}\right) = \Delta K_{app} \tag{5}$$

$$R_{eff} = \frac{K_{app\min} + K_{res}}{K_{app\max} + K_{res}} \tag{6}$$

K_{res} is the stress intensity factor due to the RS, which can be calculated by either the finite element or weight function method [18]. Therefore, if the distribution of RS is available, both $(da/dN)_b$ and $(da/dN)_R$ can be calculated. Hence, Δ_1 could be obtained by:

$$\Delta_1 = \left(da/dN\right)_R - \left(da/dN\right)_b \tag{7}$$

2.3. Method for determining Δ_2

It may be imagined that if a weld procedure introduces no RS, then the only difference in crack growth rates between BM and WM is due to the change in material prosperities. In this case, the crack growth rate should be the intrinsic one which does not related to RS (in consequence to the specimen configuration):

$$\left(da/dN\right)_{Int} = \left(da/dN\right)_b + \Delta_2 \tag{8}$$

Since the change in crack growth rate is due to microstructural changes, $(da/dN)_{int}$ cannot be estimated by the theory of macroscopic fracture mechanics. It cannot be measured either because no weld procedure will introduce zero RS. However, it is possible to estimate Δ_2 by Eq. (9) after Δ_1 is

determined.

$$\Delta_2 = \Delta - \Delta_1 = \left[\left(da/dN\right)_w - \left(da/dN\right)_b\right] - \left[\left(da/dN\right)_R - \left(da/dN\right)_b\right] = \left(da/dN\right)_w - \left(da/dN\right)_R \quad (9)$$

where $(\mathrm{d}a/\mathrm{d}N)_w$ can be obtain by crack growth tests of WM specimens, quantity $(\mathrm{d}a/\mathrm{d}N)_R$ could be determined by Eq. (4).

3. Demonstration Example of the Isolating Method

3.1. Introduction of the Example

Due to the availability of RS and FCG rate test data, 2024-T3 VPPA weld specimens are used as a demonstration example. The VPPA welding process was firstly investigated in 1940s and developed extensively in 1980s by the NASA for achieving high quality welds in aluminium alloys [19]. During the welding process, the molten pool and the heat input produce significant metallurgical changes compared with the BM. Both middle crack tension (MT) and compact tension (CT) specimens are used in this example. The specimen geometries are shown in Fig. 2. Measured RS distributions in the MT and CT specimens are given in Fig. 3 [7, 13]. For the configurations with longitudinal weld, crack grows across the fusion zone (FZ), heat affected zone (HAZ) and BM. The hardness in the FZ, where the molten material is solidified, is the lowest as this area contains a fairly coarse dendritic structure with little precipitation hardening [20]. Material in the HAZ has been thermally treated by the heat input during welding. These microstructure changes result in different crack growth rates comparing with that of the BM. FCG tests data are reported in [7, 21] and shown here in Fig. 4. Two applied loading conditions are considered, i.e. constant amplitude (CA) and constant ΔK (CK), of which $R = 0.1$ and 0.6 for the CA condition and $\Delta K = 6$, 11, and 15 MPa$\sqrt{\text{m}}$ for the CK condition.

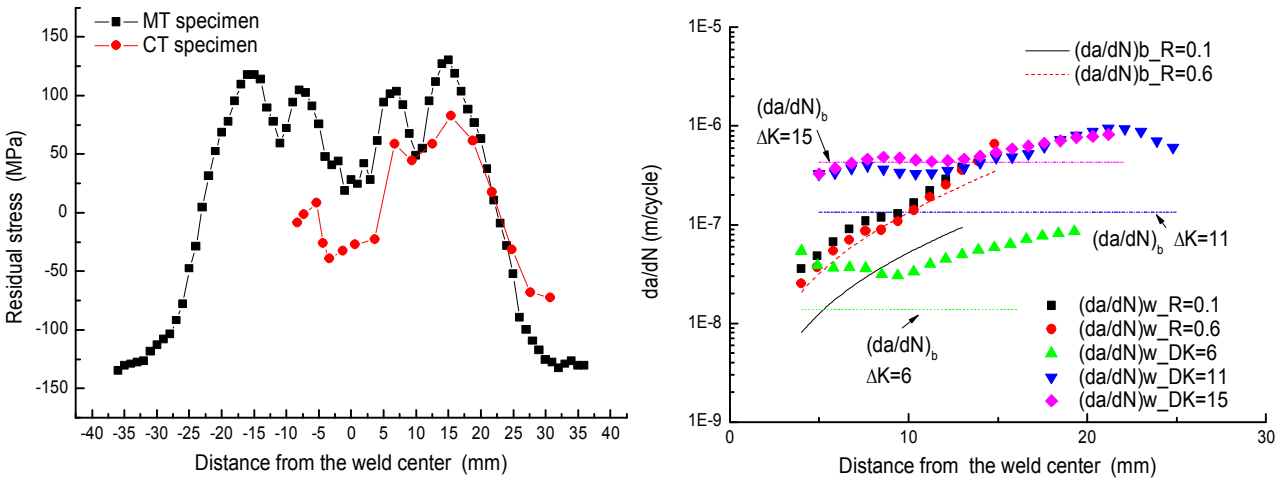

Fig 3. Longitudinal RS distribution

Fig. 4. Measured crack growth rates in BM & WM

3.2. Estimation of Δ_1

Δ_1 can be evaluated by Eq. (7), in which, both $(da/dN)_b$ and $(da/dN)_R$ are calculated by the NASGRO equation [16] expressed in Eq. (10)-(12). For $(da/dN)_b$, ΔK and R corresponding to the externally applied load, whereas, for the calculation of $(da/dN)_R$, ΔK and R in the following equations should be replaced by ΔK_{tot} and R_{eff} as given in Eq. (5) and (6). While, the material constants used in the equations are kept unchanged of the BM according to the presented method, which are available in the data base of the software AFGROW.

$$\frac{da}{dN} = C\left[\left(\frac{1-f}{1-R}\right)\Delta K\right]^n \frac{\left(1-\frac{\Delta K_{th}}{\Delta K}\right)^p}{\left(1-\frac{K_{\max}}{K_{crit}}\right)^q}, \tag{10}$$

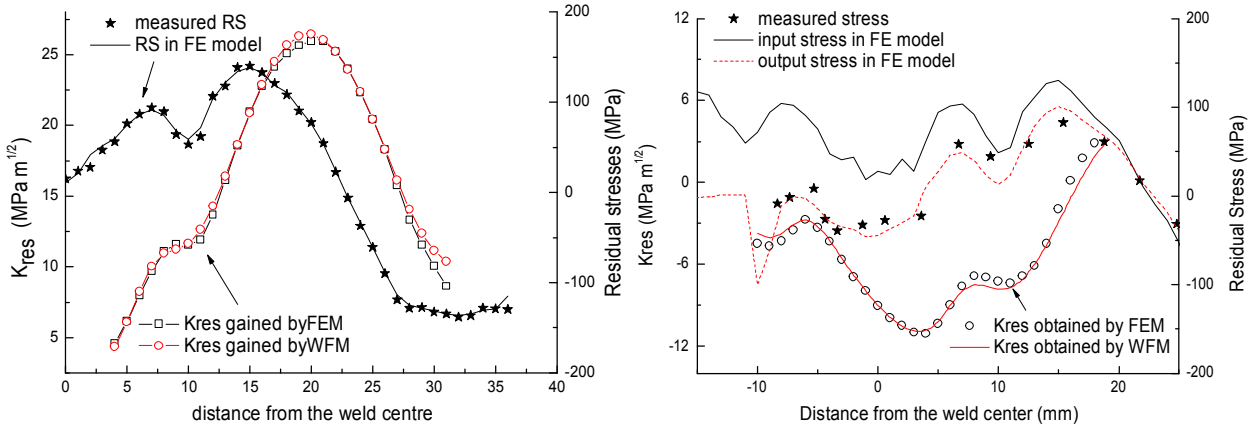
$$f = \frac{K_{op}}{K_{\max}} = \begin{cases} \max(R, A_0 + A_1 R + A_2 R^2 + A_3 R^3) & R \geq 0 \\ A_0 + A_1 R & -2 \leq R \leq 0 \\ a_0 - 2A_1 & R \leq -2 \end{cases}. \tag{11}$$

$$\Delta K_{th} = \Delta K_0 \frac{\left(\frac{a}{a+a0}\right)^{\frac{1}{2}}}{\left(\frac{1-f}{(1-A_0)(1-R)}\right)^{1+C_{th}R}}. \tag{12}$$

where C, n, p, q, f are empirical material constants. Coefficients A_0, A_1, A_2 and A_3 are parameters associated with the stress state (sample thickness). The thickness effect is also considered by the apparent fracture toughness K_{crit}. Intrinsic crack length a_0 is set as 0.0015 in (0.0381 mm).

In the procedure of evaluating $(da/dN)_R$, one of the most important work is to calculate K_{res}. Both the Finite Element Method (FEM) and Weight Function Method (WFM) can be used [18]. It is worth mentioning that the RS will redistribute during the cutting of the specimens or during the self-balance procedure in the FE analysis. Therefore, it is of great importance to make sure that the distribution of RS in the FE model agrees reasonably with that in the specimen. The input and output RS in the example are given in Fig. 5. It can be seen that there is a difference in the input and output RS in the CT specimen. The input one is the same as that in MT specimen since CT specimen is cut from the MT specimen. The output RS is the redistributed result after making a slot in FE model, which is consistent with that in the actual CT specimen [7]. If the measured RS in CT specimen was input into the FE model, then the output RS would be much smaller than that in the actual specimen, which will lead to underestimation of K_{res}. K_{res} is subsequently calculated using soft package ANSYS. Calculated K_{res} distributions are also shown in Fig. 5 and compared with the WFM solution from [22]. Calculated Δ_1 values are illustrated in Fig. 6.

It can be seen from Fig. 5(a) that estimated Δ_1 varies with the specimen configuration and externally applied load. Fig. 5(b) indicates that for the MT specimens the ratio $\Delta_1/(da/dN)_b$ shows similar characteristic shape as the K_{res} distribution except for the case of $R = 0.6$. The influence of applied stress on Δ_1 will be discussed in Section 4. Evaluated Δ_1 for the CT specimen is negative indicating that crack growth rate in CT specimen is reduced remarkably due to the presence of residual stress.



(a) (b)

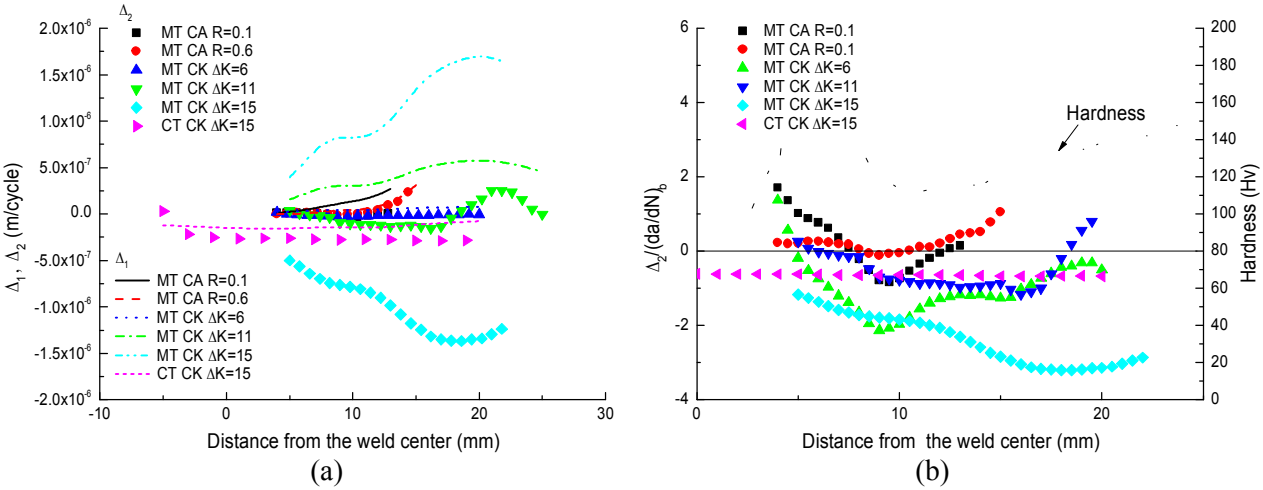
Figure 6. (a) Estimated Δ_1 and (b) ratio $\Delta_1/(\mathrm{d}a/\mathrm{d}N)_b$

3.2. Evaluation of Δ_2

Since $(\mathrm{d}a/\mathrm{d}N)_w$ is obtained by tests, $(\mathrm{d}a/\mathrm{d}N)_R$ is calculated in section 3.1, Δ_2 can be evaluated by Eq. (9). The calculated results are given in Fig. 7. It can be seen from Fig. 7 that: (1) for the MT specimen with longitudinal weld (weld line parallel to the external stress), evaluated Δ_2 is lower than Δ_1 except the case ΔK=15MPa√m, which will be discussed in Section 4; (2) the ratio $\Delta_2/(\mathrm{d}a/\mathrm{d}N)_b$ shows similar characteristic shape as the hardness variation.



(a) (b)

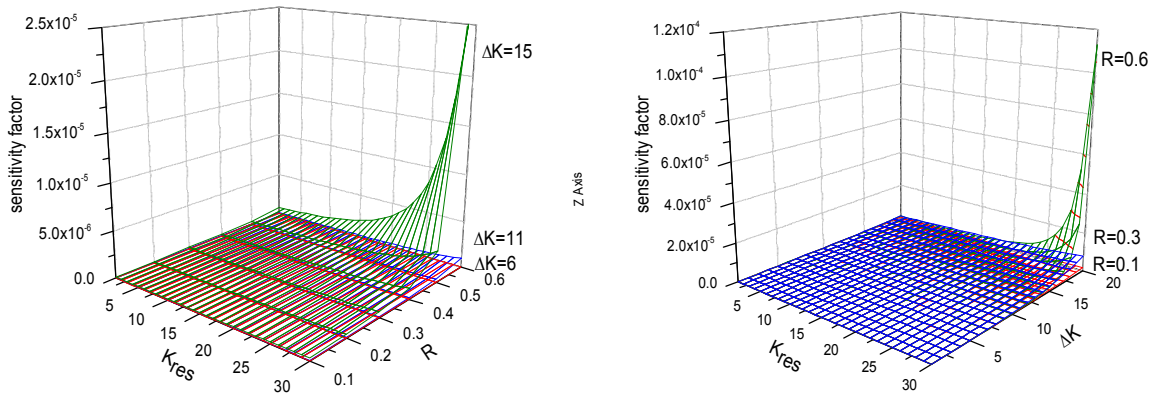
Figure 7. (a) Estimated Δ_2 and (b) ratio $\Delta_2/(da/dN)_b$

4. Discussion on the Isolation Method

According to the results in Fig. 6 and 7, MT geometry is a better choice than the CT for isolating Δ_1 and Δ_2 in longitudinal weld specimen. Therefore, the following discussion is based on the MT configuration only.

4.1. Influence of applied stress level on isolation results

Evaluated Δ_1 and Δ_2 are functions of the externally applied stress, as shown in Fig. 6(a) and 7(a). Effect of applied stress on crack growth rate could be correlated by R_{app} and ΔK_{app}. Since $\Delta_1 = (da/dN)_R - (da/dN)_b$ and $\Delta_2 = (da/dN)_w - (da/dN)_R$, in which $(da/dN)_w$ is test data, evaluated Δ_1 and Δ_2 depend on the calculation of $(da/dN)_R$. Sensitivity analysis on the effects of R_{app} and ΔK_{app} on $(da/dN)_R$ is carried out. For the discussion of the effect of R_{app}, constant ΔK loading condition is considered with the applied ΔK = 6, 11, and 15 MPa√m, respectively. For the sensitivity of ΔK_{app}, three stress ratios are selected, i.e. R = 0.1, 0.3, 0.6. Sensitivity factors are obtained by taking the partial derivative of the output $(da/dN)_R$ with respect to an input factor R_{app} or ΔK_{app}. The results are given in Fig. 8.



(a) (b)

Figure 8. Sensitivity analysis on (a) R_{app} and (b) ΔK_{app}

Fig. 8(a) indicates that if the applied ΔK level is low, e.g. 6 MPa√m, then calculated $(da/dN)_R$ is not very sensitive to the stress ratio; if the applied ΔK level is high, e.g. 15 MPa√m, the sensitivity factor increases significantly with the increase of R_{app} and K_{res}. Fig. 8(b) tells that if R_{app} levels are keep low, e.g. below 0.3, $(da/dN)_R$ is not very sensitive to ΔK_{app} level. Since $(da/dN)_R$ represents the effect of RS on crack growth rate, it is expected that $(da/dN)_R$ is sensitive to RS rather than applied stress. Therefore, high R ratios and high ΔK levels are not suitable for isolating Δ_1 and Δ_2.

4.2. Sensitivity analysis on K_{res}

Since K_{res} is calculated from measured RS distribution and scatter in RS data is unavoidable, it is unexpected that dispersion in RS data will introduce significant variation in the evaluated Δ_1 and Δ_2. Since K_{res} is calculated directly from RS, which keeps the error in RS, sensitivity analysis on the effects of K_{res} on $(da/dN)_R$ is performed using the same method as in Section 4.1. Two kinds of externally applied stress are used, one is the CA condition of $\Delta\sigma$ = 35 MPa and R_{app} = 0.1, 0.3 or 0.5,

the result is given in Fig. 9(a); the other is the CK condition with ΔK levels of 6, 11, and 15 MPa$\sqrt{m}$, corresponding results are shown in Fig. 9(b).

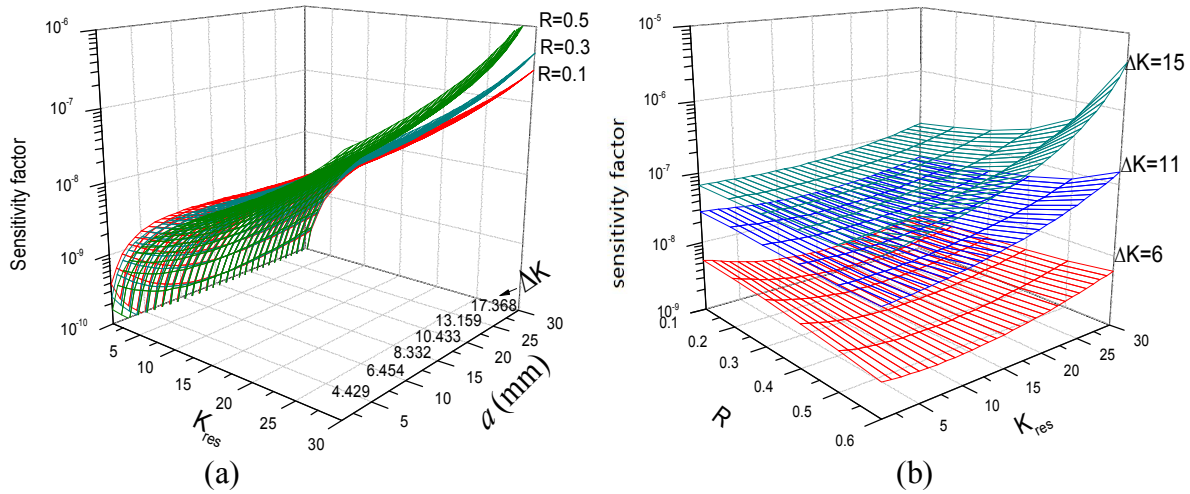


Figure 9. Sensitivity analysis on K_{res}

Fig. 9 indicates that the sensitivity factor of $(\mathrm{d}a/\mathrm{d}N)_R$ with respect to K_{res} depends on the ΔK level significantly, while, R_{app} shows little effect on it. It is expected that $(\mathrm{d}a/\mathrm{d}N)_R$ has certain sensitivity on K_{res} to reflect the effect of RS on crack growth rate, but sensitivity factor could better be kept in an acceptable level, otherwise, the error in measure RS data will show remarkable influence on the isolation results.

4.3. Influence of Crack Growth Laws on Isolation Results

The above discussions on the isolation method are all based on the NASGRO equation as shown in Eq. (10-12). Many other forms of crack growth rate correlation are available. Any crack growth law can be used in the isolation procedure if the parameters of R_{eff} and ΔK_{tot} are included in the equation. A popular and simple one is the Walker Equation [22] shown in Eq. (13).

$$\frac{\mathrm{d}a}{\mathrm{d}N} = C(\Delta K(1-R)^{(m-1)})^n . \tag{13}$$

Let the crack growth rate in BM be described by the Walker equation in accordance with that in the NASGRO equation, parameters in the Walker equation are set as $C = 4.8\times 10^{-11}$, n=3.2, m=0.6937, in unit of m and MPa. The loading case studied is the CA condition of R = 0.1, $\Delta\sigma_{\text{app}}$ = 35 MPa. Comparison of $(\mathrm{d}a/\mathrm{d}N)_b$ and $(\mathrm{d}a/\mathrm{d}N)_R$ obtained by these two equations is shown in Fig. 10(a) and evaluated Δ_1 and Δ_2 are in Fig. 10(b). It is can be seen that: (1) $(\mathrm{d}a/\mathrm{d}N)_R$ calculated by the two equations are slightly different, although $(\mathrm{d}a/\mathrm{d}N)_b$ correlated by the two equations are almost the same; (2) $(\mathrm{d}a/\mathrm{d}N)_R$ calculated by the Nasgro equation is a little higher than that by the Walker equation. This is because the effect of fracture toughness K_C is considered only in the Nasgro equation, and when $K_{\max} + K_{\text{res}}$ is close to K_C, the Nasgro equation will give better prediction; (3) the evaluated Δ_1 and Δ_2 by these two equations are the same in trends and show slightly difference in value, this difference could be covered by the scatter in crack growth rate; (4) the Walker equation is simple in format and easy for assessing the influence of applied and residual stresses, which is a good choice when the applied and residual stresses are in a acceptable level.

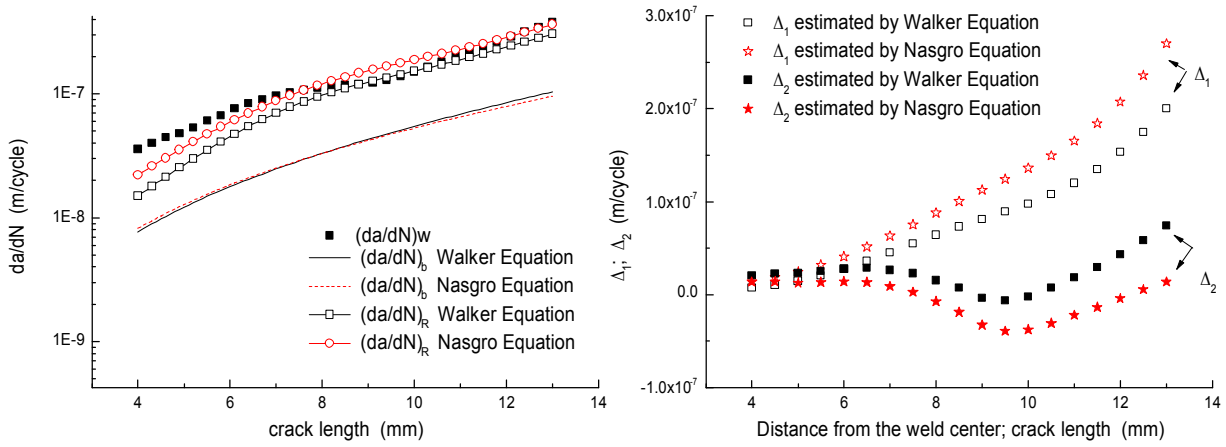

Figure 10. Comparison of the isolation results obtained by the Walker and Nasgro Equations

5. Conclusion

An isolation method for the contributions of residual stress and microstructural change in weld on fatigue crack growth rate is presented, and the factors affecting the isolation results are identified. It can be concluded that: (1) the presented method is applicable; (2) for specimens containing longitudinal weld, MT configuration is better than CT in the application of the isolation method; (3) the isolation results are found to be influenced by the test loading condition. High R_{app} or high ΔK_{app} are not good choice for studying the influential factors, but too low in R_{app} or ΔK_{app} can introduce crack closure in negative RS region, which is not good choice either; (4) if the applied stress is kept in a suitable level, a simpler crack growth law that include the effect of R and ΔK can be used in the presented method.

Abstract The ability of geckos to adhere to vertical solid surfaces comes from their remarkable feet with millions of projections terminating in nanometer spatulae. In this paper, we present a simple yet robust method for fabricating directionally sensitive dry adhesives. By using electrospun nylon 6 nanofiber arrays, we create gecko-inspired dry adhesives, that are electrically insulating, and that show shear adhesion strength of 27 N/cm^2 on a glass slide. This measured value is 270% that reported of gecko feet and 97-fold above normal adhesion strength of the same arrays. The data indicate a strong shear binding-on and easy normal lifting-off. Size and surface boundary of fibers both affect on the shear adhesion. This anisotropic strength distribution is attributed to enhanced shear adhesion strength with decreasing fiber diameter and an optimum performance of nanofiber arrays in the shear direction over a specific range of thicknesses.

Keywords dry adhesion, high aspect ratio structure, electrospun nylon 6 nanofibers

1. Introduction

Geckos are exceptional in their ability to climb on smooth and rough surfaces. The feet of a gecko possess the most versatile adhesive known in nature which produces a clinging capability of 10 N/cm^2 [1]. With growing interest in detachable adhesives, new materials are explored such as the types that employ elastomers, thermoplastics, and pressure-sensitive polymers [2]. Generally, these adhesives produce substantial shear adhesion strengths but are considerably difficult to detach from surfaces. Commercial high strength adhesives make use of chemical interactions such as glues and permanently attach two surfaces. Subsequently, fabrication of dry adhesives with anisotropic force distributions has the potential in several applications such as tapes, fasteners, treads of wall-climbing robots, spiderman's suits, microelectronics, medical and space applications.

There are obvious size effects when the scaling decreases to nanoscale. High aspect ratio (AR) structures exhibit significant shear adhesion strength compared to ones with low AR(s) [3,4]. Electrospinning presents a versatile technique for fabricating nanofibers with significant AR [5,6]. Little has been done for fabricating dry adhesives, which are electrically insulating, and which possess significant shear adhesion strength with easy normal detachment.

With use of electrospun nylon 6 nanofiber membrane, we report herein the fabrication of electrically insulating dry adhesives with high shear adhesion strength for strong shear binding-on but with substantial normal detachment strength (V) for easy normal lifting-off. With the aid of microscopy and microanalyses, we investigate the effects of the fiber diameter, fiber surface roughness, and thickness of membrane on their corresponding adhesion strengths. Our research group first measured the adhesion work of electrospun polymer fibers [7-9] and, in this paper, we will focus on the bending stiffness and dimensional characteristics of these fiber fabrics. In our

study, we found that the stiffness of fiber fabrics and dimensional characteristics play a critical role in optimizing the van der Waals (vdW) interactions and thus the shear adhesion strength between electrospun nylon 6 and surface asperities.

2. Experimental

2.1. Collection of aligned electrospun fibers

Nylon 6 pellets (Sigma Aldrich, CAS 25038-54-4) are dissolved in formic acid (EMD Corporation, CAS 64-18-6) and magnetically stirred overnight. A syringe pump is employed for maintaining a solution drop on the tip of a stainless steel needle (Gauge 24). The latter needle is attached to a 5 mL capacity syringe filled with the solution. The needle is charged with a high voltage of 25 kV. The gap distance between the tip of the needle and the top of rotating disc collector is set to be 150 mm. Collector has a diameter of 150 mm and electrospun fibers are collected at take-up velocity of 20 m/s.

2.2. Fabrication of high AR nanofiber membrane

After collecting electrospun fibers for 10 minutes, a portion of the membrane is discarded to prepare the surface of the collector for peeling. A small part of the membrane is then placed on a glass slide using the tapered tip of a needle. The glass slide is thereafter rotated in the plane where membranes overlap one another. Subsequently, membranes with substantial thickness are obtained. These membranes are then installed in a holder.

2.3. Atomic Force Microscopy (AFM)

Contact-mode AFM is performed for investigating the elastic modulus of fiber E. A contact-mode probe (Veeco Inc.), with a tip radius of 12 nm and a cantilever spring constant of 0.125 N/m, is employed. The diameter and surface roughness of fibers are determined using tapping-mode AFM. A tapping-mode probe (MikroMasch Inc.), with a tip radius of 10 nm and a cantilever spring constant of 40 N/m, is employed. Scanning is done at a frequency of 0.5 Hz and data are analyzed by employing SPI3800N probe station software (Seiko, Inc.). Surface roughness of the nanofiber is obtained by tracing a line along the fiber axis. An average roughness of the fiber surface is determined.

2.4. Macroscopic adhesion testing

Nanofiber membrane is finger-pressed on a glass slide and then the weight is added to the end of the line. The weight consists of a beaker which is incrementally filled with water until membranes get separated from the glass slide. The contact area between membrane and a glass slide has a width and a length of 3 mm and 2 mm, respectively. The only two parameters which vary are membrane thickness and nanofiber diameter. No external normal load is applied to the membrane while being tested.

3. Results and discussion

3.1. Effects of membrane thickness (*T*) on shear adhesion

As shown in Figure 1A, nanofiber membrane displays low shear adhesion strengths for T less than 12 µm. However, for T ranging between 15 µm and 40 µm, the shear adhesion strength of nanofiber arrays substantially increases with rising T and reaches peak values. For T greater than 40 µm, the shear adhesion strength of membrane is significantly reduced with increasing T and reaches considerably low values above T of 80 µm. Shear adhesion testing is performed at an angle θ of 0° with the glass slide. The highest shear adhesion strength of 27 N/cm^2 is reached for membranes having fibers with d of 50 nm and T of 30 - 40 µm. A glass beaker is filled with water (total weight of 170 g, shear adhesion strength of 28.3 N/cm2) and carried by a small piece of membrane (3 mm by 2 mm). This shear adhesion strength is 415% greater than the one reported for PC nanofiber-based dry adhesives [10]. As shown in Figure 1B, nanofibrous membranes may be considerably flexible with a weak tensile strength for *T* less than 12 µm. Subsequently, these membranes are expected to retain a minimal real contact area with a substrate. Thus, the latter membranes have limited vdW interactions and hence could not carry a heavy load. Nevertheless, as presented in Figure 1C, it is suggested that the flexibility and tensile strength of membranes reach optimum performances for T between 30 and 40 µm. Thus, membranes retain a significant real contact area with the glass substrate during loading, which leads to a substantial shear adhesion strength. However, as shown in Figure 1D, it is proposed that nanofibrous membranes start losing their flexibility for *T* greater than 40 µm. This phenomenon causes an extensive decrease in the real contact area between the fibers and the glass slide leading to deteriorating shear adhesion strength.

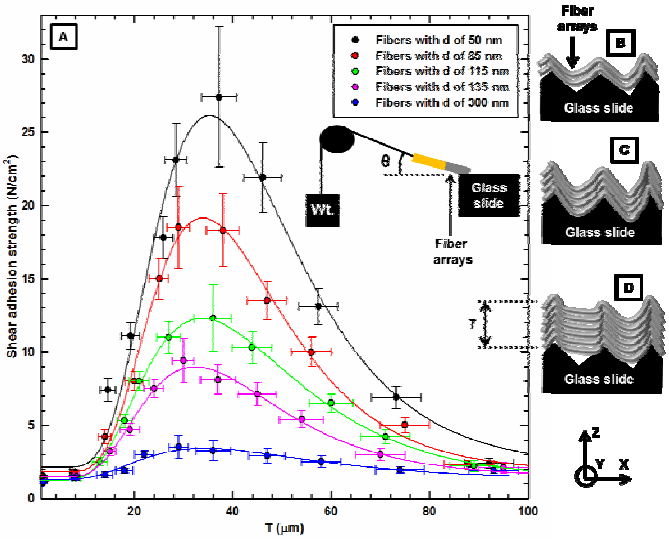

Figure 1. Shear adhesion strength as a function of *T* for aligned fiber membranes attached onto a glass slide with a preloading of 2kg

3.2. Effects of fiber packing density, nanofiber diameter (*d*) and fiber surface roughness on adhesion

As shown in Figure 2A-E, the packing density and aspect ratio of fibers are both noticeably enhanced with decreasing d. This enhancement is suggested to augment vdW interactions between

the fibers and the substrate leading to an upsurge in shear adhesion strength. As shown in Figure 2F, *d* extensively diminishes with decreasing concentration of polymer solution (*R*). The fiber packing density is characterized via SEM (FEI Quanta 200). Theoretical studies have shown that significant adhesion could be obtained by size reduction. Furthermore, the side contact of fibers with a substrate over a large contact area causes significant adhesion.

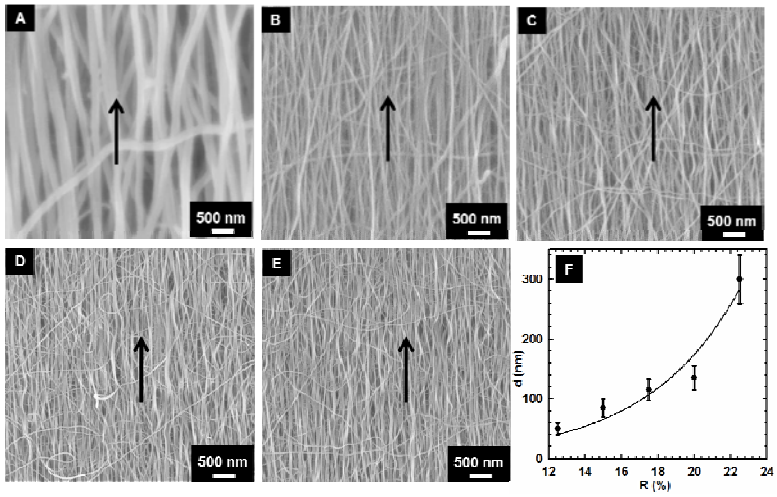

Figure 2. (A-E) Scanning electron microscopy (SEM) images of electrospun nylon 6 fibers with different *d*(s): 300 nm, 135 nm, 115 nm, 85 nm, and 50 nm, respectively; (F) *d* as a function of *R*

Surface boundary of fibers also makes contribution to the shear adhesion. For side wall contacts of fibers, the attractive force per unit length between the nanofiber and substrate is:

$$F_v = A\sqrt{d}\,/\left(16D^{2.5}\right) \tag{1}$$

Where A is the Hamaker constant, and D the gap distance between the surface of the nanofiber and the substrate [11,12]. There exists a cut-off gap distance $D=D_0$ which represents the effective separation between the nanofiber and substrate and at which the maximum F_v (F_{vM}) is estimated. The total F_{vM} is:

$$F_{vMK} = NLA\sqrt{d}\,/\left(16D_0^{2.5}\right) \tag{2}$$

Where N represents the total number of fibers along the contact width between the nanofiber arrays and the substrate (W) and is $N = W/d$. Replacing the value of N in the previous equation, we obtain:

$$F_{vMK} = LWA/\left(16D_0^{2.5}\sqrt{d}\right) \tag{3}$$

For constant values of *W* and the contact length between the nanofiber arrays and the substrate (*L*), F_{vMK} radically increases with decreasing *d*. These results suggest a substantial increase in the shear adhesion strength with diminishing *d*.

As shown in Figure 3, the surface roughness of fibers considerably diminishes with decreasing *d*. The latter decrease leads to a significant enhancement in shear adhesion strength between membrane and a substrate due to a considerable proliferation in the effective contact area.

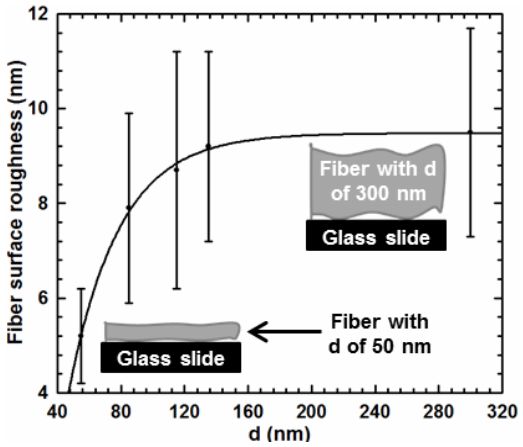

Figure 3. The surface roughness of a nanofiber as a function of *d*

3.3. Normal adhesion force

Membranes are easily peeled off a glass slide for $\theta = 90°$. For a contact area of (3x2) mm^2 with a glass slide, the normal adhesion force of the membranes is roughly 0.015 N, regardless of d and *T*. Meanwhile, the maximum shear adhesion force for nanofiber arrays is 1.6 N (Fibers with d of 50 nm) which leads to a $V = 100$. Thus, these nylon 6 fiber membranes are 10 times easier to detach from a glass slide in the normal direction dry adhesives. This significant *V* value is suggested to be due to the high AR of the nanofibers in this work. Thus, a significant decrease in the effective contact area between the nanofibers and the substrate arises during vertical detachment, which leads to an easy normal lifting-off.

3.4. Effect of Nanofiber Bending Stiffness on Adhesion

The bending stiffness of a nanofiber is $b = EI$ where *I* is the moment of inertia of the cross section of a nanofiber [13]. The indentation of a cantilever tip into the nanofiber is directly proportional to lateral deflection of the cantilever (ΔX) [2]. According to the Hertz model, ΔX is defined as:

$$h = \left[2\left(1-\nu^2\right)f/4a^{0.5}E\right]^{2/3} \tag{4}$$

Where *a* is the AFM probe tip radius, *v* the Poisson's ratio of the tested material, and f the applied normal load on a fiber. *f* is directly proportional to a sinusoidal drive signal (λ). As shown in Figure 4, ΔX continuously rises with increasing λ. Fibers with d of 300 nm display the largest slope (*P*). Fibers with d of 50 nm possess the smallest *P* where the latter is directly proportional to *E*. *P* of fibers with d of 300 nm (P_o) is taken as a reference value for determining the relative modulus of a fiber:

$$E_r = P/P_0 \tag{5}$$

As shown in Figure 5A, E_r for fibers with d of 50 nm is 6-fold above the one for fibers with *d* of 300 nm. This upsurge is mainly caused by the increase in molecular orientation during

electrospinning and nanofiber collection when d diminishes. Thus, it becomes more difficult for the tip of an AFM probe to penetrate deeper in the polymer chains of a fiber leading to a smaller ΔX value for a specific λ value [2]. Assuming that a nanofiber has a circular cross section [13],

$$I = \pi d^4/64 \tag{6}$$

The relative moment of inertia is:

$$I_r = I/I_0 = (d/d_o)^4 \tag{7}$$

Where d_0 is 300 nm and I_0 is I for d_0. The relative bending stiffness is:

$$b_r = E_r I_r \tag{8}$$

And thus:

$$b_r = E_r (d/d_0)^4 \tag{9}$$

As shown in Figure 5B, $1/b_r$ significantly rises with decreasing d for fibers with d less than 120 nm. Fibers with d of 50 nm are 150 times more flexible than the ones with d of 300 nm. As shown in insets of Figure 5B, this noteworthy flexibility is suggested to cause a substantial enhancement in the real contact area between a nanofiber and a glass slide. This enhancement could play a critical role to significantly increase the shear adhesion strength between a nanofiber and a glass slide.

4. Conclusions

We presented a technique for fabricating electrically insulating dry adhesives from electrospun nylon 6 nanofibers. These adhesives possess shear adhesion strength as high as 27 N/cm^2 on a glass slide. This measured value is 97-fold above normal adhesion strength of the same adhesive. For a definite d, the shear adhesion strength of membranes reaches optimum values for a specific range of arrays thicknesses while deteriorating otherwise. These optimum values suggest that these arrays could retain a significant real contact area with the substrate during loading. Fiber bending stiffness and fiber packing density are significantly increased with decreasing d while fiber surface roughness is noticeably reduced. These enhancements are proposed to considerably increase the shear adhesion strength between a nanofibrous membrane and a glass slide. The drastic increase is mainly attributed to a sizeable proliferation in vdW forces with enhanced contact area. This finding enables us to create electrically insulating dry adhesives with a strong shear adhesion and relatively weak normal adhesion for easy detachment.

Abstract Nanostructured piezoelectric materials hold a promise for the development of novel nanodevices in nanoelectromechanical systems (NEMS) due to their efficient electromechanical coupling. To fulfill their potential applications, it is essential to quantitatively predict their fundamental physical and mechanical properties. In this work, the unique size-dependent properties of piezoelectric nanomaterials, which are believed to attribute to surface effects and flexoelectricity, are investigated through a modified Euler beam model. The surface effects are accounted in a modified beam theory through the surface piezoelectricity model and the generalized Young-Laplace equations, while the flexoelectricity is considered by using the higher-order theory of piezoelectricity. Simulation results on the vibration analysis of piezoelectric nanobeams reveal that the influence of surface effects and flexoelectricity varies with beam thickness and aspect ratio, in particular, such influence becomes more pronounced with the decrease of beam thickness. Vibration analysis also identifies possible frequency tuning of piezoelectric nanobeams by electrical load. In addition, the effect of axial boundary constraints in modeling has been studied, which provides a clear interpretation on the relaxation phenomenon of nanobeams under certain boundary constraints. This study is expected to provide a quantitative understanding on the fundamental physics of piezoelectric materials, thus leading to a better design for piezoelectric nanobeam-based devices.

Keywords Surface effects, Flexoelectricity, Size-dependent properties, Piezoelectric nanobeam

1. Introduction

One-dimensional piezoelectric nanostructures, such as piezoelectric nanowires, nanobelts and nanorods have been extensively used in nanoelectromechanical systems (NEMS) as nanosensors [1], nanoresonators [2] and nanogenerators [3, 4]. The superior performances exhibited by these devices can be attributed to the novel electromechanical coupling properties of piezoelectric materials at nanoscale. Therefore, to reveal the underlying physical mechanisms of piezoelectric nanomaterials and to achieve the unprecedented improvements of these nanosized devices, it is essential to conduct a quantitative study on the physical and mechanical properties of nanostructured piezoelectric materials.

"Small is different", it is expected that the physical properties of piezoelectric nanomaterials differ from their bulk counterparts. Efforts have been devoted to investigating the physical properties of piezoelectric nanostructures. For example, it was experimentally observed that the elastic and fracture properties of piezoelectric nanowires demonstrated a size-dependent behavior unlike the bulk piezoelectric wires [5, 6]. The size-dependent mechanical properties of piezoelectric nanomaterials have also been confirmed by conducting atomistic modeling and simulations [7]. Based on a molecular dynamics study, the size effects were found to have a prominent influence on the polarization distribution, piezoelectric coefficient and hysteresis behaviors of $BaTiO_3$ nanowires [8]. All the aforementioned studies indicated the size effects played a significant role in predicting the mechanical and physical properties of piezoelectric nanostructures. In parallel to experimental work and atomistic studies, continuum mechanics modeling, as an alternative and efficient tool, has

been naturally resorted to investigate the mechanical properties of nanostructured materials. However, classical continuum approaches, which ignore the variation of interatomic quantities, fail to capture the size effects of materials at nanoscale. Therefore, non-classical continuum models with the consideration of size effects are necessary to conduct the mechanical and physical analysis of nanoscale structures.

Due to the large surface area to volume ratio of typical nanostructures, surface effects are believed to attribute to the size-dependent properties of these structures. By taking into account of surface effects, Gurtin and Murdoch proposed a surface elasticity model for elastic materials [9], in which a surface is modeled as a thin layer with negligible thickness adhered to the bulk without slipping, and the constitutive and equilibrium equations for the surface layer are different from those in the bulk of the solid. Using this model, the size-dependent properties of elastic nanomaterials have been successfully predicted [10-12]. However, the surface elasticity model is not sufficient to investigate the mechanical behaviors of piezoelectric nanostructures with electromechanical coupling properties. In order to solve this problem, modified continuum model with electric field dependent surface effects has been developed for piezoelectric nanostructures [13]. In this surface piezoelectricity model, the surface stresses depend on surface piezoelectricity in addition to surface elasticity and residual surface stress incorporated in the surface elasticity theory. Based on this novel surface piezoelectricity model, the static and dynamic behaviors of various piezoelectric nanostructures have been investigated [13-16]. Simulation results indicated that the surface effects had a significant influence on the static bending, vibration and mechanical buckling properties of these piezoelectric nanostructures.

In literature, flexoelectricity was also believed to be responsible for the size-dependent properties of piezoelectric nanomaterials, which refers to a spontaneous polarization of dielectric materials due to a strain gradient or a non-uniform strain field. Maranganti *et al.* proposed a theoretical framework for dielectrics with the consideration of flexoelectricity, elucidating the mechanism for size-dependent electromechanical coupling due to strain or polarization gradients [17]. The strong size-dependent enhancement of the effective piezoelectric coefficients of piezoelectric nanomaterials was demonstrated by Majdoub *et al.* [18] with the incorporation of flexoelectricity into piezoelectricity theory. Eliseev *et al.* investigated the renomalization in properties of nanoferroics due to spontaneous flexoelectric effect [19]. Recently, Liu *et al.* studied the effect of flexoelectricity on electrostatic potential in a piezoelectric nanowire [20]. These existing studies indicated the necessity of considering flexoelectric effect in characterizing the properties of nanostructured piezoelectric materials.

The objective of this work is to conduct the vibration analysis of a piezoelectric nanobeam with the consideration of surface effects and flexoelectricity. The surface effects are accounted in a modified beam theory through the surface piezoelectricity model and the generalized Young-Laplace equations. It should be mentioned that in the current study, the surface effects on the vibration of the piezoelectric nanobeam will be investigated with the consideration of axial boundary constrains, which have been ignored in existing studies. In addition, the flexoelectric effect on the vibration behavior of a piezoelectric nanobeam will be studied using the higher order theory of

piezoelectricity.

2. Surface Effects on the Vibration of Piezoelectric Nanobeams

In this work, the vibration of a piezoelectric nanobeam with length L, thickness h and width b is studied with surface effects. As seen from Fig. 1(a), the beam is modeled as a bulk core surrounded by surface layers with negligible thickness. A Cartesian coordinate (x, y, z) is used to describe the piezoelectric beam, which is poled in z direction. An electric potential V is applied between the upper and lower surfaces of the beam with the electric boundary conditions $\Phi\left(h/2\right)=V$ and $\Phi\left(-h/2\right)=0$. The electric field is assumed to exist only in the beam thickness direction and can be determined from the electric potential Φ as $E_z=-\partial\Phi/\partial z$. To account for the surface effects, a surface piezoelectricity model is adopted here [13, 14]. According to this model, the constitutive equations for the surface and bulk of the one-dimensional beam can be expressed as follows:

$$\sigma_x^{\mathrm{s}}=\sigma_x^0+c_{11}^{\mathrm{s}}\varepsilon_x-e_{31}^{\mathrm{s}}E_z,\ D_x^{\mathrm{s}}=D_x^0, \tag{1}$$

$$\sigma_x=c_{11}\varepsilon_x-e_{31}E_z,\ D_z=e_{31}\varepsilon_x+\kappa_{33}E_z, \tag{2}$$

where σ_x^{s} and D_x^{s} are surface stress and surface electric displacement; σ_x^0 and D_x^0 are residual surface stress and surface electric displacement; c_{11}^{s} and e_{31}^{s} are surface elastic and piezoelectric constants; σ_x and D_z are bulk stress and bulk electric displacement; c_{11}, e_{31} and κ_{33} are bulk elastic, piezoelectric and dielectric constants; ε_x and E_z are the strain and electric field.

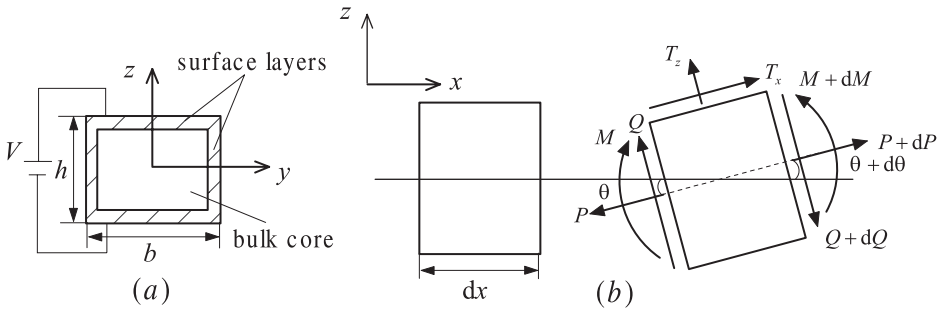

Figure 1. (*a*) Cross sectional view of a piezoelectric nanobeam with surface layers and bulk core. (b) An incremental element of the beam

The existence of surface stress induces traction jumps exerting on the bulk of the beam, as shown in Fig. 1(b). It should be mentioned that these traction jumps exist on the circumferential surfaces of the beam. According to the generalized Young-Laplace equations [21], traction jumps T_x and T_z can be written as:

$$T_x=\frac{\partial\sigma_x^{\mathrm{s}}}{\partial x},\ T_z=\frac{\sigma_x^{\mathrm{s}}}{R}, \tag{3}$$

with R being the radius of curvature defined positively when the normal of surface is pointed towards the center of curvature. Based on the free-body diagram of an incremental element of the beam, as shown in Fig. 1(b), the governing equations of the piezoelectric nanobeam are derived as follows:

$$\frac{\partial P}{\partial x}+\int_c T_x \mathrm{d}c=\rho bh\frac{\partial^2 u_0(x,t)}{\partial t^2}, \tag{4}$$

$$\frac{\partial^2 M}{\partial x^2}-P\frac{\partial^2 w(x,t)}{\partial x^2}-\int_c T_z \mathrm{d}c-\frac{\partial\int_c T_x z\mathrm{d}c}{\partial x}=-\rho bh\frac{\partial^2 w(x,t)}{\partial t^2}, \tag{5}$$

where c is the perimeter of the beam cross-section; ρ is the mass density; $P=\int\sigma_x \mathrm{d}y\mathrm{d}z$ and $M=-\int\sigma_x z\mathrm{d}y\mathrm{d}z$ are the axial force and bending moment; $u_0(x, t)$ and $w(x, t)$ are the axial displacement at z=0 and the transverse displacement.

Assuming that the beam thickness is much smaller than the radius of curvature induced by the applied loads and the beam cross section is constant along its length, thus, the Euler-Bernoulli beam theory can be adopted for modeling the piezoelectric nanobeam and the axial strain is expressed as:

$$\varepsilon_x=\frac{\partial u_0(x,t)}{\partial x}-z\frac{\partial^2 w(x,t)}{\partial x^2}. \tag{6}$$

It is worth noting that in existing studies of both elastic and piezoelectric nanobeams, $u_0(x, t)$ was assumed as zero based on the conventional Euler-Bernoulli model, therefore, the first term of Eq. (6) was ignored accordingly [10-12, 14, 15]. However, this assumption may not be accurate since $u_0(x, t)$ is not necessary zero for the nanobeam with surface effects. For example, the existence of surface stress induces an axial relaxation displacement as discussed in literature [22]. In addition, for piezoelectric nanobeams, the applied electrical load may also induce an axial displacement due to the inherent electromechanical coupling of piezoelectric materials. In fact, the beam can be either constrained without axial movement or allowed to have free movement with traction free boundary conditions. Therefore, the axial boundary conditions may influence the surface effects on the vibration behavior of piezoelectric nanobeams, which will be discussed later in this section.

In the absence of free electric charges, the electric displacement satisfies Gauss's law $\partial D_x/\partial x+\partial D_y/\partial y+\partial D_z/\partial z=0$, which gives an explicit expression of the electric field. Assuming $u_0(x,t)$ is independent of time t and substituting Eqs. (1)-(3) and (6) into Eqs. (4) and (5), the following governing equations can be obtained as:

$$\left[c_{11}bh+(2b+2h)c_{11}^{\mathrm{s}}\right]\frac{\partial^2 u_0(x)}{\partial x^2}=0, \tag{7}$$

$$(EI)^*\frac{\partial^4 w(x,t)}{\partial x^4}-N^*\frac{\partial^2 w(x,t)}{\partial x^2}=-\rho bh\frac{\partial^2 w(x,t)}{\partial t^2}, \tag{8}$$

in which $(EI)^*=\left(c_{11}+e_{31}^2/\kappa_{33}\right)bh^3/12+\left(c_{11}^{\mathrm{s}}+e_{31}^{\mathrm{s}}e_{31}/\kappa_{33}\right)\left(h^3/6+bh^2/2\right)$ is the effective bending rigidity of the beam and $N^*=\left[c_{11}\partial u_0/\partial x+e_{31}V/h\right]bh+2\left[\sigma_x^0+c_{11}^{\mathrm{s}}\partial u_0/\partial x+e_{31}^{\mathrm{s}}V/h\right]b$.

In this work, the vibration analysis will be conducted for cantilever (C-F), simply-supported (S-S)

and clamped-clamped (C-C) piezoelectric nanobeams, respectively. The boundary conditions are prescribed as:

$$u_0 = w = \frac{\partial w}{\partial x} = 0 \text{ at } x = 0,\ P^* = M^* = Q^* = 0 \text{ at } x = L \quad \text{(C-F)}, \tag{9}$$

$$\begin{cases} u_0 = w = M^* = 0 \text{ at } x = 0 \text{ and } x = L \text{ (Case 1)} \\ P^* = w = M^* = 0 \text{ at } x = 0 \text{ and } x = L \text{ (Case 2)} \end{cases} \text{(S-S)}, \tag{10}$$

$$u_0 = w = \frac{\partial w}{\partial x} = 0 \text{ at } x = 0 \text{ and } x = L \quad \text{(C-C)}, \tag{11}$$

where $P^* = \int \sigma_x \mathrm{d}y\mathrm{d}z + \int_c \sigma_x^{\mathrm{s}} \mathrm{d}c = \left[c_{11}\partial u_0/\partial x + e_{31}V/h\right]bh + 2\left[\sigma_x^0 + c_{11}^{\mathrm{s}}\partial u_0/\partial x + e_{31}^{\mathrm{s}}V/h\right](b+h)$ is the effective axial force; $M^* = (EI)^* \partial^2 w/\partial x^2$ is the effective moment; and $Q^* = (EI)^* \partial^3 w/\partial x^3 - N^* \partial w/\partial x$ is the effective shear force. It should be mentioned that two different axial boundary conditions may apply for simply-supported piezoelectric beam, as shown from Eq. (10). The beam is constrained without axial moving under the Case 1 boundary condition while traction free is adopted under the Case 2 boundary condition. The traction free boundary condition is also adopted for the cantilever beam as indicated in Eq. (9). Under this condition, an uniform strain $\varepsilon = \partial u_0/\partial x = -\left[e_{31}Vb + 2\sigma_x^0(b+h) + 2e_{31}^{\mathrm{s}}V(b+h)/h\right] / \left[c_{11}bh + 2c_{11}^{\mathrm{s}}(b+h)\right]$ is induced by the applied electrical load and surface effects, which will influence the vibration behavior of piezoelectric nanobeams. After applying these boundary conditions, the resonant frequencies of the piezoelectric nanobeams can be determined. For conciseness, the derivation procedures are omitted here.

To show the surface effects on the vibration behavior of a piezoelectric nanobeam quantitatively, PZT-5H is taken as an example material with the bulk material properties being c_{11}=126 GPa, e_{31}=-6.5 C/m^2 and κ_{33}=1.3×10^{-8} C/V·m. In addition, the surface properties are taken as $c_{11}^{\mathrm{s}} = 7.56$ N/m, $e_{31}^{\mathrm{s}} = -3\times10^{-8}$ C/m and $\sigma_x^0 = 1.0$ N/m. In the current work, only the first mode resonant frequency of the piezoelectric nanobeam is studied. Firstly, the variation of the normalized resonant frequency $\omega^{\mathrm{s}}/\omega^0$ of a simply-supported piezoelectric nanobeam with beam thickness h under both Case 1 and Case 2 axial boundary conditions is plotted in Fig. 2. ω^0 is the resonant frequency calculated without the consideration of surface effects and the applied electrical load. The beam geometry is set as b=h and L=10h. It is clearly seen from this figure that the axial boundary constraint has a significant influence on the vibration of the piezoelectric nanobeam, as evidenced by the dissimilar variation trends. For example, when the axial boundary constraint is set as described in Case 1, the combined effects of surfaces and electrical load increase the resonant frequency of the piezoelectric nanobeams. When V=-0.1 V, the influence is the largest ($\omega^{\mathrm{s}}/\omega^0$ is about 1.2 at h=10 nm). However, under Case 2 boundary constraint, the resonant frequency can be either enhanced or reduced by the surface effects and the applied electrical load ($\omega^{\mathrm{s}}/\omega^0$ is about 1.01 and 0.95 when V=0.1 V and -0.1 V, respectively at h=10 nm). It is noted that the variation of resonant frequency with the applied electric potential in this figure indicates a possible avenue for frequency tuning of piezoelectric nanobeams. It is also observed that the surface effects have more prominent influence on the resonant frequency of a beam with smaller thickness. While such surface effects decrease with the increase of beam thickness h. Fig. 3 shows the variation of the normalized resonant frequency of a piezoelectric nanobeam against the beam thickness. The beam has the same geometric parameters as the one in Fig. 2 without any applied electrical load. It

demonstrates that the surface effects on the resonant frequencies of piezoelectric nanobeams are significantly influenced by the beam boundary conditions. For the S-S beam with Case 1 boundary constraint and the C-C beam, surface effects increase the resonant frequencies, while the trend is opposite for the S-S beam with Case 2 boundary constraint and the C-F beam. Again, surface effects are more significant for the beam with smaller thickness h and reduce with the increase of h. From these two figures, it is conduced that the axial boundary condition plays a substantial role in the transverse vibration of piezoelectric nanobeams with surface effects. Therefore, it is essential to consider the axial boundary constraints in predicting the vibration behavior of piezoelectric nanobeams.

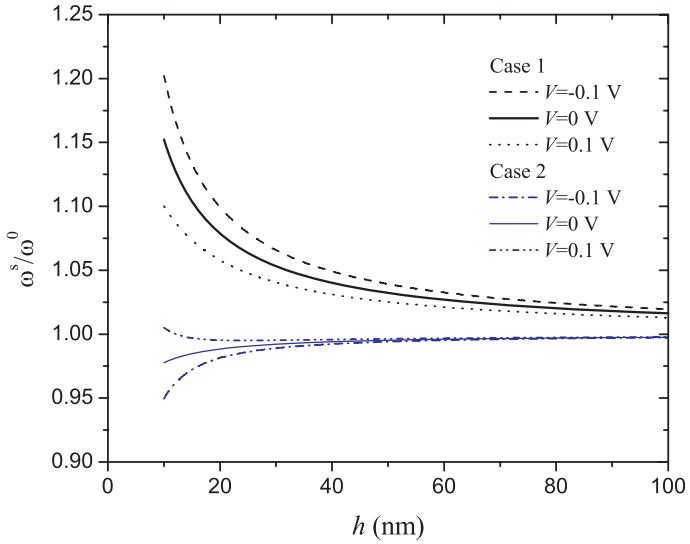

Figure 2. The normalized resonant frequency ω^s / ω^0 versus beam thickness h for a simply-supported piezoelectric nanobeam with surface effects under different axial boundary conditions

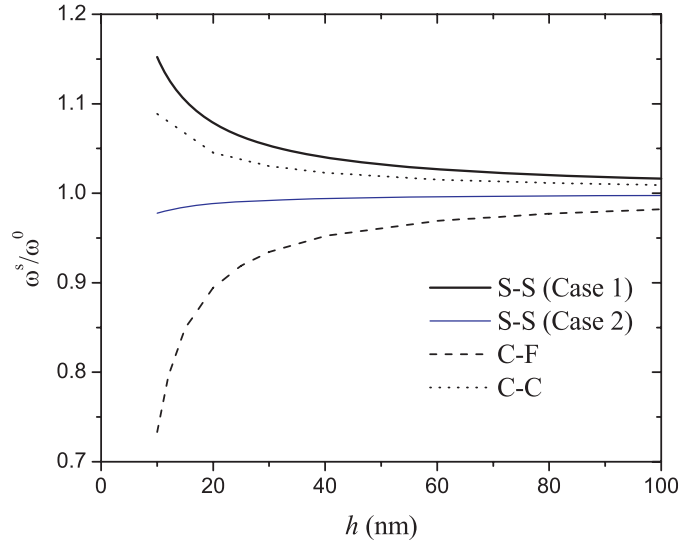

Figure 3. The normalized resonant frequency ω^s / ω^0 versus beam thickness h for a piezoelectric nanobeam with surface effects under different boundary conditions

As mentioned before, the applied electrical load and surface effects will induce an axial strain when the axial traction free condition is prescribed for the beam. As shown in Fig. 4, without the consideration of the surface effects, the product of this axial strain with the beam thickness is a

constant, i.e., $\varepsilon h = -e_{31}V / c_{11}$. When V=0 V, no axial strain is induced for the beam without considering the surface effects. However, the existence of the residual surface stress will still induce a relaxation strain as shown by the curve V=0 V with surface effects in Fig. 4. This relaxation phenomenon has been well discussed in [22] based on atomistic simulations. It is also observed in this figure that the surface effects lead to the size-dependency of this axial strain.

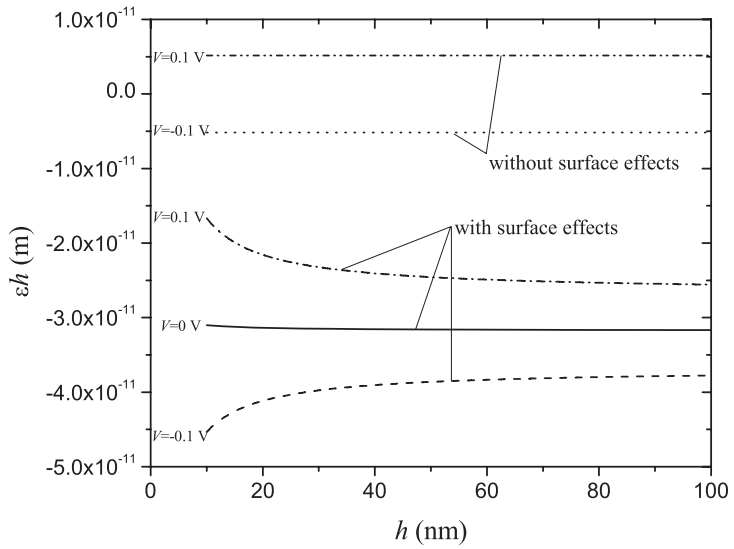

Figure 4. Axial strain εh versus beam thickness h for a piezoelectric nanobeam under different applied electrical load

3. Flexoelectricity on the Vibration of Piezoelectric Nanobeams

Flexoelectricity is induced by non-uniform deformation or strain gradient, which becomes significant as the structural size scales down to nanometers. To account for this effect, the higher order theory of piezoelectricity incorporating the strain gradient term will be adopted in the current work for a C-C beam. The same Cartesian coordinate system as shown in Fig. 1 is used to describe a piezoelectric nanobeam with flexoelectricity. The geometry, poling direction and electric boundary conditions of the beam are the same as those stated in Section 2. Under Euler-Bernoulli assumption, the axial strain can be defined as $\varepsilon_x = -z\partial^2 w / \partial x^2$. In the current study, we only consider the strain gradient $\varepsilon_{x,z}$, while $\varepsilon_{x,x}$ is ignored due to the large length scale along the beam axis direction. The relevant stress and electric field are σ_x and E_z, which can be expressed as [18]:

$$\sigma_x = c_{11}\varepsilon_x + d_{31}P_z,\ E_z = a_{33}P_z + d_{31}\varepsilon_x + f_{13}\varepsilon_{x,z}, \tag{12}$$

where P_z is polarization; a_{33} is dielectric susceptibility; and f_{13} is the flexoelectric coefficient. In addition, a higher order stress $\sigma_{xxz} = f_{13}P_z$ is introduced in the piezoelectricity theory. In the absence of free surface charges, the Gauss's law can be written as:

$$-\varepsilon_0 \frac{\partial^2 \Phi}{\partial z^2} + \frac{\partial P_z}{\partial z} = 0, \tag{13}$$

where $\varepsilon_0 = 8.85\times10^{-12}$ F/m is the dielectric permittivity of a vacuum. From Eqs. (12) and (13) with the consideration of electric boundary conditions of the beam, the polarization in the piezoelectric beam can be determined as:

$$P_z = \frac{\varepsilon_0 d_{31}}{\varepsilon_0 a_{33}+1} z \frac{\partial^2 w(x,t)}{\partial x^2} + \frac{f_{13}}{a_{33}} \frac{\partial^2 w(x,t)}{\partial x^2} - \frac{V}{a_{33} h}. \tag{14}$$

It is clearly seen from this equation that polarization can be induced by flexoelectricity. The governing equation of the flexoelectric nanobeam is formulated from Hamilton's principle [18]:

$$\delta U - \delta T - \delta W = 0, \tag{15}$$

where $U = \frac{1}{2}\int_{t_1}^{t_2}\int_{\Pi}\left(\sigma_x \varepsilon_x + \sigma_{xxz}\varepsilon_{x,z}\right)\mathrm{d}\Pi \mathrm{d}t$ (t is the time and Π is the entire domain of the structure) is the strain energy, and $T = \frac{1}{2}\int_{t_1}^{t_2}\int_{\Pi}\rho\left(\frac{\partial w}{\partial t}\right)^2 \mathrm{d}\Pi \mathrm{d}t$ is the kinetic energy. The resultant axial force is defined as $P_x = b\int_{-h/2}^{h/2}\left(\sigma_x - \sigma_{xxz,z}\right)\mathrm{d}z$, with the consideration of applied shear force Q_0, Q_L and moment M_0, M_L, the work is defined as $W = -\frac{1}{2}\int_{t_1}^{t_2}\left[\int_0^L P_x\left(\frac{\partial w}{\partial x}\right)^2 \mathrm{d}x + M_L \left.\frac{\partial w}{\partial x}\right|_L - M_0 \left.\frac{\partial w}{\partial x}\right|_0 - Q_L w_L + Q_0 w_0\right]\mathrm{d}t_0$. With these defined quantities, the governing equation is derived from Eq. (15) as:

$$A^* \frac{\partial^4 w(x,t)}{\partial x^4} + \frac{d_{31}}{a_{33}} Vb \frac{\partial^2 w(x,t)}{\partial x^2} = -\rho bh \frac{\partial^2 w(x,t)}{\partial t^2}, \tag{16}$$

with $A^* = \left[c_{11} - \varepsilon_0 d_{31}^2 / \left(\varepsilon_0 a_{33}+1\right)\right] bh^3/12 - f_{13}^2 / a_{33} bh$.

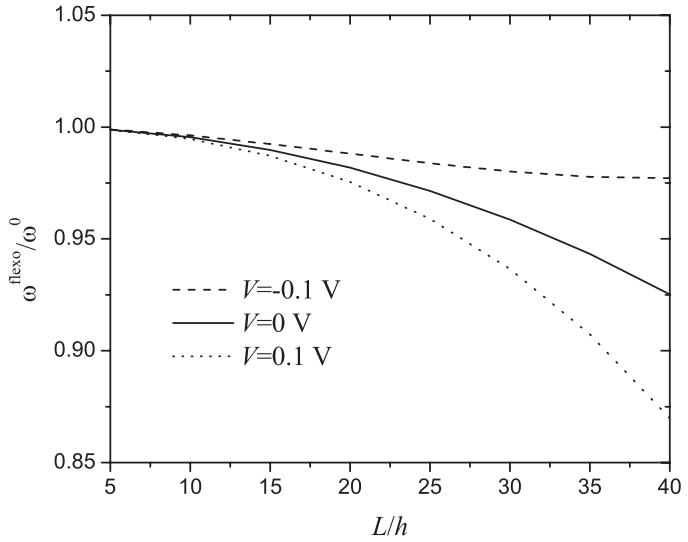

Figure 5. The normalized resonant frequency $\omega^{\text{flexo}} / \omega^0$ versus beam length to thickness ratio L/h for a piezoelectric nanobeam with flexoelectricity

For case study, the vibration of a clamped-clamped (C-C) piezoelectric nanobeam is investigated with the consideration of flexoelectricity. $BaTiO_3$ is taken as the example material with material properties being $c_{11} = 167.5$ GPa, $d_{31} = 3.5\times10^8$ V/m and $a_{33} = 0.8\times10^8$ V·m/C. The flexoelectric coefficients of $BaTiO_3$ can be determined from experiments or atomistic simulations. Following Ref. [19], in which the typical value of the flexoelectric coefficient is 1−10 V, we take $f_{13} = 5$ V. The variation of the normalized resonant frequency $\omega^{\text{flexo}} / \omega^0$ of the piezoelectric nanobeam against the beam length to thickness ratio L/h is plotted in Fig. 5, in which ω^0 is the resonant frequency calculated without the consideration of flexoelectricity and applied electrical load. The beam length is L=500 nm and b/h=1. When the applied electric potential is V=0 V, it is seen that flexoelectricity

decreases the resonant frequency of the clamped-clamped beam and this influence increases with the increase of L/h. The size-dependency of flexoelectricity is clearly demonstrated in this figure and such effect becomes negligible when the beam thickness becomes large, for example, the results with the consideration of the flexoelectricity approach to those from the classical theory when L/h=5. It is also observed that the influence of flexoelectricity on the normalized resonant frequency of the piezoelectric nanobeam depends on applied electrical load, as evidenced by the discrepancies among the results under different applied electrical load, which again indicate the possible frequency tuning of piezoelectric nanobeam by applying electrical load. However, such frequency tuning of piezoelectric nanobeams must incorporate the influence of flexoelectricity.

4. Conclusions

The influence of surface effects and flexoelectricity on the vibration behavior of piezoelectric nanobeams is investigated in the current work. Surface effects are incorporated into the modeling through the surface piezoelectricity model and the generalized Young-Laplace equations. In addition to the transverse boundary conditions, the axial boundary constraints are also considered for the beam with surface effects. Simulation results indicate both axial and transverse boundary constraints significantly influence the surface effects on the resonant frequencies of piezoelectric nanobeams. An axial strain relaxation is also observed under axial traction free boundary condition. Both applied electrical load and surface effects will affect such a relaxation phenomenon. Flexoelectricity is considered by adopting higher order theory of piezoelectricity. It is found that flexoelectric effect also has a substantial effect on the vibration of piezoelectric nanobeams. Both surface effects and the effect of flexoelectricity are more prominent for piezoelectric nanobeams with smaller thickness, which are attributed to the size-dependent properties of piezoelectric nanobeams. It is also observed that the resonant frequencies can be tuned by adjusting the applied electrical load. This work is expected to provide a better physical understanding of piezoelectric nanobeams and a guideline for the design of piezoelectric nanobeam-based devices.

Revisit on the fractal dimension in damage and fracture

Chunsheng Lu[1,*]

Abstract The catastrophic failure of materials is a complicated process, involving the nucleation, growth and coalescence of numerous cracks with a wide range of time and length scales. In this paper, the variation of fractal dimension and entropy during a damage evolution process, especially in the vicinity of a critical failure, is revisited. The results show that, as damage evolves, both the fractal dimension and entropy of the spatial distribution of microcracks decrease. A sudden drop of fractal dimension or entropy can be viewed as a likely precursor of fracture and its implications for the prediction of natural disasters such as mining-induced rock bursts and earthquakes are discussed.

Keywords Damage evolution, Fracture, Fractal dimension, Entropy

1. Introduction

The catastrophic failure of materials is a complicated natural process, which is usually induced by the nucleation, growth and coalescence of numerous cracks and/or voids with a wide range of time and length scales from micro- to macro-levels [1,2]. Although great efforts have been made on the study of the damage evolution and fracture process, it is still a big challenge of how to identify a physical parameter that can be used as a potential precursor of an impending failure. Fractal, known as the geometry of nature, has been widely applied to describe a variety of irregular, rough and fragmented structures that bear a special scaling relationship [3−9]. The study on fractal fracture has been attracting much interest from scientists in materials science and solid mechanics, and about half a hundred papers have been published each year over the last decade [10].

Experimental and simulation results have indicated that the fractal character of fracture surfaces of materials, either natural or artificial, is ubiquitous [4−10]. This finding provides both a novel method for fractography and a useful theory for building a linkage between the micro and macro-mechanics. The concept of fractal can provide insights into understanding several important issues in a damage evolution and fracture process, such as the fracture precursor and the influence of disorder on macroscopic mechanical properties.

2. Fractal dimension and entropy

Fractal refers to a geometric object or a natural phenomenon, possessing the properties of self-similarity, which can be described by a power law with the exponent defined as fractal dimension [3,5]. Let us assume that a damaged solid is divided into a number of small elements and the number of damaged elements n yields

$$n = r^{-d_f}, \tag{1}$$

where r is a dimensionless scale (e.g., the ratio of the characteristic size of microstructures and the length of a specimen) and d_f is the fractal dimension.

In continuum damage mechanics, a simple damage variable can be defined as, $D = n/N$, where N is the total number of (damaged and undamaged) elements, and $N = r^{-d}$ (d is the Euclidean dimension and here, $d = 3$). If the distribution of microcracks in a material is fractal, it is necessary to introduce fractal dimension in the definition of a damage variable [11]. According to Eq. (1), the

damage variable D can be expressed as

$$D = D_0 r^{d-d_f}, \tag{2}$$

where D_0 is the traditional damage parameter in the case of $d_f = d$. It is obvious that, therefore, $D_0 = 0$ and $D_0 = 1$ indicate the undamaged and fracture states, respectively.

Another simple method to measure the degree of disorder is to calculate the entropy of the spatial distribution of microcracks [12]. Entropy quantifies the diversity, uncertainty, or randomness of a system. Here, let us still assume that a solid consists of a total of N elements, and the number of microcracks in each element is evaluated just as in a box-counting method for calculating fractal dimension [3,5]. Then, the entropy S can be calculated by

$$S = -\sum_{i=1}^{N} \frac{n_i}{N} \ln \frac{n_i}{N}, \tag{3}$$

where n_i be the number of microcracks in the i-th element. The normalised entropy can be represented as S/S_0, where S_0 is the equipartition entropy, provided that microcracks are uniformly distributed in a sample [12]. Thus, we have $0 < S/S_0 \le 1$, and S_0 corresponds to the case with the maximum entropy. That is, as disorder of the spatial distribution of microcracks increases, entropy decreases.

3. A likely precursor of fracture

Based on the assumption of strain equivalence, the relationship between stress σ and strain ε in a damaged material can be written as, $\sigma = E(1-D)\varepsilon$, with E being the Young's modulus [13]. In consideration of the fractal distribution of microcracks, the constitutive relationship between stress and strain can be rewritten as

$$\sigma = E(1 - D_0 r^{d-d_f})\varepsilon, \tag{4}$$

where the fractal dimension d_f is a function of time t in a damage evolution and fracture process.

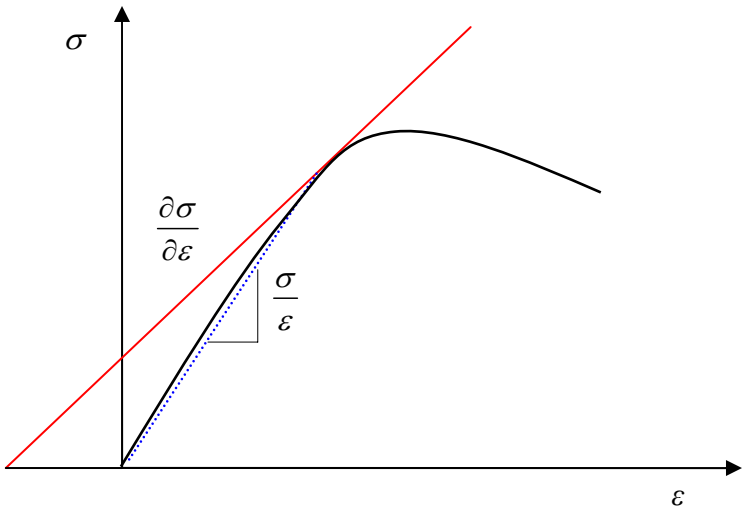

Figure 1. Illustration of a stress-strain curve during a damage evolution and fracture process, where $\partial\sigma/\partial\varepsilon$ and σ/ε are the tangent and secant slopes, respectively (adapted from [11]).

Differentiating both sides of Eq. (4), we have

$$\frac{\partial\sigma}{\partial\varepsilon} - \frac{\sigma}{\varepsilon} = -ED_0 A \frac{\varepsilon}{\dot{\varepsilon}} \frac{\partial d_f}{\partial t}, \tag{5}$$

where $\dot{\varepsilon} = \partial\varepsilon/\partial t$, $\partial\sigma/\partial\varepsilon$ and σ/ε are the slopes of tangent and secant lines of a stress-strain

curve, respectively, and $A = r^{d-d_f} \ln r < 0$ due to $0 < r < 1$ [11]. As illustrated in Fig. 1, it is seen that the following condition

$$\frac{\partial d_f}{\partial t} < 0, \tag{6}$$

is valid because of $\partial\sigma / \partial\varepsilon < \sigma/\varepsilon$, which means that, as damage evolves, fractal dimension of the spatial distribution of microcracks decreases.

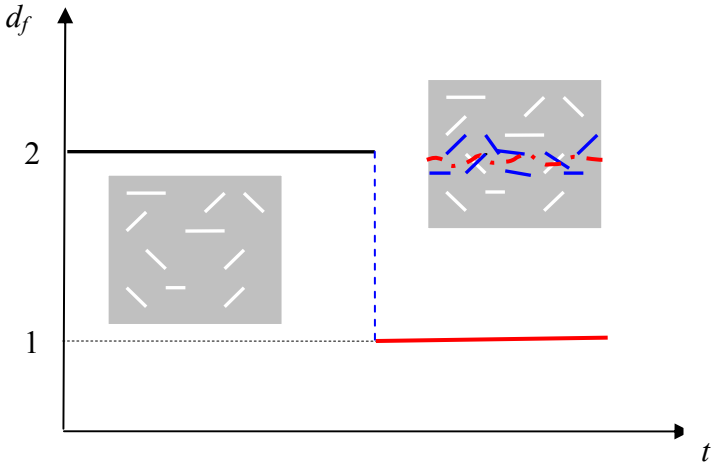

Figure 2. Schematic of fractal dimension versus time during a two-dimensional damage evolution process, where insets are two typical patterns at the initial and final damage stages (adapted from [11]).

As schematically shown in Fig. 2, in the initial damage stage, microcracks are uniformly nucleated in a specimen, but in the final stage and especially near the critical failure, cracks are localized on a surface, which will be the preferential site of fracture. As for the variation of fractal dimension, this corresponds to a roughly one-dimensional fracture profile (or a two-dimensional surface) in a two-dimensional (or three-dimensional) material. As we know, large stress or strain fluctuations in a damage evolution process indicate the divergence to failure, which is usually viewed as a critical phenomenon. As the damage localization approaches a critical point, a sudden drop of fractal dimension occurs.

4. Mining-induced rock bursts: a case study and its implications

As a case study, let us examine the data of a rock-burst-prone pillar in a galena mine, monitored by acoustic emission techniques [14]. The distribution of rock noise locations for 5 days prior to a major rock burst was collected. Based on Eqs. (1) and (3), fractal dimension and entropy of the spatial distribution of daily rock bursts can be calculated [6,11]. Fig. 3 shows the variation of fractal dimension and normalised entropy, and it is seen that both the fractal dimension and entropy decrease as the increase of time. The increase of the clustering degree of microcracks can be intuitively observed from the spatial distribution of rock bursts [14]. Prior to the major rock burst on 24 May, a sudden drop of fractal dimension or entropy occurs. This is in good agreement with our theoretical analysis. Thus, the reduction and sudden-drop of fractal dimension or entropy can be considered as a precursor of a catastrophic failure. However, the prediction of an exact occurrence time is still very difficult since there are small fluctuations of fractal dimension or entropy with time caused by floor de-stressing, and even there is a quiescent period before the main rock burst [11].

An earthquake is rock failure at a large scale. The well-know frequency-magnitude relationship (or the Gutenberg-Richter law) is equivalent to a fractal (power-law) distribution between the number

of earthquakes and the characteristic size of faults, and the value of fractal dimension of regional or world-wide seismicity is twice the famous *b*-value in seismology, that is, $d_f = 2b$ [15−17]. Therefore, a sudden drop of fractal dimension corresponds to the reduction of *b*-value, which is also considered as a possible precursor of earthquakes [18].

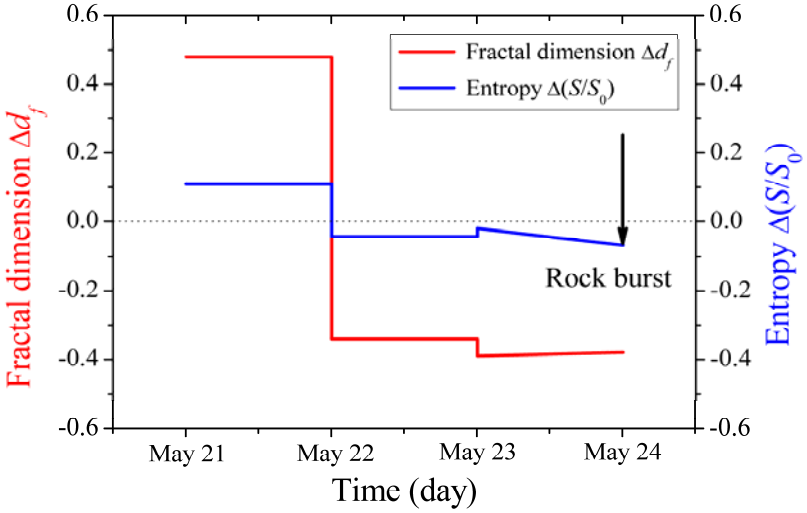

Figure 3. The variation of fractal dimension and normalized entropy versus time in a galena mine, where a major rock burst occurred on 24 May 1979 (data from [14]).

It is worth noting that, however, as the *b*-value or fractal dimension is a highly concentrated parameter, more physical details on the reduction of fractal dimension or *b*-value, especially at critical failure, are needed for reliable prediction. This can be resorted to the variation of high-order or multifractal dimensions.

5. Conclusions

In summary, the definition of a damage parameter can be extended to consider the fractal character of the spatial distribution of microcracks. It is shown that there is a universal character in a damage evolution and fracture process: the decrease of fractal dimension or entropy and the ordering of the spatial distribution of microcracks. A sudden drop of fractal dimension or entropy provides a quantitative indicator of the damage localization, which can be viewed as a likely precursor prior to catastrophic failure. Similarly, the decrease of *b*-value in seismology can be considered as a precursor for a large earthquake. These results imply that the strong fluctuations of physical parameters near the critical point such as the concentration of microcracks (mining-induced rock bursts or seismicity) could provide useful clues for the prediction of fracture and earthquakes.

Scaling Behavior in Quasi Static and Impact Fragmentation of Brittle Materials

Marina Davydova[1,*], Sergey Uvarov[1]

[1] Institute of Continuous Media Mechanics, Ural Branch of Russian Academy of Sciences, Perm 614013, Russia
* Corresponding author: davydova@icmm.ru

Abstract An investigation was conducted to examine experimentally the process of fragmentation of brittle materials (glass plates and quartz rods) under quasi-static and dynamic loading conditions. In the quasi-static tests of glass plates, two types of scaling laws were considered. Of these, one was based on the fractal relation similar to the Dielectric Breakdown Model or the Diffusion-limited Aggregation Model, and the other involved the definition of the fragment size distribution. The results of investigation indicate that fragment size distributions mainly follow power-law distributions. Variations in the fragmentation mechanism correlate with quantitative changes in the fractal dimension observed in different regions of the fragmented specimen. The dynamic fragmentation statistics was studied in the recovery experiments with quartz cylindrical rods. The mechanoluminescence-based method was used to measure the distribution of time quantities. Impact loading applied to specimens leads to the formation of fracture surfaces, which produces intensive light emission registered then by Photo Multiplayer Tubes. The data recovery technique allows us to save the fragments and to determine the size distribution of fragments. Both the fragment size distribution and the time interval distribution show evidence of obeying scaling laws.

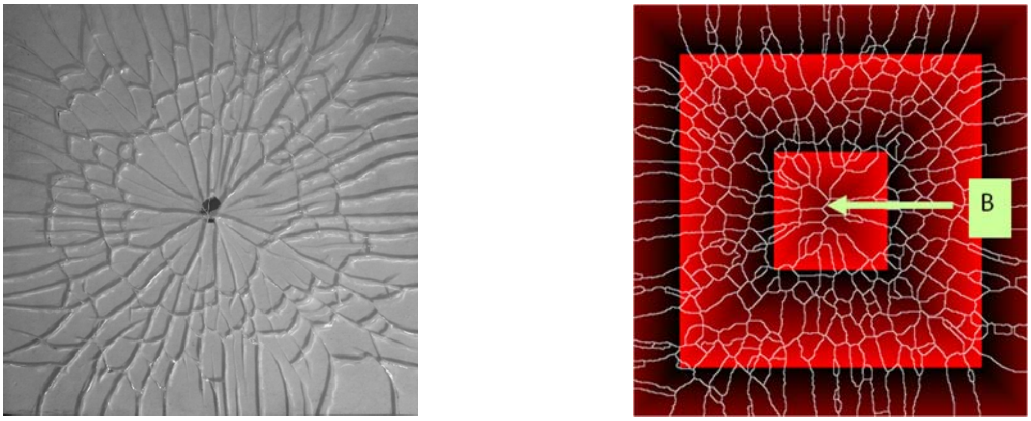
Keywords: Fractal, Brittle fragmentation, Scaling law, Self-organized criticality

1. Introduction

Results of fragmentation processes (the breakup of matter into smaller pieces) are visible everywhere. In nature these may be rock fragments of sizes varying from stones to sand and dust, or arctic sea ice fragments. Almost all kinds of explosions and collisions result in fragmentation. Common to brittle fragmentation processes is that the fragment-size distribution is given by a power law [1-8]. The origin of this power law has attracted much attention lately. The assumption that the exponential distribution is typical of the fragmentation of ductile materials and the power-law distribution characterizes brittle fragmentation has been discussed by Grady [9]. However, in some experiments with brittle materials the exponential or log-normal laws were observed [10-13]. Donald Turcotte [14] has pursued the fragmentation of brittle materials as a fractal process resulting in the power law distribution function $N \sim x^{-D}$, where N is the number of fragments, x is the linear dimension of fragments, and D is the fractal dimension. The fractal character of the distribution function in a wide range of fragment sizes allows Oddershede et al. [7] to suppose that the fragmentation exhibits self-organized criticality (SOC) [15].

2. Glass fragmentation

Fragmentation processes are complex and involve propagation of many cracks and their interaction. Therefore, it is of interest to study the overall statistical aspects. Quasi-static testing was performed in the experiments with glass plates loaded in a “sandwich” to save the glass fragmentation pictures (Fig. 1a). Using the original software, the images were transformed into the schematic pictures corresponding to the fragmentation patterns (Fig. 1b).



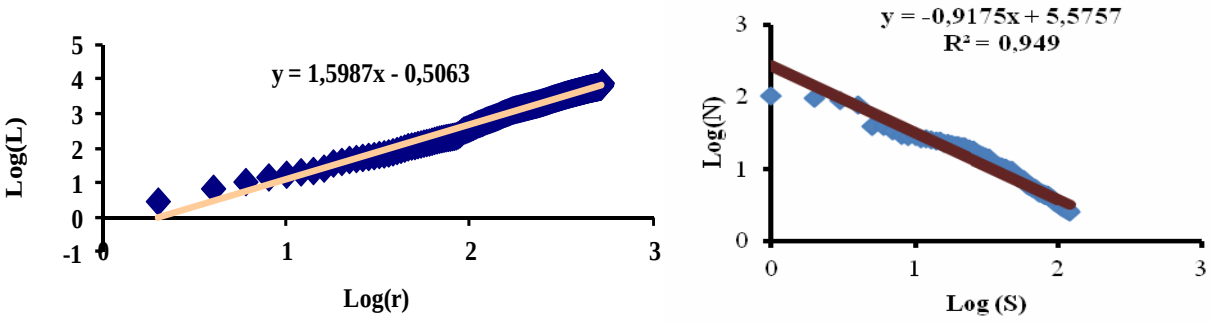
a) b)

Figure 1. a) Photographs of typical fragmentation patterns. b) Schematic pictures of fragmentation patterns to determine the size and number of fragments and the total length of cracks.

This made it possible to determine the size and number of fragments and the total length of cracks. We consider two types of scaling. The first type is based on the relation

$$L(r) \sim r^{D}, \tag{1}$$

where $L(r)$ is the total crack length in the boxes of a size $r \times r$ centred at the point B (Fig. 1b), and D is the fractal dimension. The second type is the traditional definition of the cumulative distribution of fragment sizes, that is, the calculation of the number of fragments N with a size larger than S.

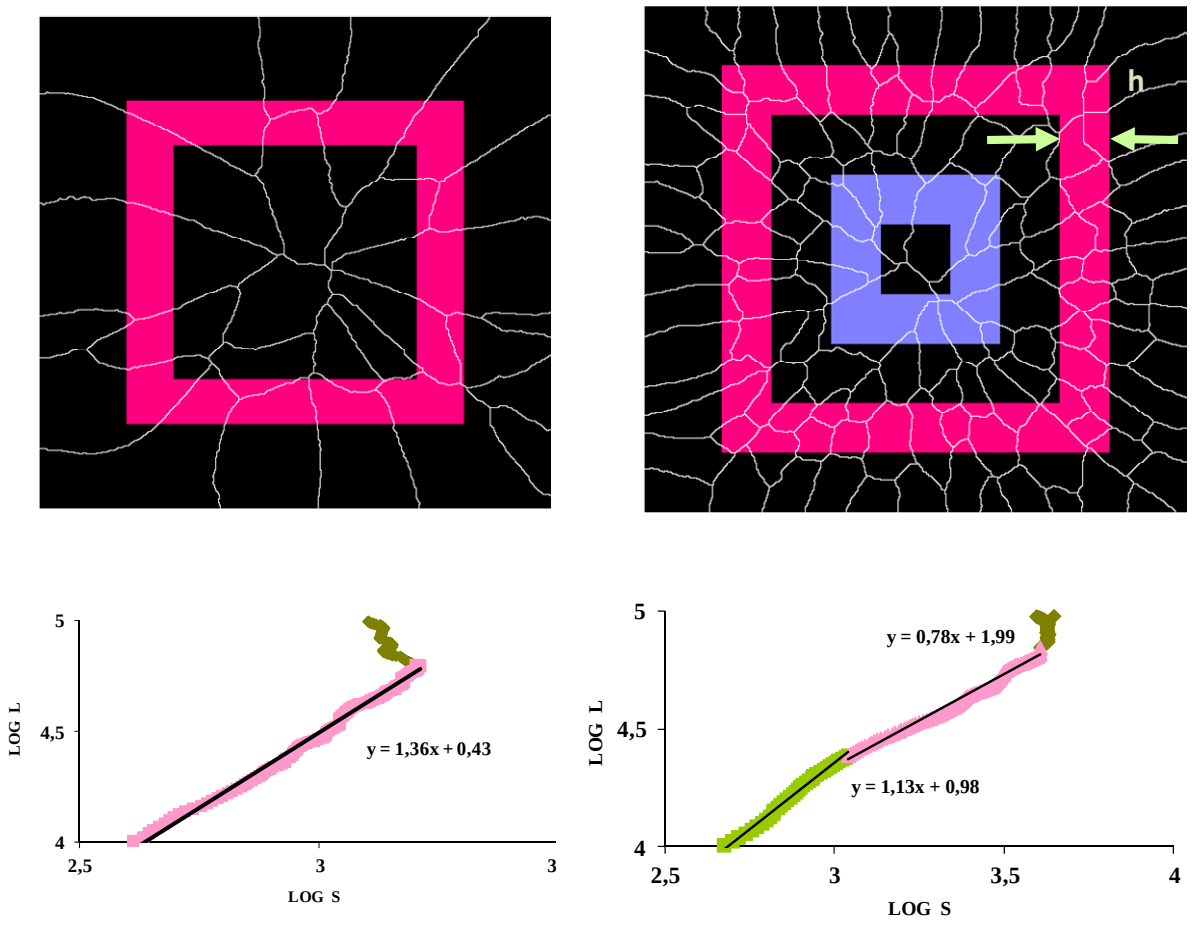


a) b)

Figure 2. a) Scaling law obtained using the relation for crack length (1). b) Cumulative log-log plots of the fragments size distributions.

The use of Eq. (1) was discussed by Sornette et al. [16]. However, it should be noted that the fracture pattern [16] does not have a distinct central point. At the same time, the examined fragmentation patterns have a central point, and their configuration is similar to that created with the

model of diffusion-limited aggregation (DLA) [17] or the model of dielectric breakdown (DB) [18]. Relation (Eq.1) can be used to define the fractal dimension for both these models. In the case of the DB model, $L(r)$ is the total length of the discharge branches within the circle of radius r For the DLA model, $L(r)$ is the number of particles. By analogy with the DLA and DB models, to determine the fractal dimension of the fragmentation patterns, we use Eq.(1), where $L(r)$ is the total length of cracks in the boxes of a size $r \times r$ centred at the point B (Fig. 1b). The minimal number of the boxes used for calculation of the fractal dimension is 200. The scaling law obtained using the relation for crack length (Eq.1) is presented in Fig. 2a. The processing of the fragment sizes shows that the relation between the fragment area and the number is also fitted by a power law (Fig. 2b and Fig. 6).



a) b)

Figure 3. a) Fragmentation pattern and fractal dimension definition for the fracture accompanied by radial crack formation. b) Fragmentation pattern and fractal dimension definition for the fracture accompanied by a change in the fracture mechanism.

There are two types of energy-dependent fragmentation patterns leading to a breakup (Fig. 3). Fig.3a presents a fragmentation pattern that illustrates the fracture accompanied by radial crack formation. The right fragmentation pattern (Fig. 3b) has two zones corresponding to two different fracture mechanisms. The central zone has a radial crack only. In the second zone, the crack

branching process is observed. Assuming that different fracture mechanisms characterize different fractal dimensions, we have

$$L(S) \sim S^D, \tag{2}$$

where $L(S)$ is the total crack length inside the square frame with a thickness h (Fig. 3b), S is the frame area, and D is the fractal dimension. Calculation the fractal dimension using expression (Eq.2) shows that, for the left fragmentation pattern (Fig. 3a), the data is fitted by a single line. For the right pattern, the log-log representation of $L(S)$ changes its slope, and the power-law exponent D decreases. A change in the fracture mechanism (from radial crack formation to crack branching) correlates with the qualitative changes in the fractal dimension.

3. Quartz fragmentation

3.1. Loading condition.

The first stage of the experiment was to evaluate the effect of loading conditions and the shape and size of the sample on the fragment size distribution function. Three types of loading conditions (I, II, III) were realized using a ballistic set-up:

- fragmentation as a result of interaction of direct and reflected compression waves (I) (Fig.4a);
- fragmentation under the action of a compression wave (II) (Fig.4b);
- fragmentation induced by a direct compression wave and its reverberation in rod (III) (Fig.4c).

Loading Condition I. The ballistic set-up consists of a gas gun with a bore of 19.3 mm diameter, a velocity registration system, and a base where the sample is mounted (Fig. 4a). The sectional glass rod is composed of a buffer and the main part covered by an elastic shell. The buffer was used for realization of uniaxial loading produced by a cylindrical projectile of mass 13.9 g accelerated up to the velocities of 6-22 m/s.

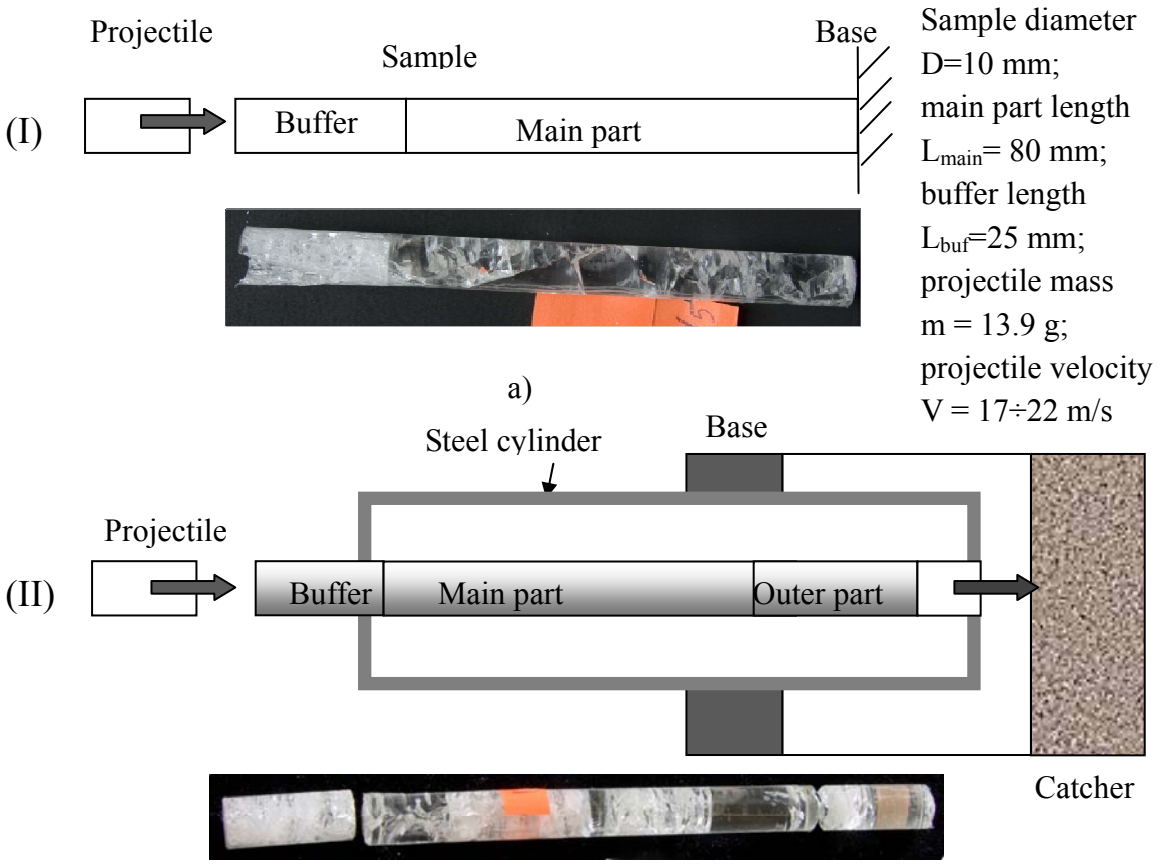
Loading Condition II. To avoid the possible influence of the reflected wave on the fragmentation scenario, the ballistic set-up was modified. The sample was placed into a steel cylinder filled with plastic foam (Fig. 4b). The sectional glass rod was composed of a buffer, main part and outer parts. The presence of the last part made it possible to catch the reflected wave.

Loading Condition III. The scheme given in Fig. 4c illustrates the experimental technique used to measure the distribution of time quantities. Impact leads to the formation of fracture surfaces, which produce intensive light emission (mechanoluminescence or fractoluminescence).The intensity of the light is registered by the Photo Multiplayer Tube connected with the oscilloscope (oscilloscope sample rate is 1 GHz).

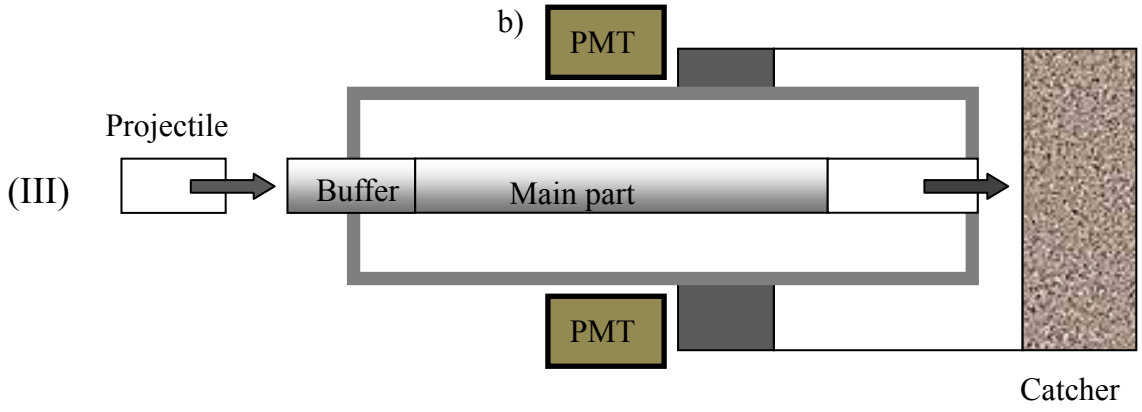
3.2. Fragment mass distribution.

The mass of the fragments passing through the sieves was obtained by weighing the fragments using an electronic balance HR-202i (accuracy 10^{-4} g). The mass of the fragments corresponding to the maximum of the probability density function varied in the range from $2*10^{-4}$g to $6*10^{-4}$ g

(Fig.5a). At low energy, a more considerable scattering was found for this value (Fig.5b). This actually means that for low energy we have two or three sieves with a comparable number of fragments, and for high energy - only one sieve with a predominant number of fragments.



Sample diameter D=12 mm; main part length L_{main} = 120 mm; buffer length L_{buf} =25 mm; outer part length L_{out}= 30 мм; projectile mass m = 6.3 g; V = 40÷50 m/s



Sample diameter D=12 mm; main part length L_{main} = 120 mm; buffer length L_{buf} =25 мм;

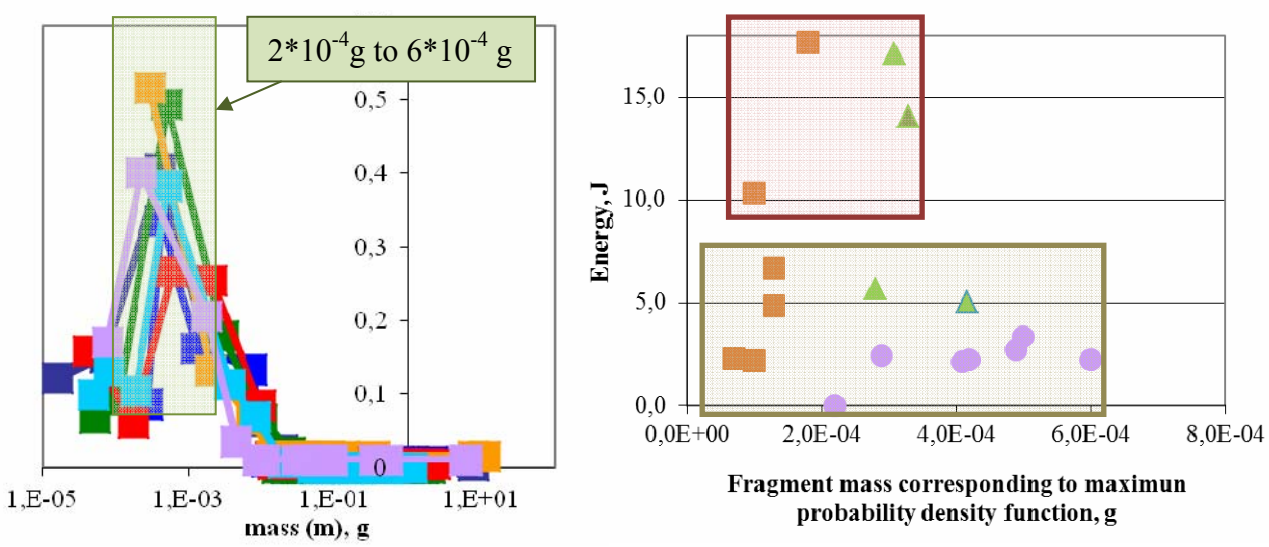
Figure 4. Schemes of loading: a) condition I; b) condition II; c) condition III.



a) b)

Figure 5. a) Probability density function. b) Dependence of the fragment mass corresponding to maximum probability density function on the projectile energy. The markers indicate the loading type: I-circles; II-triangles; III-boxes.

The fragmentation statistics was analyzed by varying the sample size and load intensity (projectile velocity). The results of experiments have indicated that the variation in the sample size and loading conditions does not lead to the change in the type of the probability density function.

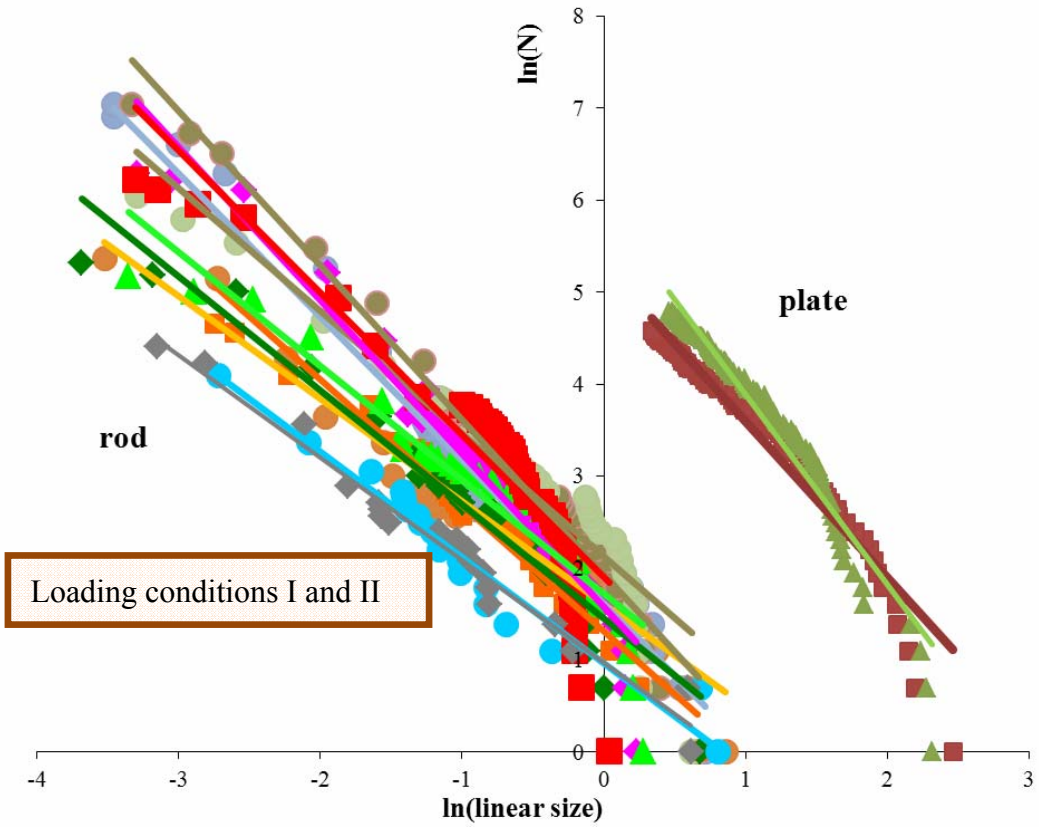


Figure 6. Double logarithmic plot of the cumulative distribution function for plate and rod.

Thus, the cumulative distributions illustrating the relation between the numbers of fragments and their linear dimension are represented as a log-log plot (Fig. 6). The linear dimension is defined as a cube root of mass or a square root of area. The distribution is fractal by nature with a power law in the form $N(>r) = Cr^{-D}$, where N is the number of fragments with a characteristic linear dimension greater than r. The fractal dimension D varies from 1.6 to 2.0 for the plate and from 1.1 to 1.7 for the rod (Loading Conditions I and II).

3.3 Distribution of time interval between the impulses of intensive light emission

To measure the scaling of spatial and time quantities corresponding to the same sample, we have developed the experimental scheme presented in Fig.4c (Loading Condition III). Fracture surfaces formed under impact loading produced intensive light emission (mechanoluminescence or fractoluminescence). The mechanoluminescence impulses were registered by two PMT connected with the oscilloscope (Fig.7). The second PMT was used to provide the reliability of measurements.

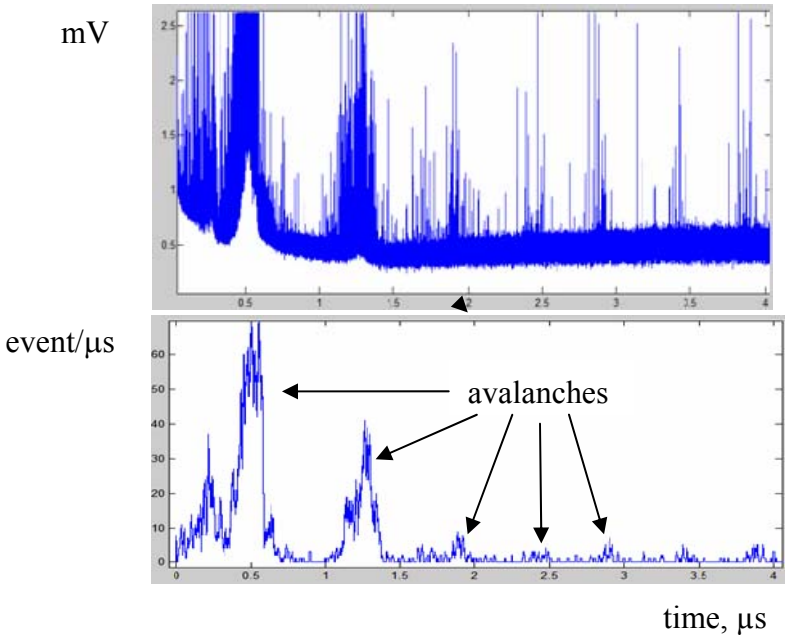

Figure. 7. Signal of the oscilloscope and the frequency of impulse appearance.

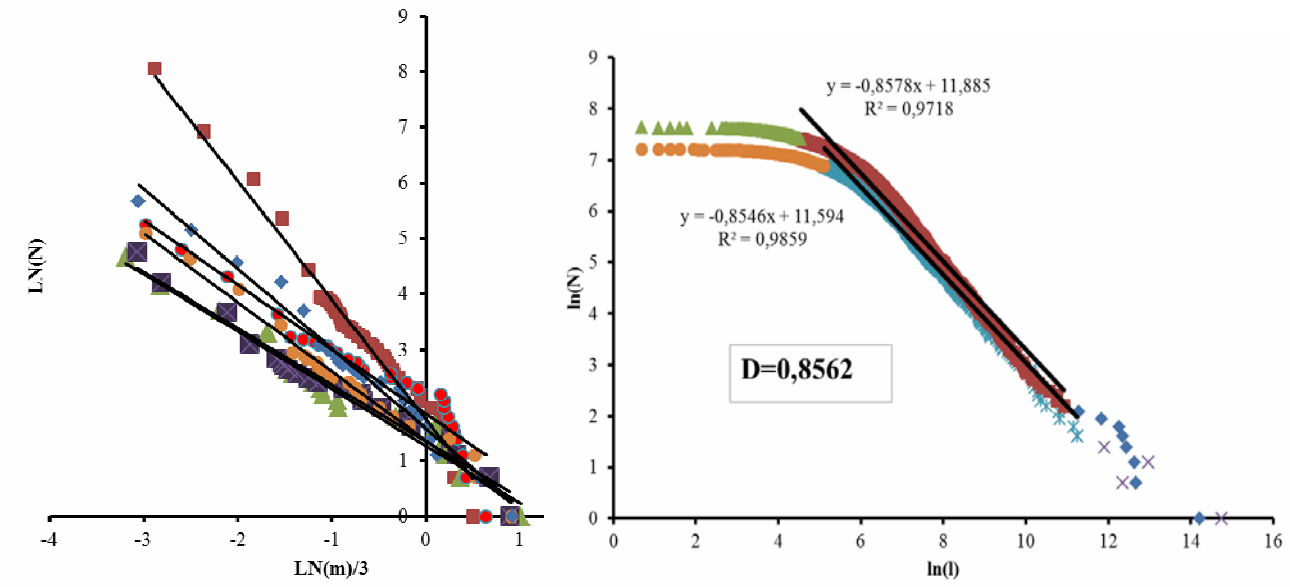
The process of light reflection looks like the process of avalanche spreading (Fig. 7). The lower plot represents the event frequency. The events are distributed in blocks.

The cumulative distribution function of the time interval (registered by two PMT) in the double logarithmic plot (Fig.8b) is fitted by the straight line (90% of the total number points). At small sizes (8% of the total number of points), the curve deviates from the straight line because the size of time interval is comparable with the oscilloscope sample rate (1 GHz). The falloff at the largest interval sizes (2% of the total number of points) is due to finite-size effects. In this case, the time interval is comparable with the process time. The central part is the line covering 90% of the total number of points. It has been found that the fragment size distributions (Fig.8a) and the time interval

distributions (Fig.8b) obey scaling laws, which suggests the possibility of self-organized criticality in fragmentation.

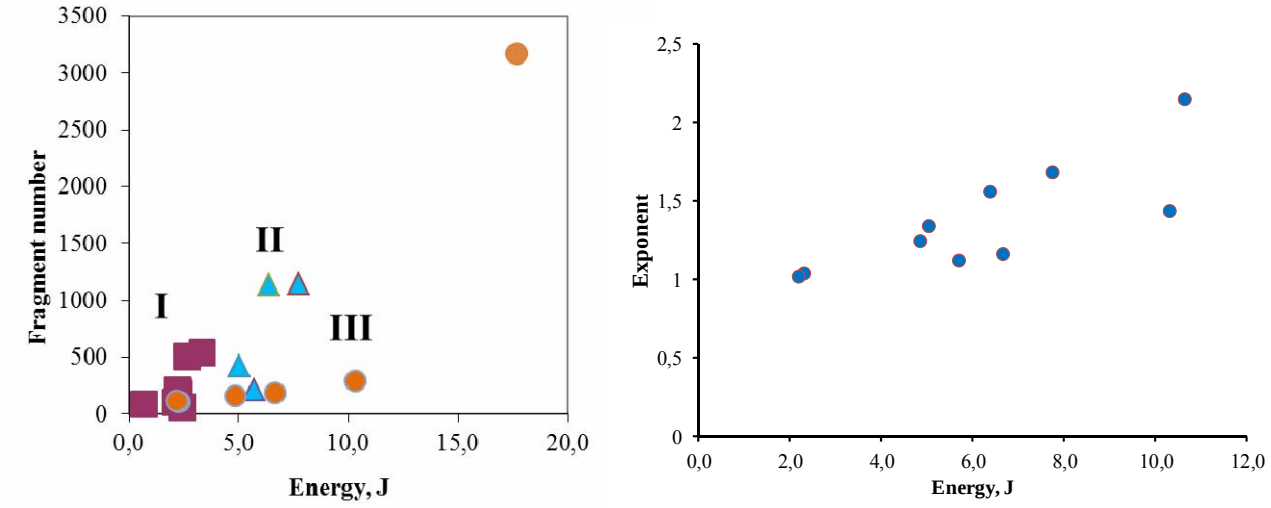


a) b)

Figure 8. a) Fragment size distribution (spatial scaling) for loading condition III. b) Distribution of time interval separating the fractoluminescence impulses (for one sample). *D* is the average exponent for the signals corresponding to two PMT placed near the opposite side of the sample.

The fractal dimension D varies from 1.02 to 2.14 for the spatial variable (Fig.8) and from 0.28 to 0.85 for the time variable (Fig.9).

4. Conclusion



a) b)

Figure 9. a) Fragment number versus projectile energy. I, II, III indicate loading conditions. b) Power law exponent for different levels of projectile energy.

Experimental investigations were carried out to examine the fragmentation of brittle materials under quasi-static and dynamic loading conditions. Based on the obtained results, the following conclusions can be derived:

- fragmentation patterns of glass plates are fractal;
- variation in the fracture mechanism of plates correlates with the changes in the fractal dimension;
- number of fragments occurred during the fragmentation of quartz rods (Fig. 9a) depends on loading conditions;
- power law exponent for fragment size distributions of quartz (Fig. 9b) increases with growth of projectile energy;
- fragment size distribution for the observed type of fragmentation (glass plates and quartz rods) is fractal and satisfies the relation $N(>r) = Cr^{-D}$;
- fragment size distributions and time interval distributions are governed by scaling laws, which is indicative of the self-organized critical behavior during the fragmentation process.

Abstract The mechanism of dynamic size effect of strength of rock is studied from the viewpoint of structural hierarchy. Relaxation model of Maxwell type for rock is used to obtain the relationship between strength, sample size and strain rate. It is shown that because of the finiteness of crack propagation velocity, when the strain rate is well above certain characteristic strain rate, dynamic loading process takes predominant role, the stresses in sample have not enough time to relax, the larger the sample size is, the more time is needed for cracks in sample to go through the sample, the ultimate applied stresses before macrofracture are greater and the strength is higher. From other hand because of the size effect the higher dynamically applied stresses will activate the cracking at smaller scale levels of rock sample, and the fragment size is smaller. Based on the presented model the characteristic strain rate separating the predominant diapasons for static and dynamic size effect is determined, and the fragment size is predicted satisfactorily.

Keywords rock, structural hierarchy, dynamic size effect, static size effect

1. Introduction

The strength of rock-like materials has size effect, i.e. it depends on the size of the samples. The general law of the size dependence of strength is that it decreases with the increase of the sample size.

Static size effect of strength has been studied by many scientists. According to Bazant size effect of strength can be separated into two kinds [1]：(1) statistical, described by the Weibull [2, 3, 4] theory of random local material strength, and (2) energetic (deterministic). The latter includes type I size effect[5-10], occurring in materials that fail at crack initiation from a smooth sample surface, and type II size effect[5, 11-14], occurring in materials with a deep notch or deep stress-free crack formed stably before reaching the maximum load. Another approach to size effect is based on the concept of fractality. The self-similarity (fractality) in concrete deformation and fracture has been studied by Z. Bazant Z.[7], Carpinteri A., Pussi. S., Pugno N.M. et al [15, 16]. And the mechanics of hierarchical materials has been also developed [17].

As to size effect of dynamic strength of rocks, the research is relatively rare and the reached conclusions are controversial [18, 19, 20, 21]. For clarification of the size effect of rock strength under dynamic loading condition, recently Hong Liang, Li Xibing et al. have performed refined research on size effect of rock dynamic strength and strain rate sensitivity[22]. The reached conclusions are interesting. The test results show that the rock dynamic strength increases with strain rate in power law which agrees with the research results of many other scientists. The interesting result is that the larger the specimen size is, the more notable the strain rate sensitivity of dynamic strength of rock is; the rock dynamic strength increases with the increase of specimen size

under the same strain rate which is opposite to the size effect under static loading condition (see Fig.1 and 2 for granite). The size effect of dynamic strength becomes weaker with the decrease of strain rate and there exist a critical strain rate below which static size effect takes dominant position. In addition, experiments show that the fragment size decreases significantly with the increase of sample size (see Fig.3). The less the sample size is, the more is the dispersion of the experimental results.

Fig.3 Fragmentation of granite specimens with different sizes

Until now the underlying mechanism of dynamic size effete of rocks has not been intepretated. Therefore in the present paper we will make a trial to perform some theoretical study aiming at clarifying the underlying mechanism of dynamic size effect of rock.

2. Mechanism underlying dynamic size effect of rock strength

As natural materials rock-like materials have complex internal structure, the scales of which span a huge scale range. For rock mass an important peculiarity is the similarity of the internal structure in a wide range of sizes. Investigations [23]showed that, a fundamental canonical series for the sizes Δ_i of geo-blocks exists：

$$\Delta_i = \left(\sqrt{2}\right)^{-i} \Delta_0 \tag{1}$$

where $\Delta_0 = 2.5 \times 10^6$ m is the radius of Earth's core; i is positive integers. As demonstrated in [24], the atomic-ionic radii of different valent orbits of 98 elements in the table of Medeleev also obey canonical series of Eq.(1). Therefore canonical series of Eq.(1) is valid for huge range of scale sizes from continental level to atomic-ionic level.

Some relation between the thickness of the weakened structural surfaces (or the opening of cracks) separating structural elements and the characteristic size of the elements at the given scale level exists. According to investigation in [25], the ratio of the openings of cracks δ_i to the characteristic linear size of the blocks Δ_i separated by the weakened structural surfaces (or cracks) at *i*-th scale level is stable, and can be described by the following relation which has a normal statistical distribution:

$$\mu_\Delta(\delta) = \frac{\delta_i}{\Delta_i} = \Theta \cdot 10^{-2} \tag{2}$$

where Θ is a coefficient changing in the interval 1/2—2, and parameter μ_Δ is termed as "geo-mechanical invariant" in [25].

In-situ observations of destruction of earth's crust[26] and theoretical and experimental studies on smaller scale rock samples [27] revealed that the deformation and fracture of rock-like materials are governed by laws of Maxwell bodies. This conclusion allows us to describe the deformation and fracture of rock-like materials by Maxwell model.

The internal structure of rocks has decisive impact on mechanical behavior of rocks. If the strength of crystals with ideal regular lattices is their theoretical strength, then the strength of real materials is about 2-3 orders lower than the theoretical strength for ideal crystals. Obviously, the complex hierarchic internal structure of real materials will causes the stress concentration and strain localization which are responsible for lowering of real material strength.

As a reference medium we take ideal crystal with ideal regular lattices. Image that such ideal crystal is subjected to intensive external loading, the intensity of which is high enough, but the induced stress state is well below the strength limit. In this case in crystal no damage and fracture occur and no stress relaxation takes place. But if the ideal crystal is replaced by real rock mass with complex internal structure, then under the action of such intensive external loading stress concentration and successively damage and fracture will occur. Consequently part of the stresses in rock mass will relax. Therefore we can think that in such solid stresses are consisted of two components: elastic stresses caused by the reversible volume and shear deformations, and the local inelastic stresses in heterogeneities which are responsible for the irreversible deformations. The elastic stresses are related to the reversible deformations linearly. As to the residual stresses (inelastic stresses), they arise at definite strain rate, and relax with time. The evolution equation for the residual stress deviator Δs_{ij}^l in heterogeneities may be described by Maxwell model

$$\frac{d\Delta s_{ij}^{l}}{dt} = 2\rho c_s^2 \dot{\varepsilon}_{ij} - \nu \frac{\Delta s_{ij}^{l}}{l} \qquad (3)$$

where Δs_{ij}^{l} is the residual stress deviator components in heterogeneities with characteristic scale l; $\dot{\varepsilon}_{ij}$ is the residual strain rate deviator components; ρ is the density of the medium; ν is the relaxation velocity, which may be looked at as the effective propagation velocity of single or multiple cracks depending on the loading conditions; c_s is the propagation velocity of the elastic shear wave. Here we suppose that all residual stress components relax with the same relaxation time. Essentially l/ν may be considered as relaxation time $\tau = l/\nu$.

The main feature of this model is that, the relaxation rate of the residual stresses in heterogeneities is proportional to the magnitude of the residual stresses, and inversely proportional to the size of the heterogeneities. The growth of residual stresses is controlled by two contradicting factors in the right hand side of Eq.(1): the residual stress growth rate $2\rho c_s^2 \dot{\varepsilon}_{ij}$ and the relaxation rate of residual stresses $\nu \Delta s_{ij}^{l} / l$. It is necessary to note that this model is applicable not only to different rock-like materials with great variation range of relaxation times, but also applicable to highly viscous fluids for which the relaxation time is relatively short [28].

The solution of Eq. (4) has the following form:

$$\Delta s_{ij}^{l} = 2\rho c_s^2 \dot{\varepsilon}_{ij} \frac{l}{\nu}\left[1 - e^{-\nu t/l}\right] = 2\rho c_s^2 \dot{\varepsilon}_{ij} \tau \left[1 - e^{-t/\tau}\right] \qquad (4)$$

For short loading time $t << \tau$, relaxation process has not enough time to develop, and the loading process is the predominant factor, in this case Eq.(4) gives

$$\Delta s_{ij}^{l} \approx 2\rho c_s^2 \dot{\varepsilon}_{ij} t = 2\rho c_s^2 e_{ij} \qquad (5)$$

i.e. the residual stresses will increase almost linearly.

For long loading time $t >> \tau$, relaxation process has enough time to develop, loading process is limited by the relaxation time, in this case Eq.(4) gives

$$\Delta s_{ij}^{l} \approx 2\rho c_s^2 \dot{\varepsilon}_{ij} \tau = 2\rho c_s^2 \dot{\varepsilon}_{ij} \frac{l}{\nu} \qquad (6)$$

For the occurrence of macrofracture, it is necessary that the loading time is greater than relaxation time $t > \tau$, therefore Eq.(6) is appropriate for study of macrofracture of the samples.

Substituting Eq.(6) into the expression $\Delta\sigma_I = \sqrt{3\Delta s_{ij}^{l} \Delta s_{ij}^{l} / 2}$ for intensity of residual stress deviator, we obtain

$$\Delta\sigma_I = 3\rho c_s^2 \dot{\varepsilon}_I \frac{l}{\nu} \qquad (7)$$

where $\dot{\varepsilon}_I = \sqrt{2\dot{\varepsilon}_{ij}\dot{\varepsilon}_{ij}/3}$ is the residual strain rate intensity.

It can be seen from Eq. (7) that if we fix the applied strain rate, then the greater the size of the heterogeneities is, the greater the residual stresses are. If the size of the body is infinite, then we can

always find large enough heterogeneities that their residual stresses are large enough to cause the fracture of the body. In this way, at constant strain rate among the parameters of solid a parameter with dimension of length arises. Stress concentration causing residual stress in heterogeneous media is the main cause for material fracture, the limit residual stress causing fracture of the body σ^* may be looked at as the strength σ_Y of the sample with size D. Therefore Eq.(7) may be rewritten as

$$\sigma_Y = 3\rho c_s^2 \&_Y \frac{D}{v} \tag{8}$$

Eq.(8) explicitly shows that dynamic strength is proportional to the size of sample, and inversely proportional to the the relaxation velocity. The physical mechanism is as follows. Experiments show that the maximum crack growth velocity is limited and is below the Rayleigh wave speed C_R [29] (Fineberg, Marder, 1999). Therefore the relaxation velocity is also limited. The larger the sample size is, the more is the time needed for the occurrence of macrofracture, and the higher is the reached ultimate amplitude of loading.

Now let us use the obtained fequation (8) to model the dynamic size effect.

For granite we take the Young's elastic modulus as $E = 5.5\times10^{10} Pa$, Poisson's ratio as $\mu = 0.29$, then the shear modulus is $G = 2.13\times10^{10} Pa$. Now let us with the help of Eq.(8) to fit the experimental data.

For sample with size $D = 22mm = 0.022m$, we obtain that the effective relaxation velocity is $v = 3515m/s$.

For sample with size $D = 36mm = 0.036m$, we obtain that the effective relaxation velocity is $v = 2465m/s$.

For sample with size $D = 75mm = 0.075m$, we obtain that the effective relaxation velocity is $v = 1867m/s$.

It is clear that the effective relaxation velocity is dependent of the specimen size and decreases with the increase of sample size. The dependence of effective relaxation velocity on sample size is shown in Fig.4.

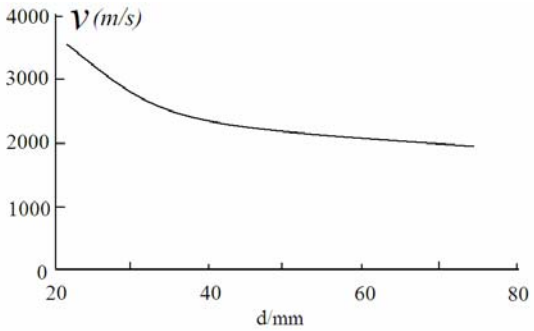

Fig.4 The dependence of velocity of crack propagagtion on specimen size

In the diapason of the sample sizes tested we will use the following equation to interpolate the

dependence of crack propagation velocity on the sample size

$$v(D)=112.59D^2-1403D+6056.6 \tag{9}$$

where the unit of d is cm.

Therefore we now should use the following equation for determination of the dynamic strength of material.

$$\sigma_Y = 3\rho c_s^2 \dot{\varepsilon} \frac{D}{v(D)} \tag{10}$$

Using Eq. (10) we can accurately fit the experimental data shown in Fig.(2) and (3).

Now let's analyze the size effect on dynamic fragmentation.

3. The determination of fragment size of rock

The static size effect and dynamic size effect are depicted in Fig.5.

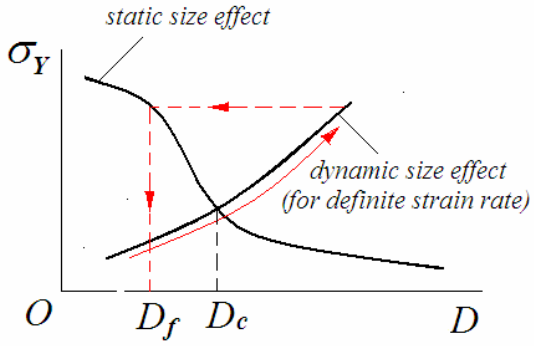

Fig.5 The mechanism of dynamic fragmentation

The static strength of rock mass depends on the sample size. Generally, the compressive strength of materials σ_D can be expressed as a function of the sample size D as follows [5]:

$$\sigma_D = \sigma_0(1+D/D_0)^{-1/2} \tag{11}$$

where σ_0 and D_0 are constants. Eq.(11) can be rewritten as

$$D = D_0\left[(\sigma_0/\sigma)^2-1\right] \tag{12}$$

where parameter σ_D is replaced by σ representing the applied loading.

For fast dynamic loading process, because of the finiteness of relaxation velocity, failure will be delayed, and overloading will take place. Therefore for large enough rock sample dynamic strength will be higher than static one. The higher loading will activate the deformation and fracture process in rock at smaller scale element levels, and the rock will fracture according to the static size effect law of rock as shown in Fig.5.

Replacing σ in Eq. (12) by σ_Y in Eq. (11), we obtain the following formula for determining the fragment size of fractured rock mass D_f :

$$D_f = D_0\left[\left(\frac{\sigma_0}{\sigma_Y}\right)^2 - 1\right] = D_0\left[\left(\frac{\sigma_0 v(D)}{3\rho c_s^2 \dot{\varepsilon} D}\right)^2 - 1\right] \tag{13}$$

For determing σ_0 and D_0, we use the data in Fig.3(a) and (b):

For $d = 75mm, \dot{\varepsilon} = 98.23s^{-1}$, the dynamic strength is $\sigma_Y = 220MPa$, and the fragment size is approximately $D_f = 0.2cm$

For $d = 36mm, \dot{\varepsilon} = 99.75s^{-1}$, the dynamic strength is $\sigma_Y = 105MPa$, and the fragment size is approximately $D_f = 1.47cm$.

From these data we obtain $D_0 = 1.75mm$, $\sigma_0 = 3.22\times10^8 Pa$.

Hence we have

$$D_f = D_0\left[(\sigma_0/\sigma)^2 - 1\right] = 1.75\times10^{-3}\left[\left(3.22\times10^8/\sigma_Y\right)^2 - 1\right] \tag{14}$$

Now let us use Eq.(14) to predict the experimental result shown in Fig.3(c). For the case shown in Fig.3(c), $d = 22mm$. We know from Fig.1 (a) that for $\dot{\varepsilon} = 164.38s^{-1}, \sigma_Y \approx 100MPa$. Substituting $\sigma_Y \approx 100MPa$ into Eq.(14) we have $D_f = 16.4mm$, which is very close to the fragment size in Fig.3 (c): $D_f \approx 22/\sqrt{2} = 15.6mm$. Therefore the model is sufficiently good for the description of the dynamic effects on strength and on dynamic fragmentation.

4. The determination of characteristic size and characteristic strain rate for rock

Now let us discuss the characteristic size and characteristic strain rate for rock samples.

For fixed strain rate $\dot{\varepsilon}$, from the following equation

$$\sigma_D = \sigma_0\left(1 + D_c/D_0\right)^{-1/2} = \sigma_Y = 3\rho c_s^2 \dot{\varepsilon} \frac{D_c}{v(D_c)}$$

we can determine the characteristic size D_C for rock, above which dynamic size effect of rock strength will predominate.

From other hand for fixed rock sample size D from equation

$$\sigma_D = \sigma_0\left(1 + D/D_0\right)^{-1/2} = \sigma_Y = 3\rho c_s^2 \dot{\varepsilon}_c \frac{D}{v(D)}$$

we obtain the characteristic strain rate

$$\dot{\varepsilon}_c = \frac{\sigma_0 v(D)}{3\rho c_s^2 D\left(1 + D/D_0\right)^{1/2}} = \frac{\sigma_0 v(D)}{3GD\left(1 + D/D_0\right)^{1/2}} \tag{15}$$

From Eq. (15) it is clear that under fixed rock sample size D, when strain rate $\dot{\varepsilon} > \dot{\varepsilon}_c$, dynamic

size effect takes dominant position, and when $\dot{\varepsilon} \ll \dot{\varepsilon}_{Ic}$ static size effect predominates. From other hand, under fixed strain rate $\dot{\varepsilon}_{Ic}$, when strain rate $D > D_c$, dynamic size effect takes dominant position, and when $D < D_c$ static size effect predominates.

Now let's evaluate the order of the predicted characteristic strain rates.

For $d = 75mm$, $v = 1867m/s$, $G = 2.13\times10^{10}\,Pa$, $D_0 = 1.75mm$, $\sigma_0 = 3.22\times10^{8}\,Pa$, the predicted characteristic strain rate is

$$\dot{\varepsilon}_{Ic} = \frac{\sigma_0 v(D)}{3GD(1+D/D_0)^{1/2}} = \frac{3.22\times10^{8}\times1.867\times10^{3}}{3\times2.13\times10^{10}\times7.5\times10^{-2}\times(1+75/1.75)^{1/2}} = 18.9/s$$

For $d = 36mm$, $v = 2645m/s$, $G = 2.13\times10^{10}\,Pa$, $D_0 = 1.75mm$, $\sigma_0 = 3.22\times10^{8}\,Pa$, the predicted characteristic strain rate is

$$\dot{\varepsilon}_{Ic} = \frac{\sigma_0 v(D)}{3GD(1+D/D_0)^{1/2}} = \frac{3.22\times10^{8}\times2.465\times10^{3}}{3\times2.13\times10^{10}\times3.6\times10^{-2}\times(1+36/1.75)^{1/2}} = 74/s$$

For $d = 22mm$, $v = 3515m/s$, $G = 2.13\times10^{10}\,Pa$, $D_0 = 1.75mm$, $\sigma_0 = 3.22\times10^{8}\,Pa$, the predicted characteristic strain rate is

$$\dot{\varepsilon}_{Ic} = \frac{\sigma_0 v(D)}{3GD(1+D/D_0)^{1/2}} = \frac{3.22\times10^{8}\times3.515\times10^{3}}{3\times2.13\times10^{10}\times2.2\times10^{-2}\times(1+22/1.75)^{1/2}} = 227/s$$

Comparing with Fig.1 we can see that if the static strength of granite is 70 Mpa, the predictions are good enough.

5. Conclusion

Rock-like materials have complex internal structure, the scales of such complex structure span a huge scale range. At the same time deformation and fracture of rocks proceed in real time, and their temporal scales are related to the internal structure and physical-mechanical properties of rocks. To understand the nature of dynamic size effect of strength of rocks it is necessary to consider the structural hierarchy and the temporal properties of deformation and fracture process of rocks. In the present paper relaxation model of Maxwell type for rock is used to obtain the relationship between strength, sample size and strain rate. It is shown that when the strain rate is well above certain characteristic strain rate dynamic loading process takes predominant role. Because of the finiteness of crack propagation velocity, the larger the sample size is, the more time is needed for cracks in sample to go through the sample, and the ultimate applied stresses before macrofracture are more and the strength is higher. Factually the dynamic strength is induced by overloading. From other hand because of the size effect of rock strength, the overloading will activate the cracking at smaller scale levels of rock sample, and the fragment size is smaller. From the present model the characteristic strain rate separating the predominant diapasons for static and dynamic size effect is determined, the dynamic fragmentation size is predicted well.

Abstract Modern engineering structures are often made of quasibrittle materials, which are brittle and heterogeneous. Typical examples include concrete, fiber composites, woven composites, tough ceramics, and nano-composites. The salient feature of quasibrittle structures is that the size of the fracture process zone is not negligible compared to the structure size, which leads to an intricate size effect on the structural strength. The current understanding of scaling of quasibrittle fracture is limited to structures with either strong stress singularities or zero stress singularities. Nevertheless, many engineering structures are designed to have complex geometries, which could cause weak stress singularities. This paper investigates the effect of stress singularities on the scaling of quasibrittle fracture both analytically and numerically. The theoretical analysis is derived from a generalized weakest link model where the energetic scaling of quasibrittle fracture is incorporated into the classical finite weakest link model. The proposed model yields a general scaling equation, which captures the transition from the energetic scaling to statistical scaling as the stress singularity gets weaker. The proposed analytical model is then verified by a numerical study on the fracture of concrete beams with a V-notch under three-point bending, where a wide range of notch angles representing different orders of stress singularities is considered.

1. Introduction

Many large-scale engineering structures, such as bridges, dams, aircraft and ships, are usually designed by extrapolating the results of small-scale laboratory experiments. In order to correctly perform this design extrapolation, it is of paramount importance to understand the scale effect on the structural strength. This study focuses on structures that are made of brittle heterogeneous (quasibrittle) materials, which include concrete, fiber composites, tough ceramics, rocks, sea ice, etc. For two-dimensional problems, the nominal structural strength is usually defined as $\sigma_N = cP_{\max}/bD$, where $P_{\max}$ = load capacity of structure, D = characteristic structural size to be scaled, b = width of the structure in the transverse direction, and c = constant which could be chosen such that σ_N represents some familiar parameter such as the maximum stress in the structure in the absence of the stress concentration. It has been demonstrated that the nominal strength of quasibrittle structures is subjected to an intricate size effect. The underlying reason is that for quasibrittle structures the size of the material inhomogenieties is not negligible compared to the structure size, which directly leads to a size-dependent failure behavior [1, 2]. So far, two independent mechanisms have been identified to explain the scaling of strength of quasibrittle structures:

1) *Type-1 size effect*: the maximum load of the structure is attained after the stable formation of a large fracture process zone (FPZ) with distributed cracking, which typically occurs in structures with a smooth boundary. The Type-1 size effect for small and medium-size structures is energetic,

which can be derived based on the Taylor expansion of the energy release rate function at zero crack length [1, 2]. The large size asymptote of this type of size effect is governed by the Weibull statistics of material strength. The statistical size effect can be amalgamated with the energetic size effect to form the complete *energetic-statistical* Type-1 size effect [3]. Recent studies also showed that this size effect can be alternatively derived from a finite weakest link model where the structure is statistically represented by a finite chain of representative volume elements (RVEs) and the probability distribution of RVE strength is derived from fracture mechanics of nanocracks propagating by small, activation-energy-controlled, random jumps through a nano-structure [4-7].

2) *Type-2 size effect*: the maximum load of the structure is reached once a single large crack is formed. The Type-2 size effect typically applied to quasibrittle structures containing a large notch or a large stress-free (fatigued) crack formed prior to maximum load. This size effect is purely *energetic* because the fracture must happen at the pre-existing crack tip. The Type-2 size effect can be derived by using the asymptotic approximation of the energy release function for the propagating crack or the J-integral [1,2,8].

It is clear that the Type-1 and Type-2 size effects can be considered as two limiting cases in terms of the order of stress singularity of the structure. The Type-1 size effect law represents the case of zero stress singularity whereas the Type-2 size effect law represents the case of the strongest stress singularity (i.e. "−1/2" stress singularity). Nevertheless, many modern engineering structures are designed with geometric discontinuities, which produce weak stress singularities. There is still a lack of understanding on the transition between these two size effects as a function of the magnitude of the stress singularities. This study aims to formulate a universal size effect equation for quasibrittle structures through both theoretical and numerical investigations on the fracture of structures with a V-notch under mode-I loading.

2. Review of energetic and statistical size effects

Consider a structure of positive geometry containing a V-notch and subjected to mode-I loading (Fig. 1), where the notch angle is denoted by γ. Positive geometry is defined such that the peak load is reached once the fracture process zone (FPZ) is fully developed. Here we further assume that the notch is sufficiently deep, i.e. $\alpha = a/D > 0.1$, where a = notch depth and D = depth of the structure (Fig. 1). In general, the stress concentration at the V-notch tip is governed by two distinct stress singularities, which represent the symmetrical and anti-symmetrical deformation modes [9-11]. For mode-I fracture, only one stress singularity λ prevails, which corresponds to the symmetrical mode. This section briefly reviews the two existing scaling theories, namely energetic and statistical scaling.

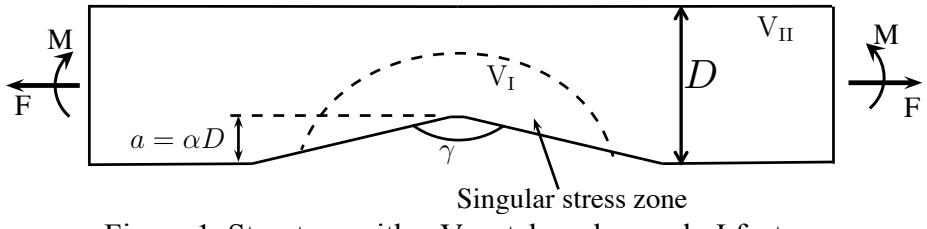

Figure 1. Structure with a V-notch under mode-I facture

2.1. Energetic scaling

Consider the case where the stress singularity is sufficiently strong. It is clear that due to the significant stress concentration the FPZ must form at the notch tip. Therefore, the corresponding scaling mechanism is deterministic. Based on the Williams solution [9], the stress field near the notch tip under mode-I loading can be written as:

$$\sigma_{ij} = Hr^{\lambda} f_{ij}(\theta,\gamma) \tag{1}$$

where r = radial distance from the notch tip, f_{ij} = dimensionless function describing the angular dependence of the stress, and H = stress intensity factor. Based on dimensional analysis, H can be further written as:

$$H = \sigma D^{-\lambda} h(\gamma) \tag{2}$$

where σ = nominal stress = cP/bD, P = applied load, and $h(\gamma)$ is the dimensionless stress intensity factor, which is determined by the structural geometry. One commonly used mode-I fracture criterion for structures with a V-notch is that the peak load is attained when the stress at the distance c_f from the notch tip reaches the material tensile strength f_t [12]. Therefore, we obtain the nominal strength of the structure:

$$\sigma_N = f_t \varphi(\gamma)(D/c_f)^{\lambda} \tag{3}$$

where $\varphi(\gamma) = h^{-1}(\gamma) f_{\theta\theta}^{-1}(0,\gamma)$, which can easily calculated by an elastic analysis.

Since Eq. 3 is derived based on the linear elastic fracture mechanics, it represents the large-size asymptote of the energetic size effect law. The small-size asymptote is very easy to construct. For small-size structures, the FPZ occupies the entire notch ligament and consequently the ligament must behave like a crack filled with plastic glue. At this plastic limit, the size effect must vanish. An approximate equation that bridges the small- and large-size asymptotes has been proposed:

$$\sigma_N = \sigma_s \left[1 + (D/D_{0\gamma})^{1/\beta_\gamma}\right]^{\lambda\beta_\gamma} \tag{4}$$

where σ_s = nominal strength at the small-size limit, β_γ = model parameter, and $D_{0\gamma}$ = transitional size $= D_0\varphi(\gamma)/\varphi(0)$ ($D_0 = D_{0\gamma}$ at $\gamma = 0$). When $\lambda = -1/2$ and $\beta_\gamma = 1$, Eq. 4 converges to the classical Type-2 size effect proposed by Bažant [1, 2], which applies to structures with a large pre-existing crack.

2.2. Statistical size effect

The statistical size effect usually applies to structures without stress singularities, e.g. unnotched beams. A salient feature of the failure of these structures is that the location of damage initiation and localization is uncertain, which is often governed by the randomness of local material strength. Furthermore, these structures reach the peak load once any one of the representative volume elements (RVEs) is damaged and thus the RVE is here defined as the smallest material volume whose failure triggers that failure of the entire structure. The size of RVE l_0 is approximately 2-3 times the size of material inhomogeneities [5]. Statistically speaking, the structure can then be represented by a chain of RVEs. Since the RVE size is about the same as the autocorrelation length of the random material strength field [7], the RVE strength can be treated as an independent random variable and the failure probability of the entire structure can be written as:

$$P_f(\sigma_N) = 1 - \prod_{i=1}^{N} \left[1 - P_1(\sigma_N s(x_i))\right] \tag{5}$$

where P_1 = cumulative distribution function (cdf) of strength of one RVE, N = number of RVEs in the structure, and $s(x_i)$ = dimensionless stress field such that $\sigma_N s(x_i)$ = maximum elastic principal stress at the center of the ith RVE located at x_i. Recent studies have shown that, based on atomistic fracture mechanics and a multiscale transition model for strength statistics, the cdf of RVE strength can be approximated by a Gaussian distribution onto which a Weibull tail is grafted at a probability about 10^{-4} — 10^{-2} [6-7].

The mean strength of the structure can then be calculated as:

$$\bar{\sigma}_N = \int_0^1 \sigma_N \, \mathrm{d}P_f = \int_0^\infty \left[1 - P_f(\sigma_N)\right] \mathrm{d}\sigma_N \tag{6}$$

By considering geometrically similar structures with different sizes, we can obtain the size effect on mean structural strength. Though a closed-form expression seems not possible, an approximate form has been proposed:

$$\bar{\sigma}_N = \left[N_a / D + \left(N_b / D \right)^{rn/m} \right]^{1/r} \tag{7}$$

where n = dimension of scaling and N_a, N_b, and r are constants, which can be determined by the statistical parameters of the cdf of RVE strength. It should be pointed out that Eq. 7 shall not be applied to structures as D approaches 0. A recent study [13] has shown that for small and intermediate-size structures the size effect derived from this finite weakest link model with the use of elastic stresses agrees well with the prediction from the nonlinear deterministic calculation. This is because the mean size effect behavior for small-size and intermediate-size structures is mainly caused by the operative stress redistribution mechanism, which can be well predicted by the nonlinear deterministic calculation. At the same time, this mechanism can also be captured by the finite weakest link model, where the statistical multiscale transition model used for the formulation of the cdf of RVE strength consists of statistical bundles and chains that represent the damage localization and load redistribution mechanisms at different scales (albeit only the elastic stresses are used) [5-7]. For large-size structures, the zone of stress redistribution is negligible compared to structure size and the size effect is mainly caused by randomness of material strength, which cannot be captured by the deterministic calculation. Therefore, the size effect curve for the case of zero stress singularity can be completely explained by the finite weakest link model [4-7].

3. Generalized weakest link model

For structures with a wide V-notch and therefore a weak stress singularity, there is no guarantee that the FPZ would form at the tip of the V-notch. This means that the failure of the structure can be statistically represented by the weakest link model. On the other hand, there exists a singular stress field at the V-notch tip even though the degree of stress concentration is not significant. Furthermore, the fracture of the V-notch itself is associated with an energetic scaling law shown as Eq. 4, which cannot be represented by the existing finite weakest link model. This prompts us to derive a new scaling model by generalizing the classical finite weakest link model to include the energetic scaling of fracture of the V-notch.

In the proposed generalized weakest link model, we isolate the singular stress zone from the remaining part of the structure (Fig. 1), where the singular stress zone can be determined by comparing Eq. 1 to the numerically simulated elastic stress field. Since the singular stress zone is influenced by the presence of the V-notch, whose fracture exhibits an energetic scaling (i.e. Eq. 4), we propose to include this energetic scaling for the calculation of the failure probability of the

singular stress zone:

$$P_{f,V_I}(\sigma_N) = 1 - \prod_{i=1}^{N_1} \left\{ 1 - P_1 \left[\mu(D) \sigma_N s(x_i) \right] \right\} \tag{8}$$

where $\mu(D) = \left[1 + (D / D_{0\gamma})^{1/\beta_\gamma} \right]^{-\lambda\beta_\gamma}$, and N_I = number of RVEs in the singular stress zone. The failure probability of the remaining part of the structure can be calculated by the usual weakest link model with the elastic principal stresses:

$$P_{f,V_{II}}(\sigma_N) = 1 - \prod_{i=1}^{N_2} \left\{ 1 - P_1 \left[\sigma_N s(x_i) \right] \right\} \tag{9}$$

where N_2 = number of RVEs in the region outside the singular stress zone. The failure probability of the entire structure can then be written as:

$$P_f(\sigma_N) = 1 - \left[1 - P_{f,V_I}(\sigma_N) \right] \left[1 - P_{f,V_{II}}(\sigma_N) \right] \tag{10}$$

from which we can calculate the mean size effect. Similar to the case of statistical scaling, a closed form expression is impossible. Since the entire framework still relies on the finite weakest link model, we can use the same asymptotic matching technique as that for the statistical scaling to obtain an approximate scaling law:

$$\bar{\sigma}_N = \sigma_0 \left\{ C_1 \left[\mu^m(D) \psi_1 + \psi_2 \right]^{-r/m} \left(\frac{D + l_s}{l_0} \right)^{-2/m} \exp[-(\lambda / \lambda_1)^2] + \frac{\mu^{-r}(D) D_b}{\exp[-(\lambda / \lambda_2)^2] D + l_p} \right\}^{1/r} \tag{11}$$

where σ_0 = reference stress, C_1, r, λ_1, λ_2, l_s, l_p, D_b = constants, m = Weibull modulus, $\psi_1 = \int_{V_I} \left\langle s(x) \right\rangle^m \mathrm{d}V(x)$, and $\psi_2 = \int_{V_{II}} \left\langle s(x) \right\rangle^m \mathrm{d}V(x)$. Note that here we introduced l_s and l_p to regularize the functional behavior as D approaches 0. Furthermore, it is easy to show that the large- and small-size asymptotes of the mean strength requires:

$$\sigma_0 C_1^{1/r} = s_0^{1/r} \Gamma(1 + 1/m) \tag{12}$$

$$\sigma_s = \sigma_0 \left\{ D_b / l_p + C_1 (\psi_1 + \psi_2)^{1/m} (l_s / l_0)^{-2/m} \exp[-(\lambda / \lambda_1)^2] \right\}^{1/r} \tag{13}$$

where s_0 = Weibull scaling parameter. The small-size strength limit σ_s can usually be obtained by simple plastic analysis by treating the ligament as a crack filled by the plastic glue.

It is clear that Eq. 11 converges to Eqs. 4 and 7 in the two limiting cases. For the transition between these two limits, the size effect consists of both energetic and statistical components. At the small-size limit, the size effect is mainly governed by the statistical scaling component since the energetic scaling term predicts a weak size effect. At the large-size limit, the scaling is governed by the Weibull statistics modified by an energetic scaling term, which leads to a compound energetic-Weibull statistical scaling. Though the focus of this study is on mode-I fracture, the present framework has been extended to general mixed-mode fracture, which is applicable to bimaterial structures. When dealing with mixed-mode fracture, the energetic scaling term would generally contain two distinct stress singularities [14].

4. Numerical simulation

To verify the proposed analytical model, we investigate the size effect on strength of concrete beams with a V-notch under three-point bending (Fig. 2). The beam has a 1:6 depth-to-span ratio and notch depth is 20% of the beam depth. In the simulation, we consider different notch angles, i.e. $\gamma = 0°$, 90°, 120°, 135°, and 170°. For each notch angle, a series of geometrically similar specimens with a size range 1: 2: 4: 8: 16: 64: 128 (the depths of the smallest and largest beams are 37.5 mm and 4.8 m, respectively) is simulated. Based on the Williams solution, these notch angles correspond to the following orders of mode-I singularity: $\lambda = -0.5,\ -0.455,\ -0.3843,\ -0.3264,\ -0.0916$.

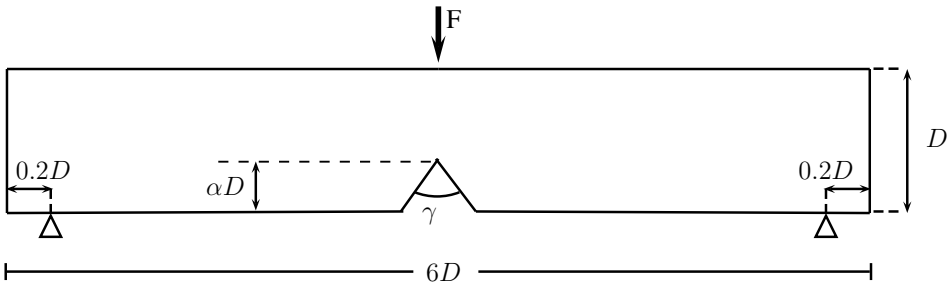

Figure 2. Numerical simulation of three-point bend beam

It is well known that concrete exhibits a complex constitutive behavior. Extensive efforts have been devoted to numerical modeling of fracture of concrete, e.g. [15-18]. Since we are interested in static mode-I fracture, we adopt the default plastic-damage model in ABAQUS because it is sufficient for the purpose of the present study; a detailed description of this constitutive model can be recovered from [19]. The material properties are chosen as follows: Young's modulus E = 30 GPa, Poisson ratio ν = 0.2, tensile strength f_t = 3 MPa, compressive strength f_c = 30 MPa, and Mode-I fracture toughness G_f = 100 N/m. Though we specify the compressive strength, the compressive region of the beam is expected to remain elastic. Therefore, the nonlinear part of the compressive behavior is not of particular interest for the present study. All the specimens undergo displacement-controlled loading. In this study, the numerical simulation is performed within a deterministic framework. Previous studies have shown that the deterministic simulation with a strain-softening constitutive model can successfully capture the entire size effect for the case of strong stress singularity and the size effect for the small- and intermediate structure sizes for the case of zero stress singularity [1-2]. Therefore, we expect that for the case of weak stress singularity the deterministic numerical model is sufficient for simulating the size effect for the small-and intermediate structure sizes. For the large-size asymptote, the deterministic simulation cannot yield the statistical scaling components. In this study, we mainly focus on the small- and intermediate size range, which is applicable to most engineering designs. Therefore, only deterministic simulation is necessary. As will be shown later, the influence of the statistical scaling component only prevails in structures of very large size.

For the finite element modeling, the notch tip is considered to have a very small width, i.e. 5 mm, which is a constant for all the geometries and sizes. For the deterministic simulation, the damage occurs near the mid-span of the beam. Therefore, to reduce computational efforts, we model the middle portion of the beam with a refined mesh (i.e. 5 mm) and the damage plasticity model whereas the rest part of the beam is modeled by a coarse mesh with a purely elastic model. For each

specimen, the assumed region, where the nonlinear material model is used, is further checked as part of the simulation. As the notch angle increases, this nonlinear region becomes larger. It should be pointed out that the present modeling is not as efficient as the crack band model and the nonlocal model, where larger element sizes can be used. However, the use of the crack band and nonlocal models requires extensive modeling efforts with special cautions such as the choice of crack band width [20] and treatment of the nonlocal weighting function along the structural boundary.

Fig. 3 presents the simulated nominal stress-relative deflection curves for specimens of all sizes and all different notch angles, where the nominal stress is defined as = P/bD and the relative displacement is defined as $\delta = \Delta/D$ (Δ = load-point displacement). It is observed that as the structure size increases the post-peak softening portion of the load-deflection curve becomes steeper, which implies a more brittle failure behavior. It should be noted that for large specimens (i.e. D = 1.2, 2.4, and 4.8m) the post-peak behavior is not captured, which indicates that a snap-back instability may have occurred. The snap-back behavior could be captured by loading the specimens by the crack mouth opening displacement. This is not done because we are interested only in the peak load.

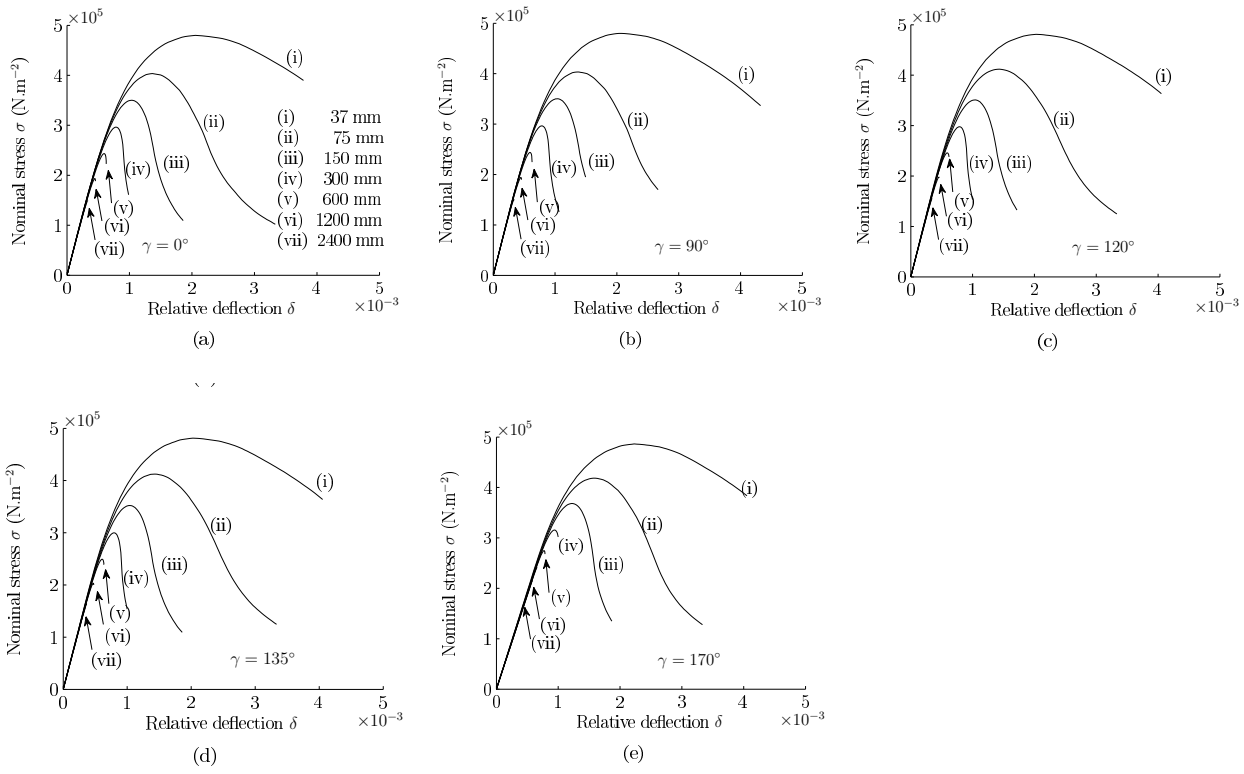

Figure 3. Simulated nominal stress-relative displacement curves

For the 2D specimens, we can simply define the nominal strength of the beam as $\sigma_N = P_{\max}/bD$, where b = 1. Fig. 4 shows the simulated size effects on the nominal strength for different notch angles and the optimum fitting by Eq. 11. As mentioned previously, the small-size strength limit σ_s can easily be calculated by plastic analysis, and the Weibull modulus for concrete is known to be 24. From the fitting, we obtain l_p = 40 mm, l_s = 150 mm, r = 0.88, s_0 = 0.488 MPa, D_0 = 90 mm, λ_1 =

0.301, $\lambda_2 = 0.208$, and β_γ =1, 1, 1.5, 2, 1.1 for γ = 0°, 90°, 120°, 135°, and 170°. It is clear from Fig. 4 that the Eq. 11 agrees well with the simulation results. It should be noted that the simulated size effect curve does not match well with Eq. 11 at the large-size limit for beams with a 170° V-notch. This is due to the fact that we used deterministic simulation, which cannot capture the associated large-size asymptote of the classical Weibull scaling relation. Furthermore, it is observed that such a difference occurs for very large beam size (i.e. D > 1.2m), which indicates that deterministic calculation is sufficient for most normal-size concrete beams.

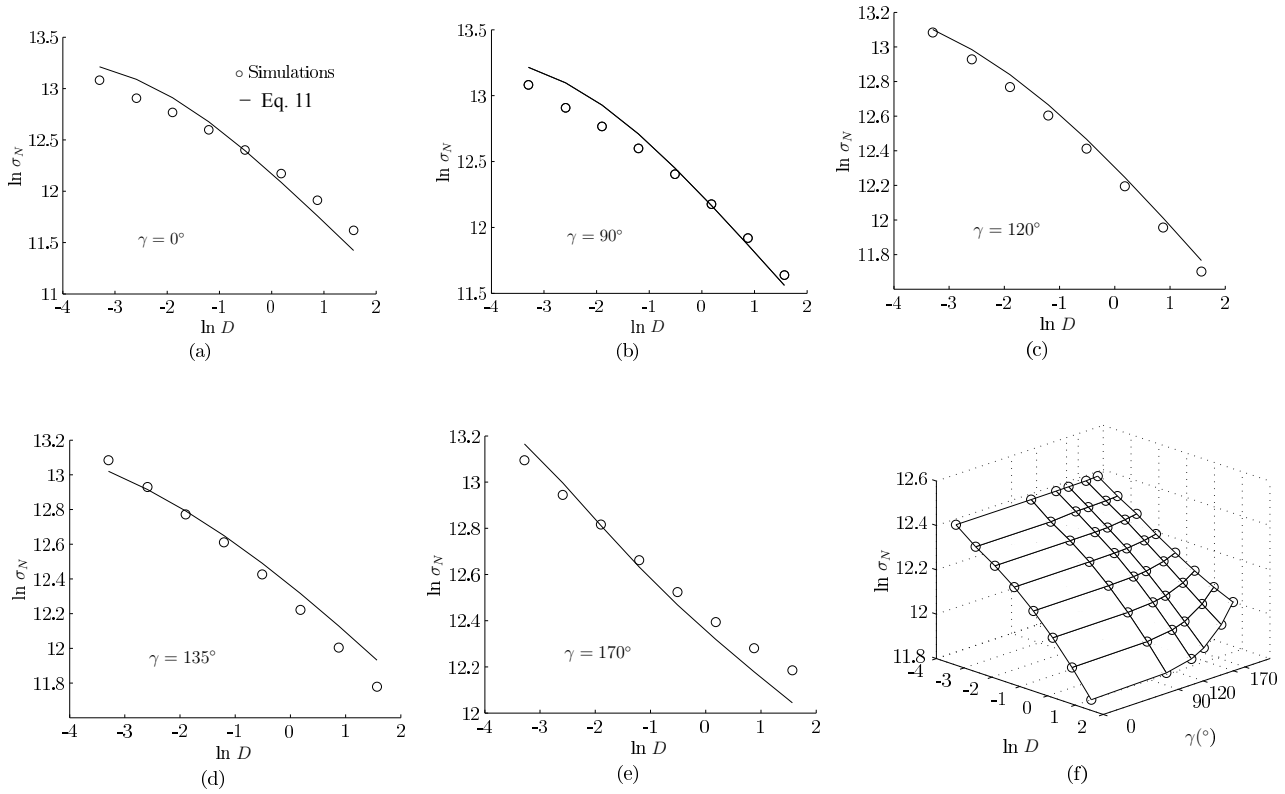

Figure 4. Size effect curves for notched beams: a)-e) Simulated size effect curves fitted by Eq. 11 and f) 3D plot of simulated effects of structural size and notch angle on nominal strength

5. Conclusions

This paper shows that the scaling of strength of quasibrittle structures is strongly dependent on the magnitude of the stress singularities. Such dependence can be derived from a generalized weakest link model, where the classical energetic scaling law is combined with the finite weakest link model. For the case of strong stress singularities, the scaling of fracture is purely energetic, which can be derived from fracture mechanics. For the case of zero stress singularity, the size effect can be explained by random material strength through the finite weakest link model. For the case of weak stress singularities, the scaling is governed by both energetic and statistical mechanisms.

Abstract The characterization of fracture resistance of ferritic steels in the ductile to brittle transition zone is problematic due to the great scatter of test results. The statistical treatment in the literature is mainly based on the Weibull distribution, but some authors based their analysis on such a distribution with two parameters (2P-W), while others use a three parameters Weibull distribution (3P-W). Besides this, it is not homogeneous the use of these distributions in terms of J or K, and in general is acceptable that the Weibull slope for a K based distribution is twice the corresponding slope for the distribution based on J values. In previous works, the authors have shown that this relationship between slopes is not valid, except for the case of a 2P-W distribution, and have proposed a new factor (ξ) different from two that is calculated once the three parameters of the 3P-W distribution are estimated. In this paper it is demonstrated, using datasets with 100% cleavage from the Euro Round Robin in order to analyze cases where the weakest link model is valid, that this new factor works quite well, and that even when 3P-W distributions based on J and K values are not equivalent, both could be used to describe the results of fracture mechanics toughness tests.

Keywords Fracture toughness, Ductile-to-brittle transition, Scatter, Weibull distribution

1. Introduction

The experimental determination of fracture toughness in ferritic steels in the brittle-to-ductile transition region is generally based on J_C tests because K_{IC} valid values require too large specimens to meet small scale yielding conditions. Additionally, this characterization is problematic because of the scatter in results that need to be adjusted with the aid of a statistical distribution, being the Weibull distribution the most employed in literature.

This distribution has been used with two (2P-W) or three parameter (3P-W), and in both cases, adjusting data from J_C tests, or data expressed in terms of K converted from J_C (K_{JC}). For instance, Landes and Shaffer [1], Iwadate *et al.* [2], Anderson *et al.* [3], Landes *et al.* [4], and Heerens *et al.* [5] made use of a 2P-W distribution based on J_C values, while Landes and McCabe [6], Neville and Knott [7], and Perez Ipiña *et al.* [8] based their analysis on the 3P-W distribution using J_C data. The use of such distributions based on K values was promoted by Wallin, with a 2P-W distribution [9], and later with a 3P-W distribution [10].

The parameters to be determined in the 2P-W distribution are the shape parameter (also known as Weibull slope), and the scale parameter. For a 3P-W distribution, the threshold parameter is added. Besides the possibility of working with two or three parameters, and also with J or K data, some authors have proposed a fixed shape parameter with a given value: 2 when working with J_C [3, 4, 5, 11] and 4 when working with K_{JC} [10, 12, 13].

The advantage of using a 3P-W distribution with a fixed shape parameter is that an adjusted to experimental data distribution would be obtained with a smaller number of tests.

According to the theoretical deduction performed by Wallin [10], the value of the shape parameter is four when adjusting K values, and by the well-known relationship between K and J for small

scale yielding, this value would be two when working with J values.

As was shown by Larrainzar *et al.* [14], this relationship is only valid for 2P-W distributions. For 3P-W distributions there is no exact equivalence between that expressed in terms of J and the one in terms of K.
Equations (1) and (2) present 3P-W distributions expressed in terms of J or K, respectively.

$$P = 1 - e^{-\left(\frac{J - J_{\min}}{J_0 - J_{\min}}\right)^{b_J}} \quad (1)$$

$$P = 1 - e^{-\left(\frac{K - K_{\min}}{K_0 - K_{\min}}\right)^{b_K}} \quad (2)$$

The scale parameter values are J_0 and K_0, while J_{min} and K_{min} are the threshold parameter values, and b_J and b_K are the shape parameter values of the distributions given by Eq. (1) and (2). All these parameters can be estimated by linear regression, using experimental data in J or these data converted to K.
As was already established, there is no exact equivalence between distributions expressed by Eqs. (1) and (2). The relationship between b_K and b_J given by Eq. (3) is not valid for a general case, instead that given by Eq. (4) has been proposed as a good approximation.

$$b_K = 2b_J \quad (3)$$

$$b_K = \xi . b_J \quad (4)$$

Where ξ is given by Eq. (5), and its value ranges between 1 and 2.

$$\xi = \frac{2K_0}{K_0 + K_{\min}} \quad (5)$$

There is an exact relationship between the threshold and scale parameters (Eq. 6 and Eq. 7).

$$K_0 = \sqrt{\frac{EJ_0}{\left(1 - \nu^2\right)}} \quad (6)$$

$$K_{\min} = \sqrt{\frac{EJ_{\min}}{\left(1 - \nu^2\right)}} \quad (7)$$

Where E is the material Young modulus, and < is the material Poisson coefficient.
In this work the relationship between shape parameters in 3P-W distributions, based in K, and J and given by Eq. (4), is validated with experimental data obtained from the Euro Fracture Toughness Dataset. For such a purpose, the parameters of both 3P-W distributions based in J and in K were estimated. Then it was performed a comparison between the parameters of the last one with those converted from 3P-W based in J (by means of Eqs. 4, 6 and 7).

2. Material and Method

Data taken from the Euro Fracture Toughness Dataset [15] were used in the present work. They

correspond to the Round Robin organized by the European Structural Integrity Society (ESIS) and all the information is available in ftp://ftp.gkss.de/pub/eurodataset.
The material tested in the project was a ferritic steel DIN 22NiMoCr37 forged, quenched and tempered.
Figure 1 shows the test matrix performed in the ESIS Round Robin. As the figure shows, tests were performed at different temperatures (-154°C, -110°C, -91°C, -60°C, -40°C, -20°C, 0°C and 20°C) and with different specimen thicknesses C(T) (½", 1", 2" and 4"), with a thickness to width ratio B/W=0.5. Specimens were fatigue pre-cracked to be inside the range 0.52 < a0/W < 0.6. Side grooving was performed after pre-cracking in a few specimens. Tests were carried out in order to obtain the fracture toughness at the point of fracture J_C.

From the tested sets, only those in which all the specimens presented cleavage were considered in the present work. They corresponded generally to the lowest temperatures and largest sizes and are color marked out in squares in Fig. 1. Figure 2 shows the results for all the analyzed sets. This selection was decided in order to avoid sets where two different failure modes coexist, implying that a 3P-W function could not adequately describe the scatter. It is important to note that some datasets included values greater than the allowed J_{max} for the corresponding thickness (½ T at -60°C, 1T at -40°C, 1T at -20°C and 2T at 0°C). Each J_C value was converted to its K_{JC} equivalent, by means of Eq. (8), considering E=210 GPa and <=0.3.

$$K_{J_C} = \sqrt{\frac{EJ_C}{\left(1-\nu^2\right)}} \qquad (8)$$

The parameters of both 3P-W distributions in terms of J and K were estimated for all the analyzed sets. In this way the slopes (b_J and b_K), the thresholds (J_{min} and K_{min}), and the scale (J_0 and K_0) parameters were obtained. Following, the parameters of another 3P-W distribution in terms of K ($K_0(J)$, $K_{min}(J)$ and $b_{K\xi}$), were calculated from the estimations of J_0, J_{min} and b_J already obtained, using Eqs. (6), (7) and (4) respectively.

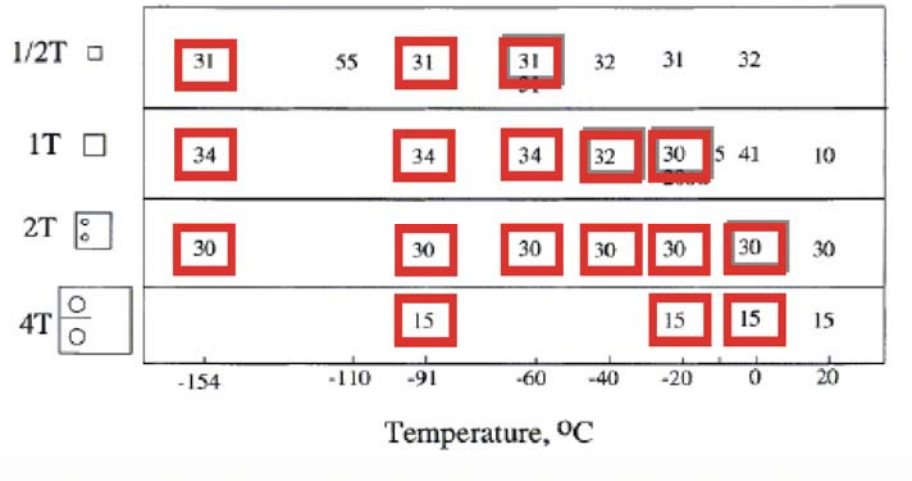

Figure1. Test matrix performed in the ESIS Round Robin. The sets marked out in squares presented only cleavage results and were analyzed in this work. Those shadowed correspond to data sets where some results exceeded J_{max}

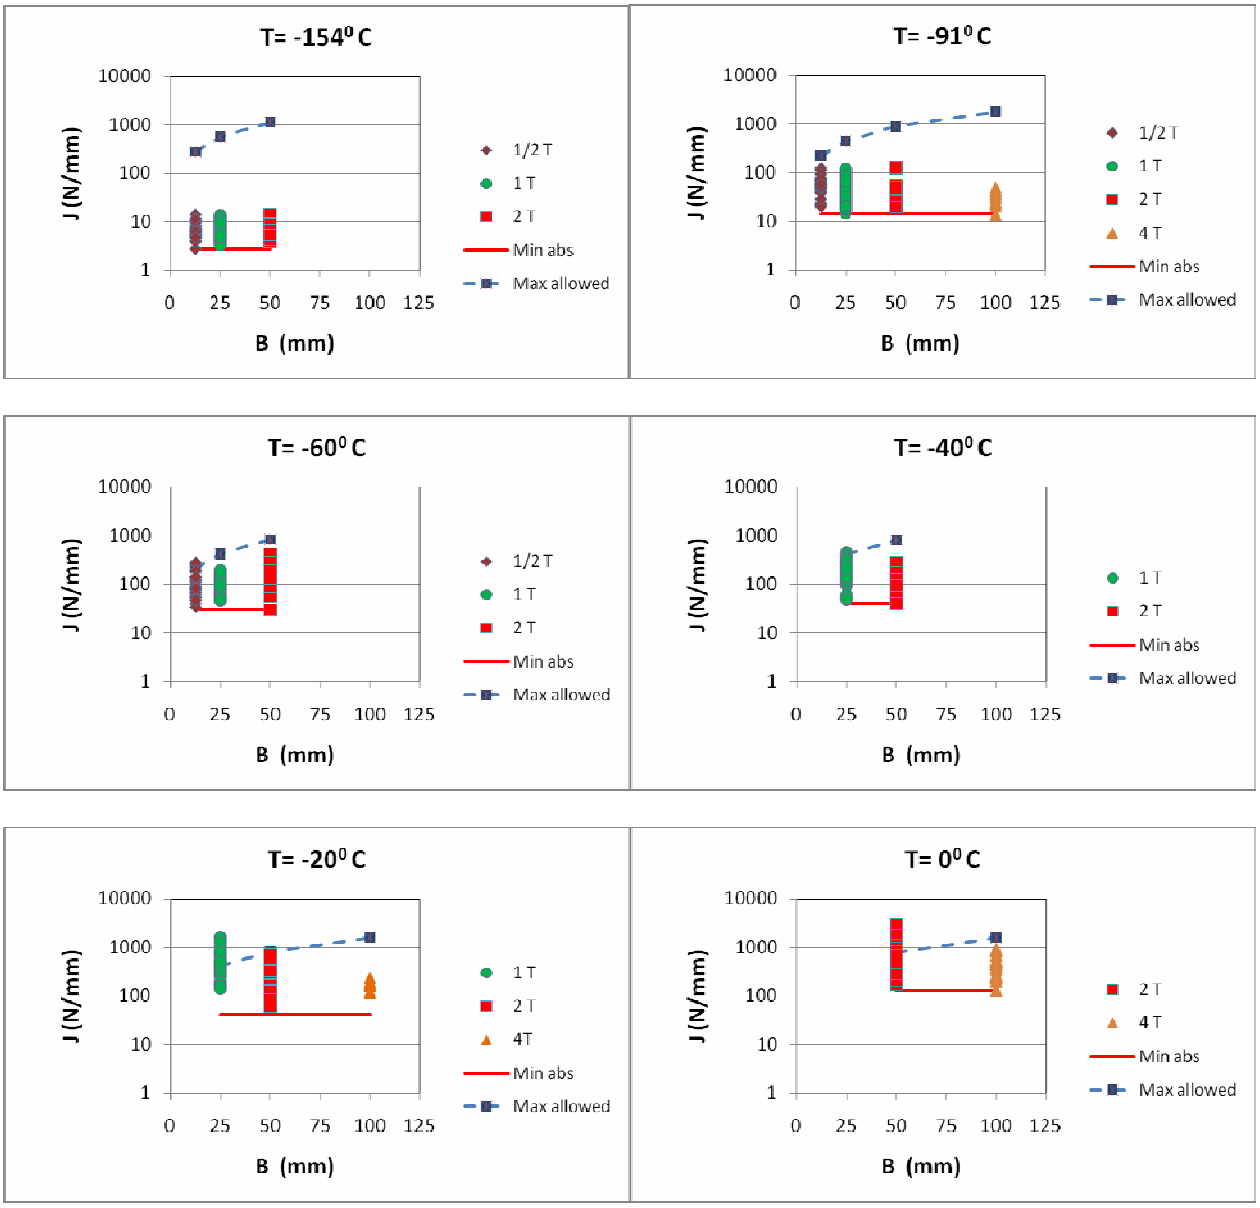

Figure 2. Experimental results for all the analyzed temperatures

3. Results, analysis and discussion

Table 1 shows the 3P-W parameters estimated for all the analyzed sets: the slopes (b_J and b_K), the thresholds (J_{min} and K_{min}), and the scale (J_0 y K_0) parameters. The parameters of the distribution in terms of K(J), calculated from the estimations of J_0, J_{min} and b_J already obtained, as well as the values of ξ , and the b_K/b_J ratio are also shown in the table.

Nearly all the sets produced "acceptable" values of Weibull parameters, especially K_{min}. The set corresponding to B=25mm and T=-40°C was the exception in which physically impossible values of J_{min} and K_{min} were obtained, so the threshold value was considered as zero. In this set, only one of the 32 results was larger than the J_{max} corresponding to this thickness, although there were more than one non-valid results in other sets and the Weibull parameters were physically "acceptable".

Table 1. 3P-W parameters in terms of **J** [kJ/m^2] and **K** [MPa/m$^{1/2}$], all temperatures and sizes

		Estimated from experimental data			Estimated from converted experimental data K_{JC}				Converted from estimated J parameters

-20	1T	564,71	125,55	1,08	357,50	162,19	1,50	1,39	361	170,21	1,47	1,36
	2T	277,41	37,70	1,52	252,25	77,60	2,43	1,60	253,02	93,27	2,22	1,46
	4T	190.96	58.45	2.97	209.89	101.59	4.44	1.49	209.92	116.14	3.83	1.29
0	2T	953.58	166.33	0.83	458.32	191.46	1.13	1.36	469.10	195.92	1.18	1.41
	4T	458.66	81.30	1.31	324.15	118.66	2.02	1.54	325.34	136.97	1.85	1.41

Table 1 shows that the parameters estimated by linear regression from K values converted from J (shown in column "Estimated from converted experimental data K_{JC}" in Table 1) and also using the parameters obtained by means of Eqs. (4), (6) and (7) (shown in column "Converted from J parameters" in Table 1) are very close. Figure 3 shows some Weibull cumulative distribution functions with parameters obtained by the two ways, together with the experimental points and the agreement is confirmed.

Table 2 and Fig. 4 show the comparison between ξ, obtained using Eq. (5), and the ratio b_K/b_J, where b_K and b_J are the shape parameters estimated for J experimental values and K_J. These values are quite similar, although b_K/b_J resulted always larger than ξ, except in one case. The horizontal line in the figure corresponds to the hypothetical case given by Eq. (3) ($b_K=2b_J$), which is not satisfied except when $J_{min}=0$, as already justified.

Figures 5 to 7 compare the three Weibull parameters in K: those obtained from the K_{JC} values and those obtained from J_C values (3P-W(J)) and transformed to K by using Eqs. (4), (6) and (7).

Figure 8 shows the predicted thresholds against the minimum experimental values. It can be

observed from this figure and also from Fig. 5 and Table 1 that $K_{min}(J)$ values, those obtained using ξ, resulted less conservative than the K_{min} ones, although their values were always lower than the corresponding experimental minimum.

As it is seen from Fig. 3, it resulted clear that the methodology proposed (that uses Eqs. 4, 6 and 7) adjusts the experimental data very well.

Table 2. Difference $b_K/b_J - \xi$ relative to ξ

T (ºC)	W=25 mm	W=50 mm	W= 100 mm	W= 200 mm
-154	7.41%	2,48 %	1,77 %	-

	-40	-34.86	-24.91
	-20	-33.27	-19.79
	0	-4.54	-2.31
4T	-91	-60.25	-45.69
	-20	-36.81	-27.76
	0	-30.55	-19.83

*: In this case, threshold parameter was forced to zero because a negative value was obtained from the estimation, resulting a difference of 100% between K_{min} and experimental K_{min}

There is no clear evidence that the 3P-W distribution based in J is better than the corresponding to that based in K values. Both fitted well the experimental results and predicted good threshold parameters.

4. Conclusions

- The theoretical relationship between b_J and b_K given by eq. (5) is consistent with the obtained from experimental data from the ESIS Round Robin.
- The Weibull slope in terms of K is not consistent with a fixed value equal to 4, instead it appears to calculate it from b_J by using Eq. (3), or estimating it from experimental data converted toK.
- The 3P-W parameters in terms of K, that can be estimated from experimental Jc converted to K_{Jc}, result more consistent with reality when they are calculated converting the corresponding estimated in terms of J.

Scale Effect of the Tensile Strength of Aligned-Flax-Fiber Reinforced Composite

Jānis Andersons[1,*], Edgars Spārniņš[1], Jānis Modniks[1]

Abstract Application of plant-derived natural fibers as the reinforcement of polymer-matrix composites is driven by economic and environmental reasons. In order to fully exploit the reinforcing effect of the fibers, they have to be aligned in the composite material. When using such UD composites in load-bearing applications, the dependence of strength on the material volume subjected to loading, i.e. the scale effect of strength, should be taken into account in design. UD-reinforced flax fiber/epoxy matrix composites, produced from prepregs, were tested in tension in fiber direction in order to elucidate the scale effect of the tensile strength. The strength distribution at a fixed specimen size and the dependence of the mean strength on the size were shown to agree reasonably well with the Weibull strength statistics, corroborating the previous results for flax-fabric-reinforced composites. A probabilistic model of the strength in tension along the reinforcement direction, using fiber strength distribution, interfacial shear strength and morphology parameters, was applied to theoretically evaluate the magnitude of scale effect.

Keywords flax fibers, polymer composites, strength, Weibull distribution

1. Introduction

Application of plant-derived natural fibers as the reinforcement of polymer-matrix composites is driven by economic and environmental reasons. In order to fully exploit the reinforcing effect of the fibers, they have to be aligned in the composite material. For bast fibers, this is achieved either by using traditional textile technologies to produce aligned fiber yarns (with a twist level optimized for processing) or by manufacturing prepregs with unidirectional (UD) bast fiber orientation. When using such UD composites in load-bearing applications, the dependence of strength on the material volume subjected to loading, i.e. the scale effect of strength, should be taken into account in design. For brittle composites, the scale effect closely follows the weakest-link statistics [1] reflected by the Weibull strength distribution:

$$P(\sigma)=1-\exp\left[-\frac{V}{V_0}\left(\frac{\sigma}{\beta}\right)^{\alpha}\right] \tag{1}$$

where V is the specimen volume subjected to stress σ and α and β denote Weibull shape and scale parameters, respectively. Aligned flax fiber composites with textile reinforcement have been shown to exhibit scale effect of tensile strength consistent with Eq. (1) when subjected to tensile loading along the fibers [2].

Probabilistic models of fracture of UD continuous-fiber reinforced composites provide expressions of Eq. (1) parameters in terms of fiber, interface and matrix properties, see e.g. [3-5]. Flax fibers, although being relatively long, are discontinuous; moreover, typical reinforcement of a UD composite contains both elementary and technical fibers, defects in the latter triggering fracture of the composite [6]. Therefore, direct application of the probabilistic strength models derived for

uniform continuous fiber composites to bast fiber composites is likely to yield an upper estimate of their strength [7]. The current study concerns experimental evaluation of the scale effect of tensile strength of UD flax-fiber composites made of commercially available prepregs. Probabilistic strength model [4] is applied for approximate evaluation of strength.

2. Experimental

2.1. Material

A composite plate was produced from LINEO flax/epoxy prepreg FLAXPLY©. Six UD prepreg plies of the areal density of 150 g/m^2 were aligned, stacked and cured in a thermopress for one hour at ~1 atm pressure and 130 ˚C temperature. Four groups of specimens, with widths w = 10, 20, 40, and 70 mm, were cut out of the plate along the fiber direction so that the gauge length to width ratio for all specimens amounted to 5.

2.2. Tests

Fiberglass tabs were glued onto the specimen ends. The specimens were tested for strength by applying a stroke-controlled tensile loading in the fiber direction. The loading rate was varied according to specimen gauge length so that the nominal strain rate for all the specimens tested amounted to 0.75 %/min. The strength was evaluated from the failure load employing the average width of a specimen and the average thickness of the plate

3. Model

3.1. Weibull scale effect

For the rectangular geometry considered, the specimen volume subjected to load is a product of its width, gauge length, and thickness $V = wLt$ (resp. unit volume $V_0 = w_0 L_0 t_0$). Due to uniform thickness of the specimens, we select $t_0 = t$, hence Eq. (1) takes the form:

$$P(\sigma) = 1 - \exp\left[-\frac{wL}{w_0 L_0} \left(\frac{\sigma}{\beta} \right)^{\alpha} \right] \tag{2}$$

It follows from Eq. (2) that the mean strength $\langle \sigma \rangle$ depends on specimen dimensions as follows:

$$\langle \sigma \rangle = \beta \left(\frac{wL}{w_0 L_0} \right)^{-\frac{1}{\alpha}} \Gamma\left(1 + \frac{1}{\alpha} \right) \tag{3}$$

Hence, having determined the strength distribution Eq. (2) parameters from test results at one gauge length, the dependence of mean strength on specimen size can be evaluated according to Eq. (3) if the Weibull scale effect of brittle fracture applies.

3.2. Strength model

A probabilistic model of the tensile strength of UD continuous fiber reinforced composites has been elaborated in [4] for fibers with the Weibull two-parameter strength distribution

$$P(\sigma)=1-\exp\left[-\frac{l}{l_0}\left(\frac{\sigma}{\beta_f}\right)^{\alpha_f}\right] \tag{4}$$

where l stands for fiber length, l_0 is a unit length, and the distribution shape and scale parameters are designated as α_f and β_f, respectively.

In the following we briefly recapitulate the principal relations of the model [4]. Distribution of the average (over cross-section of the composite normal to the fibers) stress taken by the fibers at the failure of a UD composite is given by

$$P(\sigma_f)=1-\exp\left[-\left(\frac{\sigma_f}{\widetilde{\sigma}}\right)^{\widetilde{\rho}}\right] \tag{5}$$

The scale, $\widetilde{\sigma}$, and shape, $\widetilde{\rho}$, parameters of the Weibull distribution Eq. (5) are evaluated as follows

$$\widetilde{\sigma}=\sigma_c b_{m,n} \tag{6}$$

and

$$\widetilde{\rho}=b_{m,n}/a_{m,n} \tag{7}$$

where $a_{m,n}$ and $b_{m,n}$ are expressed by following relations

$$a_{m,n}=\frac{\gamma^{**}_{n_l}}{\sqrt{2\ln(m\cdot n)}} \tag{8}$$

and

$$b_{m,n}=\mu^{*}_{n_l}+\gamma^{**}_{n_l}\left(\frac{\ln(\ln(m\cdot n))+\ln(4\pi)}{\sqrt{8\ln(m\cdot n)}}-\sqrt{2\ln(m\cdot n)}\right) \tag{9}$$

The characteristic stress entering Eq. (6) is given by

$$\sigma_c=\left(\frac{\beta_f^{\alpha_f}\tau\, l_0}{r}\right)^{\frac{1}{1+\alpha_f}} \tag{10}$$

where r is fiber radius and τ designates the interfacial shear strength (IFSS) between fibers and matrix. In Eqs. (8) and (9), $\mu_{n_l}^{*}$ and $\gamma_{n_l}^{**}$ are theoretical mean and standard deviation of strength of a bundle of n_l fibers with n_l - the number of fibers in a critical element. The latter is given by

$$n_l = 403\alpha_f^{-1.28} \tag{11}$$

for $2 \le \alpha_f \le 10$. Length of the critical element δ_l is

$$\delta_l = 0.4\,\delta_c \tag{12}$$

where δ_c is the characteristic length given by

$$\delta_c = \frac{r\sigma_c}{\tau} \tag{13}$$

In Eqs. (8) and (9), $m = L/\delta_l$ and $n = n_f / n_l$, where L is the length of composite subjected to load and n_f - number of reinforcing fibers the composite contains.

4. Results and discussion

The parameters of the strength distribution were determined from the strength data of 50-mm-gage-length specimens, shown in Fig. 1, by the maximum likelihood method, as α = 22.8 and β = 404 MPa (at $w_0 = L_0 = 1$ mm). The empirical fiber fracture probabilities, P, have been evaluated via the median rank of the measured strength values using the approximation $P = (i - 0.3)/(n + 0.4)$, where i is the i-th number in ascendingly ordered strength data of the sample and n is the number of specimens.

Flax reinforcement is inherently heterogeneous since it contains not only elementary flax fibers but also technical fibers (i.e. naturally adhering elementary fiber bundles) of various sizes; an additional characteristic length is introduced by the presence of transverse stitching fibers in a prepreg. For heterogeneous quasi-brittle materials, strength distribution has been shown to change gradually from normal to Weibull with increasing size and brittleness of the specimen or structure [8]. At intermediate sizes, the strength distribution possesses a Weibull left tail switching to normal distribution for high strengths. A kink can be discerned in Fig. 1 suggesting the presence of such a transition. It appears of interest to establish the size of a representative volume element for strength in flax-fiber composites and its relation to reinforcement structure, thus potentially enabling a more accurate modeling of the scale effect of strength.

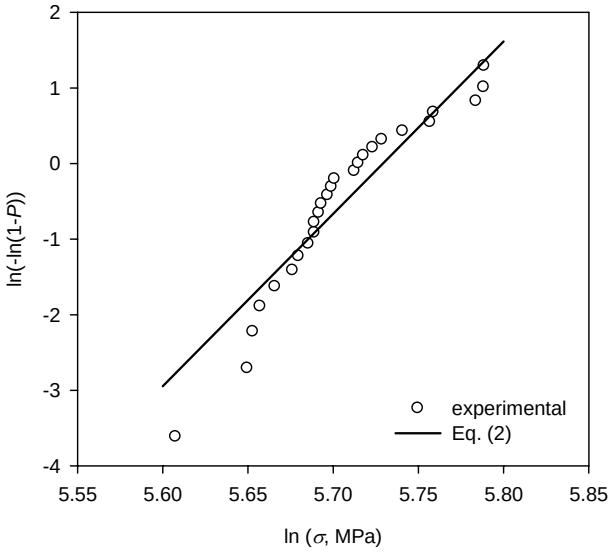

Fig. 1. Tensile strength distribution of specimens with width w = 10 mm in Weibull co-ordinates.

Comparison of the experimental dependence of the mean strength on specimen size and the prediction by Eq. (3) is shown in Fig. 2. It is seen that both, strength scatter at a fixed specimen size, Fig. 1, and strength-size scaling, Fig. 2, agree reasonably well with the Weibull statistics. Note that the sale effect of strength for a UD flax-fabric-reinforced composite has also been shown to follow the scaling of Eq. (2), although with a somewhat smaller Weibull shape parameter α of ca. 18 [2]. The higher scatter of strength in the case of textile UD reinforcement is likely to result from the additional geometrical variability associated with yarn alignment in the composite.

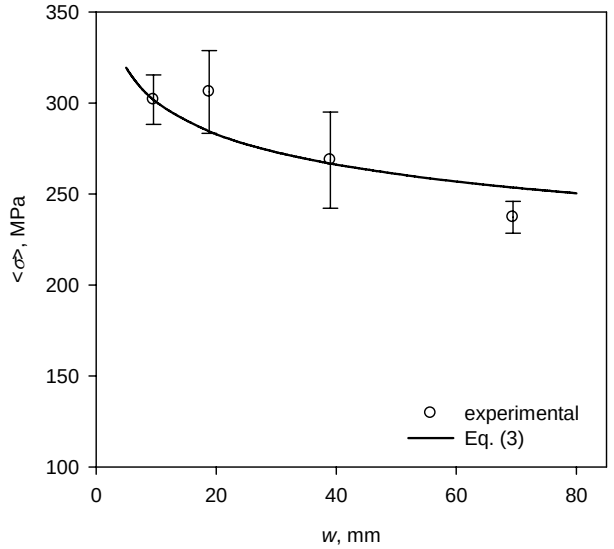

Fig. 2. Dependence of the mean tensile strength $<\sigma>$ on specimen width w

Application of the probabilistic strength models is hampered in this case by lack of information regarding flax fibers used in prepreg manufacture and their adhesion to the epoxy matrix. Nevertheless, for the purposes of qualitative comparison, strength distribution Eq. (5) parameters were estimated for several types of flax fibers assuming a plausible IFSS value. IFSS of bast fibers and epoxy matrix is reported to range from ca. 10 to 33 MPa [9-11]. For a conservative estimate,

IFSS of 10 MPa was assumed. Strength distribution Eq. (4) parameters, evaluated from test results of elementary flax fibers at 10 mm gauge length, are presented in Table 1 (at l_0 = 1 mm). Fiber diameter 16 μm was used in calculations.

Table 1. Strength distribution Eq. (4) parameters of elementary flax fibers

Reference	Shape parameter α_f	Scale parameter β_f, MPa
[12]	3	2080
[13]	1.8	2033
[错误!未找到引用源。]	2.7	1913

The parameters of composite strength distribution, Eq. (5), were evaluated for composite specimens with 50 mm gauge length and 10 mm width by Eqs. (6) and (7) using the fiber and interface parameters listed above. The results are presented in Table 2. Note that the product of fiber volume fraction and the predicted scale parameter is given in Table 2 for ease of comparison with the experimental scale parameter.

Table 2. Strength distribution Eq. (5) parameters of UD composite with 50 mm length

Fiber strength from reference	Shape parameter $\tilde{\rho}$	Reduced scale parameter $v_f\tilde{\sigma}$, MPa
[12]	107	502
[13]	117	508
[错误!未找到引用源。]	110	511

It is seen that the predicted shape parameter, characterizing strength scatter, is about 5 times higher than the experimentally determined value. This is likely to stem from such factors as fiber misalignment, heterogeneity, and clustering not allowed for in the theoretical model and increasing the variability of strength. Note also that the predicted scale parameter values exceed the experimental one, i.e. the model provides an upper limit of the tensile strength of flax fiber reinforced composite.

5. Conclusions

Scale effect of the tensile strength of UD flax/epoxy composite has been characterized experimentally and shown to comply with strength-specimen size scaling implied by the Weibull two-parameter distribution of strength. Hence strength distribution parameters, determined using only specimens of a fixed size, can be used to predict the variation of strength with volume of the composite subjected to load. A probabilistic model of composite strength has been shown to underestimate the scatter in strength and overestimate mean strength. This is likely to be related to the heterogeneity inherent in natural fiber composites and not reflected in the models derived for synthetic continuous fiber composites.

Abstract The fracture behavior of four non-symmetric radial cracks originating from a circular hole in piezoelectric materials subjected to remotely uniform in-plane electric loading and anti-plane mechanical loading is studied in this paper. The problem is transformed using the complex variable method and the technique of conformal mapping into Cauchy integral equations. To solve the Cauchy integral equations, the analytical solutions of the stress and the electric displacement intensity factors, energy release rate and mechanical strain energy release rate are obtained under the electrically impermeable and electrically permeable assumptions, respectively. Several known results are the special cases of the present results and new models used for simulating more practical defects in piezoelectric materials are derived as well, such as three radial cracks originating from a circular hole, semi-circular hole with an edge crack originating from a semi-infinite plane and a semi-infinite plane with an edge crack. Numerical examples are provided graphically to show the effects of the geometrical parameters on the energy release rate and the mechanical strain energy release rate.

Keywords Piezoelectric materials, Circular hole, Edge cracks, mapping function, Analytical solution

1. Introduction

Due to their intrinsic electromechanical coupling phenomenon, piezoelectric materials have been widely used as transducer and sensor in smart structures and devices. However, one inherent weakness of piezoelectric ceramics is the brittleness in mechanical behavior. When subjected to mechanical and electric loading in service, the stress concentrations can induce crack initiation and propagation, which will lead to the failure of these piezoelectric materials. Therefore, it is of great importance to analyze the fracture behavior of piezoelectric materials, especially when cracks emanating from holes are involved.

In recent years, the crack problems of piezoelectric materials have received considerable attention under anti-plane shear loading due to the practical importance [1-6]. In fact, there exist many kinds of complicated configurations during manufacture and service of the holed structures, e.g., cracks originating from circular hole, semi-circular hole with an edge crack originating from a semi-infinite solid, T-shaped crack, cross-shaped crack, etc. Recently, Wang and Gao [7] solved the two symmetrical cracks and a single crack originating from the edge of a circular hole in a piezoelectric solid by introducing mapping fucntion, and presented the exact solutions of the field intensity factors and the energy release rate. By developing new mapping functions, Guo et al. [8,9] investigated the two asymmetrical edge cracks emanating from an elliptical hole in a piezoelectric material under the electrically impermeable and the electrically permeable boundary conditions, respectively, and obtained the exact solutions of the field intensity factors and the energy release rate. To ours' knowledge, the existing research is focused on the collinear cracks parallel to the x-axis originating from holes. For an occurrence of the cracks parallel to y-axis direction originating from holes, however, the corresponding research is very lacking in a piezoelectric solid, which may have the surprise results. Thus, it is practical and necessary to study the fracture behavior of four

non-symmetrical radial cracks at the edge of a circular hole. Furthermore, it is very challenging and meaningful to present the analytical solutions for the complicated crack problems, since these solutions can provide the theoretical analysis for fracture problems in piezoelectric materials, and can also serve as a benchmark for the purpose of judging the accuracy and efficiency of various numerical and approximate methods.

In this paper, we study the anti-plane problem of four non-symmetrical radial cracks at the edge of a circular hole in a transversely isotropic piezoelectric solid based on two kinds of electric boundary conditions, i.e., the electrically impermeable and the electrically permeable. A new conformal mapping is developed to reduce the problem to the solution of Cauchy integral equation. In addition, the analytical solutions of the field intensity factors, the energy release rate (ERR) and the mechanical strain energy release rate (MSERE) are derived. It is seen that the stress intensity factors of some special cases derived from the present results agree well with the corresponding results of the pure elastic materials.

2. Basic formulation

In a rectangular coordinate system $x_i (i = 1, 2, 3)$, consider a transversely isotropic piezoelectric solid with the poling direction along the positive x_3 axis and the isotropic plane in the $x_1 - x_2$ plane. The constitutive equation for a linear piezoelectric media can be given as

$$[s_{3i}, D_i]^{\mathrm{T}} = \mathbf{B}_0 [g_{3i}, -E_i]^{\mathrm{T}} \tag{1}$$

where i=1, 2, T denotes a transpose of a matrix, and

$$\mathbf{B}_0 = \begin{matrix} 矫 \\ 压 \\ 猫 \\ 膜 \end{matrix} \begin{matrix} c_{44} & e_{15} \\ e_{15} & -\varepsilon_{11} \end{matrix} \tag{2}$$

where c_{44}, e_{15} and ε_{11} are the elastic constant, the piezoelectric constant and the dielectric permittivity, respectively.

The generalized strain-displacement relations have the form

$$g_{3i} = w_{,i}, \quad E_i = -\varphi_{,i} \tag{3}$$

where a comma in the subscripts stands for a partial differentiation.

The equilibrium equation and the charge conservation equation, in the absence of the body force and electric charge densities, can be written as

$$s_{3i,i} = 0, \quad D_{i,i} = 0 \tag{4}$$

Substituting Eqs. (1) and (2) into Eq. (4), we have

$$\nabla^2 w = 0, \quad \nabla^2 \varphi = 0 \tag{5}$$

The general solution of Eq. (5) can be expressed by the analytical function $\mathbf{f}(z)$ [4]

$$\mathbf{u} = \mathbf{A}\mathbf{f}(z) + \overline{\mathbf{A}\mathbf{f}(z)}, \quad \mathbf{u} = (w, \varphi)^{\mathrm{T}} \tag{6}$$

where $z = x_1 + \mathrm{i}x_2$. Thus, the stress and electric displacement can be expressed as

$$[s_{31} - \mathrm{i}s_{31}, D_1 - \mathrm{i}D_2]^{\mathrm{T}} = \mathbf{B}_0[g_{31} - \mathrm{i}g_{32}, -E_1 + \mathrm{i}E_2]^{\mathrm{T}} = \mathbf{B}_0\mathbf{f}'(z) \tag{7}$$

Let we introduce a potential function ϕ, such that

$$[s_{31}, D_1]^{\mathrm{T}} = -\mathbf{f}_{,2}, \quad [s_{32}, D_2]^{\mathrm{T}} = \mathbf{f}_{,1} \tag{8}$$

From Eqs. (7) and (8), one finds

$$\mathbf{f}'(z) = \mathbf{B}\mathbf{f}(z) \tag{9}$$

where $\mathbf{A}$ and $\mathbf{B}$ stand for the material constant matrices defined as

$$\mathbf{A} = \mathbf{I}, \quad \mathbf{B} = \mathrm{i}\mathbf{B}_0 \tag{10}$$

where $\mathbf{I}$ is a 2×2 unit matrix.

The boundary conditions along the surfaces of crack and circular hole can be written as

$$\int_s [t_3, D_n]^{\mathrm{T}}\,\mathrm{d}s = -\int_s [s_{32}\mathrm{d}x_1 - s_{31}\mathrm{d}x_2, D_2\mathrm{d}x_1 - D_1\mathrm{d}x_2]^{\mathrm{T}}\,\mathrm{d}s = -\,\mathrm{Re}\int_s \mathrm{d}\mathbf{f} = \mathrm{Re}[\mathbf{B}\mathbf{f}(z)] \tag{11}$$

where t_3 and D_n represent the anti-plane shear traction and the normal component of electric displacement along the boundary.

3. Mapping function and field intensity factors

Consider four non-symmetrical radial cracks at the edge of a circular hole in an infinite piezoelectric solid, as shown in Fig. 1. Using the technique of conformal mapping and complex variable method, we study the complex potentials, the field intensity factors, ERR and MSERR under two different electric boundary conditions as follows.

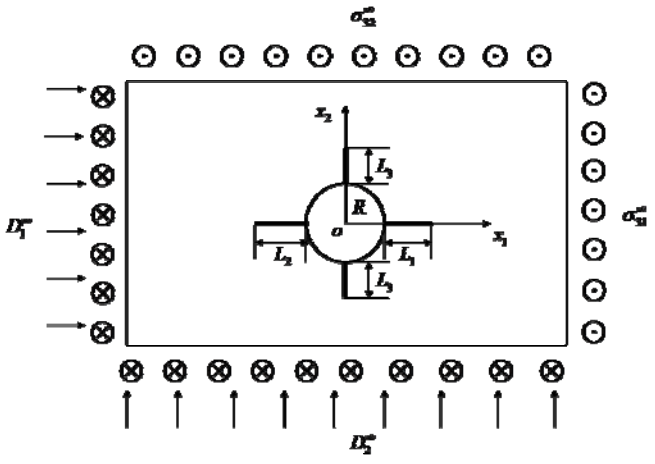

Fig. 1. Four non-symmetrical radial cracks at the edge of a circular hole in an infinite piezoelectric solid

In this case, the potential vector has the form (Zhang and Gao [6])

$$\mathbf{f}(z) = \mathbf{c}^{\infty} z + \mathbf{f}_0(z) \tag{12}$$

where $\mathbf{c}^{\infty}$ is a complex constant related to the remote loading conditions, and $\mathbf{f}_0(z)$ is an

unknown complex function that nulls at infinity, i.e., $\mathbf{f}_0(\infty)=\mathbf{0}$.

When the piezoelectric solid is subjected to uniform remote out-plane shear and in-plane electric field loadings, i.e., $\boldsymbol{\Sigma}_{2\infty}=[\sigma_{32}^{\infty},D_2^{\infty}]^{\mathrm{T}}$ and $\boldsymbol{\Sigma}_{1\infty}=[\sigma_{31}^{\infty},D_1^{\infty}]^{\mathrm{T}}$, the complex constant vector $\mathbf{c}^{¥}$ in Eq. (12) can be determined as

$$\mathbf{c}^{?}=\mathbf{B}^{1}[s_{31}^{\prime\prime}-\mathrm{i}s_{32},D_1^{\prime\prime}-\mathrm{i}D_2]^{\mathrm{T}} \tag{13}$$

In this study, two kinds of electric crack surface conditions are examined, i.e., electrically impermeable and permeable. For simplicity, they are identically expressed as

$$[s_{32},D_2]^{\mathrm{T}}=\text{矯}D_2^0]^{\mathrm{T}} \tag{14}$$

For the electrically impermeable case, $D_2^0=0$, whereas for the electrically permeable case, D_2^0 is unknown to be determined from the potential function continuity conditions along the surfaces of cracks and hole

$$\boldsymbol{\phi}^{+}=\boldsymbol{\phi}^{-},\ \varphi^{+}=\varphi^{-} \tag{15}$$

where superscript + and – denote the potential functions inside and outside the cracks and hole, respectively.

3.1. Electrically impermeable case

If the crack length is shorter than the hole-size, and the electric field inside the hole is smaller, the assumption of impermeable electric boundary condition is more reasonable. Thus, noting Eq. (13), Eq. (12) can be reduced to

$$\mathbf{B}\mathbf{f}_0(z)+\overline{\mathbf{B}\mathbf{f}_0(z)}=-(\mathbf{B}\mathbf{c}^{\infty}z+\overline{\mathbf{B}\mathbf{c}^{\infty}z}) \tag{16}$$

We develop a new mapping function as follows

$$z=\omega(\zeta)=\frac{R}{4\zeta}\left\{\sqrt{\left[f(\zeta+1)^2+g(\zeta-1)^2\right]^2-16a^2\zeta^2}+\sqrt{\left[f(\zeta+1)^2+g(\zeta-1)^2\right]^2-16(a^2+1)\zeta^2}\right\} \tag{17}$$

where

$$\begin{aligned}&f=\sqrt{a^2+c^2},\quad g=\sqrt{a^2+b^2}\\&a=\frac{1}{2}\left(\frac{R+L_3}{R}-\frac{R}{R+L_3}\right),\quad b=\frac{1}{2}\left(\frac{R+L_2}{R}+\frac{R}{R+L_2}\right),\quad c=\frac{1}{2}\left(\frac{R+L_1}{R}+\frac{R}{R+L_1}\right)\end{aligned} \tag{18}$$

It can be shown that Eq. (17) provides a mapping function from the outside region of the circular hole and cracks to the interior of a unit circle in the ζ-plane, and $z=R+L_1=\omega(1)$.

In the ζ-plane, Eq. (16) can be transformed into

$$\mathbf{B}\mathbf{f}_0(\sigma)+\overline{\mathbf{B}\mathbf{f}_0(\sigma)}=-\left[\mathbf{B}\mathbf{c}^{\infty}\omega(\sigma)+\overline{\mathbf{B}\mathbf{c}^{\infty}}\,\overline{\omega(\sigma)}\right] \tag{19}$$

where σ is the point on the unit circle, and $\mathbf{f}_0(\sigma)=\mathbf{f}_0(\omega(\sigma))$ is defined.

Taking Cauchy integrals $\frac{1}{2\pi \mathrm{i}}\int_\gamma \frac{d\sigma}{\sigma-\zeta}$ at the two sides of Eq. (19), we obtain

$$\mathbf{B}\mathbf{F}_0(\zeta)=-\boldsymbol{\phi}_{,1}^{\infty}\left[\omega'(\zeta)+\frac{R(f+g)}{2\zeta^2}\right] \tag{20}$$

The vector of field intensity factors can be expressed in the ζ-plane, as [8]

$$\boldsymbol{k}=(k_\sigma,k_D)^{\mathrm{T}}=2\sqrt{\pi}\lim_{\zeta\to 1}\frac{\mathbf{B}\mathbf{F}_0(\zeta)}{\sqrt{\omega''(\zeta)}} \tag{21}$$

Substituting Eqs. (17) and (20) into Eq. (21), one finally has

$$\boldsymbol{k}_{\mathrm{imp}}=\sqrt{\pi L_1}\begin{pmatrix}\sigma_{32}^{\infty}\\ D_2^{\infty}\end{pmatrix}K \tag{22}$$

where K called the dimensionless intensity factor is defined as

$$K=\sqrt{\frac{2Rc(f+g)\sqrt{c^2-1}}{L_1 f\left(c+\sqrt{c^2-1}\right)}} \tag{23}$$

3.2. Electrically permeable case

According to the method of Guo et al. [9], the potential functions inside the cracks and hole can be expressed as

$$\boldsymbol{\phi}^{+}=(D_2^0x_1-D_1^0x_2)\mathbf{i}_2, \tag{24}$$

$$\varphi^{+}=-E_1^0x_1-E_2^0x_2, \tag{25}$$

where $\mathbf{i}_2=[0,1]^{\mathrm{T}}$, and D_k^0 and E_k^0 are the components of the electric displacement and electric field inside the elliptical hole and the cracks, respectively, which are constant and to be determined by the loading condition.

The potential functions outside the cracks and hole can be expressed as

$$\boldsymbol{\phi}^{-}=\boldsymbol{\Sigma}_{2\infty}x_1-\boldsymbol{\Sigma}_{1\infty}x_2+2\mathrm{Re}[\mathbf{k}_0(z)], \tag{26}$$

$$\varphi^{-}=-E_1^{\infty}x_1-E_2^{\infty}x_2+2\mathrm{Im}[\mathbf{Y}\mathbf{k}_0(z)]_2, \tag{27}$$

where $\mathbf{k}_0(z)=\mathbf{B}\mathbf{f}_0(z)$, $\mathbf{Y}=\mathrm{i}\mathbf{A}\mathbf{B}^{-1}$.

Substituting Eqs. (24)-(27) into Eq. (15), we get

$$\mathbf{BF}_0(\zeta)=\frac{(a+b)(\varepsilon_1+\varepsilon_2)}{4\zeta^2}\boldsymbol{\Sigma}^{2\infty}, \tag{28}$$

$$D_2^0=D_2^\infty-\frac{e_{15}}{c_{44}}\sigma_{32}^\infty. \tag{29}$$

where $\boldsymbol{\Sigma}^{2\infty}=[\sigma_{32}^\infty, D_2^\infty-D_2^0]^{\mathrm{T}}$.

Substituting Eqs. (28) and (29) into Eq. (21), one finally has

$$\boldsymbol{k}_{\mathrm{per}}=\sqrt{\pi L_1}\begin{pmatrix}\sigma_{32}^\infty\\ D_2^\infty-D_2^0\end{pmatrix}K \tag{30}$$

The dimensionless intensity factor K can be used to determine the field intensity factors and the ERR of four non-symmetrical radial cracks at the edge of a circular hole. In some limiting special cases, the known results [7-12] are the special cases of the present solutions. Furthermore, new configurations such as three radial cracks originating from a circular hole, semi-circular hole with an edge crack originating from a semi-infinite plane and a semi-infinite plane with an edge crack can be simulated from the present results.

4. Energy release rate

As mentioned above, the stress intensity factors (SIFs) and the electric displacement intensity factors (EDIFs) are independent and they are only related to the corresponding mechanical and electrical loading for the electrically impermeable boundary condition. For the electrically permeable case, both the SIFs and the EDIFs are independent on the electrical loading at infinity. So the SIFs and EDIFs can not perfectly describe the fracture characteristics of piezoelectric materials. In this study, the ERR and the MSERR are chosen as the fracture criterion to analyze the fracture behavior of four cracks emanating from a circular hole in piezoelectric materials.

The computational expressions of the ERR and the MSERR can be written as the following forms, respectively

$$G=\frac{1}{2}\boldsymbol{k}^{\mathrm{T}}\mathbf{B}_0^{-1}\boldsymbol{k} \tag{31}$$

$$G^M=\frac{1}{2}k_\sigma k_\gamma, \tag{32}$$

where

$$k_\gamma=\frac{e_{15}k_D+\varepsilon_{11}k_\sigma}{e_{15}^2+\varepsilon_{11}c_{44}}. \tag{33}$$

Substituting Eqs. (2), (22) and (30) into Eq. (31), the ERR for the electrically impermeable and the electrically permeable cases are obtained, respectively

$$G_{\mathrm{imp}}=\frac{\pi L_1K^2}{2(e_{15}^2+\varepsilon_{11}c_{44})}\left(\varepsilon_{11}\sigma_{32}^{\infty 2}+2e_{15}\sigma_{32}^\infty D_2^\infty-c_{44}D_2^{\infty 2}\right) \tag{34}$$

$$G_{\text{per}} = \frac{\pi L_1 K^2}{2c_{44}} (\sigma_{32}^{\infty})^2 \tag{35}$$

It is seen that the ERR for the electrically impermeable case is dependent on the applied mechanical and electrical loadings at infinity, while it is only dependent on the applied mechanical loading at infinity for the electrically permeable one.

Substituting Eqs. (22), (30) and (33) into Eq. (32), the MSERR for the electrically impermeable and the electrically permeable cases are obtained, respectively

$$G_{\text{imp}}^{M} = \frac{\pi L_1 K^2}{2(e_{15}^2 + \varepsilon_{11} c_{44})} \left(\varepsilon_{11} \sigma_{32}^{\infty 2} + e_{15} \sigma_{32}^{\infty} D_2^{\infty} \right) \tag{36}$$

$$G_{\text{per}}^{M} = \frac{\pi L_1 K^2}{2c_{44}} (\sigma_{32}^{\infty})^2 \tag{37}$$

It is found that from Eq. (35) and (37), the MSERR is equal to the ERR for the electrically permeable boundary condition.

5. Numerical results

To illustrate the singular electro-elastic fields at the tip of crack, numerical examples for a cracked PZT-5H piezoelectric ceramic are given, material properties of which are [1] $c_{44} = 3.53 \times 10^{10}\ \text{N/m}^2$, $e_{15} = 17.0\,\text{C/m}^2$, $\varepsilon_{11} = 151 \times 10^{-10}\,\text{C/Vm}$ and $G_{\text{cr}} = 5.0\,\text{N/m}$, where G_{cr} is the critical energy release rate.

Figs. 2-4 show the variation of the normalized ERR with geometrical parameters for a fixed-size hole of $R = 0.01\text{m}$ under combined mechanical loading $\sigma_{32}^{\infty} = 6\,\text{MPa}$ and electric loading $D_2^{\infty} = 2\text{e}-3\,\text{C/m}^2$. It will be noted that the electrically permeable case gives the highest value of G/G_{cr}, while the electrically impermeable case yields the lowest value of G/G_{cr}. It is easily seen from Figs. 2 and 3 that an increase of the right and the left cracks length always enhances the crack growth. The same conclusion has been drawn in Refs. [7-9]. Fig. 4 shows the variation of G/G_{cr} with the perpendicular crack length L_3 for given the right crack length $L_1 = 0.005\,\text{m}$ and different values of the left crack length L_2. It is interesting to note that when the ratio of L_2/R equals to 0.5, i.e., $L_2 = L_1$, the normalized ERR at the tip of the right crack is not affected by the change of the perpendicular crack length. This conclusion is derived from the geometrical symmetry for the present model under the symmetrical loading conditions. For the other values of

L_2/R, there are following two trends: When the value of L_2/R is larger than 0.5, i.e., $L_2 > L_1$, the normalized ERR decreases with the ratio of L_3/R increasing. On the other hand, when the value of L_2/R is smaller than 0.5, i.e., $L_2 < L_1$, the normalized ERR increases as the ratio of L_3/R becomes large. The results show that if the length of left crack is larger than that of right crack, an increase of length of the perpendicular cracks can retard the crack growth. In contrast to that, if the length of left crack is smaller than that of right one, the increase of the length of the perpendicular cracks can enhance the crack propagation. These useful conclusions will provide the theoretical instruction on fracture analysis and structural design in engineering. In addition, the normalized ERR is close to constants as L_3/R tends to infinite, which corresponds to the case of semi-circular hole with an edge crack at the edge of semi-infinite solid.

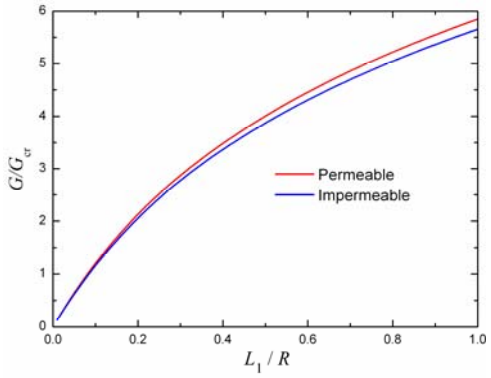

Fig. 2 Variation of G/G_{cr} with a ratio of L_1/R

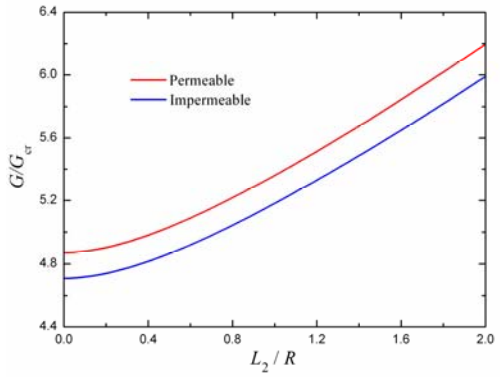

Fig. 3 Variation of G/G_{cr} with a ratio of L_2/R

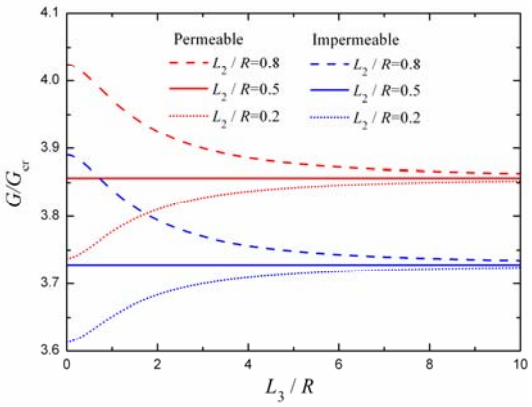

Fig. 4 Variation of G/G_{cr} with a ratio of L_3/R

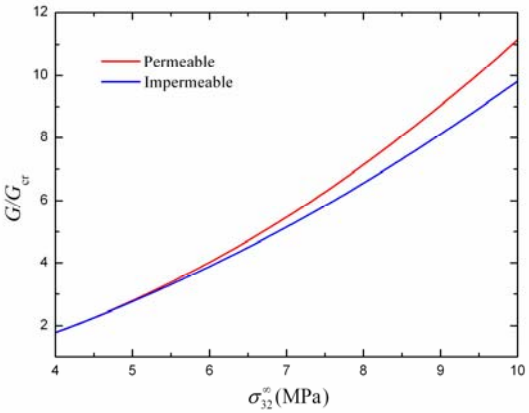

Fig. 5 Effect of applied mechanical loading on the normalized ERR

In what follows, to consider the effects of applied mechanical and electric loadings on the normalized ERR, we suppose a fixed-size hole of $R = 0.01\,\mathrm{m}$ and the cracks lengths $L_1 = 0.005\,\mathrm{m}$,

$L_2 = 0.008\,\mathrm{m}$ and $L_3 = 0.003\,\mathrm{m}$. Fig. 5 shows the influence of the applied mechanical loading on the normalized ERR under given electric load $D_2^{\infty} = 2\mathrm{e}-3\,\mathrm{C/m}^2$. As seen in the figure, the applied mechanical loading always promotes the crack growth, which is expectable. The effects of the applied electric load on the normalized ERR and the normalized MSERR are depicted under given mechanical loading $\sigma_{32}^{\infty} = 6\,\mathrm{MPa}$ in Figs. 6 and 7, respectively, where G_0^M denotes the value of the MSERR in the absence of remote electric load. It is seen from Figs. 6 and 7 that for the electrically permeable boundary condition, the normalized ERR and the MSERR are independent on the electric load, but dependent only on the mechanical loading. In other words, an applied electric field has no effect on the propagation of an electrically permeable case, which is in accordance with the results in Zhang and Gao [6]. As shown in Fig. 6, for the electrically impermeable case if a mechanical loading is applied, a negative electric load always decreases the normalized ERR, but a positive electric load either increases or decreases the normalized ERR. The result implies that a negative electric load is prone to retard the crack growth than a positive one. In contrast to Fig. 6, the positive electric field always increases the normalized MSERR, while the negative electric field always decreases the normalized MSERR in Fig. 7.

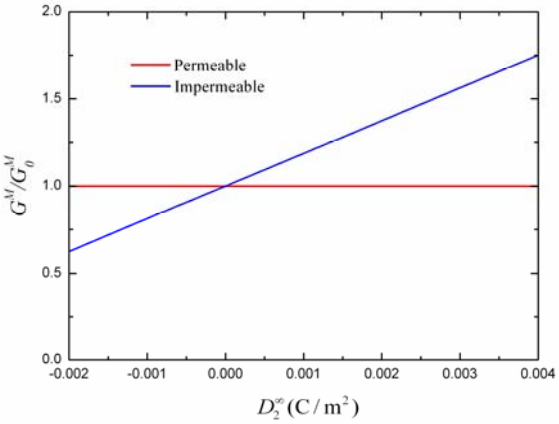

Fig. 7 Effect of applied electric loading on the normalized MSERR

6. Conclusions

The anti-plane problem of four non-symmetrical radial cracks at the edge of a circular hole in an infinite piezoelectric solid is investigated using the complex variable method and a new mapping function. This work is focused on the study of explicit and exact solutions in closed-form of the field intensity factors, ERR and MSERR. Several known results can be derived as special cases from the present solutions. Numerical results are provided to show the effects of geometrical parameters, applied mechanical and electric loads on ERR and MSERR. The results show that:

(a) The increase of the left crack length L_2 or right crack length L_1 always promotes the failure of piezoelectric materials for the case of four non-symmetric radial cracks at the edge of a circular hole.There are following three different results for the effects of the perpendicular crack on the

propagation of the horizontal crack. If the lengths of the left crack and the right crack originating from a circular hole are equal, an occurrence of the perpendicular cracks has no effect on the crack growth. If the length of left crack is larger than that of right crack, an increase of lengths of the perpendicular cracks can retard the crack growth. If the length of left crack is smaller than that of right crack, an increase of the length of the perpendicular cracks can promote the crack propagation.
(b) The electrically permeable boundary condition gives the highest value of ERR or MSERR, while the electrically impermeable case yields the lowest value of ERR or MSERR.
(c) The applied mechanical loading always promotes the crack growth, but the effects of applied electric fields on the crack growth depend on the different fracture parameters.

Abstract The dynamic response of an interface crack between magnetoelectroelastic and functionally graded elastic layers under anti-plane shear and in-plane electric and magnetic impacts is investigated by the integral transform method. The mixed boundary value problem of the interface crack is reduced to dual integral equations, which can be further expressed in terms of a Fredholm integral equation of the second kind. The singular stress fields near the crack tip are obtained asymptotically, and the stress intensity factor (SIF) is defined. Based on the criterion of maximum hoop stress, the crack will propagate along the original crack plane and won't kink. Numerical results show that the dynamic SIF is influenced by the material properties and geometric size ratios.

Keywords Dynamic response, Interface crack, Magnetoelctroelastic layer, Functionally graded elastic layer, Stress intensity factor

1. Introduction

Composites made of piezoelectric/piezomagnetic materials exhibit magnetoelectric effect that is not present in single-phase piezoelectric or piezomagnetic materials. Studies on the properties of piezoelectric/piezomagnetic composites have been carried out by numerous researchers [1, 2]. In particular, there is a growing interest among researchers in solving fracture mechanic problems in media possessing coupled piezoelectric, piezomagnetic and magnetoelectric effects, that is, magnetoelectroelastic effects. The crack initiation behavior in magnetoelectroelastic composite under in-plane deformation was investigated by Song and Sih [3]. Gao et al. [4] presented some exact treatments on the crack problems in magnetoelectroelastic solids. Wang and Mai [5] considered the mode III crack problems in an infinite piezoelectromagnetic medium using complex variable technique. Qin [6] obtained two dimensional (2D) Green's functions of defective magnetoelectroelastic solids under thermal loading, which can be used to establish boundary formulation and to analyze relevant fracture problems. Li [7] made the transient analysis of a cracked magnetoelectroelastic medium under antiplane mechanical and inplane electric and magnetic impacts. Hu and Li [8] studied the crack in a magnetoelectroelastic strip under longitudinal shear. A moving crack problem in magnetoelectroelastic materials has been solved by Hu and Li [9]. Interface crack moving along dissimilar magnetoelectroelastic materials has been studied by Hu et al. [10], and Zhong and Li [11], respectively. The dynamic response of a penny-shaped crack in a magnetoelectroelastic layer was studied by Feng et al., [12]. Boundary element method was developed by Rojas-Díaz et al., [13] to study crack problems in linear magnetoelectroelastic materials under static loading conditions. The transient anti-plane problem of a magnetoelectroelastic strip containing a crack is considered by Yong and Zhou [14]. An anti-plane shear crack in a magnetoelectroelastic layer sandwiched between dissimilar half spaces has been investigated by Hu et al. [15]. Zhou and Chen [16] analyzed a partially conducting mode I crack in a piezoelectromagnetic material. Wang and Han [17] studied the effect of interfacial cracks on the

magnetoelectric coupling properties of a magneto-electro-elastic composite laminate. Recently, Hu and Chen [18] conducted the pre-curving analysis of a crack in a magnetoelctroelastic strip under in-plane dynamic loading and the same authors [19] also studied the anti-plane problem of a magnetoelectroelastic strip sandwiched between elastic layers. Wan et al. [20] investigated a mode III crack crossing the magnetoelectroelastic bimaterial interface under concentrated magnetoelectromechanical loads.

The objective of this paper is to study an interface crack between magnetoelectroelastic and functionally graded elastic layers under anti-plane shear and in-plane electric and magnetic impact loading. Fourier and Laplace transforms are applied to reduce the mixed-boundary-value problem to dual integral equations, which can be further expressed in terms of a Fredholm integral equation. The stress intensity factors are obtained and the effect of geometric size and material properties are analyzed.

2. Basic equations

Consider a transversely isotropic, linear magnetoelectroelastic material. Suppose the Cartesian coordinates x, y, z are the principal axes of the material symmetry, and the poling direction is oriented in the z–axis. Consider only the out-of-plane displacement, the in-plane electric field and in-plane magnetic field, i.e.,

$$u_x = u_y = 0, \quad u_z = u_z(x, y, t) \tag{1}$$

$$E_x = E_x(x, y, t), \quad E_y = E_y(x, y, t), \quad E_z = 0 \tag{2}$$

$$M_x = M_x(x, y, t), \quad M_y = M_y(x, y, t), \quad M_z = 0 \tag{3}$$

$$u_x^e = u_y^e = 0, \quad u_z^e = u_z^e(x, y, t) \tag{4}$$

where u_i, E_i and M_i $(i = x, y, z)$ are components of displacement, electrical field and magnetic field, respectively; the superscript "e" denotes the quantities of the elastic layers.

The constitutive equations for magnetoelectroelastic materials and elastic materials under anti-plane shear take the forms as:

$$\begin{pmatrix} \sigma_{zy} \\ D_y \\ B_y \end{pmatrix} = \begin{pmatrix} c_{44} & e_{15} & h_{15} \\ e_{15} & -\lambda_{11} & -\beta_{11} \\ h_{15} & -\beta_{11} & -\gamma_{11} \end{pmatrix} \begin{pmatrix} \dfrac{\partial u_z}{\partial y} \\ \dfrac{\partial \phi}{\partial y} \\ \dfrac{\partial \varphi}{\partial y} \end{pmatrix}, \quad \begin{pmatrix} \sigma_{zx} \\ D_x \\ B_x \end{pmatrix} = \begin{pmatrix} c_{44} & e_{15} & h_{15} \\ e_{15} & -\lambda_{11} & -\beta_{11} \\ h_{15} & -\beta_{11} & -\gamma_{11} \end{pmatrix} \begin{pmatrix} \dfrac{\partial u_z}{\partial x} \\ \dfrac{\partial \phi}{\partial x} \\ \dfrac{\partial \varphi}{\partial x} \end{pmatrix} \tag{5}$$

$$\sigma_{zy}^e = c_{44}^e \frac{\partial u_z^e}{\partial y}, \quad \sigma_{zx}^e = c_{44}^e \frac{\partial u_z^e}{\partial x} \tag{6}$$

where σ_{zj}, D_j and B_j ($j = x, y$) are components of stress, electrical displacement and magnetic induction; c_{44}, e_{15}, h_{15} and β_{11} are elastic, piezoelectric, piezomagnetic and electromagnetic constants; λ_{11} and γ_{11} are dielectric permitivity and magnetic permeability; ϕ and φ are electric potential and magnetic potential, respectively.

By introducing two new functions Φ and Ψ as [9]

$$\Phi = \phi + mu_z = \phi + \frac{\beta_{11}h_{15} - \gamma_{11}e_{15}}{\lambda_{11}\gamma_{11} - \beta_{11}^2}u_z, \quad \Psi = \varphi + nu_z = \varphi + \frac{\beta_{11}e_{15} - \lambda_{11}h_{15}}{\lambda_{11}\gamma_{11} - \beta_{11}^2}u_z \tag{7}$$

The dynamic equilibrium equations can be obtained as

$$\nabla^2 u_z = \left(\partial^2 u_z / \partial t^2\right) / V^2, \quad \nabla^2\Phi = 0, \quad \nabla^2\Psi = 0 \tag{8}$$

$$V = \sqrt{\mu/\rho}, \quad \mu = c_{44} + \left(\gamma_{11}e_{15}^2 + \lambda_{11}h_{15}^2 - 2\beta_{11}e_{15}h_{15}\right) / \left(\lambda_{11}\gamma_{11} - \beta_{11}^2\right) \tag{9}$$

where $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the two-dimensional Laplacian operator and V, μ, and ρ are the speed of the magnetoelectroelastic shear wave, the magnetoelectroelastic stiffened elastic constant, and the mass density of the magnetoelectroelastic material, respectively.

3. Problem formulation

Now let us consider an interface crack of length $2c$ between a magnetoelectroelastic layer **(M)** and a functionally graded elastic layer **(F)**, as shown in Fig. 1. The composite structure is under anti-plane shear and in-plane electric and magnetic impacts, and the thickness of the magnetoelectroelastic and functionally graded elastic layer are h_1 and h_2, respectively. Due to symmetry in geometry and loading conditions, it is sufficient to consider the problem for $0 \le x < \infty$, $-h_2 \le y \le h_1$ only.

The material properties of the functionally graded elastic layer vary continuously along the y-direction in the form as

$$c_{44}^e = c_{44}^{e0} \cdot \exp(\beta y), \quad \rho^e = \rho^{e0} \cdot \exp(\beta y) \qquad (0 \le y \le h_1) \tag{10}$$

where β is a constant and the superscript "0" denotes the material properties of the functionally graded elastic layer at the plane $y = 0$, i.e., c_{44}^{e0} and ρ^{e0} are the elastic constant and the material density of the functionally graded elastic layer at the plane $y = 0$, respectively.

The governing equation for the functionally graded elastic layer under anti-plane deformation can be obtained as:

$$\nabla^2 u_z^e + \beta\frac{\partial u_z^e}{\partial y} = \frac{1}{V_0^2}\frac{\partial^2 u_z^e}{\partial t^2} \tag{11}$$

where $V_0 = \sqrt{c_{44}^{e0}/\rho^{e0}}$ is the speed of the elastic shear wave induced by the functionally graded

elastic layer.

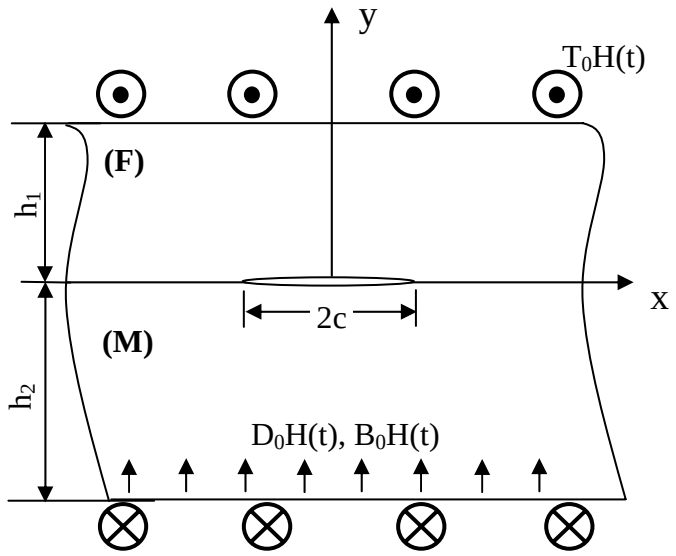

Figure 1. An interface crack between magnetoelectroelastic and functionally graded elastic layers

The electrical and magnetic boundary conditions on the edges of the magnetoelectroelastic layer are considered as follows:

$$D_y(x,0,t) = D_y(x,-h_2,t) = D_0 H(t), \quad B_y(x,0,t) = B_y(x,-h_2,t) = B_0 H(t) \tag{12}$$

where D_0 and B_0 are uniform electric displacement and magnetic induction applied on the magnetoelectroelastic layer, $H(t)$ is the Heaviside step function, $H(t) = 0$ for $t < 0$, and $H(t) = 1$ for $t \geq 0$.

The mechanical boundary conditions are:

$$\sigma_{zy}(x,0,t) = \sigma_{zy}^{e}(x,0,t) = 0, \qquad (0 \leq x < c) \tag{13}$$

$$u_z(x,0,t) = u_z^{e}(x,0,t), \qquad (x \geq c) \tag{14}$$

$$\sigma_{zy}^{e}(x,h_1,t) = \sigma_{zy}(x,-h_2,t) = T_0 H(t) \qquad (x \geq 0) \tag{15}$$

$$\sigma_{zy}(x,0,t) = \sigma_{zy}^{e}(x,0,t), \qquad (x \geq c) \tag{16}$$

where T_0 is the uniform shear stress.

4. Derivation of the integral equations

Appropriate solutions of Eq. (8) and Eq. (11) in the Laplace transform domain may be expressed as

$$u_z^{e*}(x,y,p)=\frac{2}{\pi}\int_0^\infty [A_1(s,p)\exp(k_1 y)+A_2(s,p)\exp(k_2 y)]\cos(sx)ds + a_0\,[\exp(-\beta y)-1]/p \tag{17}$$

$$u_z^{*}(x,y,p)=\frac{2}{\pi}\int_0^\infty [B_1(s,p)\exp(ky)+B_2(s,p)\exp(-ky)]\cos(sx)ds + b_0\frac{y}{p} \tag{18}$$

$$\phi^{*}(x,y,p)=\frac{2}{\pi}\int_0^\infty [C_1(s,p)\exp(sy)+C_2(s,p)\exp(-sy)]\cos(sx)ds + c_0\frac{y}{p} - \frac{2}{\pi}m\int_0^\infty [B_1(s,p)\exp(ky)+B_2(s,p)\exp(-ky)]\cos(sx)ds - mb_0\frac{y}{p} \tag{19}$$

$$\varphi^{*}(x,y,p)=\frac{2}{\pi}\int_0^\infty [D_1(s,p)\exp(sy)+D_2(s,p)\exp(-sy)]\cos(sx)ds + d_0\frac{y}{p} - \frac{2}{\pi}n\int_0^\infty [B_1(s,p)\exp(ky)+B_2(s,p)\exp(-ky)]\cos(sx)ds - nb_0\frac{y}{p} \tag{20}$$

where p is the Laplace transform parameter, $A_j(s,p)$, $B_j(s,p)$, $C_j(s,p)$ and $D_j(s,p)$ ($j=1,\ 2$) are the unknown functions to be solved and a_0, b_0, c_0 and d_0 are real constants determined by considering the boundary and interface conditions as

$$a_0=-T_0/(c_{44}^{e0}\beta)$$
$$\begin{pmatrix} b_0 \\ c_0 \\ d_0 \end{pmatrix}=\begin{pmatrix} \mu & e_{15} & h_{15} \\ 0 & \lambda_{11} & \beta_{11} \\ 0 & \beta_{11} & \gamma_{11} \end{pmatrix}^{-1}\begin{pmatrix} T_0 \\ -D_0 \\ -B_0 \end{pmatrix} \tag{21}$$

and the parameters k and k_1, k_2 are defined as

$$k=\sqrt{s^2+p^2/V^2},\quad k_{1,2}=\left[-\beta\pm\sqrt{\beta^2+4(s^2+p^2/V_0^2)}\right]/2 \tag{22}$$

A simple calculation leads to the expressions for the stresses as

$$\sigma_{zy}^{e*}=T_0/p+\frac{2}{\pi}c_{44}^{e}\int_0^\infty [k_1A_1(s,p)\exp(k_1y)+k_2A_2(s,p)\exp(k_2y)]\cos(sx)ds \tag{23}$$

$$\sigma_{zy}^{*}=T_0/p+\frac{2}{\pi}\int_0^\infty k\mu[B_1(s,p)\exp(ky)-B_2(s,p)\exp(-ky)]\cos(sx)ds + \frac{2}{\pi}\int_0^\infty e_{15}s[C_1(s,p)\exp(sy)-C_2(s,p)\exp(-sy)]\cos(sx)ds + \frac{2}{\pi}h_{15}\int_0^\infty h_{15}s[D_1(s,p)\exp(sy)-D_2(s,p)\exp(-sy)]\cos(sx)ds \tag{24}$$

From the boundary conditions (12), (15) and (16), there is only one independent unknown function (say $B_1(s,p)$). The following dual integral equations can be obtained from the mixed

boundary conditions in Eqs. (13, 14) as

$$\int_0^\infty k\mu[1-\exp(-2kh_2)]B_1(s,p)\cos(sx)ds = -\frac{\pi T_0}{2p}, \quad (0 \le x < c) \tag{25}$$

$$\int_0^\infty F(s,p)B_1(s)\cos(sx)ds = 0, \qquad (x \ge c) \tag{26}$$

where function $F(s,p)$ is defined as

$$F(s,p) = 1+\exp(-2kh_2) + \frac{k\mu[1-\exp(-2kh_2)]\{k_2\exp[(k_2-k_1)h_1]-k_1\}}{c_{44}^{e0}k_1k_2\{1-\exp[(k_2-k_1)h_1]\}} \tag{27}$$

The dual integral equations can be solved by introducing auxiliary functions $\Phi(x,p)$ as

$$B_1(s,p) = -\frac{\pi(\mu+c_{44}^{e0})T_0}{2c_{44}^{e0}\mu pF(s,p)}c^2\int_0^1 x\Phi(x,p)J_0(scx)dx \tag{28}$$

where $J_0(\ \ )$ is the zero-order Bessel function of the first kind, and the function $\Phi(x,p)$ satisfies the Fredholm integral equations of the second kind

$$\Phi(x,p) + \int_0^1 \Phi(\eta,p)Q(\eta,x,p)d\eta = 1 \tag{29}$$

where the kernel functions $Q(\eta,x,p)$ is defined as

$$Q(\eta,x,p) = \eta\int_0^\infty s[R(s/c,p)-1]J_0(sx)J_0(s\eta)ds \tag{30}$$

where

$$R(s,p) = \frac{k(c_{44}^{e0}+\mu)[1-\exp(-2kh_2)]}{c_{44}^{e0}sF(s,p)} \tag{31}$$

5. Field intensities

Once functions $\Phi(x,p)$ is obtained by solving the Fredholm integral equations of the second kind Eq. (30), the singular stress fields near the crack tip in the Laplace domain can be obtained asymptotically as

$$\sigma_{zy}^*(r,\theta,p) + i\sigma_{zx}^*(r,\theta,p) = \exp(-i\theta/2)K^{T*}(p)/\sqrt{2\pi r} \tag{32}$$

where r and θ are defined as

$$r = \sqrt{(x-c)^2+y^2}, \quad \theta = \tan^{-1}[y/(x-c)] \tag{33}$$

the stress intensity factor (SIF) K^{T*} is defined as

$$K^{T*}(p) = \lim_{r\to 0^+}\sqrt{2\pi r}\,\sigma_{zy}^*(r,0,p) = T_0\Phi(1,p)\sqrt{\pi c}/p \tag{34}$$

The stress intensity factor in the time domain can be expressed as

$$K^T(t) = T_0\sqrt{\pi c}\,/2\pi i\int_{Br}\exp(pt)\Phi(1,p)/p\,dp \tag{35}$$

where "*Br*" stands for the Bromwich path of integration. It should be noted that the stress intensity factor is only dependent on the mechanical loading, as seen from Eqs. (34), (35) and (27)-(31).

The dynamic hoop stress around the crack tip can be obtained as

$$\sigma_{z\theta}(r,\theta,t) = K^T(t)/\sqrt{2\pi r}\cos(\theta/2) \qquad (-\pi \le \theta \le \pi) \tag{36}$$

It is clear that the maximum hoop stress always appears at the direction $\theta = 0^{\circ}$, which means that if the fracture toughness of the material is same in all directions, the crack will propagate along the original crack plane and no crack kinking should appear.

6. Numerical results and discussions

The material properties of the magnetoelectroelastic layer are taken as [21]

$$\begin{aligned} &c_{44} = 5.0\times10^{10}\ (\mathrm{N/m^2}), \quad e_{15} = 0.2\ (\mathrm{C/m^2}), \quad h_{15} = 180\ (\mathrm{N/Am}) \\ &\lambda_{11} = 2.5\times10^{-10}\ (\mathrm{C^2/Nm^2}), \quad \gamma_{11} = -2.0\times10^{-6}\ (\mathrm{Ns^2/C^2}) \\ &\beta_{11} = 5.3\times10^{-9}\ (\mathrm{Ns/VC}), \quad \rho = 5.7\times10^{3}\ (\mathrm{Kg/m^3}) \end{aligned} \tag{37}$$

Fig. 2 shows the variation of the normalized dynamic SIFs K_T versus normalized time for different values of functionally graded material parameter β when $V = V_e$ and $h_1/c = h_2/c \to \infty$. The SIFs increase as the dimensionless time increases and reach the peak points at about $tV/c = 2.1$ and oscillate about their static values. As $tV/c \to \infty$, the dynamic SIFs appoach their static values. The magnitudes of the SIFs decrease as the functionally graded material parameter β increases from negative to positive value. Fig. 3 displays the normalized dynamic SIFs K_T vs normalized time for different values of geometric size ratio $h_1/c = h_2/c$ when $\beta = +1$ and $V = V_e$. It needs more time for the cracked composite with smaller size ratio $h_1/c = h_2/c$ to reach the stabilized values of K_T. The second peak value of the dynamic SIF seems to increase and appear earlier when the geometric size ratio $h_1/c = h_2/c$ decreases. Fig. 4 shows the normalized dynamic SIFs K_T vs normalized time for different material property

$R = c_{44}^{e0}/\mu$ when $\beta = +1$, $\rho = \rho^{e0}$ and $h_1/c = h_2/c \to \infty$. The increase of the ratio $R = c_{44}^{e0}/\mu$ will lead to the larger peak values of the dynamic SIFs as well as larger corresponding static values.

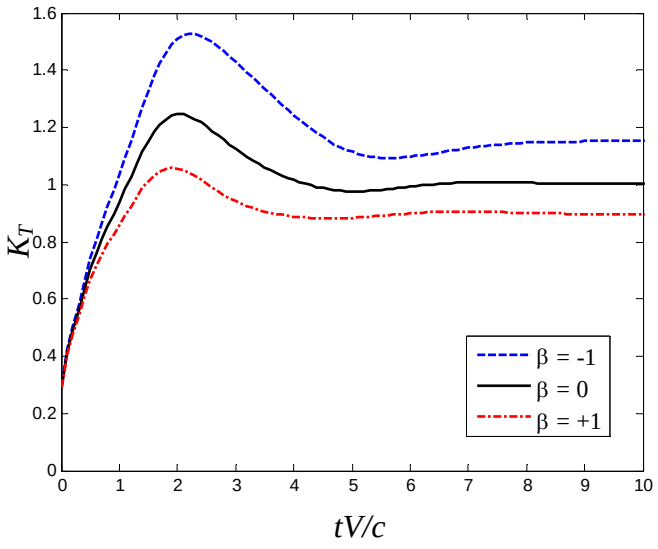

Figure 2. Normalized dynamic SIFs K_T vs normalized time for different functionally graded material parameter β when $V = V_e$

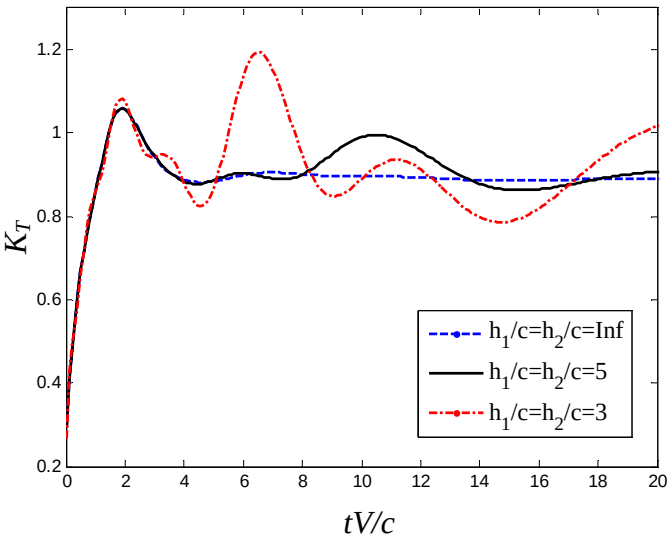

Figure 3. Normalized dynamic SIFs K_T vs normalized time for different geometric size $h_1/c = h_2/c$ when $\beta = +1,\ V = V_e$

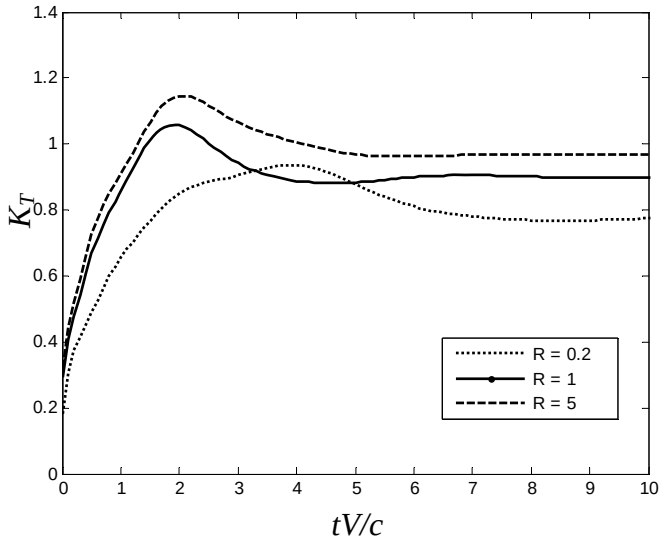

Figure 4. Normalized dynamic SIFs K_T vs normalized time for different material property $R = c_{44}^{e0} / \mu$ when $\beta = +1$

7. Conclusions

The dynamic fracture analysis of an interface crack between magnetoelectroelastic and functionally graded elastic layers under anti-plane shear and in-plane electric and magnetic impacts is performed using the integral transform method. The mixed-boundary-value problem of the interface crack is reduced to solving dual integral equations, which are further expressed in terms of Fredholm integral equations of the second kind. The asymptotic stress fields near the crack tip are obtained and the stress intensity factor is calculated. Crack propagation direction is predicted based on the maximum hoop stress intensity factor criterion, which shows that the crack will propagate along the extension of the original plane. Numerical results show that the SIFs are influenced by the geometric size ratios and the material properties of the magnetoelectroelastic composite. The obtained results are very useful for the safety and reliability design of the magnetoelectroelastic composite.

Abstract This paper focuses on application of immune clone algorithm to identify parameters of a modified dynamical hysteresis model for giant magnetostrictive materials (GMM). The domain flexing function proposed by Damijan Miljavec et al, is added into this model, which resulted in one extra parameter, to overcome the unphysical negative susceptibility problem. Thus, the immune clone algorithm is applied to identify the parameters in this revised model. The efficiency of the parameter identification with immune clone algorithm is verified by comparing the model generated curves between the identified parameters and the selected parameters. Moreover, it can be seen the unphysical behavior of minor hysteresis loop is suppressed by comparing the identified model curve with the original model curve and a set of representative experimental data.

Keywords Parameter identification, Immune clone method, Hysteresis, Minor loop

1. Introduction

Some magnetic materials when located in an applied magnetic field can elongate or contract in magnetization direction due to an induced magnetic field in these materials. The generated strains are attributed to the realignment of a large amount of magnetic domains caused by spontaneous magnetization. This phenomenon is called magnetostriction. Giant magnetostrictive materials (GMM) have some distinctive advantages over other smart materials, for example, the ability to generate large forces at a lower voltage than piezoelectric ceramic material (PZT), to react more rapidly than shape memory alloy (SMA), to keep their properties even been grinded into particles. Such distinctive advantages motivate many researchers to investigate the applications of GMM in many aspects such as high power ultrasonic transducers, linear motors, micro pumps, micro valves, micro positioners and active vibration absorbers[1-2].

To utilize the full potential of GMM in practical applications, the intrinsic nonlinear magnetic-elastic-thermal coupling properties and hysteresis behavior of GMM need be described clearly. Thus, different models, including physical-based and nonphysical ones [3-5], have been proposed to describe the unique characteristics of GMM. Extended from the most typical physical-based J-A model, Zheng and her co-workers proposed a new model [6] in which nonlinear magnetic-elastic-thermal coupling properties and hysteresis behavior are displayed clearly. However, like the J-A model, this new model encountered the same parameter problem in choosing optimal parameters. Thus, a general method to obtain the optimal parameters is needed for this constitutive relation of GMM.

Generally speaking, two kind methods to overcome the parameter problem of J-A model have been proposed. First, a step-by-step methodologies based on the physical meaning of the determinable parameters are available [7]. But this classic procedure sensitive to initial values of parameters and the order of evaluation of the equations, may pose convergence problem as noticed in [8]. Second, a mathematical approach of the parameter identification disregarding the physical background works in the parameters state-space and tries to find the optimal combination of the parameters [9-12]. The main idea of using immune clone method to optimization problem is heuristic searching in the

trusted solution space and recording the optimal solution in each iteration step until no better solution can be found [13-14]. Thus, adopt the immune clone method to do parameter identification is feasible.

The aim of the present paper is to provide an alternative estimation procedure of parameters based on immune clone algorithm for the modified dynamical hysteresis model of GMM. In section 2 the dynamical magnetic-elastic-thermal coupled hysteresis model is modified by introducing the domain flexing function. Then the immune clone algorithm is adopted to identify the parameters in this devised model in section 3. The immune clone algorithm is verified by comparing the identified model curve with the reduced static model generated curve. In section 4, by comparing the identified model curve with a set of representative experimental data the unphysical behavior of minor hysteresis loops are suppressed.

2. Dynamic hysteresis model and the domain flexing function

The following form of dynamic hysteresis model is considered [6]:

$$\begin{aligned}&\frac{\mu_0 d^2}{2\rho\tilde{\beta}}\left(\frac{dH}{dt}\right)\left(\frac{dM}{dH}\right)^2+\left(\frac{GSV_0\mu_0}{\rho}\right)^{1/2}\left(\frac{dH}{dt}\right)^{1/2}\left(\frac{dM}{dH}\right)^{3/2}\\&+\left(\varsigma K-\overline{\eta}\left(M_{an}-M+\varsigma Kc\frac{dM_{an}}{dH_e}\right)\right)\left(\frac{dM}{dH}\right)\\&-\left(M_{an}-M+\varsigma Kc\frac{dM_{an}}{dH_e}\right)=0\end{aligned}\tag{1}$$

$$\lambda=-\frac{\tilde{B}\Delta TM^2}{M_s^2}+\begin{cases}\dfrac{[1-\tanh(\sigma/\sigma_s)]\lambda_s}{M_s{}^2}M^2 & \sigma/\sigma_s\geq 0\\ \dfrac{[2-\tanh(2\sigma/\sigma_s)]\lambda_s}{2M_s{}^2}M^2 & \sigma/\sigma_s<0\end{cases}\tag{2}$$

In which:

$$\overline{\eta}=\eta-\frac{2\tilde{B}\Delta T\sigma}{\mu_0 M_s{}^2}+\begin{cases}\dfrac{2\sigma-2\sigma_s\ln[\cosh(\sigma/\sigma_s)]}{\mu_0 M_s{}^2}\lambda_s, & \sigma/\sigma_s\geq 0\\ \dfrac{4\sigma-\sigma_s\ln[\cosh(2\sigma/\sigma_s)]}{2\mu_0 M_s{}^2}\lambda_s, & \sigma/\sigma_s<0\end{cases}\tag{3}$$

$$M_{an}=M_s\frac{\left(1-\dfrac{\Delta T+T_r+273}{T_c+273}\right)^x}{\left(1-\dfrac{T_r+273}{T_c+273}\right)^x}\left(\coth\left(\frac{3\chi_m\left(1-\dfrac{T_r+273}{T_c+273}\right)^x}{M_s\left(1-\dfrac{\Delta T+T_r+273}{T_c+273}\right)^x}H_e\right)-\frac{M_s\left(1-\dfrac{\Delta T+T_r+273}{T_c+273}\right)^x}{3\chi_m H_e\left(1-\dfrac{T_r+273}{T_c+273}\right)^x}\right)\tag{4}$$

$$H_e=H+\eta M-\frac{2\tilde{B}\Delta T\sigma M}{\mu_0 M_s{}^2}+\begin{cases}\dfrac{2\sigma-2\sigma_s\ln[\cosh(\sigma/\sigma_s)]}{\mu_0 M_s{}^2}\lambda_s M, & \sigma/\sigma_s\geq 0\\ \dfrac{4\sigma-\sigma_s\ln[\cosh(2\sigma/\sigma_s)]}{2\mu_0 M_s{}^2}\lambda_s M, & \sigma/\sigma_s<0\end{cases}\tag{5}$$

And $\mu_0=4\pi\times 10^{-7}H/m$ is the vacuum permeability, d is diameter for Terfenol-D rod, ρ is the resistivity, $\tilde{\beta}=16$ and G = 0.1356 are a geometrical factor for cylinders and a dimensionless constant respectively, S is the cross-sectional area and V_0 is a parameter representing the internal

potential experienced by domain walls, the parameter ς is taken +1 and −1 respectively when the intensity of the applied AC field increases and decreases, K is the pinning constant, c is the ratio of the initial normal magnetic susceptibility to the initial anhysteretic susceptibility. η is the Weiss molecular field coefficient, $\tilde{B}$ is equal to the slope of magnetostrictive strain versus increment temperature at the saturation magnetization, $\Delta T = T - T_r$ (where T is temperature and T_r is the spin reorientation temperature, T_c stands for the Curie temperature), χ_m is the magnetic susceptibility at the initial linear segments of magnetic curves. M_s, σ_s and λ_s are reference magnetization, stress and strain，respectively.

The domain flexing function is introduced as follows [16]:

$$c(H) = c_0 + e^{(|H|/H_{\max})-(1+\beta)} \tag{6}$$

In which, constant parameter c_0 is physically identical to the original parameter c. It describes the amount of the domain wall translation and bending with regard to the difference between the anhysteretic and irreversible magnetization. The exponential part with parameter β characterizes the amount of reversible relaxation of the domain wall bulged. The parameter β also depends on the maximum induction level. H represents a temporary value of the excitation magnetic field and $H_{\max}$ is its maximum value.

Now substituting (3)–(6) into (1) and then substituting the solved M into (2), the calculated magnetostriction λ can be obtained.

In order to identify the parameters, the follow optimization problem is constructed:

$$\begin{aligned} \min \quad & E(\boldsymbol{\theta}) = \sum_{k=1}^{Q} \left(\lambda(k) - \tilde{\lambda}(k)\right)^2 = \sum_{k=1}^{Q} e^2(k, \boldsymbol{\theta}) \\ \text{s.t.} \quad & d_r \le \theta_r \le b_r \qquad r = 1, 2, \ldots \end{aligned} \tag{7}$$

In which k is the *kth* sample time, Q is the number of all samples, $\tilde{\lambda}(k)$ is the experimental magnetostriction, $\lambda(k)$ is the calculated magnetostriction, $e(k, \boldsymbol{\theta}) = \lambda(k) - \tilde{\lambda}(k)$ is the magnetostriction error, θ_r is the *rth* element of the parameter $\boldsymbol{\theta}$, d_r and b_r are the lower and upper bounds on θ_r. Let $e(\boldsymbol{\theta}) = \left[e(1, \boldsymbol{\theta}) \quad e(2, \boldsymbol{\theta}) \quad \ldots \quad e(Q, \boldsymbol{\theta}) \right]$ be the magnetostriction error vector, the minimization problem (7) can be solved using the following immune clone algorithm.

3. Implementation of immune clone algorithm

As detailed in [13-14], immune clone algorithm can be used in optimization problem effectively. So here the minimization problem (7) is solved with it. The pseudocode is as follows:

Repeat:

a. Select a representative experimental magnetostriction $\tilde{\lambda}(k)$ (an antigen A) from a set of experimental data (population of antigens PA).
b. Take randomly R parameter vectors $\boldsymbol{\theta}$ (antibodies) from parameter space $\mathbf{d} \le \boldsymbol{\theta} \le \mathbf{b}$ (population of antibodies PS).
c. Substitute each parameter vector $\boldsymbol{\theta}$ (antibody) into the modified dynamical hysteresis model, then obtain the calculated magnetostriction $\lambda(k)$, match it against the selected experimental data $\tilde{\lambda}(k)$ (antigen A).
d. Find the parameter vector $\boldsymbol{\theta}$ (antibody) with the highest match score.
e. Add match score of winning parameter vector $\boldsymbol{\theta}$ (antibody) to its fitness.

Until the max number of cycles reached.

4. Identification results and discussions

First, in order to check the parameter identification program the dynamical magnetic-elastic-thermal coupled hysteresis model is reduced to a static form as follows [6]:

$$\left(\frac{dM}{dH}\right)=\frac{\left(M_{an}-M+\varsigma Kc\frac{dM_{an}}{dH_e}\right)}{\left(\varsigma K-\bar{\eta}\left(M_{an}-M+\varsigma Kc\frac{dM_{an}}{dH_e}\right)\right)} \tag{8}$$

$$\lambda=-\frac{\tilde{B}\Delta TM^2}{M_s^2}+\begin{cases}\dfrac{[1-\tanh(\sigma/\sigma_s)]\lambda_s}{M_s^{\,2}}M^2\\ \dfrac{[2-\tanh(2\sigma/\sigma_s)]\lambda_s}{2M_s^{\,2}}M^2\end{cases} \tag{9}$$

A hysteresis curve has been generated by the above form itself to check the agreement between the original and the fitted curve. The generated curve is considered to be the experimental curve and then the identification program is used to fit curve while the identified parameters is also obtained in the same procedure. Figure 1 shows the fitted results matched perfectly with the generated one. From table 1, one can see that the discrepancies between the original parameters and the estimated parameters are less than 5%. Figure 2 displays the convergence procedure of parameter identification. These results confirm us that the identification program proposed above is effective and successful.

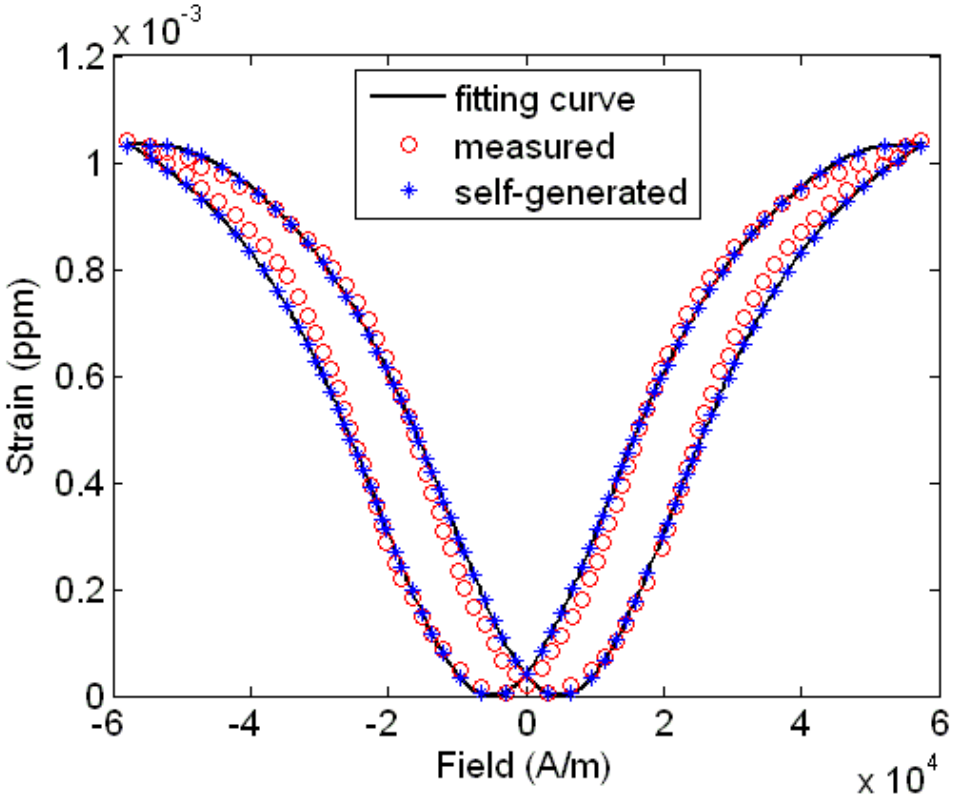

Figure 1 Fitting to the self-generated hysteresis loop of magnetic field versus strain relation.

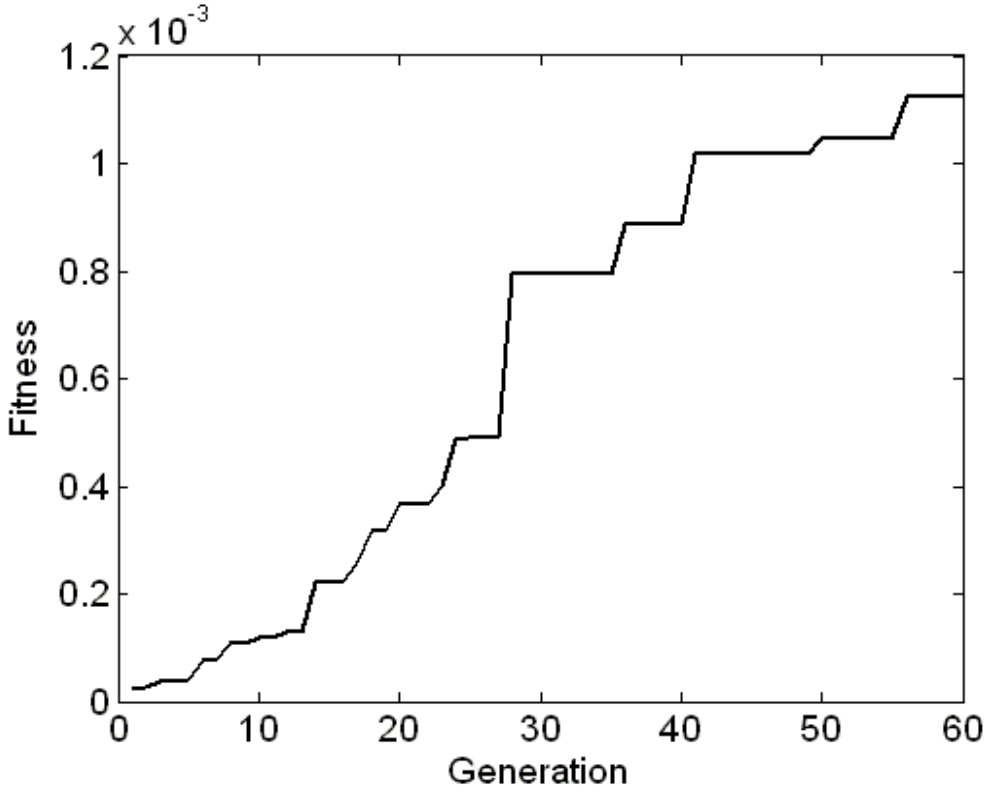

Figure 2 Fitness in the iteration procedure.

Table 1: The bounds for parameters, the parameters for self-generated curve, the estimation results and the estimation errors for parameters ($\mu_0 = 4\pi \times 10^{-7} H/m$)

Parameter	Parameter range	Original Parameter	Estimated parameter	Error (%)
K	$[3000.0\times\mu_0 ; 6000.0\times\mu_0]$	$5000.0\times\mu_0$	$4964.8\times\mu_0$	0.70
c	$[0.0000 ; 0.3000]$	0.1000	0.0956	4.40
M_s	$[0.6000/\mu_0 ; 1.5000/\mu_0]$	$0.9500/\mu_0$	$0.9493/\mu_0$	0.08
σ_s	$[150.00\times10^6 ; 250.00\times10^6]$	200.00×10^6	200.44×10^6	0.22
η	$[0.0100 ; 0.0300]$	0.02000	0.01995	0.25
χ_m	$[10.000 ; 50.000]$	35.000	35.103	0.29

Next, to overcome the unphysical phenomena of the minor loops encountered in previous models, the modified model and parameter identification program proposed in this paper are adopted. Figure 3 demonstrates the fitted results when the exciting frequency is 100Hz. It is clear to see that the unphysical tip of the minor loop is suppressed effectively. That means an optimal parameter vector for 100Hz is identified. Then the proposed parameter identification algorithm is adopted to predict the curve when exciting frequency is 500Hz. Figure 4 shows that the modified model does not give us the expected results when exciting frequency is 500Hz due to dynamical effect of the transducer under higher exciting frequency [12, 17-19].

Now the domain flexing function is considered more specifically. One can see clearly that an extra parameter β in the domain flexing function is introduced but do not give any explicit meaning of it. According to the above numerical results, perhaps the extra parameter is a function of the exciting frequency. A further step investigation of the extra parameter is lost in this paper, because of the limited experiment data.

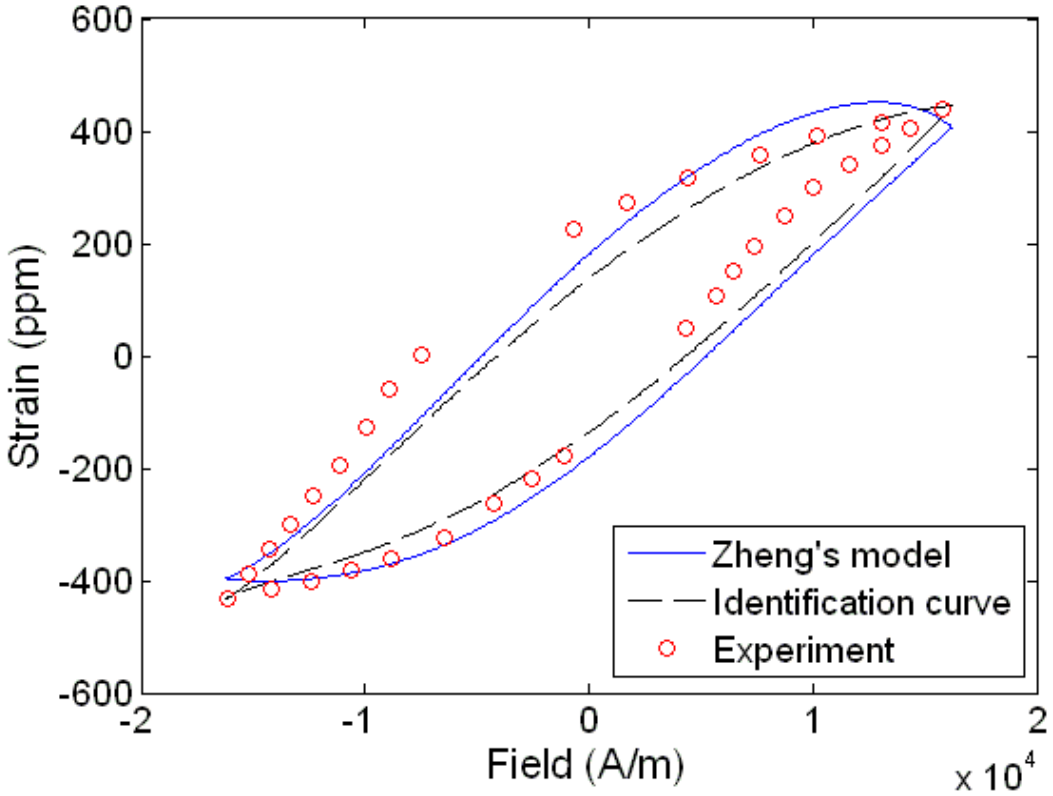

Figure.3. Fitted curve when exciting frequency is 100Hz.

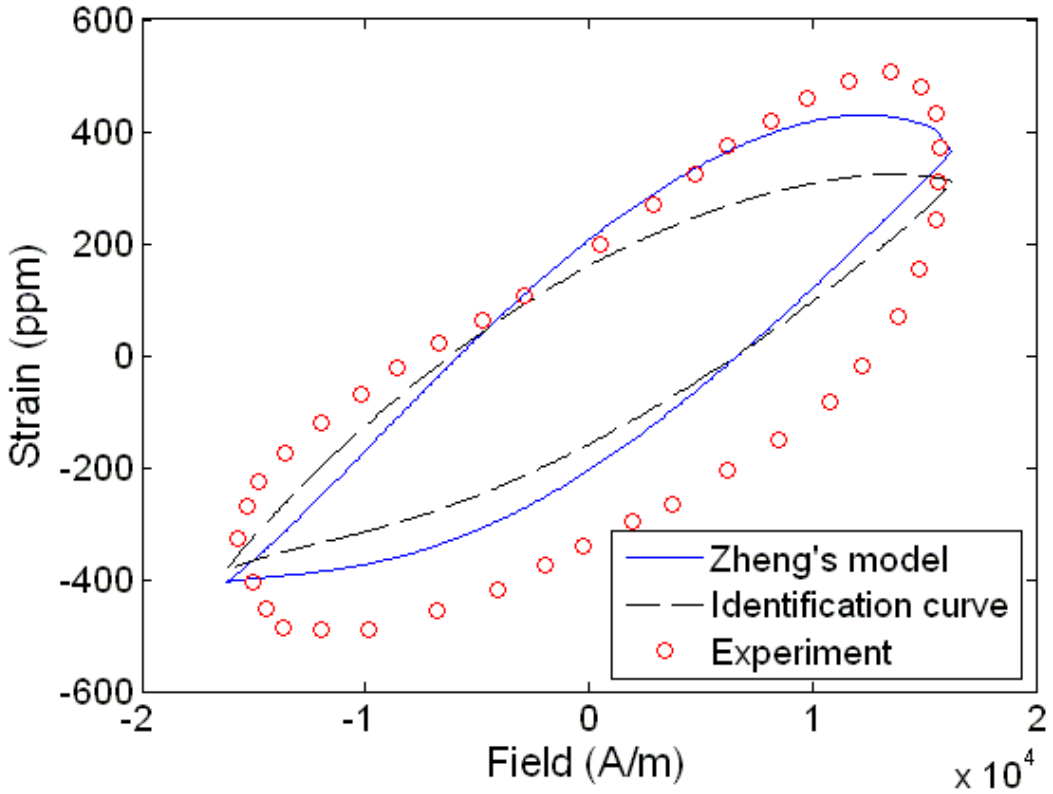

Figure.4. Fitted curve when exciting frequency is 500Hz.

5. Conclusions

The domain flexing function is introduced to the dynamical magnetic-elastic-thermal coupled hysteresis model to overcome the unphysical minor loop tip encountered in previous models. After doing so an immune clone algorithm is adopted to identify the model parameters. The results show that the modified model has effectively suppressed the unphysical phenomena appeared on the tips of minor loops when frequency of the exciting magnetic field is 100 Hz. But the extra parameter in domain flexing function has a great influence on the predicting results. A further investigation of this extra parameter will be included in the future investigation.

The parameter identification procedure based on the immune clone algorithm is performed successfully in above cases. The effectiveness of this procedure is proofed in Figure1 and Table1. Discrepancies between the identified parameters and the original chosen parameters are less than 5%.

Abstract In previous studies of fracture analysis for a thermo-magneto-electro-elastic solid, the crack-face thermal boundary condition is always assumed to be fully insulated or conductive. In the present paper, an opening crack model is proposed by considering the various physical properties of crack interior. The thermal flux, electric displacement and magnetic induction at the crack surfaces are assumed to be dependent on the crack opening displacement. The effects of applied magneto-electro-mechanical loadings and the thermal conductivity inside a crack on the thermal stress intensity factor are investigated. The obtained results reveal that the thermal stress intensity factor depends not only on applied thermal loadings but also on applied magneto-electro-mechanical loadings and various physical properties of crack interior.

Keywords Thermo-magneto-electro-elastic solid, Opening crack model, Thermal stress intensity factor

1. Introduction

Due to the giant magnetoelectric coupling effects, magnetoelectroelastic materials own significant technological promise in manufacturing the novel multifunctional devices [1]. Moreover, since the temperature change will affect the overall performance of the smart devices, it is important to investigate the responses of magnetoelectroelastic materials under a thermal loading [2-4]. It is noted that the fracture analysis of a cracked thermo-magneto-electro-elastic solid has attracted much attention [5-9]. One can see that the thermal boundary condition on the crack surfaces is always assumed to be thermally insulated, and the effects of the thermal properties inside the crack on the crack-tip fields are not considered. Recently, in order to investigate the effects of the medium inside a crack on the thermal stress intensity factor, the thermal-medium crack model has been proposed [10]. The obtained results have also revealed that applied mechanical loadings have great influences on the thermal stress intensity factor. On the other hand, some known observations show that the electric permittivity and magnetic permeability of crack interior cannot be disregarded for the fracture analysis of a cracked magnetoelectroelastic solid [11]. It is also seen that the semi-permeable crack-face magnetoelectric boundary conditions have been proposed [12]. Consequently, to address the effects of various physical properties of medium inside a crack, we propose the following crack-face boundary conditions for a cracked thermo-magneto-electro-elastic solid:

$$D^c = -\varepsilon^c \frac{\Delta\phi}{\Delta u_z}, \qquad B^c = -\mu^c \frac{\Delta\varphi}{\Delta u_z}, \qquad q^c = -\lambda^c \frac{\Delta\theta}{\Delta u_z} \tag{1}$$

where the constants ε^c, μ^c and λ^c denote the dielectric permittivity, magnetic permeability and thermal conductivity of crack interior and they are given as $\varepsilon^c = \varepsilon_r\varepsilon_0 (\varepsilon_0 = 8.85\times10^{-12} F/m)$, $\mu^c = \mu_r\mu_0 (\mu_0 = 1.26\times10^{-6} Ns^2/C^2)$ and $\lambda^c = \lambda_r\lambda_0 (\lambda_0 = 0.024 W/Km)$ respectively. D^c, B^c and q^c are the electric displacement, magnetic induction and heat flux at the crack faces respectively. $\Delta\phi, \Delta\varphi$ and $\Delta\theta$ are the jumps of electric potential, magnetic potential and temperature change across the crack, respectively. One can find that eight ideal crack models associated with a

combination of permeable and impermeable thermal-magnetic-electric boundary conditions can be obtained by considering the limiting cases of Eq. (1).

The objective of the present paper is to investigate the dependence of the thermal stress intensity factor on applied magneto-electro-mechanical loadings and various physical properties of crack interior. Applying the boundary conditions in Eq. (1), the stationary behavior of a cracked thermo-magneto-electro-elastic solid is considered under a combination of applied magneto-electro-mechanical loadings and a uniform heat flux. The closed-form solution of the thermal stress intensity factor is obtained. Numerical results are carried out to show the variations of the thermal stress intensity factor on applied magneto-electro-mechanical loadings and various physical properties of crack interior.

2. Basic equations and boundary conditions

Consider that a Griffith crack is embedded in a transversely isotropic magnetoelectroelastic solid with the thermal effect. As shown in Fig. 1, we use Cartesian coordinates system *xoz* and assume that the crack is located at $-a < x < a$. Applied thermo-magneto-electro-mechanical loadings σ_0, D_0, B_0, q_0 are acting on the crack surfaces. Using the boundary conditions in Eq. (1), we have

$$\sigma_{zz}(x,0) = -\sigma_0, \qquad D_z(x,0) = -(D_0 - D^c), \qquad -a < x < a \tag{2}$$

$$B_z(x,0) = -(B_0 - B^c), \qquad q_z(x,0) = -(q_0 - q^c), \qquad -a < x < a \tag{3}$$

Hereafter $\sigma_{ij}, D_i, B_i, q_i$ stand for the components of stress, electric displacement, magnetic induction and heat flux.

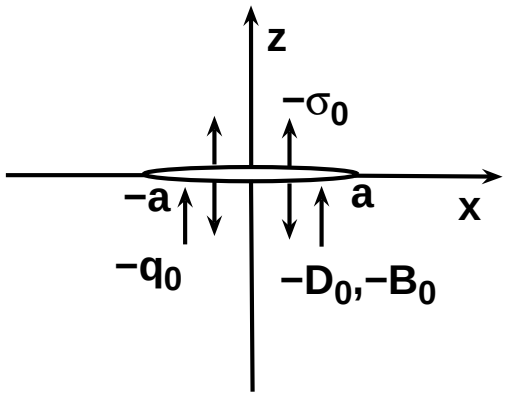

Figure 1. An opening crack in a thermo-magneto-electro-elastic solid

Under the assumption of plane deformation and linear thermo-magneto-electro-elasticity, the constitute equations can be written as

$$\sigma_{xx} = c_{11}\frac{\partial u_x}{\partial x} + c_{13}\frac{\partial u_z}{\partial z} + e_{31}\frac{\partial \phi}{\partial z} + h_{31}\frac{\partial \varphi}{\partial z} - \beta_x \theta \tag{4}$$

$$\sigma_{zz} = c_{13}\frac{\partial u_x}{\partial x} + c_{33}\frac{\partial u_z}{\partial z} + e_{33}\frac{\partial \phi}{\partial z} + h_{33}\frac{\partial \varphi}{\partial z} - \beta_z \theta \tag{5}$$

$$\sigma_{xz} = c_{44}\left(\frac{\partial u_x}{\partial z} + \frac{\partial u_z}{\partial x}\right) + e_{15}\frac{\partial \phi}{\partial x} + h_{15}\frac{\partial \varphi}{\partial x} \tag{6}$$

$$D_x = e_{15}\left(\frac{\partial u_x}{\partial z} + \frac{\partial u_z}{\partial x}\right) - \varepsilon_{11}\frac{\partial \phi}{\partial x} - d_{11}\frac{\partial \varphi}{\partial x} \tag{7}$$

$$D_z = e_{31}\frac{\partial u_x}{\partial x} + e_{33}\frac{\partial u_z}{\partial z} - \varepsilon_{33}\frac{\partial \phi}{\partial z} - d_{33}\frac{\partial \varphi}{\partial z} + p_z\theta \tag{8}$$

$$B_x = h_{15}\left(\frac{\partial u_x}{\partial z} + \frac{\partial u_z}{\partial x}\right) - d_{11}\frac{\partial \phi}{\partial x} - \mu_{11}\frac{\partial \varphi}{\partial x} \tag{9}$$

$$B_z = h_{31}\frac{\partial u_x}{\partial x} + h_{33}\frac{\partial u_z}{\partial z} - d_{33}\frac{\partial \phi}{\partial z} - \mu_{33}\frac{\partial \varphi}{\partial z} + m_z\theta \tag{10}$$

where u_i, ϕ, φ and θ are the components of elastic displacement, electric potential, magnetic potential and temperature change. $c_{ij}, e_{ij}, h_{ij}, \varepsilon_{ij}, d_{ij}, \mu_{ij}, p_z$ and m_z are the elastic, piezoelectric, piezomagnetic, dielectric permittivity, magnetoelectric, magnetic permeability, pyroelectric and pryomagnetic constants, respectively. β_x and β_z are the stress-temperature coefficient. Application of the equilibrium equation leads to the following partial differential equations

$$c_{11}u_{x,xx} + c_{44}u_{x,zz} + (c_{13}+c_{44})u_{z,xz} + (e_{31}+e_{15})\phi_{,xz} + (h_{31}+h_{15})\varphi_{,xz} = \beta_x\theta_{,x} \tag{11}$$

$$c_{44}u_{z,xx} + c_{33}u_{z,zz} + (c_{13}+c_{44})u_{x,xz} + e_{15}\phi_{,xx} + e_{33}\phi_{,zz} + h_{15}\varphi_{,xx} + h_{33}\varphi_{,zz} = \beta_x\theta_{,z} \tag{12}$$

$$e_{15}u_{z,xx} + e_{33}u_{z,zz} + (e_{31}+e_{15})u_{x,xz} - \varepsilon_{11}\phi_{,xx} - \varepsilon_{33}\phi_{,zz} - d_{11}\varphi_{,xx} - d_{33}\varphi_{,zz} = -p_z\theta_{,z} \tag{13}$$

$$h_{15}u_{z,xx} + h_{33}u_{z,zz} + (h_{31}+h_{15})u_{x,xz} - d_{11}\phi_{,xx} - d_{33}\phi_{,zz} - \mu_{11}\varphi_{,xx} - \mu_{33}\varphi_{,zz} = -m_z\theta_{,z} \tag{14}$$

On the other hand, from the theory of the Fourier heat conduction, one has the following constitute and equilibrium equations

$$q_x = -\lambda_x\frac{\partial \theta}{\partial x}, \qquad q_z = -\lambda_z\frac{\partial \theta}{\partial z}, \qquad \frac{\partial q_x}{\partial x} + \frac{\partial q_z}{\partial z} = 0 \tag{15}$$

Then it follows that

$$\lambda^2\frac{\partial^2\theta}{\partial x^2} + \frac{\partial^2\theta}{\partial z^2} = 0, \qquad \lambda = \sqrt{\frac{\lambda_x}{\lambda_z}}\,. \tag{16}$$

3. Thermal stress intensity factor

Since the considered problem is linear and only related to the stationary behavior of a cracked thermo-magneto-electro-elastic solid, the magnetoelectroelastic field can be obtained by considering the superposition of that induced by applied magneto-electro-mechanical loadings and that induced by applied uniform heat flux. For the temperature field, similar to those given in [13], one can easily obtain the jump of temperature change across the crack as

$$\theta(x,0) = -\frac{q_0 - q^c}{\lambda\lambda_z}\sqrt{a^2 - x^2}\,, \qquad -a < x < a\,. \tag{17}$$

Moreover, using the known results in [12], we give the jump of elastic displacement across the crack, namely

$$u_z(x,0) = \frac{\sigma_0}{\sum_{j=1}^{4}\beta_{1j}a_j}\sum_{j=1}^{4}\eta_{3j}\alpha_j a_j\sqrt{a^2 - x^2}\,, \qquad -a < x < a \tag{18}$$

where the constants $\beta_{kj}, \alpha_j, a_j$ and η_{3j} are defined as those given in [12]. From the third relation in Eq. (1) , Eqs. (17) and (18), the heat flux q^c can be calculated as

$$q^c = \frac{\lambda^c q_0 \sum_{j=1}^{4}\beta_{1j}a_j}{\lambda^c\sum_{j=1}^{4}\beta_{1j}a_j + \lambda\lambda_z\sigma_0\sum_{j=1}^{4}\eta_{3j}\alpha_j a_j} \quad \text{for } \sigma_0 \neq 0\,, \tag{19}$$

$$q^c = \frac{\lambda^c q_0 \sum_{j=1}^{4} \beta_{4j} a_j}{\lambda^c \sum_{j=1}^{4} \beta_{4j} a_j + \lambda\lambda_z (D_0 - D^c) \sum_{j=1}^{4} \eta_{3j} \alpha_j a_j} \quad \text{for} \quad \sigma_0 = 0, D_0 \neq 0, \qquad (20)$$

$$q^c = \frac{\lambda^c q_0 \sum_{j=1}^{4} \beta_{6j} a_j}{\lambda^c \sum_{j=1}^{4} \beta_{6j} a_j + \lambda\lambda_z (B_0 - B^c) \sum_{j=1}^{4} \eta_{3j} \alpha_j a_j} \quad \text{for} \quad \sigma_0 = 0, B_0 \neq 0. \qquad (21)$$

As observed in [10], the heat flux q^c is dependent on the material properties, applied mechanical loading and thermal conductivity of crack interior. In addition, applied magnetoelectric loadings, electric permittivity and magnetic permeability of crack interior also have influences on the heat flux q^c since they may affect crack opening displacement. Moreover, when $\lambda^c = 0$, one has $q^c = 0$ and the crack is thermally insulated. When $\lambda^c \to \infty$, we get $q^c = q_0$ and the crack is fully conductive.

On the other hand, we can give the explicit solution of the stress field near the crack tip induced by applied uniform heat flux. For saving spaces, we neglect the detail solution procedure and give the thermal stress intensity factor as

$$K_{II} = -\frac{\kappa(q_0 - q^c)a}{2\lambda\lambda_z} \sqrt{\pi a} \sum_{j=1}^{4} \beta_{2j} b_{j1}, \qquad (22)$$

where

$$[b_{kj}]_{4\times 4} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ \beta_{11} & \beta_{12} & \beta_{13} & \beta_{14} \\ \beta_{41} & \beta_{42} & \beta_{43} & \beta_{44} \\ \beta_{61} & \beta_{62} & \beta_{63} & \beta_{64} \end{bmatrix}^{-1}. \qquad (23)$$

The constant κ is only related to the material properties and it can be calculated as

$$\kappa = \frac{M_1 \sum_{j=1}^{4} \beta_{2j} b_{j1} - \kappa_1 \sum_{j=1}^{4} \beta_{2j} b_{j2} - \kappa_2 \sum_{j=1}^{4} \beta_{2j} b_{j3} - \kappa_3 \sum_{j=1}^{4} \beta_{2j} b_{j4}}{\sum_{j=1}^{4} \beta_{2j} b_{j1}}, \qquad (24)$$

with

$$\begin{bmatrix} M_1 \\ M_2 \\ M_3 \\ M_4 \end{bmatrix} = \begin{bmatrix} c_{11} - \lambda^2 c_{44} & -(c_{13} + c_{44})\lambda & -(e_{31} + e_{15})\lambda & -(h_{31} + h_{15})\lambda \\ (c_{13} + c_{44})\lambda & c_{44} - c_{33}\lambda^2 & e_{15} - e_{33}\lambda^2 & h_{15} - h_{33}\lambda^2 \\ -(e_{31} + e_{15})\lambda & e_{33}\lambda^2 - e_{15} & \varepsilon_{11} - \varepsilon_{33}\lambda^2 & d_{11} - d_{33}\lambda^2 \\ -(h_{31} + h_{15})\lambda & h_{33}\lambda^2 - h_{15} & d_{11} - d_{33}\lambda^2 & \mu_{11} - \mu_{33}\lambda^2 \end{bmatrix} \begin{bmatrix} \beta_x \\ \beta_z \lambda \\ p_z \lambda \\ m_z \lambda \end{bmatrix}, \qquad (25)$$

$$\kappa_1 = c_{13} M_1 - c_{33} M_2 \lambda - e_{33} M_3 \lambda - h_{33} M_4 \lambda - \beta_z, \qquad (26)$$

$$\kappa_2 = e_{31} M_1 - e_{33} M_2 \lambda + \varepsilon_{33} M_3 \lambda + d_{33} M_4 \lambda + p_z, \qquad (27)$$

$$\kappa_3 = h_{31} M_1 - h_{33} M_2 \lambda + d_{33} M_3 \lambda + \mu_{33} M_4 \lambda + m_z. \qquad (28)$$

It is seen that the thermal stress intensity factor K_{II} is dependent on the heat flux at the crack faces q^c. When $q^c = 0$, corresponding to a thermally insulated crack, the thermal stress intensity factor is only dependent on applied thermal loading, material properties and the crack length. When $q^c = q_0$, corresponding to a fully conductive crack, the thermal stress intensity factor is zero. When a crack is full of a medium, the thermal stress intensity factor is dependent on applied thermo-magneto-electro-mechanical loadings and various physical properties of the medium inside the crack. For convenience, the thermal stress intensity factor for $q^c = 0$ is rewritten as K_m and

one get

$$\frac{K_{II}}{K_m}=1-\frac{q_c}{q_0}. \tag{29}$$

That is, application of (19)-(21) yields

$$\frac{K_{II}}{K_m}=\frac{\lambda\lambda_z\sigma_0\sum_{j=1}^{4}\eta_{3j}\alpha_j a_j}{\lambda^c\sum_{j=1}^{4}\beta_{1j}a_j+\lambda\lambda_z\sigma_0\sum_{j=1}^{4}\eta_{3j}\alpha_j a_j}\quad \text{for}\ \ \sigma_0\neq 0, \tag{30}$$

$$\frac{K_{II}}{K_m}=\frac{\lambda\lambda_z(D_0-D^c)\sum_{j=1}^{4}\eta_{3j}\alpha_j a_j}{\lambda^c\sum_{j=1}^{4}\beta_{4j}a_j+\lambda\lambda_z(D_0-D^c)\sum_{j=1}^{4}\eta_{3j}\alpha_j a_j}\quad \text{for}\ \ \sigma_0=0, D_0\neq 0, \tag{31}$$

$$\frac{K_{II}}{K_m}=\frac{\lambda\lambda_z(B_0-B^c)\sum_{j=1}^{4}\eta_{3j}\alpha_j a_j}{\lambda^c\sum_{j=1}^{4}\beta_{6j}a_j+\lambda\lambda_z(B_0-B^c)\sum_{j=1}^{4}\eta_{3j}\alpha_j a_j}\quad \text{for}\ \ \sigma_0=0, B_0\neq 0. \tag{32}$$

4. Numerical results and discussions

In order to investigate the effects of applied magneto-electro-mechanical loadings and the physical properties of crack interior on the thermal stress intensity factor, we choose a special thermo-magneto-electro-elastic solid for numerical computations and the material properties are given in Table 1 [3]. For the sake of simplicity, we further suppose that $\varepsilon_r=\mu_r=\lambda_r=\omega$. When $\omega=0$, the crack is fully thermo-magneto-electric impermeable. When $\omega\to\infty$, the crack is fully thermo-magneto-electric permeable. When $\omega=1$, the crack is full of air.

Table 1. The material properties

Elastic constants ($\times10^{10}$ N/m^2)				Piezoelectric constants (C/m^2)			Dielectric permittivity ($\times10^{-11}$C^2/Nm^2)	
c_{11}	c_{13}	c_{33}	c_{44}	e_{31}	e_{33}	e_{15}	ε_{11}	ε_{33}
7.41	3.93	8.36	1.32	-0.16	0.347	-0.138	8.26	9.03

Magnetic permeability ($\times10^{-6}$Ns^2/C^2)		Electromagnetic constants ($\times10^{-11}$Ns/VC)		Piezomagnetic constants (N/Am)		
μ_{11}	μ_{33}	d_{11}	d_{33}	h_{31}	h_{33}	h_{15}
5	10	-3612.68	-2.4735	580.3	699.7	550

Thermal moduli ($\times10^5$N/Km^2)		Pyroelectric constant ($\times10^{-6}$C/N)	Pyromagnetic constant ($\times10^{-6}$N/AKm)	Heat conduction coefficients (W/Km)	
β_x	β_z	p_z	m_z	λ_x	λ_z
6.21	5.51	-2.94	5.187	9	9

Fig. 2 is depicted to show the variation of the normalized thermal stress intensity factor K_{II}/K_m versus ω under the loadings of $\sigma_0=10MPa$, $D_0=1\times10^{-4}C/m^2$ and $B_0=0.01N/Am$. It is seen from Fig. 2 that with the increasing of ω, the normalized thermal stress intensity factor K_{II}/K_m is decreasing rapidly. The phenomenon is in accordance with that given in [10] for an opening crack in a purely elastic material. For $\omega=0$, one has $K_{II}/K_m=1$. For $\omega\to\infty$, $K_{II}/K_m=0$. For a crack full of a medium, the thermal stress intensity factor is located between

that for a fully permeable crack and that for a fully impermeable one. One can see that the thermal stress intensity factor is always overestimated for a thermally insulated crack.

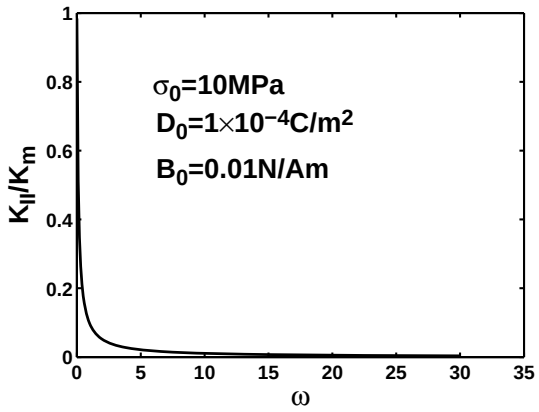

Figure 2. The variations of the normalized thermal stress intensity factor K_{II}/K_m versus ω under the loadings of $\sigma_0 = 10MPa$, $D_0 = 1\times10^{-4} C/m^2$ and $B_0 = 0.01N/Am$.

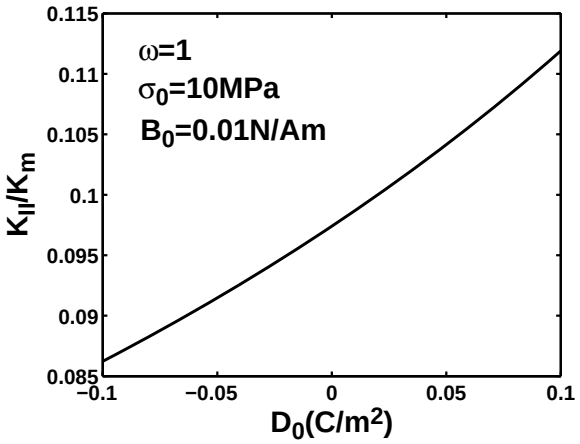

Figure 3. The variations of the normalized thermal stress intensity factor K_{II}/K_m versus D_0 under the loadings of $\sigma_0 = 10MPa$ and $B_0 = 0.01N/Am$ for an air crack.

Moreover, for an air crack, it is very interesting to investigate the effects of applied magneto-electro-mechanical loadings on the thermal stress intensity factor, since the important issue is little to be considered in the open literatures [5-9]. Fig. 3 presents the variations of the normalized thermal stress intensity factor K_{II}/K_m versus the electric loading D_0 for $\sigma_0 = 10MPa$ and $B_0 = 0.01N/Am$. One can find from Fig. 3 that a positive electric loading enhances the normalized stress intensity factor, and a negative one impedes the normalized stress intensity factor. It is attributed to the fact that for an air crack, a positive electric loading aids the crack opening displacement and a negative one decreases the crack opening displacement [12]. Similarly, it is seen from Fig. 4 that the effects of applied magnetic loadings on the normalized thermal stress intensity factor are in agreement with those of applied electric loadings. On the other hand, Fig. 5 is drawn to show the dependence of the normalized thermal stress intensity factor on applied mechanical loadings. It is found that an increase of applied mechanical loading σ_0 enhances the normalized thermal stress intensity factor, which is similar to the observation in [10]. For a practical situation, always a combination of applied thermo-magneto-electro-mechanical loadings is acting on the smart devices. One can observe from the above phenomena that to address the thermal stresses near the crack tips, the effects of applied magneto-electro-mechanical loadings and the physical properties of crack interior should be considered comprehensively.

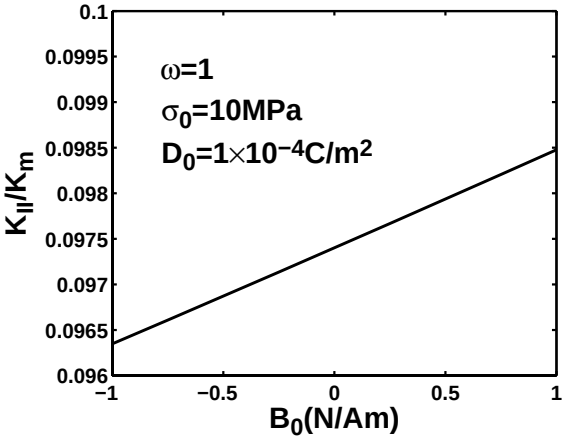

Figure 4. The variations of the normalized thermal stress intensity factor K_{II} / K_m versus B_0 under the loadings of $\sigma_0 = 10MPa$ and $D_0 = 1\times10^{-4} C / m^2$ for an air crack.

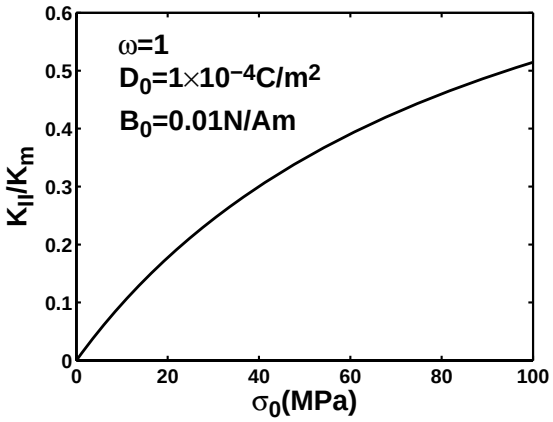

Figure 5. The variations of the normalized thermal stress intensity factor K_{II} / K_m versus σ_0 under the loadings of $D_0 = 1\times10^{-4} C / m^2$ and $B_0 = 0.01N / Am$ for an air crack.

4. Conclusions

To address the effects of various physical properties of crack interior on the thermal stress intensity factor, an opening crack model is proposed in the paper. Eight ideal crack models are the limiting cases of the proposed one. The problem of an opening crack embedded in an infinite thermo-magneto-electro-elastic solid is investigated. The closed-form solution of the thermal stress intensity factor is given. Numerical results are carried to show the influences of applied magneto-electro-mechanical loadings and various physical properties of crack interior on the thermal stress intensity factor. The results reveal that for an opening crack full of a medium, the effects of applied magneto-electro-mechanical loadings and various physical properties of crack interior on the thermal stress intensity factor should be considered. Under the assumption of thermally insulated crack model, the thermal stress intensity factor is always overestimated.

Abstract The physical mechanisms of interfacial fracture in a multiferroic bimaterial under magnetostriction or electrostriction have been investigated by the methods of distributed dislocations and Green's function. The numerical results of the stress intensity factor are discussed and the physical mechanisms are then explained.

Keywords Magnetostriction, Electrostriction, Piezomagnetic stiffening, Piezoelectric stiffening, Interfacial fracture

1. Introduction

In layered multiferroic composites composed of alternate piezoelectric and piezomagnetic layers [1], interfaces are key regions to realize the magneto-electric coupling performance [2]. However, when these composites are in service, their interfaces might be damaged by magnetostriction or electrostriction. Therefore, it is significant to investigate the interfacial fracture behavior of layered multiferroic composites. In preceding work [2-3], we analyzed the idealized problems of a single interfacial crack. For practical composites, multiple cracks may simultaneously exist on their interfaces, which would affect the magneto-electric coupling behavior more seriously and also give more difficulties to fracture analysis. The present paper continues to study the more general problem of multiple interfacial cracks in a bi-layered multiferroic composite, and try to give theoretical explanation on the underlying physical mechanisms of magnetostrictive or electrostrictive interfacial fracture.

2. Problem formulatiuon and fracture analysis

Consider a bi-layered multiferroic composite with multiple interfacial cracks shown in Fig. 1. The two layers are poled along the z direction and isotropic in the xoy plane. Assume that it is loaded by in-plane magnetic field H_0 or electric field E_0 normal to the interface and surfaces, and the upper and lower surfaces are constrained mechanically. Then, only the anti-plane deformation is coupled with the in-plane magnetic/electric field, and the basic equations reduce to

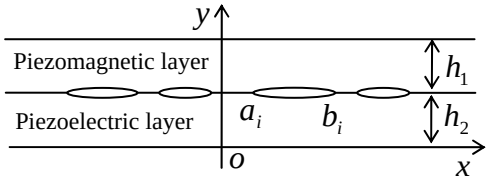

Fig. 1 Interfacial cracks in a multiferroic composite

$$\left.\begin{aligned} \tau_{kz}^{(1)} &= c_{44}^{(1)}\frac{\partial w_1}{\partial k}+h_{15}\frac{\partial \varphi}{\partial k};\quad B_k = h_{15}\frac{\partial w_1}{\partial k}-\mu_{11}\frac{\partial \varphi}{\partial k} \\ \tau_{kz}^{(2)} &= c_{44}^{(2)}\frac{\partial w_2}{\partial k}+e_{15}\frac{\partial \phi}{\partial k};\quad D_k = e_{15}\frac{\partial w_2}{\partial k}-\varepsilon_{11}\frac{\partial \phi}{\partial k} \end{aligned}\right\},\ k=x,y \tag{1}$$

The governing equations are [2]

$$\nabla^2 w_j = 0\,,\ (\,j=1,2\,),\ \ \nabla^2\varphi = 0\,,\ \ \nabla^2\phi = 0\,. \tag{2}$$

For the magnetostriction (MS) case, the boundary and continuity conditions are

$$\tau_{yz}^{(1)}(x,h_1+h_2) = \tau_{yz}^{(2)}(x,0) = \tau_0\,,\ \ \tau_{yz}^{(1)}(x,h_2) = \tau_{yz}^{(2)}(x,h_2) \tag{3}$$

$$B_y(x,h_1+h_2) = B_y(x,h_2) = H_0\,,\ \ D_y(x,h_2) = D_y(x,0) = 0 \tag{4}$$

$$w_1(x,h_2) = w_2(x,h_2)\,,\ \ x\notin(a_j,b_j)\,,\ \ j=1,2,\Lambda\,,n \tag{5}$$

$$\tau_{yz}(x,h_2) = 0\,,\ \ x\in(a_j,b_j)\,,\ \ j=1,2,\Lambda\,,n \tag{6}$$

where τ_0 is the mechanical constraining traction that can be determined by magnetoelectroelastic analysis [2]. For the electrostriction (ES) case, Eq. (4) should be replaced by

$$B_y(x,h_1+h_2) = B_y(x,h_2) = 0\,,\ \ D_y(x,h_2) = D_y(x,0) = D_0 \tag{7}$$

The methods of distributed interfacial dislocations, Green's function and Cauchy singular integral equation are employed to perform the fracture analysis [4]. For simplicity, the details of the theoretical derivation and numerical computation are omitted here.

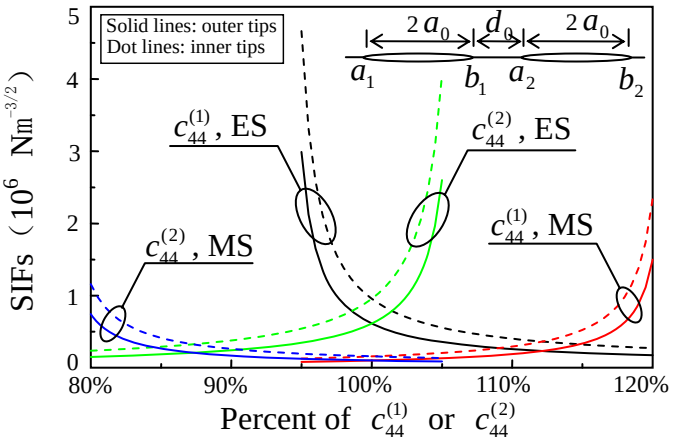
3. Numerical results and conclusion

Assume that the piezomagnetic and piezoelectric layers are CoFe2O4 and BaTiO3, respectively, and their material constants are perturbed to reveal their effects on the stress intensity factor (SIF), respectively. Based on the numerical results of SIF shown in Fig. 2, the magnetostrictive or electrostrictive interfacial fracture behavior is explained through the following physical mechanisms of "initiative/passive deformation", "magneto/electro-mechanical coupling" and "piezomagnetic/piezoelectric stiffening".

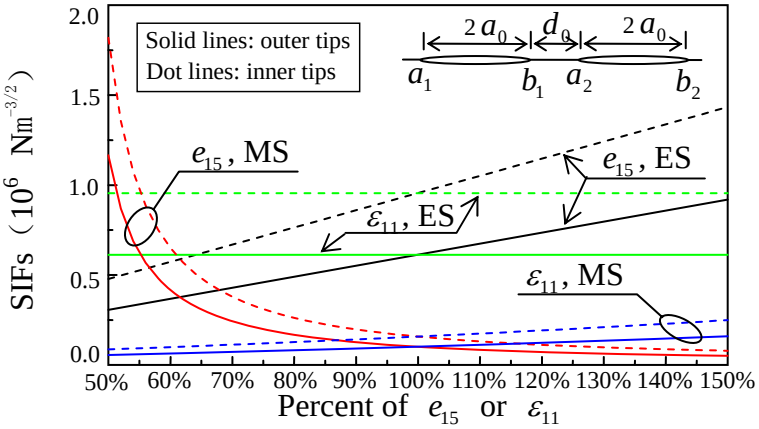
(a) The shear modulus (i.e. material stiffness) affects the SIF via the mechanism of initiative and passive deformation.

(b) The piezoelectric and dielectric coefficients affect the SIF in the ES case via the mechanism of electromechanical coupling, but they affect the SIF in the MS case through the mechanism of piezoelectric stiffening.

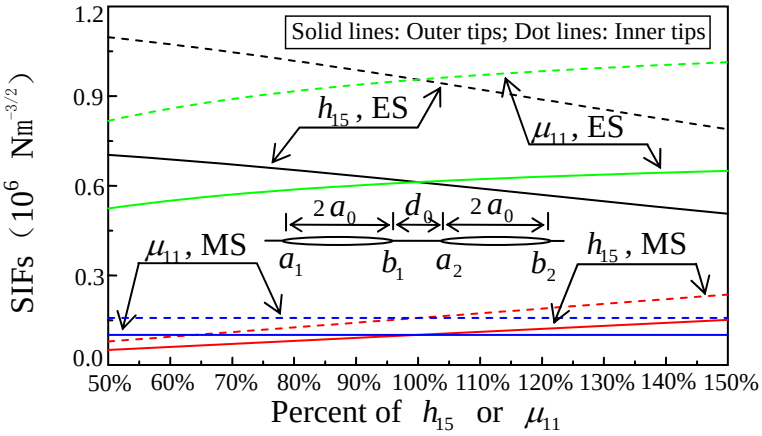
(c) The piezomagnetic coefficient and magnetic permeability affect the SIF in the MS case through the mechanism of magnetomechanical coupling, but they take effect in the ES case through the mechanism of piezomagnetic stiffening.



(a) Perturbation of shear modulus



(b) Perturbation of piezoelectric coefficient and dielectric coefficient



(c) Perturbation of piezomagnetic coefficient or magnetic permeability

Fig. 2 Effects of material parameters on the SIF

($h_1 = h_2 = 10$mm; $d_0 = 0.1$mm; $a_0 = 1$mm)

On the Dynamic Behaviour of Surface-Bonded Piezoelectric Sensors/Actuators with Partially Debonded Adhesive Layers

Congrui Jin, Lu Han, Guoliang Huang, Xiaodong Wang*

Department of Mechanical Engineering
University of Alberta, Edmonton, Canada T6G 2G8

Abstract The current work presents the analytical study of the effect of the mechanical and geometrical properties of the adhesive layer on the coupled dynamic electromechanical behaviour of thin piezoceramic sensors/actuators bonded to elastic media. A sensor/actuator model with an imperfect adhesive bonding layer is proposed to simulate the two dimensional electromechanical behaviour of the integrated system. The analytical solution of the problem is provided to study the effect of the bonding layer upon the dynamic behaviour of the sensors/actuators under different loading frequencies. The interfacial debonding and its effect on the interlaminar strain and stress transfer mechanisms are discussed in detail. Numerical results obtained show that even for perfectly bonding cases the dynamic coupling between the sensors/actuators and the host structure is significantly affected by the material and geometric properties of the bonding layer. For imperfect bonding layers, debonding and loading frequency interact strongly to each other at certain frequencies, showing a significant coupling effect.

Keywords Piezoelectric, Electromechanical, Debonding, Sensor, Actuator

1. Introduction

Using piezoelectric sensors/actuators in smart structures for position control, vibration control, and damage detection has attracted significant attention from the research community [1-4]. Piezoelectric patches could be permanently bonded to host structures using proper adhesives. The adhesive layer transfers the load between the sensor/actuator elements and the host structure and significantly influences the efficiency of the sensing/actuating process. It is, therefore, an important issue to study the effect of the adhesive layer in such smart structures.

Beam, plate and shell elements have been extensively used [5-7] to study the global electromechanical behaviour of piezoelectric structures. To understand the load transfer through bonding layers in these structures, detailed local deformation near actuators/sensors must be studied. A one-dimensional actuator model has been developed to study the static local stress field near a thin-sheet piezoelectric element attached to an infinite elastic medium [8]. A similar analysis was also conducted based on a more general model which included both interfacial and normal stresses [9, 10]. The development of techniques of generating and collecting diagnostic elastic waves using piezoelectric actuators/sensors has showed the great potential of continuous monitoring of composite structures using distributed piezoelectric actuators/sensors [11]. The study showed very promising results for using integrated piezoelectric actuator/sensor systems in structural health monitoring. A special application of piezoelectric actuators/sensors is in the electromechanical impedance method, which was developed for identifying damage by monitoring the changes in the impedance of the structure [12-15]. Piezoelectric actuators/sensors are also used to generate wave propagation in smart structures for the health monitoring of the structures. To study the high-frequency dynamic behaviour of a piezoelectric thin-sheet actuator, a one-dimensional model was developed and used to evaluate the effect of geometric and loading parameters upon the load transfer between the actuators and the host structure [16, 17]. This actuator model is further modified to study problems with varying electric field distribution along the actuators [18]. Newly developed piezoelectric actuators can sustain a very high electric field without electric breakdown, and, therefore, can generate relatively high strain in the adhesive along the edge of the actuator, and

may finally result in debonding [19, 20]. Existing studies on the electromechanical behaviour of piezoelectric actuators with imperfect bonding have been mainly confined to the global response of piezoelectric structures [21-23].

The current work reviews and presents the analytical study of the effect of the mechanical and geometrical properties of adhesive layers on the coupled dynamic electromechanical behaviour of thin piezoceramic sensors/actuators bonded to elastic media. A sensor/actuator model with an imperfect adhesive bonding layer is used to simulate the two dimensional electromechanical behaviour of the integrated system. The analytical solution of the problem is provided to study the effect of the bonding layer upon the dynamic behaviour of the sensors/actuators under different loading frequencies. The interfacial debonding and its effect on the interlaminar strain and stress transfer mechanisms are discussed. Numerical results obtained show that even for perfectly bonding cases the dynamic coupling between the sensors/actuators and the host structure is significantly affected by the material and geometric properties of the bonding layer. For imperfect bonding layers, debonding and loading frequency interact strongly to each other at certain frequencies, showing a significant coupling effect.

2. Formulation of the Problem

For surface-bonded piezoelectric thin sheets with the poling direction along the thickness, as either actuators or sensors, the axial deformation will play a dominant role. Since the thickness of the host medium is usually much larger than that of the piezoelectric elements, the host medium can be modelled as a semi-infinite medium. Accordingly, consider the plane strain problem of a thin piezoceramic sheet bonded to a homogeneous and isotropic elastic half plane through a thin bonding layer, as illustrated in Fig. 1. In the figure *a* represents the half length of the actuator/sensor, and the thicknesses of the actuator and the bonding layer are assumed to be *h* and *h'*, respectively. Debonding at the bonding layer forms an interfacial crack, with the half length being *d*.

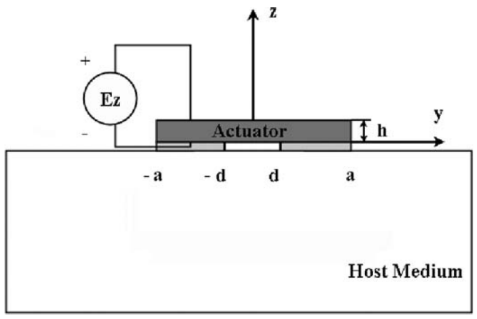

Figure 1. A surface piezoelectric element with debonding

For an actuator, a voltage is applied between the upper and lower electrodes of the piezoelectric element, which results in an electric field $E_z\, exp(-i\omega t)$ along the thickness of the actuator, where *Ez* is the magnitude of the electric field intensity, and ω is the angular frequency. For steady state problems, all field quantities contain the same temporal factor $\exp(-i\omega t)$, which is hereafter omitted for brevity.

2.1 Modelling of the piezoelectric elements

For a thin-sheet actuator/sensor, the axial stress and strain can be assumed to be uniform across the thickness. The normal stress between the actuator and the host medium is ignored because the upper surface of the thin actuator/sensor is traction free. The piezoelectric element can then be modelled

as a one-dimensional element subjected to interfacial shear stress and electric field with the governing equation being

$$\frac{\mathrm{d}\sigma_y^a(y)}{\mathrm{d}y} + \frac{\tau(y)}{h} + \rho^a \omega^2 u_y^a = 0 \tag{1}$$

where $\sigma^a{}_y$, ρ^a, and $u^a{}_y$ are the axial stress, the mass density, and the axial displacement of the actuator, respectively. The axial stress of the actuator is related to the axial strain $\epsilon^a{}_y$ and the electric field E_z by the following general constitutive relation

$$\sigma_y^a(y) = E^a \epsilon_y^a(y) - e^a E_z \tag{2}$$

where E^a and e^a are the effective stiffness and piezoelectric constants [].

Based on this simplified model, axial the strsin and displacement in the piezoelectric element can be determined in terms of the interfacial shear stress (τ) and the applied electric field intensity (E_z) as

$$\begin{aligned}
\epsilon_y^a(y) = {} & \frac{e^a E_z}{E^a}\frac{\cos k^a y}{\cos k^a a} + \frac{\sin[k^a(a+y)]}{E^a h \sin 2k^a a}\int_{-a}^{a}\cos[k^a(\xi-a)]\tau(\xi)\mathrm{d}\xi \\
& -\frac{1}{E^a h}\int_{-a}^{y}\cos[k^a(y-\xi)]\tau(\xi)\mathrm{d}\xi, \quad |y|<a, \\
u_y^a(y) = {} & \frac{e^a E_z}{E^a}\frac{\sin k^a y}{k^a \cos k^a a} - \frac{\cos[k^a(a+y)]}{k^a E^a h \sin 2k^a a}\int_{-a}^{a}\cos[k^a(\xi-a)]\tau(\xi)\mathrm{d}\xi \\
& -\frac{1}{k^a E^a h}\int_{-a}^{y}\sin[k^a(y-\xi)]\tau(\xi)\mathrm{d}\xi, \quad |y|<a,
\end{aligned} \tag{3}$$

which represents the deformation of the piezoelectric element caused by the interfacial shear stress and the applied electric field.

2.2 The bonding layer

The bonding layer connects the piezoelectric element and the host medium by transferring shear stress. The shear stress in the bonding layer is given by its constitutive relation as

$$-\tau(y) = \frac{\mu^b - i\omega\gamma^b}{h'}[u^+(y) - u^-(y)] \tag{4}$$

where μ^b and γ^b are the shear modulus and the coefficient of viscosity of the bonding layer, respectively, and $u+$ and $u-$ are the longitudinal displacements of the upper and lower surfaces of the bonding layer, respectively.

2.3 The governing equations for debonded piezoelectric elements

When debonding occurs, the shear stress in the debonded part of the piezoelectric element will be zero. By solving the governing equations for the piezoelectric element and that for the elastic host medium, and satisfying the continuity conditions at all interfaces, the following governing equation for the entire system with interfacial debonding can be obtained,

$$\frac{e^a E_z}{E^a}\frac{\cos k^a y}{\cos k^a a} = -\frac{1}{\pi\mu^h}\int_0^\infty \left[\frac{\beta k^2 s}{(2s^2-k^2)^2-4s^2\alpha\beta}+\frac{\lambda_0}{2}\right]\left\{\int_{-a}^{-d}\tau(\xi)\sin[s(y-\xi)]\mathrm{d}\xi + \int_d^a \tau(\xi)\sin[s(y-\xi)]\mathrm{d}\xi\right\}\mathrm{d}s + \frac{\lambda_0}{2\pi\mu^h}\left[\int_{-a}^{-d}\frac{\tau(\xi)}{y-\xi}\mathrm{d}\xi + \int_d^a \frac{\tau(\xi)}{y-\xi}\mathrm{d}\xi\right] - \frac{h'}{\mu^b - i\omega\gamma^b}\frac{\mathrm{d}\tau(y)}{\mathrm{d}y},$$
$$-\frac{\sin[k^a(y+a)]}{E^a h\sin 2ak^a}\left\{\int_{-a}^{-d}\cos[k^a(\xi-a)]\tau(\xi)\mathrm{d}\xi + \int_d^a \cos[k^a(\xi-a)]\tau(\xi)\mathrm{d}\xi\right\}$$
$$+\frac{1}{E^a h}\left\{\int_{-a}^{-d}\cos[k^a(y-\xi)]\tau(\xi)\mathrm{d}\xi + \int_d^y \cos[k^a(y-\xi)]\tau(\xi)\mathrm{d}\xi\right\}, \quad d<y<a, \tag{5}$$

which represents the continuity condition across the adhesive layer. In addition, in the debonded part of the adhesive layer following continuity condition should be satisfied,

$$-\frac{1}{\pi\mu^h}\int_0^\infty \left[\frac{\beta k^2 s}{(2s^2-k^2)^2-4s^2\alpha\beta}+\frac{\lambda_0}{2}\right]\int_{-d}^{d}\left\{\int_{-a}^{-d}\tau(\xi)\sin[s(y-\xi)]\mathrm{d}\xi + \int_d^a \tau(\xi)\sin[s(y-\xi)]\mathrm{d}\xi\right\}\mathrm{d}y\mathrm{d}s + \frac{\lambda_0}{2\pi\mu^h}\int_{-d}^{d}\left[\int_{-a}^{-d}\frac{\tau(\xi)}{y-\xi}\mathrm{d}\xi + \int_d^a \frac{\tau(\xi)}{y-\xi}\mathrm{d}\xi\right]\mathrm{d}y$$
$$+\frac{h'}{\mu^b - i\omega\gamma^b}[\tau(-d)-\tau(d)] = \frac{2(\sigma_d + e^a E_z)\tan k^a d}{E^a k^a}. \tag{6}$$

from which the interfacial shear stress can be determined. In this equation, $\lambda_0=2(1-\nu^h)$, and

$$\alpha = \begin{cases} \sqrt{s^2-K^2} & |s|>K, \\ -i\sqrt{K^2-s^2} & |s|<K, \end{cases} \qquad \beta = \begin{cases} \sqrt{s^2-k^2} & |s|>k, \\ -i\sqrt{k^2-s^2} & |s|<k, \end{cases}$$

which are determined from the elastodynamic solution of the host medium. $K=\omega/c_L$, $k=\omega/c_T$ are two wave numbers with c_L and c_T being the longitudinal and transverse shear wave speed of the host medium.

2.4 The singular behaviour of the debonded piezoelectric elements

Interficial debonding forms interfacial cracks. In general, oscillating singularity will occur at the tips of the debonding. For the current piezoelectric element with a partially debonded layer, however, the well-known oscillating singularity disappears based on the model used and the corresponding governing equations, because the oscillating singularity occurs only at perfectly bonded interfaces.

3. Results and Discussion

The existence of adhesive layers could significantly affect the behaviour of the piezoelectric actuator/sensor [24-27]. The response of the piezoelectric element to an applied electric field

(actuator) or an incident wave (sensor) has been studied under different geometric and loading conditions to evaluate the effect of the bonding layer upon the load transfer between the actuator/sensor and the host medium. In the following discussion, only the magnitude of the physical stress is presented. The numerical calculation is conducted by solving the governing equations using Chebyshev polynomials expansion of the shear stress τ. The convergence of the solution has been carefully evaluated.

The piezoelectric material considered is piezoceramics with its material property being given in Table 1 [28]. The properties of the bonding layer [3] and the host medium [29] are given in Table 2. The mass densities of the actuator and the host medium are assumed to be 2,700 kg/m^3 [28].

Table 1. Piezoelectric properties

Elastic	c_{11}	c_{12}	c_{13}	c_{33}	c_{44}
(Pa)	13.9×10^{10}	6.78×10^{10}	7.43×10^{10}	11.5×10^{10}	2.56×10^{10}

Poisson's ratio ν^h	0.3
Bonding layer	
Shear modulus μ^b (Pa)	1.0×10^9

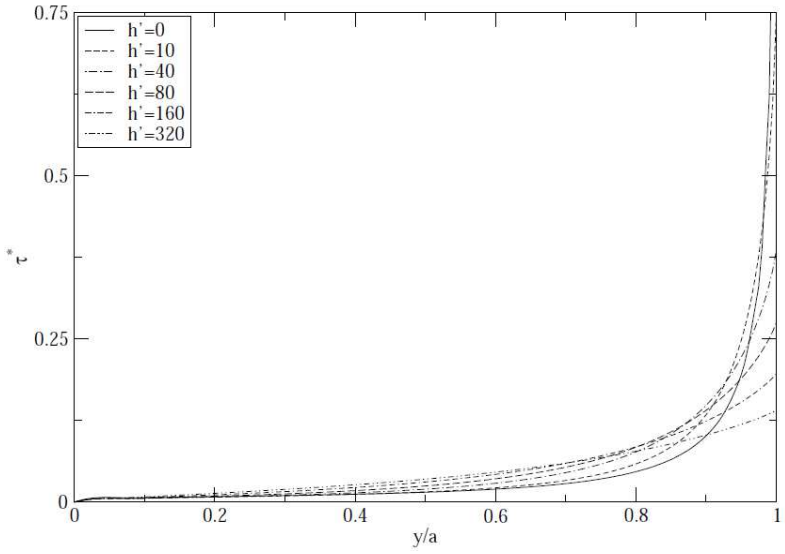

Figure 2 Shear stress distribution along the adhesive layer of an actuator

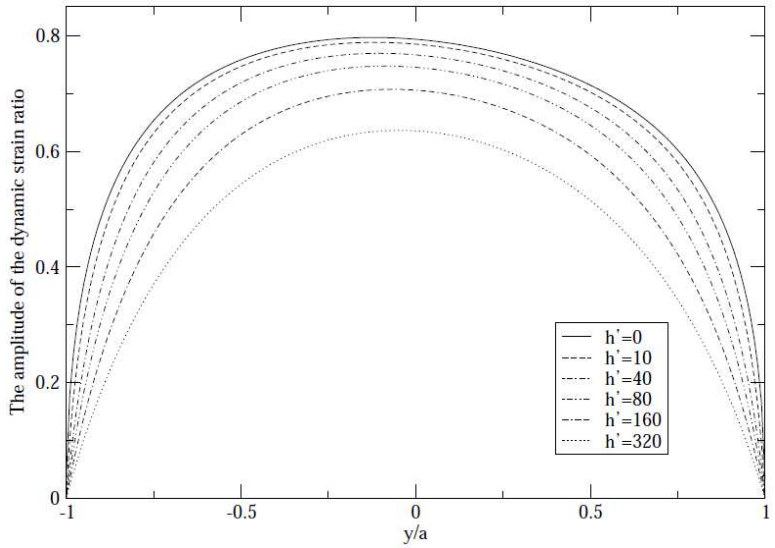

Figure 3 Axial strain distribution along a sensor

One major effect of the adhesive layer is that it reduces stress concentration at the end of an actuator. Figure 2 shows the shear stress distribution ($\tau=qE^aE_z$, $q=\pi E^h/(1-\nu^{h2})/E^a$) along an actuator with $a=1cm$ and $h=0.5mm$, for the case where the loading frequency is $ka=1.0$ and $\gamma_b = 0.0$ for different thicknesses of the bonding layer. Evaluating the six curves in this figure shows that, as the h' value increases from 0 to $320\mu m$, the stress concentration at the tip of the actuator, $y/a = 1.0$, decreases significantly. The adhesive layer also has a significant effect on the response of the piezoelectric element as a sensor. Figures 3 shows the amplitude of the normalized strain along the sensor caused by a normal incident wave for the case where $ka=1.0$ for different bonding layer thickness $0, 10, 40, 80, 160$ and $320\ \mu m$. Significant decrease of the strain with increasing bonding layer thickness is observed.

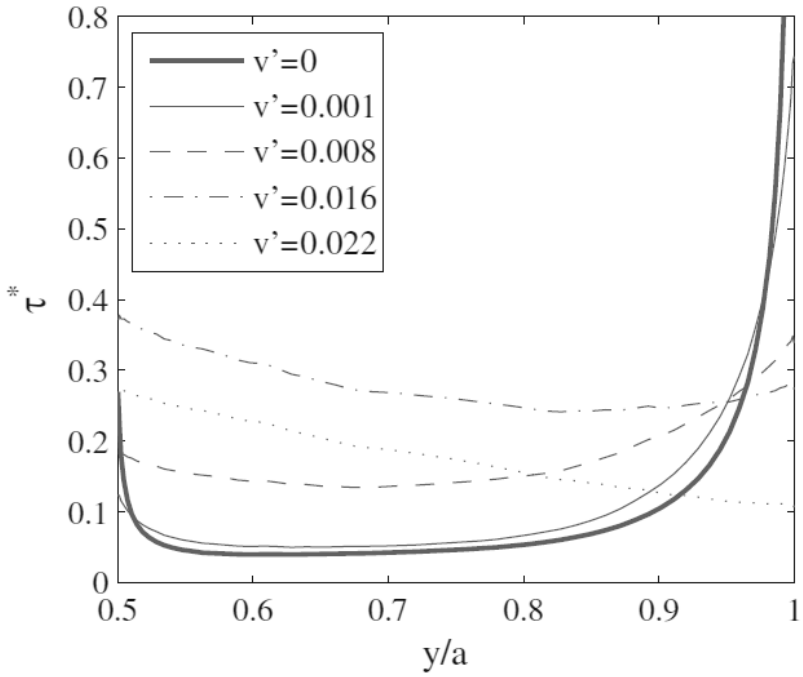

Figure 4 Shear stress distribution along a partially debonded adhesive layer of an actuator

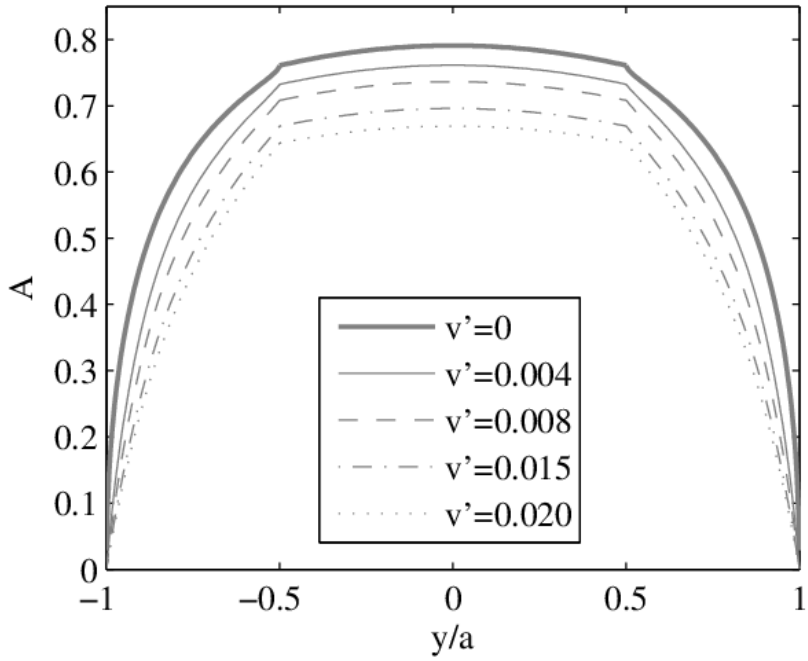

Figure 5 Axial strain distribution along a partially debonded sensor

When debonding occurs at the adhesive layer, the shear stress in the debonded region will disappear and the shear stress will be redistributed in the bonded region. Figure 4 shows the shear stress distribution in the bonded region of the adhesive layer for an actuator under the same geometric and loading conditions as that discussed in Figure 2, for the case where the debonding region is *-0.5a<y<0.5a,* for different thicknesses of the bonding layer (*v'=h'⁄a*). For very small layer thickness the shear stress shows square-root singularity at both the end of the actuator and the tip of the debonding. The existence of the adhesive layer will remove this singularity and generate stress concentration, which reduces with the increase of the layer thickness. Figure 5 shows the corresponding normalized axial strain distribution of a sensor in response to a normal incident wave. Significant decrease of the strain with increasing bonding layer thickness is observed. The adhesive layer also has a significant effect on the response of the piezoelectric element as a sensor. Figures 5 shows the amplitude of the normalized strain along the sensor caused by a normal incident wave for the case where *ka = 1.0* for different bonding layer thickness *0, 10, 40, 80, 160* and *320* μ*m*. It is observed that debonding (*-0.5a<y<0.5a*) significant decreases the strain level in the sensor bot only in the debonded region but also in the bonded parts of the sensor.

Abstract Experimental investigations on superelastic shape memory alloy (SMA) wires subjected to isothermal stress cycling show significant performance degradations, including the accumulation of the plastic strain, the reduction of the maximum transformation strain and the evolution of the transformation temperatures. The cyclic degradation of SMAs must be carefully studied and understood when the alloys are used in the SMA based actuators and vibration isolators. Motivated by these issues, the present work aims to develop a comprehensive approach for the cyclic behavior of SMAs taking into account degradations caused by isothermal stress cycling in the superelastic regime. The new cyclic constitutive model is constructed based on the thermodynamic frame proposed by Boyd and Lagoudas, and evolution laws for the plastic strain as well as non-constant material parameters including the maximum transformation strain and four transformation temperatures are also constructed. Finally, numerical simulations based on the proposed constitutive model are also performed in our work, and good correlations are observed.

Keywords Shape Memory Alloys, Cyclic Degradation, Constitutive Model, Non-constant Material Parameters

1. Introduction

Shape memory alloys (SMAs) exhibit many special properties due to their thermo-elastic martensite transformation, such as shape memory effect, superelasticity (or pseudoelasticity) and damping [1]. Among these thermal-mechanical behaviors, superelasticity is particularly interesting. Superelastic behavior is revealed when the SMA material is mechanically loading under a surrounding temperature higher than the austenite finish temperature. After unloading, SMA material can recover its initial shape and the stress–strain response shows a typical hysteretic loop. This unique superelasticity promotes SMAs to be used in medical applications, such as arterial stents, medical guidewires and catheters [2]. Also, the typical hysteretic loop in the stress–strain space reveals that SMA is a kind of energy dissipation material. Taken the advantage of this property, SMAs are also used in vibration isolation applications, such as seismic isolation and mechanical vibration isolation.

Motivated by these applications, many constitutive models were developed to simulate the thermal-mechanical behavior of SMAs in the superelastic regime over the last thirty years [3-10]. However, among these investigations, very few studies consider the performance degradation of SMAs under isothermal stress cycling, which is more pertinent when SMAs are used in vibration isolation applications [11-15]. Until recently, Kan and Kang introduced the cumulated martensite volume fraction as an internal variable to account for the evolution of residual induced martensite and transformation induced plastic strain during stress-controlled cyclic loading [16]. Zaki and Moumni used internal stress, residual strain and cumulated martensite volume fraction as internal variables to simulate the behavior of SMA in the case of cyclic superelasticity [17]. Saint-Sulpice et al. introduced the residual martensite volume fraction to account for the evolution of residual strain and transformation surface during isothermal stress cyclic loading [18].

The aforementioned models usually consider the plastic strain accumulation and/or the transformation surface evolution (which is associated with the evolution of maximum

transformation strain). However, the transformation temperatures of the alloy were demonstrated to change as a function of the thermal/stress cycling number [19-21]. Moreover, the evolution of transformation temperatures can significantly affect the critical stresses for the onset and finish of phase transformations and the area of the stress–strain hysteretic loop.

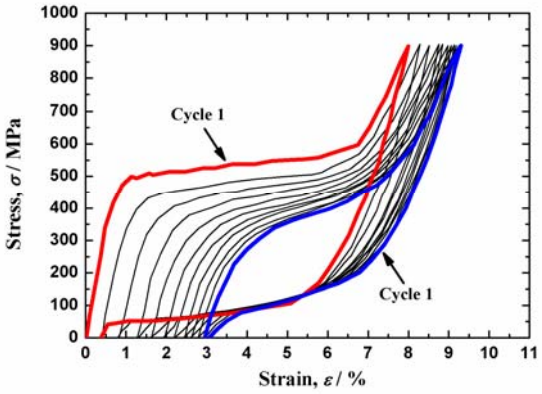
Therefore, this paper aims to develop a constitutive model for SMAs taking into account the isothermal stress cycling degradation, including the accumulation of plastic strain, the evolution of the maximum transformation strain and four transformation temperatures. The new constitutive model is constructed based on the thermodynamic frame proposed by Boyd and Lagoudas [22, 23]. The organization of the paper is as follows: Section 2 presents the observation of cyclic degradation in SMAs through the isothermal stress cycling experiment. The 1-D constitutive model considering the cyclic evolution of the plastic strain, the maximum transformation strain and transformation temperatures is presented in Section 3, while in Section 4, numerical examples are presented and discussed. The conclusions and future work are summarized in the final section.

To simplify the presentation, we denote the two phases related with superelasticity by A and M^d for austenite and detwinned martensite, respectively. The forward and reverse phase transformations are denoted by $A \rightarrow M^d$ and $M^d \rightarrow A$ for austenite to detwinned martensite and detwinned martensite to austenite, respectively.

2. Observation of cyclic degradation

We performed an isothermal stress cycling experiment to a NiTi wire, the wire was repeatedly stressed up to 900 MPa under 28 ^oC. The stress–strain response of the wire is shown in Fig. 1, a simplified diagram which features the evolution of plastic strain, maximum transformation strain and transformation temperatures is shown in Fig. 3, and typical features of cyclic degradation are outlined as follows:

1) The isothermal stress cycling of the NiTi alloy presents an apparent cyclic accumulation of the plastic strain. As shown in Fig. 3(a), after the first cycle, the NiTi wire cannot recover to its original length, and a plastic strain, donated as ε^{p1}, is produced. Similarly, after the second cycle, the total cumulated plastic strain is ε^{p2}, and after the *n*th cycle, the accumulation of the plastic strain becomes ε^{pn}. Furthermore, the plastic strain evolves as an exponential function of cycle number before stabilizing, as shown in Fig. 1 and Fig. 2.



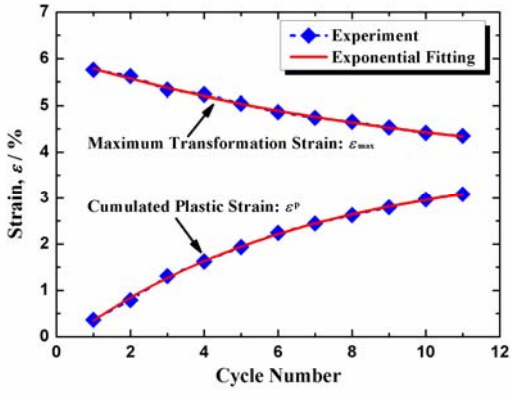


Figure 1. Experimental results of isothermal stress cyclic loading on NiTi wire
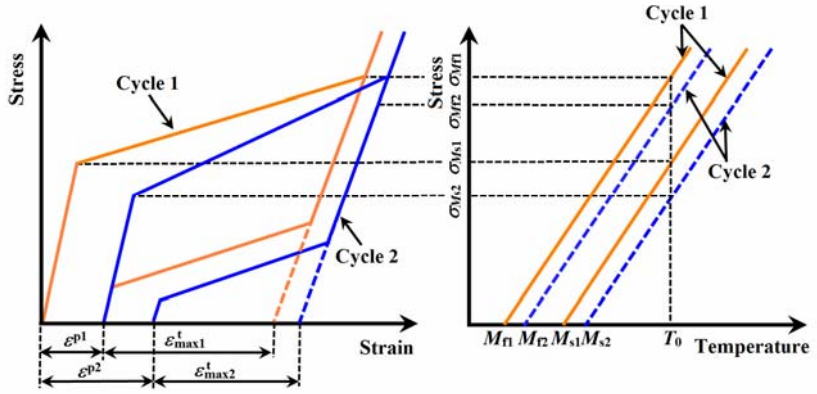
Figure 2. Evolution of the maximum transformation strain ε_{max} and plastic strain ε^p during cyclic loading, the experimental results are compared with the exponential fitting results

2) The maximum transformation strain (also referred to as the saturation recovery strain) changes from cycle to cycle. As shown in Fig. 3(a), the maximum transformation strain for cycle 1 is ε_{max1}, while for cycle 2, it reduces to ε_{max2}. Similarly, after the nth cycle, the maximum transformation strain will reduce to ε_{maxn}. Also, as shown in Fig. 2, ε_{max} is found to increase exponentially with respect to the cycle number up to an asymptotic value.

3) The four transformation temperatures change as a function of the cycle number. As shown in Fig. 3 (b), during the first cycle, the four transformation temperatures are M_{s1}, M_{f1}, A_{s1} and A_{f1}, respectively. While in the second cycle, the four temperatures change to M_{s2}, M_{f2}, A_{s2} and A_{f2}. So we can deduce that the four temperatures will change as the cycle number increases. The same phenomenon was reported in literatures [19-21].



(a) strain evolution (b) transformation temperatures evolution

Figure 3. The evolution of (a): plastic strain, maximum transformation strain in the stress–strain space and (b): transformation temperatures in the stress–temperature space under isothermal stress cycling. For clarity, the evolution of austenite start and finish transformation temperatures is not shown in the stress–temperature space

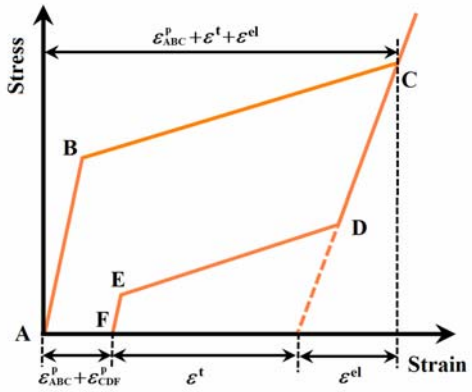


Figure 4. Schematic explanation for the evolution of plastic strain

In order to investigate when the evolution of plastic strain occurs during the whole transformation process, the stress vs. strain response of a typical cycle is presented in Fig. 4. We assume that the plastic and transformation strains produced in A→M^{d} (corresponding loading path is ABC) are separately ε^{p}_{ABC} and ε^{t}, and the elastic strain of point C is ε^{el}. Following these assumptions, the total strain of point C (shown in Fig. 4) becomes:

$$\varepsilon_{C} = \varepsilon^{el} + \varepsilon^{p}_{ABC} + \varepsilon^{t} \tag{1}$$

Assume that the plastic strain for M^{d}→A (corresponding loading path is CDEF) is ε^{p}_{CDF}. Therefore the plastic strain cumulated during the forward and reverse transformations (corresponding loading

path is ACF) is $\varepsilon^{p}_{ABC}+\varepsilon^{p}_{CDF}$. Since the transformation strain can be fully recovered after the $M^{d}\rightarrow A$ transformation, the reduction of the transformation strain during $M^{d}\rightarrow A$ is ε^{t} (corresponding loading path is CDEF, as shown in Fig. 4). Consequently, the total strain of point C can be expressed as:

$$\varepsilon_{D} = \varepsilon^{el} + \varepsilon^{p}_{ABC} + \varepsilon^{p}_{CDF} + \varepsilon^{t} \tag{2}$$

From Eqs. (1) and (2), we can deduce that $\varepsilon^{p}_{CDF}=0$. Following the derivation above, we can assume that the accumulation of plastic strain ε^{p} only occurs during $A\rightarrow M^{d}$.

Consequently, to model the cyclic degradation of shape memory alloys under isothermal stress cycling, the evolution of the plastic strain and maximum transformation strain in $A\rightarrow M^{d}$ and the evolution of transformation temperatures in both forward and reverse transformations must be considered, also related evolution laws should be established.

3. Constitutive model

A constitutive model taking into account the cyclic degradation due to isothermal stress cycling is proposed. It is constructed in the generalized plasticity framework which was employed by Boyd and Lagoudas [22, 23] to simulate the thermo-mechanical behavior of SMA. The construction of the constitutive model is stated in details as follows.

3.1. Strain decomposing and internal variables

3.1.1. Strain decomposing

With the infinitesimal strain assumption, the total strain ε is decomposed into an elastic strain ε^{el} and an inelastic strain ε^{in}:

$$\varepsilon = \varepsilon^{e} + \varepsilon^{in} \tag{3}$$

In which, the inelastic strain ε^{in} can be further decomposed into a thermal expansion strain ε^{th}, a transformation strain ε^{t}, and a plastic strain ε^{p}:

$$\varepsilon^{in} = \varepsilon^{th} + \varepsilon^{t} + \varepsilon^{p} \tag{4}$$

The thermal expansion strain ε^{th} is neglected because the value is much smaller than the others, so the following expression can be got:

$$\varepsilon = \varepsilon^{el} + \varepsilon^{t} + \varepsilon^{p} \tag{5}$$

3.1.2. Internal variables definition

As shown in Eq. (5), two internal variables are needed to account for the evolution of the transformation strain ε^{t} and the plastic strain ε^{p}. Generally, the martensite volume fraction ξ is used as an internal variable to related with ε^{t} [24]:

$$\varepsilon^{t} = \varepsilon_{max}\xi \tag{6}$$

Where ε_{max} is the maximum transformation strain. Following the observation of cyclic degradation stated in Section 2, the plastic strain ε^{p} and the maximum transformation strain ε_{max} change as a function of the cycle number. In order to account for these evolution processes, the cumulated martensite volume fraction ξ^{c} is defined:

$$\xi^{c} = \xi^{ac} + \xi^{mc} \tag{7}$$

Where ξ^{ac} and ξ^{mc} represent the cumulated martensite volume fractions in A→M^{d} and M^{d}→A, respectively. Following these definitions, ξ^{ac} and ξ^{mc} can be expressed as follows:

$$\xi^{ac} = \int \left| \dot{\xi}^{A\to M^{d}} \right| dt,\ \xi^{mc} = \int \left| \dot{\xi}^{M^{d}\to A} \right| dt \tag{8}$$

In which, t is a kinematic time. $\dot{\xi}^{A\to M^{d}}$ and $\dot{\xi}^{M^{d}\to A}$ denote the martensite production rate during A→M^{d} and M^{d}→A.

3.2. Free energy and transformation hardening function

The total Helmoltz free energy ψ for polycrystalline SMAs is given based on Boyd and Lagoudas's work:

$$\psi = E\left(\varepsilon - \varepsilon^{t} - \varepsilon^{p}\right)^{2} \Big/ 2\rho + c\left[\left(T - T_{0}\right) - T\ln\left(T/T_{0}\right)\right] + u_{0} - \eta_{0}T + f(\xi, \dot{\xi}) \tag{9}$$

Where E, c, ρ, η_0 and u_0 are the Young modulus, effective specific heat, mass density, effective specific entropy, and effective specific internal energy at the reference state, respectively. The symbols T and T_0 denote the temperature and reference temperature, respectively. The terms $E(\varepsilon-\varepsilon^{t}-\varepsilon^{p})^{2}/2\rho$, $c[(T-T_0)-T\ln(T/T_0)]$ and $u_0-\eta_0 T+ f(\xi,\dot{\xi})$ represent the elastic strain energy, thermal energy, and the energy related to transformations, respectively.

The effective specific heat c hardly varies during phase transformations, so it is assumed to be constant. However, other material properties in Eq. (9) are assumed to vary with the martensite volume fraction as:

$$E\left(\xi\right) = E^{A} + \xi\left(E^{M} - E^{A}\right) = E^{A} + \xi\Delta E \tag{10}$$

$$\eta_{0}\left(\xi\right) = \eta_{0}{}^{A} + \xi\left(\eta_{0}{}^{M} - \eta_{0}{}^{A}\right) = \eta_{0}{}^{A} + \xi\Delta\eta_{0} \tag{11}$$

$$u_{0}\left(\xi\right) = u_{0}{}^{A} + \xi\left(u_{0}{}^{M} - u_{0}{}^{A}\right) = u_{0}{}^{A} + \xi\Delta u_{0} \tag{12}$$

Where the superscripts A and M represent the austenite and martensite phases, respectively. The symbol Δ denotes the difference of the corresponding material parameter between the martensite and austenite phases.

In particular, the term $f(\xi,\dot{\xi})$ is the transformation hardening function which is used to account for the interactions between the austenite phase and the martensite phase. In this work, a nonlinear transformation hardening model is established:

$$f(\xi,\dot{\xi}) = \left\{a\left[1-\mathrm{sgn}\left(\dot{\xi}\right)\right] + b\left[1+\mathrm{sgn}\left(\dot{\xi}\right)\right]\right\}\left[\left(\frac{\xi}{2}\right)^{2} + \frac{\left(\xi - 1/2\right)^{4}}{2} + \frac{\xi}{4}\right] \tag{13}$$

Where a and b are constitutive model parameters for transformation hardening and they are related to material constants. The function sgn(·) is a signum function of a real number m, it is defined as follow:

$$\mathrm{sgn}(m) = \begin{cases} 1 & \text{if } m > 0 \\ 0 & \text{if } m = 0 \\ -1 & \text{if } m < 0 \end{cases} \tag{14}$$

3.3. Thermodynamic force and constitutive relation

Following the formalism of Truesdell and Noll [25], the Helmoltz free energy ψ and the internal energy u are substituted into the first and second law of thermodynamics to derive thermodynamic constraints on the state of the system resulting in the following constitutive relation:

$$\sigma = \rho \frac{\partial \psi}{\partial \varepsilon} = E\left(\varepsilon - \varepsilon^{\mathrm{t}} - \varepsilon^{\mathrm{p}}\right) \tag{15}$$

Similarly, thermodynamic force X, which is conjugate to the martensite volume fraction ξ, is given:

$$X = -\rho \frac{\partial \psi}{\partial \xi} = -\left[\frac{1}{2}\Delta E\left(\varepsilon - \varepsilon^{\mathrm{t}} - \varepsilon^{\mathrm{p}}\right)^2 - \sigma \frac{d\varepsilon^{\mathrm{t}}}{d\xi} + \rho\left(\Delta u_0 - \Delta \eta_0 T\right) + \frac{df}{d\xi}\right] \tag{16}$$

As assumed in Section 2, the accumulation of plastic strain ε^{p} and the reduction of maximum transformation strain $\varepsilon^{\mathrm{t}}_{\max}$ only occur during A→M$^{\mathrm{d}}$. Therefore, the thermodynamic force Q, which accounts for the evolution of ε^{p} and $\varepsilon^{\mathrm{t}}_{\max}$, is conjugate to the cumulated martensite volume fraction ξ^{ac}. Similar to thermodynamic force X, it can be expressed as:

$$Q = -\rho \frac{\partial \psi}{\partial \xi^{\mathrm{ac}}} = \rho\left(\frac{d\varepsilon^{\mathrm{p}}}{d\xi^{\mathrm{ac}}} + \frac{d\varepsilon^{\mathrm{t}}}{d\xi^{\mathrm{ac}}}\right) \tag{17}$$

3.4. Transformation functions and Kuhn-Tucker inequalities

Borrowed from yield functions in the classical theory of plasticity, transformation functions associated with A→M$^{\mathrm{d}}$ and M$^{\mathrm{d}}$→A are defined as:

$$F^{+} = X + Q - R^{+} \quad \text{when } \dot{\xi} > 0 \quad \text{For the phase transformation: A}\rightarrow\text{M}^{\mathrm{d}} \tag{18}$$

$$F^{-} = -X + Q - R^{-} \quad \text{when } \dot{\xi} < 0 \quad \text{For the phase transformation: M}^{\mathrm{d}}\rightarrow\text{A} \tag{19}$$

Where the constitutive model parameters R^{+} and R^{-} are the radius of the respective transformation domains.

Constraints on the evolution of the martensite volume fraction for the forward and reverse phase transformations are expressed in terms of the Kuhn-Tucker inequalities:

$$\begin{cases} \dot{\xi} \geq 0 \quad F^{+} \leq 0 \quad \dot{\xi} F^{+} = 0 & \text{For the phase transformation: A} \rightarrow \text{M}^{\mathrm{d}} \\ \dot{\xi} \geq 0 \quad F^{-} \leq 0 \quad \dot{\xi} F^{-} = 0 & \text{For the phase transformation: M}^{\mathrm{d}} \rightarrow \text{A} \end{cases} \tag{20}$$

3.5. Evolution laws

Following Eq. (6), the evolution law for the transformation strain ε^{t} can be got:

$$\dot{\varepsilon} = \varepsilon_{\max} \dot{\xi} \tag{21}$$

It is concluded from the experimental results that the material parameter: maximum transformation strain $\varepsilon_{\max}$, varies as an exponential function of the cycle number, as shown in Fig. 2. Furthermore, as explained in Section 3.1.2, $\varepsilon_{\max}$ is assumed to vary only in A→M$^{\mathrm{d}}$, which implies that $\varepsilon_{\max}$ changes as an exponential function of ξ^{ac}. Therefore, from a theoretical point of view, a non-constant material parameter $\varepsilon_{\max}$ can be defined using the evolution law:

$$\dot{\varepsilon}_{\max} = m6\varepsilon^{t}_{\max} e^{-\xi^{ac} m6} \dot{\xi}^{c} \tag{22}$$

Analogous to $\varepsilon_{\max}$, evolution laws of $\varepsilon^{p}_{\max}$ and four material parameters: M_s, M_f, A_s and A_f are given:

$$\dot{\varepsilon}^{p}_{\max} = m5\varepsilon^{p}_{\max} e^{-\xi^{ac} m5} \dot{\xi}^{c} \tag{23}$$

$$M_s = M_{s0} - M_{s\max}\left(1 - e^{-\xi^{c} m1}\right) \tag{24}$$

$$M_f = M_{f0} - M_{f\max}\left(1 - e^{-\xi^{c} m2}\right) \tag{25}$$

$$A_s = A_{s0} - A_{s\max}\left(1 - e^{-\xi^{c} m3}\right) \tag{26}$$

$$A_f = A_{f0} - A_{f\max}\left(1 - e^{-\xi^{c} m4}\right) \tag{27}$$

Where $\varepsilon^{t}_{\max}$, $\varepsilon^{p}_{\max}$, M_{fmax}, M_{smax}, A_{fmax} and A_{smax} denote saturation values of $\varepsilon_{\max}$, ε_p, M_f, M_s, A_f and A_s due to cyclic loading, which can be got through isothermal stress cycling experiments. The variables $m1$~$m6$ can be obtained from the experimental curves by nonlinear fitting method.

So far, the constitutive model of SMAs taking into account the function degradation caused by isothermal stress cyclic loading has been fully established. In the following section, numerical simulations will be performed to verify the proposed model.

4. Simulated results and discussions

To show the model's capability of simulating the macroscopic behaviour of SMA material under isothermal stress cycling, we performed a cyclic tensile test at 5.5% strain amplitude under 27.5 ^{o}C for a SMA wire. Fig. 5 illustrates cyclic stress vs. strain response of the SMA wire for 10 cycles. Numerical simulations are obtained using the constitutive model proposed in this work, and the related material parameters are shown in Table 1. The simulated cyclic stress vs. strain response is shown in Fig. 6. From Fig. 5 and Fig. 6, it may be noticed that the model is able to simulate correctly the main characteristics of the isothermal stress cyclic response of a SMA wire. In particular, the stress vs. strain curves for the 1st, 4th and 10th cycles are shown in Fig. 7 and good agreements between experimental and simulated results are observed.

Table 1. Material parameters used in the constitutive model.

General material parameters	Values	Cyclic material parameters	Values
E^{A}	42200 MPa	M_{smax}	21 K
E^{M}	23500 MPa	M_{fmax}	1.5 K
$\Delta\eta_0$	– 17.77 J /(kg·K)	A_{smax}	0 K
Δu_0	– 20 J /kg	A_{fmax}	0 K
c	4×10^{6} J /(kg·K)	$\varepsilon^{t}_{\max}$	0.0121
ρ	6.5×10^{-9} kg/m^3	$\varepsilon^{p}_{\max}$	0.0141
$A_s(0)$	274K	$m1$	0.14
$A_f(0)$	300 K	$m2$	0.98
$M_s(0)$	270 K	$m3$	0.081
$M_f(0)$	232 K	$m4$	0.05
C_A	9.4 MPa/K	$m5$	0.271
C_M	6.7 MPa/K	$m6$	0.23
$\varepsilon_{\max}(0)$	0.0348		

In order to further investigate the ability of the model to predict the evolution of $\varepsilon_{\max}$, ε^{p} and four

transformation temperatures, the corresponding experimental results are compared with simulated results, as shown in Figs. 8 and 9. It can be seen from these figures that for the evolution of ε_{max}, ε^{p}, M_s, M_f and A_f, the experimental and simulated results are close to each other. However, for the evolution of A_s, a certain disagreement occurs, which can perhaps be explained that A_s indeed does not evolve exponentially with respect to the cycle number.

5. Conclusions and future work

A new 1-D phenomenological model of SMA taking into account the evolution of the plastic strain, maximum transformation strain and transformation temperatures during isothermal stress cycling was introduced in this paper. Since different phase transformation has different influence in the cyclic behaviour, the cumulated martensite volume fraction ξ^{c} was decomposed into ξ^{ac} and ξ^{mc} to account for cyclic effects during corresponding transformation processes. Non-constant material parameters including maximum transformation strain and four transformation temperatures are used. Evolution laws for the non-constant material parameters and plastic strain were established to depict the evolution of maximum transformation strain, transformation temperatures and plastic strain under cyclic loading. Experimental verifications were given and the results showed that the model was able to quantitatively capture the effect of isothermal stress cyclic loading. However, the model cannot simulate the evolution of A_s correctly, which maybe attribute to that A_s actually evolves with a non-experimental function. As a result, future work will introduce a new evolution law for A_s based on experimental studies.

Abstract A plane strain problem for two magnetoelectroelastic (MEE) half-planes adhered by a thin isotropic interlayer is considered. A novel crack model, i.e., a magnetoelectrically permeable interface crack with pre-fracture zones is introduced for MEE bimaterial system. The stresses in pre-fracture zones and the lengths of pre-fracture zones are unknown, which are determined by solving the corresponding Hilbert problem and solving nonlinear equations introduced by yielding condition on the pre-fracture zones. Some particular cases are further analyzed and numerically discussed. In the suggested model, any singularities connected with the crack are eliminated, and the results presented in this paper should have potential applications to the design of multilayered MEE structures and devices.

Keywords Pre-fracture zone, Interface crack, Magnetoelectrically permeable, Magnetoelectroelastic plane

1. Introduction

Magnetoelectroelastic (MEE) materials have been widely used in electronics industry. In the design of MEE structures, it is important to take into account the defects/imperfections, such as cracks, which are often pre-existing or are generated by external loads during the service life. Therefore, in recent years, research on fracture mechanics of MEE materials has drawn a lot of interest, and lots of achievements have been made for two-dimensional (2-D) internal crack problems [1-5] and 2-D interface crack problems [6-8]. It is noted that in the works of [7] and [8], the contact zone model is firstly extended to interface crack problems of MEE materials.

However, all the above-mentioned works related to interface crack problems, the singularity behavior on the crack tips always exists. On the other hand, two kinds of MEE materials, as well known, generally cannot be connected directly. Thus, in this study, a novel interface crack model for MEE bimaterial, i.e., the model of interface crack with pre-fracture zones is put forward. For simplicity, the interface is assumed to be magnetoelectrically permeable. The problem is reduced to solve a Hilbert problem and two nonlinear equations introduced by Mises yielding condition. The particular cases of symmetric loads and identical MEE material are further analyzed, and some numerical results are presented. These obtained results and/or conclusions could be of interest to the analysis and design of smart sensors/actuators constructed from MEE composite laminates.

2. Statement of the problem

Referring to Ref. [9], it is assumed that the MEE half-spaces are adhered by means of an isotropic interlayer with shear modulus μ, Poison's ratio ν and yield limit σ_{Y}. Furthermore, the half-spaces are assumed to be loaded at infinity with uniform stresses $\sigma_{33}^{(m)}=\sigma_0$, $\sigma_{31}^{(m)}=\tau_0$, uniform electrical displacement $D_3^{(m)}=d_0$ and magnetic induction $B_3^{(m)}=b_0$ (m=1 stands for the upper domain, and m=2 for the lower one). In this paper, although the interlayer thickness will not be taken into account as usual, the properties of the interlayer and its influence upon the fracture process will be considered by means of introduction of pre-fracture zones with cohesive stresses. As shown in Fig. 1, the pre-fracture zones are, respectively, denoted by $[a_1, a]$ and $[b, b_1]$, and the

open part of the crack is denoted by $[a, b]$.

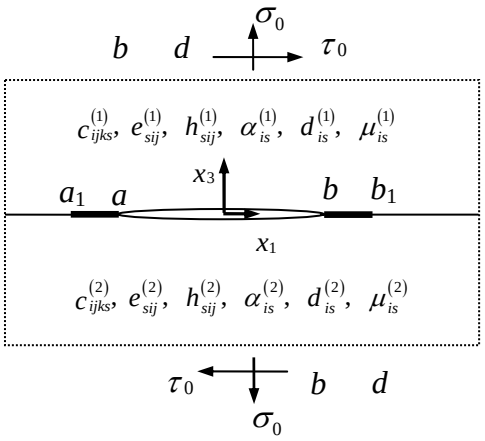

Figure 1. An interface crack with pre-fracture zones between two semi-infinite MEE planes

Assume that the MEE materials are poled in the x_3-direction. As pointed out before [8], the displacement u_2 decouples in the $(x_1, x_3)-$plane from the displacement components u_1, u_3, electrical potential φ and magnetic potential ϕ. And in present study, our attention will be focused only on the generalized plane strain problem for the components u_1, u_3, φ and ϕ. Thus, for the considered magnetoelectrically permeable interface crack, the continuity and boundary conditions at the interface can be written in the form

$$\left[[u_1],\ [u_3],\ [\varphi],\ [\phi]\right]^{\mathrm{T}} = \mathbf{0},\ \left[[\sigma_{31}],\ [\sigma_{33}],\ [D_3],\ [B_3]\right]^{\mathrm{T}} = \mathbf{0},\ x_1 \notin (a,b), \tag{1}$$

$$[\varphi] = 0,\ [D_3] = 0,\ [\phi] = 0,\ [B_3] = 0,\ x_1 \in (a,b), \tag{2}$$

$$\sigma_{33}^{(m)}(x_1,0) \equiv p_1(x_1) = \begin{cases} \sigma' & x_1 \in [a_1, a], \\ \sigma, & x_1 \in [b, b_1], \\ 0, & x_1 \in [a, b], \end{cases} \quad \sigma_{31}^{(m)}(x_1,0) \equiv p_2(x_1) = \begin{cases} \tau' & x_1 \in [a_1, a], \\ \tau, & x_1 \in [b, b_1], \\ 0, & x_1 \in [a, b], \end{cases} \tag{3}$$

where T denotes transposition, $[\Pi] = \Pi(x_1 + \mathrm{i}0) - \Pi(x_1 - \mathrm{i}0)\ (\Pi = u_1, u_3, \text{etc.})$, and the values σ, τ, σ' and τ' are unknown to be determined.

In addition, as pointed out in Ref. [9], because the interlayer is usually much softer than the MEE materials, the interlayer yielding or damage will appear firstly. Thus, some law of interlayer material yielding or damage, for example, $f(\sigma, \tau, \sigma_1) = 0$ for the right pre-fracture zone and $f(\sigma', \tau', \sigma_1') = 0$ for the left pre-fracture zone, respectively, should be satisfied. For simplicity, $\sigma_1 = \sigma_1' = 2\sigma_{\mathrm{Y}}$ are assumed in present study [9].

Up till now, boundary conditions (i.e., Eqs. (1-3)) together with the known governing equations (see Ref. [8]) have formulated a plane strain problem of linear fracture mechanics for a crack $[a_1, b_1]$ between two half-planes, where the components σ, τ, σ' and τ' at the crack faces and the positions of point a_1 and b_1 are all unknown to be determined.

3. The magnetoelectroelastic solution

From the early work [8], it is known that for the case of plane strain, the following expressions at

the interface hold true:

$$\mathbf{V}'(x_1)=\left[V_1',\ \ V_3',\ \ V_4',\ \ V_5'\right]^{\mathrm{T}}=\left[u_1'(x_1),u_3'(x_1),\varphi'(x_1),\phi'(x_1)\right]^{\mathrm{T}}=\mathbf{W}^{+}(x_1)-\mathbf{W}^{-}(x_1),$$

$$\mathbf{t}^{(1)}(x_1,0)=\left[\sigma_{31}^{(1)},\ \ \sigma_{33}^{(1)},\ \ D_3^{(1)},\ \ B_3^{(1)}\right]^{\mathrm{T}}=\mathbf{G}\mathbf{W}^{+}(x_1)-\bar{\mathbf{G}}\mathbf{W}^{-}(x_1),$$

where $\mathbf{W}(z)=\left[W_1(z),\ \ W_3(z),\ \ W_4(z),\ \ W_5(z)\right]^{\mathrm{T}}$ is an introduced unknown vector function, and $\mathbf{W}^{+}(x_1)=\mathbf{W}(x_1+\mathrm{i}0)$, $\mathbf{W}^{-}(x_1)=\mathbf{W}(x_1-\mathrm{i}0)$; the matrix $\mathbf{G}$ has been given in Ref. [8].

Considering that the crack is magnetoelectrically permeable, and that $\mathbf{t}^{\infty}=\mathbf{t}^{(1)}(x_1,0)\big|_{x_1\to\infty}=\left(\mathbf{G}-\bar{\mathbf{G}}\right)\mathbf{W}(z)\big|_{z=x_1+\mathrm{i}x_3\to\infty}$ with $\mathbf{t}^{\infty}=\left\{\tau_0,\ \ \sigma_0,\ \ d_0,\ \ b_0\right\}^{\mathrm{T}}$, we easily get

$$W_4=\left\{\left(\mathbf{G}-\bar{\mathbf{G}}\right)^{-1}\mathbf{t}^{\infty}\right\}_3,\ \ W_5=\left\{\left(\mathbf{G}-\bar{\mathbf{G}}\right)^{-1}\mathbf{t}^{\infty}\right\}_4.$$

Taking into account that $W_4(z)=\mathrm{const}$ and $W_5(z)=\mathrm{const}$ and noting the structure of **G**, we can further obtain

$$\sigma_{33}^{(1)}(x_1,0)+\mathrm{i}\,m_j\sigma_{31}^{(1)}(x_1,0)=t_j\left[\Phi_j^{+}(x_1)+\gamma_j\Phi_j^{-}(x_1)\right],\tag{4}$$

$$\left[u_1'(x_1)\right]+\mathrm{i}s_j\left[u_3'(x_1)\right]=\Phi_j^{+}(x_1)-\Phi_j^{-}(x_1).\tag{5}$$

where

$$\Phi_j(z)=\Omega_j(z)+\Phi_j^0,\ \ \Phi_j^0=\frac{2\mathrm{i}\left(g_{34}W_4+g_{35}W_5\right)}{t_j\left(1+\gamma_j\right)},\quad j=1,3,$$

$$\Omega_j(z)=W_1(z)+\mathrm{i}\,s_jW_3(z),\quad \gamma_j=-\frac{g_{31}+m_jg_{11}}{t_j},\ \ t_j=g_{31}-m_jg_{11},\quad j=1,3,$$

$$\left[u_1'\right]=W_1^{+}-W_1^{-},\ \ m_{1,3}=\mathrm{m}\sqrt{-\frac{g_{31}g_{33}}{g_{11}g_{13}}},\ s_{1,3}=-m_{1,3},$$

and g_{ij} are the elements of **G**.

Considering that $\Phi_j^{+}(x_1)=\Phi_j^{-}(x_1)=\Phi_j(x_1)$ for $x_1\notin(a_1,b_1)$, it follows from Eq. (4) that

$$\Phi_j(z)\big|_{z\to\infty}=\left(\sigma_0+\mathrm{i}\,m_j\tau_0\right)\big/t_j\left(1+\gamma_j\right).\tag{6}$$

Using Eq. (4) for $j=1$ and the corresponding interface conditions (3) yields the following Hilbert problem

$$\Phi_1^{+}(x_1)+\gamma_1\Phi_1^{-}(x_1)=P(x_1)/t_1,\quad x_1\in(a_1,b_1),\tag{7}$$

where

$$P(x_1)=p_1(x_1)+\mathrm{i}m_1p_2(x_1).$$

The solution of Eq. (7) satisfying Eq. (6) can be expressed as

$$\Phi_1(z)=\frac{1}{2\pi\,\mathrm{i}\,X(z)}\left[C_0+C_1z+\frac{1}{t_1}\int_{a_1}^{b_1}\frac{P(t)X^{+}(t)}{t-z}\mathrm{d}t\right],\tag{8}$$

where

$$X(z)=(z-a_1)^{0.5-\mathrm{i}\varepsilon}(z-b_1)^{0.5+\mathrm{i}\varepsilon},$$

$$C_0=-2\pi\mathrm{i}\frac{\sigma_0+\mathrm{i}m_1\tau_0}{t_1\left(1+\gamma_1\right)}\left(\frac{a_1+b_1}{2}+\mathrm{i}\varepsilon l_1\right),\ \ C_1=2\pi\mathrm{i}\frac{\sigma_0+\mathrm{i}m_1\tau_0}{t_1\left(1+\gamma_1\right)},\varepsilon=\ln\gamma_1/2\pi,\ \ l_1=b_1-a_1.$$

Substituting Eq. (8) into Eq. (4) and noting that $\Phi_j^{+}(x_1)=\Phi_j^{-}(x_1)=\Phi_j(x_1)$ for $x_1\notin(a_1,b_1)$, the following relation at the interface can be derived

$$\sigma_{33}^{(1)}\left(x_1,0\right)+\mathrm{i}\,m_1\sigma_{31}^{(1)}\left(x_1,0\right)=\frac{1}{2\pi\,\mathrm{i}\,X\left(x_1\right)}\left\{2\pi\,\mathrm{i}\left(x_1-\frac{a_1+b_1}{2}-\mathrm{i}\,\varepsilon l_1\right)\left(\sigma_0+\mathrm{i}m_1\tau_0\right)+\right.$$
$$\left.\left(1+\gamma_1\right)\left[\left(\sigma'+\mathrm{i}\,m_1\tau'\right)\int_{a_1}^{a}\frac{X^{+}\left(t\right)}{t-x_1}\mathrm{d}\,t+\left(\sigma+\mathrm{i}m_1\tau\right)\int_{b}^{b_1}\frac{X^{+}\left(t\right)}{t-x_1}\mathrm{d}\,t\right]\right\}. \tag{9}$$

Noting the finiteness of the stresses at the point a_1 and b_1, we can further obtain the following system of linear algebraic equations

$$\begin{Bmatrix}\sigma'+\mathrm{i}m_1\tau'\\ \sigma+\mathrm{i}m_1\tau\end{Bmatrix}=\frac{\pi\,\mathrm{i}\,l_1}{1+\gamma_1}\left(\sigma_0+\mathrm{i}m_1\tau_0\right)\left[\mathbf{N}\right]^{-1}\begin{Bmatrix}1+2\,\mathrm{i}\,\varepsilon\\ -\left(1-2\,\mathrm{i}\,\varepsilon\right)\end{Bmatrix}, \tag{10}$$

where the components of matrix $\mathbf{N}=\left[N_{ij}\right]\left(i,j=1,2\right)$ have the following form

$$N_{11}=\int_{a_1}^{a}\left[\left(t-b_1\right)/\left(t-a_1\right)\right]^{0.5+\mathrm{i}\varepsilon}\mathrm{d}\,t,\quad N_{12}=\int_{b}^{b_1}\left[\left(t-b_1\right)/\left(t-a_1\right)\right]^{0.5+\mathrm{i}\varepsilon}\mathrm{d}\,t, \tag{11a}$$

$$N_{21}=\int_{a_1}^{a}\left[\left(t-a_1\right)/\left(t-b_1\right)\right]^{0.5-\mathrm{i}\varepsilon}\mathrm{d}\,t,\quad N_{22}=\int_{b}^{b_1}\left[\left(t-a_1\right)/\left(t-b_1\right)\right]^{0.5-\mathrm{i}\varepsilon}\mathrm{d}\,t. \tag{11b}$$

For the sake of simplicity to calculate, Eq. (11) can be further approximated (see Ref. [9]).

After substituting Eq. (10) into yielding conditions, a system of nonlinear equations is then derived as

$$\Psi_i\left(\Delta_a,\Delta_b,\sigma_0,\tau_0\right)=0\quad i=1,2, \tag{12}$$

where $\Delta_a=a-a_1$ and $\Delta_b=b_1-b$ are the pre-fracture zone lengths.

Using Eq. (5), (7) and using (8), one arrives at the following equation on displacement jumps

$$\left[u_1\left(x_1\right)\right]+\mathrm{i}s_1\left[u_3\left(x_1\right)\right]=\frac{1}{2\pi\,\mathrm{i}\,\gamma_1 t_1}\left\{2\pi\,\mathrm{i}\left(\sigma_0+\mathrm{i}m_1\tau_0\right)\left(x_1-a_1\right)^{0.5-\mathrm{i}\varepsilon}\left(x_1-b_1\right)^{0.5+\mathrm{i}\varepsilon}+\right.$$
$$\left.\left(1+\gamma_1\right)\left[\left(\sigma'+\mathrm{i}m_1\tau'\right)J_1\left(x_1\right)+\left(\sigma+\mathrm{i}m_1\tau\right)J_2\left(x_1\right)\right]\right\}-\frac{1-\gamma_1}{2\gamma_1 t_1}h\left(x_1\right), \tag{13}$$

where

$$J_1\left(x_1\right)=\int_{a_1}^{x_1}\frac{1}{X\left(v\right)}\int_{a_1}^{a}\frac{X^{+}\left(t\right)}{t-v}\mathrm{d}\,t\,\mathrm{d}\,v,\ J_2\left(x_1\right)=\int_{a_1}^{x_1}\frac{1}{X\ \left(v\right)}\int_{b}^{b_1}\frac{X^{+}\left(t\right)}{t-v}\mathrm{d}\,t\,\mathrm{d}\,v,h\left(x_1\right)=\int_{a_1}^{x_1}P\left(t\right)\mathrm{d}\,t.$$

The integral for $h_1\left(x_1\right)$ can be calculated analytically, and the integrals for $J_1\left(x_1\right)$ and $J_2\left(x_1\right)$ can be presented via hyper-geometric functions. As well known, for a real MEE bimaterial, ε is very small [6] and the influence of the oscillation on the value of $J_1\left(x_1\right)$ and $J_2\left(x_1\right)$ is negligibly small. Therefore by assuming $\varepsilon=0$ in evaluating $J_1\left(x_1\right)$ and $J_2\left(x_1\right)$, one gets [9]

$$J_1\left(x_1\right)\approx J_{10}\left(x\right)=\cos^{-1}\left(\alpha_1\right)\sqrt{\left(x-a_1\right)\left(b_1-x\right)}+\frac{x-a}{2}H\left(a_1,b_1,x,a\right),$$

$$J_2\left(x_1\right)\approx J_{20}\left(x\right)=\cos^{-1}\left(\alpha_1\right)\sqrt{\left(x-a_1\right)\left(b_1-x\right)}-\frac{x-b}{2}H\left(a_1,b_1,x,b\right),$$

where $\alpha_1=\left(b_1+a_1-2a\right)/l_1$, and $H\left(a,b,x,\xi\right)$ is a known function given in [9].

Thus, Eq. (13) can be rewritten as

$$\left[u_1\left(x_1\right)\right]+\mathrm{i}s_1\left[u_3\left(x_1\right)\right]=\left(\sigma_0+\mathrm{i}\,m_1\tau_0\right)\left(x_1-a_1\right)^{0.5-\mathrm{i}\varepsilon}\left(x_1-b_1\right)^{0.5+\mathrm{i}\varepsilon}/\gamma_1 t_1+$$
$$\left(1+\gamma_1\right)\left[\left(\sigma'+\mathrm{i}\,m_1\tau'\right)J_{10}\left(x_1\right)+\left(\sigma+\mathrm{i}\,m_1\tau\right)J_{20}\left(x_1\right)\right]/2\pi\,\mathrm{i}\,\gamma_1 t_1-h\left(x_1\right)\left(1-\gamma_1\right)/2\gamma_1 t_1. \tag{14}$$

Crack opening displacements (COD) at the initial crack tips are defined as follows

$$\delta_1^a=\left[u_1\left(a\right)\right],\quad \delta_3^a=\left[u_3\left(a\right)\right],\quad \delta_1^b=\left[u_1\left(b\right)\right],\quad \delta_3^b=\left[u_3\left(b\right)\right]. \tag{15}$$

After substituting $x_1 = a, b$, respectively, into the expressions of $\left[u_1(x_1)\right]$, $\left[u_3(x_1)\right]$ and the COD in Eq. (15) will be then acquired as well. In addition, carrying out a similar derivation to the one given in [9], the expressions for the electrical displacement and magnetic induction at different segments of the interface can be easily obtained (omitted here).

It is remarked that both the electrical displacement $D_3^{(1)}(x_1, 0)$ and magnetic induction $B_3^{(1)}(x_1, 0)$ are not singular as well at either the initial crack tips or the points a_1 and b_1. Thus, the proposed model removes singularities in all components of the magnetoelectromechanical field. On the other hand, it should be pointed out that both the electrical displacement and magnetic induction in the pre-fracture zone are not only directly related to the material parameters of MEE bimaterial and the applied tension load, but also related to $\left[u_1'(x_1)\right]$ and the normal stress in the pre-fracture zone, and that the electrical displacement in the pre-fracture zone depends on the applied electrical load, and magnetic induction on magnetic load. However, both the normal and shear stresses in the pre-fracture zone are independent of the applied magnetoelectrical load.

4. Simplified case of symmetrical loads

For the case of symmetrical loads, i.e., $\tau_0 \equiv 0$, placing the apex of the coordinate system in the middle point of the crack, one has $a = -b$, $a_1 = -b_1$, $\tau' = -\tau$, $\sigma' = \sigma$. In Eq. (10), only one of the equations is necessary, which can be expressed as

$$\left(\sigma - \mathrm{i}\, m_1 \tau\right) N_{21}^{sym} + \left(\sigma + \mathrm{i}\, m_1 \tau\right) N_{22}^{sym} = -\frac{2\pi \mathrm{i}\, b_1}{1+\gamma_1} \sigma_0 \left(1 - 2\mathrm{i}\,\varepsilon\right). \tag{16}$$

where

$$N_{21}^{sym} = \frac{1}{1.5 - \mathrm{i}\,\varepsilon}\left(-2b_1\right)^{-0.5+\mathrm{i}\varepsilon}\left(b_1 - b\right)^{1.5-\mathrm{i}\varepsilon}, \quad N_{22}^{sym} = -\frac{1}{0.5 + \mathrm{i}\,\varepsilon}\left(2b_1\right)^{0.5-\mathrm{i}\varepsilon}\left(b - b_1\right)^{0.5+\mathrm{i}\varepsilon}.$$

Extracting the real and imaginary parts of Eq. (16), we arrive at the system of linear algebraic equations with respect to σ and τ. The solution of the obtained system can be expressed as

$$\sigma = r m_1 \sigma_0 \left(2\varepsilon a_{22} - a_{12}\right), \quad \tau = r \sigma_0 \left(2\varepsilon a_{21} + a_{11}\right), \tag{17}$$

where the expressions for r and $a_{ij}(i, j = 1, 2)$ are the same as those given in [9]. It is worth noting that the values of r, a_{ij} and consequently σ and τ all depend on the pre-fracture zone length $g = b/b_1$.

Substituting Eq. (17) into the second equation of Eq. (12) and taking into account that $\Delta_a = \Delta_b$ in the considered case, one arrives at a transcendental equation with respect to g as follows

$$\left[m_1\left(2\varepsilon a_{22} - a_{12}\right) - \frac{\sigma_1}{r\sigma_0}\right]^2 + 4\left(2\varepsilon a_{21} + a_{11}\right)^2 = \frac{4}{3r^2}\left(\frac{\sigma_Y}{\sigma_0}\right)^2,$$

where the Mises yielding condition $f(\sigma, \tau, \sigma_1) \equiv \left(\sigma - \sigma_1\right)^2 + 4\tau^2 - \frac{4}{3}\sigma_Y^2 = 0$ and $\sigma_1 = 2\sigma_Y$ are used [9].

From Eq. (14), the displacement jumps for $x_1 \in \left(-b_1, b_1\right)$ can be then obtained as

$$\begin{aligned}\left[u_1(x_1, 0)\right] + \mathrm{i}\, s_1 \left[u_3(x_1, 0)\right] \approx{}& \sigma_0 \left(x_1 + b_1\right)^{0.5-\mathrm{i}\varepsilon}\left(x_1 - b_1\right)^{0.5+\mathrm{i}\varepsilon} \Big/ \gamma_1 t_1 \\ &+ \left(1+\gamma_1\right)\left[\left(\sigma - \mathrm{i}\, m_1 \tau\right) J_{10}^{sym}(x_1) + \left(\sigma + \mathrm{i}\, m_1 \tau\right) J_{20}^{sym}(x_1)\right] \Big/ 2\pi \mathrm{i}\, \gamma_1 t_1 - h(x_1)\left(1 - \gamma_1\right)/2\gamma_1 t_1,\end{aligned}$$

where $J_{i0}^{sym}(x_1) = J_{i0}(x_1)(i = 1, 2)$ with $a = -b$, $a_1 = -b_1$. And the electrical displacement and magnetic induction can be expressed as

$$D_3^{(1)}(x_1,0)=-\gamma_{43}\gamma_{33}^{-1}\sigma_0+d_0+\begin{cases}\eta_1\left[u_1'(x_1)\right]+\gamma_{43}\gamma_{33}^{-1}\sigma, & x_1\in(a_1,a)\cup(b,b_1),\\ \eta_1\left[u_1'(x_1)\right], & x_1\in(a,b),\\ \gamma_{43}\gamma_{33}^{-1}\sigma_{33}^{(1)}(x_1,0), & x_1\notin(a_1,b_1),\end{cases}$$

$$B_3^{(1)}(x_1,0)=-\gamma_{53}\gamma_{33}^{-1}\sigma_0+b_0+\begin{cases}\eta_2\left[u_1'(x_1)\right]+\gamma_{53}\gamma_{33}^{-1}\sigma, & x_1\in(a_1,a)\cup(b,b_1),\\ \eta_2\left[u_1'(x_1)\right], & x_1\in(a,b),\\ \gamma_{53}\gamma_{33}^{-1}\sigma_{33}^{(1)}(x_1,0), & x_1\notin(a_1,b_1),\end{cases}$$

where $\eta_1=\gamma_{41}-\gamma_{43}\gamma_{31}/\gamma_{33}$, $\eta_2=\gamma_{51}-\gamma_{53}\gamma_{31}/\gamma_{33}$.

5. Case of equivalent properties of the upper and lower bimaterial components

In this case, $\gamma_1=1$, $\varepsilon=0$ hold true and Eq. (9) takes the form

$$\begin{aligned}\sigma_{33}^{(1)}(x_1,0)+\mathrm{i}m_1\sigma_{31}^{(1)}(x_1,0)=&\frac{\sigma_0+\mathrm{i}m_1\tau_0}{X_0(x_1)}\left(x_1-\frac{a_1+b_1}{2}\right)+\\&+\frac{1}{\pi\mathrm{i}\,X_0(x_1)}\left[(\sigma'+\mathrm{i}m_1\tau')\int_{a_1}^{a}\frac{X_0^+(t)}{t-x_1}\mathrm{d}t+(\sigma+\mathrm{i}m_1\tau)\int_{b}^{b_1}\frac{X_0^+(t)}{t-x_1}\mathrm{d}t\right],\quad x_1\notin(a_1,b_1),\end{aligned}\tag{18}$$

where $X_0(z)=\sqrt{(z-a_1)(z-b_1)}$.

Using Eq. (10), the pre-fracture zone stresses can be calculated by the following formula

$$\begin{Bmatrix}\sigma'+\mathrm{i}m_1\tau'\\ \sigma+\mathrm{i}m_1\tau\end{Bmatrix}=\frac{\pi\mathrm{i}l_1}{2}(\sigma_0+\mathrm{i}m_1\tau_0)\mathbf{N}^{-1}\begin{Bmatrix}1\\-1\end{Bmatrix}.$$

Components of the matrix **N** can be written exactly as

$$N_{11}=\mathrm{i}\frac{l_1}{2}\left[\sqrt{1-\alpha_1^2}+\cos^{-1}(\alpha_1)\right],\qquad N_{12}=\mathrm{i}\frac{l_1}{2}\left[\cos^{-1}(\alpha_2)-\sqrt{1-\alpha_2^2}\right],$$

$$N_{21}=\mathrm{i}\frac{l_1}{2}\left[\sqrt{1-\alpha_1^2}-\cos^{-1}(\alpha_1)\right],\qquad N_{22}=-\mathrm{i}\frac{l_1}{2}\left[\cos^{-1}(\alpha_2)+\sqrt{1-\alpha_2^2}\right],$$

where $\alpha_2=(2b-b_1-a_1)/l_1$.

For this case, the expression for the displacement jump has the following form

$$\begin{aligned}\left[u_1(x_1,0)\right]+\mathrm{i}s_1\left[u_3(x_1,0)\right]=&(\sigma_0+\mathrm{i}m_1\tau_0)\sqrt{(x_1-a_1)(x_1-b_1)}/t_1\\&+\left[(\sigma'+\mathrm{i}m_1\tau')J_{10}(x_1)+(\sigma+\mathrm{i}m_1\tau)J_{20}(x_1)\right]/\pi\mathrm{i}t_1,\quad x_1\in(a_1,b_1).\end{aligned}\tag{19}$$

And δ_1^a, δ_3^a, δ_1^b and δ_3^b can then be obtained easily.

In this case of homogeneous material with symmetrical loading, one has $\tau=\tau'=0$ and $\sigma'=\sigma$. In the coordinate system with apex in the middle of the crack, $\sigma_{31}^{(1)}(x_1,0)=0$, $a=-b$, $a_1=-b_1$ hold true. And only one equation of Dugdale –type $\sigma=\sigma_c$ [10] can be considered. In addition, according to the von Mises yielding condition given before, σ_c is related to the material parameters of interlayer, which can be taken as $2\left(1+1/\sqrt{3}\right)\sigma_{\mathrm{Y}}$. Furthermore, for this case $\alpha_2=\alpha_1=b/b_1$ and Eq. (18) can be reduced as

$$\sigma_{33}^{(1)}(x_1,0)=\frac{1}{\sqrt{x_1^2-b_1^2}}\left\{\sigma_0x_1+\frac{\sigma_c}{\pi\mathrm{i}}\left(\int_{-b_1}^{-b}+\int_{b}^{b_1}\right)\frac{\sqrt{t^2-b_1^2}}{t-x_1}\mathrm{d}t\right\},\quad x_1\notin(a_1,b_1).\tag{20}$$

By setting the expression in the brackets to zero, one gets the following equation

$$\frac{b}{b_1}=\cos\frac{\pi\sigma_0}{2\sigma_c}. \tag{21}$$

Thus, the pre-fracture zone length can easily be determined from Eq. (21). By the way, it is easily known that for internal crack problem of identical MEE material, although the length of pre-fracture zone depends on σ_0, σ in the pre-fracture zone is independent of it.

It is worth noting that after evaluating the integrals in Eq. (20) and using (21), one gets [9]

$$\sigma_{33}^{(1)}\left(x_1,0\right)=\sigma_c+\frac{\sigma_c}{\pi}\left[\sin^{-1}\frac{b_1^2-x_1b}{b_1\left(x_1-b\right)}-\sin^{-1}\frac{b_1^2+x_1b}{b_1\left(x_1+b\right)}\right],\quad x_1\notin\left(a_1,b_1\right).$$

Considering only imaginary part of Eq. (19) and noting $\left[u_1\left(x_1\right)\right]=0$ and Eq. (21), we have

$$\left[u_3\left(x_1\right)\right]=\frac{\sigma_c}{2\pi t_1s_1}\left[\left(x_1-b\right)H\left(-b_1,b_1,x_1,b\right)-\left(x_1+b\right)H\left(-b_1,b_1,x_1,-b\right)\right]. \tag{22}$$

The COD at the initial crack tip can be obtained for $x_1=b$ and can be written in the form

$$\delta_3^b=-\frac{2b\sigma_c}{\pi t_1s_1}\ln\left(\cos\frac{\pi\sigma_0}{2\sigma_c}\right). \tag{23}$$

It is important to note that for the case of isotropic upper and lower bimaterial components with $t_1=2\mu/\left(1+\kappa\right)$, $s_1=1$ [11], Eqs. (22) and (23) formally coincide with the associated equation of Panasyuk [12], and that the expressions for the electrical displacement and magnetic induction at the interface can be expressed in a simple form (omitted here).

6. Numerical results and discussion

In this section, for simplicity, numerical calculations only for the case of symmetric loads are carried out. As an example, material combination A/B of material A (upper material) and B (lower one) is mainly investigated. The material constants of them for material A with volume fraction v_f=0.3 and for material B with volume fraction v_f=0.5 are given by Sih and Song [13]. The interface layer was assumed to be elastic-perfectly plastic material with yield stress $\sigma_{\mathrm{Y}}=220\mathrm{MPa}$ [9]. In addition, loading combination parameters $\lambda_D=d_0\,e_{33}^{(1)}/\left(\sigma_{\mathrm{Y}}\alpha_{33}^{(1)}\right)$ and $\lambda_B=b_0\,h_{33}^{(1)}/\left(\sigma_{\mathrm{Y}}\mu_{33}^{(1)}\right)$ are introduced to reflect the applied electrical and magnetic loads, respectively.

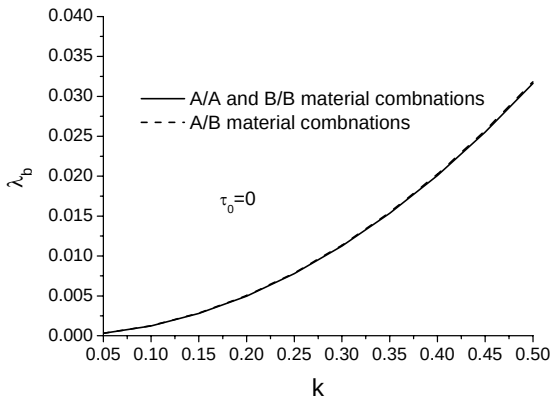

Figure 2. Relative pre-fracture zone lengths versus the applied tension load

The numerical results for the relative pre-fracture zone lengths, stresses in pre-fracture zones and

the CODs at the initial crack tips with respect to the normalized applied normal load for different material combinations are presented in Figures 2-6, where $k=\sigma_0/\sigma_Y$, $l=(b-a)/2$, $\lambda_b=\Delta_b/l$ and $\lambda_D=\lambda_B=0$. And if no special explanation is given, all the curves in these figures consider only A/B combination. It is remarked that because of the symmetry, only the corresponding numerical results for the right pre-fracture zone are plotted.

Figure 2 shows that the pre-fracture zone length of all current material combinations increases with the increasing of applied tension load and it is interesting to note that the pre-fracture zone length of A/B material combination is only slightly larger than that of A/A or B/B material combinations. Besides, the values of pre-fracture zone length are much smaller than the crack length, even for a relatively large external load. Figure 2 also indicates that for the internal crack problem of identical MEE material, the pre-fracture zone length is independent of the material properties of MEE material.

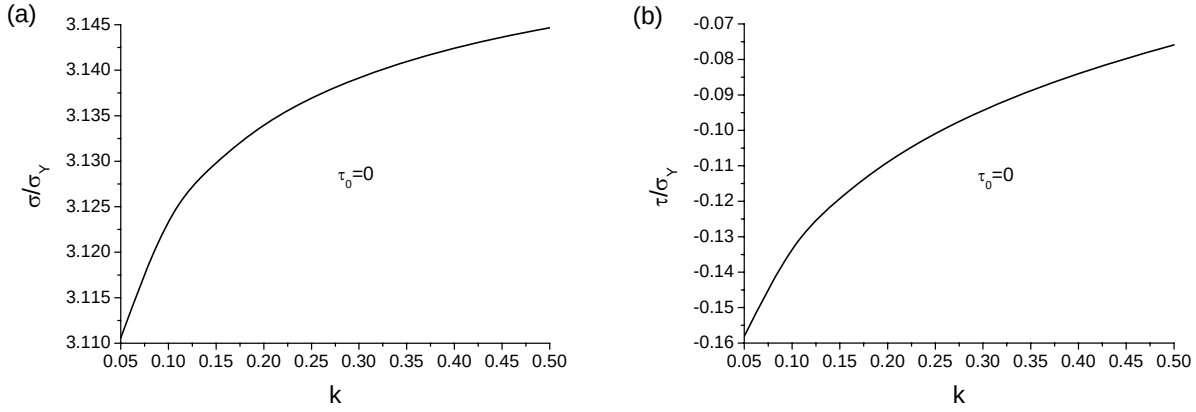

Figure 3. Normalized (a) normal stress and (b) shear stress in the pre-fracture zone versus the applied tension load

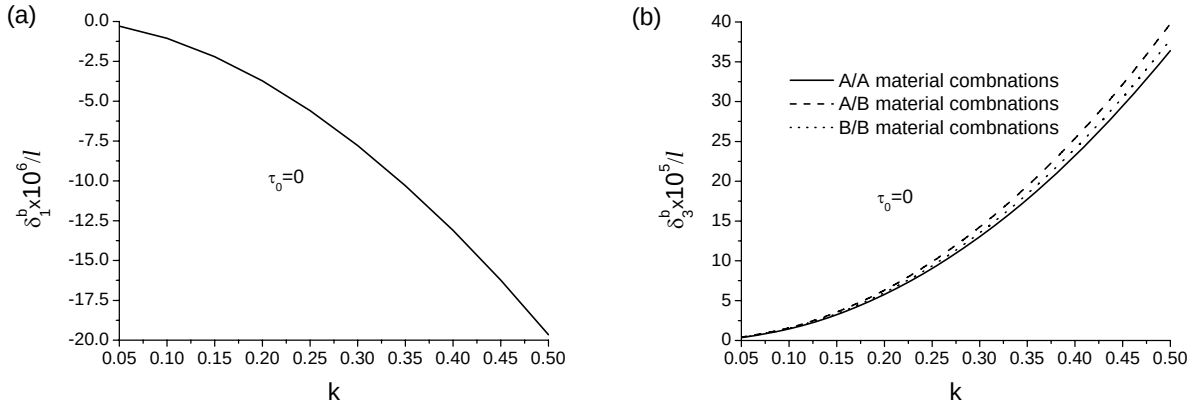

Figure 4. Normalized CODs at the initial crack tip versus the applied tension load

From Figure 3, it can be seen that for A/B material combination, the normal stress in the pre-fracture zones increases with the increasing of normalized normal load k, while the magnitude of shear stress decreases with the increasing of normalized tension load. The similar phenomena have been observed by Loboda et al. [9] for interface crack problem of piezoelectric bimaterial.

As shown in Figure 4, with the increasing of normalized normal load, although δ_1^b is negative, the

magnitude of δ_1^b at initial crack tips increases for A/B combination, and δ_3^b increases for A/B, A/A and B/B combinations. It should be pointed out that, as expected, for the considered loading cases, δ_3^b is much larger than δ_1^b. In addition, it is interesting to note from Figure 4b that for A/B combination, δ_3^b is slightly larger than that of both A/A and B/B combinations, which is a novel phenomenon different to the one observed in [9] for piezoelectric bimaterial problem.

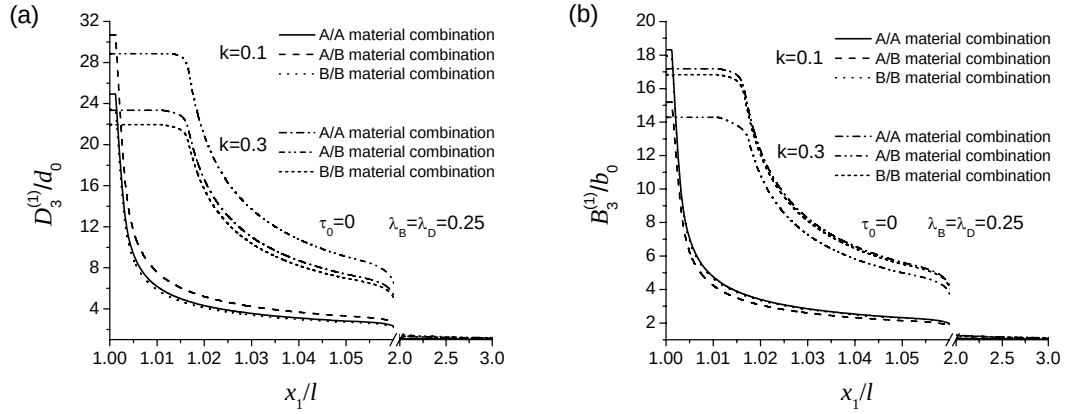

Figure 5. Normalized (a) electrical displacement and (b) magnetic induction along the interface under different tension loads

In Figure 5, the distributions of normalized electrical displacement $D_3^{(1)}\left(x_1,0\right)/d_0$ and normalized magnetic induction $B_3^{(1)}\left(x_1,0\right)/b_0$ along the crack face are presented, where $\lambda_D=\lambda_B=0.25$. For $k=\sigma_0/\sigma_Y=0.1$ and 0.3, the pre-fracture zone lengths can be easily determined by Eq. (21). They are, respectively, $\lambda_a=\lambda_b=0.00124$ and 0.01124, which, in fact, are the same as those given by Loboda et.al [9] for piezoelectric crack problem with pre-fracture zone. As shown in Figure 5, on one hand, the applied tension loads have significant effects on both the electrical displacement and magnetic induction in the pre-fracture zone. On the other hand, for a definite tension load, both the electrical displacement and magnetic induction in the pre-fracture zone are almost unchanged. In addition, with the increasing of x_1/l, both the electrical displacement and magnetic induction decrease rapidly, and as expected, the values of $D_3^{(1)}\left(x_1,0\right)/d_0$ and $B_3^{(1)}\left(x_1,0\right)/b_0$ finally approach to 1.

6. Conclusion

A plane strain problem for two MEE half-planes adhered by means of a very thin isotropic interlayer has been considered. A novel interface crack model, i.e., an interface crack with both open part and pre-fracture zone is put forward. The crack surfaces are assumed to be magnetoelectrically permeable. The problem is firstly reduced to a Hilbert problem on the unknown normal stress and shear stress in the pre-fracture zones, which can be solved exactly. By introducing Mises yielding conditions on interface layer, a system of nonlinear equations is established to determine pre-fracture zone lengths. Finally, the corresponding results for both cases of symmetric load and equivalent properties of the upper and lower bimaterial components are further obtained. From the theoretical and numerical results, the following conclusions can be drawn:

• For the suggested model, all mechanical, electrical and magnetic characteristics are limited in the near-crack tip region, i.e., all singularities connected with the model are eliminated.

• For the magnetoelectrically permeable interface crack with pre-fracture zones, δ_3^b plays a very important role in the fracture analysis of the interface crack because it is much larger than δ_1^b. And in general, increasing tension loads will cause crack growth and propagation.
• For the internal crack problem of identical MEE material under symmetrical load, the pre-fracture zone lengths are independent of material properties, and the normal stress in the pre-fracture zone is independent of applied tension load.

Abstract This paper is focused on the determination of the ideal (theoretical) tensile strength of the NiTi martensite crystal with B19' and BCO structures which contain (100) compound twins. For comparison, the strength of a perfect austenitic B2 structure is also studied. The model of the twinned martensite is represented by a supercell containing 40 atoms (20Ni:20Ti) arranged in two variants of the martensite. The results show that the presence of twins slightly decreases the ideal strength of NiTi martensite. The ideal strength of the B2 structure is three-times higher than that of the BCO one.

Keywords NiTi SMA, twinning, theoretical strength, ab initio

1. Introduction

The shape memory alloys (SMA) represent advanced materials usable in many industrial as well as medical applications owing to their shape memory effect which is based on transformations between austenitic and martensitic phases. The most frequently used SMA is a binary alloy with a nearly equiatomic proportion of nickel and titanium (NiTi). The NiTi alloy crystallizes either into a high temperature B2 (austenite) or a low temperature B19' (martensite) structure. An extensive overview regarding the NiTi SMA can be found in the paper of Otsuka [1].
There is, however a disagreement between experiment and theory since ab initio simulations predict, as a structure with the lowest total energy E_{tot} the base centered orthorhombic structure (BCO) instead of the experimentally observed monoclinic B19' one [2]. This disagreement raises a question why the theoretical simulations do not predict and confirm the experimentally observed martensitic structure. One of possible explanations is that the experimental results were measured on a polycrystal while the theoretical models consider a perfect crystal that does not contain the planar crystallographic defects, like twins or dislocations. Indeed, the real NiTi martensite always contains twins and, therefore, it is necessary to include these defects into the theoretical model. In our previous ab initio study we considered a sample of the (100) compound twins in NiTi martensite. Received results revealed that presence of the selected twins can significantly contribute to stabilization of the B19’ structure against the BCO one. Hence, the knowledge of the twinning in NiTi SMA at atomistic level is important for deeper understanding the ongoing processes (detwinning, martensitic transformation, etc.) in this unique material.
In this theoretical study we present the ab initio simulations of the (100) twinned NiTi martensite subjected to a uniaxial tensile loading that is oriented perpendicular to the twinning planes.

2. Theoretical model of the twinned NiTi martensite

2.1. NiTi twinned martensite

The studied theoretical model of the (100) compound twins in the NiTi martensite is represented by a supercell containing 40 atoms (20Ni:20Ti) arranged in two variants of the martensite. From now on, this basis will be referred to as TSC – twinned supercell. This TSC is identical to that already published in our previous research paper [3] that also contains a detailed description the TSC construction. The sample of the (100) twinned structure is depicted in Fig. 1.

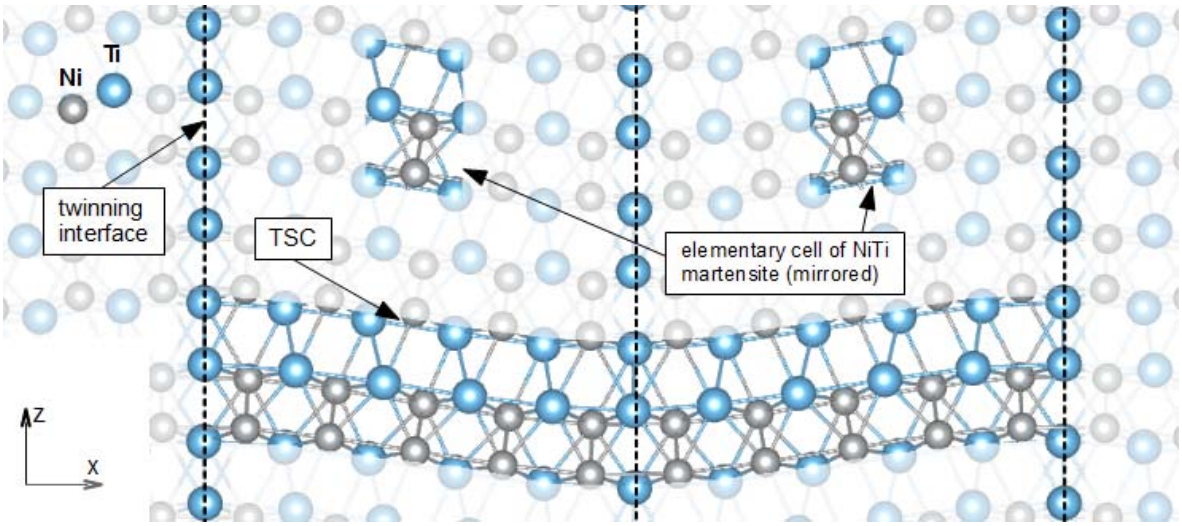

Figure 1. The sample of (100) twinned NiTi martensite with marked twinned supercell (TSC), both martensite variants and twinning interfaces. The tensile loading was applied parallel to the z axis.

2.2. Theoretical simulations

The ab initio simulations were performed within the density functional theory (DFT) developed by Kohm and Sham [4]. We used the VASP code (Vienna Ab initio Simulation Package) [5, 6] as a particular implementation of DFT to determine the total energy (E_{tot}) of the studied system, the stress tensor (σ_i in Voigt notation) and the forces (F) acting on individual atoms. The VASP uses the pseudopotential approach that represents a very efficient way how to reliably describe the valence electrons.

In the present study we utilized the PAW (Projector Augmented Waves) [7] pseudopotential treating p-electrons of Ti as valence and the exchange correlation energy by mean of the GGA (Generalized Gradient Approximation) with parametrization of Perdew Wang [8]. The cut-off energy restricting the number of plane waves in the basis set was 500 eV and the solution is considered to be self consistent when the difference of two subsequent total energies is lower than 1.0×10^{-8} eV. Meshes containing 1×13×13 (for TSC), 19×13×13 (for BCO) and 19×19×19 (for B2) of equidistantly spaced k-points were constructed for integration over the Brillouin zone.

The modeled deformation of a crystal lattice is represented by a uniaxial distortion of TSC in the selected direction that is perpendicular to the twinning interfaces. The relaxation procedure was applied during the entire deformation process to achieve the Poisson contraction (relaxation of the lateral stress tensor components). This relaxation means alternating the optimization of the translation vectors with optimization of the atomic positions until the relaxed stress tensor components reached values below 200 MPa and forces between individual atoms were lowered to 1×10^{-2} eV/ Å.

3. Results

3.1. Structure optimization

The uniaxial deformation begins from the equilibrium state and therefore it was necessary to determine lattice parameters for all studied structures. The lattice parameters of TSC were taken from our previous ab initio study [3] whereas the lattice parameters of the BCO and the B2

structures were obtained by a full optimization of those experimentally measured. These parameters are listed in Table 1 along with the experimental data [1, 9]. Comparing the presented ab initio data with those published in literature one can note a good agreement. This proves that the selected VASP settings are sufficient for reliable ab initio simulations.

Table 1. The computed equilibrium lattice parameters of the NiTi SMA. The table also contains the experimental and the theoretical data that are available in literature.

Structure	a_0 / Å	b_0 / Å	c_0 / Å	β / [°]
TSC [3]	28.7	4.11	4.65	90.0
BCO present *	2.94	4.00	4.93	107.3
BCO [2]	2.85	3.92	4.82	107.2
B19' experiment [9]	2.90	4.11	4.65	97.8
B2 present	3.00	3.00	3.00	90.0
B2 experiment [1]	3.02	3.02	3.02	90.0

3.2. Theoretical tensile strength

The investigated structures were subjected to a uniaxial loading in the ⟨100⟩ direction. The deformation path started with the equilibrium lattice parameters and continued until the tensile stress exceeded its maximal value. The tensile stress σ_1 is plotted in Fig. 2 as a function of the strain ε_1 for all studied structures. The theoretical strengths of the TSC and the perfect martensite are identified with the maxima in the stress-strain dependences (see Fig. 2a) since behind these maxima, the structures transform into different ones. Fig. 2b contains the stress-strain dependence for the austenite where two maxima can be found. Since, there is no structure change during the deformation we consider the global maximum as the ideal strength of the austenite.

The highest theoretical strength σ_1 = 34.5 GPa corresponds to the B2 austenite whereas the lowest value of 7.6 GPa to the TSC structure. The value of 8.8 GPa for the BCO structure is rather close to that computed for the TSC but, indeed, the presence of selected twins slightly reduce the strength of the NiTi martensite. The results also revealed that the computed theoretical strengths for both the

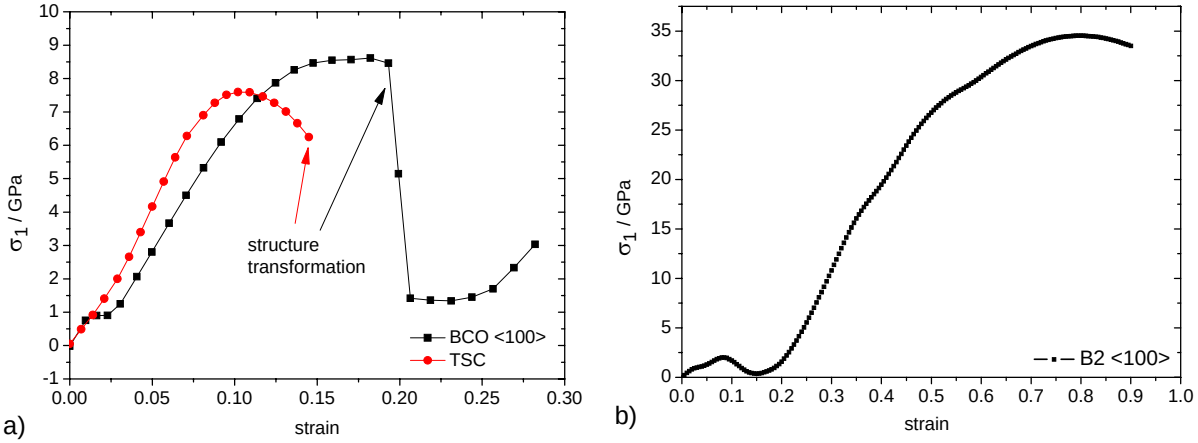

Figure 2. The dependence of the tensile stress σ_1 on the axial strain ε_1 for the twinned structure (TSC) and the perfect structures (B2 and BCO) of NiTi. The direction of deformation is perpendicular to the twinning interfaces.

TSC and the BCO lattice are significantly different from that for the austenite which is three times higher. A similar difference can be found when comparing the critical strain values. All the computed theoretical data are summarized in Table 2.

Table 2. The theoretical tensile strengths σ_{max} of the studied structures along with strain values.

Structure	σ_{max} / GPa	ε
TSC	7.6	0.106
BCO	8.8	0.219
B2	34.5	0.795

4. Conclusion

The theoretical tensile strength of the twinned NiTi martensite in the ⟨100⟩ direction was computed using the ab initio simulations and compared with those of perfect martensite and austenite structures. The results revealed that the presence of twins in the NiTi martensite only slightly reduces its theoretical strength. The results also show that the strength of the austenitic crystal is three times higher than that of the martensitic one.

Machining effects on damage evolution in sinter powder metals

S. Ma, H. Yuan*

Department of Mech. Engineering, University of Wuppertal, Wuppertal 42119, Germany
* Corresponding author: h.yuan@uni-wuppertal.de

Abstract The sinter powder metals have found extensive engineering applications in industry. The mechanical property of sinter metals is characterized by high porosity and micro-cracks. Inelastic behavior of the materials is coupled with micro-crack propagation and coalescence of open voids. The machining of sinter metals has significant influence on material behavior. In the present paper the machining effect on damage evolution of sinter iron is investigated under tension and torsion loading conditions experimentally and computationally. The tests indicated that damage of the sinter iron initiated already at a stress level much lower than the macroscopic yield stress. Based on the uniaxial tensile test an elastic-plastic continuum damage model was developed which predicts influence of machining on the damage evolution in the sinter iron under tension and torsion loading conditions. The proposed damage model can reasonably predict the damage evolution under tension loading for sintered iron. Deviation to the torsion damage is significant which implies anisotropic damage evolution.

Keywords Sintered metal, continuum damage model, damage evolution, machining effects

1. Introduction

Powder metallurgy (PM) technology has many advantages in comparison with melting metallurgy technology, e.g. low manufacturing cost, high production efficiency, high precision geometry and flexible composition of metal elements. With development of powder metallurgy technology many high performance components working under high and complex loading conditions are made of PM steel in recent years. Microstructure of sintered metals is characterized by high porosity and micro-cracks. Inelastic behavior of the material is coupled with inelastic deformations of powder particles, micro-crack propagation and coalescence of voids [6]. Interconnected porosity may cause higher stress concentrations near the particle connecting necks, while isolated porosity results in more homogeneous deformations [13]. Microscopic damage mechanism of sintered metals is investigated in monotonic in-situ tensile tests [3]. It is found that micro-cracks always initiate at pores of which the long axis is perpendicular to the tensile axis. These micro-cracks open and/or propagate under the mode I crack direction. Additional effects on material property are related to machining of sinter materials [13]. Experimental observations confirm that both mass density and elasticity modulus are significantly changed due to turning manufacture. A dramatic drop is determined in the fracture strain, which decreases from 14% to 3-4%, as reported in [13]. It is of importance to quantify effects of machining in mechanical property of sinter metal parts.

In the present work, damage from machining is studied experimentally and computationally. The damage evolution in specimens fabricated in two different machining processes is investigated under tension and torsion loading conditions. The damage variable is defined within the framework of thermodynamics and experimentally determined by monitoring changes of Young's modulus or shear modulus. It is found that damage in the sintered iron nucleates at a load level much lower than yield stress and fractured in the semi-brittle manner in spite of large plastic deformations. The machining effects on the mechanical properties were experimentally quantified and represented as state variable in the proposed continuum damage model. The continuum damage model should be able to predict the damage evolution in the sintered iron and verified based on detailed experiments. The influence of machining on the damage evolution was predicted with the proposed damage model, where the initial damage duo to machining is considered.

2. Materials and Specimen fabrication

To investigate mechanical behavior of sinter metals, the pure iron powder (atomized Hoeganaes ASC.100.29) from Hoeganaes Corporation was used to produce specimens. The organic binder (0.6% HDL-wax) is added into iron powder to improve lubricity during compaction of the green material. The green material is sintered at 1120°C for 60 min in the 95% N_2 and 5% H_2 atmosphere. The binder was burned out in the first stage of sintering. The average density of material after sintering is 7.2g/cm3, that is, the material contains ca. 8% air, i.e. porosity. The tensile bars specimens (Fig. 1) are fabricated directly by compacting and sintering, which is considered as reference material to determine machining effect on mechanical properties of material. The tubular specimens (Fig. 2), however, cannot be sintered directly and have to be machined from large piece of sinter materials. In the present work, the tubular parts are taken from cylindrical blanks with a diameter of 200mm. Generally speaking, the material property of the sinter iron is very sensitive to machining process.

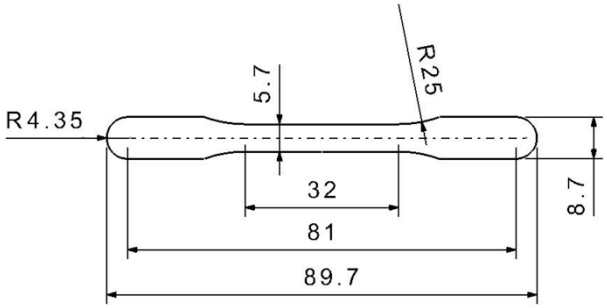

Figure 1. MPA specimen without machining

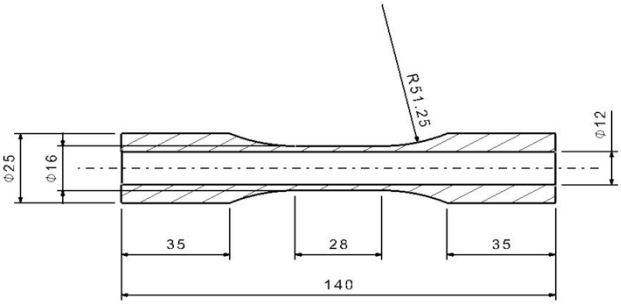

Figure 2. Thin-walled tube specimen by machining

The tubular specimens were machined with two different fabrication procedures in order to investigate the influence of machining procedure. The first procedure is followed by a conventional mechanical machining procedure of tubular specimen: Drilling-boring-turning (TBD). In this machining procedure the machining speed was well controlled. With the second machining method, the hole of the tubular specimen was mainly fabricated with the wire cut electrical discharge machining (WEDM) technology. After wire cutting, the remained thin oxide layer was removed by grinding. In compare with conventional machining procedures, the second fabrication procedure is more time-consuming.

3. Experimental results

3.1. Machining effect on the stress-strain curve

For investigating the effect of machining on mechanical properties of sintered iron, tensile tests were carried out with both tensile bar specimens und tubular specimens fabricated by different machining procedures. The tensile bar specimen is as-sintered without additional machining, which is the reference specimen for tension test of sintered steel according to DIN EN ISO 2740. In Fig. 3, it is shown that the tensile bar specimen shows a distinct Lüder's band, whereas it was not observed in the tubular specimen fabricated by TBD. The machining induces severe plastic deformations into specimen and the material seems strong to be hardened due to cold-working. The Lüder's band disappear in the TBD tubular specimen. With WEDM the tubular specimen seems not much different and its stress-strain curve nearly coincides with that of the tensile bar specimen (Fig 3). The most dramatic change due to machining is observed in the fracture strain, whereas the tensile bar specimen was broken at 12-14% of elongation, the TBD specimen shows 3.8% as fracture strain. More mechanical properties of both as-sintered and machined specimens are summarized in Table 1. Whereas WEDM does not distort sinter material, TBD generates significant damage to the specimen. Damage from conventional machining can affect sinter metal property substantially.

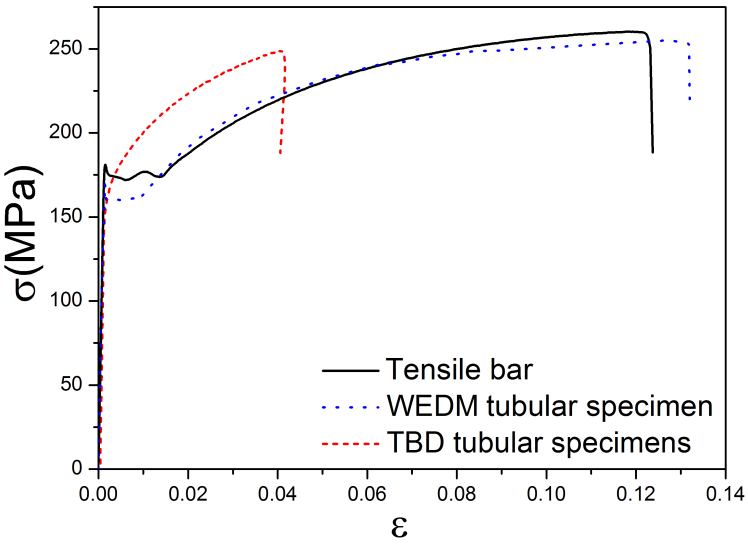

Figure 3. Stress-strain curves from differently fabricated specimens.

The porosity of specimens was measured before and after conventional machining by image analysis technique and Archimedes method, respectively. Optical micrographs revealed a significant increase of porosity after TBD machining. The average density of specimens after machining was increased from 7.2g/cm^3 to 7.4g/cm3, which is higher than the density before machining. In other words, the porosity of specimen before machining was reduced from 8.5% to 6% after machining procedure (TBD). The material of specimen was densified during machining.

Table 1. Mechanical properties of tensile specimen and tubular specimens.

Specimen Type	E [GPa]	σ_y [MPa]	σ_u [MPa]	ε_f [%]
Tensile bar without machining	164	135	255	12.3
Tubular specimen (TBD)	163	130	248	3.8
Tubular specimen (WEDM)	162	134	254	12.7

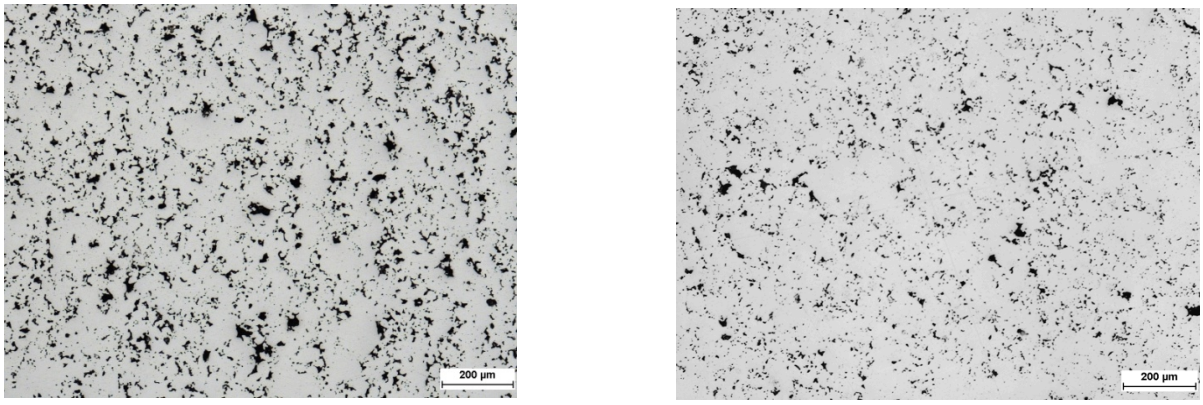
For sintered metal, Young's modulus can be expressed as a function of the porosity of material

$$\frac{E}{E_{ful}} = (\frac{\rho}{\rho_{ful}})^{\omega}, \tag{1}$$

where ρ is the porosity of material, ρ_{ful} is density of fully dense material (ρ_{ful}=7.86g/cm^3 for iron), and E_{ful} is the Young's modulus of fully dense material (according to literature the Young's modulus of fully dense iron is 201GPa) [3]. With the elastic modulus of specimen for density 7.2 g/cm^3, one obtains that ω=2.46. For the material of density 7.4 g/cm^3 the theoretical elastic modulus should be 176GPa. Compared with elastic modulus determined in the experiment, it implies that the specimen contains initial damage after conventional machining, which reduces the elastic modulus.

Summarizing observations above, one may conclude that the conventional machining procedure will harden and embrittle the sintered iron significantly. Furthermore, the material is densified and damaged during machining. With the WEDM machining, the machining effect is insignificant. The material properties of as-sintered material can be approximated by the WEDM

tubular specimen.



(a) (b)

Figure 5. Microstructures of the sintered iron ASC.100.29 with density 7.2g/cm^3. (a) Before machining. (b) After conventional machining (TBD) the material is densified to 7.4g/cm^3.

3.2. Damage evolution in different specimens

The loading and unloading cycles were designed to accomplish in different loading stage in order to investigate the damage evolution in the whole loading range. All tests were performed at a strain rate about 10^{-4}/s and at room temperature in MTS 809 axial/torsion testing machine. Axial/torsional extensometer of MTS Corp. was used to measure axial and torsional strains during tests. The gauge length of the extensometer used was 25mm.

Material damage can be expressed by diminishing of the elastic modulus [10],

$$D = 1 - \frac{E(\epsilon)}{E_0} \tag{2}$$

where E_0 denotes the initial elasticity modulus of the sintered metal without damage and E depending on deformations stands for actual elasticity modulus. With developing material damage, the material stiffness, i.e. E-modulus, decreases. In experiments E is determined from unloading controlled by stress to avoid compression according to the suggestion of Lemaitre [10], as shown in Fig. 6(a). Since unloading is limited within a small range, damage due to unloading is negligible.

The damage evolution in the uniaxial tension test is plotted in Fig. 6(b). In the figure the damage evolutions of tensile bar and WEDM tubular specimen are nearly identical. That is, the WEDM machining has negligible influence on the damage evolution. On the other side, the material stiffness loses dramatically in very small strain and then diminishes almost linearly. This result implies that material damage nucleates even under elastic loading condition and develops with further inelastic strains. The relation between damage and stress/strain can be approximated by the known Ramberg-Osgood model, as

$$D = A\sigma + B\epsilon^m \tag{3}$$

with A, B and m>1 as fitting parameters. The damage relation in Eq. (3) is shown in Fig. 6(b) and its development is dominated by the linear term in small loading region. Damage is nucleated under elastic material state and mainly linear proportional to applied stress, since the nonlinear term is vanishingly small for small strain. If the material becomes plastic, the strain will grow over-proportionally, so that the influence of the linear term disappears. The exponent m is larger than 1, so that the damage curve for the sintered metals is convex. From dense ductile materials it is known that damage nucleates at large plastic strain and grows very gradually, the damage evolution curve is concave [10]. The convex development implies a very different damage mechanism in the

sintered metal.

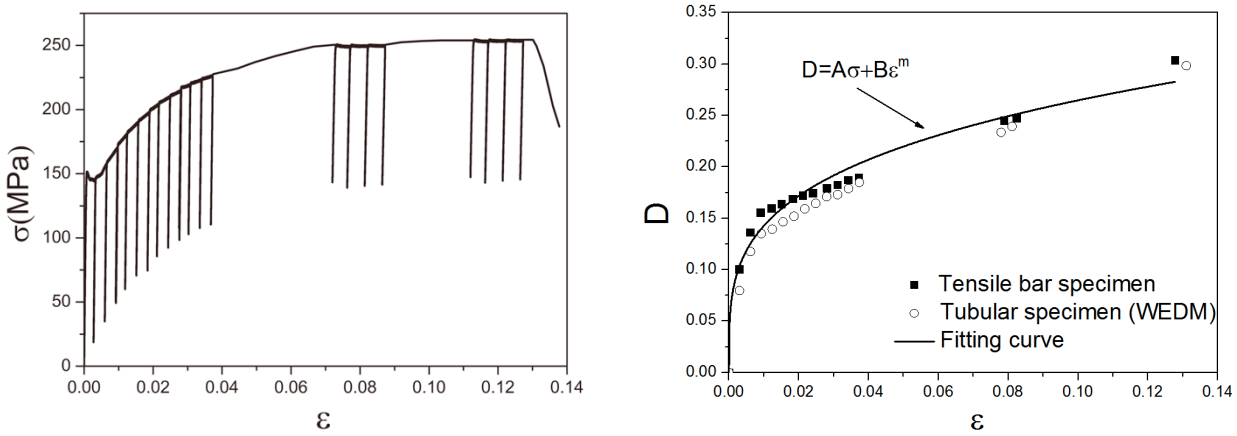


Figure 6. Uniaxial tensile tests. (a) Loading-unloading cycle to determine elastic modulus. (b) Damage as a function of strain.

Damage evolution in torsion can be determined in the same way as that in tension. The influence of machining on damage evolution is shown in Fig. 7 for both tension and torsion loadings, where damage is expressed as a function of the equivalent strain, $\varepsilon_{eq} = \sqrt{\varepsilon^2 + \gamma^2/3}$. The experiments reveal that the damage evolution under shearing is similar to that under tension. But the fracture strain of torsion is dramatically larger than that from tension, which implies effects of the stress triaxiality. As expected, damage in the TBD specimens develops more quickly than that in the WEDM specimens and the TBD specimens fail at smaller strains for both tension and torsion loadings. But the influence of machining on the damage evolution under torsion loading is smaller than under tension.

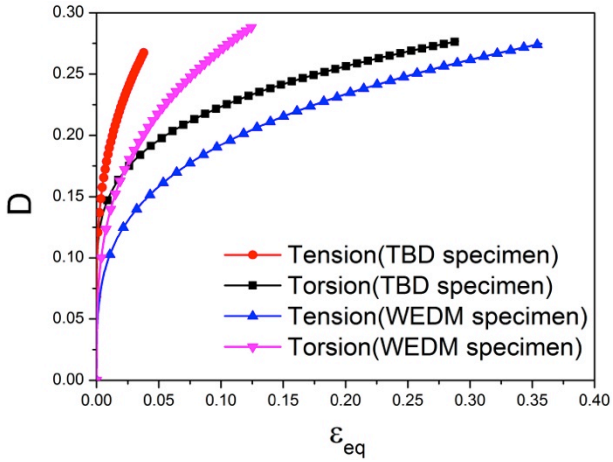

Figure 7. Evolutions of damage in different specimens.

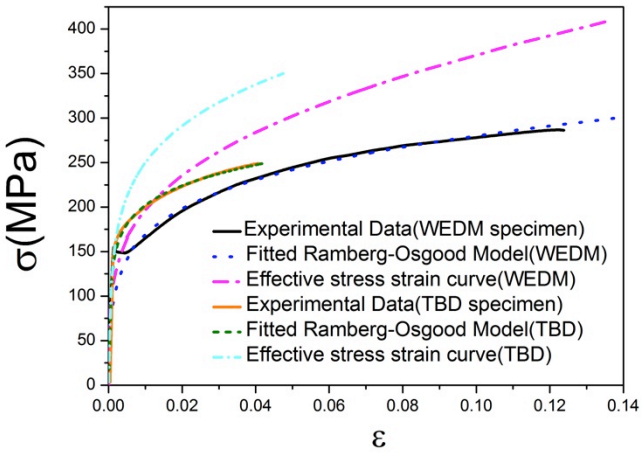

Figure 8. Effective stress-strain curves

4. Continuum damage model

In the framework of infinitesimal deformation, the strain rate tensor is decomposed into elastic and plastic part as

$$\dot{\epsilon}_{ij} = \dot{\epsilon}^e_{ij} + \dot{\epsilon}^p_{ij}. \tag{4}$$

In the present work, the scalar damage variable as defined in (1) is introduced to describe degradation of the sintered metal in the framework of continuum damage mechanics. Based on the strain equivalence hypothesis, the effective stress in the undamaged configuration is defined as [1,2,10]

$$\tilde{\sigma}_{ij} = \frac{\sigma_{ij}}{(1-D)}. \tag{5}$$

The effective stress-strain curves for both types of specimens are plotted in Fig. 8. Then, the thermodynamic driving force associated with damage variable D is given based on the thermodynamic framework for continuum damage model proposed by Lemaitre [8,10] as

$$Y = \frac{\sigma_e^2}{2E_0(1-D)^2} f(\eta), \tag{6}$$

with

$$f(\eta) = \frac{2}{3}(1+\nu) + 3(1-2\nu)\eta^2. \tag{7}$$

Above $f(\eta)$ represents dependence on the stress triaxiality, $\eta = \sigma_H / \sigma_{eq}$, where σ_H is the hydrostatic stress and σ_{eq} is Mises stress.

4.1. The damage evolution law with initial damage

Experimental observations for the sintered metals reported in the previous section reveal that material damage occurs under very low stress amplitude, i.e. damage is induced by elastic deformations before the material is plastic. Thus, the damage variable can be decomposed into elastic damage and plastic damage, as

$$D = D^e + D^p. \tag{8}$$

Obviously, the decomposition is consistent to experimental data for the uniaxial state, Eq. (3).

4.1.1. Elastic damage evolution

The elastic damage was known in brittle materials, such as concrete, rocks etc. Various elastic CDM models have been developed for modeling elastic damage accumulation in the brittle materials [7，9], which can be extended to characterize the elastic damage in the sintered metal. The potential function for the elastic damage is defined as

$$F_e^D = Y - Z(D_e), \tag{9}$$

where Z is the material resistance against material damage. Following the material resistance can be expressed in the exponential form

$$Z = Y_0 + \frac{1}{b}\ln\left(\frac{D_e^{sa} - D_e^0}{D_e^{sa} - D_e}\right), \tag{10}$$

where Y_0 is the initial resistance against material damage and b is a model parameter. D_e^{sa} represents the saturation of the elastic damage since in elastic-plastic materials the elastic damage will not finally destroy the structure but accelerate the final failure. D_e^0 denotes initial elastic damage, which can be induced by manufacturing process or previous loading history. From the maximum dissipation principle, the damage evolution law is expressed in the rate-form as

$$\dot{D}_e = \dot{\lambda}_b \frac{\partial F_e^D}{\partial Y} = \dot{\lambda}_b. \tag{11}$$

In case with damaging, the damage multiplier $\dot{\lambda}_b$ is determined by the damage consistency condition,

$$dF_e^D = \frac{\partial F_e^D}{\partial Y}\dot{Y} - \frac{\partial Z}{\partial D_e}\dot{\lambda}_b = 0. \tag{12}$$

The evolution equation of the elastic damage is expressed as

$$\dot{D}_e = (D_e^{sa} - D_e^0)\, b \exp\left[-b\left\langle Y - Y_0 \right\rangle\right]\dot{Y}, \tag{13}$$

or

$$D_e = D_e^0 + (D_e^{sa} - D_e^0)\left\{1 - \exp\left[-b\left\langle Y - Y_0 \right\rangle\right]\right\}. \tag{14}$$

where $\left\langle \cdot \right\rangle$ is the Macauley bracket, i.e. $\left\langle x \right\rangle = \left(|x| + x\right)/2$.

4.1.2 Plastic damage evolution

In ductile materials the damage is mainly accumulated due to plastic deformations. Following the concept by Bonora et al. [1, 2] interactions between plastic dissipation and damage dissipation can be neglected. The plastic damage dissipation potential F exists and can be expressed as sum of plastic damage potential, F_p^D, and plastic deformation potential, Ψ_p, as

$$F = F_p^D + \psi_p. \tag{15}$$

Based on the hypothesis of the strain equivalence and the effective stress concept, the plastic dissipation potential for the material can take the form of the J_2 plasticity theory,

$$\psi_p = \tilde{\sigma}_e - \tilde{\sigma}_{y0} - R(r), \tag{16}$$

where the effective Mises stress is defined as

$$\tilde{\sigma}_e = \sqrt{\frac{3}{2}\left(\frac{s_{ij}}{1-D}\right)\left(\frac{s_{ij}}{1-D}\right)} \tag{17}$$

with s_{ij} as the deviatoric stress tensor. The damage dissipation potential proposed after Bonora et al. [1, 2] for the plastic damage model is written as

$$F_p^D = \left[\frac{1}{2}\frac{Y^2}{S_0}\frac{1}{1-D}\right]\frac{(D_{cr}^p - D_p)^{(\alpha-1)/\alpha}}{p^{(2+n)/n}}, \tag{18}$$

where S_0 is damage material parameter, n is the plastic hardening exponent in the Ramberg-Osgood model, α is the damage exponent that determines the shape of the damage evolution law and p is the accumulated plastic strain. D_p^{cr} is critical plastic damage value.

Based on the maximum dissipation principle, the evolution of internal variables can be obtained via the normality rule as

$$\dot{\epsilon}_{ij}^p = \dot{\lambda}_p \frac{\partial F}{\partial \sigma_{ij}} = \dot{\lambda}_p \frac{\partial \psi_p}{\partial \sigma_{ij}}, \dot{D}_p = \dot{\lambda}_p \frac{\partial F}{\partial Y} = \dot{\lambda}_p \frac{\partial F_p^D}{\partial Y}, \dot{\lambda}_p = \dot{p}(1-D). \tag{19}$$

The effective stress can be formulated as a function of the plastic strain in the Ramberg-Osgood law,

$$\tilde{\sigma}_{eq} = \frac{\sigma_{eq}}{1-D} = Kp^{1/n}. \tag{20}$$

Recalling Eqs. (18) - (20) and Eq. (6), the plastic damage evolution law is derived as

$$\dot{D}_p = \begin{cases} 0 & \text{if } p < \epsilon_{th} \text{ or } \sigma_H \le 0), \\ \dfrac{K^2}{2E_0 S_0} f(\eta) \left(\dfrac{(D_p^{cr} - D_p)^{(\alpha-1)/\alpha}}{p} \right) \dot{p} & \text{if } p \ge \epsilon_{th} \text{and } \sigma_H \ge 0). \end{cases} \tag{21}$$

It is assumed that the plastic damage will not grow in the compression stress state [2]. The plastic damage process remains inactive until the effective accumulated plastic strain p reaches the threshold strain ϵ_{th} for the positive hydrostatic stress.

With $D_p = D_p^{cr}$ at $p = p_{cr}$ as the final critical damage to fracture, integrating the equation above over $[D_p^0, D_p^{cr}]$ for D and $[\epsilon_{th}, p_{cr}]$ for p under proportional loading condition, where D_p^0 is initial plastic damage, one gets

$$[D_p^{cr} - D_p^0]^{1/\alpha} = \frac{1}{\alpha} \frac{K^2}{2E_0 S_0} f(\eta) \ln\left(\frac{p_{cr}}{\epsilon_{th}} \right). \tag{22}$$

Integrating the equation above over $[D, D_p^{cr}]$ for D and $[p, \epsilon_{cr}]$ for p, one gets

$$[D_p^{cr} - D^p]^{1/\alpha} = \frac{1}{\alpha} \frac{K^2}{2E_0 S_0} f(\eta) \ln\left(\frac{p_{cr}}{p} \right). \tag{23}$$

For uniaxial tension $f(\eta) = 1, p_{cr} = \varepsilon_{cr}$, Eq. (23) can be re-written into

$$[D_p^{cr} - D_p^0]^{1/\alpha} = \frac{1}{\alpha} \frac{K^2}{2E_0 S_0} \ln\left(\frac{\varepsilon_{cr}}{\epsilon_{th}} \right). \tag{24}$$

Dividing Eq. (24) with Eq. (23), one obtains the explicit expression for plastic damage as a function of the equivalent plastic strain for proportional loading cases

$$D_p = D_p^0 + (D_p^{cr} - D_p^0) \left\{ 1 - \left[1 - \frac{\ln(p/\epsilon_{th})}{\ln(\epsilon_{cr}/\epsilon_{th})} f(\eta) \right]^{\alpha} \right\}. \tag{25}$$

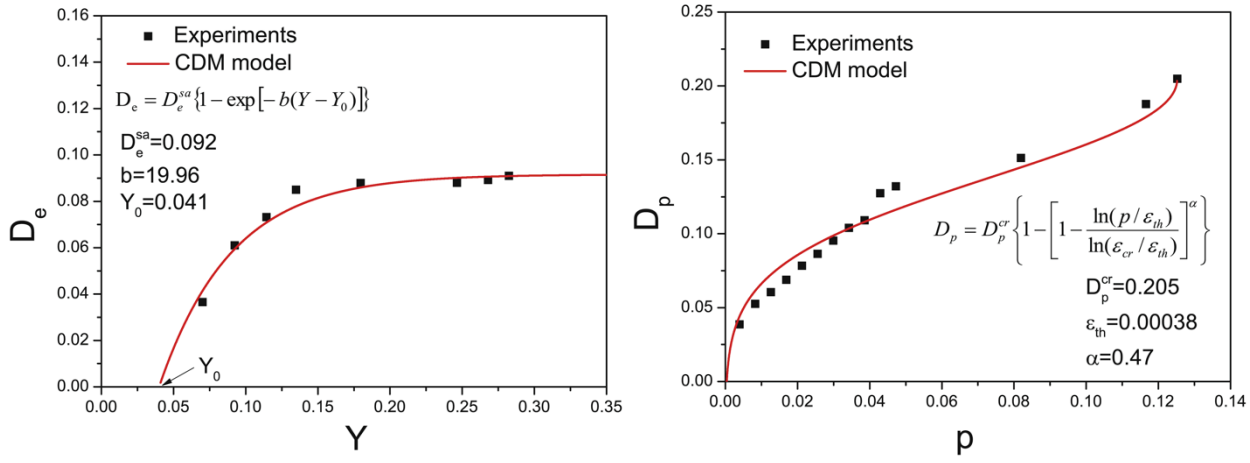
Dividing Eq. (23) by Eq. (25), the fracture strain under proportional loading can be expressed as

$$p_{cr} = \epsilon_{th} \cdot \left(\frac{\varepsilon_{cr}}{\epsilon_{th}} \right)^{1/[f(\eta)]} \tag{26}$$

4.2. Identification of model parameters

Identification of the damage model parameters is accomplished with uniaxial tests using the WEDM tubular specimens, i.e. tensile and compressive tests. For verification, the fracture strain in multi-axial experiments and influence of machining on the damage evolution of specimen should be predicted by the CDM [11].

In Fig. 8, the material parameters for Ramberg-Osgood power law can be obtained by fitting for both machining procedures. According to the experimental results, the average density of material is increased after machining. On the other words, the material is compressed during machining. It is well known that ductile damage grows more slowly in compression stress state. The initial plastic damage is negligible. The initial damage is considered as elastic damage. And the initial plastic damage is not activated during machining, $D_p^0 = 0$. The initial elastic damage is calculated by $D_e^0 = 0.074$, E_0 is 176GPa for material with density 7.4g/cm^3.



(a) (b)

Figure 9. Development of the damage as a function of applied load. Symbols denote experimental data and curves are results from the CDM model. (a) Evolution of the elastic damage with energy release rate. (b) Plastic damage evolution with the plastic strain.

Since it is assumed that plastic damage will not accumulate in the compressive stress state, the compression test is used to identify the model parameters of the elastic damage evolution for the isotropic elastic damage. The elastic damage becomes almost stationary for higher loading. The model parameters D_e^{sa}, b and Y_0 are identified by fitting the experimental curve as shown in Fig 9(a).

The plastic damage evolution should be obtained from the elastic-plastic tensile tests. From the uniaxial tensile tests the critical ductile damage can be approximated by $D_p^{cr} = D_{cr} - D_e^{sa}$. The result of Eq. (25) is plotted in Fig. 9(b), in which the ductile damage is expressed as a function of the plastic strain. The material parameters of the elastic-ductile damage model for sintered iron are summarized in Table 2.

Table 2. Summary of the material model parameters for the sintered iron

Elasto-plastic material properties:
Tubular specimen(Conventional machining)
E_0 = 176000MPa; ν = 0.27; σ_{y0} = 135MPa; n = 4.955; K = 608MPa
Tubular specimen(WEDM)
E_0 = 162000MPa; ν = 0.27; σ_{y0} = 135MPa; n = 4.714; K = 549MPa
Elastic damage evolution law:
D_b^{sa} = 0.091; b = 19.961; Y_0 = 0.04MPa,
Plastic Bonora damage evolution law:
ϵ_{th} = 0.00038; α = 0.47; S_0 = 27.85MPa; ϵ_{cr} = 0.12522; D_p^{cr} = 0.205; D^{cr} = 0.296

4.3. Failure Prediction of the CDM model

Using the material parameters identified in the previous section, damage evolution of sintered iron is predicted for both tension and torsion loading condition according to Eq. (25). Furthermore, the equivalent fracture strain is also predicted for combined tension-torsion condition with Eq. (26).

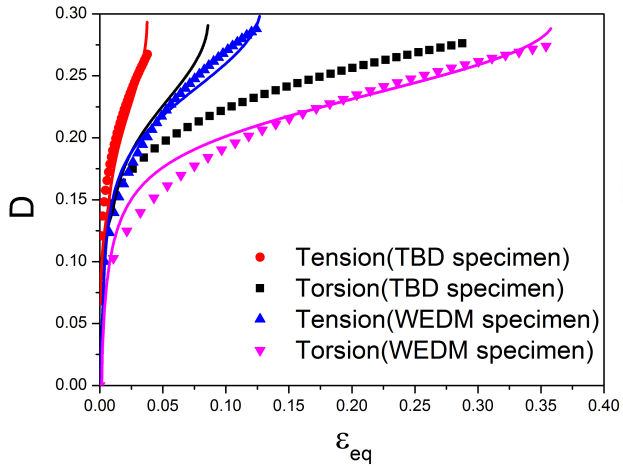


Figure 10. Comparison between experiments and computational predictions

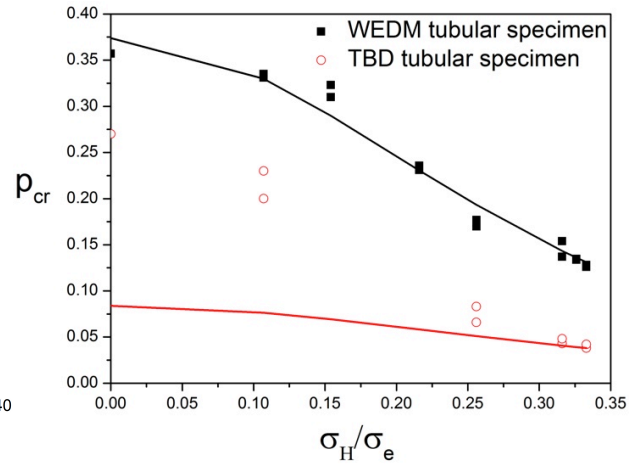

Figure 11. Variations of final fracture strain in tension-torsion specimens.

Experimental observations of different sinter metal specimens are plotted in Figs. 10 and 11 in which symbols denote experimental data. With increasing stress triaxiality, the material behaves more brittle, that is, the fracture strain decreases rapidly. Obviously, the prediction from the CDM model is accurate for the WEDM specimens in comparison with the tension and torsion tests.

For the TBD specimen, it is seen that the proposed model is not able to accurately predict the machining effect on the damage evolution under torsion loading. The deviation becomes more significant with decreasing stress triaxiality in the range of $\eta < 0.25$. That means that the machining influence on the damage evolution is strongly depending on loading mode. In the machining process, the initial damage induced by mainly shearing in specimen. Under this situation the damage in the form of micro-cracks would be perpendicular to the specimen axis, which is very sensitive to axial tension, not to the torsion. That is, the damage is strongly anisotropic. Additionally, the initial damage is not constant in the tubular specimen. It will lead to stress gradient in the subsurface of specimen. For this reason, the initial damage gradient has to be considered in investigation of machining effect in order to reasonably predict the damage evolution of material contains machining effect.

5. Conclusions

In the present work damage evolution in a sinter iron is studied experimentally and computationally. Based on both analytical and computational discussions following conclusions can be drawn:

- Experiments on both tension and torsion tests confirm that the sinter material stiffness decreases rapidly with applied load. The degradation of material occurs at much lower load level than yield stress.
- The damage variable in the continuum damage model is decomposed into elastic damage and plastic damage, where the elastic damage is characterized by the stress and the plastic damage is mainly controlled by the plastic strain. The evolution equations for both damage variables have been developed within the framework of thermodynamics. The initial damage is considered in the damage evolution law. Explicit expressions for both damage evolutions have been obtained.
- Conventional machining (TBD) has significant influence on the mechanical properties of the

sintered iron. The sinter metal is densified，hardened and damaged. Fracture strain decreases dramatically. The machining changes the dependence of damage evolution on loading mode. The results show that the proposed damage model is able to predict machining influence on damage evolution under tension loading, but not under torsion.

Abstract
Hydrogels were prepared from bovine and porcine gelatin powders of different Bloom values. Gelatin concentration and pH were selected to obtain self-supporting gels with stiffness in the range of those employed in structural applications in foodstuff, ballistic and pharmacy. Glycerol and sorbitol were also added in gel formulations. Deformation and fracture behaviors were assessed by means of gel strength measurements, uniaxial compression tests and wire cutting experiments. All gels showed non-linear elastic deformation with strain hardening and brittle fracture. Large deformation was described with a first order Ogden constitutive model. Strain hardening was attributed to protein chains renaturation capability under stress. It was found that neat porcine gelatin gels displayed higher gel strength, shear modulus, failure strain and stress, fracture toughness and water retention than bovine gelatin gels. The addition of sorbitol and glycerol caused an increase in water retention capability and a marked enhancement in gels´ fracture toughness. The major content of hydrophilic amino acids in the gelatin, the stronger the effect of glycerol and sorbitol on gelatin network morphology. The correlation between large deformation and fracture toughness parameters with the technological gel strength values was also investigated.

Keywords: hydrogels, gelatin, fracture toughness, depth sensing indentation

1. Introduction

Hydrogels consist of three-dimensional hydrophilic polymer network with the ability of swelling and retain large volumes of water without dissolution [1]. Hydrogels can be obtained from synthetic polymers, but those derived from biopolymers such as proteins and polysaccharides are being preferred due to their renewable nature, low toxicity, biodegradability and biocompatibility [2]. Among natural polymers gelatin is an attractive candidate as raw material for preparing hydrogels because its gelling ability. It is unique among hydrocolloids in forming thermo-reversible physical gels with a melting point close to body temperature [1].

The main gelatin hydrogels applications include their use as: *i)* ingredients to improve elasticity, consistency and stability of foods [3]; *ii)* human tissue simulants in ballistic studies [4]; *iii*) carriers for drug delivery systems [5]; iv) scaffolds for cell growth in tissue engineering [6]. Mechanical requirements for hydrogels in the aforementioned applications are large deformation capability together with proper toughness and stiffness level. Independent tuning of elastic modulus, deformation capability and fracture toughness becomes highly desirable to the development of hydrogels with tailored properties. So that, the assessment of mechanical properties and the knowledge of whether they are influenced by gelatin source and additives are of fundamental importance and constitute the aim of this research.

Determining reliable mechanical properties of soft materials like hydrogels is a challenged task due to its low modulus (of the order of kPa) and complex mechanical behavior. Hydrogels are soft but exhibit brittle failure and show dependence with strain rate, as polymers does (see for example in [7]).

The gel strength is the most popular property used to mechanically characterize gelatin gels [8]. It is determined using the so-called Bloom test, which consists on performing an indentation test under

specifically defined conditions -gelatin concentration (6.67 %), temperature (10 ºC), maturation time (17 h), indentation depth (4 mm), cylindrical plunger (12.5 mm diameter)- thus allowing gel strength to be expressed in the normalized Bloom value. It has been shown that the Bloom value is linked to the stiffness of the gel network [9].
In this work, deformation behavior and fracture toughness of gels based on two commercial mammalian gelatins differing in collagen source (*ie.* with different amino acid composition [10]) and Bloom value are assessed. Large deformation behavior is evaluated by uniaxial compression experiments and for fracture toughness, the Gc parameter is determined by the wire cutting technique [7]. The effect of adding sorbitol and glycerol, two common additives in gels formulations, on mechanical performance is also analyzed and discussed. The relationship between gel strength and shear modulus, fracture toughness and ultimate deformation properties is also investigated.

2. Experimental

2.1. Gelatin Gels preparation

Bovine hide gelatin type B, Bloom 200, isoionic point (Ip) 4.7-5.4 and porkskin gelatin type A, Bloom 250, Ip 7-9 were kindly supplied by Rousselot (Argentina). Glycerol analytical grade were purchased from DEM Chemicals (Mar del Plata, Argentina). D-Sorbitol monhydrate (S) and buffer solution pH 7 and pH 10 were purchased from Anedra (Buenos Aires, Argentina).
Gelatin solutions were prepared by dissolving the gelatin powder (20wt%) in a buffer solution with continuous stirring at 50ºC. The buffer was selected over the gelatins' isoionic points (pH=7 for bovine and pH=10 for porcine gelatins). In addition, glycerol and sorbitol were incorporated at a concentration of 25wt% (based on dry gelatin powder). Glycerol and Sorbitol are non-solvents for gelatins so that the initial gelatin concentration in water was kept constant in each formulation. The designation of prepared gels is *B0*, *B1* and *B2* for bovine based gels containing neat gelatin, glycerol and sorbitol, respectively. Analogous, porcine gelatin gels are designated as *P0*, *P1* and *P2*.
The resulting homogeneous solutions were poured into specially design Delrin® molds and kept at room temperature during 15min to form the gels. Specimens were then wrapped in film in order to minimize drying out and stored at 4 ºC during 48 h. Before testing samples were conditioned at 21 ºC during 2 h.

2.2. Physical and mechanical characterization

2.2.1 Water Retention: For each formulation, three gel specimens were dried in an air circulating oven at 105ºC until constant mass. Samples were weighted with an accuracy of 0.0001g before and after drying to determine the initial mass (m_i) and the gelatin dry matter (m_0), which was normalized by the glycerol and sorbitol content. Gel water retention (WR) was then calculated as:

$$WR(\%) = \frac{m_i - m_0}{m_0}.100 \quad (1)$$

2.2.2 Transmission optical microscopy (TOM): Inspection was performed on gels samples employing a Leica DMLB microscope provided with a video camera Leica DC 100.
2.2.3 Scanning Electron Microscopy (SEM): Inspection was performed in a JEOL JSM-6460LV microscope in order to analyze the ultra-structure of gelatin gels. The prepared samples were frozen, lyophilized, cryofractured and coated with a thin film of Au/Pd before inspection.
2.2.4 Gel Strength: Measurements were carried out on prepared gels using an INSTRON 3369 universal testing machine. Samples were cylindrical blocks having 25 mm of diameter and height. Gel strength was determined as the maximum load measured after a steel cylindrical plunger penetrated 4mm into the sample surface [11]. The plunger was flat-faced and had a diameter of 10 mm. A Load cell of 0.1 kN was used and the penetration speed was 25mm/min. The gel strength was taken as the average value of four measurements performed on different samples.
2.2.5 Uniaxial compression: Tests were performed on cylindrical samples with a diameter and height of 25mm in an INSTRON 4469 universal testing machine. Experiments were conducted at two loading rates (5 and 25 mm/min). A 0.5 kN load cell was used. A Teflon spray was applied at the interface between sample and compression platens in order to diminish friction. At least five replicates were tested at each loading rate. Samples were loaded up to fracture. The obtained load (P)- displacement (v) data were converted to true stress (σ) vs. true strain (ε) curves assuming that the material was incompressible. Data were also expressed in terms of and true stress (σ) – stretch ratio ($\lambda = e^{\varepsilon}$).
2.2.6 Wire Cutting tests: Experiments were carried out in an INSTRON 4469 universal testing machine equipped with a specially designed grip and a 0.5 kN load cell. The grip allows the wire to be tight and perfectly aligned with the sample surface. Seven steel wires of different diameters (d) ranging from 0.2 to 0.8 mm were used and the cutting rate was 25 mm/min. The samples were rectangular blocks of length 30 mm, width 20 mm and height 20 mm. For each wire diameter at least five cuts were performed. The steady-state cutting energy was obtained by dividing the cutting force, F_c, by the specimen width, b. A linear relationship between the normalized cutting force F_c/b and wire diameter d is postulated [12]:

$$\frac{F_c}{b} = G_c + \sigma_y \left(1 + \mu_k\right) d \tag{2}$$

where σ_y is a characteristic stress and μ_k is the kinetic friction coefficient. By extrapolating the steady state cutting energy to zero wire diameter, G_c is obtained (Eq. 2) since the work input is consumed solely by the propagating crack.
2.2.7 Statistical Analysis: Analysis of variance (ANOVA) was carried out to find differences in the measured properties of gelatin gels due to the addition of glycerol and sorbitol. The bovine gelatin gel series (*B0, B1* and *B2*) and the porcine gelatin gel series (*P0, P1, P2*) were analysed by an independent ANOVA. Differences between means were analysed using the Tukey´s test for post hoc comparison ($p < 0.01$). Analysis was performed using STATISTICA 6.0 (Statsoft, Inc., Tulsa, USA).

3. Results and Discussion

Gelatin powder concentration, pH and temperature values used in gels formulation were selected to obtain self-supporting gels with stiffness in the middle range of those employed in structural applications in foodstuff, ballistic and pharmacy (E = 1 to 10^3 kPa) [13,14]. Gelatin concentration

was kept constant in all materials, but owing to the different amino acid composition [10] and molecular weight of both types of gelatins and due to the presence of additives, different gel mechanical properties are expected.
All prepared gelatin gels show optically clear appearance and transparency. The incorporation of additives- glycerol and sorbitol- seems to not alter their physical integrity or optical appearance.

3.1 Water Retention Capability

As can be seen in Table 1, *P0* gel shows higher water retention capability than *B0*. The incorporation of glycerol and sorbitol increases the amount of retained water in both types of gels. In comparison, the increase in water retention capability is larger in gels containing glycerol than in those with sorbitol because glycerol molecules are more hygroscopic than sorbitol ones due to its smaller size.

3.2 Gel Strength

Gel strength values of gelatin gels are also given in Table 1. Gel strength of *P0* is higher than *B0* in agreement with the larger Bloom value of porcine gelatin. As well, all porcine gelatin based gels are stronger than bovine based ones, being *P2* the strongest gel of the series.
Gel strength values do not decrease with increasing water content in modified gels, indicating a strong impact of glycerol and sorbitol on gelatin gels network structure. The increase in gel strength is consistent with the explanation that the addition of polyhydric alcohols may create a shorter mean distance between junction zones by increasing the number of crosslinking points [15] and that co-solvent do not participate in the interlinking of protein molecules but they reduce the available water by preferential hydrogen bonding with water molecules [16].

Table 1. Water retention and gel strength of prepared gelatin gels.

Gel	Water Retention (%)	Gel Strength (N)
B0	355.6 ± 1.5^{a}	4.09 ± 0.12^{a}
B1	447.7 ± 1.9^{b}	3.61 ± 0.24^{b}
B2	365.7 ± 3.1^{c}	3.88 ± 0.14^{ab}
P0	429.3 ± 6.4^{A}	4.40 ± 0.08^{A}
P1	448.3 ± 2.9^{B}	4.12 ± 0.01^{B}
P2	437.4 ± 1.8^{B}	4.71 ± 0.10^{C}

Different letters in the same column indicate significant differences between means ($p<0.05$).

3.2 Large Deformation Properties

Previous investigations [17, 18] demonstrated that the uniaxial compression response of the studied

gelatin gels is independent of strain rate within a range from 0.1 to 10min^{-1} and that it is completely reversible.

Figure 1 shows the stress-strain curves obtained for bovine (Fig. 1-a) and porcine (Fig. 1-b) based gelatin gels in uniaxial compression experiments at a strain rate of 1/min. The compression response of all gels is non-linear elastic with strain hardening up to catastrophic fracture. The scattering in uniaxial compression curves is wider in porcine gels than in bovine gels. This maybe related to the higher content of trapped air microbubbles in the porcine gels as thrown by TOM inspection of gel samples.

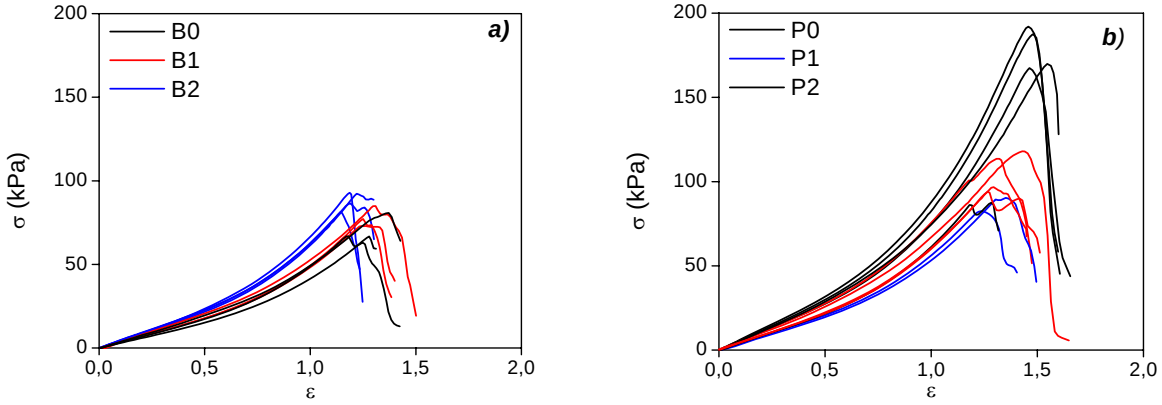

Figure 1. Stress-strain curves obtained in uniaxial compression tests for a) bovine and b) porcine based gelatin gels.

The simplest law used to model materials that behave elastically and show strain hardening when subjected to large strains is the first order Ogden constitutive equation. It can be expressed in terms of true stress σ and stretch ratio λ, as:

$$\sigma = \frac{2\mu}{\alpha}\left(\lambda^{\alpha} - \lambda^{-\alpha/2}\right) \tag{3}$$

where μ is equal to the material shear modulus and α is a parameter related with strain hardening capability [19]. More negative α values indicate large strain hardening, while less negative ones stands for more linear elastic behavior.

For each experimental set of curves, a least square fit was performed taking all stress-stretch ratio data up to λ=0.35. The obtained model parameters are given in Table 2. This simple model (Eq. 3) is able to well describe the behavior of gelatin gels as judged by the values of the regression coefficients (R^2) and the errors in the model parameters. The source of strain hardening capability of gelatin gels may rely on the ability of the protein molecules to recover the native collagen triple helix configuration under stress. This behavior has already been suggested to explain improvements in mechanical properties of gelatin films [20]. As protein renaturation is a completely reversible process, gelatin gels are capable to recover its original configuration after load removal, displaying non-linear elastic behavior. *P0* is more able to strain harden than *B0* (see the more negative α value in Table 2).

The shear modulus of *P0* gel is larger than the one determined for *B0* gel (Table 2), consistently with its higher Bloom value. The addition of sorbitol and glycerol slightly modifies the Ogden constitutive parameters except for the *P2* gel in which α becomes less negative and μ decreases. The change in α is consistent with a larger amount of physical crosslinking points in the gelatin network, which

constrains renaturation of protein molecules under stress. The decrease in μ maybe related to the higher water content in the gel.

Table 2. Mechanical parameters obtained from uniaxial compression tests.

Gel sample	μ (kPa)	α	R^2	Fracture stress (kPa)	Fracture strain
B0	9.29 ± 0.09^{a}	-1.40 ± 0.02^{a}	0.9826	69.2 ± 8.1^{a}	1.23±0.12
B1	12.07 ± 0.06^{b}	-1.44 ± 0.01^{b}	0.9954	90.6 ± 3.5^{b}	1.20±0.02
B2	9.57 ± 0.04^{c}	-1.37 ± 0.01^{c}	0.9983	79.1 ± 5.1^{ab}	1.23±0.06
P0	14.59 ± 0.15^{A}	-1.53 ± 0.01^{A}	0.9747	176.6 ± 35.4^{A}	1.42±0.14
P1	13.52 ± 0.19^{B}	-1.38 ± 0.04^{B}	0.9599	102.8 ± 32.9^{B}	1.31±0.04
P2	10.88 ± 0.19^{C}	-1.14 ± 0.05^{C}	0.9507	83.1 ± 7.4^{B}	1.37±0.10

Different letters in the same column indicate significant differences between means. Differences in fracture strain were not significative for both B and P series ($p<0.05$)

The ultimate properties obtained from the failure point in the stress-strain curves are also reported in Table 2. Fracture stress and strain are related to crosslinking density and network strength but also depend on microstructural defects. *B0* gel displays lower ultimate properties than *P0* gels despite the presence of microbubbles. In brief, porcine gelatin gels structure is more resistant and has a larger deformation capability than bovine gelatin one. Surprisingly, the addition of sorbitol and glycerol has a marked impact in the ultimate properties of porcine based gels but slightly influences the bovine ones. The detriment in fracture strain can be explained by an increase in protein-protein interactions, which leads to a more physically crosslinked network.

The ultra-structures of *P0*, *P2*, *B0* and *B2* gels were analyzed by SEM. The images of the morphologies are shown in Figure 2. All gels exhibit a network structure, but the addition of sorbitol in gel formulations appears to promote a large number of bridging sites in the gel main network (Fig. 2 *b* and *d*). This effect is more pronounced in P2 gel (Fig. 2 *b*), consistently with the major change in ultimate stress and strain hardening capability. It can also be observed that the network is more opened in *P2* gel even it is more interconnected. These features can explain the decrease in gel stiffness and are in agreement with the higher water retention capability of *P2* gel.

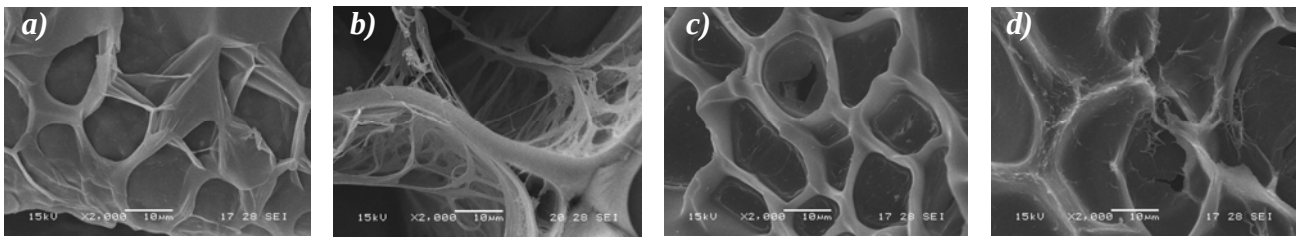

Figure 2. SEM images of gelatin gels revealing the detailed morphology of gelatin network ultra-structure a) P0, b) P2, c) B0 and d) B2.

3.3 Fracture Toughness

For all samples, wire cutting curves show two phases: an indentation phase and a steady- state cutting phase. First, the wire indented into the gel up to a given point at which the material starts to fracture. From such point, the load decreased suddenly reaching an almost constant force that corresponds to the steady-state cutting phase, F_c. In every case, the cutting force increases with increasing wire diameter. Figure 3 shows typical force-displacement curves obtained at different wire diameters for one of the tested gels (*B0*). The same wire cutting behavior was described for other soft materials [see for example in [7, 12, 21].

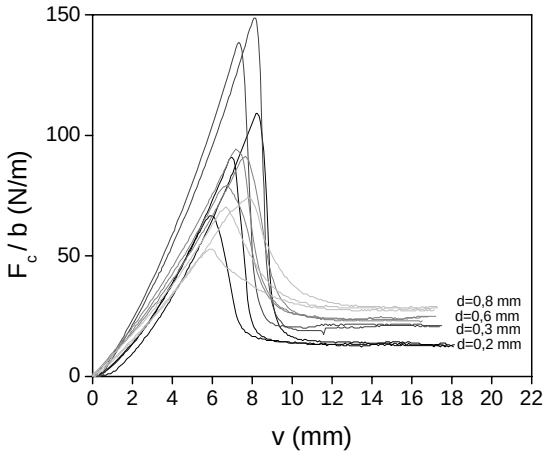

Figure 3. *Typical normalized load-displacement data measured in wire cutting tests of B0 gel using different wire diameters.*

The cutting energy versus wire diameter plots are shown in Figure 4. All data obtained for each wire diameter were averaged and plotted with its error. Data were linearly fitted according to Eq. 2 using Least Squares. Data lying outside the 95% confidence limits from the first best fit line were eliminated from the analysis. The arisen fitted parameters are listed in Table 3.

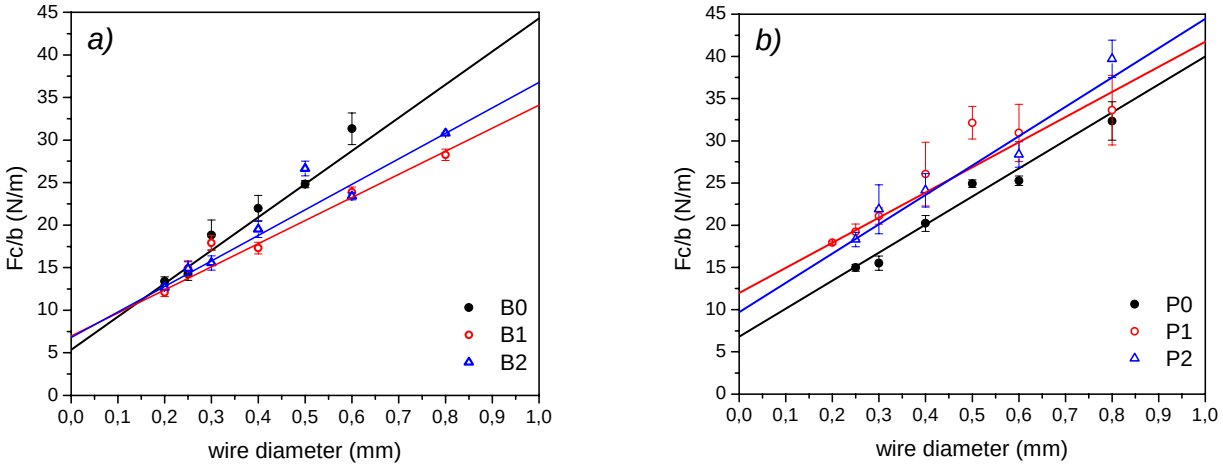

Figure 4. *Wire cutting data measured for a) bovine and b) porcine gelatin gels.*

The resulting experimental trend agreed with the wire cutting method proposal (Eq. 3) as judged by the obtained R^2 values greater than 0.93. Better regression coefficients values yield from bovine gelatin gels than for porcine gelatin gels. This can be attributed to the larger content of

microbubbles in the porcine gels.

The fracture toughness values are in the range of those required in pharmacy and tissue engineering applications (1 to 10 N/m) [13]. *P0* gels exhibit higher fracture toughness than *B0* gels, despite its larger amount of retained water. This is also true for the whole bovine and porcine series. Moreover, the addition of sorbitol and glycerol in gel formulation has a beneficial effect on the fracture toughness of both bovine and porcine gelatin gels. The enhancement in fracture toughness is more pronounced in porcine gels according to the development of a more interconnected network (Figure 2).

Table 4. *Fracture toughness of gelatin gels, G_c*

Gel sample	Gc (N/m)	$\sigma_0(1+\mu)$ (kPa)	R^2
B0	5.35± 0.78	38.95± 1.98	0.99222
B1	6.96± 0.71	27.15± 1.44	0.98887
B2	6.81± 0.25	29.96± 0.33	0.99951
P0	6.81± 1.66^{A}	33.16± 3.81	0.93736
P1	11.98± 0.42^{B}	29.75± 1.99	0.97802
P2	9.70± 1.58^{B}	34.44± 3.76	0.95393

Different letters in the same column indicate significant differences between means. Differences in Gc were not significative in B serie ($p<0.05$).

4. CONCLUSIONS

Gelatin hydrogels with stiffness values in the range required for applications in ballistic, food, pharmaceutical and tissue engineering were prepared from commercial powders and their large deformation and fracture behaviors were investigated. The main findings of this research are summarized as follows:

- Under uniaxial compression, bovine and porcine gelatin gels behave as non-linear elastic materials with strain hardening, which can be attributed to partial protein renaturation under stress. Gelatin gels were able to support deformation levels over 120% before failure.
- Gelatin gels show brittle fracture behavior with fracture toughness values in the range of those required in pharmacy and tissue engineering.
- Neat porcine gelatin gels exhibit higher gel strength, shear modulus, failure strain and stress, fracture toughness and water retention capability than bovine gels.
- The addition of sorbitol and glycerol causes an increase in water retention capability of both types of gelatin gels as well as a marked enhancement in fracture toughness.
- The ultra-structure of modified gelatin gels presents a more opened network but contains a higher amount of interconnection sites than the neat gelatin gels.
- The effect of additives on elastic modulus and ultimate properties is detrimental in porcine gelatin gels and negligible in bovine gelatin gels.
- A correlation between the technological gel strength measurement with fracture and mechanical parameters was not found for gelatin gels containing additives.

Abstract Dielectric elastomer actuators are susceptible to electromechanical instability, limiting operational voltages and attainable deformations. In this work, electromechanical stability is investigated at the example of a cone dielectric elastomer actuator. Under the preload and applied voltage, deformation of cone actuator is inhomogeneous. The electromechanical instability occurs when the Hessian of free-energy function of anyone particle in the membrane ceases to be positive definite. Critical voltage of the membrane decreases as the preload increases. The critical actuation stretches are proportional to the critical voltages. As the prestretch increases, the critical voltage decreases while the critical true electric field increases. These results can be used to guide the design of cone actuator.

Keywords dielectric elastomer actuator, electromechanical instability, inhomogeneous deformation

1. Introduction

Dielectric elastomer (DE) is a particularly promising class of EAP (Electroactive polymers) which can overcome many limitations of traditional smart material and transducer technologies. DE based actuators usually consist of elastomer membranes coated with compliant electrodes on both sides. Giant deformation of area expansion rates over 100% can be achieved by applying a voltage.[1] This kind of actuators have been rising as a potential candidate in diverse applications including medical device, soft robotics, energy harvesters and optics etc.[2-4]

Despite good laboratory performance, DEAs are susceptible to various modes of failure[5-6] which prevent their practical application. One of important failure modes is the electromechanical instability, limiting operational voltages and attainable deformations. The study on the failure and nonlinear electromechaniacl stability of DEAs has attracted intensive research [7-9]. Zhao and Suo[7] proposed a general method based on the nonlinear field theory of deformable dielectrics to study the stability. Along this line a series of works have been completed. Xu *et al.*[9] presented an explicit expression for critial stability electric fields by the concept of total stress. In these works, EMI is investigated at the example of parallelepiped actuators.

Cone actuators have a potential application as artifical muscles and were studied by Artificial Muscle Inc.(AMI) and MIT. The understanding of the electromechanical stability for cone actuators is important for their design. In this paper, we consider the definite positiveness of the Hessian matrix representing the electromechanical stability criteria. The critical voltages under different preload of the cone actuator are obtained. The actuation stretches of the actuator are related to the critical voltages. The effect of prestretch on the the critical voltage and the critical true electric field is also investigated.

2. State equations of cone actuators

Figure 1 gives a schematic illustration of cone actuator. A circular dielectric membrane in the undeformed state with thickness H and radius B is coated by two compliant electrodes on both sides [Fig.1(a)]. A general particle of the membrane is at a distance R from the center. Cone actuator is finished by sticking the membrane with a rigid inner frame of radius a and a rigid outer ring of radius b. When a preload F is applied to the inner frame and a voltage ϕ is applied between the two electrodes, the elastomer deforms into an out-of-plane axisymmetric shape with stretches

λ_1, λ_2 and λ_3 as well as gains a distance *u* of the inner frame relative to the ring and an amount of charge Q on either electrodes, and the particle *R* moves to a place with coordinate *r*(*R*) and *z*(*R*) [Fig.1(b)]. Where the longitudinal stretch λ_1 is defined by the distance between the two particles in the deformed state divided by that in the undeformed state, $\lambda_1 = dl/dR$ and the latitudinal stretch is $\lambda_2 = r/R$. Suppose the membrane is incompressible, the free energy density is a function of the three kinematic variables as

(*a*)

(*b*)

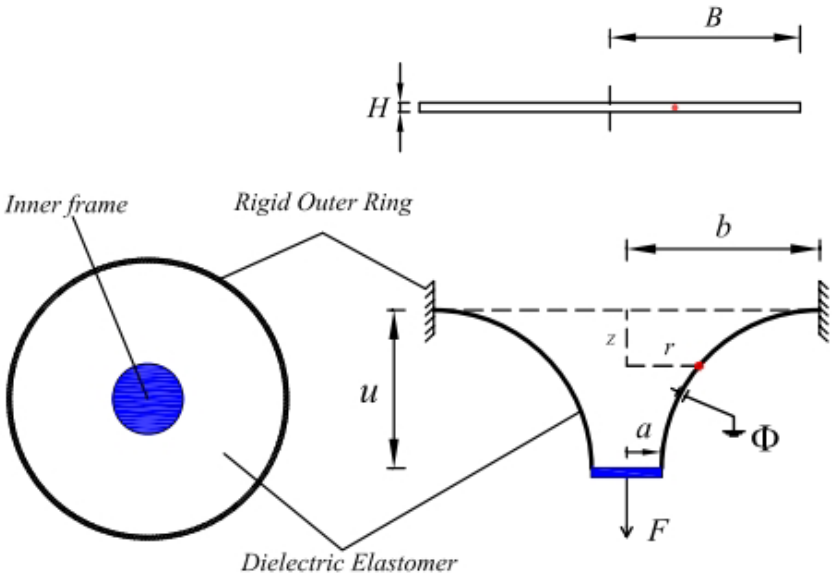

Figure 1. schematic illustration of a cone actuator

$W(\lambda_1, \lambda_2, \tilde{D})$, where $\tilde{D}$ is the nominal electric displacement defined as charge divided by the undeformed area of the membrane. Nominal stresses s and nominal electric field $\tilde{E} = \phi/H$ (the electric field in the undeformed state) can then be expressed as

$$s_1 = \frac{\partial W(\lambda_1, \lambda_2, \tilde{D})}{\partial \lambda_1}, \qquad s_2 = \frac{\partial W(\lambda_1, \lambda_2, \tilde{D})}{\partial \lambda_2}, \quad \tilde{E} = \frac{\partial W(\lambda_1, \lambda_2, \tilde{D})}{\partial \tilde{D}} \tag{1}$$

The true stresses σ_1 and σ_2 relate to the nominal stress as $\sigma_1 = \lambda_1 s_1$ and $\sigma_2 = \lambda_2 s_2$. Adopting the Neo-Hookean strain energy model and the linear electrostatic energy function, the free energy function take the form[10]

$$W(\lambda_1, \lambda_2, \tilde{D}) = \frac{\mu}{2}(\lambda_1^2 + \lambda_2^2 + \lambda_1^{-2}\lambda_2^{-2} - 3) + \frac{\tilde{D}^2}{2\varepsilon}\lambda_1^{-2}\lambda_2^{-2} \tag{2}$$

where μ is the shear modulus, ε is the permittivity.

Inserting Eq.(2) into Eq.(1), we get

$$s_1 = \mu(\lambda_1 - \lambda_1^{-3}\lambda_2^{-2}) - \frac{\tilde{D}^2}{\varepsilon}\lambda_1^{-3}\lambda_2^{-2}, \quad s_2 = \mu(\lambda_2 - \lambda_2^{-3}\lambda_1^{-2}) - \frac{\tilde{D}^2}{\varepsilon}\lambda_2^{-3}\lambda_1^{-2} \tag{3}$$

$$\tilde{E} = \frac{\tilde{D}}{\varepsilon}\lambda_1^{-2}\lambda_2^{-2} \tag{4}$$

Equations of equilibrium can be obtained by balancing forces in the directions of *z* and *r* as

$$\frac{F}{2\pi HR\sin\theta} = s_1 \ , \qquad \frac{d(Rs_1\cos\theta)}{dR} = s_2 \tag{5}$$

For the actuator system, the thermodynamic stability requires that the following Hessian matrix

$$H=\begin{bmatrix} \mu(1+3\lambda_1^{-4}\lambda_2^{-2})+\dfrac{3\tilde{D}^2}{\varepsilon}\lambda_1^{-4}\lambda_2^{-2} & 2\mu\lambda_1^{-3}\lambda_2^{-3}+\dfrac{2\tilde{D}^2}{\varepsilon}\lambda_1^{-3}\lambda_2^{-3} & -\dfrac{2\tilde{D}}{\varepsilon}\lambda_1^{-3}\lambda_2^{-2} \\ 2\mu\lambda_1^{-3}\lambda_2^{-3}+\dfrac{2\tilde{D}^2}{\varepsilon}\lambda_1^{-3}\lambda_2^{-3} & \mu(1+3\lambda_2^{-4}\lambda_1^{-2})+\dfrac{3\tilde{D}^2}{\varepsilon}\lambda_2^{-4}\lambda_1^{-2} & -\dfrac{2\tilde{D}}{\varepsilon}\lambda_2^{-3}\lambda_1^{-2} \\ -\dfrac{2\tilde{D}}{\varepsilon}\lambda_1^{-3}\lambda_2^{-2} & -\dfrac{2\tilde{D}}{\varepsilon}\lambda_2^{-3}\lambda_1^{-2} & \dfrac{1}{\varepsilon}\lambda_1^{-2}\lambda_2^{-2} \end{bmatrix} \tag{6}$$

must be definite positive at the equilibrium state. Eqs.(3～5) can determine the equilibrium values of the generalized coordinates $\lambda_1, \lambda_2, \tilde{D}$. It is noticeable that the deformation is inhomogeneous, so the λ_1 and λ_2 are different along coordinate r in the membrane. For a given dead mechanical preload F, we vary the voltage ϕ. When the voltage is small, the Hessians of all particles are positive definite. Once the Hessian of anyone particle ceases to be positive definite, the voltage reaches a critical value ϕ_c. The critical condition of EMI is set by $\det \mathrm{H}=0$. The condition $\det \mathrm{H}=0$, along with the equilibrium equations [Eqs.(3～5)], determine the critical values $\tilde{E}_c$, $\tilde{D}_c$ and the distrubtion of λ_1^c, λ_2^c in the membrane for any given dead preload F.

3. Electromechanical instability analysis and discussions

The stability criteria can be expressed as the positive sign for the Hessian matrix containing the second–order variations of the energy function as it has been formulated above, which we solve numerically. In presenting the results, we normalize the four variables into dimensionless forms: $\dfrac{F}{2\pi\mu Ha}$, $\dfrac{Q}{2\pi\sqrt{\varepsilon\mu}a^2}$, $\dfrac{\Phi}{H\sqrt{\mu/\varepsilon}}$, $\dfrac{D}{\sqrt{\varepsilon\mu}}$. We first fix the geometrical dimensionless parameters to special values, $b/B=1$, $b/a=4$. This condition means there is no prestress in the membrane.

Fig.2 shows the effect of the dead preload on the critical voltage ϕ_c. As the preload increases, the critical voltage of the membrane decreases. The result reveals a drop of the withstanding voltage ϕ_c of the membrane is part due to the decrease in the thinkness with increasing deformation of preload. Recall that the membrane deformation is inhomogeneous while the applied critical voltage ϕ_c is homogeneous in the membrane. the distribution of the critical true electric field E_c in the membrane is ploted in Fig.3. This figure shows that the distribution is more uneven and lower as the preload is bigger, but the maxima at the inner frame boundary are very close.

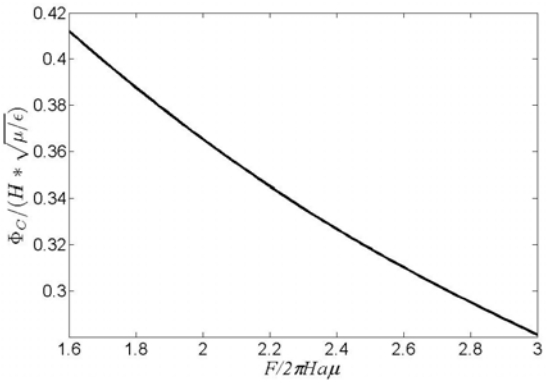

Figure 2. The effect of the dead preload on the critical voltage

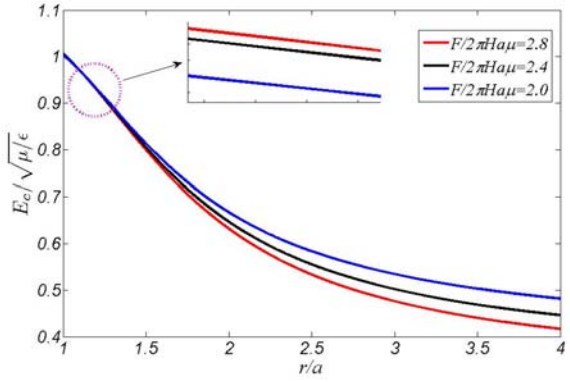

Figure 3. The distribution of the critical true electric field in the membrane

The longitudinal true stress σ_1 is always tensile in order to balance the preload. However, the latitudinal true stress σ_2 can become compressive when the applied voltage is large. The loss of

tension may cause the membrane to buckle. Figure 4 shows the possible failure modes of the actuator. It is indicated that the loss of tension is expected to occur first and EMI comes next. EMI may finally result in electrical breakdown. Rupture will not occurr. This trend coincides with the experimental report.

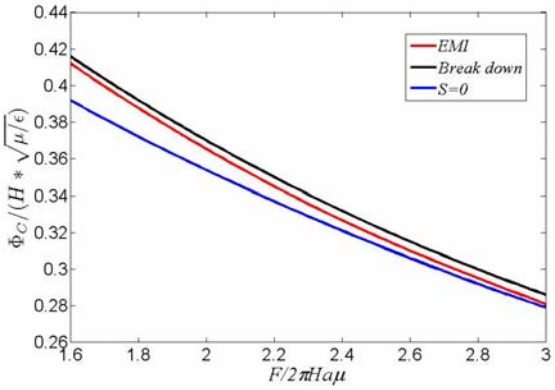

Figure 4. The possible failure modes of the actuator

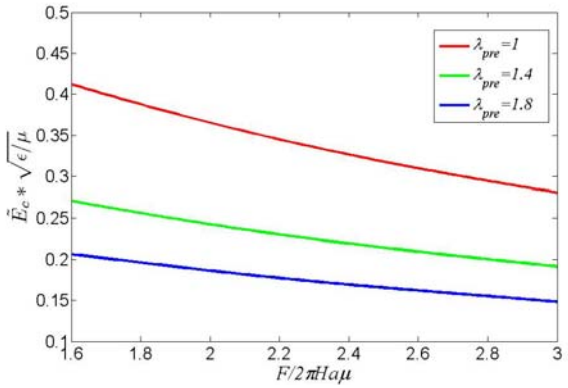

Figure 5. The effect of equal biaxial prestretch on the critical voltage

Figure 5 and Figure 6 show the effect of equal biaxial prestretch on the critical voltage and critical true electric field, respectively. As the prestretch increases, the critical voltage decreases while the critical true electric field increases. It is desirable for the cone actuator to work under a low voltage and a low true electric field, but generate large displacement output. Displacement output is an important performance of actuator and will also influence the force output. The displacement output vs preload is ploted in figure 7. The displacement output is decreases as the preload increases and

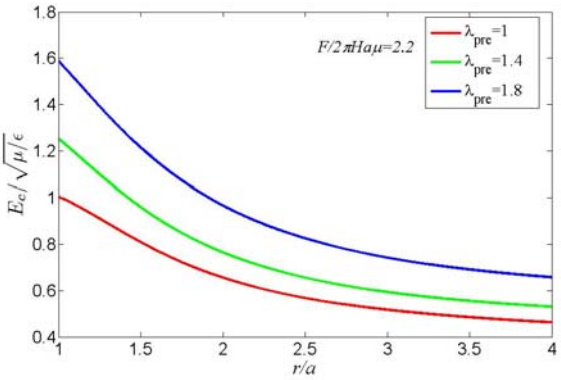

Figure 6. The effect of equal biaxial prestretch on the critical true electric field

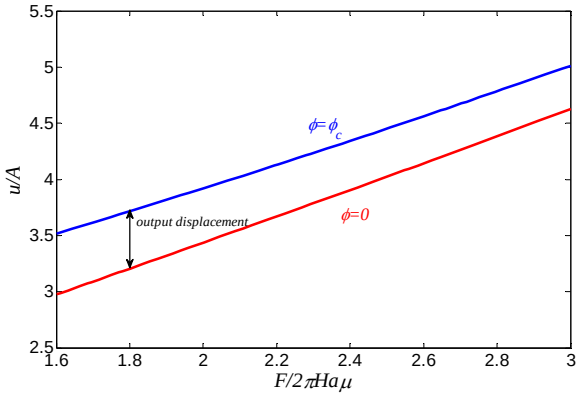

Figure 7. The dead preload vs the output displacement

critical voltage decreases. According to the presented theoretical model, when the actuator is applied by low preload and prestressed, the critical voltage is high, and the actuation stretch and displacement output is large. As a summary, The electromechanical instability occurs when the Hessian of free-energy function of anyone particle in the membrane ceases to be positive definite. The dead preload has significant influence on the electromechanical stability of cone actuator. As the preload increases, the critical voltage of the membrane decreases. Prestress can markedly increase the critical voltage and decrease the critical true electric field.

Abstract

Engineered soft hydrogels have recently garnered attention for their application as scaffolds for tissue engineering, drug delivery, and as model extracellular matrices such as arteries and cartilage that experience dynamic loading. Hydrogels exhibit nonlinear, composite, viscoelastic, and anisotropic behaviors and hence, mechanical models used to describe such materials are challenging. In this study, we synthesized three dimensional gelatin and elastin hydrogels of varying compositions and crosslinking degrees and characterized their structure-property relationships. Mechanical properties were measured using monotonic compression, dynamic mechanical analysis (DMA), and quasi-static stress relaxation tests. Compressive moduli for the gels range from 1.5 to 15 kPa and these measurements correlate with the values of storage modulus obtained from DMA studies ($p<0.05$). Ongoing studies are aimed at using stress relaxation data to create mechanical spring-dashpot models to describe the viscoelastic behavior of these materials. Scanning electron microscopy was used to assess the gel microstructure. Our results demonstrate that varying the gelatin and crosslinker concentrations leads to significant ($p<0.05$) changes in pore sizes with the lowest stiffness group exhibiting considerably larger porosity. Incorporation of elastin resulted in increased stiffness, change in hydrogel microstructure and swelling properties of the hydrogels.

Keywords: hydrogels, viscoelasticity, gelatin, elastin, tissue engineered scaffolds

1. Introduction

Tissue engineering scaffolds aim to synthesize living tissues *in vitro* by creating suitable mechanical and chemical environments for tissue growth. These scaffolds typically have compositions and mechanical properties similar to that of the native tissues which predominantly contain structural proteins collagen and elastin [1]. Collagen, of which gelatin is a denatured form, is a ubiquitous protein that gives tissues stiffness and mechanical strength. In contrast, elastin is a fatigue resistant rubber-like protein present in dynamic structures, such as arteries and ligaments, which undergo repeated cyclic deformation. Collagen and elastin composite hydrogels present multiple challenges towards our understanding of the material responses due to their non linear and viscoelastic nature while being fracture resistant and able to sustain cyclic loads to serve as biological replacements. Earlier studies characterizing the mechanical properties of biocompatible hydrogels have employed various mechanical testing methods from monotonic compression and tension [2, 3], to viscoelasticity studies through dynamic mechanical analysis and stress relaxation [4–7]. These tests provide insights into the material response of soft materials for a better tuning of the tissue properties. Few studies have however focused on characterizing the mechanics of elastin and collagen based composite hydrogels aimed toward better design of scaffolds that replicate the *in vivo* cellular environments.

The aims of this study are threefold: first, to fabricate gelatin and elastin based crosslinked hydrogels of varying material stiffness to emulate native tissue environments. Crosslinking of hydrogels is necessary to maintain the integrity and long term viability of the hydrogels. Second, to study the microstructure and water uptake behavior of the hydrogels using scanning electron microscopy and swelling experiments. Third, to quantify mechanical properties through monotonic compression tests, dynamic mechanical analysis and stress relaxation experiments. Ongoing studies in our lab are also aimed at characterizing the fracture properties of hydrogels. Because the growth

and behavior of biological tissues are exquisitely sensitive to the mechanical properties of their environment, we hope such studies will help in the design of engineered hydrogels to better emulate native tissue environments [8].

2. Materials and Methods

2.1 Isolation of elastin from bovine aorta

Native aortic tissues typically contain elastin, collagen and proteoglycans. Protocols for elastin isolation from native tissues rely on its chemical inertness and insolubility in various reagents at elevated temperatures. We used the hot alkali treatment to extract elastin from bovine thoracic aorta in this study to obtain a relatively pure and insoluble elastin protein [9]. In this method, artery samples were thoroughly washed with distilled water to clean tissues, minced using a grinder and kept in a solution of 0.1 M NaCl overnight. Treated tissues were washed thrice with distilled water to remove the salt and boiled for 45 minutes in 0.1 M NaOH solution at 95°C to remove contaminant proteins, such as collagen and proteoglycans, from aorta samples. Tissues were washed twice with distilled water and dried at 60°C to obtain purified and insoluble elastin. Finally, the dried material was powdered, sieved (150 µm pore size) and stored at 4°C until use.

2.2 Preparation of crosslinked gelatin and elastin hydrogels

Porcine gelatin Type-B powder (Sigma Aldrich, India) was dissolved in double distilled water at 50° C to obtain a clear solution. Because gelatin is soluble in water, it is necessary to crosslink the material to preserve the hydrogel structure. Collagenous materials, such as gelatin, are generally crosslinked using methods which exploit the large number of functional side groups. We used glutaraldehyde (Sigma Aldrich, India, 25% stock) as a crosslinking agent by combining it with dissolved gelatin solution in this study [10]. A cylindrical mold, containing 9 wells of dimensions 16 mm diameter and 20 mm height each, was fabricated using polydimethylsiloxane (PDMS, Sylgard ®184, Dow Corning). The inner surface of each individual well of the mold was coated with petroleum jelly to prevent adhesion to the hydrogel. Two different concentrations of gelatin and one composite gelatin-elastin hydrogel were prepared in this study. Gels were poured in each well and cured at 4° C for 6 hours. To reduce dehydration of the hydrogels during crosslinking, the mold was wrapped in plastic film. Finally, the gels were soaked in 0.1 M glycine solution to block additional glutaraldehyde action and stored in distilled water overnight prior to mechanical testing [11]. Gelatin-elastin hydrogels were prepared by suspending the insoluble elastin in gelatin solution and vortexing the mixture before adding glutaraldehyde to crosslink the gels.

Table 1 Composition of hydrogels used in the study

Group	Gelatin (gm/ml)	Elastin (gm/ml)	Glutaraldehyde (%v/v)
3G	0.03	0	0.5
5G	0.05	0	1
5GE	0.05	0.05	1

2.3 Swelling characteristics of hydrogels

Hydrogel samples were lyophilized for 24 hrs and their dry weight measured. Samples were immersed in 5 ml of distilled water at room temperature and the wet weight was measured at

regular time intervals. Before weighing, the samples were gently patted dry using tissue paper and the swelling ratios calculated at each time point as

$$Swelling\ Ratio\ (\%) = \frac{W_s - W_d}{W_d} \times 100 \quad (1)$$

w_s is the weight of the swollen sample at each time period. To determine the fluid content of the hydrogels in their maximum swollen state, Equilibrium Water Content (EWC) was calculated using

$$EWC(\%) = \frac{W_e - W_d}{W_e} \times 100 \quad (2)$$

w_e is the equilibrated sample weight and w_d is the sample weight in its dry state in equation (2).

2.4 Mechanical Tests

2.4.1 Determination of modulus of the hydrogels

Monotonic compression tests were performed on a Bose Electroforce® 3200 (Bose Corp., USA) Dynamic Mechanical Analysis (DMA) instrument equipped with two parallel compression platens. Displacements were measured using a LVDT and the forces obtained using a transducer (Bose Corp., ±22.5N). The height and diameter of gels were measured from a photograph of the gels (Nikon D7000 camera) using ImageJ software [12]. Hydrogel specimens were preloaded in the DMA instrument to 5 grams and preconditioned for 30 cycles of 10% compressive strain at 0.05Hz to obtain a repeatable material response [6, 13]. Following preconditioning, samples were compressed at a rate of $0.01s^{-1}$ until either the maximum displacement limit of the instrument was reached or the gels failed. Custom written programs in MATLAB (v7.8.0.347 (R2009a)) were used to analyze the data. Compressive moduli were calculated using the stress-strain data upto 4% strain. In all, 4 samples were tested in each of the 3G, 5G and 5GE groups and an average modulus was calculated for each group.

2.4.2 Dynamic Mechanical Testing

To obtain viscoelastic properties of the hydrogels in each of the three groups, we used fresh compression samples by preloading the hydrogel to 5 gram force and subjecting them to cyclic sinusoidal loading between 0 and 10% compressive strain over a frequency range of 0.05 to 130 Hz. 4 samples were tested in each hydrogel group. Data were acquired at least 30 times the loading frequency and the traces (Figure 1) were analyzed using custom software. In this method, a discrete Fourier transform was performed on the stress and strain data for each acquired frequency block. The phase and amplitude of the relevant portion of the resulting spectra of the stress and strain were used to compute the storage modulus (E′), loss modulus (E″) and phase angle (δ) for the hydrogel [14].

Variation in the strain with angular frequency (ω) is given as

$$\varepsilon(t) = \varepsilon_o \ \sin(\omega t) \quad (3)$$

Stress corresponding to the strain loading is represented by

$$\sigma(t) = \sigma_o \ \sin(\omega t + \delta) \quad (4)$$

σ_o and ε_o are the amplitudes of the sinusoidal stress and strain curves respectively.

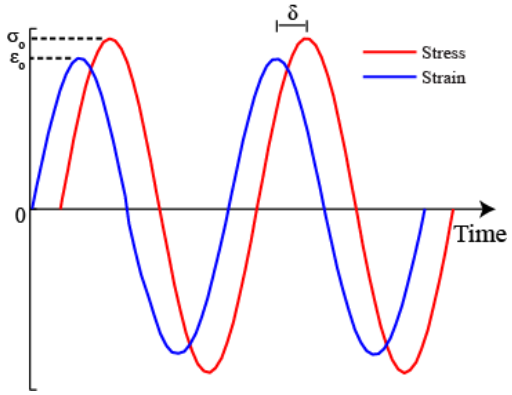

Figure 1. Schematic representation of stress-strain traces from DMA experiments used to compute the various parameters as described below.

The complex modulus, given as $E^* = E' + iE''$, has components

$$E' = \frac{\sigma_o}{\varepsilon_o}\cos(\delta) \text{ and } E'' = \frac{\sigma_o}{\varepsilon_o}\sin(\delta) \quad (5)$$

2.4.3 Stress Relaxation Experiments

We also performed quasi-static stress relaxation experiments by subjecting the hydrogels to a step displacement loading of 10% and a hold time of 15 minutes. Prior to this, each hydrogel was preloaded to 5 gram force as described earlier. Strains in the hydrogels were next increased to a total of 30% in two discrete steps with a hold time of 15 minutes (Figure 2). Data were acquired at 30 Hz for the first five minutes after each strain increment followed by 3Hz for the next five minutes. The remaining data were acquired at 1Hz to capture the total decay in forces during the hold period. Such experiments are useful to arrive at suitable viscoelastic models, obtained using a combination of springs and dashpots, to describe the mechanics of hydrogels.

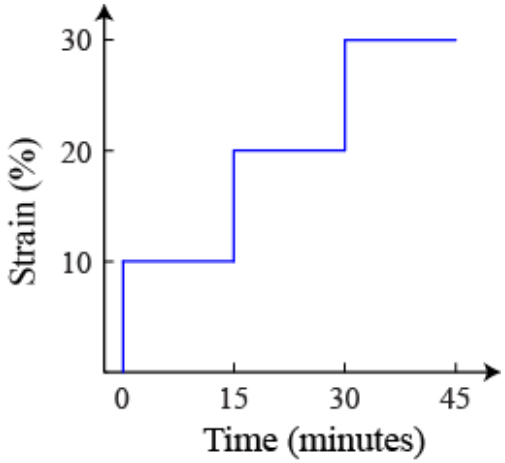

Figure 2. Schematic plot of a stress relaxation experiment obtained by imposing a constant step strain to the sample for a finite period

2.5 Microstructure of the hydrogels

Transverse sections of hydrogel samples were lyophilized for 20 hours and observed using an environmental scanning electron microscope (ESEM, Quanta 200). Image J was used to calculate the pore sizes of the hydrogels [12].

3. Results and Discussion

3.1 Morphology of hydrogels

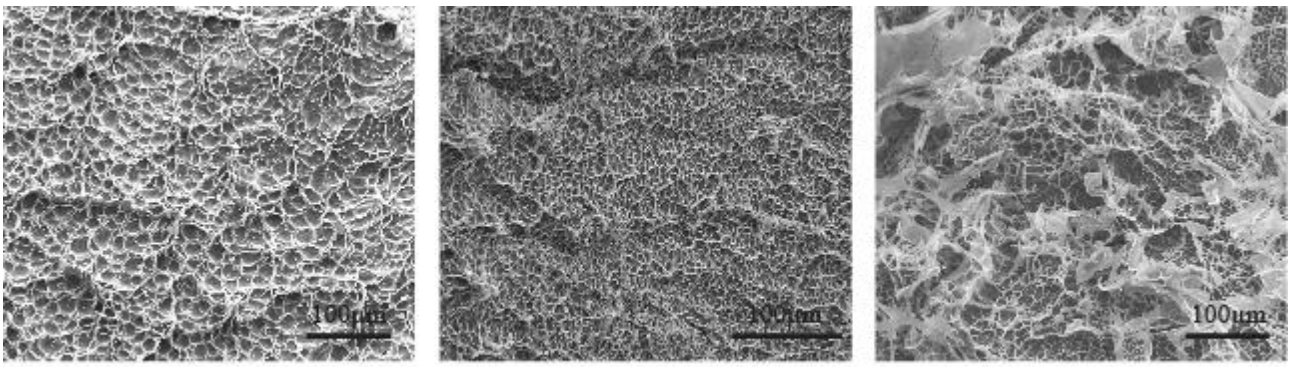

Figure 3. ESEM of gelatin and gelatin-elastin hydrogels show differing microstructures

When imaged using ESEM, hydrogels display a highly porous microstructure (Fig 3.) with variations in the degree of porosity and heterogeneity between the different groups considered in the study. The 3G and 5G hydrogels are predominantly homogeneous with differing porosities. In contrast, regions of heterogeneity exist in the 5GE gels with insoluble elastin forming sheet-like fibrous islands shown as white regions in the micrograph. To quantify the areal porosity of hydrogels, we used image processing tools in ImageJ. These results show that there are no significant differences ($p<0.05$) in the average pore size for the 5G (6.2±1.4 μm) and 5GE (6.5±1.5μm) samples. However, we note a significant difference in average pore size in comparisons of the 3G (15.8±3.4 μm) gel with the other groups respectively ($p<0.05$). Differences in the hydrogel porosity are attributed to variations in the polymer and crosslinker concentrations used in the fabrication of the 3G and 5G hydrogels. An increase in polymer concentration, while keeping other processing variables constant, may lead to a tighter packing of individual biopolymer chains and consequently a smaller pore size. Further, the amount of glutaraldehyde was doubled in the 5G gels as compared to the 3G hydrogels which may lead to a higher crosslink density and a possible reduction in the pore size. Similar results on decrease in pore size with an increase in the base polymer concentration is observed in non crosslinked gelatin hydrogels [15]. Because gel porosities affect diffusion of nutrients in the hydrogels, control of these pore dimensions will ultimately be dictated by requirements posed by different cells cultured in the hydrogels to serve as viable tissue engineered scaffolds.

3.2 Variation in the swelling characteristics of the hydrogels

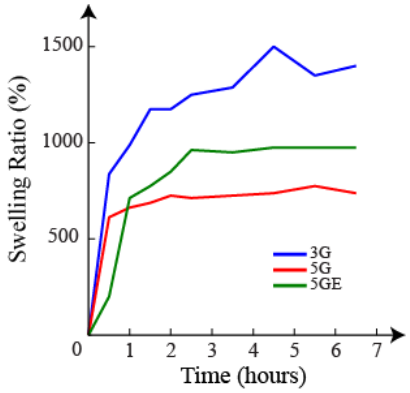

Figure 4. Swelling ratios of 5G 5GE and 3G hydrogels calculated as a function of time

Data from swelling studies (Figure 4) suggest that an increase in polymer and crosslinker concentrations leads to decrease in the swelling ratio that are in agreement with earlier work [16]. The EWC for the hydrogels also decreases with increasing polymer and crosslinker concentration with the 3G gels having the highest EWC and the 5GE gels showing the lowest EWC (Table 2). Increasing the monomer concentration leads to the formation of a higher number of network chains that reduces the diffusion of solvent through the sample and hence a corresponding decrease in hydrogel swelling behavior. Further, an increase in the crosslinker concentration causes the formation of a higher density of crosslinked chains that may consequently reduce the swelling of the hydrogels [17]. The decrease in pore size due to increasing polymer and crosslinker concentration hence results in the lowering of the EWC of the hydrogels because of reduced water absorption and retention in the hydrogel. The presence of sheet-like fibrous islands of elastin in the 5GE gels may further lead to blocking of pores in the gel that prevent water uptake and hence results in the low EWC noted in this study. However, additional samples are required to show statistically significant results.

Table 2. Equilibrium water content (EWC) for a hydrogel sample in each group

Group	EWC (%)
5G	**88.05**
5GE	**76.74**
3G	**93.33**

3.2 Mechanical Characterization

3.2.1 Variation in the moduli of the hydrogels

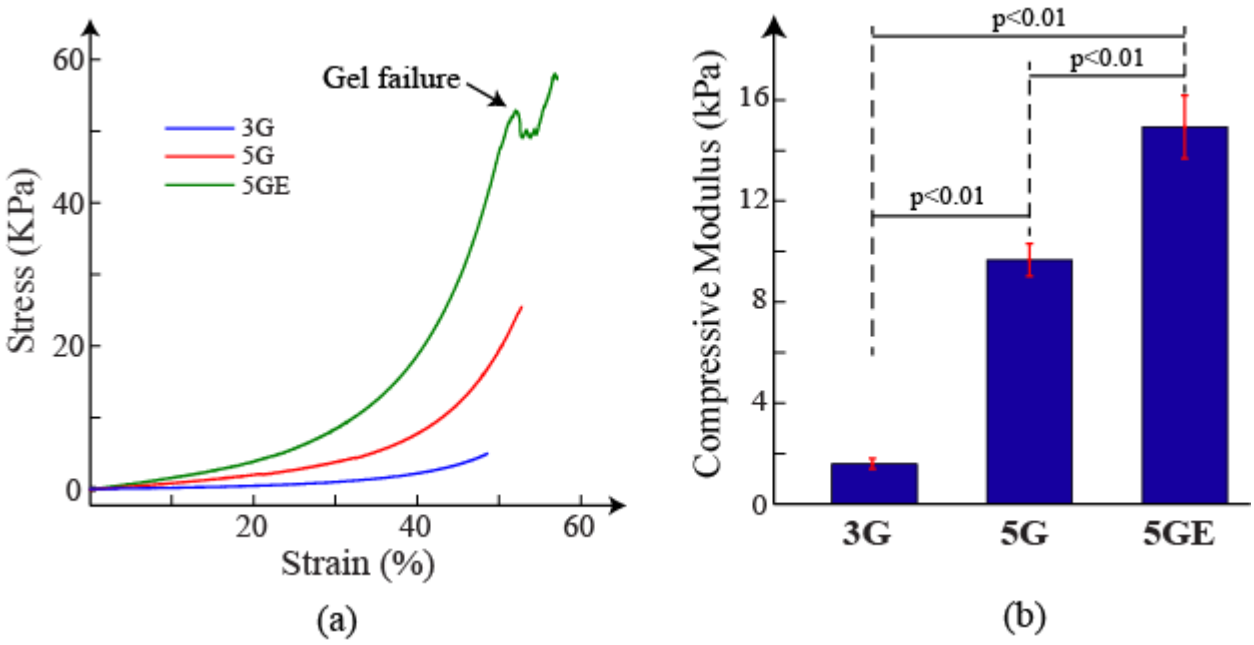

Figure 5. (a) Representative traces from monotonic compression tests on Gelatin and Gelatin - Elastin hydrogels (b) Compressive modulus for Gelatin and Gelatin - Elastin hydrogels at 4% strain

Preconditioning of gels, though not reported in most studies [2, 18], seems crucial and is an established method for reporting the stress-strain results for soft tissue materials [13]. Our results show a clear variation in the peak amplitude of load from the first to the last reported cycle during preconditioning with maximum differences visible between the first and second cycles of loading.

In contrast, data from the last five cycles show repeatable stress-strain response for all hydrogel groups in this study. Representative traces of stress-strain responses (Figure 5a) corresponding to the three hydrogel groups show that an increase in gelatin content or addition of elastin leads to an increased nonlinear material response in the observed strain range. The 5G and 5GE groups demonstrate a response similar to that observed for native tissues such as arteries and cartilage whereas the 3G gels have a highly compliant response [2, 13, 18]. Compressive moduli were calculated for all samples and are reported in Figure 5b. The higher moduli in the 5EG group (14.938±1.253 kPa) and 5G samples (9.669±0.644 kPa) correlate with an increase in the amount of material and glutaraldehyde concentrations as compared to the 3G group (1.591±0.210 kPa). However, our studies show that elastin containing hydrogels fractured at strains of about 0.54±0.02 whereas the gelatin gels showed no signs of damage at these strains.

3.2.2 Viscoelastic characterization of hydrogels

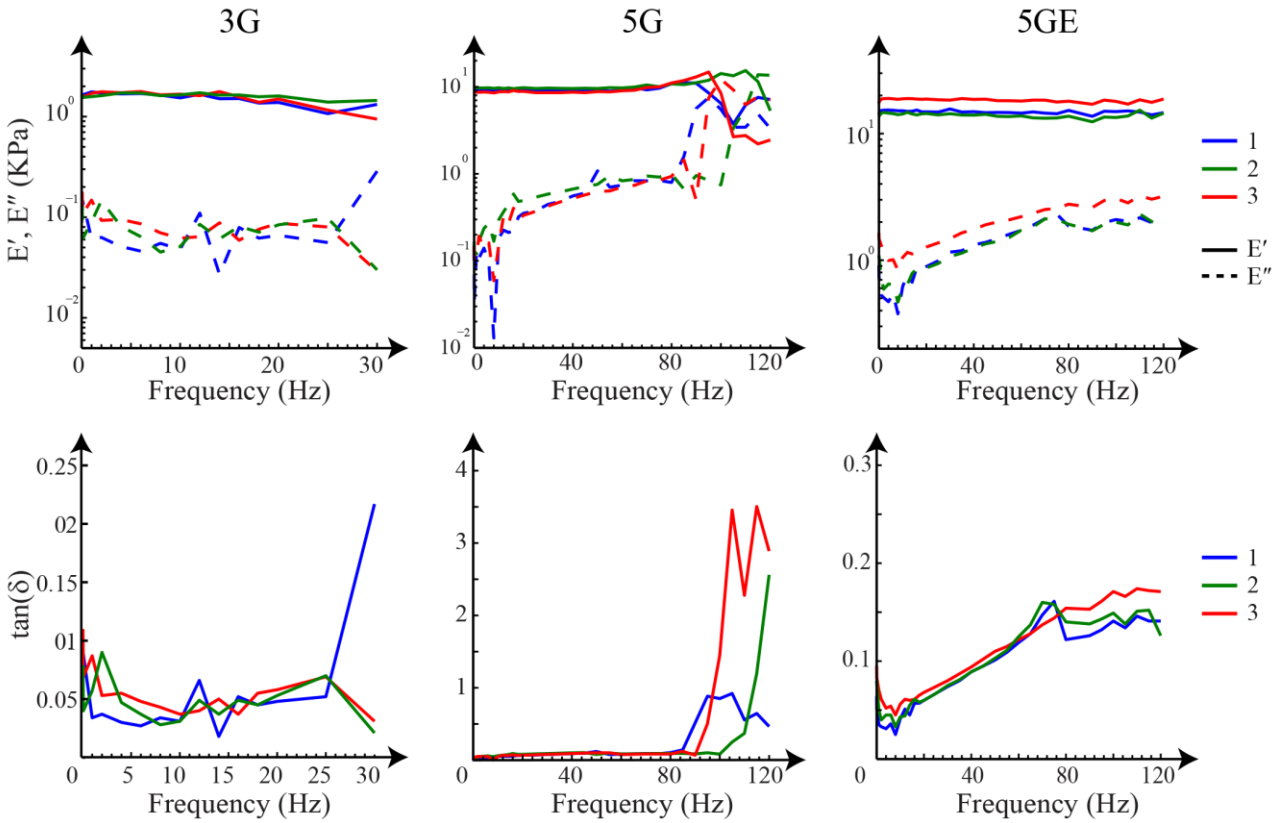

Figure 6. Variation in E′, E″ and tan δ with frequency for each of the hydrogels

Table 3 Mean values of tan δ, E′ and E″ for 3G gels upto 25Hz, 5G gels upto 80Hz and 5GE gels upto 6Hz (n=3)

	3G Group	5G Group	5GE Group
Compressive Modulus (kPa)	1.591±0.210	9.669±0.644	14.938±1.253
Storage Modulus (kPa)	1.594±0.032	9.341±0.428	15.872±2.214
Loss Modulus (kPa)	0.082±0.011	0.456±0.067	-
tan δ	0.051±0.006	0.048±0.005	-

Gelatin gels show a mostly flat response in E′ and E″ with variation in the frequency (Figure 6). However, we note unusual behavior in the 3G gels above a frequency of about 30 Hz that lead to negative values in tan δ. We do not hence report results for 3G samples above this frequency.

Further, we note a high increase in the tan δ in the 5G group above 80 Hz. These effects may be due to possible resonance and cavitation occurring in the hydrogels that results in micro-damage to the samples [19]. Results from our study show that the storage moduli for the gelatin-elastin hydrogels have the highest values. The gelatin gels had lower storage moduli with 5G gels having greater values than the 3G gels. These storage moduli results also showed good correlation with the moduli obtained from monotonic compression experiments ($p<0.05$) (Table 3). However, DMA tests showed no significant difference in the tan δ values between the tested groups. Since 5GE gels show increase in the tan δ and E″ and a decrease in E′ with frequency, we calculated an average E′ over a small range of frequencies for these gels. There is a drop in the tan δ and loss modulus at 85 Hz for these gels, which might also be due to the resonance effects described above.

We hypothesized that the addition of elastin would result in a more elastic behavior. However data suggests that there is no significant difference in the response. This is likely due to the use of insoluble elastin which does not form a homogenous hydrogel. These are, to the best of our knowledge, the only available results from DMA experiments on crosslinked gelatin and gelatin-elastin hydrogels. Future experiments aim to use soluble elastin to delineate the mechanical properties and assess differences in the fracture properties of hydrogels using single edge notch samples. Biopolymers like elastin are present in animals that have a closed circulatory system and see minor variations in temperature. Because elastin and collagen containing tissues such as arteries and cartilage undergo variation in their loading frequencies and rates, we performed a frequency sweep instead of a temperature sweep in this study to obtain physiologically relevant results.

3.1.3 Stress Relaxation of the hydrogels

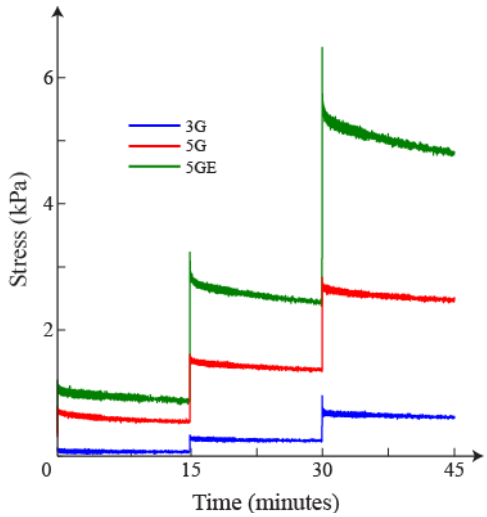

Figure 7. Representative traces from stress relaxation tests on gelatin and gelatin - elastin hydrogels

Stress relaxation data (Figure 7) indicate no significant difference in the amount of relaxation for each of the tested groups ($p<0.05$). This is in agreement with the results from DMA analysis which show no significant difference in the viscoelasticity between the gel groups. The hydrogel samples are covalently cross linked and hence the stress relaxation occurs mainly through migration of water through the gel [4]. It is possible that choosing a wider range of gel compositions may result in significant differences in the stress relaxation properties owing to larger differences in fluid migration through the gel. Although we hypothesized the addition of elastin would result in less relaxation of the gels, our data indicate otherwise that may likely be attributed to the presence of heterogeneous distribution of insoluble elastin through the sample. Future studies are aimed at using soluble elastin which has been shown to interact better with gelatin [18] and hence might show a

larger difference in the stress relaxation behavior due to formation of a homogenous network. The shape of the observed stress relaxation curves show similarity to those reported in other studies [5, 6] though variations have been observed among other studies [4–6]. Ongoing studies are aimed at modeling this response of the hydrogels and quantifying the relaxation times.

4. Conclusions

Our data on gelatin and elastin-gelatin composite hydrogels show that a variation in the monomer and crosslinker concentrations allow for tuning of the hydrogel stiffness which is essential in the fabrication of tissue engineered constructs. Microstructural analysis reveals differences in porosities of hydrogels which affects the permeability and mass transport properties through the gels. This is important in the case of nutrient transport through hydrogels when used for cell culture. The water uptake of hydrogels is also dependent upon monomer and crosslinker concentration. Addition of elastin leads to a decrease in the water content as well as the swelling ratios of the hydrogels. DMA and stress relaxation studies show no significant differences in viscoelastic nature of the gelatin hydrogels. Because incorporation of insoluble elastin did not have a significant effect on the viscoelastic properties of gels, we hope to use soluble elastin in future studies. We hope that such studies on soft materials will be useful in fabrication of tissue engineered constructs capable of closely mimicking the *in vivo* mechanical environment of the tissue.

Abstract: This paper describes our experimental testing of linear viscoelastic creep behaviors in Hami Melon. Experimental data shows that Hami Melon has complex viscoelastic property which can not be well described by the standard model. Consequently, this study develops a fractional derivative model to describe such complex viscoelastic creep behaviors of Hami Melon. The analytical creep function of the proposed fractional linear viscoelastic models is derived via the Boltzmann superposition principle and discrete inverse Laplace transform. And then such analytical solutions are used to fit the experimental data of viscoelastic Hami Melon. Our study shows that the present fractional linear viscoelastic model with merely three parameters is more efficient and accurate than the generalized Kelvin viscoelastic model of six parameters to describe the stress—strain constitutive relations of Hami Melon. It is noted that the present fractional model with adjustable parameters can also be used to describe creep damage.

Keywords: Hami Melon; experiment; viscoelasticity; fractional derivative; creep

1. Introduction

Hami Melon is famous for its delicious taste and aroma, and has become one of the most characteristic fruits in Xinjiang, China. However, a large amount of Hami Melon is often destroyed due to decay in storage and transport, which may be attributed to its high water content and maturates in hot summer. It has been recognized that biomaterials exhibit unique viscoelastic behaviours [1]. Such viscoelasticity has been investigated to minimize physical damage and improve textural quality of fruits. However, it is noted that the transient and dynamic measurements in most existing methods are restricted to small deformations within the linear viscoelastic range of specimens [4,5].These traditional linear models can not accurately describe complex viscoleastic behaviors of Hami Melon.

On the other hand, the characterisation of non-linear behaviour of apple flesh under stress relaxation and the basic homogeneous assumption have been studied by Lu and Puri [1]. The measured vibrations can be visualised with experimental modal analysis, used in the past with pineapples and melons [6]. However, the classical nonlinear models are mathematically complex and require some obscure parameters which are not easy to obtain from measurement data.

In recent decade, fractional derivative model has attracted great attention in the description of memory-dependent mechanics behaviours, such as dynamical behaviours of complex viscoelastic materials [7]. Fractional derivative viscoelastic models are presented by some researchers [7-14] and have been applied to a wide range of problems in bioengineering [15-19]. But little has so far been done on melon [6,15].

In this study, we employ the fractional-order Maxwell viscoelastic model to characterize the viscoelasticity of Hami Melon. Compared with the classical viscoelasitc model, our results show

that the present fractional derivative model can characterize creep behaviour of Hami Melon with better accuracy and fewer parameters.
Among the objectives of this study are:
(1) to describe experiments for measuring the anisotropic creep properties of Hami Melon;
(2) to present a fractional linear viscoelastic model and determine its creep function;
(3) to make a comparison between the fractional and classical models in terms of our experimental data.

2. Experimental materials and methodology

2.1. Preparation of Hami Melon specimens

Fresh Hami Melons for experiments were hand-harvested on 25 August 2010 from the same orchard in Hami city, Xinjiang, China and were selected in terms of uniformity and placed in cold storage (6°C to 7°C and 70–80%RH). Four hours before testing, melons were taken to equilibrate at room temperature (20°C). Each specimen was peeled and cut in half longitudinally. After having removed the central and near the hull (approximately 1.5cm of each side) parts, cylindrical axial and radial specimens (50mm diameter by 10mm height) were put into a sealed container for experimental measurements.
Anisotropic creep properties of melons were evaluated using cylindrical specimens taken in orthogonal radial and axial orientations, as shown in Fig. 1.

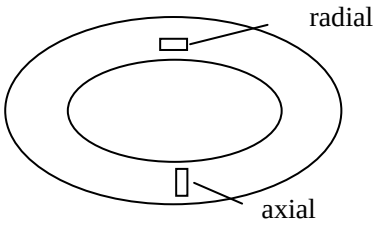

Figure 1. Location of specimens

2.2. Creep testing

Creep tests, in which a shear stress is instantaneously applied to the specimen and then maintained constant, allow us to observe elastic, viscoelastic, and viscous flow behaviours, separately. Deformation and compliance increase with time. In the initial state of creep, the sample material behaves like a solid and subsequently like a fluid. Viscoelastic properties were characterized at 20°C in a TA.XT plus Texture Analyser made by Stable Micro Systems Ltd, UK. 0.06% strain value was selected for experiments to ensure linearity for all specimens.
Creep tests of melons were conducted by enforcing a constant shear stress 20Pa for duration of 60 seconds. An often-encountered problem in measuring the physical properties of fresh or minimally processed tissues is that they are usually alive and respiring, and can be dehydrated by high strain rate during measurements. Thus, the interpretation of creep behaviour in this paper ascribes considerable importance to the time scale over which creep occurs.

2.3. Analysis of data

In this section, compliance data from creep experiments were fitted by a mechanical model consisting of one Maxwell model connected in series with two Kelvin models. It is noted that each Kelvin model has a spring and a dashpot in parallel as shown in Fig.2, which is described by the generalized Kelvin six parameters model [5],

$$J(t,\sigma_c)=(J_0)+\sum_{i=1}^{2}(J_i)(1-e^{-t/\lambda_i})+t/\eta_0\ , \tag{1}$$

where $J(t,\sigma_c)=\varepsilon(t)/\sigma_c$ denotes the creep compliance, $\varepsilon(t)$ is the strain at instant *t*, and σ_c is the constant stress; $J_0=1/E_0$ stands for the instantaneous compliance at *t*=0; $J_i=1/E_i$ (i=1,2) means the retarded compliances; $\lambda_i=\eta_i\times J_i$ (i=1,2) represents the retardation times, and η_i (i=1,2) is the coefficients of viscosity associated with the Voigt elements; η_0 denotes the coefficient of viscosity associated with Newtonian flow, and its inverse is the steady-state fluidity of the material. The parameters are optimally chosen by an exhaustive algorithm which results in the minimum errors between the fitting curve and the observed data.

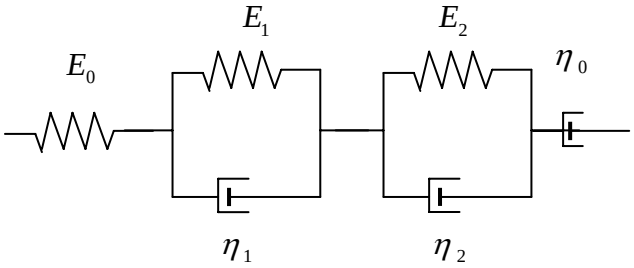

Figure 2**.** Generalized Kelvin model describing creep behaviours of

2.4. Fractional Maxwell modelling of creep

The configuration of a fractional Maxwell model is shown in Fig.3 and consists of a spring and an Abel dashpot connected in series, which is characterized by replacing a Newtonian dashpot in the classical model with the fractional derivative Abel dashpot.

$$\sigma_E=E\varepsilon_E\ ,\quad \sigma_V=\eta d^{\alpha}\varepsilon_V/dt^{\alpha}\quad (0\le\alpha\le 1), \tag{2}$$

$$\varepsilon=\varepsilon_E+\varepsilon_V\ ,\quad \sigma=\sigma_E=\sigma_V\quad , \tag{3}$$

where σ and ε denotes the stress and strain, respectively; *E* represents elastic coefficients of the spring; η is the viscous coefficient of the Abel dashpot; subscript *E* means the spring, and subscript *V* devotes the dashpot.

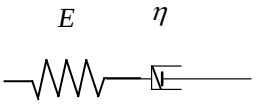

Figure 3**.** Fractional Maxwell

Fractional Maxwell model of constitutive equation is as follows

$$\frac{d^{\alpha}\sigma}{dt^{\alpha}}+\frac{1}{\tau}\sigma=E\frac{d^{\alpha}\varepsilon}{dt^{\alpha}}\ ,\quad \tau=\frac{\eta}{E}\ , \tag{4}$$

where τ is the retard time. The fractional integral is defined by, see Ref. [9,20],

$${}^{R}I^{\alpha}f(t)=\frac{1}{\Gamma(\alpha)}\int_a^t(t-\tau)^{\alpha-1}f(\tau)d\tau(0<\alpha<1). \tag{5}$$

Applying the Laplace transformation to Eq. (4) yields

$$s^{\alpha}\bar{\varepsilon}=\frac{1}{E}s^{\alpha}\bar{\sigma}+\frac{1}{\eta}\bar{\sigma}\ . \tag{6}$$

Consequently, we have

$$J(s)=\eta^{-1}\sum_{k=0}^{\infty}(-1)^k(\frac{\eta}{E})^k s^{-\alpha k-\alpha-1}\ . \tag{7}$$

Applying the discrete inverse Laplace transformation, we obtain

$$J(t)=\frac{1}{E}+\frac{1}{\eta}\frac{t^{\alpha}}{\Gamma(1+\alpha)}\ \ , \tag{8}$$

where $\Gamma(g)$ denotes the Gamma function,

$$\Gamma(z)=\int_0^{\infty}e^{-t}t^{z-1}dt\ . \tag{9}$$

In particular, when α is equal to 1, Eq. (8) is reduced to the standard Maxwell model for creep compliance,

$$J(t)=\frac{1}{E}+\frac{1}{\eta}\frac{t}{\Gamma(1)}=\frac{1}{E}+\frac{t}{\eta}\ , \tag{10}$$

namely, Eq.(10) is the standard integer-order model [7].

3. Results and discussions

3.1. Classical viscoelastic model

Creep compliance curves of Hami Melon specimens are illustrated in Fig. 4. Deformation of all samples is finite after 60s creep. Figs. 4(a) and 4(b) display the curves of radial and axial specimens, respectively. For the time scale of the experiments, the behaviours were described via the six parameters in the creep model Eq. (1). Table 1 provides the mechanical parameters that define creep behaviour of Hami Melon tissues. According to the interpretation in Mittal [21], J_0 represents those bonds of structural units that are stretched elastically when the stress is applied and characterizes instantaneous and complete recoveries when the stress is removed. The linear region of Newtonian compliance t/η_0 reflects those bonds that are ruptured during the shear creep, and its time required to deform is longer than the creep-recovery period.

As seen from Fig. 4, the viscoelastic creep compliances are significantly different between axial and radial specimens. The axial specimen has larger creep compliance than the radial one.

Table 1 displays the relatively larger standard deviations observed in the creep experiments for measured viscoelastic properties of melon tissues. Much of this variability can be attributed to physiological factors, i.e., anisotropism and non-homogeneity, which change their mechanical properties with age, moisture content, and locations around the melon and depth from which the specimen is taken [21,22].

Table 1 Creep compliance parameters of fresh Hami melon tissues in Eq. (1)

specimen	J_0 (1/Pa)×10^{-5}	J_1 (1/Pa)×10^{-5}	J_2 (1/Pa)×10^{-5}	λ_1(s)	λ_2(s)	η_0 (Pa·s)×10^{7}
radial	0.5	0.41	0.21	18	3.1	5
axial	0.65	0.72	0.51	18.1	5.1	7

3.2. Fractional Maxwell model

It is worth stressing that the curves displayed in Fig. 4 match quite well with the experimental creep data. This highlights the validity of the present fractional constitutive expression of Hami Melon

viscoelasticity, which captures experimental data of creep tests by using merely the three parameters as shown in Table 2. The next experiment will examine if the fractional order constitutive model can depict the nonlinear gradual process of strain in creep.

Table 2. Creep compliance parameters for fresh Hami Melon tissues in Eq.(8)

Sample	E(MPa)	η(MPa.s)	α
radial	0.2	0.56	0.3
axial	0.14	0.49	0.38

3.3. Comparisons

We can see from Fig. 4(a) that compared with the classical viscoelasitc models, the fractional Maxwell model has the same level of accuracy in the fitting of experimental data but requires significantly fewer adjustable parameters. Fig. 4(b) shows that the classical model only fits well the elastic variation, initial small value of *J*, and then has a large departure from experimental data when viscosity comes into play. In stark contrast, the fractional model agrees pretty well with the experimental data for the whole viscoelastic duration with three parameters. In general, our results show that the present fractional derivative model can characterize creep behaviour of Hami Melon with better accuracy and fewer parameters.

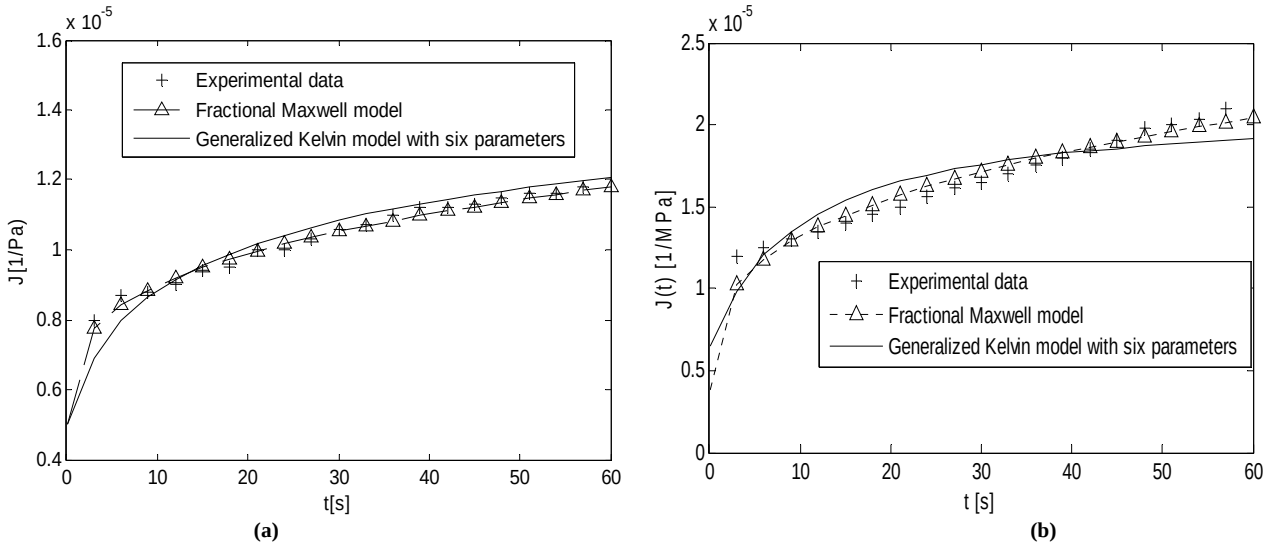

Figure 4. Creep compliance curve; a)radial; b)axial

4. Conclusions

This work shows the experimental results of creep tests of Hami Melon. All tests have been conducted in a range of small deformation, so that such creep can be reasonably treated as linear viscoelasticity. The standard linear and the present fractional derivative creep models have been investigated for comparisons in fitting our experimental data. The fractional derivative model not only reduces the computational effort in identification of coefficients, but also appears more promising in modeling of different loading conditions, with fewer parameters.

The creep tests for the specimens in different locations of Hami Melon has illustrated that the creep modulus is significantly influenced by the location and orientation of the specimens. The proposed fractional derivative model can accurately simulate the creep characteristics of different specimens, and the creep damage of Hami Melon in the transport and storage can be predicted. This study is very encouraging and more work is under way to apply the fractional model to damage behaviours of fruits, which will be reported in a subsequent paper.

Abstract When the elastomer submerged in aqueous solution, temperature-sensitive hydrogels undergo a phase transition at a particular temperature, i.e. the volume of hydrogels changes with temperature discontinuously. In this paper, the inhomogeneous large deformation of temperature-sensitive hydrogels has been studied. Based on the monophasic gel inhomogeneous field theory, the governing equations and conditions of equilibrium for temperature-sensitive hydrogel have been derived. Furthermore, the free-energy function and derived constitutive equations for temperature-sensitive hydrogel are implemented using Finite Element Method. As an example, a uniaxially constrained-swelling hydrogels with cubic initial shape is studied. The simulating results are in reasonable agreement with available experimental data and analytical solutions. By analyzing the factors affecting the phase transition temperature of hydrogel, we suggest one possible chemical mechanism for the swelling behavior of temperature-sensitive gel during the phase transition process. Also we demonstrate the application of the proposed approach in the analysis of the complex phenomenon, such as to explain the deformation of implant in skin reconstruction. We hope this approach can explain various complex phenomena and provide a useful tool for further theoretical and experimental studies.

1. Introduction

Long and flexible polymers chains can chemically crosslink to a three-dimensional network by covalent bonds. When the rubber-like material is submerged into an aqueous solvent, the network imbibes the solvent and swells, resulting in an elastomer gel. Great attention has been drawn to these polymeric gels due to their large and reversible deformation variation to many stimuli, including pH values[1, 2], forces[3], ionic concentration[4], temperature[5], electrical field[6, 7], and magnetic field, etc. For example, a temperature-sensitive hydrogel PNIPAM based on poly-(N-isopropyl-acrylamide) which exhibits the volume phase transition, has been investigated in the past years and the temperature-sensitive hydrogel has been developed for numerous applications[8-11], such as actuator[12], sensor[13, 14], switching device[15]. Furthermore, the temperature sensitive gels can be developed as drug delivery systems in the human body, where the gel releases a drug at a particular location in the body in response to the change of temperature.

The stimuli responsive behaviors of hydrogel have also motivated a large number of theoretical and numerical studies. Based on the statistical-mechanical hydrogel model developed by Flory and Rehner, Suo group proposed a gel theory coupling the two phase's deformation into a single phase[16]. Following this approach, Hong et al. implemented the finite element method (FEM) on polymeric gel theory by coding a UHYPER subroutine in the commercial software ABAQUS[17]. Meanwhile Marcombe et al. and Cai and Suo developed FEM for pH-sensitive gel[2] and temperature-sensitive gel[5], respectively. To perform the transient analysis of large deformation, Zhang et al. formulated FEM of mass transport in gel microfluidic valves, using fluid-structure

interaction (FSI)[18]. Liu et al. studied the buckling phenomena of gels[19, 20]. Toh et al. developed a dynamic FEM for inhomogeneous deformation[21, 22].

In this paper, we adopt Suo's monophasic model for temperature-sensitive hydrogel[5], which regard the interaction parameter as a function of temperature and concentration, and then a specific material model is employed in the finite element implementation by providing a user subroutine to analyze the deformation of the PNIPAM hydrogel. This implementation enables us to analyze diverse phenomena of temperature-sensitive gel including large deformation, contact, bifurcation, buckling of hydrogel, etc.

2. Gel theory for temperature-sensitive gel

When a dry polymer network is immersed in a solvent, e.g. water, the solvent molecules enter the polymer network and result in swelling. We define the initial state as the reference state X_K and the deformed state as the current state x_i. The state of deformation is characterized by the deformation gradient F_{iK}, defined by the mapping from the reference coordinates to the current coordinates,

$$F_{iK} = \frac{\partial x_i(X)}{\partial X_K}, \tag{1}$$

Using statistical theories and simplified network models, a free energy expression can be formulated. A free energy expression for the temperature-sensitive gel includes two parts (i) the stretching of the network W_s and (ii) the mixing energy of the polymer and the solvent W_m.

$$W = W_s + W_m = \frac{1}{2}NkT[F_{ik}F_{ik} - 3 - 2\log(det\mathbf{F}) + kT[Clog\frac{\upsilon C}{1+\upsilon C} + \frac{\chi C}{1+\upsilon C}] \tag{2}$$

where N is the number of polymer chains per unit dry volume, kT is the temperature in terms of energy, ν is the volume per water molecule, $\mathbf{F}$ is the deformation gradient relative to the dry network, C is the nominal concentration of solvent water molecule and χ is a dimensionless measure of the strength of pairwise interactions between species. This parameter χ is used to fit experimental data in the following form:

$$\chi(T, \phi) = \chi_0 + \chi_1\phi \tag{3}$$

$$\chi_0 = A_0 + B_0T, \chi_1 = A_1 + B_1T \tag{4}$$

Hong et al. assume that these individual long polymers and solvent molecules are incompressible[17]. The condition of molecular incompressibility can be expressed as following:

$$\phi = \frac{1}{1+\upsilon C} = \frac{1}{det(\boldsymbol{F})} \tag{5}$$

ϕ is the volume fraction of the polymer in the hydrogel. The values of A_0, B_0, A_1 and B_1 will be different for different types of temperature-sensitive hydrogel. Afroze et al. [23] provided the values of these parameters for a particular polymer: poly(N-isopropylacrylamide) (PNIPAM) as:

$$A_0 = -12.947, B_0 = 0.04496, A_1 = 17.92, B_1 = -0.0569 \tag{6}$$

To fully define the material in the subroutine, we adopt the above properties of PNIPAM gels in the examples presented herein.

The free energy is written in the form of $W = W(\mathbf{F}, T, C)$. Since the chemical potential must be a constant at the equilibrium state, we introduce another free-energy function $\widehat{W}$ with $\mathbf{F}$, μ and T as independent parameters via Legendre transform.

$$\widehat{W}(\mathbf{F}, T, \mu) = W - \mu C \tag{7}$$

$$\widehat{W}(\boldsymbol{F},T,\mu)=\frac{1}{2}NkT\left[J^{\frac{2}{3}}\bar{I}_1-3-2\,log(J)\right]+\frac{KT}{v}\left[(J-1)\log\left(\frac{J-1}{J}\right)+(J-1)*\left(\frac{\chi_0}{J}+\frac{\chi_1}{J^2}\right)\right]-\frac{\mu}{v}(J-1) \quad (8)$$

Define the nominal stress as,

$$s_{iK}=\frac{\partial\widetilde{W}}{\partial F_{iK}}=NkT(F_{ik}-H_{ik})+J\left[log\left(\frac{J-1}{J}\right)+\frac{1}{J}+\frac{\chi_0-\chi_1}{J^2}+\frac{2\chi_1}{J^3}\right]H_{ik}-\frac{\mu}{v}JH_{ik} \quad (9)$$

where **H** is the transpose of the inverse of the deformation gradient **F**. This equation of state relates the nominal stress to the deformation gradient when the gel is hold at a constant chemical potential and constant temperature. The finite element modeling of large deformation process of temperature-sensitive gel is possible by utilizing currently gel monophasic theory and properties of PNIPAM.

3. Phase transition

Phase transition phenomena have been observed and studied by many researchers. The phase transition temperature is referred to as the temperature of the coexistent state, at which a sharp volume transition can be observed. Since gel's swelling process can be referred as a hydrated reaction, we assume that the gel may have two different phases before and after phase transition temperature, which imply two different hydrated quantities of hydrogel. In our previous work[24], we inferred variation of temperature leads to different hydrated quantities of hydrogel and thus the volume of gel changes significantly. When gel reaches the phase transition temperature, the free energy density function $W(\mathbf{F},\mu,T)$ has two local minima of equal value. Specifically, if the chemical potential is kept at a certain constant value μ_0, at a particular temperature T^*-the so called phase transition temperature, the two local minima of the free energy density function $W(\mathbf{F},\mu,T)$ would occur at two different deformation gradients $\mathbf{F_1}$ and $\mathbf{F_2}$, i.e.,

$$W(\mathbf{F_1},\mu_0,T^*)=W(\mathbf{F_2},\mu_0,T^*) \quad (10)$$

4. Numerical examples and discussions

4.1. Uniaxially constrained-swelling hydrogels

In our previous work[24], we investigated a PNIPAM hydrogel cube, which immersed in water ($\mu=0$) at certain temperature and allowed to frees welling. Now we adopt 8-node brick elements to model the uniaxial constrained swelling hydrogel. In the modeling, a hydrogel bar is first submerged in water and reaches an isotropic swelling stretch λ_0, and then the gel bar is stretched in longitudinal directions with fixed length. The stress in the transverse directions vanish, so that (9) gives

$$\frac{Nv}{{\lambda_2}^2\lambda_1}(\lambda_2^2-1)+\ln\left(1-\frac{1}{{\lambda_2}^2\lambda_1}\right)+\frac{1}{{\lambda_2}^2\lambda_1}+\left(\frac{\chi_0-\chi_1}{\lambda_2^4\lambda_1^2}+\frac{2\chi_1}{\lambda_2^6\lambda_1^3}\right)-\frac{\mu_0}{kT}=0 \quad (11)$$

$J=\frac{V}{V_0}={\lambda_2}^2\lambda_1$; for water $\mu_0=0$. Using the material model, we can also obtain the volume-temperature curve numerically by FEM. Since the value for Nv was not given in the report Suzuki et al. [25], we have to vary the value of the parameter Nv to fit the experiment data. The symbol k is the Boltzmann constant, and T_0 = 300K, $kT_0\approx 4.14\times10^{-21}J$. It's clearly shown in Figure 1 that when the level of longitudinal stress is different, volume changes sharply but the phase transition temperature alters just mildly.

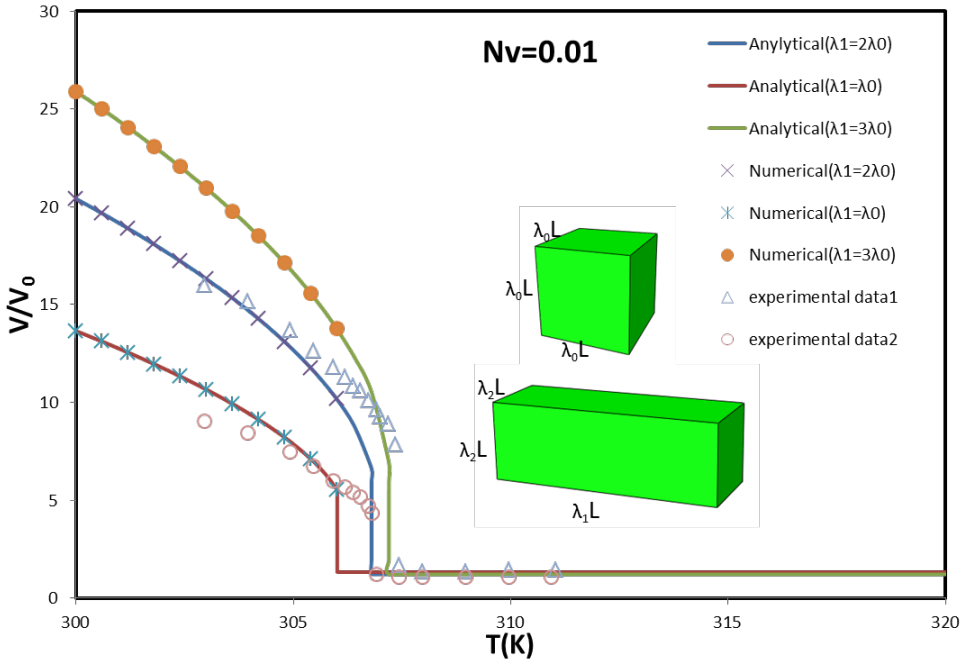

Figure 1. The volumes of uniaxially constrained-swelling hydrogels as functions of temperature. The solid curves are calculated for hydrogels of three levels of longitudinal stretches. The solid curves are obtained analytically for the free swelling of hydrogel at the three values of crosslink density. The marks on the curves are the corresponding numerical predictions. The triangle and circle symbols are experimental data for the corresponding longitudinal stretches taken from Suzuki et al[25].

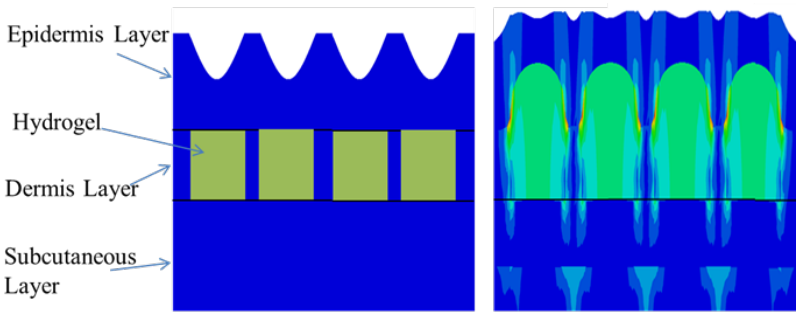
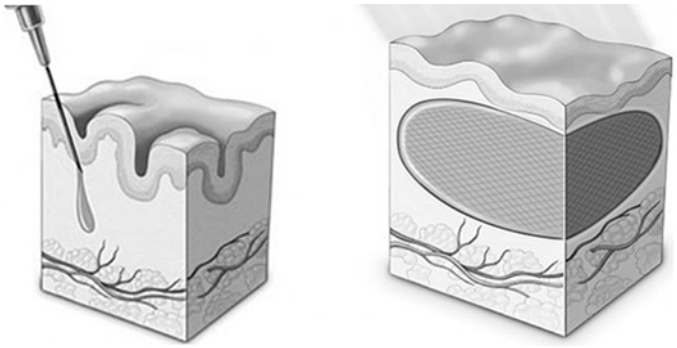
4.2. Simulation of the reconstructed skin

When aged or damaged, the skins of human beings can easily result in winkles or scars. Hillel et al. developed a biosynthetic soft gel replacement that can be injected and swelling in situ with stimuli[26], whereby the swelling of soft fillers of skin reduces or eliminates the skin wrinkles. In this study, we try to model the skin reconstruction procedure and explain how the soft fillers works in skin repair by using temperature-sensitive hydrogel deformation. It is assumed that the skin implant could be modeled as a temperature-sensitive gel material, in which temperature-sensitive hydrogel is injected into the dermis layer. Furthermore, by modulating the parameters of temperature-sensitive hydrogel, we can control the repair process.

As the temperature changes, the injected temperature-sensitive gel will swell. This corresponds to the deformation of soft fillers in the skin repair process. Fig. 2 (a) shows the initial stage which injected implant gel has not been deformed. The deformation pattern of the skin under reconstruction at deformed stage is illustrated in Fig. 2 (b). From Fig. 2 (b), it can be observed that the skin wrinkles can be eliminated. To better understand the skin repair process, the schematic diagrams of reconstructed skin procedure which is taken from Hillel et al.[26] are also shown in the Fig. 2 (c) and (d).



(a) (b)



(c) (d)

Figure 2. After the temperature-sensitive gel is injected into beneath of skin, the wrinkled skin can be eliminated. (a) The pattern of the repaired skin at initial stage; (b) the pattern of the repaired skin at deformed stage. (c) and (d) the schematic of the reconstructed skin taken from Hillel et al[26].

Conclusion

This paper focuses on large deformation of temperature-sensitive hydrogels in equilibrium with a solvent and mechanical load at varying temperature. Adopting a specific free energy density function and obtained constitutive equation, we have developed a finite element method for equilibrium analysis of temperature-sensitive hydrogels and implemented the theory via a user-defined subroutine in ABAQUS. From the simulated results, we demonstrate the potential applications of the proposed approach in the analysis of the complex phenomenon, such as how to explain the deformation of implant in skin reconstruction. We hope that this work can explain various complex phenomena in nature and can provide a useful tool for the future theoretical and experimental studies on temperature-sensitive hydrogel.

Abstract Dielectric elastomer actuator can be used to adjust the properties of many optical elements. For example, place a diffractive transmission grating on the center of a circular ring actuator. The deformation of the actuator under voltage can change the grating period. The circular ring actuator is an annular dielectric elastormer coated with soft electrodes sandwiched between an elastic circle and an elastic annulus. When subject to a voltage, the active dielectric region will expand and compress the central elastic circle as well as the outer elastic annulus. The compressive deformation of the central elastic circle changes the grating period. We study the properties of circular ring actuators based on the ideal dielectric model combined with the Arruda-Boyce hyperelastic constitutive law and obtain the relationship between the applied voltage and the grating period. The strategy presented here is generic and the results may contribute to the use of dielectric actuators in optical devices.

Keywords Dielectric elastomer actuator; Tunable grating; Ideal dielectric

1. Introduction

Adaptive optical elements are of great importance in a wide range of scientific applications [1]. For the active dynamic tuning of the optical elements, a variety of methods has been proposed, ranging from change the refractive index of a material [2] to rely on the acousto-optic effect[3]. But so far, these methods are not so successful in the tuning of optical elements.

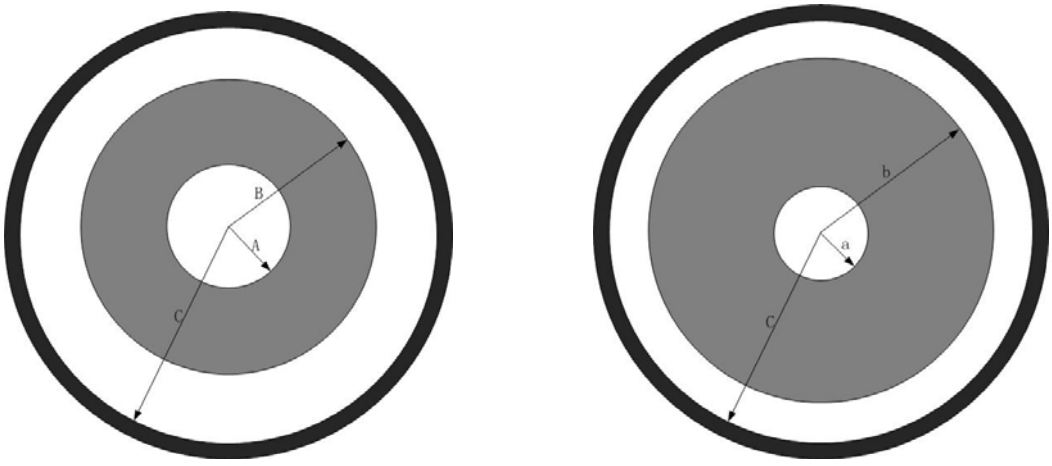
Now the tunable diffraction grating is based on relatively stiff materials and can only achieve a limited spatial tuning grating. A promising approach for combining rapid response time, good optical quality and large actuation amplitude is the use of dielectric actuators [4-6], which is known as "artificial muscles". When a DE is used as an actuator, it can achieve a large voltage-induces strain and can be driven at acoustic frequencies [7].

Here, we investigate a pre-stretched polymer film of VHB4910 which is fixed by a rigid frame and partially covered with high conductive carbon grease as electrodes. Then a polymeric diffractive structure is bonded onto the actuator, similar to the previous work[8-10]. our work is investigate the previous structure with new theory analysis method. The results can be used in the calculation of the tunable transmission grating.

2. Circular ring actuator analysis

The schematic arrangement of a circular ring dielectric actuator is shown in Fig. 1. A circular ring actuator is made from pre-stretched elastomer with a soft electrode annulus which is sandwiched by two electrode-less regions. When subject to a voltage, the active dielectric region will expand and compress the central elastic circle as well as the outer elastic annulus. The inner passive region deforms from its reference configuration with initial radius A, to its current configuration with radius a. The active region evolve from its reference configuration with inner radius A and outer radius B to its current configuration with inner radius and outer radius b, respectively. The outer passive region evolves from its reference configuration with inner radius B and outer radius C to its current configuration with inner radius b and outer radius fixed, respectively. All kinetic variables are

expressed in the reference polar coordinates R, Θ, Z systems, which are denoted by the subscript 1, 2 and 3.The inner passive region, middle active region and outer passive region, are denoted by superscript 1, 2 and 3, respectively.



Voltage off Voltage on

Figure 1. The schematic of a typical experimental arrangement of a circular ring dielectric actuator. The central gray area is the dielectric actuator, and outer black area is the rigid frame to apply pre-stretch.

Here the strain energy of an ideal dielectric material is rewritten in terms of stretches and nominal electric field, i.e.,

$$W(\lambda_1, \lambda_2, \tilde{E}) = W_0(\lambda_1, \lambda_2) + W_{ele}(\lambda_1, \lambda_2, \tilde{E}), \tag{1}$$

For the two passive regions, the material laws are only given the first term of the Eq. (1). Based on the elastic theory, the geometric relationship can be obtained readily as

$$\lambda_1 = \frac{\partial r}{\partial R}, \quad \lambda_2 = \frac{r}{R} \tag{2}$$

where λ_1 and λ_2 are radial and hoop stretches, respectively. The equilibrium equation is

$$\frac{\partial s_1}{\partial R} + \frac{s_1 - s_2}{R} = 0 \tag{3}$$

We use the Arruda-Boyce material to express the hyper-elastic part $W_0(\lambda_1, \lambda_2)$, and it gives

$$W_0(I) = \mu\left[\frac{1}{2}(I-3) + \frac{1}{20N}(I^2-9) + \frac{11}{1050N^2}(I^3-27) + \ldots\right] \tag{4}$$

where $I = \lambda_1^2 + \lambda_2^2 + \lambda_1^{-2}\lambda_2^{-2}$ is the first principle invariant. We use nominal stress and nominal electric field as well as electric displacement as mechanical and electrostatic measures. The nominal stresses of the material are given by the following material laws

$$s_1 = \frac{\partial W}{\partial \lambda_1} = \frac{\partial W_0}{\partial I}\frac{\partial I}{\partial \lambda_1} + \frac{\partial W_{ele}}{\partial \lambda_1} \tag{5}$$

$$s_2 = \frac{\partial W}{\partial \lambda_2} = \frac{\partial W_0}{\partial I}\frac{\partial I}{\partial \lambda_2} + \frac{\partial W_{ele}}{\partial \lambda_2} \tag{6}$$

Taking derivative of Eq. (5) with respect to R and substituting Eq. (5) and (6) into Eq. (2) gives the

following ODE

$$\frac{\partial \lambda_1}{\partial R} = \frac{1}{R} g_1(\lambda_1, \lambda_2)(\lambda_2 - \lambda_1) + \frac{1}{R} g_2(\lambda_1, \lambda_2) \tag{7}$$

Another equation can be deduced by invoking Eq. (2) and gives

$$\frac{\partial \lambda_2}{\partial R} = \frac{1}{R}(\lambda_1 - \lambda_2) \tag{8}$$

The $g_1(\lambda_1, \lambda_2)$ and $g_2(\lambda_1, \lambda_2)$ functions in Eq. (7) are expressed as

$$g_1(\lambda_1, \lambda_2) = \frac{\dfrac{\partial^2 W_0(I)}{\partial I^2}\dfrac{\partial I}{\partial \lambda_1}\dfrac{\partial I}{\partial \lambda_2} + \dfrac{\partial W_0(I)}{\partial I}\dfrac{\partial^2 I}{\partial \lambda_1 \partial \lambda_2} + \dfrac{\partial^2 W_{ele}}{\partial \lambda_1 \partial \lambda_2}}{\dfrac{\partial^2 W_0(I)}{\partial I^2}\left(\dfrac{\partial I}{\partial \lambda_1}\right)^2 + \dfrac{\partial W_0(I)}{\partial I}\dfrac{\partial^2 I}{\partial \lambda_1^2} + \dfrac{\partial^2 W_{ele}}{\partial \lambda_1^2}} \tag{9}$$

$$g_2(\lambda_1, \lambda_2) = \frac{\dfrac{\partial W_0(I)}{\partial I}\left(\dfrac{\partial I}{\partial \lambda_2} - \dfrac{\partial I}{\partial \lambda_1}\right) + \left(\dfrac{\partial W_{ele}}{\partial \lambda_2} - \dfrac{\partial W_{ele}}{\partial \lambda_1}\right)}{\dfrac{\partial^2 W_0(I)}{\partial I^2}\left(\dfrac{\partial I}{\partial \lambda_1}\right)^2 + \dfrac{\partial W_0(I)}{\partial I}\dfrac{\partial^2 I}{\partial \lambda_1^2} + \dfrac{\partial^2 W_{ele}}{\partial \lambda_1^2}} \tag{10}$$

For the passive region, the inner region's deformation are equal biaxial and $\lambda_1 = \lambda_2 = \lambda$ and $s_1 = s_2 = s$. The nominal stress $s_{1,2}$ is given by

$$s_{1,2}^1 = \frac{\partial W_0(I)}{\partial I} 2\left(\lambda - \lambda^{-5}\right) \tag{11}$$

For the active region, the stresses are given by Eq. (5) and Eq. (6):

$$s_1^2 = \frac{\partial W_0}{\partial I}\left(2\lambda_1 - 2\lambda_1^{-3}\lambda_2^{-2}\right) - \varepsilon E^{\theta/\theta_0}\lambda_1\lambda_2^2 \tag{12}$$

$$s_2^2 = \frac{\partial W_0}{\partial I}\left(2\lambda_2 - 2\lambda_1^{-2}\lambda_2^{-3}\right) - \varepsilon E^{\theta/\theta_0}\lambda_1^2\lambda_2 \tag{13}$$

And the outer passive region' stresses can be obtained in the same way:

$$s_1^3 = \frac{\partial W_0(I)}{\partial I}\left(2\lambda_1 - 2\lambda_1^{-3}\lambda_2^{-2}\right) \tag{14}$$

$$s_2^3 = \frac{\partial W_0(I)}{\partial I}\left(2\lambda_2 - 2\lambda_1^{-2}\lambda_2^{-3}\right) \tag{15}$$

The stresses given by Eq. (11) ~ (15) should satisfy the following force balance requirement

$$s_1^1(R = A) = s_1^2(R = A) \tag{16}$$

$$s_1^2(R = B) = s_1^3(R = B) \tag{17}$$

The stretches across the interface should also fulfill the following boundary conditions

$$\lambda_2^1(R = A) = \lambda_2^2(R = A) \tag{18}$$

$$\lambda_2^2(R = B) = \lambda_2^3(R = B) \tag{19}$$

Eq. (7) and (8) together with the boundary conditions (16) ~ (19) constitute the nonlinear ODEs that

should be calculated numerically. We use a shooting technique to solve these ODEs by iterating a assumed radial stretch until the computed hoop stretch on the outer boundary equals to the prescribed pre-stretch, and the computed stress on the inner boundary fulfill the force balance equation, Eq. (16) and (17).

Based on the above-mentioned procedure, the properties of the circular ring dielectric actuator can be evaluated. In a simulation example, we fixed A=4mm, B=9mm, C=10.5mm, λ_p =1.2 and $\bar{E}=E\sqrt{\mu/\varepsilon}$=0.5 .Fig. 2 shows the deformation of the circular ring actuator under a pre-stretch and a dimensionless nominal electric field. It is noted that the middle active region's deformation is unhomogeneous and the inner radius deforms greater than the others which results the inner passive region is compressed more obvious. Also the radical's deformation is incontinuous along the radius which is unknown before the calculation. Fig. 3 shows the dimensionless nominal stress versus radius R. From this figure, we know the distribution of the nonimal stress along the radius and the radius R=A and R=B are likely to suffer loss of tension when the voltage is increasing.

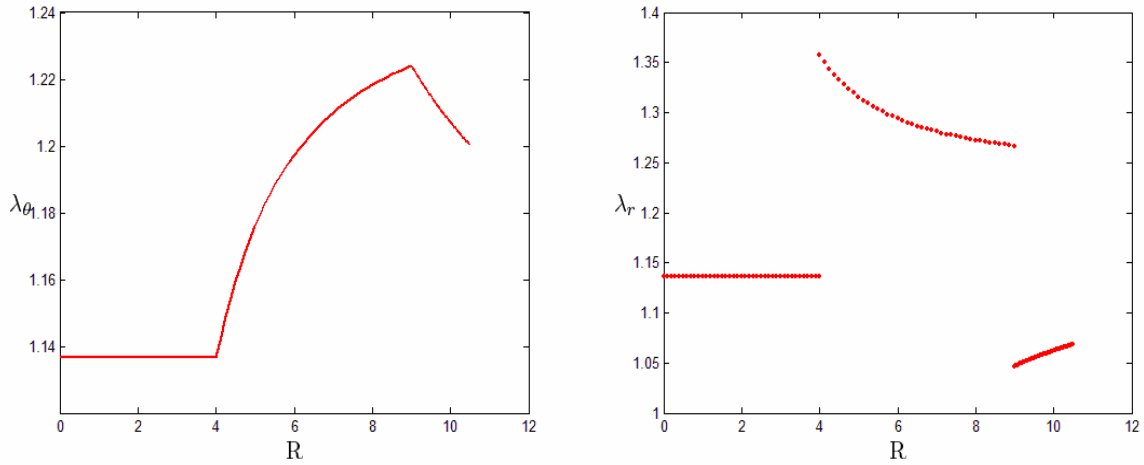


Figure 2. The radius R versus hoop and radial stretches

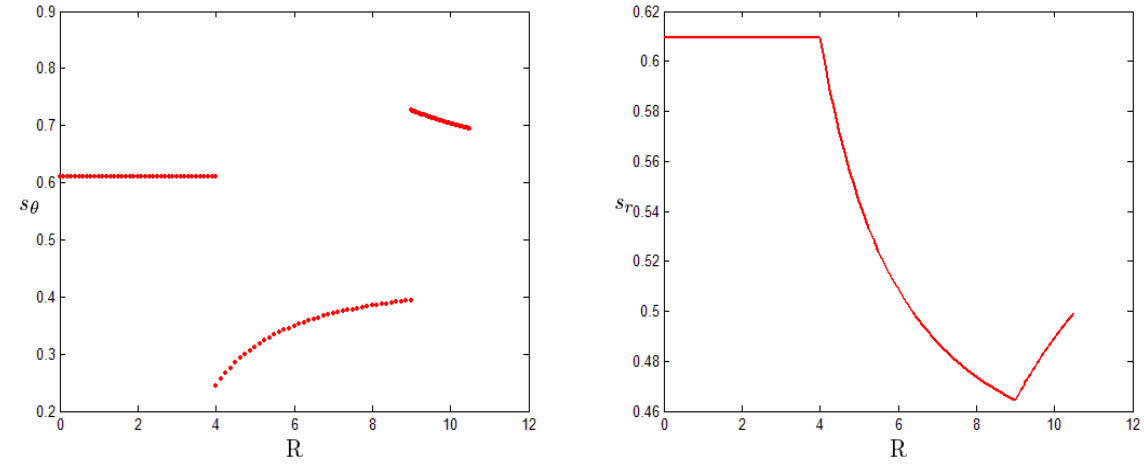

Figure 3. The radius R versus hoop and radial dimensionless nominal stress

3. Applications in tunable transmission grating

Tunable transmission grating is bonded onto circular ring actuator, as showed in Fig. 4. When the voltage is applied, the middle active region enables a compact implementation and results in a change of the grating period,

$$d = (1 - s_{center})d_0 \tag{20}$$

where d_0 is the grating period at $V = 0$, and s_{center} is the planar strain in the inner passive region. In the above simulation example, the grating period changes from $2\mu m$ to $1.9\mu m$

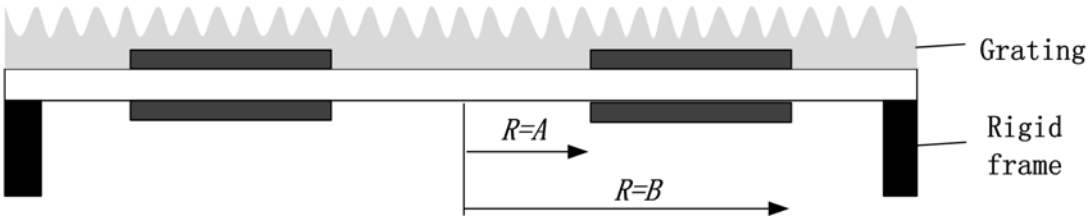

Figure 4. The tunable transmission grating based on circular ring dielectric actuators

Once the stretch in the inner passive region under a certain voltage is calculated, the grating period is also determined by Eq. (20).

Abstract To obtain a theoretical solution for the critical condition of swell-induced surface instability, a graded hydrogel layer on a rigid substrate is divided into *n* fictitious sub-layers. By considering the boundary condition and interface continuity, a governing equation for surface instability is established. Hydrogel layers with the crosslink density varying in the thickness direction are examined in details. The results show that both the critical condition and the instability mode relate to the variation of the material properties. For a soft-on-hard graded layer, the onset of surface instability is determined by a short-wave mode with a limiting short wavelength. In contrast, for a hard-on-soft graded layer, a long-wave mode with a finite wavelength emerges as the critical mode at the onset of surface instability. The critical swelling ratio of the long-wave mode for hard-on-soft graded layers is considerably lower than that of the short-wave limit for soft-on-hard ones with the same shape factor. In addition, we found that both the critical swelling ratio and the characteristic wavelength depend on the gradient profile of material properties.

Keywords Hydrogel, Surface instability, Graded layer

1. Introduction

A hydrogel swells significantly when imbibing a large amount of solvent. Swell-induced surface instability of hydrogels has been observed by many researchers[1-6], and a lot of theoretical and numerical studies have also been reported[7-12]. Most of the theoretical studies to date have assumed the hydrogel to be homogeneous before swelling. Recently, a series of experiments by Guvendiren et al.[7,13,14] have observed a rich variety of surface patterns (including creases and wrinkles) by using hydrogels with depth-wise crosslink gradients. It was found that both the critical condition and the characteristic length scale of the surface patterns depended on the crosslink gradient. Motivated by these experiments, we present a theoretical analysis on swell-induced surface instability of graded hydrogel layers, i.e., the layer with material properties varying in the thickness direction.

The critical condition for the onset of swell-induced surface instability in hydrogels has become an interesting subject of theoretical studies recently. By an energetic consideration, Hong et al.[7] predicted a critical strain for surface creasing of an elastomer. More recently, Cao and Hutchinson[12] found that surface wrinkling in an elastomer is highly unstable and extremely sensitive to imperfections that could significantly reduce the critical strain. For a hydrogel layer on a rigid substrate, the critical condition for swell-induced surface instability is similar to the elastomers under compression, but with subtle differences due to the interaction between solvent and the polymer network. Following a procedure similar to Biot's linear perturbation analysis, Kang and Huang[9] predicted that the critical swelling ratio for wrinkling instability of a hydrogel layer varies over a wide range, depending on the material parameters.

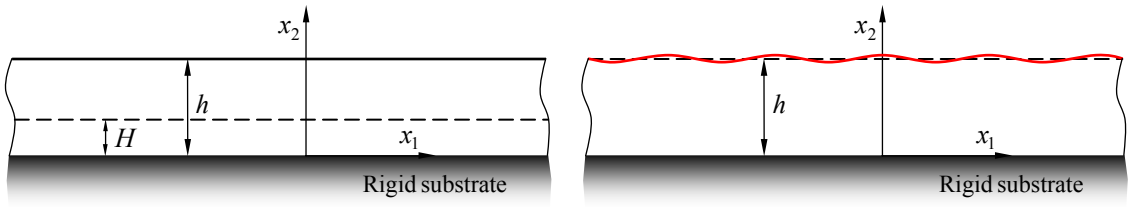
The theoretical studies predict no characteristic length scale for the surface instability in homogeneous elastomers and hydrogels. By considering the effect of surface tension, Kang and Huang[10] predicted a characteristic wrinkle wavelength that scales almost linearly with the

thickness of the hydrogel layer. Alternatively, a characteristic length scale may be introduced by assuming a thin skin layer at the surface of the hydrogel[15] or more generally, by assuming a gradient of the material properties in the thickness direction. In this paper, by dividing a layer into fictitious sub-layers, we present theoretical results for the stability analysis for swelling of graded hydrogel layers. The results suggest that both the critical condition and the characteristic wavelength depend sensitively on the depth-wise variation of the material properties in the hydrogel layer.

2. Theory of confined homogeneous hydrogel layers

In this section we briefly review the homogeneously swelling and a linear perturbation analysis for confined hydrogel layers[9,16,17].

2.1. Constrained swelling



(a) (b)

Fig. 1. Schematic of a hydrogel layer on a substrate: (a) a homogeneous swollen state; (b) a perturbation to the swollen state.

A homogeneous hydrogel layer is attached to a rigid substrate as shown in Fig. 1a. Since confined to the substrate, the hydrogel will swell only in the thickness direction with the thickness varying from H (at dry state) to h (at the swollen state). In the equilibrium state, the swelling ratio $\lambda_h = h/H$ can be obtained as a function of the chemical potential ($\hat{\mu}$) of external solvent in the following form[9]:

$$\log\left(1-\frac{1}{\lambda_h}\right)+\frac{1}{\lambda_h}+\frac{\chi}{\lambda_h^2}+N\Omega\left(\lambda_h-\frac{1}{\lambda_h}\right)=\frac{\hat{\mu}-p\Omega}{kT} \tag{1}$$

where $N\Omega$ and χ are two dimensionless parameters for material properties of the hydrogel, N represents the effective number of polymer chains per unit volume of the polymer network at the dry state, Ω is the volume per solvent molecule, χ reflects the interaction between the solvent molecules and the polymer, $\hat{\mu}$ is commonly a function of the temperature (T) and pressure (p), k the Boltzmann constant. Assuming an ideal gas phase ($p < p_0$) and an incompressible liquid phase ($p > p_0$), the external chemical potential is given by

$$\hat{\mu}(p,T)=\begin{cases}(p-p_0)\Omega, & \text{if } p>p_0,\\ kT\log(p/p_0), & \text{if } p<p_0,\end{cases} \tag{2}$$

where p_0 is the equilibrium vapor pressure of the solvent.

2.2. Linear perturbation fields

For a linear stability analysis, a two dimensional perturbation is assumed as small displacements added to the swollen state of the confined hydrogel layer (Fig. 1b), namely

$$u_1 = u_1(x_1,x_2) \quad \text{and} \quad u_2 = u_2(x_1,x_2). \tag{3}$$

The nominal stresses are obtained by the partial differentiation of the free energy with respect to the deformation gradient components as

$$s_{iJ} \approx NkT[\widetilde{F}_{iJ} - (\lambda_h - \xi_h \varepsilon) H_{iJ}] - pH_{iJ} \tag{4}$$

where $\xi_h = \frac{1}{\lambda_h} + \frac{1}{N\Omega}\left(\frac{1}{\lambda_h - 1} - \frac{1}{\lambda_h} - \frac{2\chi}{\lambda_h^2}\right)$, $\varepsilon = \frac{\partial u_1}{\partial x_1} + \frac{\partial u_2}{\partial x_2}$, and $H_{iJ} = \frac{1}{2} e_{ijk} e_{JKL} F_{jK} F_{kL}$.

Assume the perturbation displacements to be periodic in the x_1 direction, taking the form:

$$u_1 = U_1(x_2)\sin \omega x_1 \quad \text{and} \quad u_2 = U_2(x_2)\cos \omega x_1, \tag{5}$$

where ω is the wave number. Applying Eq. (5) to Eq. (4) and then inserting it to the mechanical equilibrium equation

$$\frac{\partial s_{iJ}}{\partial X_J} = 0, \tag{6}$$

the equilibrium equation is finally derived as follows:

$$\lambda_h^2 U_1'' - \omega^2 (1 + \lambda_h \xi_h) U_1 - \omega \lambda_h \xi_h U_2' = 0, \tag{7}$$

$$\omega \lambda_h \xi_h U_1' + \lambda_h (\xi_h + \lambda_h) U_2'' - \omega^2 U_2 = 0. \tag{8}$$

And the perturbation displacement field can be solved from Eqs. (7) and (8) as

$$U_1(x_2) = A_1 e^{\omega x_2 / \lambda_h} + A_2 e^{-\omega x_2 / \lambda_h} + A_3 e^{\beta \omega x_2} + A_4 e^{-\beta \omega x_2}, \tag{9}$$

$$U_2(x_2) = -A_1 \lambda_h e^{\omega x_2 / \lambda_h} + A_2 \lambda_h e^{-\omega x_2 / \lambda_h} - A_3 \beta e^{\beta \omega x_2} + A_4 \beta e^{-\beta \omega x_2}, \tag{10}$$

where $\beta = \sqrt{(1 + \lambda_h \xi_h)/(\lambda_h^2 + \lambda_h \xi_h)}$.

3. A model of graded hydrogel layers

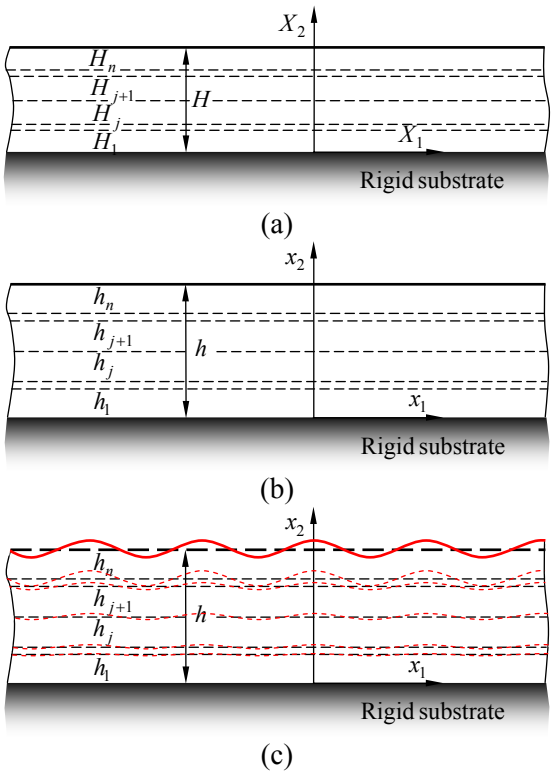


Fig. 2. Schematic of a graded hydrogel layer: (a) the dry state; (b) a transversely homogeneous swollen state; (c) a perturbation to the swollen state.

Consider a confined graded hydrogel layer as shown in Fig. 2. Set a Cartesian coordinate system in the dry state so that X_1 and X_3 are along the interface and X_2 in the thickness direction (Fig. 2a). Now we divide the layer into n fictitious sub-layers, each of which may have different thickness and different material properties. When n approaches infinity, the thicknesses of the sub-layers approach zero uniformly and also the laminated layers approach graded layer.

For the ith sub-layer considered as a homogeneous layer, the perturbation displacements (Fig. 2c) are in the form as Eqs. (9) and (10), i.e.,

$$U_1^{(i)} = A_1^{(i)} e^{\omega x_2/\lambda_{hi}} + A_2^{(i)} e^{-\omega x_2/\lambda_{hi}} + A_3^{(i)} e^{\beta_i \omega x_2} + A_4^{(i)} e^{-\beta_i \omega x_2}, \tag{11}$$

$$U_2^{(i)} = -A_1^{(i)} \lambda_{hi} e^{\omega x_2/\lambda_{hi}} + A_2^{(i)} \lambda_{hi} e^{-\omega x_2/\lambda_{hi}} - A_3^{(i)} \beta_i e^{\beta_i \omega x_2} + A_4^{(i)} \beta_i e^{-\beta_i \omega x_2}, \tag{12}$$

where $\beta_i = \sqrt{(1+\lambda_{hi}\xi_{hi})/(\lambda_{hi}^2 + \lambda_{hi}\xi_{hi})}$.

For the laminated layers, in addition to the boundary conditions, namely

$$U_1^{(1)} = U_2^{(1)} = 0, \qquad \text{at } x_2 = 0, \tag{13}$$

$$(\xi_{hn} - \lambda_{hn})\omega U_1^{(n)} + (\xi_{hn} + \lambda_{hn})\frac{\mathrm{d}U_2^{(n)}}{\mathrm{d}x_2} = 0 \quad \text{and} \quad \frac{\mathrm{d}U_1^{(n)}}{\mathrm{d}x_2} - \omega U_2^{(n)} = 0, \quad \text{at } x_2 = h, \tag{14}$$

the perturbation displacements and the associated tractions must be continuous along the interface of any two adjacent sub-layers, namely

$$U_1^{(j)}(x_{hj}) = U_1^{(j+1)}(x_{hj}) \quad \text{and} \quad U_2^{(j)}(x_{hj}) = U_2^{(j+1)}(x_{hj}), \tag{15}$$

$$s_{12}^{(j)}(x_{hj}) = s_{12}^{(j+1)}(x_{hj}) \quad \text{and} \quad s_{22}^{(j)}(x_{hj}) = s_{22}^{(j+1)}(x_{hj}), \tag{16}$$

where $x_{hj} = h_1 + h_2 + \mathrm{K} + h_j$ (j = 1, 2, …, n–1). Substituting Eqs. (11) and (12) into Eqs. (13)-(16) yields 4n linear homogeneous equations with respect to the coefficients $A_m^{(i)}$ ($m = 1 \sim 4$, $i = 1 \sim n$), which can be written in a matrix form:

$$\mathbf{DA} = \mathbf{0}, \tag{17}$$

where $\mathbf{D}$ is a $4n \times 4n$ matrix.

The critical condition for onset of the surface instability in the graded hydrogel layer is then obtained by setting the determinant of the matrix $\mathbf{D}$ equal to zero, namely

$$\det(\mathbf{D}) = f(\omega H, \mu; N_i\Omega, \chi_i, k_i) = 0. \tag{18}$$

For each normalized wave number (ωH), we solve Eq. (18) to find the critical chemical potential μ_c, which depends on the material properties of sub-layer ($N_i\Omega$, χ_i) as well as its volume fraction $k_i = H_i / H$. The swelling ratio of each sub-layer at the critical chemical potential, $\lambda_{hi}(\mu_\mathrm{c})$, is then calculated from Eq. (1). Subsequently, the general critical swelling ratio for the graded layer can be calculated from

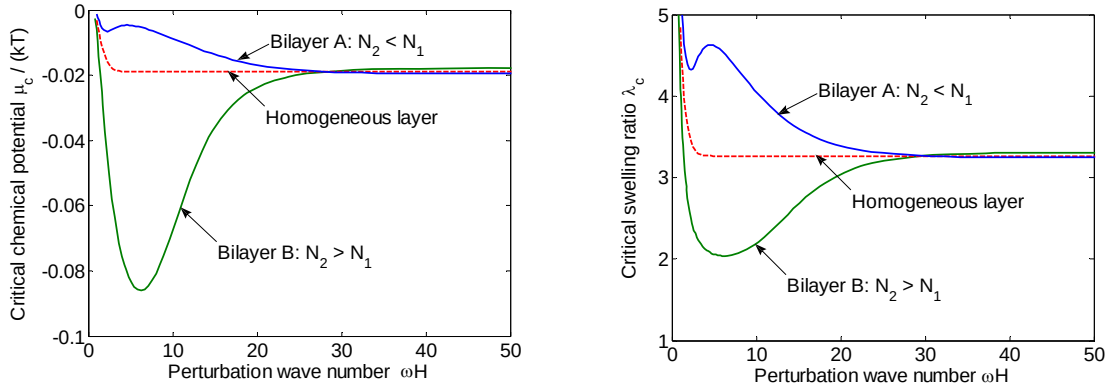
$$\lambda_\mathrm{c} = h/H = \sum_{i=1}^{n} k_i \lambda_{hi}. \tag{19}$$

4. Results and discussion

In this section, we apply the approach developed in the previous section to present the analytical results for the critical condition of surface instability for both hydrogel bilayers and graded hydrogel layers, and the effects of material properties are discussed as well.

4.1. Hydrogel bilayer instability

Fig. 3a plots the critical chemical potential as a function of the perturbation wave number for two bilayers (A and B), in comparison with a homogeneous layer. The corresponding critical swelling ratios are plotted in Fig. 3b. For the bilayers, the critical chemical potential varies with the perturbation wave number non-monotonically. If the top layer is softer than the underlayer ($N_2 < N_1$), the critical chemical potential has a local minimum μ_c^*, corresponding to a long-wave mode ($\omega = \omega^*$). The local minimum μ_c^* however is greater than the critical chemical potential at the short-wave limit ($\omega \to \infty$), i.e., $\mu_c^* > \mu_c^\infty$. Therefore, the onset of surface instability for such a bilayer (*soft-on-hard*) is expected to be determined by the short-wave limit. On the other hand, if the top layer is stiffer than the underlayer ($N_2 > N_1$), the minimum critical chemical potential occurs at a long-wave mode and is lower than the short-wave limit, i.e., $\mu_c^* < \mu_c^\infty$. Consequently, the critical condition for onset of surface instability for such a bilayer (*hard-on-soft*) is determined by a critical long-wave mode, with a characteristic length ($L^* = 2\pi/\omega^*$). In this case, the critical chemical potential for long-wave mode and the corresponding critical swelling ratio are considerably lower than that for a homogeneous layer.



(a) (b)

Fig. 3. (a) Critical chemical potential and (b) the corresponding swelling ratio versus the perturbation wave number for two hydrogel bilayers (A: $N_2\Omega = 4\times10^{-4}$; B: $N_2\Omega = 2\times10^{-3}$), both with $N_1\Omega = 10^{-3}$ and $k_1 = 0.9$, in comparison with a homogeneous hydrogel layer ($N\Omega = 10^{-3}$).

To highlight the distinct surface instability behaviors for the soft-on-hard and hard-on-soft hydrogel bilayers, a nonlinear finite element method developed previously[8] is used to simulate swell-induced deformation and evolution of surface instability of the hydrogel bilayers, as shown in Fig. 4. The two models are identical in geometry, mesh, initial surface perturbation, boundary conditions, and volume fraction $k_1 = 0.9$. The common material properties are: $N_1\Omega = 10^{-3}$ and $\chi_1 = \chi_2 = 0.4$. The soft-on-hard bilayer, with $N_2\Omega = 4\times10^{-4}$, develops multiple surface creases without appreciable wrinkling (Fig. 4a and 4b), similar to that of a homogeneous layer[9]. For the hard-on-soft bilayer, with $N_2\Omega = 10^{-2}$, the behavior is drastically different: the wrinkles grow significantly before creases form (Fig. 4c and 4d). The critical chemical potential or the critical swelling ratio for the onset of surface wrinkling in the hard-on-soft bilayer is considerably lower than that for surface creasing in the soft-on-hard bilayer.

Therefore, the two types of hydrogel bilayers (soft-on-hard vs hard-on-soft) exhibit distinct behavior at the onset of surface instability: for the soft-on-hard bilayer, with no characteristic length, surface wrinkling is highly unstable and is likely to collapse into creases; for the hard-on-soft

bilayer, surface wrinkling is stable with a finite wavelength.

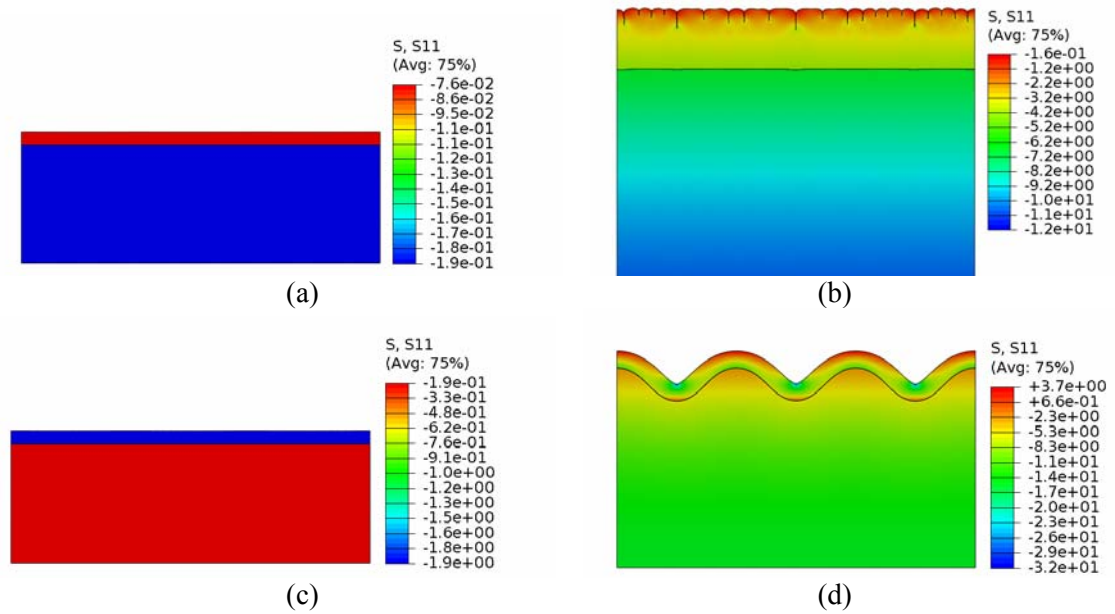


Fig. 4. Numerical simulations of swell-induced surface instability. (a) and (b): μ/kT =-1.158 and -0.004 for a soft-on-hard bilayer ($N_1\Omega$ = 10^{-3} and $N_2\Omega$ = 4×10^{-4}); (c) and (d): μ/kT =-1.158 and -0.1513 for a hard-on-soft bilayer ($N_1\Omega$ = 10^{-3} and $N_2\Omega$ = 10^{-2}).

4.2. Graded hydrogel layer instability

To illustrate the effect of material parameters varying in the thickness direction on surface stability, we consider a graded hydrogel layer with linearly or exponential graded crosslink density. Since the effective number of polymer chains per unit volume is proportional to the crosslink density, we have

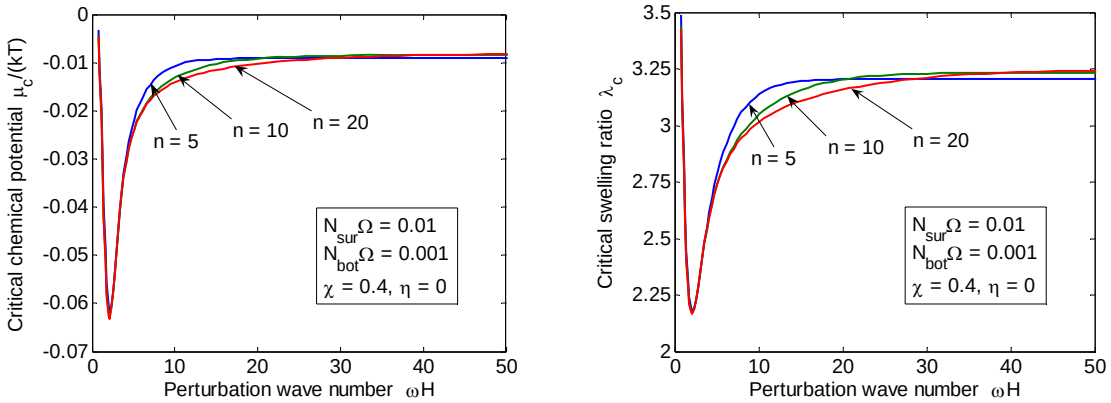
$$N(X_2) = N_{\text{bot}} + (N_{\text{sur}} - N_{\text{bot}})\frac{X_2}{H}, \tag{20}$$

or

$$N(X_2) = N_{\text{bot}} + (N_{\text{sur}} - N_{\text{bot}})\frac{\exp(\eta X_2/H)-1}{\exp(\eta)-1}, \tag{21}$$

so that $N = N_{\text{bot}}$ at the bottom face of the hydrogel layer ($X_2 = 0$) and $N = N_{\text{sur}}$ at the surface ($X_2 = H$). The other material parameter, χ, is assumed to be a constant.

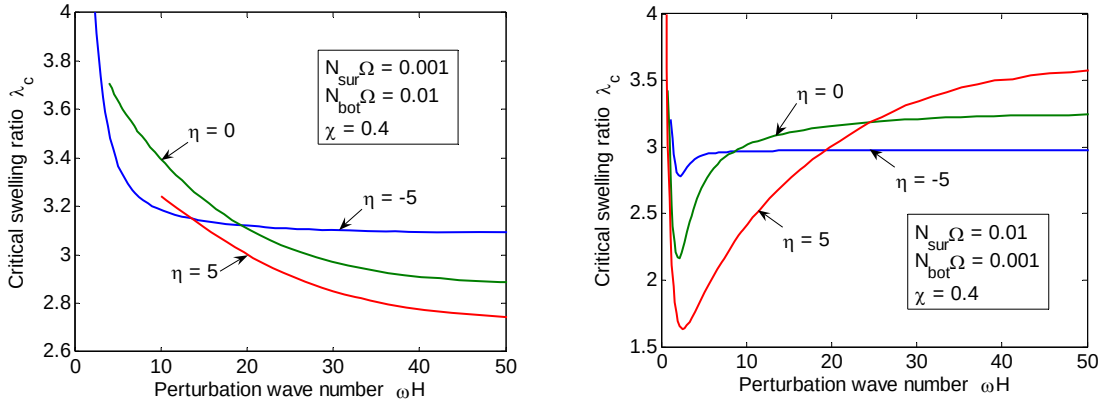
Fig. 5 shows the critical chemical potential and the critical swelling ratio as functions of the perturbation wave number for the graded hydrogel layer with $N_{\text{sur}}\Omega$ = 0.01, $N_{\text{bot}}\Omega$ = 0.001, χ = 0.4, and the shape factor η = 0. The three curves in each figure represent the results for the graded layer divided into 5, 10, and 20 sub-layers, respectively. Similar to the hard-on-soft hydrogel bi-layer in Fig. 3, there exist the minimum critical chemical potential μ_c^* at a long-wave mode ω^*. It can also be observed that the results converge very fast, especially μ_c^*, ω^*, and the according critical swelling ratio λ_c^* coincide very well. Therefore, the enough accurate results may be obtained by using 20 sub-layers.



(a) (b)

Fig. 5. (a) Critical chemical potential and (b) the corresponding swelling ratio versus the perturbation wave number for the graded hydrogel layer divided into 5, 10, 20 sub-layers, respectively.

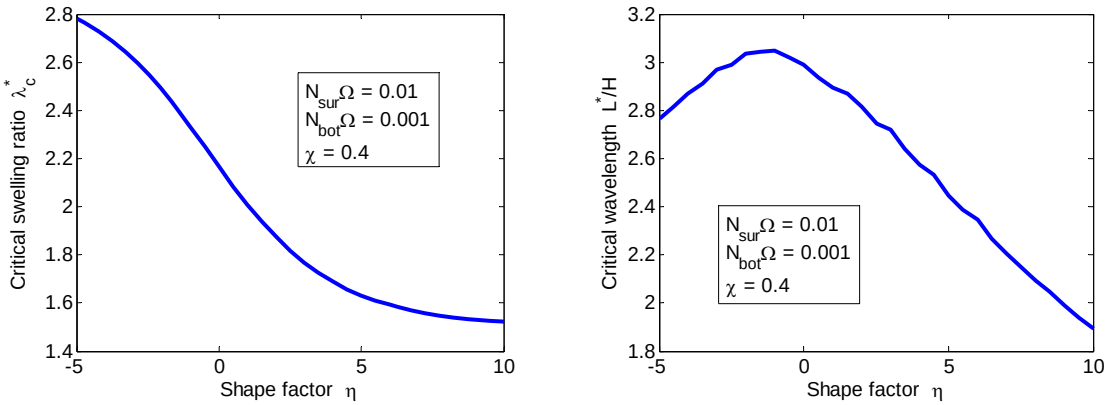
The critical swelling ratios for different gradient profile with η = -5, 0, 5 are plotted in Fig. 6. It is interesting that critical swelling ratios relate to the shape factor η. For soft-on-hard graded layers (N_{sur}<N_{bot}), the critical swelling ratio decreases monotonically with increasing wave number, which is similar to the case of soft-on-hard bi-layers, but without a local minimum λ_c^*. The onset of surface instability is determined by short-wave limit and the according swelling ratio λ_c^∞ decreases as the shape factor increases (Fig. 6a). For hard-on-soft graded layers (N_{sur}>N_{bot}), the critical swelling ratio for the long-wave mode (λ_c^*) and the according wavelength (L^*) depend on gradient profile as shown in Fig. 6b, and apparently λ_c^* is considerably lower than λ_c^∞ for the soft-on-hard graded layer with the same shape factor. The critical swelling ratio for the long-wave mode (λ_c^*) varies with the shape factor η monotonically as shown in Fig. 7a. The swelling ratio decreases as the shape factor increases. However, the wavelength of the critical long-wave mode ($L^* = 2\pi/\omega^*$), normalized by the layer thickness H, first increases and then decreases with the increasing shape factor η as plotted in Fig. 7b.



(a) (b)

Fig. 6. Critical swelling ratio obtained by 20 sub-layers versus the perturbation wave number for: (a) soft-on-hard and (b) hard-on-soft graded hydrogel layers with different shape factors.

From the results for graded hydrogel layers, we can predict that the behavior at the onset of surface instability for graded hydrogel layers is similar to that of hydrogel bilayers, i.e., the soft-on-hard graded layer with no characteristic length and the hard-on-soft graded layer with a finite wavelength. Furthermore, both the critical swelling ratio and the wavelength depend on the gradient profile.



(a) (b)

Fig. 7. (a) The critical swelling ratio for the long-wave mode and (b) the corresponding wavelength with shape factor η ranging from -5 to 10.

5. Conclusions

Based on the theory for homogeneous hydrogel layers, we presented a theoretical solution for the critical condition of swell-induced surface instability for a graded hydrogel layer on a rigid substrate. Graded hydrogel layers with the crosslink density varying in the thickness direction as well as hydrogel bilayers were examined as examples. The results show that both the critical condition and the instability mode depend on the variation of the material properties. For a soft-on-hard graded layer, the onset of surface instability is determined by a short-wave mode with a limiting short wavelength. In contrast, for a hard-on-soft graded layer, a long-wave mode with a finite wavelength emerges as the critical mode at the onset of surface instability. The critical swelling ratio of the long-wave mode for hard-on-soft graded layers is considerably lower than that of the short-wave limit for soft-on-hard ones with the same shape factor. In addition, we found that both the critical swelling ratio and the characteristic wavelength depend on the gradient profile of material properties.

Abstract The purpose of the present paper is to propose an analytical model that enables the evolution of transverse ply cracking to be investigated in fiber reinforced laminated composites subjected to in-plane tensile loading and thermal residual stress. The strain energy release rate associated with matrix cracking in transverse layer is derived using a 2-D shear-lag stress analysis and the equivalent constraint model (ECM). An energy criterion, based upon the fracture mechanics approach, is proposed to describe the initiation and propagation of the transverse ply cracking. This work is also concerned with statistical distributions of the defects with due consideration given to the scale size effect. Monte-Carlo simulation technique is implemented to predict mechanical behaviors of composite structures by taking into account the statistic of critical fracture toughness G_c of the transverse ply. The results deduced from the numerical procedure are in good agreement with the experimental results obtained for laminated composites formed by unidirectional fiber reinforced laminae with different orientations.

Keywords Laminated composites, Transverse cracking, Fracture mechanics, Statistical analysis, Modelling

1. Introduction

Composite laminates have gained widespread acceptance in many structural applications on account of their high specific strength and stiffness. There is a strong need of comprehensively understanding damage mechanisms to ensure the structural integrity of composite materials.

Performance in service of a composite structure is influenced by the progressive occurrence and interaction of some or all of the many multi-mechanisms of damage such as matrix cracking, delamination, fiber fracture and fiber/matrix debonding under loading and environment conditions. The early stage of damage is dominated is matrix cracking parallel to the fibers in the off-axis piles. These matrix cracks develop in the fiber direction and extend across the laminates from the free edges of test specimens. The number of cracks increases with increasing the load until a saturation crack density. Matrix cracking is usually referred as transverse cracking because the crack plane is commonly transverse to the laminate middle-plane. It can result in significant deterioration of the residual stiffness and loading-bearing capacity of laminates and triggers development of other more harmful damage mechanisms [1].

The detailed mechanisms of transverse ply cracking in laminates have been a subject of active research effort. A large variety of analyses have been conducted to investigate the damage phenomena of composite laminates: different modifications of the shear-lag model [2], variational approach based on minimization of complementary energy [3], continuum damage mechanics approach [4] and numerical methods, for example, based on finite element analysis [5]. The overwhelming majority of studies investigating behavior and properties of composite laminates with matrix cracks assume that cracks are equally spaced [6]. Such a deterministic approach, which ignores the fact that transverse cracking is a progressive damage mode, predicts the appearance of many transverse cracks simultaneously when the first transverse cracking strain is reached [7]. In fact, the transverse matrix cracking is an inherently stochastic process due to the random variations of local material properties of the plies caused by inner original defects [8]. The random distribution

of these defects is the major factor that affects both crack initiation and propagation. Prediction on the durability of these materials tends to be probabilistic in character. Modelling of transverse cracking in laminated composites should, therefore, consider the details of its construction and the use of statistical analysis.

In the present study we derive an analytical model which has the capacity of representing and predicting the fracture of laminated composite structures damaged by transverse cracking, appropriate for the mechanical analysis of fiber reinforced composite laminates. The energy release rate associated with matrix cracking in the transverse layer of general symmetric composite laminates is presented using a 2-D shear lag stress analysis and the equivalent constraint model (ECM) [9,10]. An energy criterion, based on fracture mechanics approach, is proposed to predict and describe the ignition and propagation in symmetrical composite laminates subjected to in-plane loading. This work is also concerned with a stochastic description of the inner defects with due consideration given to the scale size effect. The random properties are introduced with the use of Weibull two-parameter probability density function. A numerical procedure is developed to investigate the multiplication of transverse cracking and predict the statistical failure strengths of composite structures by taking into account the statistic of critical fracture toughness. The results are also compared with those obtained from experiments and other existing models.

2. Formulation and algorithm

2.1. Analytical model

Micro-cracking has been a mechanism of failure extensively studied in many investigations. This mechanism occurs under transverse tensile or longitudinal shear loading conditions. A known analytical modeling of mechanical properties due to transverse cracking was performed by using the suggested “equivalent constraint model” (ECM) to determine the in-plane stress distributions in the damaged layers [11, 12]. The reduction in stiffness properties due to transverse ply crack was described by two in-situ damage effective functions introduced in Refs. [9, 11, 12]. It was shown that a crack lamina behaves within a laminate in a different manner compared to an infinite effective medium containing many cracks [13].

Our simulation reproduces the initial crack and its propagation in the thickness direction using the energy criterion. Indeed, the potential energy method has been presented by Zhang et al.[12, 14] for the evaluation of the energy release rate for damage initiation and propagation due to transverse ply cracking. The required energy release rate, G, for damage growth can be calculated using energy approach and then predicting that damage will grow when G exceed the critical energy release rate, G_c , or toughness of the material.

Energy release rate G associated to the appearance of a crack for a given stress state according to fracture mechanics is defined by the following expression,

$$G = \frac{\partial}{\partial A}\Pi(\sigma, A). \tag{1}$$

where Π is the strain energy of the whole laminate. A is crack surface area. σ is the applied laminate stress.

An opening displacement of transverse crack (COD) solution for a crack is introduced to obtain the strain energy release rate due to matrix cracking, such that

$$G_n(\sigma, D_n) = g_n(L, D_n)\left(\frac{\sigma_x^{0(2)}}{Q_{22}^0}\right)^2. \tag{2}$$

where $\sigma_x^{0(2)}$ is the x-axis normal stress in the xy-plane and superscript 0 is used to indicate the quantities that belongs to the undamaged state. Q_{ij}^0 are the in-plane stiffness components of an undamaged lamina, and $g_n(L, D_n)$ is the normalized energy release rate, which is independent of the applied load. A complete description of the strain energy based model was presented by Zhang [10, 15].

A damage criterion is proposed to predict the evolution of matrix cracking. Estimated quantity is compared with the associated critical value of the stain energy release rate

$$G(\sigma, D_n) = G_c. \tag{3}$$

where G_c denotes the fracture toughness of the composite materials.

2.2. Modelling of progressive cracking

The origins of transverse cracking are the inherent material defects such as the microcracks, voids, debonded fibers, areas of high fiber volume fraction, etc [8]. This causes the transverse layer to have a statistical nature of the fracture toughness along its length. Thus the transverse cracking propagation can be investigated by assigning a random distribution of the fracture toughness along the transverse layers.

In the present paper, the crack multiplication can be simulated by dividing the initial gage length into equal elements along the direction of the length $2L$ and randomly assigning fracture toughness G_c to each of them in accordance with two-parameter Weibull distribution.

Based on the Weibull statistics, the fracture toughness is given as

$$G_c = G_0 \cdot \left[\ln\left(\frac{1}{1-F}\right)\right]^{\frac{1}{m}}. \tag{4}$$

where G_0 represents the scale parameter, or characteristic quantity of the material. The Weibull modulus or shape parameter m controls the degree of disorder in the distribution, experimentally found to describe a variety of materials. $F \in [0,1]$ is a random number. The parameters m and G_0 can be calculated by statistical method

$$\overline{G}_c = E(G_c) = G_0 \Gamma\left(1 + \frac{1}{m}\right), \tag{5}$$

$$D(G_c) = G_0^2 \left\{\Gamma\left(1 + \frac{2}{m}\right) - \left[\Gamma\left(1 + \frac{1}{m}\right)\right]^2\right\}. \tag{6}$$

Where $E(G_c)$ and $D(G_c)$ are the mean and variance of random variable, respectively. In the approach we use here, transverse cracking at some location takes place when the energy released by a cracking event becomes equal to the critical strain energy release rate, G_c , at this position.

In fiber-reinforced composites, the largest portion of the loads is resisted by the fibers. When matrix

crackings occur, the internal loads must redistribute to other areas of the structures, and may cause a structural collapse [16]. For every state of stress, a simple criterion such as Hoffman criterion is expressed mathematically in the following fashion,

$$\frac{\sigma_1^2 - \sigma_1\sigma_2}{X_t X_c} + \frac{\sigma_2^2}{Y_t Y_c} + \frac{X_c - X_t}{X_t X_c}\sigma_1 + \frac{Y_c - Y_t}{Y_t Y_c}\sigma_2 + \frac{\tau_{12}^2}{S^2} = 1. \quad (7)$$

in which σ_1, σ_2 and τ_{12} are longitudinal stress, transverse stress and shear stress, respectively. X_t, X_c are the tensile strength and compressive strength of the unidirectional layer parallel to the fiber direction; Y_t, Y_c are the tensile strength and compressive strength one of the unidirectional layer transverse to the fiber direction; S is the shear strength of the unidirectional layer transverse and parallel to the fiber direction, respectively.

It should be mentioned that in the present study the ultimate failure of materials takes place when the stress state of the primary load-bearing lamina satisfies the condition mentioned [17].

2.3. Numerical algorithm

The simulation was conducted by controlling the stress loading of the model. Fig. 1 shows the progressive failure analysis algorithm for estimating damage growth:

Step 1. Ply material and ply orientation are selected to form a laminate. The critical strain energy release rate, G_c , is assigned to of each element. A virtual crack was introduced in all positions as possible sites for failure and the work performed to close the crack surfaces [18] was calculated. New transverse cracking happens in any location once the energy released by a cracking event is equal to the critical value. The virtual cracking procedure was repeated unceasingly until cracking is terminated under the same applied stress.

Step 2. The equivalent constraint model is employed to analyzing the damaged lamina. In the ECM, all the laminae below and above the damaged lamina under consideration are replaced with homogeneous layers [9]. The reduced stiffness properties of the damaged layer can be calculated by applying the laminated plate theory to the ECM. Thus, the in-plane microstresses of the primary loading-bearing lamina can be obtained by the constitutive relationship.

Step 3. With the stresses calculated, they are substituted in the failure criteria Eq. (7) to check for failure. When the loads are increased monotonically, the matching strains are computed and the resulting stresses are substituted in the failure criteria until they are satisfied. The ultimate load of the laminate is thus determined.

4. Results and discussion

A detailed analysis is conducted to assess the predictive capabilities of the present methodology. The mechanical properties of each type of unidirectional laminate used in this work are given in Ref [17]. Each set of Monte-Carlo simulation consists of 200 data points. The element length of 2.5×10^{-2} mm is chosen for the sake of efficiency [7].

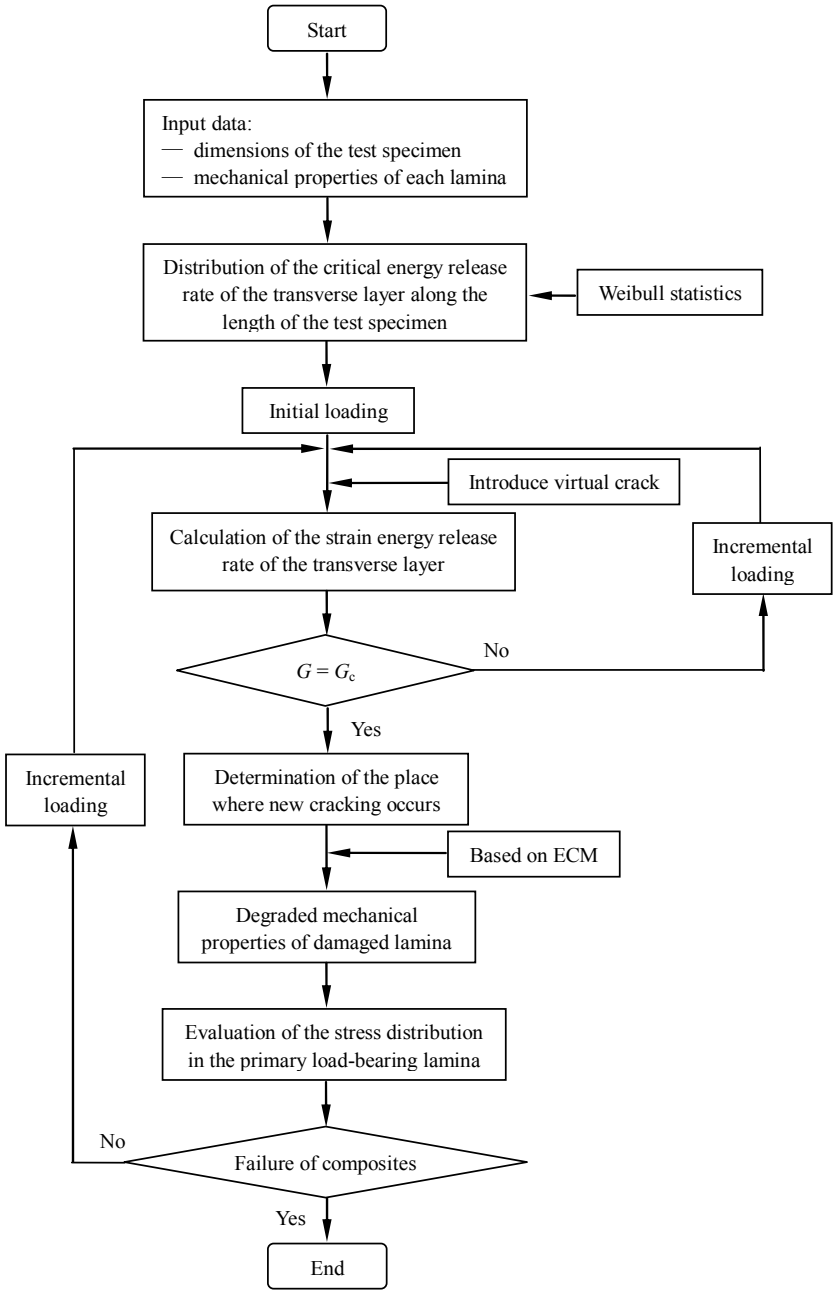

Figure 1. Schematic diagram of the procedure implemented for the analysis of the progression of transverse cracking

4.1. Prediction of stiffness reduction

It is well understood that transverse matrix cracking may occur long before final failure. Matrix cracking causes stiffness degradation and induces other failure modes. Figs. 2 and 3 shows the evolution of the longitudinal Young's modulus and Poisson's ratio for $[0_2/90_4]_s$ glass-fibre/epoxy laminate as a function of matrix crack density. It must be pointed out that the numerical result of each case is the average value of 200 data. The figures exhibit the comparison between the predictions provided by the analytical approach and experimental values. It is shown that the degradations in Poisson's ratio are much higher than the ones observed for the longitudinal Young's modulus. This can be explained by the fact that the Poisson's ratio is a transverse property as compared to the longitudinal nature of the Young's modulus.

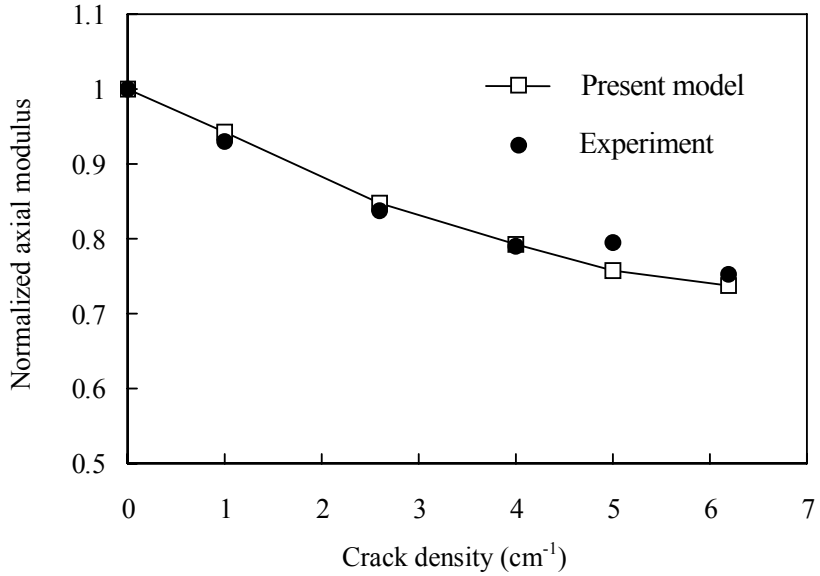

Figure 2. Change of normalized axial modulus as a function of crack density for $[0_2/90_4]_s$ laminate

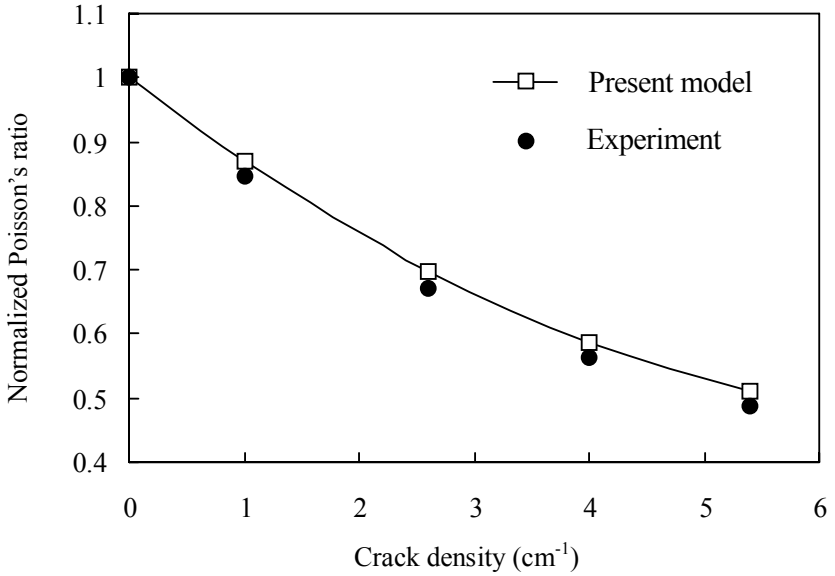

Figure 3. Change of normalized Poisson's ratio as a function of crack density for $[0_2/90_4]_s$ laminate

4.2. Analysis of progressive cracking

Transverse cracking is a progressive damage mode which evolves with increasing in the applied load and a measure of accumulated damage is the crack density. $G_0 = 750\ J/m^2$ and $\beta = 10$ are used as the scale parameters in the Weibull distribution for the glass-epoxy laminates with a stacking sequence of $[\pm 15/90_4]_s$. The simulation results are shown in Fig. 4 compared with experimental values. Since the fracture toughness in transverse layer follows Weibull distribution, the transverse cracking procedure is related to statistical aspect instead of deterministic one. Indeed, the distribution of cracking space is determined by load level and transverse fracture toughness distribution. It is found that the energy criterion can predict and describe the initiation and propagation of matrix cracking.

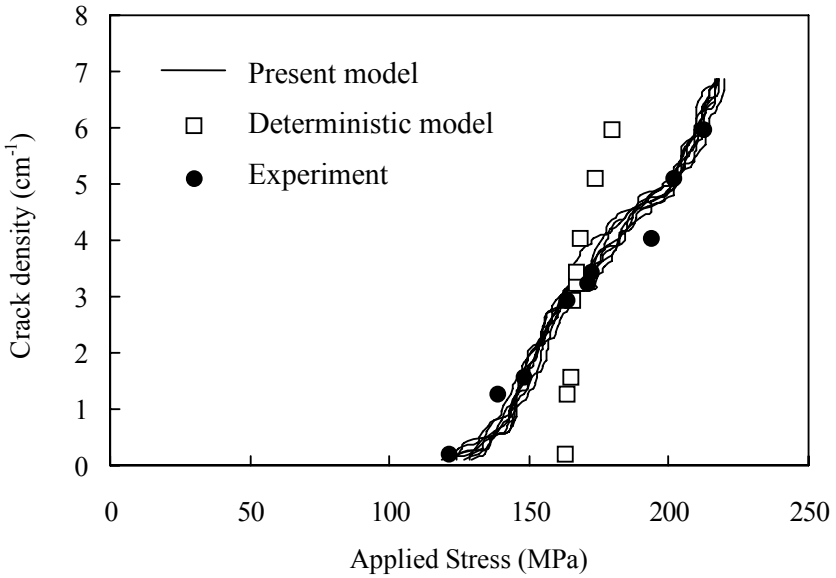

Figure 4. The crack density as a function of the stress applied to $[\pm 15/90_4]_s$ glass-fibre/epoxy laminates

4.3. Estimation of ultimate strength

In Fig. 5, the uniaxial strengths predicted by the current analysis are compared with experimental measurements for the CFRP $[0_2/90_m]_s$ laminates. The prediction is in good agreement with experimental data. The observed offset of ultimate strength is due to the lack of the micro-delamination mechanism in this approach. Especially for thicker layers, delamination at the interface is the dominant damage mode. One feature worthy of note, which is demonstrated by the deterministic model predictions [17], is that the current theory correctly takes account of the effects of the variability in fracture toughness due to microflaws distributed randomly along the length.

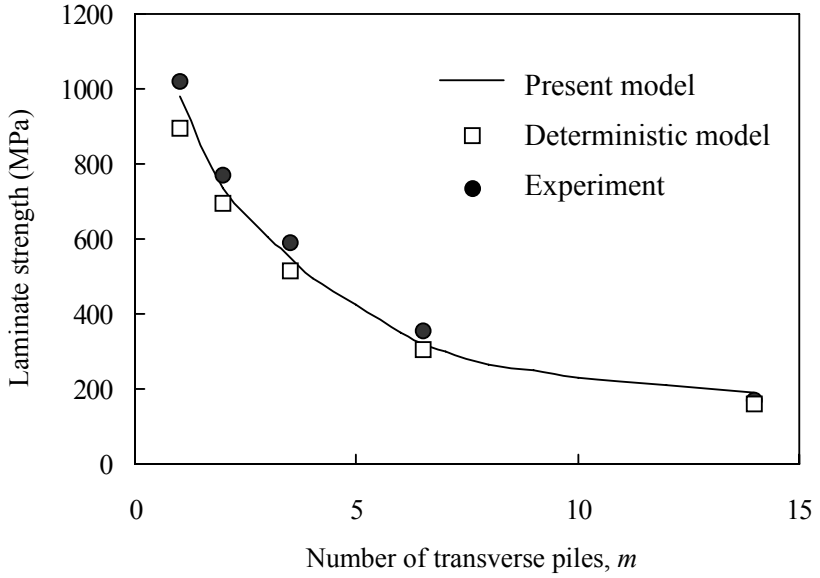

Figure 5. Influence of the 90° lamina thickness on the ultimate strength of the $[0_2/90_m]_s$ CFRP laminates

4.4. Investigation of faliure envelopes

Fig. 6 is biaxial failure envelopes predicted for a $[90/\pm45/0]_s$ AS4/3501-6 epoxy laminate under combined σ_x and σ_y stresses. It is clearly seen that numerical predictions exhibit good agreement with the experimental results present by Soden et al. [19]. It is interesting to note that locating the 90° ply adjacent to the laminate mid-plane will lower the laminate strength. This is because in such case the length of ply cracks in the through-thickness direction is double that for the other laminates, leading to a larger stress concentration in the 0° plies and to fiber failures at lower stresses [20].

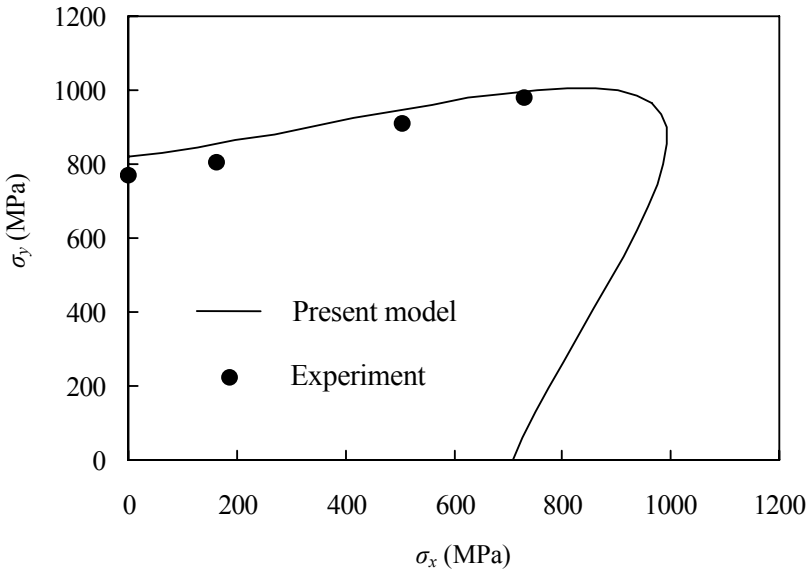

Figure 6. Biaxial failure envelope for $[90/\pm45/0]_s$ laminate made of AS4-3501/6 under combined loading

5. Conclusions

The objective of this exercise is to approach the modelling of progressive damage and failure in composite laminates. A statistical model based on the computation of the strain energy release rate associated with matrix cracking is proposed to study the stiffness reduction and predict ultimate strength of in symmetric laminated composite. The statistical distribution of the critical energy release rate, G_c, in the transverse layer is described by a two-parameter Weibull function in this article. Several sets of application examples and comparison with experimental results show that the present numerical model is able to reproduce the mechanical behavior of laminated composite formed by unidirectional fiber reinforced laminae with different orientations.

Abstract

Stress enhancement in the vicinity of brittle cracks makes the macroscale failure properties extremely sensitive to the microscale material disorder. As a result, crack propagation is sometimes observed to display a jerky dynamics with seemingly random sudden jumps spanning a broad range of scales, reminiscent of earthquakes. This so-called crackling dynamics cannot be captured via standard continuum fracture theory. The understandings of the key processes that drive such a dynamics then represent a crucial step toward predictive statistical models for heterogeneous brittle failure.

In this context, we designed an experimental setup which permits to drive brittle cracks in opening mode at adjustable velocity throughout model materials of adjustable microstructure. During the fracture, both the mechanical behavior and the acoustic emission are recorded in real time, and *post-mortem*, the morphology of the fracture surface is obtained by profilometry. Accurate statistical analysis of these experimental data and their interplay is believed to provide a deeper understanding of the key mechanisms responsible for crackling in heterogeneous brittle fracture.

Brittle crack, Experiment, Crackling dynamics, Model rock, Acoustic

1. Introduction

The effect of materials heterogeneities onto their failure properties remains far from being understood (see [1,2] for reviews of recent progresses in this field). In particular, in heterogeneous materials under slow external loading, cracks growth sometimes displays a jerky dynamics, with sudden jumps spanning a broad range of lengthscales. Such a complex dynamics, also referred to as crackling noise [3] was directly imaged in interfacial crack experiments [4]. It was also suggested from the acoustic emission accompanying paper peeling experiments [5], from the anomalous activity recorded in some calorimeters for high energy physics experiments [6], and - at much larger scale - from the seismic activity associated to earthquakes [7,8]. The salient features of such a crackling dynamics is to exhibit universal scale free statistical features reminiscent of self-organized-criticality [3].

Standard continuum approaches fails to describe such a crackling dynamics. Conversely, recent theoretical and numerical works suggested that some of the approaches developed in statistical and non-linear physics may be relevant. In this context, it has been proposed to identify the crack front with a long-range elastic line [9,10] and to map crack destabilization with a critical depinning transition [11,12]. By subsequently extending this formalism to stable crack growth, it then becomes possible to reproduce a crackling dynamics [13], and to precise the conditions required to

observe it [14]. Still, these models are derived by invoking very restrictive assumptions (1D line moving within a 2D random potential) and lack for quantitative comparisons with real fracture experiments (i.e. breaking of bulk 3D solids). One need also to further understand how the crackling statistics predicted theoretically translates into the acoustic emission and seismograph signals analyzed in fracture and earthquake problems.

The goal of the experiments described thereafter is to fill this lack.

2. Experimental setup

Slow stable cracks are driven via the wedge-splitting geometry [15] sketched in Fig. 1. Specimens were prepared from rectangular plates of size 12x14cm² and thickness 1.5cm. A notch is machined in each of the specimens i) by cutting out a 2.5x2.5cm² square from one side; ii) by subsequently adding a 8mm long thick groove with a diamond saw; and iii) by finally introducing a seed crack (~2mm-long) with a razor blade. The resulting specimens are loaded by placing two steel jaws equipped with roller bearing (to avoid friction) on both sides of the cutout and by pushing a steel wedge (semi-angle of 15°) in between. The opposite side is also made laid on a pivot to avoid friction when breaking. This geometry permits a stable propagation of the crack tip splitting the sample in two symmetric halves.

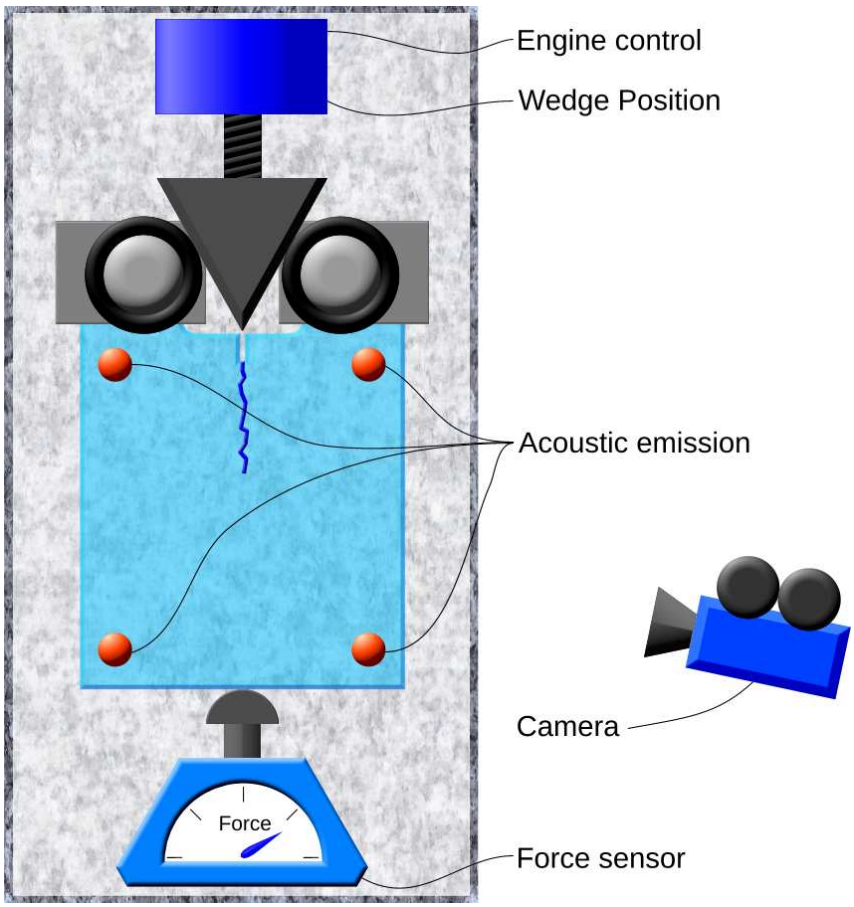

Figure 1. Experimental wedge-splitting device

Fracture experiments are performed on artificial rocks made from sintered polymer beads (Fig. 2D): Plexiglas or polystyrene monodisperse beads of an adjustable diameter (Fig. 2A) are heated up to a temperature slightly below glass transition (110° C), and then compressed in a rigid mold at a fixed pressure during 45min (Fig. 2B). An annealing process just above the glassy temperature during 1h is then applied to limit residual stress, and the so-obtained specimen is slowly cooled down (Fig. 2C).

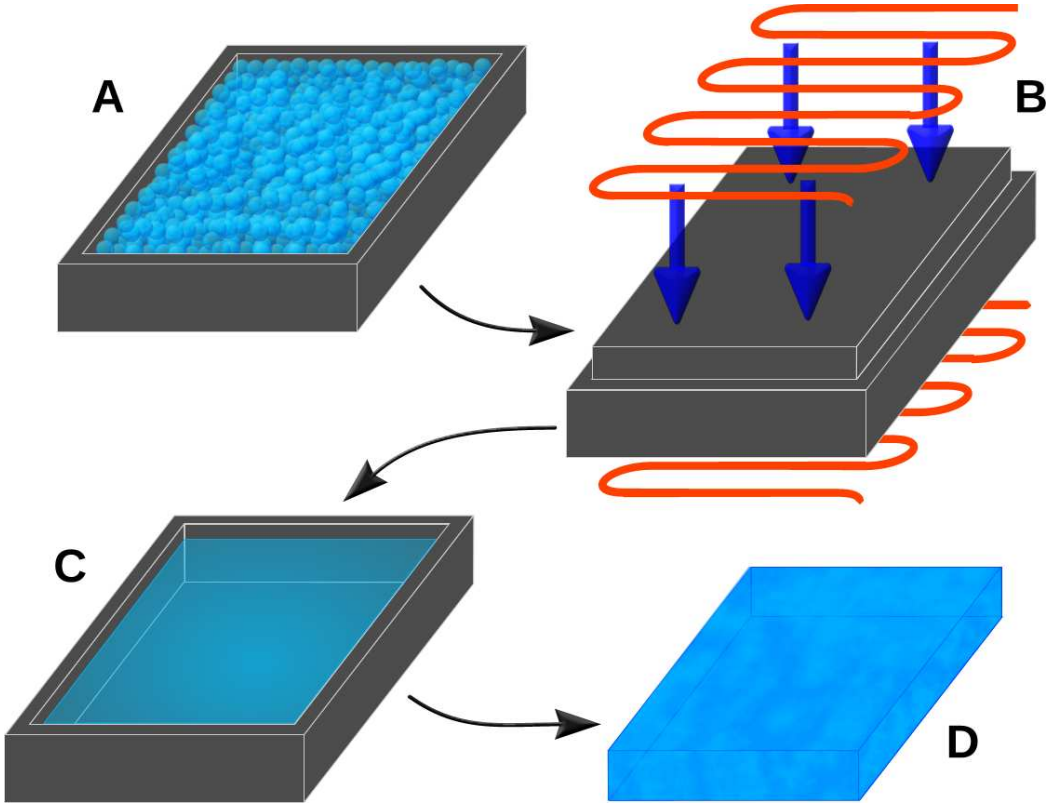

Figure 2. Protocol to synthesize artificial rock of adjustable microstructure

Bead diameters and sintering pressure have been varied, from 20 to 500µm and from 10 to 800kPa respectively, to modulate the microstructure length-scale and the porosity. Wedge speed was varied from 1.6 to 1600 nm/s to study the effect of driving rate. During the tests, a force sensor connected to the bottom of the sample (see Fig. 1) records in real-time the force f applyed on the specimen (acquisition rate of 50kHz with an accuracy of 1N). Similarly the wedge position u is recorded at each time step (acquisition rate of 1Hz) with nanometer precision. Crack propagation is imaged at the specimen surface (30 frames per second with a pixel size of 130µm) and 8 acoustic sensors (4 on both side of the sample) permit a record of the acoustic emission (and its further localization) with MHz acquisition rate and aJ precision.

3. Experimental results

Measurement of the wedge position u and of the applied force f gives full access to the exact mechanical energy stored in the system at each time step (see Fig. 3A). It also provides the time variation of the specimen stiffness (f / u). This signal is plotted as a function of the crack length c

measured from the direct imaging of the surface (Fig. 3B). This curve is noisy, but since noise has no physical meaning in this case, the curve is smoothed and an accurate one-to-one measure of the crack length as a function of the stiffness and of the time is get (black arrows in Fig. 3B). The failure speed can then be directly deduced, with a fairly high signal to noise ratio, by differentiating these data (see Fig. 3C). By limiting friction and plastic dissipation in our experiments, we ensured that the fracture process zone at the tip of the propagating crack is the sole source of mechanical energy dissipation in the system. Hence, from the knowledge of the time evolution for stored elastic energy and crack length, one can compute the energy release rate *G* (see Fig. 3D). Acoustic sensors give access to the energy (see Fig. 3E) of the acoustic events and time delays permit to localize each acoustic source (see Fig. 3F). Finally, the fracture surface is analyzed post-mortem via profilometer (see Fig. 3G).

As seen in Fig. 3, a crackling signal is observed in our experiments. The statistical analysis of the various signals and their interplay are currently underway and will be presented at ICF13.

4. Concluding discussion

The experimental setup presented here is the first one which permits to observe a crackling dynamics for the steady bulk crack propagation within a 3D brittle solid. A precise sintering protocol has been set up to build this material from mono-disperse polymer beads. Hence, all material parameters (microstructural texture, porosity, toughness) are tunable. The wedge-splitting experimental device set up to fracture this material controlling the loading permits to have access to an accurate measurement of the acoustic and mechanical parameters evolution.

The statistical analysis of these quantities and their interplay is currently in progress. It will allow qualifying the depinning approaches developed in statistical physics [8] to address the problem of brittle heterogeneous fracture.

Abstract: Experimental studies show that fracture surfaces exhibit rather remarkable scaling properties characterized by universal roughness exponents, close to $\zeta = 0.4$ in brittle materials and close to $\zeta = 0.8$ in quasi-brittle and ductile materials. In this work, we go beyond the value of the roughness exponent, and focus on the distribution of height fluctuations on the fracture surface of a large range of materials, from brittle to ductile and quasi-brittle solids. At first, we show how damage accompanying crack propagation results on average into deviations to the Gaussian statistics observed on brittle fracture surfaces. Then, we identify on the fracture surface the location of the largest jumps responsible for the fat tails observed on these distributions, and show that these extreme events are actually organized in a network of clusters made of connected events. The statistical analysis of these clusters show many interesting features, including a characteristic sizes reminiscent of the typical size of the damage processes in the material studied, a power law distribution of cluster size for ductile and quasi-brittle fracture surface, while their probability distribution decay exponentially in brittle fracture surface. This new approach in the analysis of the morphology of fracture surface is a first step into a better understanding of the damage processes occurring within the process zone during crack propagation, and open promising perspectives into the description of damage mechanisms in a large range of materials by an unified theory.
Keywords: Fracture surface, roughness statistics, scaling behavior.

1 Introduction

Understanding the failure properties of a solid is a constant goal in material science. A fine description of these properties can have important applications for the design of new materials and the expertise of failures. Experimental studies show that fracture surfaces exhibit rather remarkable scaling properties characterized by universal roughness exponents, close to $\zeta = 0.4$ in brittle materials and close to $\zeta = 0.8$ in quasi-brittle and ductile materials. However, much more information about the failure process remains encoded in the fracture surface as the crack roughness reveals the interaction between the crack fronts and the material microstructure. Therefore a fine description of the statistics of fracture surface shall guide the development of more accurate models of fracture propagation and therefore allows a finer understanding of the failure process.

2 Material and methods

Aluminum alloy and mortar are chosen as the archetypes of ductile and quasi-brittle materials, respectively. The alloy specimens are aluminum 4 wt$\%$ copper with an as-casted microstructure. They are broken under uniaxial mode I tension with constant traction velocity (strain rate of approximately $1.6 \times 10^{-2}\mathrm{s}^{-1}$)[1]. Their fracture surfaces are observed with a scanning electron microscope at two tilt angles. A high resolution elevation map is produced from the stereo pair using the cross-correlation based surface reconstruction technique. The reconstructed image of the topography represents a rectangular field of 3.7×2.7 mm (1250×950 pixels). The in-plane and out-of-plane resolutions are of the order of $3\ \mu$m. We present results for sample broken at different temperatures, i.e. $480°$ for the sample #1 and $620°\mathrm{C}$ for the sample #2. A part of the fracture surface of aluminum #2 (2.7×2.7 mm) is represented on Fig. 1(a). Mortar fracture surfaces are obtained by applying four points bending under controlled displacement conditions to a notched beam. The length of the beam is $1400\,\mathrm{mm}$ and its height and thickness are both equal to $140\,\mathrm{mm}$. The topography of the fracture surfaces is recorded using an optical profilometer. The maps include 400 profiles of 4096 points each. We make sure that the analyzed profiles are located far enough from the initition region, so that the roughness properties are statistically stationnary. The sampling step along profiles is $20\,\mu$m. Two successive profiles are separated by $50\ \mu$m along the direction of crack propagation. The lateral and vertical accuracy are of the order of $5\,\mu$m (see [2] for more experimental details). A part of the fracture surface #2 (20×20 mm) is represented on Fig. 1(b). In situ observations and acoustic emissions analysis show that failure occurs by multicracking processes present in an extended zone ahead of the notch. To compare our findings with a reference material that does not involve damage mechanisms, fracture surfaces of brittle ceramics made of sintered glass beads are also analyzed. For this material, the process zone was shown to be much smaller than the diameter $d \simeq 100\,\mu$m of the grains [12]. Tapered Double Cantilever Beam with width and length equal to $20\,\mathrm{mm}$ (perpendicular to the crack propagation) and $60\,\mathrm{mm}$ (parallel to it) respectively, are broken at constant opening rate. The tapered shape of these specimens allows us to obtain a stable quasi-static mode I crack growth. The roughness of the fractured specimens is measured using a mechanical stylus profilometer (™Talysurf Intra) with a $10\,\mathrm{nm}$ vertical and a $2\,\mu$m lateral resolutions. The obtained fracture surface (8×8 mm) is shown on Fig. 1(c).

3 Non-Gaussian statistics of fracture surface roughness

We first study the distribution of height fluctuation on the fracture surfaces. For a given increment $\delta\vec{x}$ of the coordinates in the average fracture plane, we note $p(\delta h|\delta\vec{x})$ the probability distribution of an height increment $\delta h = h(\vec{x}) - h(\vec{x} + \delta\vec{x})$ where the sampling of the distribution is done on all admissible coordinates $\vec{x}$. We also note $p(\delta h|\delta r)$ the distribution of δh where the sampling is done on all admissible $\vec{x}$ and $\delta\vec{x}$ such as $|\delta\vec{x}| = \delta r$. The distribution $p(\delta h|\delta r)$ at different δr is shows in a semi-logarithmic scale on Fig. 2 for (a) aluminum alloy sample $\#2$, (b) For the aluminum and mortar samples (Fig. 2(a)(b)), the distribution of height fluctuations shows a strong non-Gaussian behavior at small scale δr with prononced fat tail. As the scale δr is increased, the tails of the distribution become less pronounced. At a sufficiently large scale, the distribution can barely be distinguished from a Gaussian distribution , taking a parabolic shape in this semi-logarithmic representation. For

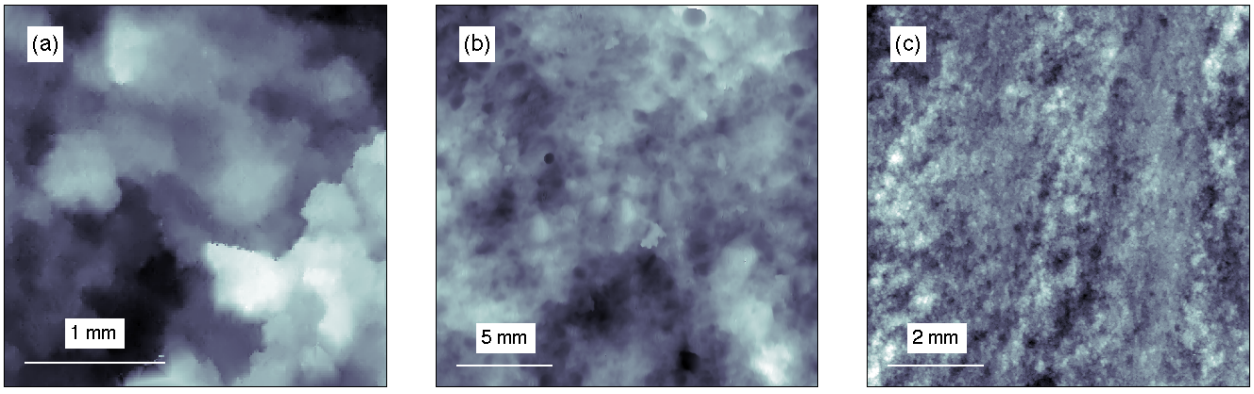

Figure 1: Fracture surfaces of (a) aluminum #2 (2.7×2.7 mm), (b) mortar (20×20 mm) and (c) a brittle ceramics (8×8 mm): the height of the surface is encoded using grey shades, with white representing the highest points while black corresponding to the lowest ones. The typical height denivelation on this surface is (a) $1.3\,\mathrm{mm}$, (b) $2.3\,\mathrm{mm}$ and (c) $250\,\mu\mathrm{m}$, respectively.

the brittle ceramic sample (Fig. 2(c)), the distribution of height fluctuations shows an essentially Gaussian behavior at all scales. As the scale δr is increased, the standard deviation of the distribution is increased but the shape of the distribution remains essentially the same. The evolution of these distributions can be described by a familly of Student t distributions (Fig. 2). The detailed analysis of this behavior will be presented elsewhere [4].

4 Spatial organization of large fluctuations on fracture surfaces

The distributions of height fluctuations in the materials investigated do not follow a Gaussian behavior because of the fat tails. In this part, we proceed to a detailed analysis of these extreme events or largest height variations that are present in an abnormally high proportion on fracture surfaces and that are directly responsible for these tails. Our analysis will reveal a fundamental difference between the morphology of fracture surfaces obtained by brittle failure, and the one obtained by damage mechanisms. It will also provide interesting clues on the origin of this deviation from the Gaussian behavior.

4.1 Revealing the spatial organization of the extreme events on fracture surfaces

The maps of extreme events with clusters are extracted from the fracture surface using the following procedure. We define the operator

$$\overline{\delta h}(\delta r, \vec{x}) = \langle [h(\vec{x} + \delta\vec{x}) - h(\vec{x})]^2 \rangle^{\frac{1}{2}}_{|\delta\vec{x}|=\delta r} \tag{1}$$

where the average $\langle . \rangle$ is done on a circle of radius δr, i.e. for all admissible $\delta\vec{x}$ such as $|\delta\vec{x}| = \delta r$. This operator has several interesting properties. First, at a given scale δr, the operator is uniquely

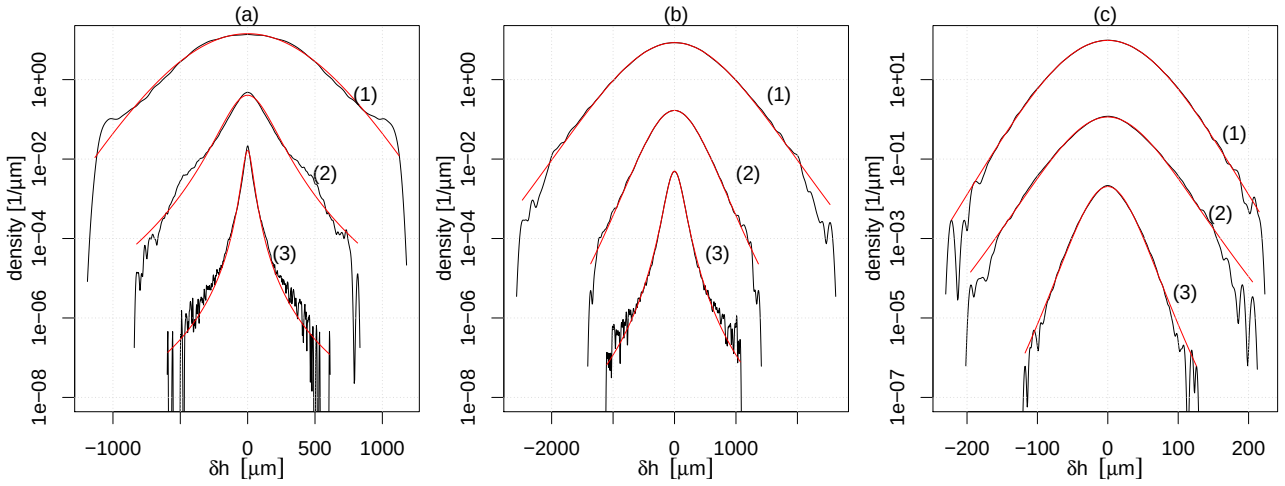

Figure 2: Distribution of height fluctuations $p(\delta h|\delta r)$ at various scales δr.(a) Aluminum alloy $\#2$ with δr = (1) 25 μm, (2) 115 μm, (3) 550 μm; (b) Mortar sample with δr = (1) 225 μm, (2) 915 μm, (3) 3.8mm; (c) Brittle ceramic sample with δr = (1) 60 μm, (2) 310 μm, (3) 1.5mm. The experimental distributions are represented in black, and the corresponding fit with a Student t distribution are representend in red/grey. For readability the distributions have been multiplied by 10^4 for (1) and by 10^2 for (2)

defined for each point of the experimental map and defines a transformation of the original map. Second, it is perfectly isotropic. Third, the average procedure makes it robust to measurement artifact. Qualitatively, this operator describes the local intensity of the height variation at a scale δr. The fields $\overline{\delta h}(\delta r, \vec{x})$ obtained from (a) the aluminum #2, (b) the mortar and (c) the ceramics fracture surfaces are represented on Fig. 3 at scale $\delta r = 6\,\mu$m, $\delta r = 100\,\mu$m and $\delta r = 15\,\mu$m, respectively. Here, the largest height variations are presented in white while the smallest ones are in black. Strikingly, the extreme events are spatially correlated and form a network of rough lines for the alloy [Fig. 3(b)] and the mortar [Fig. 3(c)], while they are rather uniformly distributed for the ceramic fracture surface [Fig. 3(a)]. At first sight, the differences between these maps are obvious. But to proceed to a quantitative analysis and describe their differences, we need to threshold these maps. As we are interested by the fat tails only, we define maps that contain the largest height variations only. As a result, we introduce a threshold $\delta h_{\rm th}$ so that for value of $\overline{\delta h}(\delta r, \vec{x})$ higher than h_c, we assign a value unity to the point $\vec{x}$ (in white on Fig. 4), while a value zero is attributed to the points $\vec{x}$ for which $\overline{\delta h}(\delta r, \vec{x}) < \delta h_{\rm th}$ (in black on Fig. 4). Two parameters need to be chosen in order to obtain the maps of extreme events represented on Fig. 4: the value of δr that sets the scale at which the height variations $\overline{\delta h}(\delta r, \vec{x})$ are computed and the value of the threshold that distinguish the extreme events from the regular ones. In the following, instead of $\delta h_{\rm c}$, we will use the quantity $p_{\rm th}$ that indicates the proportion of points $\vec{x}$ with value $\overline{\delta h}(\delta r, \vec{x}) > \delta h_{\rm c}$ defined as extreme events. Since we investigate the tail of the roughness distribution, typical values of $p_{\rm th}$ will be in the range $5\% - 25\%$. In the following, we will see that the actual value of $p_{\rm th}$ as well as the value of δr have actually a limited influence on the statistical properties of the extreme events.

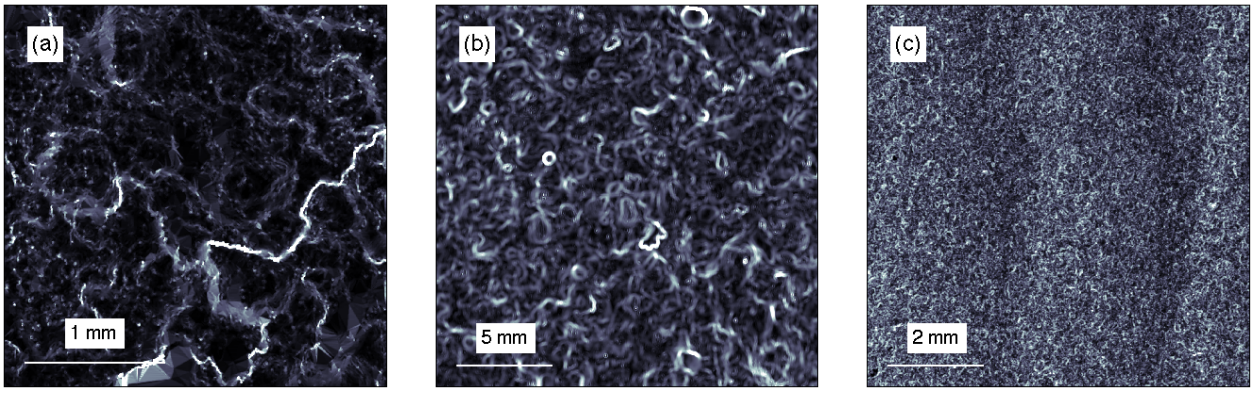

Figure 3: Maps of height variations $\overline{\delta h}$ computed on the fracture surfaces of (a) the aluminum alloy #2 for $\delta r = 6\mu\mathrm{m}$, (b) the mortar and (c) the brittle ceramics shown on Fig. 1.

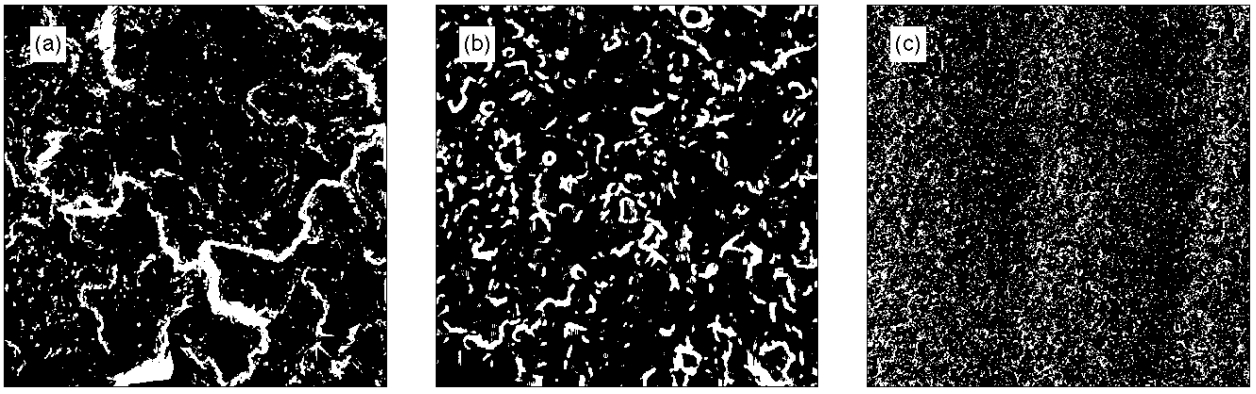

Figure 4: Threshold maps of the height variations $\overline{\delta h}$ shown on Fig. 3 computed on the fracture surfaces of (a) the aluminum alloy #2, (b) mortar and (c) brittle ceramics. Here, only the largest events that represents $p\mathrm{th} = 15\%$ of all the points on surfaces have been kept.

4.2 Statistical properties of clusters of extreme events

A rapid look at the spatial distribution of the extreme events shown on Fig. 4 shows that they organize in clusters of connected points. In this part, we investigate the properties of these clusters, such as their fractal dimension and their size distribution. For analyzing the cluster statistics, we define for each cluster isolated from the other ones three quantities that characterize their size, namely ℓ_x, ℓ_z and R_g, as well as one quantity S characterizing their area. ℓ_x is the maximum extent of the cluser along the x direction while ℓ_z is the maximum extent of the cluster along the z direction - let us note that x and z corresponds to the direction of the propagation, and the perpendicular one, respectively. R_g is the radius of gyration of the cluster. It is obtained by defining the center of gravity C of each cluster, and then compute the average distance between C and the points $\{M_k\}_{1\leq k\leq N}$ belonging to the cluster, i.e. $R_g = \sqrt{\sum_{k=1}^{N} |C\vec{M}_k|^2}$ with $\sum_{k=1}^{k} C\vec{M}_k = 0$. For each cluster, we have so three variables characterizing its length while S defined as the total number N of of points of pixels that belongs to

the cluster times the area of one pixel represents its area. As shown on the Figs. 5 that shows the relation between length and area for each cluster for the , the three quantities ℓ_x, ℓ_z and R_g are found to follow the same scaling $S \sim \ell^D$ with the cluser area S. This indicates a fractal geometry of these objects with dimension $D \simeq 1.70$ that depends very weakly of the considered material (see Table 1 for the values of D of each material). This result indicates that any of the three quantities ℓ_x, ℓ_z and R_g can be used to investigate the cluster size distribution. In the following, we choose the radius of gyration. The probability distribution of the cluster sizes is shown on Fig. 6 for (a) aluminum alloy #1

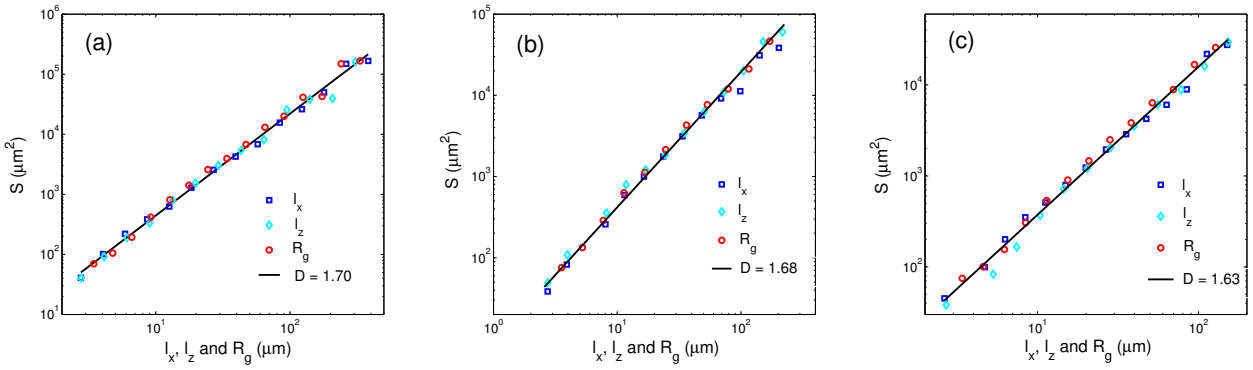

Figure 5: Relationship between length and area of the clusters of extreme events for (a) the aluminum #1, (b) the mortar and (c) the brittle ceramics. The scaling of the cluster rarea with its radius of gyration indicates a fractal dimension $D \simeq 1.70$, irrespective of the material considered.

and (b) mortar for different values of $p_{\rm th}$ for $\delta r = 6\,\mu$m and $\delta r = 100\,\mu$m, respectively. Irrespective of the actual value of the threshold probability $p_{\rm th}$, the distribution for mortar and aluminum fracture surfaces follow a power law $P(R_g) \sim R_g^{-\alpha}$ with exponent $\alpha \simeq 2.2$. The picture is rather different

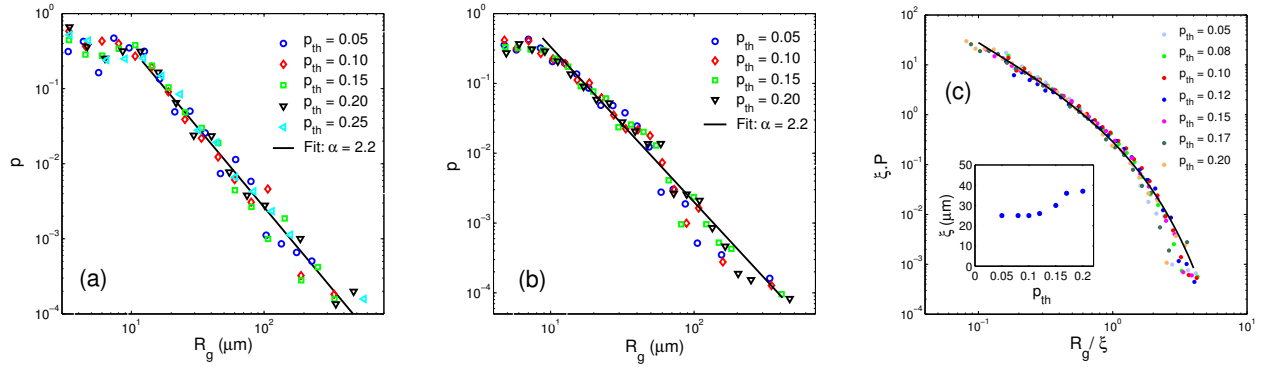

Figure 6: Distribution of cluster sizes R_g for (a) the aluminum alloy #1, (b) the mortar and (c) the brittle ceramics fracture surfaces.

for brittle fracture surfaces: as shown on Fig. 6(c) for $\delta r = 16\,\mu$m, the distribution of cluster sizes follows an exponential law $P(R_g) \sim e^{-R_b/\xi}$ characterized by the length scale $\xi \simeq 25\,\mu$m, the value of which depends very weakly of the threshold $p_{\rm th}$, as shown in the inset of Fig. 6(c). This exponential

behavior confirms the visual observations made on Fig. 4: for ceramics fracture surfaces, the largest height variations do not form any large scale structures, contrary to mortar and aluminum. As a result, clusters of size larger than $\xi = 25\,\mu$m are exponentially rare. These results are confirmed on another brittle material, a natural sandstone. For its fracture surface also, the density probability of cluster size decreases exponentially, with a characteristic length scale $\xi \simeq 50\,\mu$m (see Table 1). This length might be directly related to the material microstructure since the grain size d in the ceramics and the sandstone are of the same order than this cut-off length, i.e. $d = 100\,\mu$m and $d = 200\,\mu$m, respectively [5, 6]. We investigate now the effect of the length scale δr chosen to compute the field of height variations $\overline{h}(\delta r, \vec{x})$ on these properties. Figure 7 shows such maps obtained on the aluminum #1 fracture surface calculated at different scales, i.e. for (a) $\delta r = 6\mu$m, (b) $\delta r = 12\mu$m and (c) $\delta r = 18\mu$m. We see that changing this scale mainly affects the thickness of the lines constituting the network of extreme events, but does not really affect their geometry. This impression is confirmed on Fig. 8 where the statistical properties of the clusters obtained from these different maps are compared. The scale δr has a weak effect on both (a) the relation between the area and the radius of gyration of each cluster and (b) their size distribution. In other words, changing the scale δr in the range investigated does not affects significantly the value of the exponents $D \simeq 1.70$ and $\alpha \simeq 2.2$.

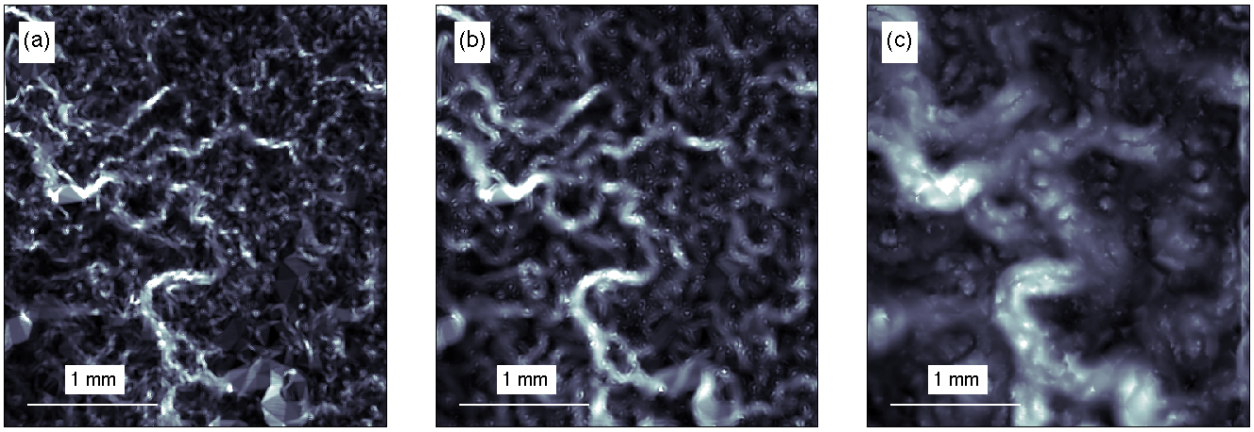

Figure 7: Map $\overline{\delta h}(\delta r, \vec{x})$ of height vatiations computed at different length scales (a) $\delta r = 6\,\mu$m, (b) $\delta r = 12\,\mu$m and (c) $\delta r = 18\,\mu$m for the aluminum #1.

5 Discussion

We would like now to connect the statistical properties of the roughness showing deviations to the Gaussian behavior with the complex spatial distribution of extreme events observed on the height variations maps $\overline{\delta h}(\delta r, \vec{x})$. To bridge these both properties, it is relevant to consider the decomposition $\delta h(\vec{x}, \delta\vec{x}) = h(\vec{x}, \delta\vec{x}) - h(\vec{x}) = \sum_{k=1}^{n} h(\vec{x} + \frac{k}{n}\delta\vec{x}) - h(\vec{x} + \frac{k-1}{n}\delta\vec{x}) = \Sigma_{k=1}^{n}\delta h(\vec{x} + \frac{k-1}{n}, \delta\vec{x}/n)$ that expresses a height variation calculated at the scale $\delta r = |\vec{\delta x}|$ in position $\vec{x}$ as the sum of n height variations calculated at a smaller scale $\delta r/n$ near $\vec{x}$. For an uncorrelated map of height variations, the central limit theorem predicts then that the statistics of height variations - that writes as the sum

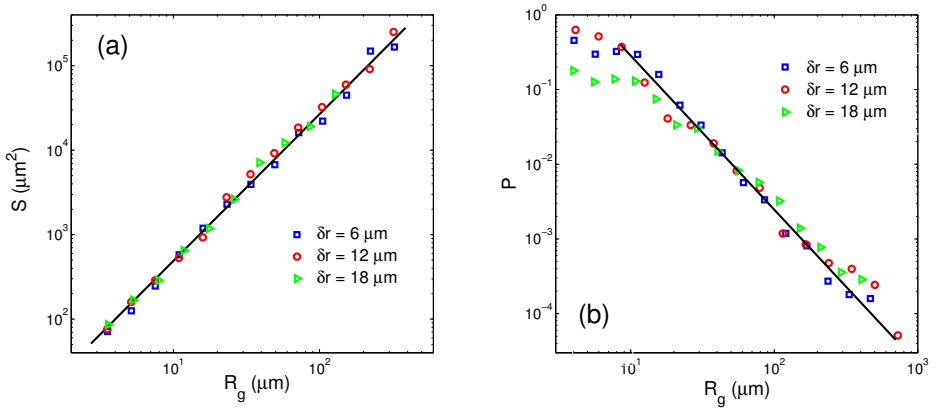

Figure 8: Effect of the length scale δr on the statistics of clusters of extreme events: (a) Relationship between area and length of clusters showing $D \simeq 1.70$ for the fracture surface of aluminum #1. (b) Distribution of cluster sizes R_g showing $\alpha \simeq 2.1$ on aluminum #1 fracture surface.

of uncorrelated variables - belongs to one of the three stable distributions, i.e. Gumble, Weibull or Gaussian distributions. Here, we expect the statistics of our fracture surfaces to follow a Gaussian distribution. This agrees with our observations made on brittle fracture surfaces that exhibit both Gaussian statistics and uncorrelated maps of height variations. On the contrary, quasi-brittle and ductile failure mechanisms that produce correlated height variations maps [Fig. 4 (a) and (b)] also display strong deviations to the Gaussian behavior. But once investigated at scales much larger than the typical size of those patterns, the height variations becomes uncorrelated, and so a Gaussian statistics might be expected: this explains the transition from fat tail distribution at small scale to a Gaussian statistics at large scales, as shown on Fig. 2. An analysis of the distribution $p(\delta h|\delta r)$ of height variations at different scales δr allows for an estimation of the crossover length $\delta r = \xi$ corresponding to the transition from fat tails to Gaussian statistics. Its value measured on mortar and the various aluminum alloys fracture surfaces is given in Table 1 . In this case, a typical value of the cluster size could not be extracted from their distribution as for brittle failure, due to the limited dimension of the fracture surfaces investigated. However, the previous connection between the roughness statistics and the patterns of extreme events suggests that the roughness recovers a Gaussian behavior once δr is much larger than the typical cluster size. This means that the length scale extracted from the cluster size distribution might be quite close to the crossover length between power law tail and Gaussian statistics. For this reason, we have used the same notation ξ whenever this length was extracted from the roughness statistics or the cluster size distribution. Our results show that that when fracture surfaces investigated at scales $\delta r \ll \xi$ display spatially correlated roughness characterized by a power law tail statistics, while investigated at scale $\delta r \gg \xi$, they follow a Gaussian behavior without exhibiting any spatial correlation on the height variations map. Interestingly, the deviations to the Gaussian behavior that are characterized by a change in the shape of the roughness distribution $p(\delta h|\delta r)$ with the scale δr results in a multi-affine behavior, that means that the various moments of this distribution scale with different exponents, contrary to mono-affine brittle surfaces for which one roughness exponent ζ is sufficient to fully describe the roughness statistics and the scaling of the different moments. Multi-scaling is classically associated with the presence of spatially correlated fluctuations. This in-

	ζ	D	α	ξ
Aluminum #1	0.74	1.70	2.2	$450\,\mu$m
Aluminum #2	0.73	1.70	2.3	$550\,\mu$m
Mortar	0.73	1.61	2.2	$1.3\,$mm
Sandstone	0.45	$\times$	$\times$	$25\,\mu$m
Ceramics	0.43	$\times$	$\times$	$25\,\mu$m

Table 1: Scaling exponents extracted from the fracture surfaces resulting from ductile and quasi-brittle (upper part of the table) and brittle failure (lower part): the roughness exponent ζ characterizes the scaling behavior of the roughness correlation, the exponents D and α describe the patterns made by the largest height variations on the fracture surfaces presented on Fig. 4. The length ξ provides the crossover length between fat tail and Gaussian statistics for damage accompanied failure (alloy and mortar) while it gives the characteristic length of the exponential decay of the cluster size distribution for brittle failure.

terpretation is then fairly consistent with our observations. Let us note that this might also be the case in various other materials where multi-scaling were reported at small scale, before a transition towards a Gaussian behavior [7, 8]. We would like now to propose a physical interpretation of the length ξ and the origin of the complex features observed on the height variations maps. Various findings presented here suggest that the deviations to Gaussian statistics and the associated patterns of extreme events find their origin in the microcracking processes accompanying failure of mortar and aluminum alloys. This is supported by the following observations:

(i) For mortar and aluminum fracture surfaces, abnormally large height fluctuations producing fat tail statistics of crack roughness organizes into a network of rough lines. This features are not present on brittle fracture surfaces for which damage mechanisms does not come into play, suggesting a direct link between clusters of extreme events and damage processes.

(ii) The size of the clusters observed on the height variation maps is power law distributed, up to a cut-off length scale ξ that coincides well with the typical size associated with the damage processes in these materials: a few grain or a few hundreds of micrometers in aluminum alloy and a few millimeters in mortar. In addition, direct observations of the failure processes within the damage zone ahead of cracks in some quasi-brittle rocks show the presence of a forest of microcracks with power law distributed sizes. Direct observations have not been reported in mortar nor in aluminum alloys, but the acoustic emission following power law statistics in these materials suggest a similar behavior.

(iii) In a recent study, networks of lines observed on PMMA fracture surfaces were shown to result from microcracking processes [9]. The mechanisms into play can be described by considering the coalescence of two interacting microcracks that start to avoid before attracting each to let a bump on the fracture surface [10]. Contrary to mortar or aluminum alloys, the PMMA is rather homogeneous at the scale where these lines where observed, allowing a straightforward observation, and even a quantitative interpretation of these features in terms of microcracking

history in the material [11]. In mortar and aluminum alloy, the network made by these lines is hidden by the surrounding roughness generated by the material heterogeneities. In addition, the microcrack density might be much larger in these materials, so that such an interpretation of the clusters observed for these materials is much more complex. However, they might be signature of microcracking and their size distribution might be closely connected with the size distribution of microcracks.

6 conclusion

The fracture surface investigated in this study revealed a much more complex roughness than their classical description based on the measurement of the roughness exponents. Neglecting for this study the anisotropy of fracture surfaces [12], we showed that one roughness exponent $\zeta \simeq 0.4$ remains sufficient to fully describe the roughness statistics. However, in quasi-brittle and ductile materials where the roughness exponent is found to be larger with $\zeta \simeq 0.75$, the full distribution of height variations is found to be highly non-Gaussian with the presence of fat tails. However, these deviations disappear as the investigation scale increases, leading to a Gaussian statistics at a sufficiently large scale. This behavior can be described with a family of Student's t distributions.
We proceeded then to the analysis of the largest height jumps on the surface, responsible for the fat tails observed in the roughness distribution. For this purpose, we defined maps of extreme events that displayed connected clusters of large fluctuations. These clusters of spatially correlated large fluctuations are shown to follow power law statistics: they have a fractal geometry with dimension $D \simeq 1.7$ with a power law distributed size with exponent $\alpha \simeq 2.2$. In brittle materials like sandstone and ceramics, the size distribution of these cluster follows a power law distribution characterized by the length scale ξ. In other words, we have a very small probability to find big clusters in brittle material that was shown to be in agreement with a Gaussian statistics.
The length scale ξ that we defined alternatively on quasi-brittle and ductile fracture surfaces from the crossover length from fat tail statistics at small scale to Gaussian statistics at large scale reveals the microscale failure mechanisms of materials. Our observations suggest that this length is connected with the typical length of micro cracks in materials. A possible interpretation is that the coalesence between micro cracks leads a signature on the fracture surface that we identified as abnormally large height fluctuations. According to this scenario, the length ξ extracted from the fracture surfaces might be connected to the typical damage zone size ahead of the crack during failure.

Abstract Effective properties and progressive failure of SiC matrix composites reinforced by tri-axially woven SiC fibers (SiC_f) (as a fabric) are predicted. Three different orientations of the woven fabric are considered in geometrical modeling, including –60°-0°-60°, –55°-0°-55° and –45°-0°-45°. Three-dimensional unit cells with the matrix reinforced by the fabrics in such orientations are constructed and used. Homogenization analyses are carried out using the finite element method (FEM). It is found that the –60°-0°-60° fabric orientation provides the highest values for the effective elastic moduli, while the –45°-0°-45° orientation gives the lowest values. The effective properties obtained are then used to conduct a progressive failure analysis of the SiC_f-SiC composite subjected to uni-axial tensile loading. The progressive failure analysis incorporates both geometrical and material non-linearities, and describes the progressive damage induced by crack initiation and propagation through a material degradation model. The Tsai-Wu failure criterion is used, and a two-parameter Weibull distribution is employed to account for the changes in strength with increasing specimen volume. Based on this progressive failure analysis, stress-strain curves for the SiC_f-SiC composites are plotted, and the –60°-0°-60° orientation is found to have the smallest deformations at given loads.

1. Introduction

SiC fabric reinforced SiC matrix composites have emerged as a class of strong, radiation-resistant, high-temperature structural materials that are suitable and ready for nuclear fusion applications [1]. SiC has been used as a nuclear fuel cladding material since it offers greater strength at high temperatures than conventional zirconium alloys. SiC has excellent irradiation tolerance, low chemical reactivity, and low tritium permeability [2].

Textile composites represent a class of advanced materials that are reinforced by fabric preforms. The smallest constituent of a textile composite is a fiber. A yarn is an assembly of fibers. Yarns are generally used as unit elements to form fabrics. A tri-axially woven fabric has three sets of yarns forming equilateral triangles at the intersections. Tri-axially woven fabrics have no weak dimension or bias and offer high resistance to shear or tear. They also have the ability to accommodate compound curvatures and are therefore suitable for molded manufacturing. These features make tri-axially woven fabric composites ideal for cladding tube applications, where high temperatures can cause considerable normal and shear stresses in cladding tubes.

Effective properties and progressive failure of tri-axially woven SiC_f-SiC ceramic matrix composites are studied in the current paper using micromechanics and the finite element method. Representative volume elements are identified for three different fabric configurations. The matrix material is regarded as isotropic, while the fabric yarns are treated as transversely orthotropic. Homogenization analyses are performed to determine effective properties, and progressive failure studies are then conducted to obtain stress-strain curves for the SiC_f-SiC composites.

2. Unit Cells

Most fabrics are woven with two sets of orthogonal yarns called the warp and weft yarns [3]. This is known as bi-axial weaving. The most common tri-axially woven fabrics are the ones where the fiber yarns are arranged in the +45°, 0°, and –45° orientation. However, tri-axially woven fabrics can be made with any orientation ranging from ±20° and ±70°. In the current study, three different orientations are considered to evaluate effective properties of tri-axially woven SiC_f-SiC ceramic matrix composites. The three orientations considered are –60°, 0°, +60°; –55°, 0°, +55°; and –45°, 0°, +45°. For each of these three configurations, a repetitive structure can be taken as a unit cell. The cross section of each yarn is assumed to be lenticular, as was done by others. Figure 1 shows a unit cell of the composite reinforced by the –60°- 0°-60° fabric.

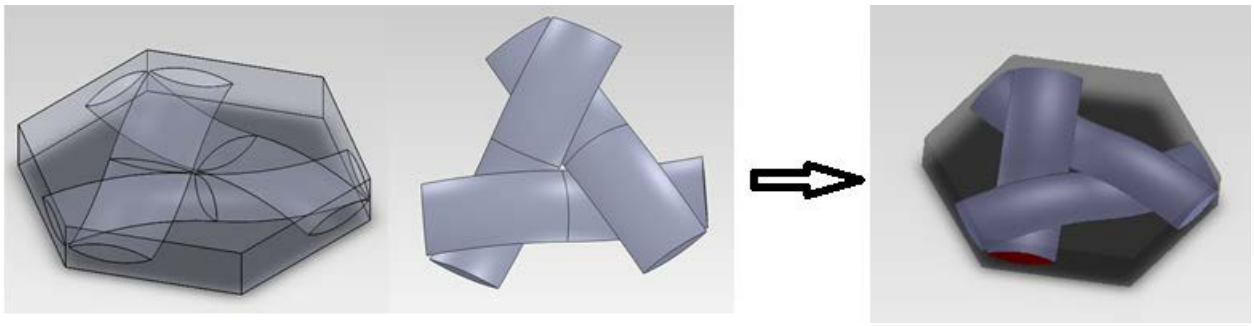

Figure 1. Unit cell of a tri-axially woven fabric reinforced composite

The tri-axially woven fabric of SiC fibers will serve as the reinforcement of the ceramic matrix composite. It can be seen from Figs. 1 and 2 that the tri-axially woven yarns form equilateral triangles and hexagonal holes, which change in size with the yarn orientation, as shown in Fig. 3. For SiC_f-SiC composites, the matrix and fibers are made from the same material. Therefore, the matrix adds considerable stiffness to the composite and the matrix material in the holes and triangles may not be neglected in a homogenization analysis. In constructing the models, the matrix pocket and woven fabric are first generated separately. The fabric and matrix pocket are then assembled to yield the composite unit cell, as shown in Fig. 1. Bonded contact between the matrix and the fabric is assumed to represent perfect bonding.

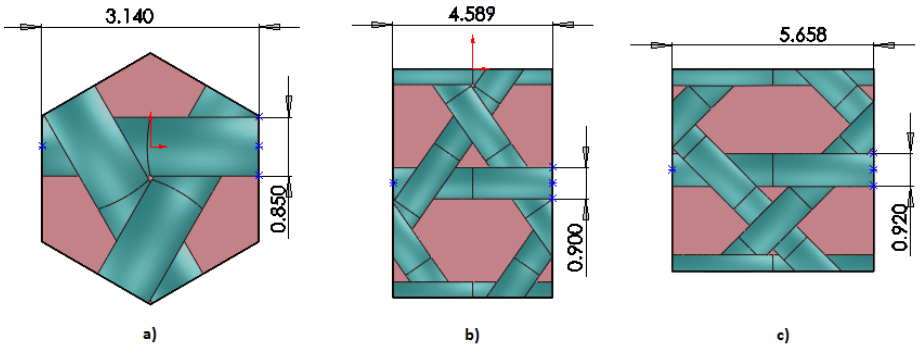

Figure 2. a) Hexagonal unit cell for the –60°-0°-60° fabric configuration; b) rectangular unit cell for the –55°-0°-55° configuration; and c) rectangular unit cell for the –45°-0°-45° configuration

In the homogenization analysis, the matrix material is considered as isotropic, and the fiber yarn is regarded as a transversely isotropic material that has five independent elastic constants.

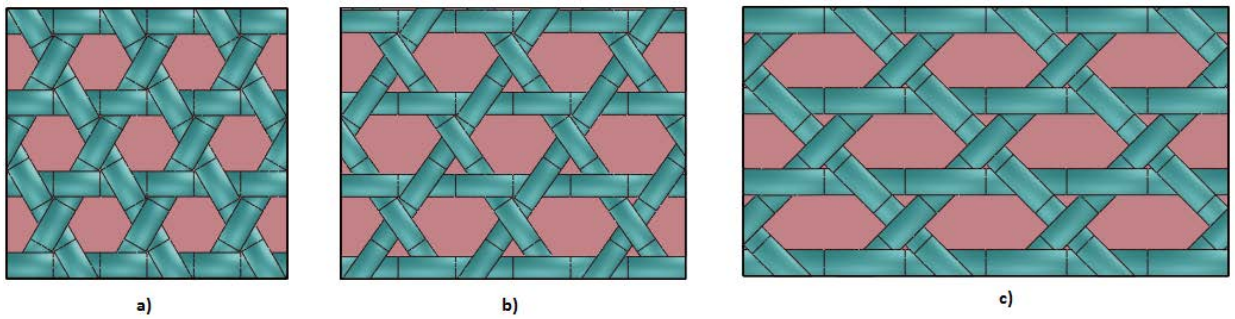

Figure 3. Composite specimens: a) –60°-0°-60°, b) –55°-0°-55°, and c) –45°-45°-45°

3. Finite Element Analysis

A finite element analysis is performed on each of the three unit cells identified in Fig. 2 to obtain effective properties of the SiC_f-SiC ceramic matrix composites using the commercial software package ANSYS. The material properties used are listed in Table 1, which are taken from [4]. The unit cell is meshed using three-dimensional, 10-node solid elements, as shown in Fig. 4. These elements are well suited to model irregular geometries. Each of these solid elements has three degrees of freedom at every node: translations in the X, Y and Z nodal directions.

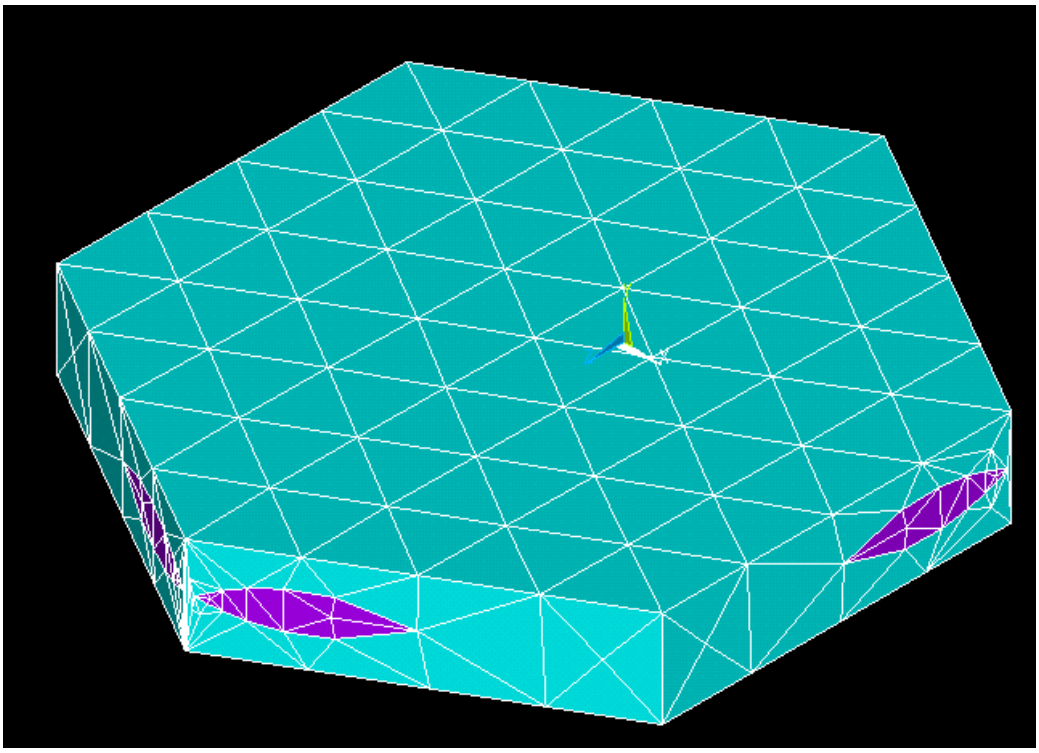

Figure 4. Finite element mesh for the unit cell shown in Fig. 2a)

3.1 Periodic Boundary Conditions

In modeling uniaxial and biaxial tensile tests, displacement boundary conditions are frequently used. Since a representative volume element (RVE) is cut out of an infinite composite, spatially periodic

boundary conditions should be applied to ensure that the predicted properties of the RVE represent those of the composite [5-7].

The periodic boundary conditions are implemented using the CE option available in ANSYS. Deformations of two unit cells subject to periodic boundary conditions are shown in Fig. 5.

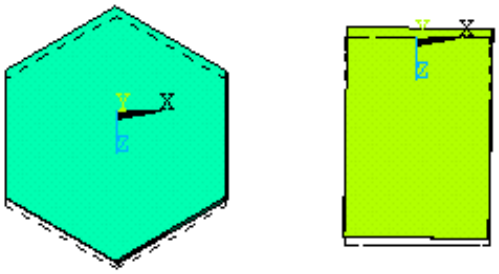

Figure 5. Deformations of hexagonal and rectangular unit cells under periodic boundary conditions

3.2 Model Validation

The model validation is carried out by comparing the simulation results with the experimental data obtained in Fujita et al. [8] for a tri-axially woven carbon fiber reinforced epoxy matrix composite. As shown in Fig. 6, the effective tensile modulus predicted by the current unit-cell based model using periodic boundary conditions agrees well with the experimental value of Fujita et al. [8], thereby supporting the model.

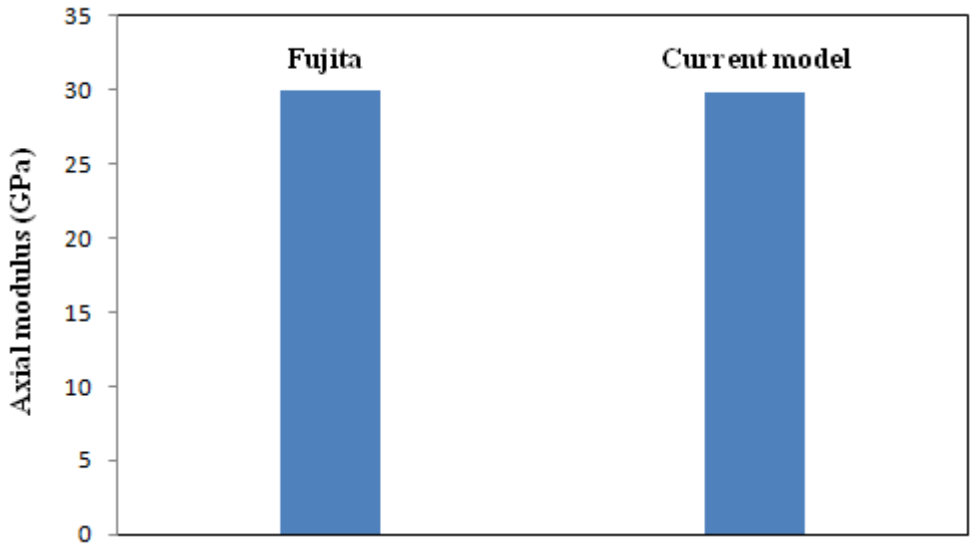

Figure 6. Comparison with the experimental result of Fujita et al. [8]

3.3 Effective Properties

With the unit-cell based FE model validated, simulations are performed using the three unit cell configurations shown in Fig. 2 and the constituent properties listed in Table 1. The in-plane effective properties obtained in the simulations are given in Table 2.

Table 2**.** Effective properties for different fabric orientations

Boundary Conditions	**Effective Properties**	**60° Orientation**	**55° Orientation**	**45° Orientation**
Periodic Boundary Conditions	E_{11} (GPa)	285.857	244.333	239.8992
	E_{22} (GPa)	252.587	242.992	226.224
	E_{33} (GPa)	252.587	242.992	226.224
	ν_{12}	0.1713	0.15266	0.15814
	G_{12} (GPa)	105.26	98.644	98.111

The fiber volume fraction for all the three unit cells is kept equal (within ±2%). It can be seen from Table 2 that the –60°-0°-60° orientation has the highest values of the elastic moduli, while the –45°-0°-45° orientation has the lowest values.

4. Progressive Failure Analysis

Catastrophic failure of a composite structure does not occur at the material failure strength. Composite structures typically fail after propagation or accumulation of localized damages such as matrix cracking, fiber breakage, and fiber-matrix debonding. These mechanisms ultimately lead to the loss of load-carrying ability of the composite structure. Hence, progressive failure analysis is needed to simulate damage propagation and ultimately failure of a composite structure. In the current work, a progressive failure analysis is carried out for uniaxial tension tests. Stress-strain curves are determined for all three fabric reinforcement configurations.

The procedure for the progressive failure analysis is as follows:

a. Each composite specimen (see Fig. 3) is subjected to uniaxial tension. Before the initiation of the first failure, only geometrical nonlinearities (large deformations) are accounted for.
b. After each load increment, stresses at each node are evaluated against a failure criterion.
c. If there is no failure initiation, load is further increased.
d. Upon failure initiation at a node, the elastic modulus in the loading direction is degraded for all elements connected to that node using a material degradation model.
e. The load is then increased.

This procedure is repeated until the specimen loses its load-carrying capability or up to a certain strain level.

5. Failure Criterion and Material Degradation Model

The Tsai-Wu failure model [9,10] is used as the failure criterion. Failure analysis by comparing with a failure criterion is deterministic in nature [11]. In such an analysis, the risk of fracture remains unknown. Therefore, probabilistic fracture analysis is required for better predictions. For a brittle material like SiC, its properties display strong scattering. Brittle materials also show a pronounced

decrease in strength with increasing specimen volume owing to defect distributions. As the material volume increases, the occurrence probability of critical defects increases. Probabilistic analysis takes into account uncertainties in material properties, loading conditions, and defect distributions. In the current work, these uncertainties are accounted for by using the following two-parameter Weibull distribution [4,11]:

$$P_f = 1 - \exp\left[-\frac{V}{V_0} \left(\frac{\sigma - \sigma_u}{\sigma_0} \right)^m \right], \tag{1}$$

where P_f is the fracture probability, V is the specimen volume under consideration, σ is the stress induced in the specimen, V_0 and σ_0 are normalization parameters, m is the Weibull shape parameter, and σ_u is the threshold stress below which the fracture probability is zero. For SiC, m can be taken as 7.6, σ_0 as 270 MPa, V_0 as 65.49 mm^3, and σ_u as zero [1]. P_f gives the failure probability for the specimen volume V under stress σ. For every load increment, P_f is evaluated for each individual element. Failure occurs if P_f = 0.99.

When failure is detected at any node in the composite, the elastic properties are reduced for all the surrounding elements containing that node using a material degradation model. The crack band theory developed for concrete [12] is adopted as the material degradation model. According to the crack band theory, the post failure relation between the normal stresses σ_x, σ_y, σ_z and the normal strains ε_x, ε_y, ε_z can be written as

$$\begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_z \end{Bmatrix} = \begin{bmatrix} C_{11}\mu^{-1} & C_{12} & C_{13} \\ & C_{22} & C_{23} \\ symmetric & & C_{33} \end{bmatrix} \begin{Bmatrix} \sigma_x \\ \sigma_y \\ \sigma_z \end{Bmatrix}, \tag{2}$$

where μ is a cracking parameter, and C_{ij} are compliance constants. The cracking parameter μ depends on the material properties and strain level and is given by

$$\frac{1}{\mu} = \frac{E}{-E_t} \frac{\varepsilon_x}{\varepsilon_0 - \varepsilon_x}, \tag{3}$$

where ε_x is the strain in the loading direction, E is Young's modulus, E_t is the tangent (softening) modulus, and ε_0 is a constant. Note that μ = 1 in an un-cracked material and μ = 0 is a continuously cracked material. After failure is detected, Young's modulus in the loading direction is degraded by a factor μ, while the other properties remain the same. When a crack is introduced in the composite, no normal stress can be transferred across the crack surfaces. However, after the load is increased, the stresses in the surrounding region still increase because of the load transfer from undamaged parts of the composite. Therefore, multiple cracks can occur in one element. This simulation is continued until the composite loses its ability to carry any more load.

6. Stress-Strain Curves

The properties obtained in the progressive failure analysis are used to plot stress-strain curves for all

three configurations, as shown in Figs. 7 and 8. These are based on the uniaxial tension tests of the composite specimens displayed in Fig. 3.

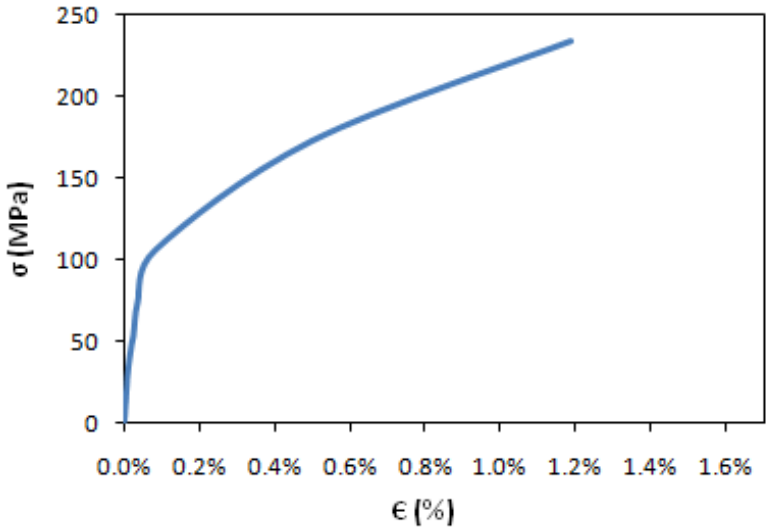

Figure 7. Stress-strain curve from the –60°-0°-60° specimen

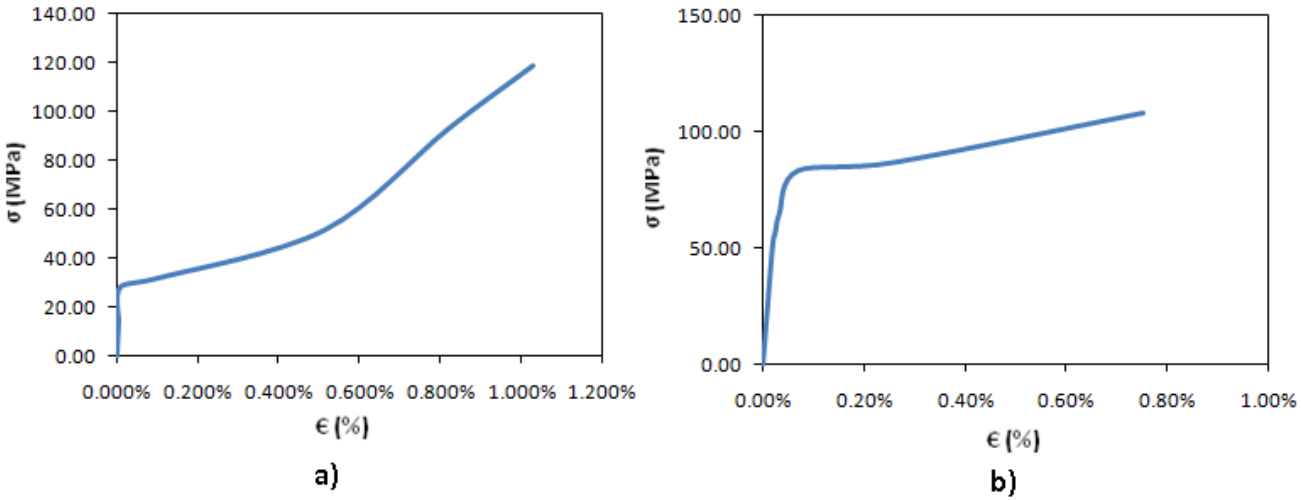

Figure 8. a) Stress-strain curves from a) the –55°-0°-55° specimen and b) the –45°-0°-45° specimen

The progressive failure analysis has revealed that crack initiation occurs first in the transverse direction and at the fabric-matrix interfaces. The linear material behavior ends with the initiation of cracks. The material degradation model discussed in Section 5 is then applied to introduce Mode I cracks in the mesh. After the cracks have been introduced, stresses in the composite specimen may increase or decrease in the next immediate load increment, since no normal stress can be transferred across the crack surfaces. However, as the load is further increased, the stresses begin to increase because of the stress transfer from the surrounding undamaged parts of the composite.

It can be seen from Figs. 7 and 8 that the –60°-0°-60° configuration has the smallest deformations at given loads.

Abstract This paper presents a new method to indirectly determine the probability distribution function of strength of quasibrittle structures. Based on the finite weakest link model, which relates the probability distribution of the structural strength to the size dependence of mean strength, it is shown that that the cumulative distribution function of structural strength can be directly determined from the parameters of the mean size effect curve. A comprehensive experimental set of tests, which includes both strength histograms and mean size effect tests on specimens of asphalt mixture at low temperature, is used to verify the proposed method. The predicted strength histograms obtained with this method are found to be in very good agreement with the experimental histograms of asphalt mixture specimens of different sizes, confirming the validity of the newly proposed formulation.

Keywords Strength Statistics, Histogram Testing, Scaling, Weakest Link Model

1. Introduction

Most engineering structures, such as buildings, bridges, are designed for a very low failure probability (less than 10^{-6}) [1]. Determining the design strength corresponding to such low failure probability directly from histogram testing is prohibitive and, therefore, we need to rely on probabilistic models for indirectly determining the statistics of structural strength.

Simple statistical models can be used for describing the strength distribution in the case of perfectly ductile and brittle structures. For ductile structures, the peak load is equal to the weighted sum of random strengths of material elements along the failure surface. Therefore, according to the Central Limit Theorem, the cumulative distribution function (cdf) of strength of ductile structures follows the Gaussian distribution. On the other hand, the failure of brittle structures is triggered by the failure of one material element whose size is negligible compared to the structure size. Based on the infinite weakest link model (WLM), the strength cdf of brittle structures follows the Weibull distribution [2, 3]. Both Guassian and Weibull distribution are two-parameter probability distribution functions for which the statistical parameters can be easily obtained by histogram testing involving a limited number of specimens.

This is not true for structure made of quasibritte materials, which are brittle heterogenous materials such as concrete and asphalt mixture (at low temperature). For this type of structures the size of inhomogenieties is not negligible compared to the structure size. By limiting our focus to quasibrittle structures for which the peak load is reached as a macro-crack initiates from one representative volume element (RVE) [2-4], it is possible to statistically model this class of structures as a finite chain of RVEs [2-4]. Therefore, the cdf of strength of each RVE must be known for calculating the strength cdf of the entire structure. Recent studies [3, 4] showed that the strength cdf of one RVE can be described by a Weibull distribution grafted on the left tail of a Gaussian cdf. At structural level, the finite WLM shows that the strength cdf consists of an upper part, which can be calculated as a finite chain of Gaussian elements, and a lower segment that follows the Weibull distribution [2-4] resulting into an intricate size effect on the mean structural strength. Determining such a type of strength distribution through histogram testing requires a large number of specimens, which could be very costly and time consuming, due to material and labor.

This paper presents an alternative method to determine the strength cdf of quasibrittle structures, which is anchored at the analysis of the mean size effect curve. The proposed method is experimentally verified by a comprehensive set of tests on the asphalt mixture at a low temperature.

2. Theoretical background

The weakest link model schematizes a structure as finite chain of RVEs. Based on the joint probability theorem, which provides a mathematical expression of the WLM, the failure probability of the entire structure, P_f, made of N RVEs can be obtained according to Eq. 1:

$$P_f(\sigma_N) = 1 - \prod_{i=1}^{N}\left[1 - P_1(s_i\sigma_N)\right] \tag{1}$$

where P_1 is the cdf of strength of one RVE having characteristic size l_0, $\sigma_N = cP_{max}/bD$ is the nominal strength of the structure, P_{max} is the maximum load that the structure can sustain, D is the structure characteristic size, b is the width of the structure, c is a constant such that σ_N represents the maximum elastic principal stress in the structure and s_i dimensionless stress field such that $\sigma_N s_i$ corresponds to the maximum elastic principal stress at the center of i^{th} RVE. Based on atomistic fracture mechanics and a statistical multi-scale transition model [3,4] it was recently demonstrated that the failure cdf of one RVE can be approximated by a Weibull cdf grafted on the left tail of a Gaussian cdf (core) at a point with a probability of about 10^{-4}—10^{-2}. The grafted cdf of strength of one RVE can be expressed as [2-4]:

$$P_1(\sigma) = 1 - \exp[-(\sigma / s_0)^m] \approx \langle \sigma / s_0 \rangle^m \qquad (\sigma_N \le \sigma_{gr}) \tag{2a}$$

$$P_1(\sigma) = P_{gr} + \frac{r_f}{\delta_G\sqrt{2\pi}}\int_{\sigma_{gr}}^{\sigma_N}\exp\left\{-\left[\frac{(\sigma' - \mu_G)^2}{2\delta_G^2}\right]\right\}d\sigma' \qquad (\sigma_N > \sigma_{gr}) \tag{2b}$$

where σ is the maximum elastic principal stress at the center of the RVE, m is the Weibull modulus, s_0 is scale parameter of the Weibull tail, $\langle x \rangle = \max(x, 0)$, μ_G and δ_G are the mean and the standard deviation of the Gaussian core. P_{gr} is the grafting probability between the Gaussian and the Weibull parts of the distribution, σ_{gr} is the grafting stress and r_f is a scaling factor ensuring that Weibull-Gaussian grafted cdf is normalized: $P_1(\sigma \to \infty) = 1$. Six statistical parameters, μ_G, δ_G m, s_0, r_f and σ_{gr} are used to describe the failure distribution of one material RVE; however, due to normalization and continuity conditions, only four of these parameters are independent, and suffice to define $P_1(\sigma)$.

The strength distribution of the entire structure can be calculated by mean of the WLM together with Eqs. (2a) and (2b). The mean structural strength for structures of different sizes can be obtained according Eq. 3:

$$\bar{\sigma}_N = \int_0^1 \sigma_N \mathrm{d}P_f = \int_0^\infty [1\text{-}P_f(\sigma_N)]\mathrm{d}\sigma_N \tag{3}$$

However, a closed form does not exist for Eq. 3, and, therefore, a numerical solution is needed to determine the effect of structure size, D, on the mean strength for geometrically similar specimens. Based on asymptotic matching, Bažant and co-workers [2, 5] proposed an approximate expression for the size dependence of the mean strength:

$$\bar{\sigma}_N = \left[C_1 / D + \left(C_2 / D\right)^{rn/m}\right]^{1/r} \tag{4}$$

where m is the Weibull modulus, n is the number of dimensions to be scaled (n = 1, 2 and 3). C_1, C_2, and r can be determined using the following asymptotic conditions for small and large-size limits: $[\bar{\sigma}_N]_{D\to l_m}$, $[d\bar{\sigma}_N / dD]_{D\to l_m}$ and $[\bar{\sigma}_N / D^{n/m}]_{D\to\infty}$, where l_m represents the small size limit of the structure.

3. Relation between mean size effect curve and strength distribution of one RVE

In this section a method to relate the statistical parameters, μ_G, δ_G m, s_0, of $P_1(\sigma)$ to the properties of the size effect curve of mean structural strength is proposed as an alternative to calibration through histogram testing. The mean size effect (Eq. 4) is determined by five parameters: n, m, r, C_1 and C_2. The scaling dimension, n, is known a priori, while m is the Weibull modulus, which is also one of the four statistical parameters of $P_1(\sigma)$. Therefore, the remaining three parameters μ_G, δ_G and s_0, must be determined from the three statistical parameters r, C_1 and C_2.

Since $rn/m << 1$, the large-size limit of Eq. 4 can be rewritten as $\bar{\sigma}_N = (C_2 / D)^{n/m}$. In such a case the RVE size becomes negligible compared to the structure size. Therefore, the classical extreme value statistics can be applied. Since the strength cdf has a power-law tail, the resulting strength cdf of the entire structure must follow the Weibull distribution [2, 3, 6, 7]. Therefore, the mean strength of very large structures can be calculated as [2-4, 8]:

$$\bar{\sigma}_N = s_0 \Gamma\left(1+1/m\right)\left(D_0 / D\right)^{n/m} \tag{5}$$

where $D_0 = l_0 \left[\int_V \left\langle s(\xi)\right\rangle^m \mathrm{d}V(\xi)\right]^{-1/m}$, $\xi = \mathbf{x}/D$ is the normalized coordinate, and $\Gamma(x)$ is the Eulerian gamma function. By equating Eq. 5 with the large size expression of Eq. 4, it is possibile obtaining the Weibull scaling parameter s_0 in terms of the parameter C_2:

$$s_0 = \left(C_2 / D_0\right)^{n/m} \Gamma^{-1}\left(1+1/m\right) \tag{6}$$

In order to use Eq. 6, the RVE size l_0 must be known a priori. Based on a recent study [2] the RVE size can be estimated as 2 times of size of the material inhomogeneities, which can be determined through digital image analysis [9] or from the aggregates gradation curve as was done in this study. At the small size limit two asymptotic conditions can be written for relating μ_G and δ_G to r and C_1:

$$\bar{\sigma}_N\big|_{D\to l_m} = \int_0^\infty \prod_{i=1}^{N_m} [1 - P_1(s_i\sigma_N)]\mathrm{d}\sigma_N = \left[\frac{C_1}{l_m} + \left(\frac{C_2}{l_m}\right)^{rn/m}\right] \tag{7}$$

$$\left.\frac{\mathrm{d}\bar{\sigma}_N}{\mathrm{d}D}\right|_{D\to l_m} = -\int_0^\infty \frac{\mathrm{d}P_f}{\mathrm{d}D}\mathrm{d}\sigma_N = -\frac{1}{r}\left[\frac{C_1}{l_m^2} + \frac{nr}{ml_m}\left(\frac{C_2}{l_m}\right)^{rn/m}\right]\left[\frac{C_1}{l_m} + \left(\frac{C_2}{l_m}\right)^{rn/m}\right]^{1/r-1} \tag{8}$$

where N_m is the number of RVEs in the structure at the small-size limit and l_m is the smallest specimen size which makes physical sense. Recent studies showed that for beams under three-point bending, which is commonly used in the laboratory testing, the minimum depth of the beam for the WLM to be valid is about 4 RVEs [10]. By using the logarithm of the WLM (Eq. 1) and integrating over the entire structure, the left hand side of Eq 8 can be rewritten as:

$$-\int_0^\infty \frac{\mathrm{d}P_f}{\mathrm{d}D}\mathrm{d}\sigma_N = \frac{n}{D}\int_0^\infty \prod_{i=1}^{N_m}[1 - P_1(s_i\sigma_N)] \sum_{i=1}^{N_m} \ln[1 - P_1(s_i\sigma_N)]\mathrm{d}\sigma_N \tag{9}$$

At the small size limit, N_m is usually small (i.e. 4 RVEs) and, therefore, it is expected that the Weibull tail of the strength cdf is very short. Hence, the cdf of strength can be entirely approximated by the Gaussian core; $P_1(\sigma)$ can be replaced by a Gaussian distribution, which has a mean μ_G and standard deviation δ_G. Eqs. 7 and 8 can then be reformulated as:

$$\int_0^\infty \prod_{i=1}^{N} [1 - \Phi_G(s_i\sigma_N, \mu_G, \delta_G)]\mathrm{d}\sigma_N = \left[\frac{C_1}{l_m} + \left(\frac{C_2}{l_m}\right)^{rn/m}\right]^{1/r} \tag{10}$$

$$\frac{n}{l_m}\int_0^{\infty}\prod_{i=1}^{N_m}[1-\Phi_G(s_i\sigma_N,\mu_G,\delta_G)]\sum_{i=1}^{N_m}\ln[1-\Phi_G(s_i\sigma_N,\mu_G,\delta_G)]\mathrm{d}\sigma_N = \\ =-\frac{1}{r}\left[\frac{C_1}{l_m^2}+\frac{nr}{ml_m}\left(\frac{C_2}{l_m}\right)^{rn/m}\right]\left[\frac{C_1}{l_m}+\left(\frac{C_2}{l_m}\right)^{rn/m}\right]^{1/r-1} \tag{11}$$

where $\Phi_G(s_i\sigma_N,\mu_G,\delta_G)=(2\pi)^{-1/2}\int_{-\infty}^{s_i\sigma_N}\exp[-(x-\mu_G)^2/2\delta_G^2]\mathrm{d}x$.

By solving the system of Eqs. 10 and 11, together with Eq. 6 and the Weibull modulus m, it is possible to determine the four parameters of the strength cdf of one RVE (μ_G, δ_G m, s_0) from the mean size effect curve. This permits us to calculate the strength distribution of structures of any size and geometry through the WLM.

4. Material and testing

A comprehensive set of experiments, including both mean strength tests on asphalt mixture specimens of different sizes and strength histogram testing at a low temperature, was used to verify the proposed method for indirectly determining the strength distribution from the mean strength curve. The asphalt mixture used for the experimental phase was prepared with a blend of aggregates, consisting of taconite aggregates (55% of MIN TAC tailings and 10% of ISPAT tailings) and pit sand (35%), and a PG 64-34 asphalt binder (7.4% by weight) [11]. The nominal maximum aggregate size was 4.75mm. Based on the sieve size analysis, the dimension of the asphalt mixture RVE was estimated to be twice the size of the material inhomogeneities, which for asphalt mixture corresponds to the average aggregate size. For the particular asphalt mixture considered in this study, we estimated an average aggregate size to be 1.22 mm and an RVE volume V_0 to be 14.4 mm^3.

Since the objective of this study is to derive the strength distribution from the mean size effect curve, a large size range is needed. Therefore, size effect tests were performed by using three-point bend (3PB) beams (Fig. 1).

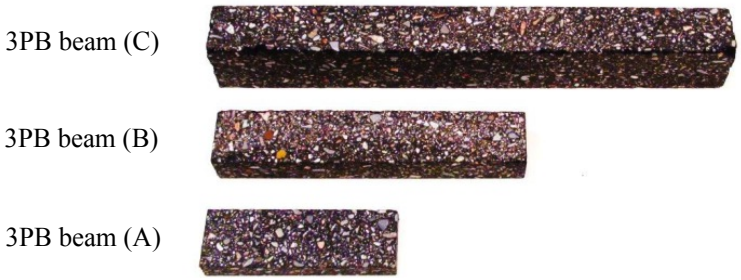

Figure 1. Beam specimens

Nevertheless, the sizes of the climatic chamber and of the testing machine limited the size of the beam specimens. Therefore, an alternative type of test was required to achieve a sufficiently large range of sizes to fully verify the ductile-to-brittle transition of material behavior as structure size increases. For this reason, mean strength tests were also conducted on prismatic specimens in direct tension (DT) configuration. Such an approach was selected because by varying test type and geometry both stress field and failure probability change. Therefore, given the same mean strength, it is possible to convert the dimensions of a structure for a specific stress field and geometry into a different structure with different stress field and geometry [2]. Since Weibull distribution governs the cdf of very large structures, the size of the DT specimen was set as the largest possible. This

ensures that the DT specimen consists of a large number of RVEs and thus the classical Weibull statistics can directly be used to calculate the size of the equivalent three-point bend beam.

Specimens were obtained from twenty-six slabs of asphalt mixture (size 380mm by 200mm) compacted at target air voids of 7% by mean of a Linear Kneading Compactor (LKC). Asphalt mixture beams for 3PB tests present thickness to span ratio equal to 1 : 6 and size ratio $1:\sqrt{3}:3$; since 2D scaling was used for beams, a constant width b = 40 mm was selected. The forth specimen type used for DT tests was prepared by cutting one-size asphalt mixture prisms. Table 1 presents detailed information on the specimens used. The thickness of the beams, D, and the width of the prism were assumed as characteristic dimensions for the three-point bend and DT specimens, respectively (Figure 2a and 2b). The dimensions of the specimens were chosen based on the dimensions of the compacted slabs and on the limitation imposed by the climatic chamber and loading frame.

Table 1. Specimen details and mean strength results

Specimen ID	Replicates #	Dimensions (L x D x b)	Test Type	Mean/Histogram	Mean Strength $\overline{\sigma}_N$(MPa)
A	12	100 x 16.7x 40 mm	3PB	Mean	14.3
B	28	173 x 28.9 x 40 mm	3PB	Histogram	12.4
C	30	300 x 50 x 40 mm	3PB	Histogram	11.4
D	7	255 x 55 x 55 mm	DT	Mean	8.2

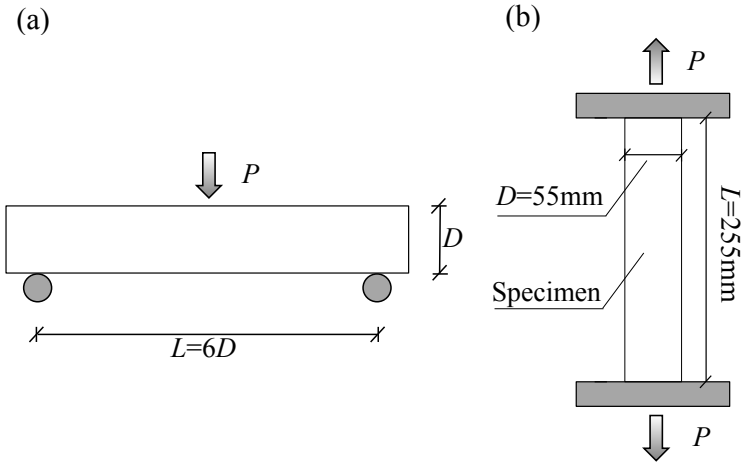

Figure 2. Schematics of (a) three-point bend test and (b) direct-tension test

Testing temperature was set to T=-24°C (low PG+10°C), which is close to the glass transition temperature of the asphalt mixture used. Together with very short tests duration this reduces the viscoelastic effect of the binder component. The desired testing temperature was achieved through a controlled flow of nitrogen inside the climatic chamber of the MTS device used for testing; a conditioning time of three hours was imposed to all the type of specimens before testing.

DT tests were performed by gluing the specimens to a set of plates with an epoxy compound, and then attached to loading frame through a set of screws. Since only the peak load is of interest for this study, both 3PB and DT tests were conducted in load-control mode. In order to minimize the loading rate effect and achieve a similar loading rate of the fracture process zone (FPZ), a time to failure of about 5 minutes was set for all the specimens. Consequently, different loading rates were set for each specimen type; for this reason, a rate calibration was initially performed by testing four

to six additional specimens at each testing condition.

5. Size effect analysis

The nominal strength of three-point bend σ_N^B and direct tension σ_N^T were calculated as $\sigma_N^B = (3P_{\max}L)/2bD^2$ and $\sigma_N^T = P_{\max}/bD$, where P_{max} is the peak load, L is the length of the beam, D is the scaling dimension (the thickness of the beam or the width of the DT prism) and b is the depth of the beam for three-point bend (40mm) or the depth of the prism (55mm) for DT specimens. Table 1 presents the mean nominal strength for all the specimens and the number of replicates used. In order to calculate the probability distribution of nominal strength of beam series B and C (Table 1), the strength values were ranked in an ascending order, i = 1, ...,N, where i is the rank and N is the total number of test specimens, and the strength cdf was next calculated according to the midpoint position method [12] as $P_f(\sigma_N^B) = (1-0.5)/N$. The resulting strength histogram is shown in Fig. 3 on the Weibull scale.

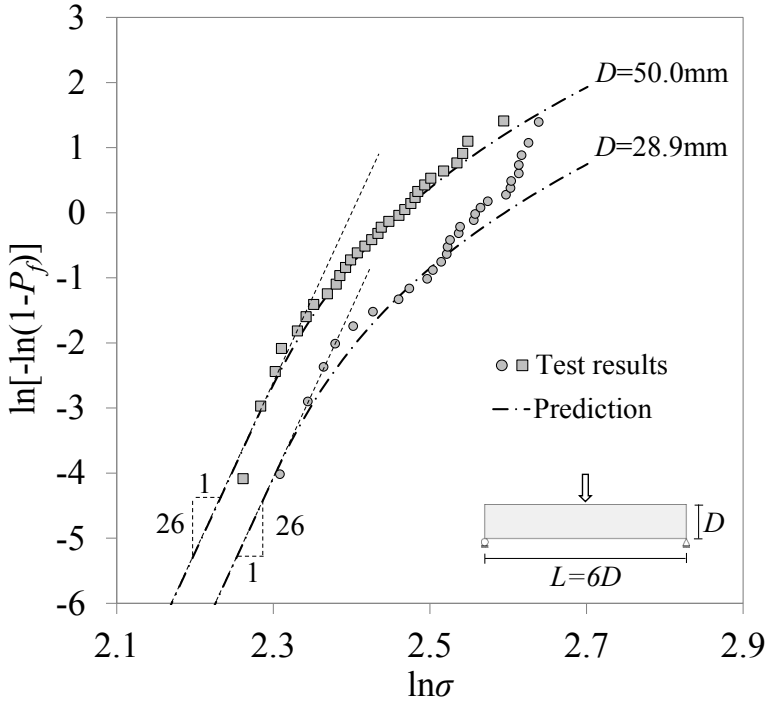

Figure 3. Experimental strength histograms and WLM predictions

The experimental strength histogram presents a trend which is common to many other quasibrittle materials such as concrete and engineering ceramics [13, 14], and is composed of two segments separated by a kink point: the lower segment follows a straight line (i.e. a Weibull distribution) while the upper portion is curved, according to the finite WLM. The experimental histograms indicate that the strength distribution strongly depends on the structure size: as the size increases, the Weibull portion becomes more and more dominant. The Weibull modulus, m, of the lower part of the two histograms can be obtained by fitting; this value is identical and equal to 26, which implies that the Weibull modulus does not vary with the structure size.

The mean strength of DT specimens needs to be converted into the corresponding equivalent 3PB beam to be next used for plotting the mean strength size effect curve. The DT specimen used in this investigation has a volume of 756,000 mm^3 (Table 1), which consists of almost $5.25 \cdot 10^4$ RVEs (V_0=14.4 mm^3). Such a large number of RVEs ensures that the failure cdf of DT specimens is fully

governed by the Weibull distribution, and, therefore, by the two parameters m and s_0. The mean strength of DT specimens, σ_N^T, and the mean strength of the equivalent 3PB beams, σ_N^B, can be written as:

$$\bar{\sigma}_N^T = N_T^{-1/m} s_0 \Gamma\left(1+1/m\right) \quad \text{and} \quad \bar{\sigma}_N^B = N_{eq,B}^{-1/m} s_0 \Gamma\left(1+1/m\right) \tag{12}$$

where N_T is the number of RVEs in the direct tension specimen and the equivalent number of RVEs in the 3PB beam is obtained as: $N_{eq,B} = \frac{b}{l_0^3}\int_V [(\sigma(\mathbf{x})/\sigma_N^B)]^m \, \mathrm{d}V(\mathbf{x})$, where V is the volume of the beam.

The equivalent characteristic size, D_{eq} (thickness), of the three-point bend beam, which has a nominal strength equal to $\bar{\sigma}_N^T$, is obtained by equating Eqs. 12:

$$D_{eq} = \sqrt{[(m+1)^2 N_T V_0]/(3b)} = 2143 \text{ mm} \tag{13}$$

Therefore, by simply selecting a different loading mode it is possible to achieve significantly different equivalent structure sizes, which allows obtaining size effect curve for a much wider size range. At the same time, based on the measured mean strength of DT specimens, and by using Eq. 12 for DT, we can directly estimate the value of the Weibull scaling parameter s_0 = 12.68 MPa. For beam specimens with 2D scaling (i.e. n = 2), we can consider that the damage is throughout the entire beam thickness. Therefore, the effective size of the RVE can be obtained as $l_0 = \sqrt{V_0/b} = 0.6$ mm; based on this condition and on Eq. 6, the following value of C_2 can be calculated: $C_2 = (m+1)/\sqrt{3} \cdot l_0 s_0^{m/2} \left[\Gamma\left(1+1/m\right)\right]^{m/2} = 1.55 \cdot 10^{15}$.

Fig. 4 shows the mean size effect curve of structural strength for 3PB beams and DT specimens (with their equivalent 3PB size). The experimental mean strength curve presents a pattern that is typical to that observed in other quasibrittle structures such as concrete beams [5, 15].

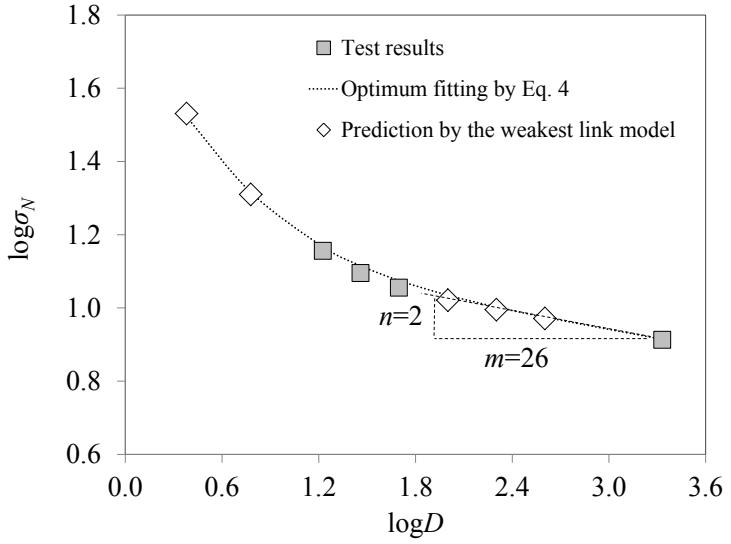

Figure 4. Mean strength curve

However, it is clear that the four mean strength data points obtained experimentally are not sufficient to determine the large-size asymptote of the size effect curve. For this reason, the Weibull modulus, m, was determined from the lower portion of the strength histogram as shown earlier in this paper. Therefore, *C2* was calculated from the DT specimen Weibullian mean. If we tested DT specimens of two different sizes, m could be calculated easily by fitting the linear portion of the mean strength curve at the large size limit and, hence, obtain s_0 directly from Eq. 6.

Parameters C_1 and r in Eq. 4 can be finally determined by non-linear fitting of the experimental mean strength data: the following values were obtained: C_1 = 49.49 and r = 1.01 which agrees well with the analytically derived size effect on the modulus of rupture of three-point bend beams [16]. By knowing C_1 and r, and solving Eqs. 10 and 11, it is possible to obtain the remaining two parameters of the Gaussian core, μ_G, δ_G, of the of the RVE strength cdf. Since for this computation we are interested to the small size limit, the smallest beam size which can be used has a characteristic size $D = 4l_0$ (Fig. 5). According to the elastic stress field two layer of RVE are subjected to tensile stress. The stress at the center of the RVEs upper-layer is half of the stress at the center of the RVEs bottom-layer. Moreover, along the beam span there is a significant decay of stress moving away from the two central RVEs, "C", of 9.5% and 26% for RVEs "L" and "A", respectively. Given the large value of the Weibull modulus, it is reasonable to only include the bottom-layer RVEs "C" and "L" for the calculation of μ_G, δ_G.

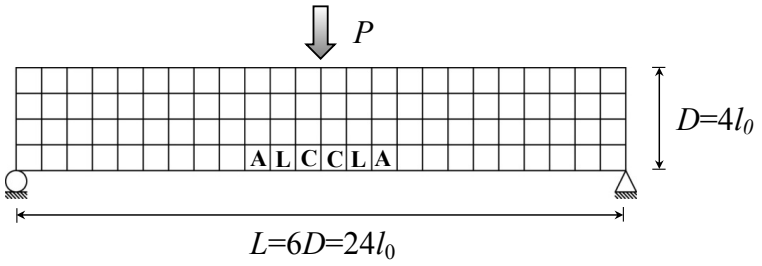

Figure 5. Small size limit beam

Therefore, Eqs. 10 and 11 can be rewritten as:

$$\int_0^\infty \prod_{i=1}^{2} [1-\Phi_G(s_i\sigma_N,\mu_G,\delta_G)]^2 \mathrm{d}\sigma_N = \left[\frac{C_1}{4l_0}+\left(\frac{C_2}{4l_0}\right)^{2r/m}\right]^{1/r} \tag{14}$$

$$\frac{1}{l_0}\int_0^\infty \left\{\prod_{i=1}^{2}[1-\Phi_G(s_i\sigma_N,\mu_G,\delta_G)]^2 \sum_{i=1}^{2}\ln[1-\Phi_G(s_i\sigma_N,\mu_G,\delta_G)]\right\}\mathrm{d}\sigma_N = \\ = -\frac{1}{r}\left[\frac{C_1}{16l_m^2}+\frac{2r}{4l_0 m}\left(\frac{C_2}{4l_0}\right)^{2r/m}\right]\left[\frac{C_1}{4l_0}+\left(\frac{C_2}{4l_0}\right)^{2r/m}\right]^{1/r-1} \tag{15}$$

where s_1 = 0.718, and s_2 = 0.656. The system of Eqs. 14 and 15 can be numerically solved, yielding μ_G = 45.24 MPa and δ_G = 14.82 MPa, which, can be easily demonstrated, are the only couple of values satisfying Eqs. 14 and 15.

With knowing μ_G, δ_G m and s_0 the strength distribution of one RVE (Eqs. 2a and 2b) can be evaluated. With the finite WLM (Eq. 1), it is possible predicting the strength cdf of beams series B and C. Fig. 3 shows that the predicted strength cdf matches very well the measured strength histograms for both beam sizes. This indicates the statistical parameters of strength cdf can be calibrated from the mean size effect curve. By using the WLM we can further calculate the strength distribution and the mean strength of beams with other different sizes; Fig. 4 indicates that the mean structural strength predicted from the WLM lies on the size effect curve represented by Eq. 4, supporting the validity of this expression in providing a good approximation of the exact size effect curve calculated from the finite WLM.

In previous studies [2-4] it was shown that the finite WLM could correctly describe the deviation of the strength histogram of quasibrittle structures of a single size from the two-parameter Weibull distribution. Based on the strength histograms of structures of two sizes, this study provides a

further validation of the finite WLM; by properly selecting specimen sizes and number of replicates the size effect on the grafted strength distribution was clearly demonstrated (Fig. 3). The good agreement between the predicted and measured strength distributions of beams of two sizes indicates that the recently proposed finite WLM can well capture the size effect on the strength cdf of quasibrittle structures.

6. Conclusions

In this paper an analytical and experimental demonstration on the possibility of indirectly determining the strength cdf of quasibrittle from the mean size effect curve was presented. This method provides a valid alternative to the conventional histogram testing, it requires a smaller number of specimens, and it is less prone to experimental errors. The size effect tests on the strength histogram of asphalt mixture indicates that the probability distribution of structural strength strongly depends on the structure size, and such dependence can be well explained by the finite weakest link model.

Abstract Defects play crucial role in the process of nucleation and propagation of fracture. We study fracture as a non-equilibrium statistical mechanical system with a threshold activated extremal dynamics. The dispersion δ in the breaking thresholds shows a transition at $\delta = \delta_c$. For $\delta < \delta_c$, the fracture or failure takes place sharply at a certain applied stress or voltage. For $\delta > \delta_c$, the fracture or failure takes place gradually with increasing stress or voltage, leading to a non-linear region in the stress-strain or current-voltage curve prior to failure. We discuss the transition point For δ_c from the point of view of ductile-brittle transition. We present analytical results on fiber bundle model and numerical results on two dimensional random resistor network model.

Keywords Ductile-brittle transition, Threshold activated dynamics, Fiber bundle model, Random resistor network model.

1. Introduction

In material science and engineering ductile and brittle behaviors have received lots of attention over the past years. It is widely known that most ductile materials become brittle when the temperature or pressure is lowered or by radiation bombardment and atmospheric reaction. This phenomenon, known as ductile-brittle transition, has been extensively studied by engineers, material scientists and physicists. Disorder is known to play a crucial role in fracture. It is now known that topological disorders like dislocations and their cooperative motion give rise to ductile fracture. Brittle fracture on the other hand originates from a single micro-crack, the most vulnerable one. Thus ductile fracture can be thought of as a co-operative process of defects whereas brittle fracture is determined by extreme events [1]. Though several aspects of fracture are now understood, the mechanism and the nature of ductile-brittle transition is not clear yet. In this paper, we study the effect of dispersion (δ) in the local strengths in a material on the nucleation and propagation of fracture. We show for low δ the system behaves like a brittle material where failure happens sharply at a certain value of applied stress or voltage and the response of the system remains linear up to the failure point. For high δ the breakdown of the system happens gradually through local failures till the entire system breaks. The stress-strain curve in the elastic system or the voltage-current characteristics in electrical system shows non-linear region prior to failure. We argue for a transition point δ_c separating the low and high δ regions.

We have studied two models: fiber bundle model and random resistor network model. The fiber bundle model is solved analytically under mean field approximation. We have provided the numerical results for both the models. The models perceive fracture as a threshold activated extremal dynamical system. The disorder in these models is introduced in terms of random threshold stress of individual fibers or current in resistors.

We have found a transition point of threshold distribution ($\delta = \delta_c$) which clearly separates two different regions in the model. For $\delta < \delta_c$, the fracture phenomena is very sharp and similar to that of brittle fracture. The sharpness of this failure is expressed by the sudden jump of the fraction of unbroken bonds in fiber bundle model and conductance in random resistor network model, at the fracture point. Where for $\delta > \delta_c$, the bonds or resistors break in a correlated manner producing avalanches of all sizes and the model shows the features of ductility. We have also studied the

mechanical and electrical response of the model. For δ less then δ_c the response curve shows a perfectly linear brittle like nature where as for δ greater than δ_c, the response curve contains a ductile like non-linear or plastic region.

2. Fiber Bundle Model

The review of modern physics written by S. Pradhan, A.Hansen and B.K.Chakrabarti has a very good overview on fiber bundle model [2]. The model consist of two parallel bars between which rigid fibers are attached (Fig 1a). One of the two bars is fixed and an amount of force F is applied on the other one. If there are N number of fibers then force per fiber i.e stress applied on the system is, f_0 =F/N.

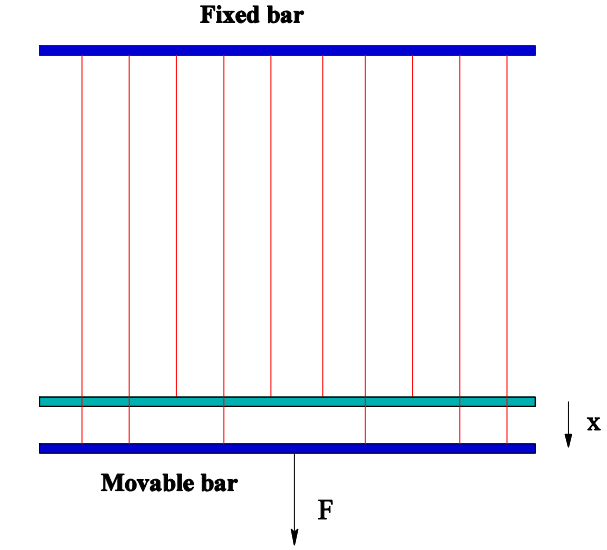

Figure 1a: Fiber Bundle Model

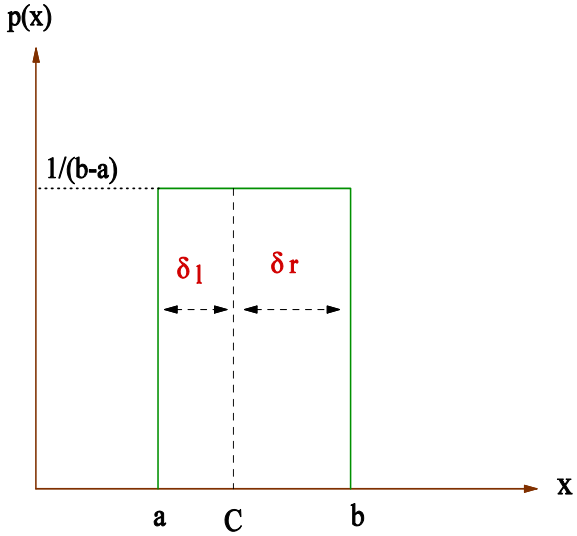

Figure 1b: Threshold Distribution

Every fiber has some threshold stress value and when the external stress exceeds this value it breaks. After breaking of one fiber the stress is re-distributed among all other fibers according to global stress re-distribution scheme; which would increase the stress and may cause further breaking of fibers. For example, at a constant applied force F, the re-distributed stress will be F/(N-1) after breaking of one

fiber, F/(N-2) after breaking of two fibers and so on. This process will continue until either all the fibers break or the redistributed stress is less than the next threshold value. At this stage the model comes to equilibrium. The number of remaining fibers at each equilibrium is denoted by N_{eq}. Then the fraction of fibers remained at equilibrium point is $n_{eq} = N_{eq}/N$. Next we increase the external stress ($F \rightarrow F+\Delta F$); which leads to further breaking, re-distribution and equilibration. This process goes on until all the fibers break. The threshold stress is given to the fibers in a random way, picking random numbers between 0 to 1 from an uniform distribution around any mean value C and width δ_r and δ_l respectively on right and left side of the mean value (Fig 1b). We are considering the vulnerability of the defect in the form of a breaking threshold of a fiber. The threshold distribution represents the fluctuations of these vulnerabilities in mean field limit (where the stress fluctuation on the bonds are neglected). The fiber bundle model gives us an idea of the correlations in the breaking processes in fibers. The fluctuations in the breaking threshold gives rise to the cooperative nature in the breaking processes in fibers which is the essence of ductile fracture.

2.1 Analytical Calculations

In this paper we provide the analytical calculations for the static and dynamic behavior of the model. We have compared our results with some previously calculated values depending on some specific choices of the mean and width of threshold distribution. At first we will study the distribution for giving threshold to the fibers. From figure 1b we can see that the mean is at C which is in between 0 and 1. Then the point 'a' and 'b' is at ($C- \delta_l$) and ($C+ \delta_r$) respectively. Now we can take $\delta_r=\delta$ and relate this with δ_l by the relation : $\delta_l=\alpha\delta_r=\alpha\delta$. For the analytical calculations we will take $\alpha=1$. This will give us a distribution of width 2δ ranging from a to b. Then the fraction of broken bond at every equilibrium will be given by

$$1 - n_{eq} = \int_0^{f_0/n_{eq}} P(\sigma)d\sigma \qquad \ldots\ldots\ldots\ldots 1$$

We are interested in the region $a \leq f_0/n_{eq} \leq b$ as the other regions are quite trivial. For $f_0/n_{eq} > b$, all fibers are broken while for $f_0/n_{eq} < a$, all fibers are intact.

2.1.1 Determination of fraction of unbroken bonds at equilibrium points

Within the region $a \leq f_0/n_{eq} \leq b$ we can express the fraction of unbroken bonds as

$$1 - n_{eq} = \int_a^{f_0/n_{eq}} \frac{1}{2\delta} d\sigma$$

$$= (1/2\delta)(f_0/n_{eq} - a) \qquad \ldots\ldots\ldots\ldots 2$$

This will give us a quadratic equation of n_{eq} :

$$n_{eq}{}^2 - \left(1 + \frac{a}{2\delta}\right) n_{eq} + \frac{f_0}{2\delta} = 0 \qquad \ldots\ldots\ldots\ldots 3$$

The solution of the above equation will give us the fraction of unbroken bonds :

$$n_{eq} = \frac{1}{2}\left(1 + \frac{a}{2\delta}\right) \pm \frac{1}{2}\sqrt{\left(1 + \frac{a}{2\delta}\right)^2 - \frac{2f_0}{\delta}} \qquad \ldots\ldots\ldots\ldots 4$$

2.1.2 Determination of critical stress of the model

At critical point all the bonds break on application of an external stress, f_c, known as critical stress. The number of fractional bonds remaining just before the breakdown is nc. Thus at $f_0=f_c$, n_{eq} has only one value. This implies that the term in the square root in Eq.(4) should be zero; which in turn gives us,

$$\frac{2f_c}{\delta} = \left(1+\frac{a}{2\delta}\right)^2$$

Or, $f_c = \frac{\delta}{2}(1 + a/2\delta)^2$ ……..5

2.1.3 Fraction of unbroken bonds at critical stress

We can get the fraction of unbroken bond at critical stress by inserting the value of f_c from Eq.(5) in Eq.(4). Then we will get

$$n_c = n_{eq}|_{f_0=f_c}$$

Or, $n_c = \frac{1}{2}(1 + a/2\delta)$ ……..6

We find from Eq.(6), n_c starts increasing from a value 0.5 at $\delta = 0.5$ and reaches a value 1 at $\delta = \delta_c$. For $\delta < \delta_c$, n_c remains at 1 since it is at its maximum point and can't attain a higher value.

2.1.4 Study of Ductile-Brittle transition point

We have the expression of the critical stress given by Eq.(5). Now for $f_0/n_{eq} < a$, all bonds are intact and at the critical limit we can write

$$\frac{f_0}{n_{eq}}|_{f_0=f_c, n_{eq}=n_c=1} = a \qquad \ldots\ldots\ldots 7$$

Replacing the value of f_c from Eq.(5) in Eq.(7) we get the critical value of $\delta(\approx \delta_c)$ as :

$$\frac{\delta}{2}\left(1+\frac{a}{2\delta}\right)^2|_{\delta=\delta_c} = a$$

Or, $\delta_c = a/2$ ……8

2.2 Numerical Results

For numerical results we will set C=0.5 and α=1. This gives a threshold distribution with a mean at 0.5 and width δ on both side of the mean. The system size is taken to be 10^6. All simulated results are over 100 configuration averages.

2.2.1 Variation of fraction of unbroken bonds (n_{eq}) with applied stress (f_0)

We have plotted the fraction of unbroken bonds at each equilibrium (n_{eq}) with applied stress (f_0) for a series of δ's between 0.1 and 0.5. The results are given by figure 2. As δ increases the critical applied stress(f_c) at which the total model breaks decreases from 0.5 and reaches 0.25 at δ=0.5.

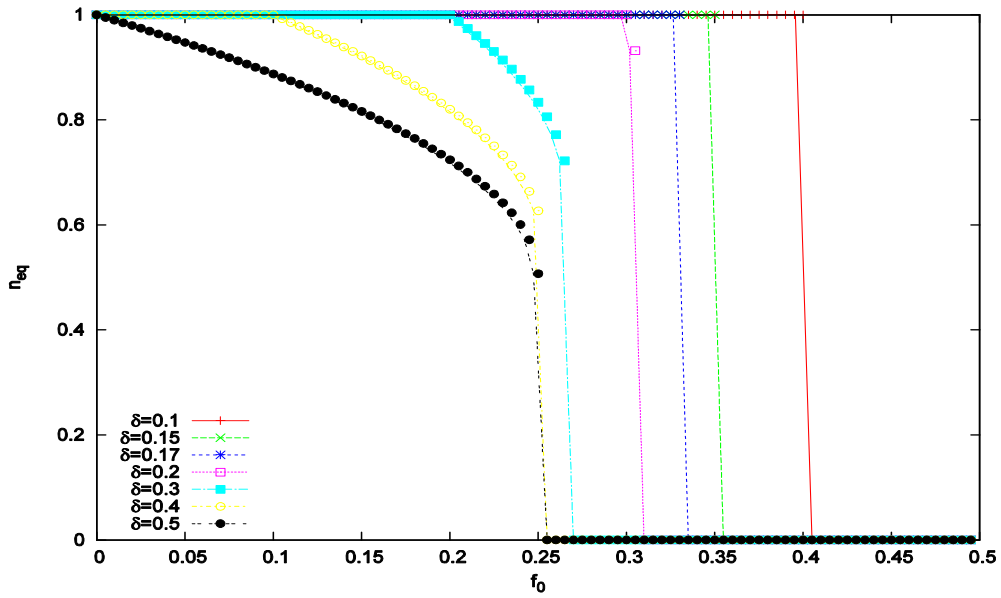

Figure 2: Fraction of unbroken bonds(n_{eq}) with applied stress(f_0)

Moreover up to a certain value δ≈0.17, the fraction of unbroken bonds at critical point (n_c) remains 1. Beyond this value, n_c starts decreasing and comes to a value 0.5 at δ=0.5. The point δ≈0.17 is like a critical point. This is quite consistent with the value we obtained analytically. At one side of the this point the model behaves like ductile materials showing a fracture through a number of equilibrium configurations at a low critical stress; where on the other side it behaves like brittle materials showing an abrupt fracture at a higher critical stress. We have studied this critical point in detail in our other simulated results.

2.2.2 Variation of redistributed stress ($f=f_0/n_{eq}$) with applied stress (f_0) for different δ's

Since the fibers are totally rigid, there is no strain in the model in true sense. We will treat the re-distributed stress as strain since the non-linearity is introduced in the model through this re-distributed stress.

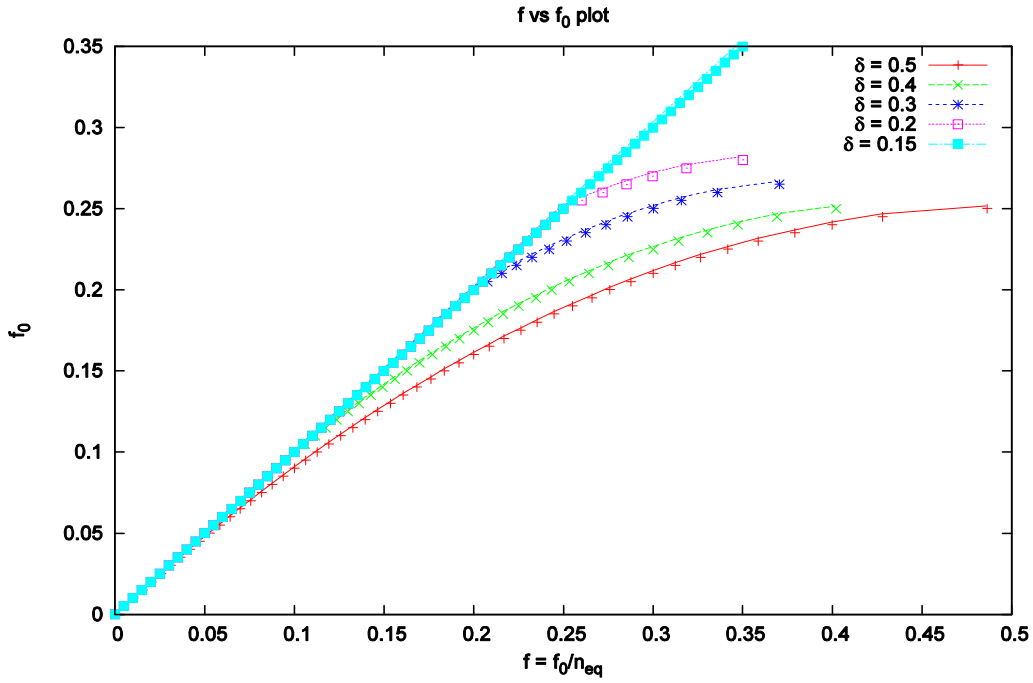

Figure 3: Stress-strain curve (f_0 vs f_0/n_{eq}) for the model

This is very similar to the response curve of mechanical systems. We have plotted f_0 with f_0/n_{eq} for different δ's with in 0.1 and 0.5. Figure 3 shows that for $\delta \leq 0.15$, the model behaves like brittle materials while for $\delta \geq 0.2$ the model shows ductility. There must be a critical value of threshold distribution width (δ_c) within the range $0.15 < \delta_c < 0.2$, where this ductile-brittle like transition occurs.

2.2.3 Variation of critical stress (f_c) with threshold distribution width (δ)

We have already shown that the critical stress to create fracture in the model increases with decreasing δ values. Figure 4 gives us an idea how this critical stress decreases with a continuous increase in threshold distribution width. Figure 4 shows that, the critical stress (f_c) decreases with increasing δ and falls from 0.4 to 0.25 within the range between 0.1 and 0.25 in δ value. Though the transition point is not quite evident from the plot, we can estimate it as the average of the above mentioned δ region. So, from above study we get $\delta_c \approx 0.17$. This agrees with the value we obtained analytically and other simulated results. The variation of critical stress (f_c) with δ and the nature of response curve is obtained before in two dimensional fiber bundle model which consists of two square plates in which fibers are intact [3]. We have reproduced the same result in a relatively easier model.

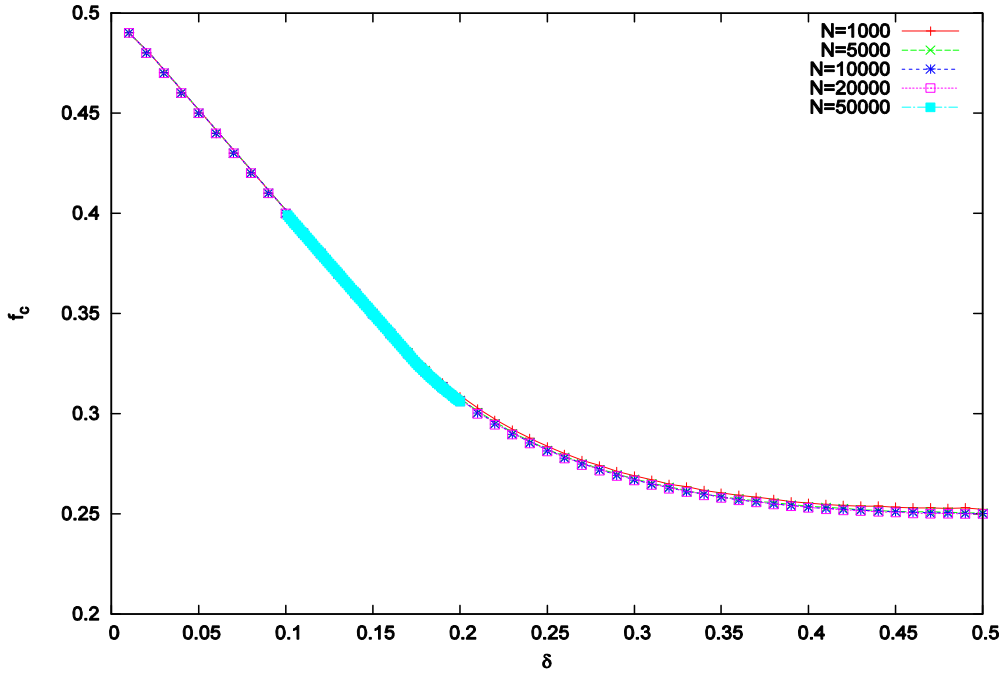

Figure 4: Variation of critical stress (f_c) with δ

2.2.4 Fraction of unbroken bonds (n_c) at critical stress with threshold distribution width (δ)

Above study of critical stress is unable to give us a clear distinction between ductile and brittle region in the model. This distinction can be drawn from the study of fraction of unbroken bonds at critical point (n_c) with varying δ value.

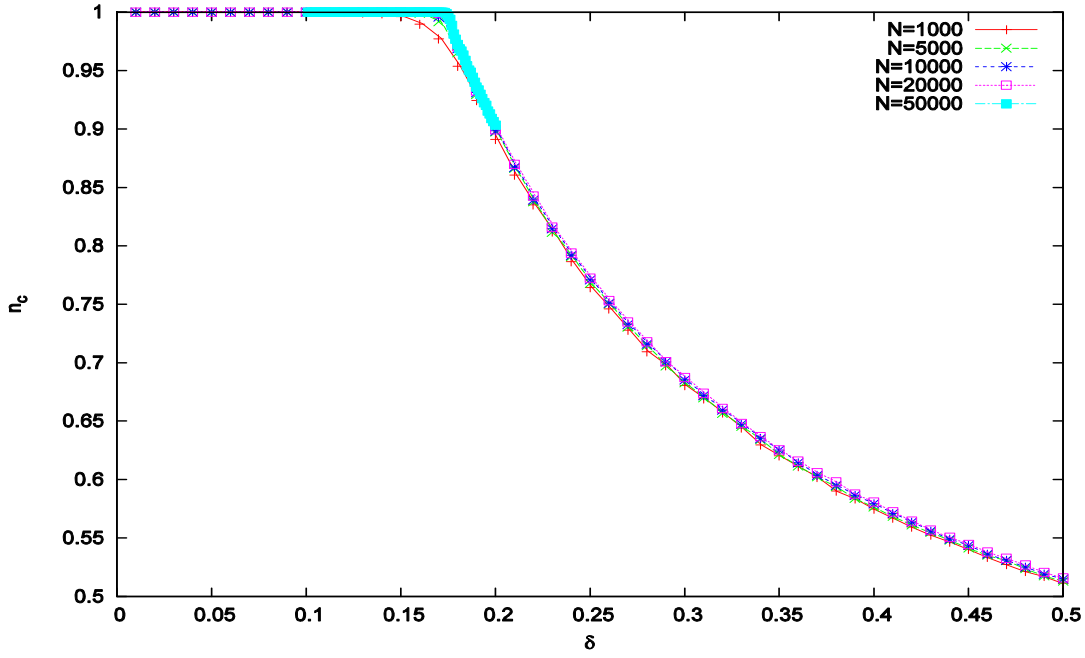

Figure 5: Variation of n_c with δ

One of the strong points that helps us to denote low δ region as brittle is, the value n_c remains 1 up to a certain low value of δ characterizing a abrupt fracture in the model. Figure 5 reflects the same

fact. Up to a value $\delta_c \approx 0.17$, n_c remains 1. This is the brittle region for the model. If we increase δ beyond this n_c starts to fall and goes to 0.5 at $\delta=0.5$. This is the ductile region. The above critical point ($\delta_c \approx 0.17$) separates these two regions very clearly.

2.2.5 Variation of (f_c/n_c) with threshold distribution width (δ)

A plot of f_0/n_{eq} with δ gives us a clear idea about the point at which the ductile to brittle like transition occurs. The point with coordinate ($f_0/n_{eq}=0.32$, $\delta_c \approx 0.17$) in the plot denotes the transition point from brittle to ductile region and vice verse.

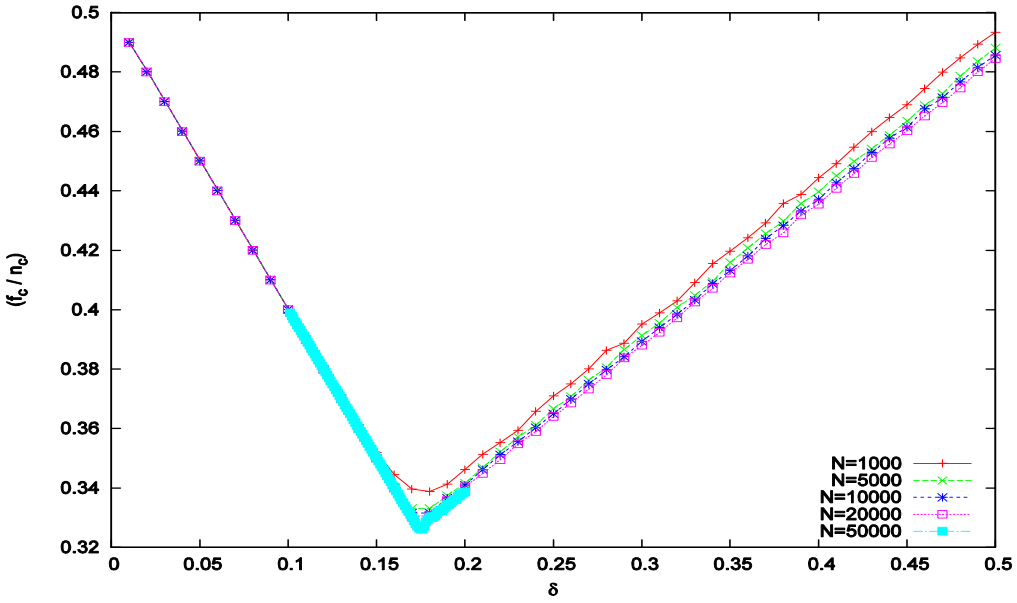

Figure 6: Variation of f_c/n_c with δ

The obtained value of δ at which the transition occurs is $\delta_c \approx 0.17$; which is very similar to the values obtained from other numerical studies and analytical calculation.

2.2.7 Phase diagram for the model

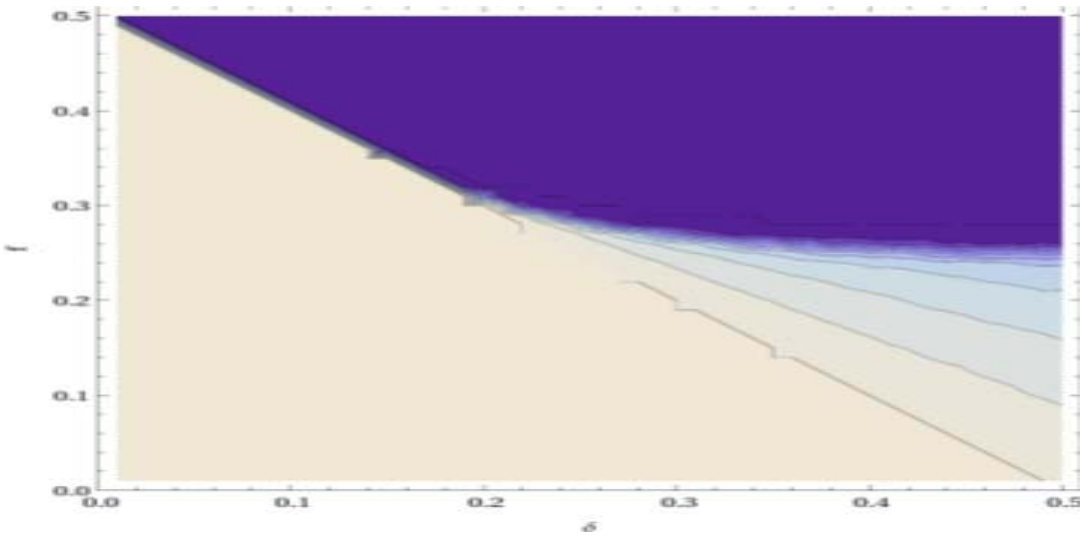

Figure 7: Phase diagram for fiber bundle model

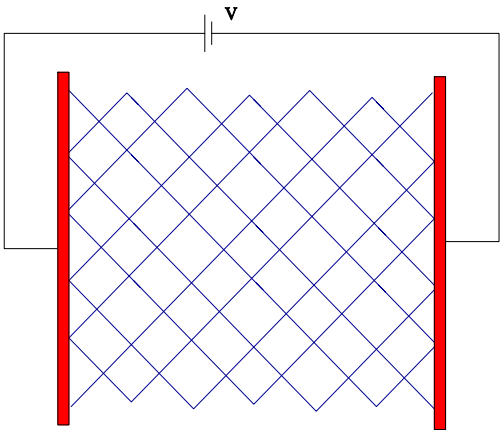
We have constructed a phase diagram for the model and given by figure 7. The darkest color corresponds to n_{eq}=0 and the lightest color for n_{eq}=1. A very important observation is related to this diagram. For δ<0.166, n_{eq} fall to zero abruptly. When we cross this particular point the behaviour of n_{eq} changes. For δ>0.166, n_{eq} falls to zero after crossing a number of equilibrium points. This is the point where the transition occurs. On one side of this point the material shows ductile like fracture and on the other side the fracture resembles abrupt brittle fracture.

3. RANDOM RESISTOR NETWORK MODEL

We have constructed a tilted square lattice whose each bond is a resistor with a resistance 1. A potential difference of V volts is applied to two opposite ends of the lattice. On the other two ends periodic boundary condition is applied (Fig 8a). All resistors are given a random threshold taken from the same uniform distribution same as the case of fiber bundle model.



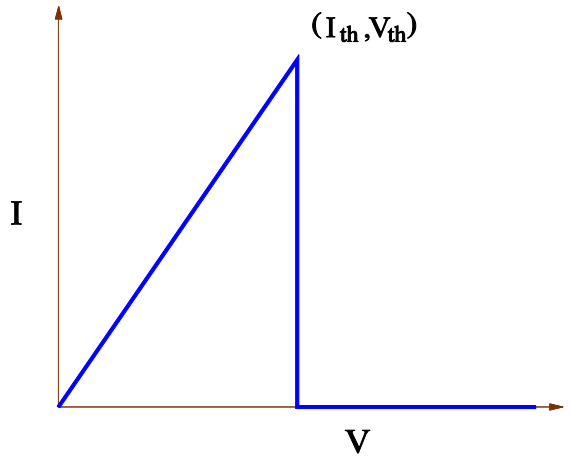


Figure 8a: Random resistor network model

Figure 8b: Response of individual resistors

The potential at each lattice point is calculated by solving 'Kirchoff's law' with a series of iterations. Whenever the potential drop between two lattice points becomes less than the threshold value given to the resistor joining these two points, the resistor breaks irreversibly (Fig 8b). Then we apply 'Kirchoff's law' again to calculate the new potentials due to the breaking of the fiber. When no more fiber breaks, we increase the applied potential and do the same thing. This process goes on until the conductance of the system becomes zero. This is the critical point for the model.

3.1 Numerical Results

For numerical simulations we have taken the same specifications like fiber bundle model. The lattice size is taken to be 16×16.

3.1.2. Variation of conductance (G) with applied voltage

Conductance is the parameter which denotes the fracture point for the model. The rate at which the conductance drops to zero is the abruptness of the fracture. We have plotted conductance with applied voltage and observed its behavior at various values of δ.

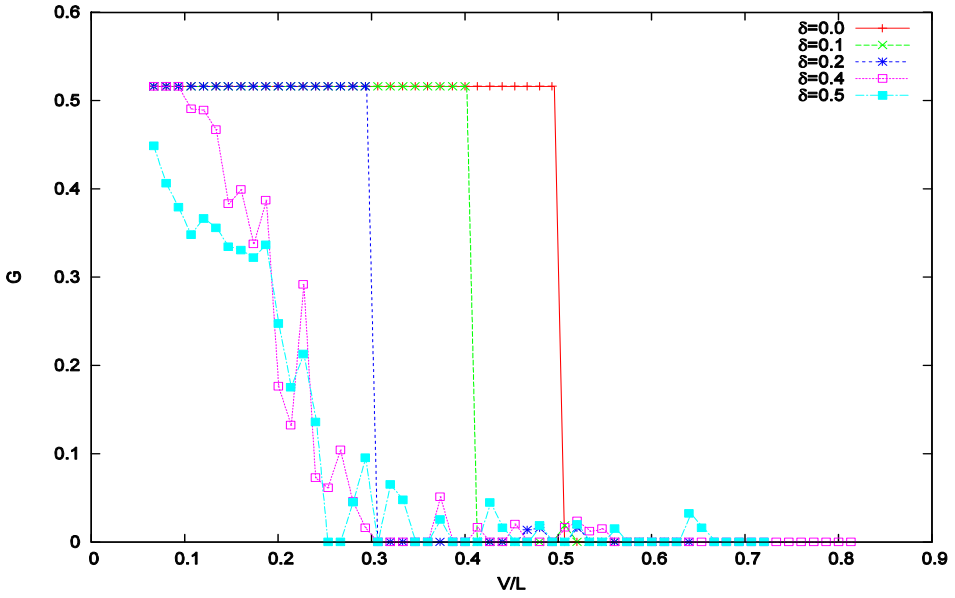

Figure 9: Variation of conductance with applied voltage

Up to δ=0.2 the conductance falls very sharply causing an abrupt fracture in the model. This behavior is analogous to sharp brittle fracture. With increasing δ this sharpness decreases. For δ ≥0.3 the fracture occurs in a co-operative manner like ductile materials. Moreover the constant initial value of conductance corresponds to a linear region in current voltage characteristic curve prior to fracture. This behavior is like brittle materials. As δ increases the conductance start decreasing from this constant value after a certain value δ= δ_c. Above this δ value current-voltage charecteristics curve stars showing non-linearity and behaves like a ductile material.

4. DISCUSSION AND CONCLUSIONS

As an outcome of this paper we can point out some important results :
1. Variation of conductance in random resistor network and fraction of unbroken bond at critical point (n_c) in fiber bundle model with δ shows that the behavior of the model in low δ is brittle like and that for high δ is ductile like.
2. The mechanical and electrical response shows a pure linear or a linear behavior with small non-linear part before some critical value of δ. Beyond that the model behaves non-linearly like ductile materials. For fiber bundle model this critical value is, $\delta_c \approx 0.16667$. For random resistor network model this critical value δ_c remains within δ value 0.2 and 0.3. More studies are required to locate the exact transition point for random resistor network model.
3. The critical stress to create fracture in the fiber bundle model decreases to lower values with increasing δ's. This signifies a decrease in hardness of the model when δ is increased.
At this stage it is difficult to draw some analogy between any exact material property that causes ductile-brittle transition and the parameter δ in our model. Still we can suggest a possible parameter similar to δ. Early studies in material science prove that ductility in materials is a consequence of cooperative motion of defects (mainly dislocation) within it [1]. The material becomes brittle if the defects within it are immobile. There are also some external parameter like temperature or pressure [4] that control this mobility of defects. Because of this characteristic, materials show ductile-brittle transition with respect to these parameters. If we can define any quantity that deals with the cooperative motion of the defects in the materials and increases with increasing mobility of defects, then that quantity will be analogous to the δ parameter. If it is possible to find some critical value of this quantity, depending on the change of external parameters (temperature, pressure or any other

parameters), which distinguishes between ductile and brittle region in the materials; then it will be similar to δ_c, the ductile-brittle transition point.

Abstract: Effect of highly heterogeneous fracture properties on tensile penny-shape planar crack propagation governed by Irwin's criterion is investigated numerically by taking into account the large crack front deformations induced by the high toughness contrasts. To compute the variations of stress intensity factor (SIF) along the crack front arising from its progressive deformation, perturbation approach based on Bueckner-Rice weight function theory is used iteratively. Effective fracture toughness is obtained from the local toughness map for a few examples. It is shown that when Irwin's criterion is satisfied all along the crack front, the effective toughness is equal to the mean value of the local ones along the crack front. This value depends on the shape of the front, and so is different from the total mean value of the toughness in the plane. In the examples studied here, the weak toughness zones are favored by the crack front deformations, so that the effective toughness is lower than its spatial average.
Keywords: Tensile planar crack; Heterogeneous medium; Effective failure properties; Perturbation method; Linear elastic fracture mechanics.

Quantifying the effective fracture properties of a planar crack propagating in a heterogeneous material is a key issue in material science. Since the crack propagation results from the interplay of local material properties with long range elastic interactions, the problem is not trivial and can not, in general, be reduced to take the spatial mean value of the fracture properties. Two regimes shall be distinguished [1]: For slightly fluctuating maps of local toughness, the elasticity of the crack front dominates over the destabilizing effects of heterogeneities, and the motion of the front is smooth (weak pinning). For materials with stronger heterogeneities with larger gradient of toughness, the crack front can jump abruptly from one equilibrium position to the other (strong pinning) [3]. In the weak pinning regime, it has been shown in the limit of a first order approach that the effective macroscopic toughness can be obtained by averaging the local toughnesses, contrary to the strong pinning case where the effective macroscopic toughness is *larger* than the average local toughness [1].

Here, we address these questions in the context of highly heterogeneous local fields of toughness for which the first order approach can not be used. In particular, we take into account the effect of large crack front deformations induced by high toughness contrasts, and investigate the relationship between local toughness map and macroscopic effective toughness. In this paper, we will limit our

study to the weak pinning quasistatic regime. We consider the case of a circular embedded crack propagating under remote mode I loading in an axisymmetric toughness map (see § 1). We solve the problem by using an incremental method [4, 5], based on Rice's perturbation approach [6, 7]. This method is presented in § 2 and then applied in § 3 to the resolution of our problem.

1 Problem definition

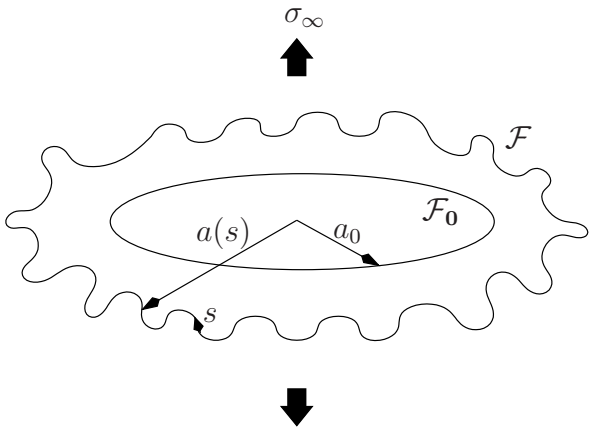

Figure 1: A tensile planar crack in an infinite body under uniform stress σ_∞

Consider a planar penny shape crack $\mathcal{F}$ of initial radius a_0, embedded in an infinite isotropic elastic medium with heterogeneous fracture toughness properties and loaded in pure mode I through some uniform remote stress applied at infinity σ_∞ (see Fig. 1). We assume a quasistatic propagation of the crack front, so that the crack advance at a point M of the front is governed by Irwin's criterion:

$$\begin{cases} K(M) < K_c(M) & : \quad \text{no crack advance} \\ K(M) = K_c(M) & : \quad \text{possible crack advance,} \end{cases} \tag{1}$$

where $K(M)$ is the SIF and $K_c(M)$ the toughness at point M. Let us denote $\overline{K_c}$ the average material toughness, $\kappa_c (= \Delta K_c / \overline{K_c})$ its relative contrast and $\eta(M)$ the toughness fluctuations. With these notations, we have:

$$K_c(M) = \overline{K_c}\,[1 + \kappa_c \eta(M)] \tag{2}$$

We suppose that the remote loading σ_∞ adapts in order to stay in the quasistatic regime and to ensure crack propagation at least, on some part of the front. This implies that at each moment:

$$\max_{M \in \mathcal{F}} \frac{K(M)}{K_c(M)} = 1 \tag{3}$$

Under the assumption of quasistatic propagation, the problem is to find, for a given toughness map $K_c(M)$, the successive positions of the crack front and the corresponding loading σ_∞. From them, one can obtain the SIF along the crack front and consequently its mean value. In the homogeneous

case ($\kappa_c = 0$), the problem can be solved analytically. One has at each moment $K = \overline{K_c}$ all along the front, the successive positions of the crack front are circles of radius a and the corresponding loading follows $\sigma_\infty = \frac{\overline{K_c}}{2}\sqrt{\frac{\pi}{a}}$. In the heterogeneous case, the crack front deforms. In an homogenization process, we shall replace it by an equivalent circular crack of

- radius a_m given by the mean value of the crack extension a:

$$a_m = \frac{1}{L}\int_{\mathcal{F}} a(M(s))\mathrm{d}s \tag{4}$$

- SIF K_m given by the mean value of K:

$$K_m = \frac{1}{L}\int_{\mathcal{F}} K(M(s))ds \tag{5}$$

where s is the curvilinear abscissa and L is total length of the crack front.
We will see in the following that in the cases investigated here, K_m tends to a constant stationary value after some transient propagation regime. As a result, this stationary value will be used to define the macroscopic effective toughness K_c^{eq} of the heterogeneous media studied here. Alternatives would have been to define K_c^{eq} as the maximum value of K_m during crack propagation or its mean value during propagation. However, we would like to define an effective toughness as a quantity that does not depend of the initial geometrical configuration of the crack, so the value of K_m in the stationary regime seems the most appropriate definition.
The aim of the paper is to discuss the influence of the toughness map $K_c(M)$ on this effective toughness. In this paper, we consider it periodical and axisymmetric given by:

$$K_c(M) = \overline{K_c}\,[1 + \kappa_c \cos(k\theta(M))] \text{ where } \theta(M) \text{ denotes the polar angle of } M, \tag{6}$$

and discuss the influence of toughness contrast κ_c and spatial wavenumber k on K_m, hence on K_c^{eq}. This choice of K_c allows to obtain a weak pinning regime and to focus, as wanted, on the influence of the large deformations of the crack front on the effective toughness.

2 Numerical Procedure

A characteristic feature of this problem is that the shape of crack is determined by the variation of SIF and material properties. In general, neither the distribution of SIF, nor the geometry of the crack are known a priori and must be determined as part of the solution. An appealing perturbative technique for solving such problems is provided by the studies of Rice [6], who has developed a linear scheme for calculating the variation in SIF due to small changes in the crack geometry. For large deformations of the front, Bower and Ortiz [4] followed by Lazarus [5], developed a powerful method based on the iteration of the linear scheme. The efficiency of this method arises from the need for the sole 1D meshing of the crack front. In the sequel, we extend the numerical notations and procedures developed by Lazarus [5]. For dimensional reasons, we can introduce the dimensionless SIF $\widehat{K}$ by writing:

$$K = \sigma_\infty \sqrt{a_0}\,\widehat{K} \tag{7}$$

This quantity depends only on the crack shape.
We start from the initial situation of a crack of radius a_0 for which $\widehat{K} = \frac{2}{\sqrt{\pi}}$. We then use a regularization of Irwin's criterion to obtain the crack front displacement $\delta a(s)$ by a Paris' type law [5]:

$$\delta a(s) = \delta a_{max} \left(\frac{\widehat{K}(M(s))/K_c(M(s))}{\max_{M\in\mathcal{F}} \widehat{K}(M(s))/K_c(M(s))} \right)^{\beta} \text{ with } \beta \gg 1. \tag{8}$$

where δa_{max} corresponds to the maximum crack advance during a numerical step. The corresponding loading is obtained by introducing the definition 7 of $\widehat{K}$ in equation 3:

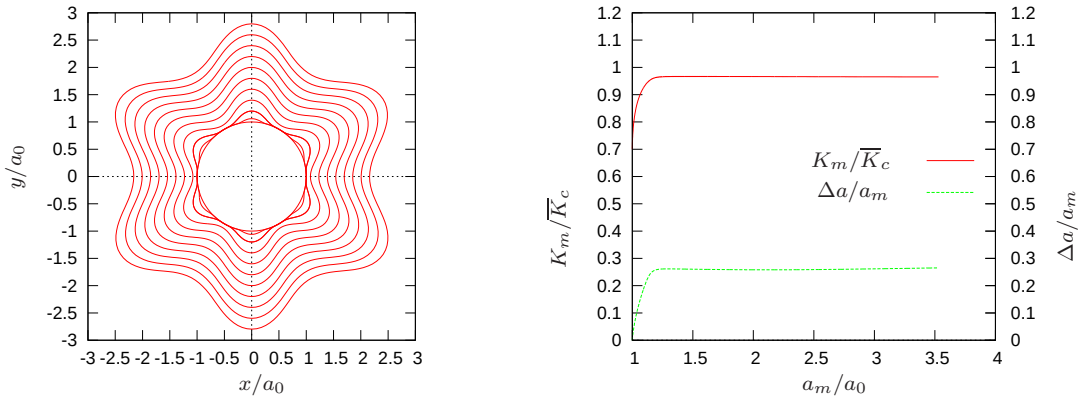
$$\frac{\sigma_\infty \sqrt{a_0}}{\overline{K}_c} = \left[\max_{M\in\mathcal{F}} \frac{\widehat{K}(M)}{1+\kappa_c \eta(M)} \right]^{-1} \tag{9}$$

Subsequently, Rice's formulae (see Refs. [6, 5]) are used for updating the dimensionless SIF $\widehat{K}$ corresponding to the advance $\delta a(s)$ and the whole step (determination of δa, updating of $\widehat{K}$) is reitirated as long as necessary.

3 Results

The previous procedure is applied to the toughness map given by Eq. (6). In § 3.1, the propagation in the case of a given value of k and κ_c is studied. In §3.2, the influence of those parameters on the mean quantities K_m and a_m is considered.

3.1 Propagation for a given toughness map



(a) Successive crack front positions

(b) Evolution of key quantities during propagation

Figure 2: Case $k = 6$ and $\kappa_c = 0.3$

As a typical example, the results for $k = 6$ and $\kappa_c = 0.3$ are shown in Fig. 2. On Fig. 2(a), successive equilibrium positions of the crack fronts are plotted. The propagation is continuous without jumps,

showing that the pinning is weak. One can notice that first the crack front deforms from a circular crack to a k-petals flower shape, which then remains the same. The process is as follows. In the initial stage, the crack is circular, so that only the points where K_c is minimum propagate. Then, more and more points reach the threshold and propagate at the same time. Finally, the crack front attains and stays in a shape for which all of its points satisfy $K = K_c$ (stationary regime) so that K_m is equal to the mean value of K_c along the crack front:

$$K_m = \frac{1}{L}\int_{\mathcal{F}} K_c(M(s))\mathrm{d}s \tag{10}$$

To quantify the moment where the crack shape becomes stationary, we introduce the amplitude Δa of $a(s)$, the value of $\Delta a/a_m$ remaining constant for a given shape. The evolutions of $\Delta a/a_m$ and of the normalized mean SIF $K_m/\overline{K}_c$ as a function of the mean radius a_m are plotted on Fig. 2(b). It can been seen that both quantities increase until a plateau is reached. The plateau corresponds to the stationary regime. Once in this stationary regime, the effective toughness K_c^{eq}, whether it is defined as the maximum or mean value of K_m, corresponds to the value of this plateau, hence to the mean value of K_c along the crack front. It shall be noticed that $K_c^{\mathrm{eq}} < \overline{K}_c$. Physically, it is due to the fact that the length of the crack front which is in the weaker zone is higher than in the stronger one, so that the mean value of K_c along the crack front is lower than the mean value $\overline{K}_c$ of K_c in the whole plane. This result is specific to the circular geometry, and it is linked to the dependance of the SIF on the crack size. In next section, we discuss the influence of k and κ_c on the value of K_c^{eq}.

3.2 Influence of the geometrical parameters of the toughness field

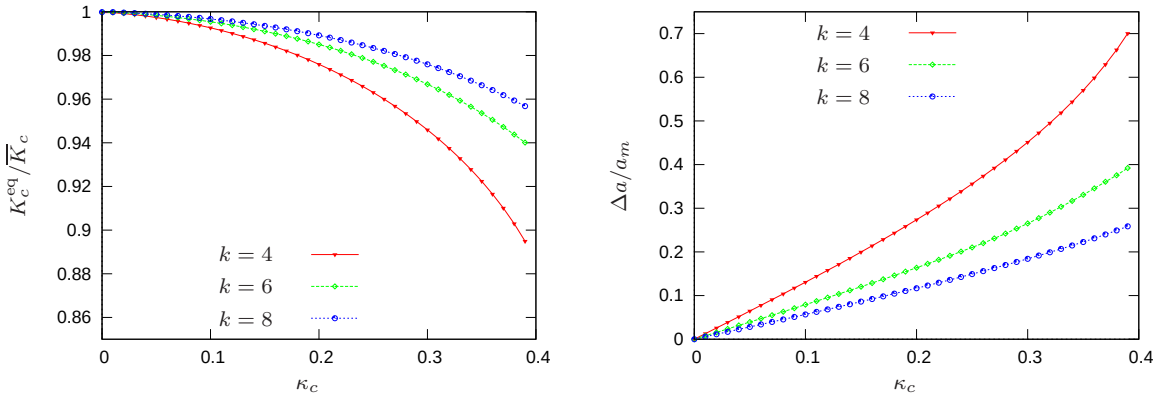
Figure 3 shows the effect of the toughness contrast κ_c and toughness spatial repartition k on the normalized effective toughness $K_c^{\mathrm{eq}}/\overline{K}_c$ and on the crack front deformation $\Delta a/a_m$.

For a given values of k, $K_c^{\mathrm{eq}}/\overline{K}_c = 1$ for $\kappa_c \ll 1$ and decreases, whereas $\Delta a/a_m$ increases, with κ_c. Physically, it looks obvious, that in case of higher contrast, the crack front deforms more, hence propagates more in weaker regions and therefore, the mean toughness along the front is decreasing as the contrast increases. For small $\kappa_c \ll 1$, it remains equal to one, as linear theory predicts [1, 8].

Now for a given value of κ_c, $K_c^{\mathrm{eq}}/\overline{K}_c$ increases, whereas $\Delta a/a_m$ decreases with the heterogeneity wavenumber k, that is when the number of defects increases along the crack front. Physically, it is due to the fact that when k increases, the amplitude of the deformation has less space to develop, and so the front becomes more straight.

4 Conclusion

In this paper, we defined the effective toughness K_c^{eq} of a heterogeneous field of toughness as the stationary mean value of the SIF along the crack front. In order to focus on the effect of the large crack front deformations on this effective toughness, we studied numerically the case of a circular crack propagating in an axisymmetric infinite toughness map. This allows us to reach a stationary crack front shape regime in which Irwin's threshold is reached at each point of the front. In this



(a) Normalized mean toughness versus κ_c

(b) $\frac{\Delta a}{a_m}$ versus κ_c

Figure 3: Influence of mapping parameter on the stationary regime

regime, we find that the SIF K_m averaged along the front reaches a plateau that is equal to the mean value of K_c along the crack front. Since the crack front deforms due the heterogeneities, this mean value is different from the mean value $\overline{K}_c$ of K_c in the whole plane. It depends on the crack front deformations, which themselves depend on the local toughness values. In the case studied here, the deformations are more important in the weak part of the toughness map so that K_c^{eq} is lower than $\overline{K}_c$, the ratio $K_c^{\text{eq}}/\overline{K}_c$ decreasing with increasing toughness heterogeneity or with decreasing the number of obstacles. The next step is to extend this study to the case of strong pinning with large crack front deformations. Defining the equivalent toughness from the macroscopic loading required to make the crack propagate, and not only from the local values of SIF along the front might then become crucial.

Abstract Compression is a loading mode that stabilizes microcrack propagation. Consequently, the weakest-link approach becomes inappropriate to account for size effects on compressive strength of brittle materials such as rocks, ice, or concrete. Instead, compressive failure is characterized by an apparent power law decay of the mean strength at small sizes but a non-vanishing strength towards large sizes, associated to an increasing variability towards small sizes. Here we show from a progressive damage model that compressive failure can be considered as a critical phase transition, with a correlation length diverging at failure. Specific scaling laws for the mean as well as the standard deviation of the strength ensue, which are in full agreement with the experimental observations.

Keywords compressive strength, size effect, critical transition, rocks

1. Introduction

The size effect on strength of materials is an old problem, already discussed by Leonardo da Vinci [1] and Edmé Mariotte [2] several centuries ago. The experimental tensile strength is generally orders of magnitude lower than expected from atomic scale calculations, decreases with increasing scale and is associated to a large scatter that also decreases with increasing scale. A statistical approach based on the presence of internal defects and on the weakest-link concept has been developed for structural materials a long time ago [3,4]. This weakest-link approach is based on the following assumptions: (i) defects do not interact with one another, (ii) failure of the whole system is dictated by the activation of the largest pre-existing flaw, and (iii) the material strength can be linked directly to the critical defect size. Assuming a power law distribution of defect size s, $P(s) \sim s^{-\alpha}$ (with generally $\alpha >> 3$), and following linear elastic fracture mechanics (LEFM) principles for which the activation of a flaw of size s occurs at a stress $\sigma_c \sim s^{-1/2}$, one gets extremal Weibull statistics for the strength σ_f, and the following scalings for the mean strength $\langle \sigma_f \rangle$ and the associated standard deviation $std(\sigma_f)$:

$$\langle \sigma_f \rangle(L) \sim std(\sigma_f)(L) \sim L^{-d/m} \quad (1)$$

where $m=2(\alpha-1)$ is Weibull's modulus and d the topological dimension [5]. Although based on strong assumptions, this approach has been successfully applied to the statistics of failure strength of structural materials under tension (e.g.[4,6]), with m in the range 6 to 25. Relation (1) implies a continuously decreasing average strength towards large scales, i.e. a vanishing strength for $L \to +\infty$, although this decrease can be rather shallow, owing to the large values of m often reported.

These assumptions are reasonable for materials with relatively weak disorder loaded under tension, but do not hold for heterogeneous materials with a broad distribution of initial disorder, or

for loading conditions that stabilizes crack propagation, such as compression. Nevertheless, it has been shown recently that the weakest link hypothesis remains essentially valid even in the presence of long-range elastic interactions in heterogeneous media [7]. We consider here a different problem, the case of compressive failure of brittle materials such as rocks, concrete, or ice; a loading mode that stabilizes microcrack propagation, making the assumptions of the weakest-link approach inappropriate.

2. Brittle compressive failure and associated size effects

Brittle compressive failure is a complex process, as the local tensile stresses at crack tips are counteracted by the far-field compressive stresses. Consequently, Griffith-like energy balance arguments, or related LEFM tools such as fracture toughness, cannot be developed in this case to describe the instability leading to terminal failure, thus making the weakest-link approach inoperative. Instead, compressive failure involves an initiation phase, elastic interactions and stress redistributions, as well as frictional sliding along rough surfaces. During the initiation phase, secondary cracks nucleate from the local tensile stresses generated by the frictional sliding along pre-existing defects such as grain boundaries, small joints, or microcracks [8,9]. The propagation of these mode I secondary cracks is however rapidly stopped by the far-field compression. Instead, such nucleation events locally soften the material and thus cause a redistribution of elastic stresses, which in turn can trigger other microcracking events. Then, in the course towards the failure, the linking of en echelon arrays of secondary cracks is considered to be at the onset of shear fault formation, from which the macroscopic instability is thought to result [9]. This process is characterized by a progressive localization of microfracturing and deformation along a fault [10]. From this qualitative description, one sees that all the assumptions of the weakest-link theory listed above are inappropriate.

When the compressive strength of brittle materials is measured from laboratory tests over a limited scale range (generally between ~ 10^{-2} m and ~ 10^{-1} m), either non-significant [11,12] or limited (e.g. [13]) size effects are reported on $\langle\sigma_f\rangle$, whereas, when reported, the associated variance is relatively large and increases towards small scales [11]. Consequently, empirical or theoretical size effect formulations are hardly constrained by these results. Some studies were performed several decades ago over a much larger scale range (~ 10^{-2} m to few m), combining laboratory experiments and in-situ tests [14,15,16]. All of them reported a significant decrease of $\langle\sigma_f\rangle$ at small scales, which can be tentatively and empirically fitted as a power law decrease $\langle\sigma_f\rangle(L)\sim L^{-\beta}$ [16], but also a saturation of this decay towards large scales which is not explained by the weakest link approach. Note that these results were obtained for natural rock samples that did not contain a pre-existing fault or joint coming through the entire sample. Indeed, in this latter case, one may expect that the flaw size dependency on sample size and the reactivation of this flaw would lead to a power law decrease of $\langle\sigma_f\rangle$ with L, with $\beta\approx1/2$ and without saturation at large sizes [17].

So far, there is no clear explanation for this non-vanishing compressive strength at large sizes in the literature. Instead, empirical [16,18] or more theoretical formulations (based on stored strain energy caused by buckling [5]) of size effects on compressive strength of brittle materials generally

ignore such asymptotic behaviour. Following observations at small sizes, all these formulations share a common power law scaling $\langle\sigma_f\rangle(L)\sim L^{-\beta}$, with β varying from very small values [13] (i.e. almost no size effect), to values between 1/2 and 1. The weakest-link concept has been sometimes put forth to explain this scaling for small β values [13], although it is clear from above that this approach is irrelevant in case of compressive failure.

In what follows, we propose an entirely different approach, based on the mapping of brittle compressive failure on a critical phase transition. Using a numerical progressive damage model, we demonstrate the relevance of this mapping, and show that it implies a formulation of size effects on strength which explains (i) the power law-like decay of the mean strength at small sizes, (ii) a non-vanishing strength for $L\rightarrow+\infty$, and (iii) an increasing variability towards small sizes.

3. A model of progressive damage

The model, described in more details elsewhere [19,20], considers a continuous 2D elastic material (Hooke's law) under plane stress, with progressive local damage. Damage is represented by a reduction of the isotropic elastic modulus Y_i of the element i, $Y_i(n+1)=Y_i(n)d_0$, with d_0= 0.9, each time the stress state on that element exceeds a given threshold. This elastic softening simulates an increase in microcrack density at the element scale [21] as supported by experiments [22]. The stress field is recalculated each time a damage event occurs by solving the equation of static equilibrium using a finite element scheme. As the result of elastic interactions, the stress redistribution following a damage event can trigger an avalanche of damage, which stops when the damage threshold is no longer fulfilled by any element.

The Coulomb criterion, $\tau=\mu\sigma_N+C$, of wide applicability for brittle materials under compressive stress states [23], defines the damage threshold. τ and σ_N are respectively the shear and normal stress on the element (sign convention positive in compression), μ is an internal friction coefficient identical for all elements, whereas quenched disorder is introduced through the cohesion C randomly drawn from a uniform distribution ($0.2\times10^{-3}Y_0\leq C\leq 10^{-3}Y_0$). We use μ = 0.7, a common value for most geomaterials [23]. This envelope is completed by a truncation in tension in the Mohr's plane, i.e. the element is damaged if σ_N= $-2.10^{-3}\times Y_0$. The simulations start with undamaged material ($Y_i = Y_0$ = const) and are performed on rectangular meshes of randomly oriented triangular elements. Uniaxial compression is applied by increasing the vertical displacement of the upper boundary (strain-driven loading), while left and right boundaries can deform freely.

Series of simulations with meshes of linear size L varying from 8 to 128, composed of N=4L(L-1) triangular elements, were performed with the following number of independent simulations: 5×10^4 for L=8, 3×10^4 for L=16, 5×10^3 for L=32, 10^3 for L=64, and 100 for L=128.

It was shown previously that this model remarkably well reproduces both the macroscopic (strain softening before failure, large stress drop at failure) and microscopic (progressive localization of damage towards the failure along an inclined shear fault, increasing rate of damage avalanches,..) features of compressive failure [19,20]. In a recent work [20,24], we have shown from this modeling framework that brittle compressive failure can be considered as a critical phase

transition: (i) the size of the largest damage cluster as well as of the largest damage avalanche diverge at peak load, which just precedes failure, and (ii) the divergence of a correlation length ξ at failure can be identified either from a spatial correlation analysis of damage events, or from a coarse-graining analysis of the strain-rate field. This divergence takes the form $\xi \sim \Delta^{-1/\nu}$, where $\Delta = \frac{\epsilon_{mf} - \epsilon_m}{\epsilon_{mf}}$ is the control parameter, ϵ_m the macroscopic (applied) strain, ϵ_{mf} the corresponding value at peak load (failure), and ν=1.0±0.1 a critical exponent.

If this interpretation is correct, ν is a finite-size exponent and one may expect and the following size effect on strength, from a mapping of this critical transition to the depinning transition of an elastic manifold [25,26]:

$$std(\sigma_f)(L) \sim L^{-\frac{1}{\nu}} \tag{2a}$$

$$\langle \sigma_f \rangle (L) = A\, L^{-\frac{1}{\nu}} + \sigma_\infty \tag{2b}$$

where A is a constant and σ_∞ a non-vanishing asymptotic value of the strength for $L \to +\infty$.

4. Results and conclusion

Figure 1 shows the standard deviation of the compressive strength in the model, defined as the maximal macroscopic stress in the direction of loading, as a function of system size. The power law scaling is in full agreement with equation (2a), however with a corresponding finite-size scaling exponent ν=1.47 larger than the value expected from the divergence of the correlation length at failure.

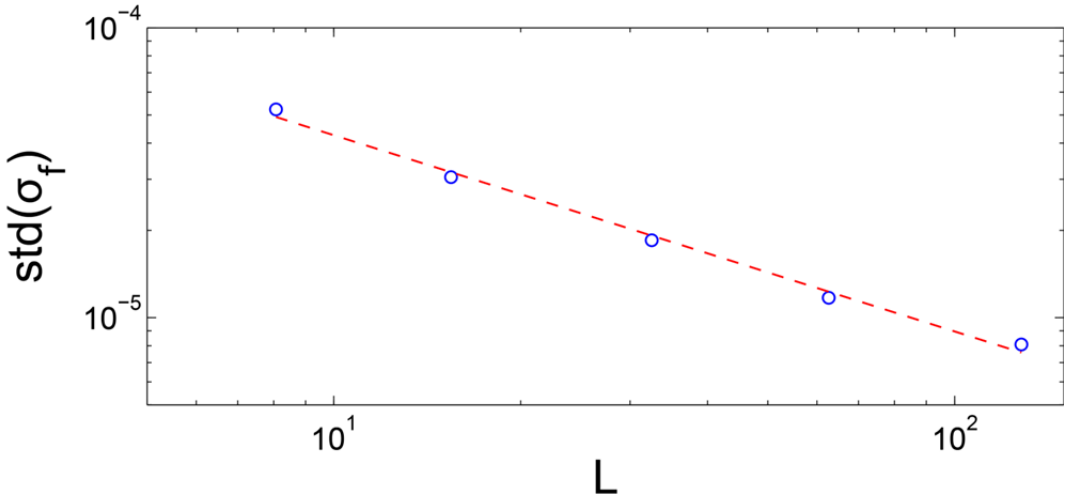

Figure 1. Progressive damage model: Evolution of the standard deviation of the compressive strength, $std(\sigma_f)$, in units of Y_0, as a function of system size L. The red dashed line shows a power law scaling with a exponent of -0.68, corresponding to a finite-size exponent of ν=1.47, in agreement with relation (2a).

This value of ν can be used to test the relevance of equation (2b) to describe the scale dependence of the mean strength. Figure 2 demonstrates the validity of this scaling and the existence of a

non-vanishing strength for $L \to +\infty$.

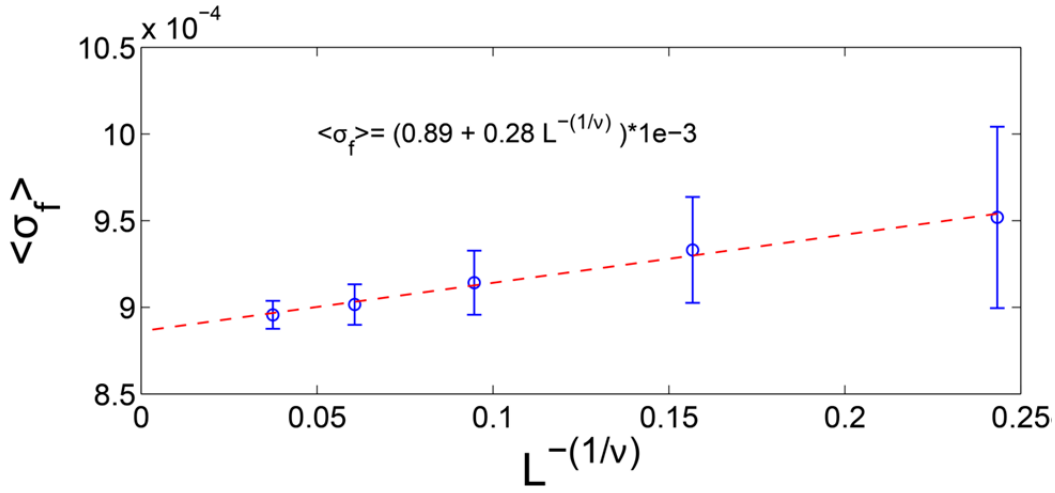

Figure 2. Progressive damage model: Mean compressive strength $\langle \sigma_f \rangle$ as a function of $L^{-\frac{1}{\nu}}$, where L is the system size and ν=1.47 is obtained from Figure 1. The red dashed line corresponds to equation (2b) with an asymptotic strength σ_∞=8.9 $10^{-4}\times$ Y_0.

Figure 3 shows the distributions of compressive strength at various scales in a normal probability plot. The collapse along a straight line (i) demonstrates that compressive strengths are distributed according to a Gaussian PDF, and (ii) confirms the power law scaling of the standard deviation (equation (2a)). Compressive strengths are therefore clearly not distributed according to a Weibull distribution (the same data are not aligned and do not collapse in a Weibull probability plot). This is a further confirmation of the irrelevance of the weakest-link concept in compressive failure.

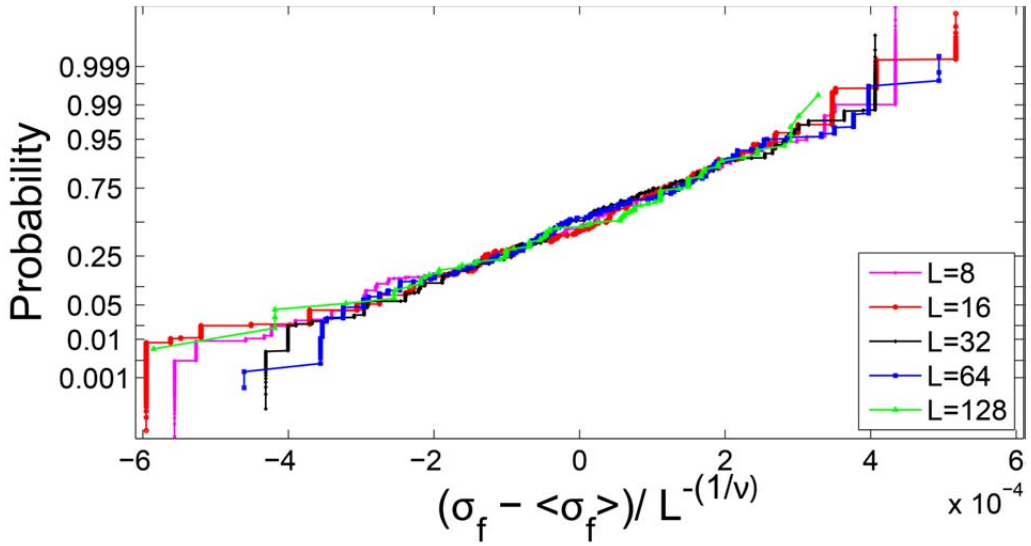

Figure 2. Normal probability plot of the distributions of strength at various scales. Albeit minute deviations, the plot shows a collapsed straight line, as expected for a Gaussian distribution. The collapse also confirms the power law scaling of the standard deviation (equation (2a)).

In conclusion, we have shown that the weakest-link concept is irrelevant for brittle failure under compressive stress states. Instead, compressive failure is a complex process characterized by the divergence of a correlation length at peak (failure) load. This argues for an interpretation of

compressive failure as a critical phase transition. From this interpretation, and mapping this transition to the well-described depinning transition, we propose specific scaling laws for the mean compressive strength as well as the associated variability (equation (2)). This scaling implies (i) an apparent power law decay of the mean strength at small sizes, (ii) a non-vanishing strength for $L \to +\infty$, and (iii) an increasing variability towards small sizes; these three aspects being in full agreement with experimental data (see section 2). In addition, modelling results show that compressive strengths are normally distributed.

This has important consequences including the fact that brittle compressive strengths are expected to be less scattered (normally distributed) than tensile strengths (extremal Weibull statistics), and a reasonable estimate of large scale compressive strength can be obtained from laboratory tests if the obtained experimental size effect is limited.

Abstract Subcritical fracture driven by thermally activated crack nucleation is studied in the framework of a fiber bundle model. Based on analytic calculations and computer simulations, we show that, in the presence of stress inhomogeneity thermally activated cracking results in an anomalous size effect, i.e., the average lifetime of the system decreases as a power-law of the system size. We propose a modified Arrhenius law which provides a comprehensive description of the load, temperature, and size dependence of the lifetime of the system. On the microscopic level, thermal fluctuations trigger bursts of breaking events which proved to have a power-law size distribution. The waiting times between consecutive bursts are also power-law distributed with an exponent switching between 1 and 2 as the load and temperature are varied. Analyzing the structural entropy and the location of consecutive bursts, we show that, in the presence of stress concentration, the acceleration of the rupture process close to failure is the consequence of damage localization.

Keywords Subcritical fracture, Fiber bundle model

1. Introduction

Sub-critical rupture, occurring under a constant load below the fracture strength of materials, is of fundamental importance in a wide range of physical, biological, and geological systems. Depending on the type of materials, creep rupture can have a wide variety of microscopic origins from the existence of frictional interfaces through the viscoelasticity of the constituents, to thermally activated aging processes. Recent experimental and theoretical investigations revealed the high importance of thermally activated micro-crack nucleation in creep phenomena with consequences reaching even to geological scales [1–7]. Under creep loading failure often occurs as a sudden unexpected event following a short acceleration period which addresses safety problems for e.g. components of engineering constructions. Additionally, creep rupture underlies natural catastrophes such as landslides, stone and snow avalanches and it is also involved in the emergence of earthquakes.

On the macroscopic scale the rupture process is characterized by the strain-time diagram and by the lifetime of the system, which both have a complex dependence on the external load and on the temperature. In spite of the smooth macroscopic evolution, thermally activated breakdown proceeds in bursts on the microscopic scale. They may be exploited to gain information about the approach of the system to failure. In the present paper we investigate this problem in the framework of a fiber bundle model of thermally activated breakdown. In order to reveal the effect of the range of load redistribution we carry out computer simulations considering strongly localized stress redistribution after failure events and compare the outcomes to the analytic results obtained in the mean field limit [10–12].

2. Model

Our approach is based on the fiber bundle model (FBM), which has proven very successful during

the past decades for the investigation of fracture phenomena [1–15]. In the model we consider N parallel fibers having a brittle response with identical Young modulus E. The bundle is subject to a constant external stress σ parallel to the fibers' direction. During the past decades several ways have been proposed to introduce time dependent rupture in stochastic fracture models. Following the pioneering works of Coleman on time dependent FBM [5], the models were further extended to a broad class of time dependent damage accumulation laws and fiber strength by Phoenix and Curtin [6–8]. In our work we apply the approach of Guarino et al. [1–4], i.e. we assume that the local load σ_i of fibers has time-dependent fluctuations $\xi_i(t)$ due to the presence of thermal noise so that the actual load of fiber i at time t reads as

$$\sigma_i(t) = \sigma_i^0(t) + \xi_i(t) . \tag{1}$$

Here $\sigma_i^0(t)$ denotes the deterministic part of the stress, i.e., the local stress arising due to the external load and to load transfer following breaking events. The fibers have a finite strength characterized by a failure threshold σ_{th}^i, which is, in general, a random variable. A fiber fails during the time evolution of the bundle when the total load on it $\sigma_i(t)$ exceeds the respective threshold value σ_{th}^i. For simplicity, we assume that the system consists of homogeneous fibers, i.e. all the breaking thresholds are the same $\sigma_{th}^i = \sigma_{th}$, $i = 1,\mathrm{K}\,,N$, where $\sigma_{th} = 1$ is set. The assumption of homogeneity implies that there is no quenched disorder in the system. Thermally induced stress fluctuations $\xi(t)$ have a Gaussian distribution with zero mean and a variance controlled by the temperature T of the system

$$p(\xi) = \frac{1}{\sqrt{2\pi T}} \exp\left(-\frac{\xi^2}{2T} \right), \tag{2}$$

from which the complementary cumulative distribution follows as $P(\xi) = \int_{\xi}^{+\infty} p(x)dx$. The strength of thermal fluctuations is controlled by the value of T which can be scaled to the absolute temperature of the system. After fiber breakings, the load of broken fibers has to be redistributed over the remaining intact ones. In order to understand the effect of the range of load transfer on the process of thermally enhanced creep, we consider two limiting cases for the load redistribution: in the case of equal load sharing (ELS) all surviving fibers overtake equal fraction of the load. ELS ensures that the stress distribution remains homogenous in the bundle until the end of time evolution which also facilitates to perform analytical calculations. To study the effect of stress inhomogeneity on thermally activated breakdown, in our model the fibers are organized on a square lattice of size $L \times L$ and localized load sharing (LLS) is considered: the load of broken fibers is redistributed over their nearest intact neighbors, giving rise to high stress concentration around failed regions. Since the LLS case cannot be investigated by analytical means, computer simulations were carried out varying the load σ, temperature T, and the lattice size L in broad ranges.

3. Results and Discussions

Subjecting the bundle to a constant external load σ, two competing physical mechanisms contribute to the failure of fibers: When the load is small enough even a single fiber can sustain the entire load and the load increments arising in the vicinity of failed fibers are not sufficient to trigger further breakings. Hence, in this load regime, the failure process is dominated by the thermal fluctuations and there is practically no difference between ELS and LLS calculations since the range of interaction is irrelevant. However, at high load values $\sigma \to \sigma_{th}$, the load redistributions give rise to considerable increments of the local load on intact fibers leading to additional breakings. In the initial state of the system all the fibers have the same load $\sigma_i^0 = \sigma$, $i = 1,\mathrm{K}\,,N$. When a fiber breaks

due to thermal noise $\sigma_i^0 + \xi_i \geq \sigma_{th}$, the deterministic part of the load σ_i^0 is transferred to its four intact neighbors resulting in the increment $\Delta\sigma^0 = \sigma/4$. If the updated load exceeds the breaking threshold $5\sigma/4 > \sigma_{th}$ the fibers break again transferring the load further to their intact neighbors. Once this breaking sequence starts, removing all four neighbors of the initial one, it does not stop until all fibers break leading to macroscopic fracture. It follows that due to the localized stress transfer, the system has a critical load $\sigma_c = 4\sigma_{th}/5$ above which even a single fiber breaking triggers the immediate collapse [10–12].

3.1. Scaling behavior of lifetime

The most important macroscopic characteristic quantity of the system is the average lifetime $\langle t_f \rangle$ which has a finite value even at zero external stress $\sigma = 0$ in the model if the temperature is finite $T > 0$. Under the assumption of equal load sharing it has been shown analytically in FBMs with a fixed breaking threshold σ_{th} that $\langle t_f \rangle$ follows the Arrhenius law $\langle t_f \rangle \propto \left(\sqrt{2\pi T}/\sigma\right)\exp\left((\sigma_{th}-\sigma)^2/2T\right)$ without any dependence on the system size N [1,2].

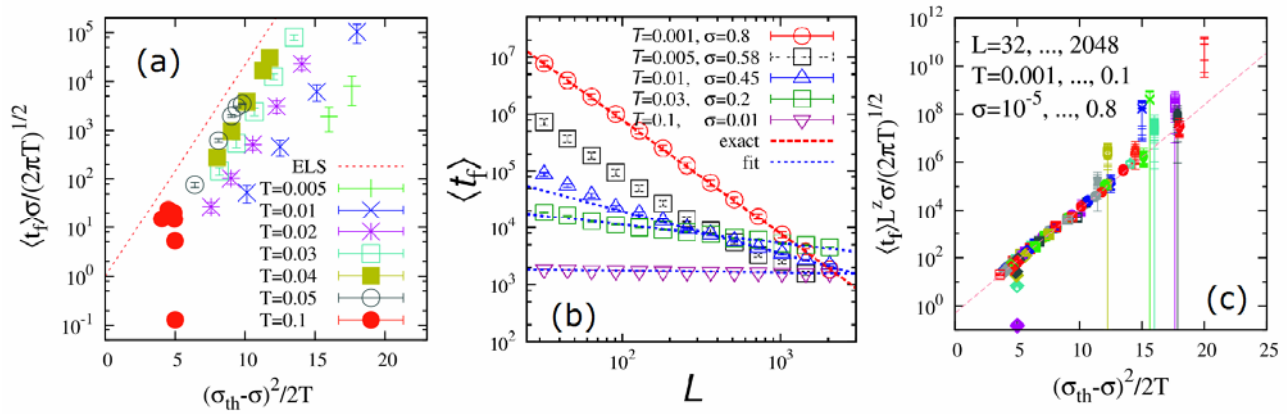

Figure 1. (a) Scaling plot of lifetime $\langle t_f \rangle$ obtained at different load σ and temperature T values by LLS simulations on a square lattice of size $L = 1024$. No data collapse is obtained. The simple Arrhenius law is indicated by the straight line of ELS. (b) Size scaling of lifetime. When stress concentration is dominated, power-law dependence is obtained with a high precision. Note that $\sigma_c = 0.8$ in the model. (c) Correcting the Arrhenius scaling form with the size dependence of lifetime a high quality data collapse is obtained.

Figure 1(a) presents the scaling plot of lifetime obtained by our computer simulations with the LLS FBM at the system size $L = 1024$ varying the load σ and the temperature T. No data collapse is obtained in the figure, which implies that the simple Arrhenius law does not hold when stress concentrations are present [10]. Our analytical and numerical calculations revealed that the interplay of stress concentrations and annealed disorder results in an anomalous size effect of the lifetime of the system, which is responsible for the discrepancy observed above [10]. In order to clarify the size scaling of the lifetime we carried out computer simulations varying the system size in a broad range $L = 32 - 2048$. These simulations showed that at any finite load value σ the average lifetime of the system decreases as a power law of the lattice size $\langle t_f \rangle \propto L^{-z(T,\sigma)}$. See Fig. 1(b). For the limiting cases of low ($\sigma \to 0$) and high ($\sigma \to \sigma_c$) loads the exponent z can be obtained analytically to be 0 and 2, respectively. Numerical calculations showed that varying the temperature

and external load the scaling exponent z takes values between the two limits $0 \le z(T,\sigma) \le 2$ [10]. We propose a modified form of the Arrhenius law which takes into account the size scaling of lifetime

$$\langle t_f \rangle \cong \frac{L^{-z(T,\sigma)}}{2} \frac{\sqrt{2\pi T}}{\sigma} \exp\left(\frac{(\sigma_{th} - \sigma)^2}{2T} \right). \tag{3}$$

Figure 1(c) demonstrates that the modified Arrhenius law provides an excellent scaling of the numerical data obtained by computer simulations of LLS FBM varying the system size L, the temperature T, and the external load σ in the ranges $L = 32 - 2048$, $T = 0.001 - 0.1$, and $\sigma = 10^{-5} - 0.8$, respectively.

3.2. Microscopic time evolution

On the microscopic level, the fibers primarily break due to thermal fluctuations when their actual load exceeds the fixed breaking threshold $\sigma_i(t) > \sigma_{th}$. Of course, depending on the temperature in a given time step more than one fiber can break at the same time. The load of broken fibers is then redistributed over the intact ones according to the selected load sharing rule. The load increments on intact fibers can trigger additional breakings and eventually generate an entire breaking burst. Hence, irrespective of the range of load sharing, the failure of the bundle proceeds in bursts which are separated by silent periods with no breakings. The size of the burst Δ is simply the number of fibers breaking in a correlated trail of failure events, while the waiting time t_w is defined as the number of iteration steps without breaking events between two consecutive avalanches.

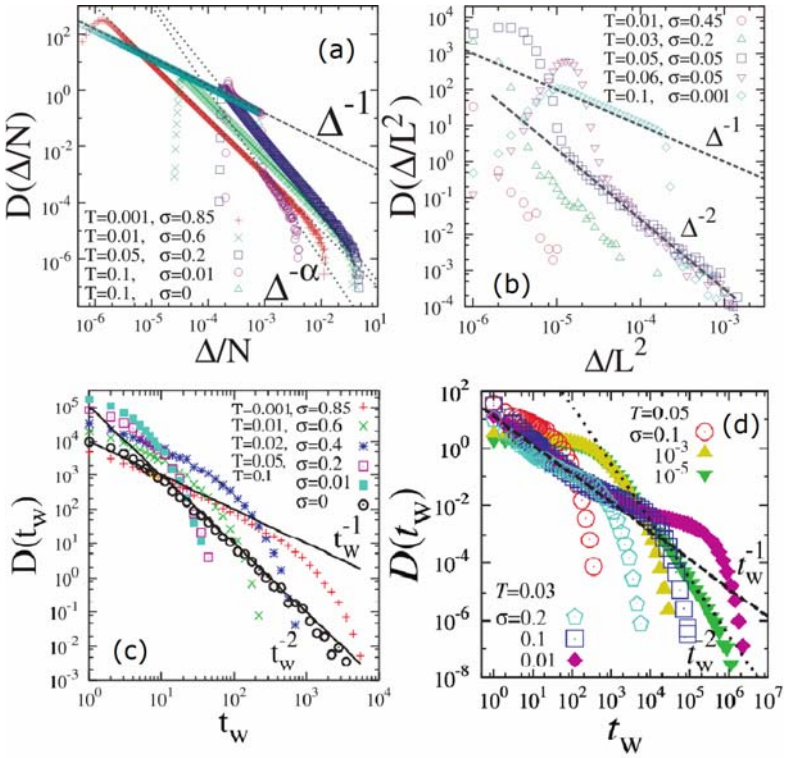

Figure 2. Size distribution of bursts for ELS (a) and LLS (b), and that of waiting time for ELS (c) and LLS (d). Power law functional forms are obtained followed by an exponential cutoff.

Bursts of breaking events generate acoustic waves so that they are responsible for the crackling noise accompanying the process of creep rupture [3]. In order to characterize the statistics of crackling events of our model, we analyzed the probability distribution of burst sizes $P(\Delta)$ and

waiting times $P(t_w)$. For the ELS case the burst size distribution $P(\Delta)$ proved to have a power law functional form $P(\Delta) \propto \Delta^{-\alpha}$ with an exponential cutoff. See Fig. 2(a). The value of the exponent has a complex dependence on the load and temperature [10]. For localized load sharing computer simulations revealed that $P(\Delta)$ has a Gaussian form for small bursts followed by a power law regime over a broad range. See Fig. 2(b). It is important to emphasize that the power law exponent α of the LLS case does not vary continuously with the model parameters. Instead, it suddenly switches from $\alpha = 1$ to $\alpha = 2$ when the external load approaches the critical value $\sigma \to \sigma_c$, which is accompanied by the shrinking of the Gaussian regime. In the vicinity of σ_c, the system becomes very sensitive to the thermal fluctuations and cannot tolerate large bursts, which is expressed by the higher value of the exponent α (Figs. 2(a) and (b)). This is an important unique feature of thermally driven creep rupture; when quenched disorder dominates the rupture process the opposite effect occurs, i.e. the burst exponent decreases when approaching catastrophic failure [13–15]. The probability distribution of waiting times $P(t_w)$ shows the same qualitative behavior as the distribution of burst sizes, i.e. $P(t_w)$ has a power law functional form $P(t_w) \propto t_w^{-\beta}$ with an exponential cutoff, where the value of the exponent β depends both on the load and on the temperature [12]. See Figs. (c) and (d)

3.2. Acceleration due to localization

The overall time evolution of the rupture process can be characterized by studying the average waiting time $\langle t_w \rangle$ between consecutive bursts as a function of the fraction of broken fibers ϕ, where $0 \le \phi \le 1$ holds. For ELS $\langle t_w \rangle(\phi)$ can be cast into a closed analytical form, while for LLS we determined it numerically [12]. Calculations showed that at zero load the breaking process continuously slows down in such a way that the average waiting time has a power law divergence $\langle t_w \rangle \propto (1-\phi)^{-1}$ when approaching macroscopic failure $\phi \to 1$. It can be observed in Fig. 3(a) that for finite load values $\sigma > 0$ the slow-down is followed by acceleration such that the accelerating regime starts earlier when the load increases. It is interesting to note that when the load is high enough, acceleration is obtained right from the beginning of the process, i.e. in this parameter regime the rupture process continuously accelerates towards failure [12]. The most remarkable feature of the results is that in the case localized load sharing the qualitative behavior remains the same, however, the acceleration sets on earlier (see Fig. 3(a)).

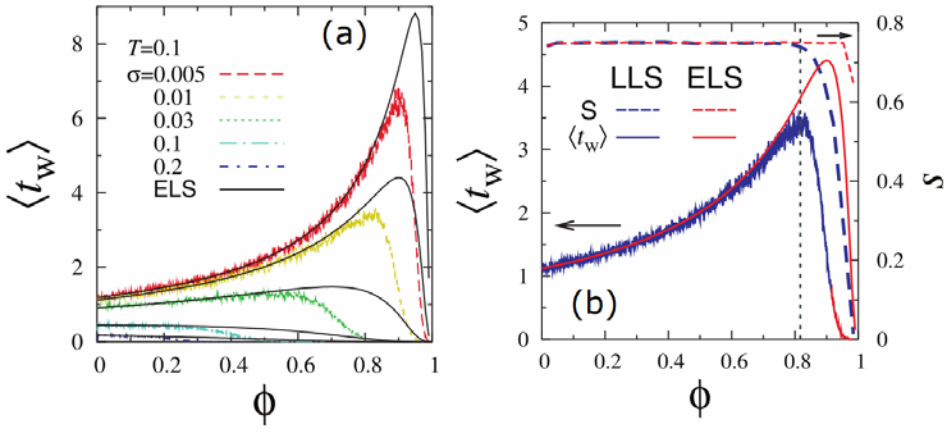

Figure 3. (a) Average waiting time for ELS and LLS as function of the fraction of broken fibers ϕ. (b) Comparison of the curves of average waiting time and entropy as a function of ϕ. For LLS the

entropy starts to decrease when the acceleration sets on.

In order to understand the background of early acceleration for LLS systems, Figs. 4(a)–(d) presents snapshots of the time evolution of an LLS bundle. Two regimes can easily be distinguished: at the beginning of the process cracks occur randomly all over the bundle (Fig. 4(a)). As time elapses more cracks nucleate and some of the previous cracks extend their size (Fig. 4(b)). Along the perimeter of growing cracks large stress is concentrated on the intact fibers, which increases the probability of further crack growth. As a consequence, one of the cracks gets selected and starts to grow rapidly, i.e. all bursts get localized along the front of a growing crack which then accelerates the process and leads to global failure (Figs. 4(c) and (d)) [12]. To quantify the degree of localization we introduced a so-called structural entropy S, which measures how scattered the new breaking events are in the bundle [12]. Large value of the entropy $S \to 1$ implies random cracking, while the small one $S \to 0$ marks the onset of localization. It can be observed in Fig. 3(b) that in the ELS case where there is no stress concentration and spatial correlation in the system the entropy is always high $S \approx 0.8$, even during the acceleration phase.

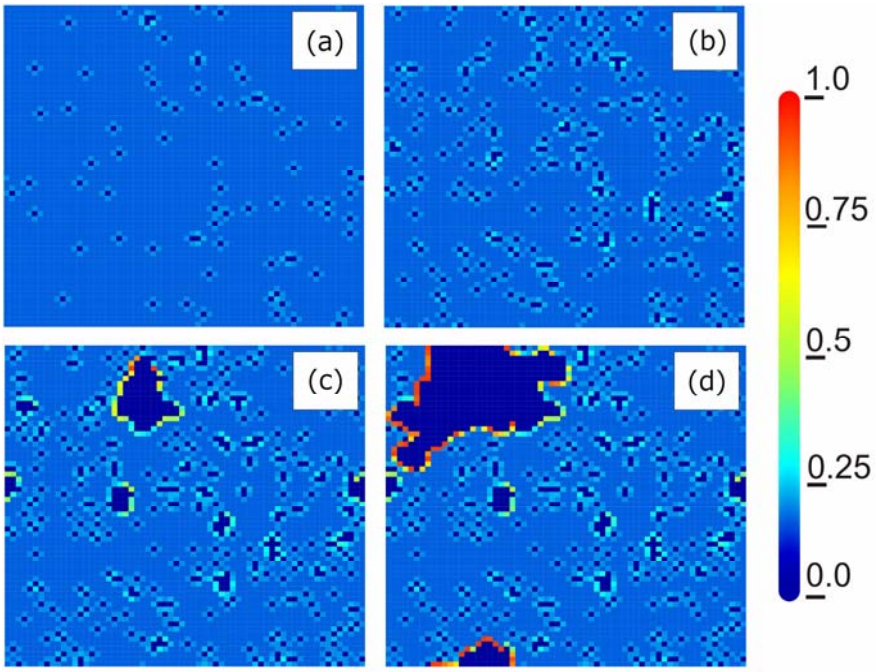

Figure 4. Snapshots of an evolving system, where fibers are colored according to their load. Deep blue represents zero load hence indicating cracks in the system.

On the contrary, in the presence of stress concentration, the entropy is high during the slow-down phase, however, it rapidly decreases to zero as soon as acceleration sets on (see Fig. 3(b)). Our results give a quantitative proof that the acceleration towards failure occurs due to the spatial localization of breaking events to the front of a growing crack [12].

4. Conclusions

Based on a fiber bundle model we showed that stress inhomogeneity play a crucial role in the process of thermally activated subcritical rupture giving rise to a broad spectrum of novel behaviors. Stress concentrations, arising in the vicinity of failed regions of the material, make the system more sensitive to thermal fluctuations. As a consequence, an astonishing size effect emerges where the average time-to-failure of the model system decreases as a power law of the system size. The size scaling exponent depends both on the temperature and on the external load. We proposed a

modified form of the Arrhenius law of lifetime which provides a comprehensive description of thermally activated breakdown phenomena [10–12].

On the micro-level, thermally driven breakdown proceeds in bursts of breakings which are separated by waiting times. The size distribution of bursts and the distribution of waiting times between consecutive events proved to have power law functional forms followed by an exponential cutoff. The power law exponents have a complex dependence on the load and temperature of the system [10,12]. To characterize the overall time evolution of the system, we analyzed the average waiting time between bursts as a function of the fraction of broken fibers. Calculations showed that the thermally induced creep process has two phases: at low loads and high temperatures the process slows down after the load is set, which is then followed by an accelerating period. However, when the load is high enough the system continuously accelerates towards failure. We demonstrated that in the case of localized load sharing, the stress concentration around cracks leads to spatial correlation of breaking events and to an enhanced breaking probability which in turn is responsible for the early acceleration [10–12].

In order to quantify the effect of spatial correlation on the time evolution of the creep rupture process, we evaluated the structural entropy of avalanches and their consecutive positioning. As a very important outcome, our calculations revealed that the decreasing extension and the spatial localization of avalanches to a bounded region of the specimen are responsible for the acceleration towards macroscopic failure. Final failure is driven by a single growing crack which becomes unstable as the avalanches localize to its perimeter [12].

Abstract The fracture dynamics of heterogeneous materials is a rich subject with obvious practical interests, especially the subcritical fracture, where a material breaks through a series of successive, non-correlated and localized fracture events until the arriving to a critical situation where the whole material fails. Paper has been a common model material to study this phenomenon, and high-resolution and high-speed visualization are the usual ways to follow the dynamics of the process. However, visualization presents many limitations, especially for long experiences. That is one of the reasons why we are coupling acoustics to the measurements in an attempt to establish it as the main source of information. Acoustics presents a much better temporal resolution and captures a higher number of events than visualization. By thresholding the amplitude of the acoustic signal, it is possible to get similar activities in both measurements. The waiting times between events and the energy of the events are both distributed in power laws with exponents which are similar for the two different kind of measurements (visualization and acoustics), corroborating that the recorded acoustic data corresponds indeed to the fracture process.

1. Introduction

Industrial designs evolve continuously toward thinner and lighter, however stronger structures, many of them submitted to a permanent stress. It is known that stresses intensify around a flaw in the material [1]; and even if the system resists at a particular instant, a micro-crack can start growing, in an intermittent manner (the case of heterogeneous materials), until reaching a critical length where the whole system fails. This process, denominated *subcritical fracture*, has captured the attention of scientist and engineers for more than half a century, and the progresses in experimental results are quite related to the technological advances in the period. Already in the sixties, some models based on thermally activated rupture were proposed [2, 3], supported by measurements of the lifetime of the sample as a function of the global stress and the temperature [2, 3]. In the nineties, during the early stages of the digital era, acoustics allowed the statistical analysis of the burst-like fracture events provoked by the intermittent growing of a crack [4, 5]. Power law distributions of amplitude and waiting time between fracture events were often interpreted as a signature of a "self-organized critical" process [6, 7]. In the latest years, high-speed and high-resolution video acquisition have played a major role in the study of the subcritical fracture of diverse materials [8-10]. Paper presents several good properties that have set it as a common model material: two-dimensionality, high degree of heterogeneity and variability, quasi-brittle character and a very low cost. Many different results have been obtained with direct observations in paper [8, 11, 12]. However, several issues seem favoring the implementation of acoustics measurements. Beyond lab limits, most objects are three-dimensional and non-transparent, thus analyzing their interior belongs mainly to the acoustics' domain. The earth's interior is one of their most relevant examples, and the statistical similitude between earthquakes and subcritical fracture [13] is an invitation to use the same source of information, i.e., acoustics. Also, in high-speed cameras there is a compromise between spatial resolution and frame rate, as well as size of the image vs. number of images. Having two characteristic frequencies in our study: one low, where a priori there is not much activity, and another very high, taking place during a local fracture event, direct observation may result in a lost of information. We are coupling acoustic to the measurements in an attempt to

establish it as the main source of information. The main aim of this paper is to verify the agreement between acoustics and direct observation. By thresholding the amplitude of the acoustic signal, we get a very similar temporal activity in both measurements. The waiting times between events and the energy of the events are both distributed in power laws with exponents which are similar for the two different kind of measurements (direct observation and acoustics), corroborating that the recorded acoustic data corresponds indeed to the fracture process. Earlier studies have used acoustic as the main source of information to analyse a fracture process in paper [14-15]; however, as far as we know, this is the first report validating the results of the acoustic measurements through simultaneous direct observations.

We also discuss the advantages and challenges of the use of acoustics in our experiment. Some experiments have been done to study the acoustic emission of fracturing paper [14-15], but as far as we know this is the first time that acoustics are compared to another observation method-direct visualization of fracture propagation.

2. Experimental procedure

We use fax paper samples from *Alrey* having a thickness of 50 μm and effective dimensions 21 cm × 4 cm, being fixed along the longer sides and free in the perpendicular direction. An initial crack of length l_0 is prepared at one free side of the sample, both in a parallel direction and equidistant from the fixed borders. Experiments are performed by applying a constant force F perpendicularly to the direction of the initial crack. By adjusting l_0 = 4.75 cm and F = 200 N, the crack grows reaching a critical length, l_c ~ 8 cm, approximately between 10 minutes and 30 minutes after the application of the force. The critical length l_c separates the slow dynamics from the quasi-instantaneous rupture. Two piezoelectric transducers of diameter 2.3 mm (*Valpey Fisher VP-1.5*) are placed in contact with the paper at 5 cm and 9 cm from the free side containing the initial crack and at 1 cm from the fixed border (which also corresponds to a 1 cm distance to the direction of the initial crack). An ultrasonic gel guarantees a good contact between the sensor and the sheet of paper. The acoustic signals are amplified 64 db and recorded continuously during the whole experience by a *NI USB-6366* card at 2 MHz. A high-speed camera (*Photron FASTCAM SA4*) takes images in a rectangular area containing the advancing crack at a frequency of 10 Hz and a spatial resolution of 100 μm / pixel. All experiences have been performed under the same conditions. The temperature and relative humidity were 26.5 ± 1 °C and 45 ± 2% respectively. A scheme of the experimental setup with the crack and the position of the sensors is represented on figure 1.

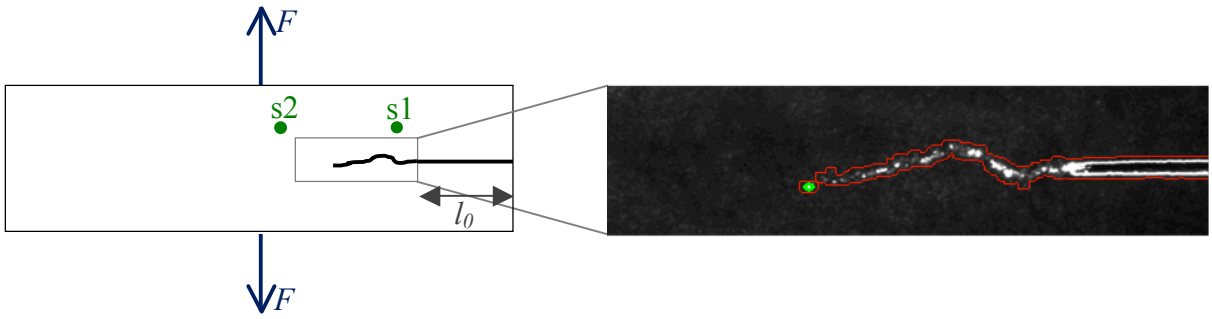

Figure 1. On the left, scheme of the experimental setup. l_0: initial crack length, s_l: projection of the crack length on the initial crack direction, F: applied force, s1 and s2: positions of the piezoelectric transducers. On the right, experimentally obtained image of the crack with the extracted crack contour (red line) and crack tip (green).

The amplitude of the acoustic signal depends on the contact between the transducer and the sheet of paper, which varies between different realizations. In order to compare events from different experiences, a calibration was performed. It consisted of the averaged response of each sensor to six localized rupture events produced on every sample (by piercing it with a computer controlled thin needle of 250 μm of diameter) before complete loading. Additional series of experiments were performed in order to study the attenuation of the acoustic waves in paper. 10 to 20 localized rupture events were induced on a sheet of paper submitted to a force of 200 N, but with no initial crack so to be sure that no uncontrolled rupture would occur. The events were made on a line parallel to the longer sides of the paper, in the same direction as the fracture in previous experiments. The acoustic signal was recorded by two sensors placed at 4 cm from each other.

2.1. Data Analysis

Images: crack contours are extracted using a digital image analysis routine. For each image the position of the crack tip is found (figure 1). Three variables are defined: s, the real length of the interface of the fracture created between two consecutive images; the size of the jump s_s, defined as the distance between the crack tip of two successive images, and s_l, defined as the projection of s on the initial direction of the crack.

Acoustics: The detection of acoustic events is made through the *spectral distance* calculation, which corresponds to the spectral distance between the recorded signal and the noise (the noise sample is recorded during the calibration, before the complete loading of the paper, so no cracks have occurred during it) over a temporal window of length w=100 μs. Spectral distances are usually calculated using the logarithms of the power spectra [16, 17], but we prefer using the power spectra directly so to obtain a distance that is directly proportional to the acoustic energy:

$$D(t) = \frac{1}{w}\int_{t-\frac{w}{2}}^{t+\frac{w}{2}} \langle S(t')\rangle - \langle \overline{N}\rangle \, dt' \qquad (1)$$

where $\langle S(t)\rangle$ is the mean value of the signal's power spectrum averaged over all the frequencies and $\langle \overline{N}\rangle$ the mean value of the noise's power spectrum averaged over time and frequency. Detecting acoustic events and determining their duration is done by thresholding the spectral distance. The energy of an event is calculated as the integral of the spectral distance over its duration. Thanks to the spectral distance the number of detected events is almost four times greater than by thresholding the raw data and we are able to detect events with slightly smaller energy.

3. Results

As the applied force is subcritical and the material heterogeneous, the initial crack propagates in an intermittent manner [8]: images show that the length of the fracture is constant for most of the time and increases by making fast discrete crack steps, denominated *jumps* or avalanches. The acoustic data shows discrete *bursts* with a finite duration. Each burst constitutes an acoustic event. First, we compared the number and occurrence times of jumps and acoustic events, without considering their energy value. For each experiment the number of acoustic events was significantly larger than the number of jumps, even when adjusting the acoustic time resolution to the images' frame rate. This is a clear indication that the acoustics is much more sensitive to crack propagation than the image analysis. Nevertheless, if we only consider acoustic events having an energy larger than a threshold value their number will decrease. By setting the threshold energy to an optimal value we can get the

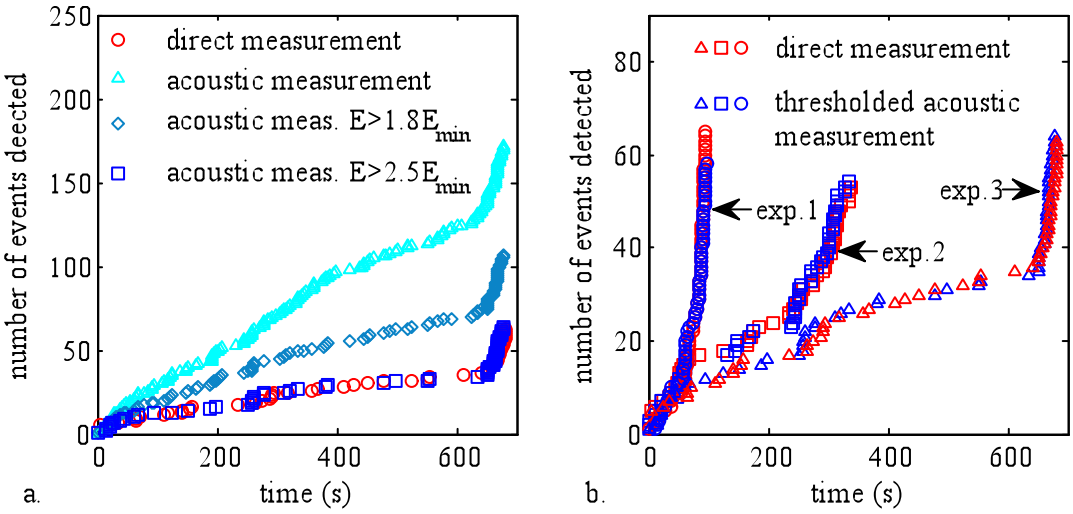

Figure 2. a. Activities obtained by direct observation (jumps) and acoustic monitoring for one experiment: acoustic monitoring results in much more events than direct observation. By considering only acoustic events with energy superior to a threshold value we get very similar activities for both methods. b. Comparison of activities obtained by direct observations and acoustic monitoring for three experiments.

same number of events for both methods. In this situation, time intervals with many acoustic events correspond to the ones with many jumps (figure 2). This global similarity between the two activities confirms the relationship between the propagation of the crack (jumps) and acoustic events. However, when considering the events' energy, the relationship between jumps and acoustics events is not as obvious as previously. Large jumps are not always associated to high acoustic energy and the temporal correlation between the two signals is very poor. The temporal correlation between the two signals is also very poor in the case of not considering the energy values. This can be a consequence of the combination of two facts: the low acquisition rate of the images (10 Hz) and the fact that there is a temporal shift between the rupture of the material (acoustic event) and the macroscopic opening of the fracture (jump). This lack of correlation makes it impossible to match jumps and acoustic events individually, but our data is suitable for statistical analysis: each experiment results in approximately 50 jumps and few hundreds to few thousands of acoustic events, providing enough data for such approach. Here we will study and compare the probability distributions of two different variables characterizing subcritical fracture: waiting times and energies.

Waiting Times: For subcritical fractures the time between two discrete events, referred to as the waiting time, follows power-law distributions [18-20]. Figure 3 shows the probability distributions of waiting times between the events for the jumps and the acoustic data. Both waiting times are power law distributed (with a slight cutoff for long waiting times). The distributions were fitted as power laws within the domains delimited by the vertical lines on the figures, and the exponent obtained are very similar: 1.1 and 1.0 for the jumps and acoustic waiting times respectively.

The distributions are represented on the same plot in figure 4. Since acoustic data acquisition has a much better time resolution, acoustic waiting times spread on a larger set of values. To compare the two distributions we can adjust the distributions' normalization coefficients. Figure 4.a shows that with well-chosen coefficients the distributions collapse. Another solution is ignoring acoustic waiting times smaller than the image frame rate (0.1 s). In this case the two distributions also match (figure 4.b). The similitude between the two probability distributions indicates that the acoustic activity and the detected propagation of the fracture are indeed issued from the same mechanism.

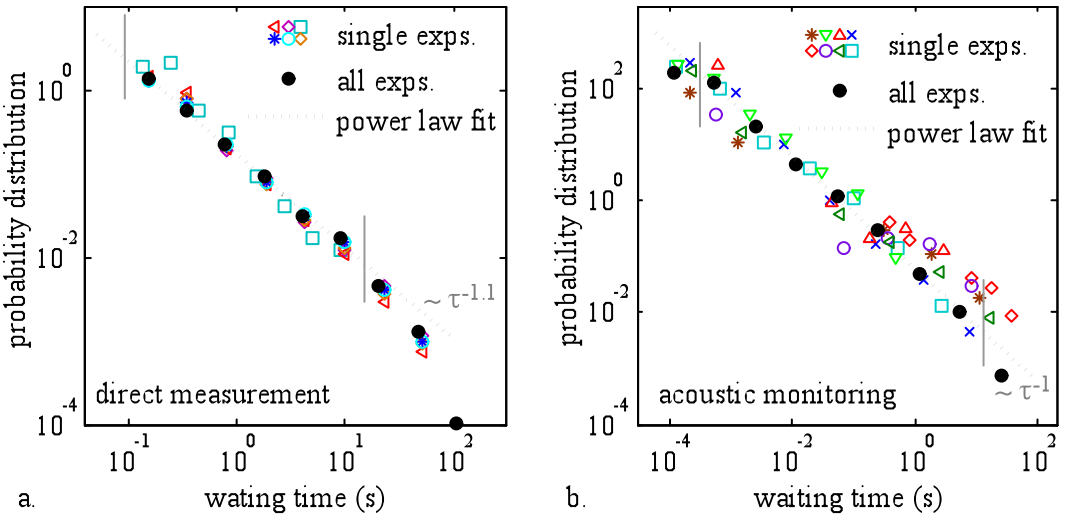

Figure 3. a. Distribution of waiting times determined by the direct observations (jumps). b. Distribution of waiting times determined by acoustic monitoring. Open symbols: waiting times of each experiment separately, solid symbols: waiting times of all the experiments, dotted line: a power law fit of the distribution of the waiting times of all experiments in a range limited by vertical lines.

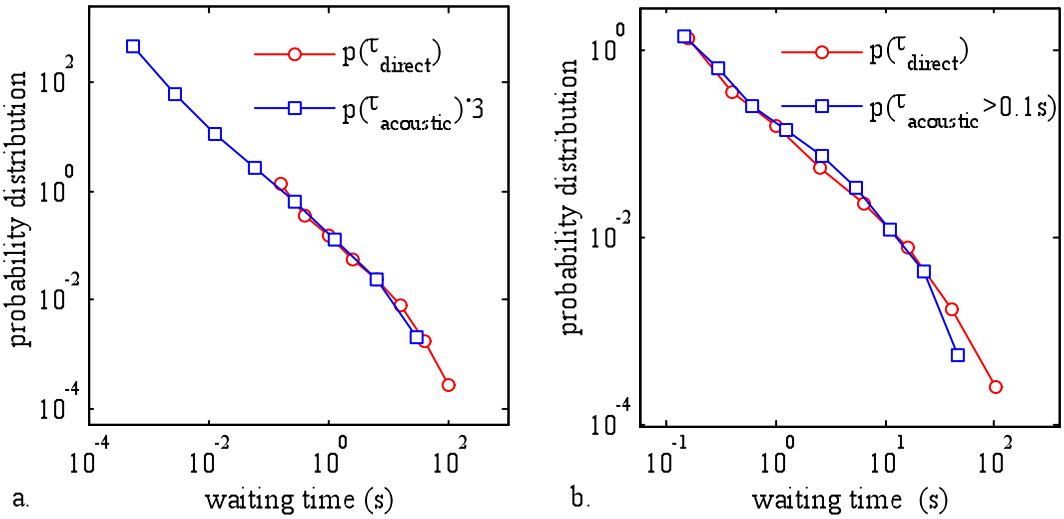

Figure 4. a. Distribution of waiting times of the jumps, obtained by direct observations (red circles) and distribution of waiting times obtained by acoustic monitoring multiplied by 3 (blue squares). b. Distribution of waiting times obtained by direct observations (red circles) and distribution of waiting times greater than the image frame fate (0.1 s) obtained by acoustic monitoring (blue squares).

Furthermore, some test showed that the acoustic waiting time distribution is not affected by thresholding the event's energy; and considering all the detected acoustic events, the same power law distribution is found. This result indicates that all the acoustic bursts correspond to fracture events.

Energies: in this two-dimensional system fracture energy scales as the fracture's length. Therefore, the normalized distribution of jump sizes is equal to the normalized distribution of jump energies. The probability distribution of s (the real crack length), s_s (the distance between crack tips on two successive images) and s_l (the projection of s on the initial direction of the crack), are represented in

figure 5.a. The three distributions follow a power law over approximately a decade followed by a cutoff. We extracted power laws with exponent 1.2 for s_s and s_l and 1.0 for s. Because of the relatively small number of jumps and the limited span of the power law we must consider these results with precaution and will not discuss the differences between the probability distributions. We will rely on results from previous experiments: an exponent of 1.23 has been found previously for the power law distribution of s_l [8, 21], which matches our observations.
The energy of acoustic events is defined as the integral of the spectral distance (equation 1) over an event's duration. The event is the part of the spectral distance overcoming a chosen threshold. We prefer this definition to the maximal amplitude of the signal (or of the spectral distance) because acoustic events are not single punctual bursts: they sometimes have irregular shapes in time, presenting few local maxima as consequence of the fact that few fibers can break consecutively in a very small lapse of time, appearing as one single event. Taking into account only one of these maxima would result in neglecting a considerable proportion of the acoustic energy. Integrating the spectral distance rather than the square of the signal itself decreases the influence of the noise. This definition provides an estimation of the acoustic energy detected by the sensors, which does not exactly correspond to the energy at the event's source. This energy needs to be corrected by taking into account the attenuation of the acoustic waves, which can be scattered or absorbed by paper fibers. The experiments on crack-free paper provided data on the position and energy of about hundred events relative to the two different sensors. By comparing the energy ratio of signals detected by the two sensors, to the distance separating each event from the sensors, we obtained that the energy is attenuated exponentially with a characteristic length of 3.2 cm. To determine the position of the source of an acoustic event we use the images and suppose that it occurred at the position of the crack tip at the corresponding time. By knowing the distance between the source and the sensor, we can compute the attenuation of the energy. Figure 5.b shows the distribution of the estimated acoustic energy at the events' source. Energies follow a power law over more than three decades with an exponent of 1.3, very close to the one found for the distributions of jump sizes. Once again, the similarity between the power laws of jumps and acoustic energy indicates that acoustic emissions are a consequence of the paper's fracture.

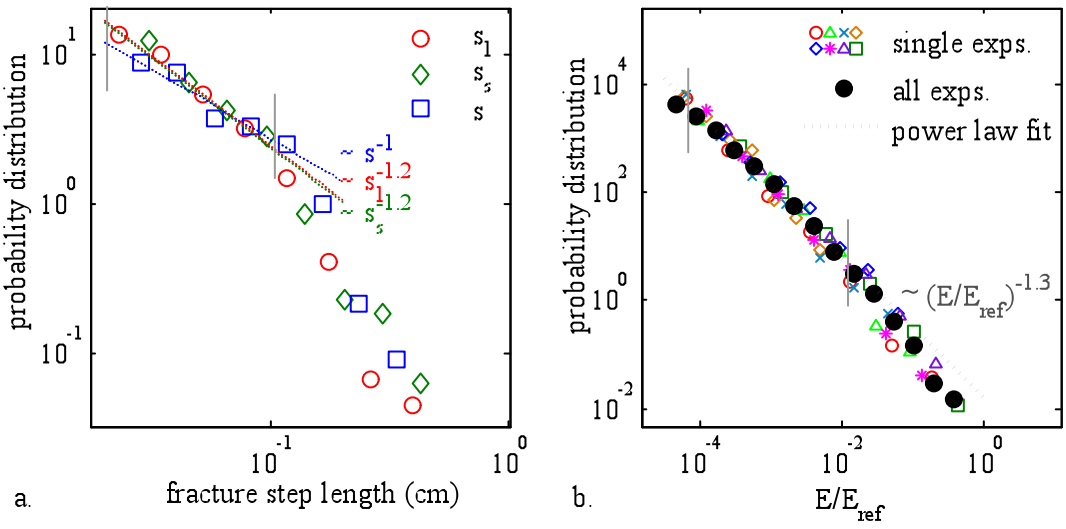

Figure 5. a. Probability distribution of fracture jumps (s, s_l and s_s) with power law fits in a range limited by vertical lines. b. Distribution of the energies of the acoustic events. Open symbols: energies of each experiment separately. Solid symbols: energies of all the experiments, dotted line: a power law fit of the distribution of the energies of all experiments in the signalized range.

4. Conclusion

We studied the subcritical crack growth of a single crack in a sheet of paper submitted to constant force. The system was observed directly by image analysis and indirectly by recording the acoustic emissions. Both methods show similar activities over time. Two variables, the waiting times between the events and the energy released at each event, were statistically analyzed. They both present power law distributions that are very similar for the two different measurements (direct or acoustic emissions), corroborating that the recorded acoustic data corresponds indeed to the fracture process. Having better time resolution and sensibility than image analysis, acoustic monitoring seems more promising for the future development of subcritical fracture in heterogeneous materials.

Abstract A series of uniaxial low cycle fatigue tests on pure Aluminum is investigated via the analysis of acoustic emission (AE). The different stages of macroscopic fatigue behavior are clearly differentiated in terms of AE. We define five different stages: initial hardening, initial softening, secondary hardening during shakedown stage, onset of secondary softening and failure. When most of the acoustic activity recorded in the two/three first stages is related to dislocation dynamics, the acoustic activity in the last stages is mostly due to the fracture phenomenon. Now, a detailed analysis of the discrete AE allowed to highlight the appearance, in the last third of the test, of acoustic signals occurring almost every cycle at a same given stress and having a quasi identical acoustic signature. We hypothesize that such multiplets, shown for the first time in acoustic emission, are the signature of the propagation, cycle after cycle, of a fatigue crack whose trace may be seen post-mortem with the fatigue striations on a fracture surface. This way, these signals could be considered as fracture precursors about several hundred cycles before the final failure of the material.

Keywords Acoustic Emission, Fatigue, Fracturing process, AE multiplet, Cracks

1. Introduction

Fatigue is perhaps the most dangerous and simultaneously less well understood mechanism of mechanical failure encountered in a variety of modern structures ranging from nuclear reactors to micro-electronic connections in cell-phones. Failure in cyclic loading appears unexpectedly when the structure is operating in a safe and apparently steady state regime. Despite a long history of theoretical and experimental studies, modern technology still lacks reliable tools capable of predicting the catastrophic failure in cyclic loading. The situation is particularly troublesome with early precursors of fatigue and thus it would be important to find new ways to follow fundamental changes in the development of fatigue at a microstructural scale in order to identify early precursors to fracture.

An appropriate tool to analyze dynamic instabilities involving such topological defects as dislocations, twin/martensitic boundaries and micro-cracks is certainly the monitoring of the Acoustic Emission (AE). To simplify the analysis of the signal, it seems appropriate to reduce the different possible sources of AE events. Therefore, for an easier understanding, we have chosen to work on pure Aluminum for which the expected AE sources are associated with dislocation dynamics and microcraking only.

AE monitoring has been developed as an effective non-destructive technique for the detection, location and monitoring of fatigue cracks. Several studies showed a correlation between AE count rates and crack propagation rates [1-3] or a relationship for acoustic emissions and the applied range of stress intensity [4]. We focus here on discrete AE (signals above a threshold) to study the dynamics of dislocations and cracks during low cyclic fatigue tests and we explore AE waveforms to extract promising information about the signature of crack propagation. In particular, we reveal the existence of multiplets, i.e. almost identical waveforms reoccurring at each fatigue cycle during the final part of the fatigue life, and which likely signatures of fatigue crack growth.

2. Experimental details

2.1. Material and experiments

We chose to study 99.95% pure aluminum in order to restrict the potential sources of AE to collective dislocation motions and microfracturing process. Indeed, impurities and phase transformations [5] in a material are possible AE sources but do not exist for pure aluminum. The base material was not pretreated, its polycrystalline structure consisting of large elongated grains, ~10 mm for the major axis and ~3 mm for the minor axis. This large grain size implies a lower impact of grain boundaries on the acoustic activity generated in the material [6].
Uniaxial tension-compression ($\varepsilon_{min}/\varepsilon_{max}$=-1) low cycle fatigue tests are performed at room temperature using an hydraulic machine designed and realized at MATEIS Lab [7, 8]. The cyclic total strain was imposed with an amplitude $\Delta\varepsilon$ varying from 0.5% to 1.8% and a loading frequency from 0.1 to 1 Hz. The specimens are cylindrical with 18mm gauge length and 9mm diameter. Stress and strain are recorded up to the macroscopic fracture.

2.1. Acoustic Emission

Acoustic emission is continuously monitored during the tests using a PCI2 Mistras data acquisition system of European Physical Acoustic (EPA) with a 8MHz sample rate and a 60 dB pre-amplification, the bandwidth being 50 kHz–1.2MHz. Our measurements are achieved with two resonant Nano30 EPA piezoelectric sensors (peak of resonance at 140 kHz) coupled to the material with silicon grease. The sensors are placed on the heads of the specimens. Three kind of measurements are performed: (i) the continuous AE measuring the mean acoustic power, sampled at 10Hz all along the test, (ii) the discrete AE which is an automatic detection of transient elastic waves distinguished from the background noise, above a given threshold (34dB) and (iii) a complete recording of the acoustic signal, sampled at 5 MHz: "datastreaming" for a few selected loading cycles.
In this paper, we focus on the discrete AE only. We distinguish AE hits from events: hits are AE signals detected by a single sensor whereas events are signals whose intensity is big enough to reach both sensors and that can be located along the specimen length. In general the form of the primitive wave changes during propagation through the medium, and the amplified signal from a resonant piezoelectric sensor bears little resemblance to the original pulse. Nevertheless, this coloration does not erase the differences or similarities in the sources and we assume that if the signals are similar at the source then the signals received by the sensors are similar.

3. Results and discussion

3.1. Macroscopic cyclic response and discrete AE

Let us take the example of a 1 Hz cyclic fatigue test at imposed total strain $\Delta\varepsilon$=0.96% that failed after 3383 cycles. The macroscopic response (maximum stress reached at each cycle) is represented in Figure 1 together with the evolution of the discrete AE activity (cumulative number of hits (Figure 1a) and acoustic energy of hits (Figure 1b)). The different stages of fatigue are clearly differentiated in terms of AE. We define five different stages, each of them being associated to a color: (1, black) initial hardening during the first cycles, (2, red) initial softening at the beginning of a shakedown stage corresponding to a saturation of the stress, (3, green) secondary hardening during shakedown stage, (4, green) onset of secondary softening stage associated to increasing damage before (5, pink) the final failure of the material.

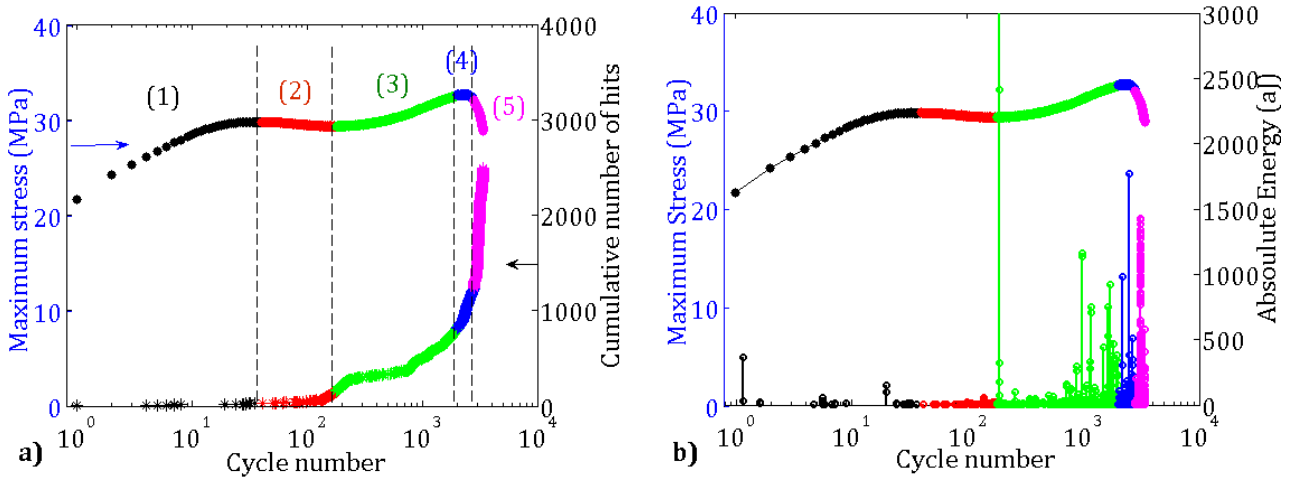

Figure 1 Evolution of the maximum stress during a fatigue test at Δε=0.95% on aluminum (99.95%) along the five different stages, together with a) the cumulative number of hits and b) the acoustic energy of the hits.

The acoustic activity is also represented in Figure 2 with the stress as a function of time along the cycles; Figure 2a shows the occurrence of hits and events and Figure 2b represents the evolution of the discrete AE (normalized number of hits) during selected loading stages of the fatigue test.

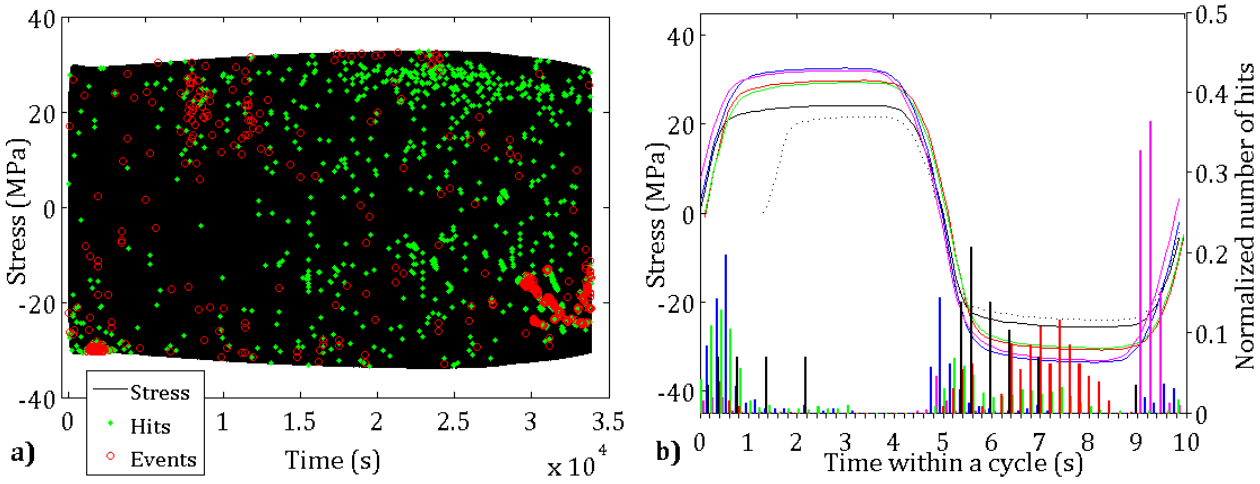

Figure 2 a) Acoustic activity during a fatigue test at Δε=0.95% on aluminum at 1Hz b) Normalized number of hits for each fatigue stage: time of occurrence within a cycle (10s) in correspondence to the stress. Black, red, green, blue, pink colors correspond to the five different stages respectively.

During the first stage, formation of dislocation structures such as cells and walls result in a strong strain hardening of the loaded material [9, 10]. AE hits, recorded during the elastic-plastic transition (Figure 2b), may be due to collective dislocation avalanches. The initial softening exhibits a lower and less energetic discrete AE activity that may be due to the formed microstructures which restrains the spreading of dislocation avalanches. Stronger hits are recorded at the secondary hardening during shakedown stage associated with sudden dislocation cell rearrangements. This stage is characterized by AE hits of various sizes in both tension and compression (Figure 2b). The hits recorded in the last part of this third stage could already be the onset of microcracking and damage. The secondary softening is associated with a strong increase of discrete AE activity that could be a signature of the cell structure destabilization. During the last stage, the acoustic activity rises even more as the result of microcracking leading to the collapse of the macroscopic properties of the material. This activity, mainly due to the fracture phenomenon, is strongly asymmetrical (tension vs compression): most of the hits occur when the material is loaded only, at the onset of

stretching but still under compression (Figure 2b). These AE signals could then be an indicator of the friction between the surfaces of the cracks and their growth.

3.2. AE multiplets

On the last third of the studied cyclic fatigue tests carried out on pure aluminum, we have observed the appearance of acoustic signals occurring almost every cycle at a given stress level during a certain number of cycles. Figure 3 shows these lines of hits or events arising at a quasi-identical level of stress (plotted as a function of time) in the end of a fatigue test at $\Delta\varepsilon$=0.95%. We notice several lines at negative stresses but Figure 3b evidences that the AE signals appear at positive stress rate.

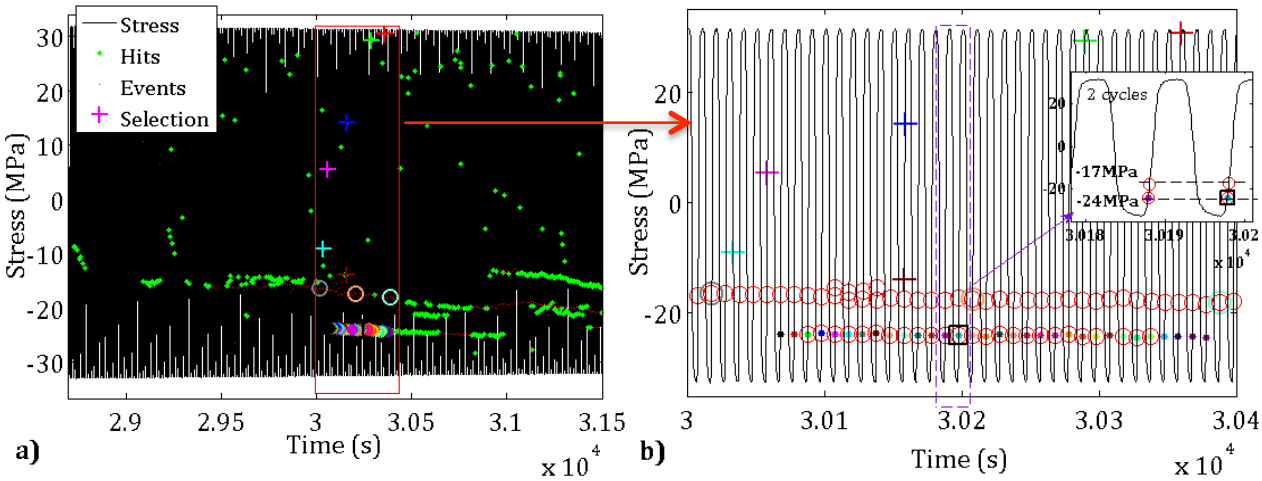

Figure 3 a) Hits or events occurring at specific values of stress, cycle after cycle, in the last stage of a fatigue test at $\Delta\varepsilon$=0.95%. b) Zoom corresponding to the red rectangle. Colored dots correspond to AE signals occurring almost every cycle at a same given stress (~ -24 MPa). Red circles are events. Crosses correspond to random hits occurring at random stress. Inset: 2 cycles.

In order to compare their waveforms, we select several AE signals (colored dots of Figure 3) arising at about -24MPa (when the material is loaded again), cycle after cycle, in a 310s time window (30068s-30378s, 32 waveforms in 32 cycles). We notice in Figure 4a that their waveforms are almost identical. We therefore name these acoustic signals occurring at a same stress level "AE mutliplets". Multiplets have been studied in seismology [11-13]: multiplet is a group of microseismic events with very similar waveforms and is likely the expression of stress release on the same structure. Here they are AE multiplets and we notice in the cyclic fatigue tests we have studied on pure Aluminum that they appear several hundred cycles before the final failure.
In addition, Figure 4a shows a slight tendency for the values of the waveform maximum amplitude to increase with the stress at which they occurred -the amplitude increases roughly of 0.06V (or about 3dB) per Mpa-.
In Figure 4b we compare waveforms taken randomly in the same time window: the colored crosses, the grey orange green circles and the black square of Figure 3. We notice this time that they do not match, thus confirming the special nature of the aforementioned multiplets.

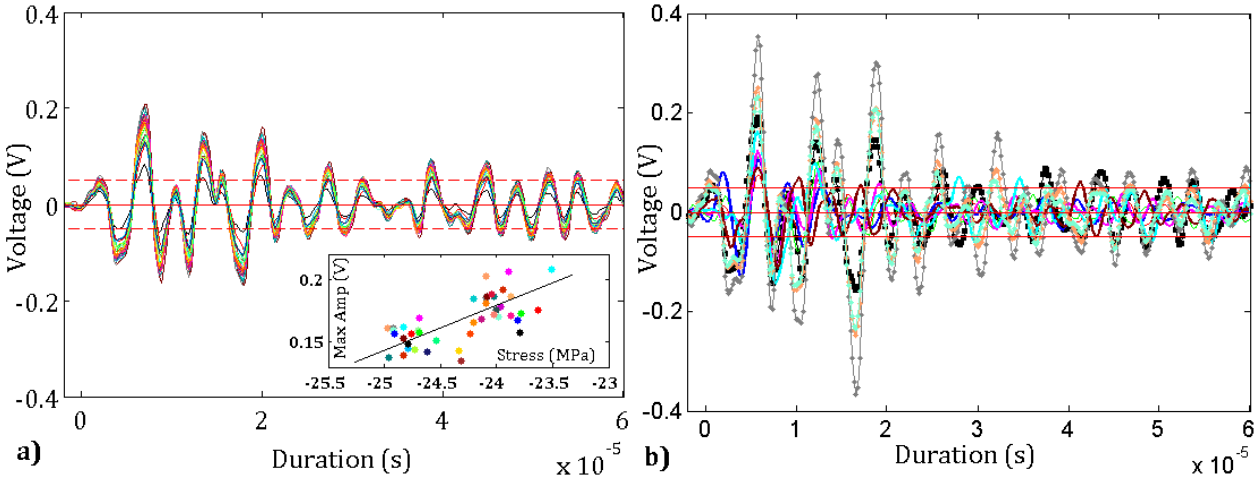

Figure 4 a) Waveforms corresponding to the colored dots of figure 3 (AE signals occurring every cycle at ~ -24 MPa during more than 30 cycles). Inset: maximum of amplitude as a function of the stress where the AE signal occured. b) Ten waveforms corresponding to the selection of AE signals of figure 3 (colored crosses at random stresses, grey orange green circles at ~ -17 MPa and the black square at ~ -24 MPa). Colors of waveforms correspond to colors of markers.

Figure 5a exhibits two other groups of AE events occurring at a given level of stress in the last stage of the test: colored crosses around -17 MPa and colored stars around -15 MPa. Figure 5b shows the location along the gauge length of the specimen and the waveforms of those AE events. We notice that the AE signals appearing at the same stress level are located at about the same site on the specimen and have a same type of waveform (Figure 5b).

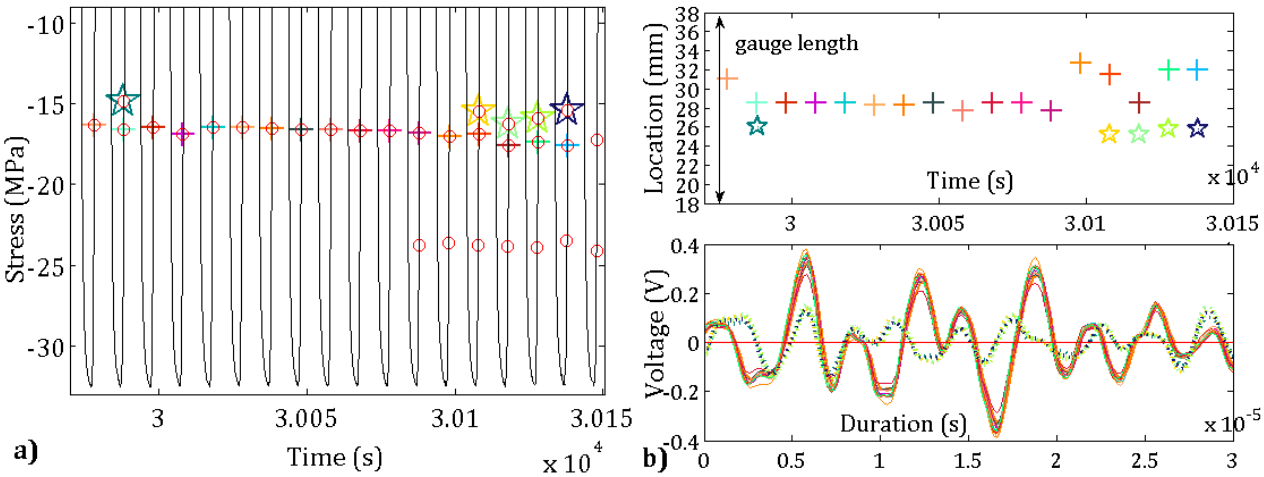

Figure 5 a) Groups of AE events occurring at a same level of stress in the last stage of a fatigue test on aluminum ($\Delta\varepsilon$=0.95%). b) Linear location of AE events along the gauge length of the specimen and corresponding waveforms, continuous lines for the crosses and dashed lines for stars.

Each line of AE signals would come from the same source, being activated again when approximately the same level of stress is reached. Therefore, we hypothesize that such multiplets, shown for the first time in acoustic emission, are the signature of the propagation, cycle after cycle, of a fatigue crack whose trace may be seen post-mortem with the fatigue striations on a fracture surface (Figure 6).

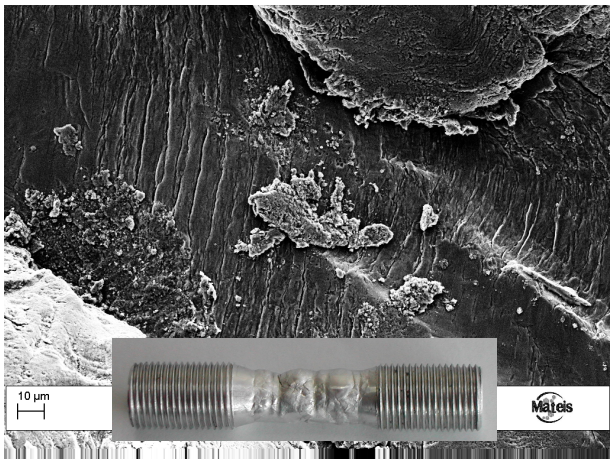

Figure 6 SEM observation of fatigue striations on a fracture surface of pure aluminum after 3024 cycles of a fatigue test at $\Delta\varepsilon$=0.95%. Inset: picture of a specimen just before final failure.

3. Conclusion

Although preliminary, these results give insights into the presence of multiplets in acoustic emission being the signature of the propagation, cycle after cycle, of a fatigue crack. These acoustic signals, with identical waveforms, could therefore be considered as fracture precursors as they appear several hundred cycles before the final failure of the material.

Abstract: More than 80% of France's electricity needs are met via nuclear power plants. Due to France's nuclear power program it maintains a high level of energy independence and one of the lowest costs of electricity in the world. Furthermore, with today's worry about global warming, it also lays claim to an extremely low level of CO_2 emissions per capita. However a big disadvantage to nuclear energy is the long term storage of the nuclear waste. The high-level wastes are stored in a complex borosilicate glass matrix to protect the environment from radioactivity for hundreds to thousands of years. But glass is a brittle material which the life time can be limited by micro cracks generated during the fabrication. This glass must also resist to leaching by groundwater. It's why it is important to understand the mechanisms of crack propagation in a corrosive environment. The aim of this study is the comprehension of how the toughness is affected by the structural changes on simplified borosilicate glasses under irradiation and variation of the chemical composition of the glasses.

Simplified borosilicate glasses are irradiated to simulate alpha and beta decays using He^{2+} ions and electrons. The subcritical stress corrosion fracture properties of glasses are studied using DCDC samples which permit fracture growth in this regime. The experimental measurements of the crack propagation velocities as a function of the applied stress intensity factor is presented as a $v=f(K_I)$ curves. To understand how structural modifications are linked to failure mechanisms RAMAN, NMR and EPR spectra are investigated.

Keywords: Fracture, stress corrosion, irradiation

1. Introduction

Originally spent fuel was supposed to remain in spent fuel pools for 10-15 years. However many countries have left the fuel in for more than 20 years, and there is no end in sight. Spent fuel contains Uranium (~95%), Plutonium (~1%), Minor Actinides (~0.1%; Neptunium, Americium, and Curium), and Fission Products (~4%), and it poses a significant security risk as seen during Fukushima. France has chosen to close the fuel cycle by reprocessing spent fuel. Uranium (~95%), Plutonium (~1%) are reprocessed into MOX fuel, and the minor actinides and fission products are imbedded into nuclear glass packages (NGP, a complex Borosilicate Glass matrix frequently called R7T7 in France). These systems are subject to self-irradiation stresses which arise due to α disintegrations and β/γ decay processes of minor actinides (^{237}Np, ^{241}Am, and ^{244}Cm to name a few) and fission products in NGP. Piecewise studies concerning the structural modifications and how they affect the material properties have been conducted; however the origin and the extent to which these modifications affect the glass are not fully understood [1, 3, 5, 8, 9, 13, 16, 18, 19].

Numerous studies carried out investigate the impact of alpha and beta irradiation at macroscopic and microscopic scales[6, 15, 17, 18]. Variations in mechanical properties include: (1) up to 30% decrease of the hardness depending on irradiation doses and (2) about 60% increase in the toughness before stabilization.

Some authors concluded these evolutions are due to variations of the glassy molecular structure.

Over the past century multiple methods have been discovered and implemented and moreover today are widely used to study structural variations. Two techniques which will be implemented herein are Electron Paramagnetic Resonance (EPR) which is a very sensitive tool for the analysis of paramagnetic defects in glasses and Raman spectra usually employed in the examination of vibrational, rotational and other low frequency modes in complex sodium borosilicate glasses. From these spectra, scientists are able to extract information on the electronic defects, and some structural characteristics about local entities, local angles, local coordinations [7][5]…. Moreover after heavy ions irradiation scientists have evidenced[9][8][14, 17]: (1) decreasing of Si-O-Si angle; (2) depolimerization of the borate network; (3) change in sodium's role (network compensator/modificator)…. These structural evolutions are proposed to explain the modifications of the macroscopic properties. These recent conclusions contradict some older experiments that suggest these variations are due to electronic process[1].

To better understand the source of the changes in the macroscopic properties, and in particular the hardness of nuclear glasses, simplified borosilicate glasses are subject to a controlled external irradiation. Herein we will report results on samples which undergo electron irradiation. Hardness results are acquired via Vickers indentation tests. An investigation is also underway concerning how the fracture behavior at macroscopic scale and the structure modification at microscopic scale are linked.

2. Experimental methodology

2.1) Glass samples:

Nuclear glass packages are complex systems which contain more than 30 different oxides and undergo self-irradiation. In order to understand the role of each oxide the composition has to be simplified. A reasonable simplification of the NGP is sodium borosilicate glasses (SiO_2-B_2O_3-Na_2O), or SBN glasses, as these are the three main components of the NGP system. Herein we will concentrate on three compositions: SBN14, SBN35 and SBN55 (see table 1) which are defined by R_{OG} ($[Na_2O]/[B_2O_3]$) and K_{OG} ($[SiO_2]/[B_2O_3]$). It should be noted that due to the crucibles used in the glass fusion processes, a minimal amount of iron was found in all samples. Secondly as crucibles are recycled SBN35 and SBN55 also have a minimal amount of zirconium. The amount of iron and zirconium has been quantified and it is less that .1% molar mass.

To simulate electronic damage due to self-irradiations, the glasses are externally irradiated via electrons. Electron irradiations were conducted at LSI Sirius. Sirius is a 2.5 MeV Van de Graaff accelerator. At 2.5MeV electrons can penetrate the full our sample thickness (0.8mm thick). Thus our samples are considered homogeneous irradiation. An integrated dose of 0.5, 1, 1.5 or 2 GGy irradiation dose was reached on each sample with a 12 µA beam. During irradiation the sample temperature was maintained at less than 40°C.

OG name	SiO_2	Na_2O	B_2O_3	R_{OG}	K_{OG}
SBN14	67.73	14.23	18.04	0.79	3.76
SBN 55	55.3	29.99	14.71	2.04	3.76
SBN 35	43.95	35.42	20.63	1.72	2.12

Table 1: Composition of glasses (% of molecular oxides)

2.2) Marco-hardness tests:

Microscopic indentation tests were conducted using an Anton Paar MHT-10 Microhardness Tester. These tests were performed on glass specimens irradiated with electrons, and the load mass varied from 10g to 100g. The duration of each load was 15 seconds. The hardness values are determined as follows:

$$H_v = \frac{2*F*\sin(\frac{\theta}{2})}{d^2} \qquad (1)$$

where F is the applied force in Newtons, θ corresponds to the angle of the indenter (136° herein), and d is the averaged diagonal length of the residual print in mm (figure1). Hardness values presented herein are the average of 10 tests with a load of 50g.

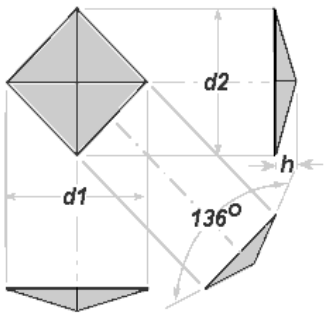

Figure 1 : Sketch of the Vickers diamond pyramid indenter

2.3) Structural measurements

Structural quantifications have been conducted via two techniques herein: RAMAN and EPR measurements. These measurements provide us with some insight on local variations and defects creation.

RAMAN measurements:

Raman spectroscopy measures the vibration modes of a system; moreover, it depends on Raman (inelastic) scattering of visible light. The incident photon interacts with the electron cloud; the return to a lower level emits a photon shift if the final state is different from the initial state. The frequency shift is called the Stokes shift. To improve the weak Raman intensity why several techniques are invoked (filters, high power...). Herein a Jobin Yvon HR 800 spectrometer was used to acquire RAMAN spectra. The wavelength of the laser on the instrument was 532 nm. Also the laser power was maintained at a low level to avoid heating of the sample.

EPR measurement:

Electron Paramagnetic Resonance (EPR) techniques permit a detailed identification of paramagnetic defects on the atomic scale in solids. Within the literature, there are several common defects which EPR spectroscopy can detect: oxygen hole center, E' centers, hole centers associated with boron atoms, hole centers near alkaline ions, etc**[4, 12]**Hence, the aim of this work is to inspect the paramagnetic defects as a function of the irradiation dose, and secondly how the paramagnetic defects vary as a function of the chemical composition in SBN samples. Electron Paramagnetic Resonance (EPR) spectra were obtained to

evaluate the paramagnetic defects due to electron irradiation. EPR spectra are obtained using an X band (v~10GHz) ESP300 Bruker spectrometer. Multiple spectra were run at different powers (1µW, 1mW and 10mW) to enhance or subdue defects.

2.4) Stress corrosion cracking

In moist environments, subcritical crack propagation, or stress-corrosion fracture, is feasible, i.e. $K << K_c$, due to the stress enhanced corrosive action of water molecules on the stretched molecules within the PZ[10]. The stress-corrosion cracking regime is of primary importance in the storage of nuclear waste since it can modify the storage quality over the long term. In this regime, the crack velocity can be very small, down to a few picometers per second. The global form of the curve $v(K,T,H)$ in OG (where K, T, and H refer to stress intensity factor, temperature and humidity, respectively) has partially rationalized over these last 4 decades[20][11] for a recent review]. It was shown to exhibits three regions:

- Region I where the crack velocity is set by the rate of the stress enhanced chemical reaction between water molecules and stretched chemical bonds in the OGs.
- Regime II where the crack velocity is limited by the transport of water molecules to the crack tip.
- Regime III where the velocity raises sharply with K.

The experimental set up which will be employed herein has been tested frequently over the past 10 year within the Complex systems and Fracture Group. These experiments are performed on DCDC (Double Cleavage Drilled Compression) specimens. Samples will be placed between the jaws of a compressive Deben machine (Figure 2). The force will then be gradually increased up to the initiation of two cracks that propagate symmetrically on both sides of the hole. During the propagation of cracks, a CDC camera will be used to gather information on the velocity of the crack front. Thus with this information we can plot the velocity versus the stress intensity factor (K_I).

Figure 2 : Experimental setup used to fracture glass sample at low velocity in stress corrosion.

3. Experimental results

In SBN samples presented herein electrons should uniformly irradiate the system; hence leaving homogenous samples to be examined. This is contrary to light and heavy ion irradiation (not presented herein) which only penetrate the samples by a few μm. SBN55 and SBN35 irradiated from until 0 to 2GGy were found to have little to no variation on the hardness. On the contrary the SBN14 composition presents another behavior: the hardness decreases by about 20 % at 1 GGy (figure 3).

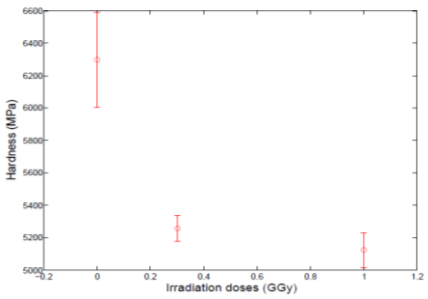

Figure 3 : Hardness variation (MPa) versus electronic irradiations doses for SBN 14 glass

In order to quantify and qualify some of the smallest variations, i.e. variations in the paramagnetic defects of the glasses, we will study the EPR spectra. In all cases non-irradiated glasses revealed defects due to contamination during elaboration (Zr^{3+} and Fe^{3+})[2]. SBN14 irradiated glasses (figure 4a)) did expose E' centers, Oxygen hole centers, hole centers near alkaline ions [4]…. A dependence on the irradiation dose is revealed. Moreover we find an evolution in paramagnetic defects versus the chemical composition (figure 4a et 4b) right).

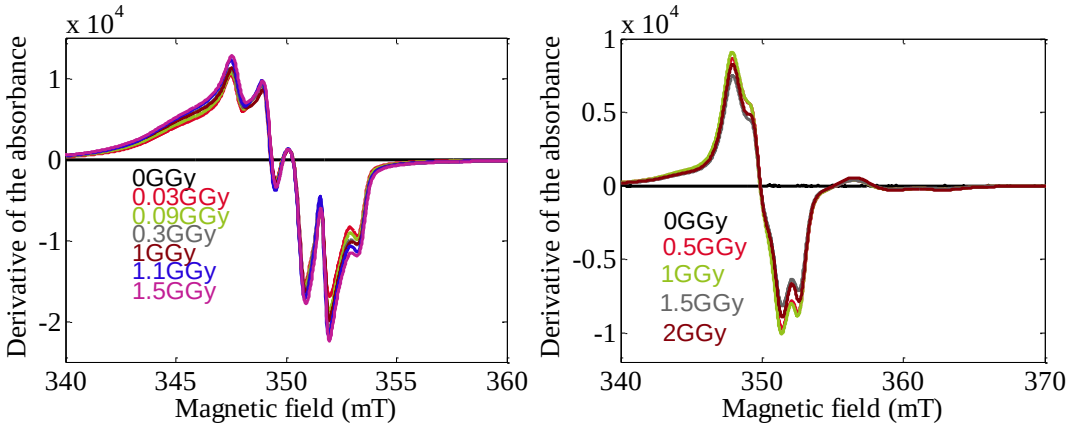

Figure 4 : EPR spectra for a) SBN 14 and b) SBN 35 at 1μW.

Figure 6 depicts the RAMAN spectra for SBN35 at irradiation doses 0, 0.5, 1, 1.5 and 2GGy,. Herein minute dependencies are found on the dose for SBN35 samples.

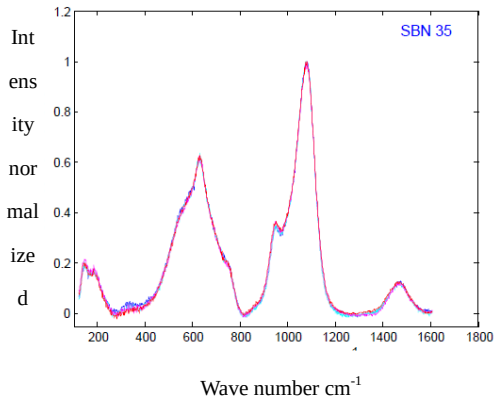

Figure 5 : RAMAN spectra for SBN 35 at different doses: 0, 0.5, 1.5 and 2GGy

4. Discussion and conclusion

Electronic damages induced in glass vary with composition. No influence until 2 GGy have been observed for two borosilicate glasses SBN35 and SBN55. The SBN 14 presents a marked behavior.

The variations affect the macroscopic scale with a decrease of the hardness value and an increase of the toughness which can be explained by the variation at microscopic scale. To understand the relation between electronic damages and glass compositions other studied are needed. Finally let us add that stress corrosion fracture studies are still underway and will be presented at the conference.

5. Acknowledgements

Electron irradiation were conducted at LSI (Laboratoire des Solides Irradiés), Palaiseau, France and supported by the French Network EMIR. The electron irradiation facility at LSI was supported by grants from Région Ile-de-France. Atomic Force Microscopy results were conducted at SPCSI (Service de Physique et Chimie des Surfaces et Interfaces), CEA-Saclay, Gif-Sur-Yvette, France and supported by grants from Région Ile-de-France and Triangle de la Physics (RTRA).

Thickness-dependent lower bounds of fracture toughness of ferritic steels in the ductile-to-brittle transition regime

Abstract. The inherent scatter of fracture toughness of ferritic steels in the brittle-to-ductile transition regime require statistical methods to be applied for testing and evaluation. However, for engineering purposes lower bounds of K_{Ic} such as the ASME-reference curve are often preferred since they allow deterministic worst-case predictions to be made. So the question is how to derive lower bounds of a quantity that is governed by weakest-link-statistics. Actually, neither the MC-approach nor the empirical ASME-reference curve deliver well-founded lower bounds for components of relatively small thicknesses. A theoretical model is suggested to fill this gap. The key element of the approach is the hypothesis that the weakest-link-effect is saturated at a certain thickness. The corresponding upper limit of size-dependence turned out to be close to the minimum thickness required for plane-strain conditions at the crack-front. The derived mathematical relations enables K_{Ic} to be calculated from K_{Jc} as measured on a smaller specimen. In reverse, from a lower-bound K_{Ic} as provided by the ASME-code a thickness-dependent lower bound of K_{Jc} can be obtained. The proposed model is shown to yield predictions that are consistent with experimental data as well as with the ASME-lower bound.

Keywords Ductile to brittle transition, reference temperature, ferritic steel, lower bound, fracture toughness, plane strain.

1. Introduction

For physical reasons fracture toughness of ferritic steels in the brittle-to-ductile transition regime is affected by a pronounced scatter, which requires statistical methods to evaluate test data as well as to predict the load-bearing capacity of a structural component that contains a crack. Since initiation of cleavage is governed by weakest-link-statistics, fracture toughness is associated with a certain probability of failure and dependent on the size of the tests specimen or structural component. According to the Mastercurve- (MC-) approach [1, 2] fracture toughness K_{Jc} of ferritic steel exhibited by a 1T-specimen (i.e. thickness of B_{1T}=1inch=25.4 mm) can be expressed in terms of the cumulative probability of failure (p_f) as

$$K_{Jc}(B_T = 0.0254m, p_f) = K_{\min} + \left[\ln\left(\frac{1}{1-p_f}\right)\right]^{1/4} \{11 + 77\exp[0.019\cdot(T - T_0)]\} \qquad (1)$$

where K_{min}=20 MPa·m$^{0.5}$. The reference-temperature T_0 is a characteristic material property that has to be determined experimentally as prescribed in [2]. If the thickness B deviates from B_{1T}=0.0254 m, then K_{Jc} shall be size-adjusted by

$$K_{Jc}(B, p_f) = K_{\min} + \left[K_{Jc}(B_T, p_f) - K_{\min}\right] \cdot \left(\frac{B_T}{B}\right)^{0.25} \quad (2)$$

where B is the arbitrary thickness of a component and B_T is the thickness of the test specimen, for example B_T =0.0254 m for standard 1T-specimens [2].

In an engineering safety analysis usually fracture toughness corresponding to very low values of p_f and relatively large thicknesses are required. It is plain to see that (1) and (2) do not exhibit the correct asymptotical behaviour of K_{Jc} for $p_f \rightarrow 0$ and for $B \rightarrow \infty$, since both of them predict K_{Jc} to approach K_{min}=20 MPa·m$^{0.5}$, which is a auxiliary number that serves well to evaluate test-data, but not to predict fracture toughness values for low p_f and high B. Instead, for physical reasons a lower-bound of fracture toughness that depends on temperature and yield strength is expected to exist [3, 4, 5]. In fact, there is strong experimental evidence that K_{Jc}(B) does not follow (2) for about $p_f < 0.025$ but approaches for $p_f \rightarrow 0$ a well-defined lower bound value $K_{Jc(LB)}$ [6].

Concerning the effect of thickness on fracture toughness, the classical concept of linear-elastic fracture mechanics presumes that fracture toughness reaches a minimum denoted as K_{Ic} if plane-strain-conditions prevail in the plastic zone. According to current K_{Ic}-testing standards [7, 8, 9] this is guaranteed if the specimen thickness B_T fulfills the condition

$$B_T \geq B_{p\varepsilon} = \alpha \cdot \left(\frac{K_{Jc}}{R_p}\right)^2 \quad (3)$$

with α=2.5 and R_p denoting the yield stress. However, like K_{Jc}, K_{Ic} in the ductile-to-brittle transition regime of ferritic steels is affected by an inherent scatter. For this reason in engineering safety analysis it is common to use lower bound fracture toughness values. For reactor pressure vessel (RPV-) steels, the ASME-code [10] provides the following lower bound of K_{Ic}:

$$K_{Ic(ASME)}(T) = 36.5 + 22.8 \cdot \exp\left[0.036 \cdot (T - RT_{NDT})\right] \quad (4)$$

RT_{NDT} is the so-called nil-ductility temperature that originally had to be determined by Charpy- and drop- weight-tear-tests [10]. Both eqs. (1) and (4) contain just one material parameter, i.e. T_0 and RT_{NDT}, respectively, so a relation between them is expected to exist. In fact, experimental data of RPV-steels revealed the following empirical correlation [11, 12]:

$$RT_{NDT} = T_0 + 19.4K \quad (5)$$

Despite of this relationship, concerning the thickness-effect there is a fundamental inconsistency between the MC-approach and the classical concept of linear-elastic fracture mechanics, where plane strain fracture toughness is regarded as the asymptotical minimum value of K_{Jc}. In the framework of the ASTM-standards this conflict is resolved simply by excluding ferritic steels from K_{Ic}-testing according to E399 [7], which is not quite satisfying from a scientific point of view. Inspired by a similar task by Merkle et al. in [13], in the present paper an attempt is made to bridge the gap between the above mentioned approaches by imposing an upper limit on the range of validity of Weibull-statistics as far as the thickness is concerned, and by introducing a temperature- and size-dependent lower bound of the corresponding fracture toughness as far as the failure probability is concerned. In reverse, the present approach leads in a straightforward way to an

effective thickness-dependent lower bound of fracture toughness for structural components that are too thin to fulfill criterion (3) for plane strain. These are cases where eq. (4) tends to predict too low fracture toughness values, which can lead to an over-conservative assessment of the safety of the corresponding structure.

2. Saturation of statistical thickness-effect

According to Weibull-statistics, the cumulative probability of failure, p_f, is a function of the fracture-controlling volume V_c next to the crack-front, where the stresses are high enough for cleavage to be initiated. Whether or not an unstable crack extension is triggered depends on the presence of a weak spot such as a local defect or a brittle particle. The in-plane dimensions of V_c are known to be in the order of the crack-tip opening displacement (CTOD) [3], which is proportional to K_I^2, so V_c is proportional to $K_{Jc}^4(B)\cdot B$ for a component of thickness B. For a 2-parameter Weibull-distribution this leads to the following dependence of K_{Jc} on the component thickness B:

$$K_{Jc}(B, p_f) = K_{Jc}(B_T, p_f)\cdot\left(\frac{B_T}{B}\right)^{0.25} \tag{6}$$

Obviously, the asymptotical behaviour of (6) for $B\rightarrow\infty$ is not correct. However, instead of using a 3-papameter approach with a threshold K_{min} as in eq. (2), we postulate that the validity of (6) is restricted to the range $B_{p\sigma}<B<B_{sat}$. Its lower limit, $B_{p\sigma}$, is imposed by the transition to plane stress conditions, which can be considered as a cut-off at upper-shelf toughness $K_{J(US)}$. The upper limit, B_{sat}, reflects the hypothetical assumption that the thickness-effect (6) saturates at a certain thickness B_{sat}, so K_{Jc} for $B>B_{sat}$ is no longer decreasing, but remains constant at the level K_{sat}, as sketched in Fig. 1.

The postulated saturation of the thickness effect for $B>B_{sat}$ is attributed to the extreme slenderness of the fracture-controlling volume V_c along the crack front. V_c has a width of B and in-plane dimensions in the order of magnitude of CTOD, which is in the order of $K_{Jc}^2/(E\cdot R_p)$, thus two or three orders of magnitude smaller than B. Physically, the postulated saturation can be explained by the unlikeliness that under a given load a cleavage fracture can be obtained by a further increase of B, if the latter is already two or three orders of magnitudes larger than the in-plane dimensions of V_c. Unstable crack extension is much more likely to be obtained, if CTOD is increased, since in this case not only V_c but also the global energy release rate are increased. Thus, the saturation is likely to occur if the ratio B/CTOD reaches a certain value. Therefore the parameter

$$\beta = \frac{B\cdot E\cdot R_p}{K_{Jc}^2} \tag{7}$$

is introduced to quantify the slenderness of V_c. The postulated saturation of the thickness effect is assumed to be reached for

$$\beta \geq \beta_{sat} = \frac{B_{sat}\cdot E\cdot R_p}{K_{Jc}^2} \tag{8}$$

The corresponding curve $K_{Jc}(B, p_f)$ shown in Fig. 1 can be written as

$$K_{Jc}(B, p_f) = \begin{cases} K_{Jc}(B_T, p_f) \cdot \left(\frac{B_T}{B}\right)^{0.25} & for\ B_{p\sigma} < B < B_{sat} \\ K_{sat}(p_f) & for\ B > B_{sat} \end{cases} \quad (9)$$

B_{sat} is obtained as the intersection of (6) with

$$K_{Jc} = \sqrt{\frac{B \cdot E \cdot R_p}{\beta_{sat}}} \quad (10)$$

that follows from (8). Equalizing (10) and (6) delivers

$$B_{sat} = \left(\frac{\beta_{sat}}{R_p \cdot E}\right)^{2/3} \cdot B_T^{1/3} \cdot K_{Jc}^{4/3}(B_T) \quad (11)$$

By inserting (11) in (10) one obtains

$$K_{sat} = \left(\frac{B_T \cdot E \cdot R_p}{\beta_{sat}}\right)^{1/6} \cdot K_{Jc}^{2/3}(B_T) \qquad \text{for } B_T < B_{sat} \quad (12)$$

Eq. (12) enables K_{sat} to be predicted from K_{Jc} measured by a specimen with relatively small thickness B_T, provided β_{sat} is known. The latter is determined in Section 4.

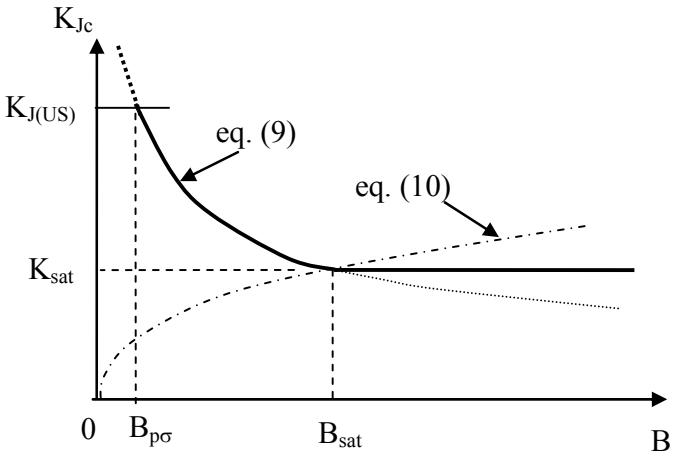

Fig. 1: Dependence of $K_{Jc}(p_f)$ on the thickness B according to the proposed model

3. Lower bound $K_{Jc}(B)$

K_{sat} as given in eq. (12) represents a lower limit of K_{Jc} only with respect to the effect of thickness, but not with respect to p_f. However, as discussed in the introduction, a certain minimum K_I is required for unstable cleavage to occur for energetic reasons. Thus, there must be a lower bound of the scatter band of K_{sat}. It is likely that $K_{Ic(ASME)}(T)$ according to eq.(4), which was determined

empirically as the lower envelope to a large number of valid K_{Ic}-data, represents a good approximation of the physical lower bound of K_{sat}. This means formally

$$K_{sat}(T, p_f = 0) = K_{Ic(ASME)}(T) \tag{13}$$

Since eq. (12) holds for any value of p_f, it also does for the hypothetical case "p_f=0" that represents a lower bound. Correspondingly, as shown graphically in Fig. 2, $K_{Ic}(T, p_f=0)$ is associated with a lower bound curve $K_{Jc(LB)}$ for $B<B_{sat}$. This curve is obtained by equalizing K_{sat} given in (12) with $K_{Ic(ASME)}$ given in (4), which results in

$$K_{Jc(LB)}(B) = \left(\frac{\beta_{sat}}{R_p \cdot E \cdot B}\right)^{1/4} \cdot \left\{36.5 + 22.8 \cdot \exp\left[0.036 \cdot (T - T_0 - 19.4K)\right]\right\}^{3/2} \quad \text{for } B<B_{sat(LB)} \tag{14a}$$

and

$$K_{Jc(LB)} = 36.5 + 22.8 \cdot \exp\left[0.036 \cdot (T - T_0 - 19.4K)\right] \quad \text{for } B>B_{sat(LB)} \tag{14b}$$

where

$$B_{sat(LB)} = \frac{\beta_{sat} \cdot K^2_{Ic(ASME)}}{R_p \cdot E} \tag{14c}$$

As shown in the next section, an appropriate value of β_{sat} turned out to be 1150.

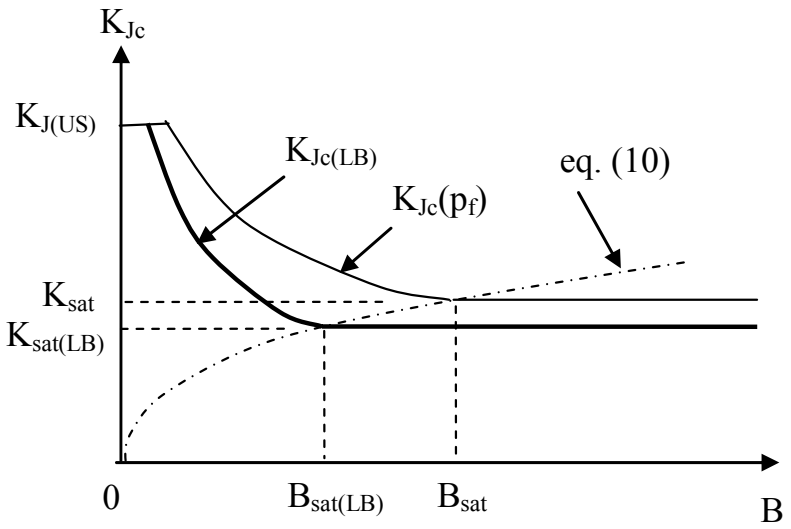

Fig. 2: Dependence of the lower bound of K_{Jc} on the thickness B according to the proposed model

(*) not enough specimens available to determine a valid T_0 according to [2]

4. Experimental Confirmation

Eqs. (14) represent a lower bound of $K_{Jc}(B)$ analogously to $K_{Ic(ASME)}$ as given in eq. (4), but for thicknesses $B<B_{sat(LB)}$. In the following, the predicted lower bound is compared with experimental data. Since (14a, c) contain the open parameter β_{sat}, this comparison offers the possibility to determine β_{sat} experimentally. As a representative test material RPV-steel 22NiMoCr 3-7 was chosen, which is similar to steel A508. Standard 1T-CT-specimens (B=25.4 mm) and 3-point bending specimens (SEB) of square cross sections and different sizes were used (from B=W=10 mm (denoted as 0.4T) up to B=W=80 mm (3.2T)). The multi-temperature option of [2] was applied to evaluate T_0 for each specimen type and size. The test procedure and the results are documented in detail in [14]. The obtained T_0 are given in Table 1. Note that T_0 from the 0.4T-SEB-specimens are significantly lower than T_0 from CT-specimens, which corresponds to a well-known bias of T_0 [15]. In the following comparisons, T_0 corresponding to 1T-CT-specimens (i.e. T_0 =-71°C) is taken as the reference value.

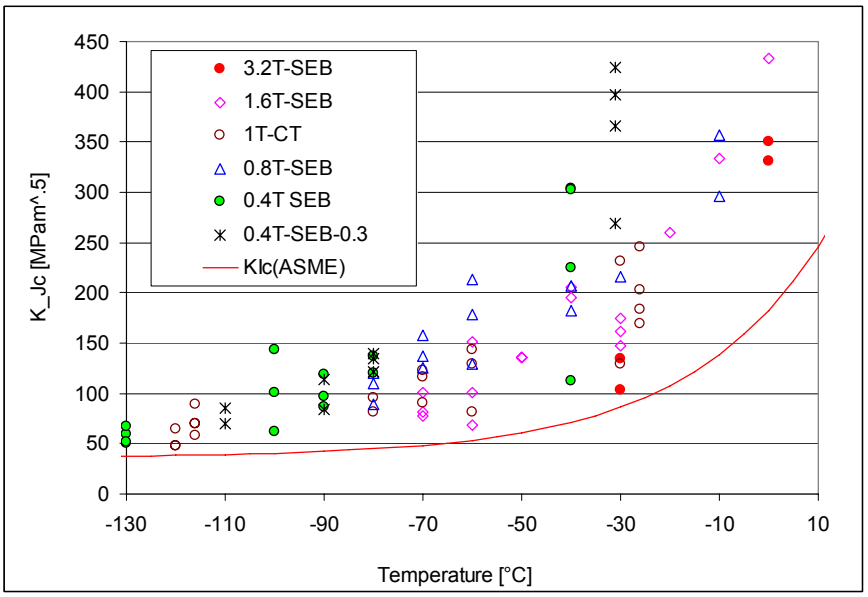

Fig. 3: K_{Jc}-data of different specimens in comparison with the lower bound $K_{Ic(ASME)}(T)$

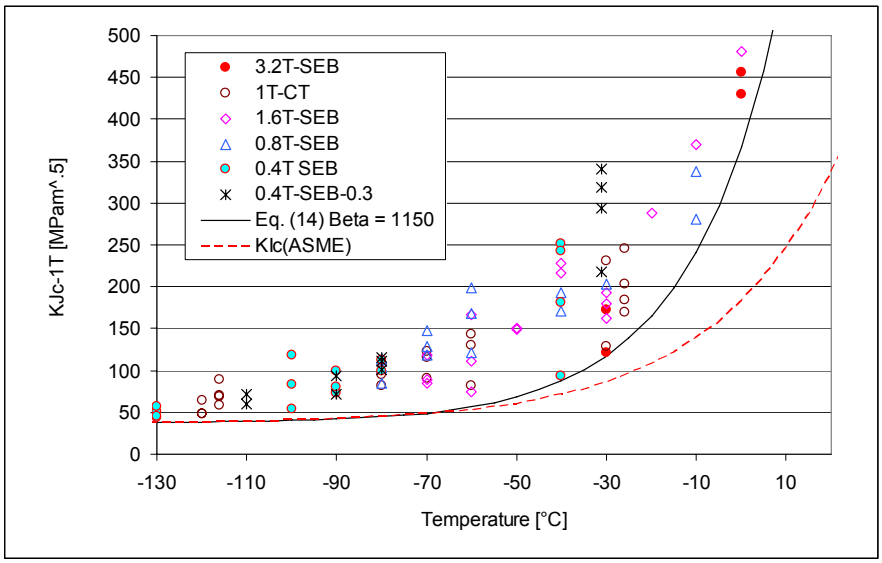

Fig. 4: Experimental data normalized to B_T=0.254m in comparison with eq. 14 with β_{sat}=1150

Fig. 3 shows the experimental K_{Jc}-data, in comparison with the lower bound eqs. (4)/(5). Obviously, the latter envelopes the experimental data with a rather large margin of safety, particularly in the upper transition range. In order to compare the experimental data with the lower bound predicted by eqs. (14) the K_{Jc}-values shown in Fig. 3 are normalized in Fig. 4 to the thickness of standard 1T-specimens (i.e. B=0.0254 m) by means of eq. (2). The parameter β_{sat} was chosen such that eqs. (14) forms the close lower envelope shown in Fig. 4, which is the case for

$$\beta_{sat}=1150 \qquad (14d)$$

In Fig. 5 the experimental data of the individual specimen sizes are compared with the lower bounds predicted by eqs. (14) with β_{sat} according to eq. (14d). Note that the predicted size-dependent lower bounds envelope not only the valid data, but also those beyond the validity limit of E1921. Actually, eqs. (14) seem to hold approximately up to the transition to upper-shelf behaviour, which takes place at about K_I=350MPa for the present steel. As expected and also shown in Fig. 5, $K_{Ic(ASME)}(T)$ is significantly too low if applied to relatively small specimens or components. In all cases eqs. (14) represents more realistic lower bounds. Furthermore, as shown by the example of p_f=2.5% in Fig. 5, one can see that tolerance bounds based on the MC-approach (eqs. (1) and (2)) match even worse with the experimental data, particularly for the larger specimens.

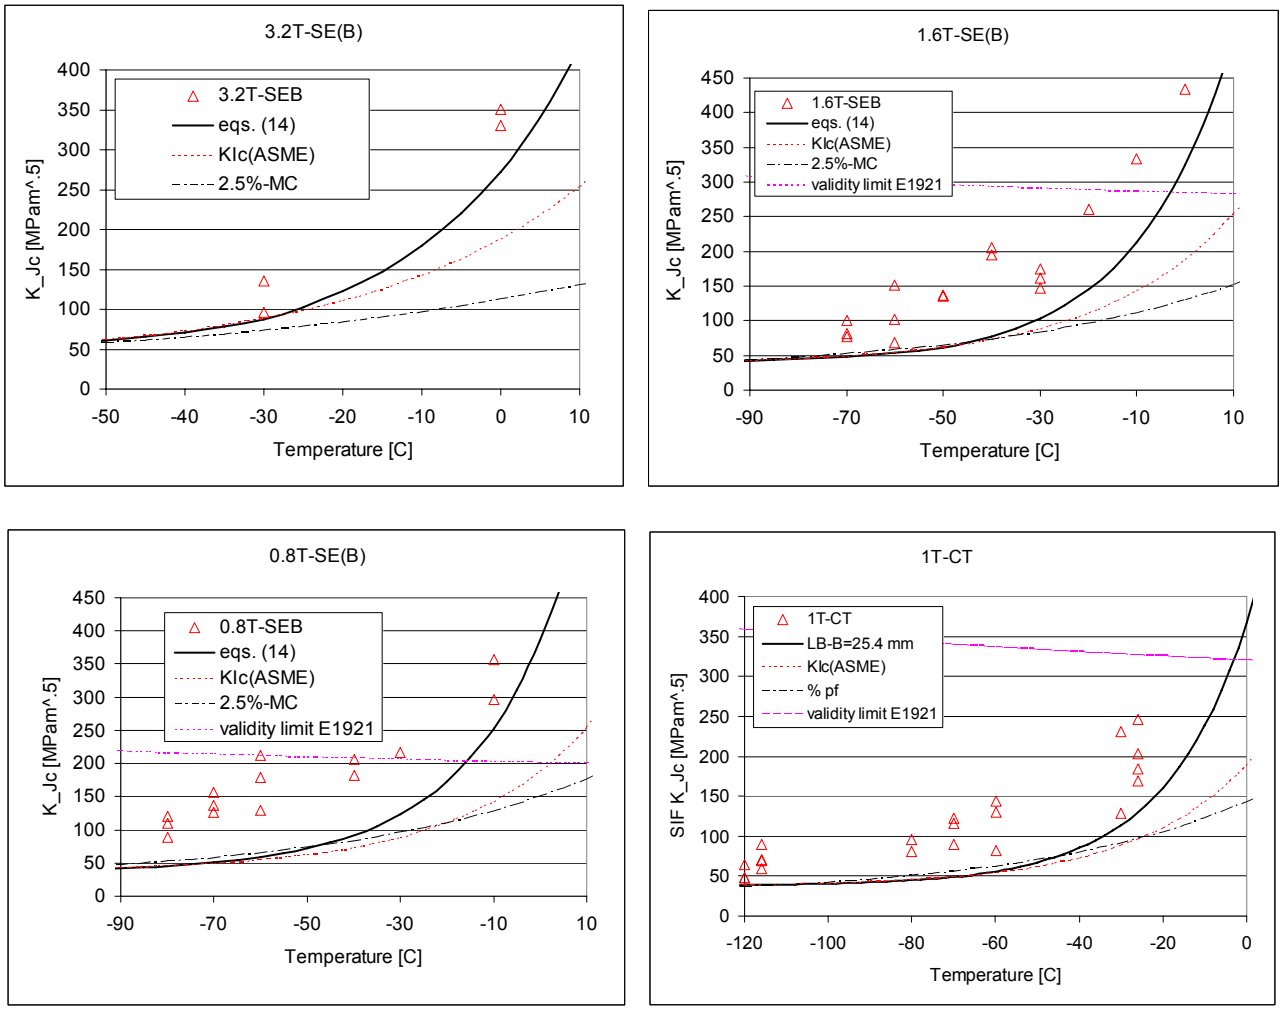

Fig. 5: K_{Jc}-data obtained from SEB-specimens of different sizes and 1T-CT-specimens, in comparison with possible lower bounds as discussed in the text.

5. Discussion

The lower-bound of K_{Ic} reflects a threshold that is imposed by physical requirements for unstable cleavage [4]. $K_{Jc(LB)}$ as given by eqs. (14) is different. It has to be regarded as an "effective" lower-bound, which is caused mainly by effects of weakest-link-statistics. However, as shown by comparison with experimental data, it still represents a reliable lower bound of K_{Ic}. It can serve as a basis for failure assessment of relatively small components, where the ASME-lower-bound tends to over-conservative predictions. Since it is governed by weakest-link statistics, it also is applicable to surface cracks, where B has to be replaced by the length of the crack-front.

In the derivation of the size-dependent lower bound use is made of the lower-bound of K_{Ic} according to ASME [10]. Thus, formally, eqs. (14) underlie the same restrictions as eqs. (4) and (5) as far as the material is concerned. However, according to the MC-concept, fracture toughness of all ferritic or bainitic steels with yield strengths lower than 800 MPa is characterized just by T_0. Correspondingly, lower bounds are expected to depend on just one parameter as well. This means that the applicability of eqs. (14) corresponds to the one of [2], thus to ferritic or bainitic steels with $R_p < 800$ MPa. Since R_p appears in eq. (14) only in the power of ¼, a rough estimation of $R_p(T)$ at the actual temperature is sufficient. Detailed knowledge of $R_p(T)$ is not required.

The presented model is similar as the one proposed by Merkle et al. in [13]. However, besides some minor differences in the mathematical derivations, there is a fundamental difference in the assumptions concerning the saturation of the thickness-effect: Based mainly on intuition, in [13] saturation was assumed to occur at $B=B_{p\varepsilon}$, which means that α as defined in eq. (3) was chosen to be 2.5, whereas in the present model this effect is attributed for physical reasons to the slenderness of the fracture controlling volume in the vicinity of the crack front. The corresponding thickness of saturation was considered as unknown by introducing an open constant β_{sat} that was determined by comparison with experimental data. A comparison of (3) and (7) reveals that β_{sat} is related to α by

$$\beta_{sat} = \frac{\alpha \cdot E}{R_p} \tag{15}$$

From eq. (15) one can see that $\beta_{sat}=1150$ as found above (eq. (14d)) is nearly equivalent wit $\alpha=2.5$ for medium strength steel (with R_p being about 450 MPa). This confirms the assumption in [13] and means that K_{sat} evaluated by eq. (12) represents a "valid" plane strain fracture toughness value K_{Ic}. Inserting (15) with $\alpha=2.5$ in eq. (12) leads to the simple equation

$$K_{Ic}(p_f) = 0.858 \cdot R_p^{1/3} \cdot B_T^{1/6} \cdot K_{Jc}^{2/3}(B_T, p_f) \qquad \text{for } B_T < B_{p\varepsilon} \tag{16}$$

which enables "valid" K_{Ic} to be estimated from a K_{Jc}–value measured on a smaller specimen of thickness B_T. Quantitatively, the resulting K_{Ic} is nearly the same as the one from the mathematically more complex relation provided in [13]. Note that the obtained K_{Ic} is associated with the same probability of failure p_f as the original K_{Jc}-value. If applied to an empirical lower envelope to experimental date, such as the curve shown in Fig. 4, eq. (16) enables a lower-bound curve for K_{Ic} to be predicted. In this way, one could have obtained from the presented experimental data a lower bound that is in very good agreement with the ASME lower bound, eqs. (4) and (5), confirming these empirical relations semi-analytically.

Using (15) with α=2.5 leads to the following approximation of eq. (14a) and (14(c):

$$K_{LB(B)}(T) = \frac{1.257}{B^{0.25} \cdot \sqrt{R_p}} \cdot \left\{36.5 + 22.8 \cdot \exp\left[0.036 \cdot (T - T_0 - 19.4°)\right]\right\}^{3/2} \quad \text{for } B < 2.5 \cdot \left(\frac{K_{LB(B)}}{R_p}\right)^2 \quad (17)$$

6. Conclusions

An engineering model is presented by which the fundamental conflict between the weakest-link statistics and the classical concept of lower-bound plane strain fracture toughness can be resolved. It is based on the hypothesis that the statistical thickness-effect saturates at a certain thickness. The latter turned out to be roughly the same as the one required for plane strain fracture toughness testing, confirming a similar hypothesis made by Merkle et al. in [13]. The model enables "valid" K_{Ic}-values to be calculated from K_{Jc} measured on relatively small specimens and – in reverse – lower bounds of K_{Jc} for relatively small components (or crack-front lengths, respectively) to be predicted from lower-bound K_{Ic}–values. These lower bound curves are less conservative than the ASME lower bound for smaller thicknesses. They are shown to be much closer to the experimental data than the original ASME-lower bound curve, which means that a safety assessment based them results in less conservative – i.e. more realistic - predictions.

The present investigation confirms independently the model of Merkle et al. [13] and its underlying assumptions. Furthermore, the ASME lower bound, which was determined empirically as the lower envelope of a large number of valid K_{Ic}-tests, could be obtained semi-empirically from relatively few K_{Jc}-data. This good agreement confirms mutually the presented theory as well as the empirical ASME-curve. Note that for eq. (5) to be valid T_0 as obtained from 1T-CT-specimens should be used; T_0 from 0.4T-SEB-specimens can lead to non-conservative predictions.

Tolerance bounds based on the statistical MC-relations are shown to be less suitable as lower bounds, particularly if applied to relatively large components. Therefore and because of their formal restriction to $T<T_0+50K$, it is recommended that the MC-approach is used just for the evaluation of T_0 from test data, but not to predict K_{Jc} for larger components at the low failure probabilities required in an engineering failure analysis.

Abstract In the present investigation experimental verification of optimal strain gage locations and their importance in accurate determination of mode I stress intensity factors (SIFs) using Dally and Sanford's single strain gage technique (DS technique) has been carried out. The results of the present experimental study are also used to substantiate the efficacy of the methodology for determination of maximum permissible strain gage radial location proposed earlier by the same authors for locating the optimal strain gage locations. Experiments have been conducted using an edge cracked plate made of Polymethylmethacrylate. Results clearly demonstrate that very accurate values of mode I SIFs can be determined if the strain gages are placed at the optimal locations. On the other hand, the experimental results also show that the mode I SIFs obtained using strain gages placed at non-optimal locations contain significant and unacceptable errors. The results of the present investigation clearly confirm the importance of knowing the maximum permissible strain gage radial location corresponding to an experimental specimen before conducting experiment for determination of mode I SIF using the DS strain gage technique.

Keywords Stress intensity factor, Strain gage, Gage location, Optimal

1. Introduction

Stress intensity factor is an important parameter in linear elastic fracture mechanics. Strain gage based experimental techniques for the determination of stress intensity factors (SIFs) are equally powerful in experimental fracture mechanics as other methods such as photoelasticity, caustics and moiré interferometry etc. [1]. For many years, local yielding, high strain gradients, strain gradient effects due to finite size of gages and three dimensional effects near the crack tip were the major problems associated with the application of strain gage techniques for accurate determination of SIFs.

Dally and Sanford [2] was the first to propose a practically feasible single strain gage technique to overcome most of the above mentioned difficulties. Their technique (DS technique) is theoretically well supported and is proposed for determination of mode I SIF, K_I of two dimensional single ended cracked configurations made of isotropic materials. Many different strain gage techniques for determination of SIFs under different situations have been proposed subsequently by various researchers [3-6]. Among the available strain gage techniques for the determination of K_I, DS technique [2] has been more widely employed [7-11] in different contexts.

Referring to Fig. 1, it is evident that in order to obtain accurate values of the SIFs, it is very important to decide strain gage angular location and orientation (defined by θ and α) with

respect to the crack axis and radial location (r) from the crack tip to the center of the gage. The most difficult and challenging problem is in deciding the appropriate radial distance (r) for each of the selected number of strain gages for the measurement of K_I. The radial location of strain gages r is restricted by plasticity effects, three dimensional (3D) effects, strain gradients and the analytical strain series used. To avoid plasticity, strain gradient and 3D effects strain gages should not be placed very close to the crack-tip [2, 6]. On the other hand, strain gages placed at a large distance from the crack-tip may not be represented by the selected strain series. Thus, the radial location of a strain gage from the crack-tip is one of the most important parameters required to be known apriori for accurate determination of the SIFs using strain gage techniques.

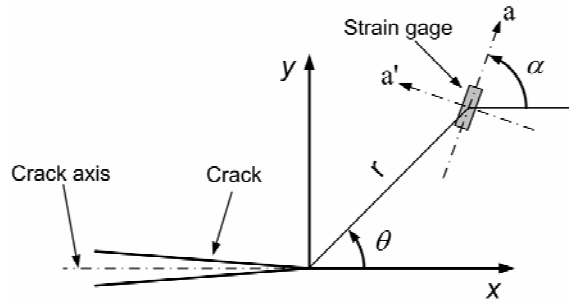

Figure 1. Location of a strain gage from the crack tip

Literature review on strain gage techniques [2-11] show that until recently, no recommendation, or no methodology, or no solution in any form is available for selection of appropriate radial locations (r) for the strain gage in the DS technique despite its popularity. As a consequence, the issue of valid strain gage locations for determination of SIFs using the DS technique remained as an open problem for long time [1].

Recently, Sarangi et al. [12, 13] proposed an approach for determination of optimal or valid radial locations for single strain gage in the DS technique. A methodology based on the finite element analysis (FEA) supported by theoretical foundations has been presented by them [12, 13] for the first time for obtaining the optimal radial gage locations. They defined a parameter $r_{\max}$ which is the upper bound on the radial location for the strain gage which in turn can be used for locating the optimal or valid radial locations for strain gages. Further details on $r_{\max}$ can be found in Refs. [12, 13].

No experimental investigation is reported till date to demonstrate the existence of optimal radial locations for strain gages and their usefulness in accurate determination of mode I SIFs using the DS technique. Thus, the objectives of the present investigation are (a) experimental verification of the optimal strain gage locations obtained using the approach proposed by Sarangi et al. [12, 13], (b) to show the usefulness of these locations in obtaining accurate mode I SIFs of cracked configurations using the DS technique and (c) to substantiate the usefulness of methodology for

determination of maximum permissible strain gage radial location $r_{\max}$ proposed by Sarangi et al. [12, 13] for locating the optimal strain gage locations.

2. Theoretical Background

A very brief theoretical background on the DS technique [2] and determination of optimal strain gage locations for this technique proposed by Sarangi et al. [12, 13] is presented in this section. It can be shown that the strain ε_{aa} (Fig. 1) at a point *P* (defined by r and θ) in the direction of an arbitrary angle α (with respect to the crack axis) for plane stress conditions is given by [2, 12, 13]

$$\begin{aligned} 2G\varepsilon_{aa} = A_0 r^{-1/2}\left[\kappa\cos\frac{\theta}{2} - \frac{1}{2}\sin\theta\sin\frac{3\theta}{2}\cos 2\alpha + \frac{1}{2}\sin\theta\cos\frac{3\theta}{2}\sin 2\alpha\right] \\ + A_1 r^{1/2}\cos\frac{\theta}{2}\left[\kappa + \sin^2\frac{\theta}{2}\cos 2\alpha - \frac{1}{2}\sin\theta\sin 2\alpha\right] + B_0\left(\kappa + \cos 2\alpha\right) \end{aligned} \tag{1}$$

where $\kappa = (1-\nu)/(1+\nu)$ and A_0, A_1 and B_0 are unknown coefficients. Eq. (1) is obtained using the three parameter representation of the strain field (in terms of coefficients A_0, A_1 and B_0) around the crack tip. Using the definition of K_I it can be shown that the singular coefficient A_0 is related to the mode I SIF K_I as

$$K_I = \sqrt{2\pi}\, A_0 \tag{2}$$

The coefficient of B_0 term in Eq. (1) can also be eliminated by selecting the angle α such that

$$\cos 2\alpha = -\kappa \quad = -\frac{1-\nu}{1+\nu} \tag{3}$$

Similarly coefficient of A_1 can also be made zero if the angle θ is selected as

$$\tan\frac{\theta}{2} = -\cot 2\alpha \tag{4}$$

With α and θ as defined by Eqs. (3) and (4), the simplified form of Eq. (1) is given by

$$2G\varepsilon_{aa} = \frac{K_I}{\sqrt{2\pi r}}\left[\kappa\cos\frac{\theta}{2} - \frac{1}{2}\sin\theta\sin\frac{3\theta}{2}\cos 2\alpha + \frac{1}{2}\sin\theta\cos\frac{3\theta}{2}\sin 2\alpha\right] \tag{5}$$

Thus, by placing a single strain gage (Fig. 1) with α and θ as defined by Eqs. (3) and (4) the strain ε_{aa} can be measured and K_I can be determined using Eq. (5).

Using numerical and experimental studies [14, 15] it has been established that the 3D effects prevail up to a radial distance equal to half the thickness of the plate from the crack tip. Therefore, the minimum radial distance $r_{\min}$ for strain measurements on the free surface should be greater than half the thickness of the plate [2]. As a consequence, the optimal or valid radial location r for a strain gage in DS technique can now be given as

$$r_{\min} \quad (= \frac{\text{thickness of plate}}{2}) \leq r \leq r_{\max} \tag{6}$$

where the unknown parameter $r_{\max}$ is defined as the maximum permissible radial distance for the strain gage or the extent of validity of Eq. (5) from the crack tip. It is clear that Eq. (5) can accurately describe the strain field in the given direction θ only up to a radial distance $r_{\max}$ from the crack tip and beyond this radial distance more number of coefficients other than A_0, A_1 and B_0 are needed to represent the strain field. Clearly, with this definition of $r_{\max}$, any radial distance of strain gage satisfying the Eq. (6) is an optimal radial location. According to Sarangi et al. [12, 13], for a given configuration, applied load, Young's modulus E and Poisson's ratio ν Eq. (5) can be simplified as,

$$\varepsilon_{aa} = \frac{C}{\sqrt{r}} \tag{7}$$

where C is a constant. Taking logarithm on both sides of Eq. (7)

$$\ln(\varepsilon_{aa}) = -\frac{1}{2}\ln(r) + \ln(C) \tag{8}$$

Clearly Eq. (8) is valid along the line given by Eq. (4) for $r \leq r_{\max}$. Thus a plot of Eq. (7) on log-log axes ($\ln(\varepsilon_{aa})$ versus $\ln(r)$) depicts a straight line of slope equals to – 0.5, with an intercept of $\ln(C)$. Theoretically, the straight line property will break beyond $r > r_{\max}$ as more than three parameters are needed in Eq. (1) to estimate the ε_{aa}. Using the straight line property exhibited by Eq. (8), the value of $r_{\max}$ can be accurately estimated from the log-log plots of ε_{aa} and r. Other details on computation of $r_{\max}$ can be found in Refs.[12, 13].

3. Experimental Verification

Present section describes experimental verification of optimal radial locations of strain gages obtained using the approach described in the previous section and their use in determination of accurate mode I SIFs. The following equations are employed for determination of normalized SIF K_I

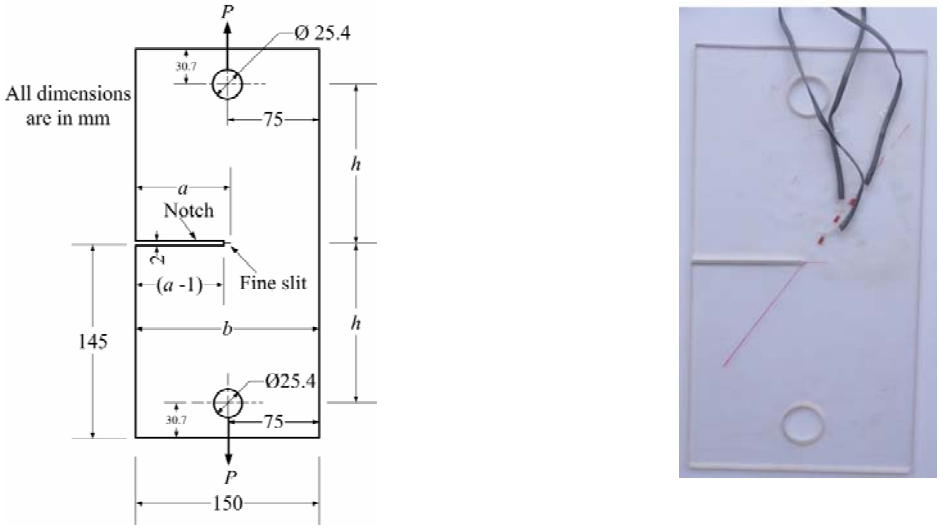
$$F_I = \frac{K_I}{\sigma\sqrt{\pi a}} \tag{9}$$

where σ is the nominal stress and a is the crack length and the % relative error in F_I is calculated as

$$\%\,\text{Relative error} = \left(\frac{F_I^{\textit{reference solution}} - F_I^{\textit{experimental}}}{F_I^{\textit{reference solution}}} \right) \times 100 \tag{10}$$

3.1 Details of experimental specimen

In the present experimental investigation, commercially available Polymethylmethacrylate (PMMA) has been used as the material for the test specimen. It is well known that PMMA is a homogeneous, isotropic and brittle material at room temperature [16]. The test specimen considered in the present investigation is straight edge cracked plate subjected to tensile loading as shown schematically in Fig. 2(a). The details of geometry and that of pre-crack are also shown in Fig. 2(a). Experiments have been conducted using an edge cracked plate having a/b ratio 0.493. The geometric and other details of the experimental specimen have been presented in Table 1. Fig. 2(b) shows actual specimen with strain gages mounted on the surface. Dimensions and loading conditions in the test specimen have been chosen so as to ensure plane stress conditions during the experiments. The elastic properties of PMMA sheet obtained from tensile tests have also been presented in Table 1.



(a) (b)

Figure 2. (a) schematic of edge cracked specimen (b) actual specimen

3.2 Determination of $r_{\max}$ and normalized mode I SIF of the experimental specimen

Material properties from the tensile tests (Table 1) for the PMMA have been used to evaluate the $r_{\max}$ values for the selected mode I edge cracked experimental specimen (Table 1 and Fig. 2).

Following the numerical approach proposed by Sarangi et al. [12, 13] the r_{max} of the experimental edge cracked specimen is found to be 37.0 mm which is indicated in Table 1. Further, using the same FE meshes (that are used for determination of r_{max}) mode I SIF K_I has been computed. Result of computed normalized SIF, F_I (Eq. 9) for the selected experimental specimen is also presented in Table 1. All these finite element analyses have been carried using commercial software ANSYS^{TM}.

Table 1 Details of different parameters of the edge cracked experimental specimen

Parameters	Values
a/b	0.493
Crack length a	74 mm
Width b	150 mm
Height h	114.3 mm
Thickness t	5.6 mm
Young's modulus E	2916.91 MPa
Poisson's ratio ν	0.382
r_{max}	37 mm
Normalized mode I SIF F_I	2.777738

3.3 Details of experiment

The selected edge cracked specimen has been loaded in a closed loop servo hydraulic INSTRON 8801 machine with 100 kN capacity under displacement control with an actuator speed 0.1 mm/min. Clevis grips have been used for transferring the tensile load from the machine to the specimen. Strain measurements on the loaded specimens have been carried out using the electrical resistance strain gages of type FLA-1-11-3LT (gage length of 1 mm) and make: TML Japan. The measured strains have been acquired, digitized and processed using NI data acquisition system comprising of cDAQ9178 chassis. Strain measurements have been carried out using NI 9237 (4 channels 24 Bit, half-full bridge analog input module). Experiments have been repeated three times to ensure the repeatability of the results.

4. Results and Discussion

Here mode I SIFs have been determined using the DS technique (single strain gage technique) in

order to verify the optimal strain gage locations in mode I specimen and validation of methodology for determination of r_{max} (which is useful in deciding optimal locations) proposed by Sarangi et al. [12, 13]. Fig. 2(b) shows the photograph of the edge cracked specimen with $a/b = 0.493$ and made of PMMA which has been used in the present experiments. Corresponding to Poisson's ratio ν = 0.382 of the specimen material (Table 1), the orientation of the gage line θ is 53.13^0 (Eq. 4) and the orientation of the gage α is 58.28^0. (Eq. 3).

According to Sarangi et al. [12, 13], the optimal locations for the strain gages should be in the range $t/2 \le r \le r_{max}$ in order to obtain the accurate value of SIF. Strain gages located beyond the r_{max} will result in inaccurate values of SIF K_I and thus are non-optimal locations. Based on these observations, strain gage locations have been decided in the present experiments as shown in Table 2.

Table 2 Selected radial locations for strain gages

r_{max} (mm)	Radial locations		
	r_1 (mm) (Optimal)	r_2 (mm) (Optimal)	r_3 (mm) (Non-optimal)
37.0	17.5	35	50

Fig. 3 show the raw data of measured strain ε_{aa} (circled data points) by the strain gages at r_1 = 17.5 mm, r_2 = 35 mm and at r_3 = 50 mm, respectively in a typical test versus the applied load. Fig. 3 also shows best-fit straight lines (solid lines) to the raw data with the corresponding slopes and the correlation coefficients R^2. As anticipated, at all the strain gage locations, the measured strains are linearly proportional to the applied load as shown by very good values of R^2. Similar trends with identical values of slopes of best-fit lines and correlation coefficients R^2 have been obtained at all the locations of strain gages in all the three repeated tests.

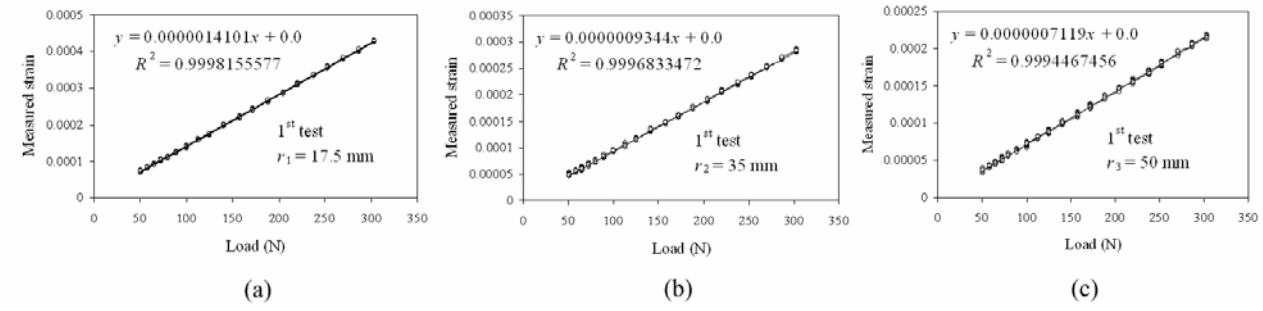


Figure 3. Measured strain versus load (a) at r_1 = 17.5 mm (b) at r_2 = 35 mm and (c) at r_3 = 50 mm

Table 3 shows the experimental values of F_I obtained at all three gage locations r_1, r_2 and r_3 for each of the three repeated experiments for a/b = 0.493 and their average values. It could be observed that in all the three tests at a given location F_I values are very close to each other showing the good repeatability of the results.

Table 4 Experimental values of F_I obtained in all three repeated tests

Test	F_I		
	$r_1 = 17.5$ mm	$r_2 = 30$ mm	$r_3 = 50$ mm
1	2.68641731	2.51751109	2.29249573
2	2.81463225	2.60103297	2.38073057
3	2.84759092	2.66946702	2.53659065
Average	2.78288016	2.59600369	2.40327232

Table 5 shows the comparison of experimentally determined averaged F_I values (Table 4) obtained at the optimal and non-optimal locations of strain gages (r_1, r_2 and r_3) with the reference solution obtained using ANSYS (Table 1) in terms of the % relative error. The percent relative error in F_I is determined using Eq. (10).

Table 5 Experimental values of F_I at different gage locations ($r_{max} = 37$ mm)

Location	F_I		% Relative error
	Reference solution (Table 1)	Experimental value	
Optimal ($r_1 = 17.5\,\text{mm} < r_{max}$)	2.777738	2.78288016	0.19
Optimal ($r_2 = 35\,\text{mm} < r_{max}$)		2.59600369	6.54
Non optimal ($r_3 = 50\,\text{mm} > r_{max}$)		2.40327232	13.48

It is interesting to observe from Table 5 that the % relative error in F_I is only 0.19% for the strain gage located at the optimal location i.e., at $r_1 = 17.5\,\text{mm}$ $(< r_{\max})$ while F_I determined based on the strain gage readings at the non-optimal location $r_3 = 50\,\text{mm}$ $(> r_{\max})$ is as high as 13.5%. Since the other optimal strain gage location $r_2 = 35\,\text{mm}$ which is very close to $r_{\max}$, slightly more error can be noticed at this location as compared to the gage location at r_1. However, this error is still within the acceptable limits. These experimental observations clearly verify the existence of optimal gage locations and their use in determination of accurate values of mode I SIFs. It should be noted that these optimal and non-optimal gage locations have been decided based on the Eq. (6) for which $r_{\max}$ is required for a configuration. Thus, the experimental results in Table 5 also substantiate the efficacy of methodology proposed by Sarangi et al. [12, 13] for determination $r_{\max}$ and its importance in deciding the optimal strain gage locations for accurate determination of mode I SIF. Moreover, the results in Table 5 clearly show the importance of $r_{\max}$ for selection of optimal strain gage locations.

5. Conclusions

The present investigation examines the experimental verification of optimal strain gage locations and their importance in accurate determination of mode I SIFs. This examination also validates the methodology for determination of maximum permissible strain gage radial location $r_{\max}$ proposed by Sarangi et al. [12, 13] and its use in locating the optimal strain gage locations for accurate determination of SIFs using the DS technique. The results of the present investigation clearly demonstrate that very accurate mode I SIFs can be determined using the DS technique if the strain gages are placed within the $r_{\max}$ value i.e., optimal locations. The results also show that the experimentally obtained SIFs using the strain gages placed at non-optimal locations (i.e., beyond $r_{\max}$ value of a specimen) contain significant errors.

Abstract The ship size has been rapidly increased in recent years. Consequently, many aspects of ship structural safety have been concerned, i.e. fatigue strength. Since fatigue cracks are found in the early stage of a ship's service life, it might be that the classical cumulative fatigue rule is insufficient to consider the effects of many uncertain factors, such as variable wave environment loads. The wave load history hinges on the short-sea history. It means that the accuracy of fatigue assessment is affected by the used wave model. There are several established wave models, which could be used to simulate wave load history as in the real ocean conditions. In this paper, wave load histories of a 2800TEU container ship are generated by two different wave models. It is used for crack propagation analysis in the changing routes and trades. The result in the simulated crack propagation lives is examined and discussed.

Keywords fatigue crack propagation, fatigue damage sensor, hindcast data, ship structures

1. Introduction

Fatigue is an important issue for maritime industry. Large ship designers must consider the fatigue strength of ship structures. The traditional ship fatigue assessment is conducted by using a simplified method, in which Palmgren-Miner linear cumulative law and S-N curves are used. In this method, all parameters are provided by classification societies' rules. A comparative study shows that this method gives wide scatter of fatigue life predictions [1]. Thus, fatigue cracks are observed much earlier than expected, challenge the safety of structural integrity and final failure in shipping. This is caused by many uncertain factors, e.g. chosen S-N parameters, load spectrum range, fatigue assessment method, etc.

The solving alternately starts from how to get the structural stress history for various sea-states. A sea-state is characterized by its energy spectra, which is a function of significant wave height (*Hw*) and mean wave period (*Tw*). The transfer function of structural stress response, also known as RAOs, is obtained from a direct calculation by considering wave loads for all loading conditions, ship speeds, and heading angles. It can be combined with the wave energy spectrum of a sea state to compute the stress spectrum. The fatigue crack propagation theory is capable to predict fatigue crack propagation length in a real service voyage [1][2].

The accuracy of fatigue propagation analysis hinges on the load sequence's reproducibility of the actual sea-state history. Ship owners' concern about fatigue damage is growing, and the ship operation / route is changed constantly according to the weather condition. The load sequence obtained from the wave scatter diagram in classification society rules may be different from that of the actual load [3]. This may affect the accuracy of the crack propagation analysis.

Recently, many sources of wave data, i.e. hindcast, satellite measurement, and onboard measurement can be utilized for load history simulation. In this study, the effect of the wave environments encountered by a 2800TEU container ship in North Atlantic Ocean on the fatigue crack propagation life is discussed. The crack propagation analyses are conducted by using stress histories simulated from the ship's encountered sea-state history. In these simulations, two stochastic wave models are utilized, and the difference in the simulated crack propagation lives is examined.

2. The two established wave models

This section explains the capability and reliability of two wave models in load sequence and fatigue damage estimation. These wave models are developed based on statistical analysis of ocean wave measurements. The first model is the 'Spatio-temporal wave model' developed by using satellite wave data [5]. The other model is the '3G-storm model' developed by using the hindcast data [7]. The target ship is a 2800TEU container ship. The sea-states were measured onboard on this ship, and the onboard data are used as a reference. The ship sailed on the North Atlantics routes in the first half-year of 2008 as shown in Fig. 1. Details of this target ship are described in [4].

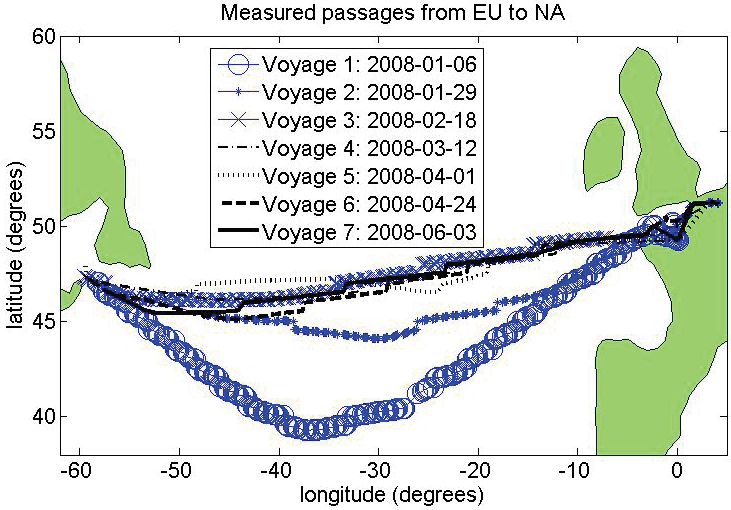

Figure 1. Voyage from EU to USA of 2800TEU container ship along first semester of 2008 (the arrival date of each voyage is indicated in the legend) [3].

2.1 The spatio temporal wave model

The significant wave height *Hw* at position ***p*** and time *t* is accurately modeled by means of lognormal cumulative distribution function (cdf). Let $X(\mathbf{p},t) = ln(Hw(\mathbf{p},t))$ denote a field of logarithms of significant wave height that evolves in time. For a fixed *t*, the local field $X(\mathbf{p},t)$ is assumed to be homogeneous Gaussian with covariance changes for the location ***p***. The Gaussian field $X(\mathbf{p},t)$ is assumed to have a mean that varies annually due to the periodicity of the climate. In the model, the mean value of the Gaussian field is assumed as:

$$\mu(t) = E\left[\mathrm{X}(p,t)\right] = \beta_0 + \beta_1 \cos(\phi t) + \beta_2 \cos(\phi t) + \alpha t \tag{1}$$

where $\phi = 2\pi/365.2$ is chosen to give an annual cycle for time in days. The parameters in Eq. (1)

can be computed from the satellite measurements.

Suppose t_0 be the starting date of a voyage, and the position on the planned route is given as $\boldsymbol{p}(t) = (x(t), y(t))$, for the time period $[t_0, t_1]$, and the ship's velocity as $v(t) = (v_x(t), v_y(t))$. For a given route let $z(t) = X(\boldsymbol{p}(t),t)$ be the encountered logarithms of Hw. (The encountered significant wave height is $Hw(t) = exp(z(t))$.) Obviously it will be different for $\boldsymbol{p}$ close to the coast and for $\boldsymbol{p}$ in the middle of the ocean. Hence, the encountered process $z(t)$ will be Gaussian but non-stationary.

In principle, the mean value and variance of the Gaussian field are needed in order to compute the distribution of Hw along the route. The covariance structure should also be provided if the variance of fatigue damages is required. In general, the data from both satellites and buoys are necessary to get the parameters of the covariance structure in the model. The median value of Hw in February and August in the spatio-temporal model is shown in Fig. 2. Further description of the model can be referred to [5].

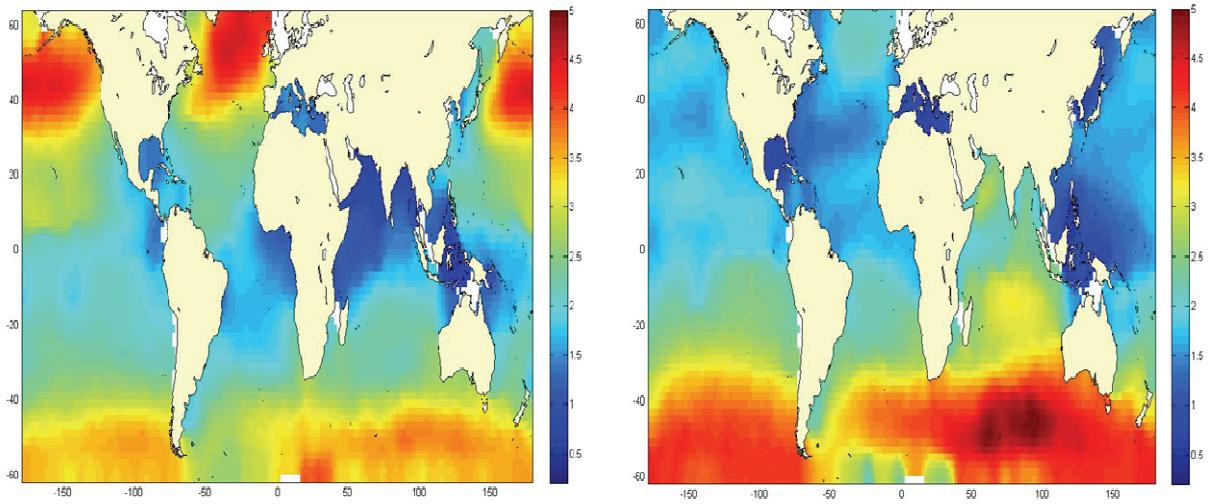

Figure 2. The median value of Hw (meters) in February (left) and in August (right).

2.2 The 3G-storm model

In order to simulate load sequences in the real oceans, Tomita [6] proposed the storm model. It was assumed that ocean conditions could be classified into either calm-sea or storm. Calm-seas are modeled as time-independent random waveforms, while storms are modeled as individual wave sequences with crescendo de-crescendo amplitude waveforms. Tomita's storm model was modified by Prasetyo and Osawa [7] so that the correlation between Hw and Tw and the variance of storm duration can be taken into account. This modified model is called '3G-storm model'. Storm profiles are determined by assuming that the long-term probability distribution of Hw obeys Weibull distribution [6]. The detail and procedure to determine storm profile parameters is described in [7]. Once Hw is determined, Tw is determined by using a wave scatter diagram (a joint probability distribution of Hw and Tw, $P(Hw,Tw)$).

2.3 Comparison of the two wave models

Figure 3 shows the comparison of probability density function (pdf) of *Hw* simulated by using the spatio-temporal wave model and the 3G-storm model along the North Atlantic voyages of Fig. 1. In this figure the pdf of H_w from the onboard measurement and that provided in DNV recommendation [8] are also presented. This figure shows that both wave models give more frequent mid-range waves (2m < *Hw* < 4m) than the onboard measurement and the DNV recommendation. The fatigue damage accumulated during 7 voyages of Fig. 1 is compared and presented in Table 1. Two wave models give about 25% overestimation comparing with the total rainfall damages which is computed using the recorded stress signals. Generally speaking, for each voyage, the difference of fatigue damage is negligible except the voyage 2008-06-03. It means that the two wave models could be used for the design purpose to generate *Hw* history and fatigue damage estimation.

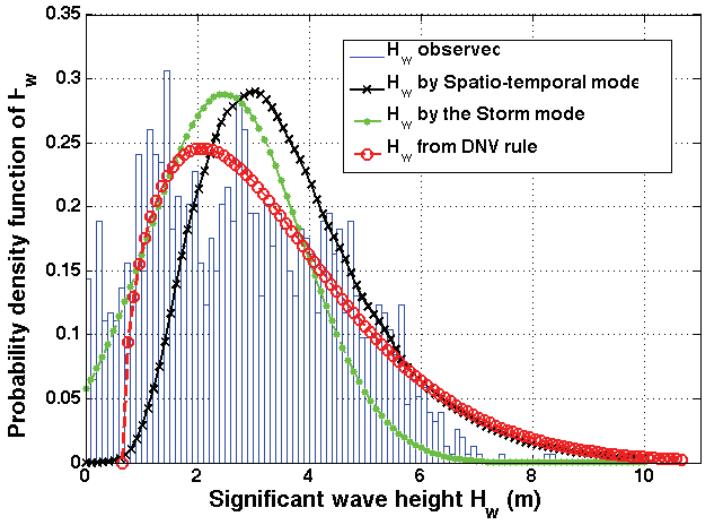

Figure 3. Probability density function (PDF) of *Hw*.

3. Fatigue crack propagation analysis

3.1 Comparison of stress history

Sea-state histories (*Hw*, *Tw*) can be simulated by the 3G-storm model. Once a sea-state is simulated, the stress history can be generated by using the wave spectrums and the transfer function of ship

structural stress, known as RAO. Once (*Hw*, *Tw*) are given, the power spectral densities of wave, $S(\omega)$, is determined. Ocean wave spectrums such as JONSWAP spectrum, modified Pierson-Moskowitz (ISSC) spectrum [9] are utilized in this analysis. In the stress calculation, the history of the ship's heading angle to the wave, χ, is needed because the RAO depends on not only *Hw* and *Tw* but also χ. Once *Hw*, *Tw* and χ are given, the power spectral densities of stress is determined as the cross spectrum, then the individual stress waveform is generated by assuming that the stress amplitude follows Rayleigh distribution whose parameter are determined from the cross spectrum.

The cdf of *Hw* is estimated by the spatio-temporal wave model at a given time and point. Once the probability distribution of *Hw* is given, the energy spectrums of wave and stress response can be computed by using ocean wave spectrums and RAOs for stress response. It is known that for fatigue assessment, the ship structural stresses can be assumed to Gaussian distributed. For one stationary sea-state, the Gaussian stresses are fully defined by its spectral density and the mean value. Hence, one could also simulate the stress signal from the obtained stress spectral density for each sea-state; see Fig. 4 for an example.

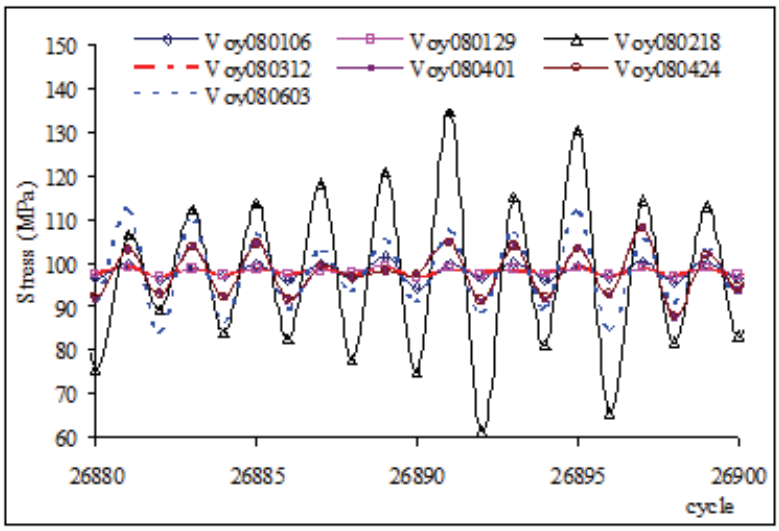

Figure 4. Examples of simulated stress histories of the 2800TEU container ship for different voyages from EU to USA using the 3G-storm model' in a certain cycle.

In the following discussion, the stress history generated by 3G-storm model is called 'model 1', and that generated by the spatio-temporal wave model is called 'model 2'. In order to make the maximum stress amplitude of two histories to be of almost equal level, the simulated stresses are normalized by a correction factor. Figure 5 shows the relation between the stress amplitude S_a and the occurrence frequency. The S_a threshold of crack propagation for the given initial crack size, $S_{a,th}$=49.5MPa, is presented in this figure. It is shown that the occurrence frequency of S_a derived from Spatio temporal model is larger than that of 3G-stom model for cases where $S_a > S_{a,th}$.

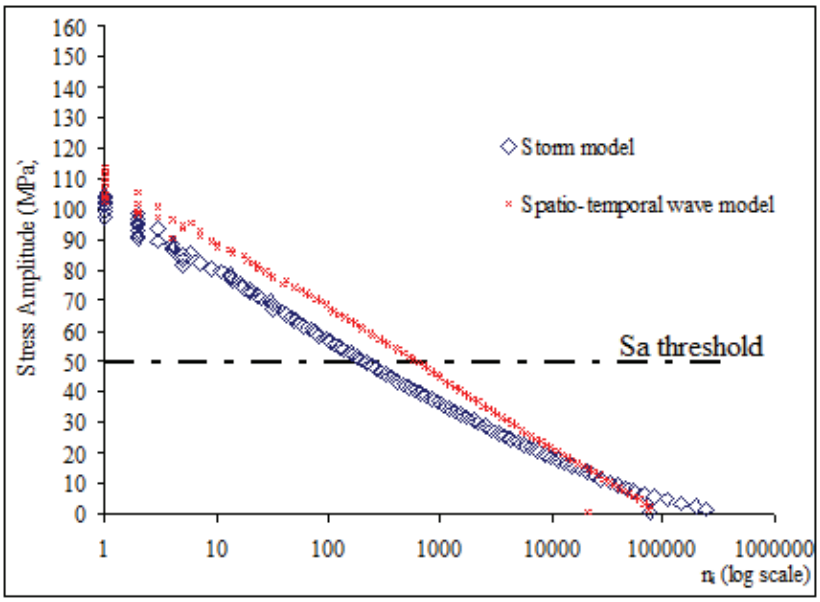

Figure 5. The relation between the stress amplitude S_a and the occurrence frequency of stress histories generated by the 3G-storm and spatio-temporal wave models.

3.2 Fatigue crack propagation model and analyses

Fatigue crack propagation analysis might concern some uncertainty factors on its computation [1]. Analyses results depend on crack growth formula and the accuracy of stress intensity factor (SIF) calculation. In this study, crack propagation is computed by FASTRAN II [12], which is based on cohesive yield model and crack closure concept. The software was developed using crack closure concept [11][12]. Details of the background theory of this code are described by Newman [11][12]. In this study, the crack propagation of a surface crack in a weld of ship structural member is analyzed. SIF range ΔK is calculated by using the modified Newman-Raju formula [10], given as:

$$\Delta K = K_s . M_k . \left(\Delta\sigma_m . F_m \left(c, a, t \right) + \Delta\sigma_b . F_b \left(c, a, t \right) \right) \sqrt{\pi a} \tag{2}$$

where, K_s is the stress concentration factor of structural detail, and it can be calculated by FE direct calculation or by using the engineering formula provided by classification society rules. M_k F_b and F_m are correction factor for weld bead and finite plate size, and they are presented in [10]. The parameters a and c are the depth and surface length of a semi elliptical surface crack defined in Fig. 6 and t is the thickness of the main plate.

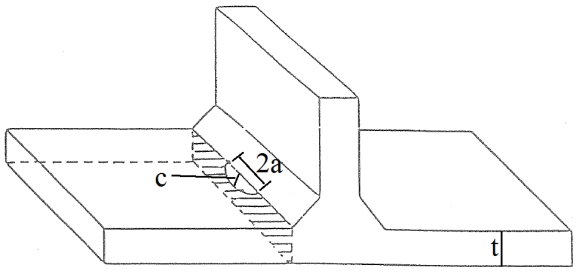

Figure 6. Typical semi-elliptical surface crack on weld toe of fillet weld joint.

The crack growth rate is calculated by modified Paris-Elber law (Eq.3):

$$\frac{da}{dN} = C\left\{\left(\Delta K_{eff}\right)^m - \left(\left(\Delta K_{eff}\right)_{th}\right)^m\right\} \tag{3}$$

where C and m are the material parameters. ΔK_{eff} and $\left(\Delta K_{eff}\right)_{th}$ are the effective SIF range and its threshold.

3.3 Results: fatigue propagation analyses

The crack propagation analysis of two stress histories (model 1 and model 2) is conducted. The initial surface crack length is 0.2 mm, and the initial aspect ratio is 1/2. The propagation analyses are continued until the crack depth exceeds 8 mm or the surface length exceeds 10 mm. Crack growth is computed by using Eq. (3). The material parameters, C and m are 1.45e-11m/cycle and 2.75, respectively. Let Sa_{th} be the threshold of stress range so that the initial crack can growth. The threshold of the stress intensity $\left(\Delta K_{eff}\right)_{th}$ is equal to 2.45MPa.m$^{1/2}$ and Sa_{th} is about 49.5MPa. The stress history is simulated 15 trials in order to provide statistical data of crack propagation analysis and the mean stress is chosen to be 98.0MPa.

The statistics of propagation lives analyzed is presented in Table 2. Figure 7 shows the comparison of the relationship between the growth rate and SIF range for the cases with the shortest propagation life as listed in Table 2. In this table, it is shown that the model 1 leads to longer lives than those of model 2 in most voyages while fatigue damages derived from these two models are almost equal (see Table 1). The model 2 leads to rapid crack growth rate for the cases with same SIF range (i.e. 14MPa.m$^{1/2}$ ≤ SIF ≤ 17MPa.m$^{1/2}$) than the model 1 as seen in Fig. 7.
It is supposed that the retardation of crack growth rate for the cases of model 1 is caused by the excessive load of the generated storm state in Hw history. This shows that the loading sequence of the excessive load affects to crack propagation behavior.

Table 2. Calculated crack propagation life of stress history that it is computed using the 3G-storm model and the spatio-temporal model.

4. Conclusions

Wave environment loads could be simulated based on different wave models for the fatigue strength assessment. In this study, two different wave models (the spatio-temporal wave model and the 3G-storm model) are compared with the onboard measurement of a 2800TEU containership. The comparison shows that the two wave models give the same probability density function of *Hw* along these measured routes. Subsequently, the generated stress history could be obtained for different routes, but there is some difference in occurrence frequency of stress amplitude computing from stress spectra.

Retardation and acceleration of crack growth is shown by optimizing different routes with simulated load sequence of two wave models. The crack propagation analysis can be utilized in ship design to be more realistic.

A Weight Function for Zr-2.5Nb Pressure Tube Burst Test Specimens

(DRAFT FOR REVIEW)

Steven X. Xu*, Douglas A. Scarth

Structural Integrity and Risk Assessment, Kinectrics Inc., Toronto M8Z 5G5, Canada
* Corresponding author: steven.xu@kinectrics.com

Abstract Based on a literature review, the weight function for an axial through-wall crack in a cylinder has not been reported in the open literature. A weight function for an axial through-wall crack in a cylinder that is applicable to the pressure tube burst test specimens has been developed and is described in this paper. Three-dimensional finite element analyses were performed to calculate the stress intensity factors corresponding to line loads on the crack face. The calculated stress intensity factors were used to develop a weight function for the pressure tube burst test specimens based on regression analysis and engineering judgment.

Keywords Weight function, Stress intensity factor, Axial through-wall crack, Pressure tube, Burst test

1. Introduction

In CANDU® nuclear reactors, the primary containment for the uranium dioxide fuel is provided by thin-walled Zr-2.5Nb pressure tubes, which are nominally 6.3 m long, 103 mm in diameter, and 4.2 mm thick [1, 2]. During operation, the pressure tubes undergo corrosion with the heavy water coolant, D_2O. A portion of the deuterium (D) released by the corrosion reaction is absorbed by the pressure tube and its accumulation over time represents a primary integrity concern. Technical requirements for in-service evaluation of Zr-2.5Nb pressure tubes in CANDU reactors are provided in the CSA Standard N285.8 [3], including evaluation of service conditions for protection against fracture of operating pressure tubes, as well as defense-in-depth demonstration of leak-before-break. Evaluation procedures for protection again fracture and demonstration of leak-before-break are based on use of the fracture toughness versus temperature relationship. Fracture toughness measurements from pressure tube burst tests have shown that hydrides associated with high levels of hydrogen equivalent concentrations can have a significant effect on reducing the fracture toughness at reactor operating temperature during reactor warm-up and cool-down [4]. To support safe operation of pressure tubes at late life where the projected hydrogen equivalent concentrations are of high levels, there has been an initiative in CANDU industry in Canada to gain mechanistic understanding of the effect of levels of hydrogen equivalent concentrations on fracture toughness. A cohesive-zone based engineering fracture toughness model is being developed to assess the effect of zirconium hydrides on the fracture toughness of Zr-2.5 Nb pressure tubes. The knowledge of weight function is required in the calculation of crack opening displacement in the cohesive-zone modeling. Based on a literature review, the weight function for an axial through-wall crack in a cylinder has not been reported in the open literature. A weight function for an axial through-wall crack in a cylinder that is applicable to the Zr-2.5Nb pressure tube burst test specimens have been developed and is described in this paper.

2. Considerations for Development of Weight Function for Burst Test Specimens

A schematic illustration of the pressure tube burst test specimen is given in Figure 1. Three-dimensional finite element analyses were performed to calculate the stress intensity factors corresponding to line loads on the crack face. The calculated stress intensity factors were used to develop a weight function for the burst test specimens based on regression analysis and engineering

® CANDU is a registered trademark of Atomic Energy of Canada Ltd.

judgment**.** The following considerations for the development of a weight function for the burst test specimens were identified.

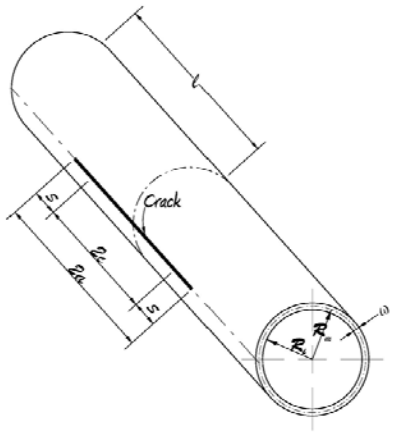

Figure 1. Illustration of pressure tube burst test specimen

(1) Consideration was given to ranges of dimensions for the burst test specimens. Variations in inner radius R_i and wall thickness w of pressure tube burst test specimens are insignificant. The dimension ranges for pressure tube inner radius and wall thickness were not considered. A representative inner radius R_i = 52 mm and wall thickness w = 4.0 mm were used in the weight function development. The initial crack length of a burst test specimen, $2c$, is typically 55 mm. An axial through-wall crack with length $2a$ of 50 to 75 mm was considered in the weight function development.

(2) Consideration was given to the crack model as one dimensional. The axial through-wall crack was treated as one dimensional, and the crack geometry was characterized by the crack length. The treatment of a one-dimensional crack in the axial direction of the pressure tube is considered to be reasonable since the ratios of pressure tube radius to wall thickness of burst test specimens exceed ten. The overall behavior of a pressure tube burst test specimen is expected to be representative of a plane stress state. This assumption was verified through finite element calculations as described in Section 3.

(3) Consideration was given to characterization of the crack-tip singularity. It was assumed that a through-wall axial crack in a pressure tube and a through-wall crack in a flat plate have the same type of singularity. This assumption forms the basis for the proposed format for the weight function for the burst test specimens. Using the notation as illustrated in Figure 2, one format of the weight function for a through-wall crack in an infinite flat plate, $m_0(x,a)$, is given by Eq. 1 [5].

$$m_0(x,a) = \frac{2}{\sqrt{\pi a}} \frac{1}{\sqrt{1-\left(\frac{x}{a}\right)^2}} \tag{1}$$

where x is x-coordinate relative to the crack center in an infinite plate.

(4) Consideration was given to the format of the weight function for the burst test specimens. Further to the consideration in (3), it was assumed that the weight function for an axial through-wall crack in a pressure tube, $m(x,a)$, can be written in terms of the weight function for a through-wall crack in an infinite flat plate with a modification coefficient. It is assumed that the modification coefficient is a function of the location parameter x/a, and the geometry parameter $a/\sqrt{R_m w}$, as expressed in Eq. 2. This assumption is based on engineering judgment. As discussed later in Sections 4 and 5, finite element calculation results provided support for this assumption.

$$m(x,a) = m_0(x,a)\, F\left(\frac{x}{a}, \frac{a}{\sqrt{R_m w}}\right) \tag{2}$$

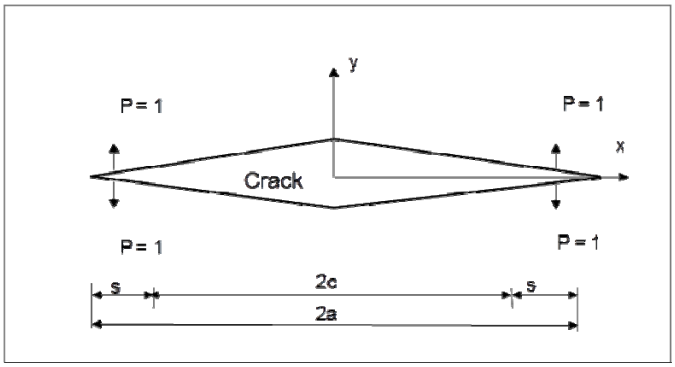

Figure 2. Weight function notation for a central through-wall crack in a flat plate or an axial crack in a pressure tube

3. Confirmation of Thickness Averaged Behavior of Plane Stress State

Three-dimensional elastic finite element analyses were performed to calculate the stress intensity factors for an axial through-wall crack in an internally pressurized long cylinder. The geometry of a representative burst test specimens was used. The inner radius of the cylinder was R_i = 52 mm and wall thickness was w = 4.0 mm. Two cases of crack length were considered, $2a$ = 50 mm and $2a$ = 75 mm. The length of the cylinder was set to 50 times crack length in the finite element model. Crack face pressure loading was included. Only one quarter of the cylinder was modeled and analyzed due to the symmetry consideration. The fracture mechanics specific three-dimensional finite element mesh generation tool FEACrack was used [6]. The generated three-dimensional finite element mesh for a 50 mm long axial through-wall crack is shown in Figure 3. The mesh contains 107,246 nodes and 24,360 20-node brick elements. Twenty one elements were used across the wall thickness near the crack-tips. The spider-web mesh design was used with concentric rings of elements focused towards the crack tips. The element edge length for the first ring elements was 5 μm. The mid-side nodes at the crack-tips were move to the one-quarter points. The crack-tip nodes were tied together. A similar mesh was used for the case of a 75 mm long crack. The mesh for the 75 mm long crack contains 119,446 nodes and 26,985 20-node brick elements. Elements around the crack-tips were essentially the same as in the case of 50 mm long crack.

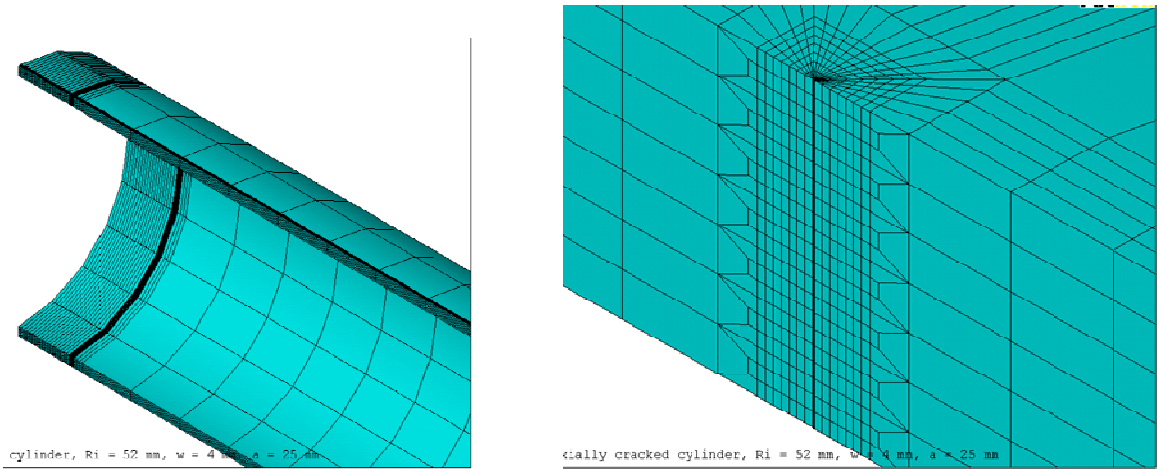

Figure 3. Three-dimensional finite element mesh of one quarter of a pressure tube burst test specimen

Two cases of Poisson's ratio were considered, $\upsilon = 0.3$ and $\upsilon = 0.4$. Finite element analyses were performed using ANSYS [7]. Stress and strain data obtained from ANSYS were read to FEACrack for calculation of the J integral. The path independence of J integral results was confirmed. Forty-three values of the J integral were obtained along the wall thickness for each case of crack depth and Poisson's ratio. Each value of J was converted to a stress intensity factor, K_I, using either plane stress or plane strain conditions. An internal pressure of p = 100 MPa was used in the calculation, with inclusion of crack face pressure. Since the calculations are based on linear elastic material behavior, the level of internal pressure is arbitrary in the context of development of weight functions. The thickness averaged K_I results for crack length $2a$ of 50 and 75 mm for plane stress and plane strain conditions, when Poisson's ratio $\upsilon = 0.3$ was used in the finite element calculations, are listed in Table 1. The mid-thickness K_I results are also listed for comparison. In addition, the K_I results calculated based on the commonly used bulging factor are listed in Table 1 [3]. The bulging factor is based on the shallow shell theory and calculated K_I results correspond to plane-stress conditions [8, 9, 10]. It is seen that the thickness averaged K_I results for plane stress conditions are in reasonable agreement with the K_I results calculated based on the bulging factor. The mid-thickness K_I results also generally agree with K_I results calculated based on the bulging factor, but the agreement is not as good as the thickness averaged K_I results. Similarly, the thickness averaged K_I results and the mid-thickness K_I results when Poisson's ratio $\upsilon = 0.4$ was used in the finite element calculations are listed in Table 2. The K_I results calculated based on the bulging factor are also listed in Table 2. Again, it is seen that the thickness averaged K_I results for plane-stress conditions are in reasonable agreement with the K_I results calculated based on the bulging factor.

The above observations from Tables 1 and 2 confirm that the thickness averaged behavior of the pressure tube is of a plane stress state. This average over the wall thickness approach was subsequently used to extract stress intensity factor results from three-dimensional finite element results for the development of the weight function for the burst test specimens as described in Sections 4 and 5.

Another observation from Tables 1 and 2 is that the effect of Poisson's ratio on the thickness averaged K_I results for plane-stress conditions is insignificant. In Table 1 with $\upsilon = 0.3$, the thickness averaged K_I are 854 and 1406 MPa√m for crack lengths $2a$ = 50 and 75 mm, respectively. In Table 2 with $\upsilon = 0.4$, the corresponding K_I are 849 and 1398 MPa√m for crack lengths $2a$ = 50 and 75 mm, respectively. This observation provides additional support for using the wall thickness averaged result when extracting three-dimensional finite element results for the development of the weight function for burst test specimens.

Table 1. Stress intensity factors for an axial through-wall crack in a pressure tube with internal pressure of 100 MPa, Poisson's ratio of 0.3 used in finite element calculation

METHOD TO CALCULATE STRESS INTENSITY FACTOR		STRESS INTENSITY FACTOR, K_I (MPa√m)	
		$2a$ = 50 mm	$2a$ = 75 mm
Averaged result over thickness based on 3-D FE results	Plane stress	854 MPa√m	1406 MPa√m
	Plane strain	895 MPa√m	1474 MPa√m
Mid-thickness result based on 3-D FE results	Plane stress	874 MPa√m	1441 MPa√m
	Plane strain	917 MPa√m	1511 MPa√m
Result based on the bulging factor [3]		834 MPa√m	1409 MPa√m

Table 2. Stress intensity factors for an axial through-wall crack in a pressure tube with internal pressure of 100 MPa, Poisson's ratio of 0.4 used in finite element calculation

METHOD TO CALCULATE STRESS INTENSITY FACTOR		STRESS INTENSITY FACTOR, K_I (MPa√m)	
		$2a$ = 50 mm	$2a$ = 75 mm
Averaged result over thickness based on 3-D FE results	Plane stress	849 MPa√m	1398 MPa√m
	Plane strain	927 MPa√m	1526 MPa√m
Mid-thickness result based on 3-D FE results	Plane stress	882 MPa√m	1455 MPa√m
	Plane strain	962 MPa√m	1587 MPa√m
Result based on the bulging factor [3]		834 MPa√m	1409 MPa√m

4. Finite Element Calculation of Weight Function for Burst Test Specimens

A one-dimensional weight function can be interpreted as the stress intensity factor for a pair of opposing unit line loads acting on the crack faces of a three-dimensional cracked body. Three-dimensional finite element analyses were performed to calculate the stress intensity factors for a line load on the crack faces, or discrete values of the weight function, for pressure tube burst test specimens.

As discussed in Considerations (3) and (4) in Section 2, it was assumed that the normalized weight function for the pressure tube burst test specimen, $m(x,a)/m_0(x,a)$, does not contain any singularity, where $m_0(x, a)$ is the weight function for a through-wall crack in an infinite flat plate. It was also assumed that the normalized weight function $m(x,a)/m_0(x,a)$ is a function of the location parameter x/a and the geometry parameter $a/\sqrt{R_m w}$.

Table 3. Finite element calculation matrix for development of weight function for burst test specimen

CALCULATION SET	CRACK LENGTH, $2a$ (mm)	LOAD LOCATION, x/a
I	12 values distributed between [2, 100]	0
II	50	10 values distributed between [0, 1)
III	75	10 values distributed between [0, 1)

The finite element calculation matrix for the development of a weight function for the burst test specimens is listed in Table 3. The pressure tube inner radius R_i of 52 mm and wall thickness w of 4.0 mm were used in all cases. Poisson's ratio $\upsilon = 0.3$ was used. Based on the discussion in Section 3, the effect of Poisson's ratio on the wall thickness averaged K_I values for plane-stress conditions has been confirmed to be insignificant. Three sets of finite element calculations in Table 3 were chosen based on parameter combinations of load location and crack length. In calculation Set-I, the load was always applied on the crack center line, *i.e.* $x/a = 0$. Discrete values of the weight function from calculation Set-I were used to characterize the trend of the weight function with the geometry parameter $a/\sqrt{R_m w}$. In calculation Set-II, the crack length was fixed to $2a$ = 50 mm, and pressure load was applied to lines located at ten different locations between crack centers and crack-tips.

Calculation Set-III is similar to Set-II, except that the crack length was $2a$ = 75 mm. The finite element mesh design was the same as described in Section 3. An example of a crack-tip zoomed-in view of the three-dimensional finite element mesh of one quarter of a burst test specimen with line load of pressure applied on the crack face is given in Figure 4.

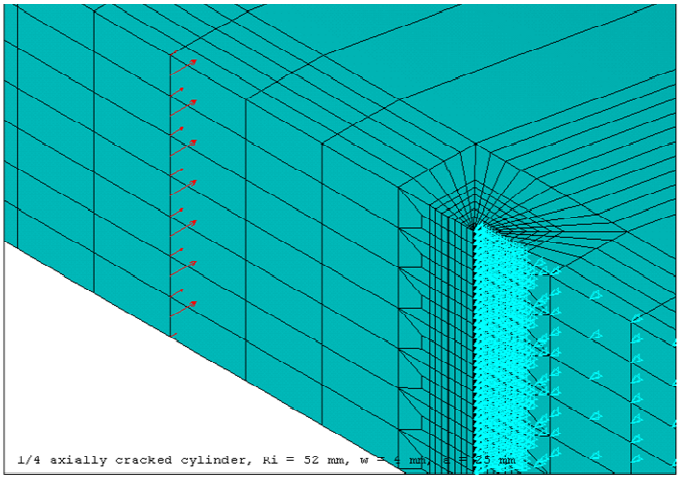

Figure 4. Crack-tip zoomed-in view of three-dimensional finite element mesh of one quarter of a pressure tube burst test specimen with inner radius of 52 mm, wall thickness of 4 mm, and 50 mm long axial through-wall crack, line load of pressure applied on crack face (denoted by red arrows)

The wall thickness averaged K_I results for plane-stress conditions, or the discrete values of weight function $m(x, a)$, were extracted from the three-dimensional finite element results. The normalized weight functions $m(x,a)/m_0(x,a)$ were obtained for the calculation Sets-I, II and III, respectively.

5. Regression Fit and Proposed Weight Function

The wall thickness averaged finite element results of normalized weight function obtained in Section 4 were fitted to an engineering equation using TableCurve2D [11], in conjunction with engineering judgment.

The discrete values of normalized weight function at the crack center for the calculation Set-I in Table 3 were found to fit well with the following simple equation.

$$\frac{m(0,a)}{m_0(0,a)} = \sqrt{1+3.696\frac{a^2}{R_m w}} \tag{3}$$

The R^2 coefficient of variation was 0.999, the fit standard error was 0.0612, and F-statistic was 11570. The comparison of finite element data and the fitted equation is plotted in Fig. 5. The maximum fitting error was 2.1%.

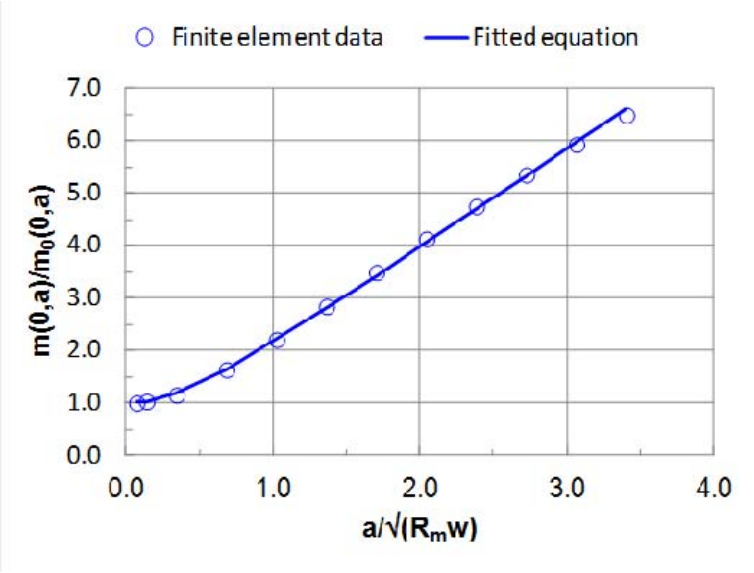

Figure 5. Finite element results and fitted equation of normalized weight function for the calculation Set-I for an axial through-wall crack in a pressure tube

The trend of normalized weight function with the location parameter *x/a* was investigated using the finite element data for the calculation Set-II and Set-III in Table 3. The discrete values of normalized weight function $m(x,a)/m_0(x,a)$ for a crack length of $2a$ = 50 mm for the calculation Set-II were fitted as a function of *x/a*. A separate fit was performed for the data for the calculation Set-III for a crack length of $2a$ = 75 mm. It was found that the equation format of Eq. (4) fits well to the data for both calculation sets. For the case of the 50 mm long crack, the fit standard error was 0.0371, and the *F*-statistic was 3635. For the case of the 75 mm long crack, the fit standard error was 0.0478, and the *F*-statistic was 6160.

$$\frac{m(x,a)}{m_0(x,a)} = C_1 + C_2\left(\frac{x}{a}\right)^2 \tag{4}$$

where C_1 and C_2 are fitting coefficients.

The fitting of C_1 and C_2 in Eq. (4) were used to determine the appropriate functional form of $m(x,a)/m_0(x,a)$, and were not used in the final form of the weight function. In the absence of using a three-dimensional fitting tool and with limited finite element data, engineering judgment was applied to establish an engineering equation using equation formats of Eqs. (3) and (4). The engineering equation is written as

$$\frac{m(x,a)}{m_0(x,a)} = M - (M-1)\left(\frac{x}{a}\right)^2 \tag{5}$$

with

$$M = \sqrt{1 + 3.696\frac{a^2}{R_m w}} \tag{6}$$

The comparison of finite element data for the calculation Set-II and Sec-III and the engineering equations of Eqs. (5) and (6) is plotted in Figure 6. The maximum fitting error was 4.2% for the data for the calculation Set-II, and 6.7% for the data for the calculation Set-III. These fitting errors were considered to be acceptable. An improved equation fit might be obtained if a proper three-dimensional fitting tool was used in the fitting process. Generating additional finite element data for crack lengths other than $2a$ = 50 and 75 mm may be necessary for improvement in the equation fit.

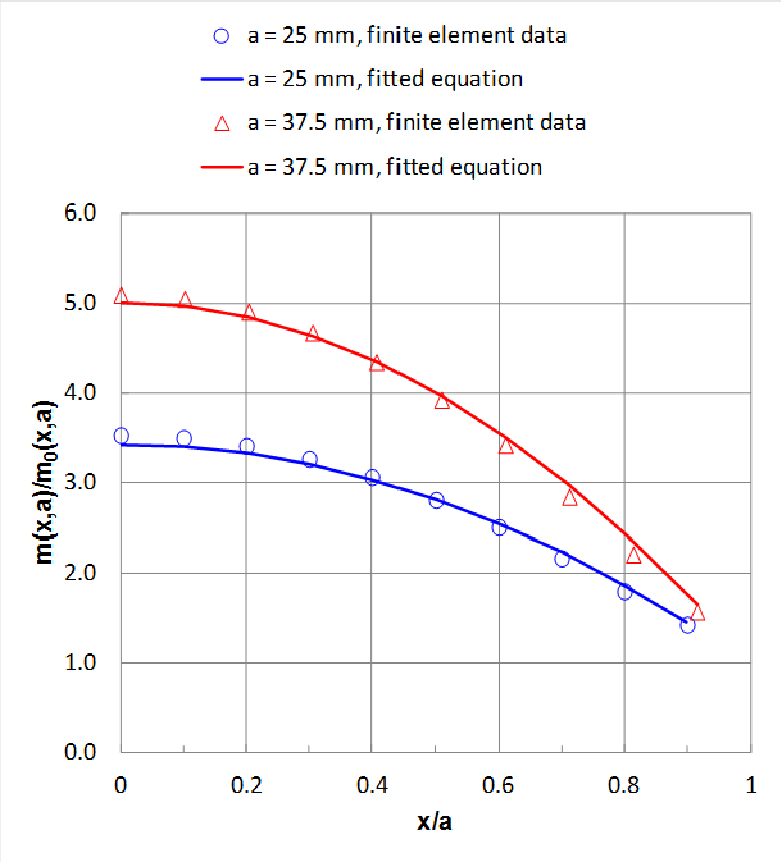

Figure 6. Finite element results and fitted equation of normalized weight function for calculation Set-II and Set-III for an axial through-wall crack in a pressure tube

The proposed weight function for the burst test specimen is given by

$$m(x,a) = \frac{2}{\sqrt{\pi a}} \frac{1}{\sqrt{1-\left(\frac{x}{a}\right)^2}} \left[M - (M-1)\left(\frac{x}{a}\right)^2 \right] \tag{7}$$

where the parameter M is given by Eq. (6).

It is reasonable to expect that, when loading on the crack face is uniform, the stress intensity factor calculated using the developed weight function is consistent with the conventional calculation approach based on the bulging factor for an axial through-wall crack. This consistence was checked. When the internal pressure is p, the stress intensity factor for the burst test specimen using the

bulging factor M_b, $K_I(M_b)$, is written as Eqs. (8) and (9).

$$K_I(M_b) = p\frac{R_i}{w}M_b\sqrt{\pi a} \tag{8}$$

with

$$M_b = \sqrt{1+1.255\frac{a^2}{R_m w}-0.0135\left(\frac{a^2}{R_m w}\right)^2} \tag{9}$$

With the use of the weight function approach, the stress intensity factor for the burst test specimens, $K_I(m)$, is written as

$$K_I(m) = \int_0^a m(x,a)\, p\frac{R_i}{w}dx \tag{10}$$

Substitution of Eq. (7) into Eq. (10) results in

$$K_I(m) = p\frac{R_i}{w}\left(\frac{M+1}{2}\right)\sqrt{\pi a} \tag{11}$$

The numerical values of $K_I(M_b)$ and $K_I(m)$ were compared for four cases of crack length, $2a$ = 50, 60, 75 and 100 mm. The percentage differences between $K_I(M_b)$ and $K_I(m)$ are within 5%.

Abstract Three kinds of welding and heat treatment procedures are commonly used to make mooring chains for offshore structure in this paper. In order to determine the toughness, several specimens extracted from the welded joints and base metals are subjected to mechanical testing by means of Crack Tip Opening Displacement (CTOD) tests. Considering the data obtained, it can be recommended that the materials are safe enough in toughness to construct engineering structures (higher than the acceptable value specification by DNV).M2 tempered with 640℃ (for 60 minutes) presents the highest CTOD and yield strength, followed by M3 tempered with 650℃. M1 tempered with 600℃ presents the lowest CTOD and yield strength. That means tempering at 640℃ can obtain best toughness together with yield strength. The fracture surface and microstructure of the samples are characterized using scanning electron microscopy. Quantitative examinations including grain size analysis and carbide content measurements are carried out. The fracture parameter CTOD is correlated with the fracture surface and microstructures. The carbide contents of M2 and M3 are greater than those of M1 and the greater the carbide content is, the higher the CTOD value will be. And the grain size has the same trend.

Keywords Offshore,Welded joint, Mooring chain, CTOD, Microstructure

1. Introduction

As one of the most important components, mooring chain is playing a key role in the marine structure. When the operating depth becomes deeper, the higher demand is required especially when under the depth of 1000m. In the deep sea, the temperature of water is low and the environment is corrosive, so cracks easily occurs (especially for stud link chains).In the welding process, weld metal is heated to melt, and it experiences crystallization and solid transformation when it cools down; various parts of the weld joints are subjected to different thermal cycles which bring about the differentiation and heterogeneity. Toughness is the ability to resist crack initiation and propagation under external loads and the ability to absorb energy in deformation process. It is a comprehensive performance of the strength and plasticity. Compared with the materials with bad toughness, the good ones can prevent the procedure from micro-crack to macro-crack from happening therefore. to avoid the disaster . Because of the bad toughness, the micro-cracks in the weld joint shown in Fig.1 [1] may easily turn into macro-cracks, and the whole structure may break down suddenly.

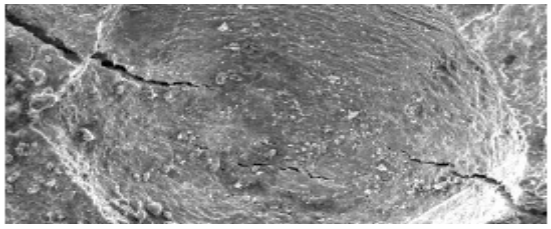

Fig.1.Micro-cracks of weld joints

Crack Tip Opening Displacement (CTOD) test is widely used to evaluate the toughness of steel structures especially the marine steel. There have been some studies about the relationship between toughness and microstructure in the past years [2, 3]. This paper aims at a further study of this issue and seeks for some ways to improve the microstructure to make the toughness and strength better.

Then the cracks will not initiate and propagate. As is known that the strength and toughness are contradicted, when the toughness becomes higher, the strength normally goes down. There are three types of mooring chains in this study, the first one is weak in both toughness and strength but the last two have better performance. Some reasons can be found in the microstructure for this phenomenon.

2. Tests procedure

2.1. Material

There are three types of mooring chains in this study: M1 with the diameter of 160mm, M2 with 124mm and M3 with 125mm. The mooring chains are provided by Foshan Marine Anchor Chain Ltd. and the flash butt welding is adopted. The production process is shown as follows: Cutting bars → Induction preheating→ Bending→ Flash butt welding→ Pressing→ Continuous heat treatment→ Mechanical tests. Table1 and Table2 have shown the Chemical composition of M1 (with the specimens 62-66), M2 (with the specimens 11-13) and M3 (with the specimens 1-3).

Table1. Chemical composition of M1（R3）

C	Si	Mn	P	S	Cr	Mo	Ni	Nb	Cu	Alt
0.27	0.15	1.40	≤	≤	≤	≤	≤	≤	≤	0.020
-0.33	-0.35	-1.90	0.025	0.025	0. 25	0.08	0.30	0.05	0.20	-0.050

Table2. Chemical composition of M2 and M3 (R3S)

C	Si	Mn	P	S	Cr	Mo	Ni	Nb	Cu	Alt
0.23	0.15	1.15	≤	≤	0.45	0.20	0.10	0.02	≤	0.020
-0.31	-0.30	-1.65	0.025	0.025	-0.75	-0.50	-0.20	-0.06	0.20	-0.050

2.2. CTOD and Charpy impact test

Three-point bending CTOD test was performed in accordance with BS7448:part2 [4] and EN 10225:2009[5] with WAW-1000kN tester controlled by computer, the testing temperature is -20℃. The schematic illustrations of CTOD test set-up is shown in Fig.3. According to the DNV's standard [6]: the specimen location is shown in Fig.2. The weld side specimen is named A specimen and the non-weld side one is named B specimen.

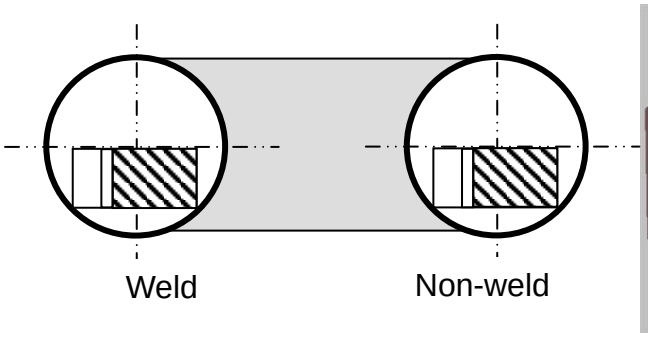

Fig.2. Location of CTOD test specimens

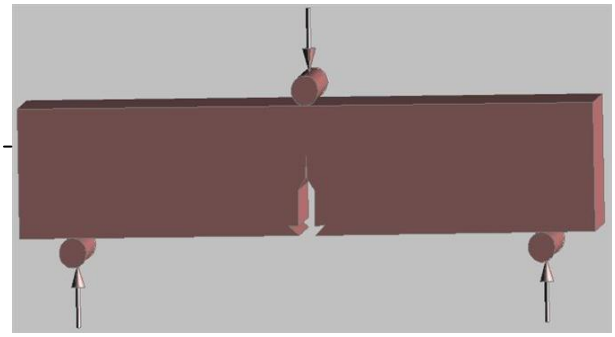

Fig.3. schematic illustrations of CTOD test set-up

The specimens are prepared perpendicular to the rolling direction and the weld bead. The facility to make fatigue pre-crack is JXG-200kN computer controlled high-frequency fatigue tester. The position of machining notch has been figured out in Fig.3. In order to reduce the effect of the weld residual stress on the fatigue pre-cracking, the fatigue pre-cracking is divided into two steps according to BS7448 Part 2 and each step uses different fatigue stress ratios (R). For the first step, the stress ratio R=0.1 is used until the fatigue pre-crack has grown to a length of about 2.5 mm .In

the second step, R is 0.7 and the fatigue pre-crack grown to 0.5mm. All the specimens are pretreated by local compression before pre-cracking. According to FV curve and other obtained data, CTOD value δ can be calculated referring with Eq. 1.

$$\delta = \delta_e + \delta_p = \left[\frac{FS}{BW^{3/2}} \cdot f(\frac{a_0}{W})\right]^2 \frac{(1-\mu^2)}{2\sigma_s E} + \frac{r_p(W-a_0)}{r_p(W-a_0)+a_0+z} \cdot V_p \qquad \text{Eq. 1}$$

Charpy impact was carried out according to DNV's standard, the testing temperature is -20℃. The samples were extracted through thickness notches, transverse to the weld bead and notched at the weld position. The average value of the three test results meets the specified requirement，no individual value is below the minimum average value specified.

2.3. Micro-analysis

The samples for metallographic and fracture analysis are extracted from the rupture specimens which have Conducted the CTOD fracture toughness tests. Positions to extract samples for microanalysis and sample geometry are presented in Fig.4. Samples A perform metallographic analysis. Other kinds of samples contain fracture surface and microstructure next to the cross-section are samples B. Samples B are along with the crack propagation direction and perpendicular to the crack surface.

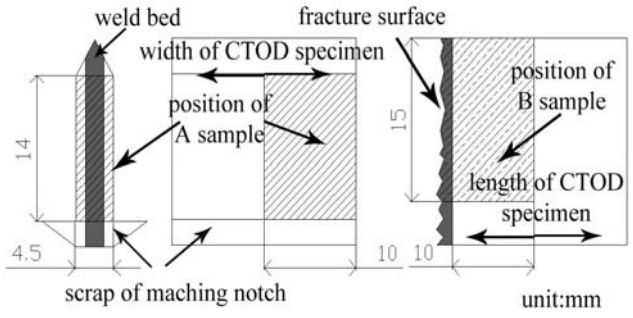

Fig.4. Position to extract samples for microanalysis

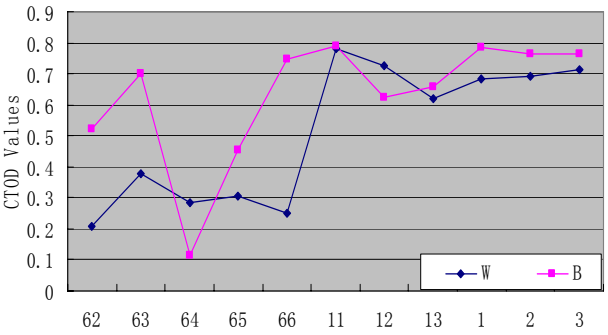

Fig.5.Tendency of CTOD values

The samples used to analyze microstructure should be grinded, polished and etched with 4% alcohol solution of nitric acid at first. Both the fracture surface and microstructure of samples were characterized using Scanning Electron Microscopy (SEM).

3.Test Results and Discussions

3.1. CTOD and Charpy impact test results

Through the CTOD test, Vp and a0 are measured, then referring to equation1, the δ is obtained and listed in Table5 and Table6. CTOD values of M1 specimens (with the number 62-66) are greater than those of M2 and M3 (with the number 1-3 and11-13). Fig.5 shows the tendency of CTOD values and table 7 gives the Charpy impact energy of different specimens.

Table5. CTOD values of weld specimens

Specimen	W62	W63	W64	W65	W66	W11	W12	W13	W1	W2	W3

akv (J)	43	61	40.5	39.5	36.5	144	140	146	99	91	110

From Fig.6, some features can be found from the macro section: There are both stable and unstable cracks in the specimens of all; The crack propagation of M1（with the specimens 62-66）is unstable，large parts of the crack face of both base metal and weld. Lots of parts of the crack of base metal are grey and the bright parts are not straight, it experiences some plastic deformation with obvious signs of tearing; the cracks of weld specimens are bright without any obvious signs of tearing.

Fig.6. fracture cross-section of different CTOD specimens

All of these phenomena conform to the tendency of CTOD values. Both the crack propagation of base metal and weld of M1 and M2 are unstable, the rupture areas of the base metal are smooth with obvious 45°shear lip.

3.2. Microstructure Analysis Results

Through the micro test using SEM, something about the microstructure can be obtained. Metallographs of the center of the weld and base metal of sample A in specimens (W62,W63,W66) of M1 are obtained. From the microstructure of base metal in W62A shown in Fig.7.a, ferrite and a small amount of martensite are presented. Fig.7.b shows the ferrite and cementite on the grain boundaries in the center of weld of W62A. The lath martensite, ferrite, sorbite and cementite on the grain boundaries are distinguished as is shown in Fig.7.c Carbide, sorbite and a little ferrite are found in Fig.7.d There are some ferrite, cementite and a little sorbite in Fig.7.e and Fig.7.f.

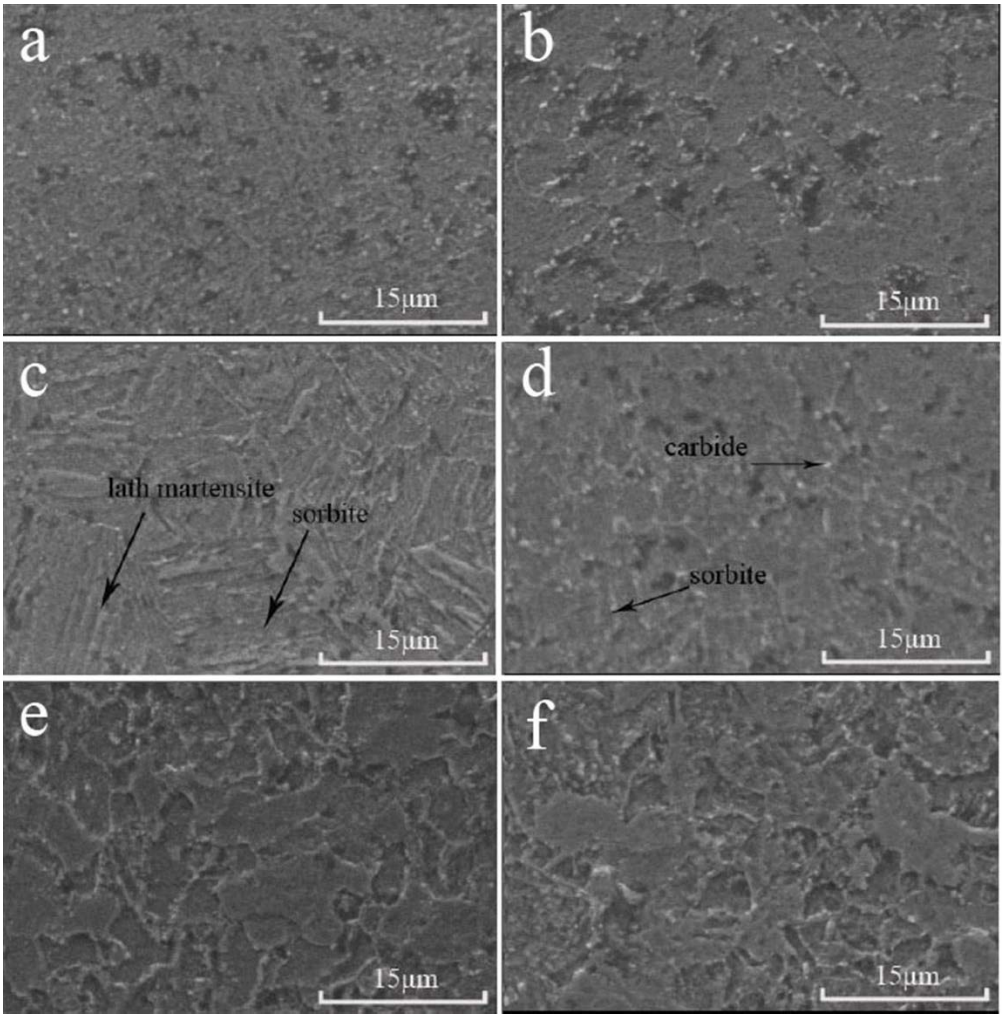

Fig.7. Microstructure of sample W62A,W63A and W66A
a.Base metal of W62A; b.Weld center of W62A; c.Base metal of W63A;
d.Weld center of W63A; e.Base metal of W66A; f.Base metal of W66A

The micro-morphology near the crack face is listed in Fig.8. Fig.8.a shows the microstructure near the crack of W62B: the grains have distinct directivity caused by plastic deformation and the elongated direction parallel to the crack face; Fig.8.b shows the secondary cracks, large inclusions, Carbide and ferrite near the fracture edge: The crack is caused by mixed influence of stress and inclusion; Fig.8.c shows the microstructure of W63B: there are lath martensite and sorbite without any deformation; Fig.8.d shows some inclusions but no secondary crack; Grains in Fig.8.e have obvious directivity and elongated direction perpendicular to the crack face. Secondary crack in Fig.8.f is classic facing a 45 ° angle with the main crack and the microstructure is ferrite and fine carbide.

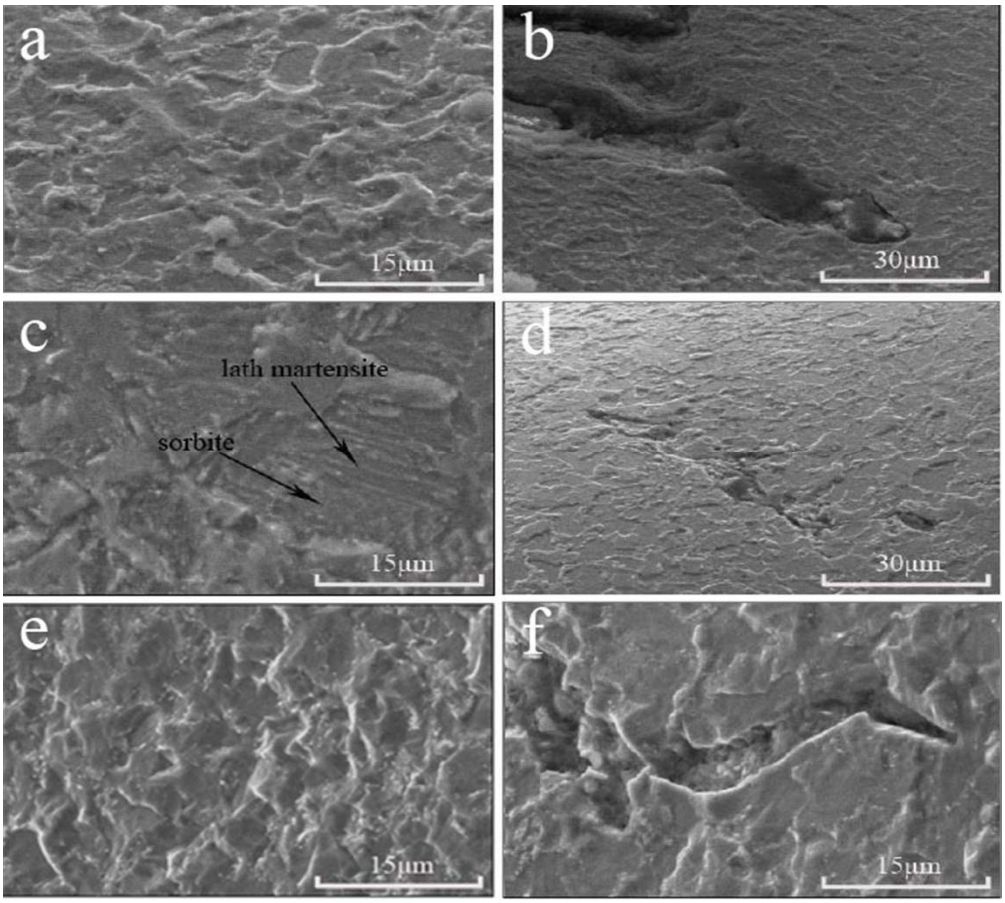

Fig.8. Microstructure of sample W62B,W63B and W66B

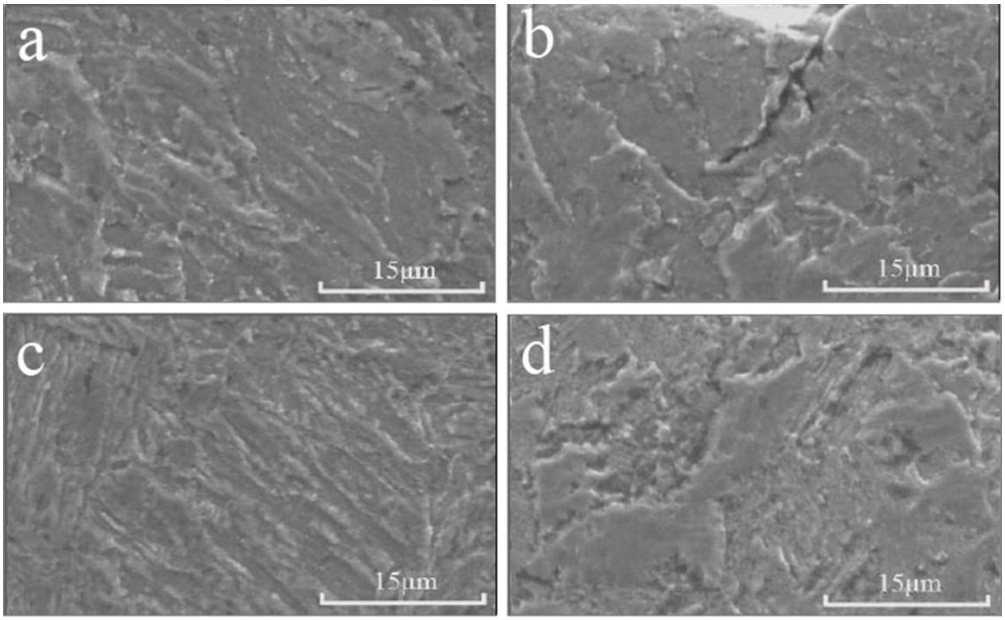

Fig.10. Microstructure of sample W3B and W13B
a.Near crack edge in W3B; b.Secondary crack of W3B;
c.Near crack edge in W13B; d.Cavity near crack edge in W13B

Fig.9 and Fig.10 show the microstructure of W3 and W13 coming from M2 and M3 respectively. Fig.9.a shows some lath martensite and ferrite; Fig.9.b shows ferrite and sorbite; the grains in the microstructure of base metal in W13A shown in Fig.9.c are so fine and disorganized. There are sorbite and ferrite in Fig.9.d; Fig.10.a shows some sorbite, a small amount of martensite and a small amount of carbide precipitation on the edge of fracture face in W3B; Fig.10.b shows the secondary cracks caused by small holes near the fracture edge of W3B and the crack is smaller than that in Fig.8.b and Fig.8.f. The crack direction is approximately perpendicular to the cross-section. There are martensite and sorbite in Fig.10.c and ferrite and sorbite in Fig.10.d.

3.3. Discussions about the results

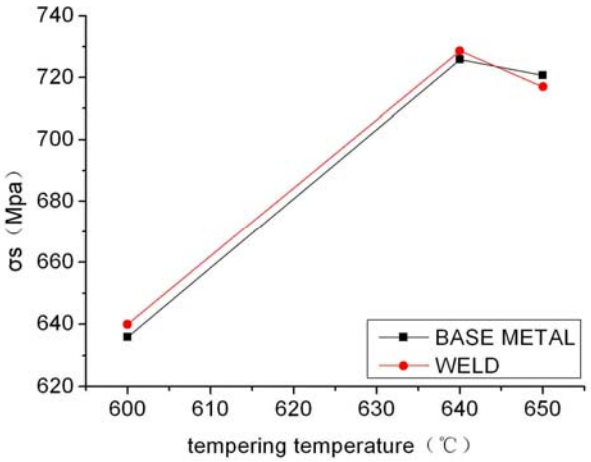

Fig.11.CTOD-tempering temperature

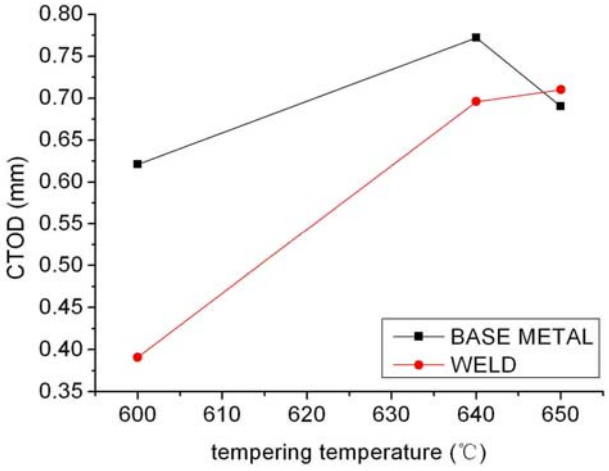

Fig.12. σs-tempering temperature

Some studies have shown that the large inclusions and the secondary cracks caused by them are bad for the toughness [7]. Compared with the W13 and W3, there are more secondary cracks and

inclusions in the microstructure and micro-fracture photographs of W62, W63 and W66 while the CTOD values conform to the rule. The sharp crack tips of the secondary crack in W62B, W63B and W66B indicate that it is relatively easy to expand compared with that of W3B and W13B. At the same time, the toughness conforms to this phenomenon. Grains of martensite and sorbite near the fracture face with small deformations may be caused by the content of carbide. There are mainly martensite in the base metal and sorbite in the weld center. The content of carbide particle between the spaces of α-phase in the weld and base metal of M1 is more than that of M2 and M3.

The relationship between tempering temperature and CTOD values and between tempering temperature and yield strength are shown in Fig.11 and Fig.12. The specimens tempered with 640℃(for 60 minutes) show the highest CTOD values and yield strength from the figures. That means tempering at 640℃ can obtain good toughness together with yield strength. This result is different with related reference [8,9]: increasing of tempering temperature (at 600-650 ℃) will makes the toughness worse.

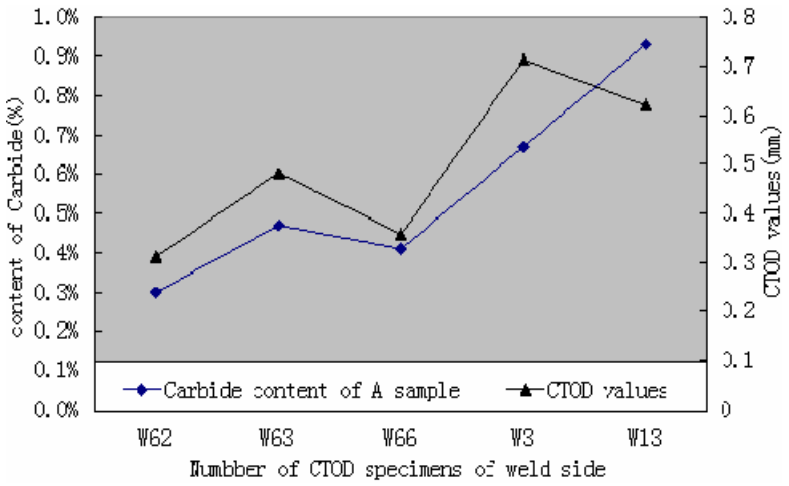

Fig.13. Variations in CTOD values and carbide content

According to the law of Dreiser, the quantitative measurements of content of carbide and grain size grade of weld center and the base metal in W62A, W63A, W66A, W3A, and W13A have been presented through using computer image processing system on scanning electron microscope images. Distribution of the content of carbide and the relationship with the CTOD are shown in Fig.13.The distribution of grain size grade and relationship with CTOD are shown in Fig.14.

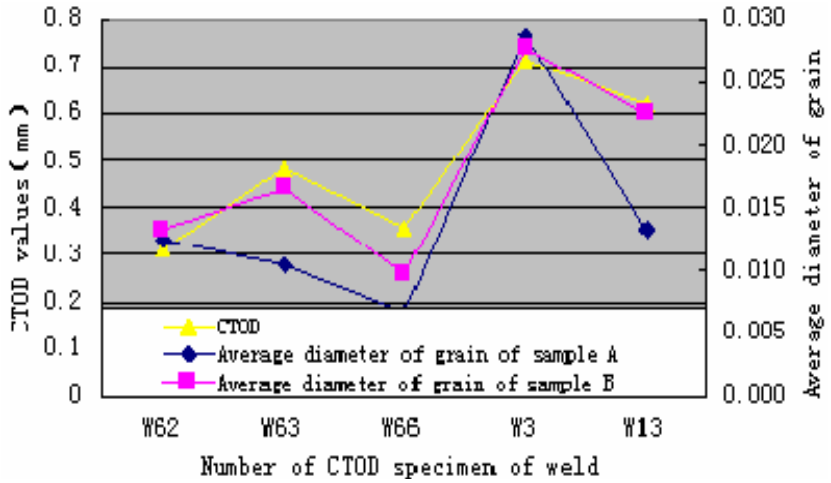

Fig.14. Variations in CTOD values and Grain size grade

Fig.13 shows that the carbide contents of M2 and M3 are greater than those of M1 and the greater the carbide content is, the higher the CTOD value will be. This situation conforms to the reference [10]. The grain size grades vary with the positions of the samples: weld center, base metal or near the edge of fracture face. The higher the grain sizes grade are， the lower the CTOD values will become, which is contrary to the common law. The specific reasons can be summarized as follows: 1. The CTOD values of M2 and M3 are all very large (all greater than 0.6 mm) and all the CTOD values are highly discrete. All the CTOD values are higher than the acceptable value 0.15 specified by DNV. That means the materials are safe enough in toughness for constructing engineering structures. However, the CTOD（toughness）is a macro concept and reflects the mechanical properties of the macro-structure. Samples for microscopic analysis are only taken from a small part of the macro-structure and the microscopic image is just a small part of the sample. Because of the existence of one-sidedness, it cannot reflect the overall situation of the organization. 2. The analysis of the forms of the grains (for the lath martensite in base metal, the strength is determined by the carbon content, but substructure plays an important role in toughness. It can be organized as follows: The compositions of microstructure in the weld center are mainly sorbite, ferrite and cementite mixture. Carbides are mainly distributed in the ferrite in the weld of M1, but those of M2 and M3 are fine and distributed on the grain boundaries. This is the reason why the specimens have better toughness and higher strength in M2 and M3. 3. From the contrast of alloy elements in Table 2 and Table 3, the contents of Cr and Mo in M2 and M3 are higher than those of M1. According to reference [10], the high content of Cr and Mo is good for strength but bad for toughness when the Mn content is near 1.6%.

4.Conclusions and Further studies

Through the results and discussions，some conclusions can be drawn as follows:

1. M2 tempered with 640℃ (for 60 minutes) presents the highest CTOD and yield strength, followed by M3 tempered with 650℃. M1 tempered with 600℃ presents the lowest CTOD and yield strength. That means tempering at 640℃ can obtain good toughness together with yield strength.

2. The fracture parameter CTOD is correlated with the microstructures. The carbide contents of M2 and M3 are greater than those of M1 and the greater the carbide content is, the higher the CTOD value will be. The grain size has the same trend .

In the discussions of this paper， limitations and one-sidedness also have been put forward in the study of the relationship between CTOD toughness and microstructure. More experimental and theoretical analysis is needed in the further studies.

Abstract An analytical fracture mechanics model for predicting the finite life fatigue strength of components is presented which combines a number of well established and newly developed approaches such as Murakami's and McEvily's approach for describing the transient behaviour of crack closure of short cracks, the analytical (long) crack closure function of Newman, the R6 procedure modified by a method for improving the ligament yielding correction proposed by the authors and other elements. Basic assumption is the preexistence of initial flaws such that the crack initiation or nucleation stage is small and can be neglected. The application of the model is demonstrated for small tension plates of aluminium Al 5380 H321 with artificial initial defects generated by FIB technology, the size of which was fixed on the basis of fractographic investigations on broken, smooth specimens.

Keywords fatigue strength, S-N curve, fracture mechanics, crack propagation, short cracks

1. Introduction

The lifetime of a cyclically loaded component can be roughly subdivided into three stages: crack initiation, fatigue crack propagation and fracture. Frequently the crack initiation stage is defined such that it covers nucleation and early crack propagation until the crack reaches some tenth of a millimetre at surface. However, a closer look reveals that this phase can be subdivided in a number of sub-stages (e.g. [1]):

(a) The crack initiation sub-stage in a narrower sense which is characterised by the accumulation of microscopic plastic deformation sometimes occurs at the smooth surface but more frequently it happens at scratches, pores, inclusions and similar defects which act as micro-notches and/or due to strain concentration zones caused by different stiffness properties of defect and matrix material. In the case of very high cycle fatigue (fracture after 10^8 loading cycles or more) initiation takes place subsurface but also at material defects [2].

(b) Subsequent to crack initiation the crack size is in the range of micro-structural features such as the grain size. Its propagation is characterised by a irregular crack front and alternating phases of acceleration and retardation or even crack arrest. The arrest of the largest of a number of initially growing cracks is associated with the fatigue limit phenomenon [3].

(c) With the increasing crack size the effect of the microstructure on local fatigue crack propagation diminishes and the propagation rate becomes rather steady. When the crack size reaches the order of mechanical discontinuities such as the plastic zone size or a notch stress field the crack is designated as mechanically short. Its propagation, in principle, can be described by classical fracture mechanics, however not by the linear elastic ΔK concept. As the micro-structurally short crack also the mechanically short one can be arrested under constant applied loading due to the gradual build-up of the plasticity-induced crack closure phenomenon.

(d) Long cracks propagate above a crack-size independent long-crack threshold ΔK_{th}. Their growth can be described by the da/dN-ΔK curve concept when the crack closure phenomenon is taken into account. The long crack propagation is terminated by the fracture of the component.

The crack initiation sub-stage in the narrower sense frequently is very limited for many engineering materials. Instead of a detailed discussion a statement of Polak in Elsevier's"Comprehensive Structural Integrity" shall be cited here: "Numerous studies have shown that in the majority of materials and under normal loading conditions, the period of crack initiation in smooth specimens without defects amounts to less than 5-20% of the fatigue life. In materials containing defects, the fraction of life spent in crack initiation is even lower. The major part of the life is spent in the growth of cracks, namely in the growth of short cracks." [1]. This fact allows to model metallurgical defects as initial cracks without yielding over-conservative lifetime predictions.

2. Model Proposed for Predicting Finite-life Fatigue Strength and Lifetime

The observation that the essential part of fatigue lifetime of many engineering materials is covered by short crack growth requires a fracture mechanics model which is able to describe this stage in an adequate manner. The authors proposed such a model in [4] where the reader can also find a more detailed description as it is possible here due to limited space. The model, for a number of partial aspects, uses and combines otherwise established approaches because of which there exist similarities with alternative models (e.g. [5-8]) which also cannot be discussed here in any detail. Instead, the reader is referred to [4]. Fig. 1 summarises the input and model parameters and the analysis steps of the present procedure. In the following the analysis steps shall be exemplarily explained for tension plates of aluminium alloy Al 5083 H 321. This will then be added by validation exercises on two more aluminium alloys the data of which were taken from the literature.

2.1 Initial crack size

For the present study fracture surfaces of cyclically tension loaded flat plates were fractographically analysed. A fracture surface containing an initial defect is shown along with a micrograph section and statistics of the defect sizes found on all specimens in Fig. 2. In Fig. 2(d), following a proposal of Murakami (e.g. [2]), the initial crack size is given as the square root of its area, $\sqrt{\text{area}}$, with the index "i" standing for "initiation". The statistical upper bound of the initial defect depth was found to be in the order of 50 μm which is quite typical for aluminium alloys [9].

2.2 Material properties

The material properties needed as input parameters of the proposed model comprise the da/dN-ΔK curve for the stress ratio $R = K_{min}/K_{max}$ of interest (in the present case R = 0.2), the long crack fatigue threshold ΔK_{th} for the same R, the intrinsic threshold (no plasticity-induced crack closure) and the stabilised cyclic stress-strain curve. The Paris range of the da/dN-ΔK curve was experimenttally determined for R = 0.2 on four specimens. The average value of C was $C = 4.05 \cdot 10^{-12}$ (ΔK in $\text{MPa}\sqrt{\text{mm}}$; da/dN in mm/loading cycle) for an n assumed as n = 3. The threshold values for R = 0,2 und $R \rightarrow 1$ (intrinsic value) were 1.5 $\text{MPa}\sqrt{\text{m}}$ and 0.925 $\text{MPa}\sqrt{\text{m}}$ respectively.

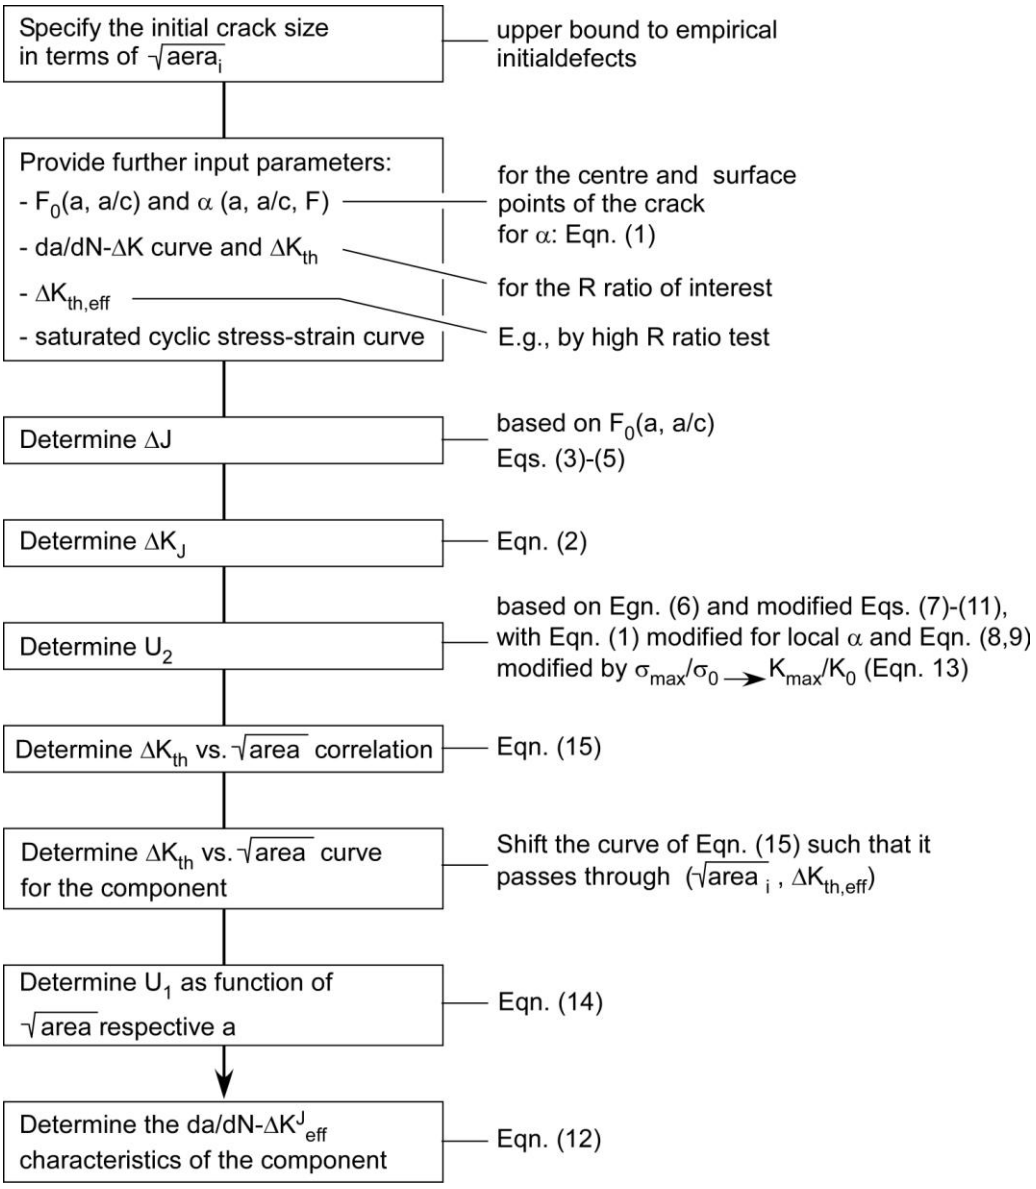

Fig. 1: Input and model parameters and steps of the fracture mechanics model presented here.

2.3 Model parameters

The model parameters of the analysis are the linear elastic stress intensity factor K for the deepest and the surface points at the crack front which were obtained by the solution of Raju and Newman [10] and confirmed by finite elements.

Following a proposal of the authors in [11] the reference load F_0 replaces the limit load in assessment procedures such as R6 [12] or SINTAP [13]. It is defined as that load at which the ligament plastification $L_r = F/F_0 = 1$. This may be different for different positions at the crack front.

A local constraint parameter α was determined instead of the global value according to Newman [14] the latter being given by Eqn. (1):

$$\alpha_g = \frac{1}{A_T} \sum_{m=1}^{M} \left(\frac{\sigma_{yy}}{\sigma_0} \right)_m A_m \qquad (1)$$

(A_m = projected area of a yielded element m on the uncracked ligament, σ_{yy}/σ_0 = normalized crack opening stress for the element m, A_T = total projected area of all elements (M) which have yielded)

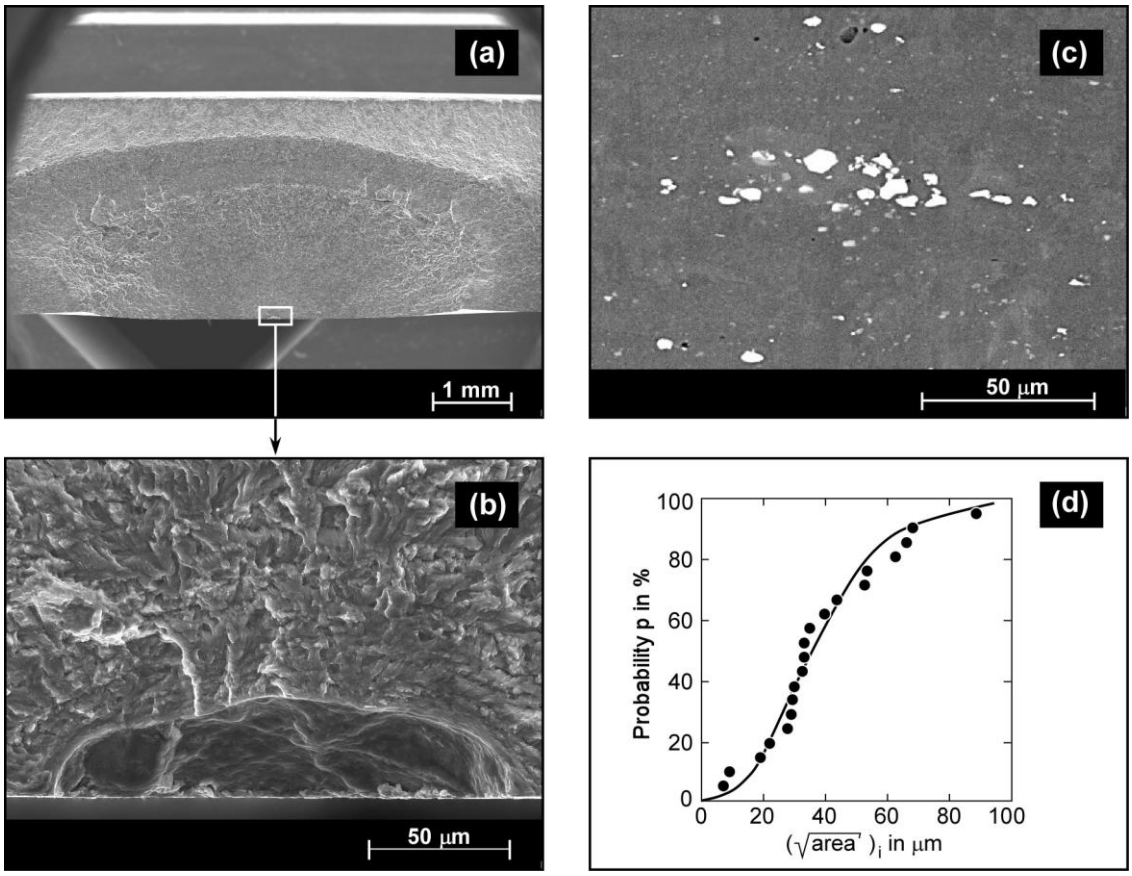

Fig. 2: Initial defects in the material AL5380 H321, fractographic and metallographic investigations: (a) and (b) example for an initial defect; (c) a cluster of inclusions with increased concentration of manganese, iron and nickel; (d) statistical distribution of the initial crack depth.

The parameter has been obtained by finite elements as a local parameter separately for the deepest and surface points of the semi-elliptical surface crack by modifying Eqn. (1) such that the total area of the plastic zone ahead of the crack, A_T, is replaced by local areas around the two points of interest. A more detailed description of the concrete realisation is found in [15].

2.4 Crack driving force of mechanically short cracks

The considerations in this paper mainly focus on short crack propagation (see Section 1). This is no problem insofar as the maximum initial defect sizes found at the fracture surfaces (see Fig. 2d) were sufficiently large not to be micro-structurally short cracks any more. It has already been mentioned that mechanically short cracks cannot adequately been described by the ΔK concept since the size of the plastic zone ahead of the crack is in the same order as the crack length. In order to address the local yielding effect ΔK is replaced by a ΔK^J which is formally obtained as

$$\Delta K^{J} = \sqrt{\Delta J \cdot E'}$$

$$E' = \begin{cases} E & \text{plane stress} \\ E/\left(1-\nu^2\right) & \text{plane strain} \end{cases} \tag{2}$$

With respect to a discussion of the cyclic J integral, ΔJ, the reader is referred to [4]. Within this paper a (slightly modified) approach of McClung [16,17] is applied by which ΔJ is determined by

$$\Delta J = \frac{\Delta K^2}{E'} \cdot \left[f \;\; \Delta L_r \right]^{-2} \tag{3}$$

with $$\Delta L_r = \frac{\Delta F}{2F_Y} = \frac{\Delta \sigma_{ref}}{2\sigma_Y} . \tag{4}$$

and $$L_r = F/F_0 . \tag{5}$$

2.5 Modelling the plasticity-induced crack closure pheneomenon

With respect to modelling the crack closure effect it has to be distinguished between long cracks (the effect is completely build-up) and short cracks (the effect is still gradually developing). Crack closure is described by a parameter U (U_1 – short crack; U_2 – long crack). For the long crack the so-called NASGRO equation is used which is based on results obtained by applying the modified strip yield model of Newman [18]:

$$U_2 = \frac{\Delta K_{eff}}{\Delta K} = \frac{1-f}{1-R} \tag{6}$$

$$\text{with } f = \frac{\sigma_{open}}{\sigma_{max}} = \begin{cases} A_0 + A_1 R + A_2 R^2 + A_3 R^3 & \text{for } R \geq 0 \\ A_0 + A_1 R & \text{for } -2 < R < 0 \end{cases} \tag{7}$$

The coefficients A_i are given by

$$A_0 = \; 0.825 - 0.34\alpha_g + 0.05\alpha_g^2 \left[\cos\left(\frac{\pi/2 \cdot \sigma_{max}}{\sigma_0} \right) \right]^{1/\alpha_g} \tag{8}$$

$$A_1 = \; 0.415 - 0.071\alpha_g \; \frac{\sigma_{max}}{\sigma_0} \tag{9}$$

$$A_2 = 1 - A_0 - A_1 - A_3 \tag{10}$$

$$A_3 = 2A_0 + A_1 - 1 \tag{11}$$

For the present model Eqs. (8) to (11) have been modified in several aspects:

(a) The ΔK parameter is replaced by ΔK^J. The determination of the parameter is as described above. The complete modified crack propagation equation is then:

$$\frac{da}{dN} = C\ \left(\Delta K^J_{eff}\right)^n = C \begin{cases} U_1 \Delta K^J{}^n & a_i < a < a^* \\ U_2 \Delta K^J{}^n & a_i \geq a^* \end{cases} \tag{12}$$

(b) Originally the f function in Eqn. (7) has been obtained for centre-cracked plates subjected to uniform tension. The question arises whether it can also be applied to other configurations, for example bending geometries. McClung at al. [19] (see also [17]) carried out extended finite element investigations on M(T) center-cracked plates in tension, SE(T) single-edge-cracked plates in tension, SE(B) single-edge-cracked plates in bending and pure bending geometries and concluded that the f-function and, as a consequence, the crack opening stress σ_{open} (or K_{op}) are more accurately correlated by the K_{max}/K_0 ratio than by σ_{max}/σ_0 in Eqs. (8) and (9). They proposed to substitute the latter by K_{max}/K_0:

$$\frac{K_{max}}{K_0} = \frac{Y\sigma_{max}\sqrt{\pi a}}{\sigma_0\sqrt{\pi a}} \tag{13}$$

Other authors [20,21] have also found K_{max}/K_0 to be a superior parameter. Therefore, it is adopted in the present study too.

(c) The constraint parameter α in Eqs. (8) and (9) is not used as a fixed parameter as in the NASGRO approach but determined by finite element analyses based on Eqn. (1), but determined as local parameter for points A and C of the crack.

(d) The reference stress σ_0 in Eqs. (8), (9) and (13) is not chosen as the average of the quasi-static yield and tensile strength as in NASGRO but as the cyclic yield strength.

With respect to the gradual build-up of the plasticity-induced crack closure effect for the short crack stage the model assumes that the latter is mirrored in the development of the short crack fatigue threshold (as e.g. in [6]). The parameter U_1 can then be determined by

$$U_1 = \frac{U_2}{\Delta K_{th}\ \ a\ \big/ \Delta K_{th,lc}} \tag{14}$$

with the index „lc“ designating the long crack. The ΔK_{th}-crack depth function is described by an approach of McEvily et al. [22]

$$\Delta K_{th} = \Delta K_{op} + \Delta K_{th,eff} = \left[1 - e^{-k\cdot\ a - a_0}\ \right] \cdot \Delta K_{op,max} + \Delta K_{th,eff} \tag{15}$$

but modified by replacing the crack depth a by an equivalent crack depth $\sqrt{area}$ as introduced above. In Eqn. (15) k is a fit parameter which describes how the crack closure effect develops as a function of $a\text{-}a_0$ or $\sqrt{area} - \sqrt{area_0}$ respectively. Since Eqn. (15) includes two fit parameters, k and a_0

or $\sqrt{area_0}$, a minimum of two conditional equations is necessary. The first one is ΔK_{th} = 0 für $\sqrt{area}$ = 0; the second on is given by $\Delta K_{th} \propto \sqrt{area}^{1/3}$ for an arbitrary crack size. For steels, according to [2], this can be realised by an estimate

$$\Delta K_{th} = 3{,}3 \cdot 10^{-3} \ \ HV + 120 \ \Big/ \ \sqrt{area}^{1/3} \tag{16}$$

with HV being the Vickers hardness. However, for the aluminium alloy investigated in this study no similar solution exists. Therefore, an alternative solution had to be found which will be described in Section 3.

As assumed in [22] the threshold ΔK_{th} is subdivided into an intrinsic value, $\Delta K_{th,eff}$, and an additional amount due to the crack closure effect, $\Delta K_{th,op}$. The intrinsic term is a lower bound which exists even if no crack closure effect occurs (therefore the designation "eff"). It can, e.g., be determined by experiments at different R ratios and extrapolation for R → 1 as realised in the present paper. Because the state of the initial defect is characterised by both, the intrinsic threshold $\Delta K_{th,eff}$ and the initial crack area (respective its square root $\sqrt{area}_i$ the curve according to Eqn. (15) has to be shifted to pass through this point such as shown in Figure 3. The prediction of the ΔK_{th} versus crack size curve in the component is then provided by the un-dotted dark line. The transition between short and long crack propagation occurs at $\sqrt{area}^*$, where the ΔK_{th} according to the (shifted) Eqn. (15) curve intersects the long crack threshold value.

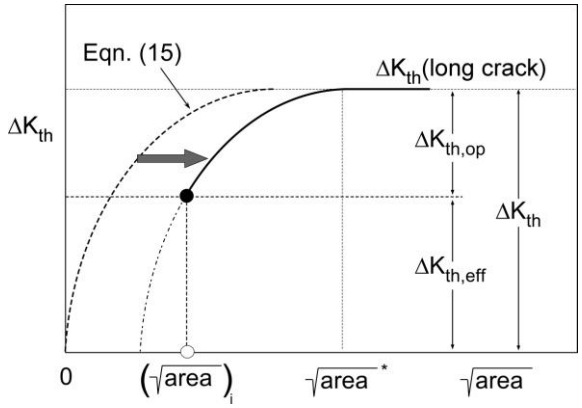

Fig. 3: Proposed method for determining the ΔK_{th}-crack size correlation for short cracks in the present model.

3. Validation on AL5380 H321 specimens

The validation of the model was performed with specimens prepared with artificial initial defects. Using the FIB (Focus Ion Beam) technology notches with a notch width of 6 μm, a depth of a = 37.4 μm and a length at surface 2c = 101.25 μm were generated.[1)]

[1)] The authors wish to thank Dr. Erica Lilleodden, HZG Geesthacht, who prepared the FIB cracks.

The notch dimensions were identical for all validation specimens. With an area of 3230 μm^2 or $\sqrt{\text{area}}_i \approx 57$ μm the size of these artificial defects referred to the upper tail of the statistical distribution of the natural defects found on the fracture surfaces as shown in Fig. 2(d). The prepared specimens were then used to generate an S-N curve. The tests were interrupted when cracks of about 2c = 3 mm were visible at the specimen surfaces. The stress-strain data of the material were: cyclic proof strength $R_{p0.2,cyc}$ = 341 MPa and cyclic modulus of elasticity E_{cyc} = 68.4 GPa.

It has already been mentioned in Section 2.5 that Eqn. (16) was not applicable to the aluminium alloy investigated. Therefore, an alternative second conditional equation had to be used. This is given by a general form

$$\Delta K_{th} = 3.3 \cdot 10^{-3} C_0 \left(\sqrt{\text{area}}\right)^{1/3} \tag{17}$$

with $\sqrt{\text{area}}_i$ referring to the size of the artificial initial defect and C_0 being a material constant which, according to Murakami [2], correlates with the fatigue limit σ_e (in the present case the fatigue strength at 10^7 loading cycles) by

$$C_0 = \frac{1}{1.43} \sigma_e \left(\sqrt{\text{area}}\right)^{1/6}. \tag{18}$$

With σ_e = 80 MPa and $\sqrt{\text{area}}_i$ = 56.85 the parameters in Eqn. (15) have finally been determined as $\sqrt{\text{area}}_0$ = 20.86 μm, k = 0.0652 μm^{-1} and $\sqrt{\text{area}}^*$ = 140 μm. As mentioned above Eqn. (15) curve had to be shifted such that it passed through the point ($\sqrt{\text{area}}_i$, $\Delta K_{th,eff}$). This is realised in Fig. 4.

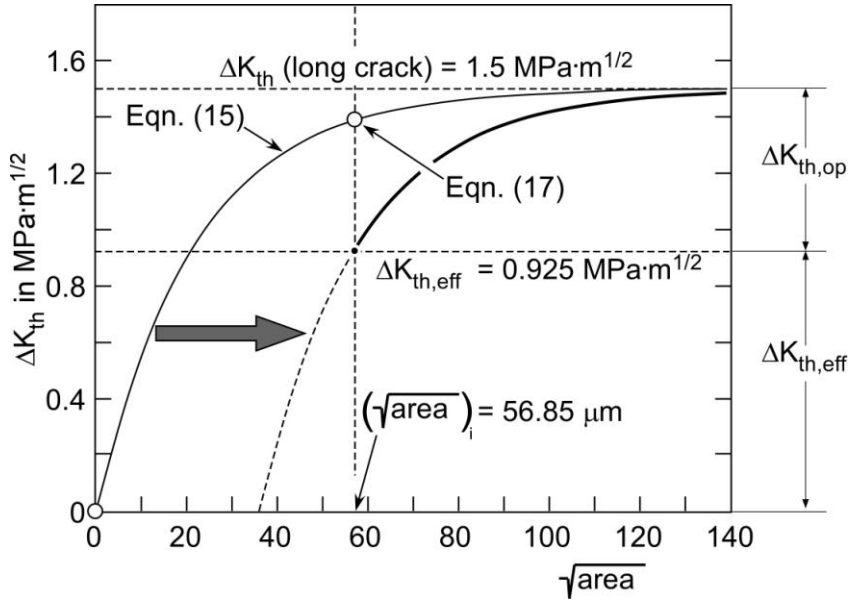

Fig. 4: Application of the model of Figure 3 to the present example.

As the final result the fatigue strength for finite life was predicted as shown in Fig. 5. The analyses were performed for each individual specimen. In addition the predicted and experimental values of the crack size, a and 2c, at test end, are compared in Fig. 5. It shows up that all experimental data were predicted with satisfying accuracy.

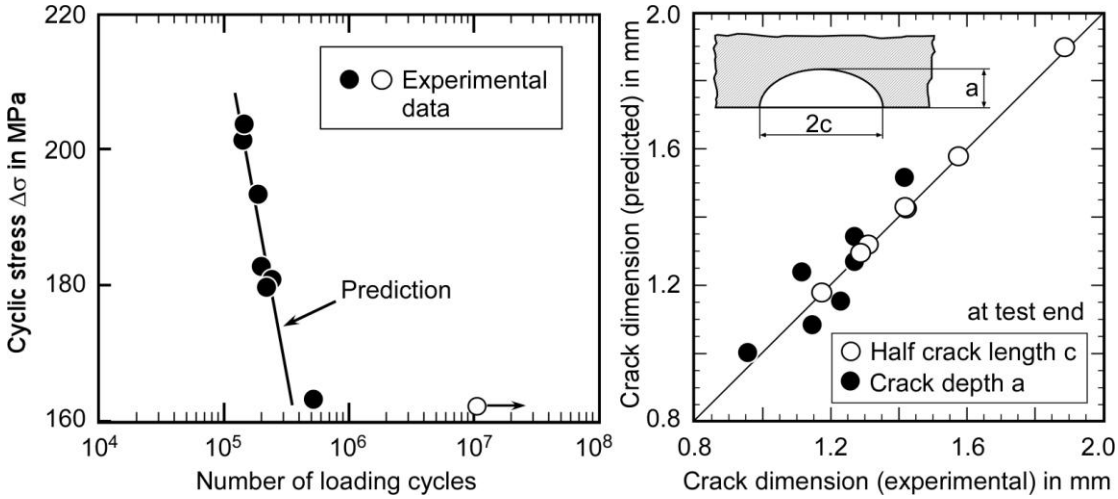

Fig. 5: S-N curve obtained for the tensile plates with artificial (FIB) cracks. Comparison between the experiments and the predictions with the present model.

4. Validation on further aluminium alloys (literature data)

Further validation of the model has been conducted using short crack propagation data from the literature which are available for aluminum alloys commonly used in the aerospace field. In particular, two different alloys have been considered: Al 2024-T3 and Al 7075-T6. An extensive collection of data for these materials is provided in [23] and [24]. Figure 6 shows the S-N lines used for validation. In case of the Al 2024-T3, experimental test data were available for two different load ratios (R = 0, -1) whereas the Al 7075-T6 has been tested at R = 0 only. The specimens did show almost no stress concentration which allowed the use the stress intensity factor and reference load equations already applied to the validation example of section 3. Since no finite element calculations have been conducted for the constraint factor α, such as above, Schijve's equation [25]

$$U = 0.55 + 0.33 \cdot R + 0.12 \cdot R^2 \tag{19}$$

has been used to determine the effective stress intensity factor range for long cracks.

The analytical simulation for the Al 2024-T3 has been performed for a suggested initial crack size of a_i = 20 μm, which resulted from an approximation of the experimental S-N data for both R = 0 and -1. In case of the Al 7075-T6, two different crack sizes have been employed in order to show the impact of a different starting crack size on the calculated number of cycles to failure. Figure 6b shows slightly conservative results a_i = 20 μm which were, however, improved when fractographic data of a_i = 6 μm were used. All simulations have been stopped when the crack reached a final depth of 80% the plate thickness.

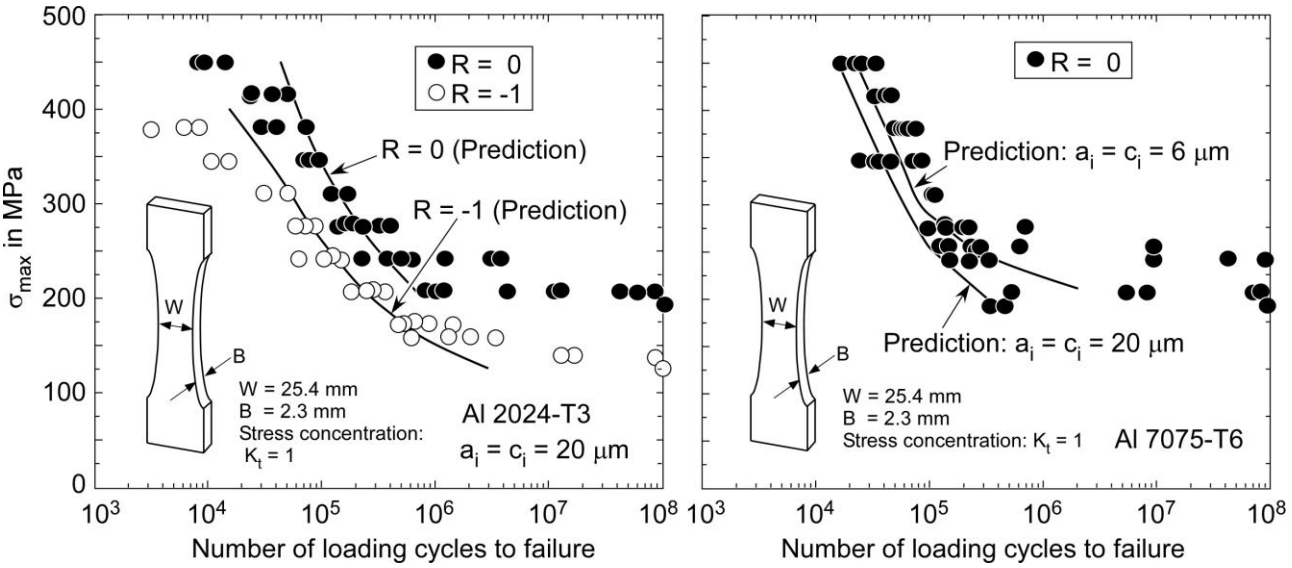

Fig. 6: S-N curves obtained for the tensile plates of two aluminium alloys compared with predictions based on the present model. S-N data taken from [23,24].

5. Summary and Outlook

An analytical fracture mechanics model for predicting the finite life fatigue strength range of the S-N curve was developed. Its application was demonstrated for tension loaded small plates made of different aluminium alloys. The results were promising.

The model is based on a number of assumptions:

(a) In engineering materials fatigue crack propagation initiates at pre-existing material defects such as welding flaws, pores, inclusions etc.

(b) The crack initiation sub-stage in a narrower sense during which a crack develops from the pre-existent defect is typically rather limited. Therefore, a fracture mechanics based lifetime prediction (which per definition is a residual lifetime prediction) yields conservative but not over-pessimistic lifetimes. Note, however, that this has not to be the case for any material.

(c) The initial crack size has been determined by fractographic investigation of fracture surfaces of cyclically loaded specimens.

(d) Since the major part of lifetime belongs to short crack propagation specific issues such as the transient behaviour of crack closure of short cracks and local ligament plasticity effects had to be taken into account.

(e) The presented model is limited to the propagation of mechanically short cracks and not applicable to micro-structurally short ones.

(f) Fracture mechanics based determination of fatigue strength provided significant potential as compared to and in addition to classical fatigue strength concepts because it takes parameters such as weld geometry, residual stresses etc. explicitly into account.

Abstract Strain gage based methods for experimental determination of stress intensity factors (SIFs) are equally powerful as compared to the other methods such as photoelasticity and caustics. However, a major problem with the strain gage methods is the lack of practical recommendations for appropriate radial locations for strain gages for accurate measurement of SIFs. Determination of valid gage locations is thus an open problem. In order to obviate this important problem, a finite element based approach has been suggested in the present investigation for determination of valid or optimal strain gage locations for determination of the mode I SIFs. The proposed approaches are strongly supported by the theory. The present work attempts to estimate the maximum permissible radial distance r_{max} for strain gages (from the crack tip) using the proposed finite element based approaches. This r_{max} of a configuration in turn can be used to obtain the valid locations for strain gages for accurate determination of mode I SIFs. The results of the present investigation show that very accurate values of r_{max} can be obtained using the proposed approach. Dependence of r_{max} on crack length to width ratio has also been investigated in the present work.

Keywords Strain gage, Stress intensity factor, Radial location, Fracture

1. Introduction

The most important parameter in linear elastic fracture mechanics (LEFM) is the stress intensity factor (SIF) as its limiting value decides whether an existing crack in a component grows or not. It is a measure of severity of the crack tip and is frequently used in control of fracture and in life prediction estimations. Accurate values of SIFs are necessary for correct application of LEFM principles in predicting and preventing fracture of the engineering components. Three approaches are currently used to estimate stress intensity factors viz., analytical, numerical and experimental methods. Analytical methods are generally restricted to the simple configurations and collection of such solutions of SIFs can be found in various handbooks [1, 2]. Numerical and experimental techniques are widely used in relatively complex situations [3].

Most widely used experimental techniques for the measurement of SIFs are caustics [4, 5], compliance method [6, 7], photoelasticity [8, 9] and strain gage techniques [10-14]. Among the experimental techniques, strain gage techniques are relatively simple and easy for the determination of SIFs due to direct measurement of strains near the crack tip. Irwin [15] first suggested the use of strain gages for the determination of SIF. However, factors such as the local yielding, high strain gradients, three dimensional state of stress at the crack tips and finite size of the gages strongly affected against the development of strain gage techniques.

To eliminate the above difficulties, Dally and Sanford [10] developed a practically feasible strain gage technique (DS technique) for measuring the static mode I SIF (K_I) in two dimensional

isotropic single ended cracked bodies. A truncated strain series (based on the generalized Westergaard approach [16]) consisting of three unknown coefficients for the representation of the strains has been employed in their technique. A major advantage of their approach is that, only a single strain gage is sufficient to determine mode I SIF and it can be located at a distance sufficiently away from the crack tip. However, no suggestions were made by them on the valid gage locations.

Wei and Zhao [11] proposed a different strain gage method based on the two parameter strain equation which requires two strain gages for measuring the mode I SIF. However, the suggested radial locations of gages necessitate *a priori* knowledge about the plastic zone size which depends on the unknown SIF.

Kuang and Chen [12] employed the asymptotic strain expressions for the measurement of mode I SIF. They suggested that gages could be placed at distances greater than half the thickness of the specimen from the crack tip in spite of the fact that at large distances the measured strains could not be accurately represented by asymptotic equations alone.

It could be seen from the literature that DS technique has been more widely used as compared to other strain gage techniques. While there are some recommendations available for radial locations of strain gage techniques developed by Wei and Zhao [11] and Kuang and Chen [12], no method has been presented until recently for determination of appropriate radial location of strain gages corresponding to the DS technique in experimental determination of the mode I SIFs. Due to uncertainty over the radial location of strain gage in DS technique, very limited amount of work has been published using this technique for corroborating the analytical or numerical SIFs [14]. Determination of valid gage locations for DS technique is thus an open problem.

The present paper aims at development of an efficient finite element based approach for accurate and consistent evaluation of the maximum permissible radial distance $r_{\max}$ for strain gages (from the crack tip) for accurate measurement of mode I SIFs in configurations with single ended cracks. This $r_{\max}$ of a configuration in turn can be used to obtain the valid locations for strain gages for accurate determination of mode I SIFs. Another objective of the present work is to study the dependence of $r_{\max}$ on crack length to width ratio of a given configuration. The proposed numerical methodology is well supported with theory.

2. Theoretical Background

This section describes the background theory for the estimation of $r_{\max}$ value for accurate measurement of mode I SIF using Dally and Sanford [10] single strain gage technique. According to this technique the region around a crack tip is divided into three zones viz. zone I, zone II and zone

III as shown in Fig. 1. Zone I is close to the crack tip and first term of the strain series (singular term) is sufficient to represent the strains within this zone. However, it is not a valid zone for accurate measurement of strains as the stress state in this region is three dimensional [10, 17] and the measured strains will be severely affected by plasticity effects.

Zone III is again not suitable for measurement of strain data because, very large number of terms in the strain series is required to yield accurate results. Therefore, the intermediate region or zone II is favorable and optimum zone for accurate measurement of the surface strains. This is defined as a zone in which a singular term and a small number of higher order terms will accurately describe the strain field.

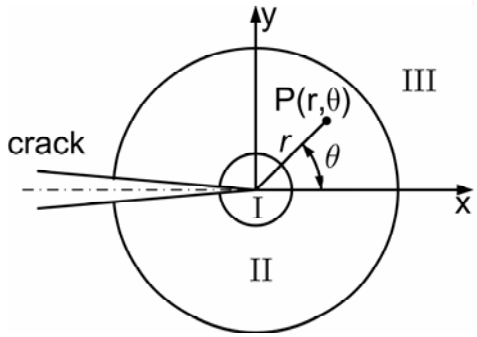

Figure 1. Different zones at the crack tip

The generalized Westergaard approach can be employed to obtain the expressions of different strain components within the zone II. The modified Airy stress function in this approach is given by [16]

$$\phi = \mathrm{Re}\,\overline{\overline{Z}}(z) + y\,\mathrm{Im}\,\overline{Z}(z) + y\,\mathrm{Im}\,\overline{Y}(z) \tag{1}$$

where

$$\frac{d\overline{\overline{Z}}}{dz} = \overline{Z}, \quad \frac{d\overline{Z}}{dz} = Z, \text{ and } \quad \frac{d\overline{Y}}{dz} = Y \tag{2}$$

and the complex analytic functions $Z(z)$ and $Y(z)$ are defined as

$$Z(z) = \sum_{n=0}^{\infty} A_n\, z^{n-\frac{1}{2}} = \frac{K}{\sqrt{2\pi z}} + \sum_{n=1}^{\infty} A_n\, z^{n-\frac{1}{2}} \tag{3}$$

$$Y(z) = \sum_{m=0}^{\infty} B_m\, z^m = \frac{\sigma_{0x}}{2} + \sum_{m=1}^{\infty} B_m\, z^m \tag{4}$$

which are series type functions (in terms of complex variable $z = x + iy$) containing infinite number of coefficients ($A_1, A_2, ..., A_\infty$; $B_1, B_2, ..., B_\infty$). The strain field in the zone II can be sufficiently represented by the three parameter series with unknown coefficients A_0, A_1 and B_0 [10] which depend on boundary conditions. Assuming plane stress conditions, the three term representation of strain field in this zone is therefore,

$$
\begin{aligned}
2G\,\varepsilon_{xx} &= A_0\, r^{-1/2}\cos\frac{\theta}{2}\left[\kappa-\sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right]+\frac{2B_0}{(1+\nu)}+A_1\, r^{1/2}\cos\frac{\theta}{2}\left[\kappa+\sin^2\frac{\theta}{2}\right]\\
2G\varepsilon_{yy} &= A_0\, r^{-1/2}\cos\frac{\theta}{2}\left[\kappa+\sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right]-\frac{2\nu B_0}{(1+\nu)}+A_1\, r^{1/2}\cos\frac{\theta}{2}\left[\kappa-\sin^2\frac{\theta}{2}\right]\\
2G\,\gamma_{xy} &= A_0\, r^{-1/2}\left[\sin\theta\cos\frac{3\theta}{2}\right]-A_1\, r^{1/2}\left[\sin\theta\cos\frac{\theta}{2}\right]
\end{aligned}
\tag{5}
$$

where $\kappa=(1-\nu)/(1+\nu)$ and A_0, A_1 and B_0 are unknown coefficients which can be determined using geometry of the specimen and loading conditions. Using the definition of K_I it can be shown that

$$K_I=\sqrt{2\pi}\,A_0 \tag{6}$$

The strain component ε_{aa} at the point *P* located by r and θ (Fig. 2) is given by

$$
\begin{aligned}
2G\varepsilon_{aa} &= A_0\, r^{-1/2}\left[\kappa\cos\frac{\theta}{2}-\frac{1}{2}\sin\theta\sin\frac{3\theta}{2}\cos 2\alpha+\frac{1}{2}\sin\theta\cos\frac{3\theta}{2}\sin 2\alpha\right]\\
&+A_1\, r^{1/2}\cos\frac{\theta}{2}\left[\kappa+\sin^2\frac{\theta}{2}\cos 2\alpha-\frac{1}{2}\sin\theta\sin 2\alpha\right]+B_0\left(\kappa+\cos 2\alpha\right)
\end{aligned}
\tag{7}
$$

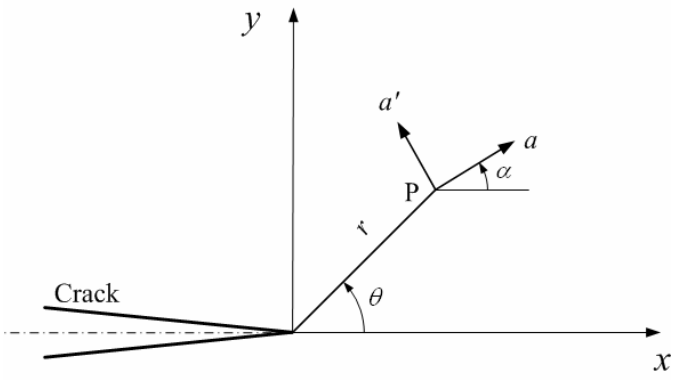

Figure 2. Strain gage orientation and location

The coefficient of B_0 term in Eq. (7) can be eliminated by selecting the angle α such that

$$\cos 2\alpha=-\kappa \quad =-\frac{1-\nu}{1+\nu} \tag{8}$$

Similarly coefficient of A_1 can also be made zero if the angle θ is selected as

$$\tan\frac{\theta}{2}=-\cot 2\alpha \tag{9}$$

Thus by placing a single strain gage (Fig. 2) with α and θ as defined by Eqs. (8) and (9) the

strain ε_{aa} can be measured which in turn is related to K_I by

$$2G\varepsilon_{aa} = \frac{K_{\mathrm{I}}}{\sqrt{2\pi r}}\left[\kappa\cos\frac{\theta}{2} - \frac{1}{2}\sin\theta\sin\frac{3\theta}{2}\cos 2\alpha + \frac{1}{2}\sin\theta\cos\frac{3\theta}{2}\sin 2\alpha\right] \tag{10}$$

It should be noted that the above equation accurately determines ε_{aa} upto a radial distance say $r_{\max}$ and it can be written as

$$\varepsilon_{aa} = \frac{1}{\sqrt{r}}\left[\frac{K_{\mathrm{I}}}{G\sqrt{8\pi}}\left(\kappa\cos\frac{\theta}{2} - \frac{1}{2}\sin\theta\sin\frac{3\theta}{2}\cos 2\alpha + \frac{1}{2}\sin\theta\cos\frac{3\theta}{2}\sin 2\alpha\right)\right] \tag{11}$$

For a given configuration, applied load, Young's modulus E and Poisson's ratio ν the expression within the square bracket on the right hand side of Eq. (11) is a constant. Therefore,

$$\varepsilon_{aa} = \frac{C}{\sqrt{r}} \tag{12}$$

where C is a constant. Taking logarithm on both sides of Eq. (12)

$$\ln(\varepsilon_{aa}) = -\frac{1}{2}\ln(r) + \ln(C) \tag{13}$$

Eq. (13) is valid along the line given by Eq. (9) for $r \le r_{\max}$. Thus a plot of Eq. (12) on log-log axes depicts a straight line of slope equals to – 0.5, with an intercept of $\ln(C)$. Theoretically, the straight line property will break beyond $r > r_{\max}$ as more than three parameters are needed in Eq. (7) to estimate the ε_{aa}. Using the straight line property exhibited by Eq. (13), the value of $r_{\max}$ can be accurately estimated from the log-log plots of ε_{aa} and r.

Several experimental and numerical studies have established that 3D effects prevailed up to a radial distance equal to half the thickness of the plate from the crack tip [17]. It was reported that the state of stress is neither plane stress or plane strain within this distance [10, 17]. Therefore, the minimum radial distance $r_{\min}$ for strain measurements on the free surface should be grater than half the thickness of the plate. As a consequence, the optimal or valid radial location r for strain gage in DS technique can now be given as

$$r_{\min}\left(=\frac{1}{2}\text{thickness of plate}\right) \le r \le r_{\max} \tag{14}$$

3. Results and Discussion

In this section, $r_{\max}$ is determined for a single-ended cracked plate using the theoretical formulation described in Section 2. For this purpose, edge cracked plates (Fig. 3(a)) with $a/b=0.1-0.8$ (in steps 0.1) and subjected to uniform tensile stress are considered in this study. Due to symmetry only half of the domain as shown in Fig. 3(b) is employed for FEA. Width $b=1200\,\text{mm}$ and $h/b=3.0$ are considered for this example. Poisson's ratio $\nu=1/3$, and Young's modulus $E=200\,\text{GPa}$ have been assumed. The applied stress σ is set to 100 MPa. Plane stress conditions have been assumed.

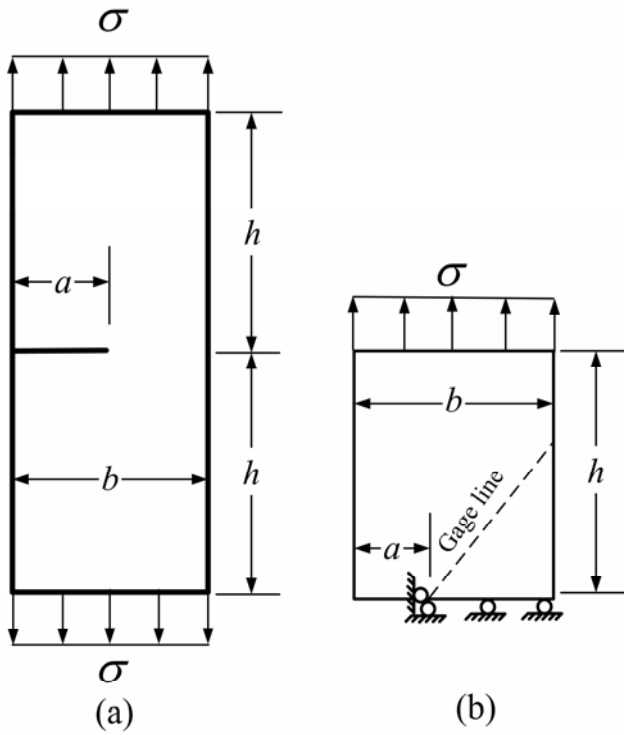

Figure 3. (a) A typical edge cracked plate (b) solution domain for edge cracked plate

To determine the $r_{\max}$ value of the above configurations, a typical finite element mesh for one half of the plate is shown in Fig. 4 (a). The mesh (Fig. 4(a)) is so designed that nodes of several elements are made to lie along the gage line which makes an angle of θ with the axis of crack (Eq. 9). In all the meshes, this line (gage line) begins at the crack tip and terminates at the outer boundaries of the cracked plate. According to DS technique, a single strain gage is required to be placed at an appropriate location on the gage line in the direction of α (Eq. 8) in order to measure the linear strain ε_{aa}. The strains calculated in global coordinate along the gage line are then transformed into linear strain ε_{aa} in the direction α. The radial distances (r) of each of the nodes on the gage line from the crack tip are then computed.

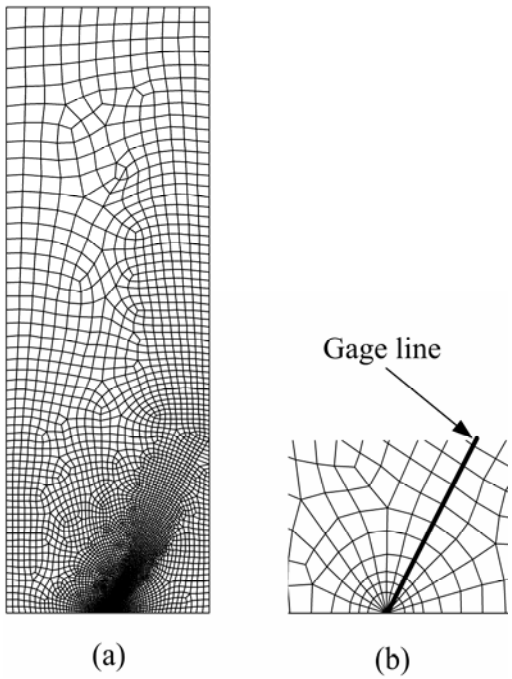

Figure 4. (a) Typical mesh used for edge cracked plate (b) enlarged view at the crack tip corresponding mesh

Following the procedure described in section 2, plot of $\ln(\varepsilon_{aa})$ versus $\ln(r)$ for all values of a/b is shown in Fig. 5. Crack tip point is not plotted as the radius of this point is zero. It is interesting to notice from Fig. 5 that, each plot consists of distinguishable linear portion followed by nonlinear portion (in logarithmic scale) as predicted by theory (section 2). The linear trend distinctly exists up to a certain radial distance and thereafter gradually turns to the nonlinear portion. This can be observed in plots for all values of a/b of edge cracked plate.

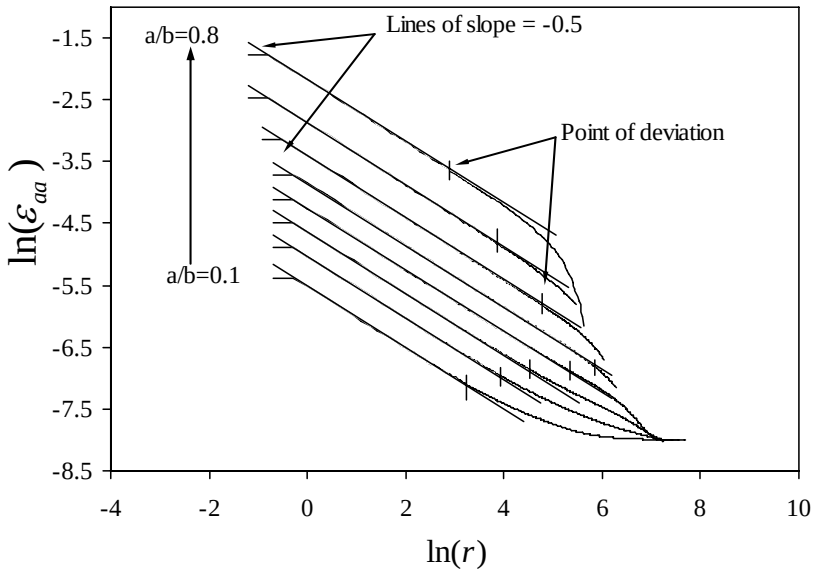

Figure 5. Variation of $\ln(\varepsilon_{aa})$ with $\ln(r)$ along the gage line for the edge cracked plates

As discussed earlier, the initial linear part is due to the dominance of the three parameters and nonlinear part is due to the presence of more than three parameters in the expression in equation for ε_{aa} (Eq. 7). The end point of the linear portion of the plots in Fig. 5 clearly indicates the extent of the three parameter strain series which is the upper bound for strain gage locations i.e. $r_{\max}$ according to the proposed theory.

For determination of $r_{\max}$, straight lines having slope of -0.5 are superposed onto the all plots of $\ln(\varepsilon_{aa})$ versus $\ln(r)$ in Fig. 5. It is interesting to notice from Fig. 5 that both the initial straight line portion of the plots and superposed lines are congruent to each other up to a certain radial distance for all a/b values and the numerical results deviate from the superposed line thereafter due to the dominance of coefficients other than A_0, A_1 and B_0 in Eq. (7). The estimated values of maximum permissible radial distance $r_{\max}$ or the extent of validity of the three parameter zone are marked in Fig. 5 as per the procedure described in [18]. The corresponding numerical values of the $r_{\max}$ are presented in Table 1. A plot of variation of $r_{\max}$ with a/b is also presented in Fig. 6.

It can be seen from the results of Table 1 and Fig. 6 that as the crack length is increased, the value of $r_{\max}$ increases initially until it reaches a maximum value around $a/b = 0.5$ ($r_{\max}$ = 505.34 mm) and thereafter it decreases with the increase of the crack length.

Table 1 Variation of the $r_{\max}$ with crack length a/b

a/b	a (mm)	$r_{\max}/b$
0.1	120	0.021
0.2	240	0.043
0.3	360	0.077
0.4	480	0.174
0.5	600	0.290
0.6	720	0.101
0.7	840	0.040
0.8	960	0.015

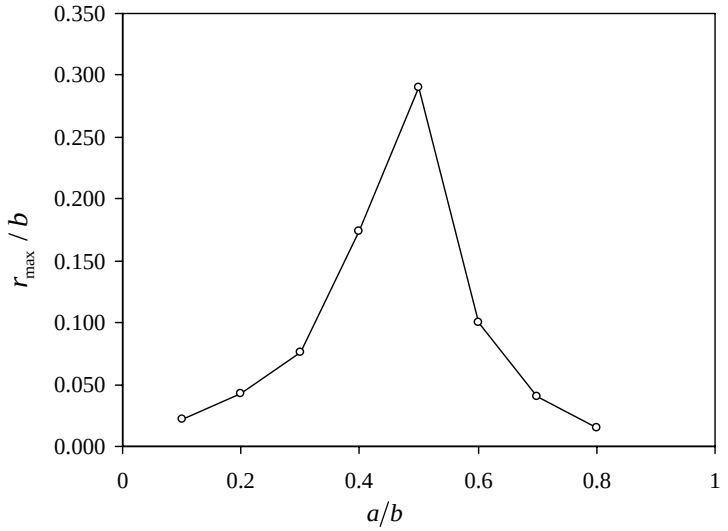

Figure 6. Graph of the r_{max} as a function of a/b (0.1-0.8) for the edge cracked plate.

4. Conclusions

In this paper, a finite element based approach is presented for determination of the valid or optimal radial location of strain gages corresponding to DS technique. The proposed approach is based on efficient computation of the maximum permissible radial distance r_{max} of a strain gage. The existence and determination of the r_{max} is shown theoretically. To demonstrate the proposed approach single ended cracked configurations have been analyzed. Variation of the computed strains in the direction of strain gage along the gage line is as per the theoretical predictions. The results of present investigation show that the maximum permissible radial distance (r_{max}) increases initially with the increase in a/b and decreases with further increase in a/b values. The present method will be extremely useful in placing strain gages for accurate experimental determination of the SIF using DS technique.

Abstract
The factor of safety against rupture of castings subject to high-strength loads, such as transport and pressure vessels as well as windmill components, is assessed taking into account fracture mechanical characteristic values for the static, cyclic and dynamic load condition. The experimental investigation of dynamic crack initiation values with regard to cast iron-specific aspects was the subject of a contribution at the 12th ICF in Ottawa.

Continuing the examination, the contribution on hand describes the effect of the microstructure on the mechanical and fracture-mechanic properties of ferritic and ferrite-pearlite cast iron materials at low temperatures. The strength and sensibility to brittle fracture are conventionally evaluated by applying the characteristic values of the tensile test or the notched bar impact test. During the recording of the notched bar impact work-temperature curves in the temperature range of 180 °C to -60 °C, the transition temperature curves are defined by comparing various criteria. The dynamic crack initiation values at -40 °C are determined via the recording of cracking resistance curves (J integral concept). In addition, via the determination of the crack arrest toughness K_{Ia} at 50 mm thick CCA samples, the crack arrest behaviour is controlled in the temperature range of -40 °C to -80 °C.

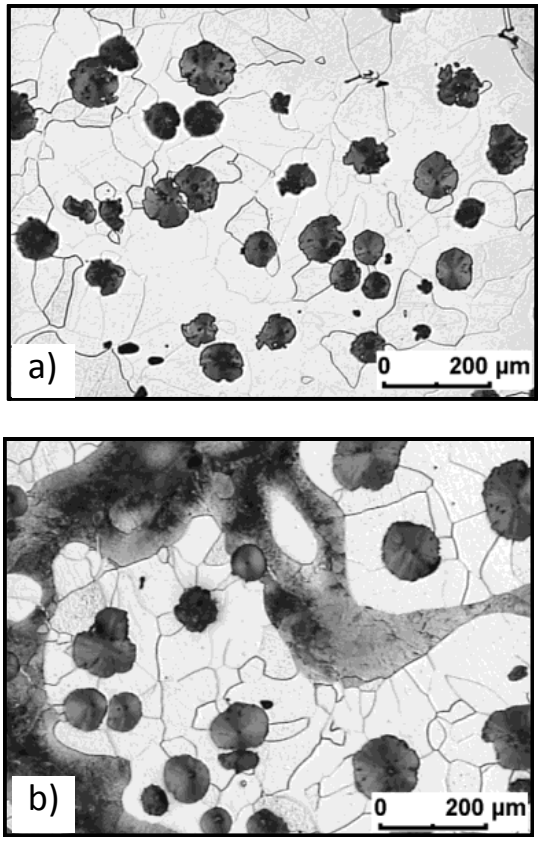
Keywords Cast iron, perlite content, crack resistance behavior, dynamic loading

1 Introduction

Resulting from various solidification and cooling conditions, microstructures may develop distinguishing themselves clearly with regard to the graphite morphology and pearlite content. Using the example of ferritic or ferrite-pearlite ferritic cast iron materials, the contribution on hand describes their effect on the mechanical and fracture-mechanic properties at low temperatures.

2 Materials

The examinations were performed on ductile ferritic cast iron materials with various pearlite content (Fig. 1), designated in the following GJS (4) and GJS (29).



Microstructure parameters:

Diameter of the graphite particles: 63 µm
Ferrite grain size: 62 µm
Particle separation: 88 µm
Form factor: 0.71
Number of particles: 47 mm^{-2}

Pearlite content: 4 %

Microstructure parameters:

Diameter of the graphite particles: 69 µm
Ferrite grain size: 62 µm
Particle separation: 102 µm
Form factor: 0.74
Number of particles: 32 mm^{-2}

Pearlite content: 29 %

Figure 1: Microstructure and microstructure parameters a) GJS (4), b) GJS (29)

3 Mechanical characteristic values

The characteristic values of the tensile test were always determined on three tensile tests according to DIN EN 10 002 at RT and taking into account the special application at -40 °C (Tab. 1).

Table 1: Mechanical characteristic values and hardness values

Material	Temperature °C	$R_{p0.2}$ MPa	R_m MPa	A %	Z %	E GPa	ν	HBW 2.5/187.5
GJS(4)	RT	245	367	12	13	172	0.28	137
	-40	273	393	10	11			
GJS(29)	RT	284	424	11	12	174	0.28	163
	-40	315	427	5	5			

The notched bar impact test according to DIN EN 10 045-1 was performed with ISO-V samples (10x10x55 mm) using a 300 J pendulum striking mechanism in a temperature range of 180 °C to -60 °C, whereby at each temperature three samples were tested. Following the determination of the notched bar impact work used KV and the lateral expansion LE the approximation of the KV-T or LE-T-curves is performed according to Eq. 1

$$KV, LE = X + Y \tanh \frac{T - T_0}{Z} \quad (1)$$

The transition temperature T_t was determined by calculating the KV-T or LE-T curves at 0.5 (KV_{max} + KV_{min}) or 0.5 (LE_{max} + LE_{min}), Tab. 2.

Table 2: Characteristic values of the notched bar impact test

	Parameter equation (1)				KV (RT)	KV (-40 °C)	T_t^{KV}
Material	T_0 °C	X -	Y -	Z -	J	J	°C
GJS (4)	-2.2	10.54	6.14	28.30	17	5	-2
GJS (29)	66.6	12.44	8.24	42.56	7	5	67
Material	T_0 °C	X -	Y -	Z -	LE (RT) mm	LE (-40 °C) mm	T_t^{LE} °C
GJS (4)	3.3	0.27	0.25	38.03	0.43	0,10	3
GJS (29)	66.6	0.32	0.27	55.54	0.18	0,07	67

The differently determined transition temperatures show a good correlation.

4 Fracture mechanical characteristic values

The static fracture mechanical characteristic values of the J integral concept at -40 °C (Tab. 3) were determined at 20% side grooved SENB-samples (10x20x120 mm) according to ESIS P2-92 applying the compliance method, and the J_R curves approximated with the extended power approach, Eq. 2

$$J = A(\Delta a + B)^C \quad (1)$$

The physical crack initiation values $J_{i/BL}$ are determined with the J_R curve at the point of intersection of the blunting line according to Eq. 3

$$J = 3.75 \cdot R_m \cdot \Delta a \quad (2)$$

The technical crack initiation values $J_{0.2}$ are determined at Δa = 0.2 mm (Fig. 2). The conversion of the J values into the respective characteristic values of the K concept is performed via the elastic constants according Eq. 4 to.

$$K(J) = \left[\frac{J \cdot E}{1 - \nu^2}\right]^{1/2} \quad (4)$$

Apart from the determination of the crack initiation values, the increase in the cracking resistance curve distinguishes the material resistance against a constant crack propagation, which can be defined as T module (tearing modulus) according to Eq. 5

$$T^J = \frac{dJ}{da} \cdot \frac{E}{\left(R_{p0.2}\right)^2} \quad (3)$$

Here, the T^J module is quantified during the applied nonlinear curve adjustment according to the Eq. 5 via the increase of the secant in the range of Δa = 0.2 mm to Δa = 1 mm.

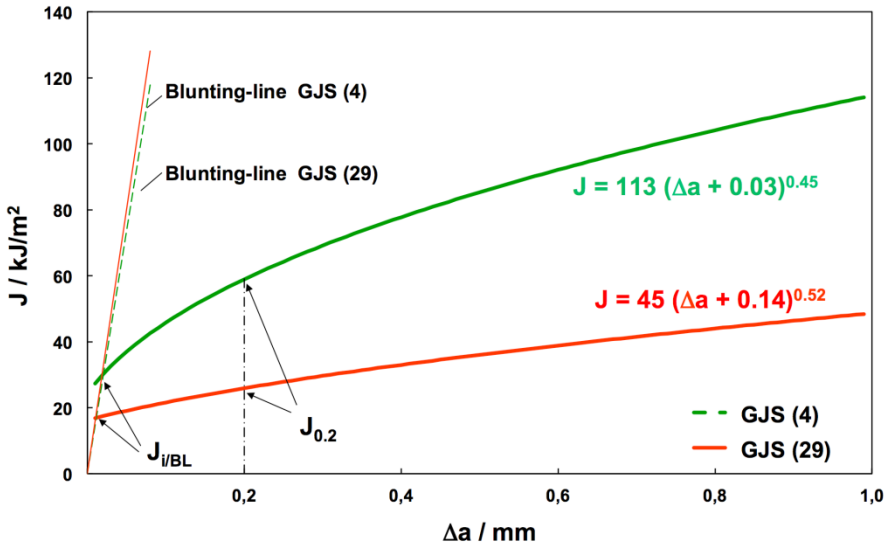


Figure 1: Static J_R curves at -40 °C

Table 3: Static fracture toughness characteristic values of the J integral concept at -40 °C

Material	A -	B -	C -	$J_{i/BL}$ kJ/m²	$J_{0.2}$ kJ/m²	K ($J_{i/BL}$) MPa√m	T^J
GJS (4)	113	0.03	0.45	28	59	73	162
GJS (29)	46	0.14	0.52	16	26	55	50

The experimental investigation of the dynamic cracking resistance curves of the J-integral-concept (J_{dR}-curves) was carried out on 20 % side-grooved SENB samples (10x10x55 mm) with fatigue cracking according to the "low-blow"-technique using an instrumented pendulum. Thereby, six to eight samples in the range $2.8 \cdot 10^4$ MPa√m/s ≤ $\dot{K}$ ≤ $5.7 \cdot 10^4$ MPa√m/s were stressed, the J_d values were determined via the calculated dynamic force-distance diagrams and the Δa values were determined on the fracture surfaces of the samples. Testing procedure and evaluation were performed in adaptation to ESIS P2-92. Contrary to the static load, the stable ductile crack propagation for the dynamic load is replaced with a stable cleavage-faced crack propagation. The resulting material-specific aspects with regard to recording, evaluation and definition of the dynamic crack initiation values have been described in [1] and [2]. The determined J_{dR}-curves or the characteristic values derived from these are shown in Fig. 3 and Tab. 4. Occurring "pop-in"-effects can be attributed to pearlite islands or graphite degenerations. For GJS (29) no experimental determination of a J_d-Δa-curve was possible at -40 °C, since only "pop-in" effects occurred. They are to be attributed to the increased pearlite content and are shown in Table 4 as J_{dc} values. The range of the J_{dc} values corresponds with the size and/or the number of the pearlite islands in front of the crack tip.

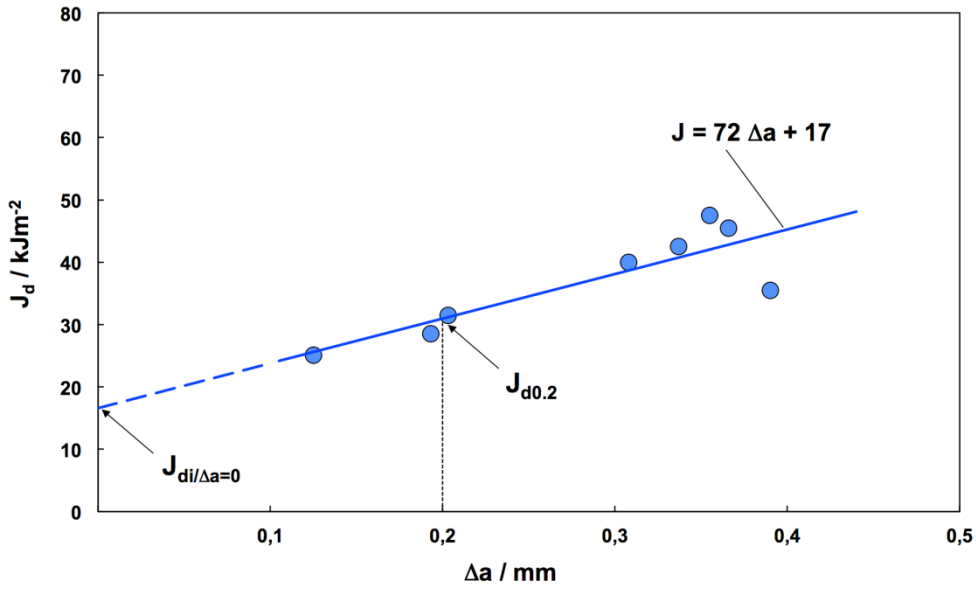

Fig. 2: Dynamic J_{dR} curve of the GJS(4) at -40 °C

Table 4: Dynamic fracture toughness characteristic values of the J integral concept at -40 °C

Material	$J_{di/\Delta a=0}$ kJ/m²	$J_{d0.2}$ kJ/m²	$K(J_{di/\Delta a=0})$ MPa√m	T_d^J	J_{dc} kJ/m²	$K(J_{dc})$ MPa√m
GJS (4)	17	31	56	64	22[1)]	64
GJS (29)	-	-	-	-	10[2)]	34

[1)]…Mean value of 6 samples with J_{dc}^{min} = 16 kJ/m² and J_{dc}^{max} = 27 kJ/m²
[2)]…Mean value of 10 samples with J_{dc}^{min} = 6 kJ/m² and J_{dc}^{max} = 14 kJ/m²

While the dynamic fracture toughness distinguishes the material resistance against instable crack propagation for impact load, the crack arrest toughness K_{Ia} evaluates the ability of the material to trap a crack propagating at high speed. A crack arrest presents a special case of an instable crack propagation aiming to secure components with high requirement on the safety against fracture on the material and / or load side so that instably propagating cracks as a result of overstress and / or embrittlement on the material side are trapped again before a catastrophic failure occurs. The crack arrest toughness K_{Ia} is determined according to ASTM E 1221-06 on 50 mm thick CCA-samples in the temperature range of -40 °C to -80 °C.

A temperature equalisation is possible via the cooling system of the base plate, on which the CCA-sample rests. After setting the test temperature, the sample is loaded with 5 to 10 mm/min via a wedge firmly connected to the crosshead of the testing machine. Thus, this is pressed into the divided jaws located in the bore, and the sample is loaded until, starting at the notched welding bead, instable crack propagation occurs (Fig. 4).

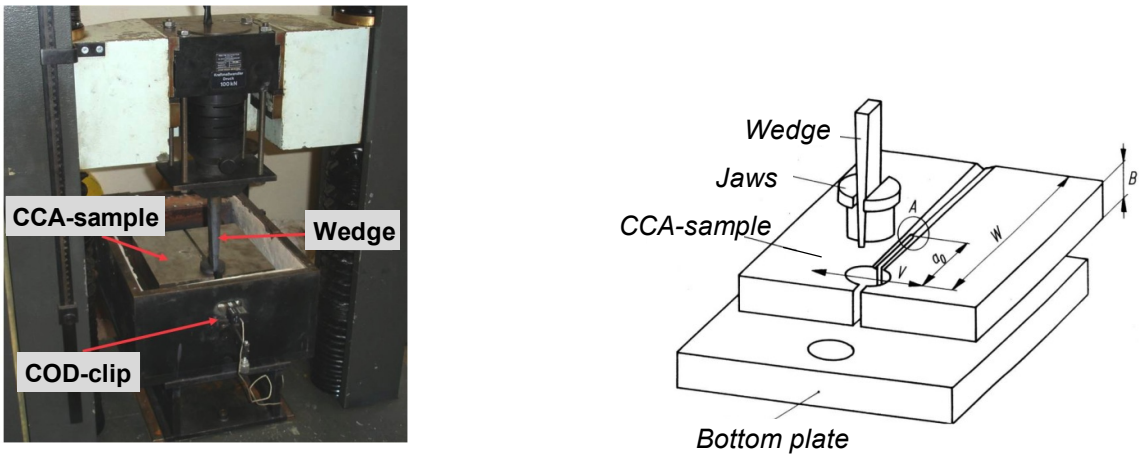

Fig. 3: Test set-up and transversal wedge load of the CCA-samples according to ASTM E 1221-06 (A: brittle build-up welding with notch)

During the test, the force and the notch opening (COD clip) are registered. An abrupt notch opening with a simultaneous reduction of force indicates an instable crack propagation. Details on the test evaluation are specified in ASTM E 1221-06. To this end, with regard to the validity criteria concerning the minimum and maximum crack length as well as the verification of the required minimum sample thickness B implementing the level elongation state according to

$$B \geq 2.5 \left(\frac{K_{Ia}}{R_{dp0.2}} \right)^2 \tag{6}$$

It must be taken into account that this requires knowledge of the dynamic yield strength $R_{dp0.2}$. The determination of $R_{dp0.2}$ for ferritic cast iron materials is possible via the Arrhenius equation (Eq. 7) describing the dependence of the dynamic yield strength of the elongation rate $\dot{\varepsilon}$ and the temperature according to

$$R_{dp0.2} = \sigma_i + \sigma_0^* \left[1 - \frac{k \cdot T \cdot ln \, {\dot{\varepsilon}_0}/{\dot{\varepsilon}}}{\Delta G_0} \right]^m \tag{7}$$

The parameters of the Arrhenius equation ($\dot{\varepsilon}_0 = 8.68 \cdot 10^8$/s, σ_i = 212 MPa, σ_0^* = 621 MPa, $\Delta G_0 = 2.2 \cdot 10^{-19}$ J, m = 3.43) determined within extensive examinations [3] of 15 batches at T = -80 °C and $\dot{\varepsilon}$ = 1/s result in a value for $R_{dp0.2}$ = 422 MPa. The specified elongation rate corresponds with $\dot{K} = dK/dt$ values between 10^4 MPa√m/s and 10^5 MPa√m/s existing during impact bending tests determining dynamic K_{Id} values. For ferrite-pearlite cast iron materials, the value $R_{dp0.2}$ = 385 MPa determined in [4] for $\dot{\varepsilon}$ = 1/s and -40 °C can be used. The crack-arrest tests performed on 50 mm thick CCA-samples in the temperature range of -40 °C to -80 °C show that due to the failure to achieve the "minimum crack length" required by the standard, at -40 °C

and -60 °C no valid K_{Ia} values can be determined. The cause is the still available high crack initiation toughness. This also applies to the ferritic as well as the ferrite-pearlite cast iron. The conditions for the check of the level elongation state are only met at -80 °C, and valid K_{Ia} values can be determined, which are in the range 44 MPa√m ≤ K_{Ia} ≤ 61 MPa√m. The crack propagation occurs at -80 °C, also within the fracture surface area of the crack-arrest, exclusively cleavage-faced, whereby crack trapping can be attributed material-specific to the energy-dissipative effect of the graphite particles.

5 Summary

A summarising evaluation of the effect of the pearlite content on the mechanical and fracture mechanical characteristic values is performed based on a graphical representation of the characteristic values determined (Fig. 5 to Fig. 7). In addition to the expected work-hardening with declining temperature and higher pearlite content, only with higher pearlite content and -40 °C a significant decrease of the plasticity occurs, i.e. a more than 50 % decrease of the fracture elongation A or the percentage reduction of fracture Z (Fig. 5).

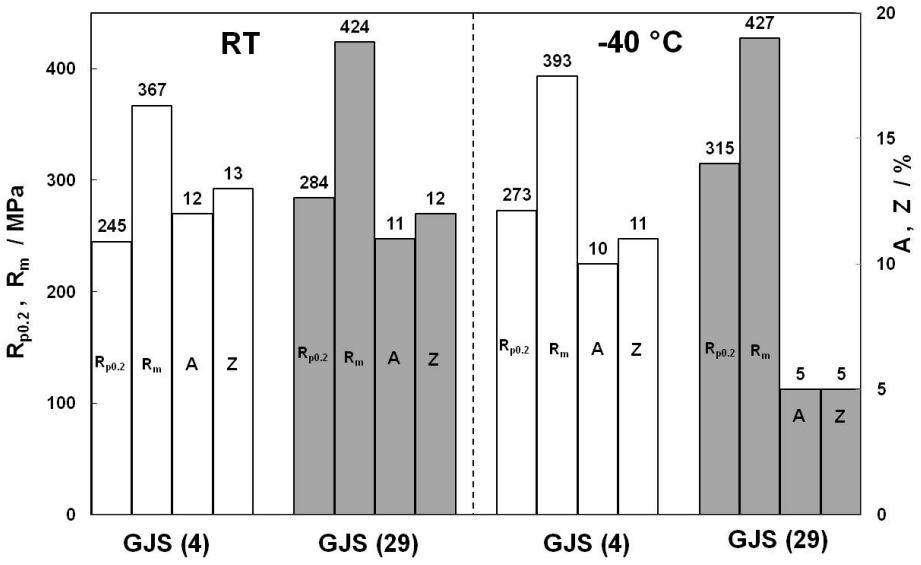

Figure 5: Mechanical characteristic values of the tensile test

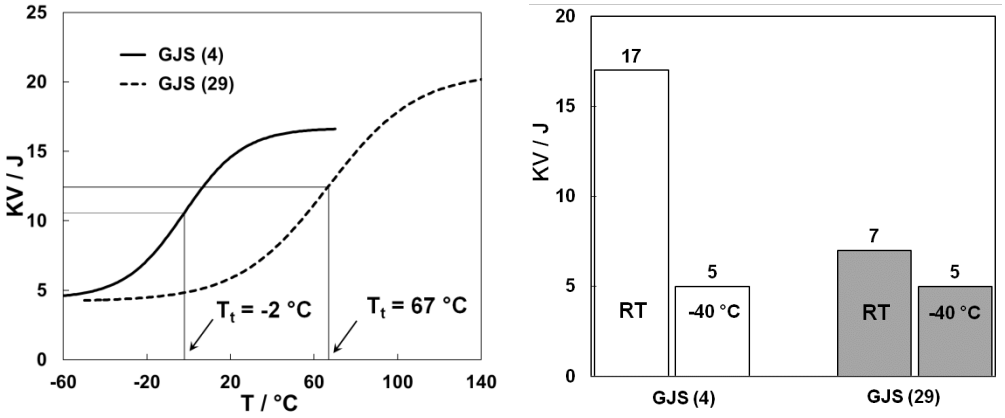
With a sudden load, the increased pearlite content leads to a significant decrease in toughness, as resulting from the course of the KV-T curves (Fig. 6a) and the notched bar impact work used KV at RT as well as the transition temperature T_t (Fig. 6b). At -40 °C, both materials are located in the lower position of the KV-T-curve.



a) KV-T curves b) KV values (RT and -40 °C)

Figure 4: Mechanical characteristic values of the notched bar impact test

It results from the comparison of static fracture-toughness values at -40 °C that the increased pearlite content leads to a significant reduction of the material resistance against crack initiation ($J_{i/BL}$, $J_{0.2}$) and ductile stable crack propagation (T^J). As the dynamic fracture-toughness values of the GJS (4) show, a shock load at this temperature leads, due to the cleavage-faced stable crack propagation, to a significant decrease of the crack resistance behaviour (Fig. 7). With these loading conditions, the effect of the pearlite becomes also apparent with the occurrence of "pop-in"-effects, occasionally with GJS (4) and exclusively with GJS (29).

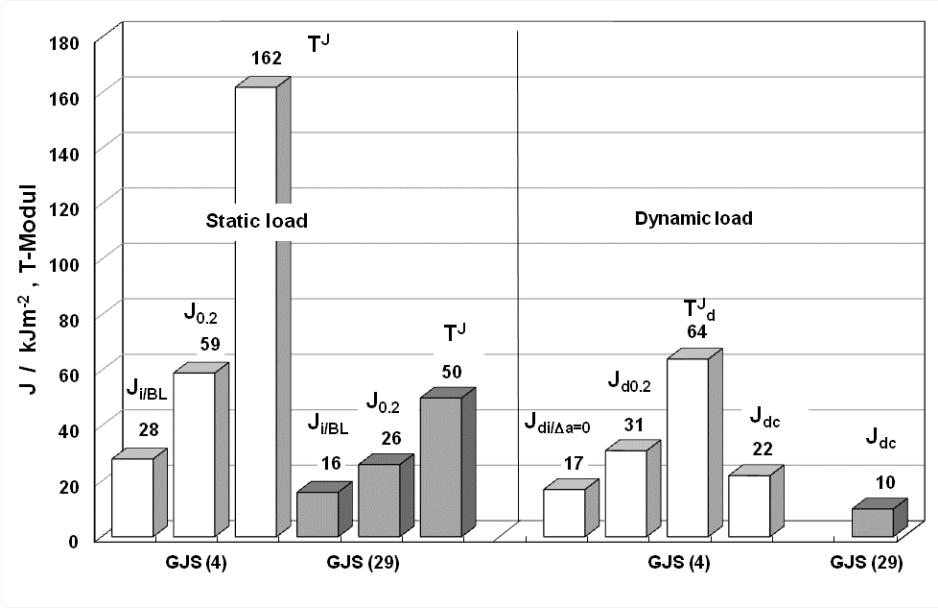


Fig. 5: Fracture mechanical characteristic values for static and dynamic load (-40 °C)

The K_{Ia} values determined at -80 °C are evaluated via the allocation to the reference curve on hand (lower-bound curves) to the temperature-dependent course of the K_{Ia} values (Fig. 8). There only tends to be an effect noticeable with regard to the increased pearlite content.

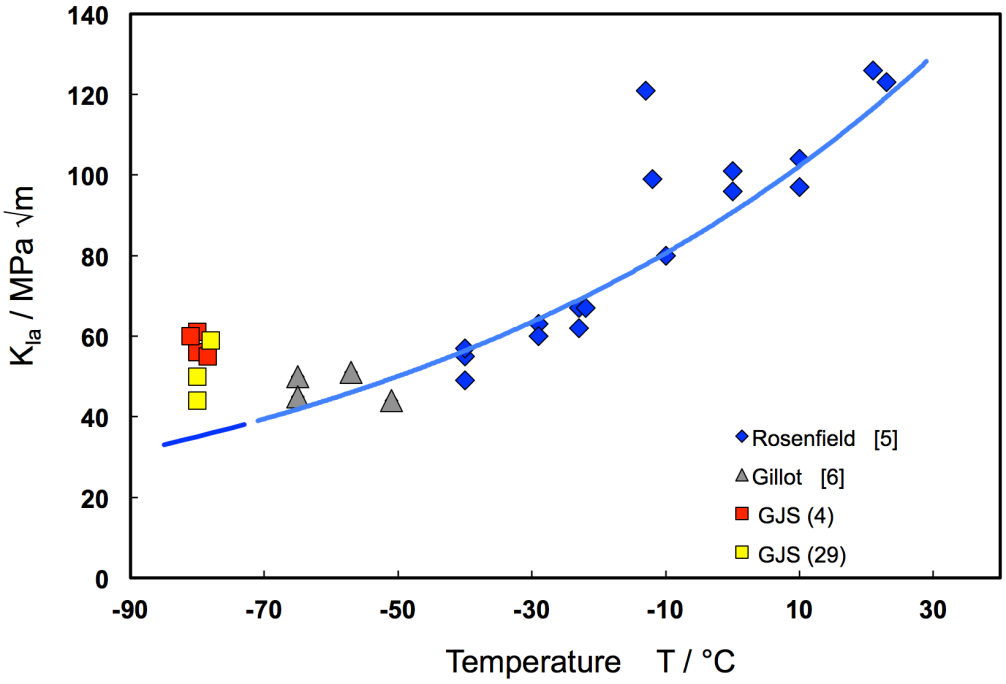

Figure 6: K_{Ia}-values for ferritic cast iron as a function of the temperature

According to [5], the determination of valid K_{Ia} values at ferritic cast iron in the temperature range of -40 °C to 20 °C is only possible by means of a duplex-arrest sample, to which a hardened steel (AISI 4340) as the crack starter is connected via a work intensive heat-treated electron-beam welded connection with the GJS-400 test specimen. In this combination, the crack does not start in a brittle build-up welding according to (Fig 4), but inside the hardened steel and runs into the cast iron at high speed. Thus, the determination of the K_{Ia} values can be implemented even at the higher temperatures specified in Fig. 7. The temperature-dependent course of the K_{Ia} values integrates the values listed in [6] as well as the K_{Ia} values determined here at -80 °C. Based on the temperature-dependent course of the K_{Ia} values, an estimation of the crack-arrest capacity after the crack initiation is possible with the knowledge of the stress intensity factor K_I dependent on the component geometry and fault type or size.

Abstract
Fracture mechanics has been widely used for mechanical integrity assessment in industrial applications. Different approaches in the fracture mechanics assessment have been developed to achieve more accurate prediction of component lifetime. This paper describes fracture mechanics assessments by applying the 2D and 3D crack growth analyses of a real mechanical component under cyclic load as an example from the power industry. In 2D crack growth analysis, both an appropriate equivalent geometry as well as the original geometry with an explicit crack model are investigated. A limitation of 2D crack growth analysis in the example is to consider load redistribution, which follows from the local stiffness change attributed to the cyclic crack growth. This can be overcome by 3D crack growth analysis with an explicit crack model. Comparison between 2D and 3D assessment results are given. The concept of local limit load and failure assessment diagram (FAD) are reviewed and studied by using finite element (FE) analysis.

Keywords fracture mechanics, crack growth, load redistribution, limit load

1. Introduction

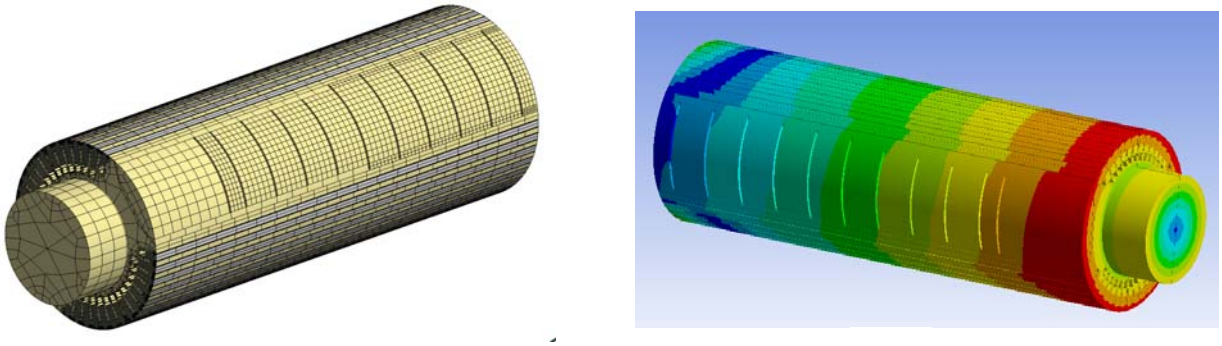
Industries have been challenged to come up with better and less costly products within shorter development cycles. Thus, product development processes have also needed to be improved. This has lead to a tremendous challenge for engineers, to continuously develop improved approaches including fatigue life time assessment of a component. In the lifetime assessment it is important to consider both crack initiation and crack propagation. Fatigue failure is caused by microscopic damage in the material that after continued cycling develops into a crack that may finally lead to a component failure. Generally the design should avoid the initiation of fatigue cracks during the design life time. However one has to assume the existence of initial flaws in the raw material, e.g. forgings. In order to determine criteria for the non-destructive testing of forgings, appropriate investigations of crack propagation are required. This paper focuses on these numerical crack propagation investigations.

In this paper, the application of fracture mechanics for mechanical integrity assessment is shown in industrial applications. Different approaches in the fracture mechanics assessment have been developed to achieve more accurate prediction of component lifetime. This paper describes fracture mechanics assessments by applying the 2D and 3D crack growth analyses of a real mechanical component under cyclic load as an example from the power industry. Some limitations in the application of crack growth simulation in 3D analysis and the potential use of a failure assessment diagram (FAD) are discussed.

2. Mechanical model

In the shaft trains of large steam turbine generator sets, the mechanical integrity of each component of the shaft train has to be verified. The rotating parts such as generator and steam turbine rotor

have to be particularly verified with accurate lifetime assessment methods. In this work, a generator rotor is taken as an example for fracture mechanics assessment. Figure 1 shows the FE-model of a generator rotor and one example of analysis results by using ANSYS [8]. A generator rotor has complicated geometries and components such as insulation, conductors and wedges. The calculation of a complete 3D rotor model is very time consuming. Therefore, a 2D model can be used to reduce the computational efforts. In 2D crack growth analysis, a stress analysis should be performed beforehand. A 2D model of generator rotor is depicted in Fig. 2. The corresponding 2D elements in ANSYS are applied in the mesh generation.



(a) (b)

Figure 1. FE model (a) and displacement results (b) of a complete 3D generator rotor

The dominating load in a generator rotor is due to centrifugal forces, i.e. the main contribution for cyclic rotor loading is related to the start/stop cycles of the shaft train. The number of design start/stop cycles is specified in IEC 60034-3. Thus, the centrifugal load at rated speed is considered for stress analysis. For 3D crack growth analysis, a simplified 3D model is created as shown in Fig. 3, where a rotor tooth is modeled. The influence of conductors and wedges is replaced with equivalent pressure applied at the rotor tooth flank.

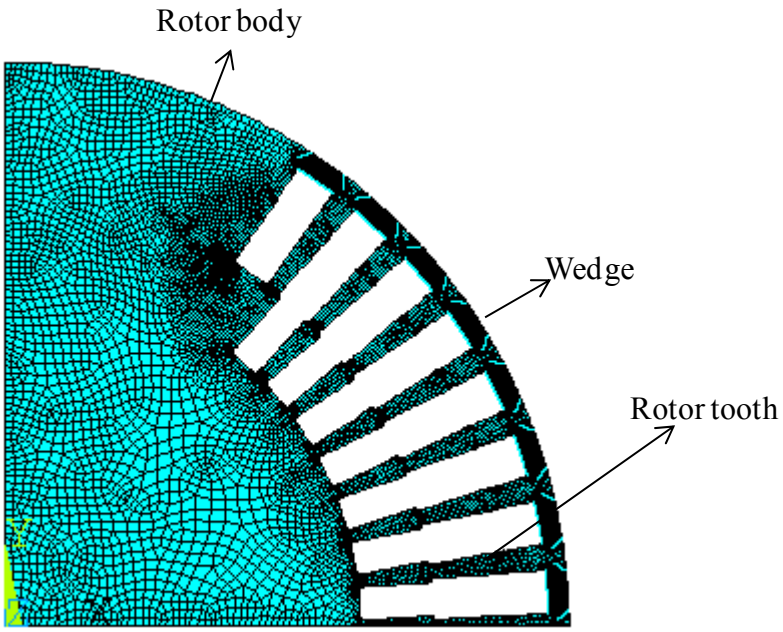


Figure 2. 2D FE model of generator rotor

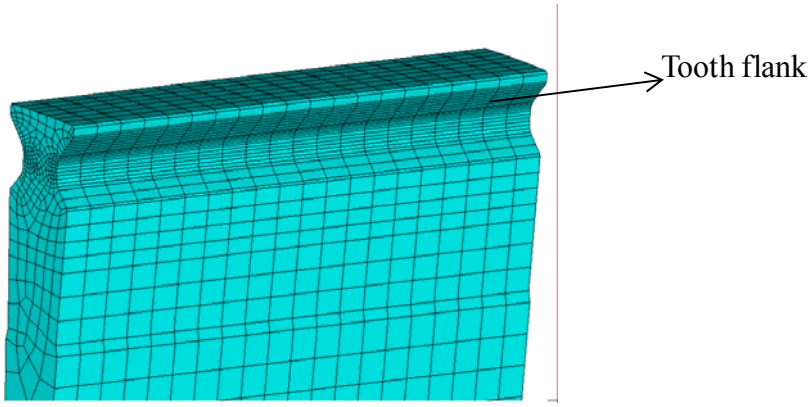

Figure 3. Simplified 3D FE-model for calculation and crack growth analysis

3. Crack growth analysis

3.1. 2D crack growth calculation

To calculate 2D crack growth the program AFGROW [1] is used in this example. AFGROW is an analytical fatigue crack growth prediction program initially developed in AFRL for airframe applications and based on the principles of Linear Elastic Fracture Mechanics (LEFM) [1]. AFGROW calculates fatigue crack growth by considering known stress intensity solutions for a particular geometry, under an applied stress field. A stress intensity solution has the following general form:

$$K = \beta\sigma\sqrt{\pi a} \tag{1}$$

in which 'K' is the stress intensity factor, 'a' is a characteristic crack length, 'σ' is the applied stress, 'β' is the geometrical factor. As the stress intensity solutions are dependent on the geometry of the components, AFGROW provides certain standard predefined geometries (crack models) for predicting crack propagation.

To create the initial crack, a surface crack model is selected as shown in Fig. 4. As input data, the corresponding model geometry and dimensions should be defined. The crack growth rates are expressed in the form of the Walker equation, which is simplified to a Paris equation. In AFGROW the stress gradient can be included in the analysis. The analytical solution for this crack model is described in [2], which is implemented in AFGROW. It is assumed that the first principal stress is always normal to the crack plane. The calculated first principal stress from the 2D finite element model described previously is shown in Fig. 5, where the stress path can be seen. Using the stress gradient along the stress path, the crack growth calculation is performed and the normalized results are depicted in Fig. 6. The crack size 'a' corresponds to the crack growth in the circumferential direction and crack size 'c' to the axial direction.

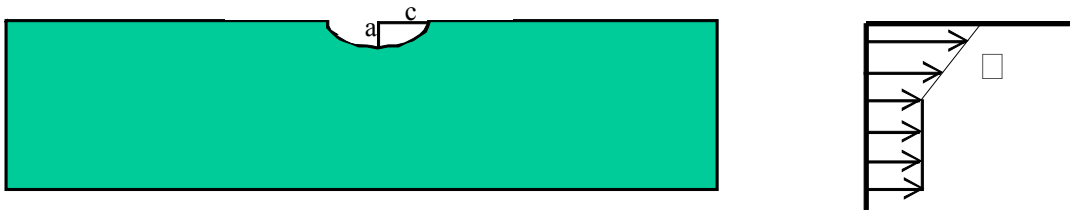

Figure 4. Crack model in AFGROW and stress gradient (schematic)

The application of the crack model has to satisfy a limit that the ratio of crack size 'a' and plate thickness 't' must be less than or equal to 0.8 ($a/t \leq 0.8$). The reason of this limitation is according to Glinka that the reference solutions used for the derivation of the weight function were valid for this range (see also [2]). Further investigation shows that the reference solution is related to the local limit load which causes local crack-ligament yielding somewhere along the crack front [5]. The local limit load will be further discussed in the next section.

2D crack growth analysis is a straight-forward approach, where the FE results can be used directly in the crack growth calculation. Its numerical effort is also acceptable. However, 2D crack growth analysis is limited by the fact that for larger crack extension compared to the geometrical dimension of the analyzed component possible load redistribution cannot be considered. The load redistribution occurs as the local stiffness around the crack changes more significantly as the crack becomes larger. Moreover, the assumption that the 1st principal stress is always normal to the crack plane may lead to a conservative result. The load redistribution may have a significant impact as demonstrated in the next section with the results of the 3D crack growth analysis of the same component.

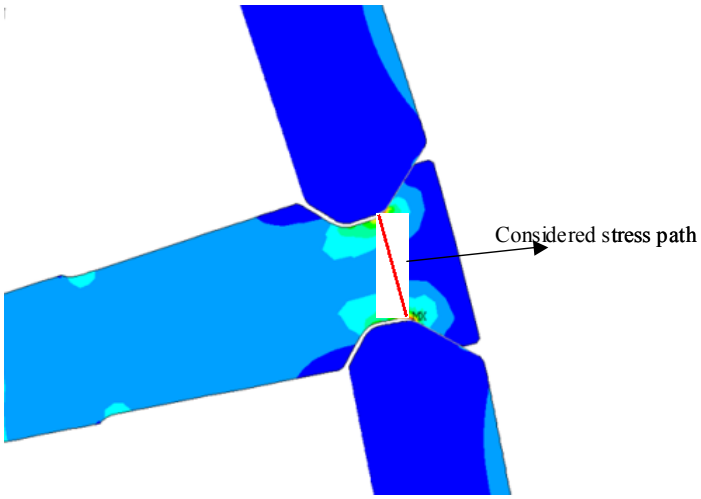

Figure 5. 1st principal stress distribution of rotor due to centrifugal load

3.2. 3D crack growth calculation

A critical issue in 3D crack growth calculation is the mesh generation. In general cases, the use of a

standard FE program faces time-consuming challenges such as:

- Component geometries are complex and time consuming to model, where cracks can occur at geometrically difficult locations, e.g. chamfers, corners.
- Initial cracks of the correct size and shape must be inserted in the component at the correct location.
- After several load cycles and depending on the loading, initial planar crack may develop into a non-planar crack.

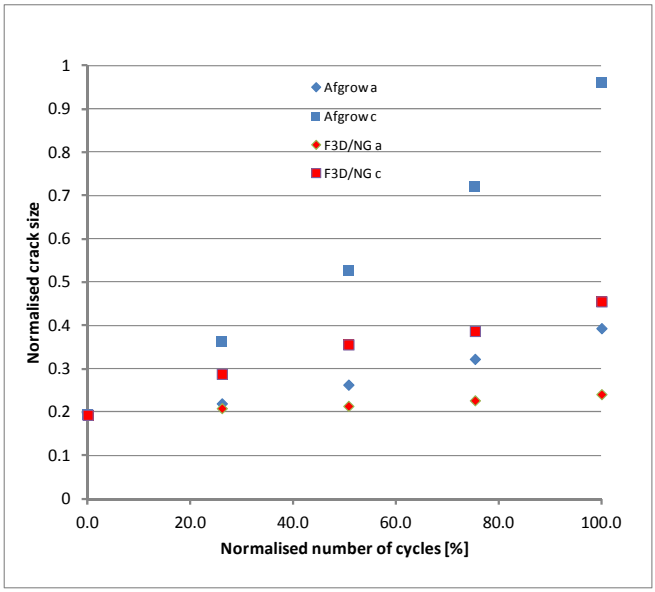

Figure 6. 2D and 3D crack growth calculations and their comparison

To alleviate the above challenges, there are several programs existing that allow users to generate/insert a crack into the FE model. In this work, the program FRANC3D/NG (short name F3D/NG) version 4.0 has been used. The methodology of F3D/NG has been documented in [3]. In F3D/NG the stress and displacement fields in the structure of interest are obtained from a Finite Element program such as ANSYS or ABAQUS [9].

The results of the FE analysis as well as geometry are read directly into F3D/NG in a text format. The F3D/NG program uses the FE program as solver to obtain the stresses and displacements after growing the crack at a user defined step size. Hence, by updating the stresses and displacements for each crack growth step with the FEA method, the simulation can more closely represent the crack's influence on the structure. The crack insertion and all re-meshing are carried out within F3D/NG in the submodel created before by using the FE program. The F3D/NG will produce a neutral format file that can be read back into the FEA code and re-analysed.

In F3D/NG the stress intensity factors of Mode I, II and III are calculated by using M-Integral (interaction integral) for isotropic and anisotropic materials [3, 4]. F3D/NG can also compute stress intensity factors using a displacement correlation approach. In this approach, the calculated displacements for nodes on the crack faces are substituted into the theoretical expressions for the crack-front displacement fields as functions of the stress-intensity factors. The applied propagation direction criterion is based on the maximum stress criterion. In this method, depending upon user's choice, the mode I and mode II with/without mode III values are combined to yield both magnitude

and direction of the propagation at the various discrete points along the crack front.

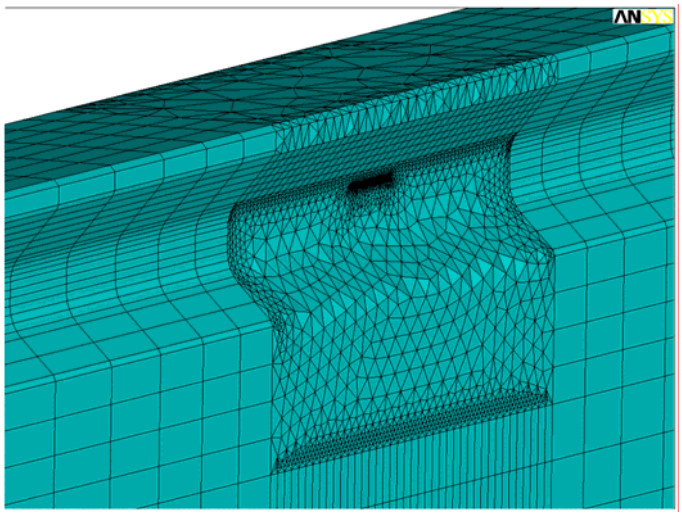

Figure 7. Example showing the submodel with finer mesh and inserted crack

Fig. 7 shows the global model and the submodel having finer mesh and inserted crack. The applied element type is an element with a quadratic shape function. The calculated equivalent stress field is shown in Fig. 8. By using the same parameter for the Paris equation as for 2D crack growth, 3D crack simulation with the same initial crack size is carried out. Small size steps and other meshing options are defined in order to get optimal results. The calculated crack sizes in both directions are presented in Fig. 6. It is clearly observed from Fig. 6 that there is a significant difference in the results from the 2D and 3D crack growth calculation yielding an overestimation of the cyclic crack growth with the 2D model. This demonstrates that the influence of load redistribution as well as the stress direction to the crack plane is significant for crack growth analysis.

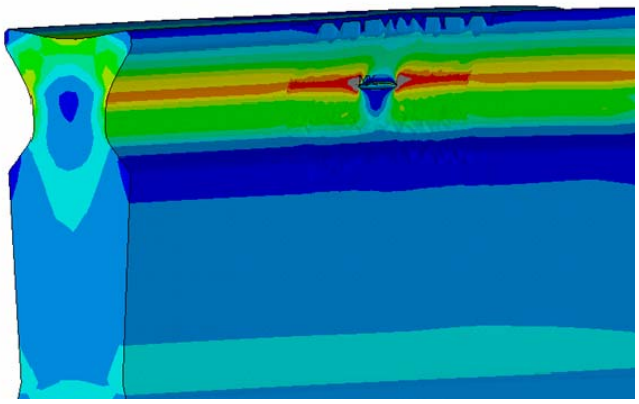

Figure 8. Stress field of model with a crack

Conventional limit load analysis computes the global (net-section) limit load, at which displacements become unbounded. However, the global limit load might be taken conservatively for a part-through crack. Thus, local limit load is proposed and defined as the load needed to cause a local crack-ligament yielding somewhere along the crack front [5]. In the paper, the local limit load is derived by finite element analysis of a plate with surface crack. In order to check the local limit

load of the rotor, elastic-plastic analysis with ideal plastic material behavior is performed on the model with sequentially increased crack sizes. The result analysis shows that the local load limit is achieved at a/t=0.8. Strain distribution at ligament yields that the limitation of up to a/t=0.8 is also valid for the component assessment.

3.3. Failure Assessment Diagram (FAD)

The failure assessment diagram (FAD) method is the broadly accepted methodology for the analysis of components containing a crack-like flaw. The FAD method is described in the engineering code, for example API 579 and FKM guideline for fracture mechanics [6]. The FAD method uses brittle fracture ratio (K_r) and plastic collapse ratio (L_r). In a FAD the non-dimensional ratio L_r is on the horizontal-axis and K_r (brittle fracture ratio) on the vertical-axis. The plastic collapse ratio is a parameter measuring the proximity to plastic collapse. The brittle fracture ratio is a parameter comparing the stress intensity factor at the crack and the fracture toughness of the material. The FAD curve can be computed if the stress-strain curve exists. In this case, the plastic collapse ratio is determined by using the reference stress, which can be computed using the J-integral results from the elastic-plastic analysis. The brittle fracture ratio is computed from the crack front stress intensity, obtained by an elastic analysis.

Fig. 9 shows a graph of FAD and the evaluation point for the example calculated in the previous section, where the ratio a/t is less than 0.5. In Fig. 9, the evaluation point inside the FAD curve indicates an acceptable crack. The evaluation point represents the quasi static condition of a crack/flaw at certain size and loading. The FAD curve is not created by using a specific structural component and a stress-strain curve. The FAD curve is derived from the following equations [6]:

$$F1(L_r) := \begin{cases} \left(1 + \frac{L_r^2}{2}\right)^{\frac{-1}{2}} & \text{if } L_r < 1 \\ \left(\lambda + \frac{1}{2\lambda}\right)^{\frac{-1}{2}} & \text{if } L_r = 1 \\ \left[\left(\lambda + \frac{1}{2\lambda}\right)^{\frac{-1}{2}} \cdot L_r^{\frac{N-1}{2N}}\right] & \text{if } L_{rmax} > L_r > 1 \\ 0 \text{ if } L_r \geq L_{rmax} \end{cases} \quad (2)$$

in which λ and N are parameters given in [6], which depend on material yield strength as well as ultimate tensile strength. The above equations are based on basic level assessment, which is more conservative than the use of stress-strain curve in FAD. However, the computed FAD curve with stress-strain curve can provide a better representation of the particular material effect and the particular structural component geometry.

If the evaluation point is above the FAD curve, the crack is unacceptable and this can indicate a predicted structural failure. The evaluation point can be updated as the crack grows to determine the end of life when the evaluation point reaches the FAD curve. Thus, an evaluation point on the FAD curve can be useful to determine predicted critical crack sizes.

4. Conclusions

This paper demonstrates the application of fracture mechanics in industrial practice. 2D crack growth analysis provides significantly less computational effort but can yield over conservative results, since the load redistribution and the actual stress state are not taken into account.

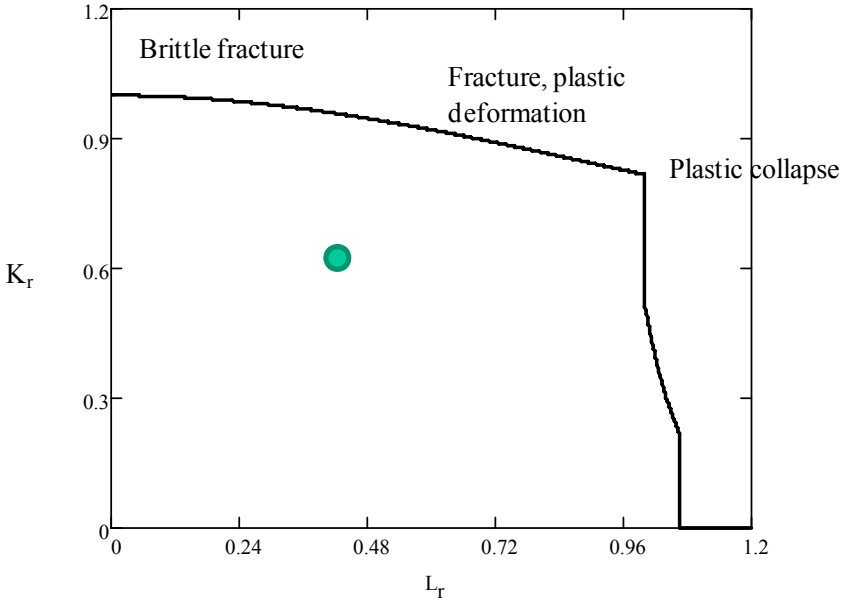

Figure 9. Calculated FAD showing the acceptable evaluation point

These weaknesses can be overcome by 3D crack growth analysis but it requires significant computational efforts. The use of submodelling in 3D crack growth analysis may reduce the computational time; however, from the practical point of view it is still a big challenge to use this method for fast development projects. Application of XFEM in the 3D crack growth calculation might offer an opportunity to extend the use of 3D crack growth analysis in lifetime assessment. However, the use of commercial XFEM code should be reviewed critically due to the result accuracy. Different strategies are currently developed for damage calculation to improve the accuracy and convergence rate of XFEM. Instead of re-meshing in the region of crack tip elements, a higher order element approach, different enrichment functions and integration rules can be applied (see e.g. [7]). Finally, the FAD assessment can be used to ensure that a component with a certain crack/flaw size is acceptable for the design load.

Abstract The fatigue life of crane steel structure will inevitably decrease in the course of work, which directly affects the work of crane. So the correct safety assessment and fatigue life evaluation is necessary. According to the results of stress testing and non-destructive examination, a framework of assessing remaining fatigue life of crane metal structures is built in this paper based on crack propagation theory. Moreover, in order to descript the analysis process, an example about fatigue life estimation of a shipbuilding gantry crane whose maximum hoist 100 ton was shown.

Keywords Crane, steel structure, fatigue life, crack propagation

1. Introduction

Crane is one kind of mechanics which is of significant characteristics such as repetitive, cycle, frequent brake and large impact load etc. . Especially, there is about 70-80% metal failure accident which is associated with fatigue. So it is very necessary to research the fatigue life estimation of metal structure. When metal structure of a crane reaches its allowable safe life, it must be retired from service. One of the most important life prediction approaches is the stress-life approach [1-2]. As parts of the damage accumulation calculations, rain flow algorithm and Miner's rule were used. However, with no cracks, this could be the ultimate tensile strength or yield strength, depending upon the failure criteria chosen. As a crack forms and grows under cyclic loading, the residual strength decreases. This decrease as a function of crack size is dependent upon material, environment, component and crack configuration, location and mode of crack growth. Considering the crack, a new analysis method based fatigue crack growth is introduced. Compared to the conventional S-N fatigue analysis, crack detection methods, using several different nondestructive inspection techniques and standard procedures, have been developed [3-6]. This paper will present a framework of assessing remaining fatigue life of in-service crane.

2. Principles of fatigue life analysis

2.1. Conventional S-N fatigue analysis

S-N fatigue analysis is a conventional approach which touches on the relationship between applied stress and expected life. And the relationship is characterized by means of the S-N curve so that fatigue life can be predicted (Fig. 1). “S” stands for the cyclic stress range while “N” represents the number of cycles to failure. The core idea of this method is stress change is the main reason of fatigue failure of materials. Of course, the S-N curve is the inherent property and is derived from

tests on samples of the material to be characterized (often called coupons) where a regular sinusoidal stress is applied by a testing machine which also counts the number of cycles to failure. The applied stress used to calculate fatigue life can be obtained by tested strain or stress analysis via finite element method.

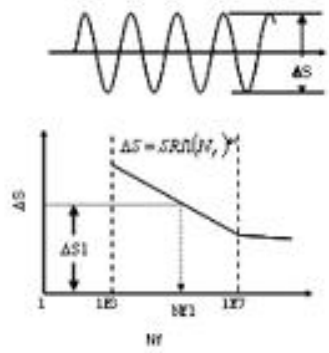

Figure 1. S-N fatigue curve

It should be noted that there are several short comings of S-N fatigue data. First, the conditions of the test specimens do not always represent actual service conditions. For example, components with surface conditions, such as pitting from corrosion, which differs from the condition of the test specimens will have significantly different fatigue performance. Furthermore, there is often a considerable amount of scatter in fatigue data even when carefully machined standard specimens out of the same lot of material are used. Since there is a considerable scatter in the data, a reduction factor is often applied to the S-N curves to provide conservative values for the design of components.

2.2. LEFM based fatigue crack growth analysis

The greatest significance in fatigue crack growth analysis in comparison to the conventional method is the existence of a crack. Cracks can form due to fatigue, or they can exist as a consequence of manufacturing processes such as deep machining marks or voids in welds and metallurgical discontinuities such as foreign particle inclusions. In fatigue life estimation process of metal structure of crane, linear elastic fracture mechanics (LEFM) is introduced to describe and predict fatigue crack growth life and fracture under the basic assumption that material conditions are predominantly linear elastic during the fatigue process. For crack growth or fracture conditions that violate this basic assumption, elastic-plastic fracture mechanics approaches are used to describe the fatigue and fracture process.

In order to perform the life estimation or prediction, several key items are needed: stress intensity factor, maximum and minimum stresses, fracture toughness (KIC), and initial crack size. Of course, environmental conditions, load history, statistical aspects, and safety factors must be incorporated in this methodology for remaining fatigue life assessment.

During the fatigue life estimation process, load history can be finished by the survey of crane usage

and statistical analysis. Nondestructive technologies such as magnetic particle testing (MT), ultrasonic testing (UT), penetrate testing (PT) and so on are usually used to detect the size of crack or flaw on the surface of structure. At the same time, the fatigue crack growth behavior is also inspected by these technologies. After idealizing the detected defection, relevant stress intensity factor will be gained via calculation or fatigue handbook. And maximum and minimum stresses can be determinated by means of finite element stress analysis. Certainly, both of them can be tested after typical load test. Furthermore, material properties such as young modulus, tensile strength, yield strength and fracture tough and so on can be obtained via tests. The issued handbooks can also be utilized if common material used in assessing structure. Finally, fatigue analysis can be performed based on measured strains and calculated stresses via finite element method. Prediction of fatigue remaining life can be carried on using professional software.

3. Interpreting methodology for remaining fatigue life assessment

As discussed previously, LEFM is one of the methodologies for remaining fatigue life assessment of metal structure of crane based on fatigue crack growth analysis. The following example shows how the procedures work.

In this example, we researched a shipbuilding gantry crane whose maximum hoist is 100 ton (Fig. 2). Then actual load history data was extracted while referring to the crane usage record. Fig. 3 shows the raw data about one week. Additionally, strains were measured at stress concentration positions, for example, cantilever and boom system. Fig. 4 shows one of the strain measure points at cantilever. All the data was used as the basic input during the estimating residual life process.

Figure 2. The photo of aged crane

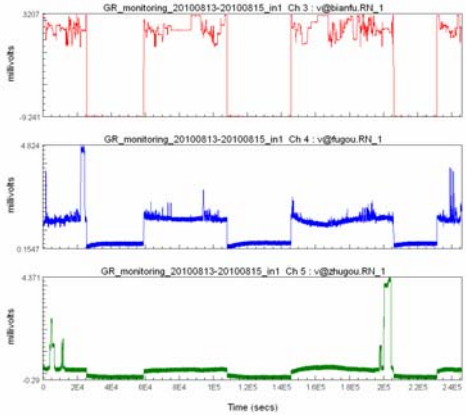

Figure 3. Actual data of load history of crane in less than one week

Finite Element stress analysis provided the primary stress concentration components of the crane. That is, cantilever and boom system. The results can be identified in Fig. 5.

Figure 4. Strain measurement point on cantilever

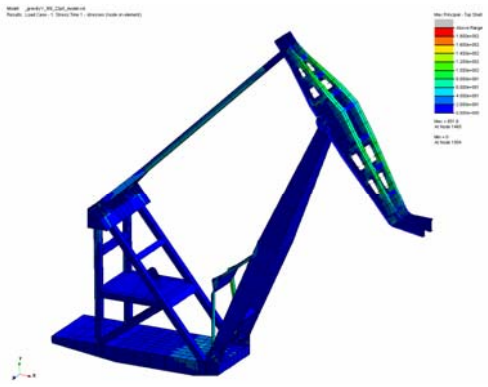

Figure 5. Stress contours of model when lifting 95 ton weight

Nondestructive inspection technology allows parts and materials to be inspected and measured without damaging them. Because LEFM is based on the fatigue crack growth analysis, the technology plays a critical role in inspecting crack or flaw of metalwork structure. During the nondestructive inspection procedure, several defections were found on the cantilever by ultrasonic phased arrays. Defections were inspected by ultrasonic phased arrays such as shown in Fig. 6. Subsequently, these defections were idealized as single edge crack of long atrip and input the fatigue analysis software. The calculation flow can be seen in Fig. 7. The remaining fatigue life of the crane was about 26 years in terms of present damage situation or structural integrity.

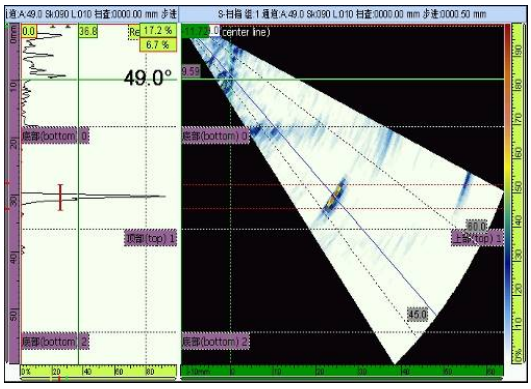

Figure 6. Defection on cantilever via ultrasonic phased arrays

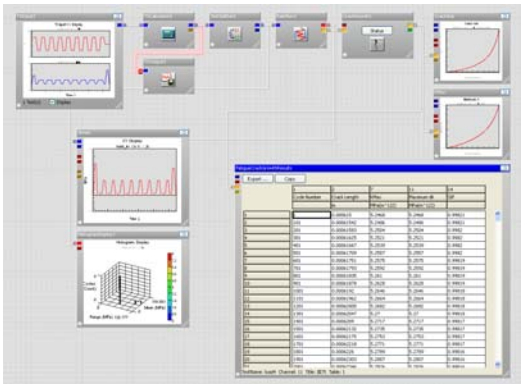

Figure 7. Calculation flow of fatigue life.

4. Conclusions

Based on fatigue crack growth analysis, linear elastic fracture mechanics (LEFM) is introduced to describe and predict fatigue crack growth life and fracture in fatigue life estimation process of metal structure of crane. Especially, the methodology is more suitable for aged crane, which exists some crack or flaw positively. The following example also shows how the procedures work.

Abstract In this paper, fracture tests and microscopic observations were conducted on an Alloy52M dissimilar metal welded joint (DMWJ) between A508 ferritic steel and 316L stainless steel in nuclear power systems. The local fracture behavior in the DMWJ was investigated, and the significance of using local fracture resistance in integrity assessment of the DMWJ was analyzed. The results show that the local fracture resistance in the DMWJ is determined by the local fracture behavior, and which is mainly related to the microstructure and local strength mismatch of materials at the crack locations. The crack growth always deviates to the materials with lower strength, and the crack path deviations are mainly controlled by the local strength mismatch. If the local fracture resistance properties could not be obtained and used for cracks in heat affected zone (HAZ), interface and near interface zone, the use of the J-resistance curves of base metals or weld metals following present codes will unavoidably produce non-conservative (unsafe) or excessive conservative assessment results. In most cases, the assessment results will be potentially unsafe. Therefore, it is recommended to obtain and use local mechanical and fracture resistance properties in the integrity assessment of DMWJs.

1. Introduction

In primary water systems of pressurized water reactors (PWRs)，low alloy ferritic steel is specifically selected to manufacture the nuclear pressure vessels for its high toughness and economical interest, while austenitic stainless steel is selected to make primary pipes for its proper strength and good corrosion resistance. In order to join the ferritic steel pipe-nozzles of the pressure vessels to the austenitic stainless steel pipes well, a transitional stainless steel safe-end pipe is usually introduced. A dissimilar metal welded joint (DMWJ) is usually utilized to join the pipe nozzle with the safe end pipe, as shown in Fig.1. Nevertheless, the welds were indicated to be vulnerable components from the international surveys, owing to their proneness to different types of flaws. Axial and circumferential defects within DMWJs caused by stress corrosion or fatigue have been found in the nuclear power plants (NPPs) in many countries [1-2]. In addition, serious leakage events on such DMWJs have also been reported [3-4]. Thus, maintaining integrity of such joints in case of defect presence and structure overloading is critical to ensure their safe service. To do this, an accurate structural integrity assessment for such DMWJ structure is very important.

Understanding local fracture behavior on the critical regions of such welded joints is essential for conducting an accurate integrity assessment and design. However, due to highly inhomogeneous nature across the DMWJ in terms of microstructure, mechanical, thermal and fracture properties, it is difficult to conduct analytical or experimental fracture investigations on the DMWJs. Only there are limited studies on the fracture behavior of the DMWJs in the literature[5-8]. In addition, in the integrity assessment methods for weld joints in existing codes, such as R6[9], SINTAP and FITNET FFS [10], the weld joints are often simplified as a sandwich composite composed of base metal and weld metal, and the effects of the interface fusion regions between different materials and heat affected zones (HAZs) are usually ignored. In fact, defects in welded structures can occur anywhere, such as in the fusion zone, HAZ, weld, near weld, interface region, base metal, etc. The use of adequate and precise material input parameters (based on the experimental observation of the local damage and fracture process in the joint area) is particularly essential to describe and predict the

critical condition in welded structures [10]. Therefore, the local fracture behavior of the DMWJs should be investigated and understood.
In this study, the local fracture behavior in a real Alloy52M dissimilar metal welded joint between A508 ferritic steel and 316L stainless steel in NPPs were investigated by using the single-edge notched bend (SENB) specimens. The significance of using the local fracture properties in integrity assessment of DMWJs was analyzed.

2. Experimental procedures

2.1 Materials and fabrication of the DMWJ

A full scale mock up of the DMWJ was fabricated by Shanghai Company of Nuclear Power Equipment in China. The pipe-nozzle material is ferritic low-alloy steel (A508), and the safe end pipe material is austenitic stainless steel (316L). The weld was manufactured by applying a buttering technique and the buttering material as well as weld material is the same nickel-base alloy (Alloy52M), but their manufacture procedures were different. The buttering layer was deposited through an Alloy52M welding wire by automatic gas-tungsten arc welding (GTAW) on the ferritic nozzle face. Then a heat treatment was conducted on the buttering to relieve the residual stress. This buttering layer material is denoted as Alloy52Mb. After buttering, welding was carried out between the buttering layer and the austenitic safe-end pipe by using the GTAW, and the Alloy52M welding wire was also used. Here, this weld metal material is denoted as Alloy52Mw.

2.2 Specimen geometry and crack locations

The single-edge notched bend (SENB) specimen was used for measuring the local fracture properties and observing fracture mechanism in the DMWJ. The SENB specimens with different crack locations were extracted by electric discharge machining from the DMWJ. The initial crack locations and specimen orientation are shown in Fig.2. The cracks 1 and 13 are located in the base metal A508 and 316L, respectively. The cracks 5 and 9 are located in the center of the butter Alloy52Mb and weld Alloy52Mw, respectively. Other cracks are mainly located in the interface regions between materials with complex metallurgical microstructures and inhomogeneous mechanical properties. The interface region cracks include the HAZ cracks in base metals (cracks 2, 6 and 12), interface cracks at fusion lines (cracks 3, 7 and 11), and the near interface zone (NIZ) cracks in weld metals (cracks 4, 8 and 10). The distance of the HAZ and NIZ cracks from the interfaces is 1.5mm. The SENB specimen geometry, size and loading method are typically shown in Fig.3 for the crack 4 specimen.

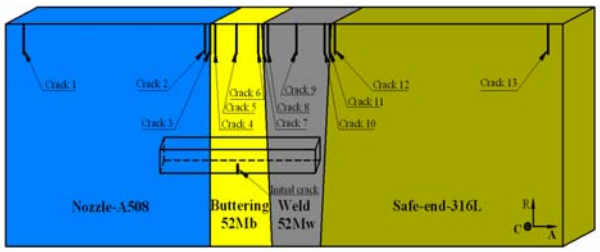

Figure 2. Schematic diagram showing initial crack positions and SENB specimen orientation in the DMWJ (C: circumferential, R: radial direction, A: axial direction)

2.3 Experiments and observations

The fracture tests of the SENB specimens were performed by an Instron screw-driven machine at room temperature. One specimen was tested for every crack location. The quasi-static loading was conducted by displacement controlled mode at a cross-head speed of 0.5mm/min. The load-load line displacement curves were automatically recorded by a computer aided control system of the testing machine. The single specimen method and the normalization technique conforming the ASTM E1820 procedure [11] were used to obtain the J-resistance curve for each specimen. After testing, the tested specimens with a certain crack growth length were sectioned at the mid-plane. One of the cut pieces was polished and etched to reveal damage and fracture patterns in microstructure ahead of the crack tip, which was observed by an optical microscope (OM) and a scanning electron microscope (SEM). Another piece was broken, and the initial crack length and the final crack growth length were measured and the fracture surfaces were observed with the SEM to understand the failure mechanism.

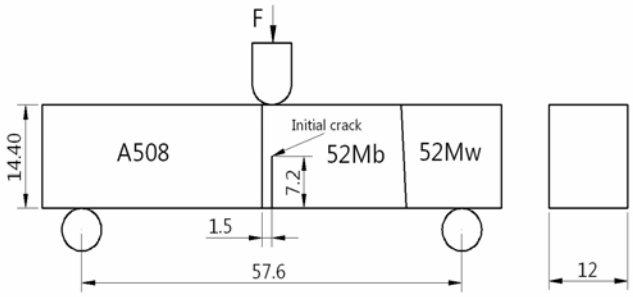

Figure 3. The SENB specimen geometry, size and loading method typically shown by the crack 4 specimen

3. Results and discussion

3.1 Local fracture properties of the DMWJ

The J-resistance curves of the SENB specimens with various crack positions are given in Fig.4. These J-resistance curves reflect local crack growth resistance of different material regions in the DMWJ. It can be seen that the three cracks (cracks 1-3) in A508 region and the two cracks (cracks 9 and 10) in weld Alloy52Mw region have lower crack growth resistance, and which represents local weak zones for fracture in the DMWJ. The fracture resistance of crack 3 at A508/Alloy52Mb interface is lowest. The J-resistance curves of crack 5 in the center of buttering Alloy52Mb and crack 13 in the base metal 316L are highest, and they represents the highest fracture resistance zones in the joint. The J-resistance curves of other cracks (cracks 4, 6, 7, 8, 11 and 12) are located

between the lower crack growth resistance curves (cracks 1,2,3,9 and 10) and the highest crack growth resistance curves (cracks 5 and 10). The cracks 6, 7 and 12 have similar resistance curves. The resistance curves of cracks 4, 8 and 11 are also basically the same, but they are lower than those of the cracks 6, 7 and 12. The local crack growth resistance in the DMWJ is determined by fracture mechanism occurring ahead of the crack tip, and which is mainly related to the microstructure and local strength mismatch of materials at the crack location. This will be analyzed in the following sections.

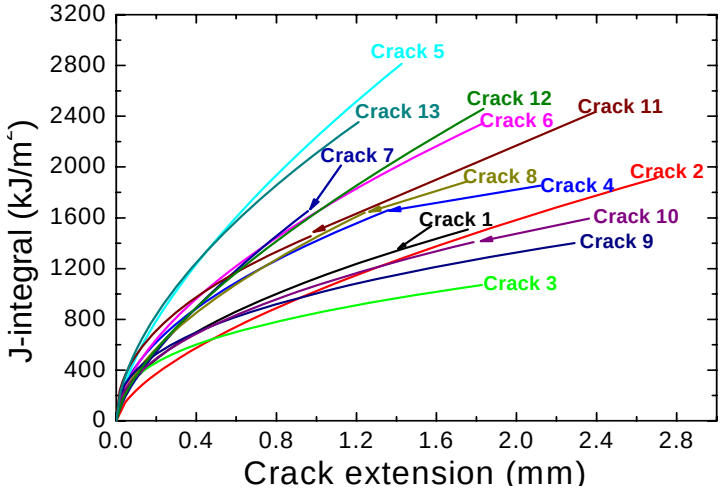

Figure 4. J-resistance curves for the 13 cracks in the DMWJ

3.2 Fracture behavior of typical cracks in the DMWJ

Because of the microstructual and mechanical heterogeneities along the DMWJ, the cracks located in different regions in the DMWJ will have different fracture behavior and leads to different local fracture properties. This can be analyzed as follows.

Fig.5 shows the fracture surface and crack growth path of the A508 HAZ crack 2. Fig.5(a) shows an overview of the fracture surface. In the area A marked in Fig.5(a) in front of initial fatigue precrack, the brittle flat fracture appearance can be seen, as shown by Fig.5(b). This indicates that local brittle fracture initiats and propagates from the the initial fatigue pre-crack tip. In the area B marked in Fig.5(a), a large amout of shollow dimples can be seen, as shown by Fig.5(c). This shows that local ductile fracture has occurred there. Because the area B is behind the area A, this implies that the fracture mode in the crack 2 specimen firstly is brittle fracture, and than changes into ductile fracture. This change in fracture mode also can be observed from the crack growth path shown in Fig.5(d). On the first crack growth length of about 1mm, edges of the crack path are flat, and this is a characteristic of brittle fracture. On the later crack growth path, irregular crack edges can be seen, and this is a characteristic of ductile fracture. This crack path deviation also can be seen by the change of fracture surface from flat (zone I) to rough (zone II) in Fig.5(a). Fig.5(d) also shows that the crack 2 has a deviation path towards A508 base metal (away from the A508/Alloy52Mb interface). The initial brittle fracture of crack 2 is related to the dominated martensite microstructure with higher strength in A508 HAZ. The high strength martensite microstructure generally has low fracture toughness, and the brittle fracture tends to occur under higher crack-tip opening stress. In addition, the A508 HAZ has steep strength gradient, as shown in Fig.6. The left side of crack 2 is near the A508 base metal, and has lower strength (Fig.6). The local higher plastic strain and stress triaxiality will occur at the left side of crack 2, which will induce the crack 2 to grow towards its left side [10]. This crack path deviation may promote the change of fracture mode from the brittle fracture to the ductile fracture. This comes from two factors. One factor is that the crack path

deviation makes the mode I crack change into mixed crack of mode I and II, and this reduces the driving stress for brittle fracture (crack-tip opening stress). Another factor is that the crack path deviates to the material with lower strength (may have higher toughness), and larger plastic deformation may relax local crack-tip opening stress, which can promote development of ductile fracture process. The mixed mechanism of brittle and ductile fracture in the crack 2 specimen leads to the lower fracture resistance curve (Fig.4). In this case, the resistance curve only reflects apparent fracture resistance of A508 HAZ due to the change of fracture mechanism and crack growth path deviation which is mainly related to the local strength mismatch.

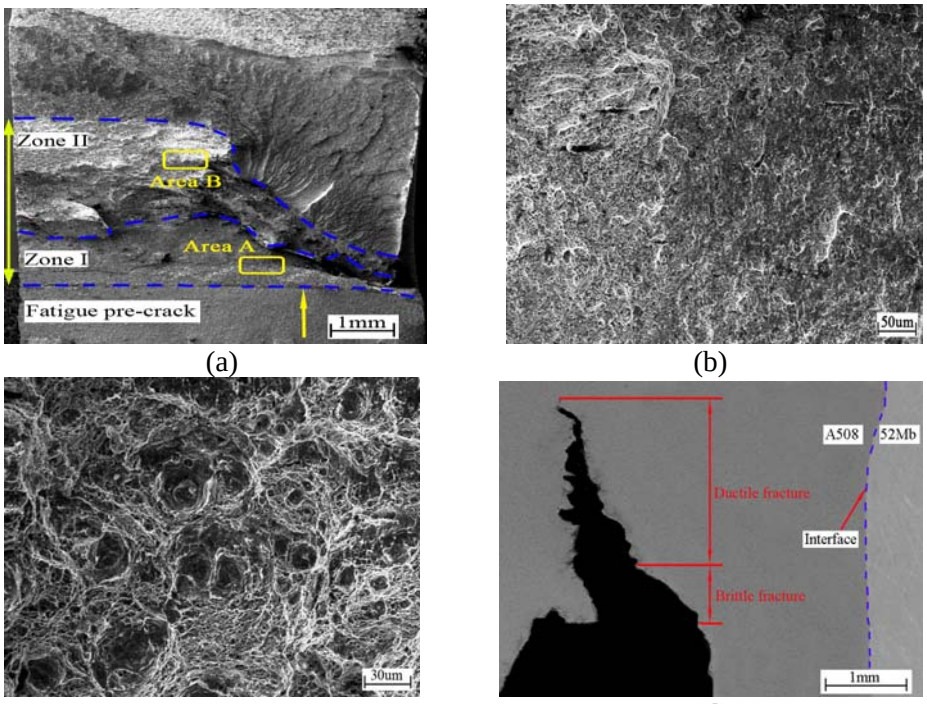

Figure 5. SEM images show fracture mechanism of the A508 HAZ crack 2. (a) overview of fracture surface, (b) higher magnification of area A in (a), (c) higher magnification of area B in (a), (d) crack growth path.

Fig.7 shows the crack growth path and fracture surface of A508/52Mb interface crack 3. It can be observed from Fig.7 (a) that the crack path deviates to the side of 52Mb with lower strength (Fig.6). The fracture surface in Fig.7 (b) displays a large amount of brittle facets with some shallow dimples. This implies that the fracture mechanism of A508/52Mb interface crack 3 is mixed brittle and ductile fracture, but is dominated by brittle fracture. This predominantly brittle fracture may result from two factors. One factor is the local strength mismatch of materials at two sides of crack 3. The essence of the strength mismatch lies on the crack tip plasticity development and effect of the strength difference between different local regions on the deformation pattern ahead of the crack tip [10]. The strength mismatch affects the constraint conditions and stress levels near the crack tip, hence affects the fracture mechanism and crack growth path inevitably. For the A508/52Mb interface crack 3, the Alloy52Mb side has lower strength than the A508 side (Fig.6). During loading the crack 3 specimen, the plastic deformation will firstly appear in the Alloy52Mb material near the interface, and higher stress triaxiality, opening stress and plastic strain will be induced in the Alloy52Mb side with increasing applied load. This has been confirmed by the finite element analyses in the Ref. [13]. The higher stress triaxiality and opening stress will promote development of the brittle fracture with little ductility, and make the crack path deviate towards the Alloy52Mb side. Another factor for producing the predominantly brittle fracture is the predominant martensite microstructure with high strength and low toughness in the A508/52Mb interface region. It can be concluded that the predominantly brittle fracture mechanism causes the lowest J-resistance curve of

the A508/52Mb interface crack 3 (Fig.4). The A508/52Mb interface region is the weakest zone for failure in the DMWJ.

Typical damage patterns ahead of crack tips for the cracks in Alloy52Mb and 52Mw are shown in Fig.8. It can be found that there are a lot of voids distributed on the grain boundarys of columnar crystals near crack, and some grain boundary cracks also have been formed by coalescence of voids. It is believed that the grain boundarys are weak zones for damage and fracture in the weld metals. The crack growth direction is approximately perpendicular to the transverse columnar crystals in buttering Alloy52Mb, but it is approximately parallel to the lognitudinal columnar crystals in weld Alloy52Mw. Fig.8(a) shows that the crack in Alloy52Mb propagtes across the transverse columnar crystal boundary, while Fig.8(b) shows that the crack in Alloy52Mw propgates along the lognitudinal columnar crystal boundary. The columnar crystal orientation relative to crack growth direction apparently affects fracture mechanism and crack growth resistance. For the cracks in buttering Alloy52Mb, the direcrion of the maximum crack-tip opening stress is parallel to columnar crystal boundaries, and the stress normal to the grain boundaries is too low to drive damage and fracture along weak grain boundaries. It needs much high driving force to propagate a crack across columnar crystals, thus the crack growth resistance is high. But for the cracks in weld Alloy52Mw, the direcrion of the maximum crack-tip opening stress is perpendicular to columnar crystal boundaries, and it is ease to drive damage and fracture developing along weak grain boundaries, thus the crack growth resistance is low.

3.3 Integrity assessment for the DMWJ structure

Although there are many methodologies for structural integrity assessment, the failure assessment diagram (FAD) is extremely simplified and convenient which is in the realm of elastic-plastic fracture mechanics. However, the use of the FAD for the DMWJ structure in nuclear power plants is a challenge due to the highly heterogeneous microstructure, mechanical and fracture properties along the joint. When the initial cracks are located at different positions (such as base metal, buttering, weld, interfaces region, HAZ, NIZ, etc.), the crack-tip plastic deformation, damage and further crack growth can occur in any materials and even the crack growth path may change from one material to the other, as shown in Figs. 5(d) and 7(a). In these cases, the crack-tip fracture parameter and plastic deformation behavior of the structure is difficult to define due to the complex strength mismatch effect in the DMWJ, thus the general FADs in current codes cannot be directly and accurately used. It has been found that the strength mismatches in similar metal weld joints have significant effects on the crack driving force, limit load and failure assessment curve [14, 15]. At present, simplified engineering integrity assessment methods have been developed for treating the problem of weld joints, and the concept of equivalent material properties is utilized so that the integrity assessment method for single material can be used for the joints [16-18]. However, the effects of the crack locations and related local strength mismatches in the DMWJ on the local fracture resistance, crack growth paths, failure assessment curves and structural deformation behavior have not been completely understood and accurately taken into account in FADs, and no specific accurate methods exist for the integrity assessment of the complex DMWJ.

In the integrity assessment methods for weld joints in existing codes, such as R6[9], SINTAP and FITNET FFS [10], the joints are often simplified as a sandwich composite composed of base metal and weld metal, and the effects of the interface region, HAZ and NIZ are ignored. In fact, defects in welded structures can occur anywhere, including in base, weld, near weld, HAZ, fusion zone, interface region, etc. The selection of strength and toughness values to be used in the integrity assessment of welded structures has significant implications on the outcome of the analysis. The use of adequate and precise input parameters (based on the experimental observation of the local damage and fracture process in the joint area) is particularly essential to describe and predict the critical condition in such structures [10]. According to the present codes, in the integrity analysis and assessment for the DMWJ structure, the DMWJ will be simplified as a composite composed of four materials (A508 steel, buttering Alloy52Mb, weld Alloy52Mw and 316L stainless steel). For the cracks located in various positions in the DMWJ, only the mechanical and fracture properties of the four materials are used. For the HAZ, interface region and NIZ cracks, if only the mechanical and fracture properties of base metals (A508, 316L) or the weld metal (buttering Alloy52Mb, weld Alloy52Mw) are used, non-conservative (unsafe) or excessive conservative results will then be potentially produced. This can be analyzed as follows for the DMWJ.

To conduct the ductile tearing assessment and leak-before-break (LBB) analysis, a ductile crack growth instability evaluation based on elastic-plastic fracture mechanics should be performed under a maximum loading condition, and a ductile crack growth resistance curve of a material is needed. For the cracks in A508 region, it can be estimated from Fig.4 that if the J-resistance curve of the A508 base metal (crack 1) is used to assess the A508 HAZ crack 2 and the A508/Alloy52Mb interface crack 3, slight non-conservative and unsafe result will be produced, respectively. This is due to that the J-resistance curve of cracks 2 and 3 is slight lower and lower than that of the A508 base metal crack 1, respectively. For the cracks in buttering Alloy52Mb region, it can be judged from Fig.4 that if the J-resistance curve of the buttering Alloy52Mb (crack 5) is used to assess the interface crack 3, NIZ crack 4, HAZ crack 6 and interface crack 7, non-conservative (unsafe) results will be produced due to the highest J-resistance curve of the buttering Alloy52Mb. Especially for the A508/Alloy52Mb interface crack 3 with local crack growth into the Alloy52Mb, the use of the J-resistance curve of the Alloy52Mb will lead to the extreme unsafe result. For the cracks in weld Alloy52Mw region, it can be predicted from Fig.3 that if the J-resistance curve of the weld Alloy52Mw (crack 9) is used to assess the interface crack 7, NIZ crack 8 and interface crack 11, it will lead to excessive conservative assessments. While the use for the NIZ crack 10 will be reasonable due to the similar J-resistance curve of cracks 9 and 10. For the cracks in 316L region, it can be estimated from Fig.4 that if the higher J-resistance curve of the base metal 316L (crack 13) is used to assess the interface crack 11 and HAZ crack 12 with lower J-resistance curve, non-conservative (unsafe) results will be obtained.

In general, the analyses described above demonstrate that without considering the local fracture resistance properties of narrow HAZ, interface region and NIZ , the use of the J-resistance curves of base metals (A508 and 316L) or the weld metals (buttering Alloy52Mb and weld Alloy52Mw) will unavoidably produce non-conservative (unsafe) or excessive conservative assessment results. In most cases, the assessment results are potentially unsafe. A recent study [19] has shown that the resistance to crack initiation and growth is greatly affected by the heterogeneity of the weldment, and the importance of the HAZ for fracture behavior of welded joints was also emphasized. Therefore, in the integrity assessment for the DMWJ structure, it is recommended to obtain and use local mechanical and fracture resistance properties of all regions of the joint if the complex local mismatch situation is a concern. The new integrity assessment methods based on local damage and fracture models also need to be developed for the DMWJs.

4. Conclusion

(1) The local fracture properties in the DMWJ are determined by fracture mechanism occurring ahead of the crack tip, and they are mainly related to the microstructure and local strength mismatch of materials at the crack locations.

(2) The fracture mechanism of A508 HAZ crack 2 and A508/52Mb interface crack 3 is a mixed brittle and ductile fracture, which is related to strength mismatch and predominant martensite microstructure. This fracture behavior leads to the lower crack growth resistance.

(3) The columnar crystal orientation relative to crack growth direction apparently affects fracture behavior and crack growth resistance of cracks in buttering Alloy52Mb and weld Alloy52Mw. The cracks in Alloy52Mb propagate across columnar crystals in a ductile mode, thus higher crack growth resistance is produced. While the cracks in weld Alloy52Mw mainly propagate along columnar crystal boundaries with low resistance in a brittle mode, which leads to lower crack growth resistance.

(4) The crack path deviations are observed for most cracks in the interface regions, HAZs and NIZs. The cracks always deviate to the materials with lower strength, and the crack path deviations are mainly controlled by strength mismatch.

(5) If the local fracture resistance properties could not be used for the heat affected zone (HAZ),

interface and near interface zone cracks, the use of the J-resistance curves of base metals (A508 and 316L) or the weld metals (buttering Alloy52Mb and weld Alloy52Mw) will unavoidably produce non-conservative (unsafe) or excessive conservative assessment results. In most cases, the assessment results will be potentially unsafe.

(6) In the integrity assessment for the DMWJ structure, it is recommended to obtain and use local mechanical and fracture resistance properties of all regions of the joint if the complex local mismatch situation is a concern. The new integrity assessment methods based on local damage and fracture models also need to be developed for the DMWJs.

Abstract The Acoustic Emission (AE) technique was used to assess the structural stability of the Asinelli Tower, the tallest building in the city of Bologna, which, together with the nearby tower, named Garisenda, is the renowned symbol of the city. AE is a passive, non-destructive structural evaluation technique based on the spontaneous emission of pressure waves by evolving fracture processes. The monitoring program was carried out with the aid of a USAM tool, which is part of the equipment used at the Fracture Mechanics Laboratory of the Department of Structural Engineering at the Politecnico di Torino. This tool makes it possible to conduct a complete analysis of AE signals, acquire a huge quantity of data from on site monitoring, and identify the microcracks triggering the damage processes in a structure.
In the second part of the paper, the results from a preliminary linear analysis are presented, in order to assess the structural behavior of the tower. The cracking and crushing strengths of the masonry have both been compared with the calculated stresses. The numerical analysis gives a valuable picture of the modal response of the tower, providing useful hints for the prosecution of structural monitoring.

Keywords Acoustic emission, monitoring, finite element method, modal analysis, structural assessment.

1. Introduction

For some years, the authors have been conducting research through the application of a material and structure control method based on the spontaneous emission of pressure waves from evolving defects. With the Acoustic Emission (AE) monitoring technique, the ultrasound signals emitted by damage phenomena are received by wide-band piezoelectric (PZT) sensors, i.e., sensors calibrated for a frequency range of between 50 and 800 kHz. The AE technique is non-invasive and non-destructive and therefore is ideally suited for use in the assessment of historic and monumental structures that are subjected to high, long-term loads or cyclic loads, or, more generally, are exposed to seismic risk. Having to identify the fractured or damaged portion of a structure, it is possible to evaluate its stability from the evolution of damage, which may either gradually come to a halt or propagate at an increasingly fast rate. Moreover, if the position of the defects is not known to begin with, it can be located by making use of a multiplicity of sensors and by triangulation, prior to assessing the stability of a structure based on the evolution of damage phenomena. Using the AE technique, the authors have acquired considerable experience in the monitoring of medieval masonry towers and other significant historic buildings [1-5].
The AE technique is ideally suited to control the evolution of structural damage caused by pulse phenomena, such as wind and seismic actions. In this study − a significant zone of the masonry structure to be analysed having been identified − the AE count obtained during the monitoring period was correlated with the frequency of seismic events in the areas around the city of Bologna. The data were used to assess the critical phenomena taking place in the structure with the aim to predict the evolution of damage over time.

2. Structural description of the tower

The authors of the various histories of the city of Bologna all agree in dating the Asinelli and Garisenda Towers to the early twelfth century, but with some minor discrepancies as to the year of construction, as pointed out by Ludovico Savioli in discussing the Asinelli Tower in his *Annali*

Bolognesi, written around the end of the eighteenth century: *"Our chronicles do not converge around the time when it was perfected, some mentioning the year 1111, others the years 1117 and 1119; a majority of them indicate the year 1109"* [6,7].

The Asinelli Tower rises to a height of 97.30 m above the ground. It has a square cross-section, tapering along its height, the sides measuring ca 8.00 m at the base and 6.50 m at the top. From the structural standpoint, the tower can be subdivided into four segments, depending on type of masonry. The thickness of the walls varies from 3.00 m at the foundations to 1.00 m at the top. The first segment, at the base of the tower, is made entirely of selenite blocks. It starts at a depth of ca 1.70 m below ground level and rises to 3.00 m above ground. The substructure of the tower is nearly square, with sides approx. 10.50 m long. The second segment, with sides tapering from 8.15 m to 7.70 m, rises to a height of 34.20 m. The third segment, which constitutes the upper part of the tower and contains the merlons added in the fifteenth century, has sides that gradually decrease in size to ca 6.50m at a height of 81.25 m above ground level. The masonry of the second and third segments is a sacco, i.e., consists of an outer and an inner face, 90 cm and 45 cm thick respectively, enclosing a mixture of rubble, bricks and mortar – and is characterised by an overall thickness of 2.80 m. At the base, up to a height of 8.00 m, the tower is surrounded by an arcade built at the end of the fifteenth century.

The studies conducted in the early twentieth century by F. Cavani [8] revealed that the Asinelli Tower leaned westward by 2.25 m; this is the reason why it is known as the tallest leaning tower in Italy. The latest measurements, made in 2009 by Prof. A. Capra by laser scanning, on behalf of the municipality, showed an overall inclination of 1.51 degrees and a deviation from verticality of 2.38 m. Thus we find that the deviation increased by 13 cm in the course of approx. one century, that is to say at an average rate of 1.30 mm/year. Figure 1 shows the Asinelli Tower and the adjacent Garisenda Tower in the city centre of Bologna. Figures 2 and 3 show the front elevations and the cross-section of the Asinelli Tower and a plan view indicating the zone of application of the AE sensors.

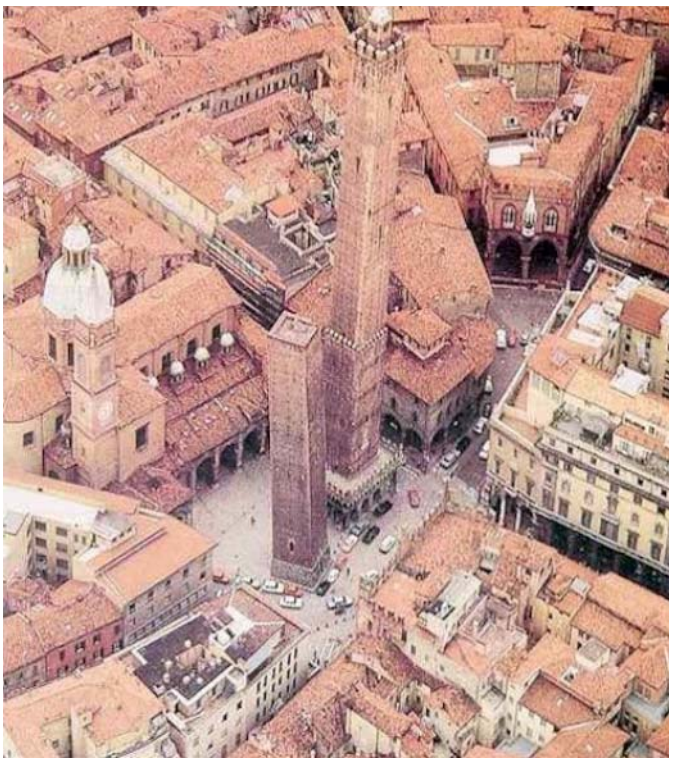

Figure 1. The Asinelli Tower and the Garisenda Tower in the city center of Bologna.

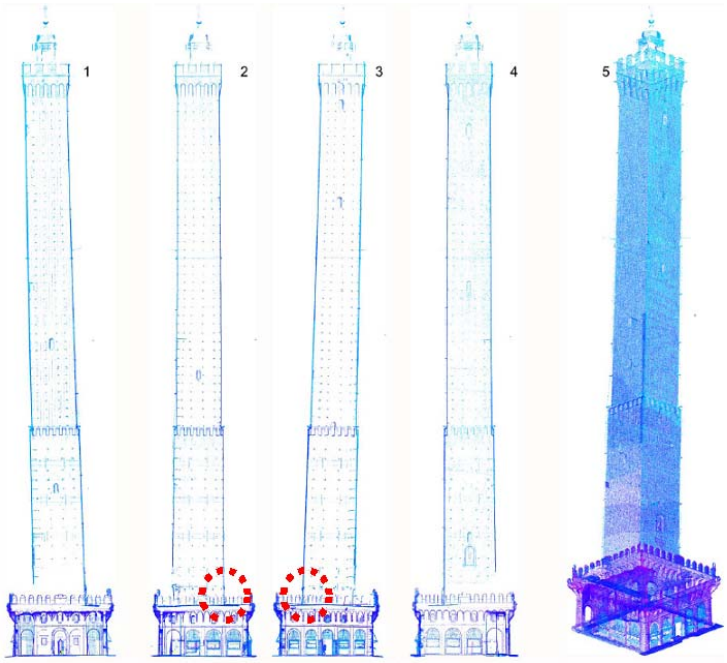

Figure 2. Front views and axonometric view of the Torre degli Asinelli. These views, supplied by the Municipality of Bologna, are taken from the measurements of the exterior of the structure made by Prof. Alessandro Capra by laser scanning. Faces (1) South; (2) East; (3) North; (4) West; (5) Axonometric view. The transducers were applied to the north-east corner of the tower, in the zones marked with a circle.

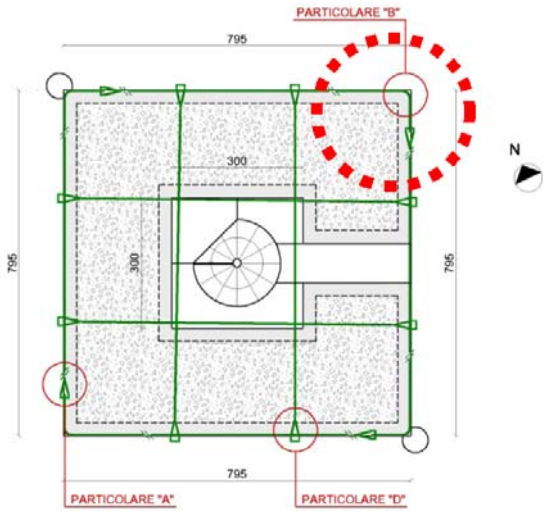

Figure 3. Cross-section of the tower at a height of ca 10 m above ground. Drawing supplied by the Municipality of Bologna. The corner where the sensors were applied is marked with a circle.

3. Monitoring with the Acoustic Emission technique

Only a limited number of sensors were available and hence the AE devices were positioned in a zone that would be both significant for monitoring purposes and easy to reach. In particular, six AE sensors were applied to the north-east angle of the tower at an average height of ca 9.00 m above ground level, immediately above the terrace atop the arcade. In this area, the double-wall masonry has an average thickness of ca 2.45 m (see Figs. 2 and 3). AE monitoring began on 23 September 2010 at 5:40 PM, and ended on 28 January 2011 at 1:00 PM. It was carried on for ca 2915 hours, corresponding to 122 consecutive days. The arrangement of the AE sensors, shown in the photos in Fig. 4, corresponds to the scheme illustrated in Fig. 5. The sensors were glued to the outer surface of the masonry with cold set silicone based adhesives, selected on account of their good ultrasound

signal transmission capacity, resulting in reduced damping at the interface between the masonry and the sensors.
The coordinates of the sensor application points are given in Table 1. The origin of the coordinate system of reference, as can be seen in Fig. 5, is at the bottom corner of the masonry at the intersection with the outer surface of the terrace surrounding the tower.

measurements in cm

4. Results of the Monitoring

The data collected during the monitoring period were analysed to evaluate crack growth and correlate it with the other phenomena considered, e.g., earthquake frequency in the areas around the city, and wind effects on the tower.
In AE analysis, the signals received by the transducers are analysed by means of a threshold detection device that counts the signal bursts exceeding a certain electric tension (measured in volts (V)). Then, cumulative curves are plotted reflecting the number of bursts recorded in a continuous manner during the testing period. This method of analysis, known as Ring-Down Counting, is widely used for defect detection purposes. As a first approximation, in fact, the total count number, N, can be compared with the amount of energy released during a monitoring period based on the

assumption that N grows proportionally to the growth of the damage zone. Needless to say, this assumption will apply only to a slowly progressing damage process. [9].
Figure 6 shows a plot of the cumulative AE count obtained on the basis of the number of events detected per monitoring day. The curve was plotted starting from the date of application of the sensors to the time the sensors were permanently removed. Throughout the monitoring period, the threshold level for the detection of the input signals coming from the PZT transducers was kept at 100 mV. Based on the authors' experience, in fact, this level is the most significant for the detection of AE signals from damage processes in non-metallic materials such as concrete and masonry [1,2,5,9].
From the curve in Fig. 6 it can be seen that the masonry is actually undergoing a damage process. The plot of the cumulative AE count, in fact, is characterised by jumps reflecting sudden increases in N that are seen to occur at certain time intervals. The discontinuities in the cumulative AE count curve denote the critical moments during which the release of energy from the microcrack formation process is greatest.
The AE count hourly distribution chart over a 24 hour time span, as determined for the entire monitoring period, is shown in Fig. 7.

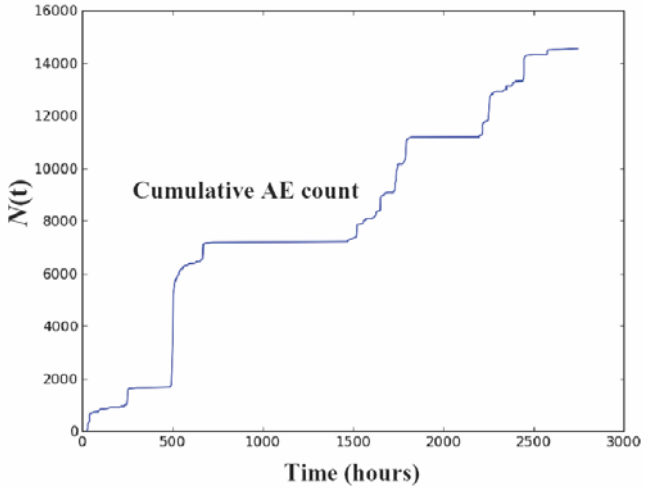

Figure 6. Cumulative AE count based on the data collected at the northeast corner of the tower, from 5:40 PM of 23 September 2010, to 1:00 PM of 28 January 2011.

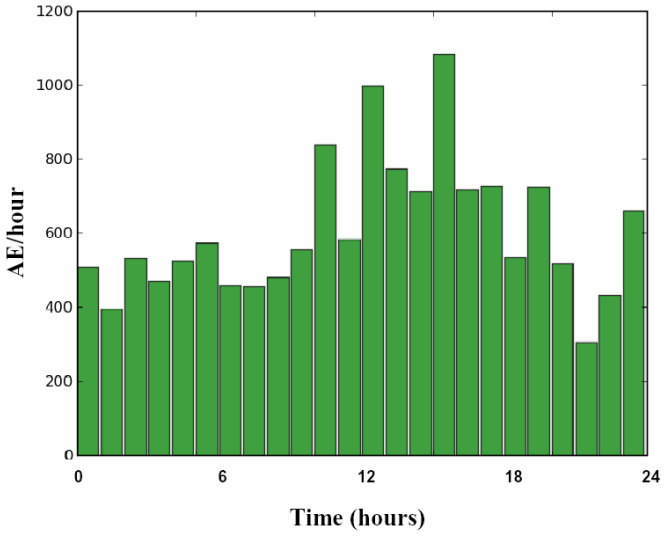

Figure 7. AE count hourly distribution chart over a 24 hour time span, as determined for the entire monitoring period.

4.1. AE and earthquakes

During the monitoring period, frequent seismic activities were recorded in the area around the city of Bologna. Earthquake data were taken from the website of the Istituto Nazionale di Geofisica e Vulcanologia (INGV). From among all the seismic events, only those that might have affected the stability of the tower were taken into account. In particular, the following seismic events were considered: the two strongest quakes –i.e., the one that hit the Rimini area on 13 October at 11:43 PM (4.1 Richter magnitude), and the one recorded in the Modena Apennines on 21 November at 4:10 PM (3.4 Richter magnitude)– and the earthquakes with a magnitude of over 0.5 that occurred within a radius of ca 20 km from the centre of the city.
The chart in Fig. 8 shows the AE count rate per hour, the earthquakes recorded within a 20-km radius from the city centre, and the two strongest quakes that hit the region. All the quakes, the two most important ones (denoted with red dots) and the weaker ones (blue dots), are shown as a function of time of occurrence and magnitude.
Fig. 8 reveals a *correlation between the AE events recorded experimentally and the seismic events.* As can be seen, in fact, the energy peaks measured through the AE count rate almost invariably occurred during a seismic event. In particular, the highest AE count peak (ca 500) was detected on 13 October, at 11:43 PM, when the Rimini area was hit by the 4.1 magnitude quake. Hence, this seismic event is the pulse phenomenon that resulted in the highest damage effect on the tower.
The second strongest earthquake, i.e., the 3.4 magnitude quake that hit the Modena Apennines on 21 November at 4:10 PM, does not introduce any significant change to the chart shown in Fig. 8, since the AE activity detected during this event was rather limited.

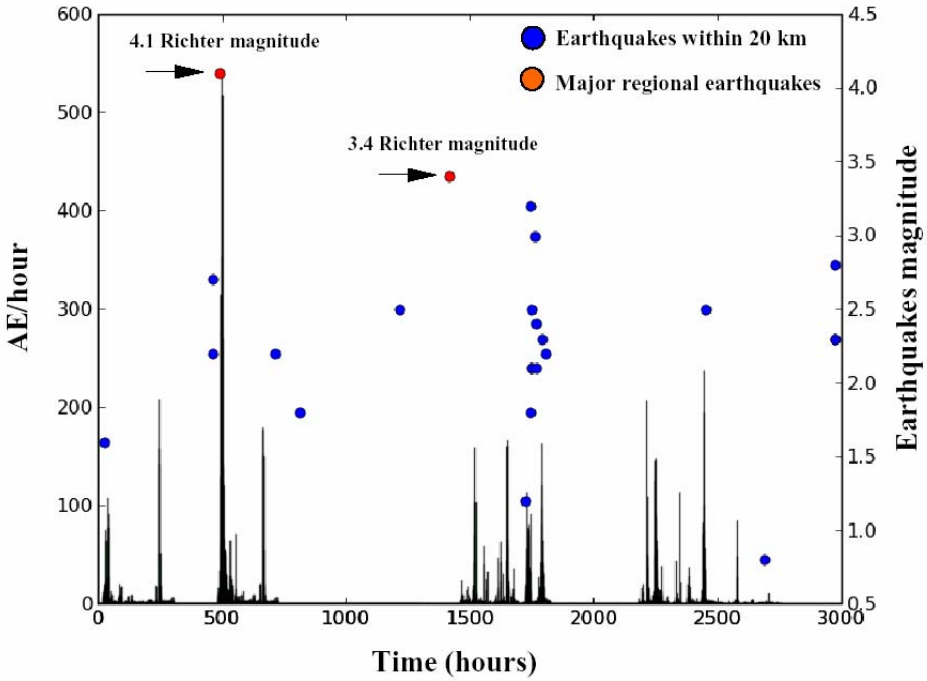

Figure 8. Historic series of the AE differential count and the earthquakes detected within a 20-km radius from the Bologna city centre. The chart also shows the two strongest regional earthquakes, which occurred in Rimini area and in the Modena Apennines. This chart refers to the entire monitoring period.

4.2. AE and wind

Further analyses were also conducted with a view to correlating the intensity of the wind acting on the tower with the AE data recorded during the monitoring period, but no clear correlation has been identified as yet. The measurements of wind velocity were obtained from data acquired by wind

velocity sensors applied at the height of 78 m on the monitored tower, and averaged for each hour. The wind velocity intensities measured during the monitoring period were comprised between 1 and 7 m/s. These velocities were unable to generate sensible aerodynamic loads on the structure.
In the chart of Fig. 9 are represented in detail the AE count rate and the wind velocity in a time window of 30 hours just after the earthquake that hit the Rimini area on 13 October 2010. The graph shows that the peaks in the AE count rate do not correspond with those of the wind velocity.
Moreover, the chart of Fig 10 relates the wind velocities and the AE count rate obtained during all the monitoring period (2915 hours). This graph makes more clear that the two phenomena are completely statistically unrelated.

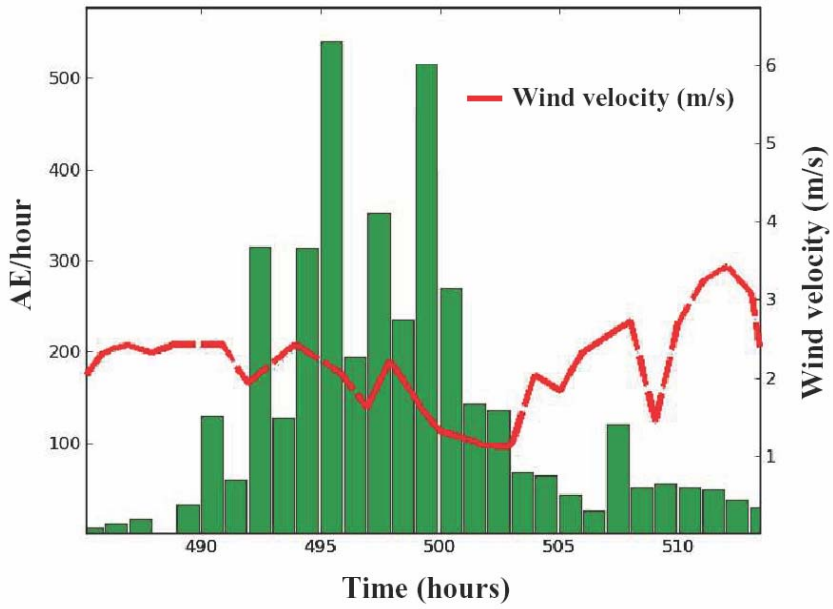

Figure 9: AE rate and wind velocity measurements during the monitoring period in a time window of 30 hours just after the earthquake of 13 October 2010.

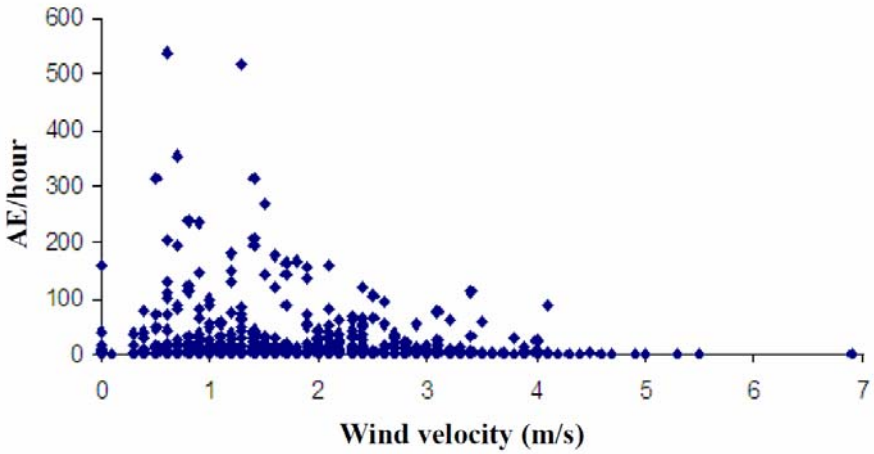

Figure 10: Chart relating the wind velocity and the AE count rate during all the monitoring time, the two time series seem to be statistically unrelated.

7. Preliminary Finite Element Analysis

A preliminary linear elastic finite element analysis has been carried out in order to assess the stress level in the tower, together with the main dynamic characteristics. The finite element model accounts for the three-dimensional geometry of the tower, and is composed of nearly 15300 wedge

and pyramid elements connecting almost 9000 nodes. The mass of the masonry and of the stone in the foundation has been assumed equal to 1800 kg/m^3. A mean value for the young modulus, accounting for the fact that up to a certain height the tower presents three leafs walls with internal filling, has been assumed equal to 5 MPa.
The preliminary linear elastic analysis considered only the self-weight of the tower (Fig. 11a). It was possible to assess that the elastic deformation of the tower is about 8 cm, which is about 1/30 of the present total deviation from verticality.
The level of stress in the masonry of the tower (Fig. 11b) is generally low, although in proximity of the monitored area, the level of vertical stress approach 2.1 Mpa, which can be critical in case of very poor masonry.
The preliminary modal analysis showed that the first mode is bending in the west-east plane, with a resonance frequency of 0.357 Hz (Fig. 11c). The second mode is bending in the orthogonal plane, with an eigen-frequency equal to 0.365 Hz (Fig 11d). The third eigen-frequency is 1.75 Hz, and the fourth is 1.78 Hz. The fifth mode is torsional (Fig. 11e) with an eigen-frequency of 3,07 Hz. Those results agree quite well with more detailed dynamic analyses carried out by other Authors [11].
The maximum vertical stress in the tower is compatible with the acquire rate of acoustic emissions from the monitored region. The fact that the first modal shape tends to increase the stress in the same area agrees well with the increase of acoustic emissions connected with seismic events.

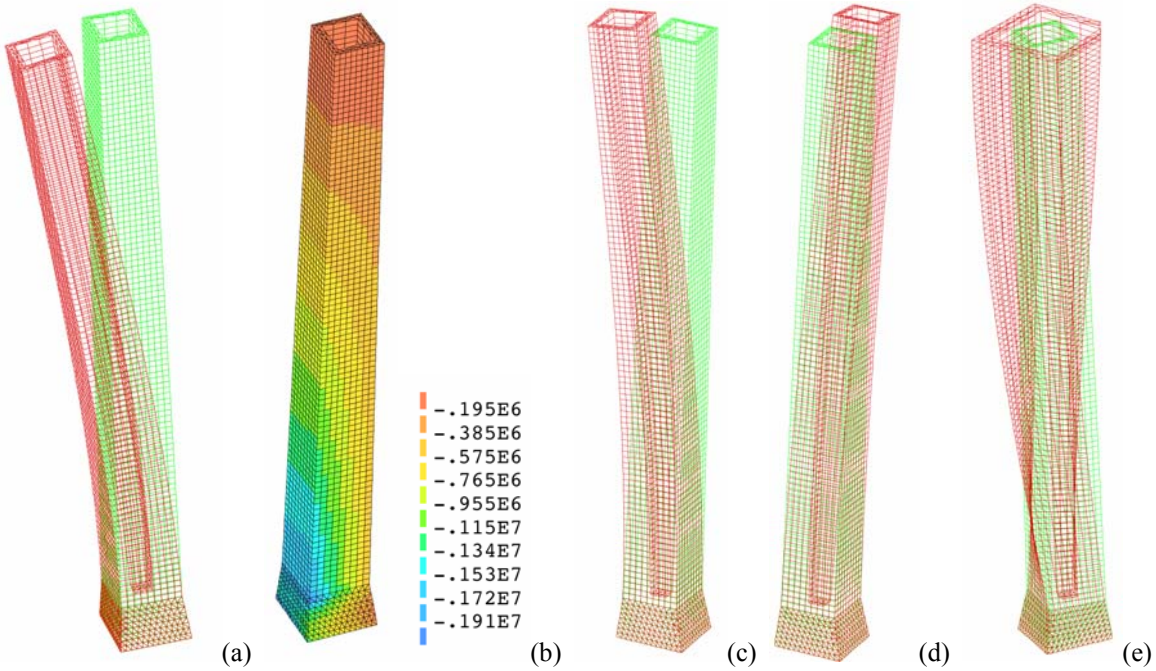

Figure 11. Deformation due to the effect of gravity (a); vertical stress expressed in MPa (b); first modal shape (c); second modal shape (d); fifth modal shape (e).

6. Conclusions

From the monitoring process carried out on a significant part of the *Torre degli Asinelli* it was possible to evaluate the incidence of seismic activity and wind action on the progress of fracture and damage phenomena within the structure.
During the monitoring period a correlation between peaks of AE activity in the structure and regional seismicity is found. The tower, in fact, as in the case of other monitored historical structures built in seismic territory [1,2,5,10], behaved as sensitive earthquake receptor.
Finally, during the monitoring, no statistical correlation was found between wind and acoustic emission.

The presented study suggests that the AE structural monitoring coupled with local earthquake activity can be a tool of crucial importance in damage mitigation of the structure.
In order to arrive at a more comprehensive and objective evaluation of the structural conditions of the tower, the results obtained with the AE technique −that analyses the ultrasound signals coming from microcracks in the masonry− should be supplemented with data obtained on other zones of the structure subject to different stress-strain conditions.
Moreover, earlier studies conducted by the authors with the AE technique on the stability of historic buildings made of stone or brick masonry have shown that the damage process is characterised by appreciable size effects on dissipated energy density. The multiscale aspect of energy dissipation can be addressed with statistical and fractal criteria in order to predict the onset of critical conditions in an actual structure [1,2].
By adopting these methods it becomes possible to introduce an appropriate energy parameter for the assessment of damage propagation in structural elements. This parameter is based on the correlation between the cumulative AE count in an actual structure and the corresponding AE activity measured on different size specimens obtained from the structure and tested up to failure [1,2]. Accordingly, if an opportunity arose to take test specimens from the tower (small cores, 2.5 to 10 cm in diameter, according to a minimally invasive approach), or if it were possible to carry out on-site double-jack tests while acquiring the AE signals, the safety and residual life of the structural parts monitored could be evaluated more effectively.
Additional significant data −as was done in [12] for the Medieval Towers of Alba− are obtained with a FEM numerical modeling of the structure that is able to capture the static effects on damage phenomena of permanent loads and the dynamic effects of seismic events and wind-structure interaction.

Acknowledgements

The financial support provided by the Regione Piemonte (Italy) RE-FRESCOS Project, is gratefully acknowledged. The authors wish to thank the Municipality of Bologna and Eng. R. Pisani for allowing this study on the Asinelli Tower.

Abstract In this paper, we proposed a non-destructive evaluation method combined digital image correlation (DIC) with acoustic emission (AE) techniques, which was used to *in-situ* monitor interface failure and internal damage of brittle coating/ductile substrate systems under different size scales by bending tests. Measurements of full/local field strain fields by DIC in the segmented coating clearly show typical heterogeneous failure process and successfully clarify several controversial assumptions introduced in theoretical models. AE results effectively reveal the damage evolution of cracking nucleation, propagation and coating spallation of the ceramic coating by combining wavelet transform with traditional parameter analysis under external loads. The conclusions show that there is a good relationship between digital image correlation and acoustic emission signals with the aid of test time during the coating failure, which can be applied to judge cracking formation and coating delamination, and to obtain the most important critical experimental data. As an example, several crucial mechanical properties of a thermal barrier coating system including fracture strength, fracture toughness and shear strength were determined.

1. Introduction

A system consisting of ductile substrate with functional brittle film/coating layers has been ubiquitous in a variety of applications such as micro-electronics, ferroelectric actuators, thermal and abrasion resistance.[1-4] Owing to mismatch of thermo-mechanical properties between film/coating and substrate, however, such a system is always subjected to residual stresses, which would eventually lead to a structural degradation of coating near interfacial regions. Therefore, how to evaluate the interface adhesion performance of a system and predict its reliability has attracted ever-increasing attention in recent years. To realize optimal design, it is necessary to measure the variation of full/local strain fields, cracking nucleation, propagation and spallation of a coating/film system during tests. However, it is difficult and inconvenient to accurately obtain information at small size scales with conventional strain gauges, displacement and force sensors, and optical microscopes. Recently, several advanced experimental techniques have been available in the investigations of coating failure and delamination. Atomic force microscopy provides a means of accurate mapping of changes in coating sub-surface that are related to the evolution of debonding.[5] Ultrasonic force microscopy was used to identify the locations of decohesion, which is sensitive to the local variation in mechanical compliance.[6] Scanning electron microscope and thermograph have been utilized to detect the damage evolution.[7,8] Unfortunately, these techniques can only be applied to qualitatively characterize the microstructure variation and cracking morphology of coating. It is difficult to provide *in-situ* quantitative stress/strain information and other detailed damage features to study interfacial properties of a coating/film system. Thus, it is urgent to

develop a real-time reliable method to monitor the microscopic failure process of a brittle coating/ductile substrate system and to provide the criteria of coating delamination.

The digital image correlation (DIC) technique, which measures strain fields by tracking random speckle patterns on specimen surface,[9-11] is suitable for continuously detecting micro/nano-scale deformations.[12,13] In addition, accompanied with cracking and coating fracture, the locally stored elastic energy is released in the form of acoustic emission (AE) signals. AE is a passive non-destructive testing technique that relies upon the detection of stress waves propagated through a solid as it undergoes strain. Thus, it is appropriate for monitoring the internal damage evolution of a material.[14,15] In previous works, DIC and AE techniques have been simultaneously applied to study the crack profile, localized plastic strain evolution and full/local strain fields of bulk materials, especially metal alloys with different scales.[16-20] However, precise matches have not been established between AE and DIC techniques to elucidate failure mechanisms of alloys. On the other hand, strain fields and crack profiles of brittle coating/ductile substrate systems are much more complicated than that of bulk materials. To the best of our knowledge, there have been few studies where both DIC and AE techniques are applied to monitor the failure process of multiple coating/film systems.

In this paper, we proposed a combined experimental method of DIC and AE techniques to realize *in-situ* tests of the failure process of brittle film/coating systems under bending tests. The main attention was on how to accurately judge the time and location of cracking formation and coating delamination by synthetically analyzing DIC, AE, and universal testing machine data. A relationship between DIC and AE techniques was established to elucidate interfacial failure mechanisms of brittle coating/ductile substrate systems at small size scales.

2. Experimental

An air plasma sprayed as-received thermal barrier coating (TBC) was selected as a typical brittle coating/ductile substrate system. Well-polished and cleaned SUS304 stainless steel plates of 40 × 20 × 2 mm^3 were used as substrate, on which a Ni–20Cr–10Al–1Y bond coat with thickness of 100 μm and an 8 wt % Y_2O_3 top coating with thickness of 300 μm were deposited, respectively, by air plasma sprayed technique. The experimental set-up is illustrated in Fig. 1. The total of 10 TBC and 5 uncoated substrate specimens were tested under three-point bending at a speed of 0.1 mm/min using the universal testing machine (REGER 2000), DIC instrument (ARAMIS), and AE equipment (SWAE-5) at room temperature. Prior to DIC testing, stochastic patterns were prepared by spraying a thin layer of black and white paint with airbrush guns. A 1624×1236 pixels charge coupled device camera equipped with a lens of 50 mm focal length was used to *in-situ* measure the macroscopic morphology and strain evolution of a region with a sampling rate of 2 images per second. DIC was performed on an image of 4 × 2 mm^2 to determine local strain fields during loading, as shown with a dashed frame in Fig. 1. The facet size was defined to be 90 × 90 μm^2 during tests. Post-processing was achieved with the commercially available DIC software (Aramis) to obtain strain data. The measuring error of strain is less than 0.05%.[9,16]

An AE sensor probe with the resonance of 70–400 kHz was located on the side of substrate, which was utilized as a *real-time* continuous monitor to record signal waves released from fracture

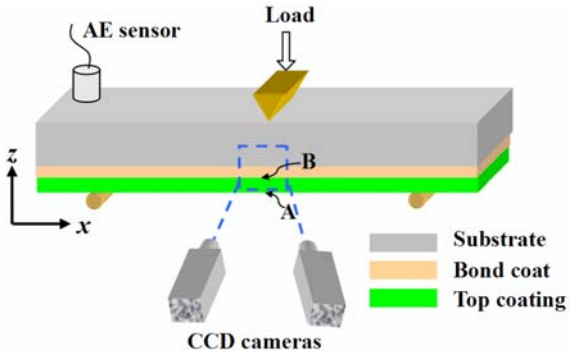

Figure 1. Schematic of three-point bending tests with DIC and AE techniques. The rectangle with dashed blue lines was defined as a region for DIC monitoring.

sources. The AE sampling rate was set to be 1 MHz. The amplitude distribution of AE signals was in the range of 0–100 dB. For TBC tests, we chose 40 dB as the amplitude threshold to avoid the influence of noise and substrate deformation. AE data were analyzed by combining wavelet transform with traditional parameter analysis. The corresponding energy coefficient was calculated by using MATLAB programs with "db8" wavelet.[14] Similarly, the scale was restricted to 5 and all signals were decomposed into 6 levels with the frequency range of D1, D2, D3, D4, D5 and C5.[14] It is found that the peak value of the energy ratio of different frequency bands corresponds to the different failure type, which is similar to the results by Seong *et al.*.[21] Therefore, according to the maximum energy ratio among the frequency bands of AE data, the dominant failure or cracking patterns can be determined with the aid of DIC observations. It is worth noting that, however, all experimental apparatus should be *synchronously* performed to validly judge crack nucleation, propagation and delamination of coating.

3. Results and discussion

3.1 AE features of uncoated substrate

To consider the influence of uncoated substrate deformation on AE signals of TBCs, the characteristics of AE events and load-deflection-time curve are shown in Fig. 2. It is seen that the amplitude and number of AE signals are weak and small even though substrate experiences elastic and plastic deformation under bending. The wavelet analysis indicates that the dominant frequency band of AE signals is D3 for substrate deformation and its corresponding energy ratio is 0.55.

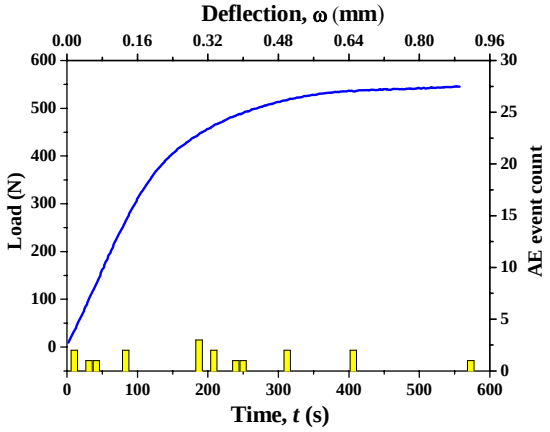

Figure 2. The distribution of AE events of uncoated substrate versus test time and the corresponding loading-deflection curve during bending.

3.2 *In-situ* monitoring of interface strain during bending

As shown in Fig. 1, the brittle coating was located underneath substrate, where fracture occurs first due to undertaking the maximum tensile or bending stress. Thus, the subsurface and interface regions were monitored and denoted with A and B, respectively. Based on the analysis of DIC data, three special points L1, L2 and L3 are extracted and marked in the curve of Fig. 3, corresponding to cracking nucleation and coating delamination. For each point, its maps of lateral strain ε_{xx} and longitudinal strain ε_{zz} are displayed and inset in Fig. 3. When the deflection ω is small, strain maps of ε_{xx} and ε_{zz} represent a homogeneous distribution behavior at the early stage (point L1). When ω increases up to 0.38 mm (point L2), the monitor of DIC shows that three apparent strain concentration regions appear close to coating subsurface. With the increase of ω, micro-cracks rapidly propagated towards the coating/substrate interface and other strain concentration regions continued to initiate near the coating subsurface region, as indicated in inset of strain maps at ω_3 = 0.68 mm (point L3). The DIC micro-observations clearly reveal that vertical cracks firstly form near the coating subsurface and then propagate to the coating/substrate interface as bending load increases. Once arriving at the interface, they gradually deflect into interface cracks and start to propagate within coating along the interface direction. Eventually, the number of surface vertical cracking stops increasing and goes into a saturation state. Partial interface cracks result in coating delamination and subsequent spallation. Thus, there are two main types of cracking patterns: surface vertical cracks and interface cracks (see inset in Fig. 3).

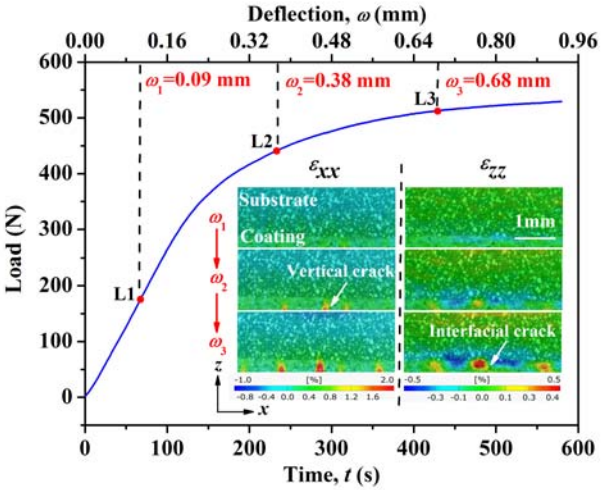

Figure 3. A typical loading-deflection-time curve of TBCs under bending. A series of strain map insets show the evolution of lateral and longitudinal strains in monitored area with the increase of ω, as shown in Fig. 1(a). Here, ω at three points L1, L2 and L3 are equal to, respectively, 0.09, 0.38 and 0.68 mm.

3.3 Failure modes and AE measurements during bending tests

The local stored elastic energy in coating would release due to cracking formation and coating fracture. The evolution of local strain and AE data of two regions A and B were extracted and re-plotted in Figs. 4(a) and (b), respectively. For region A, the magnitude of ε_{xx} gradually increases with the increase of ω. The result of a randomly selected AE signal before coating cracking shows that the dominant frequency band of AE signals is D3 and the corresponding energy

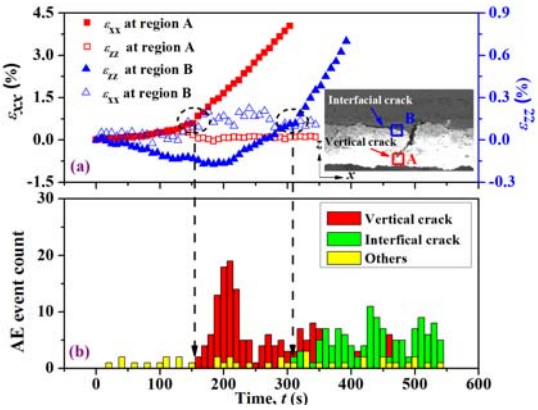

Figure 4. The evolution of local strain and AE signals as a function of loading time during bending tests. (a) The variations of ε_{xx} and ε_{zz} with test time provided by DIC, and (b) the distributions of three different kinds of AE signals with test time corresponding to different failure types.

ratio is 0.55, as presented in Figs. 5(a) and (b), respectively, which means that AE signals are mainly ascribed to substrate deformation before cracking nucleation. It is interesting to observe an abrupt transition at ε_{xx} = 0.75% when the loading time t = 152 s, which implies a surface vertical crack formation in region A. The wavelet analysis of recorded AE data indicates that AE signals change from a single type into two completely different modes (see Fig. 4(b)). The related dominant frequency band of AE signals changes from D3 into D1 and its energy ratio is 0.62, as shown in Figs. 5(c) and (d). It clarifies that before t = 152 s, AE signals are substrate deformation, as marked with yellow in Fig. 4(b). But after t = 152 s, two AE signals are composed by surface vertical cracks and substrate deformation. The new AE events are labeled by red in Fig. 4(b). It is obvious that the amplitude and energy of cracking AE signals are much more than that of substrate deformation. When ω increases, similar surface vertical cracks occur close to coating subsurface and then propagate toward the coating/substrate interface. It is observed from DIC data that the evolution of ε_{zz} in region B displays an apparent excursion and changes from compressive to tensile states at t = 312 s. The reason may be that, after the first vertical crack in region A reaches at the coating/substrate interface (region B), it transformed into a new interface crack. Simultaneously, the analysis of AE signals indicates that there appears another new kind of AE events marked with green in Fig. 4(b). In this phase, the dominant frequency band of AE signals turns from D1 into D2 and the corresponding energy ratio is 0.75, as shown in Figs. 5(e) and (f), respectively. Finally, as ω increases, brittle coating may break into a few small segmented coatings when different interface cracks link with each other. Based on the wavelet transform with traditional parameters and DIC micro-observations, the major features of AE signals of TBCs can be divided into three different phases, including no cracking, surface vertical cracks and interface cracks. Therefore, the related border lines can be determined by these special test time points, as shown in Fig. 4(b). The correlation between DIC and AE data as a function of test time can be established, which is utilized to accurately judge cracking formation and coating delamination of coating/film systems. More importantly, such a method can be used to obtain critical experimental data near transition points,

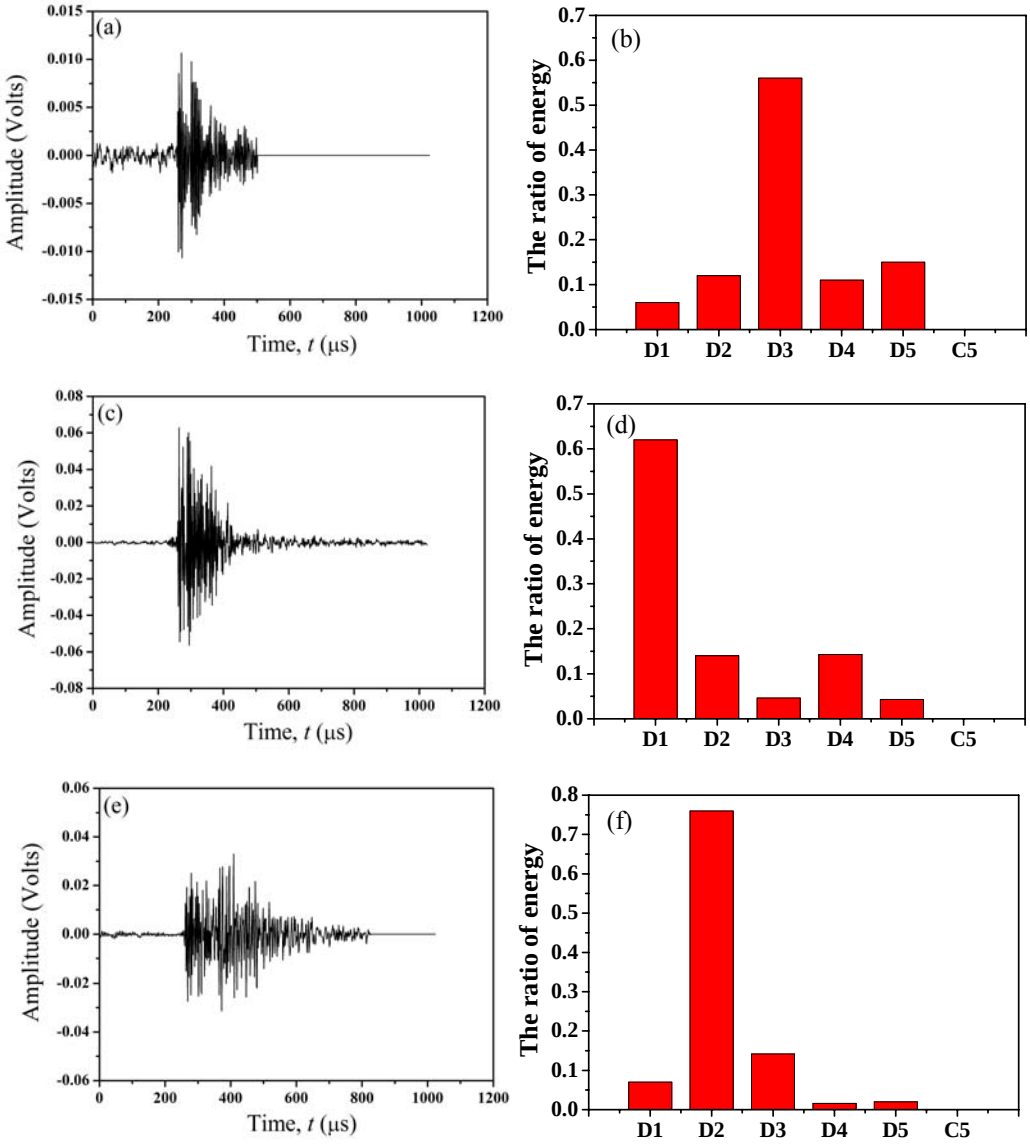

Figure 5. Three typical AE waveforms extracted from different test time points in Fig. 4(b), i.e. (a) primary phase, (c) t = 152 s and (e) t = 312 s, respectively. Figures (b), (d) and (f) are their energy coefficient ratios after wavelet analysis.

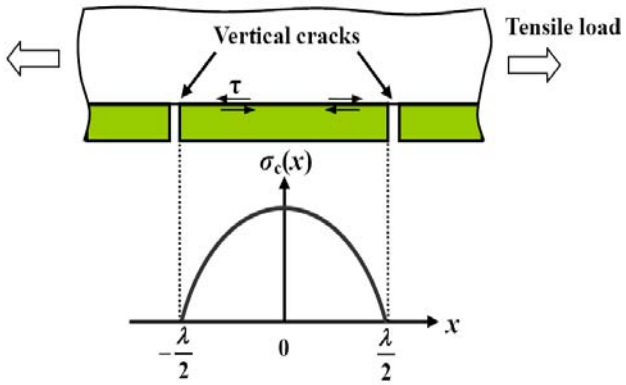

Figure 6. Schematic of the shear lag model for a segmented coating

which are crucial to deduce mechanical properties of coating/film systems, such as interface adhesion strength, fracture toughness and energy release rate.

3.4 Evaluation of interface fracture toughness

Using the critical experimental data obtained above, a shear-lag model was introduced to estimate the fracture toughness of TBCs.[22,23] In our tests, deflection is currently restricted within a very small range. Assumed that the segmented coating mainly undertakes tensile stress,[24] as illustrated in Fig. 6, the stress distribution in a coating segment can be written as [25]

$$\sigma_c(x) = E_c\varepsilon_s\left[1-\frac{\cosh(x/\xi)}{\cosh(\lambda/2\xi)}\right] \tag{1}$$

where λ and $\sigma_c(x)$ are length and tensile stress of the segmented coating, respectively, ε_s is average tensile strain in substrate, and ξ is defined as $\xi=\sqrt{E_c d_1 d_2/G_i}$. Here, E_c is Young's modulus of coating and G_i is shear modulus of interlayer, and d_1 and d_2 are thicknesses of coating and interlayer, respectively. The strain energy accumulated in the coating segment per unit length under tensile stress can be approximated by

$$U=\int_{-\frac{\lambda}{2}}^{\frac{\lambda}{2}}\frac{\sigma_c^2(x)d_1}{2E_c}\mathrm{d}x \tag{2}$$

Inserting Eq. (1) into Eq. (2), the strain energy is

$$U=\frac{E_c\varepsilon_s^2 d_1}{2}\left[\lambda+\frac{\lambda}{1+\cosh(\lambda/2\xi)}-3\tanh(\lambda/2\xi)\right] \tag{3}$$

As the length a of interface delamination grows, the length of bonded part is reduced as $\lambda=\lambda_o-2a$, where λ and λ_o denote the current and initial lengths of the bonded coating. For simplicity, it is assumed that only the strain energy in coating drives delamination.[26] Then, the energy release rate G associated with interface delamination can be written as

$$G=-\frac{\partial U}{\partial a}=\frac{E_c\varepsilon_s^2 d_1}{2}\left\{2+\frac{2}{1+\cosh\left[(\lambda_o-2a)/\xi\right]}-3\sec h^2\left(\frac{\lambda_o-2a}{2\xi}\right)+\frac{2(\lambda_o-2a)\sinh\left[(\lambda_o-2a)/\xi\right]}{\xi\left[1+\cosh\left[(\lambda_o-2a)/\xi\right]\right]^2}\right\} \tag{4}$$

Thus, the interface fracture toughness G_c can be deduced based on the delamination onset strain $\varepsilon_{\mathrm{crit}}$ at $a=0$. For an as-received TBC system, E_c = 10 GPa [27], G_i = 4.5 GPa, d_1 = 300 μm, d_2 = 100 μm, λ_o = 0.83 ~ 1.16 mm, and $\varepsilon_{\mathrm{crit}}$ = 0.64 − 0.72 % by DIC measurements. The interface fracture toughness of TBCs was estimated to be 103−129 J/m^2 by Eq. (4), which are agreement well with available results.[28,29]

4. Conclusions

The interface failure characteristics of TBCs were studied by bending tests with the aid of DIC and AE techniques. An important correlation between DIC and AE was established as a function of test time, which can be used to judge cracking nucleation and coating delamination of TBCs. Compared with traditional strain measurements and crack observation methods, this non-destructive measurement method has an advantage in dynamically monitoring the coating/film failure and assessing their reliabilities at different size scales. Using crucial experimental data, the fracture

toughness of top coating/bond coat interface was estimated to be 103−129 J/m^2 by a shear-lag model. For tensile tests, according to the dominant frequency bands and SEM observations, the correlations between AE signals, fracture types and failure mechanisms can be successfully established. Such a method can be also applied in non-destructive *real-time* evaluation of mechanical characteristics of bulk and coating/film materials at high temperatures.

* Qingsheng Yang: qsyang@bjut.edu.cn

Abstract The fiber push-out test is a basic method to probe the mechanical properties of the fiber/matrix interface of a fiber-reinforced composite. In this paper, the interfacial mechanical properties of carbon fiber/epoxy composites are analyzed effectively combing nano-indention technique with cohesive element modeling. Based on the load-displacement curve obtained from the nano-indention experiments, the interfacial shear strength is calculated about 13.7MPa. Furthermore, the finite element method (FEM) model of a fiber-reinforced composite is built in software ABAQUS, in which cohesive zone model is chosen to represent of carbon fiber/epoxy composites interface. The computed results are consistent with experiment data.

Keywords Nano-indentation, Cohesive element, Fiber push-out test, Interfacial shear strength

1. Introduction

Due to the superb properties of high stiffness, high modules, high strength and low thermal, carbon fiber-reinforced composites material are widely used in many fields such as aerospace, electronic and medical engineering [1]. The carbon fiber-reinforced composite is consisting of three components, ie. fiber, matrix and interface. A good interfacial bonding is important to the effective load transfer from matrix to fiber, which helps reducing stress concentrations. Besides, fracture toughness and fatigue life of fiber-reinforced composites also rely on their interfacial properties. Therefore, research on the interface between fiber and matrix can help designing fiber-reinforced composites material with improvement of the above properties [2].

In recent decades, three main methods are used to analysis interfacial bonding strength, namely, single fiber pull-out, single fiber push-out and fiber fragmentation (Figures1-3). The fiber push-out test is the most effective measure method to quantify the in situ characterization of interfacial properties of the fiber-reinforced composite. Nowadays, most experimental investigations of the fiber push-out debonding are based on universal testing machine (UTM), in which the fiber diameter is chosen larger than the one used in actual composites. However, compare to UTM, nano-indentation push-out test has higher precision, in which mechanical properties of interface is investigated under micro-nanoscale, A.Urena[3]studied the interfacial mechanical properties of AA6061(aluminum alloy) reinforced by short carbon fibers coated with different metallic films using the nano-indentation technique and presented the load-displacement curve. In order to obtain accurate interfacial parameter, combined experimental and numerical studies of carbon fiber/polymer composites are more used in this paper. Cohesive zone in finite element analysis (FEA) is a common method to build the interfacial model, which was proposed by Barenblatt[4]and Dugdale[5]. Afterwards, many studies pay attention to mode Ⅰ fracture failure by using cohesive zone simulation. For example, cohesive finite element method (CFEM) is employed by X. Guo [6] to investigate the paradox of a brittle nano-structured interface (nano-grained interface layer) and a ductile layered stainless steel. However, less attention has been paid to cohesive modeling of fiber push-out test. In our work, the interface is built by zero thickness cohesive elements in ABAQUS

software.

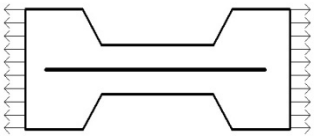

Figure 1. Fiber fragmentation

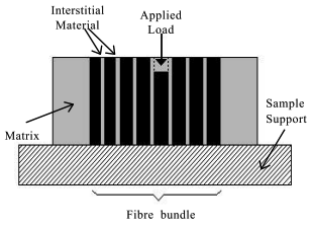

Figure 2. Fiber push-out

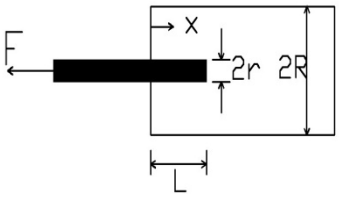

Figure 3. Fiber pull-out

2. Experiment details

Push-out tests were performed on carbon fiber-reinforced epoxy composite material where the fiber volume fraction is about 0.6. The specimens were cut from the original composite by wire cutting machine and the uniform size is 20mm in length, 18mm in width and 10mm in thickness. Afterwards, the specimens are polished by using Sic abrasive paper with 2500 grain size, a thickness 100μm can be obtained. In order to make sure that fiber has enough space to be pushed out, we designed a sample table (as shown in Figure4). There is a circle hole in the centre of sample table; the specimens cut-well were glued on the top face. Besides, the direction of fiber layer should be perpendicular to the sample table.

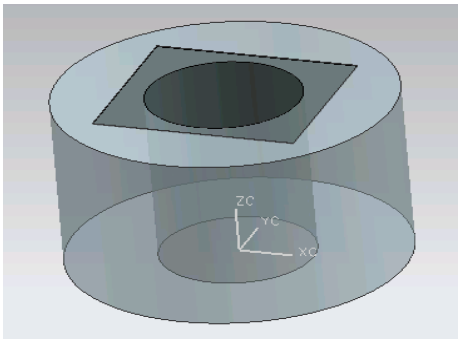

Figure 4. Sample for fiber push-out

The load-displacement curve of a single fiber push-out process is measured by nano-indention instrument and illustrated in Figure 5. It is shown that the whole process can be divided into three stages. In the first stage, fiber displacement is increased linearly with the applied load; and in the second stage, fiber begins to slide from the matrix and crack start to propagate in the interface, until interfacial failure, both the maximum load of fiber debonding and maximum displacement can be achieved in this stage. At last stage, because of indenter contact the matrix, the load continues to grow with the growth of the displacement, this stage means the end of push-out test.

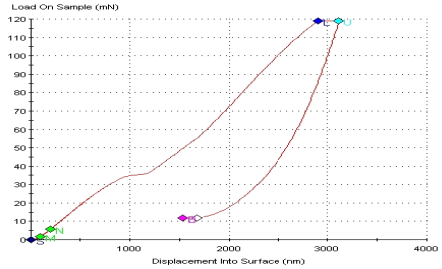

Figure 5. Load-displacement curve of fiber push-out test

In this paper, single fiber nano-indentation push-out tests were performed by using a spherical indenter with a contact diameter of 10μm.The applied load on the fiber was increased at a constant rate of 0.05μm/s. The load-displacement curve was obtained in which the maximum load is 32-35mN and the related displacement is about 1μm.It is assumed that the shear stress was uniform distribution at the interface, so the interface shear strength can be calculated as equation (1).

$$\tau_{max} = \frac{p_{max}}{2\pi RL} \quad (1)$$

where P_{max} indicates the maximum load, R represents fibre radius, L denotes the thickness of the sample, the calculated shear strength is about 13.7MPa.

3. Numerical simulation

3.1 FEM model and material parameters

Currently there are three main kinds of interface element: represented-line spring element [7], represented-Contact element [8] and CFEM. Particularly in CFEM, the damage variable can be specified by an initiation criterion and evolution law, thus the CFEM has been widely used for interface failure and debonding study [9-11].

In this paper, the FEM model is built by commercial software ABAQUS, which consists of carbon fiber, epoxy matrix, and interface (Figure6). Four-node axi-symmetric plane element (CAX4R) is used for both fiber and matrix and four-node axi-symmetric plane cohesive element (COHAX4) is used for interface between them. In total, there are 4097 CAX4R elements and 250 COHAX4 elements. Moreover, the material properties of fiber and matrix are listed in tables 1 and 2.

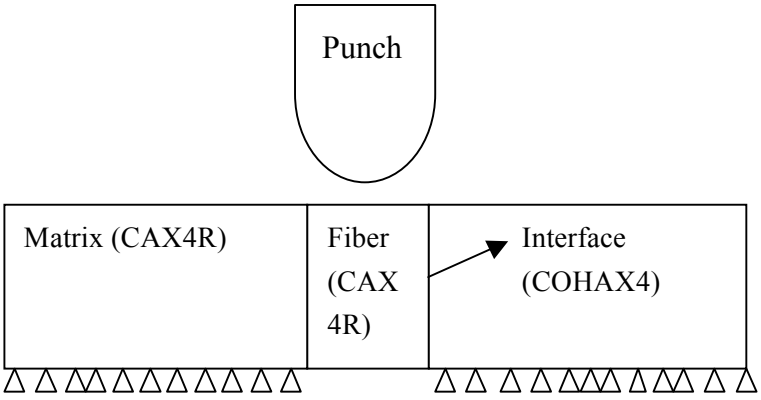

Figure 6 . FEM model

Table 1. Mechanical properties of carbon fiber [1]

Parameter	Carbon fiber(T300)
Transverse modulus (GPa)	15
Axial modulus (GPa)	230
Axial shear modulus (GPa)	27
Transverse shear modulus (GPa)	7
Axial Poisson's ratio	0.013
Fiber radius (μm)	3.5

Table 2. Mechanical properties of epoxy [1]

Parameter	Epoxy 3501
Modulus (GPa)	4.3
Poisson ratio	0.3

3.2 Cohesive zone traction-separation law

In addition, a traction-separation law is implemented to describe the interface cohesive elements between the fiber and the matrix for FEM simulation as shown in Figure 7. The debonding in push-out process is a pure mode II fracture problem. At first, the stress of crack tip in cohesive zone increases linearly with the separation displacement until the displacement reaches the initiation point of damage δ_{init} at where the crack begins to propagate. Afterwards, the tensile stress of crack will be decreased linearly with the displacement. When the stress is reduced to zero at the point of δ_{fail}, the crack is extended along the whole interface surface which leads to the interface failure of the material.

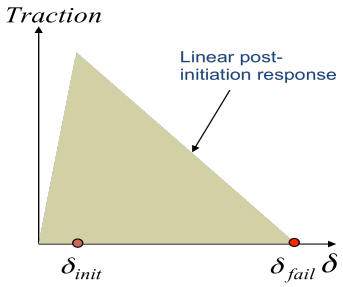

Figure 7. Traction-separation law proposed for interface fracture modeling

The interfacial shear stress τ_{is} can be expressed as equation (2) where τ_{max} is the interfacial crack initiation stress under shear loading condition

$$\tau_{is} = \begin{cases} \frac{\tau_{max}}{\delta_{init}}\delta & 0 \le \delta \le \delta_{init} \\ \frac{\tau_{max}}{\delta_{fail}-\delta_{init}}(\delta_{fail}-\delta) & \delta_{init} \le \delta \le \delta_{fail} \end{cases} \tag{2}$$

Correlating to energy-based fracture toughness and load-displacement curve, the fracture energy can be calculated as equation (3):

$$G_{IIC} = \frac{1}{2}\tau_{max}\delta_f \tag{3}$$

The cohesive element stiffness equal to the material stiffness .The uncoupled elastic constitutive relation is written as equation (4):

$$T = \begin{pmatrix} T_n \\ T_s \end{pmatrix} = \begin{bmatrix} K_{nn} & K_{ns} \\ K_{ns} & K_{ss} \end{bmatrix} \begin{pmatrix} \varepsilon_n \\ \varepsilon_s \end{pmatrix} = \begin{pmatrix} \delta_n \\ \delta_s \end{pmatrix} \tag{4}$$

The damage and fail law of the cohesive elements is according to the traction-separation relation, while the traction-separation relation was defined by the initiation and evolution. Damage initiations rely on the beginning of stiffness degradation. In our work, the linear maximum nominal stress criterion was used. Damage is initiated when the maximum nominal stress ratio reaches unity [10].

$$\max\left[\frac{T_n}{T_n^0}, \frac{T_S}{T_S^0}\right] = 1 \tag{5}$$

where T_n^0, T_S^0 represent the peak nominal and shear stress, the damage evolution law describes the rate at which the effective material stiffness degrades after damage initiation.

4. Numerical results

By numerical simulation, a typical fiber push-out load-displacement curve can be obtained. The whole process a divided into three stages that can be shown in Figure 8, the first stage of curve is mainly fiber elastic deformation occurs. The second stage of curve is a nonlinear relationship, due to the punch increase load on interface characterized by cohesive element damaged and failure, Led to the separation between fibers and matrix. The third stage, the fiber and matrix lose bonding; there is only friction between them.

Compared with previous experimental curve, the reason why the experimental curve different with Simulation curve was attributed to that our work was not consider the contact between punch and fiber, the effect of contact with matrix is meaningless. While debonding force and failure displacement from the simulation and experimental are the same value.

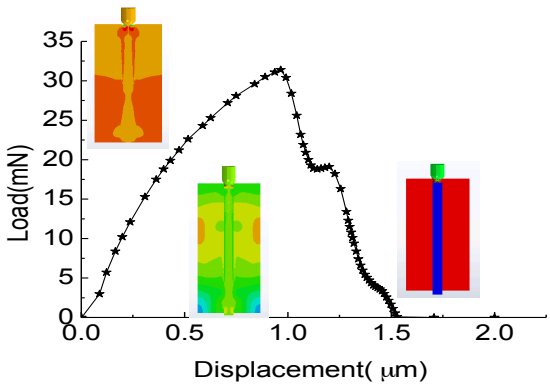

Figure 8. Load-displacement curve of numerical simulation

As the lateral friction will be produced when punch contact fiber, the numerical simulation which fully considered. The coefficient of friction in simulation are 0、0.3、0.6、0.9. The results are shown in Figure 9.

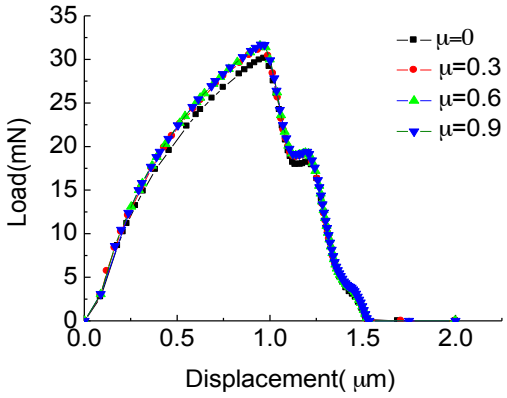

Figure 9. Variation of load with push-out displacement of carbon fibers with different fiction coefficients

Because the interface characterized by cohesive element, wherein the relationship exists between modulus, strength and fracture energy release, therefore, fracture energy release rate is important parameters, its impact is shown in Figure 10.

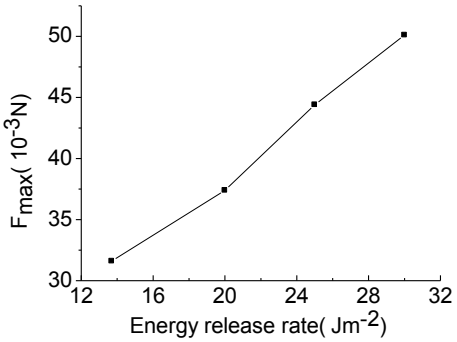

Figure 10. Relation of fracture energy release and maximum debonding force

5. Conclusions

In this paper, the interfacial shear strength of carbon fiber-reinforced composite was investigated by nano-indentation experiment. The interface was also simulated by cohesive element in software ABAQUS. The conclusions are as follows.

(1) The load-displacement curve of carbon fiber push-out derived from experiments is different with the one obtained from the simulation. However, the debonding force and failure displacement are the same from the simulation and experiment as the contact between punch and fiber is ignored.

(2) The effect of lateral friction between punch and fiber can be ignored due to its slight effect on the experimental results.

(3) The maximum debonding force is related to the fracture energy release of cohesive elements and increases with the interfacial strength.

Abstract Former studies shows that the impact resistance of composite can be significantly enhanced by insterting shape memory alloy (SMA) fibers. The interfacial delamination behavior of SMA reinfored composite plate is numerically studied with the cohesive zone model. Our results indicate that the interfacial damage of SMA reinforced composite plate is apparently decreased compared with traditional composite plates.

Keywords Interfacial delamination, SMA, Composite, Low velocity impact

1. Introduction

As is well known, fiber reinforced compoistes (FRC) are prone to impact damage. The scientific community has sought different ways to improve the impact performance of FRC. Shape memory alloys such as NiTi alloys, have long been known as a class of smart materials, which possess pseudoelastic behavior and shape memory effect, depending on the temperature of the enviroment. When the SMAs display pseudoelastic behavior, the recovery strain can reach 8%. A large amount of deformation energy can be absorbed in a loading cyclic. This special character of SMAs has importatn potential applications to improve the mechanical performance of FRCs.

The idea of inserting SMA fibers into FRC was initilized by Paine and Rogers in 1994 [1]. They revealed by experiments that the damage of the composites can be largely reduced by inserting SMA fibers. A large amount of the deformation energy was absorbed by the SMAs during the deformation process. Jia et al.[2] further studied the impact behavior of SMA reinforced composites. Their study also shows that the impact behavior of the composites is largely enhanced due to the pesudoelastic behavior of the SMA fibers. Lau [3] and his collabrators studied the interfacial delamination behavior of SMA reinforced composites both experimentally and theoretically. Again, the beneficial effects of the inserting SMA fibers were identified. This paper studies the interfacial delamination of SMA reinforced composites by finite element analysis. The cohesive zone modelling is adopted to simulate the delamination behavior of the composite laminates. The influences of the position of the inserted SMA fibers and the enviroment temperature on the delamination behavior of the composites under low velocity impact are systematically studied.

2. FEM Models and Simulations

Former studies have shown that matrix fracture and interfacial delamination are two main damage modes of fiber reinforced composites. In order to see how the SMA fibers enhance the delamination behavior of the composite laminates, we adopt the FEM model shown in Figure 1.. In Figure 1., eight layers of composite laminates are considered. For the upper four layers, the fibers are along

the zero degree direction while for the lower four layers, the fibers are along the 90 degree direction. Inbetween the middle two layers, the cohesive elements are inserted to simulate the interfacial delamination.

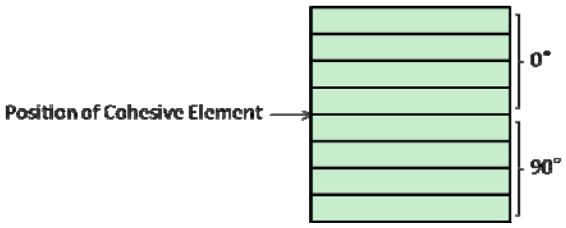

Figure 1. The numerical model to simulate the interfacial delamination.

A cylindrical projectile with a spherical head is adopted to introduce the low velocity impact. The velocity of the projectile is calculated according to the impact energy and the mass of the projectile. We assume the the cross section of the SMA fibers is of rectangular shape. The thickness of of the SMA fiber is the same as that of the laminate. In the simulation, we assume the projectile is rigid. In the impact zone, the mesh of the FE model is refined. The mesh of the FE model is shown in Figure 2.. The simulation was conducted on the finite element software ANSYS/LS-DYNA.

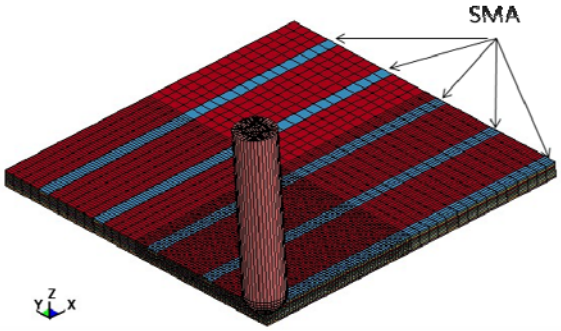

Figure 2. The mesh of the FE model.

In order to simulate the pseudoelastic behavior of NiTi SMA, we adopt the constitutive equation given by Kim et. al. [4]. The constitutive relation of the NiTi SMA is dependent upon the environment temperature. As only limited experimental results are available, only three temperatures are adopted, i.e., 350K, 370K and 390K, as shown in Figure 3..

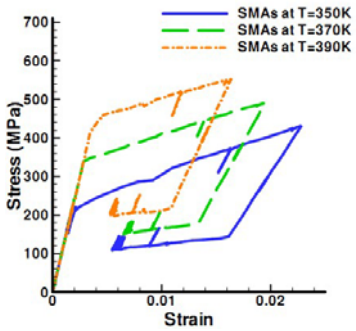

Figure 3.The constituve behavior of SMA under different temperatures [4].

3. Results and Discussions

In order to validate our simulation, we assume there are no SMA fibers inserted in the FE model. The shape of the delaminated zone is then recorded. The simulated results show that the shape of the delaminated zone is consistent with the experimental measurements, which implies that the FE model is reliable to simulate the interfacial delamination of the composite laminates. After that, the influences of the SMA fibers on the delamination behavior is further studied.

Figures 4 and 5. compares the delamination area and maximum deflection of the laminate during the impact process. In these two figures, the SMA fibers are inserted into the third and sixth layers respectively. From these two figures, we can see that the delamination behavior of the composite laminates can be largely enhanced by inserting the SMA fibers.

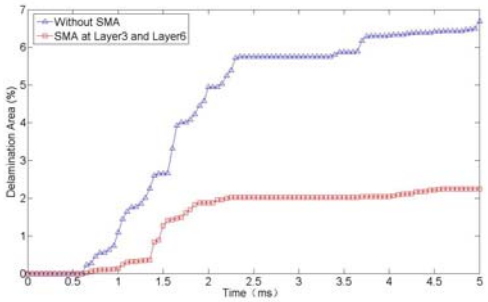

Figure 4. The time history of the delamination ratio. The impact energy is 4J.

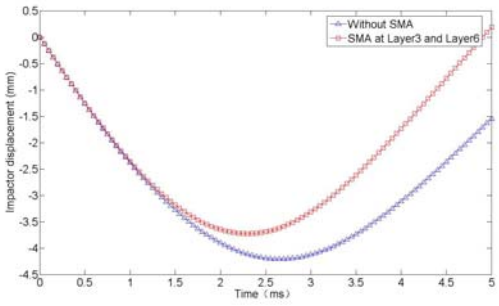

Figure 5. The deflection of the compoiste plate. The impact energy is 4J.

The delamination behavior of the composite laminates under different temperatures are also simulated, as shown in Figure 6.. From Figure 6., we can see that the delamination area under different temperatures doen't change much. This is due to the fact that the mechanical behavior of the SMA fibers in the temperature range 350K-390K doesn't change significantly. It is believed that the temperature will influence the delamination behavior more significantly when the temperature changes in a larger range.

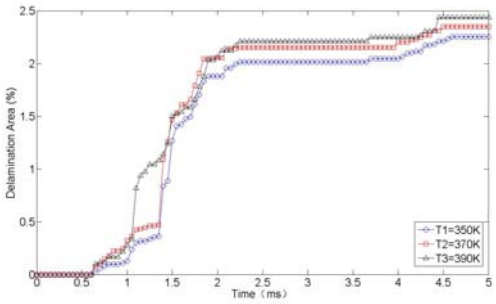

Figure 6. The delamination ratio under different temperatures. The impact energy is 4J.

In Figure 7, the position of the inserted SMA fibers are studied. In Figure 7., the SMA fibers are inserted in the sixth, seventh and eighth layer respectively. We can see that as the position of the SMA fibers is further from the impact point, the beneficial effects of the SMA fibers to prevent delamination become more pronounced.

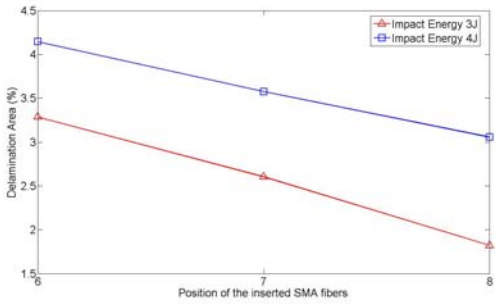

Figure 7. The influence of the position of the SMA fibers on the delamination ratio.

Abstract Inconel 718 is a Ni-based superalloy that can perform excellently at elevated temperatures. However, surface and subsurface damages in the form of microstructural and property changes and tensile residual stresses are common in a machined Inconel 718 component because of its poor machinability. Such damages have a significant influence on performance and the life time of the part. To characterise microstructural damages and understand how they are correlated to machining conditions are not only important for the evaluation of surface integrity but also for the optimization of machining operations to minimise effects from the machining process. This paper uses the ECCI (electron channelling contrast imaging) and EBSD (electron back scatter diffraction) methods to study the effect of cutting tools and cutting speeds on subsurface plastic deformation of machined Inconel 718. When turning at 200 m/min, a comparable level of plastic deformation was found under the surface machined with uncoated cubic boron nitride (CBN), titanium nitride coated CBN and whisker reinforced alumina (WRA). With an increase in cutting speed, the plastic deformation depth increased, and uncoated CBN tools showed superior performance in term of subsurface microstructure alterations compared to the other tool materials.

Keywords Inconel 718, High speed turning, Surface integrity, Plastic deformation, EBSD

1. Introduction

Superalloys which can maintain high performance at elevated temperatures are widely used in aerospace, automotive, and power industries. Ni-based superalloys are outstanding members in this big family because of their high resistance to corrosion, mechanical and thermal fatigue, mechanical and thermal shock, and creep at high temperatures [1, 2]. However, Ni-based superalloys are difficult-to-cut materials due to their superior mechanical properties and the low thermal conductivity. High cutting heat tends to generate in the contact area between cutting tools and the component during machining processes. The high temperature which can be in excess of 1200 °C leads to rapid tool wear because of softening of tool materials [3, 4]. These characterizations consequently result in surface damages, and eventually affect the mechanical performance and service life of final products. In industries, the finish machining of Ni-based superalloys is generally performed by using traditional cemented carbide tools at low cutting speeds (30-90 m/min) to maintain a reasonable tool life [5]. However, in recent years, more aggressive cutting conditions, such as higher cutting speeds, are promoted for the purpose of increasing production efficiency and reducing manufacturing costs. These accelerate the application of new tool materials like whisker reinforced ceramics (WRC) and cubic boron nitride (CBN) [3, 6, 7]. WRC tools can maintain a high hardness at elevated temperatures and the toughness is dramatically improved by adding whiskers of silicon carbides. The achievable cutting speed varies from 200 m/min to 750 m/min, depending

on the hardness of the superalloy [8]. Compared to WRC tools, CBN tools have a better strength and resistance to fracture but poorer chemical stability [7, 8]. By applying coatings, a diffusion barrier forms which can suppress the chemical wear of CBN tools [9].

During high speed machining operations, the alloy will be exposed to high thermal and mechanical fields which can lead to microstructure alterations near the surface, such as plastic deformation, phase transformation and recrystallization [10-12]. These alterations play a significant role in determining the final fatigue strength of the machined component [13]. Therefore, the surface integrity provided by using these novel machining tools should be investigated in order to predict the quality of machined components. The aim of this study is to evaluate and compare microstructure alterations with focus on the plastic deformation under the machined surface produced with uncoated CBN, coated CBN and WRC tools at high cutting speeds.

2. Experimental details

Solution annealed and aged Inconel 718 with 45HRC hardness was chosen for this study. The chemical composition is given in Table 1. A bar with 70 mm diameter and 200 mm in length was machined at finishing turning conditions. Cutting tools consisted of uncoated CBN (UCBN), titanium nitride-coated CBN (CCBN) and whisker reinforced alumina (WRA). UCBN and CCBN tools have low CBN contents (approximately 50% vol.). The thickness of the titanium nitride coating was 2 μm. Whisker reinforced alumina inserts with honed cutting edge and 0.1×20° chamfer were employed. The insert was mounted in the tool holder provided 6° inclination and -6° rake angle. Coolant was used throughout all cutting tests. Two cutting speeds, v_c =200 m/min and 350 m/min, were selected. The cutting feed rate f =0.1 mm/rev and the cutting depth a_p =0.3 mm, were constant for all tests. Cutting forces in the cutting, feed and radial directions were measured with a force dynamometer, Kistler 9121.

Table 1. Chemical composition (wt. %) of Inconel 718

Ni	Cr	Nb	Mo	Ti	Al	C	Si	Fe

The ECCI (electron channelling contrast imaging) technique is based on variations of the collected backscattered electrons intensity, and observed channelling contrast is attributed to lattice misorientations introduced during fabrication or deformation processes [14]. The EBSD (electron back scatter diffraction) technique can be used to quantitatively measure the extent of plastic deformation beneath the machined surface by offering grain orientations as well as information about intragranular misorientations [15]. In this study, ECCI and EBSD techniques were used to characterize microstructure and measure the deformation intensity and depth. All these studies were conducted on a Hitachi SU-70 FED electron scanning microscope installed with an EBSD set-up. Results of the density of low angle grain boundaries were obtained using the Channel-5 software from HKL technology.

3. Results and discussions

3.1 Subsurface microstructure

Typical microstructure alterations introduced during the machining process are presented in Fig. 1a. Based on the observed morphology, four obvious zones can be identified in the machined subsurface region [16]. The very thin layer (less than 1 μm) close to the top surface is the heat affected zone. The microstructure was strongly affected by the heat generated during the cutting process, as a consequence of the high cutting speed. The high resolution image shows that the structure in the heat affected zone is highly refined with nano-scaled grain size which is much smaller than the grain size of the bulk material (Fig.1b). This ultrafine nanostructure corresponds to the white layer often found after high speed cutting [17]. The formation of the white layer is generally attributed to a high cutting temperature followed by rapid cooling or severe plastic deformation [18]. Beneath the heat affected zone, the severe deformation can be characterized by bending and elongation of grains, grain boundaries and slip bands towards the cutting direction. This morphology varies as the depth increases. In the slight deformation zone, only some slip bands can be observed. The intensity of the plastic deformation declines following the temperature and mechanical load gradient from the surface to the bulk material.

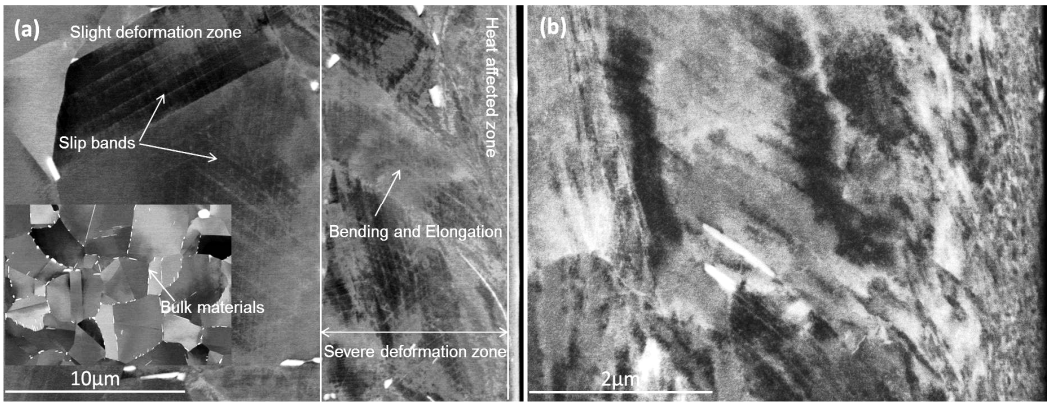

Figure 1. Typical microstructure of (a) machined surface and subsurface layers (b) the heat affected zone (CCBN tools, 350 m/min)

Figs. 2a and b show the effect of cutting speeds on the plastic deformation beneath the surface machined with WRA tools. When the cutting speed was increased from 200 m/min to 350 m/min, more distinguishable bending and slip bands were observed and the whole deformation area in the subsurface layer became much larger. Since the cutting force components of WRA tools were found to slightly decrease with the increased cutting speed (Fig. 3a), it may be concluded that the increased cutting temperature at the higher cutting speed is responsible for the greater level of the plastic deformation in the subsurface zone [19]. The same influence of cutting speeds was observed in the machined surface produced by UCBN tools and CCBN tools (Fig. 2c-f). Besides cutting speeds, the type of cutting tools is also an essential parameter affecting the plastic deformation in the machined subsurface. At 350 m/min, the most severe and deeper plastic deformation was found in the subsurface machined with WRA tools (Fig. 2b). It was also found that cutting with CCBN

tools resulted in a larger extent of plastic deformation in the machined subsurface compared with UCBN tools (Figs. 2d and f). These observed differences in the plastic deformation level can be explained by the increased cutting forces (Fig. 3b). The highest force level found for WRA tools leads to the largest plastic deformation under the machined surface. For the case of CBN tools, the higher cutting forces given by CCBN tools are responsible for the greater level of subsurface plastic deformation. It is expected that CCBN tools should show a lower cutting force than UCBN tools due to a lower friction coefficient and thermal conductivity of the titanium nitride coatings [20]. The opposite result is mainly due to the different tool microgeometry. Simulation and experimental results indicated that cutting forces increase as the tool radius increases [21, 22]. In this study, the edge radius r_β is 15-18 μm for UCBN tools, 20-22 μm for CCBN tools, 25-28 μm for WRA tools. At the higher cutting speed, the cutting tools had a strong influence on the subsurface plastic deformation level. However, when cutting at 200 m/min, comparable plastic deformation was found in Figs. 2a, c and e, and no obvious differences can be distinguished in the microstructure images for the different tools.

3.2 EBSD measurement

The EBSD maps were scanned with a step size of 1 μm in both vertical and horizontal direction from the surface. The crystallographic orientation of each measured point was collected according to the Kikuchi pattern and then the crystallographic misorientation associated with plastic deformation between each two points was calculated. A misorientation angle within the range of 1° and 10° was defined as a low angle grain boundary. The EBSD maps in Fig. 4 reveal the subsurface plastic deformation induced by turning using WRA tools. Areas where the value of the misorientation angle is within the range of 1° and 5° are marked by white lines, and those within the range of 5° and 10° are marked by red lines. The red lines were found to concentrate in the top surface showing a greater level of plastic deformation in this area. Meanwhile, when moving away from the surface into the bulk material, a general decrease of the white lines can be observed which shows the decrease of the plastic deformation. This tendency is corresponding to the microstructure variation from the heat affected zone to the undeformed zone. By calculating statistical data obtained in five random areas under the machined surface, misorientation variations versus the depth were delineated to demonstrate the plastic deformation level and depth beneath the machined surface (Fig. 4c). The increase of subsurface plastic deformation at the higher cutting speed was confirmed by the higher density and the greater depth of the misorientation. The EBSD results combined with the microstructure observation demonstrate that the higher cutting speed tends to result in a larger level of plastic deformation in the subsurface area

Microstructure observations in Section 3.1 have proven that the choice of cutting tools had an effect on the subsurface plastic deformation level, but this effect highly depends on the cutting speed. Fig. 5b confirmed the increase of plastic deformation for the machined surface from UCBN tools, CCBN tools and WRA tools at 350 m/min. This increase is strongly related to the increased cutting force level. However, at the lower cutting speed of 200 m/min, although the cutting forces for WRA tools still maintain the highest level compared with UCBN and CCBN tools (Fig. 5c), the plastic deformation generated during machining operations with WRA tools shows a slightly lower level instead (Fig. 5a). Such a significant change is probably attributed to the lower cutting temperature at a relatively low cutting speed. The coherency strain hardening has been reported to be the principal strengthening mechanism in aged Inconel 718 [23]. The major strengthening phase in Inconel 718 is

the γ'' phase. When the cutting temperature is below the γ'' solvus temperature, due to the strain hardening, the further plastic deformation is restricted. Therefore, at the lower cutting speed, the cutting forces had a limited effect on determining the plastic deformation in the machined subsurface. UCBN, CCBN and WRA tools give a similar plastic deformation level.

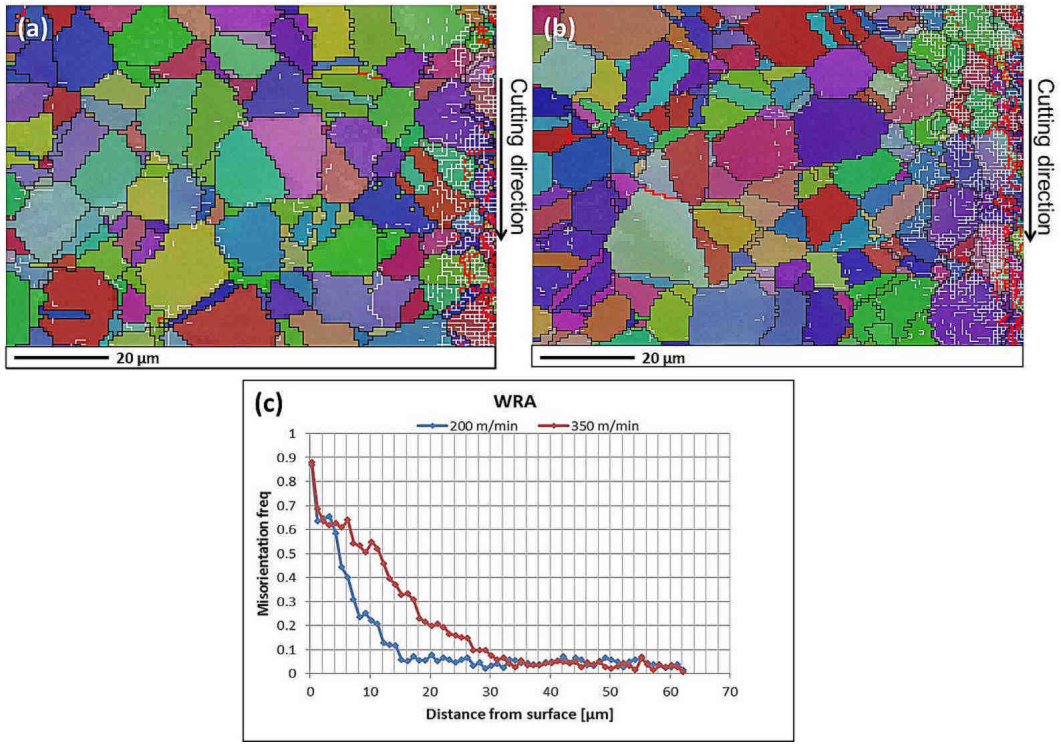

Figure 4. EBSD maps of subsurface deformation (a) WRA tools, v_c =200 m/min (b) WRA tools, v_c =350 m/min (c) Misorientation within grains beneath the surface machined with WRA tools

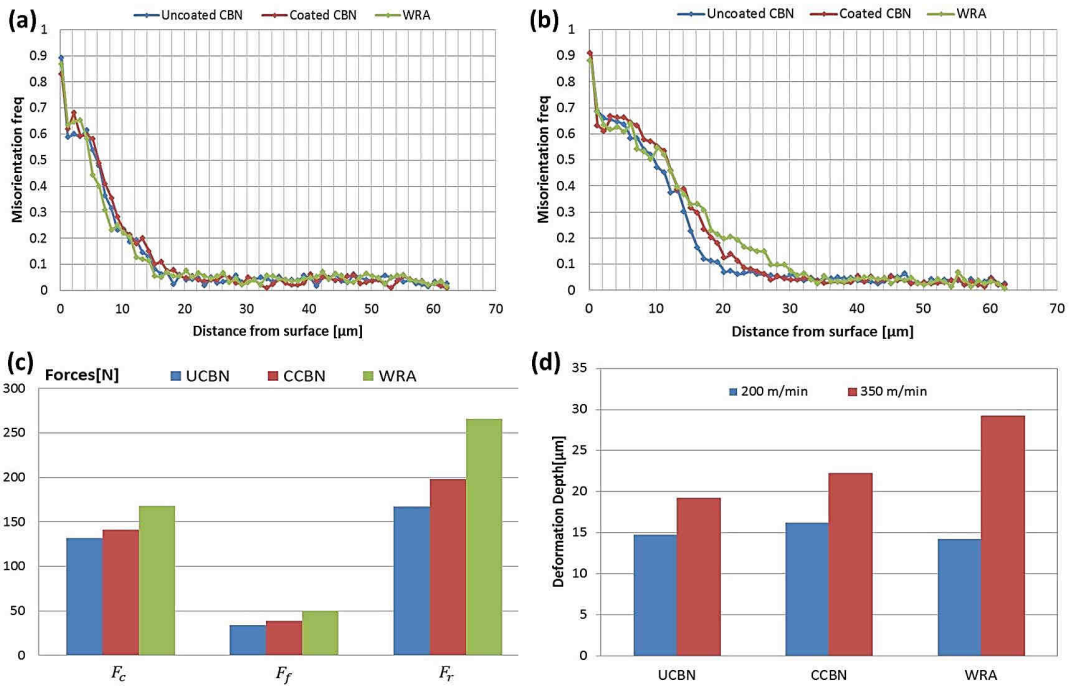

Figure 5. Misorientation within grains beneath the surface machined at (a) 200 m/min (b) 350 m/min (c) Cutting force components at 200 m/min (d) Deformation depth under different cutting conditions

Deformation depth is an essential parameter to assess the damage in form of structural alterations produced by mechanical machining processes. Fig. 5d summarises the influence of cutting conditions on the plastic deformation depth. It reveals that a higher cutting speed can significantly increase the plastic deformation depth under the machined surface. This tendency is more obvious for WRA tools, suggesting that the performance of WRA tools is much more sensitive to the cutting speed. Comparing the effect of the three cutting tools, the plastic deformation depth varies within a small range of 2-3 μm at the lower speed. However, when cutting at the higher speed, a noticeable increase of the deformation depth from UCBN tools, CCBN tools and WRA tools was found.

4. Conclusions

Microstructure alterations of Inconel 718 machined with UCBN, CCBN and WRA tools at two different cutting speeds have been investigated using ECCI and EBSD techniques. An attempt has been made to characterize the performance of the three advanced cutting tools in high speed machining in terms of influence on the subsurface microstructure. The results reveal an obvious alteration of subsurface microstructure associated with the gradient of mechanical forces and temperature along the depth direction for all the cutting conditions. The cutting speed was found to have a significant influence on subsurface plastic deformation with a larger plastic deformation level at higher cutting speeds. For the effect of cutting tools, comparable plastic deformation was observed under the surface machined with UCBN, CCBN and WRA tools at the lower cutting speed. However, at the higher cutting speed, the UCBN tools outperformed the other two types of cutting tools. Hence, for the cutting conditions studied in the current work, UCBN tools should be considered when a higher cutting speed is required in order to increase the production efficiency.

Abstract Molecular or direct bonding is an emerging technique to assemble directly two silicon wafers or metal parts. In vaccum, the two surfaces are free to bond perfectly if their lattice orientation is coincident. When defects have to be considered like a misorientation or when bonding is processed in air, a slowdown of the bonding velocity is observed and its efficiency in term of adhesion energy decreased. The aim of this project is to gain insight in the bonding process and to investigate the influence of the bonding characteristics. A specific strategy based on a non linear contact mechanics scheme is adopted to describe the bonding process: the methodology is shown to provide enough flexibility to account for the normal and tangential interactions. These latter are described with Traction-Opening displacement laws that are first derived from interactomic potential. the influence on the bonding characteristic on the bonding wavefront is investigated to attempt deriving local information of the bonding mechanism.

Keywords Cohesive model, molecular bonding, finite element simulation

1. Introduction

Molecular bonding is nowadays used in the microelectronics industry to assemble directly parts with no use of a gluing layer. The technique is based on the natural adhesion between clean surfaces that come close to each other. The technique is shown efficient when performed in vacuum (see for instance the review by Prössl and Kräuter [1] and references therein). One of the challenges for improving this technique is to perform the bonding in air instead of vacuum which induces problems related to the air wedge generated in the vicinity of the process zone (see for instance Rieutord et al. [2]). Among the features that need to be to be handled carefully is the estimation of the adhesion energy and the stress induced by the processing in the wafer. Wedge tests are performed to measure the interface energy with the so called Maszara configuration (see [3] for a review). An alternative to the Maszara test, which is not so easy to handle, is to adopt an inverse approach based on the observation of the bonding wavefront during the adhesion process. The present study focuses on this aspect. The goal is to identify the adhesion energy from the observation of the bonding wavefront profile and its velocity. To this end, a modelling of the molecular bonding is presented here that is based on a cohesive description of the molecular interactions between two Silicon wafers. The work is restricted to bonding in vaccum. The cohesive description is first postulated but could be atomistically informed with molecular dynamics simulations as reported by Kubair et al. [4] for instance.

We first describe the modelling strategy and next, present a typical simulation of molecular bonding performed with the finite element package abaqus [5]. The approach is shown able to capture qualitatively observations reported in the literature. This work precedes a parametric study currently under progress.

2. Modelling and simulation the continuum scale

2.1 Problem formulation

The two wafers are modeled as circular plates, of diameter 200 mm and thickness 0.7 nm. A linear elastic constitutive law is chosen, with values of Young's modulus E=100 GPa and Poisson's ration $\upsilon = 0.22$, typical from Si. The geometry and boundary conditions of the system are depicted in Fig.1, where only the top wafer is represented. A symmetry boundary condition is imposed along a diameter. The two wafers are originally distant from a few nanometers. A pressure is applied over an area along the edge of the upper wafer. By pushing the two wafers together, they are coming in sufficiently close contact to activate the attraction between the two surfaces. A bonding wave is hence triggered from this area, spreading all along the interface between the wafers.

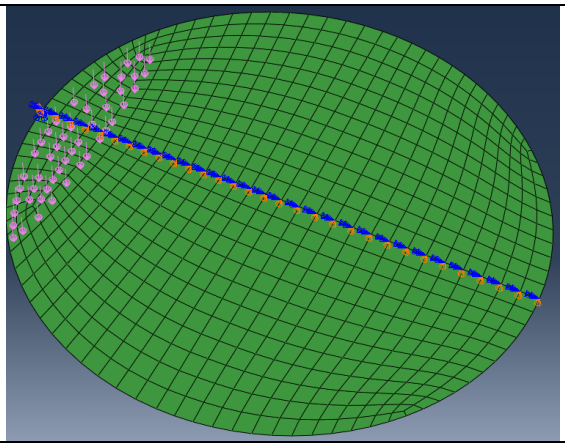

Figure 1: schematic description of the boundary conditions prescribed on the top wafer. Symmetry boundary conditions are enforced along one diameter. A pressure is applied on a small area along one edge in order to trigger the bonding process.

It is critical to model properly the interaction between the two surfaces. The Xu and Needleman (XN) cohesive model [6] is used to describe the interface behaviour. This formulation show a Traction-Separation similar to that reported in Kubair et al. [4] and therefore adopted for the case reported here. It is based on the definition of an interface potential,$\emptyset$, representing the work done when two opposing surfaces at an interface undergo a relative separation $\underline{\Delta}$The resulting tractions are given by;

$$\underline{T}(\underline{\Delta}) = \partial\emptyset(\underline{\Delta})/\partial\underline{\Delta} \tag{1}$$

The interface potential is given by;

$$\emptyset\,(\Delta_n, \Delta_t) = \emptyset_n + \emptyset_n exp\left(-\frac{\Delta_n}{\delta_n}\right)\left[\left\{1 - r + \frac{\Delta_n}{\delta_n}\right\}\left(\frac{1-q}{r-1}\right) - \left\{q + \left(\frac{r-q}{r-1}\right)\frac{\Delta_n}{\delta_n}\right\} exp\left(-\frac{\Delta_t^2}{\delta_t^2}\right)\right] \tag{2}$$

Coupling in this model is controlled through the parameters q and r;

where, $q = \emptyset_t/\emptyset_n$ $\quad r = \Delta_n^*/\delta_n$

$\emptyset_n$ and $\emptyset_t$ are the work of normal and tangential separation respectively. The normal and tangential components of the interface separation vector, $\underline{\Delta}$, are Δ_n and Δ_t respectively. The normal and tangential interface characteristic lengths are δ_n and δ_t respectively and Δ_n^* is the value of Δ_n after complete tangential separation takes place under the condition of normal tension being zero (T_n= 0).

Using equations (1) and (2), the interfacial tractions are obtained as follows;

$$T_n = \frac{\partial \emptyset}{\partial \Delta_n} = \left(\frac{\emptyset_n}{\delta_n}\right) exp\left(-\frac{\Delta_n}{\delta_n}\right)\left\{\frac{\Delta_n}{\delta_n} exp\left(-\frac{\Delta_t^2}{\delta_t^2}\right) + \frac{1-q}{r-1}\left[1 - exp\left(-\frac{\Delta_t^2}{\delta_t^2}\right)\right]\left[r - \frac{\Delta_n}{\delta_n}\right]\right\} \tag{3}$$

$$T_t = \frac{\partial \emptyset}{\partial \Delta_t} = 2\left(\frac{\emptyset_n}{\delta_n}\right)\left(\frac{\delta_n}{\delta_t}\right)\frac{\Delta_t}{\delta_t}\left\{q + \left(\frac{r-q}{r-1}\right)\frac{\Delta_n}{\delta_n}\right\} exp\left(-\frac{\Delta_n}{\delta_n}\right) exp\left(-\frac{\Delta_t^2}{\delta_t^2}\right) \tag{4}$$

The characteristic lengths δ_n and δ_t are given by;

$$\delta_n = \emptyset_n / \left(Tn_{max} exp(1)\right) \tag{5}$$

$$\delta_t = \emptyset_t / \left(Tt_{max}\left(0.5\, exp(1)\right)^{0.5}\right) \tag{6}$$

Where Tn_{max} is the maximum normal traction without tangential separation and Tt_{max} is the maximum tangential traction without normal separation. Typical shapes of the tractions are depicted in Fig. 2. It is worth noting that this constitutive law managing the interactions between the two surfaces is strongly nonlinear.

Practically, we have used q=1 and r=0, a maximum traction of 1GPa and characteristic opening δ_n=δ_t=1nm. The traction-opening profiles are reported in Fig. 2.

A viscosity term has been added according to [7] in order to avoid instability problems during the decay in the traction with opening (see Fig. 2), in the event of a strong drop in stiffness during loading (e.g. a snap-through).

The calculation are carried out using the finite element code ABAQUS [5]. The interaction between the two surfaces is accounted for through a non linear contact mechanics algorithm. The tractions representing the bonding are taken from (3-4) and implemented in Abaqus in a User INTERface routine (UINTER). The non linear contact scheme is implemented using a user subroutine linked to the implicit FEM solver. The methodology is shown to provide enough flexibility to account for the

normal and tangential interactions. Unlike the cohesive elements methods, it is easy to start in a configuration where the two plates are distant. It is also possible to activate the shear only when the distance between the two plates is smaller than $6\delta_n$, which is typically when the interaction between the two surfaces can be considered as non negligible according to the XN model. For the simulations, $Tn_{max} = 1GPa$ and $\delta_n = 1nm$. The shear interaction has been set to zero in the first place.

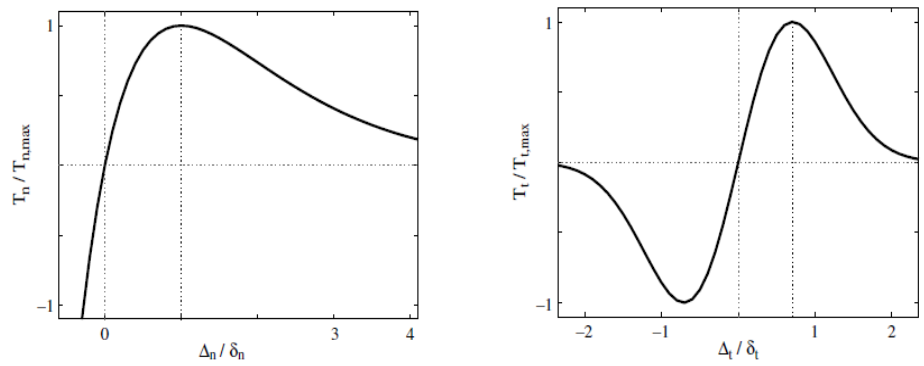

Figure 2. Description of the traction versus separation interaction between the two wafers (Eqs. 3 for normal traction and 4 for shear separation).

2.2 Results

Fig. 3 shows a typical experimental observation of the wavefront bonding observed with an InfraRed camera during the molecular bonding of two silicon wafers (top in Fig. 3). The bright zone corresponds to the bonded region, the darker to the area that is not bonded yet. On the top-left picture, the bonding is initiated on the left of the wafer. Initiation consists of applying a short pressure to trigger the process. Once the bonding propagation is initiated, the wave front runs from left to right. Due to the initiation of the bonding process, the wavefront show initially an almost circular contour but its curvature increases as the bonding extends across the interface.

In the bottom of Fig. 3, we present the results of the finite element simulations. The distribution of the displacement normal to the wafer surfaces is reported. The blue/darker corresponds to the bonded area, and the green-red area (brighter region) to the surface that is not bonded yet. The area where an initial pressure is prescribed to trigger the bonding process is more extended in the simulation compared to the experimental data reported in Fig. 3. Therefore, the curvature of the initial bonding wavefront is larger curvature. During the wavefront propagation, its curvature increases as the bonding extends, toward the middle of the wafer. When the second half of the wafer bonds; the radius of curvature of the bonding wavefront decreases until complete bonding.

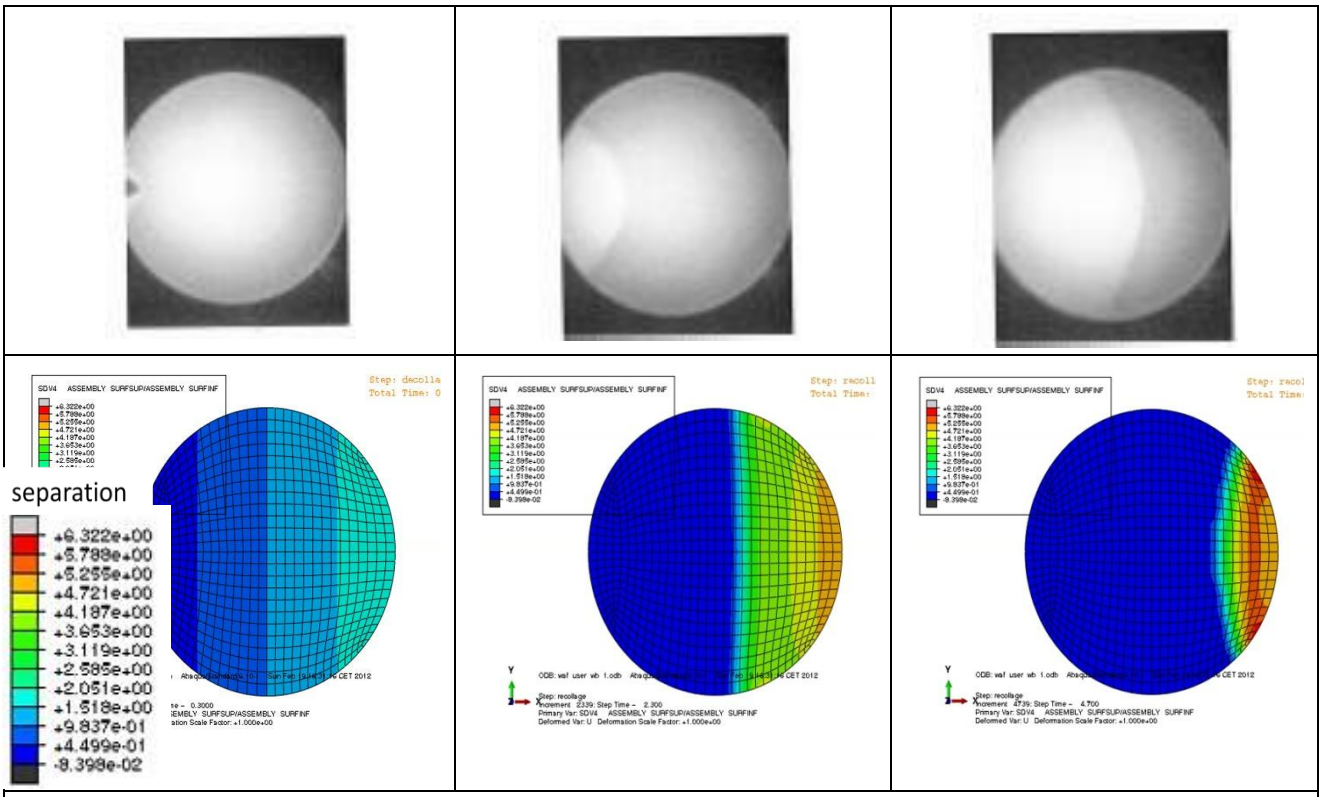

Figure 3: experimental observation (top) and numerical simulation (bottom) of the bonding front. In both cases, the bonding wave is propagating from left to right. In the simulation, the contour lines indicate the normal separation in nm. The wafers are lightly tilted at the beginning. Blue indicates a bonded area.

4. Discussion and Conclusion

We have presented a modeling of the natural bonding between two interactive surfaces by accounting for realistic adhesion interactions, at least qualitatively. The wavefront propagation predicted in our simulations is qualitatively consistent with available data of this problem.The methodology of using a contact mechanics approach to handle the cohesive interaction is found suitable for this problem. We here postulated the cohesive interaction between the two plates but some information can be extracted from the molecular dynamics calculations, in the spirit of a recent work by Kubair et al. [4] for instance. The influence of the cohesive parameters and in particular the magnitude of the maximum traction and that of the adhesion energy are currently under progress. How these could modify the wave front profile and the stress distribution in the plates will be investigated.

Abstract The contact fracture property and mechanism of electroplated Ni-P coating on stainless steel substrate were investigated using ball indentation testing, through a comprehensive experimental and numerical approach. First, the elastoplastic properties of both coating and substrate were evaluated using micro indentation tests. Next, ball indentation test with large contact force was performed, such that the brittle coating on ductile substrate suffers from cracks, including ring crack (propagates circumferentially) and radial cracks (propagates radially), owing to the coating bending effect. The fracture nucleation process was investigated using the acoustic emission technique (AET). In addition, finite element method (FEM) with cohesive zone model (CZM) was carried out to compute stress field and simulate crack initiation around the impression during the test. By using the comprehensive experimental/computational framework, the nucleation process (mechanism) of such a complicate crack system was clarified. The present technique and fracture mechanism may be applicable to the analysis of structural integrity of other brittle coatings.

Keywords Electroplated Ni-P coating, Contact fracture, Ball indentation

1. Introduction

Hard thin films or surface coatings on ductile metallic substrates are often used for contact and slide wear protection. Therefore, the characteristics and mechanism of their contact fracture are critical for ensuring their mechanical performances. Many hard coatings are deposited using the electroplate technique, which may achieve massive production with low cost and large area/ thick deposition (even when the substrate geometry is complicated) [1-5]. Among the electroplated hard coatings, Ni–P material possesses high hardness, high strength and other superior mechanical properties, providing excellent performance (such as wear and corrosion resistance) for metallic ductile substrate/components [2, 6-9]. Thus, characterizing the contact fracture properties of Ni–P coatings is the most important issue regarding structural integrity and application.

Indentation method is convenient way to simulate contact fracture against foreign object. Such a contact loading sometimes shows complicate fracture morphology, such as radial crack, ring crack and lateral crack [13, 14]. These differences are dependent on coating thickness, geometry of indenter, elastoplastic properties of both coating and substrate [15-17], which dictates various types of stress field and the maximum value that are responsible for coating fracture. One of the critical challenges lies in an understanding of the process how several different types of cracks occurs. It may require reliable method to monitor the crack propagation and fracture processes in-situ during indentation test, as well as to effectively analyze the stress field upon indentation loading and during crack propagation.

In this study, ball indentation test was carried out to simulate contact fracture of electroplated Ni-P coating on stainless steel substrate. Acoustic emission technique was utilized to monitor the timing of coating cracks. Stress field upon indentation was computed by finite element method (FEM), where the cohesive element was used to simulate crack nucleation. The comprehensive experimental/numerical approach helps to clarify stress criterion of complicate coating crack system.

2. Materials

In this study, Ni-P alloy was electroplated onto SUS304 in the plating bath. The electrolysis condition is described elsewhere [10]. The coating thickness is about 180 μm. After electroplating, heat treatment of 350°C was performed for one hour in vacuum. According to the reference [9, 10], post-heat treatment is crucial for the mechanical properties of the coating. Initially, the element of P (phosphorus) is a solution in the matrix of Ni, and then NiP_3 (having high hardness) gradually precipitates during post-heat treatment; when the post-heat treatment temperature is between 300 and 350°C, the maximum hardness (*HV*=800 - 1000) is achieved [9, 10] for wear protection, whereas the fracture toughness exhibits the lowest value [9]. Therefore, the investigation of crack morphology and cracking resistance due to contact loading is a critical issue for the Ni-P electroplated coating.

To evaluate mechanical properties (elastoplastic properties) of both Ni-P coating and steel substrate, micro indentation tests against the cross section were performed as shown in Fig. 1(a). Berkovich indenter was used with the maximum force of 100 mN. The representative *F-h* curves were plotted by solid lines in Fig. 1(b). Based on the *F-h* curves, the elastic properties (Young's modulus) were

Table 1 Mechanical properties of electroplated Ni-P coating and SUS304 substrate.

Material	Young's modulus *E* GPa	Poisson's ratio ν	Hardness H GPa	Yield stress σ_y GPa	Work hardening exponent *n*
Ni-P coating	217	0.37*	7.51	2.40	0.05
SUS304 substrate	175	0.3	3.49	0.22	0.47

* Morikawa et al. The Iron and Steel Institute of Japan (ISIJ), Vol.82, pp.935-940, 1996

estimated by Oliver-Pharr method [18, 19]. Here, the Poisson's ratio of coating is referred to be 0.37 obtained by the surface acoustic wave (SAW) technique [10]. The Young's modulus of coating/substrate shows similar values, i.e. Ni-P coating is 217 GPa, and SUS304 is 175 GPa. Subsequently, the plastic properties (stress - strain relationship) of coating and substrate were estimated by using the reverse analysis ([20, 21]). Here, the plastic properties were assumed with power-law constitutive equation, involving yield stress σ_Y and work hardening exponent n. The estimated results were shown in Table 1. To verify the estimation, finite element simulation (employing these estimated properties) of the micro indentation test was carried out and the resulting indentation curve (F-h) was shown in Fig. 1(b). The simulated results (as indicated by grey circle) agreed well with experimental data for both coating/substrate. This suggested that the estimated elastoplastic properties were robust, and can be employed for stress analysis and crack nucleation subjected deep ball indentation (see Section 5.1). Noted that, according to the reference [9], there might be internal residual stress of Ni-P coating. By using X-ray diffraction, the stress was measured to be almost zero for the present coating (with heat treatment temperature of 350C^o) [9]. Thus, we consider the internal stress-free coating.

3. Experimental Method

Ball indentation tests were performed using an electro-hydraulic testing machine equipped with a ball indenter and two eddy current sensors. The diameter of indenter ball d is 10 mm. The indentation force F gradually increases with the rate of dF/dt = 1 N/s up to the maximum indentation force F_{max} (=1000 N or 2000 N), and sustains the constant value in 50 s, and gradually decreases with the same dF/dt until the force of zero. During the test, acoustic emission (AE) signals were monitored in order to identify the timing of crack nucleation. Four small AE sensors were mounted on the side surfaces of a specimen.

4. Experimental Results

Figures 2 show the micrographs of specimen surface after the test of F_{max}=2000 N. Although the test of F_{max}=1000 N shows no clear crack (however, some friction/ wear tracks were observed), the test of F_{max}=2000 N (Fig. 2) shows complicated coating crack morphology: one type is circumferential crack, namely "ring crack", and the other type initiates from the ring crack and propagate radially, namely "radial crack". There is no delamination (coating spalling) thanks to the strong adhesive strength of the coating/substrate system. The present study therefore focuses on the formation mechanisms of ring crack and radial crack, which may provide useful insights for the mechanical/material design of coating/substrate system.

Figure 3 shows indentation curve of the test with F_{max}=2000 N. The detected AEs were plotted as triangles on the F-h curve in this figure. It is found that the first AE was detected at about F=1200 N and several AEs were subsequently monitored up to about F=1500 N. Furthermore, the unloading process was found to start AE generation from F=1600 N during unloading. Therefore, it is expected that the coating cracks occur during both loading and unloading. Based on these experimental evidences, the stress field is investigated by finite element method in the next section, so as to further clarify the contact cracking behavior.

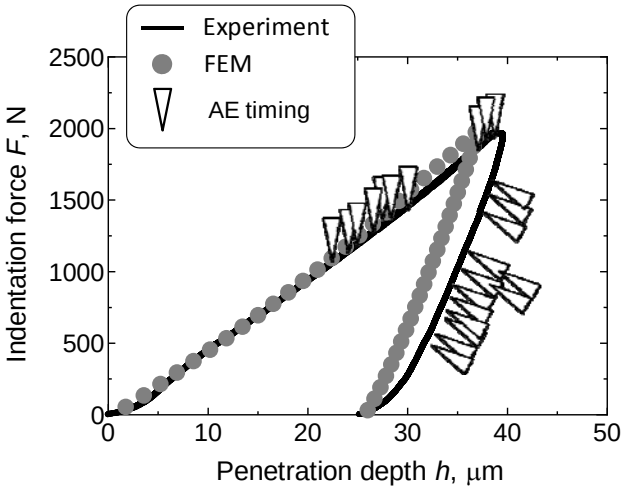

Fig.3 Indentation curve obtained by the test with maximum force of 2000 N. Triangle on the curve indicates the timing of AE generation. In addition, grey circle indicates the simulated indentation curve with finite element method.

5. Discussion

5.1 Crack initiation

By taking advantage of symmetry, an axisymmetric model is established for FEM analysis with the commercial code MARC and MENTAT. The material parameters are taken from Table 1, for both coating and substrate. A rigid ball indenter with radius d=10 mm is employed as a close analog to that used in experiment. To verify both the present FEM model and measured material property, the computed indentation curve is plotted as symbols (grey circle) in Fig. 3, showing reasonable agreement with the experimental curve.

Figure 4 represents a contour map of the indentation stress field computed by FEM simulation when the first AE was detected (as discussed in Fig.3). Fig. 4 (a) shows the map for the radial stress component (σ_{rr}), which is responsible for ring crack, and Fig. 4(b) is the circumferential component ($\sigma_{\theta\theta}$) for radial crack. For σ_{rr}, a large tensile stress (up to about 1.8 GPa) occurs outside the contact region, where the ring crack may be produced if such a tensile stress is sufficiently high. Indeed, such a prominent tensile stress is contributed by the large local bending curvature of the film, assisted by the extensive plastic deformation of the substrate [12, 15, 16]. On the other hand, $\sigma_{\theta\theta}$ (in Fig. 4(b)) is relatively small (less than about 1.0 GPa which is quite lower than the σ_{rr} component). Therefore, the first detected AE should be from ring crack, suggesting that the ring crack initiated first.

The surface distribution of σ_{rr} as a function of the indentation force is given in Fig.5. As expected, the maximum tensile stress increases and shifts outwards with increase in indentation force (deeper penetration), which is associated with the increased coating bending curvature outside the contact zone. When the indentation force reaches the critical value (F = 1200 N), the location of the maximum stress (r = 390 μm) roughly coincides with the radius of the ring crack (as indicated by dashed vertical lines) observed in experiment (see Figs. 2). Thus, we can obtain the critical fracture strength of the coating, σ_C=1.8 GPa. Note that, this value of σ_C is seemed to be the intrinsic strength of the coating (since the present Ni-P coating does not have large internal stress [9], Section 2).

From the above investigations, it is revealed that when a ball indenter makes deep contact with the

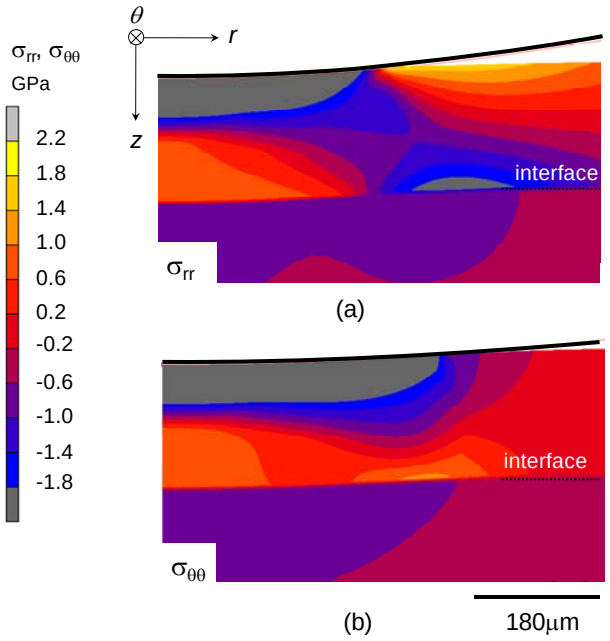

Fig.4 Counter map of stress distribution when the first AE was detected (see Fig.6). (a) normal stress along radial direction, σ_{rr}, and (b) normal stress along circumferential direction, $\sigma_{\theta\theta}$.

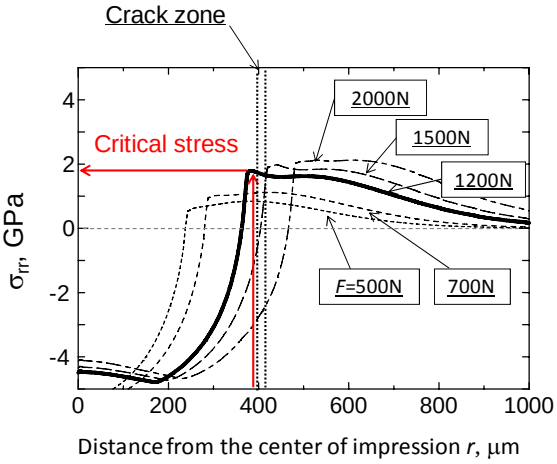

Fig.5 Radial stress σ_{rr} distribution as a function of distance r, with the increases in indentation force. The thick line corresponds to the critical indentation force of 1200 N, when first AE is detected (see Fig.6).

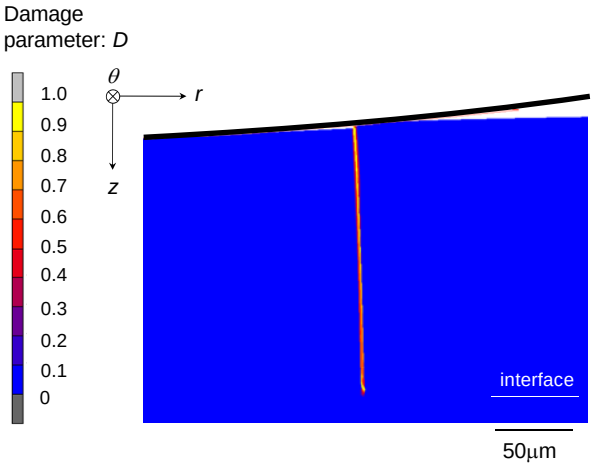
Fig.6 Contour map of CZM damage for ring crack nucleation, when indentation force is about 1200 N.



surface of brittle coating, the steel substrate undergoes extensive plastic deformation, which bends the coating and leads to large tensile stress, producing ring crack. Thus, the next question is how the radial crack initiates after the ring crack formation.

5.2 Subsequent crack initiation

To investigate how radial crack forms, the existence of ring crack must be incorporated with stress analysis during indentation. Thus, we employed the cohesive zone model (CZM) in the FEM to compute the stress field in conjunction with ring crack formation.

The CZM is applicable to both ductile and brittle materials [23-29]. The CZM essentially models the fracture process zone in a plane ahead of the crack tip. The zone is assumed to be subjected to cohesive traction. The model usually describes the gradual degradation of the adhesion between two regions along the crack propagation plane. The mechanical response of the cohesive zone obeys a

traction–separation law that yields the relationship between the separation distance v of the two material faces at an interface and the traction stress σ acting between them. Although numerous traction–separation laws for the cohesive zone element have been proposed, this study employed an exponential law (called the Smith-Ferrante type [24]) due to its simplicity. This exponential law requires two independent materials parameters, i.e. the maximum stress σ_{max} and the crack growth resistance K_C. Since the σ_{max} roughly corresponds to the critical stress (fracture strength), σ_{max} is set to be 1.8 GPa from Fig. 5. However, the other parameter K_C is unknown. Thus, several values (0.5, 1.0 and 5.5 MPa $m^{1/2}$) were employed to simulate ring crack formation.
To compute the stress field involving ring crack formation, we introduced CZM element into FEM model. Here, the CZM elements are implemented at the location where the ring crack forms (r=400 μm in Fig.2 and Fig.5). Figure 6 shows the contour map of damage parameter D around the impression (when D becomes one, crack completely forms [22, 24]). When K_c=5.5 MPa $m^{1/2}$, as shown in Fig.6, the ring crack (due to σ_{rr} component) propagates from the surface to the interface. In fact, actual crack was found to propagate up to the interface from the cross sectional observation. (Note that the choice of Kc value does not affect the subsequent stress field after crack propagation.)

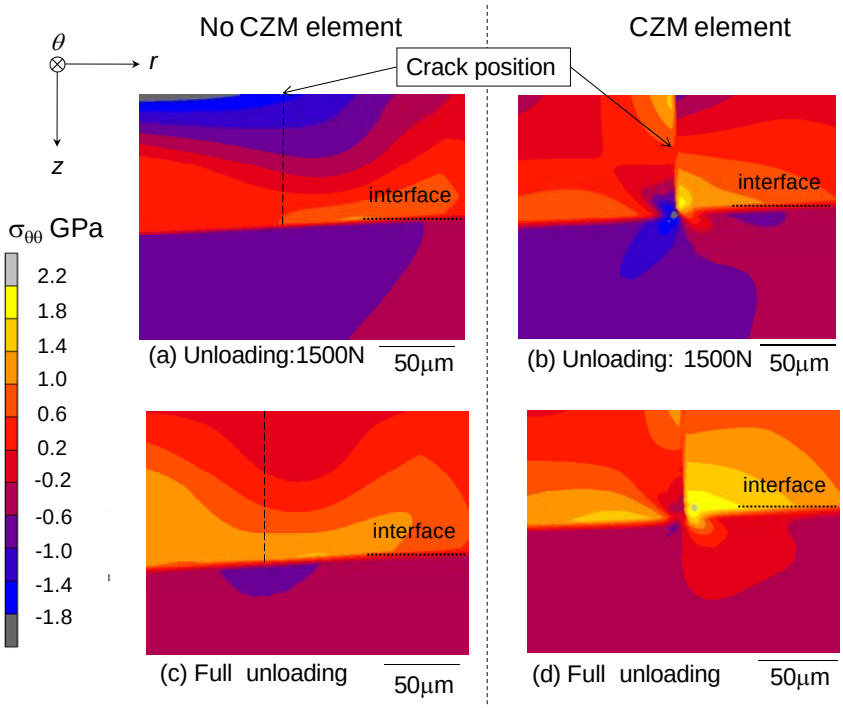


Fig.7 Contour map of stress $\sigma_{\theta\theta}$ distribution around the impression during indentation loading: homogenous model with no CZM element ((a),(c)) and model with CZM element ((b),(d)). (a) and (b) shows the map at F= 1500 N (F/F_{max}=0.75), while (c) and (d) is at the maximum force (F_{max}=2000 N). 1200 N.

5.3 Mechanism of cracking system

Figure 7 shows the snapshot of the normal stress $\sigma_{\theta\theta}$ distribution during the loading process. Fig. 7 (a) and (b) show the stress field at F=1500 N, whereas Fig. 7 (c) and (d) show the result at the maximum indentation force (2000 N). For comparison, the model with no cohesive zone element was also computed, as shown in Fig. 7(a) and (c). This model simulates the stress field due to

indenter contact, and does not induce any crack formation. Thus, $\sigma_{\theta\theta}$ (in Figs.7(a)(c)) does not show large tensile stress, which is the same trend with Fig.4(b). On the other hand, the model with CZM element in Figs.7(b)(d) exhibits different $\sigma_{\theta\theta}$ stress field, owing to the ring crack formation. In particular, possible area for large tensile $\sigma_{\theta\theta}$ develops near the interface.

Figures 8 shows a snapshot of $\sigma_{\theta\theta}$ distribution during unloading process, in a similar fashion with Fig.7. In Figs.8 (a) and (c), without the CZM element model there is no large $\sigma_{\theta\theta}$ distribution, whereas with the CZM element, the significant larger $\sigma_{\theta\theta}$ develops at the right side of crack path near interface, and its magnitude increases during the unloading process and reaches the maximum value upon full unloading. Therefore, it is found that ring crack formation significantly changes the subsequent stress field during the indentation, in particular the large $\sigma_{\theta\theta}$ upon unloading, and the radial crack is seemed to initiate at the right side of crack path.

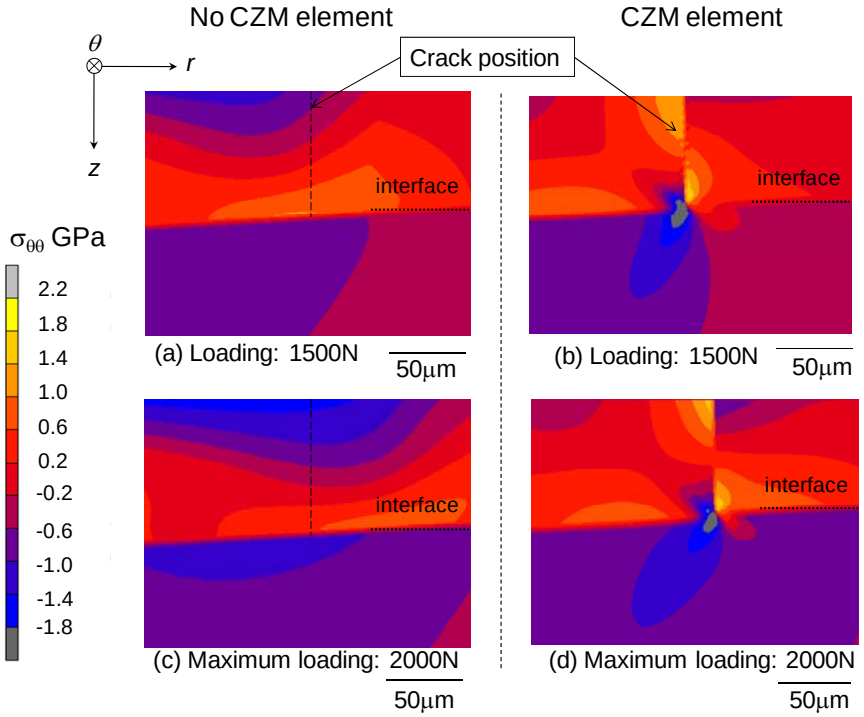

Fig.8 Contour map of stress $\sigma_{\theta\theta}$ distribution around the impression during indentation unloading: homogenous model with no CZM element ((a),(c)) and model with CZM element ((b),(d)). (a) and (b) shows the map at F=1500 N (F/F_{max}=0.75), while (c) and (d) is at the full unloading (F=0 N).

Figure 9 shows the stress $\sigma_{\theta\theta}$ distribution along the crack path with respect to the distance from coating surface to interface. The four curves indicate the results of 1500 N and 2000 N (loading) and 1500 N and 0 N (unloading). While the overall $\sigma_{\theta\theta}$ magnitude increases during the unloading process, the position of the maximum $\sigma_{\theta\theta}$ does not change (at about 175 μm below the surface). Finally, the change in the maximum $\sigma_{\theta\theta}$ value is investigated as a function of the indentation force (during unloading process) in Fig.10. As expected, the maximum $\sigma_{\theta\theta}$ increases with decreasing indentation force. Referring to Fig.3, the AE occurrence was seen at about F=1600 N under unloading. In Fig.10, this force (F=1600 N) corresponds to $\sigma_{\theta\theta}$ = 1.82 GPa, which is reasonably agreement with the critical stress σ_{rr} for ring crack in Fig.5. Therefore, it is found that radial crack is produced by $\sigma_{\theta\theta}$, which develops near the interface and ring crack path, suggesting that ring crack formation (during loading) is crucial for subsequent radial crack nucleation during unloading.

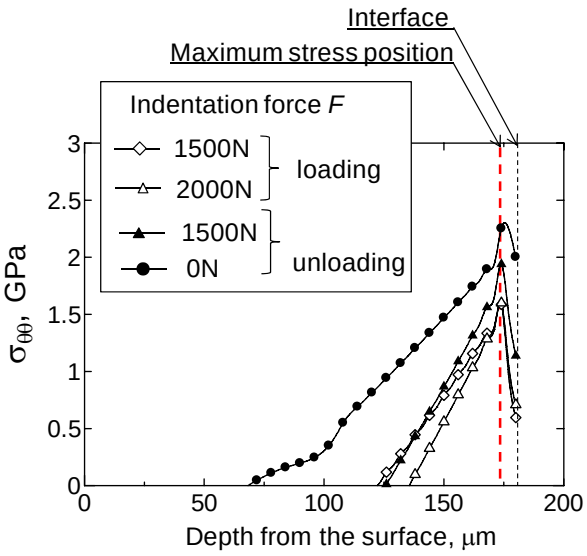

Fig.9 Stress $\sigma_{\theta\theta}$ distribution along the ring crack path (the depth from coating surface to interface). Four lines with various symbols indicate the results of 1500 N and 2000 N (loading process) and 1500 N and 0 N (unloading process).

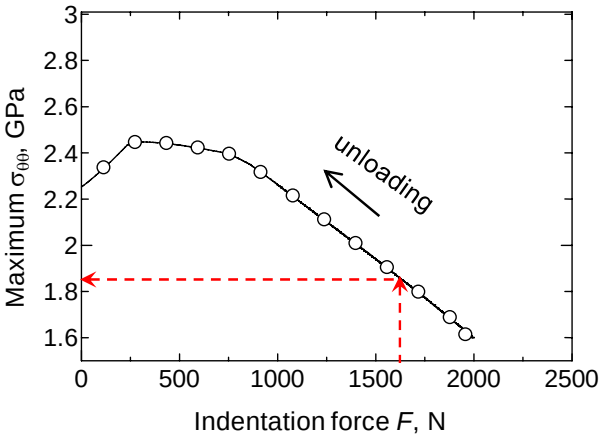

Fig.10 Changes in maximum stress $\sigma_{\theta\theta}$ (in Fig.9) as a function of indentation force during unloading.

6. Conclusion

This study investigated the contact fracture property of electroplated Ni-P coating on stainless steel substrate, which is important for its application as contact/sliding member for wear resistance. Ball indentation test with large contact/indentation force produces two types of cracks in the coating, namely the ring crack and radial crack. To elucidate the fracture process, acoustic emission technique (AET) was employed to identify the timing of crack initiation during the test. In addition, finite element method (FEM) was carried out to compute the stress field around the impression during the test. The cohesive zone modeling (CZM) was embedded with FEM to simulate the crack interaction. It is found that the ring crack first initiates during loading process, due to tensile radial stress (owing to the coating bending effect). Subsequently, radial crack nucleates from ring crack path (i.e. near ring crack tip at interface) due to the large circumferential stress developed upon unloading.

By using the comprehensive experimental/computational indentation framework (combined with AE and FEM), the mechanism of the complicate coating crack system is clarified, and the stress criterion for each cracking system is quantified. Based on these findings, further systematic study may suggest how to control or prevent the coating cracks. This will become useful guidance for material design in coating industry. The comprehensive experimental/computational framework is also applicable to other coating/substrate systems.

Abstract Thermal barrier coatings (TBC) are coating system comprising a heat insulating ceramic coating deposited on top of a oxidation resistant metallic coating. During thermal cycling, cracks grow in the metal/ceramic interface which causes the coating system to fail. In order to model such crack growth by finite element (FE) modelling, accurate interface models must be developed. The presented research studies the influence of interface roughness on the thermal fatigue life of TBCs, and suggests how interface models can be derived from interface roughness parameters. High interface roughness was found to promote longer fatigue lives. Interface models were derived from the roughness parameters Rc, Ra, RSm and Rdq and used for FE modelling of crack growth in the interface. The calculated stress intensities, KI and KII, increased with increasing interface roughness and thereby did not predict a slower crack growth with higher interface roughness as was observed experimentally.

Keywords Thermal barrier coating, Interface, Roughness, Fatigue

1. Introduction

Thermal barrier coating (TBC) systems are coating system containing a heat resistant ceramic top coat (TC), and an oxidation resistant metallic bond coat (BC) [1-4]. Such TBC systems are widely in use in gas turbines to provide heat insulation and oxidation protection for structural parts in the combustor and turbine sections; thereby prolonging the life of structural parts, as well as increasing efficiency by enabling higher combustion temperatures [1-4].

During operation, the TBC system is subjected to thermal fatigue. Thermal loads arise from the difference in coefficient of thermal expansion (CTE) of the ceramic top coat and the metallic bond coat [5-7]. Failure of TBCs often occurs close to the BC/TC interface where fatigue cracks grow under a stress field influenced by: the mismatch in CTE, the BC/TC interface roughness and the growing layer of thermally grown oxides (TGO) that form in the interface [5-7].

Predicting TBC life is a matter of great concern and several approaches to the subject exist; one of which is a fracture mechanical approach involving finite element (FE) modelling of crack growth in the BC/TC interface [5,6]. To perform such FE modelling, the BC/TC interface must be accurately modelled. The sine wave has emerged as a common interface model with amplitudes and wavelengths roughly in the intervals 5–20 μm and 20–150 μm respectively [7-13]. However, an in-depth study of the actual BC/TC interface roughness, and its influence on fatigue life, is still missing. Among the few attempts on the subject, Casu et al. [9] can be mentioned, who performed FE modelling for an interface geometry derived from an actual BC/TC interface.

The current research studies the interface characteristics by the means of common surface roughness parameters, and suggests how these can be used to create interface models. TBC coated specimens with various interface roughness were thermally cycled until failure, cross-sectioned and image analysis was used to obtain the interface roughness. The interface roughness parameters were

then used to create interface models. FE modelling of a crack growing in the interface was performed to test whether interface geometries derived in such a way would capture the experimental results from thermal fatigue testing.

1.1. Roughness parameters

The roughness parameters used in this paper are explained by Fig. 1 and Eq. (1)–(4); for further information about roughness parameters see, for example, Gadelmawla et al. [14]. In summary, it may be said that *Rc* and *Ra* are *amplitude parameters* (i.e. they contain information about profile height), *RSm* is a *spacing parameter* (i.e. contains information about profile spacing) and *RΔq* is a *hybrid parameter* (i.e. contains information about both profile height and spacing).

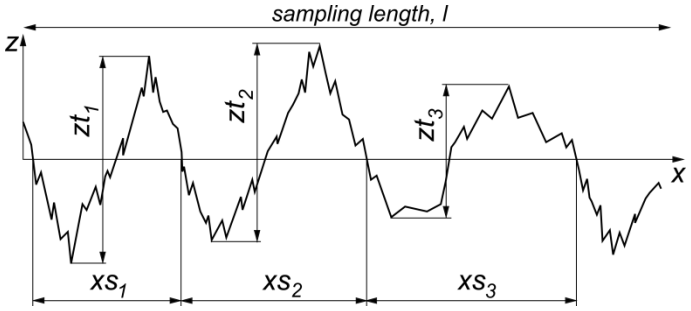

Figure 1. Generic roughness profile.

$$Rc = \frac{1}{n}\sum_{i=1}^{n} zt_i \tag{1}$$

$$Ra = \frac{1}{l}\int_0^l |z(x)|dx \tag{2}$$

$$RSm = \frac{1}{n}\sum_{i=1}^{n} xs_i \tag{3}$$

$$R\Delta q = \sqrt{\frac{1}{l}\int_0^l \left(\frac{dz}{dx}\right)^2 dx} \tag{4}$$

2. Experimental

2.1. Thermal cycling fatigue

Four TBC coated specimens with varyingly coarse BC/TC interfaces were put through thermal cycling until failure. The specimen substrates were cut from 5 mm thick Haynes 230 sheet material in 30x50 mm rectangles. The substrates were coated by 200 µm of NiCrAlY deposited by vacuum plasma spraying, and 350 µm of 7%-yttria partially-stabilised zirconia deposited by atmospheric plasma spraying (APS). The variation in BC/TC roughness was accomplished by using different feedstock powder sizes during spraying of the bond coat.

The specimens were thermally cycled in a furnace until failure. The cycle included heating to 1100 °C for 1 h, and cooling to 100 °C by forced airflow; the specimens reached 100 °C after about 10 min of cooling. After failure, which was considered to occur when more than 20 % of the top coat had spalled, the specimens were infiltrated in epoxy, cross-sectioned and polished for microscopy.

2.2. Interface roughness measurement

The interface roughness was measured on cross-sectioned specimens with an image analysis routine outlined in Fig. 2. The method involves the following steps: 1) Thresholding of the grayscale image to get a binary image, see Fig. 2 a) and b). 2) Acquisition of the interface roughness profile by simulating a profilometer stylus tip, see Fig. 2 c). 3) Filtering of the profile and establishing the mean line, see Fig. 2 d). 4) Cropping the profile to a suitable *sampling length*, see Fig. 2 e).

The results from image analysis were compared with results from a profilometer for some BC coated specimens (no top coat). This comparison was done to validate the accuracy of the image analysis derived surface roughness parameters, and to find a suitable magnification at which to perform the routine. Fig. 3 shows the results from this comparison; it can be seen that the results from the image analysis compares well to the results from the profilometer and that the lower magnification, with a resolution of 1.074 μm/pixel, was sufficient.

The setup used for image analysis can be summarised as: Roughness parameters were established and averaged from 65 interface roughness profiles with sampling lengths of 800 μm, thus resulting in a total examined length of about 5 cm which was considered enough to generate reliable mean values. The obtained profiles correspond to the BC/TGO interface. The simulated stylus tip had a radius of 5 μm. All wavelengths larger than the sampling length and smaller than two times the stylus tip radius were removed by Gaussian filtering.

3. Results

3.1. Influence of interface roughness on the thermal fatigue life

The measured *Ra* and *Rc* of the specimens are presented in Fig. 4 as a function of the number of thermal cycles the specimens withstood until failure. There is a clear tendency for higher roughness (higher *Ra* and *Rc*) to give longer fatigue lives.

Fig. 5 shows the measured *RSm* and *RΔq* versus cycles to failure. *RSm* contains information about (wave)length, and *RΔq* contains information about both length and height. For *RΔq* a correlation with fatigue life exists where higher *RΔq* gives longer life. The same cannot be said for *RSm*, however, since the *RSm* value appears to be roughly equal for all specimens; the variation between the specimens is less than ± 5 % of the mean value of 232 µm.

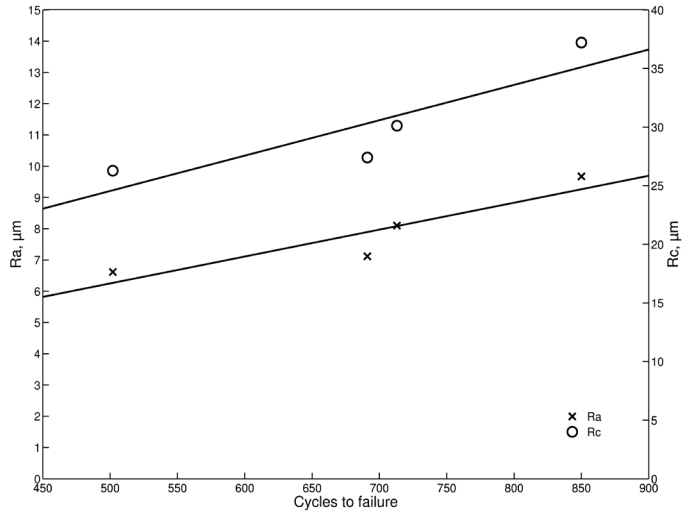

Figure 4. The influence of *Ra* and *Rc* on the thermal fatigue life.

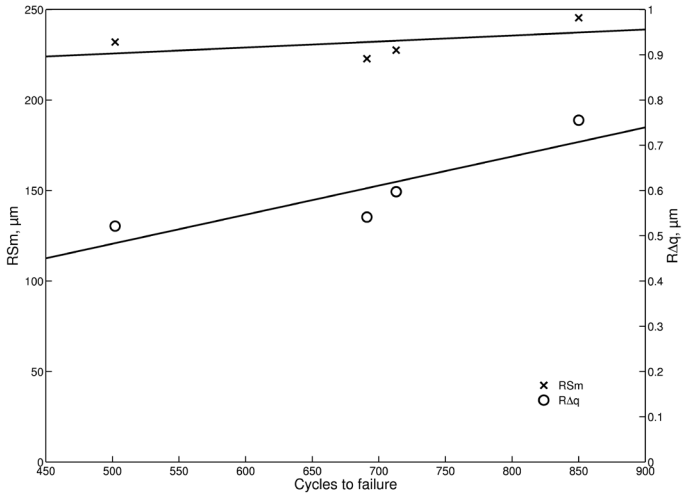

Figure 5. The influence of *RSm* and *RΔq* on the thermal fatigue life.

3.2. Interface models

In order to derive usable interface models, several assumptions have to be made. 1) Basing the model on measured interface roughness parameters will cause it to capture the main features of the actual interface. 2) Interface parameters that show a correlation with fatigue life (such as *Ra* and *Rc*) are appropriate to use as a base for model formulation. 3) For simplicity, the interface needs to be modelled as a periodic function.

Two models are presented here; they are both based on sine waves, see Eq. (5), as this is a commonly used shape for interface models in TBCs. The amplitude A and wavelength λ can then be derived from the interface roughness parameters as shown in Table 1.

$$z = A\sin\left(\frac{2\pi}{\lambda}x\right) \tag{5}$$

Model 1, see Table 1, is roughly the equivalence of measuring the height and wavelength directly in a micrograph. This model is based on *Rc* and *RSm* where *Rc* is twice the amplitude and *RSm* is the wavelength. Model 2 is derived from *Ra* and *RΔq*. It is obtained by entering Eq. (5) into Eq. (2) and its derivative into Eq. (4). Using the equations from Table 1 with Eq. (5) and values from Fig. 4 and 5, the amplitudes and wavelengths can be calculated and are listed in Table 2. For the remaining paper, only the specimen with lowest roughness (shortest life) and highest roughness (longest life) will be considered.

Table 1. Equations for the interface models.

Model	Amplitude	Wavelength
1	$A = Rc/2$	$\lambda = RSm$
2	$A = \frac{\pi Ra}{2}$	$\lambda = \frac{\pi\sqrt{2}}{R\Delta q}A$

Table 2. Amplitudes and wavelengths calculated from roughness parameters.

Specimen	Model	Amplitude, μm	Wavelength, μm
low roughness	1: *Rc*- and *RSm*-based	13.1	232
low roughness	2: *Ra*- and *RΔq*-based	10.4	89
high roughness	1: *Rc*- and *RSm*-based	18.6	245
high roughness	2: *Ra*- and *RΔq*-based	15.2	89

3.3. FE crack modelling

The two interface models were used for further FE modelling of crack growth under thermal stress. A fracture-mechanical analysis was done of a crack advancing along a sine-shaped interface of an idealised TBC. The analysis was done on a least representative cell of the TBC, as shown in Fig. 6 b), using the FE code Abaqus. The least representative cell was assumed to have a symmetry boundary on the left, and on the right hand boundary a kinematic boundary condition was applied causing the right boundary to remain plane. Crack growth was modelled both in the BC/TGO interface and the TGO/TC interface.

Fig. 6 shows the vertical stress component around a crack growing from a peak towards a valley in the TGO/TC interface. Fig. 7 shows the corresponding energy release rates, G, and stress intensity factors, K_I and K_{II}; the values in Fig. 7 are plotted versus *interface damage* where damage is defined as the horizontal length of the crack divided by half the wavelength, i.e. the damage is 1 when the crack reaches the valley. The K_I and K_{II} were obtained from Eq. (9) by post-processing of the results as demonstrated in the appendix. For both models, the specimen with high roughness gave higher G, K_I and K_{II} for most part of the crack growth; this was observed for both BC/TGO and TGO/TC cracks.

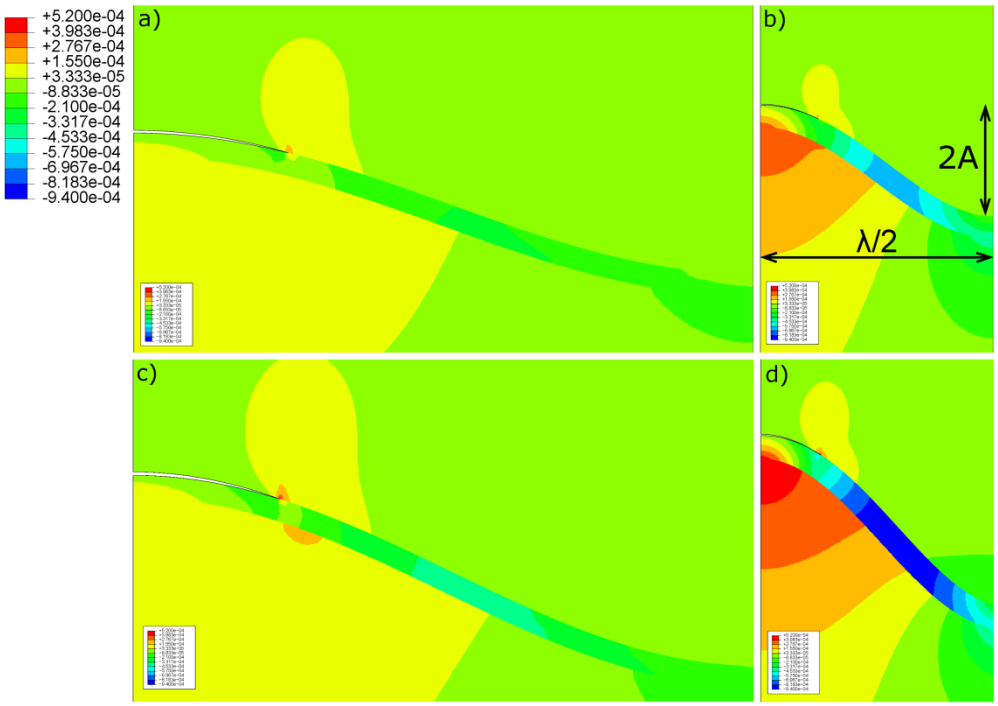

Figure 6. Vertical stress in the interface for: a) low roughness, model 1; b) low roughness, model 2; c) high roughness, model 1; d) high roughness, model 2.

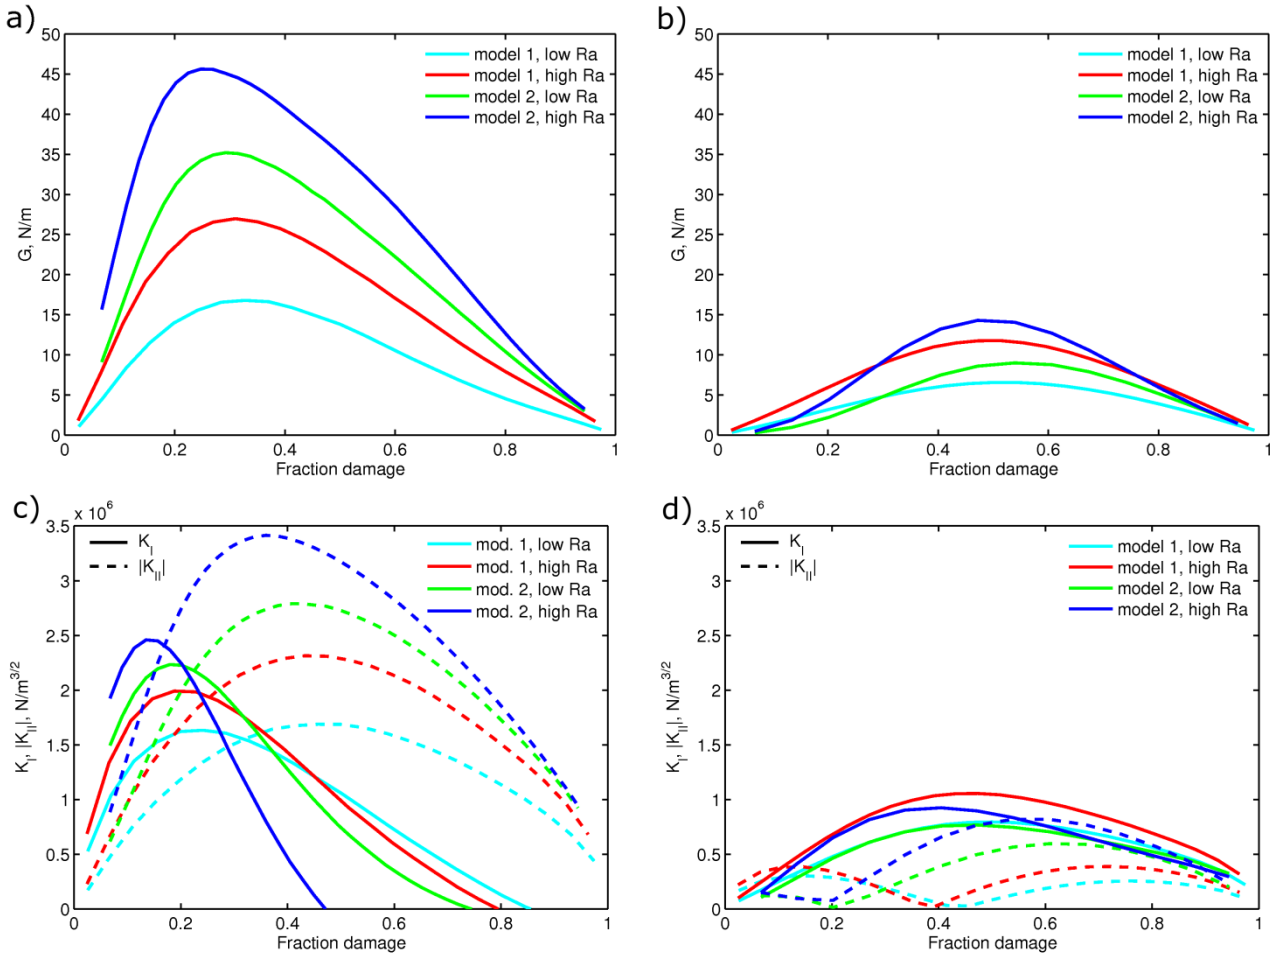

Figure 7. The calculated energy release rate, G, and stress intensity factors, K_I and K_{II} for a BC/TGO crack, a) and c), and a TGO/TC crack, b) and d).

4. Discussion

The large variation in fatigue life caused by different BC/TC interface roughness accentuates the importance of accurate interface models during FE modelling of crack growth in TBCs. Also other researchers have found the roughness to influence properties such as coating adhesion [8]. While earlier studies have investigated the influence of amplitude and wavelength on the stress field in TBCs by FE modelling [6,10-13], very little effort has been put on trying to derive those amplitudes and wavelengths from actual interfaces.

Both the suggested models were chosen so that they would agree well with the roughness parameters of the actual interfaces. Because of this, the models surely capture some of the characteristics of the interface. It is worth noting that the wavelength derived from $R\Delta q$ is the same for both specimens; also the *RSm* values indicate that the wavelengths of the specimens are in fact very similar. Casu et al. [9] argued that the wavelength could be correlated to the powder size during spraying; however, that is not the case for the specimens presented here.

The performed FE modelling may serve as a tool for evaluation of the relative behaviour of crack growth in the suggested interface models. Both model 1 and 2 showed an unexpected behaviour in that the G, as well as the K_I and K_{II}, increased with higher roughness; higher roughness was experimentally shown to increase fatigue life. Neither model 1 or 2 thus capture the experimentally observed tendency for higher interface roughness to promote longer fatigue lives.

Several explanations for this discrepancy exist, among them:

- The sine wave may be an inappropriate shape for modelling the interface.
- The increase in mechanical adhesion caused by the rougher interface may outweigh the detrimental effects of higher stresses in the interface.
- Cracks may grow in different ways than modelled here.

It is evident that further work remains before an FE model can accurately capture the experimentally observed tendency for higher interface roughness to promote longer fatigue life.

5. Conclusions

The bond coat/top coat interface roughness was shown to largely influence the thermal fatigue life of TBCs where higher roughness gave longer lives. Various roughness parameters were calculated from the interface roughness profiles, which were obtained by image analysis. *Ra*, *Rc* and *RΔq* were found to have a correlation with fatigue life where higher values gave longer life. The spacing parameter *RSm* was essentially the same for all specimens and could not have had an effect on the fatigue life. These parameters were used to establish two sine shaped interface models which were applied to FE modelling of crack growth in the specimens with shortest and longest life. The K_I and K_{II} were compared for the two specimens. Neither of the suggested models appeared to capture the experimentally observed tendency for increased life with higher roughness; the K_I and K_{II} increased with higher roughness for both suggested models. This study resulted in two interface models which were directly derived from the actual interface, but also showed that much work remains before accurate interface models can be formulated.

Appendix: Mechanics of the interface crack

From the FE solution, the energy release rate G and the crack flank displacements $u_1^{(u)}$, $u_1^{(l)}$, $u_2^{(u)}$ and $u_2^{(l)}$ at a number of nodes along the crack flank are used.

For a description of the theory of an interface crack see, for instance, [15].
The relation between G, K_I and K_{II} is given by

$$G = \frac{1}{H}(K_I^2 + K_{II}^2) \tag{6}$$

in which

$$H = \frac{2\cosh^2(\pi\epsilon)}{\frac{1}{E_1^*} + \frac{1}{E_2^*}}$$

$$\epsilon = \frac{1}{2\pi}\ln\frac{\frac{1+\nu_2}{E_2} + \kappa_1\frac{1+\nu_1}{E_1}}{\kappa_2\frac{1+\nu_2}{E_2} + \frac{1+\nu_1}{E_1}}$$

$$\kappa_i = \begin{cases} 3-4\nu_i \text{ ; plane strain} \\ \dfrac{3-\nu_i}{1+\nu_i} \text{ ; plane stress} \end{cases} ; i = 1,2$$

$$E_i^* = \begin{cases} \dfrac{E_i}{1-\nu_i^2} \text{ ; plane strain} \\ E_i \text{ ; plane stress} \end{cases} ; i = 1,2$$

Using the general fracture-mechanical solution for an interface crack, $\delta_1 = u_1^{(u)} - u_1^{(l)}$ and $\delta_2 = u_2^{(u)} - u_2^{(l)}$ are then given by

$$\begin{bmatrix}\delta_1 \\ \delta_2\end{bmatrix} = \Psi \cdot \begin{bmatrix}\sin(\epsilon\ln r) - 2\epsilon\cos(\epsilon\ln r) & 2\epsilon\sin(\epsilon\ln r) + \cos(\epsilon\ln r) \\ 2\epsilon\sin(\epsilon\ln r) + \cos(\epsilon\ln r) & -\sin(\epsilon\ln r) + 2\epsilon\cos(\epsilon\ln r)\end{bmatrix}\begin{bmatrix}K_I \\ K_{II}\end{bmatrix} \tag{7}$$

where

$$\Psi = \frac{1}{2}\left(\frac{1}{E_1^*} + \frac{1}{E_2^*}\right)\cdot\frac{8}{(1+4\epsilon^2)\cosh(\pi\epsilon)}\cdot\left(\frac{r}{2\pi}\right)^{\frac{1}{2}}$$

Eq. (7) is only used for establishing an expression for $\beta = K_I/K_{II}$:

$$\beta = \frac{K_I}{K_{II}} = \frac{[\sin(\epsilon\ln r) - 2\epsilon\cos(\epsilon\ln r)]\cdot\delta_1 + [2\epsilon\sin(\epsilon\ln r) + \cos(\epsilon\ln r)]\cdot\delta_2}{[2\epsilon\sin(\epsilon\ln r) + \cos(\epsilon\ln r)]\cdot\delta_1 - [\sin(\epsilon\ln r) - 2\epsilon\cos(\epsilon\ln r)]\cdot\delta_2} \tag{8}$$

By combining Eq. (6) and (8) we finally get

$$\begin{cases} K_I = \sqrt{\dfrac{GH}{1+\dfrac{1}{\beta^2}}} \\ K_{II} = \sqrt{\dfrac{GH}{1+\beta^2}} \end{cases} \tag{9}$$

Experimental and Numerical Investigation into the Adhesion of PVD Coatings on Minting Dies

Abstract This paper reports on the adhesion characterization of a PVD coating deposited onto mirror polished and laser frosted minting die surfaces. Experimental and numerical methods are both used to study the adhesion of the PVD coating. Stepped Rockwell-C indentation testing method is used to experimentally examine the coating adhesion. Finite element analyses of the stepped indentation adhesion tests are performed using critical loads determined from experimental testing. The analyses are performed to determine the stresses produced at the coating-substrate interface prior to coating adhesion failure and characterize the coating adhesion. The indentation simulations found that large compressive, shearing, and opening stresses were present at the coating-substrate interface in the regions where coating delamination was observed during experimental testing. The value of the compressive, opening, and shear critical stresses are found during finite element simulation of the indentation. These stress components provide good quantification of the coating adhesion strength.

Keywords PVD coating, adhesion, indentation tests, critical stresses

1. Introduction

Advances in the minting of coinage have led to the use of highly specialized die coatings. These coatings, in the form of thin hard films, are applied to die surfaces to improve their surface performance and increase their service life. The Royal Canadian Mint (RCM) uses a Cr-Ti-N based physical vapour deposition (PVD) coating applied to a hardened tool steel using magnetron sputter ion plating [1].

Coin forming is achieved by the striking of a blank disc between two dies. A collar surrounding the blanks circumference limits radial expansion of the blank during striking. The forming process produces large stresses in the die coating and steel substrate. The coating is expected to survive thousands to multiple hundreds of thousands of these impacts. To achieve long die life, the coating must be well adhered to the tool steel substrate and for this reason it is very important to ensure that adequate adhesion is achieved.

In recent years, laser engraving and frosting has started to be used on minting dies prior to coating to produce highly detailed coins with new surface finishes. Limited research has been completed in examining the effect of these new surface finishes on coating adhesion.

Many test methods exist for examining the adhesion between the coating and substrate. Among them are the indentation and the scratch adhesion tests, both of which are commonly used for testing the adhesion of thin hard coatings. These adhesion tests can be used to characterize the coating adhesion semi-quantitatively and with added analyses quantitatively [2].

Recently, the combination of experimental testing and numerical simulation has been used by several researchers to quantify coating adhesion. Indentation adhesion tests have been used together with finite element simulations to quantify the adhesion of thin hard coatings, see Pachler et al. [3], Nygards et al. [4], Xu et al. [5] and Sun et al. [6], for examples.

In this paper, the combination of experimental testing and finite element simulations of indentation tests is used to quantify the adhesion of the PVD coating used by the RCM. The adhesion to a mirror polished surface and to several laser frosted surfaces are examined. The critical loads determined during experimental testing are used in the finite element simulations. The maximum opening stress, maximum shear stress and maximum compressive stress values at the coating-substrate interface determined from finite element simulations are used to characterize the adhesion strength.

2. Background

In this section, an examination of the adhesion of thin-film systems and the testing of their adhesion are summarized. A detailed review of the use of experimental adhesion testing combined with numerical simulations to quantify the stresses produced during testing is presented for the indentation tests.

2.1. Adhesion of Thin-Film Systems

Depositing a thin hard film onto a softer substrate is only beneficial if the film has good adhesion and does not fail during normal operation. For this reason, coating adhesion must be closely examined and well understood.

Adhesion is defined as an attractive process between dissimilar materials which brings two compounds into direct contact. The strength of adhesion is difficult to quantify, but can be determined qualitatively, semi-quantitatively, and under certain scenarios quantitatively using various adhesion tests. The adhesion measurement between two materials estimated during experimental testing is generally dependent on the test method employed to determine it. For this reason, adhesion test results must be stated with the method used to determine them. Common adhesion test methods are the indentation test, scratch test, peel test, tape test, blister test, self loading test, beam bending test, pull test, and laser spallation test [2]. The indentation adhesion tests are reviewed below. Indentation adhesion tests will be used in this paper to quantify the adhesion strength of the PVD coating.

2.2. Indentation Adhesion Test

Indentation testing was first developed to quantify the hardness of materials. By applying a specific load using a standardized indenter, the hardness of a material can be determined by measuring the size of the resultant indentation crater and/or the vertical displacement of the indenter. Several varieties exist and the following is a list of the most common indentation tests: Brinell hardness test, Rockwell hardness test, Vickers hardness test, and Knoop hardness test. Corresponding ASTM standards can be found for these various tests.

Indentation tests can also be used to test the adhesion of coatings. The procedure is very similar to indentation tests completed to determine hardness except instead of measuring the indentation size, the damage caused to the coating is examined. A schematic of an indentation adhesion test is shown in Figure 1 and the apparatus used for testing in this paper is shown in Figure 2. The advantages of this test method are:

- sample preparation is minimal
- the test equipment is readily available (cost effective)
- test standards are well established
- semi-quantitative or quantitative results can be achieved

2.3. Finite Element Simulation of Indentation Adhesion Testing

In order to further understand the causes of coating failures during indentation adhesion testing, the stress state in the coating can be determined using finite element analysis. Radial and circular cracking the coatings has been studied by examining the tangential and radial stresses induced during indentation. This provides insight into through thickness coating failure. Delamination along the coating-substrate interface (adhesion failure) has been studied by examining the shear and opening stresses at the interface. Compressive stress in the coating are also be studied if buckling failure of the coating is present in experimental testing.

In this paper, indentation adhesion tests will be performed to obtain the critical load at which adhesion failure occurs for the PVD coating on each die surface. These loads will then be used in finite element analysis. The corresponding maximum opening, shear, and compressive stresses at the coating-substrate interface will be used to quantify the coating adhesion.

3. Experimental Testing of Coating Adhesion

The experimental setup, procedure, and results of the adhesion testing completed on the hard PVD coating used by the RCM are presented in this section. Eight dies were prepared and the adhesion of the coating to a mirror surface and to four laser frosted surfaces was investigated using a stepped variation of the Rockwell-C indentation adhesion test.

3.1. Sample Preparation

The dies used for testing were machined from a soft annealed bar stock of a tool steel. The bar stock was first cut to length and the top and bottom surface were machined flat using a lathe. The machined substrates were then heat treated using a vacuum heat treatment furnace. The top surface of the substrates was then polished to a mirror surface. In total eight test dies were manufactured. Four of the eight dies were laser frosted on three quarters of their surface, each with a different surface frosting (termed as Bullion, Glass Bead, Four-to-One, and Aluminum Oxide, respectively) as shown in Figure 3. The remaining four were not laser frosted. After preparing the die surface, the hard PVD coating was applied using a Teer UDP650/4 magnetron sputter ion plating system. The thickness of the Cr-Ti-N PVD coating is controlled to between two and three μm.

3.2. Stepped Indentation Adhesion Test

The stepped indentation adhesion test is a variation on the Rockwell-C indentation adhesion test. The indentation load is increased in steps and the produced indentation craters are examined for signs of coating failure. Coating delamination was defined as the failure criteria and the highest loading case which causes no coating delamination was examined for each coated die surface. The maximum survivable load provides a semi-quantitative measurement of the PVD coating adhesion and will also be used later in section 4 during finite element simulations. The maximum survivable load will be the indentation load used in simulations of indentation tests examining the stress state at the coating-substrate interface prior to coating adhesion failure.

The experimental apparatus is the same as that used for the Rockwell-C indentation adhesion tests, but for this test multiple loading conditions were used. The available weight options were 15, 30, 45, 60, 100, 150 kg_f and all were used.

3.3 Experimental Results

Multiple indentation tests were performed on each different die surface to determine the maximum load each respective coating-substrate systems could withstand. More tests were performed at loadings where the coating changed from a pass to a fail. The stepped indentation tests for the PVD coating on the mirror surface and laser frosted surfaces are conducted, in this manner. The following subsections provide observations for each die surface.

PVD coating deposited on a mirror surface

A summary of the results for the stepped indentation test of the PVD coating deposited on a mirror surface is shown in Figure 4. The indentation tests using a 45 kg_f load caused a delamination for half of the 14 tests and the tests performed using a 30 kg_f load only caused one delamination out of 14 tests. The typical results for indentations of 30 kg_f can be seen in Figure 5. Cracking is visible around the circumference of the indent crater and small radial cracks are also visible. The typical results of indents using 60, 100, and 150 kg_f were also obtained. Small delaminations are visible around the edge of the craters and the cracking is no longer radial. The 30 kg_f load was found to be the maximum load the coating could reliably survive without coating delamination.

PVD coating deposited on a Bullion type laser frosted surface

The Bullion test results show that the coating failed all three 45 kg_f and passed all three 30 kg_f. Figure 6 shows typical results for 30 kg_f loading conditions. For loads at 30 kg_f loading condition only causes cracking, while the higher loading condition causes cracking and delamination. Therefore, the 30 kg_f loading was found to be the maximum survivable indentation load for the Bullion laser frosted surface.

PVD coating deposited on a Glass Bead type laser frosted surface

The Glass Bead test results show that the maximum safe load is 15 kg_f. Typical results are shown in Figure 7 for 15 kg_f loading conditions. The 15 kg_f loading condition only causes cracking, while the 30 kg_f loading condition causes cracking and delamination. The 15 kg_f loading case was found to be the maximum survivable load for the Glass Bead laser frosted surface.

Note the other two types of laser frosted surfaces (four-to-one, and aluminum oxide), the surface roughness makes the finding of coating failure difficulty, therefore, from now on, only Bullion and Glass Bead laser surfaces are further studied together with mirror finished surface.

4. Finite Element Simulation of Indentation Adhesion Testing

This section presents the two-dimensional axisymmetric finite element simulation of indentation adhesion tests using ABAQUS [7]. The simulations are used to determine the stress state at the coating-substrate interface prior to coating failure. Focus is placed on the opening stress, the shear stress, and compressive stress at the interface since these stress components are the likely cause of delamination growth. The maximum survivable indentation loads estimated using the stepped indentation adhesion tests in Section 3 are used as indentation loads in the simulations. Simulations are completed using 15 and 30 kg_f indentation loads. The 15 kg_f simulation represents the PVD coating deposited on the Glass Bead laser frosted surface and the 30 kg_f represents the PVD coating deposited on the mirror surface and Bullion laser frosted surface.

The finite element model geometry, boundary conditions, material properties, and mesh design will be outlined below, followed by a presentation of the computed stress state at the coating-substrate interface. The opening, shear, and compressive stresses at the coating-substrate interface will provide a quantification of the PVD coating adhesion strength to the mirror surface and Glass Bead and Bullion laser frosted surfaces.

4.1 FEM Model Setup, Geometry, and Boundary Conditions

The indentation adhesion test is axisymmetric and therefore a simplified axisymmetric finite element model was used to simulate the test. ABAQUS/Standard version 6.8 [7] was used for the finite element analysis. The indentation adhesion test consists of three steps, first the indenter is lowered to the die surface and then load is applied and ramped up to the maximum load. Finally the load is removed and the indenter is raised off the die surface. The indentation test was modeled as quasi-static and all time-dependant effects were neglected. The indenter and die geometry and the boundary conditions are presented below.

Indenter Geometry

The indenter geometry used is that of a Rockwell-C cone indenter as defined by ASTM E18-8b [8]. The indenter has a 200 μm radius cone tip and 60° half angle. The axisymmetric indenter model was defined as presented in Figure 8 and the geometry was fixed to a reference point. Displacements and loads are applied to the indenter by moving or loading the reference point.

Die Geometry

The die geometry used is shown in Figure 9. An axisymmetric boundary condition is placed on the axis of symmetry and vertical displacement is fixed at the bottom of the model. The PVD coating thickness used by the RCM is controlled to be between two and three microns. The average of the thickness range, 2.5 μm, was selected for the model. The overall size of the die segment modeled was one millimetre by one millimetre and was selected after testing different model sizes. Multiple model sizes were tested and the model size selected was chosen since it minimized the model size while not affecting the stress values at the coating-substrate interface.

4.2 Material and Interface Properties

Indenter Properties

The Rockwell-C indenter tip is made of diamond which is significantly harder than the die substrate. The deflection of the diamond indenter during loading up to the maximum indentation load used, 30 kg_f, is negligible and therefore it was modeled as an analytical rigid body.

Substrate Properties

The substrate of the die samples used for experimental testing was a tool steel and it was modeled as an elastoplastic material with isotropic strain hardening. The material properties used during indentation simulations are shown in Table 1. The elastic modulus and yield strength values were taken from a tool steel material datasheet [9]. The Ramberg-Osgood stress strain relationship was used to define the materials strain hardening as follows:

$$\varepsilon = \frac{\sigma}{E} + \alpha \frac{\sigma_y}{E} \left(\frac{\sigma}{\sigma_y} \right)^n \quad (1)$$

where α is the yield offset and n is the strain hardening exponent. Assuming an industry standard strain value of 0.2 % was used when defining the yield strength of the tool steel, α can be calculated to be 0.18.

The strain hardening exponent was determined using a numerical and experimental approach as described by J. Yan et al. [10]. A strain hardening exponent value (n) of 15 was found to agree well with the experimental data and therefore n = 15 was used as the strain hardening exponent for the substrate.

Coating Properties

The material properties used for defining the Cr-Ti-N based hard PVD coating are shown on Table 2. The elastic modulus, yield strength, and Poisson's ratio values for the PVD coating were determined using nano-indentation testing completed by McLean [11]. As recommended by Piana et. al [12], Ramberg-Osgood strain hardening parameters of α = 1 and n = 100 were chosen to produce a material with minimal strain hardening.

Interface Properties

The loading conditions used during the indentation test simulations are below the failure load of the coating-substrate interface, therefore the interface between the coating and substrate was modeled as being in perfect adhesion.

The interaction between the indenter and the coating surface was defined using the "Interaction Module" built into ABAQUS [7]. A contact pair was defined, with indenter being the master surface and the coating surface being the slave surface. The indenter is ideal for the master surface because it is an analytical rigid body and is accurately defined without discretization using an arc and a line. To complete the interaction definition the tangential and normal behaviour between the two surfaces must be defined. The tangential behaviour was defined as frictionless as recommended by Piana et al. [12]. Neglecting friction has an insignificant effect on the results of indentation test simulations [12]. The normal behaviour was defined as "hard contact", which does not allow the coating top surface nodes to pass through the indenter geometry. Separation after contact was permitted to allow for unloading of the indenter.

4.3 Mesh Design

The mesh was refined towards the indentation location to properly model the large deformation and steep stress gradient. Due to the large deformation in the region of the indentation, it is important to enable nonlinear geometry in ABAQUS [7]. The finite element models were discretized using 4-node bilinear axisymmetric quadrilateral elements, which are defined as CAX4R in the ABAQUS element library [7]. This element type is a first order continuum element and uses reduced integration. Reduced integration lowers the number of constraints introduced by the elements, thus decreasing the CPU time and storage requirements and also preventing volumetric locking. The "hourglass control" is enabled to address the potential zero energy deformation modes (hourglass modes) introduced when using reduced integration [7]. The mesh design of the

coating-substrate system is shown in Figure 10. The shown model uses 4 element layers to discretize the coating, 8, 16 and 25 layered meshes were also used for mesh refinement analysis. A node set is defined along the coating-substrate interface for easy retrieval of displacement and stress data during post processing.

4.4. FEA results

Stress Transformation

In order to properly evaluate the stresses at the coating-substrate interface, the global stress components obtained from ABAQUS [7] must be transformed into local coordinate stress components. Figure 11 shows how the global coordinates axes (x-y-z) relate to the local coordinates axes (x'-y'-z'). The x' local coordinate axis is parallel to the coating-substrate interface and the y' local coordinate axis is perpendicular to the coating-substrate interface. The following equations show how the global stress components were transformed into local stress components [13]:

$$\sigma_{x'x'} = \frac{\sigma_{xx}+\sigma_{yy}}{2} + \frac{\sigma_{xx}-\sigma_{yy}}{2}\cos 2\theta + \tau_{xy}\sin 2\theta \quad (2)$$

$$\sigma_{y'y'} = \frac{\sigma_{xx}+\sigma_{yy}}{2} - \frac{\sigma_{xx}-\sigma_{yy}}{2}\cos 2\theta - \tau_{xy}\sin 2\theta \quad (3)$$

$$\sigma_{z'z'} = \sigma_{zz} \quad (4)$$

$$\tau_{x'y'} = \frac{\sigma_{xx}-\sigma_{yy}}{2}\sin 2\theta + \tau_{xy}\cos 2\theta \quad (5)$$

Going forward, $\sigma_{x'x'}$, $\sigma_{y'y'}$, $\sigma_{z'z'}$, and $\tau_{x'y'}$ will be called the radial stress, the opening stress, the hoop stress and the shear stress. Note that the stress component ($\sigma_{x'x'}$) named radial stress is not perfectly radial once x' is not aligned with x, but the name is still used for simplicity. The two out of plane shear stress components, τ_{xz} and τ_{yz}, are zero due to the problem being axisymmetric.

Results

The stress state at the coating-substrate interface was examined at two times during the simulations, first when the maximum indentation load is applied and second after unloading of the indenter. Von Mises stress, radial stress ($\sigma_{x'x'}$), hoop stress ($\sigma_{z'z'}$), opening stress ($\sigma_{y'y'}$), and shear stress ($\tau_{x'y'}$) along the coating-substrate interface for both the maximum load and after unloading states are obtained. The stress in the coating material and substrate material at the interface are both included in the presented stress results.

Von Mises Stress Results

Von Mises stress contour plots are shown in Figure 12 (maximum load case) and Figure 13 (after unloading) for the 30 kg_f indentation case. At maximum load, large von Mises stresses occur in the coating under the indenter and extend outward past the indentation radius. After unloading, the von Mises stress is significantly reduced inside the crater region, but large values are still present outside the indentation radius. Very low von Mises stress gradients are present near the bottom and right edges of the model, which shows that the model was properly sized. Results for 15 kg_f are also obtained.

The maximum von Mises stress experienced in the coating is 8.31 GPa and 8.39 GPa for the 15

and 30 kg_f loading conditions respectively. The maximum von Mises stress experienced in the substrate is 3.10 GPa and 3.23 GPa for the 15 and 30 kg_f loading conditions respectively. All the maximum von Mises stresses occur at the maximum load condition.

Results of Stress Components

The opening stress ($\sigma_{y'y'}$) distribution along the interface is obtained for (15 kg_f) and (30 kg_f). The coating and substrate opening stress distribution match very well as expected due to stress equilibrium perpendicular to the interface [14]. The maximum opening stress occurs near the indentation crater edge after unloading with values of 0.896 GPa (coating) and 0.872 GPa (substrate) for the 15 kg_f loading case and of 1.18 GPa (coating) and 1.16 GPa (substrate) for the 30 kg_f loading case. These simulated opening stresses provide a measure of the coating adhesion strength for the mirror surface and Bullion and Glass Bead laser frosted surface.

To satisfy equilibrium conditions along the coating-substrate interface, the shear stress ($\tau_{x'y'}$) in the coating and substrate materials must be equal and the results agree well with this equilibrium condition [14]. The difference between the coating and substrate shear stress value is minimal except near the indentation crater edge where a nearly 20% difference occurs. The maximum shear stress values along the interface are 1.89 GPa (coating) and 1.67 GPa (substrate) for the 15 kg_f loading case and of 2.16 GPa (coating) and 1.78 GPa (substrate) for the 30 kg_f loading case. These maximum shear stress values occur at maximum loading of the indenter and provide a measure of the coating adhesion strength for the simulated surface types.

The radial stress ($\sigma_{x'x'}$) distributions along the coating-substrate interface for the 15 and 30 kg_f loading cases are obtained. The maximum compressive radial stress occurs at maximum loading, the values for the 15 and 30 kg_f loading conditions are 11.29 GPa and 12.69 GPa. Table 3 summarised the maximum values of these stress components.

5. Conclusions

The stress state at the coating-substrate interface during 15 and 30 kg_f indentation tests has been simulated. Peak stress values were found in the region near the indentation crater edge, which is where failure was observed during experimental testing. Using finite element simulations, the PVD coating deposited on a mirror surface and Glass Bead and Bullion laser frosted surfaces was found to be capable of surviving the loads corresponding to stress values presented in Table 3. The peak opening and shear stresses at the coating-substrate interface provide a characterization of the coating adhesion strength since these two stress components are capable of directly causing delamination growth and coating adhesion failure. Significant compressive radial stress is present in the coating outside the indentation crater. In the presence of coating adhesion defects, this compressive stress can lead to coating buckling and spallation.

The three stress components (opening, shear, and radial compressive) reach their peak near the indentation crater edge, which is the location where coating delamination occurred during experimental testing at higher loads. Now that the stress state at the coating-substrate interface produced during indentation adhesion tests has been simulated and analyzed, a similar process can be performed for the scratch adhesion tests and the results can be compared.

Abstract In this work, the change of Young's modulus, hardness, and bending strength of air plasma sprayed ceramic coating systems after different thermal shock was investigated by nanoindentation tests and three-point bending tests. The results of these tests show that the Young's modulus and hardness of nanostructured coatings and the bending strength of nanostructured coating-substrate systems fluctuate relatively slightly as the thermal shock temperature difference increases, while the Young's modulus and hardness of micro-structured coatings and the bending strength of micro-structured coating-substrate systems increase with the thermal shock temperature difference monotonously. Therefore, in the temperature range we studied, the mechanical properties of nanostructured coatings are less sensitive to the change of temperature and more stable than micro-structured coatings.

Keywords Ceramic coating systems, Thermal shock, Young's modulus, Bending strength

1. Introduction

Ceramic coatings are widely used because of their excellent thermal insulation, wear resistance and corrosion resistance [1, 2]. In the service condition of ceramic coatings, thermal shock frequently occurs. Therefore, in-depth understanding of the influence of thermal shock on mechanical properties of ceramic coating systems becomes significant. Some relevant studies on the effect of thermal shock on ceramic coatings have been reported. Bo Liang et al. [3] investigated the thermal shock resistances of nanostructured and conventional zirconia coatings deposited by atmospheric plasma spraying, and found that the nanostructured as-sprayed coating possessed better thermal shock resistance than the conventional coating. Chunxia Zhang et al. [4] studied the influence of thermal shock on insulation effect of nano-multilayer thermal barrier coatings, and acquired the change of thermal conductivity and impedance as function of thermal shock number. Moreover, some researches have shown that thermal shock could obviously affect the mechanical properties of Si-SiC coated C/C composites [5], fiber concrete [6], alumina–mullite–zirconia and alumina–mullite refractory materials[7]. However, there are few reports on the influence of thermal shock on mechanical properties of ceramic coating systems. Therefore, in this work, we studied the change of elastic modulus, hardness, and bending strength of air plasma sprayed ceramic coating systems by nanoindentation tests and three-point bending tests.

2. Experimental procedure

2.1. Specimen preparation

The ceramic coating system used in this study consists of YSZ (8 wt.% Y2O3 stabilized ZrO2) top coat prepared with atmospheric plasma spraying (APS), NiCrAlY (25.42wt.%Cr-5.1wt.%Al-0.48wt.%Y) bond coat prepared with high velocity oxygen fuel (HVOF) process and Ni-based superalloy substrate. The thickness of the top coat, bond coat and substrate is approximately 0.1 mm, 0.05 mm, and 1.35 mm separately. In our study, two kinds of ceramic coating layers were prepared---nano-scale and micro-scale microstructure, respectively.

2.2. Thermal shock tests

In the thermal shock tests, the specimens were heated with a rate of 20℃/min up to a preset temperature T_m (200 ℃, 500 ℃, and 800 ℃, respectively) and held at T_m for 20 min [8]. After that, the heated specimens were quickly placed into water at the ambient temperature (25 ℃) for quenching and maintained for 10 min [8]. Therefore, the thermal shock temperature difference ΔT is 175 ℃, 475 ℃, and 775 ℃, respectively. The mechanical property was then measured using nanoindentation and bending tests at room temperature.

2.3. Nanoindentation tests

The grinded and polished coatings were analyzed by nanoindentation tests in which the Agilent Technologies Nano Indenter G200 System was used. All indentations were done with a triangular pyramid Berkovich diamond indenter. The total number of measurement points for each sample was chosen to be 10. The indentation depth was 300 nm and the maximum load was 12 mN in the tests. The typical distance between two neighboring sites is above 50 μm aiming to avoid possible interference of measurements. During the indentation test，the indentation load and depth are measured by load cell and gap sensors.

2.4. Three-point bending tests

The three-point bending tests were done with a computer control electronic universal testing machine RG2000-5. The nominal dimensions of each specimen for the three-point bending test are 3 mm wide, 1.5 mm high and 15 mm long. The span length of the support is 10 mm. The tests were carried out under constant displacement rates 0.1 mm/min at the loading point. Consequently, we could acquire a series of load-displacement curves in the loading process.

3. Results and discussion

3.1. Influence of thermal shock on Young's modulus and hardness of ceramic coatings

In the temperature range of 25-800℃，the results of these tests show that the Young's modulus E and hardness H of nanostructured coatings fluctuate relatively slightly as the thermal shock

temperature difference ΔT increases, while that of micro-structured coatings increase with ΔT monotonously, as shown in Fig. 1. For the as-spayed coating, the Young's modulus of nanostructured coating $E_c = 161.2$ GPa and micro-structured coating $E_c = 101.4$ GPa, which are in good general agreement with former reports [9] [10] ; the hardness of nanostructured coating $H_c = 11.6$ GPa and micro-structured coating $H_c = 5.4$ GPa, which are close to some data in the literatures[2, 10] [11]. After the thermal shock test, we carefully examined the microstructure of specimens and found that the porosity of micro-structured coatings reduces relatively obviously with the increase of ΔT, while that of the nanostructured coatings changes a little. From the literature[12], for porous materials, the Young's modulus E can be described empirically by $E = E_0 \exp(-ap)$, where E_0 is the zero-porosity Young's modulus, p is the porosity, and a is an empirical constant. Therefore, the Young's modulus will increase as the porosity decreases, and our test results agree with this theoretical model.

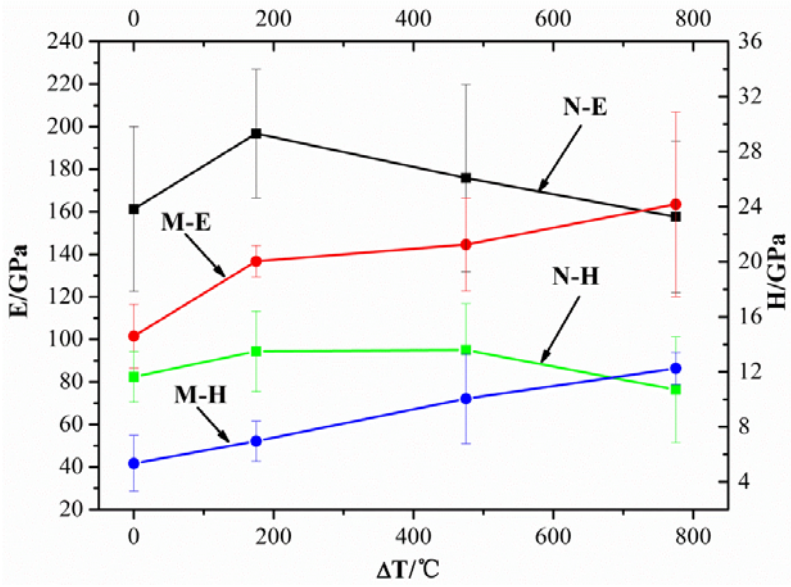

Figure 1. The change of Young's modulus and hardness of coatings with different thermal shock temperature difference ΔT (N-nanostructured coatings, M-micro-structured coatings).

3.2. Influence of thermal shock on bending strength of coating-substrate systems

One of the curves of the load F and loading point displacement w in our experiments is shown in Fig. 2. The maximum load was considered as the failure load and used to calculate the bending strength of coating-substrate systems.

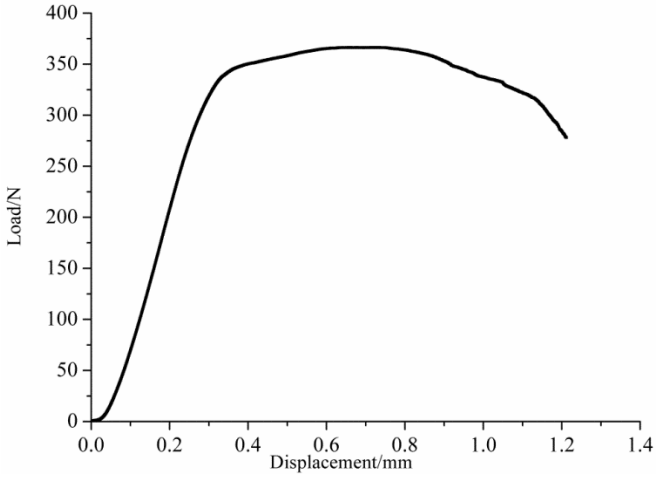

Figure 2. The load-displacement curve in three-point bending test.

During the three-point bending test, the largest normal stress at the failure load was considered to be the bending strength σ_b, which can be determined by Eq. (1) [13] as following:

$$\sigma_b = 0.8 \cdot (1 - \frac{4h}{3\pi l}) \cdot \frac{P_f l}{4} \cdot \frac{1}{M_0} \cdot \frac{E_c(h_c + \varsigma)}{E_s(h_s - \varsigma)} \qquad (1)$$

Where *l* and *h* are the span length of support and the height of specimens respectively, P_f is the failure load, h_c and h_s are the thickness of the coating and substrate respectively, E_c and E_s are the Young's modulus of coating and substrate respectively, ς is the distance between the neutral axis and the interface of the layered specimen, and M_0 is the resultant moment of the cross section. The values of ς and M_0 can be determined by $\varsigma = \frac{E_s h_s^2 - E_c h_c^2}{2(E_s h_s + E_c h_c)}$ and $M_0 = \frac{b}{3(\varsigma - h_s)}(h_s^3 - 3h_s^2\varsigma + 3h_s\varsigma^2) + \frac{E_c}{E_s}\frac{b}{3(\varsigma - h_s)}(h_c^3 + 3h_c^2\varsigma + 3h_c\varsigma^2)$, respectively, where *b* is the width of the specimen. The bending strength of all specimens obtained by Eq. (1) is presented in Fig. 3. It is worth mentioning that (1) the top coat and bond coat are considered as one layer, i.e. the coating, considering that Young's modulus of the bond coat is about 155 GPa [10, 14] which is close to that of the top coat, and the top coat and bond coat bind well according to our experimental observation, (2) the value of E_c is obtained from Fig. 2, and (3) the value of E_s is assumed constant and taken as 200 GPa [10] [15].

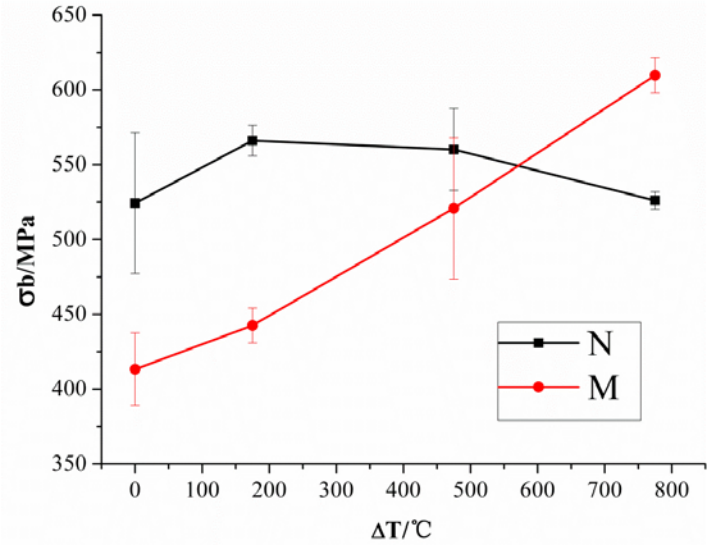

Figure 3. The change of bending strength of coating-substrate systems with different thermal shock temperature difference ΔT (N- nanostructured coatings, M- micro-structured coatings).

From Fig. 3, we can see that like the change of Young's modulus and hardness of coatings with different thermal shock temperature difference ΔT, the bending strength of nanostructured coating-substrate systems fluctuate relatively slightly as ΔT increases, while that of micro-structured coating-substrate systems increase monotonously with ΔT.

The bending strength of coating-substrate systems is determined by the strength of coating and substrate, and the interfacial bonding strength. In the temperature range of 25-800℃, the yield strength of the substrate is considered as constant[16]. Therefore, the main parameters are the strength of coating and the interfacial bonding strength. For porous materials, like the relationship between Young's modulus and porosity, the strength can be empirically described by $\sigma = \sigma_0 \exp(-kp)$ [17], where σ_0 is the zero-porosity strength, p is the porosity, and k is an empirical constant. Therefore, the strength will increase as the porosity decreases. Besides, according to our experimental observation, for micro-structured coating-substrate systems, the interfacial bonding strength decreases as the thermal shock temperature difference increases, while that of the nanostructured coating-substrate systems changes a little. Since the strength of coating-substrate systems is obviously influenced by the interfacial bonding strength, and weakening of interfaces helps to increase the bending strength of coating-substrate systems, [5] we can see that it is the combined effect of porosity of the coating and interfacial bonding strength of the coating-substrate that leads to the result of our tests.

4. Conclusions

In this work, the change of elastic modulus, hardness and bending strength of air plasma sprayed ceramic coating systems after different thermal shock was investigated by nanoindentation tests and three-point bending tests. The results of these tests show that (1) since the porosity of

micro-structured coatings reduces relatively obviously, while that of the nanostructured coatings changes a little with the increase of thermal shock temperature difference, the Young's modulus and hardness of nanostructured coatings fluctuate relatively slightly, while that of the micro-structured coatings monotonously increase as the thermal shock temperature difference increases. (2) Apart from the difference in porosity of the coating, the interfacial bonding strength of micro-structured coating-substrate systems decreases as the temperature increases, while that of the nanostructured coating-substrate systems changes a little. Therefore, the bending strength of nanostructured coating-substrate systems fluctuates relatively slightly, while that of micro-structured coating-substrate systems monotonously increases as the thermal shock temperature difference increases. In conclusion, in the temperature range we studied, the mechanical properties of nanostructured coatings are less sensitive to the change of temperature and more stable than micro-structured coatings.

Abstract In a thin-film substrate system in-plane compressive stress is commonly generated in the film due to thermal mismatch in operation or fabrication process. If the stress exceeds a critical value, part of the film may buckle out of plane along the defective interface. After delamination buckling, the interface crack at the ends may propagate. In the whole process, the compliance of the substrate compared with the film plays an important role. In this work, we study a circular film subject to compressive stress on an infinitely thick substrate. We study the effects of compliance of the substrate by modeling the system as a plate on an elastic foundation. The critical buckling condition is formulated. The asymptotic solutions of post-buckling deformation and the corresponding energy release rate of the interface crack are obtained with perturbation methods. The results show that the more compliant the substrate is, the easier for the film to buckle and easier for the interface crack to propagate after buckling.

Keywords buckling delamination, interface crack, film-substrate system, post-buckling

1. Introduction

The thin film-substrate system is widely used in various of applications, such as thermal barrier coatings and micro-electronics [1-4]. In operation or fabrication process, in-plane compressive stress is commonly generated in the film due to thermal mismatch. If the stress exceeds a critical value, part of the film may buckle out of plane along the defective interface. Delamination buckling is considered as one of the most important failure modes in thin-film substrate system. Delamination buckling on a stiff substrate is well studied in the literature [5-7]. If the substrate is compliant, the critical buckling load and the energy release rate of the interface crack can be significantly affected[8]. Yu and Hutchinson analyzed the effects of compliance of substrate by introducing compliance coefficients [9]. After delamination buckling happens, the film and the substrate are detached. In this work we study the effects of compliance of the substrate by modeling the system as a plate on an elastic foundation. We use perturbation method to obtain the asymptotic solutions of post-buckling deformation and calculate the mode-adjusted energy release rate of the interface crack after buckling happens. Analysis of a plate on a foundation is a classical problem in mechanics, which can be an effective model of analyzing film-substrate system.

2. Governing equations

2.1. A circular plate on an elastic foundation

We study the delamination buckling of the thin film as buckling of a thin plate on an elastic foundation. To focus on the effects of the compliance of the substrate we study a simple configuration, a circular plate on an infinitely thick foundation, as shown in Fig. 1. We use the linear Wrinkler foundation model

$$F = Kw, \tag{1}$$

where w is the deflection, K the stiffness of the foundation, F the effective reaction force.

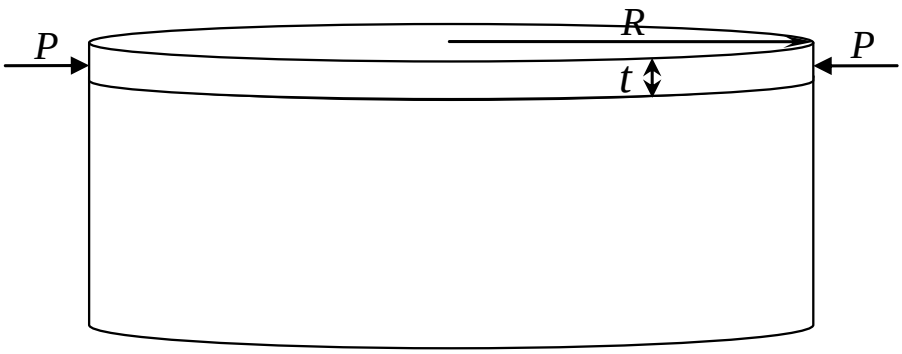

Fig.1. Schematics of a circular plate on an elastic foundation.

The equations of post-buckling of a thin plate on a linear Wrinkler foundation are [10]

$$\dddot{w}+\frac{2\ddot{w}}{r}-\frac{\ddot{w}}{r^2}+\frac{\dot{w}}{r^3}-\frac{12}{t^2}\left(\dot{u}+\frac{\dot{w}^2}{2}+\nu\frac{u}{r}\right)\ddot{w}-\frac{12}{t^2}\left(\nu\dot{u}+\nu\frac{\dot{w}^2}{2}+\frac{u}{r}\right)\frac{\dot{w}}{r}+\frac{P}{D}\left(\ddot{w}+\frac{\dot{w}}{r}\right)+\frac{K}{D}w=0, \quad (2)$$

$$\ddot{u}+\frac{\dot{u}}{r}-\frac{u}{r^2}+\dot{w}\ddot{w}+\frac{(1-\nu)\dot{w}^2}{2r}=0, \quad (3)$$

where u is the in-plane displacement, ν the Poisson's ratio, t the thickness of the plate, D the bending stiffness of the plate, P the in-plane load, $\dot{w}$ denotes derivative with respect to r. The deformation is assumed to be axisymmetric. A material point at location r in deformed state is fully described by deflection $w(r)$ and in-plane displacement $u(r)$.

We normalize the quantities as the following: radius of a material point $x=r/R$, deflection $\overline{w}=w/t$, in-plane displacement $\overline{u}=uR/t^2$, in-plane load $\overline{P}=PR^2/D$, foundation stiffness $\overline{K}=KR^4/D$. The normalized governing equations are

$$\dddot{\overline{w}}+\frac{2\ddot{\overline{w}}}{x}-\frac{\ddot{\overline{w}}}{x^2}+\frac{\dot{\overline{w}}}{x^3}-12\left(\dot{\overline{u}}+\frac{\dot{\overline{w}}^2}{2}+\nu\frac{\overline{u}}{x}\right)\ddot{\overline{w}}-12\left(\nu\dot{\overline{u}}+\nu\frac{\dot{\overline{w}}^2}{2}+\frac{\overline{u}}{x}\right)\frac{\dot{\overline{w}}}{x}+\overline{P}\left(\ddot{\overline{w}}+\frac{\dot{\overline{w}}}{x}\right)+\overline{K}\overline{w}=0, \quad (4)$$

$$\ddot{u}+\frac{\dot{u}}{r}-\frac{u}{r^2}+\dot{w}\ddot{w}+\frac{(1-\nu)\dot{w}^2}{2r}=0, \quad (5)$$

where $\dot{\overline{w}}$ denotes derivative with respect to x.

2.2. Strain energy release rate

In the film-substrate system, the interface crack may propagate after delamination buckling happens. The strain energy release rate is given in [11]

$$G=\frac{6(1-\nu^2)}{Et^3}\left(M^2+t^2\Delta N^2/12\right), \quad (6)$$

where E is the Young's modulus, M is the bending moment at the delamination edge, ΔN is the change of the in-plane force. The normalized form of these quantities are $\overline{M}=MR^2/(Dt)$, $\Delta\overline{N}=\Delta NR^2/D$, $\overline{G}=\overline{M}^2+\Delta\overline{N}^2/12$.

The crack is in a mixed mode of Mode I and Mode II. Define phase angle of mixture ψ. In this configuration the phase angle of mixture can be calculated as

$$\tan\psi=\frac{\sqrt{12}M\cos\omega+t\Delta N\sin\omega}{-\sqrt{12}M\sin\omega+t\Delta N\cos\omega}, \quad (7)$$

where $\omega=\omega(\phi,\varphi)$ is the phase factor, ϕ and φ are Dundur's elastic mismatch parameters. In the calculation, we set Poisson's ratio $\nu_{film}=\nu_{substrate}=1/3$. The details of value of ω can be found in the literature [11].

Considering the effects of mode mixture, the strain energy release rate is adjusted as

$$\bar{G}_{\psi}=\frac{\bar{G}}{f(\psi)}, \tag{8}$$

where the function $f(\psi)$ can be experimentally fitted. One of the common forms of $f(\psi)$ is

$$f(\psi)=1+(1-\lambda)\tan^2\psi, \tag{9}$$

where λ is the fitting parameter. In the calculation we set $\lambda=0.3$.

3. Asymptotic solutions

The perturbation method is an effective way of solving problems of plate undergoing large deflection[12]. We expand the displacement and load as

$$\bar{w}(x)=sw_1(x)+s^2w_2(x)+s^3w_3(x)+\ldots, \tag{10}$$

$$\bar{u}(x)=su_1(x)+s^2u_2(x)+s^3u_3(x)+\ldots, \tag{11}$$

$$\bar{P}=P_c+sP^{(1)}+\frac{1}{2}s^2P^{(2)}+\ldots, \tag{12}$$

where s is the perturbation parameter.

Inserting Eqs. (10)-(12) into Eqs. (4) and (5) we obtain the decoupled equations of coefficients in the order of s, s^2, s^3. The out-of-plane equations are

$$\dddot{w}_1+\frac{2\ddot{w}_1}{x}-\frac{\ddot{w}_1}{x^2}+\frac{\dot{w}_1}{x^3}+P_c\left(\ddot{w}_1+\frac{\dot{w}_1}{x}\right)+\bar{K}w_1=0, \tag{13}$$

$$\dddot{w}_2+\frac{2\ddot{w}_2}{x}-\frac{\ddot{w}_2}{x^2}+\frac{\dot{w}_2}{x^3}-12\left(\dot{u}_1+\nu\frac{u_1}{x}\right)\ddot{w}_1-12\left(\nu\dot{u}_1+\frac{u_1}{x}\right)\frac{\dot{w}_1}{x}+P_c\ddot{w}_2+P^{(1)}\ddot{w}_1+\bar{K}w_2=0, \tag{14}$$

$$\begin{aligned}&\dddot{w}_3(x)+\frac{2\ddot{w}_3(x)}{x}-\frac{\ddot{w}_3(x)}{x^2}+\frac{\dot{w}_3(x)}{x^3}\\&-12\left(\dot{u}_1(x)\dot{w}_2(x)+\dot{u}_2(x)\dot{w}_1(x)+\frac{\dot{w}_1(x)^2\ddot{w}_1(x)}{2}+\nu\frac{u_1(x)\ddot{w}_2(x)+u_2(x)\ddot{w}_1(x)}{x}\right)\\&-12\left(\nu\frac{\dot{u}_1(x)\dot{w}_2(x)+\dot{u}_2(x)\dot{w}_1(x)}{x}+\nu\frac{\dot{w}_1(x)^2\dot{w}_1(x)}{2x}+\frac{u_1(x)\dot{w}_2(x)+u_2(x)\dot{w}_1(x)}{x^2}\right)\\&+P_c\left(\ddot{w}_3(x)+\frac{\dot{w}_3(x)}{x}\right)+P^{(1)}\left(\ddot{w}_2(x)+\frac{\dot{w}_2(x)}{x}\right)+\frac{1}{2}P^{(2)}\left(\ddot{w}_1(x)+\frac{\dot{w}_1(x)}{x}\right)+\bar{K}w_3(x)=0\end{aligned}, \tag{15}$$

The in-plane equations are

$$\ddot{u}_1+\frac{\dot{u}_1}{x}-\frac{u_1}{x^2}=0, \tag{16}$$

$$\ddot{u}_2+\frac{\dot{u}_2}{x}-\frac{u_2}{x^2}+\dot{w}_1\ddot{w}_1+\frac{(1-\nu)\dot{w}_1^2}{2x}=0, \tag{17}$$

$$\ddot{u}_3+\frac{\dot{u}_3}{x}-\frac{u_3}{x^2}+\dot{w}_1\ddot{w}_2+\dot{w}_2\ddot{w}_1+\frac{(1-\nu)\dot{w}_1\dot{w}_2}{x}=0, \tag{18}$$

The edge is clamped. The boundary conditions are

$$u\big|_{x=0}=0,\quad \dot{w}\big|_{x=0}=0,\quad \left(\ddot{w}-\frac{\dot{w}}{r}\right)\Big|_{x=0}=0, \tag{19}$$

$$u\big|_{x=1}=0,\quad w\big|_{x=1}=0,\quad \dot{w}\big|_{x=1}=0, \tag{20}$$

We use the central deflection w_0 as the perturbation parameter. We have additional condition $w_1(0)=1$; $w_j(0)=0 \quad j\neq 1$. Inspecting the six equations (13)-(18) together with boundary conditions (19) and (20), we can easily obtain solutions $u_1=0, w_2=0$ and $P^{(1)}=0$. Therefore, only three equations (13), (15) and (17) are to be solved. The general solution of Eq.(13) is

$$w_1(x)=C_1J_0(\alpha x)+C_2J_0(\beta x), \tag{21}$$

where $\alpha=\left(\frac{P_c-\sqrt{P_c^2-4\bar{K}}}{2}\right)^{1/2}$, $\beta=\left(\frac{P_c+\sqrt{P_c^2-4\bar{K}}}{2}\right)^{1/2}$.

Inserting boundary conditions into Eq. (21) we obtain

$$C_1J_0(\alpha)+(1-C_1)J_0(\beta)=0, \tag{22}$$

$$\alpha C_1J_1(\alpha x)+\beta(1-C_1)J_1(\beta x)=0, \tag{23}$$

Once the foundation stiffness $\bar{K}$ is given, we can obtain P_c and C_1 by solving Eqs. (22) and (23). Subsequently we use Eq. (17) to solve u_2. A simple way to obtain u_2 is expanding Bessel function into Taylor series. Once w_1 and u_2 are known, we use Eq. (15) to solve $P^{(2)}$. We multiply $w_1(x)x$ on both sides of Eq. (15) and integrate from 0 to 1. Using the feature of Bessel function, the solving process can be simplified. Similar process can be iterated to obtain more accurate solution by expanding displacement fields to higher order terms and solving higher order equations. Once the displacement fields are known, the bending moment at the edge, the change of in-plane force and the energy release rate can be obtained.

4. Results and discussions

The critical buckling load P_c at different value of foundation stiffness $\bar{K}$ is plotted in Fig. 2. It can be seen that as the foundation become stiffer, the critical buckling load increases. Using the way of normalization in this work, the relation between P_c and $\bar{K}$ is approximately linear. This result is consistent with the literature, where different normalized quantities are used to plot [13].

The post-buckling path of central deflection is plotted in Fig. 3. The horizontal axis σ/σ_c is the in-plane stress over the critical buckling stress. Note that, the critical buckling stress σ_c at different foundation stiffness is different. But for the aid of comparison, we plot them into the same figure. The curve with $\bar{K}=0$ reduces to classical post-buckling path of a thin circular plate without foundation. It is found that stiff foundation lowers the central deflection, especially in the initial stage of post-buckling.

The mode-adjusted energy release rate G_ψ given by Eqs. (6)-(9) is plotted in Fig. 4. The displacement fields solved with perturbation method are relatively accurate, while the bending moment and in-plane force are not especially when the post-buckling stress is high. Therefore, in

Fig. 4 we plot the post-buckling stress up to $\sigma / \sigma_c \approx 4$. It can be seen that the more compliant the substrate is, the easier for the interface crack to propagate after buckling.

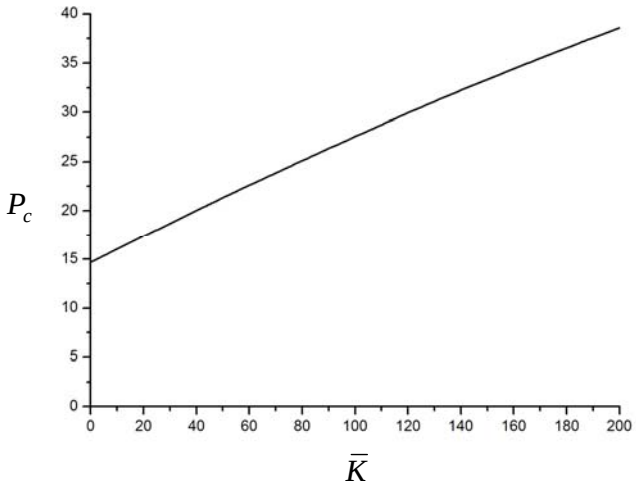

Fig. 2. Critical buckling load at different foundation stiffness.

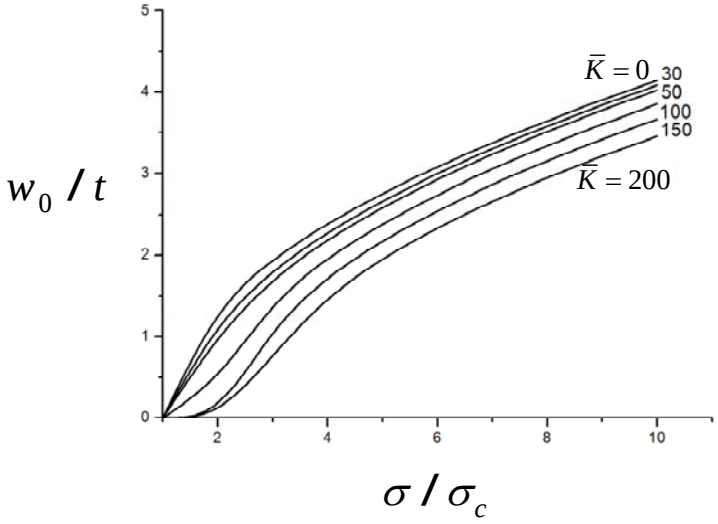

Fig. 3. Post-buckling path with different foundation stiffness.

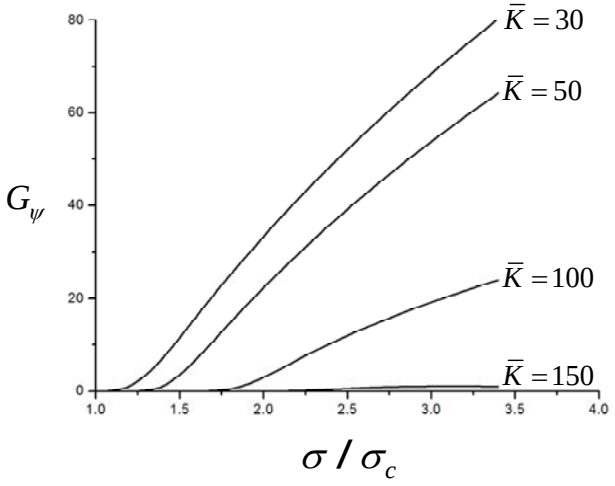

Fig. 4. Mode-adjusted energy release rate of interface crack with different foundation stiffness.

5. Conclusion

In the thin film-substrate system, compressive stress in the film can induce delamination buckling. We study the effects of compliance of the substrate by modeling the system as a plate on an elastic foundation. We use perturbation method to obtain the asymptotic solutions of post-buckling deformation and calculate the mode-adjusted energy release rate of the interface crack after buckling happens. The results show that the more compliant the substrate is, the easier for the film to buckle and easier for the interface crack to propagate after buckling.

Abstract The accurate and efficient evaluation of nearly singular integrals is one of the major concerned problems in the implementation of the boundary element method. Among the various commonly used nonlinear transformation methods, the distance transformation technique seems to be a promising method to dealing with various orders of nearly singular integrals both in potential and elasticity problems. In this paper, some drawbacks of the conventional distance transformation, such as the sensitivity to the position of projection point, are investigated by numerical tests. And a general distance transformation technique is developed to circumvent these drawbacks, which is aimed to remove or weaken the limitations of the projection point. Numerical examples are presented for curved line elements to validate the accuracy and efficiency of our method.

Keywords Boundary element method, Nearly singular integrals, Numerical integration, Distance transformation technique.

1. Introduction

The nearly singular integrals arise when the source point is very close to but not on the integration element in the implementation of boundary element method (BEM). The conventional Gauss quadrature becomes inefficient or even inaccurate to evaluate such integrals. The accurate and efficient evaluation of nearly singular integrals plays an important role in many cases, especially involving problems of thin or shell-like structures [1-3], the unknowns around crack tips [4], the contact problems [5] and the sensitivity problems [6].

Various numerical techniques have been proposed to remove the near singularities, such as the element subdivision technique [7], the rigid body displacement solutions [8], global regularization method [9, 10], semi-analytical and analytical algorithms [11, 12], and the nonlinear transformation method [13-25]. The element subdivision technique is simple but not recommended because of its inefficient. The closer the computing point is to the integration element, the more subdivisions are needed, which consumes great computation effort and may increase the accumulative error. The rigid body displacement method constructs a nearly zero factor in the denominator of kernel function by the zero factor in density function using the regularization ideas, but the accuracy of the results are not satisfactory. The analytical and semi-analytical algorithms are effective but only limited to linear or planar elements. Curved elements must be divided into a large number of linear or planar elements, thus losing efficiency and accuracy. At present, the most widely used methods are various nonlinear transformations, such as the cubic polynomial transformation [13], the bi-cubic transformation [14], the sigmoidal and semi-sigmoidal transformation [15, 16], the coordinate optimization transformation [17], the attenuation mapping method [18], the rational transformation [19], the PART method [20], and the sinh transformation [21]. The basic ideas of the above transformations can be generalized into two categories: one is removing the nearly zero factor in the denominator of the kernels using zero factor, the other is converting the nearly zero factor in the denominator of the kernels to be part of the numerator. However, most nonlinear transformations are limited to certain order of singularities or specific boundary element. The distance transformation method [22-25], which has been proposed by Ma, is a general strategy to deal with nearly singular integrals in BEM. This promising method is derived from Guiggiani's excellent work for dealing with singular boundary integrals [26]. It has been applied to two- and

three-dimensional nearly singular integrals with various orders both in potential and elasticity problems, and attractive results have been presented.

However, as the definition of the projection point, finding the projection point is essential for each computation, which may lower the efficiency of the method. And numerical tests in Section 4.1 show that the local coordinate of the projection point must be calculated accurately, otherwise undesirable results will be obtained. Moreover, if the projection point is located on the tangential line through the projection point, the method failed and another transformation should be taken. In this paper, a general distance transformation is developed to circumvent these drawbacks.

The paper is organized as follows. The general form of nearly singular integrals is described in Section 2. The conventional distance transformation is briefly reviewed in Section 3. The drawbacks for conventional distance transformation are presented by some numerical tests，and a general distance transformation is developed in the Section 4. Some illustrative numerical examples are given to verify the efficiency and accuracy of presented method in Section 5. The paper ends with conclusions in Section 6.

2. Statement of the problem

Considering the description of 2D potential problems in the domain Ω enclosed by boundary Γ, the two basic integral equations are written in terms of the flux q and the potential u on the boundary as follows:

$$c(\mathbf{y})u(\mathbf{y}) = \int_\Gamma q(\mathbf{x})u^*(\mathbf{x},\mathbf{y})\mathrm{d}\Gamma(\mathbf{x}) - \int_\Gamma u(\mathbf{x})q^*(\mathbf{x},\mathbf{y})\mathrm{d}\Gamma(\mathbf{x}) \tag{1}$$

$$c(\mathbf{y})u_k(\mathbf{y}) = \int_\Gamma q(\mathbf{x})u_k^*(\mathbf{x},\mathbf{y})\mathrm{d}\Gamma(\mathbf{x}) - \int_\Gamma u(\mathbf{x})q_k^*(\mathbf{x},\mathbf{y})\mathrm{d}\Gamma(\mathbf{x}) \tag{2}$$

where $\mathbf{y}$ and $\mathbf{x}$ are the source and the field points, respectively. c is a coefficient depending on the smoothness of the boundary at the source point $\mathbf{y}$. $u^*(\mathbf{x},\mathbf{y})$ represents the fundamental solution for 2D potential problems expressed as

$$u^*(\mathbf{x},\mathbf{y}) = \frac{1}{2\pi}\log(\frac{1}{r}) \tag{3}$$

and $u_k^*(\mathbf{x},\mathbf{y})$, $q^*(\mathbf{x},\mathbf{y})$ and $q_k^*(\mathbf{x},\mathbf{y})$ are the derived fundamental solutions

$$u_k^*(\mathbf{x},\mathbf{y}) = \frac{\partial u^*(\mathbf{x},\mathbf{y})}{\partial x_k}, \quad q^*(\mathbf{x},\mathbf{y}) = \frac{\partial u^*(\mathbf{x},\mathbf{y})}{\partial \mathbf{n}}, \quad q_k^*(\mathbf{x},\mathbf{y}) = \frac{\partial q^*(\mathbf{x},\mathbf{y})}{\partial x_k} \tag{4}$$

where r denotes the Euclidean distance between the source and the field points and $\mathbf{n}$ is the unit outward normal on the boundary Γ.

To evaluate the boundary integrals numerically, the boundary Γ is discretized into a number of linear or quadratic elements and then the boundary integrations are performed on each element. When the source point is very close to but not on the integration element, nearly singular integrals arise with different orders.

In this paper, we deal with these boundary integrals with nearly singularity of the following forms:

$$\mathrm{I} = \int_{-1}^{1} O(1/r)\, f(\xi)\phi_i(\xi)G(\xi)\mathrm{d}\xi \tag{5}$$

where $O(1/r)$ represents the nearly singular integral kernels, $\log(1/r)$ for nearly weak singular integrals, $1/r$ for nearly strong singular integrals and $1/r^2$ for nearly hyper-singular integrals. $f(\xi)$ is a bounded function for local coordinate ξ, $\xi \in [-1,1]$. $\phi_i(\xi)$ denotes the shape functions and $G(\xi)$ is the Jacobian of the transformation from $\mathrm{d}\Gamma$ to $\mathrm{d}\xi$. As the singular integrals over linear elements can be computed analytically, only quadratic elements are discussed

in this paper.

3. Conventional distance transformation

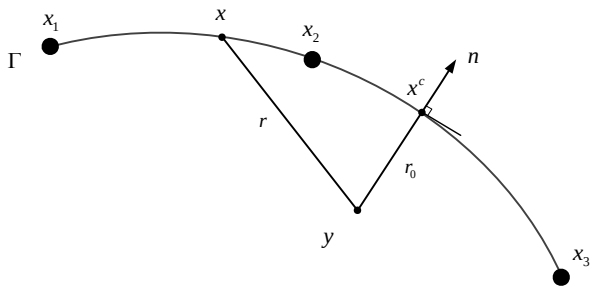

Figure 1. Definition of the projection point $\mathbf{x}^c$

In this section, we review the definition of the conventional distance function and the variable transformation technique. As shown in Fig. 1, the minimum distance r_0 from the source point to the boundary element is defined perpendicular to the tangential line, through the projection point $\mathbf{x}^c$ and the source point $\mathbf{y}$. By employing the first-order Taylor expansion in the neighborhood of the projection point, we have

$$x_k - y_k = x_k - x_k^c + x_k^c - y_k = \frac{\partial x_k}{\partial \xi}|_{\xi=c}(\xi - c) + r_0 n_k(c) + O(|\xi - c|^2) \tag{6}$$

where c is the local coordinate of the projection point $\mathbf{x}^c$. The real distance can be expanded to the following form:

$$\begin{aligned} r^2(\xi) &= (x_k - x_k^p)(x_k - x_k^p) \\ &= r_0^2 + \frac{\partial x_k}{\partial \xi}\frac{\partial x_k}{\partial \xi}|_{\xi=c}(\xi - c)^2 + 2r_0\frac{\partial x_k}{\partial \xi}|_{\xi=c} n_k(c)(\xi - c) + O(|\xi - c|^3) \\ &= r_0^2 + G_c^2(\xi - c)^2 + O(|\xi - c|^3) \\ &= G_c^2 g^2(\xi) + O(|\xi - c|^3) \end{aligned} \tag{7}$$

where G_c stands for the Jacobian at point c and $g(\xi)$ is the distance function defined as

$$g(\xi) = \sqrt{\alpha^2 + (\xi - c)^2} \tag{8}$$

This definition represents the distance in the local parametric plane and $\alpha = r_0 / G_c$. When the projection point is inside of the boundary element, the integration span is split into two parts at point c, taking the following one-order transformation pairs for the integration variable:

$$\eta(\xi) = \log[g(\xi) + (\xi - c)] \tag{9}$$

$$\xi(\eta) = \frac{1}{2}[\exp(\eta) - \alpha^2 \exp(-\eta)] + c \tag{10}$$

Substituting Eq. (9) and (10) into Eq. (5) yields

$$\begin{aligned} \mathrm{I} &= \int_{-1}^{1} O(1/r)\, f(\xi)\phi_i(\xi) G(\xi)\mathrm{d}\xi \\ &= \int_{\eta(-1)}^{\eta(c)} O(1/r)\, f[\xi(\eta)]\phi_i[\xi(\eta)] G[\xi(\eta)] g[\xi(\eta)]\mathrm{d}\eta \\ &+ \int_{\eta(c)}^{\eta(1)} O(1/r)\, f[\xi(\eta)]\phi_i[\xi(\eta)] G[\xi(\eta)] g[\xi(\eta)]\mathrm{d}\eta \end{aligned} \tag{11}$$

It is easily can be seen that the distance function $g(\xi)$ and the Jacobian of transformation play the role of damping out the nearly singularity of the kernels. For the possibility of unifying and simplifying the computer code, the one-order transformation is used for various orders of singularity, which can obtain an acceptable result even for the hyper-singular kernel [23].

4. General distance transformation

4.1. Sensitivity to the position of projection point

As we know, finding the accurate position of the projection point is an essential step for the successful implementation of the distance transformation method when dealing with nearly singular integrals. The Newton's method is widely used to finding approximate position of the projection point and an inevitable error will be produced. In this section, we investigate the influence of the position of the projection point on the accuracy of the distance transformation method. Here we assume the source point is fixed and the local coordinate ξ_a^c of the approximate projection point is determined by an offset parameter k with the following equation:

$$\xi_a^c = \xi^c + k\xi^c \tag{12}$$

where ξ_c is the accurate local coordinate of the projection point and k indicates the offset caused by the error during finding the projection point. Obviously, the approximate projection point is coincident with the accurate one when $k = 0$.

Considering the first example in Ref. [23], the relative distance describing the closeness of the near singular point to the boundary is taken as 10^{-4} and ten points Gauss quadrature is used for all the computations. The integrals with kernel u^* and q^* corresponding to different offset values of k have been computed using the conventional distance transformation and the reference value are obtained by subdivision method with enough subelements. Numerical results are shown in Fig. 2 and Fig. 3, and it can be easily seen that the results obtained with conventional distance transformation is very sensitive to the position of the projection point and poor results can be obtained even with a very little deviation of the position of the projection point. Besides, the results get much worse for high order singular integrals.

Now the drawbacks of the distance transformation method are very obvious: the computation of the position of the projection point should be very rigorous and the process of finding the projection point is time-consuming but essential for each source point, which may lower the computational efficiency. Is the projection point really essential? The work presented later is tried to overcome the shortcomings of the conventional distance transformation method.

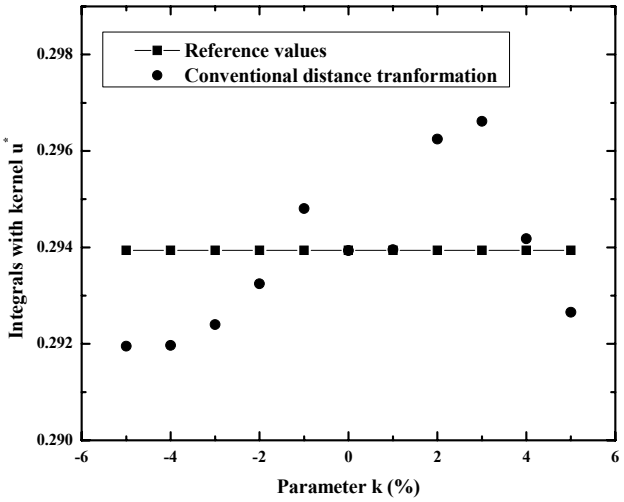

Figure 2. Various integrals with kernel u^*

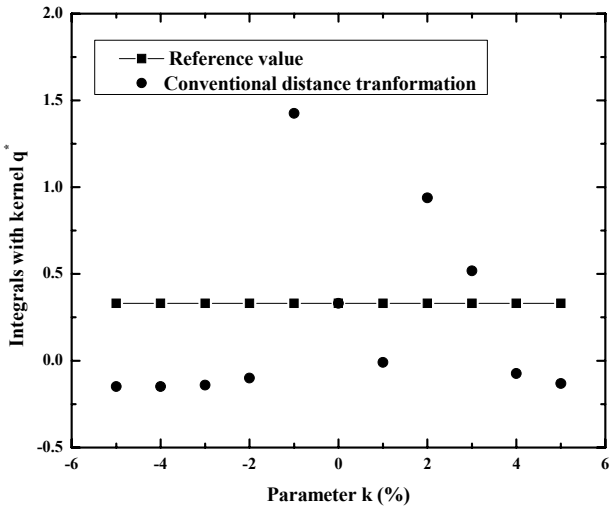

Figure 3. Various integrals with kernel q^*

4.2. Definition of general distance function

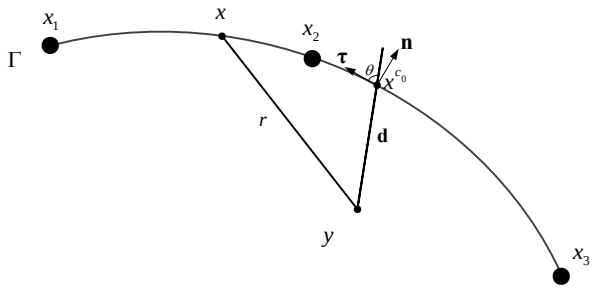

Figure 4. General definition of the projection point $\mathbf{x}^c$

In this section, a general projection point $\mathbf{x}^{c_0}$ is defined to construct a new distance function as shown in Fig. 4. The general projection point $\mathbf{x}^{c_0}$ can be located inside the integration element or on one node of the element. $\boldsymbol{\tau}$ and $\mathbf{n}$ are the unit tangential and outward normal vector, respectively. A new vector $\mathbf{d}$ from the source point $\mathbf{y}$ to the general projection point $\mathbf{x}^{c_0}$ is defined additionally, which is not required to be perpendicular to the tangential line through $\mathbf{x}^{c_0}$. By applying the first-order Taylor expansion in the neighborhood of point $\mathbf{x}^{c_0}$, we have

$$x_k - y_k = x_k - x_k^{c_0} + x_k^{c_0} - y_k = \frac{\partial x_k}{\partial \xi}|_{\xi=c_0}(\xi - c_0) + d_k + O(|\xi - c_0|^2) \tag{13}$$

where c_0 is the local coordinate of the general projection point $\mathbf{x}^{c_0}$, and d_k is one of the components of $\mathbf{d}$. The real distance can also be expanded to the following form:

$$\begin{aligned} r^2(\xi) &= (x_k - y_k)(x_k - y_k) \\ &= d_k^2 + \frac{\partial x_k}{\partial \xi}\frac{\partial x_k}{\partial \xi}|_{\xi=c_0}(\xi - c_0)^2 + 2d_k\frac{\partial x_k}{\partial \xi}|_{\xi=c_0}(\xi - c_0) + O(|\xi - c_0|^3) \end{aligned} \tag{14}$$

Noted that

$$2d_k\frac{\partial x_k}{\partial \xi}|_{\xi=c_0}(\xi - c_0) = 2G_{c_0}(\mathbf{d}\mathbf{g}\boldsymbol{\tau}) = 2G_{c_0}d\cos\theta \tag{15}$$

where G_{c_0} stands for the Jacobian at point c_0 and θ is the angle between $\mathbf{d}$ and $\boldsymbol{\tau}$, which is only related to the position of $\mathbf{x}^{c_0}$ and $\mathbf{y}$.The real distance can be rewritten as

$$\begin{aligned} r^2(\xi) &= d^2 + G_{c_0}^2(\xi - c_0)^2 + 2G_{c_0}d\cos\theta(\xi - c_0) + O(|\xi - c_0|^3) \\ &= G_{c_0}^2[\alpha^2 + (\xi - c_0)^2 + 2\alpha\cos\theta(\xi - c_0)] + O(|\xi - c_0|^3) \\ &= G_{c_0}^2 g^2(\xi) + O(|\xi - c_0|^3) \end{aligned} \tag{16}$$

where $g(\xi)$ is the general distance function defined as follows:

$$g(\xi) = \sqrt{\alpha^2 + (\xi - c_0)^2 + 2\alpha\cos\theta(\xi - c_0)} \tag{17}$$

with α being d / G_{c_0}. $g(\xi)$ represents the distance in the local parametric plane as shown in Fig. 5, which can be proved using the cosine law.

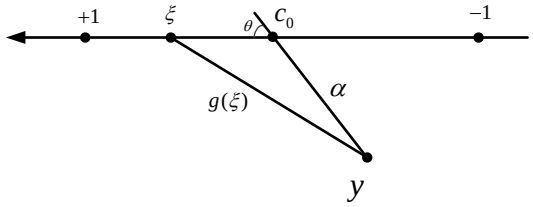

Figure 5. The distance function $g(\xi)$ in the local parametric plane

Now we introduce a similar pair of transformations for the integration variable, which is expressed as

$$\eta(\xi) = \log[g(\xi) + (\xi - c_0) + \alpha\cos\theta] \tag{18}$$

$$\xi(\eta)=\frac{1}{2}e^{-\eta}[(e^{\eta}-\alpha\cos\theta)^2-\alpha^2]+c_0 \tag{19}$$

After splitting the integration element into two parts at point $(c_0-\alpha\cos\theta)$, which is unnecessary if the general projection point is located at the vertex of the integration element, we can obtain the distance-transformed form of the near singular boundary integrals as Eq. (20). Now the nearly singular integrations with various orders can be computed accurately even if $\mathbf{x}^{c_0}$ is a little far away from the conventional projection point.

$$\begin{aligned}
\mathrm{I}&=\int_{-1}^{1}O(1/r)\phi(\xi)G(\xi)\mathrm{d}\xi\\
&=\int_{-1}^{c_0-\alpha\cos\theta}O(1/r)\phi(\xi)G(\xi)\mathrm{d}\xi+\int_{c_0-\alpha\cos\theta}^{1}O(1/r)\phi(\xi)G(\xi)\mathrm{d}\xi\\
&=\int_{\log[g(c_0-\alpha\cos\theta)]}^{\log[g(-1)+(-1-c)+\alpha\cos\theta]}O(1/r)\phi(\xi(\eta))G(\xi(\eta))g(\xi(\eta))\mathrm{d}\eta\\
&+\int_{\log[g(c_0-\alpha\cos\theta)]}^{\log[g(+1)+(1-c)+\alpha\cos\theta]}O(1/r)\phi(\xi(\eta))G(\xi(\eta))g(\xi(\eta))\mathrm{d}\eta
\end{aligned} \tag{20}$$

5. Numerical examples

In this section, numerical examples for curved lines are presented to validate the accuracy and efficiency of our method. The relative distance is given in terms of r_0/l to describe the influence of the nearly singular integrals over each element, where r_0 is the minimum distance as shown in Fig.1 and l stands for the length of the element. For the purpose of error estimation, the relative error is defined as follows:

$$error=\frac{I_{num}-I_{ref}}{I_{ref}} \tag{21}$$

where the subscripts num and ref refer to the numerical and reference solutions, respectively. The reference solutions are obtained by subdivision method with enough subelements. Ten Gauss points are used in all cases for the convenience of comparisons.

The numerical example in Ref. [23] is taken as the second example. The example is computed over a curved boundary element with the node coordinates of (2.0, 0.0), (1.0, 1.0), and (0.0, 0.5). The local coordinate of the conventional projection point c is set outside of the element interval and $c=1.01$. The relative error of nearly singular integrals using general and conventional distance transformation is presented in Table 1. The local coordinate of the general projection point c_0 is located at 0.0. For results obtained with the conventional distance transformation, the precision will decline as the range of r_0/l. The results using the general distance transformation can keep high precision in a wide range of r_0/l, far better than results obtained by conventional distance transformation.

Table 1 Relative error of nearly singular integrals using general and conventional distance transformation

The influence of the location of the general projection point is also studied for curved boundary element. As the general projection point moves along the element, computations for nearly singular integrals with r_0 / l being 10^{-4} are performed and the relative error is given out in Table 2. As the general projection point is located at the middle of the element, best results can be got compared with other locations. The results are also acceptable relative to those obtained with the conventional distance transformation.

Table 2 Relative error of nearly singular integrals with various general projection points

c_0	-1.0	-0.5	0.0	0.5	1.0	Conventional

As the local coordinate of the conventional projection c changes from 1.1 to 1.000001, the source point $\mathbf{y}$ becomes increasingly closer to the element, which may lead to poor results during computation of nearly singular integrals. Here we consider $c_0 = 0$ and $r_0 / l = 10^{-4}$ to verify the effectiveness of the conventional and general distance transformation. The results with kernel u^* as c varies from 1.1 to 1.000001 are listed Table 3. It can be easily seen that our method is less sensitive to different values of c and better results can be obtained than the conventional distance transformation.

6. Numerical examples

In this paper, the drawbacks of the conventional distance technique, such as the sensitivity to the position of projection point, are investigated by numerical tests. A general distance transformation technique is developed to remove or weaken the limitations of projection point, which is based on a more general definition of the projection point. The presented method has been verified through numerical examples with different kernel functions and relative distances.

Abstract Nanoindentation techniques are poplar methods which are used for the evaluation of the hardness and elastic modulus of very thin films. However, since the plastic and elastic regions formed underneath the indenter are much larger than its penetration depth, the thickness of films, which can be used for the nanoindentation measurement, is limited to a certain value. In the present study, microcracking caused by micro-Vickers indentation was applied to the evaluation of the tensile properties of very thin metallic films coated on brittle materials. For this purpose, gold films with the thicknesses ranging from 23 nm to 227 nm were coated on glass substrates, and the lengths of radial cracks before and after coating were measured. The crack opening displacements in uncoated glass were also measured to assess the stress intensity factor at crack tips. In the case of 34 nm thick gold film, a fracture mechanics analysis based upon the crack-tip stress intensity factor led to the yield strength of about 620 MPa and the fracture toughness of 2.0 MPa·m$^{1/2}$. The evaluation of mechanical properties of thicker films, however, became more difficult, since the elongation in thicker films are considered to become comparable with the crack opening displacement.

Keywords Thin film, Indentation fracture, Mechanical properties, Stress intensity factor, crack opening displacement

1. Introduction

The Young's modulus, yield strength, ultimate tensile strength, work hardening exponent, elongation to failure and fracture toughness, are key factors which should be measured in order to guarantee the structural integrity of metallic materials. It is well known that the hardness can be related with the tensile properties of metals [1, 2]. According to contact mechanics, especially the analysis of Love [3] given for the elastic contact of a conical indenter with a semi-infinite body, the Young's modulus of the body can be estimated from the relation of the load with the contact area. This situation is realized by measuring the load-depth curve of elastic recovery which occurs during the unloading of indentation testing. Following this principle, a nanoindetation technique using the Berkovich indenter with a sharp apex has been developed currently, since a systematic study of Oliver and Pharr [4]. Nanoindentation shows its great applicability, in measuring the hardness and elastic modulus of very thin films to which normal tensile tests or hardness tests cannot be applied.
Hill [5] proposed a cavity theory, which treats the elastic-plastic stress problem around an internally pressurized cavity in an infinite body. The cavity theory has also been shown to be applicable in the analysis of the elastic-plastic stress fields around indent. According to Johnson [6], the radius, b, of plastic zone formed underneath a conical indenter with a half apex angle of ψ_c is given by

$$b = a[E\cot\psi_c/\{6(1-\nu)\sigma_y\} + 2(1-\nu)/\{3(1-2\nu)\}]^{1/3}, \quad (1)$$

where a is the radius of contact area, and E, ν and σ_y are is the Young's modulus, the Poisson's ratio and the yield strength, respectively. As for a conical indenter having the same projected hardness H and penetration depth h as those of the Vickers indenter, ψ_c becomes 70.3° and the radius of contact area is given by $a \approx 2.8h$. When $\nu = 0.3$, thus, equation (1) gives the value of b/h ranging from 2.8

to 26 for the change of E/σ_y from 100 (ultrahigh strength steels) to 10000 (annealed metals). Nearly the same values are obtained for b/h of the Berkovich indenter. One can see from this simple estimation that the penetration depth of the indenter, should be smaller by a factor of about 30 than the thickness of film, when its mechanical properties are not known. It should be also noted that, even if this requirement is satisfied, the elastic deformation of substrates on which the films are coated influences the penetrating behavior of indenter, leading to the change of measured hardness with penetration depth, as is demonstrated by Han *et al* [7]. On the other hand, as the load is lowered, the deformation mechanism underneath the indenter changes from the one representing the bulk properties to the one reflecting the generation of dislocations and their development to surrounding. Dietiker *et al*. [8] have shown that the critical penetration depth where this transition occurs is about 10 nm in single-crystalline Au films coated on NaCl substrates, when the Berkovich indenter is used. Accordingly the interpretation of hardness measured by nanoindentation becomes more complicated in thinner films than 200 nm. In addition to these problems, since the films are compressed by indentation, there is the possibility that the measured hardness does not represent their tensile properties, which are strongly affected by defects like small cavities introduced during synthesis.

It is well known that when an indenter is impressed on the surface of a ceramic material, cracks are formed around the indent at loads higher than a critical load [9]. Among such cracks, radial cracks with a half-penny shape formed by the Vickers indentation are frequently used to measure the fracture toughness of ceramic materials. The crack opening displacement (COD), δ_{tip}, very close to the tip of a radial crack with a radius of C can be approximately expressed as

$$\delta_{tip} \approx \delta_o \sqrt{\frac{2x}{C}} \text{ , where } \delta_o = \frac{4(1-\nu^2)K_{tip}\sqrt{C}}{\sqrt{\pi}E}, \tag{2}$$

which will be mentioned later. Here x is the distance from the crack tip toward the interior of crack and K_{tip} is the stress intensity factor (SIF) at the crack tip. Eq. (2) can be easily verified to hold true for any stress state acting on a circular crack in an infinite body. However the COD profile given by this equation deviates considerably from the one which is measured at distance far from the crack tip. Fett [10] proposed a sophisticated model of COD profile for the Vickers indentation crack by computer calculation, while Burghard *et al*. [11] used a polynominal equation of $x^{1/2}$ to fit it to the measured COD profiles. When we introduce a radial crack in a brittle substrate coated with very thin film of ductile metal, it is expected that the film be elongated at the crack mouth emerging at the film/substrate interface. The elongation changes with the COD along the crack, and its magnitude is considered related with the COD profile of the substrate. Despite that this microscopic elongation test by means of microcracking is dynamical and localized, we can obtain the information on the tensile properties of the film.

In the present study, microcracking by means of the Vickers indentation is used as a nanoscale tensile testing of thin metallic films coated on brittle substrates, and a fracture mechanics model to estimate the tensile properties of the films is proposed. In order to check the validity of the model, gold film and glass substrate are used as a model film/substrate system. The Young's moduli of these materials are nearly equal so that we can ignore the misfit in elastic behavior between the film and substrate. The Vickers indentation cracks are introduced in Au film/glass substrate systems (hereafter called Au/glass) by varying the film thickness and changing the indentation load. The indent size, crack size and COD profile in uncoated glass as well as in Au/glass are measured, and the yield strength, plastic work and fracture toughness of Au films are evaluated based upon the proposed model.

2. Modeling

2.1 SIF and COD

Lawn *et al.* [11, 12] showed, by using glass, that small circular cracks were first formed underneath the Vickers indenter during loading, and then the cracks grew into semi-circular ones during unloading. Thus the driving force for the development of the radial cracks, observed after the Vickers indentation, is substantially provided by the residual pressure remaining in the plastic zone formed underneath the indent. Assuming that the stress field around the plastic zone is represented by the cavity theory [5, 6], the circumferential stress around the plastic zone is given by

$$\sigma_\theta = p_r b^3/2r^3, \tag{3}$$

Here r is the distance from the center of indent and p_r is the residual pressure within the plastic zone. The stress intensity factor (SIF) of the radial crack with a radius C is then expressed as

$$K = \frac{2\alpha Y_s Y_c}{\sqrt{\pi C}} \int_b^C \frac{\sigma_\theta r dr}{\sqrt{C^2 - r^2}}, \tag{4}$$

by applying the SIF given for a circular crack in an infinite body [13]. Here the coefficients, Y_s and Y_c, are correction factors arising from the effects of surface and crack interaction, respectively, and α is a correction factor, which modifies the deviation from the assumed cavity theory as well as the assumed half-penny shape of radial cracks. By inserting Eq. (3) into Eq. (4) and integrating it, one can obtain the following formula.

$$K = \chi P / C^{3/2} \sqrt{1 - (b/C)^2}, \tag{5}$$

where P is the indentation load and χ is a parameter that correlates the SIF due to load P with that of stress σ_θ. , *i.e.*, $\chi = \alpha Y_s Y_c p_r b^2/\pi^{1/2}/P$. It should be noted here that this equation does not involve the pressure within the plastic zone, which acts as the force to close the crack in the zone [10]. When the crack is larger by a factor of more than three than the plastic zone, *i.e.*, $C \geq 3b$, $\{1-(b/C)^2\}^{1/2} \approx 1$ so that the above equation is approximately written as

$$K = \chi P / C^{3/2}. \tag{6}$$

The condition $C >> b$ also enables us to ignore the closing effect of pressure within the plastic zone. There have been many formulae that relate χ with the properties of materials and the characteristics of indent [13]. In the present analysis, we use the formula, $\chi = 0.016(E/H)^{1/2}$, which was proposed by Anstis *et al.* [14]. Here the projected hardness is defined by $H = 2P/d^2$, where d is the diagonal length of Vickers indent.

The COD at a distance of r from the center of indent is given by [15]

$$\delta(r) = \frac{4(1-\nu^2)}{\sqrt{\pi} E} \int_r^C \frac{\sqrt{C'} K(C') dC'}{\sqrt{C'^2 - r^2}}. \tag{7}$$

The insertion of Eq. (6) into Eq. (7) and the use of the formula of integral [16] lead to

$$\delta(r) = \delta_o \frac{\arccos(r/C)}{r/C}. \tag{8}$$

This equation does not cover the COD profile over the whole crack length. However, it reproduces the COD profile at longer distances from the crack tip than Eq. (2) does. Thus Eq. (8) is satisfactory and its simple form is very useful in the present analysis of COD, as will be mentioned below. One can also see that Eq. (7) approaches Eq. (2) irrespectively of the form of K, when $x << C$.

2.2 Evaluation of yield strength of metallic films

When a ductile film deposited on a brittle substrate does not have large enough strength to close the crack mouth in the substrate, the film is considered to be elongated at the crack mouth, as is shown in Fig. 1. Since the film thickness, t_o, considered here is much smaller than the radial crack size, it is assumed that the film is elongated only at the crack mouth. It is anticipated that the film fails, when the COD exceeds the elongation to failure of the film which is isolated from the substrate. Hence the half crack length C_f observed at the surface of film/substrate system is expected to be smaller

than the half crack length C of uncoated substrate. It is also postulated that the plastic work done until the failure of the film is much larger than the surface energy of the film so that we can ignore the term related with the surface energy. Assuming that the film is a rigid-plastic body having the yield strength of σ_y, the plastic work done in an element between x an $x + dx$ is given by

$$dW_p = \sigma_y \int_0^\delta t dx d\delta , \tag{9}$$

where t is the thickness at the distance of x. The film thickness changes with δ. Assuming that plastic deformation in the film is constrained at the film/substrate surface, it is considered that the shear displacement through thickness takes place at the angles of ±45° from the surface, as shown in Fig. 2, following the maximum shear stress theory [5]. The geometrical condition of this constraint deformation leads to

$$t(\delta) = -\delta/2 + \sqrt{\delta^2/4 + {t_o}^2} . \tag{10}$$

Consequently the plastic work done in the plastic zone of the film becomes

$$W_p = \sigma_y V(R) , \tag{11}$$

where $V(R)$ implies the volume of plastic zone and is given by

$$V(R) = \int_0^R \int_0^\delta t(\delta) d\delta dx . \tag{12}$$

Here R is the distance of plastic zone in the film and is given by the difference in half crack size between the substrate and film, *i.e.*, $R = C - C_f$. The integration of $t(\delta)$ with regard to δ in the above equation leads to

$$T(\delta) = \int_0^\delta t(\delta) d\delta = \frac{\delta\sqrt{\delta^2 + 4{t_o}^2} - \delta^2}{4} + {t_o}^2 \ln\left[\tan\left(\frac{\pi}{4} + \frac{1}{2}\arctan\frac{\delta}{2t_o}\right)\right]. \tag{13}$$

On the other hand, the film/substrate system increases its fracture toughness due to the reduction in crack size. Assuming that the SIF in the film is expressed by Eq. (6), the elastic energy in the film,

(a) Before cracking. (b) After cracking.

Fig. 2. Assumed mechanism of plastic deformation in film.

which is required to reduce the crack size from C to Cf, is written as follows.

$$U_e = \int_{C_f}^{C} \frac{K(C')^2}{E_f} t_o dC' = \frac{K_C{}^2 t_o}{2E_f} \frac{CR(2C-R)}{(C-R)^2}. \quad (14)$$

where E_f is the Young's modulus of the film. By equating U_e with W_p, the yield strength of the film is given by

$$\sigma_y = \frac{K_C{}^2}{E_f t_o} \frac{CR(2C-R)}{V(R)(C-R)^2}. \quad (15)$$

Since the elongation of the film increases with increasing the distance from crack tip in the substrate, the plastic work per unit area consumed in the plastic zone of the film is also expected to increase with distance from the crack tip in the substrate. Accordingly the local plastic work per unit area can be defined as follows.

$$\gamma_p(x) = \frac{dW_p}{t(x)dx} = \frac{\sigma_y T(\delta)}{t(\delta)}. \quad (16)$$

We can evaluate the profile of local plastic work as a function of x by using the dependence of δ on x. The maximum value of local plastic work is obtained at $x = R$, which corresponds to the plastic work done to failure. Accordingly the fracture toughness of the film is given by

$$K_{fC} = \sqrt{E_f \gamma_p(R)}. \quad (17)$$

It should be noticed, that the effect of residual stress in the film is not taken into account in the present analysis, since yield strength is not affected significantly by isotropic stress.

3. Experimental procedures

Slide glass with a thickness of 1.2 mm ~ 1.5 mm and cover glass with a thickness of 0.12 mm ~ 0.17 mm were used as substrate material. Table 1 shows the chemical composition of the glass obtained by X-ray fluorescence analysis (Rigaku ZSX-100e). The Young's modulus and Poisson's ratio of these glasses are 71.3 GPa and 0.22, respectively. The thicker glass plates were used for the Vickers indentation with large loads, which formed cracks with radii larger than 50 μm. The glass plates were annealed at 723 K for 3.6 ks in order to remove pre-existing residual stresses. The films of 99.9% purity Au were deposited on the surfaces of these glass plates by using a DC sputtering machine (Eiko Engineering, IB-2). The film thickness was evaluated from the change in weight before and after the sputter-deposition, and the thickness of very thin films was measured by using atomic force microscopy. The film thickness ranged from 23 nm to 227 nm. The Vickers indentation was conducted at room temperature. The load changed from 1.96 N to 4.9 N for thinner glass substrates and from 1.96 N to 19.6 N for thicker glass substrates. The indentation tests were carried out twenty times for each load. The half-lengths of radial cracks which developed only in the diagonal directions of indent were measured by using an optical microscope (OM) and a field-emission scanning electron microscope (SEM, Hitachi S-4100H). The COD profiles of some cracks, in uncoated glass were also measured by the SEM.

Table 1. Chemical composition of glass substrate (mass%)

SiO_2	B_2O_3	Al_2O_3	Na_2O	K_2O	TiO_2	ZnO	P_2O_5	Fe_2O_3	Sb_2O_3
60.9	11.1	4.17	7.03	7.08	4.26	5.28	0.018	0.0176	0.0918

4. Results and discussion

4.1 Uncoated glass

Fig. 1 shows an example of radial cracks formed around the Vickers indent in uncoated glass. At light loads ranging from 0.98 N to 2.94 N, some cracks deviated from the diagonal directions of indent or very short cracks were formed in the diagonal direction, as is shown in this figure. These cracks were excluded in the measurement. The values of COD were measured in the direction normal to the crack propagation, as shown in Fig. 1(b). Fig. 2 shows typical examples of COD profiles measured at 2.94 N and 9.8 N. These COD profiles are similar in shape to those in soda-lime glass which were measured at the same load range by us, and those at larger loads (9.1 N - 98 N) by Burghard *et al* [14]. Solid curves in Fig. 2 are fitting curves which are obtained by applying Eq. (8) to the COD values in the range of $C/2 \le r \le C$. One can see that the solid curves agree fairly well with the measured COD profiles in this range. The values of δ_o estimated by the solid curves are 67.5 nm at 2.94 N and 92.7 nm at 9.8 N, providing 0.32 MPa·m$^{1/2}$ for the value of K_{tip} independently on the crack size or load. Broken curves in Fig. 2 are the COD profiles, which are obtained by inserting the values of δ_o into Eq. (2). The coincidence of the COD profiles predicted by Eq. (2) with the measured ones is limited to a distance of about 10% from the crack tips. As a result, the accurate determination of δ_o by using Eq. (2) is very difficult at small loads, since the measurement error as well as the scatter of COD become relatively large compared to the small COD values near the crack tips.

Table 2 shows the average values of d, C, H and K_C and γ_s in uncoated glass, where the surface energy of glass is given by $\gamma_s = K_C^2/(2E)$. All of the values of d and C listed in this table are measured by SEM observation. It should be noted here that the OM measurement yielded 6.4 GPa and 0.65 MPa·m$^{1/2}$ for H and K_C, respectively, as will be shown in Table 3. On the other hand, the SEM observations leads to slightly higher hardness and smaller fracture toughness compared to those measured by OM observation. It is considered that this discrepancy in H and K_C arises from the fact that SEM images do not have such a large sensitivity to the change in the height of surface

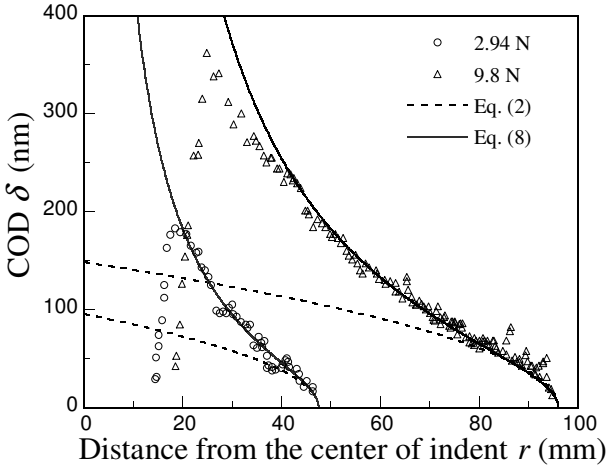

Fig. 2. COD profiles in uncoated glass at 2.94 N and 9.8 N.

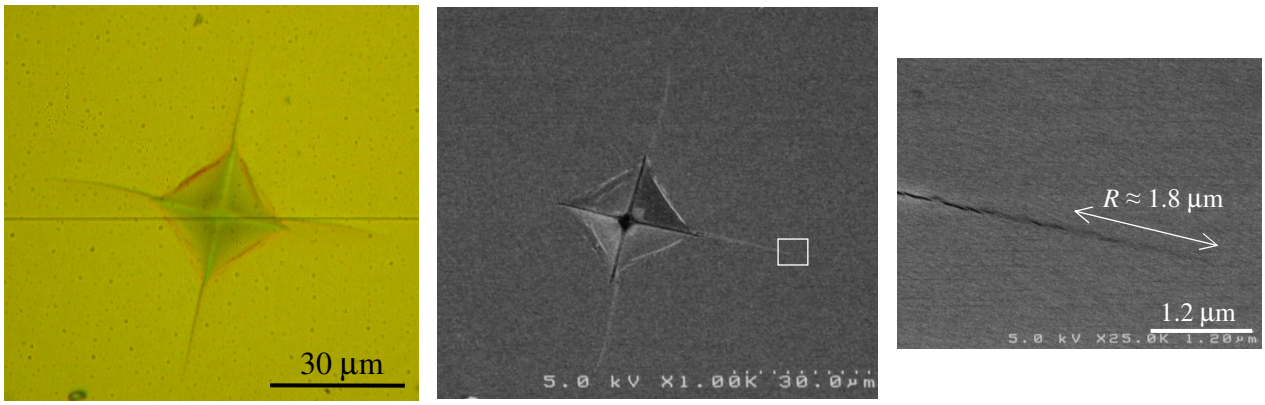
Table 2. The values of d, C, H, K_C and γ_s evaluated by SEM observation.

P (N)	d (mm)	C (mm)	H (GPa)	K_C (MPa·m$^{1/2}$)	γ_s (J/m^2)
0.98	17.1	19.7	6.70	0.585	2.40
1.96	24.0	30.2	6.81	0.612	2.62
2.94	29.3	38.2	6.85	0.643	2.90
4.90	38.3	56.0	6.68	0.611	2.62

as OM images provides, while OM observation do not give as high a resolution in the measurement of crack size as that of SEM observation. In the evaluation of the mechanical properties of thin films, we will use the data measured by SEM observation in order to avoid the systematic error arising from a difference in measurement method.

4.2 Apparent hardness and apparent fracture toughness of Au/glasss

Fig. 3 shows the OM and SEM images of 23 nm thick Au/glass indented at a load of 2.94 N. The Au film is translucent to light at this thickness, so we can estimate the crack size in glass substrate underneath the film. Table 3 shows the values of d and C in uncoated glass and 23 nm thick Au/glass, which were measured by OM observation. It is obvious that the crack size is nearly equal between these specimens, while the indent size of the Au/glass is slightly larger than that of the uncoated glass. As a result, the apparent hardness, H_A, of the Au/glass is lowered slightly compared to that of the uncoated glass. The value of χ in the Au/glass increased only by 6.5% so that its apparent fracture toughness, K_A, is close to that of the uncoated glass. On the other hand, secondary electrons in SEM are emitted from a very shallow surface layer within a depth of a few nm. Accordingly we can observe the morphology of cracks formed only in the Au film. Fig. 3(c) shows the enlarged SEM micrograph of a crack front shown highlighted by the square in Fig. 3(b). One can see from this figure, that the crack front in the Au film has a faintly dark contrast; and its length is about 1.8 μm. Comparing this result with the crack size measured by OM observation, it is considered that the Au film is elongated over this distance from the crack front in the underlying substrate.
Fig. 4 shows the load-dependence of the hardness (H) of uncoated glass and the apparent hardness (H_A) of Au/glass. The apparent hardness decreases when increasing the thickness of Au film, and the difference between H and H_A tends to increase with lowering the load. The decrease in the apparent hardness of Au/glass is brought by the plastic deformation of the Au film, which is evidenced by the morphology of the indented surface of 227 nm thick Au/glass shown in Fig 5. When the film thickness is 227 μm, radial cracks were not observed at loads less than 9.8 N. The



(a) OM photograph. (b) SEM micrograph. (c) SEM micrograph of crack front.

Fig. 3. Cracks formed around the Vickers indent in 23 nm thick Au/glass (P =2.94 N).

Table 3. The values of d, C, H, H_A, K_C and K_A evaluated by OM observation.

Crack system	d (μm)	C (μm)	H , H_A (GPa)	K_C, K_A (MPa·m$^{1/2}$)
Glass	29.2	38.2	6.38	0.645
23 nm thick Au/glass	31.2	38.7	5.62	0.675

maximum COD of uncoated glass is 182 nm at 2.94 N and 360 nm at 9.8 N (Fig. 2). Thus it is obvious that when the film thickness is larger than the maximum COD, cracks are not formed in the film. The apparent fracture toughness of Au/glass evaluated by using $\chi_A = 0.016(E/H_A)^{1/2}$ in Eq. (6) increased about twice at a thickness of 40 nm and about four times at 100 nm in comparison with the fracture toughness of uncoated glass.

4.3 Analysis of 34 nm thick Au/glass

As mentioned in sections 4.1 and 4.2, the COD profiles for $C/2 \le r \le C$ in uncoated glass obey those predicted by Eq. (8), and the Au/glass crack systems investigated here show their discontinuity at the film/substrate interfaces. As a case study, the mechanical properties of 34 nm thick Au film coated on glass substrate are evaluated here. The apparent hardness of the Au/glass decreases by about 0.5 GPa, but its apparent fracture toughness increases by a factor of about 1.8, in comparison with the hardness and fracture toughness of uncoated glass (Fig. 6). The value of R increases with load, and the ratio, R/C, is 30 - 35% irrespectively of load, as is shown in Fig. 7.

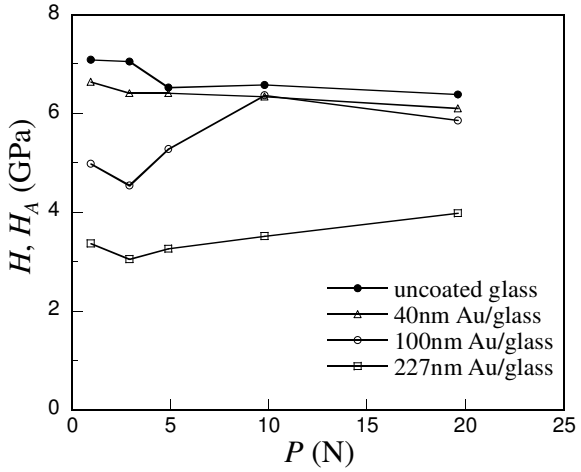


Fig. 4. Load-dependence of hardness in uncoated glass and Au/glass.

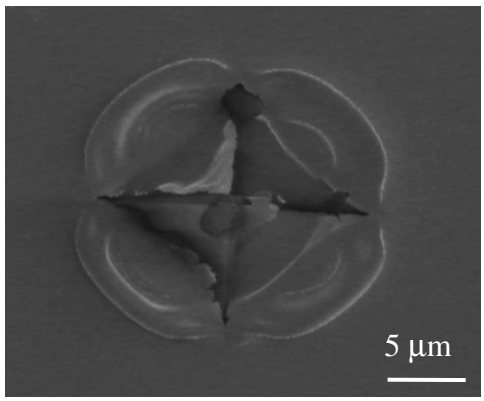

Fig. 5. Indent formed on 227 nm thick Au/glass (P = 2.94 N)

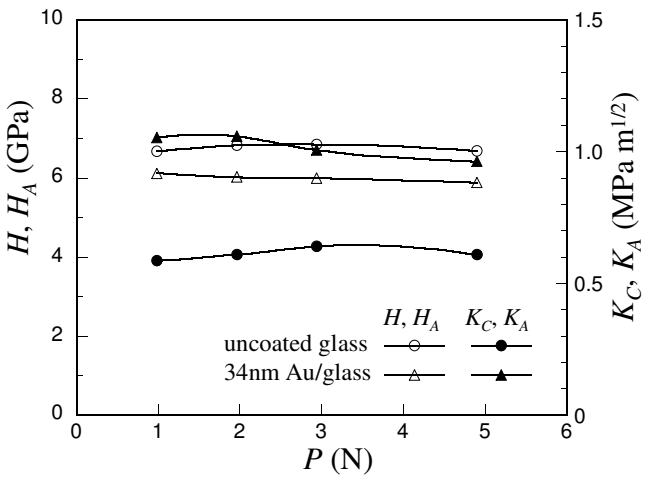

Fig. 6. Load-dependence of apparent hardness and fracture toughness in 34 nm thick Au/glass.

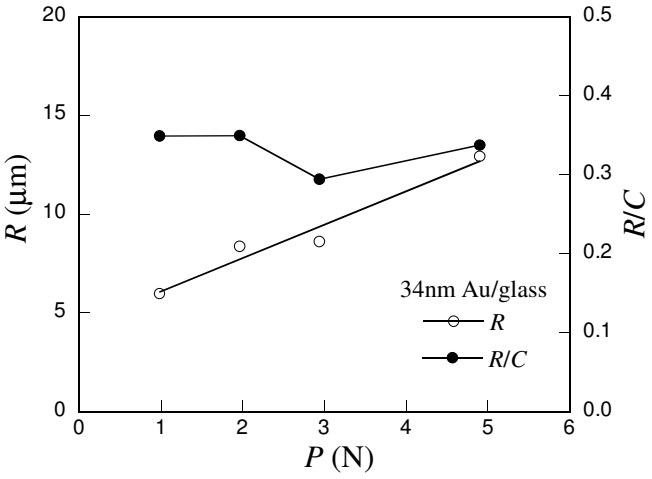

Fig. 7. Load-dependence of R and R/C in 34 nm thick Au/glass.

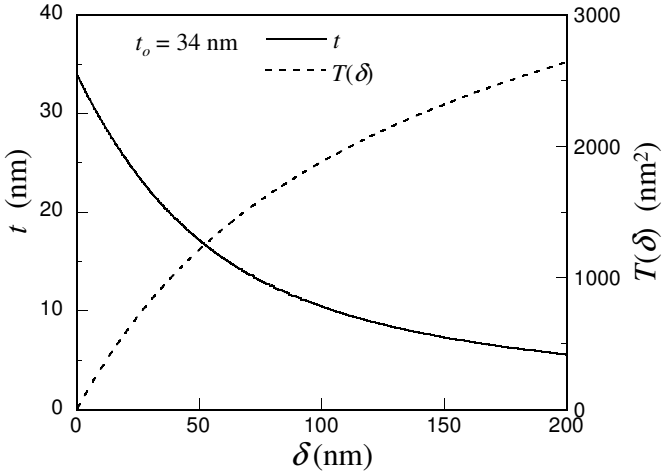

Fig. 8. The change in film thickness and $T(\delta)$ with COD in 34 nm thick Au film.

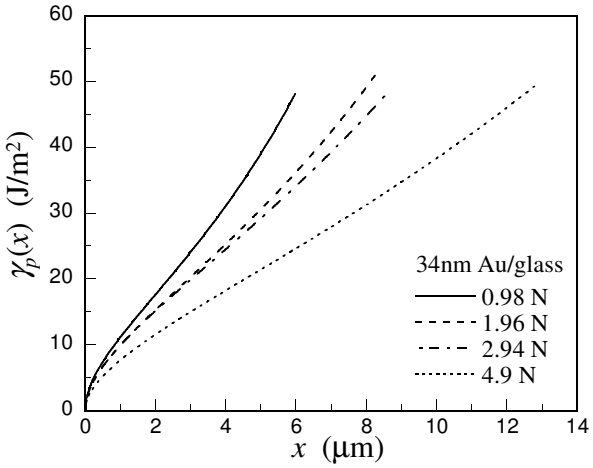

Fig. 9. The profiles of local plastic work per unit area in 34 nm thick Au film.

Table 4. Parameters and mechanical properties evaluated for 34 nm thick Au film.

P (N)	δ_o (nm)	R (μm)	$V(R)$ (x10^6 nm^3)	σ_y (MPa)	$\gamma_p(R)$ (J/m^2)	K_{fC} (MPa·m$^{1/2}$)
0.98	42.8	5.98	4.52	695	48.2	1.94
1.96	52.9	8.38	7.11	633	51.9	2.01
2.94	59.6	8.62	7.17	639	48.4	1.94
4.9	72.1	12.93	12.58	499	49.9	1.97

Therefore we can use Eq. (8) to estimate the COD profile in the substrate. Fig. 8 shows the changes of t and $T(\delta)$ as a function of δ, which are calculated by inserting Eq. (8) into Eq. (10) and Eq. (13) and using the value of δ_o determined by K_{tip} = 0.32 MPa·m$^{1/2}$.

The values of σ_y at 0.98 N - 4.9 N obtained by setting the Young's modulus of Au as 78 GPa [20] are listed with other parameters in Table 4. The average yield strength of 34 nm thick Au film evaluated in the present study is 620 MPa, which is comparable with about 400 MPa in 2.7 μm thick Au film [21] and about 600 - 900 MPa in 0.85 μm and 1.76 μm thick Au films [22]. However, it has been shown that the mechanical properties of thin Au films depend on the thickness [22, 23], temperature [21, 22] and strain rate [22]. One of the most available data to be compared with the present result may be the mechanical properties of 20 nm thick Au films examined by Olliges *et al* [24]. They elongated such very thin Au films deposited on polyimide substrates and measured the stress in the films by using synchrotron X-ray. They reported that the yield strength of the films ranged from 700 MPa to 875 MPa at room temperature, which is in a good accordance with the yield strength obtained for 34 nm thick Au film. The local plastic energy $\gamma_p(x)$ of 34 nm thick Au film increases with the distance from crack tip and its shape resembles the COD profile near the crack tip, as is shown in Fig. 9. The maximum value of COD, however, does not depend on the value of R or load. Consequently the maximum plastic work and fracture toughness of the Au film is about 50 J/m^2 and 2.0 MPa·m$^{1/2}$, respectively (Table 4).

5. Summary

In the present study, microcracking induced by the Vickers indentation was applied to the evaluation of the mechanical properties of very thin films of ductile metals. For this purpose, a simple expression was proposed for the estimation of the COD of radial cracks in brittle substrates, which agreed very well with the COD profiles measured in uncoated glass in the range of $C/2 \le r \le C$. The

comparison of the OM and SEM images of 23 nm thick Au/glass crack fronts clearly showed that the film was elongated to failure at the crack mouth of the substrate. However, when the film thickness exceeded the COD of the substrate, radial cracks were not formed in the film. These results suggest the validity of assumptions used in the present analysis of the mechanical properties of very thin metallic films. The yield strength of 34 nm thick Au film was evaluated to be about 620 MPa, which is comparable with the yield strength of very thin Au films given in literature. The maximum plastic work and fracture toughness of 34 nm thick Au film were also evaluated to be 50 J/m^2 and 2.0 $MPam^{1/2}$, respectively.

Abstract In this paper, mechanisms of defect and crack initiation in a diamond film prepared at substrate temperatures are investigated using direct current plasma chemical vapor deposition method. The study is by way of X ray diffraction (XRD), optical microscope (OM), and scanning electron microscopy (SEM) and reveals that initiation of defects and cracks during the growth of diamond films depends strongly on substrate temperature. The defects and impurities formed in high substrate temperatures include mainly residual stresses, and non-diamond phase such as graphite and amorphous carbon, which result in forming crack and microscopic hole in diamond film. X ray diffraction, optical microscope and SEM have been used to examine the temperature dependence of various defect inductions. It is found that cracks in diamond film are generally derived at grain boundary. In general, diamond films prepared in high temperature substrate will result in high residual stress at the interface between the diamond film and the substrate

Keywords Diamond film, Defect, Crack, Substrate temperature, Residual stress

1. Introduction

Due to its excellent physical and chemical properties, diamond film prepared using chemical vapor deposition (CVD) is becoming a popular material in many engineering applications such as infrared optical window, coating cutting tools, biomaterials, micromechanical, and thermal heat sink materials [1-3]. Diamond film can grow on hetero-epitaxial substrates, such as Si, Mo, Ti, and Ta substrates. It should be mentioned that diamond film deposited on the substrates mentioned above may induce some defects and impurity due to lattice mismatch and residual stress. Takeuchi et al. [4] analyzed surface defect status of diamond by photoelectron emission yield experiments; Ikeda et al. [5] investigated facture shape of polycrystalline diamond film through indentation test. Shames et al. [6] studied the localization and nature of defects for powder and compact diamond film samples. Stiegler et al. [7] investigated the impurity and defect incorporation in diamond films deposited from a carbon-hydrogen-oxygen gas system at substrate temperatures between 560 and 345 ^{o}C. Jeong et al. [8] explored mechanisms of cracking in the CVD films was investigated experimentally and theoretically. Qin and Kang et al [9, 10] investigated experimentally the effect of film thickness and size on fracture toughness. In the recent years, diamond films become popular and commercial diamond wafers are successfully used for some important fields. However, crack and defect problems reported in the literature are for large size diamond wafer only [11, 12]. For diamond film deposited on curved surface, (for example convex substrate), and it was very difficult to keep a uniform temperature on a convex substrate. It induces often cracks and defects due to non-uniform temperature distribution over the substrate surface. Crack problems for such a thin film seem not being reported in the literature. In this study, we select Mo as substrate material for depositing diamond film because of its low lattice mismatch between the diamond and the underlying Mo substrate. The mechanisms of crack and defect generation during the depositing process of the diamond film are investigated. It should be mentioned that a new substrate cooling system presented in [13] was used to ensure nearly uniform temperature over the substrate surface.

2. Experimental

The deposition system used in the present work for the growth of diamond films by direct current plasma jet CVD (DCPJCVD) is similar to that described in [14]. Using the deposition system, diamond films are prepared on convex molybdenum (Mo) substrate. The reaction gas employed is a mixture of methane (CH_4) and hydrogen (H_2), which are fed into a reaction chamber. Argon (Ar) gas is subsequently ignited by high frequency system to generate DC plasma. The anode and cathode are made of metal Mo and W, respectively. The substrate temperature is controlled by regulating the flow rate of the cooling water and the discharge current density. Typical experimental conditions for the growth of diamond film by DCPJCVD are given as follows: Source gases used are CH_4, H_2 and Ar; H_2 flow rate is 450 sccm, CH_4 flow rate is 3500 sccm; the total pressure of reaction chamber is approximately 43KPa, and CH_4 concentration is about 2.15 %. The substrate temperature is measured by an IR pyrometer and can be adjusted within the range of 830-1050℃. The diamond films are characterized by optical microscope, scanning electron microscopy, X ray diffraction with regard to surface morphology or defect, crack and their incorporation.CH_4

3. Results and discussion

As mentioned above, diamond films are prepared on Mo substrate by DCPCVD in this work. The substrate temperature is about 900-940 ℃ and the other growth conditions for the deposition process of the diamond films are kept constant or nearly constant. To illustrate the temperature distribution along radial direction, six points on the substrate surface labeled in O, A, B, C, D E as Fig. 1 and the temperatures at these points are measured on line using IR pyrometer.

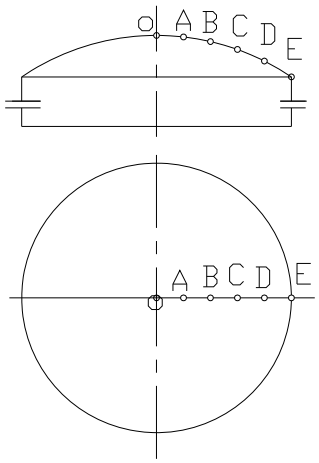

Fig. 1 Schematic diagram of radial direction of substrate

Fig. 2 shows the variation of temperature at the six points with deposition time. As expected, Fig. 2 shows that the highest temperature of the diamond film occurs at central point O and the lowest temperature presents at edge point E.

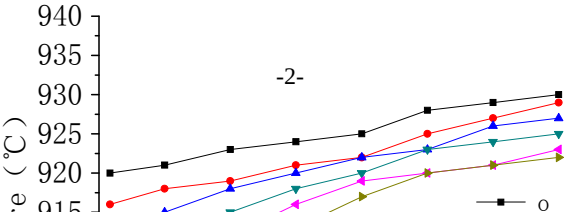

Fig. 2 Temperature distribution of diamond films at different deposition time: from 3 to 21 hours

It is also found from Fig. 2 that diamond temperature increases with the increase in deposition time. Temperature difference along the radial direction is not obvious and the maximum is about 15 ^{o}C only as Fig. 2. It is also found that surface temperature of the diamond film decreases along the outward radial direction. The temperature difference (or temperature fluctuation) on surface of substrate may significantly affect the quality of the diamond film. It is found that, when temperature difference was under 1-2% of the maximum, it has a negligible negative effect on the growth of diamond film.

When diamond film was prepared on a hetero-epitaxial substrate, some defects and impurity in diamond film may be inevitably induced due to lattice mismatch and residual stress. It is observed from the experiment that the residual stress is the main defect in diamond film, which depends strongly on the substrate temperature.

In this paper, four diamond film samples had been prepared and tested under substrate temperatures of 870, 940, 980 and 1050 ^{o}C respectively. The other growth parameters are kept the same in all experiments. The residual stress in diamond film is measured using X-ray diffraction (XRD), and the corresponding results are listed in Fig. 3.

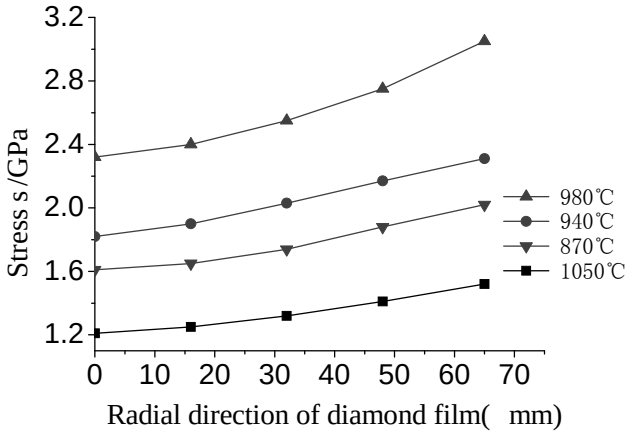

Fig. 3 Residual stress of diamond film

It is observed from Fig. 3 that the residual stress of the diamond film increases along with an increase in the substrate temperature when substrate temperature varied in the range 870-980 ^{o}C, Tensile stresses vary in range of 1.4 GPa - 3.0 GPa. It is interesting to note that the residual stress decreases significantly when the substrate temperature reaches 1050 ^{o}C. The mechanism for inducing this phenomenon should be further investigated.

It should be mentioned that, when the substrate temperature is in a higher, value, the nucleation process of some microcrystals of the original diamond film will speed up which causes the other microcrystals to slow down their emerging and growing process. As a consequence, in the thin film will be in low nucleation density and larger grain size. Noted that the coefficient of thermal expansion (CTE) of Mo substrate is higher than that of diamond, It may induce significant residual stress in diamond film when the film is cooling from a relatively high temperature, which will degrade its mechanical property [15]. If the internal stress of diamond film is greater and more than fracture strength of the diamond film, it may induce microcracks and even fracture.

To investigate further the formation mechanism of microcracks in diamond film, experimental testing using Optical microscope (OM) has been conducted. The OM photograph of diamond film is shown in Fig. 4.

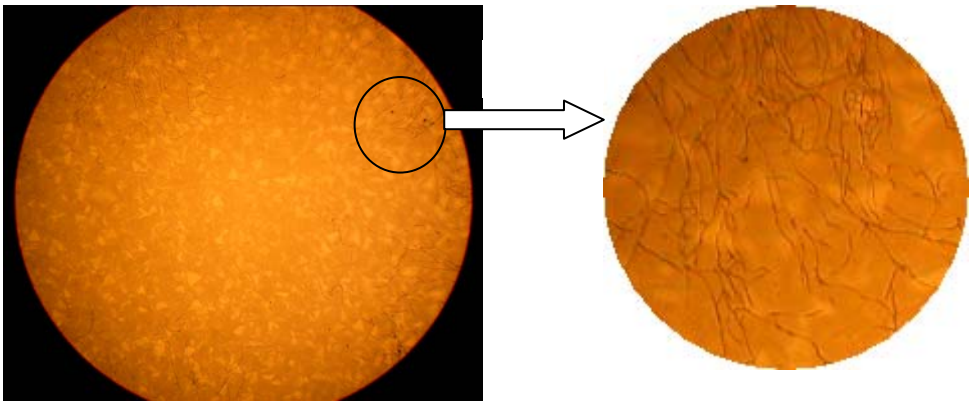

Fig.4. Optical microscope photograph of diamond film, (a) whole (30×), (b) an enlarged scale (100×)

It can be seen from Fig. 4 (a) that, in a low amplification, the size of the diamond crystals is approximately uniform and clear grain boundary appears. Fig. 4b shows an enlargement of microstructures of the diamond film. It is found that some radial microcracks penetrates the surface of diamond film and extends to the center area of the diamond film. Thus, when the substrate temperature is as high as 1050 ℃, some radial microcracks are created in the diamond and extend to the whole surface. Partial residual stress in diamond film is released with the creation of microcracks which is in agreement with the results shown in Fig. 3. Crack and defects cause significantly damage of physical and mechanical properties of the diamond film, including dimensional stability, mechanical stiffness, optical properties, and thermal conductivity.

The mechanism of defect formation in the thin diamond can also be explained as follows. Diamond film prepared on the substrate with curve surface usually accompanies some defects such as crack, non-diamond impurity, and microscopic hole due to inappropriate growth process. These defects like microcracks can extend to the surface of diamond film from somewhere inside. This is the major factor to cause diamond rupture. Fig. 5 shows a diamond film with some microcracks and non-microcrack.

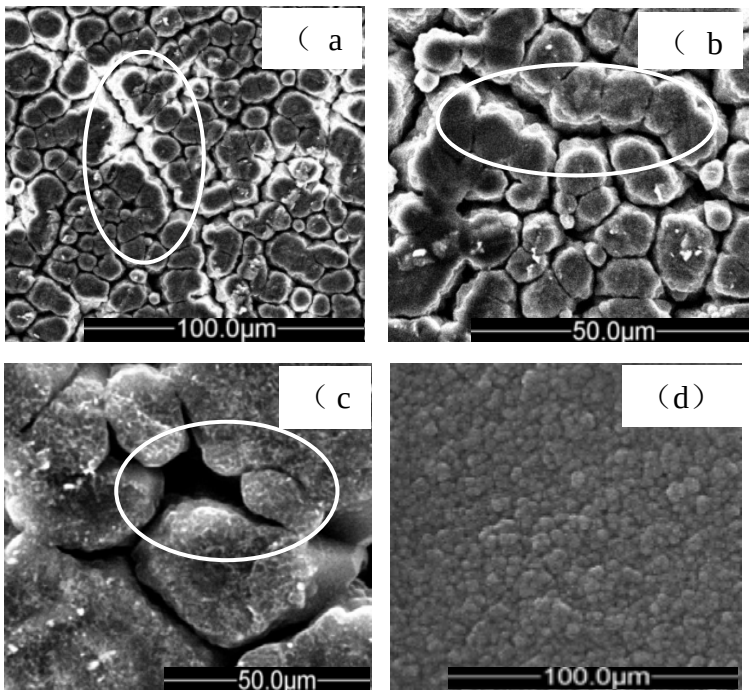

Fig.5. SEM photograph of diamond film, (a) little microcrack, (b) microcrack extending, (c) microscopic hole, (d) non-microscopic,

It is observed from Fig.5 that there exist some defects in the diamond film. In particular, some microcracks appeared in diamond film as shown in Fig. 5(a). When these microcracks further converge and accumulate, it may become a visible crack as shown in Fig. 5(b). Due to improper growth processes such as high or low substrate temperature, high CH_4 concentration and high growth rate, diamond film deposited with competitively columnar way, diamond film deposited may also contain some microstructure defects including amorphous carbon, graphite and microscopic hole as Fig.5c. It is also found from Fig. 5 that microcracks in diamond film generally appearing at grain boundary. These defects may cause sharply degrading in terms of physical and mechanical performance of diamond film.

CVD method, the process of synthetic diamond film has undergone the course of nucleation and growth. During the nucleation stage, the carbon-containing gas source under appropriate process parameters on the deposition substrate to form a certain number of isolated diamond nucleation. Growth stages of diamond nucleation continue to grow and even become one, to cover the entire surface of the substrate, and then grew along the vertical direction of the substrate; at last, it grew a certain thickness of the diamond film. While the nucleation density is usually less than 10^{12} cm^{-2} on the non-diamond substrate [16], which probably lead to a gap between the grain and the grain of the nucleation surface, so that the formation of the diamond film and the substrate are not entirely brought into close contact, and the presence of tiny non-contact area, these tiny non-contact area in the diamond film into an even cover the entire surface of the substrate still exists, leaving microvoids in the film based interface. Especially when the substrate temperature increases or high CH_4 concentration, this phenomenon is more obvious last microvoids evolved into micro-cracks as Fig. 5(a)-(c). The presence of micro-voids and microcracks weakening the binding of the diamond film and the substrate, between the interface of the diamond and the properties of diamond film, the crystal grains of the diamond film is formed the initial crack. Under external force, where the initial crack first cause stress concentration at the crack tip region caused by crack propagation, triggered coating breaking off. However, through the control of

the diamond film growth temperature, the concentration of carbon source and the substrate surface temperature uniformity optimization, we are able to prepare a high-quality, without micro-cracks diamond film, as shown in Fig.5 (d).

4. Results and discussion

The formation of defects and crack represents an intrinsic problem in fabricating diamond film structures. In this work, of the study on diamond film deposited at different substrate temperature, through combination use of XRD, OM and SEM shows that some defects rapidly increases along with an increase in the substrate temperature. XRD analysis testifies that high temperature result in high residual stress in diamond film when the substrate temperature is less than 980 ℃. When the substrate temperature exceeds 1050 ℃, diamond film prepared has very low residual stress due to having more cracks in the film and most residual stress being released. OM and SEM results reveal that some radial cracks penetrates surface of diamond film and extends to center of diamond film. When those cracks gathered and grow up, they may induce microscopic hole and even cause local fracture in diamond film.

Abstract Pressurized graphene bubbles have been observed in experiments, which can be used to determine the mechanical and adhesive properties of graphene. A nonlinear plate theory is adapted to describe the deformation of a graphene monolayer subject to lateral loads, where the bending moduli of monolayer graphene are independent of the in-plane Young's modulus and Poisson's ratio. A numerical method is developed to solve the nonlinear equations for circular graphene bubbles, and the results are compared to approximate solutions by analytical methods based on membrane and linear plate theories. The adhesion energy of mechanically exfoliated graphene on silicon oxide is extracted from two reported data sets. The strain distribution of the graphene bubbles and transport of gas molecules among the bubbles are discussed. Moreover, the effect of van der Waals interactions between graphene and its underlying substrate is analyzed, including large-scale interaction for nanoscale graphene bubbles subject to relatively low pressures.

Keywords Graphene, Adhesion, van der Waals interactions

1. Introduction

Graphene bubbles have been observed in experiments. Stolyarova et al. [1] observed nanoscale bubbles when mechanically exfoliated graphene flakes were placed on top of a silicon substrate covered with a thermally grown silicon oxide layer and exposed to proton irradiation. Much larger graphene bubbles were observed when the graphene flakes were exposed to vapors of hydrofluoric acid (HF) and water. In both cases, gas was released from the silicon oxide and trapped underneath the impermeable graphene, resulting in formation of the bubbles. More recently, Georgiou et al. [2] reported that bubbles are regularly found at the silicon oxide/graphene interface in large flakes obtained by mechanical cleavage. They observed graphene bubbles with diameters ranging from tens of nanometers to tens of microns and a variety of shapes (circular, triangular, and diamond). Bubbles have also been observed in graphene grown on metals such as Pt (111) [3] and Ru (0001) [4]. While the origin of graphene bubbles has not been fully understood and may depend on the material systems and experimental conditions, several potential applications of the graphene bubbles have emerged. Using highly strained graphene nanobubbles, Levy et al. [3] demonstrated enormous pseudo-magnetic fields and suggested strain engineering as a viable means of mechanical control over electronic structure of graphene. Georgiou et al. [2] demonstrated controllable curvature of graphene bubbles by applying an external electric field, which may be used as optical lenses with variable focal length. Zabel et al. [5] used graphene bubbles to study the Raman spectrum of graphene under biaxial strain. A well-controlled pressurization method was developed by Bunch et al. [6] to form graphene bubbles (or balloons) on patterned substrates, which was used to demonstrate the impermeability of graphene to gas molecules and to measure elastic properties of graphene. Following a similar approach, Koenig et al. [7] measured the adhesion energy between graphene and silicon oxide. On the other hand, Zong et al. [8] used intercalation of nanoparticles to generate graphene blisters on silicon surface and thereby provided a measurement of the graphene adhesion.

The present study focuses on the mechanics of graphene bubbles in order to establish a theoretical relationship between the morphology of graphene bubbles and the mechanical as well as interfacial properties of graphene. We present a nonlinear plate theory, adapted for the in-plane and bending properties of monolayer graphene. A numerical method is developed to solve the nonlinear

equations for circular graphene bubbles, subjected to gas pressure and van der Waals interactions. The numerical results are compared to the approximate solutions obtained by analytical methods. We show that, with known elastic properties of graphene, the adhesion energy between graphene and its substrate can be determined from the measurable dimensions of a graphene bubble (e.g., diameter and height). We confirm that the strain of graphene is non-uniform, varying from an equibiaxial strain at the center of the bubble to a uniaxial strain at the edge. The magnitude of the strain depends on the adhesion energy. The mechanics of graphene bubbles is extended to discuss transport of gas molecules among graphene bubbles of different sizes and the coalescence of graphene bubbles from a thermodynamics perspective.

2. A Nonlinear Plate Theory for Monolayer Graphene

The mechanical behavior of a graphene monolayer can be described by a mixed continuum mechanics formulation mapping a two-dimensional (2D) plane to a three-dimensional (3D) space [9]. Under the assumption of relatively small deformation but with moderately large deflection, a set of nonlinear equations can be used, which closely resemble the von Karman equations for an isotropic elastic thin plate. The only notable difference lies in the bending moduli of graphene. Unlike classical plate theory, the bending moduli of monolayer graphene are not directly related to the in-plane Young's modulus and Poisson's ratio. Instead, they are determined from atomistic modeling as independent properties [10-14]. As discussed in a previous study [13], the physical origin of the bending moduli of the monolayer graphene is fundamentally different from those in classical plate theory. In particular, we note that it is unnecessary to define a thickness for the graphene monolayer in the 2D continuum formulation.

Consider a circular graphene membrane subjected to axisymmetric loading. The displacements expressed in polar coordinates are: $u_r = u(r)$, $u_\theta = 0$, and $w = w(r)$. The corresponding in-plane strain components are:

$$\varepsilon_r = \frac{du}{dr} + \frac{1}{2}\left(\frac{dw}{dr}\right)^2, \tag{1}$$

$$\varepsilon_\theta = \frac{u}{r}. \tag{2}$$

The radial and circumferential membrane forces are

$$N_r = \frac{E_{2D}}{1-\nu^2}\left(\frac{du}{dr} + \nu\frac{u}{r} + \frac{1}{2}\left(\frac{dw}{dr}\right)^2\right), \tag{3}$$

$$N_\theta = \frac{E_{2D}}{1-\nu^2}\left(\nu\frac{du}{dr} + \frac{u}{r} + \frac{\nu}{2}\left(\frac{dw}{dr}\right)^2\right), \tag{4}$$

where E_{2D} is the 2D Young's modulus of graphene and ν is Poisson's ratio. The in-plane force equilibrium equation reduces to a nonlinear displacement equation

$$\frac{d^2u}{dr^2} + \frac{1}{r}\frac{du}{dr} - \frac{u}{r^2} = -\frac{1-\nu}{2r}\left(\frac{dw}{dr}\right)^2 - \frac{dw}{dr}\frac{d^2w}{dr^2}. \tag{5}$$

The bending moments are:

$$M_r = D\frac{d^2w}{dr^2} + \left(D - D_G\right)\frac{1}{r}\frac{dw}{dr}, \tag{6}$$

$$M_\theta = (D - D_G)\frac{d^2w}{dr^2} + \frac{D}{r}\frac{dw}{dr}, \tag{7}$$

where D and D_G are the two bending moduli corresponding to the mean curvature and the Gaussian curvature, respectively. The moment equilibrium equation leads to another nonlinear displacement equation

$$D\left(\frac{d^3w}{dr^3} + \frac{1}{r}\frac{d^2w}{dr^2} - \frac{1}{r^2}\frac{dw}{dr}\right) - \frac{E_{2D}}{1-\nu^2}\frac{dw}{dr}\left(\frac{du}{dr} + \nu\frac{u}{r} + \frac{1}{2}\left(\frac{dw}{dr}\right)^2\right) = \frac{1}{r}\int_0^r qrdr, \tag{8}$$

where q is the lateral loading intensity (e.g., pressure). In the present study, the lateral load intensity consists of a constant pressure (p) and the van der Waals (vdW) force between graphene and the substrate, i.e., $q = p - \sigma_{vdW}$, where $\sigma_{vdW} > 0$ for attractive force. By a simple model of vdW interactions [15], the vdW force is written as a function of deflection:

$$\sigma_{vdW}(w) = \frac{9\Gamma}{2\delta_0}\left[\left(\frac{\delta_0}{w+\delta_0}\right)^4 - \left(\frac{\delta_0}{w+\delta_0}\right)^{10}\right], \tag{9}$$

where δ_0 is the equilibrium separation and Γ is the interfacial adhesion energy. For monolayer graphene on SiO_2, experimental measurements have reported values from 0.4 to 0.9 nm for δ_0 [16-18] and from 0.09 to 0.45 J/m^2 for Γ [7, 8]. In the present study, we take $\delta_0 = 0.6$ nm and $\Gamma = 0.1$ J/m^2. For monolayer graphene bubbles, we use E_{2D} = 345 N/m, ν = 0.16, and D = 1.5 eV (or equivalently, 0.238 nN-nm). The radii of the graphene bubbles ranges from 10 to 1000 nm, and n = 1000 is used for the finite difference discretization.

3. Analytical Methods

Several approximate solutions for graphene bubbles were presented in a previous study [19]. They are briefly reviewed here for comparison with the numerical results.

3.1. Linear plate solution

For the linear plate analysis, the in-plane strain is assumed to be negligible, and Eq. (8) reduces to

$$D\left(\frac{d^3w}{dr^3} + \frac{1}{r}\frac{d^2w}{dr^2} - \frac{1}{r^2}\frac{dw}{dr}\right) = \frac{1}{r}\int_0^r qrdr. \tag{10}$$

Subjected to a uniform lateral load ($q = p$) and clamped boundary condition at the edge (i.e., $w = dw/dr = 0$ at $r = a$), Eq. (10) can be solved analytically by

$$w = h\left(1 - \frac{r^2}{a^2}\right)^2, \tag{11}$$

where a is the bubble radius and $h = \frac{pa^4}{64D}$ is the center deflection (bubble height).

3.2. An approximate membrane solution

For a membrane analysis, it is assumed that the bending stiffness is negligible. The nonlinear membrane equations however cannot be solved analytically. An approximate solution was developed by the energy method assuming the displacements [19]:

$$w = h\left(1 - \frac{r^2}{a^2}\right), \tag{12}$$

$$u = u_0 \frac{r}{a}\left(1 - \frac{r}{a}\right), \tag{13}$$

where $h = \left[\phi(\nu) pa^4 / E_{2D}\right]^{1/3}$ and $u_0 = \left[\psi(\nu) p^2 a^5 / E_{2D}^2\right]^{1/3}$, with $\phi(\nu) = \frac{75(1-\nu^2)}{8(23+18\nu-3\nu^2)}$ and $\psi(\nu) = \frac{45(3-\nu)^3(1-\nu^2)^2}{8(23+18\nu-3\nu^2)^2}$. A more accurate membrane analysis was developed by Hencky [20], which included 7 terms in the polynomial expansion of the deflection profile (as opposed to the two terms in Eq. 12) with the coefficients determined numerically for specific Poisson's ratios. In particular, for $\nu = 0.16$, the center deflection by Hencky's solution is: $h = 0.687\left(pa^4 / E_{2D}\right)^{1/3}$.

3.3. An approximate nonlinear plate solution

An energy method was used to develop an approximate solution to the nonlinear plate equations by assuming a deflection profile in form of (11) along with the radial displacement [19]

$$u = r(a-r)(c_1 + c_2 r). \tag{14}$$

Minimization of the potential energy leads to

$$c_1 = \frac{179 - 89\nu}{126}\frac{h^2}{a^3}, \tag{15}$$

$$c_2 = \frac{13\nu - 79}{42}\frac{h^2}{a^4}, \tag{16}$$

$$p = 64\eta(\nu)\frac{E_{2D}h^3}{a^4} + 64\frac{Dh}{a^4}, \tag{17}$$

where $\eta(\nu) = \frac{7505 + 4250\nu - 2791\nu^2}{211680(1-\nu^2)}$. It was shown that the approximate solution converges to the linear plate solution when the bubble height is small (h < 0.1 nm) but considerably underestimates the pressure when h > 1 nm.

4. A Numerical Method

A numerical method is developed to solve the coupled nonlinear equations, (5) and (8). For convenience we define an effective thickness, $h_e = \sqrt{\frac{12(1-\nu^2)D}{E_{2D}}}$, and re-write the equations in a dimensionless form

$$g = \frac{d^2\bar{u}}{d\bar{r}^2} + \frac{1}{\bar{r}}\frac{d\bar{u}}{d\bar{r}} - \frac{\bar{u}}{\bar{r}^2} + \frac{1-\nu}{2\bar{r}}\theta^2 + \theta\frac{d\theta}{d\bar{r}} = 0, \tag{18}$$

$$f = \frac{d^2\theta}{d\bar{r}^2} + \frac{1}{\bar{r}}\frac{d\theta}{d\bar{r}} - \frac{\theta}{\bar{r}^2} - 12\theta\left(\frac{d\bar{u}}{d\bar{r}} + \nu\frac{\bar{u}}{\bar{r}} + \frac{\theta^2}{2}\right) - \frac{1}{\bar{r}}\int_0^{\bar{r}} \bar{q}\bar{r}d\bar{r} = 0, \tag{19}$$

where $\theta = \frac{dw}{dr}$, $\bar{r} = \frac{r}{h_e}$, $\bar{u} = \frac{u}{h_e}$ and $\bar{q} = \frac{qh_e^3}{D}$. The equations are discretized by the finite difference method and solved by the Newton-Raphson method. At each iteration, the residuals are calculated and a correction vector is calculated as

$$\begin{pmatrix} \Delta\boldsymbol{\theta} \\ \Delta\bar{\mathbf{u}} \end{pmatrix} = -\begin{bmatrix} \dfrac{\partial \mathbf{f}}{\partial \boldsymbol{\theta}} & \dfrac{\partial \mathbf{f}}{\partial \bar{\mathbf{u}}} \\ \dfrac{\partial \mathbf{g}}{\partial \boldsymbol{\theta}} & \dfrac{\partial \mathbf{g}}{\partial \bar{\mathbf{u}}} \end{bmatrix}^{-1} \begin{pmatrix} \mathbf{f} \\ \mathbf{g} \end{pmatrix}, \tag{20}$$

where $\Delta\boldsymbol{\theta}$ is a vector of n-1 components ($\Delta\theta_k$, k = 1 to n-1) and same for $\Delta\mathbf{u}$, $\mathbf{f}$, and $\mathbf{g}$. The Jacobian matrix on the right-hand side of (20) consists of four square blocks, each with a rank of n-1. For the convergence criterion, we require that the L2-norm of the relative correction vector is smaller than a specified tolerance, namely

$$|\mathbf{R}| = \left[\sum_{k=1}^{n-1}\left(\Delta\theta_k^2/\theta_k^2 + \Delta u_k^2/u_k^2\right)\right]^{1/2} < \tau \sim 10^{-4}. \tag{21}$$

If not satisfied, the iteration procedure repeats with a new approximation, $\theta_k^{(i+1)} = \theta_k^{(i)} + \Delta\theta_k$ and $\bar{u}_k^{(i+1)} = \bar{u}_k^{(i)} + \Delta u_k$. Once converged, we calculate the deflection at each node by numerical integration:

$$\bar{w}_k = -\frac{\bar{a}}{2n}\sum_{m=k}^{n-1}\left(\theta_m + \theta_{m+1}\right). \tag{22}$$

for k = 0 to n-1, and the center deflection is then obtained as $h = w_0$. Moreover, we calculate the strain components at each node according to (1) and (2).

5. Results and Discussions

Using the numerical method in Section 4, we calculated the deflection profiles, $w(r)$, for graphene bubbles of various radii. Figure 1(a) shows the normalized deflection for a graphene bubble of radius a = 10 nm subject to increasing pressure (without van der Waals interaction). The deflection is normalized by the center deflection, $h = w_0$. In comparison, the analytical deflection profiles in (11) and (12) from the linear plate solution and the approximate membrane analysis are both independent of the pressure after the normalization. The numerical result agrees well with the linear plate solution at low pressures. As the pressure increases, the deflection profile approaches the membrane solution. Apparently, (12) is a reasonably good approximation for the deflection profile at high pressures. A more accurate membrane analysis [20] would yield a better approximation but also require a numerical method. Therefore, the analytical solutions in (11) and (12) may be considered as the lower and upper bounds for the deflection profiles.

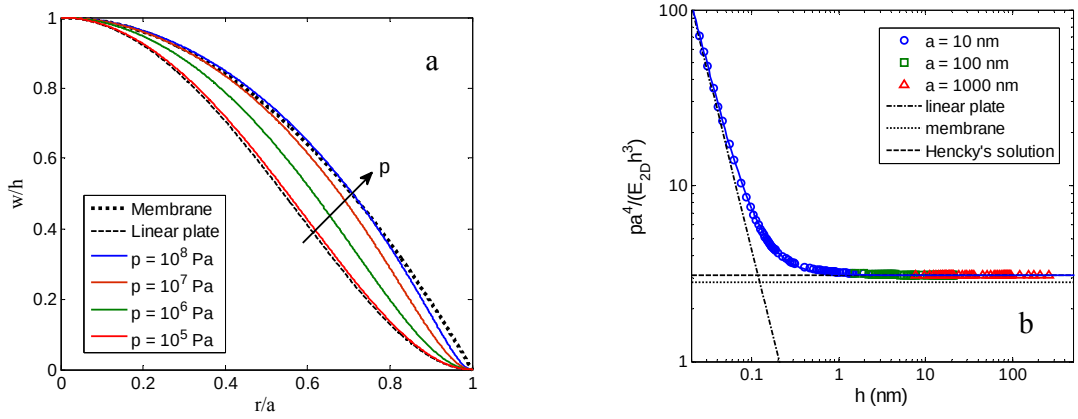

Figure 1. (a) Normalized deflection profiles of a graphene bubble (a = 10 nm) subject to increasing pressure; (b) Normalized pressure as a function of the center deflection.

The center deflection of a graphene bubble is a function of the pressure and the bubble radius. The linear plate solution predicts that the center deflection increases linearly with pressure ($h \propto p$). On the other hand, from the membrane analysis, the cube of the center deflection increases linearly with pressure ($h^3 \propto p$). We plot the center deflection versus a dimensionless group, $pa^4/(E_{2D}h^3)$, as shown in Fig. 1(b). In such a plot, the numerical results for different bubble radii collapse onto one master curve. When h > 1 nm, the numerical results agree closely with Hencky's membrane solution, while the simple membrane analysis in Section 3.2 underestimates the normalized pressure. It is found that the numerical results can be fitted by a single function that is a simple sum of the linear plate solution and the membrane solution:

$$\frac{pa^4}{E_{2D}h^3} = A(\nu) + B(\nu)\left(\frac{h_e}{h}\right)^2, \tag{23}$$

where A and B are two dimensionless functions of Poisson's ratio. From the membrane solution, $A = 1/\phi(\nu)$, which equals 2.825 for $\nu = 0.16$. On the other hand, Hencky's solution yields $A = 3.09$ for $\nu = 0.16$. From the linear plate solution, $B = \dfrac{16}{3(1-\nu^2)}$. The effective thickness, $h_e = \sqrt{\dfrac{12(1-\nu^2)D}{E_{2D}}}$, defines a length scale for the monolayer graphene. Therefore, the transition from the linear plate solution to the membrane solution depends on the ratio h/h_e. For relatively large bubbles (e.g., a > 100 nm), since the center deflection is typically much greater than h_e, the second term on the right-hand side of (23) is negligible and Hencky's membrane solution is sufficient.

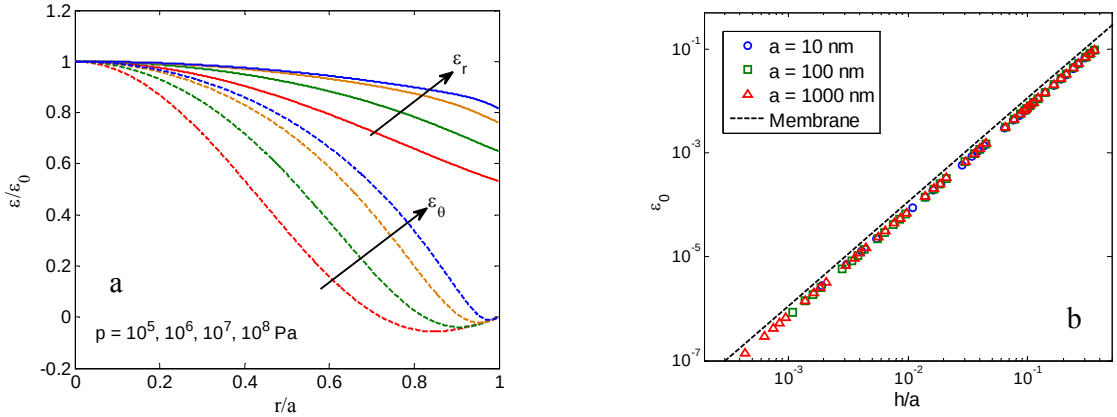

Figure 2. (a) Strain distributions in graphene bubbles (a = 10 nm) subject to increasing pressure; (b) Center strain versus h/a.

The strain distribution is important for strain engineering as a potential approach to manipulating the electronic properties of graphene [3, 4]. Figure 2(a) shows the strain distribution in graphene bubbles. By the symmetry and boundary conditions, the strain is equi-biaxial at the center (r = 0) and uniaxial at the edge ($r = a$). However, the strain distribution in between is very different from the prediction by the simple membrane analysis in Section 3.2. By inserting (12) and (13) into (1) and (2), the circumferential strain ε_θ would decrease linearly from the center to the edge, while the radial strain ε_r first decreases and then increases [19]. Moreover, the analytical membrane solution predicts that the normalized strain distribution should be independent of the pressure or the bubble radius. However, the numerical results clearly demonstrate that the strain distribution (after normalization) depends on both the pressure and the bubble radius. The difference in the strain

distribution between the numerical and the analytical solutions can be traced back to the difference in the deflection profiles as shown in Fig. 1(a). Furthermore, the in-plane radial displacement obtained by the numerical method differs from the analytical assumption in (13). Notably, the radial displacement becomes negative near the edge, resulting in compressive circumferential strain ($\varepsilon_\theta < 0$).

The equi-biaxial strain at the center ($\varepsilon_r = \varepsilon_\theta = \varepsilon_0$) is plotted in Figure 3(b) as a function of the normalized pressure. Noting that the center strain $\varepsilon_0 \propto (h/a)^2$ in both analytical solutions, we plot the numerical results as a function of *h*/*a* in Fig. 2(b). Indeed the numerical results for different bubble radii collapse onto one line with the slope 2 in the log-log plot. Therefore, the center strain may be written as

$$\varepsilon_0 = C(\nu)\left(\frac{h}{a}\right)^2, \tag{24}$$

where $C(\nu)$ is a dimensionless functions of Poisson's ratio. By the membrane solution in Section 3.2, $C(\nu) = \psi^{1/3}/\phi^{2/3}$, which equals 1.136 for $\nu = 0.16$. The numerical results can be fitted approximately by taking $C(\nu) = 0.76$. Therefore, the analytical membrane solution overestimates the center strain considerably.

Based on the membrane analysis, the adhesion energy of between graphene and its substrate can be determined from the measurements of the equilibrium bubble size (*a* and *h*) [19]. With the number of gas molecules (*N*) fixed inside the bubble, the potential energy is obtained as a function of the bubble radius

$$\Pi(a, N) = \frac{Nk_BT}{4} - Nk_BT \ln\left[\frac{p_0 a^{5/2}}{(Nk_BT)^{3/4} E_{2D}^{1/4}}\right], \tag{25}$$

where p_0 is the ambient pressure outside the bubble and k_B is Boltzmann constant. The first term on the right hand side of (25) is the strain energy in graphene, which is independent of the bubble size under the condition of constant *N*. The second term is the potential energy of the gas, relative to the reference state in the ambient condition. As the bubble radius *a* increases, the total potential energy decreases. Meanwhile, the interfacial energy increases as part of the graphene is detached from the substrate. The equilibrium bubble radius is attained when the potential energy of the bubble is balanced by the adhesion energy (Γ) of the graphene/substrate interface, which gives rise to the adhesion energy

$$\Gamma = -\frac{1}{2\pi a}\left(\frac{\partial \Pi}{\partial a}\right)_N = \frac{5Nk_BT}{4\pi a^2} = \frac{5E_{2D}h^4}{8\phi a^4}. \tag{26}$$

Combining (24) and (26), we have $\varepsilon_0 \propto (\Gamma / E_{2D})^{1/2}$. Therefore, the magnitude of the strain depends on the adhesion energy. This suggests that strain measurement could be used as an alternate approach for determining the adhesion energy [19]. On the other hand, to achieve a relatively large strain (> 5%) for strain engineering to manipulate the electronic properties of graphene [3, 4], the adhesion energy must be sufficiently high.

Georgiou et al. [2] measured the cross-sectional profile of a graphene bubble on an oxidized silicon substrate by atomic force microscope (AFM) in tapping mode. The bubble radius and central deflection were determined as $a = 1183$ nm and $h = 132$ nm. Using these values in (26), we obtain the adhesion energy Γ = 0.097 J/m^2. The data set from Koenig et al. [7] puts the adhesion energy in the range between 0.25 and 0.43 J/m^2, with an average value of 0.33 J/m^2. These values

are lower than the reported value (0.45 J/m^2) for monolayer graphene on silicon oxide [7]. The difference is partly attributed to the approximations made in the present membrane analysis as opposed to Hencky's solution used by Koenig et al. [7]. The scattering of the adhesion energy from these data suggest that the adhesion energy could be non-uniform due to the statistical nature of the surface roughness [21].

Stolyarova et al. [1] observed coalescence of graphene bubbles during annealing, which can be understood as a result of the transport of gas molecules along the interface driven by the different pressures in bubbles of different sizes. The membrane analysis predicts that the pressure inside the graphene bubble is inversely proportional to the bubble radius [19]. Consequently, the pressure is higher in the smaller bubbles and the pressure difference drives the gas molecules to diffuse from smaller bubbles to larger bubbles. The diffusion process is kinetically mediated and is enhanced by thermal annealing so that the large bubbles grow larger while the small bubbles disappear, similar to the Ostwald ripening process in thin film growth. The coalescence of graphene bubbles may also be understood from an energy consideration. It can be shown that the free energy of two small bubbles is greater than the free energy of one large bubble with the same total number of gas molecules [19]. Therefore, there exists a thermodynamic driving force for the two small bubbles to coalesce so that the total free energy is reduced. In other words, while each graphene bubble is in a thermodynamically equilibrium state, the system with a group of graphene bubbles is not in equilibrium. Since the graphene is impermeable [6], the kinetic pathways for the transport of gas molecules may include the graphene/substrate interface and the substrate bulk.

Figure 3(a) shows the deflection profiles of a graphene bubble (a = 10 nm) under the effect of vdW interaction. When the pressure is relatively low, the deflection is reduced considerably by the attractive vdW force. On the other hand, when the pressure is high, the effect of vdW force on the deflection is negligible. As shown in Fig. 3(b), the distribution of vdW force is non-uniform and depends on the pressure. In the spirit of nonlinear fracture mechanics [22], we may define an interaction zone where the vdW force is appreciable in comparison with the pressure, e.g., $\sigma_{vdW} > p/10$. Subject to a low pressure, the interaction zone spans the entire area underneath the bubble, indicating large-scale bridging from a fracture mechanics perspective. At a higher pressure level, the interaction zone is much smaller, where the condition of small-scale bridging prevails. Consequently, in the presence of vdW interactions, the relationship between the center deflection and the pressure becomes nonlinear at low pressures.

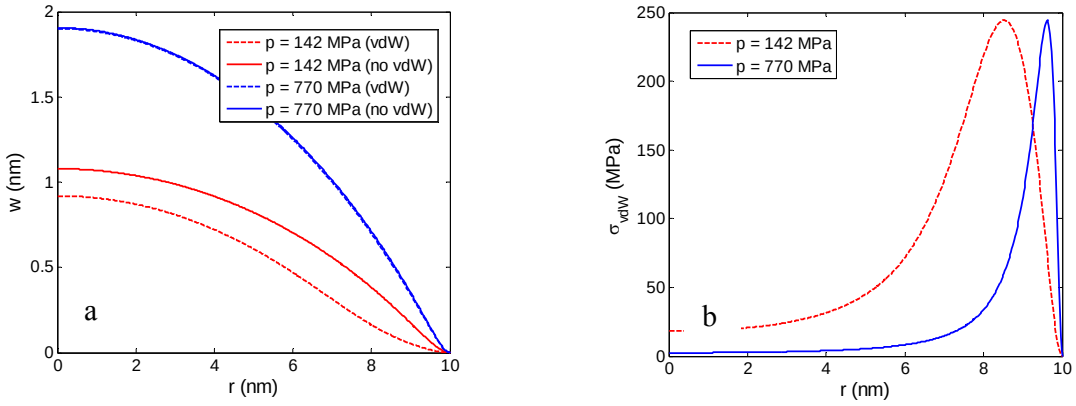

Figure 3. (a) Effect of the vdW interaction on the deflection profile of a graphene bubble (a = 10 nm); (b) Distributions of the vdW force intensity.

6. Summary

A nonlinear plate theory is adapted to describe the deformation of a graphene monolayer subject to lateral loads. A numerical method is developed to solve the nonlinear equations for circular graphene bubbles. In comparison to approximate solutions by analytical methods, it is found that the deflection profile and the strain distribution are generally not well described by the analytical solutions. Based on the numerical results, approximate formulae for the center deflection and center strain are suggested. We show that, with known elastic properties of graphene, the adhesion energy between graphene and its substrate can be determined from the measurable dimensions of a graphene bubble (e.g., diameter and height). The mechanics of graphene bubbles is extended to discuss transport of gas molecules among graphene bubbles of different sizes and the coalescence of graphene bubbles from a thermodynamics perspective. Moreover, the effect of van der Waals interactions between graphene and its substrate is found to be significant when the center deflection is relatively small due to large-scale adhesive interactions.

Abstract We investigated the self−crack−healing behavior of SiN/SiC nano-laminated film. Moreover, we discussed the healing condition including heating temperature and heating time. The films were deposited on a silicon substrate using an ion-beam-assisted deposition. The SiN/SiC nano-laminated film was fabricated with alternating layers of SiN and SiC. After the deposition, a pre-crack was introduced using a Vickers indentor. Then, the cracked samples were heated using an electric furnace in an air atmosphere at the temperature of 600 °C to 1200 °C.
In the case of the SiN and SiC monolayer films, the crack was poorly healed after heating irrespective of the temperature. This was because the size of the crack opening increased after heating. On the other hand, slight crack healing occurred at the temperature of 600 °C. Crack healing improved with an increase in the heating temperature and time. From these results, we concluded that SiN/SiC nano-laminated film has a superior self-crack-healing ability.

Keywords Self-healing, Thin film, Crack, High temperature, Oxidation

1. Introduction

Ceramic thin films are one of the key materials in micro-electro-mechanical systems (MEMS) such as sensors and micronozzles. Ceramic thin films are superior to metals in terms of strength, heat resistance, and corrosion resistance. However, the sensitivity of these thin films to defects is extremely high and their fracture toughness is much lower than those of metals. The reliability of ceramic thin films decreases significantly once a crack is initiated. Therefore, defects that occur during the deposition and etching process significantly affect the strength and life of MEMS.

For use in MEMS employed under severe conditions such as high temperature or a corrosive environment, ceramic thin films are required to be made more reliable. Self-healing is an important concept for improving the reliability and lifetime of the mechanical components. Recently, various self-healing materials such as polymers, concrete, composites, and coating have been developed by researchers [1–4]. If this ability can be applied to ceramic thin films, then minor defects can be tolerated and cracks caused from the defects during service can be healed before the entire system breaks down.

In bulk materials, certain kinds of structural ceramic composites exhibit self-crack-healing behavior at high temperatures [5–8]. One such composite is silicon nitride (Si_3N_4) reinforced by silicon carbide (SiC) nanoparticles. When a cracked Si_3N_4 composite is heated to a temperature over 800 °C in air, the SiC particles exposed on the crack plane thermochemically react to form silicon dioxide (SiO_2). As this reaction proceeds, the crack is filled by SiO_2, because the volume of SiO_2 expands as compared with that of SiC. The additional SiC plays an important role in the crack healing because of its low reaction enthalpy [8]. Other research groups have reported that a TiC/Al_2O_3 composite coating fabricated by plasma spraying also exhibits self-crack-healing by oxidation in the same manner as that in Si_3N_4 ceramic composites [9].

On the basis of the above reports, it is thought that carbide composite thin films may also exhibit a self-crack-healing ability at high temperatures. In general, thin films for MEMS are fabricated by

chemical vapor deposition (CVD) or physical vapor deposition (PVD). However, it is difficult to control the precipitation and dispersion of carbide in these methods. Nanolaminated structures are effective for increasing the crack-growth resistance. Moreover, the crack healing is always induced because a crack can pass the carbide layer surely. In this study, we investigated the self-crack-healing ability of SiN/SiC nano-laminated films at high temperatures. Cracked samples of SiN/SiC nano-laminated films were heated under various heating conditions in air to clarify the factors influencing the self-crack-healing ability of the thin films. In addition, the healed crack was observed and analyzed using scanning electron microscopy (SEM), a focused ion beam system (FIB), and Auger electron spectroscopy (AES) to further analyze the crack healing behavior.

2. Experimental procedures

SiN/SiC nano-laminated films were deposited on Si(100) substrates by ion-beam-assisted deposition (IBAD) [10]. The substrates were cleaned by successive rinsing in ultrasonic baths of acetone. After cleaning, the Si substrates were placed on a water-cooled holder. After the placement of the substrates, the chamber was evacuated to a base pressure of 3×10^{-4} Pa. Prior to deposition, the substrates were sputtered using a nitrogen ion beam at an acceleration voltage of 2 keV for 15 min.

The SiN/SiC nano-laminated films were fabricated with alternating layers of SiN and SiC. The deposition conditions for SiN and SiC are shown in Table 1. The SiN layer was obtained by an electron beam evaporation of silicon (purity: 99.99%) and the simultaneous bombardment of a nitrogen ion beam. The SiC layer was deposited by electron beam evaporation of silicon and simultaneous bombardment of argon ion beam under an ethylene atmosphere at a partial pressure of 2.0×10^{-2} Pa [11]. The fabricated laminated films consisted of four layers and the top layer was SiN. The bilayer thickness was 500 nm. Monolayer films of SiN and SiC were also fabricated in order to compare their properties with those of the SiN/SiC nano-laminated films. The total thickness of all the films was 0.9–1.2 μm.

After the film deposition, a small artificial crack was introduced using a Vickers indenter at a load of 2.0 N. Figure 1 shows an example of the indentation and crack, as observed by field-emission scanning electron microscopy (FE-SEM). A radial crack occurred from the corner of the indentation, as shown in Fig. 1. The cracked samples were heated using an electric furnace in an air atmosphere. It has been reported that the self-crack-healing behavior is dependent on various factors such as heating temperature, heating time, and atmosphere [5]. In this study, the self-crack-healing behavior of the nano-laminated films was investigated systematically by changing the heating temperature

Table 1. Deposition conditions.

	SiN	SiC
Arc voltage (V)	80	
Ion beam	Nitrogen	Argon
Gas flow rate (sccm)	4.0	1.5
Acceleration voltage (keV)	2.0	0.3
Deceleration voltage (keV)	0.3	1.0
Acceleration current (mA)	14.0	15.0
Atmosphere gas	-	Acetylene
Vapor rate (nm/s)	0.2	0.1

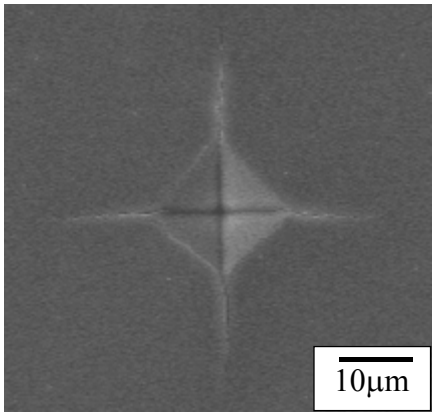

Figure 1. FESEM image of indentation and cracks on SiN film.

(T_h = 600–1200 °C) and time (t_h = 24 h, 48 h, 72 h).

The surface morphology and cross section of the samples were examined by FE-SEM. The chemical composition was analyzed by X-ray photoelectron spectroscopy (XPS). AES was used to observe the distribution of the oxides generated by crack healing. Before both analyses, Ar ion sputtering at an acceleration energy of 3 keV was conducted for 10 s to remove any contamination.

3. Results and discussion

3.1 Film morphology

Figure 2 shows the FE-SEM images of the surface and cross section of the deposited films. All films had an extremely smooth morphology. Although the interface between SiN and SiC can be observed, a columnar structure was not observed. Moreover, X-ray diffraction peaks could not be observed. On the basis of these results, it is suggested that the SiN and SiC films fabricated in this study were amorphous.

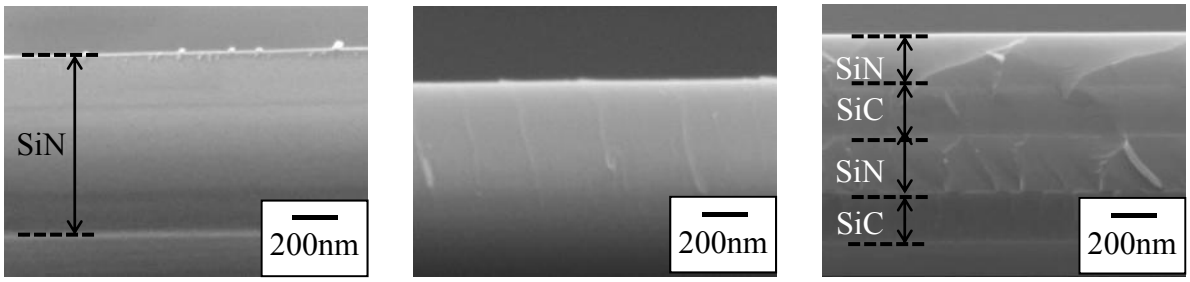
3.2 Chemical composition

The average chemical compositions obtained by XPS analysis are summarized in Table 2. Both films contained some oxygen atoms. It is postulated that the water vapor evaporated during the heating with the electron beam might have been entered the film. Therefore, it is suggested that the SiN and SiC films include some oxide compounds, most probably, SiO_2.

3.3 Crack healing behavior

3.3.1 Effect of film structure

Figure 3 shows the FE-SEM images of the indentation and crack after heating the samples at a temperature of 800 °C for 24 h. In the case of the SiN and SiC monolayer films, the crack was poorly healed after heating, as shown in Figs. 3(a) and (b), respectively; however, a slight crack healing did occur near the crack tip. Moreover, the size of the crack opening increased after heating. When SiN_x and SiC are heated in air, oxidation occurs by the following chemical reactions:



(a) SiN film (b) SiC film (c) SiN/SiC film

Figure 2 FE-SEM images of cross section of thin films.

Table 2. Chemical composition of SiN and SiC film.

Film	Si	N	C	O
SiN	59.6	25.1	–	15.3
SiC	62.7	–	16.2	21.1

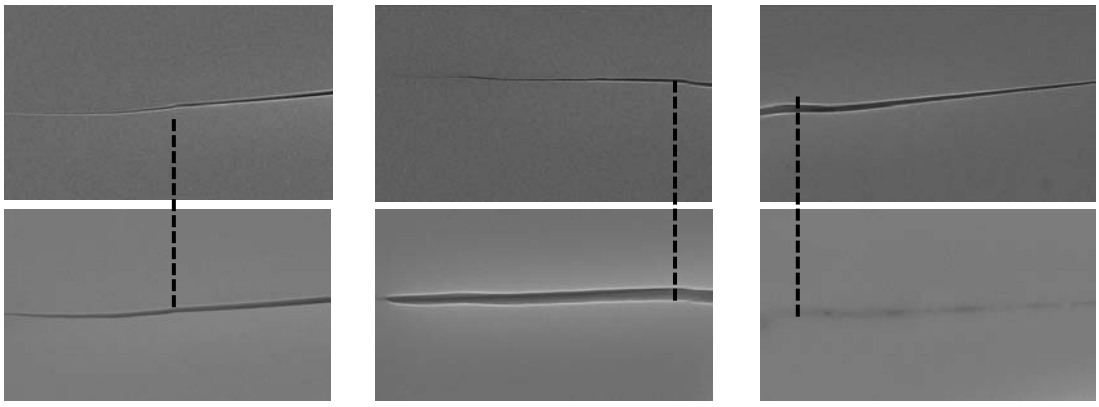
$$2SiN_x + 2O_2 \rightarrow 2SiO_2 + xN_2 \quad (1)$$
$$SiC + 3/2O_2 \rightarrow SiO_2 + CO \quad (2)$$

These chemical reactions results in volume expansion, and thereby, crack healing. In the case of the SiN and SiC monolayer films, it was concluded that the crack healing did not occur sufficiently because the volume of the crack-opening region was larger than the volume expansion due to the oxidation reaction.

On the other hand, the cracks in the SiN/SiC nano-laminated films were healed without an increase in crack opening, as shown in Fig. 3(c). The laminated structure probably decreases the residual stress. Delamination was observed around the indentation, which occurred during the heating because the delamination cross section was covered with oxidation products.

Figure 4 shows the FE-SEM image of the cross section of the healed crack. The cross section was achieved using a focused ion beam system. The crack reached the substrate through the film. It was found that the crack in the film was also healed internally. Moreover, the laminated structure was still preserved, which suggests that the oxidation reaction occurred only on the crack plane exposed to air.

The oxide distribution around the indentation and cracks after heating was analyzed using AES. Figure 5 shows a mapping image of oxygen around the indentation and cracks. The Auger electron counts for oxygen were high along the healed crack. It is suggested that the oxidation reaction induced crack healing similar to the healing of bulk Si_3N_4/SiC composites. These results indicate



(a) SiN film (b) SiC film (c) SiN/SiC film

Figure 3. FE-SEM images of crack tip before and after heating. The upper and below images indicate crack before and after heating, respectively. The dotted lines indicate the same points before and after heating.

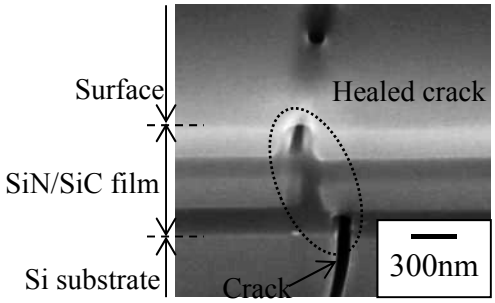


Figure 4. FE-SEM image of cross section of healed crack.

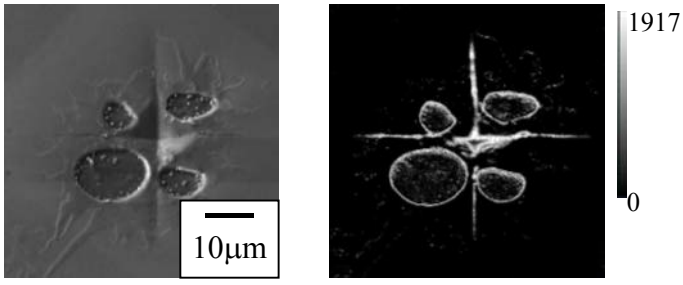


(a) SEM image (b) Oxygen mapping image

Fig. 5 SEM and AES mapping image of oxygen after heating.

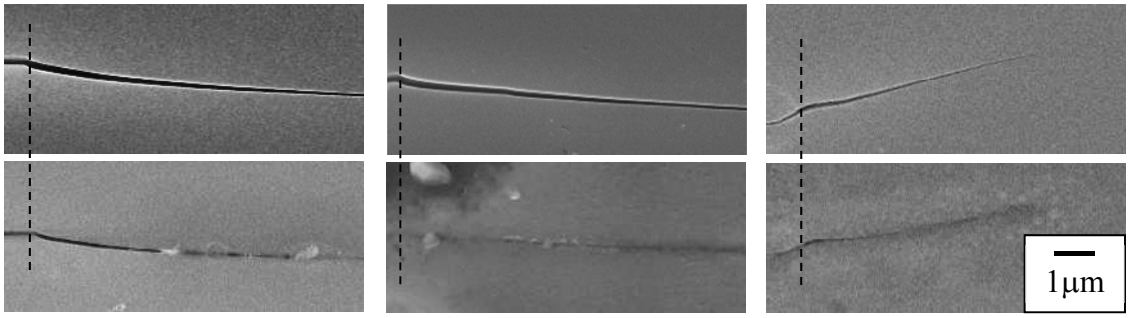
that the self-crack-healing ability of a SiN/SiC nano-laminated film is superior to that of a monolayer film.

3.3.2 Effect of heating temperature

The influence of heating temperature on the self-crack-healing behavior was investigated. The heating temperature was varied from 600 °C to 1200 °C and the heating time was fixed at 1 h. Figure 6 shows the FE-SEM images of the indentation and cracks after heating. Slight crack healing occurred at the temperature of 600 °C. Crack healing improved with an increase in the heating temperature, and heating at 1000 °C healed the crack perfectly. However, at 1200 °C, observation of the cross section and analysis of the chemical composition revealed that even though the crack was healed, the laminated structure disappeared because of oxidation. This indicates that the crack healing ability also disappears once the SiN/SiC nano-laminated film is heated to temperatures over 1200 °C.

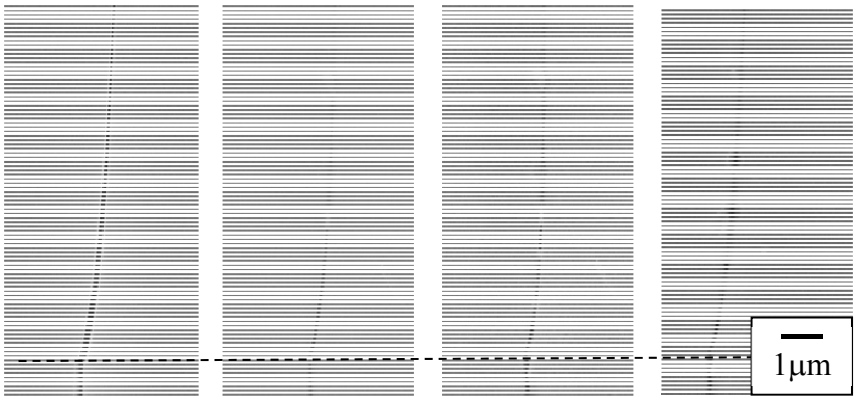
3.3.3 Effect of heating time

The influence of heating time on the self-crack-healing behavior was also investigated. The heating time was varied from 24 h to 72 h at the heating temperature of 600 and 800 °C. Figure 7 shows the FE-SEM images of the indentation and cracks after heating. At 600 °C, crack healing improved with an increase in the heating time. However, at temperatures over 800 °C, the influence of heating



(a) 600 °C (b) 1000 °C (c) 1200 °C

Figure 6. Influence on heating temperature on the crack healing. The upper and below images indicate crack before and after heating respectively. The dotted lines indicate the same points before and after heating.



(a) Before heating (b) After 24h (c) After 48h (d) After 72h

Figure 7. Influence on heating time on the crack healing. The dotted lines indicate the same points before and after heating.

time on the crack healing was not observed clearly. It was postulated that the oxidation reaction on the crack plane was almost completed at 24 h at temperatures over 800 °C because the crack plane exposed to air is extremely small in the case of a thin film.

4. Conclusions

In this study, we investigated the self-crack-healing ability of SiN and SiC monolayer films and SiN/SiC nano-laminated thin films subjected to high temperatures in an air atmosphere. We also analyzed the influence of heating temperature and heating time on the healing ability of the nanolaminated thin films. The investigation yielded the following conclusions:

1. In SiN and SiC monolayer films, cracks were poorly healed because the size of the crack opening increased significantly during heating. On the other hand, SiN/SiC nano-laminated films exhibited a superior self-crack-healing ability.
2. Around the healed crack, the oxygen concentration was found to be high. This indicates that crack healing was achieved by oxidation.
3. Crack healing was promoted by an increase in the heating temperature and time. However, at temperatures over 1200 °C, the laminated structure disappeared and the film was subjected to oxidation overall.

Abstract The key static and dynamic mechanical properties and fracture behavior of nanocomposite films composed of a poly(vinylidene fluoride) (PVDF) matrix and different contents of polyhedral oligomeric silsesquioxane (FP-POSS) were researched by nano-tensile testing. The Young's modulus, storage modulus, loss modulus, loss tangent, yield strain, yield strength, tensile strength, fracture strength, fracture strain, fracture toughness and fracture deformations of all different nanocomposite systems were obtained. The influence of FP-POSS and its contents on the mechanical properties of PVDF was analyzed. Results showed that both the stiffness and toughness of PVDF were enhanced at some specific FP-POSS content and further additions of FP-POSS brought dramatic enhancements in toughness while associated with a decline in stiffness. Dynamical mechanical properties showed that FP-POSS increased the viscosity of PVDF. The mechanism of the effects of FP-POSS on PVDF was analyzed from the unique nano scale organic-inorganic molecular structure of FP-POSS and the micro structures of the nanocomposite films

Keywords Poly(vinylidene difluoride), Polyhedral oligomeric silsesquioxanes, Nano-tensile, Mechanical properties, Fracture

1. Introduction

Poly(vinylidene difluoride) (PVDF) is a kind of semicrystalline polymer and widely used in smart structure sensors, actuators, and soft/thin transducers since it exhibits excellent piezoelectric and pyroelectric properties which derive from the two polar phases β and γ of PVDF [1, 2]. But unfortunately, neat PVDF can not completely meet the mechanical, thermal, and oxidation resistance property requirements of some harsh environments [3, 4]. Many efforts have been taken to improve the properties of PVDF. For example, incorporation of organic polymer or inorganic fillers into the PVDF matrix to produce composites has been extensively studied with the objective of further improving its properties [5-7]. However, few materials are miscible when melted with PVDF, and their improvement in one property is always accompanied by a deterioration in others. Over the past decade, Polyhedral oligomeric silsesquioxanes (POSS) have been widely known as a unique class of organic-inorganic hybrid materials which exhibits many superior thermomechanical properties in terms of wearability, thermal stability, oxidation resistance and high strength [8-10] because of the robust inorganic cage-like core structure with the Si-O atoms, while at the same time they perform very good bonding capability with polymeric base matrixes because of the alterable organic branches on the corners of the core. For a polymer matrix, it is widely accepted that inorganic fillers tend to improve in stiffness while organic ones in toughness. But as a kind of organic-inorganic hybrid compounds, how will fluorinated POSS influence the mechanical properties and fracture behaviors of PVDF needs to be researched. Our previous work has been proved that fluorinated POSS compounds and PVDF are fully miscible at any temperature and the miscibility is derived from the polar C-F bonds and the electrostatic interactions in the POSS and PVDF molecules [11]. The molecular dynamics simulation results show that the glass transition temperature of PVDF was significantly improved with (3, 3, 3- trifluoropropyl)$_8$Si$_8$O12 (FP-POSS) [12] and the moduli of PVDF were improved and the improvement effect, in general, nearly decreased with the increase of the mass ratio of FP-POSS [13]. However, simulation results need to be verified from experiments. And in addition, some other key mechanical properties, especially the fracture properties can only be effectively obtained by this means.

As a standard mechanical test method, the tensile test has been widely used to determine some important mechanical properties such as Young's modulus, fracture toughness and yield stress of materials. But a traditional tensile test is not capable of a sample with nano scale size, where a very small tensile load and very precise measure equipments are needed. In recent years, the nano-tensile test has been developed and used to characterize the tensile behaviors of very small samples such as the nanotubes, silk, fibers and so on [14-16]. The nano-tensile test is also used to determine some dynamic mechanical properties by adding a very small harmonic force with specific frequency on the sample [17]. In this work, the PVDF/FP-POSS nanocomposites were firstly prepared by the solvent evaporation method. And then the nano-tensile testings were carried out. Although similar work has been performed and some valuable results have been given [18, 19], the focus of this work is on the tensile properties of PVDF/POSS at a relative high strain rate and the fracture behaviors were analyzed in detail from the experimental data and microscopy images.

2. Experimental

2.1. Materials and sample preparation

The detailed solvent evaporation method to prepare the neat PVDF and its FP-POSS nanocomposites can be found in Ref. [18, 19]. The mass ratios of FP-POSS added to the PVDF matrix were 0%, 3%, 5%, and 8%, and nanocomposites with different FP-POSS contents are denoted as PVDF-FPi% (i = 0, 3, 5 and 8), which has the morphology of film with the thicknesses around 70~110 μm. In addition, the films were white and translucent, with the exception of neat PVDF, which appeared to be transparent. With increased percentage of FP-POSS, the transparency of the films declined. The images of PVDF-FP$_i$% (i = 0, 3, 5 and 8) films are shown as figure 1. Samples for nano-tensile testing were cut from these films. The size of the samples is about ~100um×~10mm (shown as figure 2, but not exactly the same size in each test).

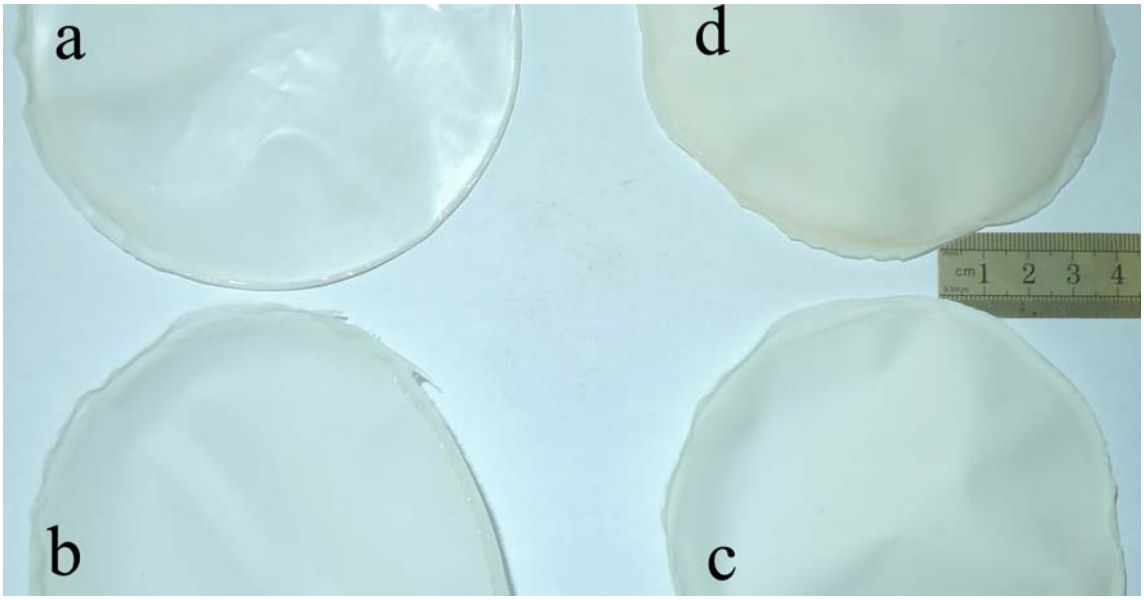

Fig. 1 Films of PVDF-FP$_i$% obtained by solution, i= (a) 0, (b) 3, (c) 5 and (d) 8.

2.3. Morphology and structure characterization

Optical microscopy was performed on the nanocomposite films to observe the fracture morphologies by using a VHX 600E digital microscope (Keyence Company) with a real-time depth composition, two/three-dimensional functions, and 20× to 5000× zoom. Scanning probe microscopy

(SPM) was performed using a SPM9500J2 microscope (Shimadzu Company) for images processing and profile analysis. The detailed results about the mciro structures and the crystallization of all the samples have been analyzed in Ref. [18].

2.3. Nano-tensile testing

A commercial nano-tensile testing system (Nano UTMTM Universal Testing System T150, Agilent Technologies, Inc.) with the method of UTM-Bionix Standard Toecomp CDA was used to conduct the tensile test in this paper. Detailed information and the image of the instrument were introduced in Ref. [18]. The samples were cut from PVDF-FP$_i$% films and seem like slender belts as shown in Fig. 2. The length and height of the belt like samples were measured by a caliper and screw micrometer, and the width was measured by the VHX 600E optical microscopy. Three individual samples have been prepared and tested in each category. The tensile strain rate was set as 1.0×10^{-2} s^{-1} here, which is ten times that of 1.0×10^{-3} s^{-1} in Ref. [18].

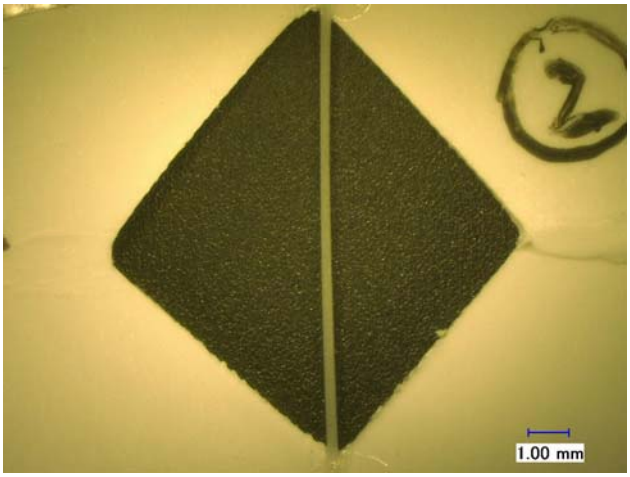

Fig.2. The image of the sample for the nano-tensile testing measured by optical microscopy.

3. Results and Discussion

3.1. Engineering stress-strain response

The engineering stress-strain responses for PVDF-FP$_i$% as obtained from the nano-tensile testing are shown in Fig. 3. The key points in these curves, such as the offset yield strain (0.2% offset), peak stress and break point, have been labeled as letters Y, P and B, respectively. The subscript numbers point out which sample these values belong to. The full stress-strain curves can be divided into three regions: (1) the elastic region (from the start point to Y), in which recoverable (elastic) deformation happens and the Hooke's law is satisfied between the stress and strain thus the Young's modulus can be computed. The stress at the offset yield strain point (σ_y) is called the tensile yield strength [20]; (2) the strain hardening region (Y→P), in which the stress is no longer proportional to strain and permanent nonrecoverable (plastic) deformation occurs. The stress at the maximum on the engineering stress–strain curve (point P) is defined as the tensile strength or ultimate strength [21]; (3) the unstable failure region (P→B), in which a small constriction or neck begins to form at some point, and fracture ultimately occurs at the neck. The fracture strength [20] corresponds to the stress at fracture and the area under the stress-strain curve up to the point of fracture is used to detect the fracture toughness, which is a measure of the ability of a material to absorb energy up to fracture and always used to delineate the brittleness or ductility of a material. All these key mechanical properties, for PVDF-FP$_i$% in the three regions are listed in table 1.

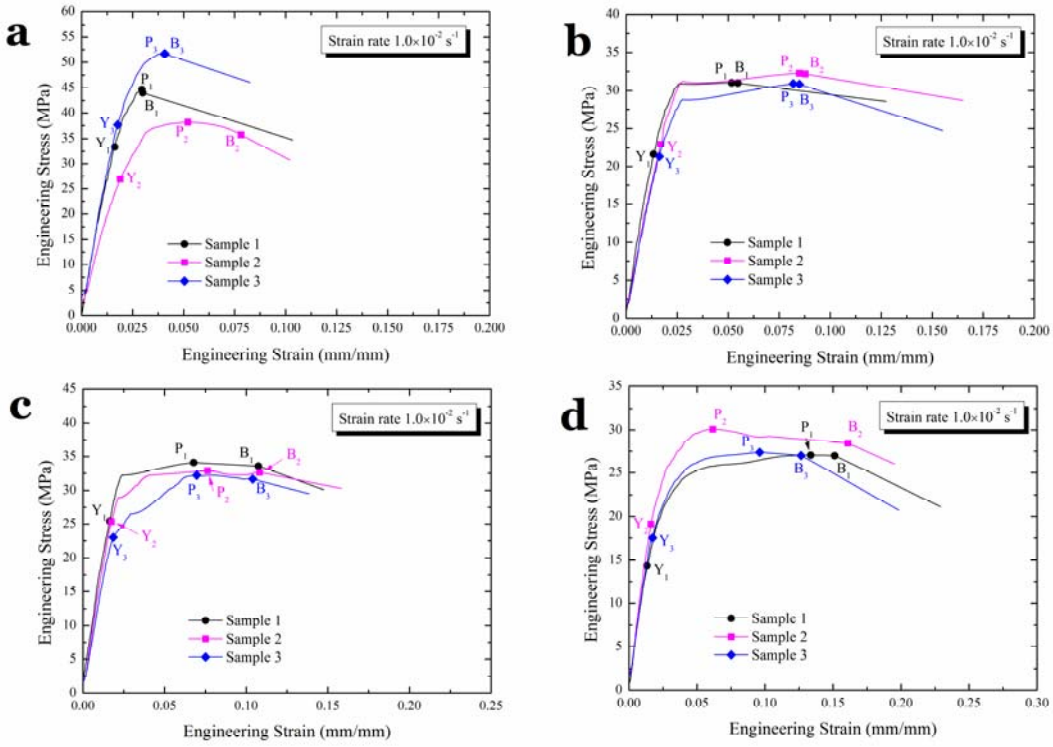

Fig. 3. Engineering stress-train response for PVDF-FP$_i$%, i= (a) 0, (b) 3, (c) 5 and (d) 8 at strain rate of 1.0×10^{-2} s^{-1}. The letters Y, P and B locate the positions of offset yield strain, peak stress and break point, respectively.

The Young's modulus of PVDF-FP$_{i\%}$ follows the orders PVDF-FP$_{0\%}$ > PVDF-FP$_{3\%}$ > PVDF-FP$_{5\%}$ > PVDF-FP$_{8\%}$. This means that the addition of FP-POSS reduced the modulus values of PVDF, which is quite different from the results in Ref. [13, 18]. This is probably resulted from two factors: (1) the much higher tensile strain rate, which is ten times that in Ref. [18]. A higher strain rate in tensile testing tends to achieve higher Young's modulus values. Thus nearly all the moduli of PVDF-FP$_{i\%}$ are greater than those obtained at the strain rate of 1.0×10^{-3} s^{-1} [18] except PVDF-FP$_{3\%}$; (2) the thinner film of PVDF-FP$_{0\%}$ (as shown in Fig.1, the film of PVDF-FP$_{0\%}$ is much thinner than the three other ones), which will bring the so called size effect during the tensile test and make the modulus value of PVDF-FP$_{0\%}$ become higher. But anyway, it is obvious that the elastic modulus of PVDF was weakened by further additions of FP-POSS at high strain rate. The values of yield strength (Y_S), tensile strength (T_S), and fracture strength (F_S) show a similar trend and indicate the FP-POSS contents have the similar effect on the strength of PVDF. The values of offset yield strain (ε_y) are almost the same for PVDF-FP$_{5\%}$ and PVDF-FP$_{0\%}$ and a little higher for PVDF-FP$_{3\%}$ and PVDF-FP$_{8\%}$, shows there is no obvious rule to describe the effect of FP-POSS on the elastic deformation range of PVDF at high strain rate.

The elongation at break (fracture strain) and fracture toughness values reveal an undoubtedly influence of FP-POSS on PVDF. The fracture strain and fracture toughness increase with the increasing content of FP-POSS. The value of εf increases from 4.9 % to 14.62 %, giving PVDF-FP$_8$% the toughness ~200 % higher than that of neat PVDF. Dramatic enhancements in fracture toughness can be observed when the FP-POSS content reaches to some extent. The content of 3 wt.% FP-POSS only brings a 26 % increase of the fracture toughness to PVDF (1.99 MPa vs. 1.58 MPa). However, when the content of FP-POSS reaches to 8 wt.%, the enhancement in fracture toughness will increase sharply to 130 % (3.63 MPa vs. 1.58 MPa). The similar mechanism to the toughness enhancements at high strain rate can be deduced from the microstructures of neat PVDF and its FP-POSS nanocomposites that have been detected [18]. The effect of FP-POSS in PVDF has

been proved to form bigger PVDF particles. FP-POSS act like the nucleating agents in PVDF mixtures and make more PVDF molecules be nucleated around them. Thus the particles are more separate and the domain size of the particles becomes larger with the increasing of the FP-POSS content. In contrast to the neat PVDF, more separate and less cross-linked particles in PVDF nanocomposites (especially in PVDF-FP_5% and PVDF-FP_8%) lead to a structure much more conductive to plastic flow under applied stress and result in a more efficient energy-dissipation, thereby reducing crack formation [22].

Table 1. The Young's modulus (E), offset yield strain (ε_y), yield strength (Y_S), tensile strength (T_S), fracture strength (F_S), fracture strain (ε_f) and fracture toughness (K_c) of PVDF-FP_i% (i = 0, 3, 5 and 8) as obtained from stress-strain responses and hardness values.

FP-POSS (wt.%)	E (GPa)	ε_y (%)	Y_S(MPa)	T_S (MPa)	F_S (MPa)	ε_f (%)	K_c (MPa)
0	2.17(0.46)	1.73(0.12)	32.14(6.21)	44.83(6.76)	44.18(7.75)	4.90(2.40)	1.58(0.80)

3.2. Dynamic mechanical properties

There is a sensitive spring installed in T150 which can provide a very small harmonic force with specific frequency on the sample thus the dynamic mechanical properties of PVDF-FP_i%, such as the storage modulus, loss modulus and loss tangent can also be obtained during the tensile procedure. To viscoelastic materials, the storage modulus measures the stored energy, representing the elastic portion; and the loss modulus illustrates the energy dissipated as heat, representing the viscous portion ; the loss tangent is defined as the ratio of viscous to elastic portion and would change with the storage and loss modulus. The value of loss tangent is important to measure the viscoelastic properties of a material. A value of 0 means that a material is fully elastic while a high value represents a material with high viscosity. Dynamic mechanical properties are helpful to understanding and confirming the energy-dissipation mechanism for PVDF-FP_i% as analyzed previously.

Table 2 lists the values of storage modulus (G'), loss modulus (G'') and loss tangent (tan δ) for PVDF-$FP_{i\%}$ (i = 0, 3, 5 and 8) obtained from the nano-tensile testing at the harmonic force of 4.5 mN and the frequency of 20 Hz. It can be observed that all the values of storage modulus are higher than the corresponding values of Young's modulus as obtained from the elastic portion of stress-strain responses (listed in table 1). This is not surprising since the storage modulus is averaged within the whole range of stress-strain responses, in which modulus with higher values is keeping after the yield strain due to a full elastic deformation. Loss modulus values for PVDF-$FP_{i\%}$ (i = 3, 5 and 8) show that the addition of FP-POSS obviously increases the viscosity of PVDF since they are much higher than that of the neat PVDF. Compared with the storage and loss modulus, loss tangent is more reliable to measure viscoelastic properties because it is the ratio of loss to storage modulus thus less influenced by the uncertain factors in measuring or some unpredictable defects in materials. The values of loss tangent in table 2 show an evidently viscosity increasing with the increasing content of FP-POSS. Compared with the loss tangent values obtained at the strain rate of 1.0×10^{-3} s^{-1} [18] (from 0.089 of neat PVDF to 0.113 of PVDF-$FP_{8\%}$), the values increase more obviously at the strain rate of 1.0×10^{-2} s^{-1} in this article (from 0.075 of neat PVDF to 0.151 of PVDF-$FP_{8\%}$), which shows the perspicuous effect of the strain rate on the viscosity of PVDF and its nanocomposites.

Table 2. The storage modulus (G'), loss modulus (G'') and loss tangent (tan δ) of PVDF-FP$_i$% (i = 0, 3, 5 and 8) as obtained from nano-tensile testing at a harmonic force of 4.5 mN and a frequency of 20 Hz.

FP-POSS (wt.%)	G' (GPa)	G'' (MPa)	tan δ
0	2.40(0.31)	169.2(78.5)	0.075(0.046)
3	1.86(0.17)	176.9(73.1)	0.097(0.065)
5	1.74(0.15)	186.0(74.9)	0.107(0.043)
8	1.43(0.18)	203.7(93.5)	0.151(0.099)

Note: Values in parentheses indicate (±) standard deviations.

3.3. Fracture appearance analysis

The fracture appearance of PVDF-FP$_i$% (i = 0, 3, 5 and 8) are shown in Fig.4. These images were obtained by VHX 600E with a real-time depth composition, three-dimensional functions at 500× or 1000× zoom. It can be found very clearly that the image of neat PVDF (Fig. 4 (a)) is quite different from the others. Compared with the three other ones, the fracture appearance of neat PVDF is more regular and the boundary is clear, shows only a small area near the fracture surface was obviously influenced during the fracture procedure. On the contrary, the fracture appearance of PVDF-FP$_i$% (i = 3, 5 and 8) (Fig. 4 (b), (c) and (d)) are irregular and the boundaries of the fracture surfaces are not obvious. These results have undoubtedly proved that the brittleness of neat PVDF is higher than its FP-POSS nanocomposites and the viscosity of PVDF will be increased by the addition of FP-POSS. Another important phenomenon is that the fracture regions of PVDF-FP$_i$% (i = 3, 5 and 8) are different. As shown in Fig. 4, the area of the fracture regions increases with the content of FP-POSS in PVDF, reveals that the brittleness drops and the viscosity rises when FP-POSS is mixed into PVDF. And more FP-POSS was mixed, more obvious this effect was displayed, which is in good agreement with the variation trend of the loss tangent values in section 3.2 and the fracture toughness values in section 3.1.

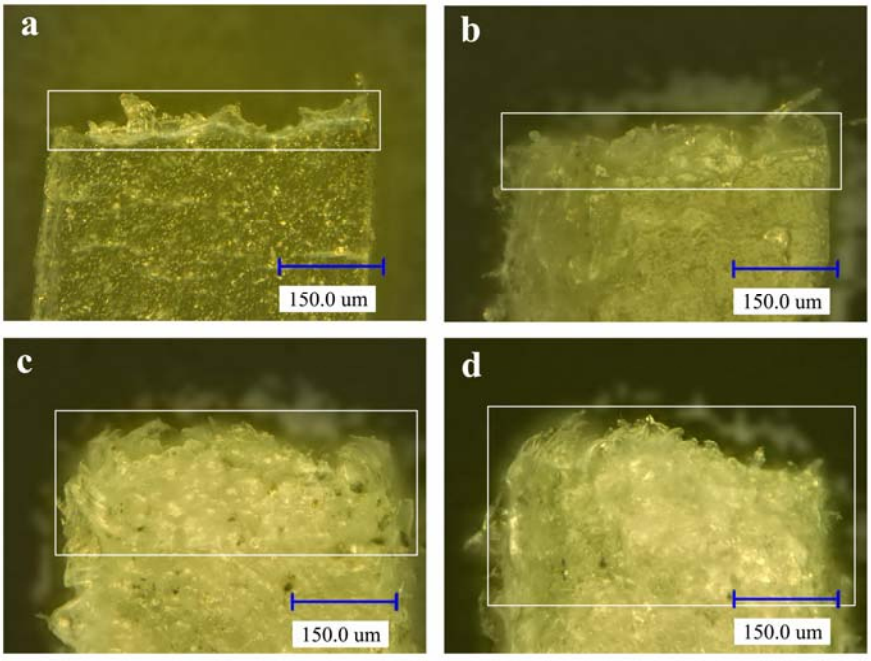

Fig. 4. Optical microscopy images of the fracture appearance for PVDF-FP$_i$% obtained by VHX 600E, i= (a) 0, (b) 3, (c) 5 and (d) 8. The square boxes locate the fracture regions.

4. Conclusions

PVDF/FP-POSS nanocompostites can be prepared by solvent evaporation method. Nano-tensile testing results at the strain rate of 1.0×10^{-2} s^{-1} showed the toughness of PVDF were enhanced by FP-POSS and further additions of FP-POSS brought surprisingly enhancements in toughness of the nanocomposites while associated with a decline in stiffness. Dynamical mechanical properties indicated the viscosity of the nanocomposites increased with the increasing FP-POSS contents in PVDF-$FP_{i\%}$. Fracture appearance analysis results showed that the fracture appearance of neat PVDF was regular and the boundary was clear, while PVDF-$FP_{i\%}$ (i = 3, 5 and 8) are irregular and not obvious. And the fracture regions increased with the content of FP-POSS in PVDF, which provided the visual evidence for the conclusions obtained from the data analysis. The great improvement effects on toughness and the increasing viscosity resulted from further additions of FP-POSS should be derived from the more separate and less cross-linked particles in the nanocomposities and the nano scale size of POSS compounds, which made the materials, are more easy to form plastic flow and more efficient on energy-dissipation.

Abstract
Thin metal films on soft substrate are conventional in flexible electronics and flexible devices. Thermal stress often exists in the thin metal films due to thermal mismatch during the physical vapor deposition (PVD) process, which leads to the fracture failure of metal films. Theoretical analysis and numerical simulations have predicted that the cracking of a thin stiff layer on a soft substrate depend on the relative stiffness and thickness of the film and the substrate. However, few experimental results reported support the hypothesis.
In this paper, An experimental investigation is conducted to study the fracture behavior of the aluminum films on soft Polydimethylsiloxane(PDMS) substrate during physical vapor deposition. It has been found that when the thickness of the aluminum film is relatively smaller, surface wrinkling is induced to accommodate the mismatched strain between the substrate and the film. When the thickness of the aluminum film is relatively larger, cracking of the film occurs.
Keywords Aluminum film, PDMS substrate, PVD process, Fracture behavior

1. Introduction

Films/substrate structures have been widely researched for the extensive application of this structure. Thin stiff film including metal film and non-metal film on soft substrate are exploited for the use of flexible electronics and devices [3,8-10,13,14]. Several ways have been applied to fabricate the relatively thin solid film on the flexible substrate forming flexible structures. Transferring the thin silicon film onto the pre-stretched soft PDMS substrate leading to the waving surface structures is a frequently used process [4]. Casting the viscous PDMS on the metal foils, and then conducting a photolithography process to obtain the structure is another means[16]. Evaporation and sputtering are two deposition means forming several nanometers to micrometers thick film on the substrate [6,11,15]. During the deposition process, the temperature on the surface of the substrate will rise and leads to thermal expansion of the substrate. The PDMS substrate is heated when the gold film is deposited onto the substrate [1]. Because the thermal expansion coefficient is several times larger than the gold film. When the surface temperature cools down, a thermal mismatch will be produced. From former observation [1], this thermal mismatch will lead to wrinkling of the film on the soft substrate, which is generally produced in other experiments [7].
In this paper it is found wrinkles will be formed on the film when the thickness of the film is the range of several hundred nanometers. When the thickness of the film exceeds this confine, approximate orthogonal cracks occur on the film. The detailed illustration of this difference is given out from the experimental results.

2. Experimental details

In our experiment, aluminum films with different thickness have been fabricated on the PDMS substrate. The PDMS is formed by mixing Sylgard 184 silicone elastomer with the curing agent at ratio 10:1 (by weight) and then the uncured mixture is spread on the glass substrate, which is placed in a vacuum drying oven at temperature 70℃ for an hour later. The cured PDMS have the same smooth surface with the glass substrate. The thickness of the PDMS substrate is in the range of 1-2mm. Pure aluminum is deposited on the PDMS substrate by E-beam evaporation at pressure of 5 ×10-5 torr. The elastic modulus of the PDMS substrate is 2.2 Mpa [7]. The elastic modulus and

Possion's ratio of the aluminum film are 72Gpa and 0.33 respectively. During the deposition process, the surface temperature of the substrate will rise and this leads to a thermal expansion of the substrate. When the deposition finished, the surface temperature cools down. Because the thermal expansion coefficient of the PDMS substrate is several times larger than that of the aluminum film, a thermal mismatch will be produced between the substrate and the film. This strain mismatch will lead to the surface wrinkles of the specimen when the thickness of the deposited aluminum film is in the range of several hundred nanometers. But when the thickness exceeds that confine, cracks will occur generally on the aluminum film. Aluminum film with thickness 40nm, 150nm, 200nm, 260nm and 700nm are fabricated on the PDMS substrate. Different experimental phenomena reflecting different mechanical behavior are observed after the deposition of the film under the microscopy.

3. Experimental results and discussions

During the deposition of the aluminum, the cooling of the aluminum steam on the surface of the PDMS substrate leads to the temperature elevating. After deposition, the temperature cools down. And this change leads to a deformation mismatch due to the distinct difference of the thermal coefficient of these two materials. The induced compressive stress in the film can be expressed as [1]:

$$\sigma = \frac{E_f(\alpha_f - \alpha_s)(T_D - T)}{(1-\upsilon_f)} \tag{1}$$

In the expression, the subscripts *f* and *s* represent the film and substrate respectively. T_D represents the deposition temperature and *T* corresponds to the cooled down temperature. α represents thermal coefficient of the film and the substrate respectively. υ is the Possion's ratio of the film. The thermal coefficient of the PDMS substrate and the aluminum film is about 300×10^{-6} and 20×10^{-6}. For the aluminum film with thickness of several hundred nanometers, wrinkles occur to accommodate the deformation mismatch.

For the film with thickness of 40nm, no surface wrinkles are found under the microscopy. This can be understood that the surface temperature during the deposition of the 40nm thick film is below the critical buckling temperature. For the film with thickness of 150nm, disordered wrinkles (Fig.1) can be observed under the microscopy. The measured wavelength for the wrinkles is about 10 μm. The overall estimation of the wavelength of the buckled wrinkles is [5]:

$$\lambda_c = 2\pi h\left[\frac{E_f(1-\upsilon_s^2)}{3E_s(1-\upsilon_f^2)}\right]^{1/3} \tag{2}$$

According to the theoretical solution, the wavelength of the film with thickness 150nm is about 20 μm, two times of the experimental result. This discrepancy comes mainly from two aspects: the simplification of the theoretical model and the neglecting of the change of the surface elastic modulus of the PDMS substrate [1].

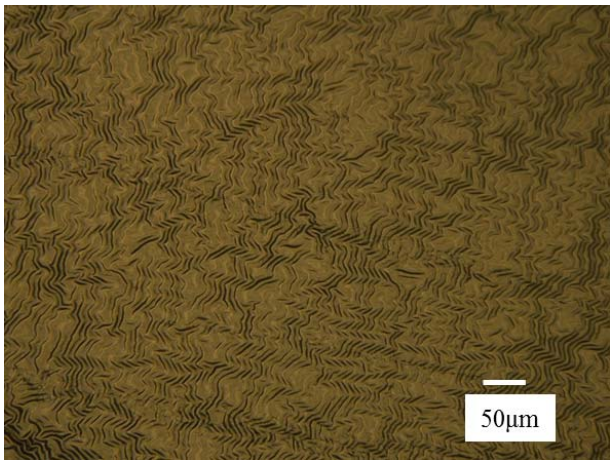

Figure 1. Wrinkling surface of the aluminum film with thickness 150nm on the PDMS substrate

The wavelength of the wrinkles of the film with thickness 200nm and 260nm are about 12 μm and 17.5 μm respectively (Fig.2). From Eq.2, it can be seen that the buckling wavelength only rely on the thickness of the film for the aluminum film on PDMS substrate. But this is not the real case. The deposition temperature varies with the thickness of the film. So the elastic modulus of the PDMS substrate changes to a certain extent. The wavelength does not simply rely on the thickness of the film, but also the surface temperature which may alter the surface elastic modulus of the PDMS substrate.

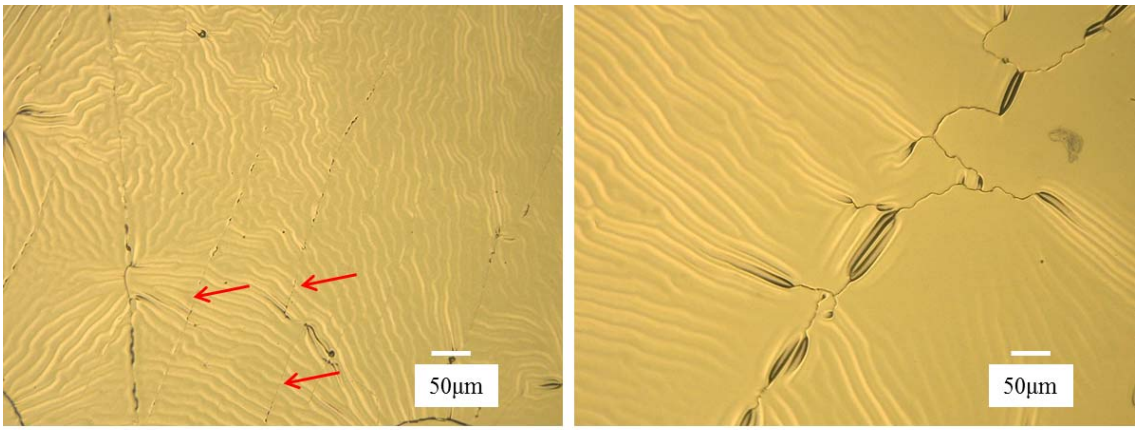

Figure 2. Wrinkled surface of the aluminum film with thickness 200nm and 260nm on soft PDMS substrate

From the observation, the wrinkles are mostly initiated from a flaw, which may induce stress concentration. There are some cracks occurring in the aluminum film (marked by red arrow in Fig.2 (a)). This can be understood that the wrinkles occurring vertical to the maximum compressive stress and. In the direction vertical to the maximum compressive stress, the tensile stress may be induced, which leads to cracking of the film in the direction vertical to the wrinkles.

For the aluminum film with thickness of 700nm, there are definitely no wrinkles formed on the film. Instead of this, approximate vertical cracks appear in the aluminum film (Fig.3). In former report, wrinkles formed on the PDMS substrate have been researched from experiments and finite element modeling. But few reports concern the cracking behavior of the stiff film on the PDMS substrate. This is mainly because the film thickness in former research work is relatively small. For film with relatively large thickness, cracking may be induced for mismatched strain. In this experiment,

aluminum film is found cracking on the PDMS substrate with thickness of 700nm.

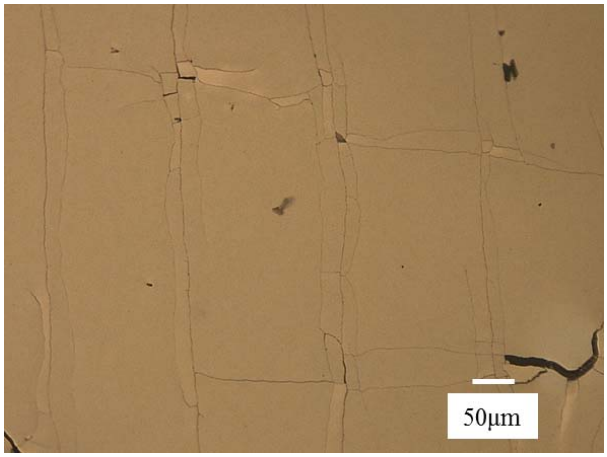

Figure 3. Cracking of the aluminum film on the PDMS substrate

Cracking substitutes wrinkling for the aluminum film with relatively larger thickness. In theoretical analysis, the bending equilibrium equation of the wrinkles formed on the thin stiff film is [12]:

$$\frac{E_f I}{1-\upsilon_f^2}\frac{d^4 w}{dy^4} + F\frac{d^2 w}{dy^2} + Kw = 0 \tag{3}$$

Where w is the displacement of the film in z direction (Fig.4), the expression of w has been obtained from both theory and experiment, which can be expressed by [2]:

$$w(y) = A(1+\cos\frac{2\pi y}{\lambda}) \tag{4}$$

Where λ is the buckling wavelength and A is buckling amplitude of the wrinkles.
$I=h^3/12$ is the second bending moment of the film around the x axis per unit width. F is the compressive force provided by the substrate in the film. K reflects the influence of the underlying substrate expressed by [2]:

$$K = \frac{E}{1-\upsilon^2}\frac{\pi}{\lambda} \tag{5}$$

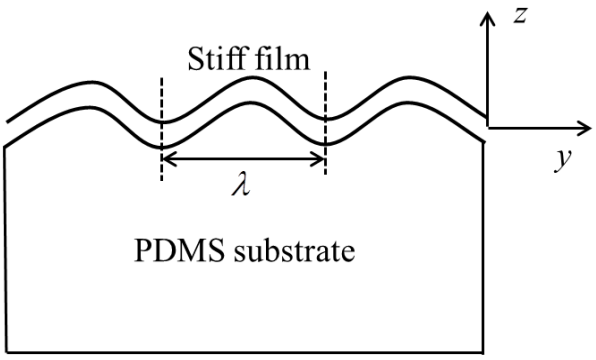

Figure 4. A schematic of the surface wrinkling on stiff film/soft substrate

F is derived from Eq.3-5 and expressed by [12]:

$$F = E_f I\left[\frac{4\pi^2}{(1-\upsilon_f^2)\lambda^2} + \frac{E}{4\pi(1-\upsilon_f^2)E_f I}\lambda\right] \tag{6}$$

In Eq.6, it can be seen that the compressive force in the film is in proportion to the thickness of the film. For the overall mechanical behavior of the film/substrate, the compressive stress is in linear with the thickness of the film. In local, the tensile stress at the crest induced by bending of the film is in the same increasing rate with the compressive stress in the film. When the tensile stress at the crest exceeds the tensile strength of the aluminum film, the film will crack instead of wrinkle to accommodate the mismatched strain. Fractured ribbons are induced during the cracking of the film (marked by red arrows). The fractured ribbons released the compressive force of the film. And the stress in the isolated fractured fragment is insufficient to lead to wrinkling of the film. The buckling and wrinkling behavior of the film transfer into the fracture behavior of the film when the thickness of the film is relatively larger.

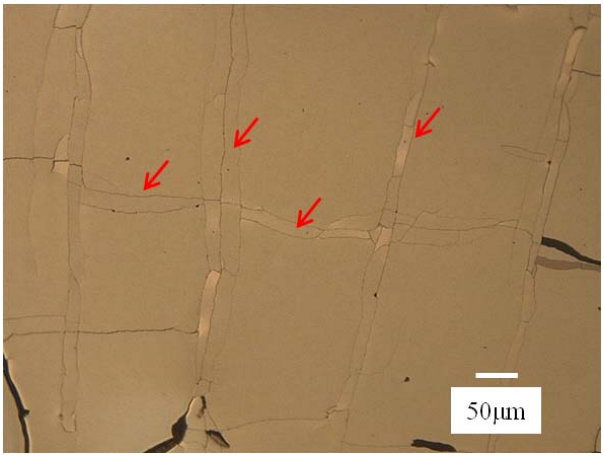

Figure 5. Approximately vertical cracking of the film and fractured ribbons (marked by red arrows)

4. Conclusions

In this paper, wrinkling and cracking behavior of the aluminum film on the PDMS substrate have been studied from experimental results. For aluminum film with smaller thickness (less than several hundred nanometers), wrinkling is mostly likely to happen due to the mismatched strain. When the thickness of the aluminum film is relatively larger, cracking substitutes the wrinkling to accommodate the mismatched deformation between the film and the substrate. The reason of this transformation lies in the increasing of the tensile stress with the thickness of the film. When the tensile stress in the film exceeds the tensile strength of the aluminum film, cracking behavior of the film predominates.

Abstract Thin films may spontaneously form buckles if the residual stresses are compressive and large and if adhesion is weak. Buckling driven delamination leads to periodic patterns, such as the telephone cord morphology which has been studied for decades. Until recently the role of adhesion in the formation of buckling patterns was rather poorly understood. The difficulties are: 1. buckling is a non-linear phenomenon 2. Adhesion is a complex process involving mode mixity at the crack tip. Here coupling buckling and mixed-mode adhesion in a FEM model, we investigate the influence of film thickness, adhesion and residual stresses on the final buckle morphology. In particular, we show that it is possible to control the delamination front to create branching morphologies. Such morphologies remain periodic and can cover large areas. Experimentally, we show how the relevant conditions can be achieved for multilayer stacks of thin films deposited by magnetron sputtering. In particular we demonstrate self-organized hexagonal networks of buckles at the 10 micron scale. We anticipate that these patterns can be scaled from the micron-scale to the nano-scale.

Keywords Buckling, Adhesion, Mode mixity, Patterning,

1. Introduction

Thin films may spontaneously form buckles[1,2] if the residual stresses are compressive and large and if adhesion is weak. Buckling driven delamination leads to periodic patterns, such as the telephone cord morphology which has been studied for decades. Until recently the role of adhesion in the formation of buckling patterns was rather poorly understood. The difficulties are: 1. buckling is a non-linear phenomenon 2. Adhesion is a complex process involving mode mixity at the crack tip. Here coupling buckling and mixed-mode adhesion in a FEM model, we investigate the influence of film thickness, adhesion and residual stresses on the final buckle morphology. We then use the results as a guideline for experiments

2. Numerical simulation

2.1. Model

In order to analyze the growth of the blister, we use a numerical model coupling finite elements with cohesive zone modeling. It is essential to use a nonlinear plate model to capture the buckling equilibrium. The surface of the plate is defined as the (O,x,y) plane and the out-of-plane displacement is $w(x,y)$. In order to take into account the presence of a purely rigid substrate, the unilateral contact condition $w(x,y)>0$ is introduced. The calculations are made for large displacements w, using the Green Lagrange strain tensor. When w is large, the strain tensor reduces to

$$\begin{cases} e_{xx} = \dfrac{\partial u}{\partial x} + \dfrac{1}{2}\left(\dfrac{\partial w}{\partial x}\right)^2 \\ e_{yy} = \dfrac{\partial u}{\partial y} + \dfrac{1}{2}\left(\dfrac{\partial w}{\partial y}\right)^2 \\ e_{xy} = \dfrac{1}{2}\left(\dfrac{\partial u}{\partial y} + \dfrac{\partial v}{\partial x}\right) + \dfrac{1}{2}\dfrac{\partial w}{\partial x}\dfrac{\partial w}{\partial y} \end{cases} \quad (1)$$

In Eq. (1) the terms which are non-linear in w are responsible for a third order term in the thin plate equilibrium equations and it is this non-linearity which is essential to capture the post-buckling evolution of the blisters (e.g. see [3]).

The second key point is the description of adhesion rupture for which a cohesive zone model (CZM) [29–32] is used. Detailed description of the model can be found in [4]. Cohesive elements are inserted at the interface. A bilinear softening behavior is used in order to take into account for the mode mixity of the interfacial toughness. The interfacial toughness Γ^c is defined as a function of the mode mixity angle ψ, see Fig.1, which is the relative proportion of shear and normal traction applied at the interface:

$$\tan\psi = \frac{K_{II}}{K_I} \quad (2)$$

We use for the definition of $\Gamma^c(\psi)$ the one proposed by Hutchinson in [5] and based on experimental data[6].

$$\Gamma^c(\psi) = \Gamma_I^c\left(1 + \tan^2 \eta\psi\right) \quad (3)$$

Where Γ_I^c is the mode I interfacial toughness, and η a dimension-less parameter to adjust the level of the mode II interfacial toughness Γ_{II}^c.

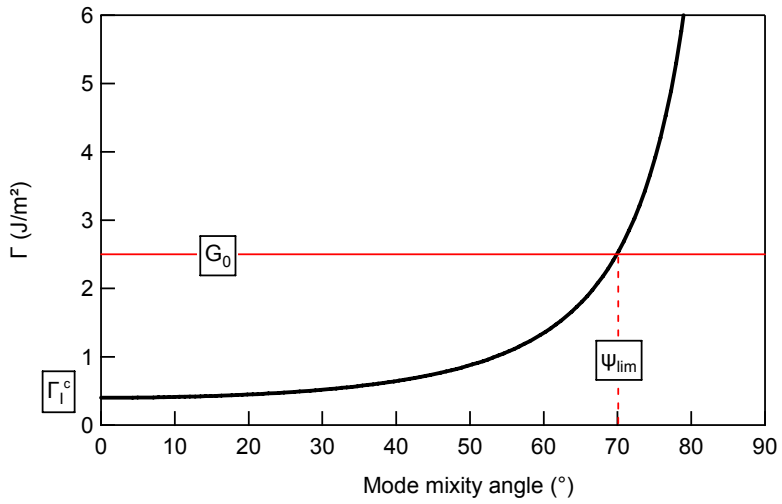

Figure 1 : Dependence of the interfacial toughness as a function of the mode mixity angle.

Thin film is modeled by a plate of thickness h, elastic modulus E and Poisson ratio ν. In-plane

stress σ_0 is introduced by a thermal expansion.

2.2. Results

We fix the materials parameters of the film to *E*=329 GPa and υ=0.31. The interfacial toughness is kept constant choosing $\Gamma_I^c = 0.4 J.m^{-2}$ and $\eta = 0.95$. The morphology of the delamination is then studied as a function of loading, which is given by the couple $(h;\sigma_0)$. It is convenient to define the total energy per unit area stored in the film due to the in-plane stress.

$$G_0 = \frac{1-\nu}{E} h {\sigma_0}^2 \tag{4}$$

We also define the limit for the mode mixity above which the interface cannot be fully separated. In case where the energy release rate is close to G_0 then

$$\psi_{\lim} = \frac{1}{\eta} \tan^{-1} \sqrt{\frac{G_0}{\Gamma_I^c} - 1} \tag{5}$$

It should be noted that $\psi_{\lim}$ is attained at the side of the blister as the film sags[4] and the mode mixity reaches pure mode II, $\psi = \pi/2$. However the interface is not fully separated at all angles above $\psi_{\lim}$.

Changing level of loading with $\psi_{\lim}$, we observe different morphologies, from no delamination to complete delamination of the film and draw a phase diagram $\psi_{\lim}$ is a relevant parameter for the instability of the blister and is equivalent to the loading ratio σ_0/σ_c of the blister. In case of the straight sided blister, the critical buckling stress σ_c corresponds to the stress needed to enter in the post-buckling regime.

$$\sigma_c = \frac{\pi^2}{12} \frac{E}{1-\upsilon^2} \left(\frac{h}{b}\right)^2 \tag{6}$$

Secondary buckling instability computation on the sides of a straight sided blister by Jensen [7], and on the collapse of a circular blister by Hutchinson [8] show that such destabilization is solely a function of G_0 and therefore $\psi_{\lim}$.

3. Experiments

We aim to study morphologies of the delamination experimentally. We use the superlayer method to make blisters [9]. A compressive stressed layer of molybdenum is deposited on top of a weak interface to provide elastic energy for buckling. The residual stress in the Mo layer before buckling is around 3GPa. The stress can be tuned changing the deposition conditions of the Mo layer during sputtering [10]. The thickness is varied from 100nm to 200nm. We here use a silver layer to create the weak interface with the substrate.

Both control over the residual stress and the thickness enable scanning different loading conditions and therefore variation of ψ_{lim}. Experimentally we observe several morphologies, from the telephone cord like blister to complete delamination, see Fig.2. Those morphologies can be compared to the numerical results and placed in a phase diagram.

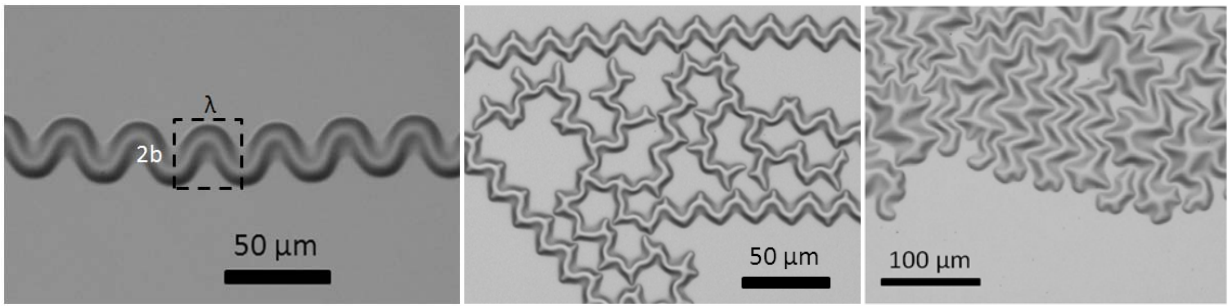

Figure 2: Evolution of the delamination morphology for Si/Ag interface for different layer of molybdenum.

In particular we use numerical simulations to demonstrate that a self-organized network of buckles can be generated and that the conditions to generate such a network experimentally can be achieved with the superlayer method.

4. Conclusions

We present a numerical model to explore the morphology of the buckling driven delamination pattern as a function of interfacial properties and loading conditions. Confronting the experimental data with the simulation, we find relevant parameters for patterning of large surfaces.

Abstract Thin films deposited on substrates are usually submitted to large residual compression stresses, causing delamination and buckling of the film into various patterns. This phenomenon has been widely investigated in the past few decades, both experimentally and with nonlinear plates models. Nevertheless, the formation of the most commonly observed pattern, the "telephone cord blister", has only be understood recently, with FEM models coupling post-buckling studies and mixed-mode adhesion. Here, relying on these models, we show remarkable properties of these wavy blisters, in particular we show that the wavelength of the telephone cord patterns scales linearly with a parameter depending on the stress level in the film, the thickness and the adhesion energy. This result has an important practical application. As a matter of fact, since it is experimentally possible to control the stress level and the film thickness during elaboration, the measurement of this wavelength can indirectly lead to a measurement of the interface toughness, even in very small films.

Keywords Buckling, Adhesion, Mode mixity, Patterning,

1. Introduction

Compressively stressed thin films with low adhesion frequently buckle and delaminate simultaneously into various patterns, amongst which the so called "telephone cords" pattern is very often observed [1,2]. Although these buckles have been studied for decades, no complete understanding of their propagation had been presented until recently. As a matter of fact, the post-buckling equilibrium shapes of the blisters require the use of non-linear plates theory (e.g. see [3]). Furthermore adhesion is a complex process involving mode mixity at the crack tip. A nonlinear plate deformation model has been coupled with a cohesive zone model to simulate the kinematics of a propagating telephone cord buckle in very close agreement with experimental observations. Proper inclusion of the dependence of an adhesion upon the mode mixity proved to be central to the success of the approach. The clarification of the mechanism allows for a better understanding of buckle morphologies and highlights remarkable properties of these wavy blisters. In particular it is shown that the wavelength of the telephone cord patterns scales linearly with a parameter depending on the stress level in the film, the thickness and the adhesion energy. This result has an important practical application: since it is experimentally possible to control the stress level and the film thickness during elaboration, the measurement of this wavelength can indirectly lead to a measurement of the interface energy, even in very small films.

2. Mechanical model for blisters propagation

2.1. Model

A nonlinear plate model is used to capture the buckling equilibria. As a matter of fact, the blisters morphologies are characterized by very large out-of-plan displacements, meaning that the equilibria are located very far in the post-critical buckling regime compared to the flat (i.e. unbuckled)

equilibrium. The thin film is modeled by a plate of thickness h, made of linear elastic material characterized by a Young's modulus E and Poisson's ratio ν. The surface of the plate is defined as the *(O,x,y)* plane and the out-of-plane displacement is denoted *w(x,y)*. In order to take into account the presence of the substrate, the unilateral contact condition *w(x,y) ≥ 0* is introduced. The calculations are made for large displacements *w*, using the Green Lagrange strain tensor. As only *w* is large, the strain tensor reduces to

$$\begin{cases} e_{xx} = \dfrac{\partial u}{\partial x} + \dfrac{1}{2}\left(\dfrac{\partial w}{\partial x}\right)^2 \\ e_{yy} = \dfrac{\partial u}{\partial y} + \dfrac{1}{2}\left(\dfrac{\partial w}{\partial y}\right)^2 \\ e_{xy} = \dfrac{1}{2}\left(\dfrac{\partial u}{\partial y} + \dfrac{\partial v}{\partial x}\right) + \dfrac{1}{2}\dfrac{\partial w}{\partial x}\dfrac{\partial w}{\partial y} \end{cases} \tag{1}$$

In Eq. (1) the terms which are non-linear in *w* are responsible for a third order term in *w* the thin plate equilibrium equations and it is this non-linearity which is essential to capture the post-buckling evolution of the blisters.

The second key point is the description of adhesion rupture between the film and the substrate. A cohesive zone model (CZM) is introduced for this purpose between the elastic film and the rigid substrate. The tractions developed in the cohesive zone at the edges of the buckle provide boundary conditions for the buckled plate. The blister extends its boundary by forcing the separation along the delaminated edge as it buckles under large in-plane compression. Details of the cohesive zone model are given in [4]. A bilinear softening traction versus separation law is used, with a damage variable d increasing monotonically with the separation. The most important feature of this cohesive zone model is the mode mixity dependence of the interfacial toughness G^c. The relationship proposed by Hutchinson in [5] and based on experimental data[6] is used :

$$G^c(\psi) = G_I^c\left(1 + \tan^2 \eta\psi\right) \tag{2}$$

where ψ is the mode mixity angle defining the ratio between shear traction and normal traction at the interface ($\tan\psi = \dfrac{T_t}{T_n}$, with T_t the shear traction and T_n the normal traction. Hence, pure normal traction is obtained for ψ=0° whereas pure shear traction is obtained for ψ=90°). The definition given in Eq. (2) is meant to take into account that it is all the more difficult to break the interface that the proportion of shear is higher at the interface. Fig.1 describes both shapes of the traction versus separation law and of the toughness. Note that the quantity G_0, which is the energy per unit area stored in the film in its plane fully adherent state, has been introduced. G_0 is defined by:

$$G_0 = \frac{1-\nu}{E} h \sigma_0^{\,2} \tag{3}$$

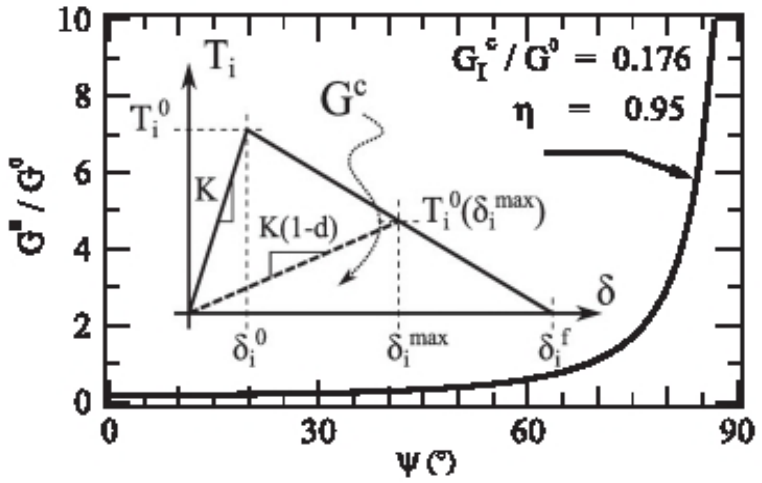

Figure 1 : From [4], Mixed-mode dependence of the work of adhesion at the film-substrate interface and bilinear traction vs separation law (Inset: i = n for mode I and t for mode II).

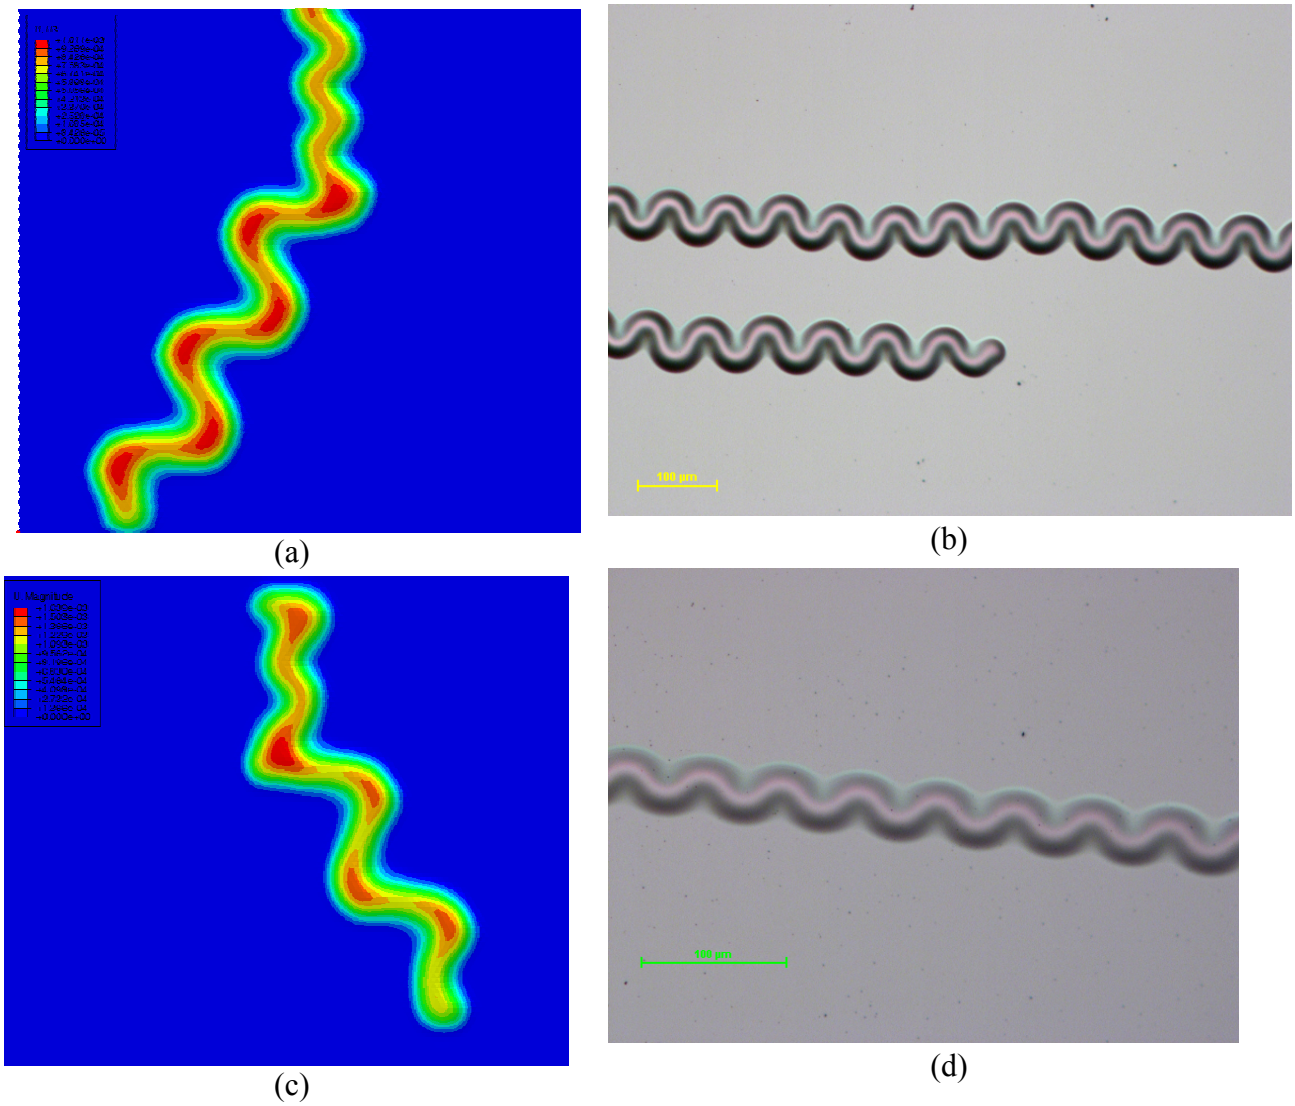
Finally, the thin film loading consists of an eigenstrain $\varepsilon_0 > 0$ uniformly applied to the plate ($\varepsilon_{xx} = \varepsilon_{yy} = \varepsilon_0$, $\varepsilon_{xy} = 0$). Since the film is relying on a rigid substrate, this is generating an equibiaxial stress state in the film ($\sigma_{xx} = \sigma_{yy} = -\frac{E}{1-\upsilon}\varepsilon_0 = \sigma_0, \sigma_{xy} = 0$). This loading is applied in the initial state. An explicit scheme is used for the calculation.
In order to trigger delamination, a small defect is created. This defect consists of an adhesion-free area. The blister is nucleated in this area.

2.2. Results

This model has been implemented in the finite element code ABAQUS [7]. As it has been described in [4], this model has been able to demonstrate the mechanism of propagation of the telephone cord blister. The specificity of this propagation comes from the pinning of the buckle front in mode II. As a matter of fact, as crack front is expanding in a circular shape with an increasing radius, a configurational instability occurs on the outer edge of the buckle front followed by the development of a strong mode II area. As G_c is much higher in mode II, the propagation is stopped in this area, which forms the pinning point responsible for the inversion of the curvature of the buckle and finally the wavy shape since the front has to go around this point for further propagation of the blister.
By varying the parameters of the model in the simulation, it is possible to obtain a wide variety of telephone cords buckles. Besides, the buckles are also obtained experimentally, with a setup allowing the control of the different parameters (film thickness h, residual stress σ_0, interface toughness G_I^c). The samples are molybdenum coatings deposited by magnetron sputtering on 30 µm thick silicon wafers. The deposition of a thin silver layer onto the substrate allows varying the adhesion (depending on the silver layer thickness). Immediately following, a 120 nm thick layer of

partially oxidized molybdenum, obtained by adding 2 sccm of O_2, is deposited. Controlling the oxygen content in the film leads to a fine tuning of the residual stress.
For the simulations, the elasticity parameters for the films are E=329 GPa and υ=0.31. The mode I interfacial toughness G_I^c is a variable, whereas $\eta = 0.95$. The calculations are carried out for different values of the film thickness h and the residual stress σ_0. Comparison between calculations results and experimental observations are reported in Fig. 2. Depending on the parameters, different aspect ratios (i.e. ratios between the wavelength and the width of the telephone cord) can be observed in the simulations. These ratios are usually observed to be ranging between 0.9 and 1.4, both in the simulations and in the experiments. Two cases are reported in Fig. 2: one large aspect ratio and one short aspect ratio.



(a) (b) (c) (d)

Figure 2 : Comparison between telephone cords simulations (a and c) and experimental observation on Mo thin films deposited on silicon wafers (b and d). The two upper cords are showing short aspect ratios (i.e. wavelength over width), whereas the two bottom cords have large aspect ratio.
(a): $h = 225nm$, $G_I^c = 1.35J/m^2$, $\sigma_0 = 2.9GPa$, aspect ratio 1. (b): 600nm thick MoOx, potential -75V, aspect ratio 1. (c): $h = 300nm$, $G_I^c = 2.83J/m^2$, $\sigma_0 = 3GPa$, aspect ratio 1.36. (d) 600nm thick MoOx floating potential, aspect ratio 1.2.

3. Scaling of the wavelength

A relationship between the wavelength λ of the telephone cords and the other parameters have been found. In order to express this relationship, it is convenient to introduce a limit mixity angle, denoted $\psi_{\lim}$. It corresponds to the mode mixity above which the interface cannot be fully separated. This is the case when the interface toughness is exceeding the stored energy ($G^c \geq G_0$), so the limit case is $G^c = G_0$. In this case, using Eq. (2) yields:

$$\psi_{\lim} = \frac{1}{\eta}\tan^{-1}\sqrt{\frac{G_0}{G_I^c}-1} \tag{4}$$

It should be noted that $\psi_{\lim}$ is attained at the side of the blister as the film sags[4] and the mode mixity reaches pure mode II, $\psi = \pi/2$. However the interface is not fully separated at all angles above $\psi_{\lim}$.

By similar arguments that can be found in [8], it is possible to show that the following non dimensional relationship is verified among the telephone cords equilibria.

$$\frac{\sigma_0}{\overline{E}}\left(\frac{\lambda}{h}\right)^2 = f\left(\psi_{\lim}\right) \tag{5}$$

So whatever the shape of the telephone cord, the wavelength can be expressed as $\lambda = h\sqrt{\frac{\overline{E}}{\sigma_0}}f\left(\psi_{\lim}\right)$. The function f is determined numerically, giving the remarkable result exposed Fig. 3. It appears that λ is proportional to the quantity L defined as:

$$L = h\sqrt{\frac{\overline{E}}{\sigma_0}}\frac{1}{\sqrt{\tan\psi_{\lim}}} \tag{6}$$

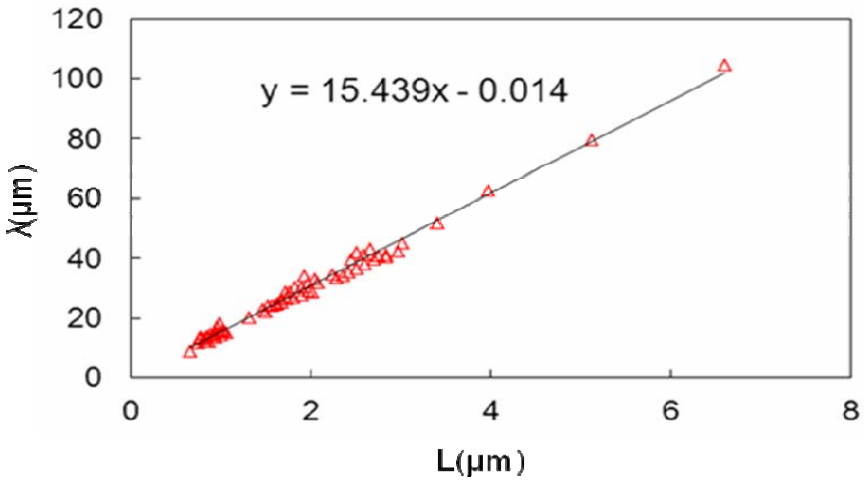


Figure 3 : Linear relationship between the telephone cord wavelength λ and the non dimensional quantity $L = h\sqrt{\frac{\overline{E}}{\sigma_0}}\frac{1}{\sqrt{\tan\psi_{\lim}}}$.

Once the relationship between λ and L is determined numerically, it is possible to find G_I^c from the experiments by measuring λ, assuming that σ_0, $\overline{E}$ and h are known, which is the case in our experiments.

4. Conclusions

We have a numerical model capable of describing the mechanisms of buckling driven delamination. A lot of patterns can be modeled, all observed in experiments. We have here emphasized the case of the telephone cords buckles, which is very often observed in experiments. The analysis of the telephone cords formation using the model has allowed for uncovering a very interesting relationship between the telephone cords wavelength, the stress level in the film, the thickness and the interface toughness. This result has an important practical application. When controlling the stress level and the film thickness during elaboration, the measurement of this wavelength can indirectly lead to a measurement of the interface toughness, even in very small films.

SDUDY OF THE CREEP DAMAGE PROPERTIES OF ASPHALT MIXTURE UNDER STATIC LOAD

Zhou Zhigang，Feng Lin，Yuan Xiuxiang，Xiong Hua

(Changsha University of Science & Technology, Key Laboratory of Road Structure & Material, Ministry of Transport of PRC, Hunan Changsha 410004)

Abstract: Asphalt concrete AC-13 and SMA-13 are designed to study their viscoelastic and damage properties under uniaxial pressure. The results indicate that the flow deformation of viscosity of asphalt mixture doesn't unlimitly increase with the loading time. As time goes by, the increment of flow deformation of viscosity decreases gradually and causes the flow deformation of viscosity to incline a stable value ultimately, which is so-called 'consolidation effect'. Moreover, under the same conditions, SMA has a stronger anti-deformation ability than AC. According to the flow characteristics of asphalt mixture, it is proposed a comparatively desirable and useful creep compliance model and visco-elastic-plastic creep model. Based on the static creep test results, the parameters concerned of the models are determined by using a constrained optimization method.

Key words: Asphalt mixture; Creep; Viscoelasticity; Damage; Model

Introduction

Asphalt mixture is thermoviscoelastic material with flow characteristics, the physical and mechanical properties is closely related to the effects of temperature and loading time. The load conditions often exhibit obvious nonlinear viscoelastic properties. The mechanical analysis generally focused on the linear viscoelastic category. In practical applications, using asphalt mixture is in non-compliance with infinitesimal deformation of the linear theory assumptions, when the deformation exceeds a certain range; linear superposition is no longer effective, so nonlinear viscoelastic theory of more universal. In recent years, road researchers have made some studies on the general nonlinear, elastic-plastic, creep, viscoelasticity of asphalt mixture [1]-[13]. As the two branch of the viscoelastic theory, liner viscoelastic theory is already quite mature, nonlinear viscoelastic theory also made a series of research results, but because of its difficulties in testing and mathematical theory, is still in development and perfected.

Damage mechanics as a subject branches is nearly 20 years. The classic nonlinear viscoelastic material constitutive theory does not consider initial defect and in actual engineering, creep failure of various loads and environmental conditions, may belong to the creep damage, more likely to be the initial defect evolution and the crack initiation and propagation. The study for the establishment of asphalt mixture viscoelastic damage constitutive model and its engineering applications is still small [14]-[25].

Therefore, based on the contrast test of AC-13 and SMA-13 two kinds of asphalt mixture road performance, focus on them under uniaxial pressure static creep damage behavior. Through the static creep test of different temperature, pressure, study the creep deformation of the characteristics and the law of variation. To reflect the creep deformation characteristics of the asphalt mixture creep deformation, establish nonlinear viscoelastic creep model and the creep damage model as the permanent deformation analysis and the high temperature stability of asphalt mixture and pavement which provides theoretical and experimental basis for evaluation.

1 Asphalt mixture design and road performance

1.1 Raw materials performance and mixture ratio design

Raw material of the test is modified asphalt, stone, mineral powder and fiber. The technical Specifications refer to references [27], which meet the technical specification for construction of highway asphalt pavement [27] requirements. Through the results of Marshall test, based on the method of technical specification for construction of highway asphalt pavements [27], AC-13 and SMA-13 asphalt mixture optimum asphalt content is 4.8%, 5.95%.

1.2 Pavement performance of asphalt mixture

The result of high temperature stability, low temperature crack resistance and water stability of two kinds of asphalt mixture according to the high-temperature rutting test, low-temperature bending test, freeze-thaw splitting test and immersion Marshall test are shown in Table 1. the results are shown in Table 2 when carried out fatigue tests under the control of stress.

Table 1 The test results of two kinds of asphalt mixture high temperature stability, low temperature crack resistance and water stability

Material type	High temperature stability	Low temperature crack resistance	Water stability	
	Dynamic stability（times/mm）	Bending limit strain(10-6)	Freeze-thaw cleavage strength (%)	Residual stability (%)
AC-13	4624	2478	87.1	90.9
Regulatory requirements [27]	≥1000	≥2000	≥75	≥80
SMA-13	5886	2645	91.0	92.1
Regulatory requirements [27]	≥2800	≥2500	≥80	≥85

Table 2 The test results of Asphalt mixture fatigue

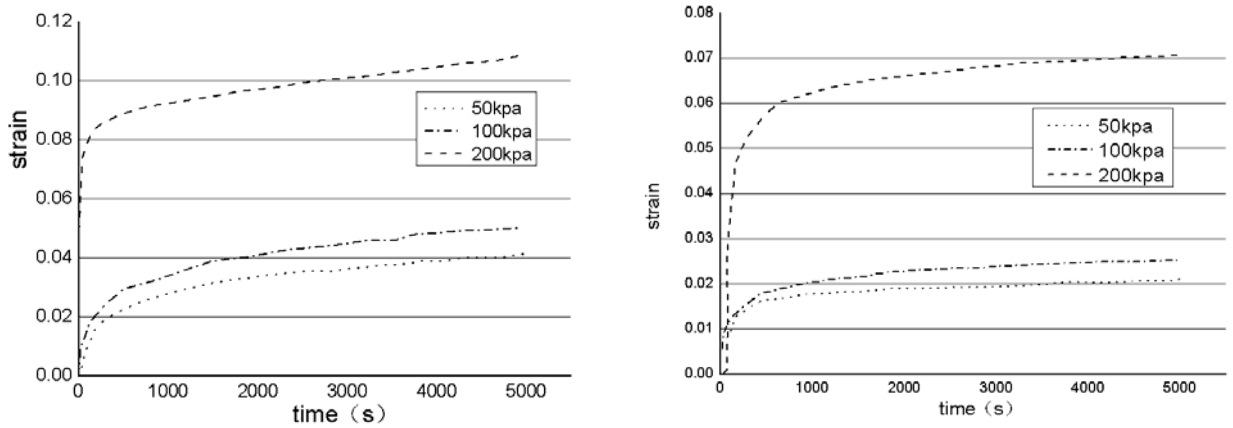
Mixture	Temperature（℃）	Stress level σ0（MPa）	Fatigue Fracture Life Ncr（time）
AC-13	25	0.1	2986
		0.2	1836
		0.3	1248
		0.7	654
SMA-13	25	0.1	3628

		0.2	2156
		0.3	1452
		0.7	800

As the results shown, the high temperature stability and low temperature crack resistance and water stability of two kinds of mixture meet the technical standard value, and the performance of SMA-13 asphalt mixture is significantly better than ordinary asphalt mixture AC-13.

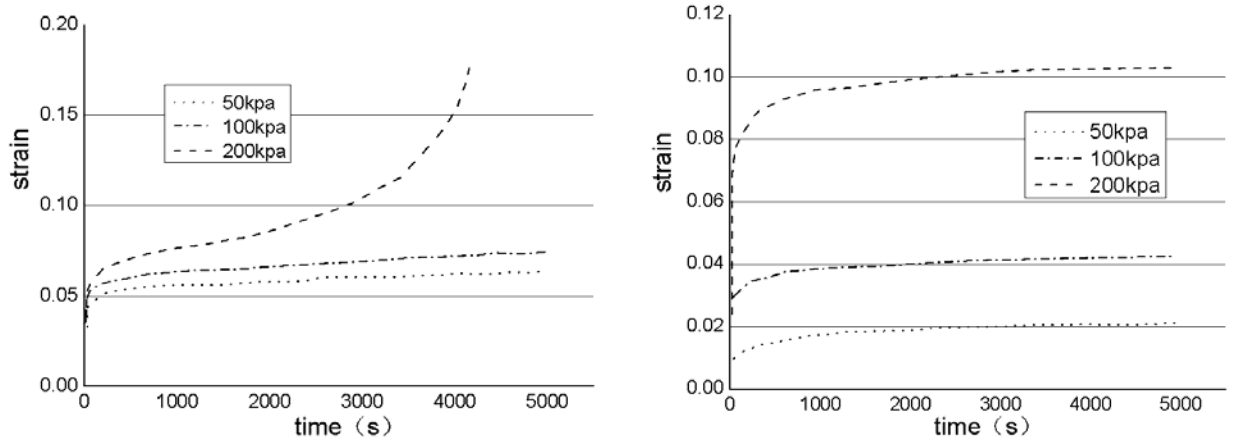
2 Creep test and analysis of static load of asphalt mixture

According to the standard test methods of bitumen and bituminous mixtures for highway engineering, the cylinder specimen for the static pressure method is controlled by the density of the Marshall test. The specimen size: diameter 100mm, height 100mm. Considering the performance of the high-temperature creep tests reflect asphalt mixture, select the test temperature is 25 ° C, 40 ° C, 60 ° C; applied three stress levels: 0.05, 0.1 and 0.2 MPa; loading time 5000s in order to facilitate the deformation full recovery. Put the sample in the environmental case for 4 hours before the test, and then after installing the servo-hydraulic materials testing machine HYD-25 applied preload 0.002Mpa, preload three minutes to prevent eccentric compression. Then loaded on specimen and the time data collected every 2 seconds. Static creep test results are shown in Figure 1 to Figure 3.



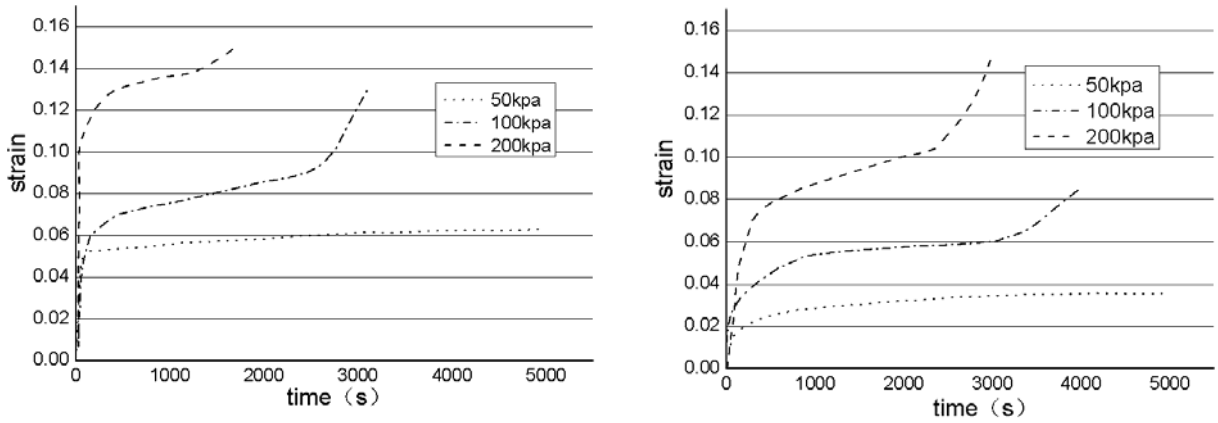
AC-13 SMA-13

Fig 1 The static creep curves at 25 ℃



AC-13 SMA-13

Fig 2 The static creep curves at 40 ℃



AC-13 SMA-13

Fig 3 The static creep curves at 60 ℃

Contrast Figures 1 to 3 static creep curves:

①Asphalt mixture at low stress levels, with the loading time, creep curve slope from large to small gradually stabilized, which shows that asphalt mixture increases the deformation resistance, resulting in further deformation is more difficult, the viscous flow of asphalt mixture with the load deformation does not affect the extension of time with load and increase infinitely, the increment decreases, finally tends to a stable value, is called the‘consolidation effect’.

②At the same temperature, high stress levels, the asphalt is too late to produce viscous and flow along with the mineral aggregate elastic deformation, with time goes on ,the start of viscous flow, VMA further reduce ,the mineral aggregate embedded squeeze more and more obvious, strain rate tend to stable, mineral aggregate porosity is further reduced, the viscous flow decreases with increasing time. But with time goes by, because of greater stress, mineral aggregate begin to slip, viscous flow of asphalt also been further extended. Therefore, the specimen is not immediately destroyed and to produce an accelerated deformation rate, which has a direct relationship with the load and temperature. Then specimen’s void ratio and clearance rate increased with increasing time and then continue to increase as the deformation, the specimen eventually completely destroyed.

③Under the same conditions, SMA has stronger deformation resistance than ordinary asphalt concrete(AC). Because the composition of SMA, coarse aggregate accounted for more than

70%,there is a lot of the mutual contact surface between coarse aggregate, and part of the stone mastic asphalt fill the gap among the coarse aggregate,. In high temperatures and loads, the coarse aggregate mutual good interlocking role, so that the mixture has better resistance to deformation. Under the condition of high temperature, stone mastic asphalt viscosity decrease which reduces the impact of the ability of resistance to deformation.

④The temperature of asphalt mixture has a great effect on deformation resistance ability, the higher the temperature, deformation resistance decreased more quickly, 2 times the deformation of high temperature of 60 ℃ to 40 ℃.Because the asphalt and asphalt mixture is a typical viscoelastic materials, these materials exhibit mechanical behavior of deformation is obviously dependent on temperature.

3 Representation to rheological model analysis of asphalt mixture viscoelastic properties

3.1 Representation to rheological model of asphalt mixture viscoelastic properties

In order to fully describe the rheological properties of the asphalt mixture under complex stress state, it is necessary to re-establish a better creep model. The first analysis of a plurality of Kelvin composite model units (as shown in Figure 4), the creep compliance is [29]

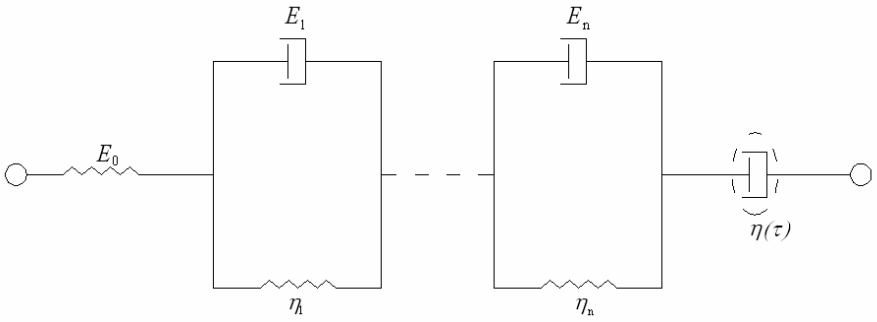


Fig 4 Several Kelvin unit composite models

$$J(t-t') = \frac{1}{E_0} + \sum_{i=1}^{n} q_i[1-e^{-\lambda_i(t-t')}] \qquad (1)$$

Where: $q_i = 1/E_i$, $\lambda_i = E_i/\eta_i$, t' is the starting moment loads. The model reflects the instantaneous elastic deformation, recoverable viscoelastic deformation and “consolidation effect", but does not reflect the unrecoverable viscous flow deformation. Therefore, the equation (1) is suitably supplemented as follows:

$$J(t-t') = \frac{1}{E_0} + \sum_{i=1}^{n} q_i[1-e^{-\lambda_i(t-t')}] + \sum_{i=1}^{m} p_i e^{-\gamma_i t'}[1-e^{-\gamma_i(t-t')}] \qquad (2)$$

Eq. (2) in the third term on the right side means that the viscous flow deformation, while it does not destroy the Eq. (1) with “consolidation effect" characteristic. Eq. (2) there is two summations. The more number of terms in summation, the more accurately express the stress and deformation characteristics of materials. But it involves too many parameters; the actual application is not conducive to the model. A simple model only considered here, each sum of only one, so the Eq. (2)

is simplified as:

$$J(t-t') = \frac{1}{E_0} + q[1-e^{-\lambda(t-t')}] + pe^{-\gamma t'}[1-e^{-\gamma(t-t')}] \quad (3)$$

There are five parameters in Eq (3), which can be determined by creep test curve.

3.2 Determination of asphalt mixture rheological model parameters

According to the creep test curves（Figure 1 to Figure 3）, the five parameters in the asphalt mixture rheological model of Eq. (3) can be constrainer optimization method (Levenberg-Marqurdt global optimization method) to determine. The model parameter values obtained at three different temperatures as shown in Table 3 below.

Table 3-1 Model parameters simulation results under 0.05MPa pressure

Types of asphalt mixture	Test temperature（℃）	E0（MPa）	q（10-4MPa）	λ（10-4s）	p（10-4s）	γ（10-4s）	Correlation coefficient R2
SMA-13	25	1620	6.86(1458)	8.44	8.46	8.12	0.9456
AC-13		1260	9.48	12.85	12.86	6.20	0.9686
SMA-13	40	1300(0.20)	11.20(893)	13.06	13.70	5.85	0.9861
AC-13		1010	13.52	19.80	19.53	5.76	0.9675
SMA-13	60	760(0.53)	14.80(676)	28.46	27.82	4.53	0.9770
AC-13		600	18.45	37.40	32.20	4.08	0.9687

Table 3-2 Model parameters simulation results under 0.1MPa pressure

Types of asphalt mixture	Test temperature（℃）	E0（MPa）	q（10-4MPa）	λ（10-4s）	p（10-4s）	γ（10-4s）	Correlation coefficient R2
SMA-13	25	1780	6.96	7.86	8.24	7.80	0.9566
AC-13		1360	8.60	12.84	12.45	5.68	0.9642
SMA-13	40	1380(0.22)	9.80	13.08	13.80	4.94	0.9712
AC-13		1120	10.67	16.50	18.46	5.12	0.9513
SMA-13	60	820(0.54)	13.90	26.45	26.48	4.40	0.9824
AC-13		680	16.88	35.81	31.80	3.96	0.9780

As we can see from table 3-3:

①Under the same condition, E0 of SMA-13 is bigger than AC-13's, and with the higher the temperature , the relative proportions of the tendency is to diminish. Under the conditions of 25℃,

40℃, 60℃ with 0.2MPa，E0 of SMA-13 are respectively higher by 29.23%, 25.71% 23.44% than AC-13's.

②In different stress but the same other conditions, the parameters variation of Model 5 is small.

4 Analysis to Nonlinear viscoelastic creep damage model for asphalt mixture

The static creep deformation reflected in Figure 1~Figure 3 usually can be divided into three stages: migration period, strain increases rapidly, but the strain rate gradually decreases with time increasing; stable period, strain steady growth, but the strain rate is essentially unchanged; Period of destruction, strain, and strain rate increases rapidly until failure increases with time. In the deformation of asphalt mixture, the modulus of the existence of a first increased and then decreased with the process, is also a first strengthened after the weakening of the process, the creep strain of asphalt mixture can be used as a nonlinear spring and a viscoplastic unit series, namely:

$$\varepsilon = \varepsilon_e + \varepsilon_{vp} \tag{4}$$

For the total strain where non-destructive condition can be expressed as:

$$\varepsilon = \frac{\sigma}{at^2 + bt + c} + [\frac{B}{A}(n+1)]^{\frac{1}{n+1}} \sigma^{\frac{m}{n+1}} t^{\frac{1}{n+1}} \tag{5}$$

In the one-dimensional problem, effective stress can be expressed as:

$$\sigma = \frac{\sigma_0}{1-\omega} (\sigma \geq 0) \tag{6}$$

Where: ω is damage factor.

Kachanov [31] uses the Norton formula obtained law of creep damage Kachanov:

$$\dot{\omega} = [\frac{\sigma_0}{C(1-\omega)}]^k \tag{7}$$

Where: *C, k* are material parameters.

Using the fully coupled method to consider the coupling effect of creep and damage of asphalt mixture, can be obtained by the constant stress damage of asphalt mixture under creep deformation equation.

$$\varepsilon = \frac{\sigma_0}{(1-\frac{t}{t_r})^{\frac{1}{K+1}}(at^2+bt+c)} + [\frac{B}{A}(n+1)]^{\frac{1}{n+1}} (1-\frac{t}{t_r})^{-\frac{m}{(K+1)(n+1)}} \sigma^{\frac{m}{n+1}} t^{\frac{1}{n+1}} \tag{8}$$

$$t_r = \frac{1}{K+1}(\frac{\sigma_0}{C})^{-K} \tag{9}$$

Where: $\frac{B}{A}(n+1) = O$, $\frac{1}{n+1} = P$, $\frac{m}{n+1} = Q$.

Fitting of Figure2,the AC-13 at 40℃,0.2MPa under load data manipulation the Levenberg-Marqurdt and the global optimization method, can obtain a creep damage model parameters, such as shown in Table 4.The comparison between creep test values calculated and creep damage model is shown in

Figure 5. The result shows, the creep damage model proposed (Eq. (9)) with high precision, can well simulate the creep damage of asphalt mixing material.

Table 4 Values of parameters in creep damage model of asphalt concrete AC-13

a(MPa)	b(MPa)	c(MPa)	t_r(s)	K	O	P	Q
3764.57	1511.66	258.66	4399.98	6.18	4.61	0.07	2.03

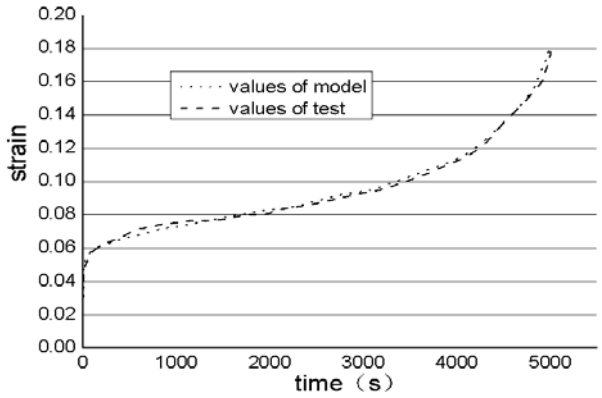

Figure 5　The AC-13 asphalt mixture creep test and creep damage model comparison under 40 ℃, 0.2MPa

5 Conclusions

（1）The results of test show that , the high temperature stability, water stability and low temperature crack resistance of the asphalt mixture of AC-13 and SMA-13 which this paper designed can meet the requirement of the construction technology, various performance indicators of SMA-13's are better than AC-13 .

（2）A　creep test is implemented on the two kinds of asphalt mixture under different temperatures and uniaxial pressure load ,and the result show that: ①The viscous flow deformation tends to a stable value after long period of loading at low stress levels which call this phenomenon as 'consolidation effect'. ②under the same level of temperature and high stress, the strain rate tends to be stable as time goes on, there will be accelerated distortion, and the rate of deformation has a direct bearing on the load and temperature. With the increase of deformation, the specimen will be destroyed completely. ③The temperature of asphalt mixture has a great effect on deformation resistance ability, the higher the temperature, the more quickly the deformation resistance decrease. ④SMA has a stronger ability to resist deformation than AC under the same conditions.

（3）A relatively ideal and practical creep model was established according to the rheological characteristics of asphalt mixture, which can express the asphalt mixture 'consolidation effect', and can reflect the permanent deformation of asphalt mixture after unloading, and also can represent rheological characteristics such as the instantaneous elastic deformation, And the effectiveness of this model was verify by comparing with the test results.

（4）A model about asphalt mixture viscoelasticity creep damage was established, and the asphalt mixture creep damage was analyzed and simulated via global coupled and the parameters of the

model were determined.

Abstract Bridges under life–long service often suffered from invisible diseases which could cause the bridge stiffness decay (rigidity) and pose great threatening to human lives. This paper focused on studying the real stiffness distribution in a simple beam. The relationship between stiffness and deflection in a bridge segment has been established which is based on the material mechanics, numerical modeling, and reciprocal displacement theorem. The conversion of the deflection curve at mid span resulted from three axle vehicle and single unit load has been developed so that by measuring the deflection caused by low speed vehicle passing over the bridge, the real stiffness distribution of the bridge could then be obtained and the assessment of the bridge damage could be carried out. Compatible software was developed in accordance with the proposed stiffness calculation method. The software was found worked well in predicting the stiffness distribution and the test results supported that the proposed prediction method is applicable. The test results showed that the stiffness distribution in longitudinal direction varied significantly, which is due to the different degrees of damage. The analysis showed that it is not good to use the overall stiffness to evaluate the damage of the whole beam.

Key words: simple supported beam, longitudinal stiffness, invisible damage, damage assessment

1. Introduction

In recent decades, as the developing of our country, the number of highway bridges increased significantly, which in turn increased the number of bridges under life–long service. Due to the climate change, environment varies, temperature drops and wind and mechanical erodes, bridge aging becomes gradually a serious problem. Cyclic traffic loading could cause bridge elements to lose its mechanic properties and evolve into fatigue damage. Some bridges currently in service suffered from concrete crack, rebar erosion, and pre–stress relaxation, which could result in the overall stiffness decay and reduce its engineering performance. When the bridge stiffness decays, the bearing capacity would be greatly reduced which prohibited its service life and threatens the human lives[1]. Currently, there are two different ways to evaluate the bridge stiffness distribution, namely the direct way and indirect way. The indirect way is that to look over the outside of the bridge, for example, conduct a walk tour throughout the bridge, look for cracks, damage points and find out weak areas, which is very objective and cannot give a very accurate evaluation. The direct way is to carry out load test and measure the real stress strain response under different loadings. The load test can reflect the real stiffness of the bridge; however, it cannot indicate the damage degree of a bridge and show where the damage area is[2]. Therefore, to check the overall quality of a bridge, and evaluate the performance of the bridge and each segment has great significance in transportation engineering.

The assessment of the bridge stiffness and damage has been studied by many researchers. Zhao et al. [3] proposed to use bridge structure bilateral difference response model to analyze the integrity of the bridge in longitudinal and transverse directions, so that to study the stiffness in longitudinal directions. Yuan et al.[4] studied the erosion of Cl^- under freezing–thaw cycles. They have proposed a method to predict the expiration life of Cl^- under freezing–thaw cycles. Y.M. et al.[5] have proposed method to calculate the rotation when the top of the beam has cracks, and to predict the service life of the beam under such situation. Yao et al. [6] studied the bearing capacity of beams

that suffered from damage in longitudinal directions. Shan et al.[7] studied the detection of damage location and damage degree of highway bridges under the vibration of vehicles moving. Z. H. et al.[8] studied the bearing capacity of bridges under service by using the dual coding genetic algorithm. Yuan et al.[9] proposed a method to calibrate the stiffness matrix which based on the assumption that the finite element mass matrix and the stiffness matrix were asymmetry, and the mass matrix was given.

The previous studies have advanced the state of the art of the knowledge of stiffness decay damage of bridges; however, there are no effective methods in determining the damage inside the bridge (ex. The invisible concrete cracks, the rebar corrosion, and pre–stress relaxation). Those common diseases could result in heavily decay of the stiffness of the bridge elements, thus influencing the service life and posing failure the bridge. This paper focused on a simple beam structure to study the real stiffness distribution at each bridge segment. The stiffness prediction is based on the measured deflection from the mid span, and used proposed method to calculate the real stiffness distribution, so that the stiffness decay degree inside the bridge could be evaluated, the location of the damage area could be found, and the damage degree could be estimated.

2. The relationship between deflection influence line and stiffness in bridge segment

2.1 Finite element equation of single beam element

Simple bridge beam does not have axle force (the traffic loading cannot cause axle force). For a beam without axial force, the four degree of freedoms are: the vertical displacement at both sides of the beam, v_1 *and* v_2; and the rotation angles at both sides, θ_1 *and* θ_2 (Fig. 1).

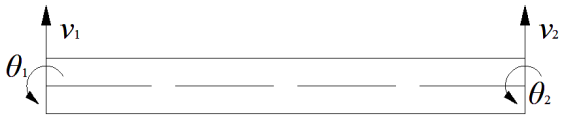

Figure 1.beam element without of axial force

According to finite element theory[9],the solution equation for a rigid beam element is:

$$K^e \cdot q^e = P^e \tag{1}$$

where: K^e is the stiffness matrix without axial force [10], K^e is the parameters in the matrix as shown in Eq.(2), E is the elastic modulus of the beam, I is the bending moment of inertia, and l is the length of the beam.

$$K^e = EI\begin{bmatrix} \frac{12}{l^3} & \frac{6}{l^2} & \frac{-12}{l^3} & \frac{6}{l^2} \\ \frac{6}{l^2} & \frac{4}{l} & \frac{-6}{l^2} & \frac{2}{l} \\ \frac{-12}{l^3} & \frac{-6}{l^2} & \frac{12}{l^3} & \frac{-6}{l^2} \\ \frac{6}{l^2} & \frac{2}{l} & \frac{-6}{l^2} & \frac{4}{l} \end{bmatrix} \tag{2}$$

q^e is the displacement matrix of the rigid beam at each nods, $q^e = \begin{bmatrix} v_1 & \theta_1 & v_2 & \theta_2 \end{bmatrix}^T$

P^e is the stress matrix, $P^e = \begin{bmatrix} P_1 & M_1 & P_2 & M_2 \end{bmatrix}^T$

2.2 Establish the relationship between deflection influence line and stiffness in bridge segment

Take simple beam as an example; divide the bridge into N segments in longitudinal direction. The deflection influence line could be achieved by superposition of the deflection resulted from each unit load that applied at the mid span of each bridge segment. From structure mechanics point of view, according to the reciprocal displacement theorem that in a rigidity beam, a force applied to point i, which caused the displacement at point j is equal to the same force that applied to j that caused the displacement that happened at i. Similarly, the unit force that applied in the mid－span of the N segment, where the resulted deflection is equal to the unit force that applied in the mid span where the resulted deflection happened at the N segment. Therefore, when the deflection influence line is known at mid span, the real stiffness is easily achieved. Because there are no element nods at the mid span, each bridge segment is subdivided into two sections, thus the overall segments become to 2N, and the computational model is shown in Fig. 2.

For the bridges under service, it is convenient to use moving vehicles passing through the bridge to collect the mid span deflection to predict the stiffness distribution (model 1),the conversion relationship between the moving vehicles and the single unit weight is shown in section 2. For the beams in laboratory and precast beams in field, the stiffness could be calculated based on the mid span loading condition (model 2).

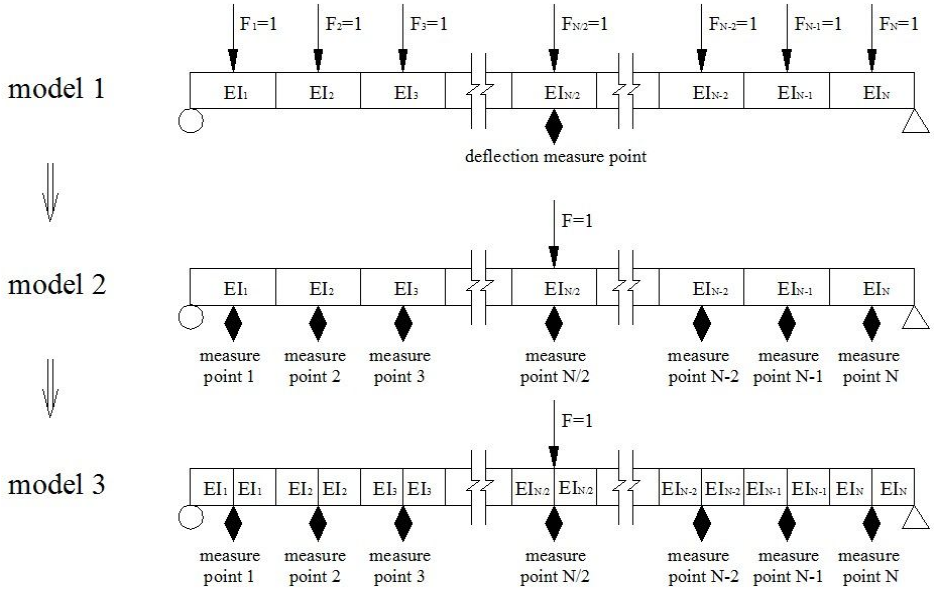

Figure 2.Computational Models

The relationship between load, deflection, and stiffness in model 3 are presented below:

$$
\begin{cases}
EI_1(\frac{12}{l_1^3}v_1+\frac{6}{l_1^2}\theta_1-\frac{12}{l_1^3}v_2+\frac{6}{l_1^2}\theta_2)=P_1 \\
EI_1(\frac{6}{l_1^2}v_1+\frac{4}{l_1}\theta_1-\frac{6}{l_1^2}v_2+\frac{2}{l_1}\theta_2)=M_1 \\
EI_i(-\frac{12}{l_i^3}v_i-\frac{6}{l_i^2}\theta_i+\frac{12}{l_i^3}v_{i+1}-\frac{6}{l_i^2}\theta_{i+1})+EI_{i+1}(\frac{12}{l_{i+1}^3}v_{i+1}+\frac{6}{l_{i+1}^2}\theta_{i+1}-\frac{12}{l_{i+1}^3}v_{i+2}+\frac{6}{l_{i+1}^2}\theta_{i+2})=P_{i+1} \\
EI_i(\frac{6}{l_i^2}v_i+\frac{2}{l_i}\theta_i-\frac{6}{l_i^2}v_{i+1}+\frac{4}{l_i}\theta_{i+1})+EI_{i+1}(\frac{6}{l_{i+1}^2}v_{i+1}+\frac{4}{l_{i+1}}\theta_{i+1}-\frac{6}{l_{i+1}^2}v_{i+2}+\frac{2}{l_{i+1}}\theta_{i+2})=M_{i+1} \\
EI_{2N}(-\frac{12}{l_{2N}^3}v_{2N}-\frac{6}{l_{2N}^2}\theta_{2N}+\frac{12}{l_{2N}^3}v_{2N+1}-\frac{6}{l_{2N}^2}\theta_{2N+1})=P_{2N+1} \\
EI_{2N}(\frac{6}{l_{2N}^2}v_{2N}+\frac{2}{l_{2N}}\theta_{2N}-\frac{6}{l_{2N}^2}v_{2N+1}+\frac{4}{l_{2N}}\theta_{2N+1})=M_{2N+1}
\end{cases}
\tag{3}
$$

where: EI_i is the stiffness of each bridge segment(i=1～2N), v_i is the vertical deflection at each

element nod(i=1～2N+1), θ_i is the rotation angle at each element nod(i=1～2N+1), P_i is the vertical load at each element nod(i=1～2N+1), M_i is the bending moment at each element nod(i=1～2N+1), l_i is the length of each element(i=1～2N), in summary, there are 12N+4 parameters.
In Eq. (3) there are some boundary conditions:

$$\left.\begin{aligned} & v_1 = v_{2N+1} = 0 \\ & P_{N+1} = 1 \\ & P_j = 0 \\ & M_i = 0 \\ & l_i = \frac{L}{2N} \\ & EI_i = EI_{i-1} \end{aligned}\right\} \tag{4}$$

where: L is the span of bridge($i = 1, 2, 3...2N$), P_j is the vertical load at each element nod when $j \neq N+1$ and $j \in i$.

2.3 Solution of the deflection stiffness equation

Maple is the most popular tool in Math and Engineering practice worldwide. Maple is also a good tool for symbolic operations, and very helpful in studying the mathematics models. In this research, therefore, Maple was adopted to solve the Eq. (3) and Eq. (4), and all the parameters (12N+4) in the equations. It is found that Maple could offer an analytic solution for those equations. The stiffness EI_i (i=1～2N)in each bridge section could be represented as follows:

$$EI_i = EI_{i+1} = \frac{L^3}{96N^4 \cdot B_i} \tag{5}$$

where: B_i is the i row in matrix $\mathbf{B}$ ($i = 1, 3, 5...2N-1$),the matrix $\mathbf{B}$ could be obtained by Eq. (6).

$$\mathbf{B} = \mathbf{A}^{-1} \cdot \mathbf{f} \tag{6}$$

In Eq. (6), $\mathbf{f}$ is the deflection at the mid span of each bridge segment, which is similar to the displacement matrix $v_i (i = 2, 4, 6...2N)$, however, matrix $\mathbf{A}$ is very complex, and the element in matrix $\mathbf{A}_{i,j}$ could be categorized into two groups according to their parity:
(1)When N is even:

$$\mathbf{A}_{i,j} = \begin{cases} (24j^2 - 24j + 8)(2N - 2i + 1) & (i > j \text{ and } j \le \frac{N}{2}) \\ (-24m^2 + 24m + 24mN - 12N - 8)(2N - 2i + 1) & (N > j > \frac{N}{2} \text{ and } i > j \text{ and } m = N - j + 1) \\ (-24m^2 + 24m + 24mN - 12N - 8)(2m - 1) - 6mN + 5N & (i = j > \frac{N}{2} \text{ and } m = N - i + 1) \\ \mathbf{A}_{N+1-i, N+1-j} & (i = j \le \frac{N}{2} \text{ or } j > \text{i}) \end{cases} \tag{7}$$

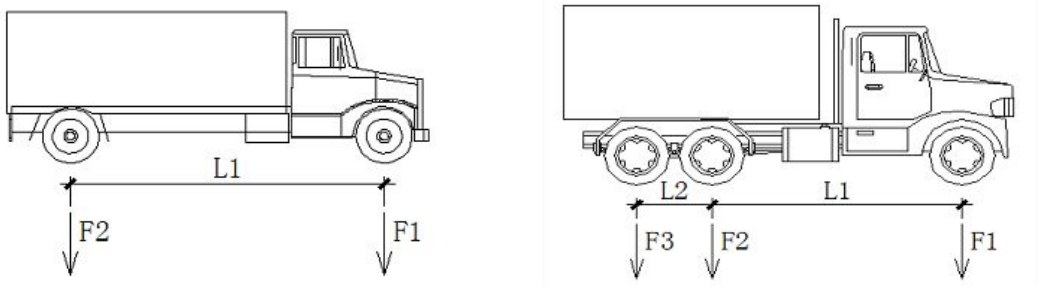
(2)When N is odd:

$$\mathbf{A}_{i,j}=\begin{cases}(24j^2-24j+8)(2N-2i+1) & (i>j \text{ and } j<\frac{N}{2})\\ (-24m^2+24m+24mN-12N-8)(2N-2i+1) & (N>j>\frac{N+1}{2} \text{ and } i>j \text{ and } m=N-j+1)\\ (-24m^2+24m+24mN-12N-8)(2m-1)-6mN+5N & (i=j>\frac{N+1}{2} \text{ and } m=N-i+1)\\ \mathbf{A}_{N+1-i,N+1-j} & (i=j<\frac{N}{2} \text{ or } j>\text{i})\\ 6N^2-3N & (i=N \text{ and } j=\frac{N+1}{2})\\ (6N^2-3N)(2N-2i+1) & (\frac{N+1}{2}<i<N \text{ and } j=\frac{N+1}{2})\\ 2N(3N^2-3N+1) & (i=j=\frac{N+1}{2})\\ \mathbf{A}_{N+1-i,j} & (i<\frac{N+1}{2} \text{ and } j=\frac{N+1}{2})\end{cases} \quad (8)$$

Based on Eq. (5) to Eq. (8), the stiffness EI_{i} (i=1～2N) of each bridge segment could be obtained from the known deflection values, hence the real stiffness of the whole bridge could be determined.

3. The Deflection Influence Line in Mid－Span

From section 1, it is known that when the mid span deflection influence line is given, the real stiffness distribution could be determined. However, it is hard to use a unit concentrated force to pass through the bridge, usually, the mobility of the load is similulated as a two axle or three axle vehicle passing over the bridge (speed at 5km/h), and measure the deflection at the mid span. The vehicle size and models are shown in Fig. 3. The conversion relationship of the resulted deflection curve in the mid span between common two axles or three axles vehicle and the unit load are achieved and showed in Eq. (9) to Eq. (12).



(a)Double axles vehicle (b)triple axles vehicle

Figure 3.Vehicle Models and Sizes

(1)Double axle vehicle

For the vehicle model in 3 (a), the single concentrated load F and vehicle length L after conversion are shown from Eq. (9) to Eq. (10).

$$F=F_1+F_2 \quad (9)$$

$$L=\frac{F_2L_1}{F_1+F_2} \quad (10)$$

(2)Triple axle vehicle

For the vehicle model in 3 (b), the single concentrated load F and vehicle length L after conversion are shown from Eq. (11) to Eq. (12).

$$F = F_1 + F_2 + F_3 \tag{11}$$

$$L = \frac{F_2 L_1 + F_3 (L_1 + L_2)}{F_1 + F_2 + F_3} \tag{12}$$

When the multiple axles loads have been converted to single concentrated unit load, use the linear relationship between concentrated load and unit load, the deflection at mid span caused by the vehicles could be converted into deflection influence line, so that to calculate the real stiffness distribution in the whole beam.

4. Case Study and the Development of the Compatible Software

When the deflection values D_1 to D_4 are known in model 1 or model 2 in Fig. 2, the real stiffness of a bridge in four segments at length of L could be obtained as presented below:
Based on Eq. (7) when N=4:

$$\mathbf{A} = \begin{bmatrix} 36 & 88 & 56 & 8 \\ 40 & 236 & 168 & 24 \\ 24 & 168 & 236 & 40 \\ 8 & 56 & 88 & 36 \end{bmatrix} \tag{13}$$

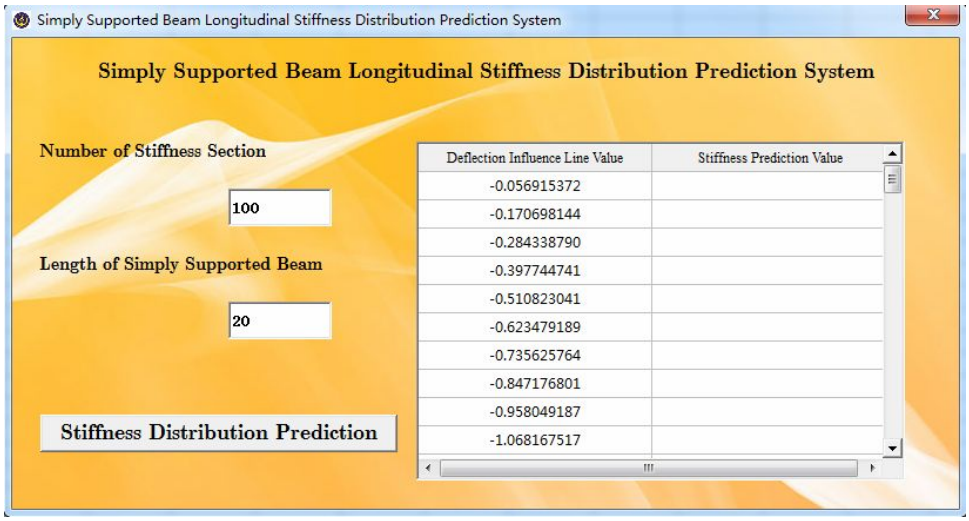
$$\mathbf{B} = \mathbf{A}^{-1} \cdot \mathbf{f} = 10^{-5} \begin{bmatrix} 4802D_1 - 1990D_2 + 308D_3 - 83D_4 \\ -949D_1 + 1263D_2 - 749D_3 + 201D_4 \\ 201D_1 - 749D_2 + 1263D_3 - 949D_4 \\ -83D_1 + 308D_2 - 1990D_3 + 4802D_4 \end{bmatrix} \tag{14}$$

From Eq. (5), the stiffness are shown below, for example, when i=1:

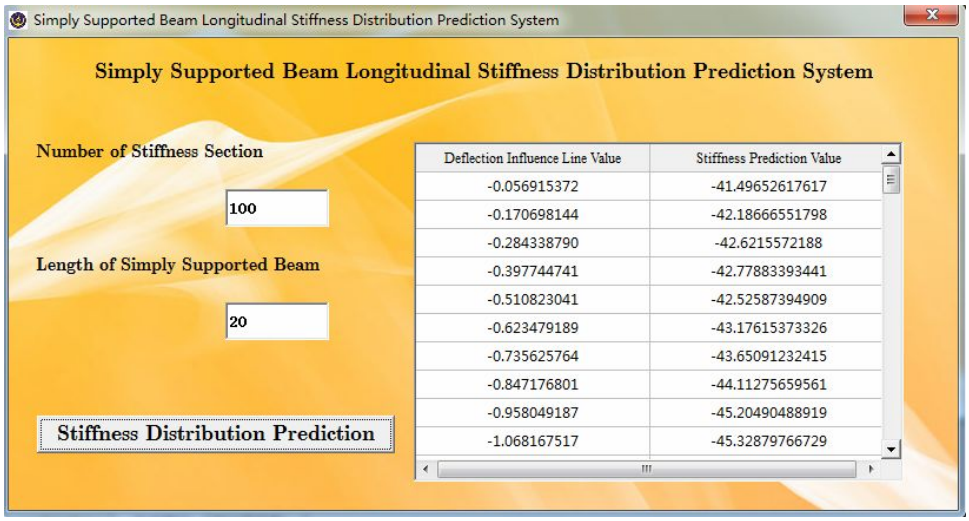
$$EI_1 = EI_2 = \frac{L^3}{96 \times 4^4 \cdot B_1} = \frac{L^3}{1180.1D_1 - 489.1D_2 + 75.7D_3 - 20.4D_4} \tag{15}$$

The Eq. (15) is the stiffness prediction equation that at the number of 4 bridge segments, the results were matched well with the published results in literature[10].

When N is large, the matrix $\mathbf{A}$ and $\mathbf{A}^{-1}$ are complex and hard to manipulate. In order to make it simple to carry out the stiffness prediction, windows based software was developed in accordance with the proposed equations and simple beam model. When the number of bridge segments, the length of the simple beam, and the influence line have been given, the real stiffness distribution could then be easily calculated, as shown in Fig. 4.



(a) Pretreatment



(b) post processing

Figure 4.the user interface

An old simple beam bridge, 20m in length, was adopted in the case study. The bridge was divided into 100 segments; the mid span deflection is tested by moving a two axle vehicle passing through the bridge at a low speed. The deflection influence line was calculated and shown in Fig. 5, and the stiffness distribution is shown in Fig. 6.

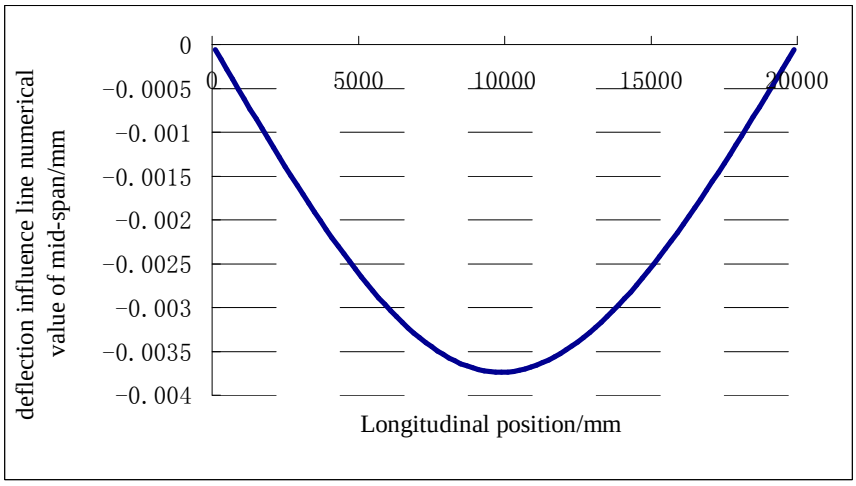


Figure 5.deflection influence line at the mid span

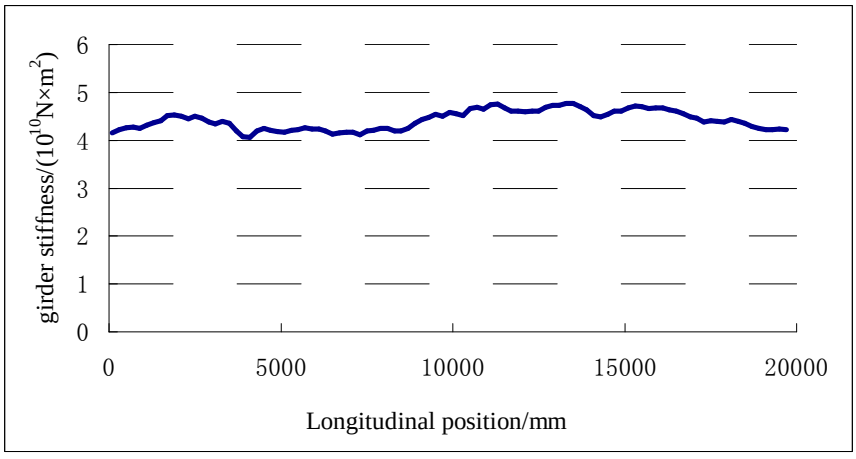

Figure 6.stiffness distribution curve

The calculation results showed that the proposed prediction methods worked pretty well, the bridge stiffness distribution could be calculated from the mid span deflection influence line. From the stiffness distribution curve the following features could be observed, the minimum stiffness is 4.09, maximum is 4.71, and the difference is 14%; significant stiffness decay happens at L/4, however, the stiffness decay was slightly at 3L/4. According to the stiffness distribution curve, the real working condition of the bridge could be evaluated, and thus helps the damage detection and bridge reinforcement work.

5. Conclusion

(1)This research is focused on the real stiffness distribution of simple beam structure in bridge engineering. The real stiffness distribution prediction equations were achieved based on the relationship between stiffness and deflection. The analysis results showed that there were analytical solutions for the stiffness distribution prediction equations, and it could be achieved from by measuring the deflection influence line in the mid span of each bridge segment.
(2)In order to simplify the measurement of the deflection in the field, the conversion method between two axles (three axles vehicles) and single unit concentrated loading condition was developed, so that to improve the measurement of the real deflection data in filed and help the prediction of the actual stiffness distribution.
(3)When calculating large numbers of bridge segments, for example, N is very large, the direct calculation work would be very heavy, therefore, a compatible software was developed to simplify the calculation work. A case study was carried out to check the workability of the software. The calculation results showed that the stiffness in each segments were slightly different. The developed software was found to actually predict the stiffness change of each segment in a bridge, estimate the decay area and decay degree, and help to improve the bridge and reinforcement work.

Abstract This paper firstly combines acoustic emission (AE) technique with monitoring of traffic loads and dynamic strain in healthy monitoring of concrete bridge structures. AE sensors and strain gauges were located on the web zone, deck plate and bottom plate of the box girder of Yaoxian Bridge, weigh-in-motion system (WIM system) was located in the pavement. Three monitoring systems clock was set synchronizedly, so they could monitor AE information, vehicles information and dynamic strain at the same time. Through the amplitude distribution and *b*-value analysis of AE signals, it finds the monitored bridge is in good service condition. The fatigue life of steel bars as well as strands in the box girders was calculated based on recorded data. Then, based on fatigue failure mechanism of concrete bridges, fatigue life evaluation approaches using S-N curves and fracture mechanics are presented. The evaluation results show that the fatigue life of the bridge is over 200 years, longer than the design service life. Finally, based on current study, it concludes that acoustic emission is an effective technique to evaluate existing concrete bridges.

Keywords existing concrete bridges, fatigue damage, fatigue load, acoustic emission, fatigue life

1. Introduction

Concrete bridges are widely used in China, accounting for 90 percent of all highway bridges. With the rapid development of highway transportation, traffic volume, vehicle weight and speed are constantly increasing, and overload phenomenon is difficult to eliminate, so fatigue damage caused by above problems cannot be neglected [1]. Current safety evaluation in China is mainly based on Code for Maintenance of Highway Bridges and Culverts and Specification for Inspection and Evaluation of Load-bearing Capacity of Highway Bridges. In order to evaluate the fatigue safety and remaining fatigue life of existing concrete bridges, emphasis should be laid on fatigue load monitoring, fatigue damage and fatigue life evaluation.

After World War II, some developed countries were beginning to research on fatigue fracture of concrete bridges, and corresponding design codes are gradually formed [2~5]. British scholar Tilly studied the reduction coefficient of fatigue strength of steel bars under different levels of corrosion [6], the result was used to evaluate durability and remaining life of concrete bridges; Schlafli and Bruhwiler of Swiss Federal Institute of Technology Lausanne have studied the basic method for fatigue evaluation of existing concrete bridges, and conducted fatigue safety evaluation of existing concrete bridges in Swiss [7].

With the development of non-destructive technique (NDT), real-time monitoring of the fatigue damage of existing bridges becomes possible [8]. Acoustic emission (AE) is a typical non-destructive technique, which can realize the effective monitoring of fatigue crack propagation in steel bridges. Nowadays some researches are trying to apply AE technique to

concrete bridges.

This paper combines weigh-in-motion (WIM) technique, dynamic strain monitoring technique with AE technique to evaluate a typical concrete bridge with box girders. Through fatigue life evaluation based on S-N curve and fracture mechanics, in combination with AE signals analysis, fatigue safety of the concrete bridge is comprehensively evaluated.

2. Fatigue Safety Monitoring Technique and Evaluation Methods

2.1 Weigh-in-motion Technique

HI-TRAC 100 is an advanced weighing system which includes two piezoelectric sensors, one induction coil sensor and a data acquisition unit (shown in Figure 1). When vehicles pass the bridge, the induction coil set in pavement picks up different responses, and the piezoelectric sensors send the information to the acquisition unit. Then the controlling unit can calculator the specific information of the passed vehicle and record the information. The system can record comprehensive information about the vehicles moving through, such as weight, speed, direction, axle number and so on.

Figure 1. TDC WIM system

2.2 Acoustic Emission Technique

AE signal is a transient elastic stress wave generated by sudden changes in materials like deformation, cracking and transformation [8~9]. Figure 2 shows the model of AE signal production and spreading, when structure or material is in the condition of tension, compression or impact, the internal crack tip of structure will lead to a transient release of stress that can produce stress waves. When the crack propagates, the stress waves spread in all directions. Then these stress waves could be picked up by AE sensors attached on the surface of structure.

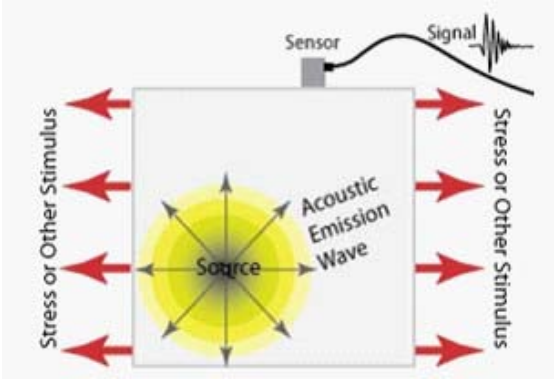

Figure 2. Model of AE production and spreading

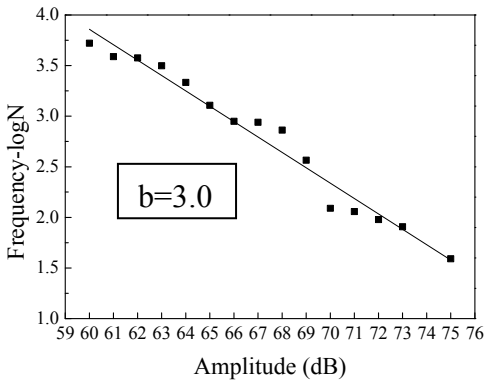

Figure 3. Example of calculation of *b*-value

Researchers began to apply AE technique to bridges monitoring in 1970s. Colombo developed *b*-value analysis method in 2003, and successfully evaluated the damage degree of reinforced concrete beam [9]. The analysis result shows that changing trend of maximum *b*-value reflects microcracks propagation; while minimum *b*-value reflects macrocracks development, which shows a good correlation with cracking process of reinforced concrete beam. Figure 3 shows *b*-value calculation method, while *N* stands for counts of different amplitude. Least-square fitting method is adopted to draw the line, the slope of the fitted line is -0.152, *b*-value is 3.04 according to the relationship between them.

2.3 Fatigue life evaluation method based on S-N curve and Miner law

According to Miner linear fatigue accumulative damage, fatigue damage can be calculated by Equation (1):

$$D = \sum_i D_i = \sum_i \frac{n_i}{N_i} \tag{1}$$

In each stress range level $\Delta\sigma_i$, the fatigue damage D_i was linearly proportional to n_i, where n_i is the number of cycles at σ_i, N_i stands for cycles under stress range level $\Delta\sigma_i$ and D is the total damage when fatigue failure occurs. Fatigue life Y can be calculated by Equation (2):

$$Y = \frac{D_{\mathrm{cr}}}{D_T} \times T \tag{2}$$

While D_{cr} stands for critical fatigue damage, T stands for monitoring time and D_T is fatigue damage during time T. Previous experiments show that, under random loading, D_{cr} is around 1, so the value of D_{cr} is taken as 1.

2.4 Fatigue life evaluation method based on fracture mechanics

In order to simulate the process of crack initiation, crack propagation to destruction in steel bars, assume the initial crack is semi-circle and the depth is a_0, so the crack propagation can be calculated by Paris formula (Equation 3).

$$\frac{\mathrm{d}a}{\mathrm{d}N} = C \cdot \Delta K^{\mathrm{m}} \tag{3}$$

While C and m are material constants; $\Delta K = Y \cdot \Delta\sigma \cdot \sqrt{\pi \cdot a}$, $\Delta\sigma$ is stress range and Y is a modified coefficient.

According to K criterion in linear elastic fracture mechanics, if $K_I \geq K_{IC}$, the steel bar tends to brittle fracture, the critical crack depth is a_{cr}; if the steel bar tends to yield dstruction along with the crack propagation, the critical crack depth is a_y. Thus the critical crack depth of fatigue failure of steel bar is a_{fr}=min (a_{cr}, a_y). Fatigue life can be calculated by Equation (4):

$$N = \int_{a_0}^{a_{fr}} dN = \int_{a_0}^{a_{fr}} \frac{1}{C \cdot \Delta K^m} da = \int_{a_0}^{a_{fr}} \frac{1}{C \cdot Y^m \cdot \Delta\sigma^m \cdot \pi^{m/2} \cdot a^{m/2}} da \tag{4}$$

3. Fatigue stress and traffic load monitoring

Accumulating fatigue damage caused by passing vehicles is needed for fatigue safety evaluation

of existing concrete bridges, but there is no fatigue vehicle spectrum in China, so it is important to acquire actual traffic load or fatigue stress.

Yaoxian Bridge (shown in Figure 4) is a key bridge of provincial road 305, from Tongchuan to Jiaopin in Shaanxi, China. It is an 8-span prestressed box girder bridge with span length of 30m. Since the bridge is near a coal mine, many coal-trucks pass the bridge everyday, so the bridge is under great fatigue stress. In this paper, the writer has conducted dynamic strain monitoring for 21 days. Figure 5 shows a typical dynamic strain curve.

Figure 4. Yaoxian Bridge

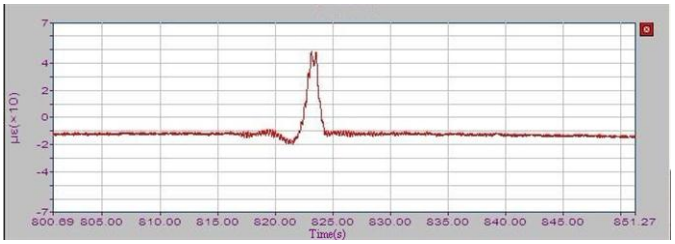

Figure 5. Example of dynamic strain curve

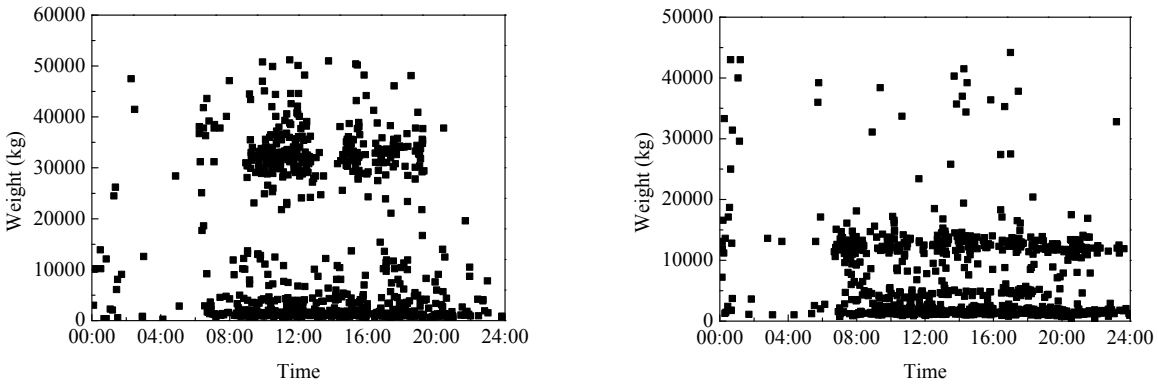
Through the analysis of recorded vehicles information, vehicle make-ups of every day are similar. Figure 6 is the vehicle load information of 4th September, 2011: passage time of full trucks is mainly from 9:00 to 13:00 and from 14:00 to 19:00; among all vehicles, weights of 1,12 and 33 tons are most, and there are more vehicles passing bridge in daylight than night. Full trucks of Tongchuan direction are mainly 30 tons to 40 tons, the maximum recorded weight is 55 tons; vehicle loads of Jiaoping direction are mainly around 1 tons and 12 tons.



(a) Tongchuan direction (lane 1) (b) Jiaoping direction (lane 2)

Figure 6. Vehicle load information during a day

Figure 7 shows the vehicle load distribution of Yaoxian Bridge. Total monitoring time is 35 days, the total number of passing vehicles is 57802, and the average traffic volume is 1650 during a day. Cars accounts for 46.7 percent, trucks with 2 axles accounts for 19.8 percent, trucks with 3 axles accounts for 25.2 percent, other kinds are 8.3 percent. Maximum vehicle load is lighter than design loads, and no overloaded vehicle is recorded. Total weight and axle weight of all vehicles are lighter than fatigue vehicles in Europe Code, and there are less than 500 trucks in

every lane during a day, so during design service life fatigue damage caused by recorded vehicle loads is little.

4. AE monitoring and signals analysis

4.1 Site monitoring information

The AE monitoring was started in 23rd August, 2011, ended in 7th September, 2011, and the NO.2 and NO.3 box girder of the first span was chosen to be the monitoring region. In order to identify the different signal characteristics of different locations, sensor locations are on the every part of the box girder, as shown in the Figure 8: NO.7 and NO.11 sensors are on the deck plates; NO.2, 5, 9 and NO.13 sensors are on the bottom plates; other 10 sensors are on the webs.

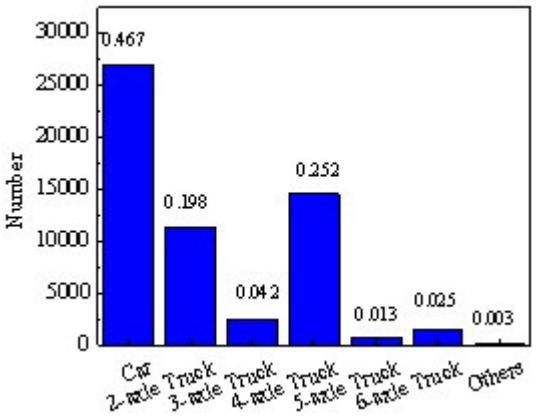


Figure 7. Vehicle load distribution

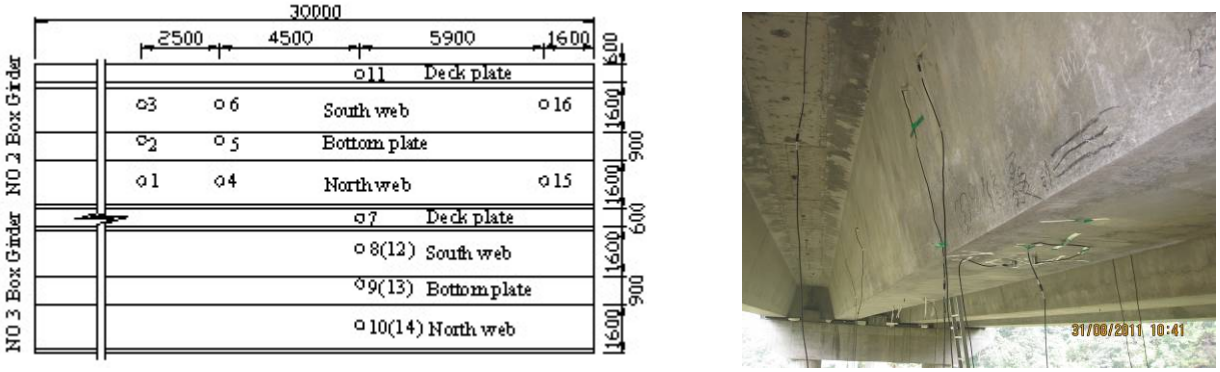

Figure 8. AE sensor locations (mm)

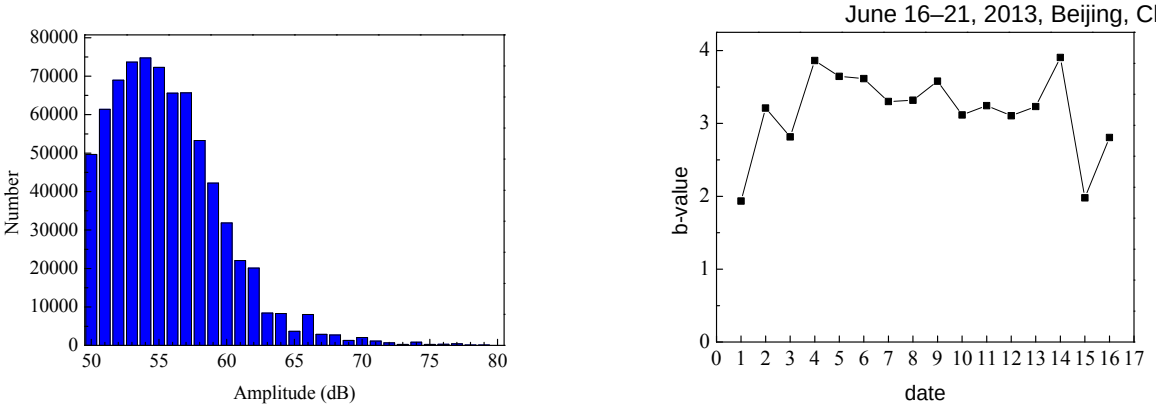
The acoustic emission equipment used in the bridge monitoring was made by Physical Acoustic Corporation, including an independent AE system: Micro-II, R3I and R15a sensors. R15a with 150 kHz-resonant-frequency was located at positions of NO.12, 13, 14, R3I with 30 kHz-resonant-frequency sensors are for the other monitoring positions. Based on the level of noise in the monitoring site, the threshold level was set at 50 dB.

4.2 Characteristics analysis of AE data

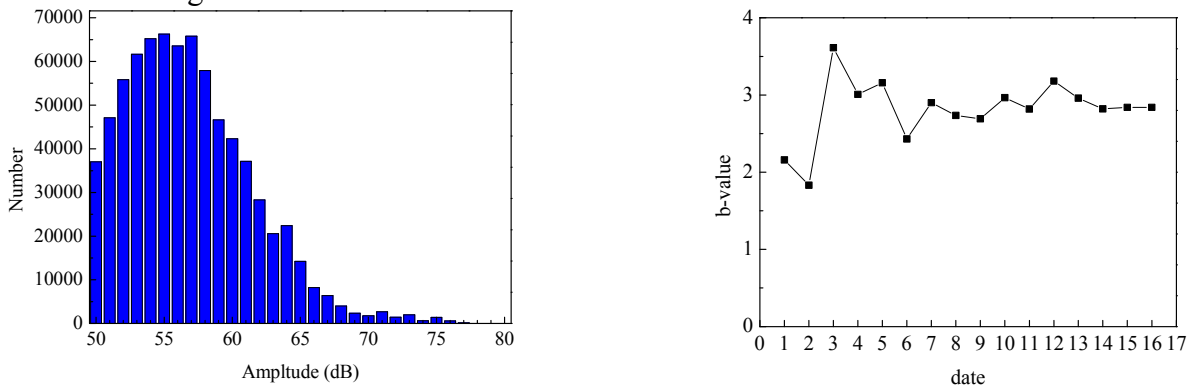
NO.2, 4, 7 sensors have recorded the most hits in 3 different locations respectively, so signals acquired by this 3 sensors were analyzed to evaluate the box girders. Figure 9 shows the analysis results of data acquired by NO.2 sensor on bottom plate: (a) is the amplitude distribution of 16 day's data, there are more than 70000 signals at 54dB, amplitudes of almost all signals are lower than 70dB; (b) is the *b*-value changing trend, the minimum *b*-value is 1.94, and the maximum is 3.90.



(a) Amplitude distribution (b) Changing trend of *b*-value

Figure 9. Data analysis of NO.2 sensor (23rd August, 2011 to 7th September, 2011)

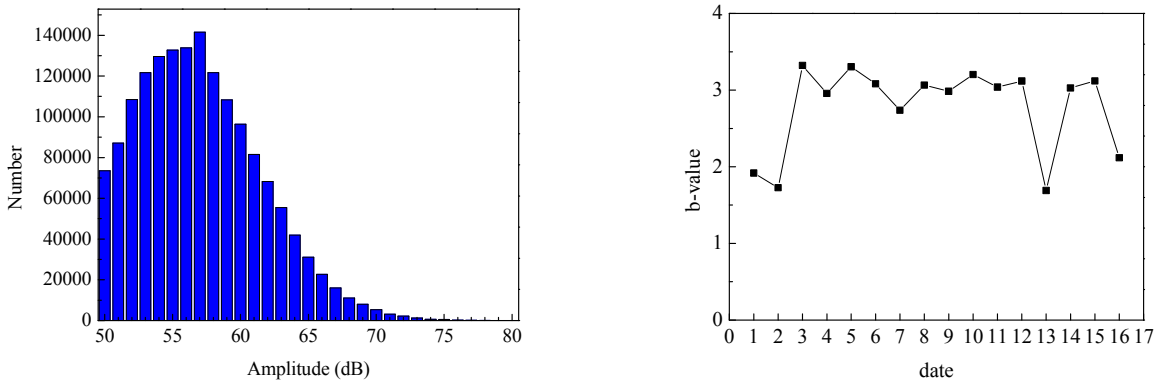
Figure 10 shows the analysis results of data acquired by NO.4 sensor on web: (a) is the amplitude distribution of 16 day's data, there are more than 6000 signals at 57dB, amplitudes of all signals are lower than 75dB; (b) is the *b*-value changing trend, the minimum *b*-value is 1.83, and others are higher than 2.00.



(a) Amplitude distribution (b) Changing trend of *b*-value

Figure 10. Data analysis of NO.4 sensor (23rd August, 2011 to 7th September, 2011)

Figure 11 shows the analysis results of data acquired by NO.7 sensor on deck plate, which acquired the most signals in all sensors: (a) is the amplitude distribution of 16 day's data, there are more than 14000 signals at 57dB, amplitudes of all signals are lower than 75dB; (b) is the *b*-value changing trend, the minimum *b*-value is 1.72 occurred in the 13rd day (4th September, 2011).



(a) Amplitude distribution (b) Changing trend of *b*-value

Figure 11. Data analysis of NO.7 sensor (23rd August, 2011 to 7th September, 2011)

From the amplitude distribution of 3 typical positions, it is easy to find sensor on deck plate acquired the most signals, and sensor on bottom plate acquired the least. Amplitudes of almost

all signals are lower than 70dB, and there are most signals at 57dB, so the noise level in site is around 57dB.

According to research by Colombo, changing trend of maximum *b*-value reflects the propagation of microcracks, and changing trend of minimum *b*-value reflects the propagation of macrocracks; when *b*-value is higher than 1.7, the structure is in period of microcracks propagation[9]. Figure 9 to Figure 11 shows the *b*-value changing trend of 3 locations, all *b*-values are higher than 1.7, and no macrocrack has been detected, and so Yaoxian Bridge is in the period of microcracks, it is in good working conditions.

5. Fatigue life evaluation

5.1 Fatigue life evaluation based on S-N curve

From all S-N curves of different fatigue details in research documents and specifications in different countries, S-N curve in European Institute of steel construction (ECCS) is adopted to evaluate the fatigue life of steel bars and strands in concrete bridges.

In this specification, fatigue strength of 2 million cycles is 80.0MPa, fatigue strength of constant stress range is 59.0MPa, and threshold of fatigue strength is 32.4MPa. The slope of curves changes from -3 to -5 when cycles are more than 5 million. Since most full trucks are on lane 1, 4 typical stain monitoring positions (shown in Figure 12) below lane 1 are chosen to evaluate the fatigue life of steel bars and strands in box girders of Yaoxian Bridge. The evaluation result is shown in Table 1: fatigue life of steel bars in deck plate (measure point BST2) is 3756 years; fatigue life of strands in bottom plate is longer than 1000 years. Therefore, it can be concluded that under the present fatigue load level, fatigue failure of Yaoxian Bridge will not occur during design service life.

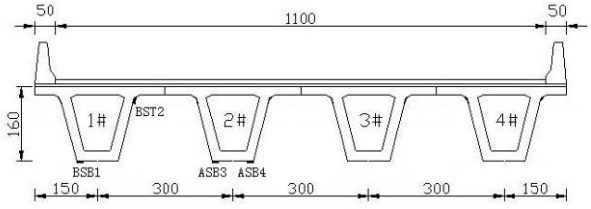


Figure 12. Strain measure points of Yaoxian Bridge.

Table 1. Fatigue life based on S-N curve

Measure point	*D* (10^{-6})	*Y* (year)
BSB1	12.16	1239
BST2	4.01	3756
ASB3	0.45	infinite
ASB4	40.31	1427

5.2 Fatigue life evaluation based on fracture mechanics

According to appearance detection, no crack was found on Yaoxian Bridge, so initial crack was assumed to evaluate the fatigue life. Fracture toughness of steel bar used in concrete bridge is $K_{IC} = 50\text{MPa}\cdot\sqrt{\text{m}}$. Fracture constants are $D = 2\times10^{-13}$ and $m = 4$ according to previous researches, threshold of crack propagation of steel bar is $\Delta K_{th} = 2.0\text{MPa}\cdot\sqrt{\text{m}}$. Fatigue life evaluation result based on fracture mechanics is shown in Table 2, under the present fatigue load level, fatigue failure of Yaoxian Bridge will not occur during design service life.

The above fatigue life evaluations are based on the present vehicle loads, with the development of transportation and other disadvantage influences, the fatigue life of concrete bridge will be far shorter.

Table 2. Fatigue life based on fracture mechanics

Measure point	Initial crack width a_0 (mm)	Maximum stress σ_{max} (MPa)	Critical crack length a_{fr} **Error! Reference source not found.**(mm)	Remaining life Y (year)
BSB1	0.1	185	7.57	245
BST2	0.1	67	10.12	1198
ASB3	0.5	47	10.49	5124
ASB4	0.1	97	9.54	578

6. Conclusions

This paper combines WIM, fatigue stress monitoring, AE with fatigue life evaluation techniques to give a comprehensively fatigue safety monitoring and fatigue life evaluation of a concrete bridge, the followings can be concluded:

(1) Using WIM and dynamic strain monitoring techniques, traffic loads monitoring for 35 days and fatigue stress monitoring for 21 days were conducted, influence of present traffic loads to concrete bridges fatigue life was studied.

(2) Fatigue safety and fatigue life evaluation model based on S-N curve and fracture mechanics is given.

(3) Through analysis of AE signals, it is found that noise level in site is around 57 dB; signals of deck is far more than of web and bottom plate of box girders, it indicates that the deck may have more fatigue damage of concrete bridges. From *b*-value analysis, Yaoxian Bridge is in period of microcracks propagation, no macrocracks was found.

(4) Fatigue life of Yaoxian Bridge based on S-N curve is 1239 years, fatigue life based on fracture mechanics is about 245 years, fatigue failure will not occur during design service life.

(5) Combination of different monitoring techniques can give comprehensive evaluation of concrete bridges.

Abstract Railway steel bridge belongs to large scale weld structures suffered with cyclic dynamic stress generated by train. In recent years, the section of bridge member becomes bigger, plate becomes thicker, connection form becomes more complicated, and steel bridge is applied to more districts even lower temperature environment. Fatigue and fracture problems become more serious. On the basis of Crack Tip Open Displacement (CTOD) test data of 372 specimens tested in different temperature, this paper discusses research work about fracture proof design that involved how to determine the criterion of Charpy V Notch (CVN) impact toughness by building the relationship between CTOD and CVN, how to prevent brittle fracture by stress control in railway steel bridge design based on COD design curve from test data, and how to do the fatigue design for railway steel bridge at -50 ℃ of design temperature in an easy way, The method of fatigue design at -50 ℃ environment has been used for railway steel bridge structure of Qinghai-Tinet Railway in China.

Keywords Railway steel bridge, Fracture proof design, Fatigue at low temperature, CTOD test, Toughness criterion

1. Introduction

Fatigue fracture is one of the most important contents in design of railway steel bridge that belongs to large scale weld structure suffered with heavy cyclic dynamic stress generated by train. In recent years, the section of bridge member becomes bigger, plate becomes thicker, connection form becomes more complicated, and steel bridge is applied to wider districts even in lower temperature environment, so as to meet the needs of construction development in China. Fatigue and fracture problems become more serious. Traditional design concept and method is just focused on building steel bridge in the south part of China with warm weather, without enough experience for using steel bridge in cold weather, so it is necessary to supplement special regulation or renew some research method. It were given by an engineering test research[1] that, fatigue strength is higher when specimen is at lower temperature than it is at room temperature in comparison tests. The conclusion were doubted[2] and is not reasonable either. With the cognition developed the idea that, elastic-plastic fracture toughness has to be applied to fracture proof design in railway steel bridge, formed and expected to obtain reasonable interpretation and solve the fatigue problems as well when the steel bridge serving in lower temperature. A series of Crack Tip Open Displacement (CTOD) tests were carried out in different temperature to the common bridge steel with the thickness of 12, 16, 24, 32, 44, 50 mm both for base metal and butt weld seam. The total numbers of specimen was 372, and the effective test data was 364. CTOD test was done by straight three point bending specimen. The regression data point for weld seam and the relationship between CTOD and

temperature after regression[3] are shown in Fig. 1 and Fig. 2.

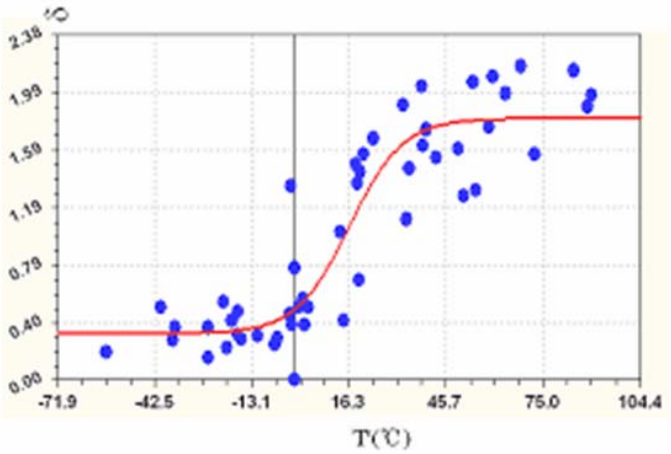

Figure 1. Statistics result of weld seam test data

Charpy V Notch (CVN) impact toughness is an important index proving toughness quality of steel material and weld joint. It is applied to engineering widely because of its simple and inexpensive test procedure compared with CTOD. In order to get the relationship between the two toughness indexes, 702 specimens of CVN impact test were also carried out in different temperature accordingly[4]. The regressed curve is shown in Fig. 3.

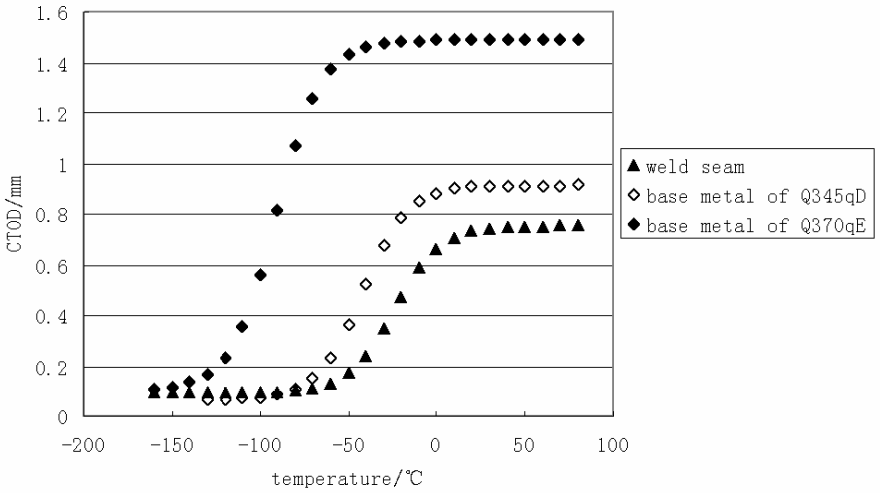

Figure 2. CTOD versus temperature of base metal and weld seam

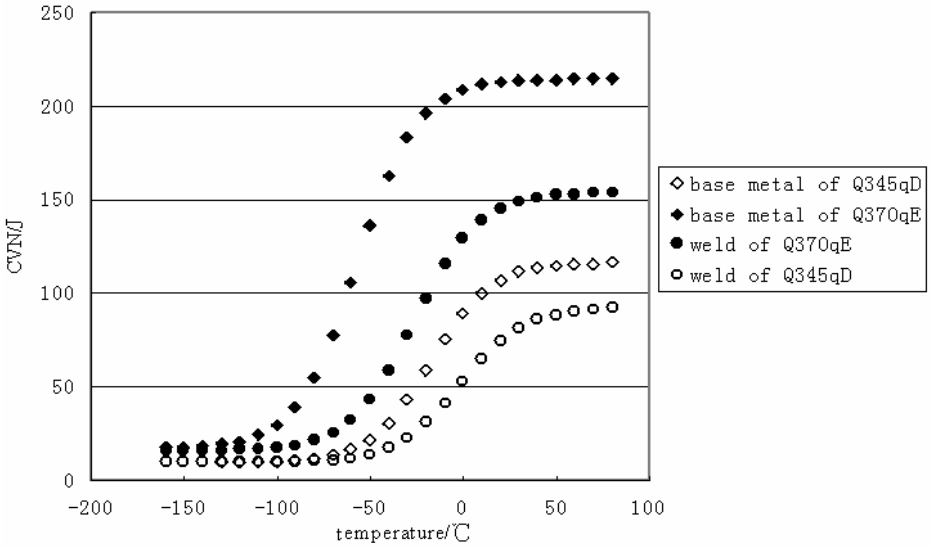

Figure 3. CVN versus temperature of base metal and weld

Three aspects of research are carried out around fatigue and fracture problem based on the test data of CTOD and CVN above: (1) to create the relationship between CTOD and CVN by absorption energy at the moment of specimen damaged in test, to find the basic CVN impact toughness of weld joint proof brittle fracture, and then to determine the toughness criterion that should be easy and practical. (2)find special stress calculation formula for railway steel bridge to check and control maximum stress level preventing from brittle fracture when the material and section of bridge member had be the fact. And (3) to determine the complementary requirement and provide method for fatigue design temperature at -50℃ to apply to Tsinghai-Tibet Railway line. The research result will be the reference of revising code later.

2. Weld toughness criterion

So far the major way to control toughness of steel material in engineering is to check the impact energy by CVN impact test. In bridge design, the first thing is to choose material and confirm the toughness criterion. Usually the lowest impact toughness criterion is determined by comparing with the similar bridge and accumulated experience. Which produce a lot of discussion and dispute. The better way to make sure the criterion is by means of CTOD test data, since it can be leant clearly that which situation would generate brittle fracture and which ductility damage. By this way it can guide to determine the toughness criterion. However, CTOD test is complicated comparatively and is unapt to inspect as normal way in engineering. Therefore, the absorption energy is taken as the instrumentality to establish the relationship between CTOD and CVN. The test record of vertical replacement at load point and loading value are utilized to get the basic absorption energy in CTOD test, and then it can be used to guide to work out basic CVN impact toughness criterion. The idea comes from the CTOD test data within temperature from room temperature to -70℃. It shows that the basic absorption energy provided by specimen is independent of test temperature when it gets to certain CTOD value. It also can leads to, on one side, the impact toughness for real bridge under the temperature from room to -70℃ should satisfy with basic absorption energy obtained from certain critical state in CTOD test. On the other side, the relationship also should be analyzed between loading velocity and character temperature for CTOD test, CVN impact test and service train passing bridge, by which the test temperature is confirmed for doing impact test. Consequently the reasonable impact toughness criterion with large amount of test basis can be prescribed.

Following regulation should be complied in analysis:：

(1) It is required for material to have the absorption energy ability that can suffer the destroy state with transition ability from brittle to ductility. In other words, when the structure gets to fracture, the maximum stress in member section would exceed yield strength, and the structure should have a certain deformation.
(2) Towards to safety direction, increasing 2 standard deviation to average value during statistics analysis.

2.1. Method to confirm basic toughness index

The step to determine the toughness criterion is followed by below items:

(1) Calculate integral to obtain the absorption energy by the test record of vertical replacement at load point and loading value;

(2) Analysis the loading model difference of CTOD test and CVN impact test, formulate the relation of energy between the absorption energy in CTOD test and impact energy in CVN test[5]. It is shown in formula (1).

$$A_{kv} = \frac{A_{CTOD}}{C_e} \tag{1}$$

where A_{CTOD} and A_{kv} = absorption energy in CTOD test and in CVN test, J; C_e = transition coefficient, $C_e = 0.32B$, B is the thickness of CTOD specimen.

(3) Sort the test data from CTOD test that were damaged at the transition situation from brittle and ductility, pick-up their absorption energy in list, and calculate the basic energy value that is corresponding to the specimen condition and is impossible to generate brittle fracture.

(4) Determine test temperature. It is shown from CTOD test that the basic absorption energy provided with a specimen when the crack tip in it open a certain displacement is independent of temperature when the thickness of specimen is certain. Meanwhile, in practical bridge the narrowest open displacement should be controlled mainly. Therefore it is no need to consider what temperature the CTOD test is done corresponding to absorption energy in step (3) above, just consider the difference of loading velocity in CTOD test and CVN impact test. It mainly affects the exact place at where the toughness-temperature character curve located on the temperature coordinate.

The analysis about temperature coordinate is shown below:

(1) As per the relation of character temperature point between fracture toughness stress intention factor K_{IC} that is tested by static or equivalently static loading and the loading velocity caused by service train, the character temperature of service train is equivalent to increase ΔT_1℃ by static K_{IC} test [6]. It can be shown by the following equation:

$$\Delta T_1 = (83 - 0.08\sigma_s)\varepsilon^{0.17} \tag{2}$$

Where: ε = loading strain velocity, s^{-1}.

(2) As per the relation of character temperature point between the loading velocity caused by service train and impact toughness test, the character temperature of service train is equivalent to decrease ΔT_2℃ from impact toughness test[7]. It can be shown by the following equation:

$$\Delta T2 = 70℉ = 39℃ \tag{3}$$

(3) The test character temperature replacement in impact test between loading slowly to and normal loading speed in engineering can be represented by ΔT_3 [8]:

$$\Delta T_3 = 120 - 0.121\sigma_s \quad (℃) \tag{4}$$

(4) As per the relation of character temperature point between fracture toughness CTOD that is tested by static or equivalently static loading and impact toughness test, the character temperature of CTOD test is equivalent to decreaseΔT_4℃ from impact toughness test according to the test in comparison above:

$$\Delta T_4 = 15 \sim 35 \quad (℃) \tag{5}$$

Taking bridge steel Q370qE as an example, the character temperature relationship above is summed up and drawn as Fig. 4.

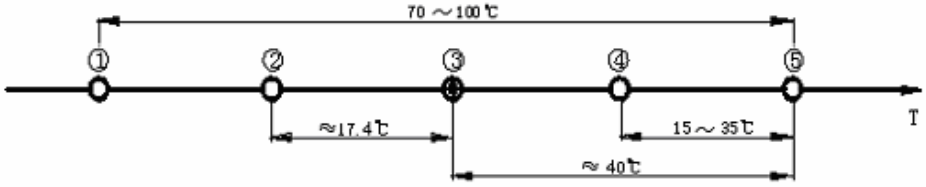

Figure 4. Comparative character temperature relation

Compared with the five situations in Fig. 4, the character temperature of CTOD test is higher than that under loading velocity caused by service train, even though it is static loading. It is understood that the loading way in CTOD test is three points bending, and the notch is sharp fatigue crack, which is very severe situation. As a result, the character temperature of service train is replaced by CTOD test temperature on the safe side, including the effect of temperature at bridge location and loading velocity. And then, the temperature replacement value from bridge site temperature to impact test is confirmed based on the character temperature relationship between CTOD and CVN test.

2.2. Analysis result and application

Followed by the steps above, the basic indexes of impact toughness proof brittle fracture are obtained in Table 1.

Table 1. Basic indexes of impact toughness

material		Thickness/mm	Environment temperature at bridge location /℃			
			-50	-40	-30	-20
Q370qE	Base metal	≤30	45J,-30℃	45J,-20℃	45J,-10℃	45J,0℃
		30-50	70J,-30℃	70J,-20℃	70J,-10℃	70J,0℃
	Weld		46J,-35℃	46J,-25℃	46J,-15℃	46J,-5℃
Q345qD	Base metal	≤32	43J,-30℃	43J,-20℃	43J,-10℃	43J,0℃
	Weld		34J,-35℃	34J,-25℃	34J,-15℃	34J,-5℃

The stipulation of steel material about the lowest impact toughness in national standard is classified by test temperature into 0℃, -20℃ and -40℃. The steel material used in railway steel bridge is the steel with -20℃ and -40℃ of requirement. Utilizing the curve equation of railway bridge steel regressed by CVN test (see Fig. 3), the equivalent index of the basic impact toughness in Table 1 are compared with the stipulation in national standard, and the commended toughness criterion for railway steel bridge is shown as Table 2-3.

Table 2. Commended lowest impact toughness criterion

material	Thickness/mm	Environment region and temperature at bridge location /℃	
		region E*	region D*

Q370qE	Base metal	≤30	41J,-40℃	41J,-20℃
		30-50	70J,-40℃	70J,-20℃
	Weld		41J,-40℃	41J,-20℃
Q345qD	Base metal	≤32	34J,-20℃	34J,-20℃
	Weld		30J,-20℃	30J,-20℃

*See Table 3.

Table 3. Region distribution for constructing bridge in China

Region mark	Name of territory	Extreme temperature in history/℃
E	Heilongjiang, Sinkiang, Inner Mongolia, Tibet, Jilin, Shanxi, Tsinghai	-40℃以下
	Liaoning, Gansu, Szechwan, Hebei, Shannxi, Ningxia	-30℃--40℃
D	Beijing, Tientsin, Shandong, Henan	-20℃--30℃
	Other	-20℃以上

3. Control stress prevent from brittle fracture

It is found by observing CTOD test process that, controlling action force on structure less than the force that would arouse brittle fracture can also prevent structure from brittle fracture. The purpose to research this subject is for exist bridges since their toughness situation had already been the fact. The controlling stress formula for railway steel bridge to prevent from brittle fracture can be deduced by means of the brittle fracture data in CTOD tests[3]. Formula (6) and (7) is for base metal, and (8) and (9) for weld seam:

$$\frac{\sigma}{\sigma_s} \le \frac{1}{1.12}\sqrt{\frac{E\delta}{2\pi a\sigma_s}} - 0.6 \tag{6}$$

$$\delta = \frac{a}{t}\left[0.1059 + \frac{1.383}{1+e^{-0.0778(T+90.666)}}\right] \tag{7}$$

$$\frac{\sigma}{\sigma_s} \le \frac{1}{1.12}\sqrt{\frac{E\delta}{2\pi a\sigma_s}} - 0.3 \tag{8}$$

$$\delta_W = \frac{a}{t}\left[0.0918 + \frac{0.6615}{1+e^{-0.0767(T+24.1927)}}\right] \tag{9}$$

Where: δ = base metal of Q370qE; δ_w = weld seam.

3.1. Analysis result

To base metal of Q370qE, elastic module $E = 2.1\times10^5\,MPa$, average yield strength $\overline{\sigma}_s = 385MPa$, and put them into Formula (6) and (7), then:

$$\sigma \le 3202.82\sqrt{\frac{1}{W}\left[0.2118+\frac{2.766}{1+e^{-0.0778(T+90.666)}}\right]}-206.25 \tag{10}$$

To weld joint, elastic module $E=2.1\times10^5 MPa$, average yield strength $\overline{\sigma}_s=377MPa$ (taking average value of base metal that is on safe side), and put them into Formula (8) and (9), then:

$$\sigma \le 3169.37\sqrt{\frac{1}{W}\left[0.1836+\frac{1.3229}{1+e^{-0.0767(T+24.1927)}}\right]}-101 \tag{11}$$

Calculating by the formula (10) and (11), the available maximum stress σ without occurring brittle fracture to different thickness of bridge member can be obtained.

3.2. Application

Suppose α is available stress coefficient, $\alpha=\sigma/\sigma_s$, the calculation results to steel bridge steel are shown in Table 4.

Table 4. The maximum available stress coefficient α

Material	Tem. ℃	Thickness of steel plate/mm									
		12	16	20	24	30	32	38	40	44	50
Base metal of Q370qE	-50	1	1	1	1	1	1	1	1	1	1
	-40 to 0	1	1	1	1	1	1	1	1	1	1
Base metal of Q345qD	-50	1	1	1	0.95	0.79	0.75	-	-	-	-
	-40 to 0	1	1	1	1	1	1	-	-	-	-
weld	-50	1	0.97	0.83	0.74	0.63	0.60	0.53	0.51	0.48	0.43
	-40	1	1	1	0.93	0.80	0.77	0.68	0.66	0.62	0.56
	-30	1	1	1	1	1	0.98	0.87	0.84	0.79	0.73
	-20	1	1	1	1	1	1	1	1	0.97	0.89
	-10	1	1	1	1	1	1	1	1	1	1
	0	1	1	1	1	1	1	1	1	1	1

Usually, the ratio of design stress to yield strength is 0.58. Compared with the values in Table 4, it can be concluded that when the weld is used at the temperature of -40℃ to -50℃, some available stress is less than its design stress. It means that even though those members with the weld suffered the action stress that is below the allowable value in design code, brittle fracture may happen at some moment. In this way, reducing working stress calculated by the method above can stop some brittle fracture.

4. Fatigue design method of steel bridge at low temperature

Tsinghai-Tibet railway line is located at high altitude and cold region in China, where the extreme lowest temperature is -45 ℃, with undeveloped traffic and atrocious environment. The length of

bridge within iced soil region exceeds 70 kilometers. In order to solve the problem of long time limit for constructing concrete bridge, the test investigation for steel-concrete composite bridge in Tsinghai-Tibet railway line were carried out. As per steel girder of composite bridge, the major effect under those bad conditions caused by the peculiar geography environment is the perennial cold weather. Low temperature would reduce toughness of steel and weld joint, make structure brittle, bring structure to a lower fatigue performance, and therefore reduce safety level of railway steel bridge suffered with very heavy live load. The current fatigue design parameter that is made and used to the structure at common temperature cannot meet the needs of Tsinghai-Tibet railway line.

4.1 Research Method

The test of fatigue crack propagation rate were carried out to 24mm thickness of Q370qD base steel and weld at -50℃ temperature. It indicated that, under -50℃ temperature the material coefficients of Paris equation in middle part of speed propagation region, $da/dN = C(\Delta K)^m$, have smaller 'C' and larger 'm', and have higher fatigue crack threshold ΔK_{th}, compared with room temperature. Furthermore, S-N curve at -50℃ is above the curve at room temperature, and its slope is even slightly from tests[1]. It leads the wrong direction that using common fatigue design method is good enough at low temperature.

However, CTOD tests indicate that, low temperature at -50℃ would reduce the critical crack open displacement, and increase the trend to brittle fracture. The average critical CTOD value at room temperature is 0.72mm, while it is only 0.14mm at -50℃.

Crack length can be expressed by Formula (12) at room temperature and Formula (13) at -50℃ according to the test result[3]:

$$a \le \frac{E\delta}{\pi(1.12\sigma + \sigma_s + 0.3\sigma_s)} \tag{12}$$

$$a \le \frac{E\delta\sigma_s}{2\pi(1.12\sigma + 0.3\sigma_s)^2} \tag{13}$$

Take $E = 2.1\times10^5 MPa$, $\delta = 0.72mm$ at room temperature and $\delta = 0.14mm$ at -50℃; $\sigma_s = 490MPa$ at room temperature[9] and $\sigma_s = 512MPa$ at -50℃[3]; $\sigma = 200MPa$ from allowable design stress in the code, the critical crack length are calculated by formula (12) and (13), that is, $a = 56mm$ at room temperature, and $a = 17mm$ at -50℃.

From Paris equation $\frac{da}{dN} = C(\Delta K)^m$, transform it into:

$$N = \int_{a_0}^{a_c} \frac{da}{C\Delta K^m} \tag{14}$$

where: $\Delta K = Y\Delta\sigma\sqrt{\pi a}$, Y= crack type coefficient. It can be taken as a destiny to bridge structure at both room and low temperature, then:

$$N = \frac{1}{CY^m \Delta\sigma^m \pi^{\frac{m}{2}} (\frac{m}{2} - 1)} \left(\frac{a_0}{\sqrt{a_0^m}} - \frac{a_c}{\sqrt{a_c^m}} \right) \tag{15}$$

4.2. Research Result

In formula (15), suppose original crack length $a_0 = 0.001m$, critical crack length $a_c = 0.056m$ at room temperature, and $a_c = 0.017m$ at -50℃. The coefficients of C and m are taken from the test data regressed with 97.7% probability, Y is taken for the most unfavourable situation in engineering when $a/W = 75\%$, and the life N is taken as the same cycles at both room and low temperature. The ratio of fatigue stress range between -50℃ and room temperature is 0.88.

This calculation result shows that, fatigue at low temperature should not be considered as a common fatigue problem. It is mainly because at low temperature, the critical fracture crack length shorten sharply. Consequently, the fatigue safety level drops, that can be noticed at the obvious intersection moving ahead between crack stable propagation region and sharp propagation region. The only way to solve the problem is to apply Fracture Mechanics theory and elastic-plastic CTOD test.

As a result, the allowable fatigue design stress range for steel bridge in Tsinghai-Tibet railway line is prescribed to 80% of the current fatigue design index. At the same time, the further requirement below should be followed:

(1) During design of bridge for Tsinghai-Tibet railway line, thinner steel plate should be preferred, so long as its local stabilization can be content.

(2) All of the steel material is required to fine microstructure by raising temperature during steel making to increase stopping-fracture ability.

(3) It should be taken into consideration to choose other kind of structure or connection style rather than to choose thicker plate when fatigue checking cannot pass the regulation at low temperature.

5. Conclusions

Fracture mechanics theory combined with the usual way for fatigue and toughness in railway steel bridge can solve the special problem when the environment is in low temperature. Three aspects of research can be concluded as below:

(1) It is important to select bridge steel that is both safe and economic. A reliable criterion can be made based on CTOD test. The recommended method this paper is easy to choose which steel category available.

(2) It is usually confused for engineer to check working stress for some bridge member with lower stress than allowable stress, impact toughness being above the normative value in the code, but the brittle fracture still happened. Additional method to check and control the stress level prevent from brittle fracture is suggested.

(3) The critical fracture crack length would be shorten sharply at low temperature. Fatigue at low temperature should not be considered as a common fatigue problem. As an example, the allowable fatigue design stress range for steel bridge in Tsinghai-Tibet railway line is prescribed to 80% of the current fatigue design value. The method is easy to be used for designer.

Abstract This paper is regard with material mechanics, fatigue and fracture properties of Lanzhou Yellow River Iron Bridge, which is an old metal bridges built about 100 years ago. An original steel angel cut off from Lanzhou Yellow River Iron Bridge was used to carry out series of tests including material properties, fracture toughness and fatigue strength of riveted joints. The results have shown that the strength of the old steel is relatively equal to A3 steel in the old code, and the ductile-brittle transition temperature is nearly -23°C，which means that the structure is unsafe in winter due to the cold climate conditions of Lanzhou city. The main regression parameters of the fatigue crack growth rate are $C=7.88\times10^{-12}$m/cycle and m=3. According to the test result, the fatigue strength of tensional plate specimens with new drilling hole is similar to the category 140 in the EUROCODE. Based on the tested result, the remaining fatigue life of Lanzhou Yellow River Iron Bridge was evaluated using S-N curve and fracture mechanics method. It can be concluded that two kinds of adverse loading situations should be restricted including people loading only on half of bridge, and truck load over 120kN.

Keywords national cultural relic steel bridges, fatigue strength, fracture toughness, fatigue crack growth rate, fatigue life

1. Introduction

Until now lots of riveted old steel bridges are still in service in many countries. In recent years, traffic load and speed on both existing railway and highway steel bridges have increased, which is much higher than those originally designed load. With the great increase of load number and magnitude, these riveted bridges may close to the end of their service life. However, the work for replacement of these old riveted bridges takes time. So capacity calculation, safety assessment and remaining fatigue life calculation are essential for these ageing bridges, which is helpful to decide whether to demolish or retrofit these bridges.

To evaluate fatigue resistance of old steel and establish fatigue categories for riveted connections, this paper conduct series of fatigue behavior tests for old riveted steel bridge for Lanzhou Yellow River Iron Bridge, which is a simple supported truss bridge over Yellow River originally built in 1909. During 100 year's service time, several repair and rehabilitation were conducted for Lanzhou Yellow River Iron Bridge, and nowadays Lanzhou Yellow River Iron Bridge is the historical cite in Lanzhou City. Material properties were studied for steel used in Lanzhou Yellow River Iron Bridge, which is fabricated more than 100 years ago. From Lanzhou Yellow River Iron Bridge, standard compact specimens are cut and fabricated for fatigue crack growth rate test, and fatigue test were also conducted for specimens with newly drilled hole. Based on the tested result, the remaining fatigue life of Lanzhou Yellow River Iron Bridge was evaluated.

2. Material Properties of Old Steel

Material property is studied initially for steel of old riveted bridge. For Lanzhou Yellow River Iron Bridge, tensile specimens and toughness specimens were cut from a demolished chord to conducted material tensile test and Charpy V notch test.

2.1. Tensile test

The tensile test was conducted according to metallic materials-Tensile testing at ambient temperature (GB228-2002) [1]. Three ratio samples with same dimensions were manufactured according to the requirements of Chinese GB2975-1998 [2]. The strains in longitudinal direction are measured by strain gages for calculating the material properties. After the test, the mechanical indexes were calculated, such as elastic modus (E), yield stress (σ_s), ultimate stress (σ_b) and elongation.

The tensile test results are listed in Table 1. It can be concluded that the strength of the old steel is roughly equal to A3 steel in the old code, but the yield-strength ratio, σ_s/σ_b, is equal to 0.629, which is slightly higher than A3 steel(0.486~0.579).

Table 1. Results of tensile test

E(GPa)	σs(MPa)	σb(MPa)	Elongation(%)	Cross section reduction(%)
194.3	275.7	438	29.1	63.77

2.2. Toughness test

According to Chinese test standard for metallic materials-Charpy notch impact test (GB/T229-1994) , Charpy V toughness tests were conducted at different temperatures ranging from -53°C to 10°C [3]. 25 Charpy V notch (CVN) standard specimens were cut from one third of steel angle leg and the notch of specimen was perpendicular to rolling direction. The dimension of CVN specimen is shown in Table 2.

Table 2. Dimension of CVN specimens (mm)

Thickness	Width	Length
10	10	55

Toughness test was conducted at eight different temperatures, including -53 ℃，-43 ℃, -32.5℃, -26 ℃, -23 ℃, -21 ℃, 0℃ and 10 ℃. After test, the impact toughness energy (A_{kv}) was recorded and the crystallinity percentage of fracture surface was measured for each specimen, shown in Figure 1. Learn from Figure 1, A_{kv} in upper region is 146J at 10℃, A_{kv} in lower region is 7J at -53℃, and A_{kv} drops apparently from -15℃ to -28℃. At -23℃, the crystallinity percentage of fracture surface is approximately 50%. It can be concluded from the result of Charpy-V tests, the temperature of ductile-brittle of old steel used in Lanzhou Yellow River Iron Bridge is nearly -23℃. And the transition is very sharp. When the temperature drops to -23℃, steel in Lanzhou Yellow River Iron Bridge will exhibit clear brittleness instantly. Learn from test results, steel in old bridge usually exhibits both low strength and low toughness. Thus, safety of the structure should be take care especially when temperature is low, even if considering the contribution of riveted member redundancy.

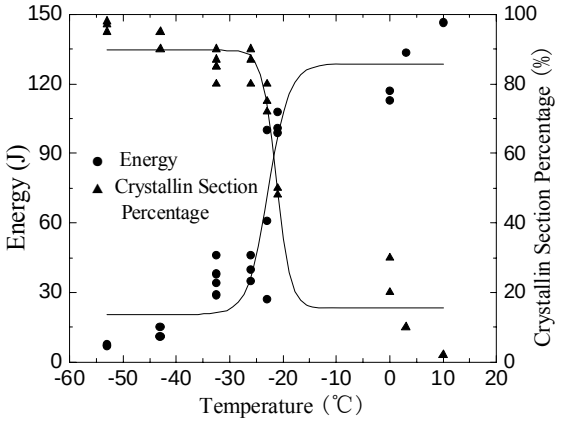

Figure 1. Toughness test result for old steel

3. Fatigue Crack Growth Rate Test of Old Steel

Fatigue crack growth rate (da/dN) tests were conducted for base steel in Lanzhou Yellow River Iron Bridge to determine its fatigue crack growth rate in region II according to requirement of ASTM E647-08 and Chinese GB/T 6398-2000 [4, 5]. da/dN tests were conducted for compact specimen [C(T)] with 11mm thick under load ratio of R=0.1, 0.5 and 0.8. The prefabricated crack for all the specimen is oriented perpendicular to the rolling direction of the steel plate (L-T). The dimension and specimen are shown in Figure 2 and Table 3.

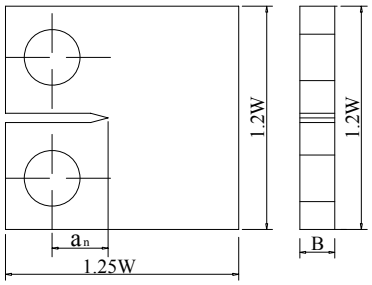

Figure 2. Compact specimen

Table 3. Specimens dimensions (mm)

B	$1.25W$	$1.2W$	a_n
11	62.5	60	12.5

After the test, the stress-intensity factor range ΔK_i under each crack length is calculated, according to Eq.1. The parameters are obtained including material constant m and C, and correlation coefficient. The da/dN test result for old steel in Lanzhou Yellow River Iron Bridge is shown in Figure 3. Learn from da/dN test result, with the increase of load ratio R, fatigue crack growth rate is increasing. Some researchers have conducted fatigue resistance behavior study for old steel. For example, the fatigue test result of Barson shows $C=6.89\times10^{-12}$ m/cycle and m=3, while Sedlacek found $C=1.26\times10^{-11}$ m/cycle and m=3 for old steel. The fatigue crack growth rate of Lanzhou Yellow River Iron Bridge is between the tested rate of Barson and Sedlacek, which serves test data for remaining fatigue life assessment of old steel bridge.

$$\Delta K = \frac{\Delta P}{B/W}\frac{(2+\alpha)}{(1-\alpha)^{3/2}}\cdot \\ (0.886+4.64\alpha-13.32\alpha^2+14.72\alpha^3-5.6\alpha^4) \tag{1}$$

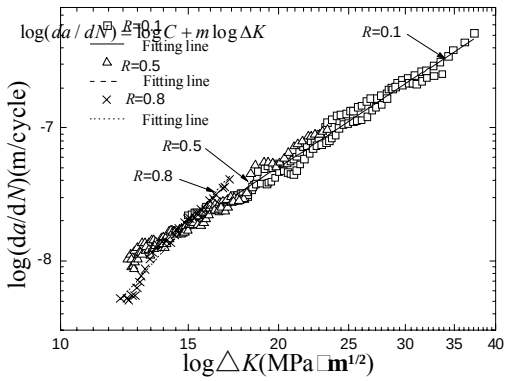

Figure 3. The da/dN~ΔK curve.

4. Fatigue Test for Drilled Specimen

3 fatigue specimens were cut from a chord of Lanzhou Yellow River Iron Bridge, and holds were newly drilled in the specimen. The dimension of fatigue specimens are shown in Figure 4 and Table 4. In order to observe the fatigue crack accurately, surface clean and polishing was conducted for each specimen. Strain gauge was located on the specimen before test. During testing procedure, the loading frequency is 15 Hz.

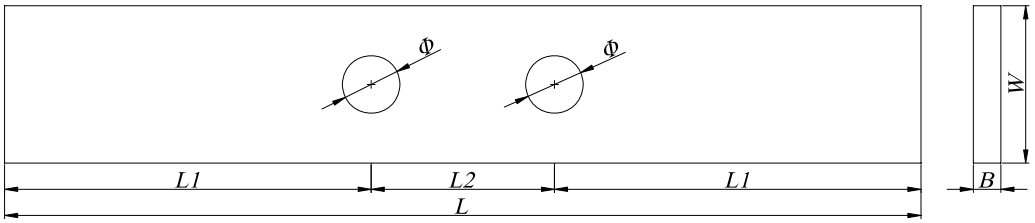

Figure 4. Dimension of fatigue specimen

Table 4. Dimension of fatigue specimen with drilled holes (mm)

Specimen	*B*	*W*	*Φ*	*L*	*L1*	*L2*
1	11	50	18	330	127	76
2	10.5	60	22	350	140	70
3	10.5	60	22	350	140	70

Fatigue test result is classified by fatigue details specified in AASHTO specification and Eurocode [6, 7]. Learning from Fig. 15 and 16, the fatigue detail of old steel with drilled hole is better than detail C in AASHTO specification and is higher than detail category 100 in Eurocode. The tested fatigue strength is greater than actual situation since two causes. Firstly, holes on specimens were newly drilled for fatigue test, avoiding fatigue crack initiate and corrosion during bridge service period over 100 years. Secondly, the surface of specimen was polished to observe and capture fatigue crack precisely, eliminating effect of surface defects.

5. Remaining Fatigue Life Evaluation

Based on the analysis of riveted steel bridge fatigue failure mechanism, the assessment model on the basis of S-N curve and fracture mechanics was applied to evaluate the remaining life of Lanzhou Yellow River Iron Bridge.

5.1. Evaluation methods

5.1.1. S-N curve and linear damage accumulation rule

Linear damage accumulation theory is based on fatigue damage D and assumes structural fatigue damage can be linearly accumulated if varying stresses spectrum was determined. The linear damage accumulation model described the sum of structure damage, D. The typical linear damage accumulation rule is Palmgren-Miner rule. It defined that D=1 indicated failure where D was the amount of damage degree in material. Sum of fatigue damage for all stress range levels is shown in Eq. 2. In Eq. 2, in which in each stress range level σ_i, the damage fraction D_i was linearly proportional to n_i, where n_i was the number of cycles at σ_i and D_i was the ratio of n_i/N_i. N_i is the total number of cycles that would cause failure under that stress range level. Loading sequence is not considered in Miner rules, but it has great affection when calculating fatigue life. The critical damage (D_{CR}) member is near 1 when failure occurs.

$$D = \sum_{i=1}^{n} D_i = \sum_{i=1}^{n} \frac{n_i}{N_i} \tag{2}$$

In this paper, detail category D in AASHTO is used during the evaluation, with reference to the riveted joint fatigue strength analysis of Lanzhou Yellow River Iron Bridge when it was built, and the fatigue tests results conducted nationally and internationally, as well as the fatigue test result of Lanzhou Yellow River Iron Bridge.

5.1.2. Fracture mechanics assessment mode

For riveted steel bridge, crack is usually propagating from edge of hole perpendicularly until member fracture. Two basic fracture mechanics modes are used in this paper. One is central crack tension (CCT) mode and another mode is double edge crack tension (DECT) mode.

Initial crack is assumed as $2a_i=D+2\times$detected value, in which D is diameter of riveted hole. With propagation of fatigue crack, the net section may be yield under loading and fracture failure may be occurred. The critical crack length (a_{cr}) can be calculated by Eq. (3) and Eq. (4). In Eq. (3) and (4), W is the width of member, R_{el} is yield strength and σ_{max} is maximum sum of dead stress and live stress.

CCT：
$$a_N = W(1 - \sigma_{max} / R_{el}) \tag{3}$$

DECT:
$$a_N = W\sqrt{2.25 + 4(1 - \sigma_{max} / R_{el})} - 1.5W \tag{4}$$

If stress intensity factor at crack tip (K_I) is greater than fracture toughness of steel (K_{IC}), fracture may be occurred. In this case, critical crack length (a_{cr}) is calculated by Eq. (5), in which Y is geometrical amend factor.

$$a_{cr} = \left(K_{IC} \Big/ Y\sigma_{\max} \right)^2 \Big/ \pi \tag{5}$$

The calculated critical crack length by Eq. (5) should be less than the max length that member can observe ($a_{\max}$). For steel angle, crack length should be no more than angle width. So, critical length is finally determined by Eq. (6).

$$a_f = \min(a_N, a_{cr}, a_{\max}) \tag{6}$$

A safety evaluation result will be obtained if is just considering $\triangle\sigma$ in Paris equation. However, threshold value relative to load ratio R (R=$\sigma_{\min}/\sigma_{\max}$) should be considered, shown in Eq. (7). When crack propagating from a_i to a_f, the remaining fatigue life is calculated by Eq. (8).

$$\frac{da}{dN} = \begin{cases} 0 & \Delta K \le \Delta K_{th} \\ C\left(\Delta K^m - \Delta K_{th}^m\right) & \Delta K > \Delta K_{th} \end{cases} \tag{7}$$

$$N = \int_{a_i}^{a_f} \frac{\mathrm{d}a}{C\left(\Delta K^m - \Delta K_{th}^m\right)} \tag{8}$$

5.2. Evaluation results

Remaining fatigue life of Lanzhou Yellow River Iron Bridge is evaluated by the following steps. Firstly, finite element mode of Lanzhou Yellow River Iron Bridge is established and influence lines for main truss members and cross beam are acquired. Secondly, traffic load survey is conducted to determine fatigue load using in fatigue life evaluation. Thirdly, stress spectrums are acquired using flow counting method when applying fatigue load on influence lines of members considering traffic load impact factor. Fourthly, considering corrosion effect and fatigue propagation rules for riveted detail, fatigue life for Lanzhou Yellow River Iron Bridge is assessed.

By the method of S-N curve, the remaining fatigue life evaluation of main truss and deck plate in Lanzhou Yellow River Iron Bridge are all more than 100 years, except inclined truss member L3 loaded by people load. When fracture mechanics method is used, only hanger member L2 in main truss structure has remaining fatigue life more than 100 years under varieties of fatigue loads. In other members, inclined member L3 has the shortest remaining fatigue life (17 years) under people load. Learn from calculation result, all members in main truss structure have infinite remaining fatigue life under fatigue load of small cars, while they have shortest remaining fatigue life under people load and truck load. As a result, to ensure the safety of bridge structure, two kinds of adverse loading situations should be restricted including people loading only on half of bridge, and truck load over 120kN.

6. Conclusions

This paper focused on study of the actual fatigue remaining life, service safety, maintenance intervals and the ultimate bearing capacity of old historical steel bridges to preserve their high cultural value. It can be concluded that: (1) the strength of the old steel is relatively equal to A3 steel in the old code, and the ductile-brittle transition temperature is nearly -23 ℃, which means that the structure is unsafe in winter considering the cold climate of Lanzhou city; (2) The main regression parameters of the fatigue crack growth rate are C=7.88×10^{-12} and m=3 for base steel; (3)through fatigue test for specimen with drilled holes, the fatigue property of Zhongshan Steel

Bridge is superior to detail C in AASHTO and detail D in BS5400 and higher than detail 100 in Eurocode; (4) according to the fatigue remaining life evaluation of main truss and deck plate in Lanzhou Yellow River Iron Bridge by the S-N curve and fracture mechanics method, two kinds of adverse loading situations should be restricted including people loading only on half of bridge, and truck load over 120kN.
