Abstract Heterogeneous materials present a mechanical response strongly dependent on the static and kinematic phenomena occurring in the constituents and at their joints. In order to analyze this kind of materials it is a common practice to distinguish a macroscopic length scale of interest from a mesoscopic one, where the mesoscopic length scale is of the order of the typical dimensions of the constituents. At the mesoscopic level the interaction between the units is simulated by mean of apposite mechanical devices. Among these devices is popular the zero thickness interface model where contact tractions and displacement discontinuities are the primary static and kinematic variables respectively. However, in heterogeneous materials the response also depends on joint internal stresses as much as on contact stresses. The introduction of internal stresses brings to the interphase model or an enhancement of the classical zero-thickness interface. With the term 'interphase' we shall mean a layer separated by two physical interfaces from the bulk material or a multilayer structure with varying properties and several interfaces. Different failure conditions can be introduced for the physical interfaces and for the joint material. The interphase model has been implemented in an open-source research-oriented finite element analysis program for 2D applications. Numerical simulations are provided to show the main features of the model.

Keywords Interphase element, Damage, Elastoplasticity, Finite element

1. Introduction

The mechanical response of all those structures that are constituted by heterogeneous materials is dependent by different static and kinematic phenomena occurring in each constituent and at their joints. Material degradation due to nucleation, growth and coalescence of microvoids and microcracks is usually accompanied by plastic deformations as decohesion and sliding that cause strain softening and induced anisotropy.

The mesoscopic approach is by now the most diffused technique to understand this kind of materials, because it overcomes the problems associated with the strong simplifications that have to be introduced when the macroscopic approach is applied. In particular, with the mesoscopic approach all the material constituents are modelled individually and their interactions are regulated by using appropriate devices able to reproduce the inelastic phenomena that usually occur at the physical interfaces. In literature, these mechanical devices are generally called contact elements, normally distinguished between link elements, thin layer elements and zero-thickness interface elements (ZTI). In the last decades interface elements have been applied in several engineering applications due to their simple formulation and to their easiness to be implemented in finite element codes [1-10].

The interface constitutive laws are expressed in terms of contact tractions and displacement discontinuities which are considered as generalized joints strains. In order to model the nonlinear behaviour caused by plastic deformations and damage evolution the constitutive laws of the interface elements are formulated making use of concepts borrowed by theory of Plasticity and Continuum Damage Mechanics.

In many cases the structural response depends also on internal stresses and strains within the joint. It is sufficient to think to the fracture that appears in the middle of masonry blocks caused by the horizontal tangential contact stresses between the mortar and the block when a masonry assembly is subjected to a pure compressive load. These tangential stresses cannot be captured by the classical ZTI model. Therefore, the usual assumption used in zero-thickness interface elements, where the response is governed by contact stress components, may require a correction by introducing the

effect of the internal stresses into the analysis. This enhancement of the ZTI is known as interphase model, for the first time proposed by Giambanco and Mròz [11].
The interphase element has been formulated by authors as a new contact element and introduced in a scientific oriented finite element code. Patch tests have been carried out in elasticity to investigate the numerical performance and convergence of the element. All the results are shown in the paper written by Giambanco el al. [12]. In particular, in that paper is shown how strategies such as the Reduced Selective Integration or the Enhanced Assumed Strain methods are necessary to avoid shear locking effects of the element.
In this work the interphase element is implemented for nonlinear applications by introducing separate limit conditions for the joint bulk material and for the physical interfaces. In particular the damage mechanics theory is used to simulate the formation and propagation of fractures in the bulk material. The elastoplastic limit condition of Mohr-Coulomb type with a tensile cut-off is adopted to describe the decohesion process of the interfaces. The contact strains are subdivided in an elastic and a plastic part. The overall model is thermodynamically consistent and the flow rules are derived by applying the Lagrangian method. With the aim to show the effectiveness of the model the interphase constitutive laws have been implemented in an open-source research-oriented finite element analysis program for 2D applications and by using the Selective Reduced Integration.
The paper is organized as follows. In Section 2 the general assumptions of the model are reported and the expression of the Helmholtz free energy is furnished. In Section 3 the state equations and the flow rules are determined on the base of the thermodynamically consistent theory. Section 4 is finally dedicated to numerical applications in order to show the effectiveness of the proposed model.

2. General assumptions and Thermodynamics.

Let us consider, in the Euclidean space $\Re^3$ referred to the orthonormal frame $(O,\mathbf{i_1},\mathbf{i_2},\mathbf{i_3})$, a structure formed by two adherents Ω^+, Ω^- connected by a third material Ω in contact with the two bodies by means of the two physical interfaces Σ^+ and Σ^- respectively, as in Fig. 1.

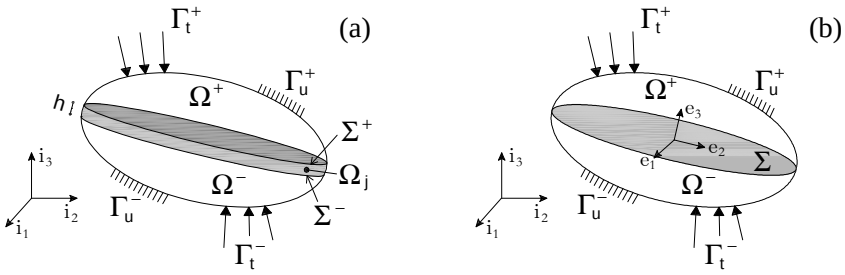

Figure 1. (a) Mechanical scheme of a third body interposed between two adherents;
(b) Interphase mechanical scheme.

It is assumed that the thickness h of the joint is small if compared with the characteristic dimensions of the bonded assembly.
The boundary of the two adherents is divided in the two parts $\Gamma_u^{\pm}$ and $\Gamma_t^{\pm}$, where kinematic and loading conditions are specified respectively.
The joint interacts with the two adherents through the following traction components:

$$\mathbf{t}^{\pm} = t_1^{\pm}\mathbf{e}_1 + t_2^{\pm}\mathbf{e}_2 + t_3^{\pm}\mathbf{e}_3 \tag{1}$$

which can be considered as the external surface loads for the joint.

In Eq. (1) $\mathbf{e}_1$, $\mathbf{e}_2$ and $\mathbf{e}_3$ are the unit vectors of the local reference system, with $\mathbf{e}_3$ oriented along the normal to the middle surface Σ and directed towards the adherent Ω^+.
The joint can be regarded as an interphase model. It is assumed that the fibers inside the interphase and directed along $\mathbf{e}_3$ are maintained rectilinear during the deformation process. In view of this hypothesis the interphase displacement field $\mathbf{u}$ can be easily obtained from the displacement $\mathbf{u}^+$ and $\mathbf{u}^-$ of the interfaces Σ^+ and Σ^-, thus

$$\mathbf{u}(x_1, x_2, x_3) = \left(\frac{1}{2} + \frac{x_3}{h}\right)\mathbf{u}^+\left(x_1, x_2\right) + \left(\frac{1}{2} - \frac{x_3}{h}\right)\mathbf{u}^-\left(x_1, x_2\right) \tag{2}$$

with x_1, x_2 and x_3 the Cartesian coordinates in the orthonormal frame $\left(O, \mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\right)$.
Since the thickness of the joint is generally small if compared to the characteristic dimensions of the adherents, we can assume the strain state $\boldsymbol{\varepsilon}$ uniform along the $\mathbf{e}_3$ direction and given by:

$$\boldsymbol{\varepsilon}(x_1, x_2) = \frac{1}{h}\int_{-h/2}^{h/2} \nabla^s \mathbf{u}\left(x_1, x_2, x_3\right) dx_3 \tag{3}$$

Substituting the Eq. (2) we have:

$$\boldsymbol{\varepsilon}(x_1, x_2) = \frac{1}{2h}\left(\left[\mathbf{u}\right] \otimes \mathbf{n} + \mathbf{n} \otimes \left[\mathbf{u}\right]\right) + \frac{1}{2}\nabla^s\left(\mathbf{u}^+ + \mathbf{u}^-\right) \tag{4}$$

where $\left[\mathbf{u}\right] = \mathbf{u}^+ - \mathbf{u}^-$, $\mathbf{n}$ is the unit normal vector to the interphase plane and ∇^s is the symmetric gradient operator defined as $\nabla^s = \frac{1}{2}\left(\nabla + \nabla^T\right)$.
Let us note that in the interphase model the joint curvatures generated by displacement field (2) and the related flexural effect are neglected.
Equilibrium equations are derived by applying the principle of virtual displacements (PVD) that asserts that the external work produced by the contact tractions equals the internal work developed in the joint. According to the hypothesis of a constant strain state, by applying the divergence theorem and assuming that $\Sigma = \Sigma^+ = \Sigma^-$, the PVD leads to the following local equilibrium relations of the interphase model:

$$\mathbf{t}^+ - \boldsymbol{\sigma}\cdot\mathbf{n} + \frac{h}{2} div\boldsymbol{\sigma} = \mathbf{0}; \quad \mathbf{t}^- + \boldsymbol{\sigma}\cdot\mathbf{n} + \frac{h}{2} div\boldsymbol{\sigma} = \mathbf{0} \quad on\ \Sigma, \tag{5}$$

$$\mathbf{m}\cdot\boldsymbol{\sigma} = \mathbf{0} \quad on\ \Gamma. \tag{6}$$

The basic kinematical hypotheses are the additive decomposition of total strain in the internal (*i*) and contact (*c*) parts and, for the contact strain only, a further decomposition in elastic (*e*) and inelastic (*p*) parts:

$$\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^i + \boldsymbol{\varepsilon}^c \tag{7}$$

$$\boldsymbol{\varepsilon}^c = \boldsymbol{\varepsilon}^{ce} + \boldsymbol{\varepsilon}^{cp} \tag{8}$$

with

$$\boldsymbol{\varepsilon}^i = \mathbf{A}\boldsymbol{\varepsilon}\mathbf{A} \tag{9}$$

being $\mathbf{A} = \mathbf{I} - \mathbf{n}\otimes\mathbf{n}$ the unit second order tensor.
In order to comply with thermodynamic requirements, the interphase Helmholtz free energy is introduced in the following form:

$$\Psi\left(\boldsymbol{\varepsilon}^i, \boldsymbol{\varepsilon}^c, \boldsymbol{\varepsilon}^{cp}, \boldsymbol{\omega}, \xi_d, \xi_p\right) = \Psi^i\left(\boldsymbol{\varepsilon}^i, \boldsymbol{\omega}, \xi_d\right) + \Psi^c\left(\boldsymbol{\varepsilon}^c, \boldsymbol{\varepsilon}^{cp}, \xi_p\right) + \Psi^{i,c}\left(\boldsymbol{\varepsilon}^i, \boldsymbol{\varepsilon}^c, \boldsymbol{\varepsilon}^{cp}, \boldsymbol{\omega}\right); \tag{10}$$

where Ψ^i and Ψ^c represent the free energies related to the internal and contact parts of the strain state respectively and Ψ^{ic} is the mixed term of the free energy which takes into account the co-presence of the contact and internal strains. ξ_d and ξ_p are the damage and plastic internal variables, respectively.

The principle considered for developing the constitutive laws is that damage occurs in the bulk material, therefore the damage tensor $\boldsymbol{\omega}$ appears in the two terms of the total free energy that are functions of the internal strains also. In this way the constitutive model takes into account the onset of microvoids and fractures along the thickness of the joint. On the other hand, debonding of the joint from the adherents, sliding and fractures developing on surfaces parallel to the middle plane of the interphase are modelled using elastoplasticity and the inelastic contact strains $\boldsymbol{\varepsilon}^{cp}$ are the related internal variables.

In this work a single scalar damage variable ω governs the loss of stiffness of the bulk material. It ranges from 0 to 1, with the inferior and superior limits having the meaning of a pristine and a fully damaged bulk material, respectively.

The explicit expression of the components of the free energy is given below:

$$\Psi^i = \frac{1}{2}(1-\omega)\left[\lambda \operatorname{tr}^2\left(\boldsymbol{\varepsilon}^i\right) + 2\mu\,\boldsymbol{\varepsilon}^i : \boldsymbol{\varepsilon}^i\right] - h_d\left[\xi_d + \ln\left(1-\xi_d\right)\right] \tag{11}$$

$$\Psi^c = \frac{1}{2}\left[\lambda \operatorname{tr}^2\left(\boldsymbol{\varepsilon}^c - \boldsymbol{\varepsilon}^{cp}\right) + 2\mu\left(\boldsymbol{\varepsilon}^c - \boldsymbol{\varepsilon}^{cp}\right) : \left(\boldsymbol{\varepsilon}^c - \boldsymbol{\varepsilon}^{cp}\right)\right] + \frac{1}{2}h_p\xi_p^2 \tag{12}$$

$$\Psi^{i,c} = (1-\omega)\lambda \operatorname{tr}\left(\boldsymbol{\varepsilon}^{\mathrm{i}}\right)\operatorname{tr}\left(\boldsymbol{\varepsilon}^{\mathrm{c}} - \boldsymbol{\varepsilon}^{\mathrm{cp}}\right) \tag{13}$$

where λ and μ are the Lamè's constants, h_d is a material parameter which governs the softening response associated to the damage onset and growth, and h_p is a material parameter specifying isotropic hardening/softening interface response.

3. State equations and flow rules.

In order to derive the interphase constitutive equations, the second principle of thermodynamics, taking into account also the balance equation (first principle) can be applied in the form of the Clausius-Duhem inequality. This inequality for isothermal purely mechanical evolutive process reads as

$$D = \boldsymbol{\sigma} : \dot{\boldsymbol{\varepsilon}} - \dot{\Psi} \geq 0 \tag{14}$$

where D is the interphase dissipation (for unit surface) or net entropy production.

From the assumed form of the Helmholtz free energy (Eq. 10) its general rate has the following expression:

$$\begin{aligned}\dot{\Psi} = &\left(\frac{\partial \Psi^i}{\partial \boldsymbol{\varepsilon}^i} + \frac{\partial \Psi^{i,c}}{\partial \boldsymbol{\varepsilon}^i}\right) : \dot{\boldsymbol{\varepsilon}}^i + \left(\frac{\partial \Psi^c}{\partial \boldsymbol{\varepsilon}^c} + \frac{\partial \Psi^{i,c}}{\partial \boldsymbol{\varepsilon}^c}\right) : \dot{\boldsymbol{\varepsilon}}^c + \left(\frac{\partial \Psi^c}{\partial \boldsymbol{\varepsilon}^{cp}} + \frac{\partial \Psi^{i,c}}{\partial \boldsymbol{\varepsilon}^{cp}}\right) : \dot{\boldsymbol{\varepsilon}}^{cp} + \\ &+ \left(\frac{\partial \Psi^i}{\partial \omega} + \frac{\partial \Psi^{i,c}}{\partial \omega}\right) : \dot{\omega} + \frac{\partial \Psi^i}{\partial \xi_d}\dot{\xi}_d + \frac{\partial \Psi^c}{\partial \xi_p}\dot{\xi}_p\end{aligned} \tag{15}$$

Particularizing Eq. (14) for a purely elastic incremental deformation process ($\dot{\boldsymbol{\varepsilon}}^{cp} = \mathbf{0}$, $\dot{\omega} = \dot{\xi}_d = \dot{\xi}_p = 0$), assuming the decomposition of the stress state similar to that used for the strain state

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}^i + \boldsymbol{\sigma}^c, \qquad \text{being} \qquad \boldsymbol{\sigma}^i = \mathbf{A}\boldsymbol{\sigma}\mathbf{A} \tag{16}$$

and considering the adopted expressions of the free energy parts (Eq. 11-13), the elastic stress-strain equations can be derived, thus

$$\sigma^i = (1-\omega)\left\{\lambda\left[\operatorname{tr}\left(\boldsymbol{\varepsilon}^i\right) + \operatorname{tr}\left(\boldsymbol{\varepsilon}^c - \boldsymbol{\varepsilon}^{cp}\right)\right]\mathbf{A} + 2\mu\boldsymbol{\varepsilon}^i\right\} \tag{17}$$

$$\sigma^c = \lambda\left[(1\text{-}\omega)\operatorname{tr}\left(\boldsymbol{\varepsilon}^i\right) + \operatorname{tr}\left(\boldsymbol{\varepsilon}^c - \boldsymbol{\varepsilon}^{cp}\right)\right](\mathbf{I}-\mathbf{A}) + 2\mu\left(\boldsymbol{\varepsilon}^c - \boldsymbol{\varepsilon}^{cp}\right) \tag{18}$$

$$\chi_p = h_p \xi_p \tag{19}$$

$$\chi_d = h_d \frac{\xi_d}{1-\xi_d} \tag{20}$$

$$\zeta = \frac{1}{2}\left[\lambda \operatorname{tr}^2\left(\boldsymbol{\varepsilon}^i\right) + 2\mu\,\boldsymbol{\varepsilon}^i : \boldsymbol{\varepsilon}^i\right] + \lambda \operatorname{tr}\left(\boldsymbol{\varepsilon}^i\right)\operatorname{tr}\left(\boldsymbol{\varepsilon}^c - \boldsymbol{\varepsilon}^{cp}\right) \tag{21}$$

where χ_p and χ_d are the static variables conjugate of the internal variables ξ_p and ξ_d respectively, and ζ the thermodynamic force conjugate of the damage variable ω.

Making use of the elastic strain-stress equation and of the previous positions, the final expression of the instantaneous dissipation is obtained:

$$D = \boldsymbol{\sigma}^c : \dot{\boldsymbol{\varepsilon}}^{cp} - \chi_p \dot{\xi}_p - \chi_d \dot{\xi}_d + \zeta\dot{\omega} \geq 0\,. \tag{22}$$

In order to regulate the activation of each dissipative mechanism, two different yield functions are defined in the space of the proper static variables, namely:

$$\Phi_p\left(\boldsymbol{\sigma}^c, \chi_p\right) \leq 0, \qquad \Phi_d\left(\zeta, \chi_d\right) \leq 0 \tag{23}$$

where Φ_p is the classical plastic yield function specifying the elastic contact domain assumed convex and Φ_d is the damage activation function also assumed convex.

The activation of each dissipation mechanism can be effectively described by a variational formulation which is represented by the generalized principle of maximum intrinsic dissipation:

$$\max_{\boldsymbol{\sigma}^c, \chi_p, \chi_d, \zeta} \left(\boldsymbol{\sigma}^c : \dot{\boldsymbol{\varepsilon}}^{cp} - \chi_p \dot{\xi}_p - \chi_d \dot{\xi}_d + \zeta\dot{\omega}\right) \tag{24}$$

subject to the constraints (Eq. 23). The Kuhn-Tucker conditions of the maximum constrained problem provide the plastic and damage evolution laws of the interphase:

$$\dot{\boldsymbol{\varepsilon}}^{cp} = \dot{\lambda}_p \frac{\partial \Phi_p}{\partial \boldsymbol{\sigma}^c}; \quad \dot{\omega} = \dot{\lambda}_d \frac{\partial \Phi_d}{\partial \zeta} \tag{25}$$

$$-\dot{\xi}_p = \dot{\lambda}_p \frac{\partial \Phi_p}{\partial \chi_p}; \quad -\dot{\xi}_d = \dot{\lambda}_d \frac{\partial \Phi_d}{\partial \chi_d} \tag{26}$$

$$\Phi_p\left(\boldsymbol{\sigma}^c, \chi_p\right) \leq 0, \quad \dot{\lambda}_p \geq 0, \quad \dot{\lambda}_p \Phi_p\left(\boldsymbol{\sigma}^c, \chi_p\right) = 0 \tag{27}$$

$$\Phi_d\left(\zeta, \chi_d\right) \leq 0, \quad \dot{\lambda}_d \geq 0, \quad \dot{\lambda}_d \Phi_d\left(\zeta, \chi_d\right) = 0 \tag{28}$$

being $\dot{\lambda}_p$ and $\dot{\lambda}_d$ the plastic and damage multiplier, respectively.

In the present study the elasto-plastic convex domain is defined by the intersection of the classical Mohr-Coulomb bilinear function with a tension cut-off:

$$\Phi_{p1}\left(\boldsymbol{\sigma}^c, \chi_p\right) = \left|\boldsymbol{\tau}^c\right| + \sigma^c \tan\varphi - c_0\left(1-\chi_p\right) \tag{29}$$

$$\Phi_{p2}\left(\boldsymbol{\sigma}^c, \chi_p\right) = \sigma^c - \sigma_0\left(1-\chi_p\right) \tag{30}$$

where $\boldsymbol{\tau}^c$ and σ^c are the tangential stress vector and the normal stress component of the contact stresses, φ is the friction angle, c_0 and σ_0 the cohesion and tensile strength of the virgin interfaces.

The two yield functions are depicted in Fig. 2. The following four zones can be distinguished:

I elastic zone: $\Phi_{p1} < 0, \quad \Phi_{p2} < 0$

II plastic activation in shear: $\Phi_{p1} = 0, \quad \Phi_{p2} < 0$

III plastic activation in tension: $\Phi_{p1} < 0, \quad \Phi_{p2} = 0$

IV plastic activation in tension and shear (corner): $\Phi_{p1} = 0, \quad \Phi_{p2} = 0$.

The damage activation function is linear and the first activation occurs when the thermodynamic force reaches the relative threshold value ζ_0:

$$\Phi_d\left(\zeta, \chi_d\right) = \zeta - \zeta_0\left(1-\chi_d\right) \tag{31}$$

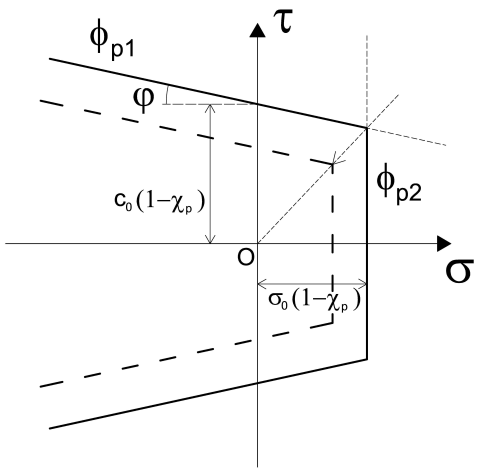

Figure 2. Plastic yield conditions represented in the stress space.

4. Numerical applications.

The interphase model presented in Sections 2 and 3 has been implemented in an open-source research-oriented finite element analysis program for 2D applications. With the aim to run a step-by-step integration, flow rules given in rate form were rewritten as discrete laws. The implicit backward-Euler difference method was applied to obtain results within the time step

$[t_n, \ t_{n+1}] \subset [0, \ T]$. In particular the nonlinear solution at time t_{n+1} has been calculated by means of an elastic prediction – plastic and/or damaging correction procedure. The interphase element has four nodes and zero-thickness. The integration of the stiffness matrix has been solved by applying the Reduced Selective Integration method, that is two Gauss are used for the integration in the direction normal to the interphase plane while one Gauss point is used in the tangential one.
The numerical applications presented in this work regard uniaxial compression and diagonal compression tests on masonry specimens. All numerical examples have been carried out under the hypothesis of plane stress state.

4.1. Uniaxial compression tests on masonry.

Uniaxial compression tests have been carried out to assess the performance of the interphase element. A brick-mortar-brick system uniformly compressed (Fig. 3) has been considered with the aim to show the formation of damage in the bulk material when the stiffness of the bricks is lower than that one of mortar. In this case, in fact, the bricks tend to expand more than the mortar in the horizontal direction because of the Poisson effect, but the higher stiffness of the mortar opposes to this displacement. The bricks are therefore subjected to compressive stresses while the mortar to tensile ones along the x-axis.

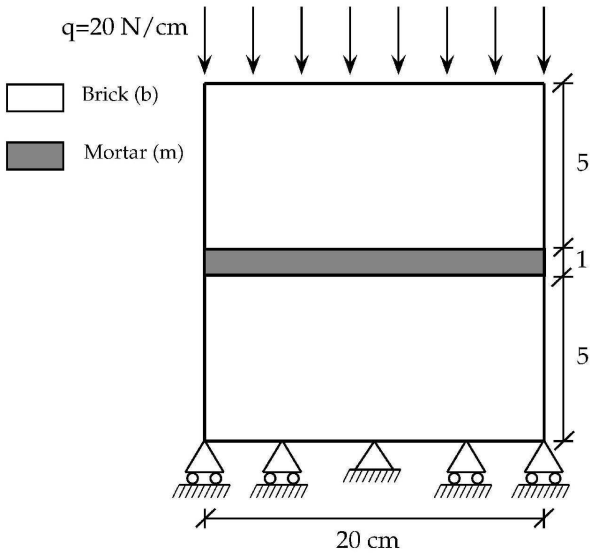

Figure 3. Uniaxial compression test on a masonry block.

The parameters used for tests are reported in Table 1, while the results are shown in Fig. 4. The numerical test has been performed under displacement control. In this paper the results obtained with a load multiplier equal to 3 and for a FE model with 80 interphase elements are reported in terms of stresses along the mortar layer.

Table 1. Parameters used for compression test.

E_{brick}	500 MPa	ν_{brick}	0.3
E_{mortar}	15000 MPa	ν_{mortar}	0.2
c_0	4.5 MPa	φ	30°
σ_0	1.0 MPa	h_p	1
ζ_0	0.001 MPa	h_d	0.0025 MPa

The diagrams depicted in Fig. 4 clearly show the points were the damage nucleation takes place. The first fracture forms in the middle of the layer and grows during the following steps. As a consequence, a redistribution of stresses takes place in the two parts on sides of the fracture. When the thermodynamic force in another Gauss point or group of Gauss points overcomes the threshold value a new fracture appears symmetrically with respect to the middle of the mortar joint. On the other hand, while σ_x stresses suddenly fall down and tend to zero, the σ_z values are little influenced by fracture. This is due to the fact that damage affects only internal and mixed terms of the free energy.

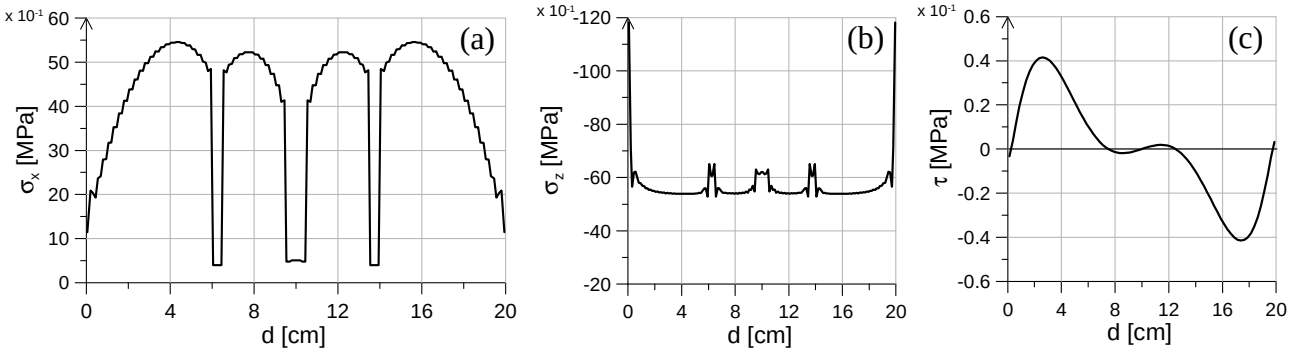

Figure 4. Uniaxial compression test on a masonry block: results at a load multiplier equal to 3. (a) normal stresses along x-axis; (b) vertical stresses; (c) tangential stresses.

4.2. Diagonal compression tests on masonry.

Diagonal compression numerical tests have been carried out on a masonry panel and compared with the experimental results obtained in laboratory. With reference to Fig. 5, the specimen is made up of four courses of sandstone blocks with calcium-cement mortar. It has a squared shape with a length of 67 cm for each side. A single block is 33 cm long and 16 cm high. The mortar layer has a thickness of 1 cm. A total number of 256 plane stress 2D solid elements and 72 interphase elements has been used to create the finite element model.

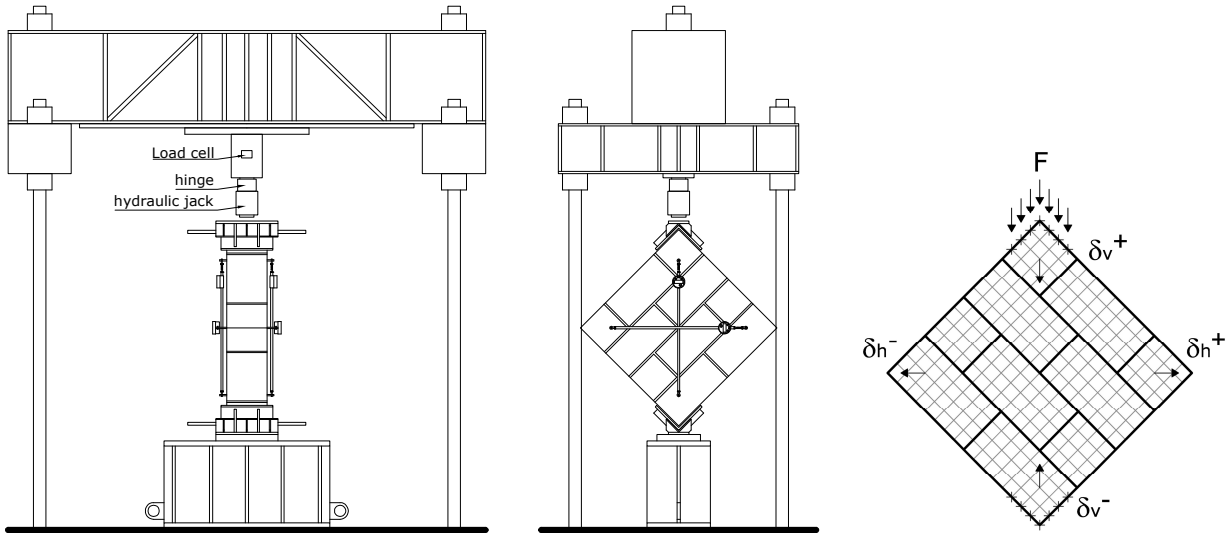

Figure 5. Diagonal compression test on a masonry panel. Experimental setup and finite element model.

The mechanical variables for blocks and mortar and the parameters used for the finite element model are reported in Table 2.

Table 2. Parameters used for diagonal compression test.

E_{brick}	11141.67 MPa	ν_{brick}	0.25
E_{mortar}	37000 MPa	ν_{mortar}	0.14
c_0	5.0 MPa	φ	35°
σ_0	1.0 MPa	h_p	0.04
ζ_0	$1 \cdot 10^{-5}$ MPa	h_d	0.001 MPa

The test has been run with 400 steps under displacement control. At each step the values of the total vertical load F and the displacement discontinuities $\delta h = \delta h^+ + \delta h^-$ and $\delta v = \delta v^+ + \delta v^-$, in horizontal and vertical direction respectively, have been evaluated and reported in the load-displacement curves of Fig. 6. A good agreement has been obtained with experimental results.

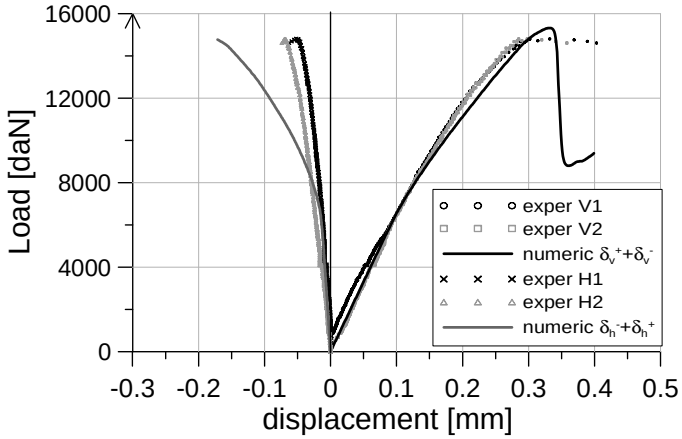

Figure 6. Load-displacement curves: comparison between numerical and experimental results.

Fig. 7 finally shows a comparison between the collapse experimental and numerical configurations. A very good agreement can be observed, even if the numerical model is not able to simulate the fracture inside the blocks because an elastic behavior was chosen for bricks.

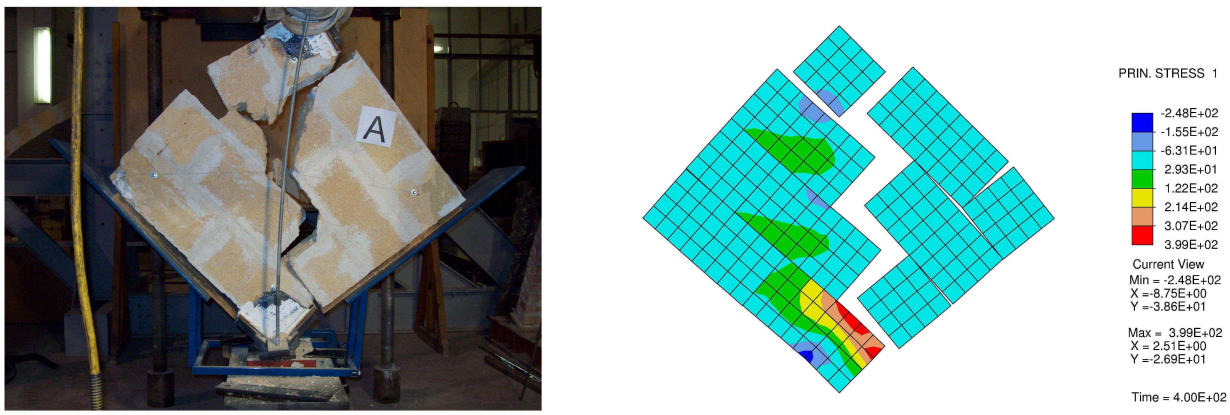

Figure 7. Comparison between numerical and experimental collapse configurations.

5. Conclusions.

The present paper deals with the mesomodelling of heterogeneous structures by means of interphase elements, that can be considered as an enhancement of the common interface elements. The possibility to distinguish internal and external contact stresses and strains permits to introduce separate failure conditions for the bulk material and for contact tractions. In particular an isotropic

damage model has been used to model the nonlinear response of the bulk material, while an elastoplastic bilinear domain governs the evolution of plasticity for contact tractions. The interphase model has been written in the framework of a thermodynamically consistent theory. State equations and flow rules have been derived and rewritten in a discrete form to be suitable to be used for finite element implementation. Two numerical applications on masonry structural elements have been conducted. In particular a compression test and a diagonal test have been carried out.
Ongoing and future efforts are devoted to the introduction of plastic activation functions on the physical interfaces between mortar and block, and to the possibility to introduce a new damage model to catch horizontal fractures also.

Abstract A meso-numerical model is set up to investigate the damage evolution of 2D woven C/SiC based on RVE(representative volume element) because the woven composite has a periodic in-plane structure. Periodic boundary conditions are imposed to the model. Three material models for the fibers, the matrix, and the yarn/matrix interface are considered. Basic damage modes and their evolutions are observed in the simulation. Firstly, the matrix is damaged at the global applied stress around 50Mpa, which agrees well with the tests. The stress/strain relation obtained from the meso-numerical model can represent the behavior of the 2D woven C/SiC under tension loading. Secondly, the void in the matrix plays an important role. The bundle/matrix interface is essential to investigate the interface debonding.
Keywords 2D-C/SiC composites, RVE, damage mechanisms

1. Introduction

C/SiC, as one of the most promising high temperature structural materials for its performance, such as low coefficient of thermal expansion, excellent thermal shock resistance, abrasion resistance, and high specific strength/modulus, has been applied in structures such as air-breathing engines, hot-gas valves and aerospace thermal structures. Consequently, the mechanical properties of the C/SiC has been an active research field for several decades. Both experimental studies and macro- or micromechanical methods have been used to obtain the mechanical properties of the C/SiC[1-13,20].

In experimental studies, the mechanical characterization of the C/SiC were studied by classical strain measurements, ultrasonic method, AE(acoustic emission) technique , infrared thermography and microstructural observations under the load of uniaxial tension[1-6], compression[1,5], in-plane shear[7], tension fatigue[8,9], thermal fatigue[10,11] and low-velocity impact[12]. Based on the expensive experiments, the damage modes found by microstructural observations are: matrix cracking, transverse bundle cracking, bundle/matrix and inter-bundle debonding, fiber cracking, ply delamination, bundle splitting and matrix wear. The damage evolution or development mention in the former studies are all deduced from the possible damage modes, which can only reflect the overall damage event and the detailed mechanical behavior of the constituents identification is beyond the detection. Fortunately, it is possible to identify detailed mechanical behavior of the constituents in FEM. However, there is not so much study on C/SiC with simulation method as experiment method. The prediction of the stiffness tensor has been carried out with FEM[13]. While, little work was done on the prediction of damage evolution and the strength[4].

Recently, simulation of plain woven fabrics based on photomicrograph measurement and idealized sinusoidal representation of the weave structure has been successfully applied to determine their mechanical properties by taking the advantages of their inherent periodicity of woven fabric architecture[14-19] at mesoscale in-plane. Both elastic moduli [14,15], damage[16] and fracture[18] behavior of the woven fabrics have been successfully predicted for the case of two-phase heterogeneous materials without considering the fiber-matrix interface using FEM by RVE (representative volume elements). While, it has been confirmed that interface obviously has great

influence on the macroscopic behavior, the toughness and strength of CMCs[20]. Interfaces are very narrow regions between matrix and fibers and are responsible for a variety of key properties, because of its significance role of stress transfer between fibers and matrix[20-23]. Recently, CZM(cohesive zone model) is being increasingly used in describing interfacial debonding and separation[23]. It was first proposed to analyze brittle fracture, and developed to model debonding of inclusions, crack growth processes in elastic-plastic solids, delamination process in composites subjected to low velocity impacts and so on. It is not so easy to simulate the bundle/matrix interface, because the mechanical properties of the interface is very difficult to obtain and the geometry of the interface in woven fabrics is curved surface.

The aim of the present contribution is to introduce the interface into the RVE model in terms of CZM, and to analyze the damage evolution in 2D woven C/SiC with the damage behavior of different constituents identified clearly. This paper is organized as follows: firstly, the geometry model and boundary conditions are presented. Next, the meso-model was outlined with the description of material models of matrix, fiber yarns and interface-matrix interface. Then, the damage of different constituents was predicted based on elastic model. In the last but one section, the damage initiation and evolution are described with different damage modes identified. Finally, conclusions are summarized in the final sections.

2. RVE and periodic boundary conditions

2D woven C/SiC is plain weave fabrics, which are formed by weaving of yarns, as shown in Fig. 1. The black yarn are in X(longitudinal) direction and the grey yarn are in Z(transverse) direction.

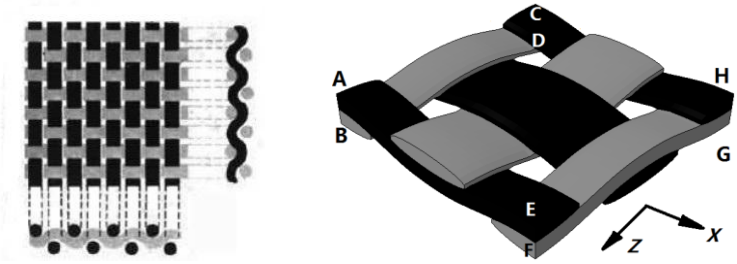

Figure 1. Sketch of 2D plain weave single lamina(left) and its RVE without matrix(right)

In order to modeling the fabric-reinforced laminates using FEM, the representative volume elements (RVE) of the respective configurations are chosen. The RVE is the repeated element that can represent the whole composite fabric structure by a periodical array. Then characteristics of the macrostructure composites can be represented by the RVE with a certain proper boundary conditions. And the data points are fit to a sinusoidal function of the form[15]:

$$f(x) = a\sin(bx + c) + d \qquad (1)$$

where, a, the amplitude of the yarn curve is 0.125mm; b=2π /1.8≈3.49, and 1.8 is the pitch of the yarn path curve in millimeters; d, the offset depicted is ±0.125mm; c is the phase adjusting factor.

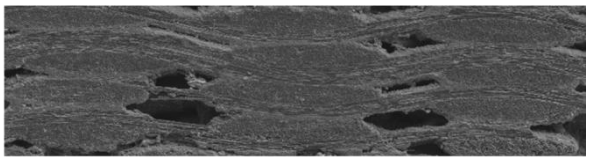

Figure 2. The photomicrograph of the 2D plain weave C/SiC

Fig. 2. is the photomicrograph of the 2D plain weave C/SiC by SEM. According to the micrograph the geometry of the fiber yarns is determined, AB=0.25mm, AE=AD=1.8mm, with the woven hole in the square of 0.2mm×0.2mm.

The periodic boundary conditions meets the requirement of displacement periodicity and continuity of the proper boundary conditions, which implies that no separation or overlap will be found between neighboring of RVEs. Each RVE in the composites has the same deformation mode. As stated by Z.Xia[18], the periodic conditions on the boundary ∂V is

$$u_i = \bar{\varepsilon}_{ik} x_k + u_i^* \tag{2}$$

where, $\bar{\varepsilon}_{ik}$ are the average strains, u_i^* is the periodic part of the displacement components on the boundary surfaces and it is related to the applied global loads. Aboudi has developed a unified micromechanical theory based on the study of interacting periodic cells, and its boundary conditions, plane-remains-plane, were applied to the RVE models in the normal traction loading conditions.

Now based on these the proper boundary conditions are the planes ABFE and CDGH keeps plane during the loading in x direction on EFHG plane. The ABCD plane keeps zero displacement in X direction. And to avoid the rigid motion, the displacement components of the center point of the ABCD plane are assumed to be zero.

3. The meso-model

In the model, RVE that used to investigate the 2D woven C/SiC under tension loading, is shown in Fig. 3. The matrix, fiber and the yarn/matrix interface are taken into account with their specific damage behavior.

(a) Matrix (b) Interface (c) Fiber bundles

Figure 3. The RVE model and its constituents

3.1. Matrix

The elastic constants for the matrix material SiC: Young's modulus E, Poisson's ratio v are found to be E=430Gpa, v=0.3. The brittle cracking material constitutive in ABAQUS is chosen to describe the damage and failure behavior of the isotropic brittle matrix. The failure stress and displacement are 200Mpa and 0.02mm, respectively. In order to consider void in matrix, the elastic constants is assumed to reduced to 10% of the original matrix, and the model with void is shown in Fig. 3(a), the small squares in the RVE is the void region.

3.2. Fiber yarns

The fiber bundles in C/SiC is regarded as transverse isotropic materials. And the properties are listed in Table 1.

Table 1. The mechanical properties of the fiber yarns

E_1(Gpa)	E_2(Gpa)	v_{12}	v_{23}	G_{12}(Gpa)	G_{23}(Gpa)	σ_f(Mpa)	ε_f
220	13.8	0.2	0.18	9	4.8	800	1.5%

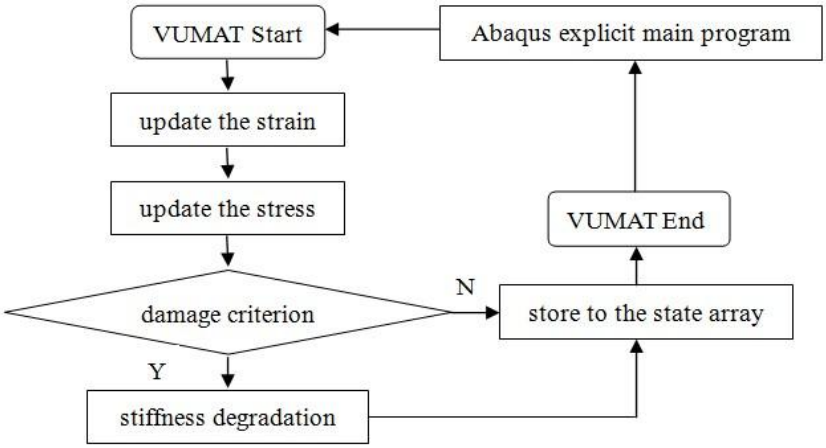

Figure 4. The flow chart for the VUMAT

To study the damage process, the damage model is introduced to the fiber yarns with VUMAT by Fortran, and the flow chart is shown in Fig. 4. Here the maximum stress criterion and linear stiffness degradation are chosen as the damage initiation criterion and damage evolution law of the fiber yarns.

3.3. Yarn/matrix interface

The interface zone plays a key role in the mechanical behavior of composite materials. Its properties can be influenced by different fiber coatings such as PyC, BN or SiC and its thickness. And the most important mechanism for improving the toughness of CMCs is the crack deflection along the interface after the initiation of the matrix cracking. In this meso-level FEM model, the inner-yarn interface is not considered, and fiber bundles is simplified as transversely isotropy.
In this work, bilinear models both for normal and tangential separation is used to simulate the response of the yarn/matrix interfacial zone. The curve of normal and tangential tractions with respect to δ_n and δ_t are shown in Fig.5, where σ_{max} and τ_{max} are the interface normal and tangential strength, are 200Mpa and 150Mpa respectively; δ_{max} is the interface characteristic length parameter; δ_n and δ_t denote the non-dimensional normal and tangential displacement respectively.

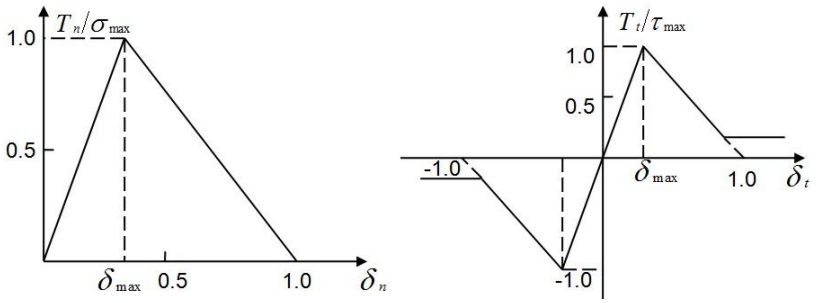

Figure 5. The curve of normal(left) and tangential(right) tractions with respect to δ_n and δ_t

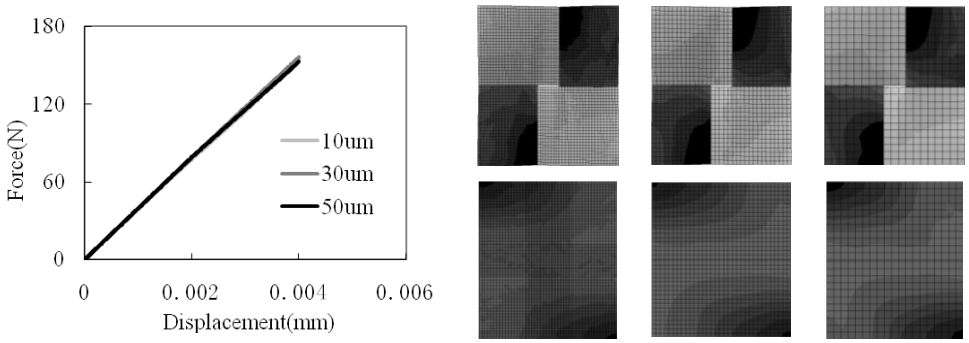
In the FE model, CZM was realized by either cohesive element or cohesive behavior and maximum stress criterion was used to predict the damage initiation in Abaqus/explicit, and detailed constitutive model for the CZM can be found in the help documentation[24].

4. The result analysis

4.1. The mesh sensibility and validation

Firstly, in order to get accurate results, the mesh sensibility was studied with mesh size 10um, 30um and 50um in the quarter model. The result of the overall force-displacement response and the mises contour are shown in Fig.6. The overall force-displacement response shows very small difference. The mises contour pictures corresponding to the loading of 1.12×10^{-3}mm for 10um, 30um and 50um are listed from left to right(white means 0Mpa, and black grey means 200Mpa, and black means exceeding 200Mpa), the maximum stress in matrix is between 203.3Mpa and 208.7Mpa, while it is 250.8Mpa and 273.1Mpa for the yarns, which shows little difference. So, 50um was accepted for its time-efficiency.



(a) Overall force-displacement (b) The mises contour

Figure 6. The effect of mesh size

The prediction of the elastic modulus is about 75Gpa. And the elastic modulus from experiments is almost between 70Gpa[10,11] and 81.2Gpa[3]. Furthermore, the damage in RVE initiates at the stress about 53Mpa in the matrix, which agrees well with the initial proportional limit of the composites[3], around 50Mpa.

4.2. The damage prediction

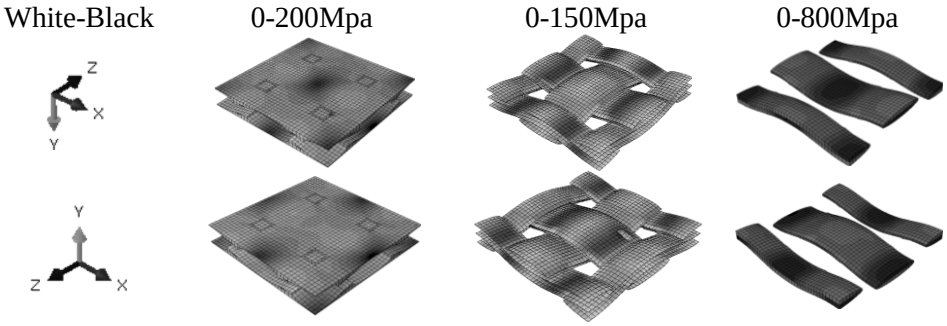


Figure 7. The mises contour of matrix(5th step)/interface/fibers(37th step)

From the elastic RVE model, the matrix is probably damaged first at the thinnest region that close to the yarns, the damage of the yarns will initiate at the woven point, and the interface is easy to get damaged at the region of woven edge, shown in black in Fig. 7.
When the stress in matrix reaches the strength, the average stress in the RVE is about 53Mpa. When the stress in the yarns reaches the strength, the average stress in the RVE is about 330Mpa,

corresponding to strain about 0.005 in Fig. 8 of the grey curve, higher than the failure stress of the composites, which indicates the limitation of the elastic model. So the damage models are introduced to the constituents of the C/SiC, and the corresponding stress-strain curve compared with no damage model is shown in Fig .8. The detailed damage process of the three constituents are shown in subsequent sections.

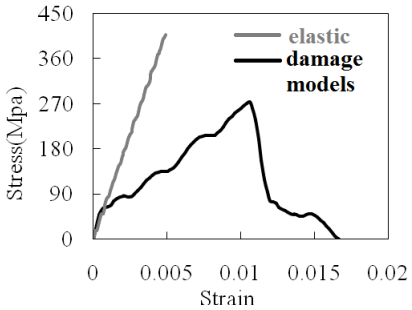

Figure 8. The stress-strain curve

4.3. The matrix damage evolution

The brittle cracking was introduced to matrix for its brittleness in fracture process. Fig. 9 shows the damage initiation and propagation process of the matrix in terms of STATUS, which represents the state of the element (1.0 means the element is active, shown in white; and 0.0 means the element is inactive, shown in black). It is found that the damage first occurs at the thinnest region close to the yarns in loading directions as predicted in the elastic model. In the upper(Y+) matrix, the damage initiates at the edge center of the RVE, while in the lower(Y-) matrix, it initiates at the center of the RVE. Then, the damage propagates in Z direction, vertical to loading. And the damage first runs through the Z direction in the lower matrix at the strain of 2200$\mu\varepsilon$, while it happens to the upper matrix at the strain of 2600$\mu\varepsilon$. The damage has already run through the cross section of the RVE at the strain of 2600$\mu\varepsilon$.

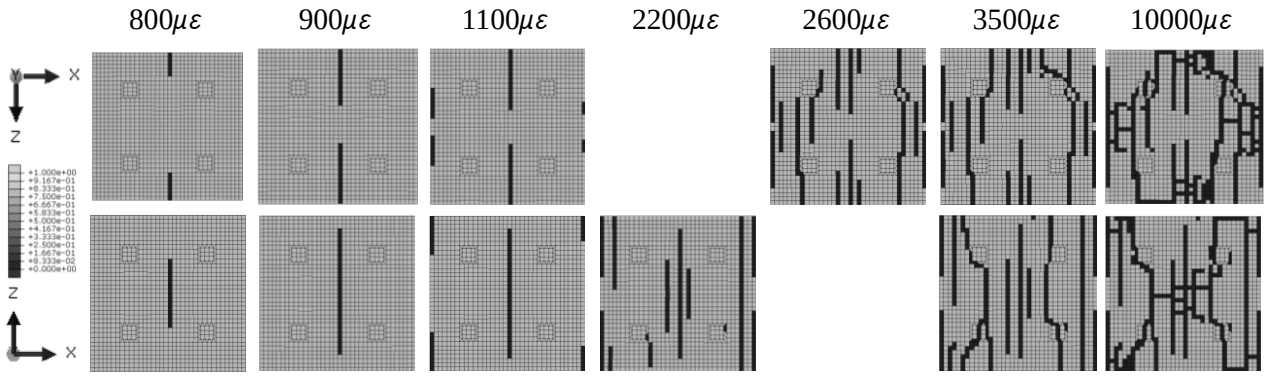

Figure 9. The damage process of the matrix

4.4. The fiber damage evolution

The simulation of fiber damage was introduced by VUMAT in Abaqus, which aims at investigating the possible damage process of fiber bundle damage. Fig. 10 shows the damage initiation and propagation process of the matrix in terms of STATUS. It is found that the damage first occurs at the weaving center of the yarns in loading directions as predicted in the elastic model. Then, the damage propagates in Z direction, vertical to loading. And the damage first runs through the Z direction in longitudinal yarns at the strain of 5800$\mu\varepsilon$, while it happens to the center yarns in

longitudinal at the strain of 6000$\mu\varepsilon$.

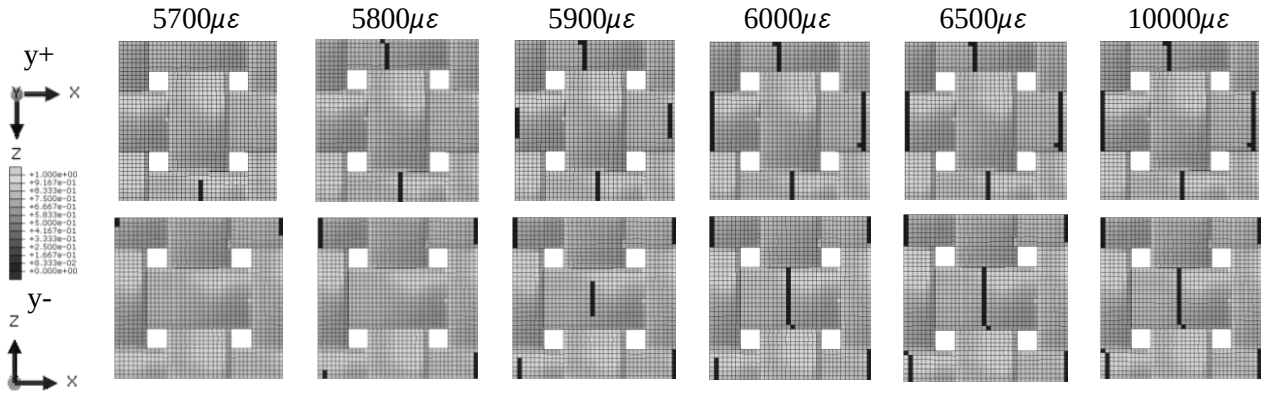

Figure 10. The damage process of the fiber bundle

4.4. The yarn/matrix interface damage evolution

The CZM was introduced to the RVE by cohesive element in Abaqus, which aims at investigating the possible damage process of yarn/matrix interface.

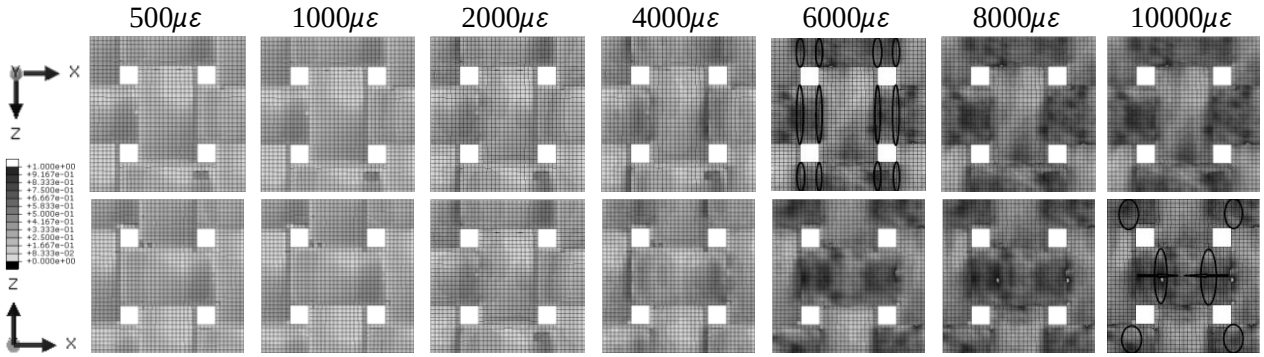

Figure 11. The damage process of the interface

Fig. 11 shows the damage initiation and propagation process of the interface in terms of MAXSCRT(0.0 means no damage occurs, shown in white grey; and 1.0 corresponding to failure, shown in black grey). It is found that the damage initiates at the weaving edge of the interface around the yarns in longitudinal direction as shown in the MAXSCRT contour of 6000$\mu\varepsilon$, then it spread to the weaving point of the RVE in longitudinal(X) direction, marked with circles and arrows. The interface around yarns in transverse(Z) direction get damaged at the strain of 10000$\mu\varepsilon$, later than it in longitudinal direction.

4.6. The effect of the void in matrix

The porosity in C/SiC may have great influence on the damage initiation, evolution. So, the RVE with void in matrix is investigated. From the photomicrograph of the 2D plain weave C/SiC, it can be found that the void in matrix is mainly around the weaving gap between yarns, so the mechanical properties of the matrix in this region, showing as four small rectangles in the matrix (the volume is about 6% of the whole volume of the RVE) is reduced to 10%. The result of the matrix damage evolution is shown below in Fig. 12. The damage of the matrix initiates around the void, which differs from the damage evolution in matrix without void compared with Fig. 8. And it is also found that the through damage in the model with void comes earlier than that without void. So the void in

matrix plays an important role in the damage evolution.

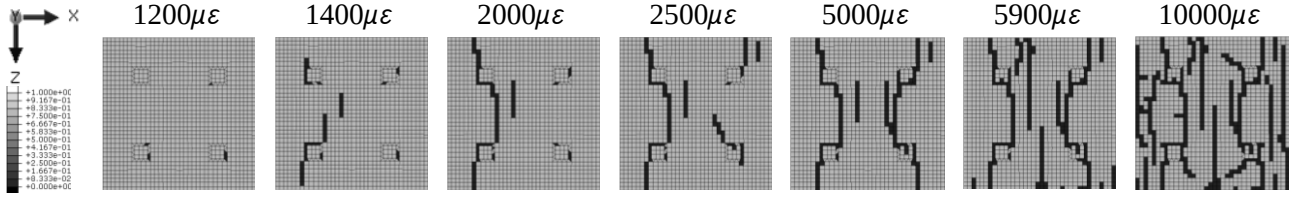

Figure 12. The damage process of the matrix with void

5. Conclusions

This paper focuses on the 2D plain woven C/SiC, and the conclusions are as follows:
1) The geometry model of RVE is established based on the photomicrograph of the 2D plain weave C/SiC by SEM with the yarn/matrix interface successfully introduced. And the damage models for the matrix, yarn/matrix interface and yarns are considered.
2) The established meso-level FEM is able to describe mechanical behavior of different constituents in the plain-woven C/SiC. Especially, the damage initiates in the matrix at the overall stress about 50Mpa, which agrees well with the experiments.
3) The damage of the matrix initiates near the void and spreads in transverse directions, and spreads through the section of the RVE; the damage of the fiber begins at the very region of the weaving point in longitudinal yarns and spreads in transverse direction; the damage of the yarn/matrix occurs near the weaving edge and spreads both in transverse and longitudinal directions.
4) The void in the matrix has great influence on the damage initiation and evolution of the matrix in the RVE model. It is found that the damage of the matrix without void initiates near the yarn in Z direction at the thin region of the matrix, while the damage of the matrix with void initiates around the void.

Structure of micro-crack population and damage evolution in concrete

Andrey P Jivkov[1,*]

* Corresponding author: andrey.jivkov@manchester.ac.uk

Abstract Tensile behaviour of concrete is controlled by the generation and growth of micro-cracks. A 3D lattice model is used in this work for generating micro-crack populations. In the model, lattice sites signify solid-phase grains and lattice bonds transmit forces and moments between adjacent sites. The meso-scale features generating micro-cracks are pores located at the interfaces between solid-phase grains. In the model these are allocated to the lattice bonds with sizes dictated by an experimentally determined pore size distribution. Micro-cracks are generated by removal of bonds when a criterion based on local forces and pore size is met. The growing population of micro-cracks results in a non-linear stress-strain response, which can be characterised by a standard damage parameter. This population is analysed using a graph-theoretical approach, where graph nodes represent failed bonds and graph edges connect neighbouring failed bonds, i.e. coalesced micro-cracks. The evolving structure of the graph components is presented and linked to the emergent non-linear behaviour and damage. The results provide new insights into the relation between the topological structure of the population of micro-cracks and the macroscopic response of concrete. They are applicable to a range of quasi-brittle materials with similar dominant damage mechanisms.

Keywords Concrete porosity; Lattice model; Cracking graphs; Macroscopic damage

1. Introduction

The mechanical behaviour of quasi-brittle materials, such as concrete, graphite, ceramics, or rock, emerges from underlying microstructure changes. At the engineering length scale it can be described with continuum constitutive laws of increasing complexity combining damage, plasticity and time-dependent effects [1-4]. In these phenomenological approaches the damage represents reduction of the material elastic constants. From the microstructure length scale perspective damage is introduced by the nucleation and evolution of micro-cracks. While the population of micro-cracks formed under loading could be sufficiently well captured by various continuum damage models, the latter cannot help to understand the effects of the population on other important physical properties of the material. In many applications the quasi-brittle materials have additional functions as barriers to fluid transport via convection/advection and/or diffusion. It is therefore important to take a mechanistic view on the development of damage by modelling the evolution of micro-crack population, which can inform us about changes in the transport properties. Such a mechanistic approach needs to account for the material microstructure in a way corresponding to the mechanism of micro-crack formation [5]. Micro-cracks typically emerge from pores in the interfacial transition zone between cement paste and aggregate in cement-based materials [6].

Discrete lattice representation of the material microstructure seems to offer the most appropriate modelling strategy for analysis of micro-crack populations. This is a meso-scale approach, where the material is appropriately subdivided into cells and lattice sites are placed at the centres of the cells. Discrete lattices allow for studies of distributed damage without constitutive assumptions about crack paths and coalescences that would be needed in a continuum finite element modelling. The deformation of the represented continuum arises from the interactions between the lattice sites. These involve forces resisting relative displacements and moments resisting relative rotations between sites. Two conceptually similar approaches have been proposed to link local interactions to continuum response. In the first one, the local forces are related to the stresses in the continuum cell, e.g. [7, 8]. In the second one, the interactions are represented by structural beam elements, the stiffness coefficients of which are determined by equating the strain energy in the discrete and the

continuum cell, e.g. [9, 10]. In both cases explicit relations between local and continuum parameters can be established for regular lattices [11], but the only isotropic material that can be represented in 3D is a material with zero Poisson's ratio. A bi-regular lattice that can represent all materials of practical interest has been proposed recently [12]. This lattice, currently formed by beams clamped at sites, is used in the current work together with microstructure data for concrete obtained with X-ray computed tomography. Failure models based on microstructure data and the new lattice have been previously used for modelling tensile and compressive behaviour of cement [13] and the compressive behaviour of concrete under various complex loading conditions [14]. This work makes a step into developing our understanding of the micro-crack population and its relation to macroscopic damage.

Most of the work relating micro-crack populations to elastic moduli follows the fundamental paper [15], where analytical statistical derivation of the relation was provided. We follow the interpretation given in [16], in which the damage is measured as a relative change of the elastic modulus and related to micro-crack population via

$$D = 1 - \frac{E}{E(0)} = \frac{\beta}{N_T} \sum_{c \geq 1} c^3 N(c), \tag{1}$$

where c is some measure of micro-crack size, $N(c)$ is the number of micro-cracks of size c, N_T is the total number of sites capable of nucleating micro-cracks, and β is a scaling parameter reported as 0.47π for cracks in a 2D medium. Eq. (1) is our point of comparison for the simulations performed with the lattice model for various tensile loading cases. In the current work we are interested in testing the range of applicability of Eq. (1) and understanding the reasons for deviation from this rule, should such occur, by explicitly analysing the micro-crack population growth.

2. Model and method

2.1. The site-bond model

The lattice model used in this work is illustrated in Fig. 1. The unit cell, shown in Fig. 1(a) is a truncated octahedron – a solid with six square and eight regular hexagonal boundaries. The 3D space can be compactly tessellated using such cells, with each cell representing a material meso-scale feature, e.g. grain, in an average sense. This representation is supported by physical and statistical arguments [12]. A discrete lattice is formed by placing sites at the centres of the cells and connecting each site to its 14 nearest neighbours; example is shown in Fig. 4(b). The lattice contains two types of bonds. Bonds denoted by B_1 are normal to square boundaries and form orthogonal set. For convenience this set is coincident with the global coordinate system and B_1 are referred to as principal bonds. Bonds denoted by B_2 are normal to hexagonal boundaries. The hexagons lie on the octahedral planes with respect to the selected system, hence B_2 are referred to as octahedral bonds.

Figure 1. Lattice illustration: (a) Unit cell showing the site with 14 coordinating bonds: six principal, B_1, and eight octahedral, B_2; (b) Discrete lattice of beam elements.

If the spacing between sites in the principal directions is denoted by L, bonds B_1 have length $L_1 = L$, and bonds B_2 have length $L_2 = \sqrt{3}\ L\ /\ 2$. Presently, the bonds are represented by structural beam elements of circular cross sections, with R_1 and R_2 denoting the radii of beams B_1 and B_2, respectively. The beams are clamped at the lattice sites. The two types of beams have identical modulus of elasticity, E_b, and Poisson's ratio, ν_b. With this setup, it has been previously shown that by calibrating four parameters: R_1 / L, R_2 / L, E_b, and ν_b, the lattice can produce a large class of isotropic elastic materials with Poisson's ratios of practical interest [12]. The reference material in this work is a concrete with $E = 46$ GPa and $\nu = 0.27$, for which the calibration, assuming isotropic elasticity, yields $R_1 / L = 0.2$; $R_2 / L = 0.32$; $E_b = 90$ GPa; and $\nu_b = 0.4$ [14]. The commercial software Abaqus [17] with Euler-Bernoulli beam formulation has been used for the calibration and the analyses reported in this work. The behaviour of the beams is linear elastic.

2.2. Pore distribution and failure criterion

Microstructure data for the reference material was obtained using X-ray Computed Tomography as reported in [14]. The pore size distribution was obtained by segmentation of reconstructed 3D images. The studied regions of interest had dimensions of 1700 x 1200 x 1200 voxels with a voxel size of ca. 15 μm, allowing for a minimum detectable pore radius of ca. 15 μm. The number of pores measured experimentally was $n \approx 41500$. The measured pore radii, c_i, were used to construct a cumulative probability distribution (CPD) with standard median ranking, where for pore radii ordered as $c_1 \leq c_2 \leq \ldots \leq c_n$, the cumulative probability for pores with radii less than c_i is given by $F(c < c_i) = (i - 0.3) / (n + 0.4)$. The CPD for the reference material is shown in Fig. 2(a), where the minimum and maximum pore radii are also depicted. The CPD is used to assign pore sizes to the lattice bonds. For each bond a uniformly distributed random number $0 \leq r < 1$ is generated and the assigned pore radius is calculated from $c = F^{-1}(r)$. This ensures that the distribution of pore sizes in the model comes from the same population as in the experiment. A fragment of the model with distributed pores is given in Fig. 2(b). The cell size, L, is calculated such that the volume of all distributed pores divided by the volume of the cellular structure equals the material porosity, which is ca. 5% for the reference material. The pore sizes shown are to scale with the sketched cellular structure. With respect to the cellular structure pores reside at cell boundaries, i.e. interfaces between grains. The lattice bonds are also depicted (diameters not to scale) in order to show that pores reside at bond centres.

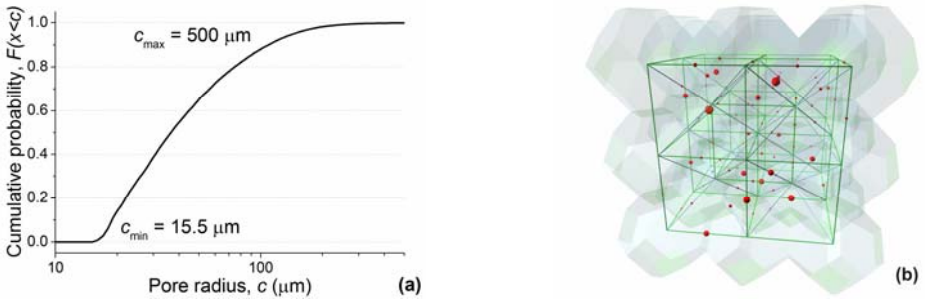

Figure 2. Pore distribution: (a) Cumulative probability of pore radii in the concrete; (b) Segment of model illustrating pores distributed to cell boundaries and corresponding. Pore sizes are to scale with the cell size.

Damage in the lattice model is introduced by removal of bonds. Propensity for bond failure is measured by the parameter

$$\Pi = \frac{N}{N_f} + \frac{|S|}{S_f} + \frac{|T|}{T_f} + \frac{|M|}{M_f}, \tag{2}$$

where N and S are the normal and shear forces in the beam; T and M are the twisting and bending moments; N_f, S_f, T_f, and M_f are critical values. N is positive for tension and negative for compression. S and M are obtained from the values in the two directions normal to the beam axis using the square root of squares rule. Eq. (2) provides an interaction between the different forces that allows for failure when $\Pi \geq 1$ under the combined action of normal and shear stresses [18, 14]. Taking only the first and fourth term was previously used in criteria with no account for shear, e.g. [19]. The second and third term allow for shear failure similarly to [10]. The failure parameters N_f, S_f, T_f, and M_f can be related [18]. For a beam of circular cross section of radius R, the tensile failure stress is $\sigma_f = N_f / (\pi R^2)$. The maximum bending stress is $\sigma_{max} = 4M / (\pi R^3)$, which equals σ_f when $M_f = N_f R / 4$. Similarly, the shear failure stress is $\tau_f = S_f / (\pi R^2)$. The maximum torsion stress is $\tau_{max} = 2T / (\pi R^3)$, which equals τ_f when $T_f = S_f R / 2$. Thus Π requires two material parameters: σ_f and τ_f. Noting that for quasi-brittle materials typically $1 \leq \tau_f / \sigma_f \leq 2$ [18], in this work $\tau_f = 2\sigma_f$ is used, representing more brittle materials.

The tensile failure strength of a bond, σ_f, is related to the size of the pore assigned to the bond. The relation used here is simpler than in the previous work [14] and based on the assumption that σ_f is the beam remote stress for which the average stress in the beam ligament outside the pore attains a critical value σ_0. Thus

$$\sigma_f = \sigma_0 \left[1 - \left(\frac{c}{R} \right)^2 \right], \tag{3}$$

where c and R are the pore and beam radii, respectively, and σ_0 can be interpreted as the tensile strength of the material without a defect. With this setup and the choice $\tau_f = 2\sigma_f$ the failure model requires a calibration of a single parameter, σ_0, against experimental stress-strain curve. However, since the beams behaviour is linear elastic, the choice of σ_0 would affect only the calculated macroscopic stresses but not the order in which damage (beam failures) would evolve in the system. Because the interest here is investigating the evolution of damage, σ_0 = 1 MPa is used for the calculations, noting that macroscopic stress response can be simply scaled by another value of σ_0.

2.3. Load cases and solution

A model of size ($20L$, $20L$, $20L$) was used. The lattice contained 17261 sites and 113260 bonds: 49260 B_1 and 64000 B_2. The coordinate system (X_1, X_2, X_3) was coincident with B_1, so that the boundary planes $X_1 = 0$, $X_1 = 20L$, $X_2 = 0$, $X_2 = 20L$, $X_3 = 0$, $X_3 = 20L$ contained 21×21 sites (nodes). Boundary conditions normal to each plane were only applied. Thus U_i and F_i denote displacements and forces of nodes on plane with normal X_i, while other displacements and rotations on this plane were unconstrained. Table 1 shows the conditions on planes $X_1 = 20L$, $X_2 = 20L$, and $X_3 = 20L$ for the analysed cases. Additionally, $U_1 = 0$ on $X_1 = 0$; $U_2 = 0$ on $X_2 = 0$; $U_3 = 0$ on $X_3 = 0$, apply to all.

Table 1. Boundary conditions for loading cases.
Values given in bold denote applied conditions. A stands for values obtained from finite element analyses.

Case	U_1	U_2	U_3	F_1	F_2	F_3	Note
C1	$\boldsymbol{d_1}$	A	A	A	**0**	**0**	Uniaxial unconfined extension
C2	$\boldsymbol{d_2}$	$\boldsymbol{d_2}$	A	A	A	**0**	Plane stress
C3	$\boldsymbol{d_3}$	$\boldsymbol{d_3}$	**0**	A	A	A	Plane strain
C4	$\boldsymbol{d_4}$	**0**	**0**	A	A	A	Uniaxial confined extension

For cases where nodal reaction forces were determined from analysis, the macroscopic stress in the

respective direction was calculated as the ratio between the total reaction force and the boundary area, i.e. $\sigma_i = \Sigma F_i / 400L^2$. For the cases where nodal displacements were determined from analysis, the macroscopic strain in the respective direction was calculated as the ratio between the average displacement and the model length, i.e. $\varepsilon_i = \Sigma U_i / (21^2 \times 20L)$.

The evolution of damage was simulated by failure of bonds, controlled by an in-house code, and repetitive solution for equilibrium performed by Abaqus with constant applied displacements. The values of $\boldsymbol{d_i}$ were selected so that the strain energy density in the system prior to damage was one for the four cases for the purpose of comparison. At each step the in-house code obtains the forces and moments in all bonds and calculates the propensity for failure, Π, for each bond. The bond with maximum Π is then removed and the updated lattice is solved for equilibrium. This leads to redistribution of forces for the continuous damage evolution. The magnitudes of Π at which consecutive failures occurred can be used to cut-back the applied strain and resulting stress and obtain a macroscopic stress-strain response. The focus of this work is not on determining the stress-strain response, but on the relation between damage and crack population. To this end we define four damage parameters, measuring the relative changes of the hydrostatic stress and the three components of the stress deviator by:

$$D_H = 1 - \frac{\sigma_H}{\sigma_H(0)}; \quad D_i = 1 - \frac{S_i}{S_i(0)}, \quad \textit{where} \quad S_i = \sigma_i - \sigma_H, \, i = 1,2,3 . \tag{4}$$

Note that for isotropic deformation and damage these parameters must be equal and equivalent to the damage parameter defined via relative reduction of Young's modulus or shear modulus.

2.4. Crack population analysis

A bond failure is thought of as a micro-crack nucleation, specifically as a separation between the adjacent cells in the cellular structure along their common face. Initially, the micro-cracks may be dispersed in the model reflecting the random distribution of pore sizes and the low level of interaction due to force redistribution. Interaction and coalescence may follow as the population of micro-cracks increases. The structure of the failed surface can be represented with a mathematical graph, where graph nodes represent failed faces and graph edges exist between failed faces with common triple line in the cellular structure, i.e. where two micro-cracks formed a continuous larger crack. Generally, the graph of a failed surface is a disconnected set of sub-graphs or components, some of which could be single nodes as at the start of damage evolution, while others could be connected sets representing larger micro-cracks as the coalescence develops. For the analysis, nodes are equipped with weights equal to the failed face areas. Edges are equipped with weights equal to the shortest path along connected faces between their centres.

The components of a failed surface graph are sorted into sets according to their areas $A_1 < A_2 \ldots < A_k$, so that each set contains N_i disconnected components of area A_i. The linear size of a component is approximated with the square root of its area so that the moment of the crack population is formed using (compare to Eq. (1))

$$M = \frac{1}{A_T} \sum_{i=1}^{k} A_i^{3/2} N_i , \tag{5}$$

where A_T is the total area of the faces in the cellular structure. This can in principle be replaced with a linear measure to conform to Eq. (1). A realistic choice is to use the component diameter which is the maximal shortest path between component's nodes calculated with the weighted edges. The process, however, is computationally expensive and does not lead to noticeable changes in the

results for the cases analysed here. Eq. (5) is used after each failure event to calculate the evolution of the moment with damage. In addition, the maximal component is monitored. This is the largest connected cracked surface.

3. Results and discussion

Figure 3 shows the results of the evolution of the damage parameters defined by Eq. (4) as functions of the moment of crack population defined by Eq. (5). Recall that a damage parameter, based on the relative change of the Young's modulus equals the damage parameters based on the individual stress components, deviatoric and hydrostatic, when the material remains macroscopically isotropic. In this case the same damage parameter describes the relative change of the shear modulus. The results for the cases of uniaxial extension, unconfined (a) and confined (d), show equality of the four damage parameters (approximate in case 4). This suggests that microscopic isotropy is maintained during damage evolution and the results reproduce very closely the linear relation predicted by the theory and given by Eq. (1). Interestingly, an estimate for the slope of the linear function from the figures is about 1.5, which is very close to the value of β reported in relation to Eq. (1).

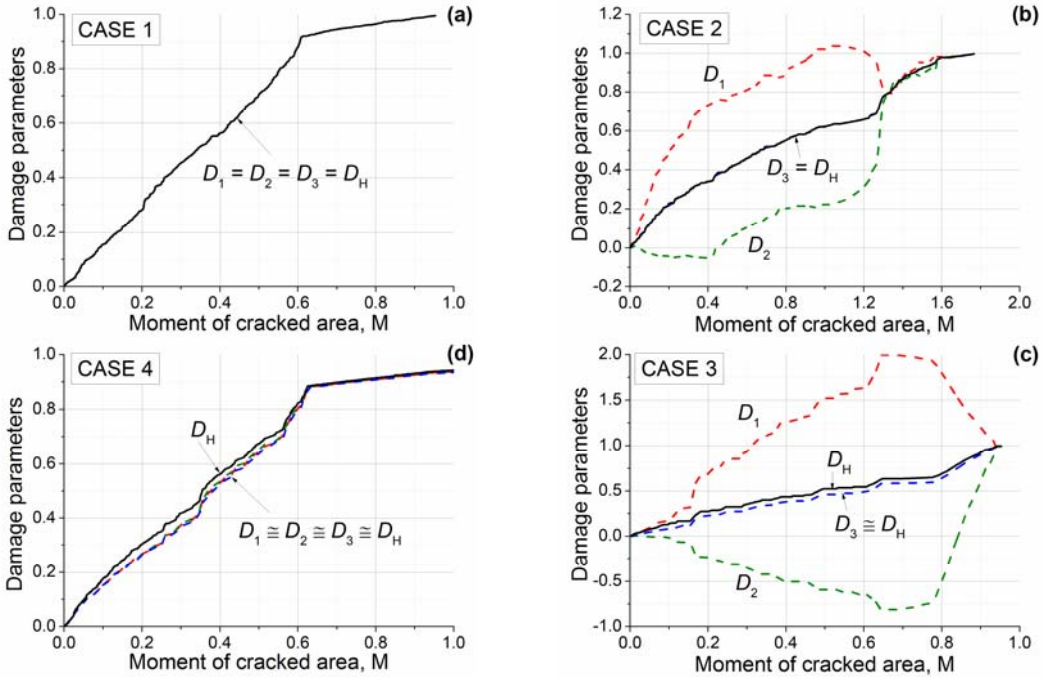

Figure 3. Damage parameters relation to crack population moment.

In the cases of plane stress (b) and plain strain (c), however, the development of damage is radically different, illustrating the development of damage-induced anisotropy. In this case the damage parameter D_i represents the relative reduction of the longitudinal shear modulus in direction X_i. Note that this is not the shear modulus relating shear stress to shear strain. In both plane cases, the evolution of D_1 suggest that the system undergoes transition into negative longitudinal shear resistance, quite more pronounces in the plane strain case (c), while the shear resistance in direction X_2 increases from its initial value. This behaviour may seem unusual, but it is not impossible for anisotropic materials. The bounds for Poisson's ratios in such materials calculated in [20, 21] allow for negative longitudinal shear moduli with the values recorded here. The results merely show that extreme anisotropy has been developed in the material with the evolution of micro-crack population under the two plane cases. The development of the hydrostatic damage is also affected in these cases, as it cannot be described as a linear function of the cracked area moment.

To understand what causes the anisotropy in the plane cases the structure of the crack population needs to be studied in more detail. This requires a single damage parameter; an appropriate choice is the relative reduction of the strain energy density in the system, $D = 1 - W / W(0)$, which is found to be approximately equal to the damage parameter defined via the relative reduction of the hydrostatic stress in all cases, see Fig. 4(a). The development of the maximal graph component, i.e. the main crack, with damage is shown in Fig. 4(b) with the ratio between the area of the maximal component, A_m, to the total cracked area, A. It is clear that the main crack becomes dominant very early in the development of damage (at damage less than 1%) and its relative area grows nearly exponentially for all cases. It seems therefore sufficient to examine the structure of the maximal component as the damage develops.

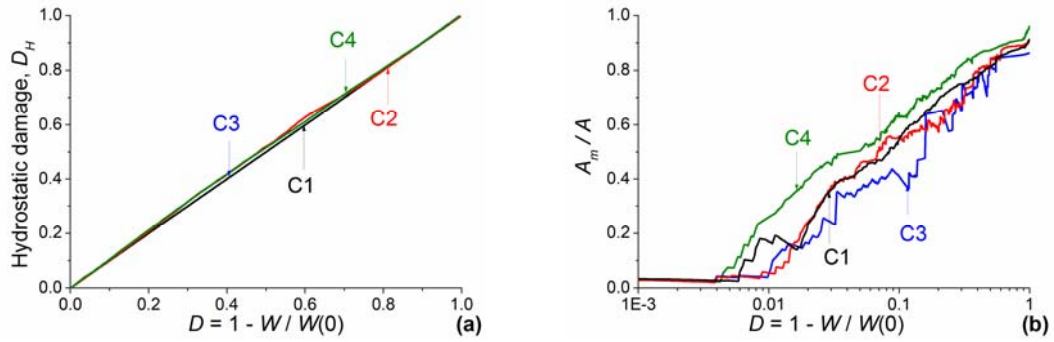

Figure 4. Hydrostatic damage (a) and relative area of main crack (b) development with damage defined as relative reduction of strain energy density.

Figure 5 shows the development of the maximal component area, split into the areas of surfaces normal to the three principal axes, A_1, A_2, A_3, and the surfaces formed on octahedral planes, A_4. All areas are normalised with the total areas of the corresponding boundaries in the cellular structure. In the cases of uniaxial extension, unconfined (a) and confined (d), the development of the main crack involves creation of surfaces normal to the applied load and on octahedral planes. Although there is a difference between the two cases in the rates of creation of normal and octahedral surfaces, the overall balance results in isotropic damage, see Fig. 3(a),(d).

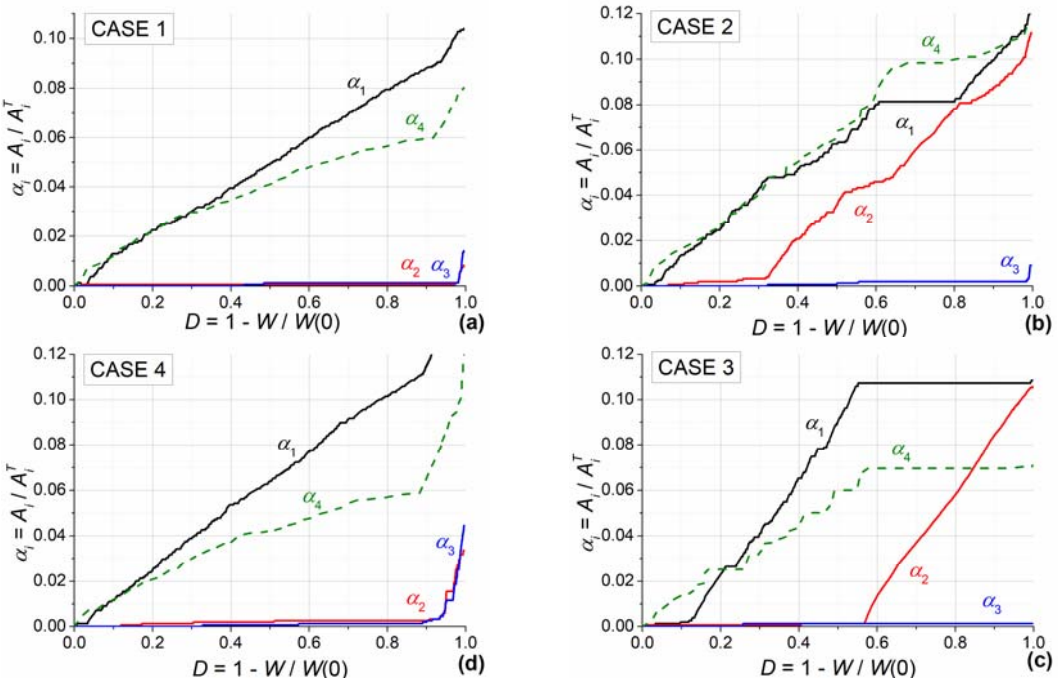

Figure 5. Structure of maximal graph component with damage.

In the plane stress (b) and plane strain (c) cases, the development of the main crack follows very different patterns. The parallel increase of normal to the first loading axis and octahedral surfaces in plane stress, Fig. 5(b), seems to be responsible for the immediate development of damage-induced anisotropy, which after that appears to be moderated by the development of surfaces normal to the second loading axis. The constraint in plane strain, Fig. 5(c), leads to a delayed but rapid increase of surfaces normal to the first loading axis together with a lower rate of creation of octahedral surfaces. This appears to delay substantially the development of cracked surfaces normal to the second loading axis and results in significantly higher anisotropy.

It should be noted that the structure-damage relations reported here were found qualitatively independent of the random assignment of pores in the lattice model as well as of the shape parameter of the pore distribution. This has been confirmed by a number of simulations with different shape of distribution and random assignments. One parameter that may affect the outcomes is the shear to normal strength ratio; this is a subject of ongoing work. It is further understood that the outcomes reported here are principally related to the selected lattice connectivity. However, the detail to which the surface topography can be studied is higher than the detail allowed by models based on cubic lattices. One unknown in the analysis is whether the crack development in the lattice is energetically equivalent to the development of continuum cracks. This question remains to be addressed in a future work. The current observations suggest that a common, constraint independent, damage evolution law might not be feasible to achieve. In such case it seems that a lattice-based analysis might be necessary as a sub-modelling approach to inform the behaviour of finite elements in a continuum model.

The last question of interest in this work is related to the use of the weakest-link statistics for global failure predictions. It was suggested in [16] that weakest-link should be applied to the population of micro-cracks in the system. However, from the simulations performed here it is evident that a single crack, the maximal connected component of the cracked surface, becomes rapidly dominating the behaviour, Fig. 4(b), with few much smaller components disconnected from the main crack. This does not allow for invoking the weakest-link as a descriptor of final failure.

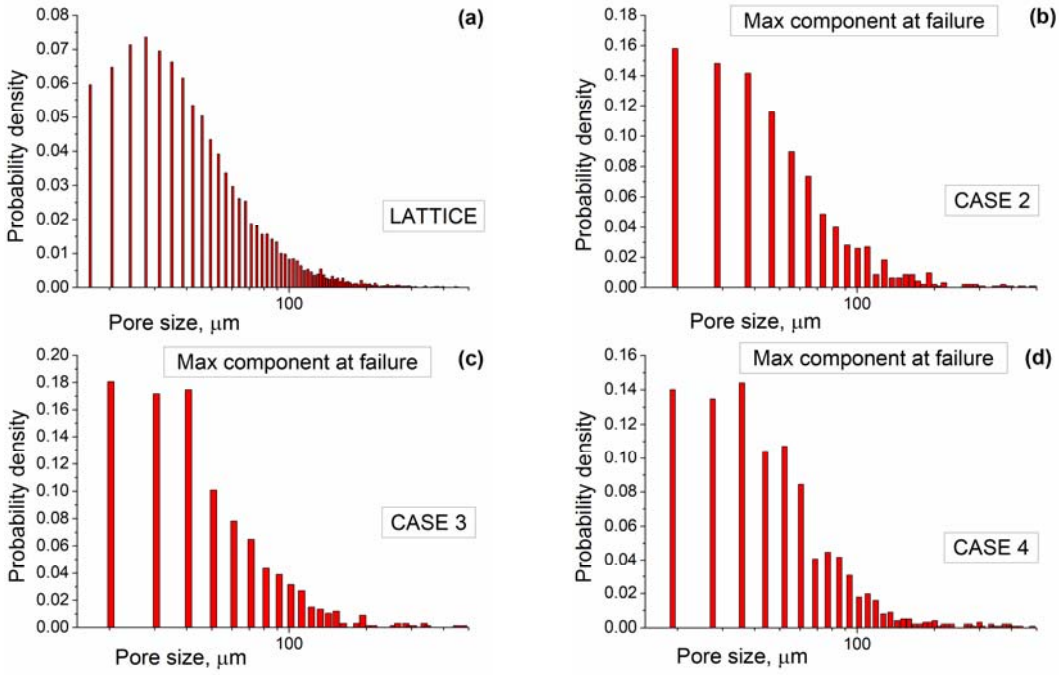

Figure 6. Probability density of pore sizes in the lattice (a) and in the maximal component at failure for three loading cases (b)-(d). Results obtain with the same distribution given by (a).

Another approach would be to base the weakest-link statistics on the microstructure information, in this case the size distribution of crack-initiation features, the pores. This is similar to the approach used in the modelling of cleavage fracture, where second-phase particles are considered to be cleavage initiators. In order to show whether this is a realistic approach, a comparison is made between the probability density of pore sizes distributed in the lattice and pore sizes contained in the maximal component at failure. The results are shown in Fig. 6 for the pores in the entire lattice (a) and three of the loading cases as depicted. The results shown correspond to one and the same random assignment of pore sizes. Evidently, the probability density of the pores belonging to the final fracture surface is different from the lattice distribution and depends on the loading mode. While the initial damage may start at one and the same location in the system, the nature of loading develops the main crack in different ways and the final failure cannot be described as a weakest-link event using the statistics of the sizes of the failure initiation sites. This makes it difficult to derive a load-independent, purely micro-structure based relation between the macroscopic damage and the probability of failure. The outcome supports further the suggestion that macroscopic failure analysis needs to be performed with an underlying lattice-based analysis of local micro-crack propagation.

4. Conclusions

- A microstructure-informed strategy for analysis of damage evolution in quasi-brittle materials was presented, whereas damage results from the formation, growth and interaction of a population of micro-cracks.
- It was demonstrated that in cases of non-uniaxial extension, such as plane stress or plane strain found ahead of a main crack, the micro-crack population development was responsible for elastic anisotropy with extreme variations of longitudinal shear moduli.
- It was shown that the damage-induced anisotropy was a complex function of the crack population structure. A load-independent damage evolution law might not be achievable and explicit analysis of crack population development, e.g. using a lattice model, might be necessary to complement continuum finite element analysis of failure.
- It was shown that the maximal connected component of the crack population, i.e. the largest crack, became dominant very early in the process of macroscopic damage and controlled the ultimate failure. The analysis if this component suggested that the global failure could not be treated as a weakest-link event.
- The graph-theoretical approach to the analysis of micro-crack populations showed significant potential to reveal the underlying topological structure of the cracked surface. Further work is required to link the topological structure to a measure for global probability of failure.

Abstract Generalized continuum theories such as couple stress theory have the potential to improve our understanding of material deformation and fracture behaviour in areas where classical continuum theory breaks down at, for example, the length scale of meso-scale features within the fracture process zone. The couple stress theory considers not only relative displacements between these features but also relative rotations, introducing a natural length scale. A model has been developed of a low stiffness matrix containing suitably situated high stiffness particles to simulate the presence of defects at the meso-scale. This has been used to assess the descriptive potential of a novel consistent couple stress theory. The model has been subjected to a set of displacement fields selected to produce strain energies with varying contributions from the coupled stresses. The results demonstrate the effect of particle size to spacing ratio on the elastic energies. These can be used to evaluate the couple stress constant as well as validate the constant experimentally for specific materials.

Keywords: generalized continuum; meso-scale defects; FE analysis; strain-curvature energy; size effect

1. Introduction

Analysis of materials at engineering length scales is based upon assumptions of classical continuum behaviour. This is adequate for most macro-scale analyses but, when considering smaller length scales where cracks, notches and defects introduce stress concentrations, the material microstructure is known to have a significant impact on material behaviour [1]. Local approaches, which incorporate mechanistic understanding of material failure behaviour at the length scale of their relevant features, are beneficial for linking microstructures to macroscopic responses [2]. However, the widely used weakest link (WL) assumption has been challenged as a realistic method of modelling size effects in cleavage [3] and quasi-brittle fracture [4] as a result of failing to account for the interaction processes during failure.

Discrete methods have shown promise for modelling materials undergoing such fracture. Lattice models consist of nodes connected into a lattice via springs [5], beams [6] or other discrete elements with the properties of these connections allowing a micro structurally informed response. Lattice modelling differs in principle from previous local approach models by using a statistically parallel system, where loads are redistributed upon the breaking of a single bond, rather than the ultimate failure seen in WL systems. This is considered to be a closer representation of the interaction and coalescence of micro-cracks and flaws, which characterize quasi-brittle materials such as graphite [7] and cement-based materials [8]. The work presented here explores aspects of the site-bond model developed by Jivkov and Yates [9] and used for studies of damage evolution from distributed porosity in cements [10]. Work on this model has shown that evaluating the stiffness coefficients of the bonds using strain energy equivalence between the discrete model and a classical continuum creates an indeterminate problem. Use of a generalized continuum theory, such as couple stress theory, offers a possible solution to this indeterminacy.

In couple stress theory (CST) each point within the continuum has three additional degrees of freedom, point rotations. These are associated with couple stresses as the classical (force) stresses are associated with strains. A general CST was proposed early in the 20th century by the Cosserat brothers [11]. It went largely unnoticed until the 1960s when a desire to understand the mechanisms behind micro-crack growth for more accurate crack assessment rejuvenated interest. One branch of CSTs considers point micro-rotations to be independent of the macro-rotations; the rotations derived from the displacement gradient [12, 13]. These are known as micropolar theories or Cosserat models with free rotations [14]. While such a view appears to be well suited for use with discrete lattice methods, it is difficult to establish a link between a continuum and a discrete representation of a material containing features that are following the deformations of the bulk. For such situations it is more plausible to assume that the micro-rotations are equal to the macro-rotation. This assumption led to a branch of CSTs known as Cosserat models with constrained rotations [14, 15]. Initially, these were based on couple stresses work-conjugate to the macro-rotation gradient. As a consequence, the spherical part of the couple stress tensor remained undetermined. Recently, Hadjesfandiari and Dargush [16] proposed a consistent CST using true kinematic quantities to remove the indeterminacy of the couple stress tensor.

The consistent CST [16] naturally introduces a length parameter. This is of key importance for the local material behaviour. But the calibration of the CST requires that the length parameter is physically related to the material microstructure; the sizes and distances between characteristic features that disturb the symmetry of the stresses. We report on work in progress investigating whether a medium with features can be used to calculate bond responses to bending and torsion in the discrete model [9] and if this can be used to calibrate the consistent CST.

2. Theory and model

2.1 Generalised continuum

The kinematics of a material point under small deformation is given by the displacement gradient, Eq. (1), where comma denotes differentiation, rounded parenthesis denotes symmetric part and square parenthesis denotes skew symmetric part of the tensor. The symmetric (strain tensor e_{ij}) and the skew symmetric (rotation tensor ω_{ij}) parts are given by Eq. (2) and Eq. (3), respectively. The right hand side of Eq. **Error! Reference source not found.** gives the rotation tensor as a vector using the permutation tensor.

$$u_{i,j} = u_{(i,j)} + u_{[i,j]} \tag{1}$$

$$u_{(i,j)} = e_{ij} = \frac{1}{2}\left(u_{i,j} + u_{j,i}\right) \tag{2}$$

$$u_{[i,j]} = \omega_{ij} = \frac{1}{2}\left(u_{i,j} - u_{j,i}\right) = \epsilon_{jik}\omega_k \tag{3}$$

In classical continuum mechanics, the elastic potential depends solely on the strain tensor. In generalised continuum, additional potential is carried by the gradient of the rotation vector, Eq. (4). The symmetric part of this gradient, χ_{ij} in Eq. (5), represent “pure” twists, and the skew symmetric part, κ_{ij} in Eq. (6), represent “pure” curvatures, which can be given by a vector as shown with the right-hand size.

$$\omega_{i,j} = \omega_{(i,j)} + \omega_{[i,j]} \tag{4}$$

$$\omega_{(i,j)} = \chi_{ij} = \frac{1}{2}\left(\omega_{i,j} + \omega_{j,i}\right) \tag{5}$$

$$\omega_{[i,j]} = \kappa_{ij} = \frac{1}{2}\left(\omega_{i,j} - \omega_{j,i}\right) = \epsilon_{jik}\kappa_k \tag{6}$$

Generally, the energy potential of the rotation gradient leads to a non-symmetric force stress tensor, σ_{ji}, Eq. (7), and the introduction of a couple stress tensor, μ_{ji}, Eq. (8). When the force stress is taken as work conjugate to the strain tensor, and the couple stress is taken as work conjugate to the gradient of the rotation, the symmetric part of the couple stress tensor becomes indeterminate.

$$\sigma_{ji} = \sigma_{(ji)} + \sigma_{[ji]} \tag{7}$$

$$\mu_{ji} = \mu_{(ji)} + \mu_{[ji]} \tag{8}$$

Hadjesfandiari and Dargush [16] suggested a solution to this problem by demonstrating that the entire rotation gradient does not have energy potential, only the curvature tensor, Eq. (6). Thus the deformation energy consists of the work done by the force stress on the strain and the work done by the couple stress on the pure curvature. The symmetric part of the rotation gradient, Eq. (5), has no forces associated with it, which solves the problem of the indeterminate spherical part of the rotation gradient. For an isotropic material, the elastic potential is given by [16]:

$$W(\varepsilon,\kappa) = \frac{1}{2}\lambda\,(\varepsilon_{kk})^2 + \mu\,\varepsilon_{ij}\varepsilon_{ij} + 8\eta\,\kappa_i\kappa_i \tag{9}$$

where λ and μ are Lamé parameters and η is a material couple stress constant.

According to this theory, a homogeneous displacement field, such as hydrostatic compression Eq. (10), does not introduce rotations and hence curvatures.

$$u_1 = x_1 \qquad u_2 = x_2 \qquad u_3 = x_3 \tag{10}$$

A displacement field producing pure twist, Eq. (11), introduces rotations, Eq. (12), but no true curvatures[16]:

$$u_1 = -\theta x_2 x_3 \qquad u_2 = \theta x_1 x_3 \qquad u_3 = 0 \tag{11}$$

$$\omega_1 = -\frac{1}{2}\theta x_1 \qquad \omega_2 = -\frac{1}{2}\theta x_2 \qquad \omega_3 = \theta x_3 \tag{12}$$

A displacement field corresponding to pure bending of a beam, Eq. (13), introduces non-zero rotations, Eq. (14), that result in a single non-zero curvature, Eq. (15), [16]:

$$u_1 = -\frac{1}{R}x_1 x_3 \qquad u_2 = -\frac{\nu}{R}x_2 x_3 \qquad u_3 = \frac{\nu}{2R}\left({x_2}^2 - {x_3}^2\right) - \frac{1}{2R}{x_1}^2 \tag{13}$$

$$\omega_1 = \frac{\nu x_2}{R} \qquad \omega_2 = \frac{x_1}{R} \tag{14}$$

$$\kappa_3 = \frac{1-\nu}{2R} \tag{15}$$

where ν is Poisson's ratio and R is the radius of curvature of the beam central axis.

2.2 Discrete site-bond model

The site-bond model [9] uses a discrete lattice, based on a regular tessellation of material space into truncated octahedral cells, Fig. 1(a). The lattice derives from the cellular structure when material particles, attached to cell centres, interact via deformable bonds. The bond properties relate to their ability to transfer shear and axial forces as well as torsion and bending moments to satisfy the six degrees of freedom of each site. A site requires 14 bonds to connect it to its neighbours, Fig. 1(b): six bonds of length $2L$ ($2L$ is the cell size) in principal directions (through square faces), and eight bonds of length $\sqrt{3}L$ in octahedral directions (through hexagonal faces). Development of this model involves bond representations with six independent elastic springs resisting three relative

displacements and three relative rotations between sites. This yields four spring types with axial, K_n, shear, K_s, twisting, K_t, and bending, K_b, stiffness [17], which could, in general, be different for principal and octahedral directions.

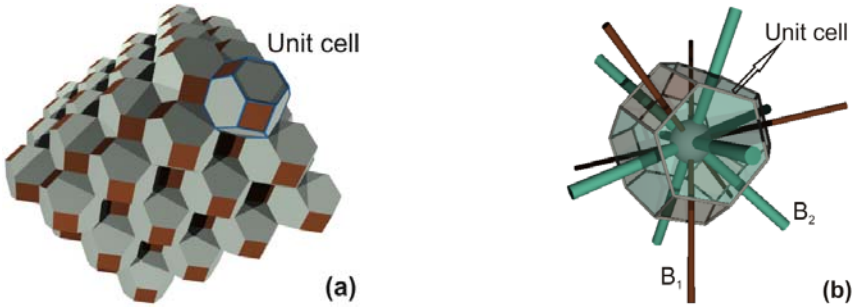

Figure 1. Cellular representation of material (a); and unit cell with bonds (b).

2.3 FE model of elastic continuum with rigid particles

For our investigation, we use a finite element model of a cube of an elastic material surrounding a truncated octahedral cell of size $2L$. The material has a unit modulus of elasticity and Poisson's ratio $\nu = 0.375$. Rigid cubic particles are introduced in the cube, so that one particle, P0, is positioned in the centre of the cell, while others are positioned outside the cell in the principal and octahedral directions as shown in Fig. 2. Three different loading conditions are used: (H) hydrostatic compression; (T) pure twist; and (B) pure bending. These are applied via displacement fields on the cube surfaces; examples for pure twist and pure bending are given in Fig. 3. In all cases we calculate elastic energies, Ω, within the unit cell surrounding the central particle. With no particles present, the cell elastic energy is given by the classical continuum solution, since no features exist to disturb stress symmetry. The displacement magnitudes for the three loading cases are selected so that Ω without particles is the same, Ω_0.

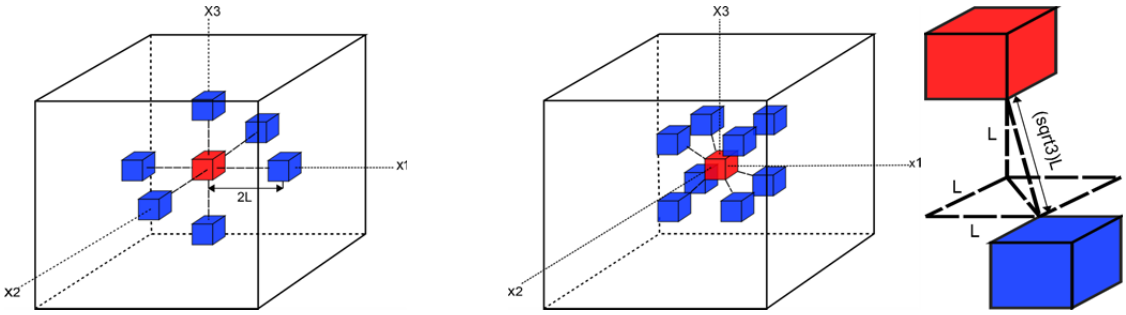

Figure 2. Particle additions in the principal (left) and octahedral (right) directions.

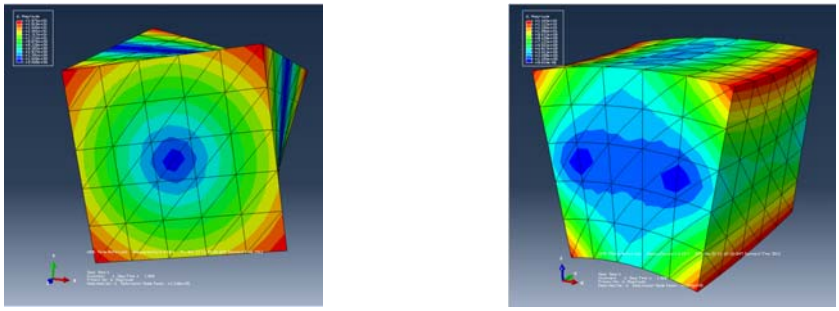

Figure 3. Displacement maps for the loading cases of pure twist (left) and pure bending (right).

To link the cell energies to kinematic quantities we calculate particle translations and rotations using three unit vectors, $\mathbf{n}_1$, $\mathbf{n}_2$ and $\mathbf{n}_3$ normal to three orthogonal faces of a particle, see Fig. 4. After deformation these vectors remain orthogonal as the particles are rigid, given with $\mathbf{t}_1$, $\mathbf{t}_2$ and $\mathbf{t}_3$ in Fig. 4. The coordinates of these, arranged in columns, form the transformation matrix, $\mathbf{T}$, for the particle. The particle motion can be represented by a single rotation, θ given by Eq. (16), around a normalized axis, α given by Eq. (17). The components of the rotation vector for a particle are calculated by Eq. (18). The relative rotations between central and any other particle are expressed in the coordinate system defined by the particular pair using the corresponding transformation.

$$\theta = cos^{-1}\left(\frac{trace\,(\mathbf{T})-1}{2}\right) \tag{16}$$

$$\alpha = \frac{1}{2\sin(\theta)}\begin{bmatrix} T_{32}-T_{23} \\ T_{13}-T_{31} \\ T_{21}-T_{12} \end{bmatrix} \tag{17}$$

$$\omega_i = \theta \times \alpha_i, \quad i = 1,2,3 \tag{18}$$

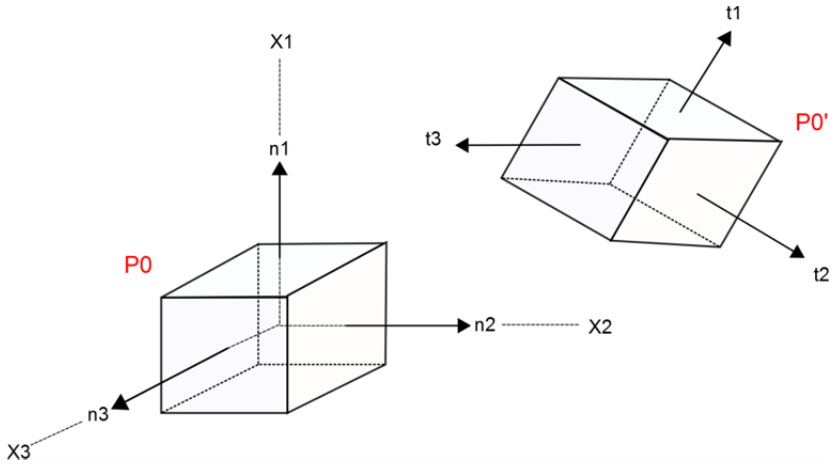

Figure 4. Orthogonal vectors, ($\mathbf{n}_1$, $\mathbf{n}_2$, $\mathbf{n}_3$) and ($\mathbf{t}_1$, $\mathbf{t}_2$, $\mathbf{t}_3$) describing the orientation of P0 before and after deformation respectively.

3. Results and Discussion

For the particle arrangement used (a central particle and all 14 particles of the site-bond model) we have used four different particle sizes relative to the cell size in order to investigate the effect of cell to particle size ratio, λ. The ratios are 3 (large particles), 4, 6, and 12 (small particles).

In the case of hydrostatic loading no rotations of particles were observed and the relative displacements between P0 and any principal or octahedral particle were only axial, conforming to Eq. (10). In the site-bond model these relative displacements should be resisted by axial springs with stiffness coefficients K_n^p and K_n^o, respectively. The relative axial displacements were found independent of λ, scaling with the applied displacements. The cell energies were found to be dependent on λ, as shown in Figure . For small particles, λ = 12, the cell energy approached Ω_0; the presence of particles has negligible effect. The cell energy and displacements from this case can be used to calibrate a linear combination of K_n^p and K_n^o. Note, that in general this case is not sufficient for calibrating stiffness coefficients separately. However, the particle size effect appears to be very

small, suggesting that the two stiffness coefficients could be assumed equal and given from the continuum solution, following [17] for example.

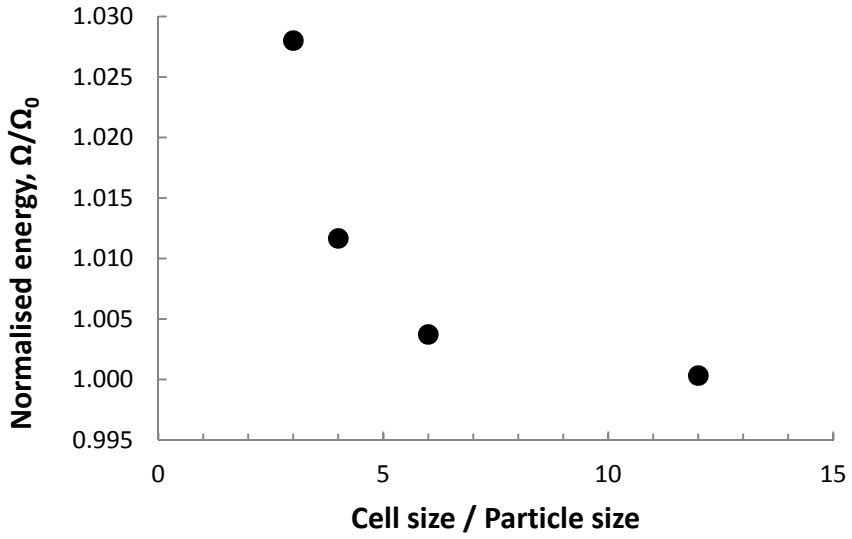

Figure 5. Normalised cell energy vs size ratio under hydrostatic compression.

In the case of pure twist the cell energies were found to be dependent on λ, Fig. 6. While this is similar to the case of hydrostatic compression the effect of particle size is substantially larger. All relative displacements between P0 and the principal particles were zero, conforming to Eq. (11). The relative displacements between P0 and octahedral particles were zero axial and non-zero transversal, again conforming to Eq. (11). This means that the only activated linear springs in the site-bond model are the shear springs in octahedral direction with stiffness K_s^o.

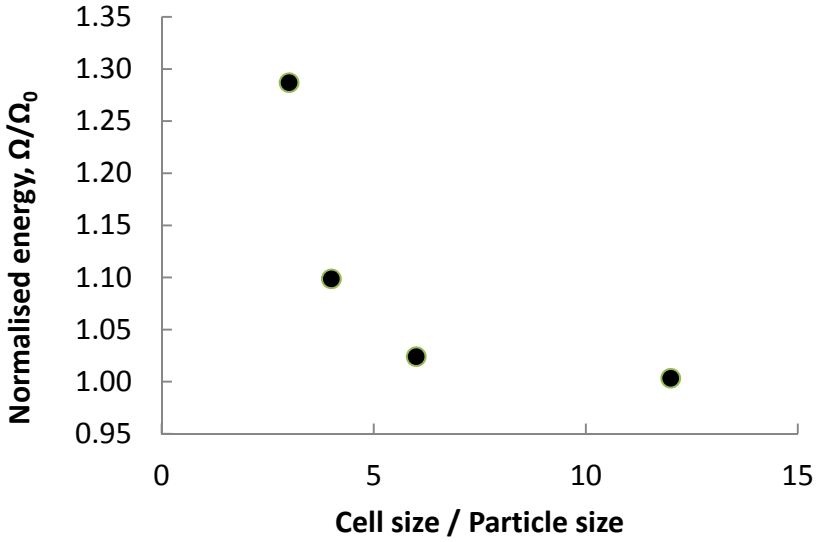

Figure 6. Normalised cell energy vs size ratio under pure twist

The calculated relative rotations between P0 and the particles in the two directions are shown in Fig.

7. The non-zero relative rotations between P0 and principal particles were twists as expected from Eq. (12) and the magnitude shown in Fig. 7 is the twist of the particle in direction X1. It is seen that this is 3-4 orders of magnitude smaller that the relative rotations between P0 and octahedral particles. The latter were found to be bend-type rotations only, conforming to Eq. (12), and suggesting that the only moment springs activated are the bending springs in the octahedral direction with stiffness K_b^o. The magnitudes of the bend-rotations of octahedral particles were found nearly independent of particle size. These results suggest that for the case of pure twist, the elastic strain energy is accumulated in the shear and bending springs in the octahedral direction only, and one can calibrate a linear combination of K_s^o and K_b^o, which should depend on the cell to particle size ratio. From this perspective the results support the analytical derivations in [16], where pure twists do not contribute to the elastic energy. From here, it can be speculated that the torsion springs in the principal directions could be omitted from the site-bond model, i.e. $K_t^p = 0$. This should be supported by considering other cases with curvature-free displacement fields which introduce twists of principal particles according to the theory.

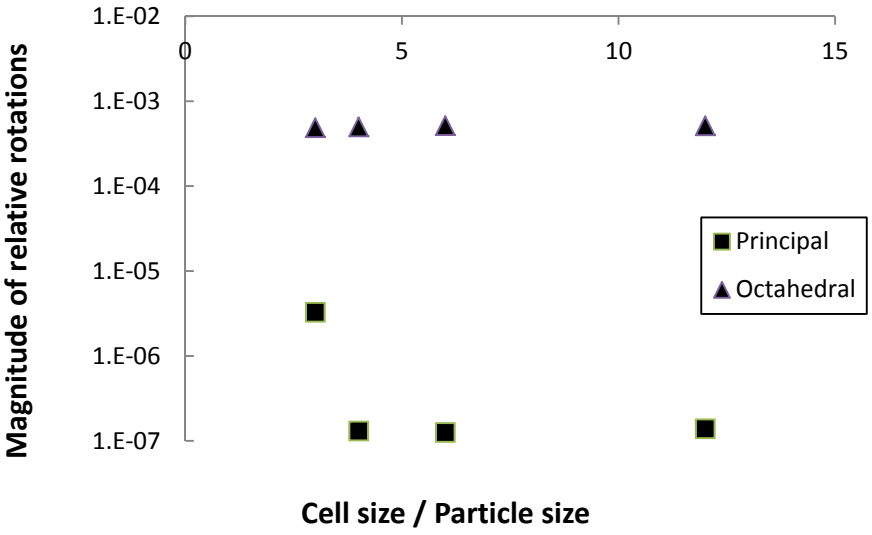

Figure 7. Relative rotation vs size ratio under pure twist

The cell energy dependence on λ for the case of pure bending is shown in Fig. 8. The effect of particle size is smaller than in the case of pure twist, but not negligible. The relative displacements between P0 and the octahedral particles were non-zero axial and tangential, conforming to Eq. (13). The relative displacements between P0 and the principal particles also conform to theory with non-zero axial for particles in X2, non-zero tangential for particles in X1 and zero displacements of particles in X3. This means that the activated linear springs in the site-bond model would be axial and shear springs in all octahedral directions with stiffness coefficients K_n^o and K_s^o, and axial and shear springs in two principal directions with stiffness coefficients K_n^p and K_s^p.

The calculated relative rotations of the particles are shown in Fig. 9. The only non-zero relative rotation of principal particles was found to be the bend-type rotation of the particles in X1, conforming to Eq. (14). However, this relative rotation was found at least an order of magnitude

smaller than the magnitude of the relative rotation between P0 and octahedral particles. The latter contains twist and bend components, suggesting an activation of both the torsion and bending springs in the octahedral direction with stiffness coefficients K_t^o and K_b^o. The much smaller rotation of the principal particles can be used to approximate the kinematics and assume zero rotation of principal particles. Thus the elastic energy is taken by the linear springs in all directions and the torsion and bending spring in the octahedral direction, allowing for calibration of a linear combination of K_n^o, K_s^p, K_n^o, K_s^o, K_t^o and K_b^o, which should depend on the cell to particle size ratio. As in the case of pure twist it can be speculated that the bending springs in the principal direction can be omitted, i.e. $K_b^p = 0$, but this needs to be supported by considering other displacement fields introducing bend-type rotations of principal particles. It can be further speculated, that the torsion stiffness in the octahedral direction should be zero, i.e. $K_t^o = 0$. This could be deduced from the theoretical requirement that pure twists have no energy potential, but requires further investigation. If these were shown to be true, the bending case would provide a calibration for the linear combination of K_n^o, K_s^p, K_n^o, K_s^o, K_b^o.

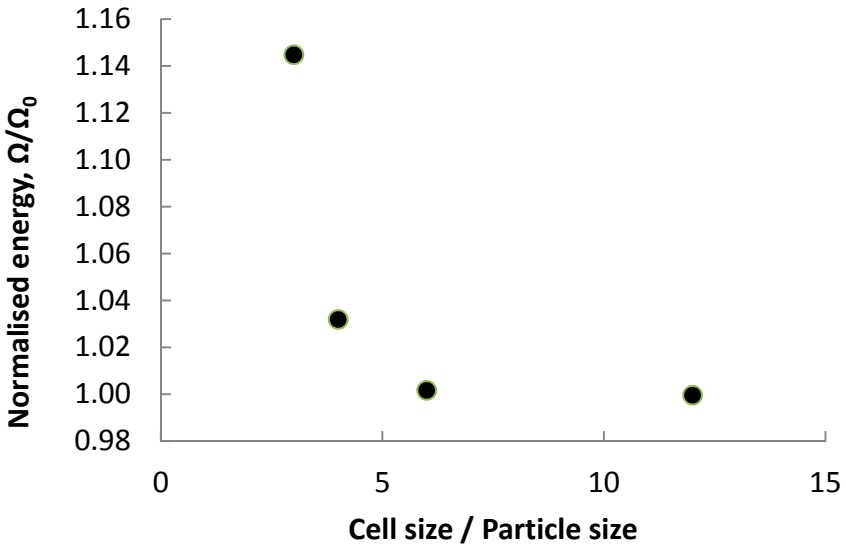

Figure 8 . Normalised cell energy vs size ratio under pure bending

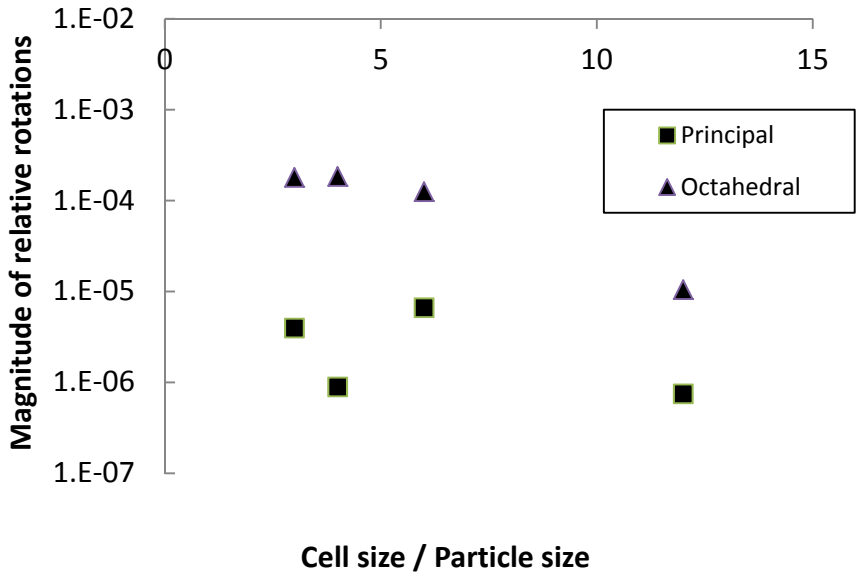

Figure 9. Relative rotation vs size ratio under pure bending

From the three cases considered in this work, it is clear that a separation between all required stiffness coefficients is not possible. However, there is a good indication that the site-bond model should not contain torsion springs and possibly bending springs in the principal directions. One way to check this is pure twist along the octahedral axis, which theoretically should provide twist and bend rotations of all particles. If this proves to be the case, the elastic energy of the continuum with features should be taken by the deformations of the remaining springs. Additional loading cases are necessary to determine the stiffness coefficients of these springs. If these are determined from curvature-free loading cases alone, a good strategy for the calculation of the coupled-stress constant can be proposed. The site-bond model with constants calibrated from curvature-free loading cases can be subjected to a case introducing curvature energy according to theory, for example pure bending, and any excess of energy between the site-bond model and classical continuum should be attributed to curvature energy.

4. Conclusions

- We have proposed a methodology for calibrating the spring constants of a special lattice model using a micromechanical model of a material containing features.
- The comparison of the results with the consistent couple-stress theory suggests that some of the possible moment springs in the lattice could be omitted, reducing the complexity and increasing the correspondence between continuum couple-stress theory and discrete representation.
- We have demonstrated that in all loading cases considered there is an effect of the distance to size ratio of the features, which must be taken into account when calibrating the constants. This suggests that actual microstructure data needs to be used for calibrating the site-bond model.
- The loading cases considered were not sufficient for complete determination of the spring constants of the discrete model. Further work is necessary with loading cases that provide different linear combinations of activated springs' kinematics.

- There is the potential that the lattice model, if fully calibrated with curvature-free loading cases, can provide a means of determining the couple-stress constant for a material with given microstructure properties such as average particle size and distance.

Abstract The virtual crack closure technique is applied to the calculation of stress intensity factor (SIF) in the framework of meshless Shepard interpolation method (MSIM). In the MSIM interpolation, the Shepard shape functions are used for the partition of unity and the local cover functions are separately constructed for the nodes on the boundary and inside the domain. There are three desirable properties in the MSIM including the completeness property, the delta property which lead to easy boundary treat and the low computational expense of the shape function. In the virtual crack closure technique, the assistant finite element mesh is added beside the crack tips, and the SIFs are calculated naturally and effectively near the tips by using the MSIM. Numerical result for a star-shaped crack in a square plate is reported to demonstrate the correctness and robust of the present method.

Keywords Meshless Shepard interpolation method, Partition of unity method, Virtual crack closure technique, Stress intensity factor

1. Introduction

Calculating of parameters such as stress intensity factor, J integral and strain energy release rate are always highly important but not well addressed in fracture mechanics, and lots of efforts have been devoted by the researchers and engineers in recent years. Analytic solutions for some particular structural components have been proposed and expressed as functions, line graft or tables, which can be referred in some handbooks compiled for the engineers [1-3]. However, the limited number of analytic solutions is far from the satisfaction of the need in the real world. The numerical calculations for the parameters in fracture mechanics become necessary in term of the realistic when considering the dramatically development of the hardware and software of computers [4-9].

J integral was proposed by Rice in 1969 and was introduced into the element free Galerkin method by Brighenti [7]. This method is attractive for the calculation of SIF because of its completeness of theory, high accuracy and path-independent integration. But the inappropriate determination of the radius of the integration circle may degrade the accuracy of J integral when dealing with problems involving short crack segment such as broken cracks and crack tips near the boundaries.

Virtual crack closure technique (VCCT) requires only 2 parameters (the nodal force and displacement near the crack tip) which can be obtained naturally in the FEM method to evaluate the SIF and, besides, the calculation results are often reliable and not effected by the small length of crack tips. Consequently, it is paid increasingly more attention by the researchers. However, at present, the VCCT is always carried out in the framework of the FEM, which is unavoidably encountered with the mesh refinement. More details about VCCT can refer to [10].

To alleviate this drawback, the meshless Shepard interpolation method (MSIM) [11] is used to model the discontinuous stress field near the crack and stress singularity near the crack tips and then, the stress and displacement results are used by the VCCT to evaluate the SIF. The time consuming remeshing process is unnecessary in this method and makes the simulation much more reliable and possessing high accuracy. Details of meshless simulation of discontinuous model and the determination of the SIF are provided. In the end, the method described here is used to analyze a square plate with a star-shape crack. The results obtained by the present method are compared with

reference solutions available showing the implementation effectively to model the discontinuous and to evaluate the SIF.

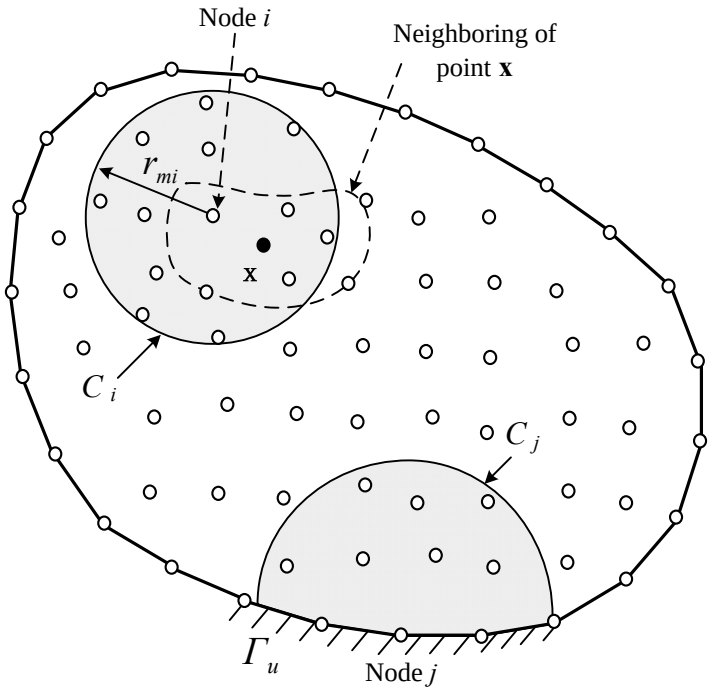

Figure 1. Discrete model of domain Ω

2. The PU-based meshless Shepard interpolation

Consider a two-dimensional domain Ω, and let Ω be discretized by N scattered nodes as shown in Fig. 1. For each node i, a circle cover (subdomain)

$$C_i = \{\mathbf{x} \in \Omega : \|\mathbf{x} - \mathbf{x_i}\| \le r_{mi}\}, \quad (1)$$

is attached. Here, r_{mi} is the radius of the cover C_i. The displacements associated with the node i are denoted by (u_{i0}, v_{i0}).

For a given point X($X \in \Omega$), based on the PU concept, a new interpolation $u^h(X)$ at X can be defined by

$$u^h(X) = \sum_{i-1}^{n} \emptyset_i^0(x)\, u_i^i(X) \quad (2)$$

where n is the total number of neighboring nodes where the position of point $\mathbf{X}$ located in the cover support. $u_i^l(\mathbf{x})$ are the cover interpolations defined on the cover of node i.

In MSIM, the interpolations are constructed separately for the nodes on the essential boundary or in the domain.. $\phi_i^0(\mathbf{x})$ is the Shepard function or zeroth-order function

$$\phi_i^0(\mathbf{x}) = \frac{w_i(\mathbf{x})}{\sum_{i=1}^{n} w_i(\mathbf{x})} \quad (3)$$

where $w_i(\mathbf{x})$ is the weight function associated with node i.

The Shepard function $\phi_i^0(\mathbf{x})$ in Eq. (3) satisfies the delta property if weight function is singular at $\mathbf{x} = \mathbf{x}_i$. The weight function[12] adopted here is

$$w_i(\mathbf{x})=\begin{cases}\dfrac{d_{mi}^2}{d_i^2+\varepsilon}\cos^2\left(\dfrac{\pi d_i}{2d_{mi}}\right), & d_i \le d_{mi}\\ 0 & d_i > d_{mi}\end{cases} \tag{4}$$

where $d_i=\|\mathbf{x}-\mathbf{x}_i\|$ is the Euclidian distance between the point $\mathbf{x}$ and node $\mathbf{x}_i$, and ε is a small number to avoid the numerical difficulty resulting from the singularity at nodes.

On each cover C_i, a local approximation is first expressed as

$$u_i^l(\mathbf{x}) = \mathbf{P}^{\mathrm{T}}(\mathbf{x})\mathbf{a}(\mathbf{x}) = \sum_{k=1}^{m} p_k(\mathbf{x})a_k \tag{5}$$

where m is the number of terms in the basis, $\mathbf{p}^{\mathrm{T}}(\mathbf{x})=[1,x,y,xy.....]$ are the nominal basis functions, a_i is their coefficients. Here, the bilinear basis $\mathbf{p}^{\mathrm{T}}(\mathbf{x})=[1,x,y,xy]$ is used as an example to introduce the construction of the MSIM interpolation.

2.1 Cover interpolation for the nodes not located on the essential boundary

For the typical node i not located on the essential boundary, the local cover approximation is directly taken as

$$u_i^l(\mathbf{x}) = u_i^{\ln}(\mathbf{x}) = a_{1i} + a_{2i}x + a_{3i}y + a_{4i}xy \tag{6}$$

Let the cover function at the node i satisfy the condition

$$u_i^{\ln}(x_i) = a_{1i} + a_{2i}x_i + a_{3i}y_i + a_{4i}x_iy_i = u_{i0} \tag{7}$$

Hence,

$$a_{1i} = u_{i0} - a_{2i}x_i - a_{3i}y_i - a_{4i}x_iy_i \tag{8}$$

Substituting Eq. (8) into Eq. (3) leads to

$$u_i^{\ln}(\mathbf{x})=u_{i0}+a_{2i}(x-x_i)+a_{3i}(y-y_i)+a_{4i}(xy-x_iy_i) = \overline{\mathbf{\Psi}}^i\mathbf{T}_x^i \tag{9}$$

where

$$\overline{\mathbf{\Psi}}^i(\mathbf{x})=[\Psi_1^i \quad \Psi_2^i \quad \Psi_3^i \quad \Psi_4^i]=[1 \quad x-x_i \quad y-y_i \quad xy-x_iy_i] \tag{10}$$

$$\mathbf{T}_x^i=[u_{i0} \quad a_{2i} \quad a_{3i} \quad a_{4i}]^T \tag{11}$$

Similarly, the y-displacement interpolation $v_i^{\ln}(x_i)$ is given by

$$v_i^{\ln}(\mathbf{x})=v_{i0}+b_{2i}(x-x_i)+b_{3i}(y-y_i)+b_{4i}(xy-x_iy_i) = \overline{\mathbf{\Psi}}^i\mathbf{T}_y^i \tag{12}$$

where

$$\mathbf{T}_y^i=[v_{i0} \quad b_{2i} \quad b_{3i} \quad b_{4i}]^T \tag{13}$$

Eq. (9) and (12) can be rewritten in the form

$$\mathbf{u}_i^{\ln}(\mathbf{x})=\begin{Bmatrix}u_i^{\ln}(\mathbf{x})\\ v_i^{\ln}(\mathbf{x})\end{Bmatrix}=\mathbf{\Psi}^i\mathbf{T}^i \tag{14}$$

where

$$\mathbf{\Psi}=\begin{bmatrix}1 & 0 & x-x_i & 0 & y-y_i & 0 & xy-x_iy_i & 0\\ 0 & 1 & 0 & x-x_i & 0 & y-y_i & 0 & xy-x_iy_i\end{bmatrix} \tag{15}$$

$$\mathbf{T}=[u_{i0} \quad v_{i0} \quad a_{2i} \quad b_{2i} \quad a_{3i} \quad b_{3i} \quad a_{4i} \quad b_{4i}]^T \tag{16}$$

(u_{i0},v_{i0}) are the nodal displacement of node i, $(a_{2i},b_{2i},a_{3i},b_{3i},a_{4i},b_{4i})$ are the extra freedoms of cover C_i. From Eq. (14), we observe that

$$\mathbf{u}_i^{\ln}(x_i, y_i) = \begin{Bmatrix} u_{i0} \\ v_{i0} \end{Bmatrix} \tag{17}$$

It means that the cover function of the node i is interpolated in terms of nodal displacements (u_{i0}, v_{i0}).

2.2 Cover interpolation for the nodes located on the essential boundary

For a typical node j located on the essential boundary, suppose that there M nodes in the support of cover C_j (Fig. 1). At the local cover C_j, a discrete error norm is defined as

$$u_j^{lb}(\mathbf{x}) = \overline{\mathbf{\Phi}}^j(\mathbf{x})\mathbf{u}_0^j = \sum_{k=1}^{M} \overline{\Phi}_k^j(\mathbf{x}) u_k \tag{18}$$

where

$$\overline{\mathbf{\Phi}}^j(\mathbf{x}) = [\Phi_1^j(\mathbf{x}) - \Phi_1^j(\mathbf{x}_j), \ \cdots, \ 1 + \Phi_j^j(\mathbf{x}) - \Phi_j^j(\mathbf{x}_j), \ \cdots, \ \Phi_M^j(\mathbf{x}) - \Phi_M^j(\mathbf{x}_j)] \tag{19}$$

x_j is the coordinate of node j.

Similarly, the y-displacement interpolation $v_j^{lb}(\mathbf{x})$ is given by

$$v_j^{lb}(\mathbf{x}) = \mathbf{\Phi}^j(\mathbf{x})\mathbf{V}_0^{\ j} = \sum_{k=1}^{M} \Phi_k^j(\mathbf{x}) v_k \tag{20}$$

where

$$\mathbf{V}_0^j = \begin{bmatrix} v_{10} & v_{20} & \cdots & v_{M0} \end{bmatrix} \tag{21}$$

Eq. (18) and (20) can be rewritten in the form

$$\mathbf{u}_j^{lb}(\mathbf{x}) = \begin{Bmatrix} u_j^{lb}(\mathbf{x}) \\ v_j^{lb}(\mathbf{x}) \end{Bmatrix} = \mathbf{\Phi}_*^j \mathbf{D}^j \tag{22}$$

where

$$\mathbf{\Phi}_*^j = \begin{bmatrix} \overline{\Phi}_1^j & 0 & \cdots & \overline{\Phi}_M^j & 0 \\ 0 & \overline{\Phi}_1^j & \cdots & 0 & \overline{\Phi}_M^j \end{bmatrix} \tag{23}$$

$$\mathbf{D}^j = \begin{bmatrix} u_{10} & u_{10} & u_{20} & u_{20} & \cdots & \cdots & u_{M0} & u_{M0} \end{bmatrix} \tag{24}$$

Substituting Eq. (14) and (22) into Eq. (2) leads to

$$u^h(\mathbf{x}) = \sum_{i=1}^{n} \phi_i^0(\mathbf{x}) u_i^l(\mathbf{x}) = \sum_{i=1}^{n_1} \phi_i^0(\mathbf{x}) u_i^{\ln}(\mathbf{x}) + \sum_{j=1}^{n_2} \phi_j^0(\mathbf{x}) \left(\sum_{k=1}^{M} \overline{\Phi}_k^j(\mathbf{x}) u_k \right) \tag{25}$$

where $n = n_1 + n_2$ is the total number of neighboring nodes where the position point $\mathbf{x}$ located in the cover support, n_1 denotes the node set not on the essential boundary, n_2 denotes the node set located on the essential boundary. The MSIM possesses the delta property and preserves the completeness of the field up to the order of the basis. The proof of these properties can be referred to [11].

3. The application of virtual crack closure technique in MSIM

Virtual crack closure technique (VCCT) is proposed by Rybicki and Kanninen [10] mainly dealing with two dimensional problems. In this method, the strain energy release rate for the crack propagation is always calculated based on the FEM analysis results. Here, taking a finite crack body as an example, the basic concept of virtual crack closure technique will be briefly introduced.

The length of crack is a, and the propagation length is Δa. When the quadrangle mesh is employed,

the stain energy release rate of the crack could be calculated by

$$G_I \cong \frac{F_{y1}\Delta v_{3,4}}{2B\Delta a} \tag{26a}$$

$$G_{II} \cong \frac{F_{x1}\Delta u_{3,4}}{2B\Delta a} \tag{26b}$$

where, F_{x1} and F_{y1} are the node forces (X direction, Y direction, respectively) belonging to node 1. $\Delta v_{3,4}$ and $\Delta u_{3,4}$ are the Y direction displacement and X direction displacement between node 3 and 4, respectively.

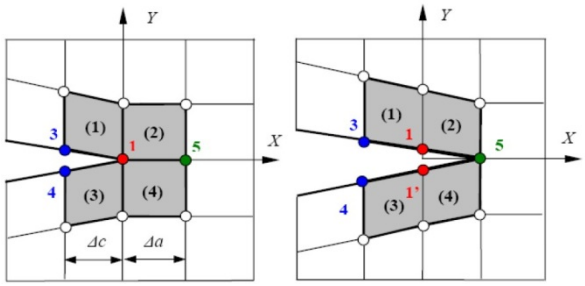

Figure 2. Illustration of calculating the strain energy release rate by the VCCT

Due to the fact that the virtual crack closure technique is always implemented in the framework of FEM, the remeshing during the simulation of crack propagation are unavoidably encountered. To solve this problem, the virtual crack closure technique will be introduced into MSIM in this section. Both the advantages of the two methods will be maintained to make the evaluation of the SIFs much more efficient. The progress will be carried out mainly in the following steps:

1) Construction of meshless numerical model;
2) Calculation of the displacement of the nodes based on the MSIM;
3) Setting the assistant mesh near the crack tip in order to calculate the nodal force
4) Constructing the global stiffness matrix of the assistant mesh and calculating the displacement of the node in the assistant mesh based on the MSIM.
5) Getting the nodal force near the crack tip by $F_e = K_e a_e$, where F_e is the assistant nodal force, K_e is the global stiffness matrix of the assistant mesh, a_e is the displacement vector of the assistant nodes.

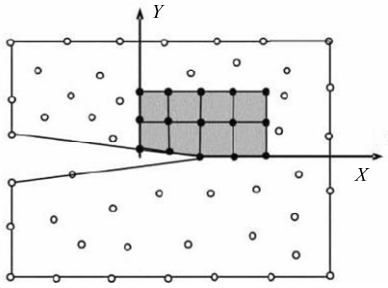

Figure 3. The assistant mesh employed in the MSIM to evaluate the nodal force

4. A case study on a finite plate with star-shaped crack

In this section, a star-shaped crack in a square plate subjected to bi-axial tension as shown in Fig.4 will be examined. The analysis is treated as plate strain problem, and the plate size is taken to be W = 2.0, and the bi-axial tension to be unity. The material constants are the Young's modulus

$E = 1 \times 10^7$ and the Poisson's ratio $\nu = 0.3$. The SIF of node A and B are calculated by both of the linear basis function and the enriched basis function with virtual crack closure technique. A meshless model is constructed as shown in Fig.5. The influence of crack geometry on the SIFs is also investigated by varying W/a (e.g.0.1W, 0.3W, 0.5W, 0.7W).

The normalized stress intensity factors at tips A and B are defined as $F_I^A = K_I^A / \sigma\sqrt{\pi a}$, $F_I^B = K_I^B / \sigma\sqrt{\pi a}$, $F_{II}^B = K_{II}^B / \sigma\sqrt{\pi a}$. The comparison between the calculation results and the reference solutions available [13] are demonstrated in Table 1. From this table, the excellent agreement of the computed SIF results and the reference solutions can be easily seen.

Table 1. Normalized SIFs comparison for a star-shaped crack

5. Conclusions

The application of virtual crack closure technique into the MSIM is presented in this paper. The remeshing and the refinement near the crack tips can be avoided in the present method, and as a result, it makes the evaluation of the SIF much easier and more efficient. The virtual crack closure technique is based on the stress analysis using the MSIM for discontinuous model here, however other meshless methods are equally viable, e.g., the element-free Galerkin method (EFG), and the meshless local-Petrov Galerkin method (MLPG). The numerical results indicate that the present method effectively calculates the SIF near the crack tips and possess a high accuracy.

Abstract Nanoscale fracture of pre-cracked graphene under coupled in-plane opening and shear mechanical loading in far-field is investigated by extensive molecular dynamics simulations. Under opening-dominant loading, zigzag edge cracks grow self-similarly. Otherwise, complex mechanical stresses concentrated in the vicinity of crack tip can manipulate the direction of crack initiation changing by 30° (or multiples of 30°) to the original crack line. Toughness determined from obtained critical stress intensity factors 2.63 ~ 3.38 nN $Å^{-3/2}$ is relatively low, which demonstrates graphene is intrinsically brittle opposite to its exceptional high strength at room temperature. Graphene is easier to break along zigzag direction. Torn edges are in either zigzag or armchair manner, while zigzag edges are observed prevalently, and armchair edges are formed occasionally under particular loading conditions. Crack kinking is related to the proportion of opening and shear components of loading, and topological defects frequently appear at turning points. Our theoretical results indicate that cracking of graphene has a dependence on local mechanical stresses, edge energy and dynamic effects, which provide a possible way to regulate the edge structure of graphene.

Keywords Graphene, Crack kinking, Stress intensity factor, Molecular dynamics

1. Introduction

Graphene, as an atomic monolayer of graphite, is extensively studied after successful laboratory exfoliation [1], and it has attracted significant attention from the scientific community for its remarkable mechanical and electrical properties that are currently being explored for a number of applications including nanoelectromechanical systems, nano-electronics, *etc*. Recent mechanical experiments have shown that graphene is the strongest material measured hitherto with an elastic modulus of 1.0 TPa [2], which exceeds those of any previously existing materials. Rafiee et al. also reported that graphene as reinforcement has extraordinary effectiveness to resist fracture and fatigue in composites [3]. However, Hashimoto et al. [4] have provided a direct experimental evidence for the existence of defects in graphene layers. The extraordinary mechanical properties can be affected by the presence of defects that cause a more reduction of the strength. The existing works have treated defects in graphene as cracks that can initiate fracture.

The research on fracture of graphene can date back to the simulations conducted by Omeltchenko et al. [5], in which a notched graphite sheet was loaded uniaxial tension and then underwent cleavage. However, that retention of the cutoff function of early version potential makes the quantitative aspects of results questionable. Recently, Belytschko et al. [6-8] carried out series of theoretical researches on the fracture of pre-cracked graphene under uniaxial tensile loading. The critical stress intensity factors under pure opening loading were obtained for zigzag and armchair cracks, while the propagation direction was manually specified. Lu et al. [9] also investigated fracture of graphene nano-ribbons (GNRs) under uniaxial tension. Furthermore, shear deformation plays an important role in the wrinkling and rippling behavior of graphene, which, in turn, controls charge carrier scattering and electron mobility [10]. It is even possible to modulate the graphene energy-gap from 0.0 to 0.9 eV by combining shear deformations with uniaxial strains [11]. In point

of fact, mixed-mode fracture inevitably occurred during the tearing of graphene sheets from graphite or other substrates to obtain free-standing sheets or narrow ribbons [12]. In [5], multiple crack branched sprouting off the primary crack front, thus tilted cracks were actually under mixed tensile and shear loading. Besides theoretical studies, Kim et al. [13] presented investigations on tears in suspended monolayer graphene membranes by high-resolution transmission electron microscopy (HRTEM). However, radiation damage by electron-beam energy and applied dose cannot be neglected for light element materials due to the limitations of HRTEM [14]. It is still a challenge to observe experimentally the cracking of graphene under pure mechanical loading without electromechanical coupling effects.

Thus far, complex mechanical loading is rarely considered in previous works on fracture in graphene. Here we will show our extensive molecular dynamics (MD) simulations on nanoscale fracture of graphene under coupled opening and in-plane shear loading of far-field (I/II mixed-mode fracture). A boundary layer model embedded with a straight crack along either zigzag (ZZ) or armchair (AC) edge is applied with complex stresses by a displacement boundary governed by crack-tip asymptotic solution. The modified second-generation reactive empirical bond-order (REBO) potential [15] is used by shifting the cut-off distance and removing cut-off function to avoid unphysical dramatic increase in the interatomic force. The evolution of atomically cleaving of graphene is then revealed without manually specified direction of crack propagation.

2. Methodology and model

The well established REBO potential for hydrocarbons has been widely used [5, 9, 16-18] to specifically describe the interatomic interaction of carbon atoms lattices and nonlocal effects via an analytic function, Lennard-Jones 6-12 potential was used to mimic the nonbonding interatomic interaction, and the potential can correctly describe the bond breaking and switching between carbon atoms. In REBO potential, two cutoff distances 1.7 Å and 2.0 Å are initially set for a smooth transition of cutoff function from 1 to 0 to limit the range of covalent interactions as the interatomic distance increases. However, as noted in several previous studies [19, 20], such a cutoff function generates spurious bond forces near the cutoff distance, which will lead to unphysical results due to discontinuity in the second derivative of the cutoff function. This artifact defect shall be avoided in the study of graphene fracture. In this study, the cutoff function is taken to be 1.0 within a cutoff distance of 1.92 Å [21] and zero otherwise, as suggested by the developers [19]. It was found that the numerical results up to fracture of GNRs are unaffected if the cutoff distance is within 1.9 Å to 2.2 Å [9].

A size-reduced model containing a small circular-shaped domain cut from the crack tip is utilized to model semi-infinite cracks in real graphene. A reasonable domain size is chosen so that its outer boundary falls in the *K*-dominant zone, which can make all-atom simulations computationally efficient. We consider an initially straight crack subject to in-plane opening and shear loading characterized by the local stress intensity factor (SIF) K field. Two prevalent cracks with orientations along ZZ or AC edges are chosen in Figure 1. Two or three rows of atoms are removed to generate cracks in our models, and the distance between two crack surfaces is big enough to

avoid self sealing, especially in pure shear case. The length of crack is more than 10 times lattice spacing to avoid unphysical Griffith fracture stress and flaw insensitiveness [22]. A total of around 4000 carbon atoms in our disk models with a radius r = 60Å are initially relaxed until the energy of the system is fully minimized for a specified temperature. The thickness of graphene is assumed to be 3.335Å under plane stress condition. Hereafter our results are divided by 3.335Å to make connection of a two-dimensional lattice with a three-dimensional solid.

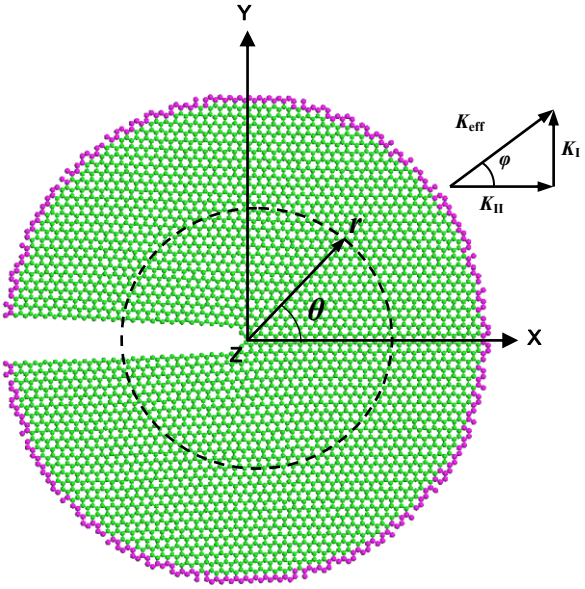

Figure 1. Boundary layer MD model and coordinates. A pre-existing straight crack along zigzag edge is embedded in a two-dimensional graphene lattice (green). The outer boundary layer (pink atoms) is subject to displacement loadings.

Williams [23] has given the asymptotic expansion of the displacement field around the crack tip in an isotropic linear elastic body. At a given SIF K^{app} applied by far-field loadings, the crack-tip asymptotic solution is as [24]

$$u_{\text{x}} = \frac{1+v}{E}\sqrt{\frac{r}{2\pi}}\left[K_{\text{I}}^{app}\cos\frac{\theta}{2}\left(k-1+2\sin^2\frac{\theta}{2}\right)+K_{\text{II}}^{app}\sin\frac{\theta}{2}\left(k+1+2\cos^2\frac{\theta}{2}\right)\right], \tag{1}$$

$$u_{\text{y}} = \frac{1+v}{E}\sqrt{\frac{r}{2\pi}}\left[K_{\text{I}}^{app}\sin\frac{\theta}{2}\left(k+1-2\cos^2\frac{\theta}{2}\right)-K_{\text{II}}^{app}\cos\frac{\theta}{2}\left(k-1-2\sin^2\frac{\theta}{2}\right)\right]. \tag{2}$$

where radius r and polar angle θ are defined in Figure 1, u_{x} and u_{y} are displacements in X and Y directions, respectively. Young's modulus E is 1.0 TPa [2], and Poisson's ratio v is 0.165 [25], and $k = (3\text{-}v)/(1+v)$ for plane stress here. $K_{\text{I}}^{\text{app}}$ and $K_{\text{II}}^{\text{app}}$ are SIF components specified by opening and shear stresses. Phase angle φ (loading mixed parameter or equivalent crack angle) is defined as $\varphi = \tan^{-1}(K_{\text{I}}^{\text{app}}/K_{\text{II}}^{\text{app}})$, and an effective SIF at the initial crack length is evaluated as $(K_{\text{eff}}^{\text{app}})^2 = (K_{\text{I}}^{\text{app}})^2 + (K_{\text{II}}^{\text{app}})^2$, see Figure 1. Therefore the far field behavior of pristine graphene is assumed to be well-represented by the solution since the singularity decreases apart from the crack tip. The boundary condition is similar to a suspended graphene spanning a hole in the TEM grid.

Mixed-mode loading in classical fracture mechanics is then imposed by initially assigning all atoms in the displacement field given by the crack-tip asymptotic solution of a specified initial $K_{\text{eff}}^{\text{app}}$. In Figure 1, atoms (pink) on the outer boundary layer are held fixed, while all the other atoms (green) are set free, and the atomic configuration is then relaxed. Then we implement the deformation-control method by applying displacement increments gradually to the fixed boundary layer separately every 500 MD steps. At each applied loading, the statically equilibrium lattice structure is calculated to minimize the total energy by the limited memory BFGS geometry optimization algorithm [26], thereby local energy minimum configurations are obtained. The velocity-Verlet time stepping scheme is used with a time step 1.0 fs at predominantly 300K with a Berendsen thermostat, and this yields a strain rate 0.0002 ps^{-1} primarily. We note that MD simulations are often sensitive to the temperature control and the loading rate, thus our results mainly provide a qualitative understanding of the fracture mechanisms.

3. Results and discussion

The energy-balance criterion by Griffith is the fundamental fracture criterion for brittle continua, which states that a crack meets the critical growth condition when the net change in the total energy of the system vanishes upon crack extension by an infinitesimal distance [27]. Using the relationship between the critical SIF of Griffith K_{th}^{c} and the energy release rate (twice of the surface energy density γ_s) for linear elastic materials, one has $K_{\text{th}}^{\text{c}} = (2E\gamma_s)^{1/2}$ [24]. Since E is assumed isotropic for graphene, K_{th}^{c} will be mainly determined by γ_s. By use of γ_s = 1.041 eV/Å and 1.091 eV/Å [28, 29] for ZZ and AC cracks, we get K_{th}^{c} = 3.162 nN $\text{Å}^{-3/2}$ and 3.238 nN $\text{Å}^{-3/2}$, respectively.

Table 1. Effective critical stress intensity factors $K_{\text{eff}}^{\text{c}}$ (nN $\text{Å}^{-3/2}$) of zigzag and armchair cracks in graphene under far-field loading at various phase angles φ.

φ		0°	15°	30°	45°	60°	75°	90°	90°	90°	90°	90°	90°
$K^{\text{c}}_{\text{eff}}$	ZZ	3.06	2.75	2.63	2.90	3.15	3.02	3.05	3.16[a]	4.21[b]	2.64[c]	6.0[d]	10.32[e]
	AC	2.87	3.30	3.28	2.87	2.78	2.85	3.38	3.24[a]	3.71[b]			

[a] Critical stress intensity factor of Griffith K_{th}^{c}; [b] Ref. 6; [c] Ref. 7; [d] Ref. 5; [e] Ref. 30.

In Table 1 and Figure 2, our results show that the effective critical SIF $K_{\text{eff}}^{\text{c}}$ of I/II mixed-mode loading falls in the range between 2.63 nN $\text{Å}^{-3/2}$ and 3.38 nN $\text{Å}^{-3/2}$ varying with φ, relatively low compared to steel, which reveals that graphene is brittle at 300K opposing its ultrahigh strength. As the difference of geometric chiral angle between AC and ZZ edges is 30°, similar trends for $K_{\text{eff}}^{\text{c}}$ are observed if φ is shifted by 30°, see Figure 2. $K_{\text{eff}}^{\text{c}}$ along ZZ edges are slightly lower indicating smaller toughness, thus graphene is easier to break along ZZ direction. For ZZ cracks under pure opening tension (φ = 90°), our $K_{\text{eff}}^{\text{c}}$ are reasonable with theoretical K_{th}^{c}, and compared with available reported datum, Table 1, the discrepancy may be due to different crack models [5, 7] and potentials [6, 30].

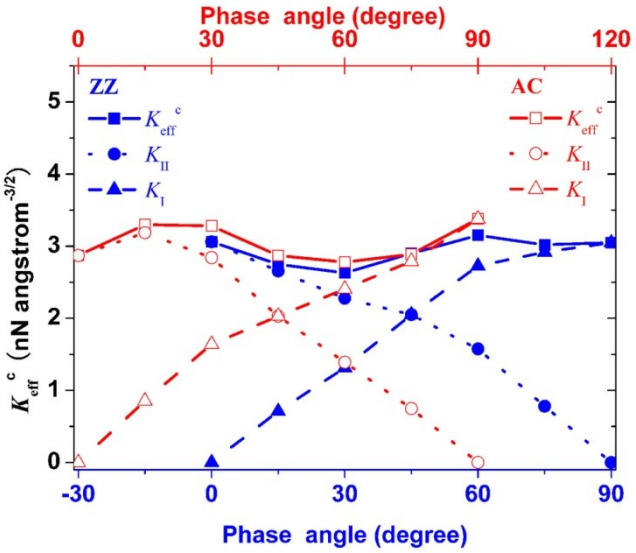

Figure 2. Effective critical stress intensity factors K_{eff}^{c} of graphene cracks, ZZ in blue and AC in red, changing with phase angles φ of far-field loading. K_I and K_{II} are opening and shear components of K_{eff}^{c}.

Up to now, no single criterion in classical continuum mechanics can give satisfactory predictions for crack initiation direction under all loading conditions. All existing criteria predict that a crack under mode II (in-pane shear, $\varphi = 0°$) loading propagates along about a 70° direction with respect to the original crack line. However, a mode II crack either propagates in mode I (opening, $\varphi = 90°$) or mode II, depending on material properties and load magnitudes [31].

Continuum criteria seem to lose efficacy in predicting direction of crack initiation in graphene. In Figure 3a-f, our results show that ZZ cracks initiate in the direction of an angle $\beta = 120°$ deviating from the original edge when in-plane shear loading is prevailing, β maintains unchanged till $\varphi = 60°$ and fresh edges are in zigzag (blue). Further increasing φ will induce the transition of β. At $\varphi = 65°$, β changes to 150°, and fresh edges are in armchair (red). This configuration coincides with the prediction that zigzag-armchair junctions with an angle of 150° would be more stable [32, 5]. Once $\varphi > 65°$, opening loading becomes dominant, crack grows self-similarly along original direction and fresh edges are in zigzag again.

For AC cracks in Figure 3g-l, initiation angle $\beta = 90°$ at $\varphi = 0°$, new crack tips nucleate prior to initial tip, and fresh edges are in zigzag. At $\varphi = 26.5°$, propagating direction changes to $\beta = 120°$, and fresh edges are in armchair. When $\varphi > 26.5°$, β transforms to 150° and keeps unchanged till $\varphi = 90°$, and fresh edges are in zigzag again.

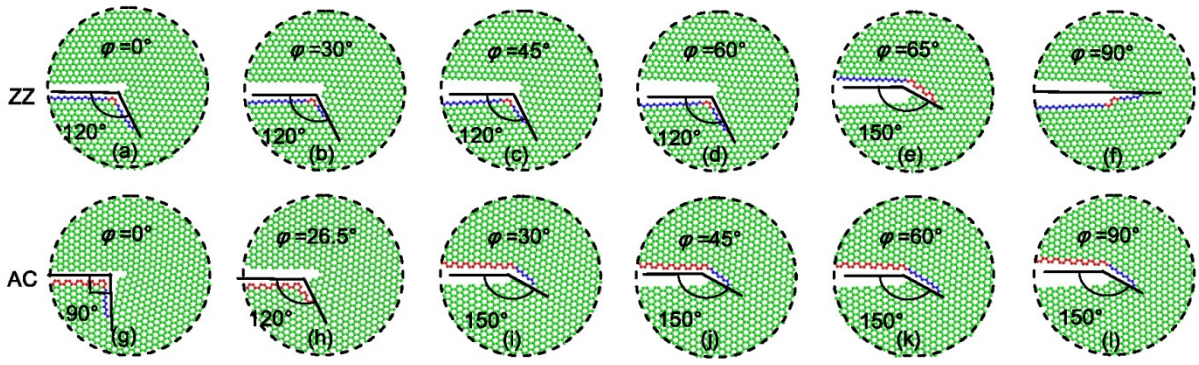

Figure 3. Insets (r = 30Å, cut from the whole models in Figure 1) of crack initiation in flawed graphene (green) under I/II mixed-mode loading. (a)-(f) ZZ cracks initiation at phase angle φ = 0°, 30°, 45°, 60°, 65°, 90°, and (g)-(l) AC cracks at φ = 0°, 26.5°, 30°, 45°, 60°, 90°, correspondingly.

Fresh edges exhibit mostly in zigzag, and armchair edges are formed during the transition of propagating direction. Under loading $K_{\text{eff}}^{\text{app}}$ = 3.21 nN Å$^{-3/2}$ at φ = 65° in Figure 3e, zigzag crack (blue) kinks and armchair edge (red) is formed. In Figure 3h, armchair crack (red) turns its direction with 120° followed by armchair edge (red) under $K_{\text{eff}}^{\text{app}}$ = 3.25 nN Å$^{-3/2}$ at φ = 26.5°. This is similar to experimental tears kinking within graphene membrane under complex mechanical stress applied by circular boundary of the Quantifoil holey carbon TEM grid [13].

With the increasing of complex loading, the stress concentrated around crack tip morphs the hexagonal carbon rings into deformed shapes. Once the bonds at the tip rotated or broken, the hexagonal symmetry of the graphene lattice is destroyed with the formation and motion of topological defects, which leads to crack kinking. The dynamic effect of a fast fracture in MD simulations can also cause kinking, while branching is not observed. Further crack extension would proceed by alternating sequence of bond breaking or rotation.

Graphene edges are of particular interest since their orientation determines the electronic properties. Crack extension with the formation of fresh edges is mainly caused by local high strain concentrated around crack tips. Our simulations demonstrate that torn edges maintain straightness and clean in either zigzag or armchair direction, in Figure 3, and can change directions by 30° or multiples of 30°, in Figure 3, coincided with experiments [13]. Under pure opening loading (φ = 90°), the growth of zigzag cracks is self-similar whereas armchair cracks advance in an irregular manner, consistent with previous reports [6]. The direction of crack growth changes definitely under coupled opening and shearing stresses and edges interconvert between ZZ and AC. Cracks preferably grow along zigzag directions in agreement with previous theoretical simulations [9, 12]. By Griffith criterion, this suggests lower edge energy in ZZ opposed to AC, which is coincided with simulations by empirical potentials [28, 29, 33]. More abundant ZZ edges appeared may be due to lower edge energy, somewhat local residual stresses and dynamic fracture effects. Experiments also showed long-term stability [34] of ZZ edges, and more ZZ edges were initially formed at high temperatures [35]. In [13], the initial torn edges were along ZZ direction under pure mechanical stress during the graphene transfer process, while heating and chemical effects, knock-on sputtering induced by electron irradiation in TEM inevitably influenced crack extension stimulated afterwards.

Another experiment [36] also confirmed that the zigzag edge is more stable than the armchair edge, although the opposite has been predicted theoretically by *ab initio* calculations which depend strongly on the choice of the density functional among different DFT calculations yielding dramatically different values in quantitative scattering.

During our simulations, total energy at each strain level is minimized for each equilibrium lattice structure. The kinematic energy changes slightly while potential energy increases gradually since the temperature is coupled with a thermostat. Energy jumps are infrequently observed, thus lattice-trapping effects are negligibly small for long-range potentials we used. Undoubtedly, temperature and strain rate can quantitatively affect K^c that increases slightly with increase of strain rates while decreases with temperature. At high temperature beyond 1000K, fracture shows plastic behaviors opposite to brittle at room temperature, the crack edges are reconstructed, fresh surfaces are bridged with carbon chains, and formation and motion of defects and vacancies appear frequently.

4. Concluding remarks

In summary, graphene embedded with pre-existing zigzag or armchair crack under complex mechanical stresses is studied by extensive molecular dynamics simulations based on the modified REBO potential. An asymptotic expansion of the displacement field in the region of crack tip is adopted to apply loading combined with in-plane opening and shear stresses. The critical effective stress intensity factors are obtained in the range of 2.63 nN $Å^{-3/2}$ to 3.38 nN $Å^{-3/2}$ varied with the phase angle of far-field loading, the predicted low toughness indicates that strong graphene is absolutely brittle at room temperature. The direction of crack initiation is also dependent on the phase angle, and changes by 30° (or multiples of 30°) to the original crack line. Straight cracks with zigzag edges grow self-similarly when opening loading is dominant, or else kinking occurred. Torn edges of fresh cracks are along either zigzag or armchair edge, while zigzag edges are more preferable. Fresh armchair edges are formed occasionally under particular stress conditions. Our theoretical results show that graphene cracking prefers along zigzag edges concerning with its lower toughness and complex mechanical stress in dynamic fracture.

Abstract In asserting structural safety it is of paramount importance to be able to evaluate the loading capacity of notched components, where stresses concentrate and can trigger cracks leading to a catastrophic failure or to a shortening of the assessed life of the structure. Restricting the analysis to brittle materials, we apply the Finite Fracture Mechanics criterion to address the problem of a V-notched structure subjected to a mixed-mode loading, i.e. we provide a way to determine the direction and the load at which a crack propagates from the notch tip and express the critical conditions in terms of the generalized stress intensity factors plus a suitable definition of the notch mode mixity. Weight functions of the stress intensity factors for V-notch emanated cracks available in the literature allow us to implement the fracture criterion proposed in an almost completely analytical manner: the determination of the critical load and the direction of crack growth is reduced to a minimization-under-constraint problem. We then highlight the size effect for a V-notched structure under mixed-mode loading and the differences between the structural behaviours of cracked and notched geometries.

Keywords sharp notches, mode mixity, size effect, finite fracture mechanics

1. Introduction

The development of suitable fracture criteria for brittle (isotropic or orthotropic) materials containing V-notches or multi-material interfaces is a problem of primary concern in order to control fracture onset phenomena taking place in mechanical components, composite materials and electronic devices. As well-known, the singularity of the stress field in the vicinity of the notch tip makes the problem non-trivial.

Concerning re-entrant corners in homogeneous media subjected to mode I loadings, since the pioneering paper by Carpinteri [1] a good correlation has been found between the critical value of the generalized stress intensity factor (i.e. the generalized fracture toughness) and the failure loads. Theoretical models to relate the generalized fracture toughness to material tensile strength, fracture toughness and re-entrant corner amplitude have been set by a number of researchers, e.g. [2-5].

Fewer contributions are available for what concerns mixed mode loading conditions [6-8]. Here we provide the generalization of the results obtained by Carpinteri et al. [5] to mixed mode problems. The proposed approach (as well as the ones previously cited) is based on the assumption that the region around the corner dominated by the singular stress field is large compared to intrinsic flaw sizes, inelastic zones or fracture process zone sizes. This hypothesis is the analogous of small-scale yielding in Linear Elastic Fracture Mechanics (LEFM).

While in LEFM there is a direct connection between the Stress Intensity Factors (SIFs) and the strain energy release rate (i.e. Irwin's relationship), this relation is missing in the case of notches, so that correlating fracture initiations with critical values of the stress intensity [1] could appear questionable. However, the recently introduced Finite Fracture Mechanics (FFM) criterion has shown this is not the case [4,5]. In fact, under the assumption of a finite crack extension at fracture initiation, it is possible to prove a relation between the Generalized Stress Intensity Factors (GSIFs) and the energy released when a crack appears at the V-notch tip.

2. Stress intensity factors for a V-notch emanated crack

Let us consider a re-entrant corner in an infinite homogeneous elastic medium with a polar coordinate system (r,ϑ) centred at the V-notch tip (see Fig.1a). After Williams, the asymptotical stress field is given by:

$$\sigma_{rr} = \frac{K_I^*}{(2\pi r)^{1-\lambda_I}} f_{rr}^{I}(\vartheta,\omega) + \frac{K_{II}^*}{(2\pi r)^{1-\lambda_{II}}} f_{rr}^{II}(\vartheta,\omega) \tag{1a}$$

$$\sigma_{\vartheta\vartheta} = \frac{K_I^*}{(2\pi r)^{1-\lambda_I}} f_{\vartheta\vartheta}^{I}(\vartheta,\omega) + \frac{K_{II}^*}{(2\pi r)^{1-\lambda_{II}}} f_{\vartheta\vartheta}^{II}(\vartheta,\omega) \tag{1b}$$

$$\tau_{r\vartheta} = \frac{K_I^*}{(2\pi r)^{1-\lambda_I}} f_{r\vartheta}^{I}(\vartheta,\omega) + \frac{K_{II}^*}{(2\pi r)^{1-\lambda_{II}}} f_{r\vartheta}^{II}(\vartheta,\omega) \tag{1c}$$

where K_I^* and K_{II}^* are the GSIFs in mode I (symmetrical) and mode II (anti-symmetrical) loading conditions respectively, λ_I and λ_{II} are the well-known Williams' eigenvalues and the functions f_{ij} are the angular shape functions (i.e. the eigenvectors). Both eigenvalues and eigenvectors depend on the notch opening angle ω. Note that the definition of the GSIFs is somewhat arbitrary, depending on the choice of the normalization factor, here taken equal to $(2\pi)^{1-\lambda_i}$ as in [2] but equal to 1 or to $\sqrt{2\pi}$ in other papers (e.g. [7] and [3], respectively). As we shall see later, the advantage of such a choice is that the critical value of the mode I GSIF continuously varies from the material tensile strength to the material fracture toughness as the re-entrant corner amplitude diminishes from 180° (flat edge) to 0° (cracked plate).

In order to apply the FFM criterion, we need to evaluate the energy necessary for the abrupt appearance of a finite length crack at the notch tip. This quantity can be easily computed if the SIFs K_I and K_{II} of a crack at the notch vertex are known. To this aim, we begin noticing that, if the crack occurs within the GSIFs dominated stress field, the SIFs depend only on the GSIFs, crack direction ϑ, crack length a and notch opening angle ω (see Fig.1b). A straightforward application of the Π-theorem (as well as the principle of effect superposition) shows that this dependency must take the following form [9]:

$$K_I = \mu_{11}(\vartheta,\omega)\, K_I^* a^{\lambda_I - 1/2} + \mu_{12}(\vartheta,\omega)\, K_{II}^* a^{\lambda_{II} - 1/2} \tag{2a}$$

$$K_{II} = \mu_{21}(\vartheta,\omega)\, K_I^* a^{\lambda_I - 1/2} + \mu_{22}(\vartheta,\omega)\, K_{II}^* a^{\lambda_{II} - 1/2} \tag{2b}$$

In case of pure mode I loaded V-notches, the emanated crack grows along the notch bisector ($\vartheta = 0$); hence K_{II} is zero and K_I simplifies into [10]:

$$K_I = \mu_{11}(\omega) K_I^* a^{\lambda_I - 1/2} \tag{3}$$

While the dimensionless μ_{ij} parameters can be found tabulated with great accuracy for a crack, i.e. for $\omega = 0°$ [11], their values for a generic notch opening angle ω are not available. Nevertheless, they can be obtained by exploiting the results provided in [12], where the SIFs for a pair of forces per unit thickness (either normal or tangential) acting on the faces of a V-notch emanated crack are given. Beghini et al. [12] evaluated such SIFs for several ω and ϑ values by proper finite element computations and provided accurate analytical expressions of the SIFs. From such expressions and by the principle of effect superposition the coefficients μ_{ij} can be obtained analytically [13].

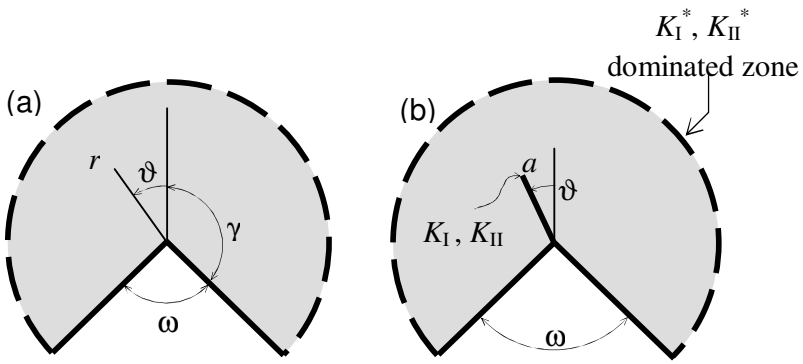

Figure 1. Polar reference system at the tip of a V-notch (a); V-notch emanated crack within the GSIFs dominated stress field region (b).

3. Coupled criterion

It is well known that both strength criteria and LEFM fail in predicting the failure load causing fracture propagation from a V-notch. In fact, the stress field given by eqn (1) is singular and strength criteria provide a vanishing failure load. On the other hand, the SIFs provided by eqn (2) vanish as the crack length a tends to zero and, consequently, LEFM provides an infinite failure load. These shortcomings can be overcome by resorting to Finite Fracture Mechanics [4,14], which couples the stress and energy approaches. Following the FFM approach proposed by Cornetti et al. [14], a crack propagates by a finite crack extension Δ if the following two inequalities are satisfied:

$$\begin{cases} \int_0^{\Delta} \mathcal{G}(a)\, \mathrm{d}a \geq \mathcal{G}_c\, \Delta \\ \int_0^{\Delta} \sigma_{\vartheta\vartheta}(r)\, \mathrm{d}r \geq \sigma_u\, \Delta \end{cases} \tag{4}$$

where σ_u is the material tensile strength and $\mathcal{G}_c$ is the fracture energy, related to the material fracture toughness by the well-known relation $\mathcal{G}_c = K_{Ic}^2 / E'$, where $E' = E / (1-\nu^2)$, E being the Young's modulus and ν the Poisson's coefficient.

The FFM criterion (4) can be regarded as a coupled Griffith-Rankine non-local failure criterion: the former inequality is an energy balance, whereas the latter is an (average) stress requirement for crack to propagate. It means that fracture is energy driven, but a sufficiently high stress field must act at the crack tip to trigger crack propagation. It is worth observing that, in the present case (which is the usual one, i.e. a positive geometry), the strain energy release rate function $\mathcal{G}(a)$ is monotonically increasing since the SIFs increase along with the crack length (see eqns (2)) while the stress $\sigma_{\vartheta\vartheta}(r)$ is monotonically decreasing with the distance r (see eqns (1)) from the notch tip (as far as both the modes provide a stress singularity, i.e. for a notch opening angle less than about 102.6°). This means that the lowest failure load (i.e. the actual one) is attained when the two inequalities are substituted by the two corresponding equations. In fact the first inequality is satisfied for crack steps larger than a threshold value, thus providing a lower bound for the set of admissible Δ-values; on the contrary, the second inequality is satisfied for crack advancements smaller than a certain value, thus providing an upper bound. For low load values, the upper bound is smaller than the lower bound and, consequently, the set of admissible Δ-values is empty. As the

external load increases, the upper bound increases and the lower bound decreases till a load value is met (i.e. the failure load) for which both conditions are strictly fulfilled. Therefore, we conclude stating that the system (4) reverts to a system of two equations in two unknowns: the crack advancement Δ and the corresponding (minimum) failure load, represented by the values K_{If}^{*} and K_{IIf}^{*} of the GSIFs in critical conditions, implicitly embedded in the functions $\sigma_{\vartheta\vartheta}$ and $\mathcal{G}$. Exploiting the well-known Irwin's relationship in plane strain and mixed mode, the system (4) becomes:

$$\begin{cases} \int_0^{\Delta} \left[K_{\mathrm{I}}^2(a) + K_{\mathrm{II}}^2(a)\right] \mathrm{d}a = K_{\mathrm{Ic}}^2 \, \Delta \\ \int_0^{\Delta} \sigma_{\vartheta\vartheta}(r) \, \mathrm{d}r = \sigma_{\mathrm{u}} \, \Delta \end{cases} \tag{5}$$

It is worth observing that the failure load estimate provided by the system (5) does depend on the crack propagation direction ϑ (see Fig.1b). Among all the possible directions, the actual one will be the direction ϑ_c providing the minimum failure load. Upon substitution of the SIFs eqns (2) into the first equation of the system (5) and integrating between 0 and Δ, we get:

$$\overline{\mu}_{11}\Delta^{2\lambda_{\mathrm{I}}}(K_{\mathrm{I}}^{*})^2 + \overline{\mu}_{12}\Delta^{\lambda_{\mathrm{I}}+\lambda_{\mathrm{II}}}K_{\mathrm{I}}^{*}K_{\mathrm{II}}^{*} + \overline{\mu}_{22}\Delta^{2\lambda_{\mathrm{II}}}(K_{\mathrm{II}}^{*})^2 = K_{\mathrm{Ic}}^2\Delta, \tag{6}$$

where, for the sake of simplicity, we have introduced the angular functions:

$$\overline{\mu}_{11} = \frac{\mu_{11}^2 + \mu_{21}^2}{2\lambda_{\mathrm{I}}}, \quad \overline{\mu}_{12} = 2\frac{\mu_{11}\mu_{12} + \mu_{21}\mu_{22}}{\lambda_{\mathrm{I}} + \lambda_{\mathrm{II}}}, \quad \overline{\mu}_{22} = \frac{\mu_{12}^2 + \mu_{22}^2}{2\lambda_{\mathrm{II}}} \tag{7}$$

Equation (6) highlights that the variation in the elastic energy is a quadratic function of the GSIFs. Equation (6) can be found also in Yosibash et al. [7], where it was derived in a different way, i.e. by directly computing coefficients of the quadratic form by suitable path independent integrals of the stress and displacement fields before and after the appearance of the finite crack advancement.

Upon substitution of the stress field represented by eqn (1) into the second equation of the system (5) and integrating between 0 and Δ, we get:

$$\overline{f}_{\vartheta\vartheta}^{\,\mathrm{I}} \, \Delta^{\lambda_{\mathrm{I}}} K_{\mathrm{I}}^{*} + \overline{f}_{\vartheta\vartheta}^{\,\mathrm{II}} \, \Delta^{\lambda_{\mathrm{II}}} K_{\mathrm{II}}^{*} = \sigma_{\mathrm{u}}\Delta \tag{8}$$

where, for the sake of simplicity, we have introduced the angular functions:

$$\overline{f}_{\vartheta\vartheta}^{\,\mathrm{I}} = \frac{f_{\vartheta\vartheta}^{\mathrm{I}}}{\lambda_{\mathrm{I}}(2\pi)^{1-\lambda_{\mathrm{I}}}}, \quad \overline{f}_{\vartheta\vartheta}^{\,\mathrm{II}} = \frac{f_{\vartheta\vartheta}^{\mathrm{II}}}{\lambda_{\mathrm{II}}(2\pi)^{1-\lambda_{\mathrm{II}}}} \tag{9}$$

4. Failure load, crack deflection and mode mixity

Under pure mode I loading condition, for symmetry reason the crack propagates along the notch bisector, i.e. $\vartheta_c = \vartheta_{Ic} = 0$. Upon substitution of eqns (6) and (8), limited to the mode I contributions, into the system (5), we get:

$$\begin{cases} \overline{\mu}_{11}\Delta^{2\lambda_I}(K_I^*)^2 = K_{Ic}^2\Delta \\ \overline{f}_{\vartheta\vartheta}^{\,I}\,\Delta^{\lambda_I}K_I^* = \sigma_u\Delta \end{cases} \tag{10}$$

The system (10) is readily solved, yielding the crack advancement Δ_c and the critical value K_{Ic}^* of the mode I GSIF K_I^* under pure mode I loading, i.e. the generalized fracture toughness [5]:

$$K_{Ic}^* = \xi(\omega)\,K_{Ic}^{2(1-\lambda_I)}\sigma_u^{2\lambda_I-1} = \xi(\omega)\,\sigma_u\,l_{ch}^{1-\lambda_I}\text{, with }\ \xi(\omega) = \lambda_I^{\lambda_I}\left[\frac{2(2\pi)^{2\lambda_I-1}}{\mu_{11}^2(\vartheta=0,\omega)}\right]^{1-\lambda_I} \tag{11}$$

where $l_{ch} = (K_{Ic} / \sigma_u)^2$ is the Irwin length. Note that, since ξ is equal to unity for ω equal to 0 or π, the generalized fracture toughness equals the fracture toughness for a cracked geometry and the tensile strength for a flat edge.

In the case of mixed mode loading, the critical values of the GSIFs can be obtained by substituting eqns (6) and (8) into the system (5):

$$\begin{cases} \left(\dfrac{K_I^*}{K_{Ic}^*}\right)^2 = \dfrac{\delta}{\xi^2\left(\overline{\mu}_{11}\delta^{2\lambda_I} + \overline{\mu}_{12}\delta^{\lambda_I+\lambda_{II}}\tan\psi + \overline{\mu}_{22}\delta^{2\lambda_{II}}\tan^2\psi\right)} \\ \dfrac{K_I^*}{K_{Ic}^*} = \dfrac{\delta}{\xi\left(\overline{f}_{\vartheta\vartheta}^{\,I}\,\delta^{\lambda_I} + \overline{f}_{\vartheta\vartheta}^{\,II}\delta^{\lambda_{II}}\tan\psi\right)} \end{cases} \tag{12}$$

where the mode I GSIF has been normalized with respect to the generalized fracture toughness K_{Ic}^*, the finite crack advancement with respect to l_{ch} ($\delta = \Delta / l_{ch}$) and ψ is the mode mixity, defined as:

$$\psi = \arctan\frac{K_{II}^*\,l_{ch}^{\lambda_{II}-\lambda_I}}{K_I^*} \tag{13}$$

The system (12) can be recast as:

$$\begin{cases} \dfrac{K_I^*}{K_{Ic}^*} = \dfrac{\delta}{\xi\left(\overline{f}_{\vartheta\vartheta}^{\,I}\,\delta^{\lambda_I} + \overline{f}_{\vartheta\vartheta}^{\,II}\delta^{\lambda_{II}}\tan\psi\right)} \\ \delta - \dfrac{\left(\overline{f}_{\vartheta\vartheta}^{\,I}\,\delta^{\lambda_I} + \overline{f}_{\vartheta\vartheta}^{\,II}\delta^{\lambda_{II}}\tan\psi\right)^2}{\overline{\mu}_{11}\delta^{2\lambda_I} + \overline{\mu}_{12}\delta^{\lambda_I+\lambda_{II}}\tan\psi + \overline{\mu}_{22}\delta^{2\lambda_{II}}\tan^2\psi} = 0 \end{cases} \tag{14}$$

The technique of Lagrange multipliers can now be exploited to solve eqn (14). In fact, eqn (14) can be interpreted as a constrained minimization problem, since, once the geometry, material and loading are fixed (i.e. ω and ψ are given), the actual crack advancement Δ_c and crack orientation ϑ_c are the ones that minimize the first equation, i.e. the dimensionless failure load K_{If}^* / K_{Ic}^*, under the constraint represented by the second equation. Once the critical value K_{If}^* of the mode I GSIF is determined, the corresponding critical value K_{IIf}^* of the mode II GSIF is provided by eqn (13).

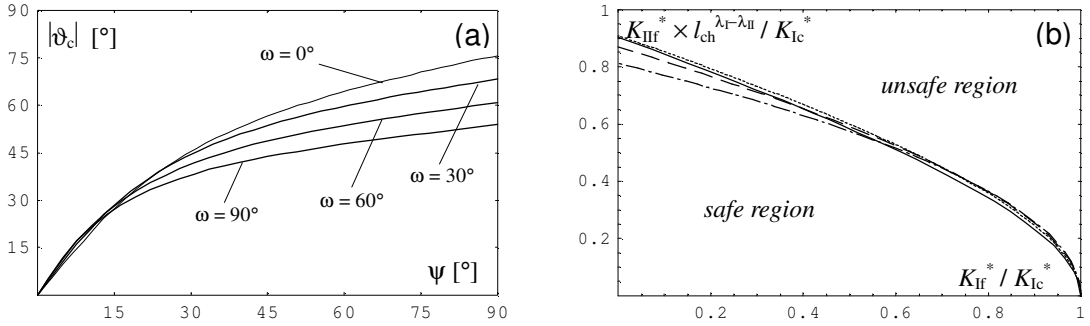

Figure 2. Crack deflection vs. mode mixity for different notch opening angle (a); safety domains in the GSIFs plane for different notch opening angles: continuous line, $\omega = 90°$; dotted line, $\omega = 60°$; dashed line, $\omega = 30°$; dot-dashed line, $\omega = 0°$ (b).

The values of the crack orientation angle are plotted in Fig. 2a vs. the mode mixity ψ for different notch opening angle ω. On the other hand, the critical values of the GSIFs can be plotted in the (K_I^*, K_{II}^*) plane for a given notch opening angle ω and varying the mode mixity ψ. In this way we obtain a curve delimiting a safety region, i.e. points lying in this domain correspond to admissible stress states, whereas points lying outside correspond to failure. It is convenient to plot the results in a dimensionless form: the mode I GSIF is normalized with respect to the generalized fracture toughness K_{Ic}^*, whereas the mode II GSIF is normalized with respect to $K_{Ic}^* \times l_{ch}^{\lambda_I-\lambda_{II}}$. The safety domains are plotted in Fig. 2b for different ω values and in Fig. 3 for $\omega = 90°$. If the external loads are increased proportionally, the ratio between the GSIFs keeps constant. It means that in the (K_I^*, K_{II}^*) plane, the loading curve is represented by a straight line starting from the origin. Furthermore, in the dimensionless plane, the angle between the loading path and the horizontal axis is exactly ψ.

According to the brittleness assumption, failure is attained suddenly when the straight line crosses the curve delimiting the safety domain, point A (Fig. 3). Apart from substitution of the SIFs with the GSIFs, this behaviour strictly resembles what occurs in the classical crack branching problem. Indeed, the crack branching problem is a particular case of the present one. However there is a substantial difference with respect to the crack kinking problem: if $\omega > 0°$, the mode mixity ψ depends also on the material brittleness through l_{ch} (see eqn (13)) and not only on the loading, i.e. on the GSIFs ratio. For a given K_{II}^* / K_I^* ratio, the slope of the loading line will diminish for brittle materials (low l_{ch}), while will increase for less brittle materials (high l_{ch}): in other words, whatever is the GSIF ratio, the failure point migrates towards point B (pure mode I failure) as material brittleness increases, whereas it moves towards point C, if the brittleness decreases (within a certain range, otherwise, as explained in the following section, the asymptotic approach does not hold any more).

As clearly shown by eqn (13), the effect of the material on the mode mixity increases as the notch opening increase. In fact, for larger ω, the gap between the Williams eigenvalues λ_{II} and λ_I grows. On the other hand, for a vanishing notch opening angle, both λ_{II} and λ_I tend to 1/2 and the effect of the material vanishes. This material dependence is valid also for the orientation of the V-notch emanated crack, see Fig. 2a: as brittleness increases, l_{ch} diminishes, ψ diminishes and the crack deflection ϑ_c tends to zero, i.e. the V-notch emanated crack tends to propagate in mode I along the bisector. On the other hand, for less brittle material, the crack deflection is higher under the same GSIFs ratio. Once more, it is worth emphasizing the fundamental difference with respect to the crack case, where the angle of the crack kinking depends only on the (dimensionless) SIFs ratio, i.e. is the same independently of the material.

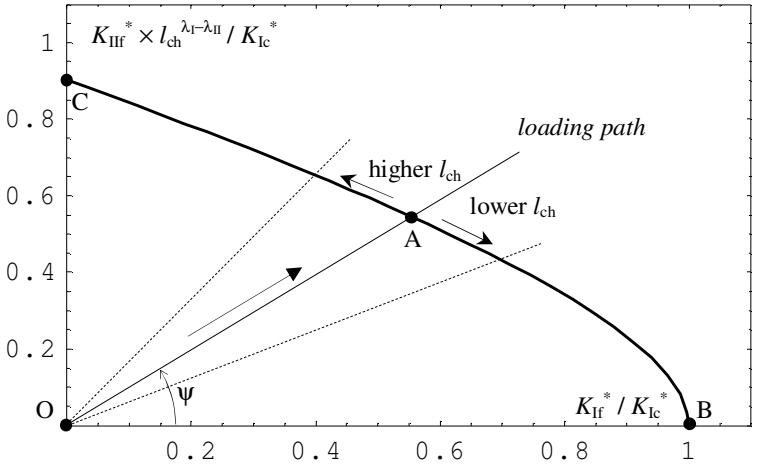

Figure 3. Resistance domain in the GSIFs plane ($\omega = 90°$): points lying beneath the thick curve correspond to admissible stress states and vice-versa.

In Fig. 2b we plotted the safety domains for different notch opening angles ω. It is evident that all the curves are similar. Of course, this fact does not imply that the failure load does not vary with ω, since the physical dimensions as well as the shape functions defining the GSIFs vary along with ω. It simply shows that the transition from mode I to mode II fracture is approximately the same for all the notch amplitudes.

5. Size effect and mode mixity

The introduction of a physical length against which to scale the notch tip GSIFs enables further aspects of the solution to be drawn out, such as the influence of a V-notch on the so-called size effect. Hence let us consider a set of self-similar geometries as the ones drawn in Fig. 4. Dimensional analysis allows us to write directly:

$$K_I^* = f_I(\omega, a/b)\,\sigma\, b^{1-\lambda_I}\,, \quad K_{II}^* = f_{II}(\omega, a/b)\,\sigma\, b^{1-\lambda_{II}} \tag{15}$$

where σ is the nominal stress, b is a characteristic size of the structure and f_I, f_{II} are shape factors depending on the geometry, here synthetically defined by the notch opening angle ω and relative notch depth a/b.

Now let us focus our attention to the size effect on the nominal stress at failure σ_f. If only either the mode I or the mode II GSIF is different from zero, failure will occur whenever the corresponding GSIF reaches K_{Ic}^* or K_{IIc}^*, respectively (the latter value being given by the intercept with the vertical axis in Fig. 3). Hence, according to eqn (15), the logarithm of the nominal stress at failure is given by [1]:

$$\ln\sigma_f = \ln\left[\frac{K_{Ic}^*}{f_I(\omega, a/b)}\right] - (1-\lambda_I)\ln b \qquad \text{or} \qquad \ln\sigma_f = \ln\left[\frac{K_{IIc}^*}{f_{II}(\omega, a/b)}\right] - (1-\lambda_{II})\ln b \tag{16}$$

It means that in a bi-logarithmic plot the strength vs. size curve is a straight line with (negative) slope equal to either $(1-\lambda_I)$ or $(1-\lambda_{II})$, see Figs. 5a,b. Since $\lambda_{II} > \lambda_I$, the size effect is stronger under mode I than under mode II loadings.

On the other hand, in the case of mixed mode loadings, we have to substitute both eqns (15) into the stress condition (8) for crack propagation. Accordingly, we get:

$$\frac{\sigma_f}{\sigma_u} = \frac{1}{f_I(\omega, a/b)\left[\overline{f}^{\,I}_{\vartheta\vartheta}\Big/\delta^{1-\lambda_I}\right] s^{-2(1-\lambda_I)} + f_{II}(\omega, a/b)\left[\overline{f}^{\,II}_{\vartheta\vartheta}\Big/\delta^{1-\lambda_{II}}\right] s^{-2(1-\lambda_{II})}} \tag{17}$$

where we introduced the brittleness number s as [15]:

$$s = \frac{K_{Ic}}{\sigma_u\sqrt{b}} = \sqrt{\frac{l_{ch}}{b}} \tag{18}$$

The terms in square brackets in eqn (17) show a modest variation with the size, so that the terms in round brackets dominate. It means that, for large sizes and/or brittle materials, the first addend at the denominator (i.e. mode I) prevails; on the other hand, for small sizes and/or less brittle materials, the second addend at the denominator (i.e. mode II) does govern the problem. The presence of the brittleness number s in (17) highlights that the transition from mode I- to mode II-governed failure depends both on size and material brittleness. Thus we conclude that the size effect for a V-notched structure under mixed mode loading is represented by a curve with two slant asymptotes in the bilogarithmic plot (see Fig. 5c): the right one with slope $(1-\lambda_I)$, the left one with slope $(1-\lambda_{II})$. This is a general trend, i.e. independent of the geometry and fracture criterion adopted.

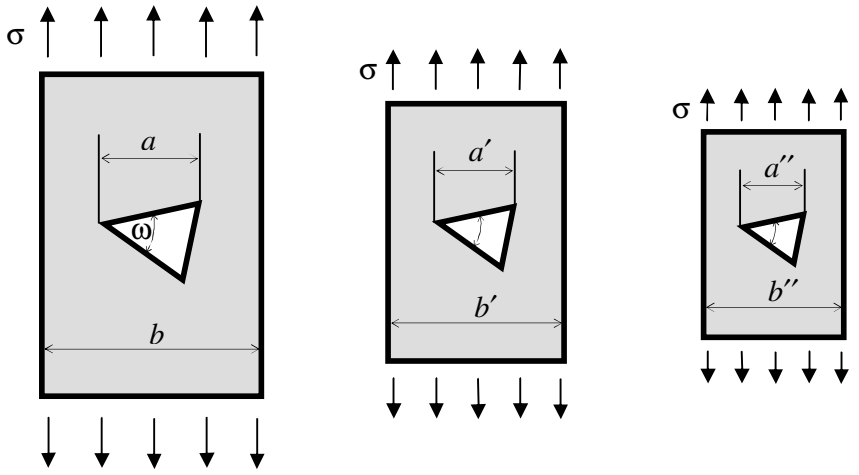

Figure 4. Self-similar specimens with a re-entrant corner of amplitude ω.

It is worth observing that the analysis of the mode mixity leads to the same conclusion. In fact substitution of eqns (15) into eqn (13) provides:

$$\psi = \arctan\left[\frac{f_{II}(\omega, a/b)}{f_I(\omega, a/b)} \quad s^{2(\lambda_{II}-\lambda_I)}\right] \tag{19}$$

Equation (19) clearly shows that, except in the crack case ($\lambda_I = \lambda_{II} = 1/2$), the mode mixity does not depend only on the shape factors, but also on the brittleness number, i.e. on the structural size. In fact, whatever is the ratio between f_{II} and f_I (provided they are both different from zero), for sufficiently large sizes the mode mixity will always tend to zero (i.e. pure mode I), whereas it will tend to $\pi/2$ for vanishing sizes (i.e. pure mode II).

While the large-size asymptote is always physically meaningful, the small-size asymptote could become only theoretical if mode II prevails for sizes too small for the asymptotic approach to hold true. In fact, when the finite crack extension is not negligible with respect to the other geometrical dimensions (e.g. for very small sizes), disregarding higher order terms in the asymptotic stress field is not acceptable. Similarly to LEFM, the asymptotic approach to V-notched structures leads to an infinite strength for vanishing sizes, i.e. to a result that, within the present coupled Rankine-Griffith criterion and under constant remote tensile stresses (see Fig. 4), must be regarded as physically unacceptable.

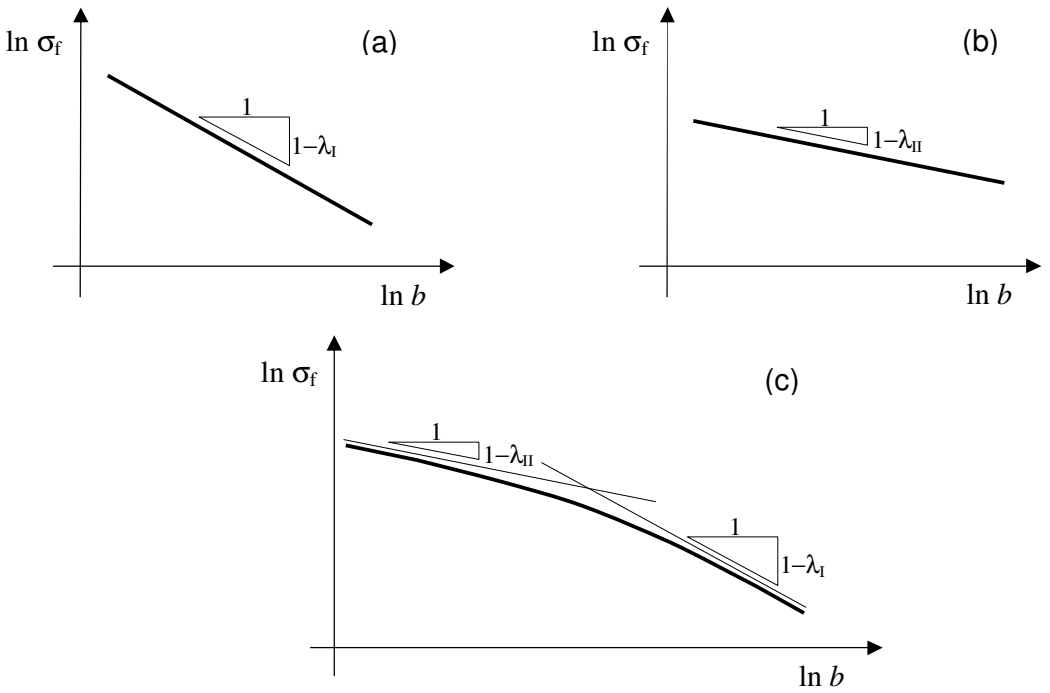

Figure 5. Size effect on nominal stress at failure: (a) pure mode I loading; (b) pure mode II loading; (c) mixed mode loading.

6. Conclusions

In the present paper we applied the FFM criterion provided in Cornetti et al. [14] to determine the critical load in V-notched structures under combined Mode I and Mode II loadings. With respect to simple Mode I loadings [5], the mixed mode problem is more complex since, beyond the failure load, also the direction of the crack onset at the re-entrant corner tip is unknown. Nevertheless, exploiting suitable weight functions for the SIFs of a V-notch-emanated crack [12], we were able to formulate the model as a standard minimization-under-constraint problem and to solve it by means of the Lagrange multiplier technique. A comparison with a broad set of experimental data (for both the failure load and the crack orientation) can be found in the recently published paper [16].

In mixed-mode loading cases, we showed that our model is able to explain the growing relevance of the mode II contribution for increasing material lengths l_{ch}, while it is negligible if l_{ch} tends to zero. Nevertheless, since the present approach is based on the asymptotic stress field, it yields accurate results only for sufficiently small l_{ch} values (with respect to the other geometrical dimensions). If this condition is not met, it is necessary to consider further terms in the stress field asymptotic expansions [17] or to tackle the problem numerically [18].

Abstract Two three-parameter descriptions for the three-dimensional (3D) crack-tip stress fields have been introduced. The three-parameter solution K-T-T_z is developed to describe the linear elastic crack-tip stress state, and the J-Q_T-T_z is to elastic-plastic crack-tip field. The conventional two-dimensional solutions such as K, K-T, HRR and the extended J-Q description which considers the in-plane constraint modification can hardly provide satisfied description for the three-dimensional crack front fields, especially for the out-of-plane stress near the crack front. It is shown that a consideration of the out-of-plane constraint and use of the three-parameter description is necessary and efficient to predict the 3D stress fields near the crack front.

Keywords Fracture mechanics, Three-dimensional stress field, Out-of-plane stress constraint

1. Introduction

The complicated three-dimensional (3D) stress fields near the crack front play a vital role in the strength of materials [1], and control the initiation and propagation of cracks [2]. The character of the stress fields near the crack front has long been extensively studied. The classical linear elastic and elastic–plastic fracture mechanics are based on the theory stemming from the one singular term of asymptotic expression and its amplitude the stress intensity factor (SIF, K) [3] and HRR solution [4, 5], respectively. Then more accurate two-parameter approaches, such as K–T [6], J–T [7], J–Q [8, 9] and J–A_2 [10, 11], have been developed to describe the crack-tip field. These approaches have been applied successfully in engineering designs though they are limited to describe the effect of the in-plane constraint on the crack-tip field and fracture toughness. In fact, fracture toughness depends on the 3D out-of-plane stress level near the crack front also [12]. It is well known that fracture toughness depends highly on the thickness of the test specimen until a threshold thickness, beyond which the toughness does not decrease further. The toughness at this thickness is called plane strain fracture toughness. It is less than the fracture toughness of thinner plates and is a material property. So the variable fracture toughness is inconvenient in the engineering applications if the 3D out-of-plane stress level is not considered accurately.

In order to describe the out-of-plane stress level, the out-of-plane stress constraint factor T_z was introduced by Guo [13-15], the factor is defined as

$$T_z = \frac{\sigma_{33}}{\sigma_{11}+\sigma_{22}}, \qquad (1,\ 2,\ 3)=(x,\ y,\ z) \text{ or } (r,\ \theta,\ z) \tag{1}$$

where r, θ, x and y are coordinates in the conventional polar and Cartesian systems with origin at the crack tip and z is the third coordinate (parallel to the crack front) in both systems. The corresponding coordinate system and a normal sheet element of a through-straight crack are shown in Fig.1. In the state of plane stress, T_z=0. In the state of plane strain, T_z changes from the Poisson's ratio v of the linear elastic material to 0.5 for elastic-perfectly plastic material.

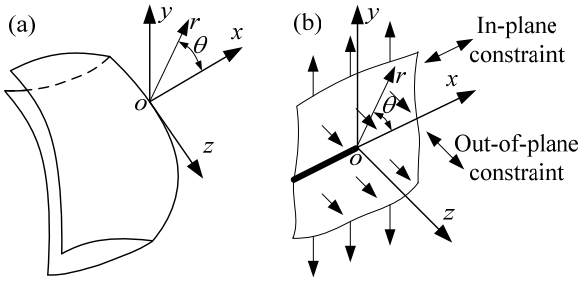

Fig. 1 The coordinate system and a normal sheet element of a through-straight crack.

The out-of-plane constraint factor T_z plays an important role in the determination of fracture toughness of a structural element. The effect of Tz on 3D crack-front fields and fracture toughness were systematically studied by Guo, then the 3D two-parameter principles of K–T_z, J–T_z have been proposed [12-16]. Combining with the in-plane constraint T or Q, the 3D three-parameter principles of K-T-T_z and J-Q_T-T_z have also been proposed [13-15, 17-22].

In this paper, the recent researches on the 3D three-parameter principles of K-T-T_z and J-Q_T-T_z are emphasisly summarized. The comparisons of the three-parameter principles with two-parameter and one-parameter principles are presented.

2. Three-parameter principle K–T–T_z for the linear elastic material

Based on the SIF K, the more accurate two-parameter approach K–T was proposed by Williams [6] for linear elastic material. For the 3D crack case, the three-parameter principle K-T-T_z was developed by Guo [13-15, 17-19] based on the K-T approach, which can be expressed as

$$\begin{cases} \sigma_{ij} = \dfrac{K}{\sqrt{2\pi r}} f_{ij}(\theta) + T\delta_{1i}\delta_{1j} \\ \sigma_{zz} = T_z(\sigma_{ii} + \sigma_{jj}) \end{cases} \qquad (i,\ j) = (x,\ y),\ (r,\ \theta) \text{ or } (1,\ 2) \tag{2}$$

where T is the T-stress,

$$f_{11}(\theta) = \cos\frac{\theta}{2}\left(1 - \sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right) \tag{3}$$

$$f_{22}(\theta) = \cos\frac{\theta}{2}\left(1 + \sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right) \tag{4}$$

$$\tau_{12}(\theta) = \cos\frac{\theta}{2}\sin\frac{\theta}{2}\cos\frac{3\theta}{2} \tag{5}$$

The three-parameter principle K-T-T_z can describe not only the in-plane constraint by T but also the out-of-plane stress constraint by T_z. Then the crack-tip stress fields described by the principle K-T-T_z for the typical cracks such as through-the-thickness crack, quarter elliptical corner crack, semi-elliptical surface crack and embedded elliptical crack are discussed. The geometry of a plate with a quarter elliptical crack under uniform tension is presented in Fig.2, the corresponding FE mesh is shown in Fig.3. The 3D singular elements with four mid-side nodes at the quarter points are used around the crack front to simulate the inverse square root singularity at the crack tip. The FE model in Fig.3 can be used to simulate the semi-elliptical surface crack and embedded elliptical

crack by altering the corresponding displacement boundary conditions.

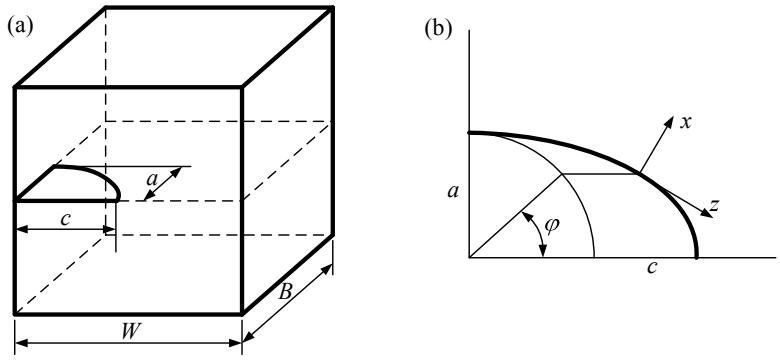

Fig.2 Geometry of a plate with a quarter elliptical crack under uniform tension. (a) The 3D geometry model. (b) Cracks with different a/c and the local rectangular coordinate system.

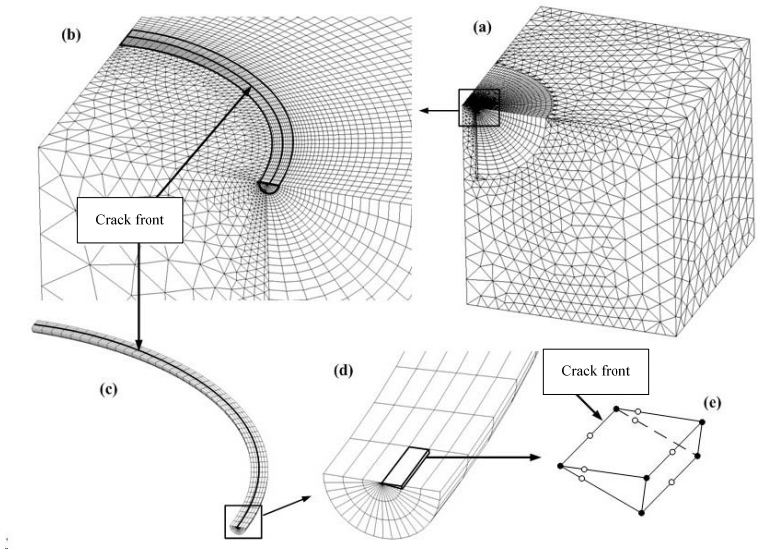

Fig.3 FE model of the quarter elliptic corner crack

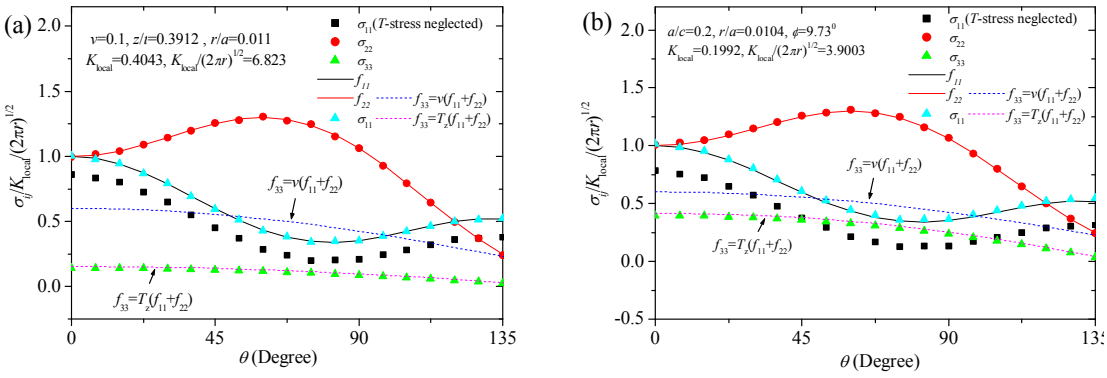
The comparisons of the three-parameter principle K-T-T_z with the FE results are presented in Fig. 4.



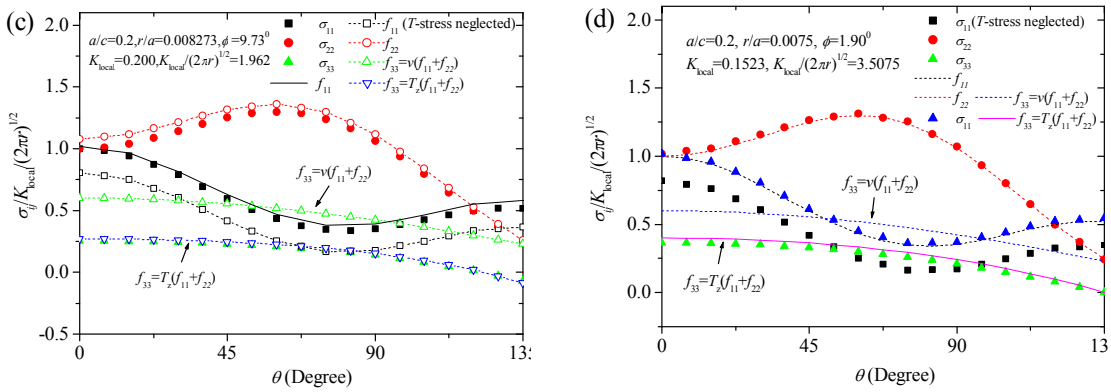


Fig.4 The angular distributions of stress components normalized by the local stress intensity factors in a normal plane of the quarter-elliptical corner crack front line. (a) through-the-thickness straight crack, (b) semi-elliptical surface crack, (c) quarter elliptical corner crack, (d) embedded elliptical crack.

As shown in Fig. 4, the angular distributions of stress components in a normal plane of various crack front lines are given in the local Cartesian coordinates. It can be seen that σ_{22} is in good agreement with f_{22}, while the differences between σ_{11} and f_{11} are great if the T-stress is neglected. When the T-stress is considered, the differences will become very small. In addition, the differences between σ_{33} and f_{33} for the plane strain state ($\nu(f_{11}+f_{22})$) are great. If the T_z factor is considered in f_{33}, f_{33} will be in good agreement with σ_{33}.

3. Three-parameter principle J–Q_T–T_z for the elastic-plastic material

The HRR stress components can be expressed as

$$\left(\sigma_{ij},\sigma_m,\sigma_e\right)=Kr^{-\frac{1}{n+1}}\left(\tilde{\sigma}_{ij}\left(\theta\right),\tilde{\sigma}_m\left(\theta\right),\tilde{\sigma}_e\left(\theta\right)\right) \tag{6}$$

where

$$K=\left(\frac{J}{\alpha\sigma_0\varepsilon_0 I\left(n\right)}\right)^{\frac{1}{n+1}} \tag{7}$$

σ_0 is the yield stress.

By considering the effects of geometry and size on crack-tip constraint, O'Dowd and Shih [8, 9] found that the near-tip stress field is governed by the two parameters of J and Q as follows:

$$\sigma_{ij}=\left(\frac{J}{\alpha\sigma_0\varepsilon_0 I\left(n\right)r}\right)^{\frac{1}{n+1}}\tilde{\sigma}_{ij}\left(\theta\right)+Q_{ij}\delta_{ij}\left(\frac{r}{J/\sigma_0}\right)^{\lambda}\sigma_0 \tag{8}$$

The first term is the HRR solution ($|\theta|<\pi/2$), Q is a function of the stress triaxiality achieved ahead of the plane strain cracks. The λ is set to zero, then Q_{rr}=$Q_{\theta\theta}$ and Q_{ij} is the form

$$Q_{ij}=\frac{\sigma_{ij}-\sigma_{ij}\big|_{HRR}}{\sigma_0} \qquad (\theta=0^{\circ},\ r=2J/\sigma_0) \tag{9}$$

The *J*-*Q* solution can effectively describe the influence of the in-plane stress parameters when the radial distances ($r/(J/\sigma_0)$) are relatively small, while the approach can hardly characterize it very well with the increase of $r/(J/\sigma_0)$ and strain hardening exponent n. On the other hand, it can hardly give a proper description of Von Mises equivalent stress σ_e because it seldom considers the out-of-plane stress constraint, so Guo and his collaborators proposed two 3D three-parameter principles of *K*-*T*-T_z and *J*-*Q*-T_z, combining with the in-plane constraint *T* or *Q*, for linear elastic and elastic-plastic materials.

Further researches by Guo [13-15, 20-22] show that I( ) is the function of n and T_z,

$$K=\left(\frac{J}{\alpha\sigma_0\varepsilon_0 I\left(n,T_z\right)}\right)^{\frac{1}{n+1}} \tag{10}$$

where

$$\begin{aligned} I\left(n,T_z\right)=\int_{-\pi}^{\pi}\{&\frac{n}{n+1}\tilde{\sigma}_e^{n+1}\cos\theta-\sin\theta\left[\tilde{\sigma}_{rr}\left(\tilde{u}_\theta-\frac{\partial\tilde{u}_r}{\partial\theta}\right)-\tilde{\sigma}_{r\theta}\left(\tilde{u}_r+\frac{\partial\tilde{u}_\theta}{\partial\theta}\right)\right]\\ &-\cos\theta\left[n\left(s-2\right)+1\right]\left(\tilde{\sigma}_{rr}\tilde{u}_r+\tilde{\sigma}_{r\theta}\tilde{u}_\theta\right)\}d\theta, \end{aligned} \tag{11}$$

$$\tilde{u}_r=\frac{\tilde{\sigma}_e^{\,n-1}}{n\left(s-2\right)+1}\left(d_1\tilde{\Phi}+d_2\frac{\partial^2\tilde{\Phi}}{\partial\theta^2}\right), \tag{12}$$

$$\tilde{u}_\theta=\frac{1}{n\left(s-2\right)}\left(2d_s\tilde{\sigma}_e^{\,n-1}\frac{\partial\tilde{\Phi}}{\partial\theta}-\frac{\partial\tilde{u}_r}{\partial\theta}\right), \tag{13}$$

$$\frac{\partial\tilde{u}_r}{\partial\theta}=\frac{1}{n\left(s-2\right)+1}\left[\frac{\partial\left(\tilde{\sigma}_e^{\,n-1}\right)}{\partial\theta}\left(d_1\tilde{\Phi}+d_2\frac{\partial^2\tilde{\Phi}}{\partial\theta^2}\right)+\tilde{\sigma}_e^{\,n-1}\left(d_1\frac{\partial\tilde{\Phi}}{\partial\theta}+d_2\frac{\partial^3\tilde{\Phi}}{\partial\theta^3}\right)\right], \tag{14}$$

$$\frac{\partial\tilde{u}_\theta}{\partial\theta}=\tilde{\sigma}_e^{\,n-1}\left(d_3\tilde{\Phi}+d_4\frac{\partial^2\tilde{\Phi}}{\partial\theta^2}\right)-\tilde{u}_r. \tag{15}$$

The d_i is the function of T_z and n, $\tilde{\Phi}=\tilde{\Phi}\left(\Phi\right)$, which is same as that in HRR solution.

The Eq.(8) can be modified

$$\sigma_{ij}=\left(\frac{J}{\alpha\sigma_0\varepsilon_0 I\left(n,T_z\right)r}\right)^{\frac{1}{n+1}}\tilde{\sigma}_{ij}\left(\theta,T_z\right)+Q_{Tij}\delta_{ij}\left(\frac{r}{J/\sigma_0}\right)^{\lambda}\sigma_0 \tag{16}$$

where

$$Q_{Tij} = \frac{\sigma_{ij} - \sigma_{ij}\big|_{J-T_z}}{\sigma_0} \qquad (\theta=0^{\circ} \text{ and } r=2J/\sigma_0) \tag{17}$$

Combining Eq.(9), the relationship between Q_{Tij} and Q_{ij} is

$$Q_{Tij} = Q + \frac{\sigma_{ij}\big|_{HRR} - \sigma_{ij}\big|_{J-T_z}}{\sigma_0} \tag{18}$$

The comparisons of the three-parameter solution J–Q_{T}–T_{z} with the solutions of J-Q and HRR are shown in Fig.5. It is shown that the three-parameter approach J–Q_{T}–T_{z} can describe the 3D stress fields effectively.

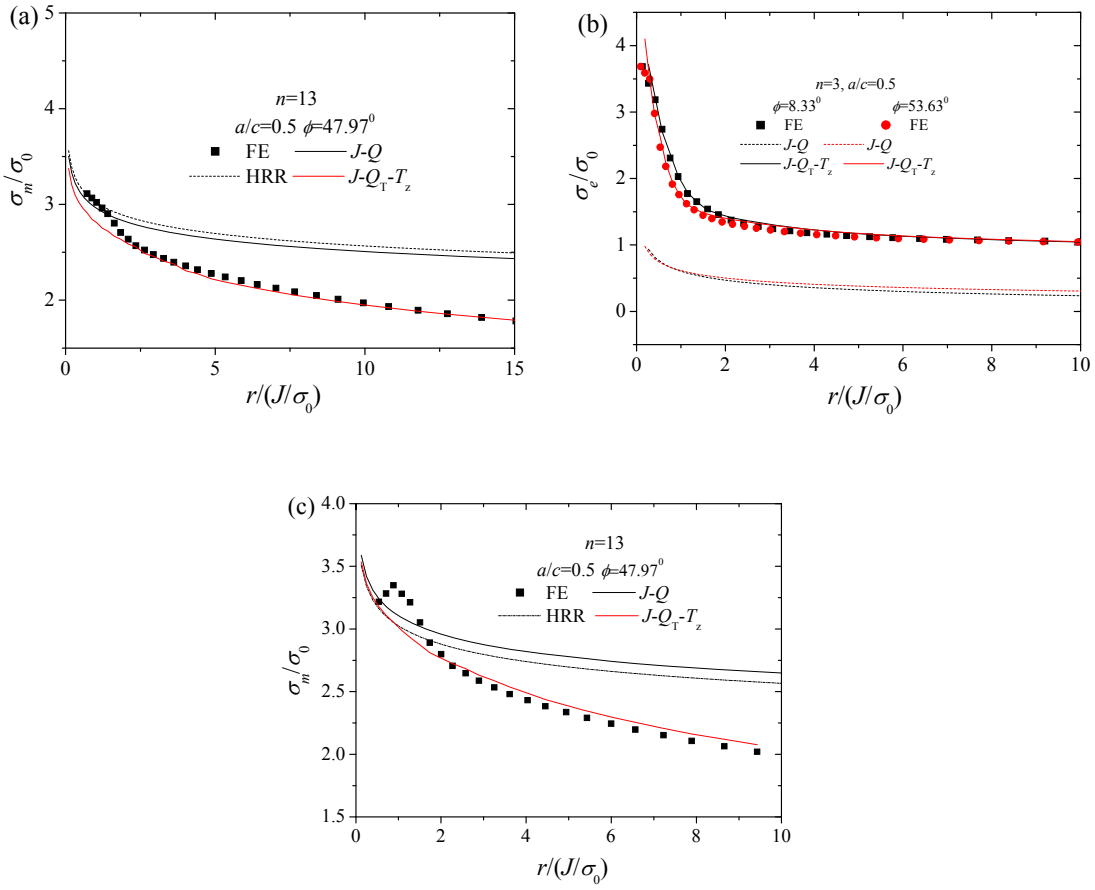

Fig.5 The radial distributions of the stress components. (a) Mean stress for a semi-elliptical surface crack, (b) Von Mises equivalent stress σ_{e} for a quarter elliptical corner crack, (c) Mean stress for an embedded elliptical crack.

4. Conclusions

Two three-parameter descriptions for the three-dimensional (3D) crack-tip stress fields have been introduced. The three-parameter solution K–T–T_z is developed to describe the linear elastic crack-tip stress state, and the J–Q_T–T_z is to elastic-plastic crack-tip field. The comparisons of the three-parameter solutions K–T–T_z, J–Q_T–T_z with the corresponding two-parameter solutions K-T, J–Q and single-parameter solutions K and HRR are presented. It is shown that the three-parameter approaches K–T–T_z, J–Q_T–T_z can describe the 3D stress fields effectively.

In-situ Observation of Mixed Mode Fatigue Crack Growth Behavior in Heat Affected Zone of a Welded Joint

Ming-Liang Zhu*, De-Qiang Wang, Fu-Zhen Xuan, Shan-Tung Tu

Key Laboratory of Pressure Systems and Safety, Ministry of Education, East China University of Science and Technology, Shanghai 200237, China

Abstract In-situ scanning electron microscope (SEM) observations of fatigue crack growth behavior in heat affected zone (HAZ) of a welded joint were performed with CTS (Compact-Tension-Shear) specimens under mixed-mode loading conditions in vacuum. Results showed that mode I fatigue behavior in the HAZ was influenced by local microstructure anisotropy and the 'zigzag' mode crack profile tended to deviate into the lower strength weld metal. With increasing the mixity of mode I/II loadings, fatigue crack growth rate was decreased with significant crack branching. Shear and branch cracks were competitive along the crack path, and fatigue cracks were often initiated from grain boundary and the interface of lath martensites. The cracks tended to orient themselves into a pure mode I condition. Three existing models were discussed with respect to their capabilities to predict crack direction under various loading conditions.

Keywords in-situ SEM, fatigue crack growth, crack growth path, mixed-mode loading, heat affected zone

1. Introduction

Generally, the various loading types in actual practices are often idealized as being mode I, mode II and mode III based on linear elastic fracture mechanics. Majority of crack growth investigations under both static and cyclic loadings were concentrated on single-mode loading mode such as the mode-I load condition. Unfortunately, single-mode loading seldom occurs in practice, and many service failures occur from cracks subjected to mixed mode loadings which involve more than one crack-tip mode. Even in pure mode I cyclic testing, any deviation of crack path or alternation of external loading direction would lead to combinations of mode II deformation in crack growth process.

Under mixed mode loading conditions, it was of importance to consider the evolution of crack growth direction. Several criteria for crack growth path prediction such as maximum tangential stress (MTS) criterion by Erdogan and Sih [1], minimum strain energy density (SED) criterion by Sih [2], the criterion of energy release rates by Nuismer [3], and the criterion of Richard [4], have been proposed and well documented in [4-6]. However, all these concepts were based on the isotropic material and limited to the linear elastic fracture mechanics [5]. Another issue in combined loading mode was the crack growth rate. Unlike the conventional stress intensity factor range ΔK in pure mode I fatigue, many parameters have been proposed to correlate mixed mode fatigue crack growth (FCG) rates. For example, Tanaka [7] and Yan [8] suggested the effective stress intensity factor range ΔK_{eff}, Patel and Pandey [9] insisted the strain energy density factor range ΔS, while Socie et al [10] proposed the equivalent strain intensity factor for small cracks.

Moreover, the fatigue thresholds [11, 12], crack closure [13, 14], microstructure [15] and loading path [16, 17] influences under mixed mode loading conditions have been investigated. While cracks were observed to propagate in homogeneous materials as widely reported, complications associated with the mixed mode fatigue crack behavior in heterogeneous microstructures, i.e., the gradient microstructures in the heat-affected-zone (HAZ), were far less well understood. In this case, the effect of microstructure anisotropy on crack growth morphology needed to be elucidated.

In the present work, mixed mode (I+II) FCG experiments were performed on an in-situ stage equipped in SEM by using CTS (Compact-Tension-Shear) specimens developed by Richard [18]. The effect of external loading angle on the crack growth rate and crack growth direction was analyzed in terms of local microstructure gradient in the HAZ. The crack growth direction was finally predicted on the basis of the existing models.

2. Materials and experiments

2.1. Materials and specimens

The material studied was the HAZ of a welded joint. The base material of the welding joint was a NiCrMoV type steel. It was undergone quenching and tempering heat treatment, and the resultant tensile strength and yield strength were 835.5 and 938 MPa, respectively. The weldment was formed by submerged arc welding (SAW) technique using filler metal of the 2.5%Ni low alloy steel. The HAZ, which had a width of about 3 mm, included three micro-zones, i.e., fully quenched-tempered zone (FQTZ), partially quenched-tempered zone (PQTZ) and tempered zone (TZ) [19]. The microstructures mainly included tempered martensites and bainites with martensite/bainite constituents altered in the HAZ.

In order to prepare CTS specimen for in-situ observation, standard three-point bending samples with a/W ratio of 0.5 and the thickness B of 16 mm were firstly machined from the welded joint. The initial notch in the sample was located in the FQTZ of the HAZ, with a distance of 120 μm to the fusion line. The samples were then pre-cracked under pure mode I loading at a stress ratio of 0.1 with a sinusoidal waveform to form a crack length of about 2 mm. Subsequently, relatively smaller specimens with a thickness of about 0.5 mm were prepared for in-situ tests. Fig. 1 shows the shape and dimensions of the CTS specimens.

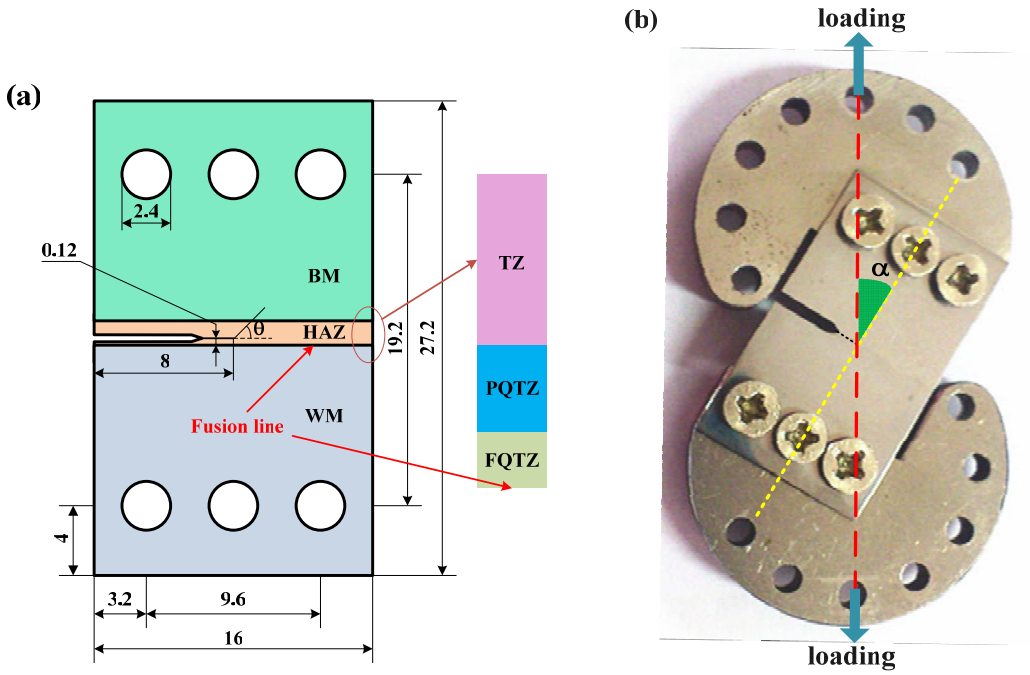

Figure 1. The shape and dimensions of the CTS specimens (a) and the loading device for mixed mode tests (b)

2.2. Fatigue experiments

Before the in-situ fatigue experiments, the CTS specimens were grounded, polished and finally

etched. Constant amplitude fatigue tests using triangular waveform with a load ratio of 0.1were performed on a loading stage equiped in the SEM in vacuum environment (9×10^{-4}–9×10^{-3} Pa). The frequency was as low as 0.03 Hz. The various values of $\Delta K_I/\Delta K_{II}$ could be achieved by changing the external loading angle α. As shown in Fig. 1b, the line of application of force F extends at an angle α to the longitudinal axis of the specimen. Depending on the size of angle α, mixed mode loadings occur at $0<\alpha<90°$. It is obvious that pure mode I loading corresponds to the α equaling to zero, whereas the α at 90° stands for the pure mode II loading. After the crack extended for a given length (less than 10 μm), the experiments were intermitted to measure crack length, record the cyclic numbers and characterize the crack morphology as well. For various loading angles, the initial mixed mode fatigue crack growth parameters, which was calculated by the Eqs. (1) - (3) developed by Richard [17], are listed in Table.1. In Eq. (3), the material parameter α_1 is set to 1.155.

$$K_{\mathrm{I}} = \frac{F\sqrt{\pi a}}{WB}\cdot\frac{\cos\alpha}{1-a/W}\cdot\sqrt{\frac{0.26+2.65\cdot\dfrac{a}{W-a}}{1+0.55\cdot\dfrac{a}{W-a}-0.08\cdot\left(\dfrac{a}{W-a}\right)^2}} \tag{1}$$

$$K_{\mathrm{II}} = \frac{F\sqrt{\pi a}}{WB}\cdot\frac{\sin\alpha}{1-a/W}\cdot\sqrt{\frac{-0.23+1.40\cdot\dfrac{a}{W-a}}{1-0.67\cdot\dfrac{a}{W-a}+2.08\cdot\left(\dfrac{a}{W-a}\right)^2}} \tag{2}$$

$$\Delta K_{\mathrm{eff}} = \frac{K_{\mathrm{I}}}{2}+\frac{1}{2}\sqrt{K_{\mathrm{I}}^2+4\left(\alpha_1 K_{\mathrm{II}}\right)^2} \tag{3}$$

Table 1. Initial mixed mode FCG parameters in the FQTZ of the HAZ

α	a_0/W	ΔK_I (MPa·m$^{1/2}$)	ΔK_{II} (MPa·m$^{1/2}$)	$\Delta K_I/\Delta K_{eff}$
0	0.5451	35.27	0	1
30°	0.5449	30.46	7.95	0.92
60°	0.5476	17.75	13.82	0.65

3. Results

3.1. *a*-*N* relationship

Fig. 2 shows the changes of crack extension as a function of cyclic numbers. It is observed that the crack extends slowly first and then become faster at all of the loading angles. However, with the decreasing of $\Delta K_I/\Delta K_{eff}$, which meant the reduced contribution of mode I loading, the crack extension was also decreased. Nevertheless, due to the proximity of the $\Delta K_I/\Delta K_{eff}$ values at α of zero and 30°, the corresponding crack extension values were also close and even converged to each other eventually. This indicated that the load mixity dependence of crack growth behavior located mainly in the initial crack growth process.

3.2. Fatigue crack growth rate d*a*/d*N*

Fig. 3 indicates the FCG rate da/dN at various loading angles. It is worth noting that the da/dN at α of zero and 30° are similar to each other but larger than those of the α of 60°. It is also worth noting that the evolution of da/dN for pure mode I loading fluctuates with the crack length, i.e., the delay and acceleration phases alternates. This reflected the influence of local microstructures. Whereas for

mixed mode of fatigue, the da/dN are tended to increase along with the crack length at both α of 30° and 60°. In this case, the important issue is that whether the local microstructures still have a large influence or are there other factors that should be considered. The roles of ΔK_{I} and ΔK_{II} in the mixed mode crack growth also need to be elucidated.

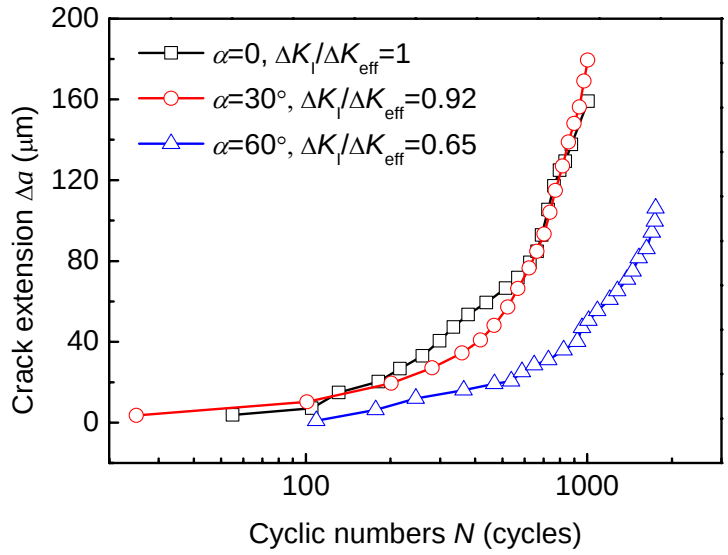

Figure 2. The crack extension Δa versus cyclic numbers N at different loading angles

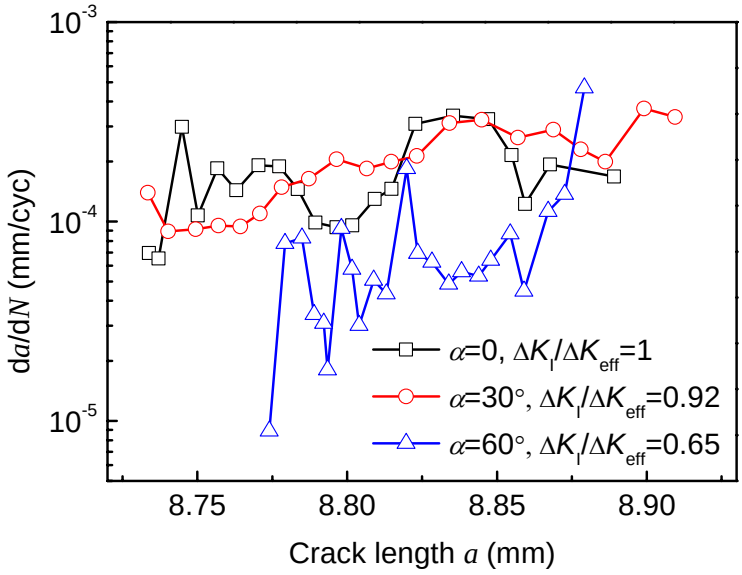

Figure 3. Fatigue crack growth rates at different loading angles

3.3. Crack growth path deflection

Fig. 4 presents the macro-crack profile at various loading angles. For mode I loading, as shown in Fig. 4a, crack deflected for about 21° from the initial pre-crack and then fluctuated, and the resultant crack path was quite tortuous. When load mode was superimposed with mode II loading at α of 30° (Fig. 4b), the initial angles of branch cracks was increased to 27°. Under this angle, crack extended for about 150 μm, after which the crack was further deviated to an angle of about 45° in

the final stage of growth of 40 μm. With the ΔK_{II} further increased, i.e., α equals 60° in Fig. 4c, the initial branch cracks deflected about 52°. The crack extension values along the crack path in the X and Y-axis directions are depicted in Fig. 5. By linear fitting of the data, the deflection angles were consequently calculated to be 25° and 50° at α of 30° and 60°, respectively. This agreed well with the work reported by Kim [20] who obtained similar values in a rail steel.

4. Discussion

4.1. Influence of loading angle on FCG

Fig. 6 shows the FCG under pure mode I loading. At the end of the pre-crack, the crack propagated with two branches, as illustrated in Fig. 6b. One of the branch crack (lower side of the pre-crack) stopped growth after initiation along the grain boundary, whereas the other branch crack deflected at an angle of 21° and propagated to become the main crack. The competition between the two branch cracks to form the main crack was observed at *N* around 513 cycles in Fig. 6c. Though the original main crack continued growing forward, the lower side branch crack grew with a higher rate in a transgranular mode, and finally produced the main crack (Fig. 6d). In this process, it seemed that the crack tended to orient itself into a pure mode I condition at which the crack path was normal to the external loading direction.

The alternation of the main crack was also observed when *N* was around 727 cycles, as shown in

Figs. 6e and f. In this case, the main crack was finally formed by propagating the short branch crack and the non-propagation of the original main crack (the lower side branch crack in Fig. 6e). With the crack length increasing, as indicated in Fig. 6g, the slanted crack was again prone to return to the pure mode I trajectory, producing multiple bifurcations along the curved crack path. The bifurcated cracks were often located at grain boundaries and martensite lath interfaces. It is worth noting that the overall crack path propagated with serious local deviations, showing a 'zigzag' mode.

It is inferred that the significant changes of crack orientation is due to the highly anisotropic microstructures at the crack tip and the gradient strength distribution in the HAZ. It is generally accepted that the crack path is governed by the plastic behavior of the crack tip [21]. Accordingly, the cracks would orient themselves into the materials with lower strength values. Therefore, it is reasonable that the crack path is tended to deflect into the weld metal, which has lower strength than the PQTZ in the HAZ.

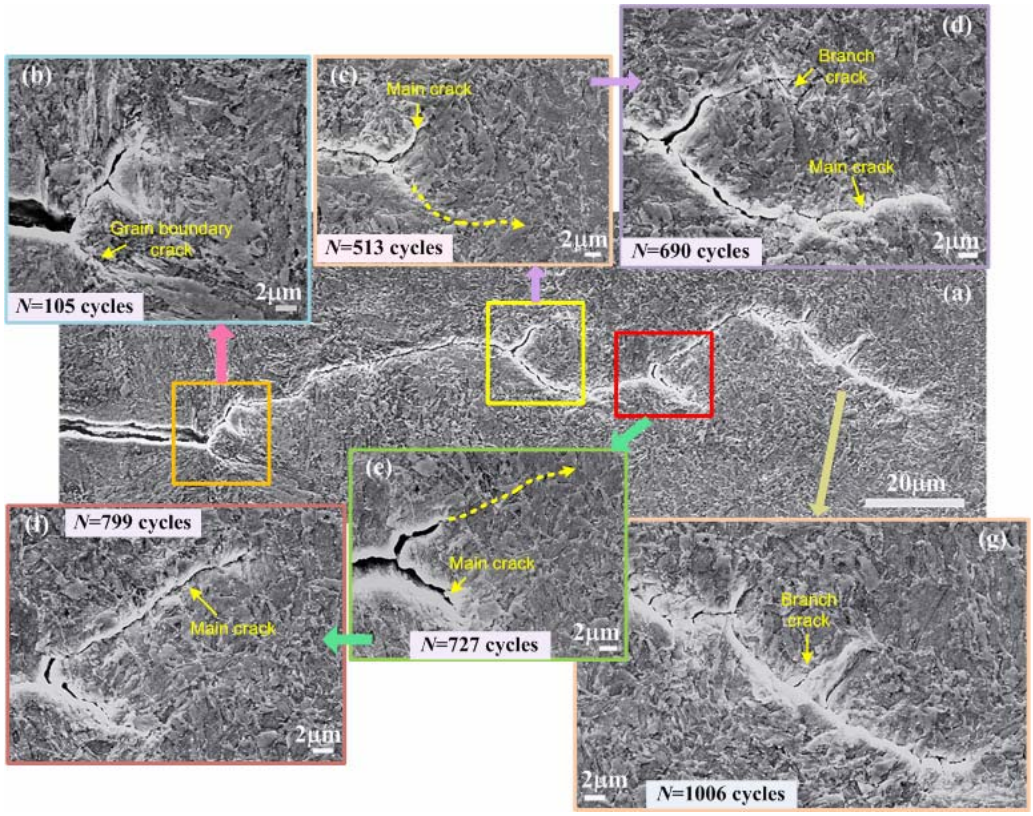

Figure 6. Fatigue crack growth morphology in pure mode I loading

Fig. 7 presents the FCG path at a loading angle of 30°. In Fig. 7a, the crack direction changed immediately from the initial pre-crack orientation with an angle of 27°. Crack bifurcations and shear cracks coexisted along with the main crack, which was resulted from the contribution of mode I and II components. As a result, the mode I component would drive the branch crack for a long length to a mode I crack direction. This was evidenced by formation of main crack based on the original branch crack in Fig. 7b. Tong et al. [22] reported that the formation and propagation of mode I branch cracks were of decisive importance for fatigue failures under combined loadings. It is also observed that the crack tip in Fig. 7a is branched along the grain boundary when N is increased to 622 cycles. On the other hand, the mode II component also contributed to FCG. With the formation of the grain boundary cracks at crack tip in Fig. 7b, a damage area containing many micro-cracks whose direction were almost parallel to the main crack was also formed, as shown in Fig. 7c. This was arisen from the shear deformation under mode II component in the mixed mode

loading.

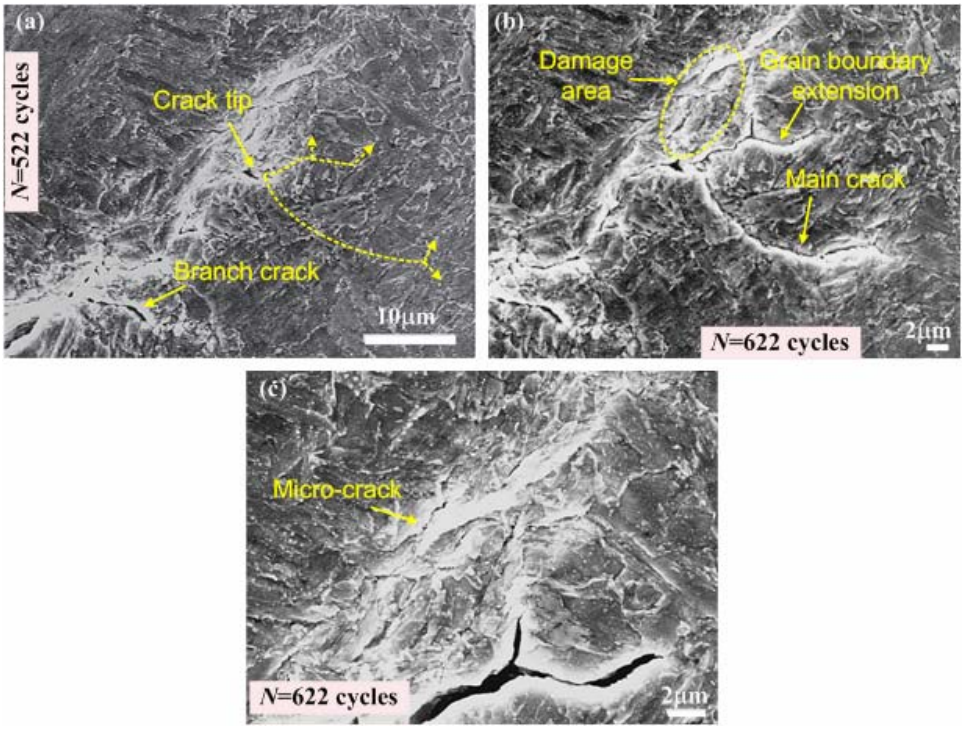

Figure 7. Fatigue crack growth path at a loading angle of 30°

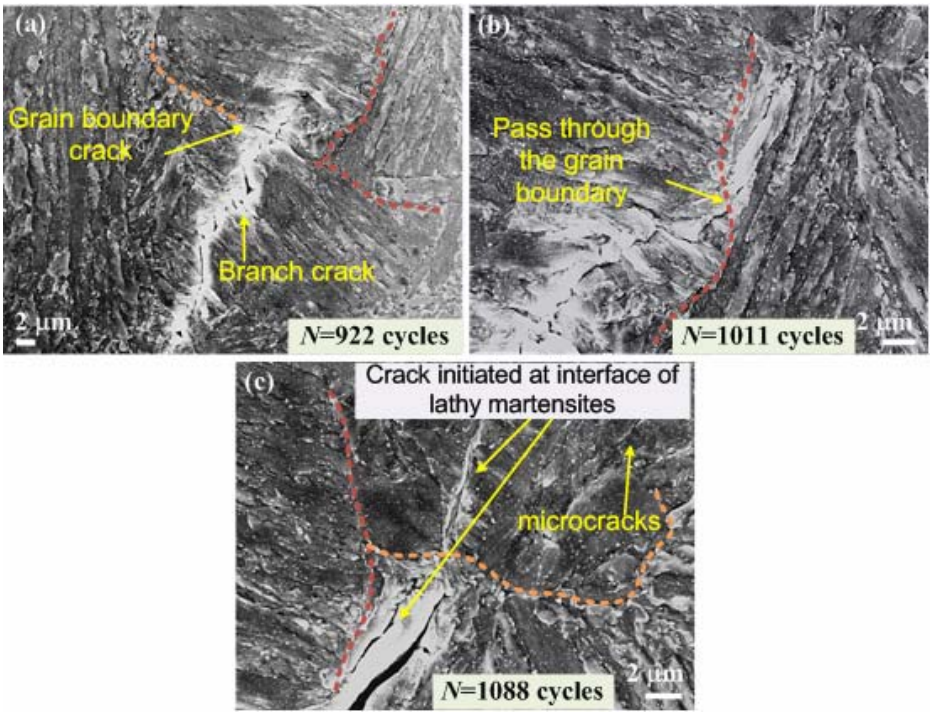

Figure 8. Fatigue crack growth path at a loading angle of 60°

The FCG behavior at a loading angle of 60° is illustrated in Fig. 8. It is observed in Fig. 8a that the crack extends transversely among the lathy martensites and propagates directly through the grain boundaries. In this process, crack bifurcated along the lath interfaces and grain boundaries. The passing through of the crack into the grain boundary was also observed in Fig. 8b, and then the crack extended along the interface of the lathy martensites. Therefore, it can be concluded that the interfaces of lathy martensites and the grain boundary are potential crack initiation sites. With the

increasing of cyclic numbers, one crack was formed again along the interface of the lathy martensites in the nearby grains, as can be seen in Fig. 8c. This would provide an easy path for the crack passing through the grain boundary since the cyclic plastic deformation has been extended to this area.

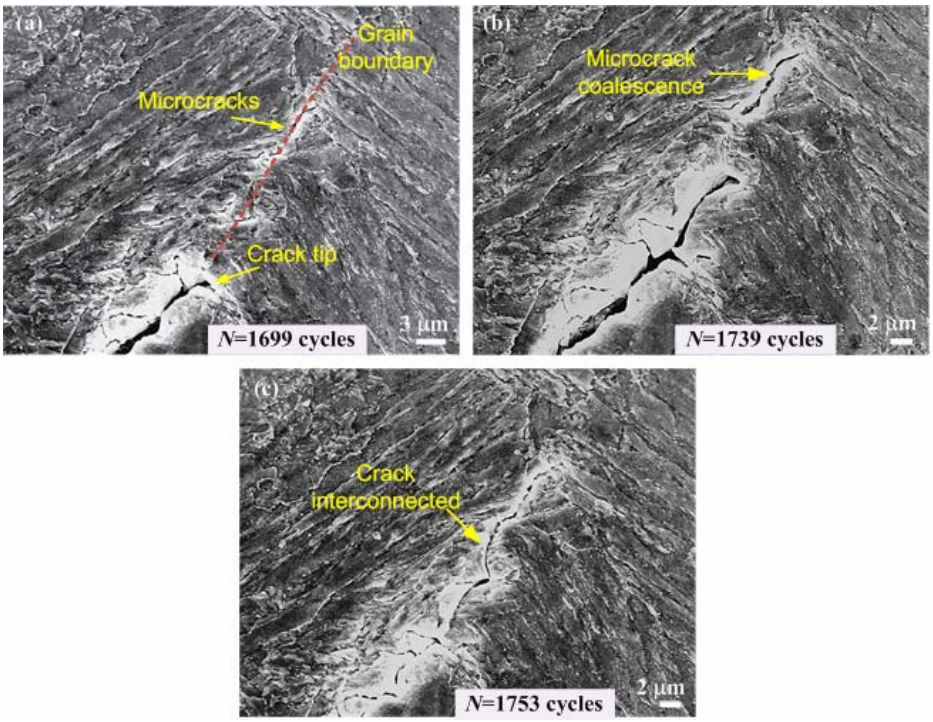

Figure 9. Coalescence of micro-cracks on the grain boundaries at the loading angle of 60°

Moreover, the damage area was dependent on the d*a*/d*N*, i.e., the higher the FCG rate, the larger the damage area. This is supported by the results in Fig. 9a, where a large number of micro-cracks has been formed at a distance about 30 μm in front of the main crack tip. Both branch and shear micro-cracks were occurred on the grain boundary. With the fatigue life increased to 1739 cycles, some micro-cracks were coalesced with each other, resulting in relatively longer cracks. Finally, all the micro-cracks were interconnected to form the main crack at N of 1753 cycles. The interconnection of grain boundary cracks increased the FCG rate considerably, which was plotted in Fig. 3. By comparing with the crack path at the loading angles of 30° and 60°, it can be observed that the length of branch cracks at α of 30° are longer and more shear micro-cracks at α of 60°. This was related to the branch versus shear crack competition in the mixed mode loading conditions.

4.2. Prediction of crack growth deflection angles

The initial deflection angles of FCG were predicted based on the SED criterion [2] in Eq. (4), the MTS criterion [1] in Eq. (5) and the criterion of Richard [4] in Eq. (6). In Eqs. (4) - (6), K_I and K_{II} are the mode I and II components, ν is Poisson's ratio, θ_0 is the critical deflection angles, and β is the angle between external loading and the crack surface. In this work, ν is set as 0.3, and the corresponding results are shown in Table 2. It is obvious that compared with the experimental data, all the predicted deflection angles for α of 30° and 60° are higher than the experimental data. Fortunately, the calculation based on MTS model was close to the experiments. Thus, the MTS criterion is suitable to predict crack growth direction in the HAZ under combined loadings. Nevertheless, all of the criteria cannot estimate the deflection of crack growth direction under pure mode I loading. This can be ascribed to the limitation of the models to homogeneous materials, and thus results in the disparities of crack deflection angle in mode I loading.

$$2(1-2\nu)\sin(\theta_0-2\beta)-2\sin\left[2(\theta_0-\beta)\right]-\sin 2\theta_0=0,\beta\neq 0 \tag{4}$$

$$K_{\mathrm{I}}\sin\theta_0+K_{\mathrm{II}}(3\cos\theta_0-1)=0 \tag{5}$$

$$\theta_0=\mathrm{m}\left[155.5°\frac{|K_{\mathrm{II}}|}{|K_{\mathrm{I}}|+|K_{\mathrm{II}}|}\right]-83.4°\left[\frac{|K_{\mathrm{II}}|}{|K_{\mathrm{I}}|+|K_{\mathrm{II}}|}\right]^2 \tag{6}$$

Table 2. Prediction of crack growth deflection angles based on different models

α	Minimum strain energy density (SED) criterion [2]	Criterion of Richard [4]	Maximum tangential stress (MTS) criterion [1]	Experiment
0	0	0	0	21°
30°	35°	28.6°	26.2°	25°
60°	55.26°	52.1°	48.98°	50°

5. Conclusions

In this study, the growth behavior of fatigue cracks in the HAZ of a welded joint under mixed mode loading conditions were studied by utilizing CTS specimens. The FCG morphology was characterized by in situ SEM observations in vacuum. The main conclusions are listed as follows.

(1) Mode I fatigue behavior in the HAZ was influenced by local microstructure anisotropy and the gradient distribution of material strength. The crack growth path tended to deflect into the lower strength weld metal, showing a “zigzag” mode.
(2) With the increasing of mixity in mode I/II fatigue loadings, FCG rate in the HAZ was decreased whereas the initial angles for crack branching were increased. Shear and branch cracks were competitive along the crack path, and fatigue crack was often initiated from grain boundary and the interface of lath martensites. Eventually the cracks tended to orient themselves into a pure mode I direction.
(3) The initial branch crack direction was predicted based on existed models, and calculation from the MTS criterion showed comparable agreement with experimental data.

Abstract This paper presents a test set-up using semi-circular bend (SCB) specimen for measuring pure mode-II fracture toughness of asphalt concretes. Three-point bend fracture tests were performed on the SCB specimens at low temperature. The results showed that this set-up could be used for conducting mode-II fracture tests on hot mix asphalt (HMA) specimens. Linear elastic fracture mechanics (LEFM) concept was used to study the fracture behavior of cracked asphalt concrete. Mode-II critical stress intensity factor, K_{IIc}, was calculated using the fracture load measured from the three-point bend tests. In addition to pure mode-II tests, similar tests were carried out for pure mode-I loading. Results showed that mode-II critical stress intensity factor was higher than that of pure mode-I loading.

Keywords Asphalt concrete, Critical stress intensity factor, Low temperature, Pure mode-II fracture.

1. Introduction

Cracking at low temperatures is one of the major sources of deterioration in asphalt concretes imposing significant costs on the pavement rehabilitation agencies annually. There are many causes for crack nucleation on asphalt pavement surface such as the temperature fluctuation and the traffic load induced from vehicle wheels. Good understanding of cracking mechanism could be helpful for reducing those costs.

Asphalt concrete is a temperature dependant material that may fall within a category of materials that are defined as brittle or quasi-brittle at low temperatures. Many researchers have studied fracture behavior of hot mix asphalt (HMA) mixtures at low temperatures (e.g. see [1-3]). Linear elastic fracture mechanics (LEFM) is a reliable approach to investigate fracture behavior of brittle materials. In LEFM, the stress intensity factor, K, is a fundamental parameter characterizing the fracture phenomenon from the crack tip. This parameter has been used by many researchers (e.g. see [4-6]) for cracks in asphalt concrete mixtures.

In the recent decades, many researchers have studied the fracture behavior of asphalt concretes under pure mode-I (opening mode) loading (see e.g. [4-7]). The temperature cycling is one of the main causes of mode-I cracking in asphalt pavements. In some cases such as reflective cracks, the crack extension is known to take place under a combination of mode-I and mode-II loading. Similarly, according to the research performed by Ameri et. al. [8], the traffic load induced by vehicle wheels at top down cracks (TDC) also results in mixed mode I-II loading. Therefore, it is important to investigate the behavior of cracked asphalt concretes under pure mode-I, pure mode-II, and mixed mode I-II loading conditions. In particular, pure mode-II fracture in asphalt concretes has been rarely studied in the past.

In this research, the semi-circular bend (SCB) specimens, prepared from the cylindrical samples were utilized for conducting three-point fracture tests under pure mode-II loading. In addition to the mode-II tests, fracture tests were performed for mode-I loading as well and the critical stress

intensity factors were calculated and compared.

2. Specimen geometry and material

While HMA behavior is strongly affected by temperature, at subzero temperatures, its mechanical behavior is often considered to be brittle or quasi-brittle. Hence, linear elastic fracture mechanics (LEFM) concept is adoptable for investigating the fracture behavior of HMA mixtures at low temperatures. Generally, the cracked asphalt concrete pavement may experience three main modes of fracture, mode-I, mod-II, and mode-III. Among these three modes, mode-I and mode-II are predominant modes of crack propagation in asphalt concrete pavements containing reflective or top-down cracks.

Several test specimens such as single edge notched beam (SENB), disk-shaped compact tension (DC-T), semi-circular bend (SCB) and so on, have been used in the past by many researchers to study the fracture behavior of asphalt concretes. In this research, an improved SCB specimen was employed to conduct the experiments. For this purpose, first several cylindrical samples (130 mm in height, 150 mm in diameter) were prepared using superpave gyratory compactor (SGC) in the laboratory. These samples were sliced into several disks of 32 mm thick by means of a water-cooled masonry sawing machine. Each disk was then halved to obtain semi-circular shaped specimens. At the next stage, an artificial edge crack (20 mm in length) was generated within the specimen utilizing a water-cooled cutting machine with a very thin blade. The width of generated crack was 0.3 mm.

According to the finite element simulations performed by Ayatollahi [9], in a SCB specimen of radius 75 mm containing an edge crack of length 20 mm, pure mode-II loading is achieved when the edge crack distance is 16 mm from the middle of the specimen (see Fig. 1). S_1 and S_2 are the left and right hand side distances of the lower fixtures from the middle of the specimen, respectively. For pure mode-II loading, the values of S_1 and S_2 were found from the FE analysis to be 50mm and 20 mm respectively.

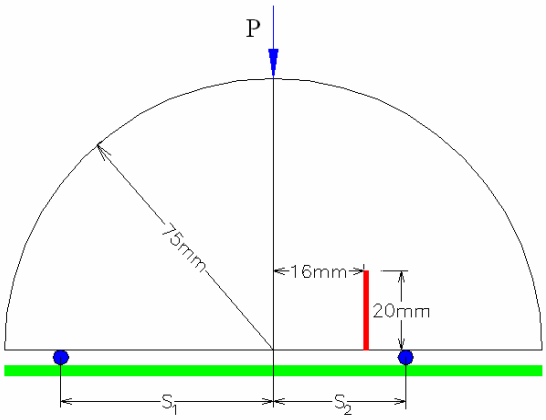

Figure 1. Test specimen used for pure mode-II fracture tests

The asphalt concrete used to prepare the cylindrical samples was similar to the one which is widely used in Iran pavement systems. Aggregate gradation of the HMA mixtures used in this study (as described in Table 1) is within the range of the recommendations by Iran Highway Asphalt Paving

Code (IHAPC). The air void of all mixtures was 4 percent. Asphalt binder with penetration grade of 60/70 was utilized for preparation of the cylindrical samples.

Table 1. HMA aggregate gradation

Sieve size (mm)	Requirements		Percent passing
	Min	Max	
19	100	100	100
12.5	90	100	95
9	67	87	77
4.75	44	74	59
2.36	28	58	43
1.18	20	46	33
0.5	13	34	23
0.3	5	21	13
0.15	4	16	9.5
0.075	2	10	8.4

3. Fracture tests and results

Three-point bend fracture tests were conducted on the SCB specimens under pure mode-II loading at -20°C. To achieve this temperature, the SCB specimens were first put into a freezer with the fixed temperature of -20°C for 4 hours. Then the tests were immediately carried out using a universal testing machine and a three-point bend fixture (as shown in Fig. 2). The displacement rate of the upper fixture was set to a constant value of 3 mm/min. In the first stage, the conventional round-tip supports were used to load the specimens. However, some of the tests were not successful. Because, the crack growth initiated from the lower and right hand side fixture and not from the crack tip (see Fig. 3).

To avoid crack initiation from undesirable locations, the lower fixtures were modified such that instead of applying the bottom loads in the concentrated points (as was the case in the first set-up) the loads were applied as distributed forces. Several finite element analyses were performed to find the width of distributed load (i.e. the magnitude of b in Fig. 4) in order to provide pure mode-II loading. Fig. 5 shows a typical mesh used in the finite element analyses. The appropriate value for the parameter b was eventually found to be 4 mm. The conventional fixtures used in the first set-up were replaced with the second set-up, and the mode-II fracture tests were repeated. By this modification, the crack extension in all the specimens took place from the crack tip (see Fig. 6). Therefore, the pure mode-II fracture test was successfully simulated experimentally using the SCB specimen. The fracture tests were also performed under pure mode-I loading and at -20°C using the same three-point test set-up. However, for this type of loading, the crack was generated in the middle of the specimen with symmetric loading supports of $S_1=S_2=50$ mm (see Fig. 1). Fig. 7 shows sample of the load-load line displacement curves recorded from the mode-I and mode-II fracture tests. In order to increase the reliability of the experimental results, four SCB specimens were tested for each mode of loading. As

shown in Fig. 7, the load increases linearly and then suddenly drops to zero. Therefore, one may suggest that the asphalt concrete failure was due to brittle fracture with negligible nonlinear deformation. Considering the area under the load-load line displacement curve, Fig. 7 shows that the asphalt mixture needs higher energy to fracture under mode-II loading than under mode-I loading.

Figure 2. Three point test set-up

Figure 3. Fracture test using first set-up

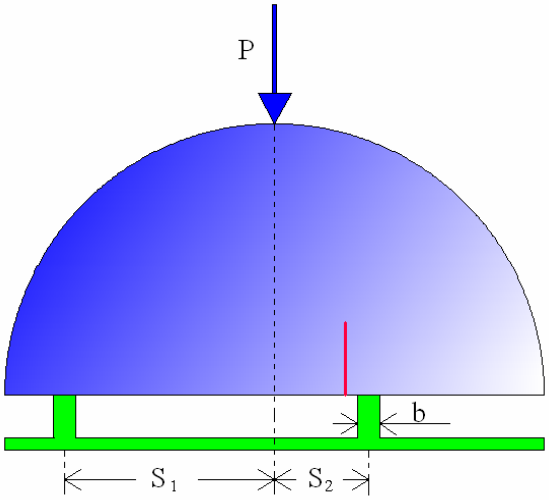

Figure 4. Three-point test (second set-up)

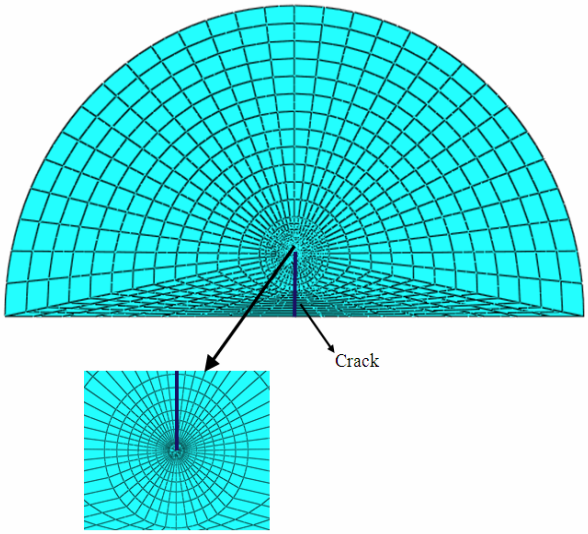

Figure 5. The finite element mesh

The fracture resistance in cracked specimens is often described by the values of critical stress intensity factors. The mode-I and mode-II critical stress intensity factors, K_{Ic} and K_{IIc} can be written for the SCB specimen in terms of the experimentally obtained fracture load P_{cr} as:

$$K_{Ic} = Y_I \frac{P_{I_{cr}}}{2Rt}\sqrt{\pi a} \qquad K_{IIc} = Y_{II} \frac{P_{II_{cr}}}{2Rt}\sqrt{\pi a} \tag{1}$$

The fracture load P_{cr} is obtained for each mode of loading from the maximum load recorded in the fracture tests. Y_I and Y_{II} are mode-I and mode-II geometry factors which were obtained from finite element analyses as 3.73 and 2.25, respectively. The specimen radius and thickness R, t, and the crack

length *a* are 75 mm, 32 mm, and 20 mm respectively.

Figure 6. Fracture test using second set-up

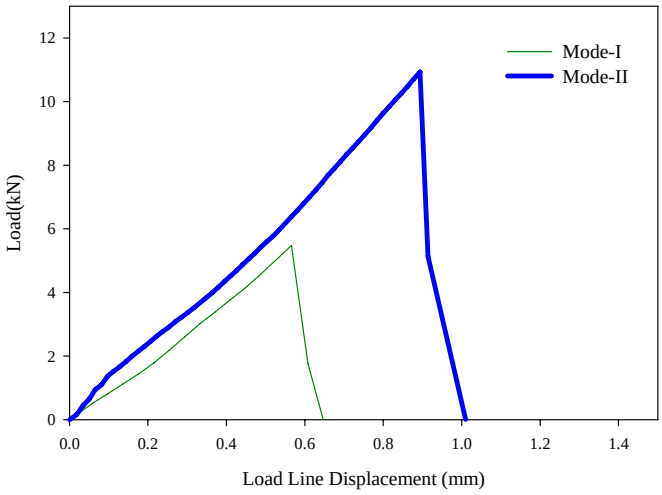

Figure 7. Load vs LLD at -20°C

Table 2. Average experimental results for mode-I and mode-II loading

Mode of loading	$P_{cr}(kN)$	Critical stress intensity factor $(MPa.\sqrt{m})$
Pure mode-I	5.3	1.03
Pure mode-II	11.2	1.3

The critical stress intensity factors (K_{Ic} and K_{IIc}) were calculated from Eq. 1 for each test conducted under mode-I or mode-II loading conditions. Table 2 shows the average values of P_{cr}, K_{Ic} and K_{IIc} obtained for asphalt samples. According to this Table, the critical stress intensity factor under pure mode-II loading is about 26% higher than that under pure mode-I loading. In other words, when a cracked asphalt concrete is under pure mode-II loading, its resistance against brittle fracture at low temperatures is more than that of mode-I loading. Moreover, the mode-II fracture load in the asphalt SCB specimens is more than twice the mode-I fracture load (see Table 2). While the crack extension in mode-I fracture tests took place along the pre-crack direction, all the mode-II cracks kinked out of the initial plane (see Fig. 6). This is mainly because the maximum tensile stress around the crack tip is no longer along the crack line when a cracked specimen like SCB is subjected to pure mode-II loading conditions [10].

4. Conclusion

In this paper, a suitable procedure was suggested for conducting fracture experiments on cracked asphalt concretes under pure mode-II loading and at low temperatures. The modified SCB specimens used for the experiments can be produced conveniently by a gyratory compactor or by coring from an existing asphalt pavement. The specimen can be used both for pure mode-I tests and for pure mode-II tests. The mode-I and mode-II tests were performed successfully on an asphalt mixture sample at -20^{o}C. The results showed that both the fracture load and the critical stress intensity factor obtained from the mode-II experiments were considerably higher than those obtained from the mode-I experiments.

Abstract A moiré interferometry-based experimental method is first introduced for high-temperature, mixed-mode fracture testing. The method allows real-time observation of surface deformation of cracked specimens and crack-tip plastic zone at elevated temperatures. Based on the moiré fringe patterns captured real time through image acquisition system, important fracture parameters, such as the crack open displacement, the crack initiation load, the ultimate load, etc., can be determined. With these data, the stress intensity factor, load bearing capacity, fracture ductility, strain, and stress fields near the crack-tip can be obtained. The method has been successfully applied to investigate pure mode I, I-II mixed-mode fracture performance of high temperature alloys. Furthermore, some significant thickness effects achieved by the group of researchers on the mixed-mode fracture performance of TC11 titanium alloy at high temperatures are cited and briefly introduced. Finally, three dimensional finite element simulations are performed for the tensile-shearing specimens at an elevated temperature. Simulation results are in agreement with measurements.

Keywords Moiré interferometry, High temperature, Mixed mode fracture, Thickness effect

1. Introduction

In industrial fields, such as aerospace, petrochemical, and dynamic transportation, there is a growing demand for high-temperature structural materials. The rising demand makes the issues of reliability design, failure analysis, and safety evaluation for high-temperature structures increasingly important [1-5]. The performance of engineering materials, especially metal materials, is always sensitive to temperature. At an elevated temperature, internal molecular motion aggravating, phase changing, cavity and micro crack emerging in materials make their fracture property significantly different from that at room temperature [3]. With the field of fracture still in development, high-temperature behavior remains one of the unresolved fundamental issues [6]. A better understanding of the fracture behavior is important. High-temperature components, such as engine turbine and blade, steam boiler and pipeline, and steam turbine bear complex loading at high temperatures. Therefore, mixed-mode fracture testing of materials from room to high temperature is necessary.

By far, the research on two-dimensional (2D) cracks of single and mixed modes under room temperature (RT) becomes better and approaches perfection day by day. However, most of the previously conducted analytical and numerical investigations in fracture mechanics were focused on 2D or axisymmetric geometries, although three-dimensional (3D) effects were often acknowledged. The stress state near an actual crack tip is always 3D, and the meaning of the results obtained within the 2D theories and their relation to the actual 3D stress distribution is still not fully understood [7].

3D effects increasingly drew attention in recent years from material experiments in laboratories to the real structure [6-8]. Experiments have shown that some damages or failure characteristic quantities, which are regarded as material constants, indeed are related to the structural geometry [5]. A large number of theoretical analysis, experimental investigations, and numerical computations reveal significant 3D effects such, as the thickness effect [9-14]. 3D fracture theory, founded in consideration both of in-plane and out-plane constraints, has made important progress [15-18]. The research on mixed-mode cracks gradually progresses from the 2D hypothesis to the 3D assumption [19-21]. Comparatively, research mainly focuses on the cracks of ideal mode I, 2D problems, theoretical analysis, and numerical computations. Experimental investigations, especially observations and measurements of real 3D fracture of mixed-mode cracks under high temperature, are very limited. There is no complete analytic solution for 3D fracture problems due to mathematical difficulties. Research on 3D fracture problem of mixed-mode cracks under high temperature still needs to be done. The existing theoretical fracture models have many weaknesses and are not verified by experiment and practical use [5]. In a conceptual paper on the past and future development of fracture mechanics, Erdogan [6] identifies 3D effects, high-temperature behaviors, computational methods, and experimental methods as the areas where further intensive research is needed.

A new fracture experimental technique based on the moiré interferometry is introduced in this study, by which I-II mixed-mode fracture phenomenon could be surveyed and recorded when temperature is high (say at least several hundreds of degrees in Celsius). Finite through-thickness cracked specimens are employed in tests under the coupling of thermal environment and mixed-mode loading. Displacement field moiré fringes around the crack are recorded. This experimental method was successfully used in investigation of fracture properties of high-temperature alloys. Several specific thickness effects at high temperatures are revealed based on the experimental results.

2. High-temperature, mixed-mode fracture test

2.1. Experimental setup and procedures

High-temperature moiré interferometry system has been successfully used in investigation of crack growth of pure mode I [22-24]. The same is employed in this present mixed-mode fracture research. The tensile-shearing specimen dimensions and mixed-mode loading fixture are given in Ref. [25]. A special orthogonal diffraction grating with high temperature resistance is chosen and fabricated on a highly polished surface of a specimen by photoetching and chemical etching [26]. Two sets of grid lines of the orthogonal grating are parallel to and perpendicular to the crack, respectively. A rotatable U-V mirror set [27] is invented for the purpose of the mixed-mode fracture experiment. The mirror set is designed to rotate by the same angle when angle β existed between loading direction and crack perpendicular, as shown in Figure 1. Consequently, the displacements normal to the crack (Mode I) and parallel to the crack (Mode II) were effectively separated, ensuring that moiré fringes corresponding to the u-displacement and v-displacement always are parallel and perpendicular to the crack at any I-II mixed-mode loading. The fracture testing procedure based on moiré interferometry at elevated temperature, including preparations of specimens, fabrication of specimen grating, heating, maintenance of temperature, and loading until fracture, is detailed in Ref.

[25].

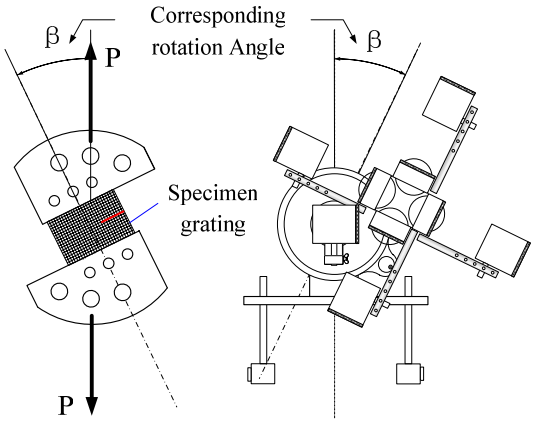

Figure 1: Mixed-mode fracture test fixture and corresponding arrangement of U-V mirror set

2.2. Evaluation of fracture parameters

Typical moiré fringes seen during the test are illustrated in Figure 2. The fringes tend to be closer to each other and move towards the crack tip with the load. Once the load increases, a small dark spot appears around the crack tip on the surface. This means a plastic zone forms and develops as the load increases. The crack mouth open displacement (COD), which is the relative displacement of point A and B in Figure 2, is measured using a v-displacement field moiré fringes based on the principle of moiré interferometry. Special image processing techniques, such as smoothing, filtering, and refining, are used to reproduce the moiré fringe for counting the number of fringes and reproducing the profile of plastic zone. The stress intensity factors K_I, K_{II}, K_{eff} are determined based on load, loading angle, and crack length when the fracture test is finished [25]. Load-COD curves and K_{eff}-COD curves then can be drawn.

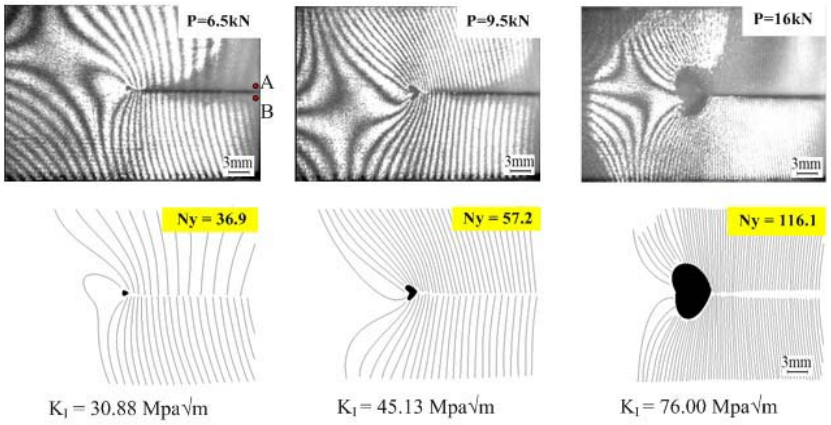

Figure 2: Representative moiré fringe patterns during the test and reproduced images

2.3. Measurement of crack initiation angle

From 2D fracture mechanics, the crack initiation angle is usually defined as the included angle between the initiation orientation and the original crack orientation at half-thickness (middle) plane. The included angle is the one between the flat region B and the pre-cracked plane A in Figure 3. It is an important parameter for mixed-mode fracture but is often difficult to measure. To obtain the angle, as a common methodology, the specimen is first cut into two separate parts from the middle plane, and then the angle is measured [19]. However, it does not work well for metallic material and thin samples. The following method is employed to measure the initiation angle. First, a CCD

camera is used to take photographs of the profile of the fractured specimens, as shown in Figure 3 (c). Subsequently, the profile photographs are processed as computer image files. The most important step in this procedure is accurately determining and drawing the tangent line at the beginning of the crack growth path at the middle thickness and the pre-crack line. Finally, the initiation angle is obtained by measuring the angle between the two lines. Based on the above mentioned scheme, the initiation angle of the specimen in Figure 3 is 27.7°. Using the same method, the included angle between the pre-cracked plane and the pre-notched plane (e.g., 5.5° in Figure 3(c)), which is the machining error and which should be distinguished from the initiation angle, also can be recorded.

3. Fracture test on TC11 titanium alloy material

Mixed-mode fracture experiments are conducted on TC11 titanium alloy specimens with varied thicknesses at RT and elevated temperature. The experiments are conducted using the newly developed testing technology, which is based on high-temperature moiré interferometry. Some results are very unusual and remarkable.

3.1. Experimental results at elevated temperature [25]

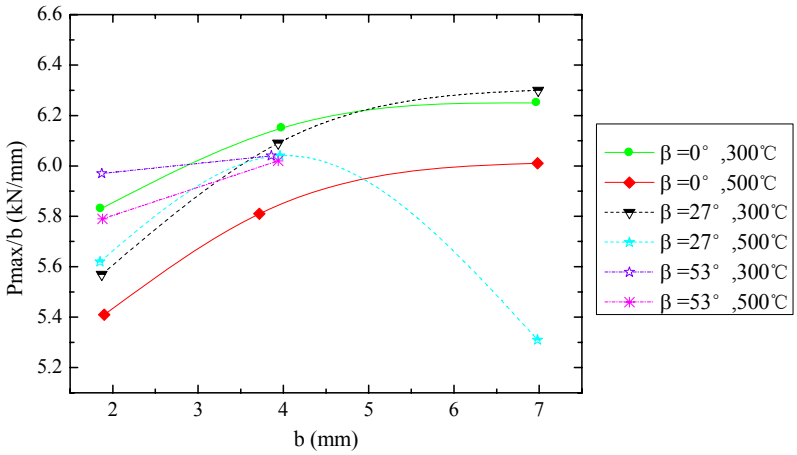

Figure 4: Load capacity versus thickness b and loading angles β at high temperatures (reproduced from Ref. [25])

Figure 4 illustrates the average results for the specimens in the same thickness group at an elevated

temperature. It shows that in addition to some individual cases, the loading capacity increases with the specimen thickness. This observation is contrary to common knowledge. Increasing temperature enhances the fracture load capacity for thick specimens, but reduces it for thin specimens. Detailed analysis is given in Ref. [25]. When fracture toughness is examined, K_{effi} (the stress intensity factor corresponding to the crack initiation load P_i) with loading angle β and specimen thickness b appears at high temperatures, as shown in Figure 5. Effects of thickness existed in K_{effi}, although regularity is not obvious. These results again confirm the complex coupled effects of thickness and temperature in the mixed-mode fracture of the alloy.

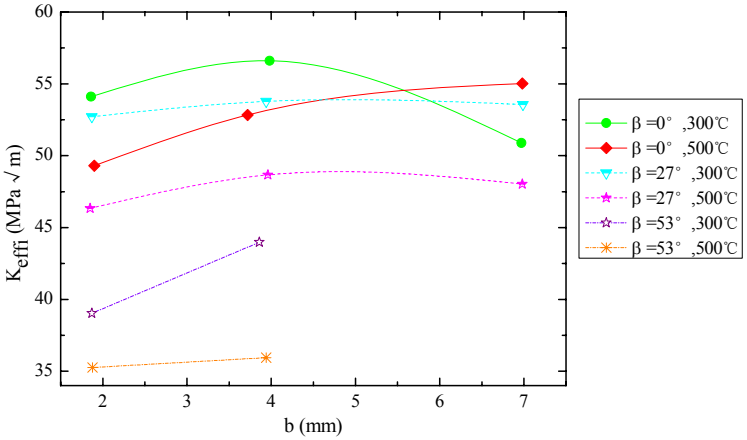

Figure 5: Results of K_{effi} versus thickness b and loading angles β at high temperatures (reproduced from Ref. [25])

The thickness effect is significantly coupled with the temperature effect in mixed-mode fracture of TC11 alloy, which is important for the development of 3D fracture theory under complex loading and temperature conditions. Why did this happen? Is this the peculiarity of titanium alloy or is this a shared property of metals or alloys? To answer the questions, further studies on fracture mechanism of high-temperature fracture should be conducted.

3.2. Qualitative comparison with finite element data

To compare the test results with the numerical solutions, specimens with the same dimensions as in the experiment are modeled using the finite element (FE) software ANSYS. In the 3D simulation, the Ramberg-Osgood constitutive relation [28] is adopted to represent the material nonlinearity. The corresponding parameters are determined through fitting of experimental data. Accordingly, the stress-strain relation is expressed as

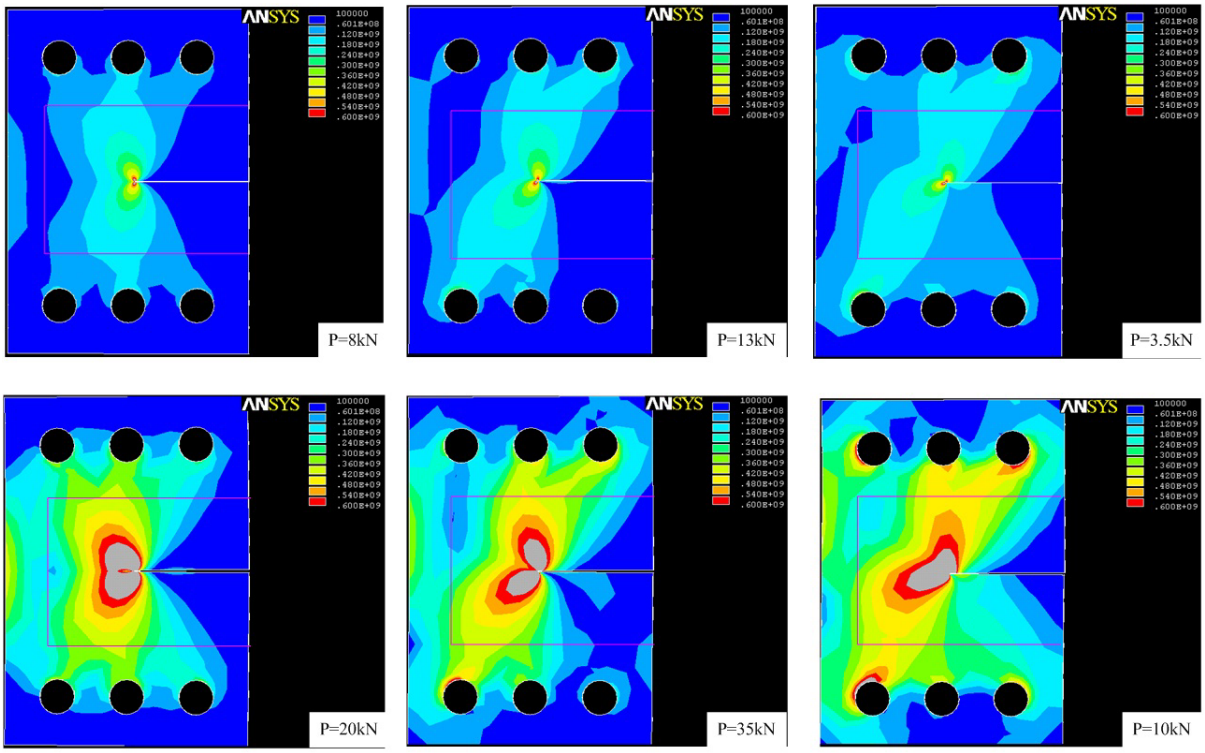
$$\varepsilon = \frac{\sigma}{120000} + 9.9879\times10^{38}\left(\frac{\sigma}{120000}\right)^{19.9578} \tag{1}$$

at RT, and

$$\varepsilon = \frac{\sigma}{98000} + 9.089\times10^{11}\left(\frac{\sigma}{98000}\right)^{6.6095} \tag{2}$$

at 500℃.

The contours of Mises stress on the front surface at 500℃ are plotted in Figure 6, where the domain bounded by red lines conforms to the visual region of moiré fringe. In Figure 7, moiré fringe of the same specimen from the tests also is presented. In the first row of Figures 6 and 7, the same load is



(a) b=4mm, 500℃, β=0° (b) b=7mm, 500℃, β=27° (c) b=2mm, 500℃,β=53°

Figure 6: ANSYS non-linear FE results (stress field and plastic zone on the front surface) at 500℃

considered. However, there are different exists in the second row, where the load is the maximum value before fracture in Figure 6 and the value under which the last clear moiré fringe is obtained in Figure 7. Based on Figures 6 and 7, numerical results apparently agree well with the experimental data. The displacement fields on the specimen surface by the moiré interferometry are invalid due to the existence of crack tip plasticity and out-plane deformation. As an amendment, the 3D FE simulation is a powerful auxiliary tool in the computation during late loading period, and the corresponding details will be described in future work. The hybrid experimental-numerical procedure [29] is believed to be an effective technique in the fracture analysis and prediction area.

Figure 7: Corresponding experimental results (displacement field and plastic zone on the front surface)

4. Conclusions

In the present paper, the newly developed fracture test equipment, techniques, and methodology based on moiré interferometry are presented in detail. Through real-time observation of fracture process around the crack tip and image acquisition of the moiré fringe at different loads, the magnitude of elastoplastic deformation and corresponding fracture parameters are extracted using the wave-front interference principle. In the test of TC11 finite specimen with through-thickness crack under mixed mode I-II loading, the duration from the beginning of loading to the ultimate fracture of specimen is relatively short, thereby causing difficulty in the determination of crack initiation moment. Moreover, no stable crack growth process is involved prior to the occurrence of unstable crack propagation. Concerning the common fracture mechanism on crack initiation, and the stable and unstable growth of metallic material, further investigation should be conducted to tell whether the size of crack tip plasticity zone on the surface can be adopted as a characteristic quantity of fracture. At the same time, the anomalous thickness effect of TC11 titanium alloy is reported, and the essence of this phenomenon is waiting to be uncovered.

Abstract This paper reports the authors' recent work on mixed-mode fracture in fiber-reinforced laminated composite beams and plates. The work considers the so-called one-dimensional fracture which propagates in one-dimension and consists of only mode I and mode II fracture modes. Fracture interfaces are assumed to be either rigidly or cohesively bonded. Analytical theories are developed within the contexts of both classical and first-order shear deformable laminated composite theories. When a rigid interface is assumed for brittle fracture, there are two sets of orthogonal pure modes in classical theory, and there is only one set of orthogonal pure modes in shear-deformable theory. A mixed-mode fracture is partitioned by using these orthogonal pure modes. The classical and shear deformable partitions can be regarded as either lower or upper bound partitions for 2D elasticity, and hence approximate 2D elasticity partition theories are developed by 'averaging' the classical and shear deformable partitions. When cohesively bonded interfaces are assumed for adhesively joined interfaces, the classical and shear deformable theories give the same pure modes. Approximate partition theories are also developed for 2D elasticity. Numerical investigations demonstrate excellent agreement with the corresponding analytical theories. Experimental data considered shows that the failure locus is strongly linear.

Keywords Composite, Energy release rate, Failure locus, Mixed-mode fracture, Orthogonal pure modes

1. Introduction

Delamination is a major concern in the application of laminated composite materials. Although it occurs often together with other fracture modes such as fiber breakage, matrix cracking and intra-laminar cracking, pure delamination is always an important research topic which provides insight and understanding of lamina interfacial mechanics, and it often occurs in one-dimensional delamination. A delamination is called one-dimensional when its crack front propagates only in one direction. Familiar examples are through-width delamination in laminated composite beams, circular ring shape delamination in laminated composite plates and shells, etc., as shown in Fig. 1. A distinct feature of one-dimensional delamination is that it usually consists of only the mode I and mode II fracture modes without any mode III. The study of one-dimensional delamination is of great importance for several reasons. It is the most fundamental problem in the fracture mechanics of materials. It is often used in experimental tests, such as the double cantilever beam (DCB), end-loaded split (ELS) and end-notched flexure (ENF) tests, to obtain the critical energy release rate (ERR) or toughness of a lamina interface in either pure mode I or mode II delamination. In the case of a mixed mode, it is often used to investigate delamination propagation criteria. Moreover, many practical cases of delamination in structures made of fiber-reinforced laminated composites can be approximated as one-dimensional. For example, the separation of stiffeners and skins in stiffened plate or shell panels made of laminated composite materials can be approximated as one-dimensional through-width delamination, and the separation of two material layers in laminated composite plates and shells in a drilling process can be approximated as one-dimensional circular ring-type delamination, etc.

Because of its importance, one-dimensional delamination has attracted the attention of many researchers including many of the world leaders in the areas of fracture mechanics and composite materials. The primary goal is to develop analytical theories to determine pure delamination modes

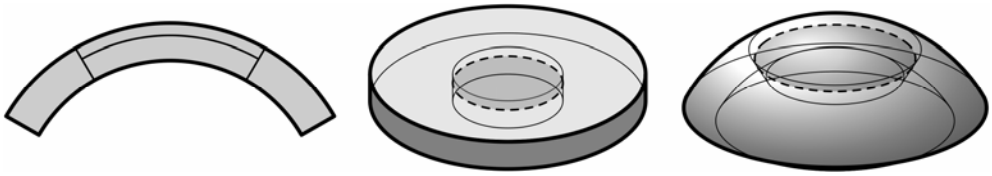

Figure 1. Some examples of one-dimensional fracture.

and then to partition a mixed mode into pure modes. Delamination propagation criteria can then be established by using the partition together with experimental data. The through-width delamination in a DCB made of isotropic material with rigidly bonded interface can be considered to be the 'simplest' one-dimensional delamination. Although it seems to be a straightforward matter to determine the pure modes and to partition a mixed mode, it has been proved to be an extremely complex and sophisticated problem. There has been a lot of confusion on the matter during the last 25 years. Ref. [1] may be the earliest work on the 'simplest' problem by Williams. A mixed-mode partition theory [1] was developed based on classical beam theory. Ref. [2] reported a combined numerical and analytical theory by Schapery and Davidson based on combined classical beam theory and 2D elasticity. It disagrees with the Williams' theory [1] and concludes that classical beam theory does not provide quite enough information to obtain an analytical decomposition of the mixed-mode ERR into its opening and shearing mode components. Hutchinson-Suo reported their work in Ref. [3] in which the mixed-mode ERR is calculated based on the classical beam theory but the partition of ERR is calculated based on stress intensity factors from 2D elasticity. Their theory [3] agrees well with the theory in Ref. [2] and claims that Williams' theory [1] contains conceptual errors. To respond to this claim, Williams reported some experimental work in Ref. [4] showing that Williams' theory [1] is in a better agreement with the test results than Hutchinson-Suo theory [3]. This has caused a lot of confusion, which has affected many academic researchers and design engineers until today. A great deal of research effort has been made during the last two decades to resolve the confusion. Among many others, the following significant works are referenced here. Ref. [5] reported a mixed-mode partition theory for laminated composite beams with rigidly bonded interface based on first-order shear-deformable beam theory, which gives different mixed-mode partitions to those from Williams' theory [1] and the Hutchinson-Suo theory [3]. The same theory as that in Ref. [5] was derived in Refs. [6, 7] but these are based on classical beam theory, which caused yet more confusion. Recently, the authors have developed analytical theories for one-dimensional delamination in laminated composite beams and plates by using a novel methodology [8–13]. All the confusion is explained. This paper reports some of the major results in Refs. [8–13].

2. Partition of mixed-mode fracture in laminated composite beams and plates with rigid interfaces

The mechanics of delamination depend on the mechanical properties of lamina interfaces. A lamina interface is considered to be a rigid interface when the interface separation is negligible before an existing delamination propagates. Otherwise, it is considered to be a non-rigid interface or as it often called, a cohesively bonded interface. Bare-bonded interfaces in the conventional manufacturing process from glass or carbon fiber epoxy pre-pregs are typical rigid interfaces because of their brittleness. While cohesively bonded interfaces are typical non-rigid interfaces which are achieved by adding adhesive layers between bare plies when manufacturing components.

2.1. Laminated composite DCBs

A laminated composite DCB with a delamination of length a is shown in Fig. 2 (a). The interface stresses in Fig. 2 (b) only show the sign convention rather than any representative distribution.

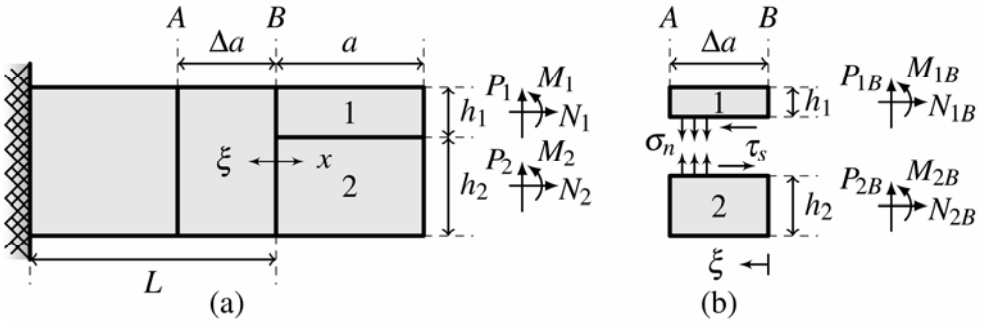

Figure 2. A laminated composite DCB and its loading conditions. (a) General description. (b) Details of the crack influence region Δa.

2.1.1. Classical beam partition theory

Using the constitutive relation in classical laminated composite beam theory, the ERR at the crack tip at location B, G is

$$G = \frac{1}{2b^2}\left(\frac{M_{1B}{}^2}{D_1^*} + \frac{M_{2B}{}^2}{D_2^*} - \frac{M_B{}^2}{D^*} + \frac{N_{1B}{}^2}{A_1^*} + \frac{N_{2B}{}^2}{A_2^*} - \frac{N_B{}^2}{A^*} - \frac{2B_1 M_{1B} N_{1B}}{B_1^*} - \frac{2B_2 M_{2B} N_{2B}}{B_2^*} + \frac{2B M_B N_B}{B^*} \right) \quad (1)$$

where subscript 'B' indicates loads at the crack tip at location B, for example, M_{1B} is the bending moment on the top sub-laminate at the crack tip. These loads are shown in Fig. 2 (b). Other quantities in Eq. (1) are

$$A_i^* = A_i - B_i^2/D_i \quad , \quad B_i^* = B_i{}^2 - A_i D_i \quad , \quad D_i^* = D_i - B_i^2/A_i \quad (2)$$

The range of subscript i is 1 and 2, which again refers to the upper and lower sub-laminates respectively. For the intact laminate, the subscript i is dropped. A, B and D are the equivalent extensional, coupling and bending stiffness of the DCB respectively.

A novel methodology to partition mixed-mode ERR G in Eq. (1) arises from the fact that G is of quadratic form and non-negative definite in terms of the crack tip bending moments M_{1B} and M_{2B}, and the crack tip axial forces N_{1B} and N_{2B}. An analogy of this is the positive definite kinetic energy of a vibrating structure, to which individual modal energies are attributed by using modal analysis from orthogonal natural vibration modes. A hypothesis is then made that the total ERR in a mixed-mode delamination can be partitioned into pure mode components by using orthogonal pure modes. There are two sets of fundamental orthogonal pure modes. The first set corresponds to zero relative shearing displacement just behind the crack tip (mode I) and zero crack tip opening force ahead of the crack tip (mode II). The second set corresponds to zero relative opening displacement just behind the crack tip (mode II) and zero crack tip shearing force (mode I). It is simple to derive the zero relative displacement modes first and then to find the zero force modes by applying orthogonality through Eq. (1). An alternative and more complex derivation considers the interface stresses. If the mode vector form is $\{M_{1B}, M_{2B}, N_{1B}, N_{2B}\}^T$, then the first set of fundamental orthogonal pure modes, referred to as the $\{\theta, \beta\}$ set, are found to be

$$\{\varphi_{\theta_1}\} = \begin{Bmatrix} 1 \\ \theta_1 \\ 0 \\ 0 \end{Bmatrix} \quad , \quad \{\varphi_{\theta_2}\} = \begin{Bmatrix} 1 \\ 0 \\ \theta_2 \\ 0 \end{Bmatrix} \quad , \quad \{\varphi_{\theta_3}\} = \begin{Bmatrix} 1 \\ 0 \\ 0 \\ \theta_3 \end{Bmatrix} \quad , \quad \{\varphi_{\beta_1}\} = \begin{Bmatrix} 1 \\ \beta_1 \\ 0 \\ 0 \end{Bmatrix} \quad , \quad \{\varphi_{\beta_2}\} = \begin{Bmatrix} 1 \\ 0 \\ \beta_2 \\ 0 \end{Bmatrix} \quad , \quad \{\varphi_{\beta_3}\} = \begin{Bmatrix} 1 \\ 0 \\ 0 \\ \beta_3 \end{Bmatrix} \quad (3)$$

with

$$\theta_1=\frac{\left(B_2^2-A_2D_2\right)\left(B_1+h_1A_1/2\right)}{\left(B_1^2-A_1D_1\right)\left(B_2-h_2A_2/2\right)}\ ,\ \theta_2=-\frac{B_1+h_1A_1/2}{D_1+h_1B_1/2}\ ,\ \theta_3=\frac{\left(B_1+h_1A_1/2\right)\left(B_2^2-A_2D_2\right)}{\left(D_2-h_2B_2/2\right)\left(B_1^2-A_1D_1\right)} \tag{4}$$

$$\beta_1=-\frac{D_2^*\left(D_1^*+D_1^*\theta_1-D^*\right)}{D_1^*\left(D_2^*+D_2^*\theta_1-D^*\theta_1\right)}\ ,\ \beta_2=\frac{\theta_2\left(\frac{h_2}{2D^*}-\frac{B_1}{B_1^*}+\frac{B}{B^*}\right)+\frac{1}{D_1^*}-\frac{1}{D^*}}{\theta_2\left(\frac{Bh_2}{B^*}-\frac{1}{A_1^*}+\frac{1}{A^*}+\frac{h_2^2}{4D^*}\right)-\frac{h_2}{2D^*}+\frac{B_1}{B_1^*}-\frac{B}{B^*}}\ ,$$

$$\beta_3=\frac{\theta_3\left(\frac{h_1}{2D^*}-\frac{B}{B^*}\right)-\frac{1}{D_1^*}+\frac{1}{D^*}}{\theta_3\left(\frac{Bh_1}{B^*}+\frac{1}{A_2^*}-\frac{1}{A^*}-\frac{h_1^2}{4D^*}\right)-\frac{h_1}{2D^*}+\frac{B}{B^*}} \tag{5}$$

The second set of fundamental orthogonal pure modes, referred to as the $\{\theta',\beta'\}$ set, has the same format as that of the first set in Eq. (3), but with

$$\theta_1'=-1\ ,\ \theta_2'=\frac{\beta_2'\left(\frac{h_2}{2D^*}-\frac{B_1}{B_1^*}+\frac{B}{B^*}\right)+\frac{1}{D_1^*}-\frac{1}{D^*}}{\beta_2'\left(\frac{Bh_2}{B^*}-\frac{1}{A_1^*}+\frac{1}{A^*}+\frac{h_2^2}{4D^*}\right)-\frac{h_2}{2D^*}+\frac{B_1}{B_1^*}-\frac{B}{B^*}}\ ,$$

$$\theta_3'=\frac{\beta_3'\left(\frac{h_1}{2D^*}-\frac{B}{B^*}\right)-\frac{1}{D_1^*}+\frac{1}{D^*}}{\beta_3'\left(\frac{Bh_1}{B^*}+\frac{1}{A_2^*}-\frac{1}{A^*}-\frac{h_1^2}{4D^*}\right)-\frac{h_1}{2D^*}+\frac{B}{B^*}} \tag{6}$$

$$\beta_1'=\frac{D_2^*}{D_1^*}\ ,\ \beta_2'=-\frac{A_1}{B_1}\ ,\ \beta_3'=-\frac{B_2^*}{D_1^*B_2} \tag{7}$$

Any four fundamental pure modes from either the first set or the second set can be used to partition a mixed mode. The partitions are given below.

$$G_{IE}=c_{IE}\left(M_{1B}-\frac{M_{2B}}{\beta_1}-\frac{N_{1B}}{\beta_2}-\frac{N_{2B}}{\beta_3}\right)\left(M_{1B}-\frac{M_{2B}}{\beta_1'}-\frac{N_{1B}}{\beta_2'}-\frac{N_{2B}}{\beta_3'}\right) \tag{8}$$

$$G_{IIE}=c_{IIE}\left(M_{1B}-\frac{M_{2B}}{\theta_1}-\frac{N_{1B}}{\theta_2}-\frac{N_{2B}}{\theta_3}\right)\left(M_{1B}-\frac{M_{2B}}{\theta_1'}-\frac{N_{1B}}{\theta_2'}-\frac{N_{2B}}{\theta_3'}\right) \tag{9}$$

where

$$c_{IE}=G_{\theta_1}\left[\left(1-\frac{\theta_1}{\beta_1}\right)\left(1-\frac{\theta_1}{\beta_1'}\right)\right]^{-1}\ ,\ c_{IIE}=G_{\beta_1}\left[\left(1-\frac{\beta_1}{\theta_1}\right)\left(1-\frac{\beta_1}{\theta_1'}\right)\right]^{-1} \tag{10}$$

and

$$G_{\theta_1}=\frac{1}{2b^2}\left[\frac{1}{D_1^*}+\frac{\theta_1^2}{D_2^*}-\frac{\left(1+\theta_1\right)^2}{D^*}\right]\ ,\ G_{\beta_1}=\frac{1}{2b^2}\left[\frac{1}{D_1^*}+\frac{\beta_1^2}{D_2^*}-\frac{\left(1+\beta_1\right)^2}{D^*}\right] \tag{11}$$

The partitions in Eqs. (8) and (9) use both sets of orthogonal pure modes. The partition theory in Ref. [1] only gives the $\{\theta_1',\beta_1'\}$ pure modes correctly. The partition theories derived in Refs. [6,7] is equivalent to using only the first set of pure modes to partition a mixed-mode. The methodologies used in Refs. [6,7] are not able to find the second set of pure modes. The partitions are easily reduced for isotropic materials. With a thickness ratio $\gamma=h_2/h_1$ now introduced, they are

$$G_{IE} = c_{IE}\left(M_{1B} - \frac{M_{2B}}{\beta_1} - \frac{N_{1Be}}{\beta_2} \right)\left(M_{1B} - \frac{M_{2B}}{\beta_1'} \right) \tag{12}$$

$$G_{IIE} = c_{IIE}\left(M_{1B} - \frac{M_{2B}}{\theta_1} - \frac{N_{1Be}}{\theta_2} \right)\left(M_{1B} - \frac{M_{2B}}{\theta_1'} - \frac{N_{1Be}}{\theta_2'} \right) \tag{13}$$

where c_{IE} and c_{IIE} are still given by Eq. (10) and $N_{1Be} = N_{1B} - N_{2B}/\gamma$. The pure mode relationships are now as follows:

$$\theta_1 = -\gamma^2 \ , \ \theta_2 = -\frac{6}{h_1} \ , \ \beta_1 = \frac{\gamma^2(3+\gamma)}{1+3\gamma} \ , \ \beta_2 = \frac{2(3+\gamma)}{h_1(\gamma-1)} \text{ for } \gamma \neq 1 \ , \ \beta_2 = 1 \text{ for } \gamma = 1 \tag{14}$$

$$\theta_1' = -1 \ , \ \theta_2' = -\frac{6(1+\gamma)}{h_1(1+\gamma^3)} \ , \ \beta_1' = \gamma^3 \tag{15}$$

The isotropic G_{θ_1} and G_{β_1} for use in Eq. (10) are

$$G_{\theta_1} = \frac{24\gamma}{Eb^2h_1^3(1+\gamma)} \ , \ G_{\beta_1} = \frac{72\gamma(1+\gamma)}{b^2Eh_1^3(1+3\gamma)^2} \tag{16}$$

2.1.2. Shear deformable beam partition theory

In the absence of crack tip shear forces, the total ERR G in a mixed-mode fracture is still given by Eq. (1) within the context of the first order shear deformable laminated composite beam theory. However, the two sets of fundamental orthogonal pure modes now coincide at the first set, i.e. the $\{\theta, \beta\}$ set and the partitions of the total G are given by

$$G_{IT} = c_{IT}\left(M_{1B} - \frac{M_{2B}}{\beta_1} - \frac{N_{1B}}{\beta_2} - \frac{N_{2B}}{\beta_3} \right)^2 \ , \ G_{IIT} = c_{IIT}\left(M_{1B} - \frac{M_{2B}}{\theta_1} - \frac{N_{1B}}{\theta_2} - \frac{N_{2B}}{\theta_3} \right)^2 \tag{17}$$

where

$$c_{IT} = G_{\theta_1}\left(1 - \frac{\theta_1}{\beta_1} \right)^{-2} \ , \ c_{IIT} = G_{\beta_1}\left(1 - \frac{\beta_1}{\theta_1} \right)^{-2} \tag{18}$$

When crack tip shear forces P_{1B} , P_{2B} are present, the following two terms need to be added to the mode I ERR in Eq. (17):

$$G_P = \frac{(H_1P_{2B} - H_2P_{1B})^2}{2b^2H_1H_2(H_1+H_2)} \ , \ \alpha_{\theta_1}\Delta G_{\theta_1 P} = \frac{\alpha_{\theta_1}}{b^2}\left(\frac{P_{1B}}{H_1} - \frac{P_{2B}}{H_2} \right)\left[\frac{H_1H_2}{H_1+H_2}\left(\frac{1}{D_1^*} + \frac{\theta_1^2}{D_2^*} - \frac{(1+\theta_1)^2}{D^*} \right) \right]^{1/2} \tag{19}$$

where H_1 and H_2 are the through-thickness shear stiffnesses and

$$\alpha_{\theta_1} = \frac{M_{2B}\beta_2 + N_{1B}\beta_1 - M_{1B}\beta_1\beta_2}{\beta_2(\theta_1 - \beta_1)} + \frac{N_{2B}\beta_1}{\beta_3(\theta_1 - \beta_1)} \tag{20}$$

In the case of layered isotropic DCBs, these partitions reduce to

$$G_{IT} = c_{IT}\left(M_{1B} - \frac{M_{2B}}{\beta_1} - \frac{N_{1Be}}{\beta_2} \right)^2 \ , \ G_{IIT} = c_{IIT}\left(M_{1B} - \frac{M_{2B}}{\theta_1} - \frac{N_{1Be}}{\theta_2} \right)^2 \tag{21}$$

The mode I contribution from crack tip shear forces reduces to

$$G_P = \frac{(\gamma P_{1B} - P_{2B})^2}{2b^2h_1k^2G_{xz}\gamma(1+\gamma)} \ , \ \alpha_{\theta_1}\Delta G_{\theta_1 P} = \frac{4\sqrt{3}\alpha_{\theta_1}(\gamma P_{1B} - P_{2B})}{b^2h_1^2(1+\gamma)(k^2G_{xz}E)^{1/2}} \tag{22}$$

2.1.3. 2D elasticity partition theory

One averaged partition theory is obtained by averaging the classical and shear deformable partitions. This partition has been found to give an excellent approximation to the partition from 2D elasticity. The mode I and II components of the ERR from the averaged partition theory denoted by G_I and G_{II} respectively. They are

$$G_I = \left(G_{IE} + G_{IT}\right)/2 + G_P + \alpha_{\theta_1}\Delta G_{\theta_1 P} \quad , \quad G_{II} = \left(G_{IIE} + G_{IIT}\right)/2 \tag{23}$$

2.1.4. Local and global partition theories

When ERR is calculated right at the crack tip, i.e. using an infinitesimally small region around the crack tip, it is called a local calculation. When it is calculated using a finite small region, it is called a global calculation. In terms of the finite element method (FEM), an infinitesimally small region means one element length in a very fine mesh, whilst a finite small region means multiple element lengths. When global ERR calculation is used, the above three local partition theories, i.e. the classical, shear-deformable and 2D partition theories give the same partitions as that of the local classical partition theory. That is, the classical partition theory unifies the three theories in a global partition. The differences between the three local theories arise from the differences of the crack tip stresses in the three theories. However, the global distribution of interfacial stresses is governed by the classical beam and plate theory.

2.2. Clamped-clamped laminated composite beams

A clamped-clamped composite laminated beam with a symmetric delamination is considered. The loads P_1 and P_2 are applied at the mid-span. The pure mode I mode in the first set of orthogonal pure modes in classical beam theory, i.e. the $\{\theta, \beta\}$ set, is given by

$$P_2/P_1 = \theta_P = -B_2^*\left(2B_1 + h_1A_1\right)/\left[B_1^*\left(2B_2 - h_2A_2\right)\right] \tag{24}$$

Its orthogonal pure mode II mode $P_2/P_1 = \beta_P$ is too complex to be presented here algebraically. The second set of orthogonal pure modes in classical beam theory, i.e. the $\{\theta', \beta'\}$ set is given by

$$\theta'_P = P_2/P_1 = -1 \quad , \quad P_2/P_1 = \beta'_P = D_2^*/D_1^* \tag{25}$$

Within the context of shear deformable beam theory, the expressions for $P_2/P_1 = \theta_P$ pure mode I and $P_2/P_1 = \beta_P$ pure mode II are too complex to be presented here algebraically. However, when the through-thickness shear effect is not excessively large, they are very close to those in classical beam theory.

2.3. Clamped circular layered isotropic plates

A clamped circular layered isotropic plate with a central delamination and central loads P_1 and P_2 are considered. The first set of orthogonal pure modes in classical plate theory are found to be

$$P_2/P_1 = \theta_P = \theta_1 \quad , \quad P_2/P_1 = \beta_P = \beta_1 \tag{26}$$

where θ_1 and β_1 are given in Eq. (14). The corresponding ERRs are given by

$$G_{\theta_P} = 3P_1^2\gamma\left(1-\nu^2\right)/\left[2Eh_1^3\pi^2\left(1+\gamma\right)\right] \quad , \quad G_{\beta_P} = 9P_1^2\gamma\left(1-\nu^2\right)\left(1+\gamma\right)/\left[2Eh_1^3\pi^2\left(1+3\gamma\right)^2\right] \tag{27}$$

The second set of pure mode I and II modes are the same as those in Eq. (15). In the first order shear deformable plate theory, the first set of pure modes is approximately pure and the second set disappears.

3. Partition of mixed-mode fracture in layered isotropic DCBs with non-rigid interfaces

3.1. Classical beam partition theory

The mode I ERR G_{IE} is considered first. The interface normal stress σ_n is found to be

$$\sigma_n = -Eh_1^3\gamma^3/\left[3(1+\gamma)^3\right]\left[\overline{w}^{(4)} + 3(1-\gamma)/(2h_1\gamma)\overline{u}^{(3)}\right] \tag{28}$$

where $\overline{w} = \overline{w}_1 - \overline{w}_2$ and $\overline{u} = \overline{u}_2 - \overline{u}_1$ are the relative opening and shearing displacements at interface. The mode I ERR is then found by using *J*-integral.

$$G_{IE} = \lim_{da\to 0}\left\{\frac{1}{da}\int_0^{da}\int_0^{\overline{w}}\sigma_n d\overline{w}dx\right\} = \int_0^{\overline{w}_B}\sigma_{nB}d\overline{w}_B \tag{29}$$

Substituting Eq. (28) into Eq. (29) gives

$$G_{IE} = G_{IE}^L + (1+3\gamma)/[b(1+\gamma)^3](P_{2B} - \beta_1 P_{1B})\overline{w}_B^{(1)} \tag{30}$$

The first term $G_{IE}^L = G_{IT}$ in Eq. (20) and the $\overline{w}_B^{(1)}$ in the second term is the relative crack tip rotation. It is seen that Eq. (30) is not completely analytical due to the second term. It is more important to note that the second set of orthogonal pure modes is not present. The mode II ERR can be considered similarly. The interface shear stress τ_s is found to be

$$\tau_s = \tau_{sP} + \tau_{s\sigma} + \tau_{s\overline{u}} \tag{31}$$

with

$$\tau_{sP} = 3\left(\gamma^2 P_{1B} + P_{2B}\right)/\left[2bh_1\gamma(1+\gamma)\right] \ , \ \tau_{s\sigma} = 3(1-\gamma)/(2h_1\gamma)\int_0^x \sigma_n dx \ , \ \tau_{s\overline{u}} = Eh_1\gamma\overline{u}^{(2)}/\left[4(1+\gamma)\right] \tag{32}$$

The mode II ERR G_{IIE} is then calculated by using *J*-integral.

$$G_{IIE} = G_{IIE}^L + \int_0^{\overline{u}_B}\tau_{sP}d\overline{u}_B \tag{33}$$

The first term $G_{IIE}^L = G_{IIT}$ in Eq. (20) and the second term can be calculated for a given cohesive law.

3.2. Shear deformable beam partition theory

It is simple to verify that the mode II ERR G_{IIT} remains the same as the G_{IIE} in Eq. (33). However, the mode I ERR G_{IT} needs reconsideration. The governing equation for the interface normal stress σ_n is

$$\sigma_n^{(2)} - \lambda^2\sigma_n = \alpha\left(\overline{w}^{(4)} + 3(1-\gamma)/(2h_1\gamma)\overline{u}^{(3)}\right) \tag{34}$$

where $\lambda = (1+\gamma)/(\gamma h_1)\left(3k^2G_{xz}/E\right)^{1/2}$ and $\alpha = k^2G_{xz}h_1\gamma/(1+\gamma)$. By using the method of parameter variation, the solution to Eq. (34) is found.

$$\begin{aligned}\sigma_n = {} & c_1e^{\lambda x} + c_2e^{-\lambda x} + \alpha\left[\lambda^2\overline{w} + \overline{w}^{(2)} + 3\overline{u}^{(1)}(1-\gamma)/(2h_1\gamma)\right] \\ & + \alpha\lambda^3/2\left(e^{\lambda x}\int_0^x \overline{w}e^{-\lambda x}dx - e^{-\lambda x}\int_0^x \overline{w}e^{\lambda x}dx\right) + 3\alpha\lambda^2(1-\gamma)/(4h_1\gamma)\left(e^{\lambda x}\int_0^x \overline{u}e^{-\lambda x}dx + e^{-\lambda x}\int_0^x \overline{u}e^{\lambda x}dx\right)\end{aligned} \tag{35}$$

The two integration constants c_1 and c_2 are determined using the conditions $\sigma_n(\Delta a) = \sigma_n^{(1)}(\Delta a) = 0$.

$$c_1 = -\alpha\lambda^3/2\int_0^{\Delta a}\overline{w}e^{-\lambda x}dx - 3\alpha\lambda^2(1-\gamma)/(4h_1\gamma)\int_0^{\Delta a}\overline{u}e^{-\lambda x}dx \tag{36}$$

$$c_2 = \alpha\lambda^3/2\int_0^{\Delta a}\overline{w}e^{\lambda x}dx - 3\alpha\lambda^2(1-\gamma)/(4h_1\gamma)\int_0^{\Delta a}\overline{u}e^{\lambda x}dx \tag{37}$$

Then, mode I ERR is found using *J*-integral.

$$\begin{aligned} G_{IT} &= -\int_0^{\overline{w}_B}\lambda^2 M_{nm}/b\,d\overline{w}_B + \alpha\left(\overline{w}_B^{(1)}\right)^2/2 + 3\alpha(1-\gamma)/(2h_1\gamma)\int_0^{\overline{w}_B}\overline{u}_B^{(1)}d\overline{w}_B \\ &= \int_0^{\overline{w}_{B\sigma_I}}\sigma_I d\overline{w}_B + \sigma_I\left(\overline{w}_B - \overline{w}_{B\sigma_I}\right) + \alpha\left(\overline{w}_B^{(1)}\right)^2/2 \end{aligned} \tag{38}$$

Note that the first term in Eq. (38) is calculated from a given interface cohesive law with $\sigma_I = -\lambda^2 M_{nm}/b + 3\alpha(1-\gamma)/(2h_1\gamma)\overline{u}_B^{(1)}$ in which

$$M_{nm} = (1+3\gamma)/(1+\gamma)^3\left(\beta_1 M_{1B} - M_{2B}\right) + h_1\gamma^2(1-\gamma)/[2(1+\gamma)^3]N_{1Be} \tag{39}$$

and

$$\overline{u}_B^{(1)} = -\left(6\gamma^2 M_{1B} + 6M_{2B} + \gamma^2 h_1^2 N_{1Be}\right)/\left(Eb h_1^2\gamma^2\right) \tag{40}$$

In the case of a rigid interface the first two terms in Eq. (40) disappear and the third term reduces to $G_{IT}^L = G_{IT}$ in Eq. (20). For a non-rigid interface the first term in Eq. (38) is calculated based on the given cohesive law and the second and third terms are not able to be determined analytically. However, for most of practical engineering problems with hard interfaces the third term in Eq. (38) can be replaced by G_{IT} in Eq. (20). Therefore, $\overline{w}_B$ in Eq. (38) can be calculated by using a given interface cohesive law and the following:

$$G_{IT}^L = \int_{\overline{w}_{B\sigma_I}}^{\overline{w}_B}\left(\sigma_{nB} - \sigma_I\right)d\overline{w}_B \tag{41}$$

Therefore, the second term in Eq. (38) is found and the mode I ERR G_{IT} for a hard interface is obtained analytically.

3.3. 2D elasticity partition theory

A DCB under crack tip bending moments M_{1B} and M_{2B} is considered here. Refer to Ref. [12] for general loading conditions. By using the two sets of fundamental orthogonal pure modes, i.e. $\{\theta, \beta\}$ in Eq. (14) and $\{\theta', \beta'\}$ in Eq. (15), approximate orthogonal pure mode I and mode II modes are

$$\theta_N(k_{er}) = \theta_{N2} + 1/2(\theta_{N1} - \theta_{N3})\log k_{er} + 1/2(\theta_{N1} - 2\theta_{N2} + \theta_{N3})(\log k_{er})^2 \tag{42}$$

$$\beta_N(k_{er}) = \beta_{N2} + 1/2(\beta_{N1} - \beta_{N3})\log k_{er} + 1/2(\beta_{N1} - 2\beta_{N2} + \beta_{N3})(\log k_{er})^2 \tag{43}$$

where $k_{er} = k/E$ is the ratio of interface stiffness to Young's modulus. θ_{N1}, θ_{N2}, θ_{N3}, β_{N1}, β_{N2}, β_{N3} are functions of the two sets of fundamental orthogonal pure modes. Detailed expressions for them are given in Ref. [12]. A mixed mode can be partitioned using this pair of pure modes.

4. Numerical and experimental assessments

The partition theories presented above have been extensively validated by using FEM simulations and in general excellent agreement has been observed [8–13]. Here, one example is presented for an isotropic DCB with non-rigid interface. The geometric dimensions of the DCB are length $L = 110$ mm, width $b = 1$ mm, total thickness $h_1 + h_2 = 2$ mm and crack length $a = 10$ mm. The material Young's modulus is $E = 1$ GPa. The loading conditions are $M_{1B} = 1$ Nm and $M_{2B} = 0$. Mixed-mode partitions from the present 2D elasticity theory and Abaqus FEM are recorded in Table 1 for various thickness ratios γ and interface stiffness to Young's modulus ratios k_{er}. An

excellent agreement is observed between the analytical and FEM results. Note that G_I / G in Table 1 is a percentage.

Table 1. Comparison between present 2D elasticity partition theory and FEM results.

		Analytical ($\times 10^6$ N/m)					FEM ($\times 10^6$ N/m)				
γ	k_{er}	0.1	0.5	1	5	10	0.1	0.5	1	5	10
1	G_I	3.000	3.000	3.000	3.000	3.000	3.029	3.029	3.028	3.024	3.022

	G_I / G	99.83	97.29	95.36	93.03	86.43	98.92	97.95	97.30	94.92	93.39

One example of experimental assessments is also presented here. Since the specimens in the tests were manufactured without adhesive layers [4] the laminar interfaces are considered to be rigid. Five partition theories, i.e. Williams theory [1], Suo-Hutchinson theory [3], Wang-Harvey classical, shear deformable and 2D theories, are assessed in Fig. 3. Although the Suo-Hutchinson and Wang-Harvey 2D partition theories are considered to be most accurate, the Wang-Harvey classical theory agrees the best with experimental data. It is suggested that the propagation of mixed-mode delamination on rigid interfaces is governed by the global partition as the global partitions of shear deformable and 2D partition theories are the same as the classical partitions.

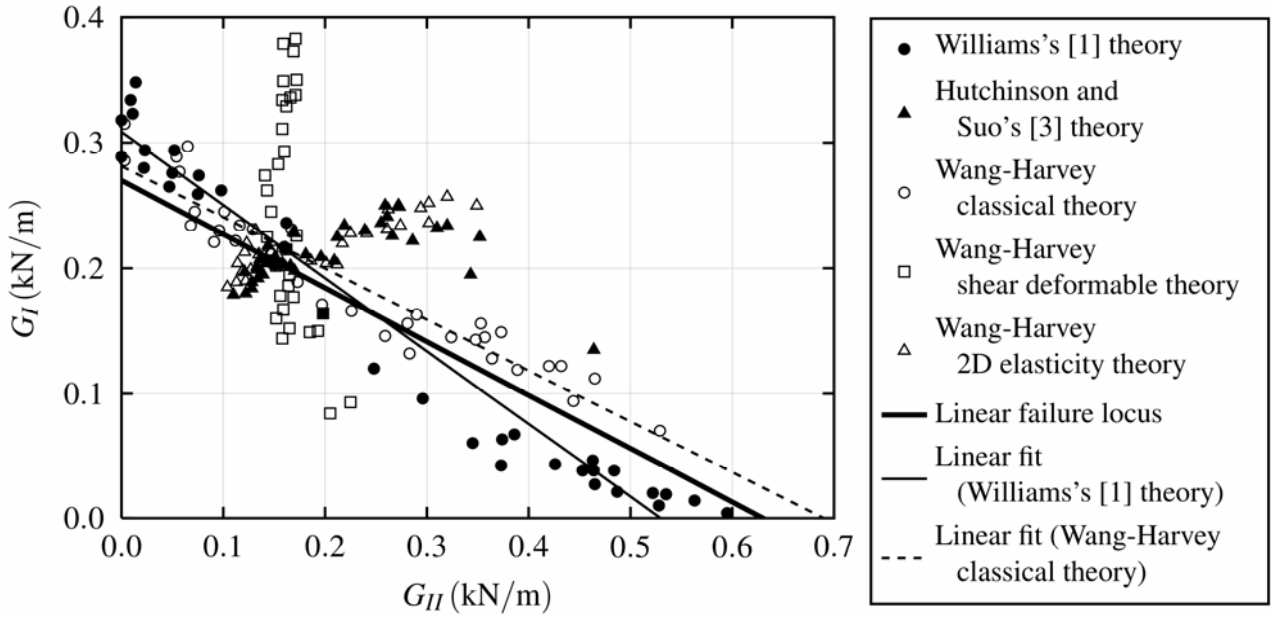

Figure 3. A comparison of various partition theories and the linear failure locus for epoxy-matrix/carbon-fiber composite specimens.

5. Conclusions

The present work discovers the most fundamental fracture modes – the two sets of orthogonal pure modes. A mixed-fracture mode can be superimposed or partitioned by these most fundamental pure modes. The two sets co-exist in classical laminated composite beams and plates and coincide in shear deformable beams and plates for rigid interfaces. When non-rigid interfaces considered the two sets coincide in both classical and shear deformable theories. By using these two sets of pure modes, a mixed-mode can also be partitioned based on 2D elasticity theory. The novel methodology is rooted in the mechanics of material and operated by a powerful mathematical method. It is capable of studying delamination in curved laminated composite beams and shells as well. It is also capable of studying general and buckling driven delamination consisting of all opening, shearing and tearing modes.

Abstract The purpose of this paper is to investigate by means of the 3D Finite Element method a coupled fracture mode generated by anti-plane loading of a straight through-the-thickness crack in a linear elastic plate. This coupled fracture mode represents one of three-dimensional phenomena, which are currently largely ignored in numerical simulations and failure assessment of structural components weakened by cracks. It arises due to the boundary conditions on the plate free surfaces, which negate the transverse shear stress components corresponding to classical mode III. Instead, a new singular stress state in addition to the well-known 3D corner singularity is generated. This singular stress state (or coupled fracture mode) can affect or contribute significantly to the fracture initiation conditions. The coupled singular mode exists even if the applied anti-plane loading produces no singularities ($K_{III} = 0$). In this case there is a strong thickness effect on the intensity of the coupled fracture mode.

Keywords Crack, anti-plane loading, coupled fracture mode, 3D modelling

1. Introduction

The first systematic study on the three-dimensional stress states of a through-the-thickness crack subjected to mode I loading was conducted in Refs [1-4]. Accurate studies on three-dimensional stress distributions in front of cracks have been carried out in those references, extending Williams' two-dimensional eigenfunction expansions [5] to the three-dimensional case, and in [6] four distinct harmonic functions have been used to solve the problem according to Papkovich-Neuber's method.
Utilising a variational principle, a system of simplified governing equations has been derived [1-4] for the extension and bending deformations of an elastic plate with a through-the-thickness crack and investigated the three-dimensional stress states surrounding the crack tip. One important result from this work is that the area of the three-dimensional stress state around the crack tip spreads in the plane direction to the distance of approximately half of the plate thickness. Beyond this distance the stress state follows the classical plane stress solution. Many experimental studies conducted in the past including those carried out in [7] who applied an optical technique confirmed this fundamental result.
Another interesting three-dimensional effect, which was first presented in [8], is the disappearance of the in-plane singularity at a point when a corner front (crack front) intersects a free surface. At this point a new three-dimensional corner singularity develops instead. The problem of a vertex (corner) singularity is now well documented in a number of articles in the last thirty years (see, among the others, Refs [9-17]). This problem was recently re-examined in [18] with reference to fatigue crack growth. In this paper, the effect of a free surface on fatigue crack behaviour was investigated experimentally and numerically for relatively thick specimens, where the solutions provided in [8] for semi-infinite space can be applied. In [9] it was underlined that the 3D corner

singularity in cracked plates, which usually can be neglected for mode I loading, should be taken into consideration for mixed mode loadings. However, despite all these studies the role of the corner singularities in fatigue and fracture phenomena remains largely unknown.

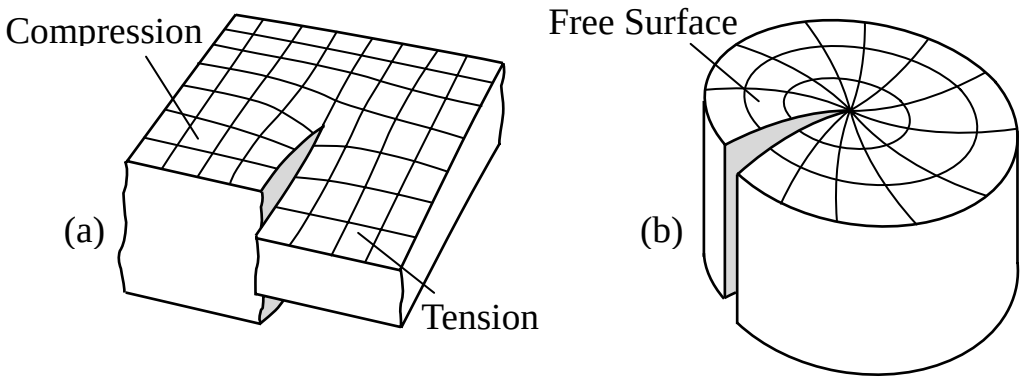

Fig.1 Generation of coupled fracture modes due to Poisson's effect and redistribution of stresses on free surfaces when a crack is subjected to shear (a) and anti-plane loading (b)

One more three-dimensional effect, which the two-dimensional numerical and analytical solutions are incapable to predict or analyse, is the existence of the coupled fracture modes. To illustrate these coupled fracture modes let us consider a through-the-thickness crack loaded in shear or anti-plane loading. In these cases additional local fracture modes are generated due to Poisson's effect and/or the redistribution of stresses on the free surfaces as illustrated: in Fig. 1 (a) – mode II loading and (b) – mode III loading in the case of a zero notch angle [16]. In many papers (see among others Refs [19, 20]) it was highlighted that modes II and III cannot exist independently and the presence of one of these modes always generates a coupled singular state.

The coupled modes induced by the primary modes II and III for through-the-thickness cracks have been known for a rather long period of time but the first systematic studies for semi-infinite cracks were conducted numerically using a careful FE modelling in [10, 21]. Recently the first coupled fracture mode (see Fig. 1a), which was called the out-of-plane or K_O-mode, was investigated for finite geometries representing welded joints as well as for sharp and round notches of arbitrary opening angle. It was demonstrated that the K_O-mode has many interesting and previously unknown features, which can influence mixed-mode fracture, crack initiation and fatigue growth phenomena.

A recent experimental and numerical study has been performed to investigate the fatigue crack growth tests in mixed-mode 2 + 3 on maraging steel and Ti-6Al-4V. The 3D evolutions of the crack fronts -measured by SEM after interrupted tests- have been analyzed [22]. A 3D finite element model of tested specimens has been prepared, with a refined mesh around the crack front. It has been shown that the profiles of stress intensity factors and energy release rate vary along the crack front. In particular due to the coupled Mode 2 and Mode 3 loadings K_2, K_3 and G have been found with an asymmetrical profile. When the inclination angle of the crack plane relative to the horizontal axis surface is equal to 45° the energy release rate is ten times higher near one free surface than on the other inducing a strong asymmetry in crack growth and showing the non

negligible effects of the coupled modes.

One of these interesting features is a coupling of this mode with the non-singular terms at shear loading. It means, if a crack is loaded in shear with $K_{II}= 0$, the intensity of the coupled K_0- mode can be different from zero. At such loading the intensity of the out-of-plane mode is finite and capable of initiating brittle fracture [23, 24]. The latter result and other three-dimensional features are in contradiction with the classical two-dimensional view on fracture, which states that brittle fracture can only be initiated with non-zero stress intensities of primary fracture modes (conventional mode I, II and III).

Important features of the out-of-plane singular mode were revealed in a careful three-dimensional numerical study of typical welded lap joint geometry [25] aimed to investigate the contribution of this mode to the overall stress state in the close vicinity of the slit/notch tip. The extension of the present study to sharp and blunt notches under mode II loading has been recently made by the present authors [26, 27].

In contrast to mode II loading, the coupled mode corresponding to mode III loading is much less investigated and there were no systematic studies focusing on the investigation of this mode except many remarks in literature on the coupled nature of modes II and III as well as the influence of this coupled mode on fracture appearance, crack path and crack initiation [19, 20]. The aim of this paper is to investigate this coupled mode using the Finite Element method and provide numerical estimates of the possible contribution of this mode to brittle fracture.

In the beginning of the present paper, a numerical technique based on FE method is developed and validated for the investigation of the coupled mode associated with the anti-plane loading. Because this mode is localised in the close vicinity of the crack tip, a careful meshing is required in order to avoid large numerical errors in this region. Further, a systematically study of this mode is carried out focusing on the effect of Poisson's ratio on the stress intensity of this mode, which also varies along the crack front. It is also demonstrated that similar to the K_0-mode, a non-singular mode III loading ($K_{III}=0$) is capable of generating the coupled singular stress state along the crack front. In this case, a strong scale effect exists and the intensity of the coupled mode strongly depends on the thickness of the plate.

2. Approach

2.1 Geometry

Because the coupled singular modes are local modes and spread to the distance of approximately half of the plate thickness as explained in the Introduction, the problem geometry is truncated to a disk with such dimensions which avoid the effect of the finite boundaries on the stress state of the coupled mode as well as the influence of bending stresses. The antisymmetric boundary conditions are utilised to further simplify the geometry. The final geometry is shown in Fig. 2 and appropriate displacement boundary conditions corresponding to anti-plane loading were applied on the cylindrical surface. The origin of the Cartesian coordinate system (x,y,z) is located at the crack tip, at the mid-surface where x direction was chosen to be the direction of the crack bisector.

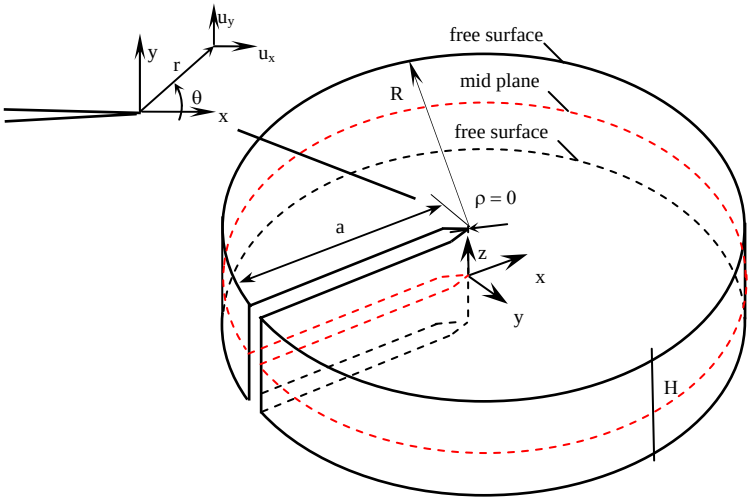

Figure 2. Geometry of the plate and coordinate system with z=0 in the mid-plane

2.2 Boundary Conditions

The displacement boundary conditions are applied to the outer cylindrical edge of the plate. In the beginning the out-of-plane displacement field corresponding to the first singular term in the asymptotic expansion of the stress field, which is valid far from the crack tip (model boundaries), was prescribed as follows:

$$w = u_z = \frac{2K_{III}}{\mu}\sqrt{\frac{r}{2\pi}}\sin\frac{\phi}{2} \tag{1}$$

$$u_x = 0$$

$$u_y = 0$$

where μ is the shear modulus. It is linked to Young's modulus by a well-known relationship:

$$\mu = \frac{E}{2(1+\nu)} \tag{2}$$

In further numerical examples Young's modulus was set at 200×10^9 Pa. However, the numerical results to be presented in the following sections can be easily rescaled for other values of mechanical properties, loading or plate thickness.

2.3 Validation

As highlighted in the Introduction section due to complexity of the numerical analysis and interpretation of the computational results there were almost no works investigating this singular mode. However, the three-dimensional effects, specifically the coupling of fracture modes II and III, were often recognised and acknowledged in many papers on stress analysis of cracked structural components, fracture and fatigue. A comparison of the present results obtained with ANSYS 11 and those published in [11] in terms of the ratio of the induced to applied stress intensity factors K_{II}^{C}/K_{III} as a function of the position along the crack front, z/H, are shown in Fig.3, demonstrating a good agreement. Description of all parameters of the modelling is given in [10] and the definition of the stress intensity factor of the coupled mode K_{II}^{C} will be provided in the next Section.

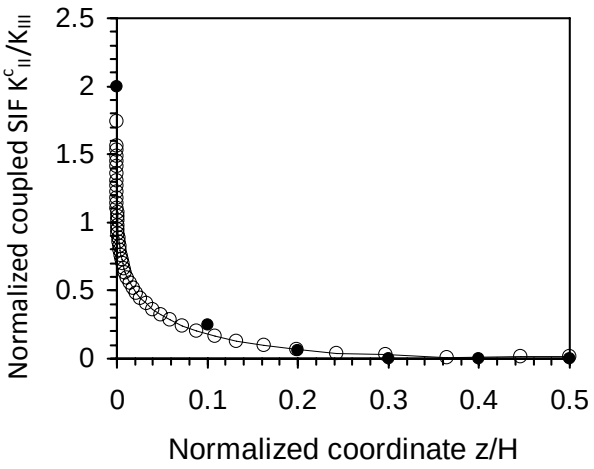

Fig.3 Comparison of the present FE calculations and published results: line is the current numerical results and filled circles are data from [11]

3. Numerical Results

3.1 Stress State

First, the results for the out-of-plane shear stress components along the bisector line for different distances from the crack tip are considered. The results can also be represented in non-dimensional form; however, the non-dimensional results are sometimes difficult to relate to practical situations. Therefore in the following computational examples, if it is not specified separately, the applied remote stress intensity factor, K_{III}= 1 MPa$\sqrt{m}$, Poisson's ratio ν=0.3 and the thickness of the plate, H= 40 mm.

The intensity of the computed stress component τ_{yz} defined similar to the classical definition of the stress intensity factor for mode II in plane problems of elasticity as

$$K_{III}(z) = \sqrt{2\pi}\lim_{x\to 0}\tau_{yz}(z)x^{1-\lambda_{III}} \qquad (3)$$

can be obtained using a standard log-log regression analysis of the stress distribution. The singular power describes the asymptotic rate at which the stress components increase as the crack tip is approached. As expected, the stress field everywhere has been found to have a degree of singularity

λ_{III}= 0.5. This value remains constant from the crack tip until the external radius is reached.
It has been found that the in-plane shear stress components associated with the coupled mode change in a wider range from zero at the mid-plane as expected to values of the same order as the applied stress intensity factor. In contrast, the out-of-plane shear stresses associated with the applied K_{III} mode do not significantly change across the thickness and the maximum shear stresses take place at the mid-plane of the plate decreasing smoothly towards the free surfaces. As mentioned above, the results were obtained for the above specified conditions (applied stress intensity factor, material properties and plate thickness) and can be easily rescaled or represented in a dimensionless form if necessary.

3.2 Stress Intensity Factors

The stress intensity factor of the coupled mode can be defined similar to mode II, or as

$$K_{II}^{C}(z)=\sqrt{2\pi}\lim_{x\to 0}\tau_{xy}(z)x^{1-\lambda_{II}} \qquad (4)$$

In general there are many similarities between the coupled mode and mode II corresponding to the shear loading of a crack. However there are some essential differences between these two singular modes. The coupled mode is a local mode, which is concentrated in the vicinity of the plate free surfaces. It is generated due to the boundary conditions, which negate the out-of-plane shear stress components corresponding to the applied mode. For this coupled fracture mode the effect of Poisson's ratio is rather small in comparison with the coupled mode generated by mode II loading [14]. The coupled modes rapidly decay with distance from the crack tip as it will be demonstrated later in this paper.
The distributions of the local intensities of mode III, $K_{III}(z)$ associated with the applied antisymmetric loading and $K_{II}^{C}(z)$, associated with the coupled mode are shown in Fig. 4. As it can be seen from this figure the coupled mode is localised in the close vicinity of the free surfaces and propagates into the thickness to the distance of approximately 0.2 H. There is a significant drop in the intensity of the applied mode in the precincts of the free surface. In the very close vicinity of the free surface the intensity of both modes is approaching to zero. As it was mentioned in the Introduction, at a point where a corner front (crack front) intersects a free surface the applied and coupled modes disappear and a new type of singularity, 3D corner singularity, develops instead. Consequently, the numerical results could be not very accurate in the vicinity of this location [10].

4. Anti-plane Loading with K_{III} = 0 and Scale Effect

4.1 Coupled Mode due to Anti-plane Loading

For an elastic plate with a crack, the possible contribution of higher order terms of the classical Williams' solution [28] to the fracture initiation was discussed with reference to a plane elastic problem in [29-31]. As discussed in Ref. [30] in some cases of practical interest, the contribution of the higher order stress terms to the stress state in the vicinity of the crack tip (in addition to the stress intensity factors and the T-stress) is not negligible. A set of equations has been proposed for accurately describing the crack tip stress components particularly for those cases where the mode I and mode II stress intensity factors used in combination with the T-stress component, are unable to capture with satisfying precision the complete stress field ahead the crack tip. In this session an

accurate analysis of mode III higher order (non-singular) terms on the induced mode II is carried.

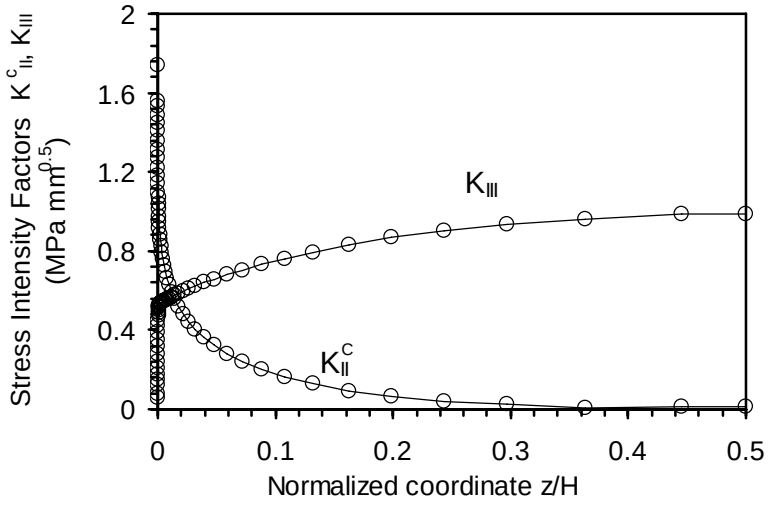

Fig. 4. Distribution of the stress intensity factors (mode III and the coupled mode) along the plate thickness, at a distance x = 0.05 mm from the crack tip.

The out-of-plane displacement, w, beyond the area of 3D effects (this 3D area is confined within a cylinder with the axis of symmetry along the crack front and radius equal to half of the plate thickness) can be expressed as [29]:

$$w = \sum_{n=0}^{\infty} \frac{r^{n+\frac{1}{2}}}{\mu} C_n \sin\left(\frac{1}{2} - n\right)\phi \tag{5}$$

with

$$C_0 = K_{III}^{\infty}\sqrt{\frac{2}{\pi}} \tag{6}$$

The previous results are related to the case when $C_0 \neq 0$ or $K_{III} \neq 0$ and all other terms in the asymptotic expansion (5) are zero ($C_n \equiv 0$ at $n = 1,2...\infty$). In Fe simulations the corresponding displacement boundary conditions far from the crack tip were applied to avoid effect of the finite boundaries of the FE model. In the following analysis the situation when a through-the-thickness crack loaded with $C_0 = K_{III} = 0$ is considered. It will be demonstrated that such a loading of a through-the-thickness crack is capable of inducing the singular coupled singular mode, the same as for the leading term in the asymptotic expansion of the two-dimensional displacement/stress field. It suggests that this coupled singular mode has a potential to cause fracture. In contrast, the classical two-dimensional theory of brittle fracture states that fracture by crack propagation is impossible due to the absence of the energy release rate when K_{III}=0.

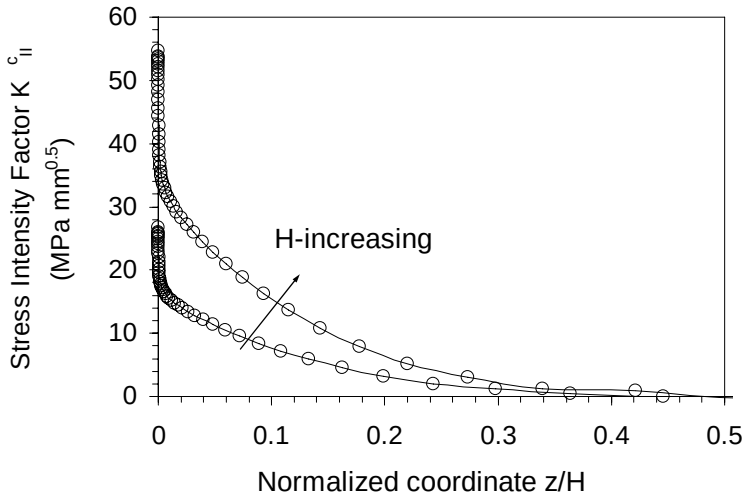

Fig.5. Effect of the thickness on the intensity of the coupled mode at distance x/H= 0.02 (a);

Consider the first non-singular term in the asymptotic expansion. Set its value C_1=1 MPa/$\sqrt{m}$ corresponding to n=1 in Eq. (5). Such loading produces no singularities corresponding to the applied antisymmetric loading, i.e. $K_{III} = 0$, which is also valid in the area of 3D effects (very close to the crack tip). The results of the FE calculations are presented in Fig.5, which reveals that a non-zero stress intensity of the coupled mode does exist at such loading. The latter effect has many implications for failure assessment. In particular, it indicates that brittle failure by crack propagation is possible even the intensity of the primary load (2D stress intensity factor) is close to zero $(K_{III} \approx 0)$.

It is interesting that the non-singular loading reveals a strong scale effect of deterministic nature, which can be also found from dimensionless considerations. Indeed, due to the localised nature of the coupled mode, its intensity has to be a linear function of the applied intensity, or $K_{II}^{C} \approx C_1$.

5. Conclusion

Below the most important findings of this work will be summarised:

a) Anti-plane loading of a through the thickness crack leads to generation of a singular stress state (or a coupled fracture mode), which has the similar singular behaviour as classical mode II. However there are some essential differences between these modes. The coupled mode is a local mode, which is concentrated in the vicinity of the plate free surfaces and is generated due to the Poisson's effect and boundary conditions, which negate the out-of-plane shear stress components corresponding to the applied mode. The coupled mode rapidly decays with distance from the crack tip. The local nature of the coupled modes means that the obtained results for the truncated geometry are applicable to other finite geometries provided that there is no interaction between the boundary conditions and the area of 3D effects.

b) The intensity of the primary (applied) anti-plane mode in the vicinity of the crack tip is moderately affected by Poisson's ratio. In contrast, the intensity of the coupled mode is largely unaffected by Poisson's ratio.

c) The singular coupled mode can be induced by, so called, non-singular anti-plane loading with $K_{III} = 0$. In this case a strong thickness effect is found and confirmed by FE calculations. The

intensity of the coupled mode decays (increases) with the decrease (increase) of the plate thickness as a power function. When several anti-plane non-singular terms are applied to the crack in an elastic plate the scale effect can be rather complicated. The influence of the higher terms on the stress intensity of the coupled mode depends on the number of the asymptotic mode, n, and this influence is more significant for the higher mode numbers.

All these theoretical findings, specifically the effects of Poisson's ratio and plate thickness on the stress intensities, have direct implications to the failure initiation conditions for cracks stressed in mode III. These findings demonstrate essential differences between classical two-dimensional considerations and 3D Fracture Mechanics. For example, the generation of the coupled singular mode at anti-plane loading with $K_{III} = 0$ indicates that contrary to the classical 2D theories, fracture under such loading conditions can be initiated due to the induced singular coupled modes. Such fracture is likely to take place close to free surfaces. It is also recognised that much work needs to be done to understand the contribution of the coupled modes to fracture initiation and fatigue.

Finally, all Finite Element results of the current study can be re-scaled to make these available for assessment of comparative studies. The only reason as to why it has been used particular values was to provide some physical feeling for the results of our finite element study.

Numerical Solutions of Second Elastic-Plastic Fracture Mechanics Parameter in Test Specimens under Biaxial Loading

Ping Ding[1], Xin Wang[1,*]

[1] Department of Mechanical and Aerospace Engineering, Carleton University,
Ottawa, Ontario, K1S 5B6, Canada
*Corresponding author: xwang@mae.carleton.ca

Abstract Extensive finite elements analyses have been conducted to obtain solutions of constraint parameter A, which is the second parameter in a three-term elastic-plastic asymptotic expansion for crack-tip field, for test specimens under biaxial loading. Three mode I plane-strain test specimens, *i.e.* single edge cracked plate (SECP), centre cracked plate (CCP) and double edge cracked plate (DECP) were studied. The crack geometries analysed include shallow to deep cracks, and the biaxial loading ratios analysed are 0.5 and 1.0. Solutions of parameter A were obtained for materials following the Ramberg-Osgood power law with hardening exponents of n=3, 4, 5, 7 and 10. Remote tension loading were applied which covers deformation range from small-scale to large-scale yielding. Based on the finite element results of constraint parameter A, crack-tip constraint effect for cracked specimens under biaxial loading is analysed. Using the relationships between A and other two commonly-used second fracture parameters, Q and A_2, the present solutions for A can be used to calculate parameters Q and A_2.

Keywords elastic-plastic fracture, second fracture parameter, biaxial loading, solutions, constraint effect

1. Introduction

In classical elastic-plastic fracture mechanics (EPFM), one-parameter approach, which describes the HRR fields [1, 2] based on J-integral [3], usually can work well for high constraint cases. For low constraint cases, under high loading conditions, the dominance of J-integral will be lost, and the one-parameter approach of J-integral will not be appropriate any more.

Two-parameter approaches have been developed to overcome the limitation of the EPFM one-parameter approach, in which a second fracture mechanics parameter is introduced to characterize the constraint effect besides the load-related parameter J-integral. Several commonly-used two-parameter approaches are, J-T [4-6], J-Q [7, 8] and J-A_2 (J-A) [9-12] approaches, where constraint parameter A is a different normalizing form of A_2 [11, 12].

Determination of J-integral and second fracture mechanics parameter, T, Q and A_2 (A), is precondition of application of J-T, J-Q and J-A_2 (A) approaches. In the early development of EPFM, J-integral solutions have been well established. The solutions of constraint parameter T-stress have also been well established in the literature. Currently, numerical method, such as finite element analysis (FEA) method, is the main method for the determination of constraint parameters Q and A_2 (A). For example, Nikishkov *et al*. [12] suggested an algorithm which determines solutions of A using a least squares procedure based on the finite element analysis results. Although with high accuracy, numerical method is a time-consuming way to obtain solutions of parameters. Correspondingly, understanding of constraint effect near crack-tip is limited because of the scarcity of solutions of constraint parameter A_2 (A) and Q.

In previous works of authors [13, 14], extensive finite element analyses were conducted to obtain solutions of parameter A for several typical two-dimensional (2D) plane-strain specimens under uniaxial loading conditions. Biaxial loading cases are of equal theoretical and engineering practical significance as uniaxial loading cases. Many researchers have focused their investigations on biaxial loading cases, for example, the results reported by Pop *et al*. [15] and Méité *et al*. [16]. In the present work, solutions for A will be obtained for biaxial loading cases for three mode I crack plane-strain specimens, single edge cracked plate (SECP), center cracked plate (CCP) and double edge cracked plate (DECP). In this work, extensive finite element analyses will be carried out for SECP, CCP and DECP cracked specimens under biaxial loading conditions with biaxial loading

ratios λ=0.5, 1.0, to determine numerical solutions of constraint parameter *A* through a least squares fitting method suggested by Nikishkov *et al*. [12]. Using the obtained numerical solutions of constraint parameter, *A*, constraint effect near crack-tip of specimens is analyzed. Numerical solutions for constraint parameter *A* under biaxial loading conditions obtained in this work can be used to estimate other two commonly-used constraint parameters A_2 and *Q* conveniently by the relationships between *A* and A_2, *Q* presented in authors' previous paper [13].

2. Theoretical background

2.1. *J-A* approach

As mentioned in introduction section, *J-A* two-parameter approach of elastic-plastic fracture mechanics, which is suggested by Nikishkov *et al*. [11, 12], is an alternate format of *J*-A_2 approach developed by Yang *et al.* [9, 10]. In these two formats of the approach, both the constraint parameter *A* and A_2 are the magnitude of the second term in a three-term series expansion of crack-tip stress fields. In this paper, the *J-A* format is used.

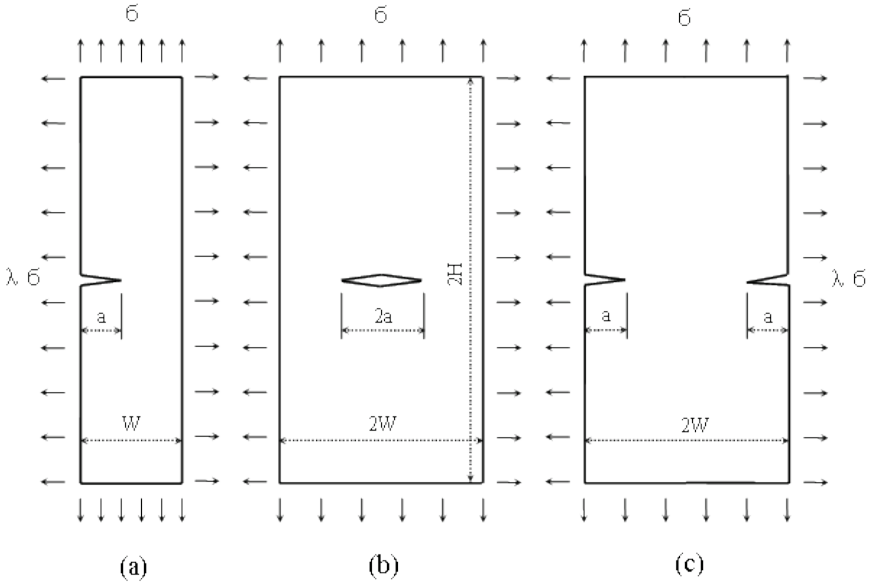

Figure 1. Cracked specimens under biaxial loading: (a) SECP, (b) CCP, (c) DECP

Considering a two-dimensional elastic-plastic specimen containing a mode I crack under plane strain condition, if the elastic-plastic behavior of the specimen material described by deformation theory of plasticity follows the Ramberg-Osgood relationship, the uniaxial stress-strain curve can be described as:

$$\frac{\varepsilon}{\varepsilon_0}=\frac{\sigma}{\sigma_0}+\alpha\left(\frac{\sigma}{\sigma_0}\right)^n \tag{1}$$

where α is a material coefficient, *n* is the hardening exponent ($n > 1$), $\varepsilon_0=\sigma_0/E$, *E* is Yong's modulus, σ is the stress applied on the remote end of specimen, and σ_0 is the material yield stress.

Table 1. Comparison of constraint parameter *Q* for CCP under *a/W*=0.5, *n*=10, λ=0.5

$\log(J/(a\sigma_0))$	-2.900	-2.491	-2.256	-2.074	-1.855	-1.593	-1.299	-0.991
Q_{SSY} [Ref.]	-0.2107	-0.3553	-0.4822	-0.5711	-0.6497	-0.7690	-0.8223	-0.9315
Q_{SSY}	-0.2196	-0.3714	-0.4849	-0.5763	-0.6758	-0.7790	-0.8739	-0.9815
Diff. (%)	4.232	4.526	0.558	0.923	4.003	1.299	6.274	5.376

In the *J-A* two-parameter approach suggested by Nikishkov *et al*. [11, 12], for the hardening exponent $n \geq 3$ and under plane-strain conditions, the three-term asymptotic solution expression for

stress field near the crack-tip in an elastic-plastic material is given as:

$$\frac{\sigma_{ij}}{\sigma_0} = A_0 \bar{r}^s \bar{\sigma}_{ij}^{(0)}(\theta) - A\bar{r}^t \bar{\sigma}_{ij}^{(1)}(\theta) + \frac{A^2}{A_0} \bar{r}^{2t-s} \bar{\sigma}_{ij}^{(2)}(\theta) \tag{2}$$

In Eq. (2), $\sigma_{ij}(\theta)$ are stress components, σ_r, σ_θ and $\sigma_{r\theta}$ in a polar coordinate system with origin at the crack-tip; $\bar{\sigma}_{ij}^{(0)}(\theta), \bar{\sigma}_{ij}^{(1)}(\theta)$ and $\bar{\sigma}_{ij}^{(2)}(\theta)$ are normalized angular stress functions. The dimensionless radius $\bar{r}$ is defined as $\bar{r} = r/(J/\sigma_0)$, where J is the J-integral at the crack-tip. Power t is an eigenvalue depending on the hardening exponent n of Ramberg-Osgood relation, and power $s=-1/(n+1)$. The polynomial coefficient A_0 is defined as [11], $A_0=(\alpha\varepsilon_0 I_n)^{-1/(n+1)}$, where I_n is a scaling integral only depending on n, see Refs. [1, 2]. Nikishkov [11] has proposed a computational algorithm to determine the values of normalized angular functions $\bar{\sigma}_{ij}^{(0)}(\theta)$, $\bar{\sigma}_{ij}^{(1)}(\theta)$, $\bar{\sigma}_{ij}^{(2)}(\theta)$, asymptotic power t, and scaling integral I_n. The three-term expansion in Eq. (2) for the crack-tip stress (displacement) fields is controlled by two parameters, the magnitude of the first term (J-integral) and a second parameter (A) controlling the second and third term.

2.2. Numerical method for determining of constraint parameter

The application of J-A (A_2) two-parameter approach depends on the determination of the load-related parameter J and constraint parameter A (A_2). The solutions of J-integral (including analytical, numerical and approximate solutions) have been well established in the literature, such as the numerical solution of J suggested by Moran and Shih [17], which has been adopted in the commercial code ABAQUS [18] utilized in the present research.

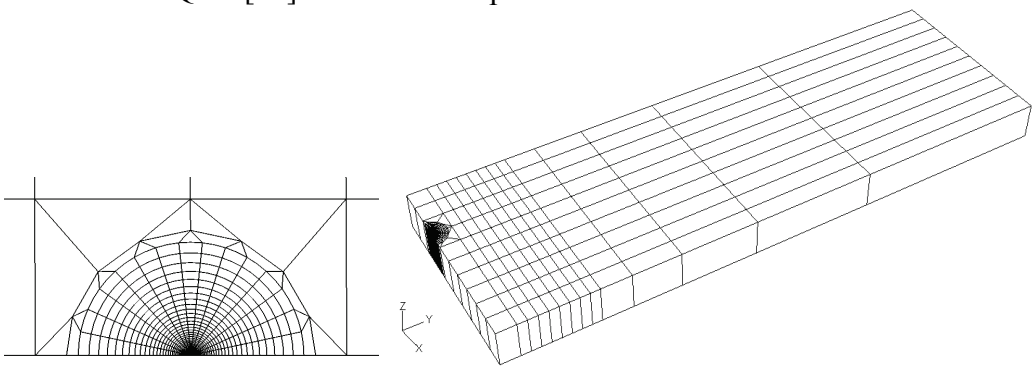

Figure 2. Typical FEA mesh, $a/W = 0.3$

Based on some stress component with corresponding finite element solutions at one or several locations (points) within the plastic zone, Yang *et al*. [9, 10] determine the A_2 values by matching a three-term expansion on crack-tip stress field. It is called the "*point match*" method by some researchers. Also based on FEA results, Nikishkov *et al*. [12] suggest a "*fitting method*" to determine parameter A values through a three-term expansion expressed by Eq. (2). In the present work, the proposed least square fitting method is utilized to obtained numerical solutions of constraint parameter A. See refs. [12] and [13] for more details about the procedure of the fitting method.

3. Finite element analysis, results and discussion

3.1. Material model and properties

The material model for finite element analyses carried out in the present work is the deformation theory of plasticity. Ramberg-Osgood power-law strain hardening relation is applied in finite element code ABAQUS [18], which is used in the present FEA.

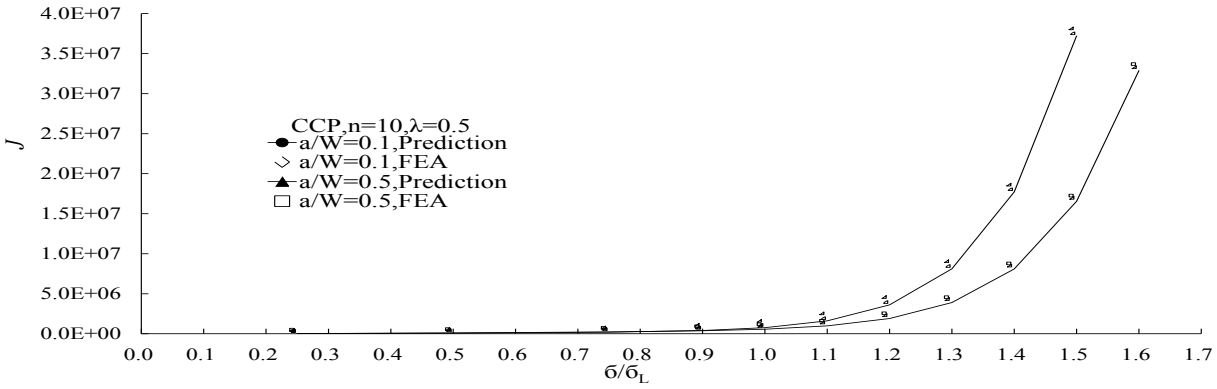

Figure 3. Comparisons of *J*-integral, CCP

Material properties used for all the analyses are specified as follows, yield stress $\sigma_0=4.0\times10^8$ *Pa*, elasticity modulus $E=2.0\times10^{11}$ *Pa*, Poisson ratio $\upsilon=0.3$, material coefficient $\alpha=1.0$, and hardening exponent n=3, 4, 5, 7 and 10. The used material properties cover a wide range of both high and low strain hardening behaviors.

3.2. 2D cracked models and FEA procedure

Three typical cracked specimens under biaxial loading (shown in Figure 1), *i.e.* single edge cracked plate (SECP), center cracked plate (CCP) and double edge cracked plate (DECP), are studied through finite element analysis method. Due to the symmetry of the specimens, only a half of the SECP or a quarter of the CCP or DECP structure is modeled in the finite element analyses. A typical three-dimensional (3D) finite element mesh used for all three specimen models is illustrated in Figure 2. Total 1196 elements are included in the mesh and element type is assigned as 20-node quadratic hybrid brick with linear pressure, reduced integration [18]. Element radial sizes of finite element mesh are varied according to a geometric progression. The value for geometry size ratio of height over width, *H/W*, is 3.0. This 3D mesh is utilized to simulate 2D plane strain conditions with an additional boundary condition, the displacement in the model thickness direction $u_z=0$. Finite element analyses for all three specimens (SECP, CCP and DECP) are carried out with two values of biaxial loading ratio, $\lambda=\sigma_x/\sigma_y=0.5$, and 1.0 (see Figure 1). The external loads applied on the remote end of the specimens are normalized by yield stress σ_0, *i.e.* σ/σ_0.

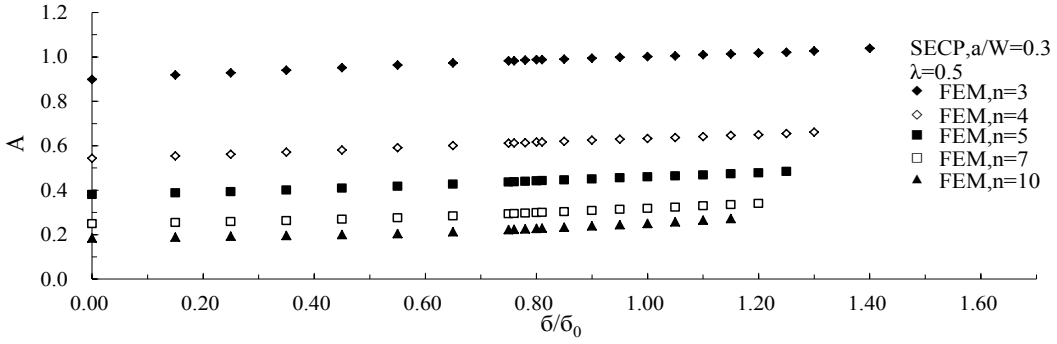

Figure 4. FEA solutions of constraint parameter *A* for SECP, *a/W*=0.3, λ=0.5

The fitting area to calculate the values of parameter *A* from FEA results by a least square fitting method suggested by Nikishkov *et al*. (see [12, 14]) is set as $1.5 \le \bar{r} \le 3$ and $0^0 \le \theta \le 45^0$, and the opening stress, σ_θ, is set as the stress component used for the least square fitting process.

Verifications of the used finite element model (mesh) and succedent fitting process for *A* values determination are carried out through comparison of solutions for two fracture parameters, load-related parameter *J*-integral and constraint parameter *Q* (*J*-*Q* approach). The comparison is based on *J*-integral estimation formulas and solutions of parameter *Q* for CCP specimen under

biaxial loading reported in the literature.

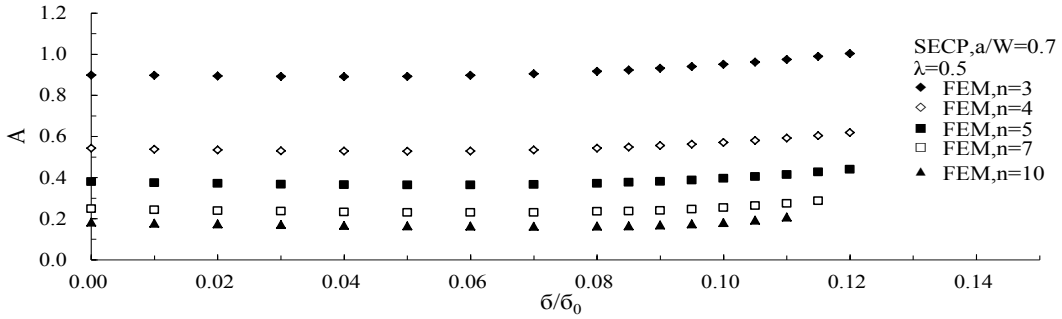

Figure 5. . FEA solutions of constraint parameter A for SECP, a/W=0.7, λ=0.5

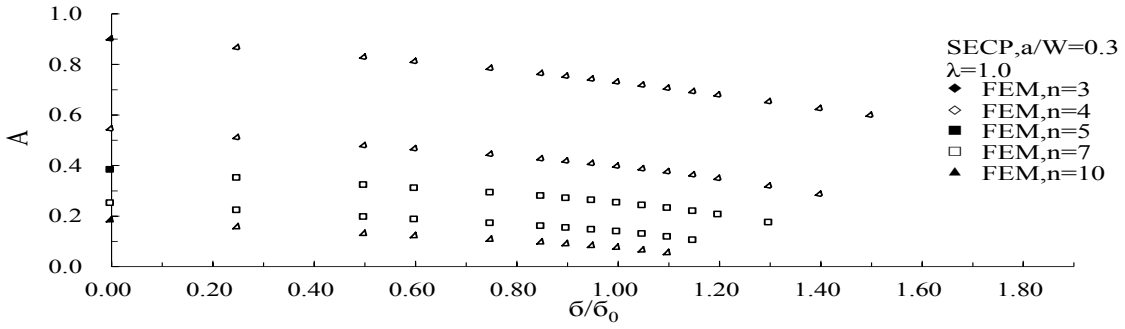

Figure 6. . FEA solutions of constraint parameter A for SECP, a/W=0.3, λ=1.0

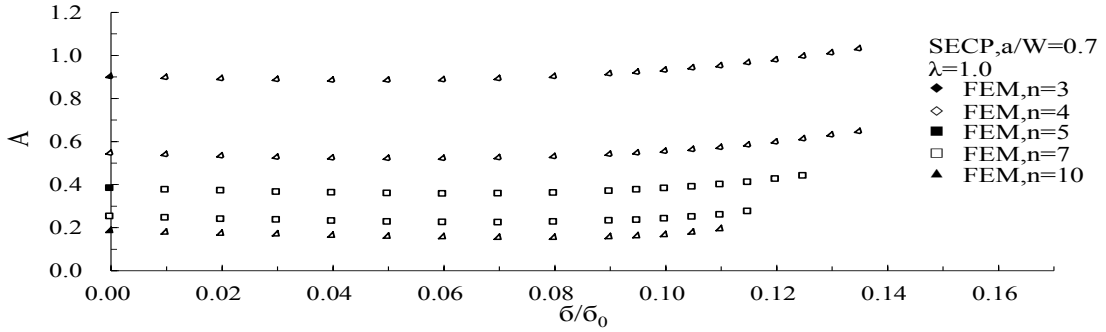

Figure 7. . FEA solutions of constraint parameter A for SECP, a/W=0.7, λ=1.0

For the purpose of comparison, finite element analysis for CCP specimen is carried out with hardening exponent n=10 for biaxial loading ratio λ=0.5 and geometry ratio a/W=0.1, 0.5. The values for J-integral from finite element analysis are compared with those obtained from EPRI estimation formulas of J [19]. Figure 3 shows the comparison results for a/W=0.1 and 0.5. It can be found that the J-integral values from FEA are very close to those from the estimation formulas. Based on the results of finite element analysis, constraint parameter A can also be obtained by using the fitting method proposed by Nikishkov *et al*. [12]. Through relationship between A and Q presented in authors' previous paper [13], the obtained solutions for A are converted to values of Q. Then determined Q values are compared with those reported by O'Dowd *et al.* [19]. It is found that, for both relative crack length a/W=0.1 and 0.5, Q solutions from the preset FEA results are close to those obtained by O'Dowd *et al.* [19]. As a numerical example, data comparison between Q values from FEA as well as A-Q relationship and those presented by O'Dowd *et al* [19] for the CCP under n=10 with a/W=0.5 and λ=0.5 is shown in Table 1.

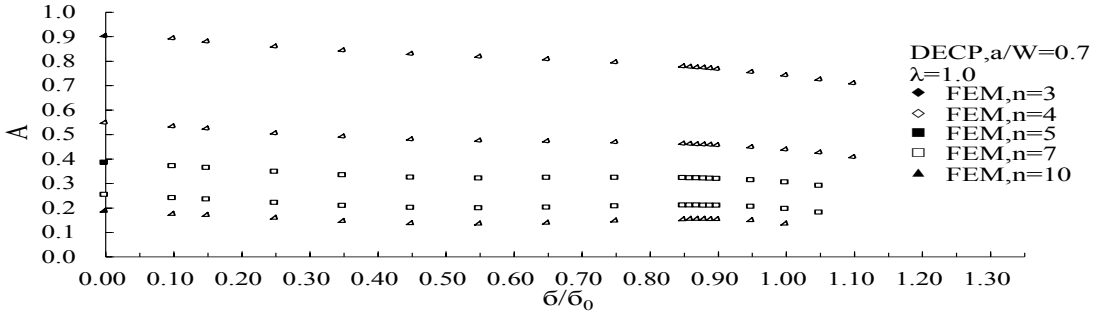

Figure 11. . FEA solutions of constraint parameter *A* for DECP, *a/W*=0.7, λ=1.0

3.3. FEA results

In the present work, a wide range of finite element analyses for three typical specimens (SECP, CCP and DECP) under biaxial loading are completed. Based on the FEA results, numerical solutions of constraint parameter *A* are determined by using the fitting method suggested by Nikishkov *et al*. [12].

The research of Chao and Zhu [20] on 2D plane strain models shows that the size requirement for ductile fracture initiation under J-A_2 dominant conditions is $a\sigma_0/J > 6$ for the shallow cracked cases or $b\sigma_0/J > 11$ for deep cracked cases, where a is the crack length and b is the remaining ligament. In the present finite element analyses (FEA), the highest load levels are those corresponding to the values mentioned above. In addition, Chao and Zhu [20] also argue that, for deep crack cases, a value of $b\sigma_0/J$ around 30 corresponds to fully plastic condition, while for shallow cracks, values of $a\sigma_0/J \leq 50$ already nearly correspond to the fully plastic deformation.

According to the above criteria, the external load ratios (σ/σ_0) used here to determine numerical solutions for parameter A from FEA for the three specimens cover the deformation range from small-scale yielding (SSY) to large-scale yielding (LSY). For example, for SECP with a/W=0.7

(deep crack), the values of $b\sigma_0/J$ at maximum loads are within 54-64 and 38-62 for λ=0.5 and λ=1.0, respectively. For the SECP with a/W=0.3 (shallow crack), the values of $a\sigma_0/J$ at maximum loads are around 4 and within 4-8 for λ=0.5 and 1.0, respectively.

The obtained numerical solutions of A for biaxial loading ratios λ=0.5 and 1.0 and relative crack lengths a/W=0.1, 0.3, 0.5, 0.7 are listed in Tables 2-3, 4-5 and 6-7 for the SECP, CCP and DECP specimens, respectively. Typical numerical solutions for parameter A for a/W=0.3, 0.7 are presented in Figures 4-5 (λ=0.5) and Figures 6-7 (λ=1.0) for the SECP specimen as well as Figures 8-9 (λ=0.5) and Figures 10-11 (λ=1.0) for DECP specimen.

3.4. Discussions on FEA results and constraint effect

Examining the solutions of A obtained from FEA results for the SECP, CCP and DECP specimens under biaxial loading, it is found that, the curve shape similarity observed by Nikishkov *et al*. [12]

not only appear in the cases of uniaxial loading and external loading ratio σ/σ_L (σ_L, limit load of specimen) but also in the cases of biaxial loading and loading normalization, σ/σ_0, see Figure 4-7 for example.

By analyzing the numerical solutions of parameter *A* for three cracked specimens (see Tables 2-7, Figures 4-11), several dependencies have been found. First, it is found that, for any specific specimen geometry (*a/W*) of some cracked body (SECP, CCP or DECP), generally the maximum external loading ratios (σ/σ_0), which are determined by the criteria suggested by Chao and Zhu [20], increase with decreasing of hardening coefficient *n*.

In addition, the effects of crack geometry, hardening exponent (*n*) and biaxial loading ratio (λ) on parameter *A* (constraint level) are also observed. For uniaxial loading cases (λ=0.0) investigated in a previous work of authors [13], it has been shown that *A* values gradually increase with external loading. The results in the current work show that, with smaller biaxial loading ratio (λ=0.5), the parameter *A* follows a general decreasing trend with increasing external loading for shallow crack geometries (*e.g.* *a/W*=0.1 for SECP and CCP, *a/W*=0.1, 0.3 for DECP). Decreased values for parameter *A* indicate the increasing constraint level. For the cases with bigger biaxial loading ratio (λ=1.0), a decreasing trend of parameter *A* appears not only for those shallowest cracks but also for cracks with larger depth and even fairly deep cracks (*e.g.* *a/W*=0.3 for SECP, 0.3, 0.5 for CCP, 0.5,

0.7 for DECP). On the other hand, generally, a deep crack is not sensitive to the variation of the λ value, except in the case of DECP. For example, for SECP, with λ value increasing from 0.5 to 1.0, the trend of *A* curves for *a/W*=0.3 (shallow crack) changes from increasing to decreasing (see Figure 4 and Figure 6), while that for *a/W*=0.7 (deep crack) almost keeps no change (see Figure 5 and Figure 7).

As for the effect of hardening exponent (*n*), with the increase of the biaxial loading ratio λ, decreasing trend of *A* curves appears earlier (under smaller external loading) or is more significant for cases with smaller *n* values than that for cases with bigger *n* values. For example, for DECP, the trend of the *A* curves for *a/W*=0.3 changes from increasing to decreasing as λ increases from 0.5 to 1.0 (see Figures 8 and 10 as well as Tables 6 and 7), but the curve for *n*=3 decreases more quickly than that for *n*=10 (see Figures 10 and Table 7).

Based on the observations represented above, it can be concluded that, (1) in general, constraint level in crack-tip fields increases with the increase of biaxial loading ratio, λ; (2) the constraint level for materials with smaller values of hardening exponent *n* increases more with increased biaxial loading ratio; (3) the constraint level for shallow cracks rises more with increase of biaxial loading ratio; (4) comparing SECP and CCP specimens, an increase of biaxial loading ratio raises the constraint level of DECP more.

4. Conclusions

In this paper, numerical (finite element) solutions for the constraint parameter *A* for three plane strain mode I specimens, SECP, CCP and DECP, under biaxial load have been obtained based on the extensive finite element analyses of specimen crack-tip fields.

Table 7. FEA results for DECP specimens under λ=1.0

Through analyzing numerical solutions of constraint parameter *A*, several dependencies (mainly on the constraint effect) for 2D cracked models under biaxial loading are founded. They are:
(1) generally, the maximum external loading ratio (σ/σ_0) for which a valid solution can be obtained increases with decreasing hardening coefficient *n*;
(2) in general, the constraint level in crack-tip fields increases with an increase of biaxial loading ratio, λ;
(3) the constraint level for materials with smaller values of hardening exponent *n* rises more with increased biaxial loading ratio;
(4) the constraint level for shallow cracks increases more than for deep cracks with an increase of biaxial loading ratio;
(5) compared with SECP and CCP specimens, a higher biaxial loading ratio increases the constraint level of DECP more.
All numerical solutions for constraint parameter *A* under biaxial loading obtained in this work can be utilized to predict corresponding values for other two commonly-used constraint parameters A_2 and *Q* by the relationships between *A* and A_2, *Q* presented in an previous paper of authors [13].

Abstract Based on the global approach and the experimental measurements by digital image correlation, the presented study proposes a coupling between these two approaches in order to evaluate energy release rate. The proposed formalism allows calculating the energy release rate fracture parameters without considering the elastic parameters of material. The experimental analysis is realized using the specimens made in PVC isotropic material and Douglas fir (orthotropic material) under different mixed mode loadings. The loading under displacement control is applied using the Arcan system. From experimental data optimized by an adjustment procedure, the kinematic state in the crack tip vicinity is evaluated through the crack opening relative displacement factors. In parallel the stress state in vicinity of the crack tip is evaluated by a numerical analysis. This analysis is performed using the finite elements method and the integral invariant Mtheta, in order to evaluate the stress intensity factors. The finite element analysis is based on the reproduction of experimental test in terms of specimen geometry, experimental boundaries conditions and loading configurations. Then the energy release rate can be estimated by coupling of these two factors calculated without considering the material elastic parameters. Moreover, this method allows defining the local mechanical behavior.

Keywords Fracture mechanics, Mixed Mode, Experimental, Numerical, Digital Image Correlation

1. Introduction

Cracked structures are most often subjected to complex loadings in mixed-mode configurations that can lead to a catastrophic collapse of the structure and modify their mechanical behavior. In this case in order to avoid structural behavior, it is necessary to evaluate fracture process parameters and local mechanical behavior. Within this field of study, several numerical investigations have been carried out in the literature for the purpose of characterizing crack tip parameters through use of the energy method for mixed-mode configurations [1-4], for isotropic and orthotropic media. At present, these efficient techniques require an explicit knowledge of material properties; for orthotropic cases in particular, the complete compliance tensor is needed. In this context, our study proposes a new formalism that allows uncoupling the fracture parameter identification relative to material elastic properties.

Based on Digital Image Correlation (DIC) and a Finite Element Method (FEM), the fracture parameter identification can be performed from the kinematic and stress distributions in the crack tip vicinity. The complementarity of these two approaches distinguishes the calculation of energy release rates relative to opening and shear modes from the calculation of local material elastic proprieties.

According to our approach, DIC is employed to measure the displacement field evolution for the specimens made from a rigid Polyvinyl Chloride polymer and Douglas fir loaded under mixed-mode configurations. The application of such an experimental technique enables capturing both strong and weak kinematic discontinuities in the crack tip vicinity so as to characterize Crack Relative Displacement Factor (CRDF) [5-9]. The iterative Newton-Raphson method is then coupled with DIC to provide not only the real crack tip position needed for an accurate CRDF determination, but also the comprehensive raw dataset optimized through Williams' asymptotic series expansion solution.

The evaluation of stress distribution is realized using a finite element model. The model is based on experimental sample geometry and experimental boundary conditions. According to the Mq

method, Stress Intensity Factor (SIF) is defined by introducing a mixed-mode separation algorithm. For isotropic as for orthotropic configurations, stress distribution into the crack tip domain is assumed to be unaffected by elastic properties [5-7].
By aggregating the results of CRDF yielded by experimental DIC and SIF, as given by a numerical FEM, the prediction of an accurate energy release rate can be proposed. Fracture mode separation is also analyzed by establishing mode I and mode II energy release rates for mixed-mode loading conditions as well as plane configurations.

2. Experimental material and methods

The experimental evaluation of has been performed for several mixed-mode ratios. As shown in Figure 1, the experimental set-up involves an electromechanical press fitted with an LVDT displacement transducer and a load cell. The specimen geometry is a single-edge notched sample made from Polyvinyl Chloride (PVC) for the isotropic case and Douglas fir in the orthotropic case. The specimen dimensions are $208 \times 44 \times 10\,\text{mm}^3$ for the PVC specimen and $210 \times 50 \times 10\,\text{mm}^3$ with a notch length equal to $75\,\text{mm}$. The various mixed-mode loading configurations are applied thanks to Arcan fixtures that allow imposing a number of different mixed-mode ratios defined by the angle between force direction and crack orientation. The test is run under a displacement control with an imposed velocity of the cross-head equal to 0.1 mm/s.

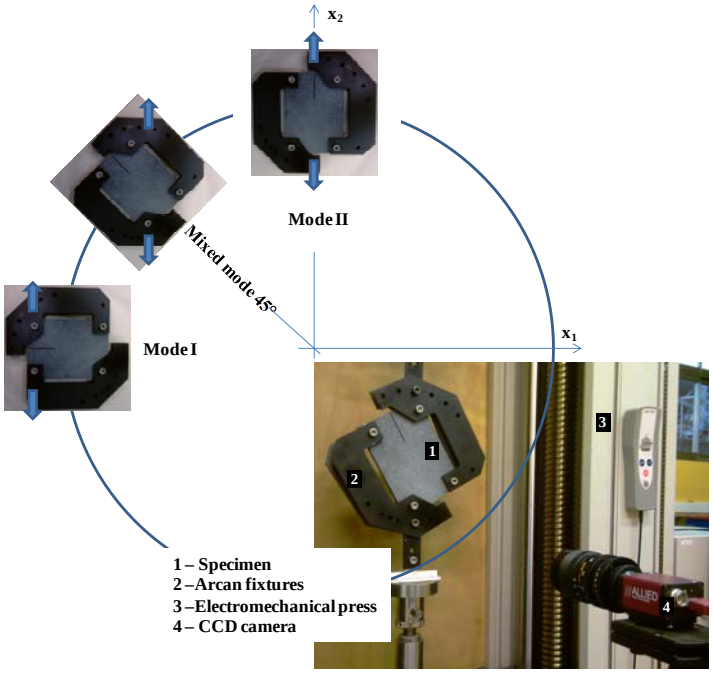

Figure 1. Experimental setup

Concerning measurement devices, the displacement field evolution is recorded on the specimen surface using an 8-bit CCD camera (1392 × 1040 pixel²). The image capture is performed at a rate of 1 frame per second and synchronized with the electromechanical press data (force and displacement). According to the DIC principle, a black-and-white speckled pattern is projected onto the specimen surface [10, 11]. The principle of this full-field method is based on a comparison between two images acquired during the test, one before deformation and the other after. The displacement field can then be obtained by comparing the reference image with the deformed image [10, 11]. The displacement fields, as presented in the present paper, are limited to 2D measurements. 3D effects are neglected (out-of-plane of crack lips or shear buckling induced by the specimen thickness), and plane stress state has been assumed.

2.1. Crack Relative Displacement Factor evaluation from experimental measurement

The experimental evaluation of CRDFs has been performed from the experimental measurements by DIC. The displacement data output by the DIC method are typically affected by experimental noise. It proves quite difficult to accurately analyze stress and strain fields from raw displacement data; moreover, real deformation fields of the crack tip and its location are difficult to obtain with precision from DIC [5-7, 11-14]. Consequently, the crack tip parameters predicted directly using raw experimental displacement data are inaccurate [5-7]. An adjustment procedure has thus been derived to avoid these difficulties.
Then, once the experimental displacement has been calculated, the adjustment procedure based on a nonlinear iterative Newton-Raphson is performed between the Williams' series forms (1) and the experimental data. By taking measurement boundary conditions (e.g. specimen geometry and symmetry, crack orientation) into account, this adjustment procedure is also able to consider a rigid body motion, crack tip localization and its orientation as unknowns. These parameters are then used to adjust the displacement fields.

$$\begin{aligned} u^1 &= \sum_{c=1}^{N} A_1^c \, r^{(c/2)} \, f_c(k,j) + A_2^c \, r^{(c/2)} \, g_c(k,j) + T_1 - R \cdot x_2 \\ u^2 &= \sum_{c=1}^{N} A_1^c \, r^{(c/2)} \, l_c(k,j) + A_2^c \, r^{(c/2)} \, z_c(k,j) + T_2 + R \cdot x_1 \end{aligned} \tag{1}$$

Where:

$$\begin{aligned} f_c &= k - \cos\left(\frac{c}{2}-1\right)j - \cos\left(\frac{c}{2}+1\right)j \\ g_c &= (-1)^c \sin\left(\frac{c}{2}-1\right)j - \sin\left(\frac{c}{2}+1\right)j \\ l_c &= k \sin\left(\frac{c}{2}-1\right)j - \sin\left(\frac{c}{2}+1\right)j \\ z_c &= k \cos\left(\frac{c}{2}-1\right)j + \cos\left(\frac{c}{2}+1\right)j \end{aligned} \tag{2}$$

The adjusted experimental field now allows defining a physical and local interpretation. The kinematic state of crack lips can in fact be identified using Crack Relative Displacement Factor $K_a^{(e)}$(CRDF) [5-9], which denote the relative opening and shear displacements of crack lips. Thanks to developments offered by Dubois, the kinematic state in the crack tip vicinity can be defined using Crack Relative Displacement Factors (CRDFs). At a very short distance x from the crack tip, the relative opening displacement $[u]_1$ and shear displacement $[u]_2$ are defined as follows (see Figure 2):

$$[u]_1 = K_2^{(e)} \sqrt{\frac{x}{2\pi}} \quad and \quad [u]_2 = K_1^{(e)} \sqrt{\frac{x}{2\pi}} \tag{3}$$

By combining Eqs. (1) with (3), we can now provide, in the crack tip vicinity, a mathematical interpretation of CRDF, such that:

$$K_1^{(e)} = 2\mu A_1^1 (k+1)\sqrt{2\pi} \quad and \quad K_2^{(e)} = 2\mu A_2^1 (k+1)\sqrt{2\pi} \tag{4}$$

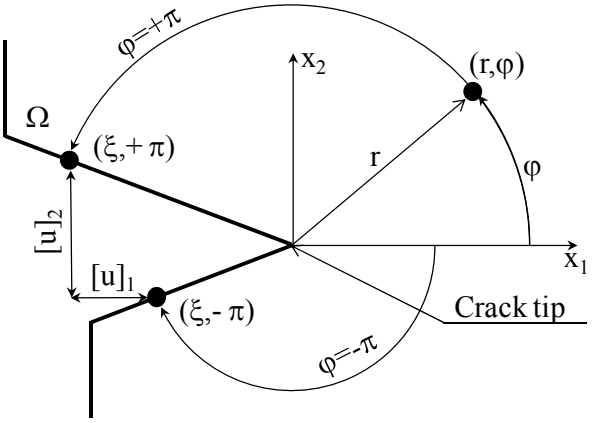

Figure 2. Relative displacements of crack lips

In Eqs. (1), (2), (3) and (4), (r, j) are the polar coordinates, k is the constant of Kolossov, A_a^c are the weighting coefficients relative to opening mode (α=1) and shear mode (α=2) and (T_1, T_2, R) are the rigid body motions.

From Eqs. (4), the CRDF can be determined without an explicit knowledge of the material elastic properties. Moreover, this initial step aims to accurately characterize the kinematic state of the crack.

2.2. Stress Intensity Factor evaluation from numerical analysis

In fracture mechanics, the stress state definition in the crack vicinity is expressed in terms of Stress Intensity Factor (SIF) $K_a^{(s)}$. As previously mentioned, the experimental test is conducted under displacement control, while the numerical model is loaded by imposing an equivalent force. In this case, SIF amplitude depends solely on model geometry, crack length and the force loading value. The definition of these factors implies developing a classical finite element model (Figure 3).

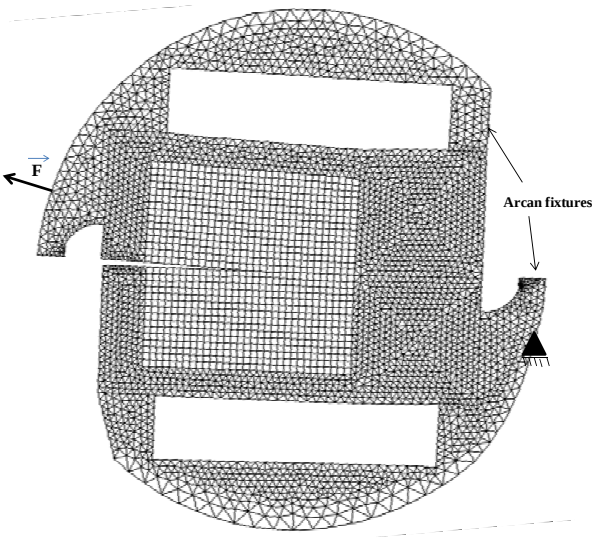

Figure 3. Finite element model

Note that the boundary conditions implemented in the finite element model have not integrated the experimental flaws, in terms of rigid body motion and crack tip orientation. Let's recall that these parameters have already been integrated into the optimized displacement fields obtained from the adjustment procedure described above. According to the finite element approach, we therefore place ourselves in an "ideal" test configuration.

In mixed-mode configurations, SIF calculations are often performed by implementing Mq method (Figure 4). The Mq-integral is an energy parameter established in order to analyze crack growth in a mixed-mode fracture by isolating various fracture modes, such as opening and shear, through a pseudo-potential that combines real displacements and kinematically admissible auxiliary displacements.

$$M\theta = \frac{1}{2} \cdot \int_V \left(\left(\sigma_{ij}\right)_{real} \cdot \left(u_{i,k}\right)_{aux} - \left(\sigma_{ij,k}\right)_{aux} \cdot \left(u_i\right)_{real} \right) \cdot \theta_{k,j} \cdot dV \tag{5}$$

The relationships between the stress tensor and the displacement vectors require introducing orthotropic elastic properties. By imposing an external force loading however, we can assume that SIF are not really influenced by elastic properties. Given these conditions, we have opted for an arbitrary elastic property rated '∼'.

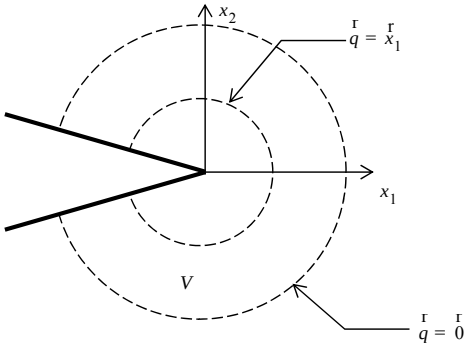

Figure 4. Integral domain

2.3. New formalism of energy release rate

The coupling between the kinematic and stress approaches allows calculating an energy release rate by the surrounding elastic proprieties. This coupling also serves to identify the actual reduced elastic compliance leading to the Young's modulus determination. Now, by replacing virtual displacements by real displacements, it has been shown that the Mq integral is mistaken for the energy release rate G [15]. More precisely, thanks to the superposition principle, in letting ${}^{real}K_a^{(s)}$ and ${}^{aux}K_a^{(s)}$ be the real and virtual Stress Intensity Factor, respectively, we can adopt the following expression:

$$Mq\left(\vec{u},\vec{v}\right) = \sum_a C_a \frac{{}^{real}K_a^s \times {}^{aux}K_a^s}{8} \tag{6}$$

where C_a is the reduced elastic compliance that allows defining local behavior in terms of Stress

Intensity Factor and Crack Relative Displacement Factor, such that:

$$K_{\alpha}^{\varepsilon} = C_{\alpha} \cdot {}^{real}K_{\alpha}^{\sigma} \tag{7}$$

Equation (6) yields a physical interpretation for Mq in the Stress Intensity Factor definition, i.e.:

$${}^{u}K_1^{(s)} = \frac{8?Mq\begin{cases}{}^{u}K_1^{(s)} & 1,\ {}^{v}K_2^{(s)} = 0\\ 0, & {}^{v}K_2^{(s)} = 1\end{cases}}{C_1} \text{ and } {}^{u}K_2^{(s)} = \frac{8?Mq\begin{cases}{}^{u}K_1^{(s)} & 0,\ {}^{v}K_2^{(s)} = 1\\ 0, & {}^{v}K_2^{(s)} = 1\end{cases}}{C_2} \tag{8}$$

For orthotropic media, these arbitrary reduced elastic compliance functions are defined by the following equations:

$$\overset{\circ}{C}_1 = \sqrt{\frac{\overset{\%}{a}_{11}\overset{\%}{a}_{22}}{2}}?\sqrt{\sqrt{\frac{\overset{\%}{a}_{22}}{\overset{\%}{a}_{11}}}\frac{2\overset{\%}{a}_{12}+\overset{\%}{a}_{33}}{2\overset{\%}{a}_{11}}} \text{ and } \overset{\circ}{C}_2 \quad \sqrt{\frac{\overset{\%}{a}_{11}\overset{\%}{a}_{11}}{2}}\sqrt{\sqrt{\frac{\overset{\%}{a}_{22}}{\overset{\%}{a}_{11}}}\frac{2\overset{\%}{a}_{12}+\overset{\%}{a}_{33}}{2\overset{\%}{a}_{11}}} \tag{9}$$

Where:

$$\overset{\%}{a}_{11} = \frac{1}{\overset{\circ}{E}_L};\ \overset{\%}{a}_{12} = -\frac{\overset{\%}{n}_{RL}}{\overset{\circ}{E}_R} = -\frac{\overset{\%}{n}_{LR}}{\overset{\circ}{E}_L};\ \overset{\%}{a}_{22} = \frac{1}{\overset{\circ}{E}_R};\ \overset{\%}{a}_{33} = \frac{1}{\overset{\circ}{G}_{LR}} \text{ in plane stress} \tag{10}$$

$$\overset{\%}{a}_{11} = \frac{1-\overset{\%}{n}_{LT}?\overset{\%}{n}_{TL}}{\overset{\circ}{E}_L};\ a_{12} = -\frac{\overset{\%}{n}_{RL}\quad\overset{\%}{n}_{RL}?\overset{\%}{n}_{TL}}{\overset{\circ}{E}_R};\ a_{22} = \frac{1\quad\overset{\%}{n}_{RT}\ \overset{\%}{n}_{TR}}{\overset{\circ}{E}_R};\ \overset{\%}{a}_{33} = \frac{1}{\overset{\circ}{G}_{LR}} \text{ in plane strain} \tag{11}$$

In which $\overset{\circ}{E}$ and $\overset{\%}{n}$ are the arbitrary elastic orthotropic properties of material.

In the case of isotropic material the arbitrary reduced elastic compliance functions are defined by:

$$\overset{\circ}{C}_a = \frac{\overset{\%}{k}+1}{\overset{\circ}{m}} \tag{12}$$

Where m is the Lamé coefficient given by :

$$\overset{\circ}{m} = \frac{\overset{\circ}{E}}{2?\left(1\quad\overset{\%}{n}\right)} \tag{13}$$

And:

$$\begin{aligned} k &= 3-4\,n \text{ in plane strain} \\ k &= \frac{3-n}{1+n} \text{ in plane stress} \end{aligned} \tag{14}$$

Now, in assuming a plane stress state, by substituting Equation (7) into the classical energy release rate expression, we obtain a new formalism:

$$G_a = \frac{{}^{real}K_a^{(s)} \times K_a^{(e)}}{8} \qquad a = 1;2 \tag{15}$$

In Eq. (15) G_{α} represents the portion of opening and shear modes in terms of energy release rate.

Next, using the numerical values of CRDFs and SIFs calculated above, the energy release rate can be estimated from Equation (15) independently of the material's elastic proprieties.

3. Results

In the case of rigid Polyvinyl Chloride polymer and Douglas fir the Figure 5 highlights a comparison between the experimental and analytical deformations after adjustment procedure.

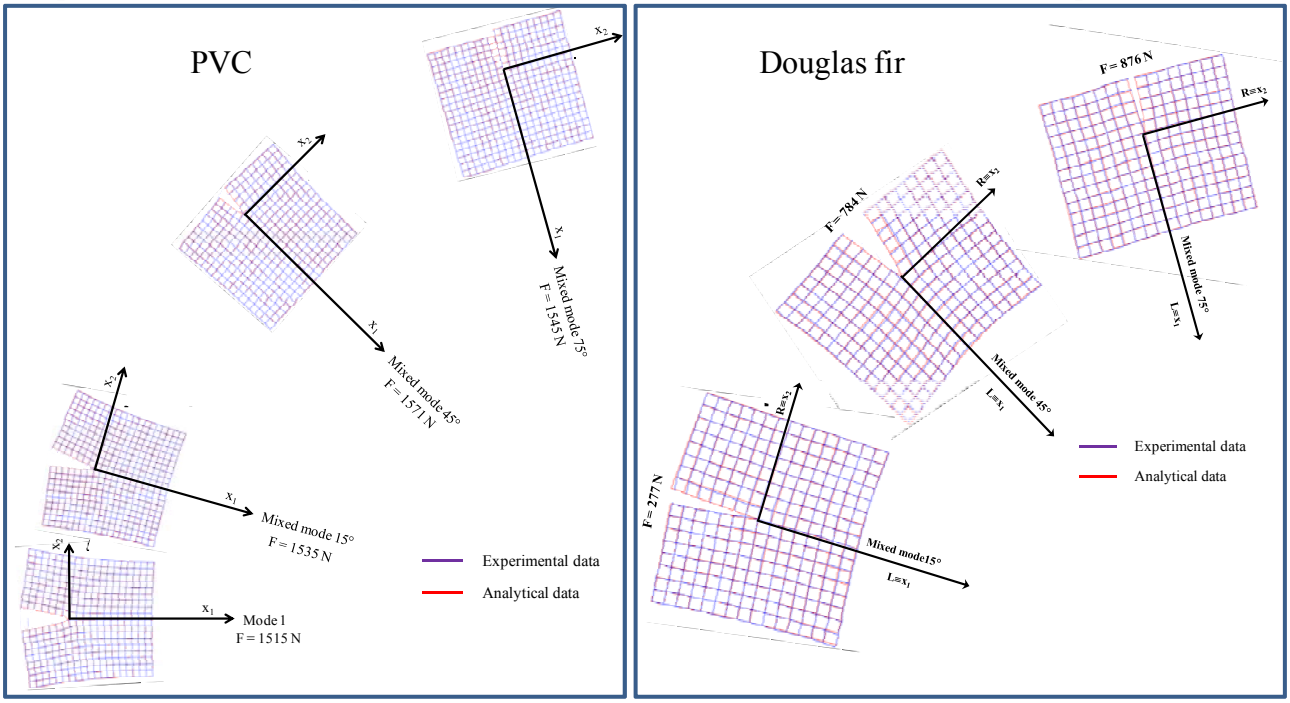

Figure 5. Results of the adjustment procedure

As is shown in Figure 5, the adjustment procedure allows obtaining an optimized displacement fields without experimental noises. Moreover, the adjustment procedure allows estimating the rigid body motion and the crack tip orientation. These parameters are essential to adjust the experimental conditions in order to obtain the specific mixed mode boundary conditions definite by the analytical expressions of displacement fields corresponding to mixed mode loading. Note that the representation of displacements fields shown in Figure 5 take into account these parameters.

According to Equations (4), the $K_a^{(e)}$ values are calculated from optimized displacement fields using the values of A_1^1, A_2^1 and k values. Then the Stress Intensity Factor can be evaluated from a FE analysis via the integral invariant Mq.

According to Equation (15), the energy release rate can be predicted by combining a kinematic approach (given by experimental testing) with a static approach (using numerical modeling) through determining CRDF and real SIF, respectively. The results of these energy release rate predictions are provided in Table 1 for isotropic case and Table 2 for orthotropic case. Not only does this method allow deducing the energy release rate, but moreover the use of the Mq-integral allows separating this energy for each part of both the opening and shear modes.

Table 1: Isotropic case

b	Force (N)	$K_1^{(\varepsilon)}$ ($m^{1/2}$)	$K_2^{(\varepsilon)}$ ($m^{1/2}$)	$K_1^{(\sigma)}$ ($MPa \cdot m^{1/2}$)	$K_2^{(\sigma)}$ ($MPa \cdot m^{1/2}$)	G_1 (J/m²)	G_2 (J/m²)

4. Conclusion

This work has presented an original coupling between Digital Image Correlation and Finite Element Analysis, making it possible to characterize both the mechanical and energy states in the crack tip vicinity.

Based on Dubois' developments, the kinematic state in the crack tip vicinity is evaluated using the Crack Relative Displacement Factors calculated from experimental measurements output by DIC. In parallel with this step, the stress distribution is evaluated by a finite element analysis according to the Mq method. The coupling of these two approaches allows distinguishing and calculating the energy release rates corresponding to opening and shear modes. The originality of this coupling procedure lies in the possibility of calculating the energy release rate independently of material elastic properties. Furthermore, our formalism allows evaluating local elastic properties via the elastic compliance correlated with Crack Relative Displacement Factors and Stress Intensity Factors.

In terms of follow-up work, crack initiation and propagation can be studied in greater depth thanks to this new technique, thus leading to a better understanding of all phenomena governing the crack tip growth process.

Abstract In reality cracks often initiate and grow due to mixed mode loading. This paper deals with questions about stable and unstable crack growth and the crack growth direction under multi-axial loading conditions. For homogeneous materials many criteria and experimental confirmations exist. This paper shows a selection of these solutions and some experimental investigations. In practice innovative manufacturing and application-oriented products considering lightweight construction gain increasingly in importance. In this context structures with graded material properties are produced. However there does not exist many concepts for these graded materials. Within this paper fracture and fatigue criteria and experimental findings are presented. In particular the $TSSR^B$-concept is used for the determination of crack growth in fracture mechanical graded materials.

Keywords Mixed Mode, fracture criteria, isotropic materials, graded materials, TSSR-concept

1. Introduction

If the two basic fracture modes (Mode I and Mode II) temporarily or permanently occur in combination, as indicated in Fig. 1, local plane Mixed Mode loading conditions at cracks can be observed.

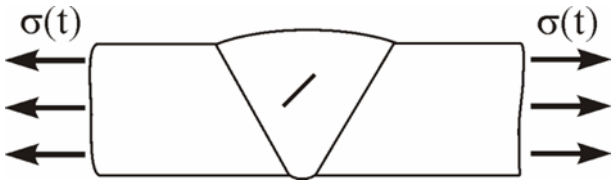

Figure 1. Mixed Mode loaded crack in a welded structure

For a fail-safe dimensioning it is important to know among other things if such a crack is able to grow, how fast and whereto does the crack grow and when unstable crack growth occurs. Answers can be found using crack propagation concepts which will be briefly described in the following chapter. An extensive description can be found in [1, 2].

2. Crack growth in isotropic and homogeneous materials

An isotropic and homogeneous structure is defined by fracture mechanical and elastic material properties which are independent of place and direction, i.e. they are the same for the whole structure. With regard to the subsequent consideration of fracture criteria for graded materials and their complexity only 2D-concepts will be regarded within this paper.

2.1. Concepts for two-dimensional Mixed Mode crack growth

In the following two theoretical concepts are presented which enable the determination of unstable crack growth. Information about further crack propagation concepts for 2D and 3D Mixed Mode situations can be found in [1-5].

2.1.1. Concept according to Erdogan and Sih

The concept of the maximum tangential stress (MTS) by Erdogan and Sih [4, 5] enables the determination of the crack growth direction as well as the start of unstable crack propagation on the basis of the tangential stress σ_φ, presented in Eq. (1).

$$\sigma_\varphi = \frac{K_I}{\sqrt{2\pi r}}\cos^3\frac{\varphi}{2} - \frac{K_{II}}{\sqrt{2\pi r}}\frac{3}{2}\sin\varphi\cdot\cos\frac{\varphi}{2} \tag{1}$$

The concept assumes that the crack propagates in the direction $\varphi_{0,MTS}$ which is perpendicular to the maximum tangential stress $\sigma_{\varphi max}$. Eq. (2) defines the kinking angle $\varphi_{0,MTS}$ according to the MTS-concept which depends on the loading condition.

$$\varphi_{0,MTS} = -\arccos\left(\frac{3K_{II}^2 + K_I\sqrt{K_I^2+8K_{II}^2}}{K_I^2+9K_{II}^2}\right) = -\arccos\left[\frac{3\left(\frac{K_{II}}{K_I}\right)^2 + \sqrt{1+8\left(\frac{K_{II}}{K_I}\right)^2}}{1+9\left(\frac{K_{II}}{K_I}\right)^2}\right] \tag{2}$$

The crack grows unstable if $\sigma_{\varphi max}$ reaches a material limit value $\sigma_{\varphi c}$ or if a maximum comparative stress intensity factor K_{Vmax} (Eq. 3), determined by the tangential stress σ_φ (Eq. 1), reaches the fracture toughness K_{IC}.

$$K_{Vmax} = \lim_{r\to 0}\left(\sigma_{\varphi max}\sqrt{2\pi r}\right) = \lim_{r\to 0}\left(\sigma_\varphi(\varphi_0)\sqrt{2\pi r}\right) = \cos\frac{\varphi}{2}\left(K_I\cos^2\frac{\varphi_0}{2} - \frac{3}{2}K_{II}\sin\varphi_0\right) \tag{3}$$

Eq. (4) shows the criterion for unstable crack growth.

$$K_{Vmax} = K_{IC} \tag{4}$$

Due to cyclic loading the tangential stress σ_φ (Eq. 1) is transformed to the cyclic tangential stress $\Delta\sigma_\varphi$ (Eq. 5) with the cyclic stress intensity factors ΔK_I and ΔK_{II}.

$$\Delta\sigma_\varphi = \frac{\Delta K_I}{\sqrt{2\pi r}}\cos^3\frac{\varphi}{2} - \frac{\Delta K_{II}}{\sqrt{2\pi r}}\frac{3}{2}\sin\varphi\cdot\cos\frac{\varphi}{2} \tag{5}$$

Fatigue crack growth starts if the cyclic comparative stress intensity factor $\Delta K_{Vmax}=\Delta\sigma_\varphi\sqrt{2\pi r}$ reaches the Threshold value ΔK_{th}. In case of cyclic loading unstable crack growth occurs if $K_{Vmax} = K_{IC}$ (Eq. 4) or if $\Delta K_{Vmax} = \Delta K_{IC} = K_{IC}\cdot(1-R)$, with the stress ratio $R = \sigma_{min}/\sigma_{max} = K_{min}/K_{max}$.

2.1.2. Concept according to Richard

The general fracture concept of Richard [1, 5, 6] is very practical and adaptive and can be used for different materials. The concept is based on a comparative stress intensity factor K_V. This value depends on the stress intensity factors K_I and K_{II} (Eq. 6).

$$K_V = \frac{1}{2}K_I + \frac{1}{2}\sqrt{K_I^2 + 4(\alpha_1 K_{II})^2} \tag{6}$$

The material parameter α_1 depends on the ratio of the fracture toughness of Mode I K_{IC} and the fracture toughness of Mode II K_{IIC}. If α_1 is set to 1.155 an excellent approximation of the fracture limit curve of the maximum tangential stress criterion is obtained. Unstable crack growth occurs as soon as K_V exceeds the fracture toughness K_{IC} for Mode I.

Furthermore the concept also enables the determination of the kinking angle φ_0 (Eq. 7), with

$\varphi_0<0$ for $K_{II}>0$, $\varphi_0>0$ for $K_{II}<0$ and K_I always larger than 0.

$$\varphi_0 = \mu\left[A\frac{|K_{II}|}{|K_I|+|K_{II}|} + B\left(\frac{|K_{II}|}{|K_I|+|K_{II}|}\right)^2 \right] \tag{7}$$

In this empirical formula the parameters have to be set to: A = 155,5° and B = -83,4°.

2.2. Comparison of the theoretical concepts and experimental findings

Experimental determined kinking angles φ_0 for different almost isotropic materials (for example PMMA, Araldit B, PVC, AlZnMgCu) are shown in Fig. 2. The kinking angle doesn't depend on the material. However the K_{II}/K_I-ratio is important. Furthermore the kinking angles determined by different fracture criteria (for example Erdogan and Sih, Richard) are presented in dependency of the Mixed Mode ratio $K_{II}/(K_I+K_{II})$. It can be seen that these crack propagation criteria are able to predict the crack kinking angle for isotropic and nearly isotropic material sufficiently exact [7]. For more information about experimental investigations see [5, 8].

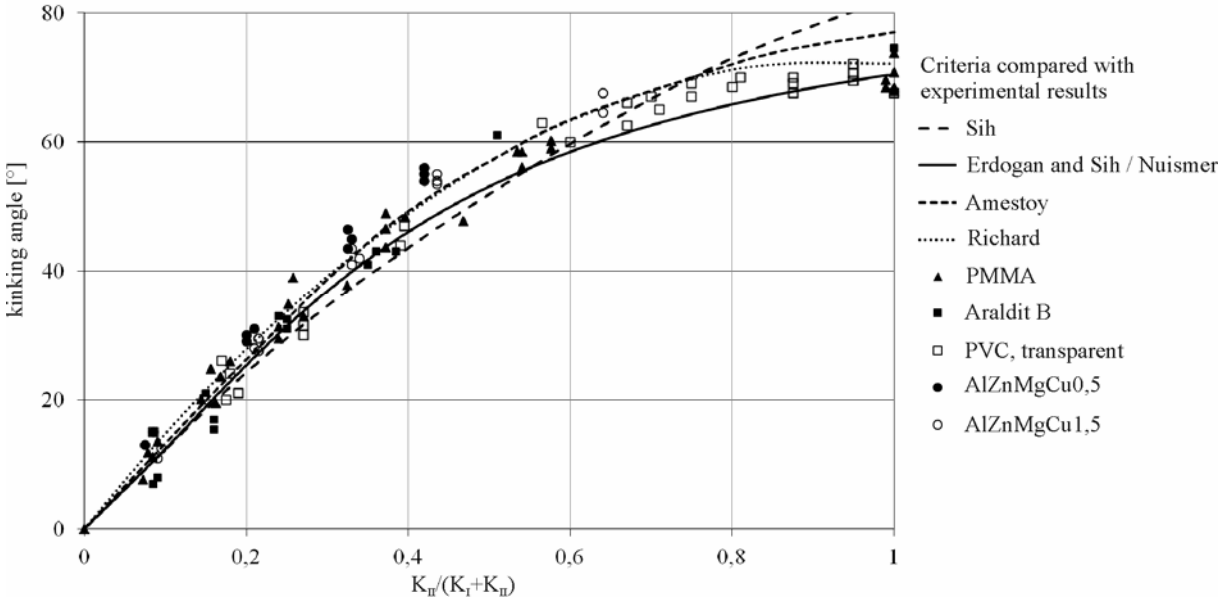

Figure 2. Kinking angle from criteria for 2D Mixed Mode cracks in comparison to experimental data

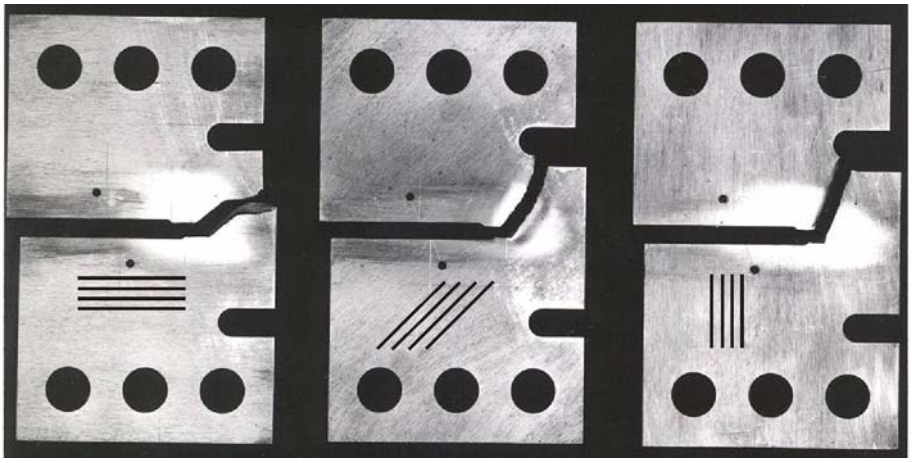
Fig. 3 shows aluminum alloy specimens which vary in their rolling direction. The specimen in Fig. 3a was rolled in crack direction, in Fig. 3b diagonal and in Fig. 3c perpendicular to the crack direction. After the production and rolling process these specimens were investigated experimentally. The resulting kinking angles φ_0 of these anisotropic structures are presented in Fig. 4. The results show that the crack propagation concepts are not able to predict the kinking angles of the rolled aluminum alloy specimens very well. The concepts are not able to consider the predominant direction due to the rolling process.



a) b) c)

Figure 3. Aluminum alloy specimens with special rolling direction: a) in crack direction, b) diagonal, c) perpendicular to the crack direction

These results lead to the knowledge that the presented concepts are able to predict the crack growth behavior very well as long as the structure is a homogeneous and isotropic one. For the description of materials with a graded property, for example in form of the shown predominant direction, other concepts have to be used considering the influence of the material gradation. Therefore hypotheses describing Mixed Mode crack growth in graded materials are presented in the following contribution.

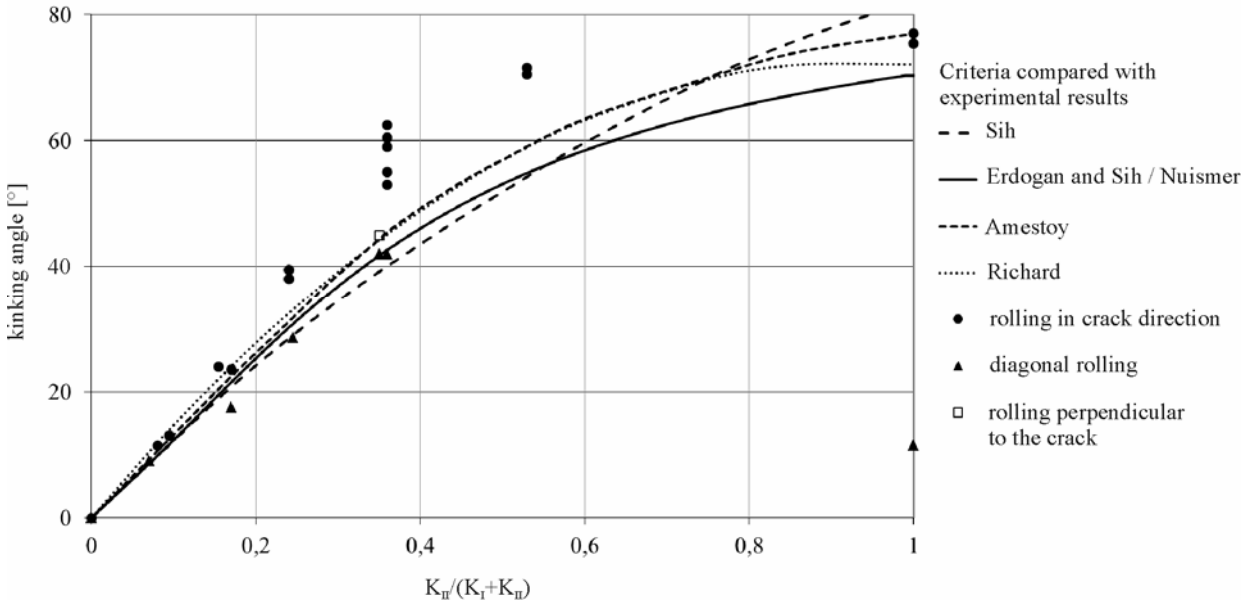


Figure 4. Kinking angle from criteria in comparison to experimental data of a rolled aluminium alloy specimens for 2D Mixed Mode cracks

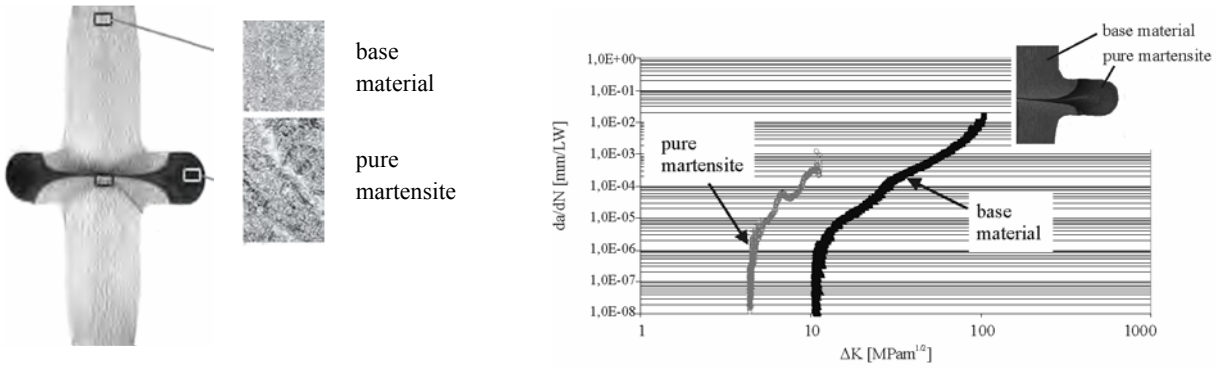
3. Crack growth in functional graded materials

In technical practice innovative manufacturing and application-oriented products, considering lightweight construction, gain increasingly in importance. In this context functional graded materials and structures take a special position. Due to the fact that these materials possess an application matched functional gradation they are able to meet different local demands such as

among other things absorbability, abrasion and fatigue of structures. The material gradation has a remarkable influence on the crack propagation behavior which is why the development of appropriate concepts is important. The material gradation can be realized by different properties. On the one hand the gradation can be defined by different fracture mechanical properties, on the other side by differences in the elastic parameters. Furthermore a combination of the fracture mechanical gradation and the elastic gradation is imaginable. The following considerations deal with a fracture mechanical gradation.

3.1. Influence of a fracture mechanical material gradation on crack propagation

A fracture mechanical material gradation exists for example within the flanged shaft, Fig. 5a, which is used as a demonstrator object by the collaborative research centre Transregio 30 with the title "functionally graded materials in industrial mass production". Besides the development and manufacturing of these innovative materials another important task is the characterization of the mechanical properties of these materials regarding the remarkable influence of the gradation on the fracture mechanical behavior and hence on the life time of such a graded structure [9]. Due to a thermo-mechanical production process the unformed region of the shaft shows ferritic-perlitic base material of the heat treatable steel 51CrV4, whereas the formed flange consists of a martensitic structure. Fig. 5b clarifies that the fracture mechanical properties of these microstructures (i.a. Threshold value $\Delta K_{th,}$ fracture toughness K_{IC}, crack velocity da/dN) differ extremely from each other. The elastic properties (Young's modulus E, Poisson's ratio ν) are not affected by the production process. Furthermore there is a defined distinctive transition zone between the mentioned microstructures which is neglected in this contribution.



a) b)

Figure 5. a) Metallographic micrograph of the flanged shaft [9], b) crack velocity curves for the steal 51CrV4 with different microstructures [10]

3.1.2. Influence on the limits of fatigue crack growth

Fig. 6 shows the correlation between cyclic stress $\Delta\sigma$ and crack length a in dependency of a fracture mechanical gradation for a Griffith crack (geometry factor Y = 1) [10, 11]. Below the Threshold value curves a crack is not able to grow, whereas the unstable crack growth is above the fracture limit curves. The region of stable fatigue crack growth is between both material curves.

The crack starts in base material and reaches the martensitic microstructure at the crack length a = 6mm. It can be seen that the region of stable fatigue crack growth is more distinctive for the base material than for martensite. Furthermore there is no real overlapping at the transition, hence the

crack becomes unstable immediately after reaching the martensitic structure.

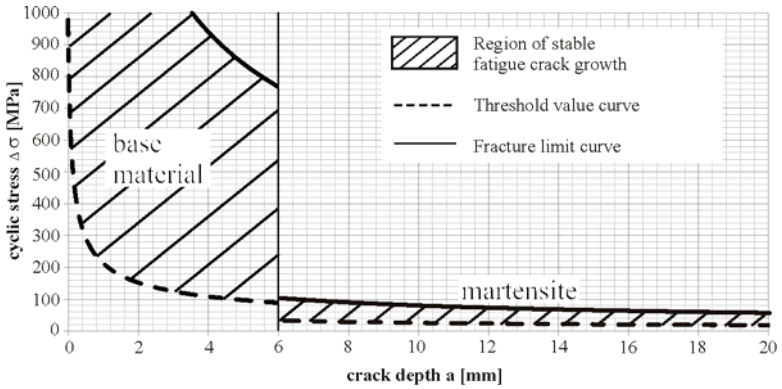


Figure 6. Δσ-a-diagram for a fracture mechanical gradation with a sharp transition at crack length a = 6mm

3.1.3. Influence on the crack growth velocity

Fig. 7a shows schematic crack velocity curves for two materials characterized by different fracture mechanical properties [10, 11]. At the beginning crack growth is starting within material 2. At reaching the other material a change to the crack velocity curve of material 1 occurs. Hence, the crack grows faster and reaches the fracture toughness much earlier as if it grows further within material 2. The worst imaginable case is that at the change to curve 1 the cyclic stress intensity factor ΔK is already larger than the cyclic fracture toughness ΔK_{C1} of material 1 leading to the immediate failure of the structure. In Fig. 7b the gradation is oriented opposite. The crack starts in the material with the worse fracture mechanical properties, material 1, and reaches material 2 afterwards. Due to the change the crack velocity slows down and more load cycles are tolerated until final fracture. At the best crack arrest occurs if the cyclic stress intensity factor ΔK is smaller than the Threshold value ΔK_{th2} of material 2 at the material change. As can be seen, a positive or a negative impact on the prospective lifetime is connected with the gradation constellation.

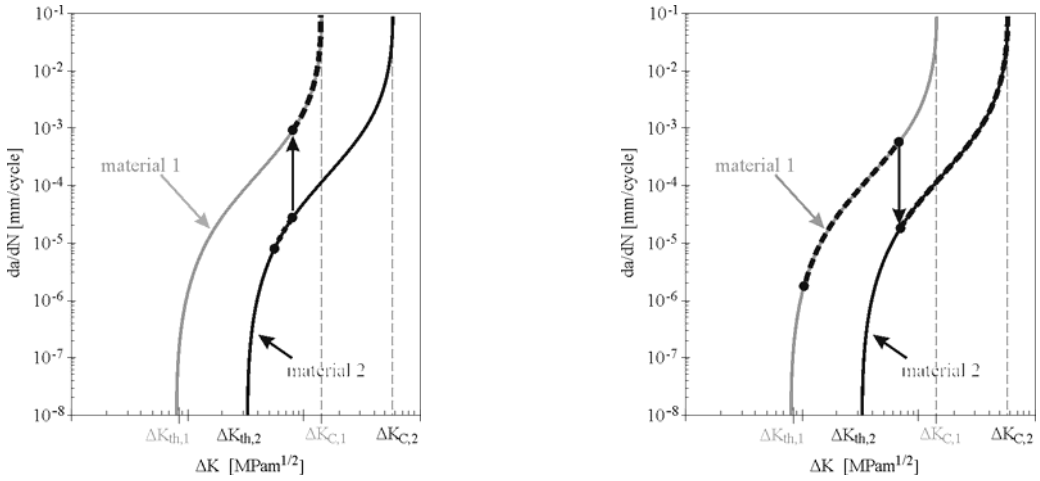

Figure 7. Schematic crack velocity curves:
a) transition from material 2 to material 1, b) transition from material 1 to material 2

3.2. TSSR^B-concept for the prediction of crack propagation in fracture mechanical graded materials

The new developed TSSR^B-concept enables the prediction of the start and the direction of the crack propagation as well as the determination of unstable crack growth in fracture mechanical graded materials [10, 11, 12]. Fig. 8 shows a crack-afflicted structure which is loaded periodically resulting in a pure Mode I loading solution. Furthermore the structure consists of two materials whose fracture mechanical properties differ from each other. The presented gradation angle $\varphi_M = 30°$ defines the position of the material transition in relation to the crack tip. The crack could kink by the kinking angle $\varphi_{0,MTS}$ which depends on the stress situation and can be determined by a crack propagation concept for homogeneous and isotropic materials (for example the MTS-concept of Erdogan and Sih). Another imaginable kinking angle is the gradation angle φ_M itself, due to the fact that the crack strives to take the way of least resistance.

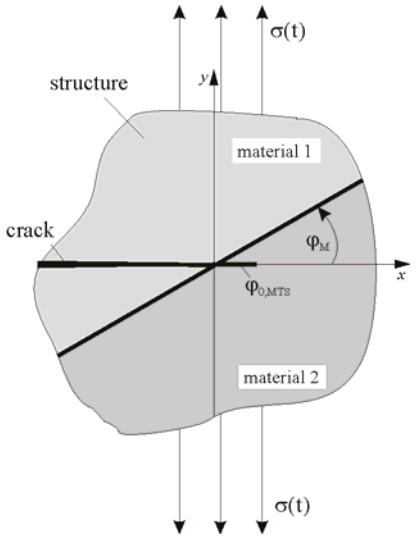

Figure 8. Fracture mechanical graded structure with gradation angle $\varphi_M = 30°$

The occurrence of fatigue crack growth as well as the entrant kinking angle φ_{TSSRB} can be determined by the TSSR^B-concept. This concept is based on the assumption that stable crack growth starts, when the cyclic tangential stress $\Delta\sigma_\varphi$ (Eq. 5) reaches a material limit value $\Delta\sigma_{\varphi,th}$ or rather when a cyclic comparative stress intensity factor ΔK_V, determined by the means of the cyclic tangential stress $\Delta\sigma_\varphi$, reaches the Threshold value curve $\Delta K_{th}(\varphi)$. This material function depends on the coordinate φ and consists of the values $\Delta K_{th,material1}$ and $\Delta K_{th,material2}$ for the different regions, see Eq. (8). Similarly the material functions $\Delta K_C(\varphi)$ and $K_C(\varphi)$ can be defined in dependency of the gradation angle φ_M.

$$\Delta K_{th}(\varphi) \begin{cases} \Delta K_{th,material1} & \varphi_M \le \varphi \le \varphi_M + 180° \\ \text{for} & \\ \Delta K_{th,material2} & \varphi_M - 180° < \varphi < \varphi_M \end{cases} \tag{8}$$

The determination of the start and the direction of fatigue crack growth is shown in Fig. 9a. The first intersection of the stress function $\Delta\sigma_\varphi\sqrt{2\pi r}$ with the material function $\Delta K_{th}(\varphi)$ (Eq. 8) identifies the occurrence and the corresponding direction of crack growth, whereas the intersection of the stress function $\Delta\sigma_\varphi\sqrt{2\pi r}$ with the material function $\Delta K_C(\varphi)$ defines the occurrence of final failure of

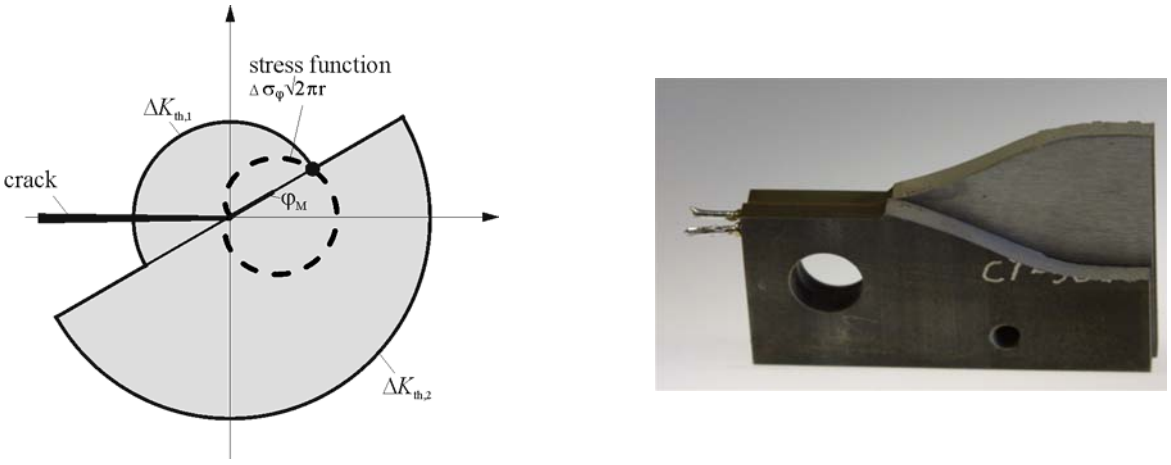
the structure. For static loading the occurrence of unstable crack growth can be predicted using the material function $K_C(\varphi)$.
At first it is assumed that the crack is not able to grow resulting in a stress function without point of contact with the material function $\Delta K_{th}(\varphi)$. Subsequently the cyclic load will be increased until the corresponding stress function has a contact with the material function. At this point the crack is able to grow. Furthermore the point of contact defines the kinking angle φ_{TSSRB} due to the loading situation and the material gradation.

3.2.1 Mode I loading in a graded material

As a special case of a Mixed Mode loading at first a pure Mode I situation is considered. In Fig. 9a a single Mode I ($\Delta K_{II} = 0$) is considered leading to the reduced stress function $\Delta\sigma_\varphi\sqrt{(2\pi r)}$, see Eq. (9), derived from Eq. (5).

$$\Delta\sigma_\varphi\sqrt{2\pi r} = \Delta K_I \cos^3\frac{\varphi}{2} \tag{9}$$

The point of contact can be found at the polar coordinate $\varphi_M = 30°$ resulting in the kinking angle $\varphi_{TSSRB} = \varphi_M = 30°$. First experimental investigations considering the same loading condition and the same gradation angle φ_M confirm this theoretical concept (Fig. 9b). In spite of pure Mode I the crack kinks due to the material gradation. For the further crack propagation the kinked crack evokes a Mixed Mode loading situation.



a) b)

Figure 9. a) Point of contact for the determination of occurrence and direction of fatigue crack growth for a Mode I loaded crack, b) experimental confirmation of the TSSR^B-concept

3.2.2 Mixed Mode loading in a graded material

The TSSR^B-concept can also be used for a Mixed Mode loading situation. Thereby the Mixed Mode ratio V, see Eq. (10), defines the combination of the pure loading cases Mode I and Mode II. Fig. 10 shows the stress functions $\Delta\sigma_\varphi\sqrt{(2\pi r)}$ (Eq. 11) for a Mixed Mode ratio V = 0,23, see also Eq. (5).

$$V = \frac{K_{II}}{K_I + K_{II}}. \tag{10}$$

$$\Delta\sigma_{\varphi}\sqrt{2\pi r} = \Delta K_{I}\cos^{3}\frac{\varphi}{2} - \Delta K_{II}\frac{3}{2}\sin\varphi\cdot\cos\frac{\varphi}{2}. \tag{11}$$

The structure in Fig. 10a and Fig. 10b possess different gradation angles φ_M. This difference in the gradation angle φ_M leads to a different kinking angle φ_{TSSRB} due to the loading condition and the material gradation. In Fig. 10a the gradation angle φ_M is 30°. The point of contact is at this coordinate leading to the kinking angle $\varphi_{TSSRB} = \varphi_M = 30°$. In Fig. 10b the structure possesses the gradation angle $\varphi_M = 60°$. Here the point of contact can be found at the coordinate with the largest stress. Hence the kinking angle $\varphi_{0,MTS} = -30°$ due to the loading condition, according to the MTS-concept of Erdogan and Sih, defines the kinking angle φ_{TSSRB} in this case.

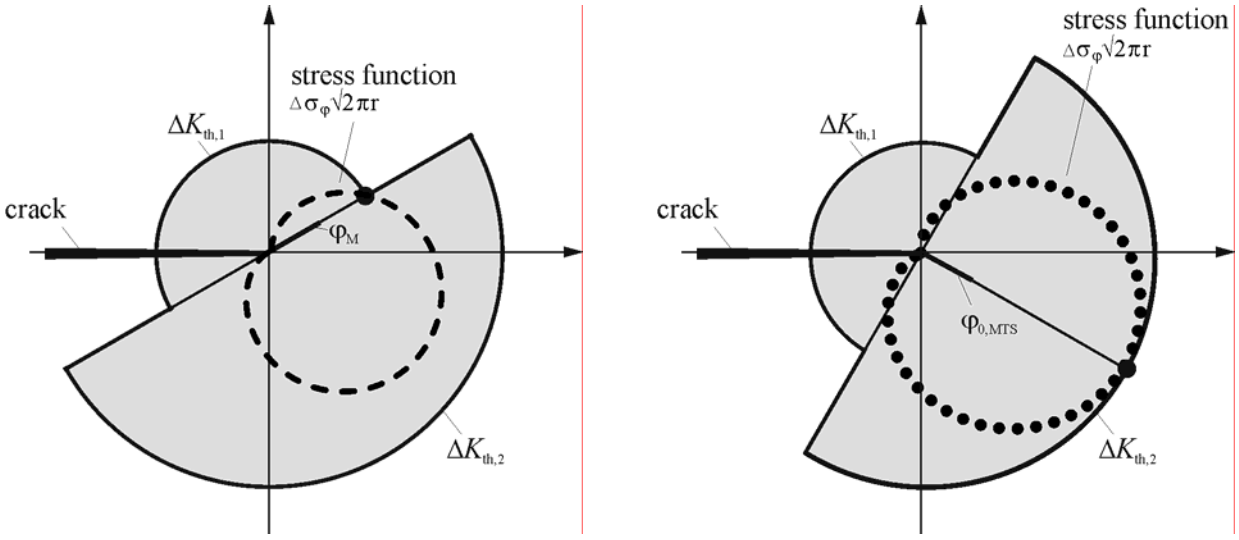


Figure 10. Occurrence and direction of fatigue crack growth for Mixed Mode loading in a fracture mechanical graded material: a) gradation angle $\varphi_M = 30°$, b) gradation angle $\varphi_M = 60°$.

In graded materials the crack propagation direction depends on the Mixed Mode loading situation and the material gradation. Which crack growth occurs can be determined with the TSSR^B-concept. Furthermore the concept enables the determination of the starting of fatigue crack growth and of unstable crack growth.

4. Conclusion

Using the presented TSSR^B-concept crack propagation as well as the direction of crack growth can be determined in fracture mechanical graded materials. By comparing the stress function $\Delta\sigma_{\varphi}\sqrt{2\pi}r$ with the material functions $\Delta K_{th}(\varphi)$, $\Delta K_C(\varphi)$ and $K_C(\varphi)$ the occurrence, the direction as well as the start of unstable fatigue crack growth and the start of unstable failure due to static loading can be determined. Furthermore this concept can also be modified for the application for an elastic material gradation as well as for the combination of a fracture mechanical and elastic material gradation.

A CMOD-Based Hybrid Approach to Determine Fracture Resistance Curve

Wuchao Yang[1], Xudong Qian[1,*]

Abstract This study proposes a hybrid approach that relies both on the numerically computed and on the experimentally measured load (P) versus the crack-mouth opening displacement (CMOD) relationships to derive the fracture resistance curve (J-R curve) for the mixed-mode I and II fracture specimen. The CMOD-based hybrid approach utilizes a single experimental specimen with a growing crack and multiple finite element (FE) models, each with a different crack depth. The experimental procedure measures the P-CMOD curve from a standard fracture specimen with a growing crack. The intersections between the experimental P-CMOD curve and the numerical P-CMOD curves from multiple FE models dictate the CMOD levels to compute the strain energy (U). This approach simplifies the J-R curve test for the single-edge-notched bend, SE(B), specimen by eliminating the multiple unloading and reloading procedures in determining the variation of the compliance during the test. This method also provides an alternative simple measurement of the J-R curves for mixed-mode I and II specimens. The validation procedure shows accurate predictions of the J-R curves for both SE(B) specimens and mixed-mode I and II specimens.

Keywords mixed-mode fracture, fracture resistance, J-R curve, hybrid approach.

1. Introduction

The traditional load-line displacement (LLD) based incremental method has become widely implemented as a convenient experimental method to determine the fracture resistance curve, namely the J-R curve, for the SE(B) specimen, as recommended by the testing standards [1, 2]. The measurement of the specimen compliance at the each unloading and reloading procedure leads to a direct evaluation of the crack extension (Δa). The area under the load versus the LLD curve corresponding to different crack lengths allows the calculation of the energy release rate, J-value [3]. However, the measurement of the LLD for the SE(B) specimen requires extreme effort to prevent the potential errors introduced by the indentation at the loading point and the deformation of the testing frame [4]. In addition, the fracture toughness tests for the mixed-mode I and II specimens face critical challenges such as the calculation of the J-value and the determination of Δa [5]. The evaluation of the bending strain energy, which contributes to the J-value, depends on the current crack size (a_i) which cannot be determined via the traditional compliance approach for mixed-mode I and II specimens due to the unknown crack path prior to the test. Therefore, the experimental determination of the fracture resistance curve for both pure mode I SE(B) specimen and the mixed-mode I and II specimen requires a simplified and accurate approach based on the readily measurable quantities from the tests.

This study proposes a hybrid, numerical and experimental approach to determine the fracture resistance curve based on the readily measureable load versus CMOD (or Δ) relationship for SE(B) specimen (CMOD-hybrid approach). This research also extends the same approach to determine the fracture resistance for the mixed-mode I and II specimens. The J-value is derived from the variation in the total strain energy (including the bending and shear strain energy) with respect to the change in the crack depth, using the P-Δ curve measured from a single experimental specimen and P-Δ curves computed from multiple FE models with different crack sizes. The comparison of the fracture resistance curve obtained using the CMOD-hybrid approach with those obtained from the experimental results for both the SE(B) specimens and mixed-mode I and II specimens confirms the accuracy of the proposed CMOD-hybrid approach.

2. The CMOD-Based Hybrid Approach

The fundamental principle underlying the hybrid numerical and experimental approach remains similar to that of the conventional, multiple-specimen experimental approach proposed by Begley and Landes [6]. The procedure in the CMOD-hybrid approach follows similarly the hybrid approach, which relies on the *P*-LLD relations, proposed by the authors [7, 8], as illustrated in Figure 1. The numerical analyses of the hybrid approach generate a series of *P*-Δ curves from large-deformation, elastic-plastic analyses of multiple FE specimens with the same geometry, dimension and material, but different crack sizes. The experimental part of the hybrid approach produces the *P*-Δ curve for a fracture specimen with a growing crack.

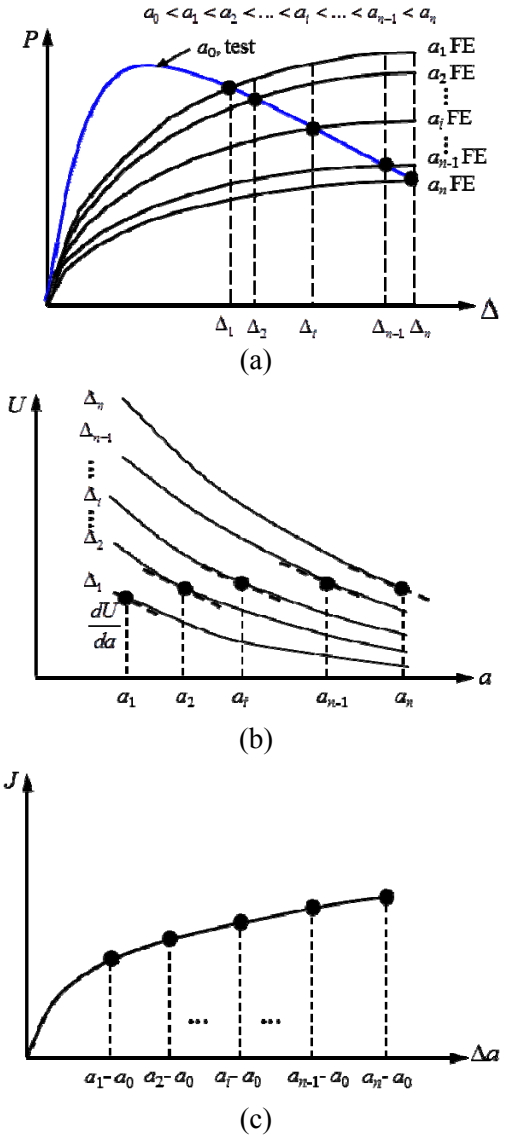

Figure 1. Schematic description for the proposed CMOD-based hybrid approach to determine the ductile fracture resistance.

Figure 1a illustrates the *P*-Δ curve obtained from the experimental specimen with the initial crack depth of a_0 and those obtained from the FE models with crack sizes ranging from a_1 to a_n. The intersection point between the experimental *P*-Δ curve and the numerical *P*-Δ curve defines a common loading and CMOD level in the FE specimen with a stationary crack and the experimental specimen with a growing crack. The crack extension (Δa_i) in the experimental specimen assumes a

value of ($a_i - a_0$) at the intersection of the test P-Δ curve and the numerical P-Δ curve computed from the FE model with a crack size of a_i. Since the crack size of the FE model equals the current crack size in the experimental specimen, the energy release rate calculated from the multiple FE specimens, using the same approach as the conventional multiple-specimen experimental approach, represents the J-value in the experimental specimen with the corresponding crack size.

The CMODs corresponding to the intersection points between the experimental curve and the numerical curves, *i.e.*, Δ_1 to Δ_n in Figure 1a, define the CMOD levels to compute the strain energy U for each crack depth. The evaluation of the strain energy U from the P-Δ curve becomes the primary step in applying the CMOD-based hybrid approach. Since the strain energy for the SE(B) specimen dissipates mainly through the rotation of the crack plane, the strain energy U equals the bending strain energy in the mode I SE(B) specimen. Based on the J-integral calculation proposed by Tohgo and Ishii [9], the bending strain energy for SE(B) specimen follows,

$$U_I = \int M d\theta \,. \tag{1}$$

Equation (1) also represents the mode I strain energy in mixed-mode I and II specimens. In such mixed-mode specimens, the shear strain energy follows,

$$U_{II} = \int F_V d\delta_V \,, \tag{2}$$

where, F_V is the shear force on the crack plane, and δ_V corresponds to the relative shear displacement between two crack planes. For the SE(B) specimens, the shear force remains zero and the bending moment M derives from equilibrium principles. The rotation of the crack plane, θ, depends on the current crack length,

$$\theta_i = \frac{\text{CMOD}}{a_{i-1} + r_p(W - a_{i-1})}, \tag{3}$$

where r_p represents the plastic rotation factor and equals 0.44 as suggested in ASTM E1820 [1] for SE(B) specimens, a_{i-1} corresponds to the crack depth determined at the previous intersection point between the experimental P-Δ curve and that obtained from the FE analysis, as demonstrated in Figure 1a.

Figure 1b illustrates the schematic variation of the strain energy with respect to the crack depth, calculated from multiple FE models. To facilitate the calculation of the energy release rate from the FE models, the hybrid approach utilizes a regression analysis to derive approximate polynomial functions in terms of the crack size, a, to describe the strain energy variations shown in Figure 1b. The solid circles in Figure 1b indicate the displacement level where the energy release rate calculated from multiple FE models equals (theoretically) the energy release rate in the experimental fracture specimen with a growing crack. The J-values at these solid circles are computed from Eq. (4),

$$J = -\frac{1}{B}\frac{dU}{da}. \tag{4}$$

Figure 1c sketches the J-values calculated at these solid circles with respect to the corresponding crack extensions. Tohgo and Ishii [9] separated the J-value for mixed-mode I and II specimens as,

$$J_T = J_I + J_{II} \,, \tag{5}$$

where, J_I and J_{II} correspond to the energy release rate contributed by the bending and shear deformation of the crack plane, respectively.

3. Validation on SE(B) Specimen

This section presents the validation of the proposed CMOD-based hybrid approach based on the

fracture resistance test results for the SE(B) specimens made of aluminum alloy (Al-alloy) 5083 H-112 reported by the authors [5]. The Al-alloy has a Young's modulus E of 69 GPa, with a Poisson's ratio of $\upsilon = 0.3$, the yield stress of $\sigma_y = 243$ MPa and the ultimate stress of $\sigma_u = 347$ MPa. Figure 2a presents the uniaxial stress-strain curves for the aluminum alloy material obtained from the axial tension test.

Figure 2a sketches the geometry of the SE(B) specimen. The total thickness of all the SE(B) specimen equals $B = 18$ mm, with the net-thickness after side-grooving equal to 80% of the total thickness, or $B_N = 0.8B$. The width of the specimen, W, equals to 36 mm, while the span over width, S/W, has a constant ratio of 4 for all SE(B) specimens. The CMOD or Δ is measured by the crack opening displacement gauge mounted at the mouth of the crack. The initial crack depth over the width ratios, a_0/W, equal 0.222 and 0.513 for the Al-alloy SE(B) specimens. The SE(B) specimen with a relatively shallow crack depth ($a_0/W \approx 0.2$) represents a fracture specimen with low crack-front constraints, while the deep crack ($a_0/W \approx 0.5$) corresponds to a high crack-front constraint condition complying with the ASTM E-1820 requirement [1].

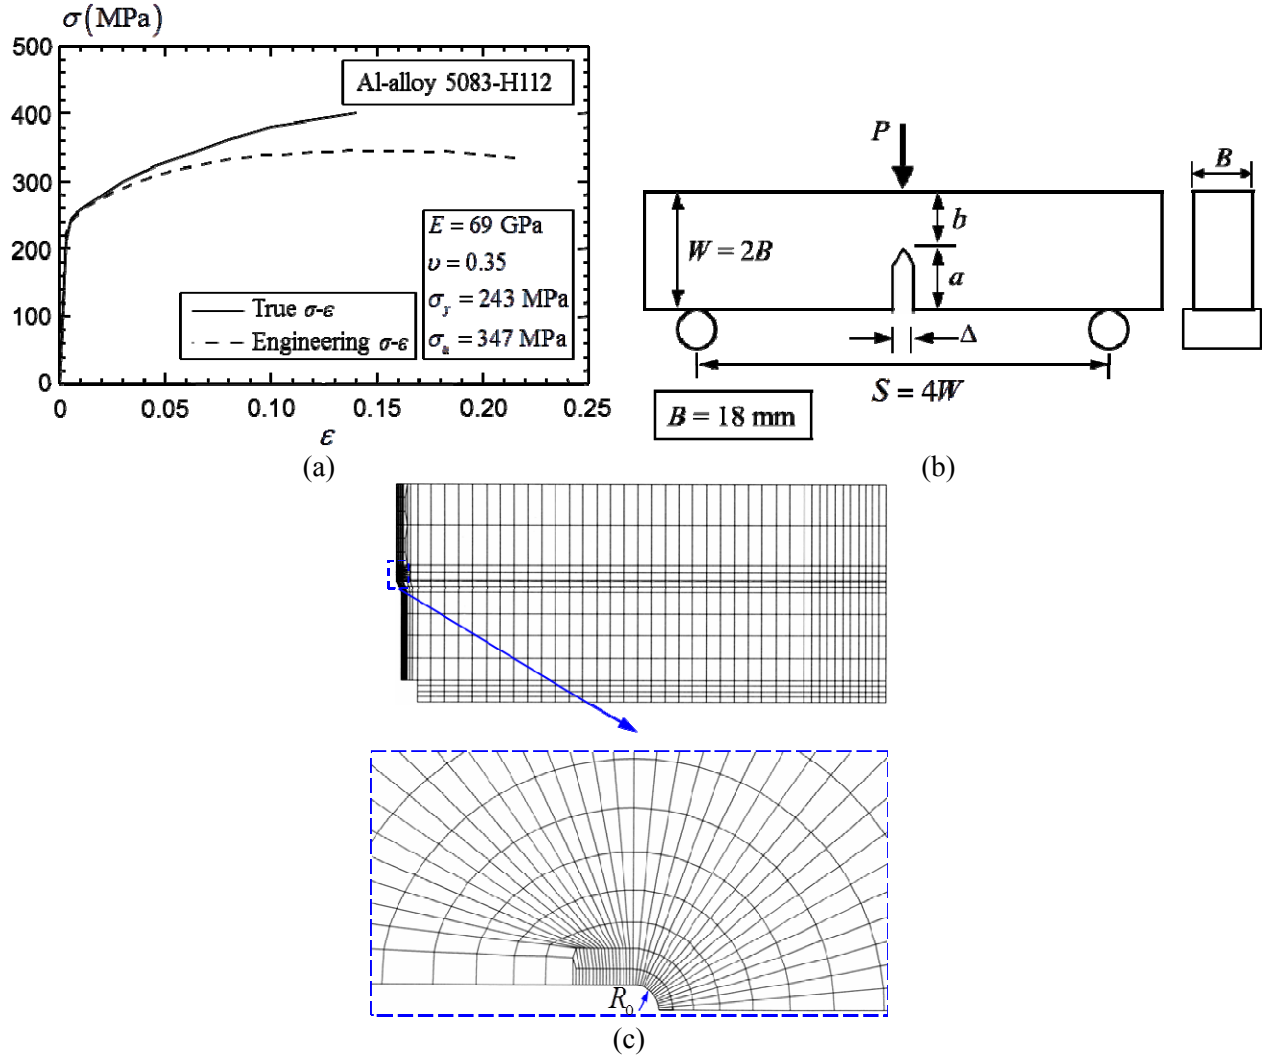

Figure 2. (a) Uniaxial stress-strain curves for the aluminum alloy material; (b) geometric configuration of the SE(B) specimen; and (c) the typical FE mesh for the SE(B) specimen.

Figure 2c shows a typical, half FE model for the Mode I SE(B) specimens, built from 3D 8-node brick elements. The FE model consists of one-layer of elements in the thickness direction, with all nodes in the FE model constrained against the out-of-plane displacement to represent the

plane-strain condition. The presence of a plane of symmetry enables a half model, with the displacement degree of freedom for all nodes on the plane of symmetry constrained in the direction normal to that plane. The crack-tip contains a focused mesh with an initial root radius of R_0 = 25 μm to facilitate numerical convergence under large deformations, as shown in Figure 2b. The total number of nodes in the FE models with different crack depths varies from 2000 to 3000, with the number of elements ranging from 1000 to 1500. The numerical computation in this study utilizes the FE research code, WARP3D [10].

For the Al-alloy SE(B) specimen with a_0/W = 0.222, this study generates thirteen FE models to compute the strain energy at thirteen different crack extensions (Δa_i), as summarized in Table 1. For the deep cracked SE(B) specimen with a_0/W = 0.511, the validation utilizes twelve FE models with various crack lengths to represent twelve different crack extensions (Δa_i), as shown in Table 1.

Table 1. The crack size in the FE models for the two SE(B) specimens made of Al-alloy 5083 H-112.

a_0/W	a_0 (mm)	Crack extensions (mm)					
		Δa_1	Δa_2	Δa_3	Δa_4 to Δa_{11}	Δa_{12}	Δa_{13}
0.222	8.0	0	0.2	0.5	1 to 4.5 @ 0.5 mm increment	5	5.5
0.511	18.5	0	0.2	0.6	1.2 to 5.4 @ 0.6 mm increment	6	-

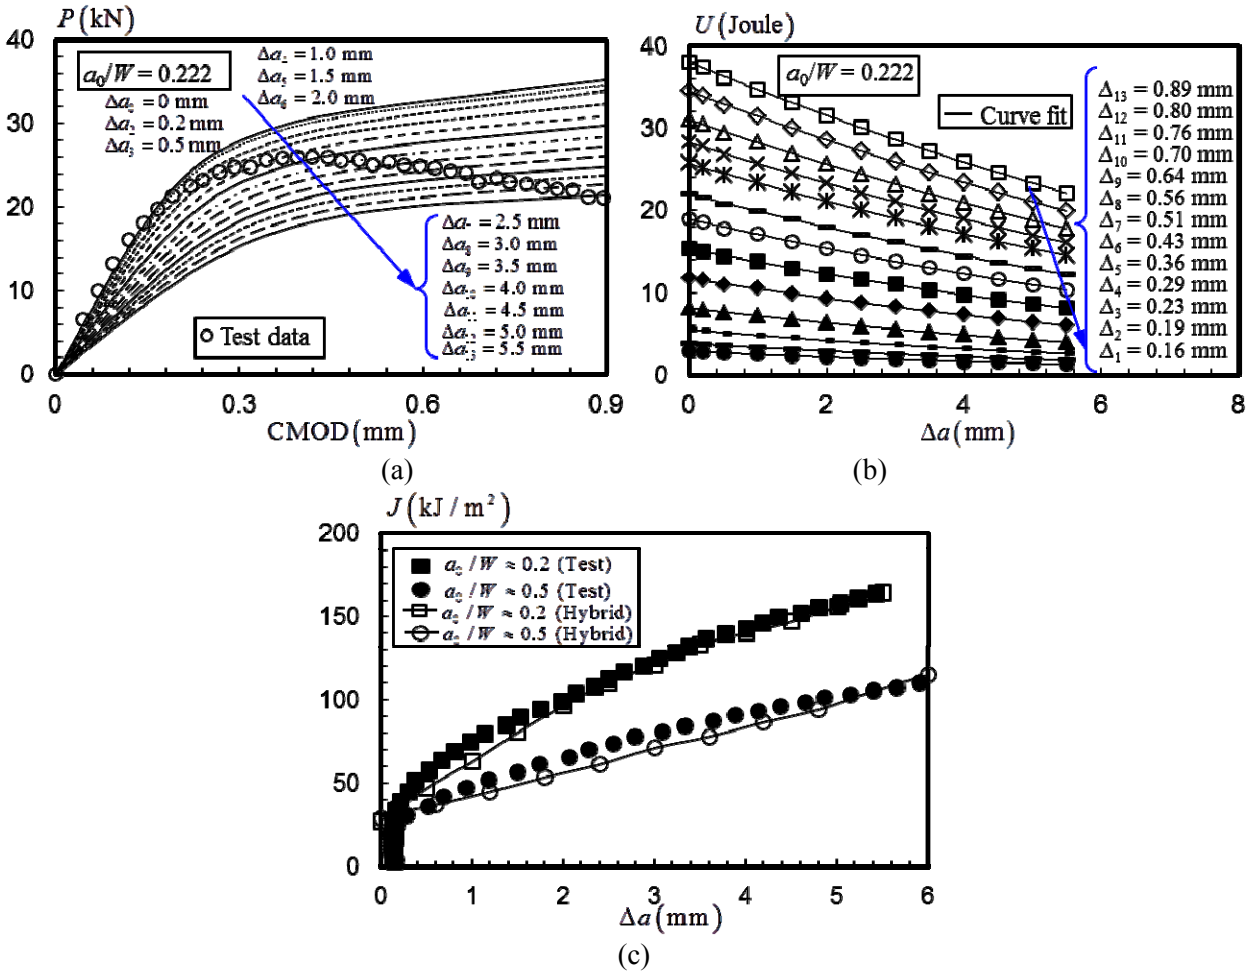

Figure 3. (a) P-Δ curve for SE(B) specimen with a_0/W=0.222; (b) U-Δa curves for SE(B) specimen with a_0/W=0.222; and (c) comparison of the J-R curves measured in the test and those derived from the CMOD-based hybrid approach for both shallow and deep cracked SE(B) specimens.

Figures 3a shows the P-Δ relationships for the experimental specimen of a_0/W = 0.222 with a growing crack indicated by the discrete circular symbols. The good agreement between the test data and the FE results at the zero crack extension, Δa = 0, confirms the boundary conditions of the FE models. In addition, the numerical P-Δ curve computed from the FE model with the same crack size as the experimental specimen at the end of the fracture test intersects with the test P-Δ curve at the end of the measured history. Figure 3b shows the strain energy U versus the crack extension evaluated from the P-Δ curves for the shallow cracked SE(B) specimen. The U value is computed at varied CMOD levels (Δ_i), which correspond to the intersections between the experimental and numerical P-Δ curves. The discrete symbols in Figure 3b represent the strain energy value computed from the FE model with the corresponding initial crack lengths $a_0+\Delta a_i$. The solid lines in Figure 3b correspond to the second-order polynomial functions derived from the regression analysis.

The J-value corresponding to each crack extension, Δa_i, can be derived from Eq. (4), using the first-order derivative of the fitted polynomial for the strain energy U (at the corresponding Δ_i) with respect to the crack depth. This leads to a J-R curve schematically shown in Figure 1c. The determination of the J-R curve by the CMOD-based hybrid approach for the SE(B) specimen with a_0/W = 0.511 follows the same procedures described in Figure 3a and 3b. Figure 3c compares the experimental J-R curves with those determined from the CMOD-based hybrid method for SE(B) specimens with two crack depth ratios, a_0/W = 0.222 and 0.511. The J-R curves obtained from the CMOD-based methods agree closely with the test results for both the shallow-crack and the deep-crack SE(B) specimens. This validates both the applicability and the accuracy of the CMOD-based hybrid method in determining the J-R curves for SE(B) specimens.

4. Validation on the Mixed-Mode Specimens

The verification of the hybrid method on the determination of the J-R curves utilizes two mixed-mode Al-alloy 5083 H-112 specimens reported by the authors [5, 11], the mode I dominant specimen AM1 (mode-mixity $\beta_{eq} = \tan^{-1}(K_I/K_{II}) = 75^o$) and the mode II dominant specimen AM5 ($\beta_{eq} = \tan^{-1}(K_I/K_{II}) = 20^o$) [5].

Figure 4a and 4b shows the typical FE models for the two mixed-mode specimens, AM1 and AM5. The geometrical configurations and the orientation of the crack planes follow exactly the test procedures described by the authors [5, 11]. Figure 4c and 4d illustrates the close-up view of the region around the crack tips for AM1 and AM5, respectively. The crack path deviates by 20^o from the original crack plane in the mode I dominant specimen AM1 and by 9^o from the original crack plane in the mode II dominant specimen AM5. The multiple FE models have varied crack lengths of $a_0+\Delta a_i$ along the crack directions observed from the tests, which have been summarized in Table 2. The verification of the CMOD-based hybrid approach on the mixed-mode specimens includes eight and six FE models with different crack sizes for the mode I dominant AM1 and the mode II dominant specimen AM5, respectively, as shown in Table 2. The crack tips for both specimens are simulated with an initial root radius of 25 μm to facilitate the convergence of the large-deformation analysis, similar to the method shown in the Figure 2c. The element type, boundary conditions and the calculation procedures follow similarly the methods described by Qian and Yang [7]. The material properties of the elements remain the same as those shown in Figure 2a.

Figure 5a and 5b show the M-θ curves and the F_V-δ_V relationships computed from the FE models listed in Table 2. The circles in Figure 5a and 5b represent the test results for AM1. Figure 5c and 5d illustrate the mode I strain energy U_I versus Δa curves and the mode II strain energy U_{II} versus Δa curves evaluated from the FE results at varied deformation levels listed in Table 2. The symbols

in Figure 5c and 5d represent the strain energy evaluated at different deformation levels (θ_i or δ_{Vi}) as listed in Table 2. The solid lines correspond to the fitted second-order polynomial functions, which are utilized to determine the first-order derivatives at various crack extensions.

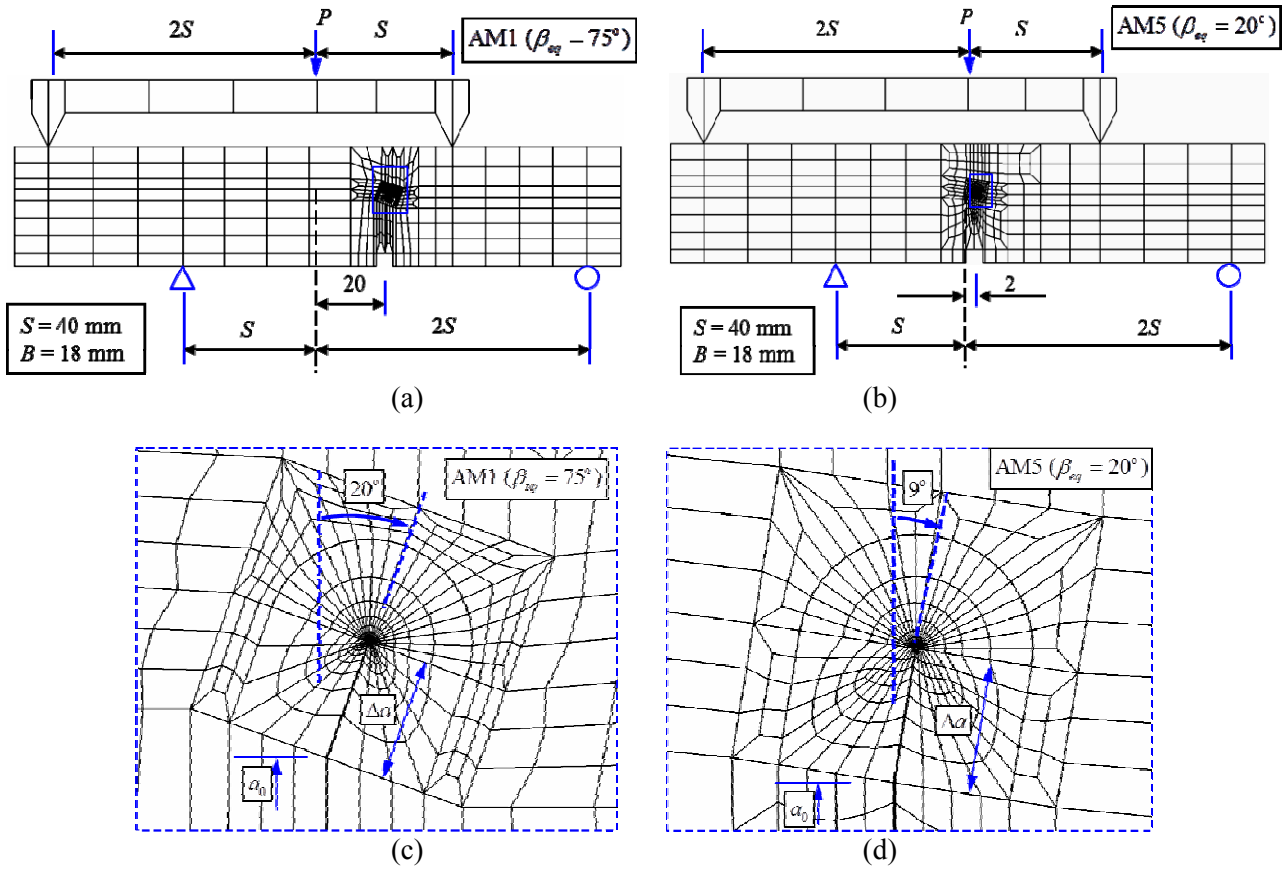

Figure 4. Typical FE models for the mixed-mode specimens made of Al-alloy 5083 H-112: (a) global FE model of the Mode I dominant specimen AM1; (b) global FE model of the Mode II dominant specimen AM5; (c) a close-up view around the crack tip for AM1; and (d) a close-up view around the crack tip for AM5.

Table 2. FE models for the mixed-mode I and II specimens made of Al-alloy 5083 H-112.

Specimen	Crack Parameters	FE models								
		$i = 0$	$i = 1$	$i = 2$	$i = 3$	$i = 4$	$i = 5$	$i = 6$	$i = 7$	$i = 8$
AM1 (Mode I dominant)	Δa (mm)	0	0.1	0.3	0.7	1.7	2.7	3.7	4.7	5.7
	θ (rad)	-	0.0247	0.0288	0.0356	0.06	0.0816	0.0924	0.106	0.115
	δ_V (mm)	-	0.052	0.09	0.159	0.273	0.486	0.588	0.672	0.749
AM5 (Mode II dominant)	Δa (mm)	0.15	0.5	1.0	2.0	3.0	3.9	4.5	-	-
	θ (rad)	-	0.017	0.019	0.021	0.022	0.023	0.024	-	-
	δ_V (mm)	-	0.604	0.731	0.911	1.050	1.233	1.412	-	-

Figure 6 compares the fracture resistance curves obtained from the hybrid approach and the test for AM1. Both the J_I-Δa and J_{II}-Δa hybrid results agree well with the test data at small crack extension, *i.e.*, $\Delta a < 1$ mm, as shown in Figure 6a. Figure 6a also shows that the hybrid approach leads to slightly lower J_I-Δa curve when $\Delta a > 1$ mm, due to the combined mode I dominant and mode II dominant fracture failure across the thickness of the specimen [11]. In general, the good agreement between the total J versus Δa curves determined using the hybrid approach and that obtained from

the test confirms the applicability of the hybrid method in predicting the fracture resistance for the Mode I dominant specimen AM1.

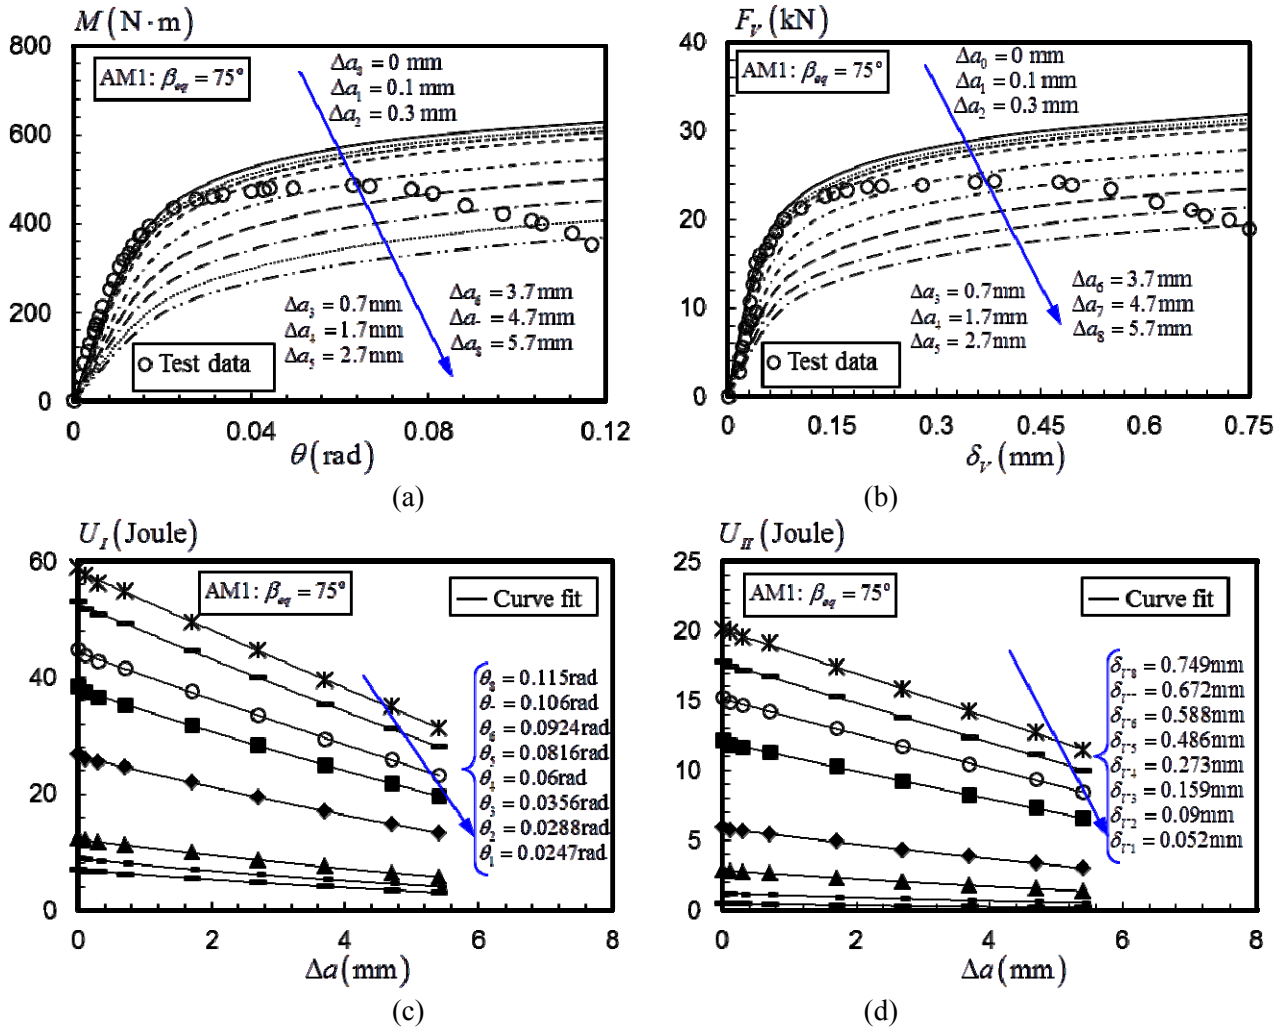

Figure 5. Determination of the strain energy for the Mode I dominant specimen, AM1: (a) The moment-rotation curves computed from multiple FE models; (b) the shear force versus shear deformation computed from multiple FE models; (c) the Mode I strain energy versus the change in the crack size; and (d) Mode II strain energy versus the change in the crack size.

Figures 6c and 6d compare the *J-R* curves reproduced from the hybrid approach and those obtained from the test for mode II dominant specimen, AM5. Very close agreement between the results obtained from these two methods is observed when $\Delta a < 1$ mm, as shown in Figure 6c and 6d. As $\Delta a > 1$ mm, the hybrid approach yields slightly lower (conservative) *J-R* curves.

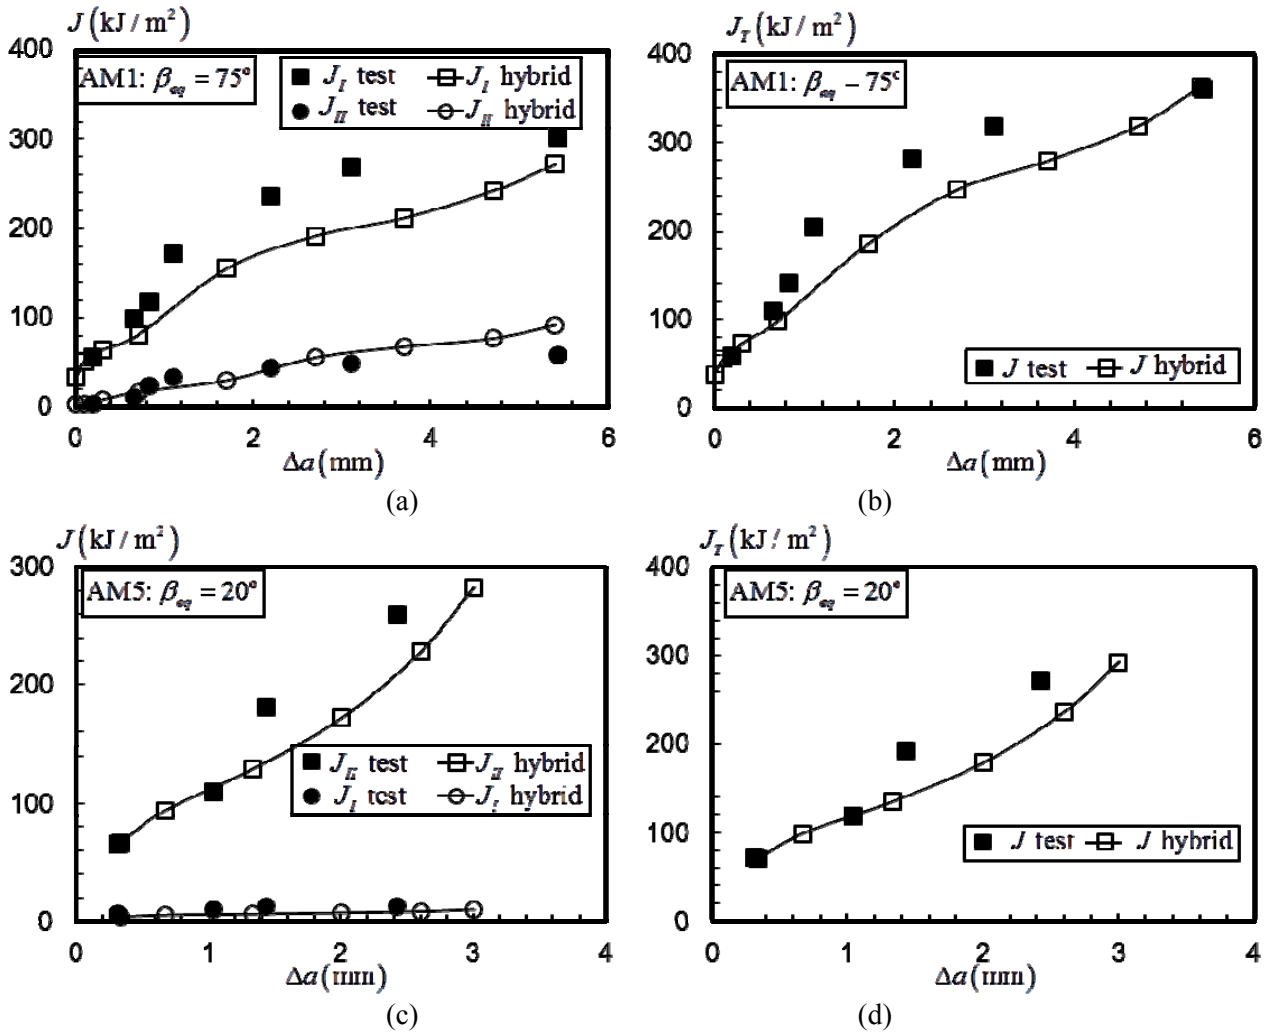

Figure 6. Verification for the mixed-mode specimen: (a) the Mode I and Mode II fracture toughness versus the crack extensions for AM1; (b) the total fracture toughness versus the crack extension curves for AM1; (c) the Mode I and Mode II fracture toughness versus the crack extensions for AM5; and (d) the total fracture toughness versus the crack extension curves for AM5.

5. Summary and Conclusions

The proposed CMOD-based hybrid method relies on a single experimental *P*-Δ curve and multiple numerical *P*-Δ curves to derive the fracture resistance curve for both the SE(B) specimen and the mixed-mode I and II specimen. The CMOD-based hybrid method simplifies the *J*-*R* curve testing procedure by eliminating the multiple unloading and reloading sequences, required to determine the specimen compliance and hence the crack size. The current CMOD-based hybrid method removes the dependence on the LLD, which requires careful instrumentation to prevent possible errors introduced by the indentation at the loading point. The close agreement between the *J*-*R* curves derived from the CMOD-based hybrid approach and those determined from the tests validates the proposed hybrid approach for both the SE(B) specimens and the mixed-mode I and II specimens.

Simulation of fracture and fatigue damage in stainless steel 304 using a cohesive zone model

Huan Li, Huang Yuan*

Department of Mechanical Engineering, University of Wuppertal, Germany.
* Corresponding author: h.yuan@uni-wuppertal.de

Abstract In the present paper a cohesive zone model coupled with monotonic and cyclic damage mechanisms for simulating elastic-plastic fracture and fatigue crack growth is introduced and applied for investigating failure processes in compact tension specimens. Fracture and fatigue crack tests are conducted on the compact tension C(T) specimen made of stainless steel 304 to study crack growth behavior under fracture and low cycle fatigue loading condition associated with severe elastic-plastic deformations. A good agreement between the prediction and the experimental result is obtained from the present simulations. It confirms that the suggested cohesive model in conjugation with the nonlinear damage evolution equations is applicable for describing the material degradation behavior of stainless steel 304 under both monotonic and cyclic loading with large plastic deformations.

Keywords Cohesive model, damage evolution, low cycle fatigue, elasto-plastic growth, crack growth rate

1. Introduction

Fatigue crack in industrial components are often subjected to heavy cyclic loading, and it is important to predict the fatigue crack growth behavior under higher stress fields. In low cycle metal fatigue problems, e.g. under loading conditions with maximum stresses beyond yield stress, specimens fail in small numbers of loading cycles.

Comparing with Paris' law, Walker model and Forman model or any other kinds of stress intensity factor based models, the cohesive model is more advantageous and gives the possibility to analyze the fatigue propagation behavior under severe plastic loading conditions, since the characterization of the cohesive zone model is generally applicable for inelastic materials [1-7]. Furthermore, it becomes possible to describe crack nucleation and propagation uniformly by the cohesive model.

Originally, the cohesive zone model was introduced to describe the fracture process zone ahead of the crack-tip by Dugdale [8] and Barenblatt [9]. In the last twenty years, the cohesive modeling has been applied in simulating monotonic fracture process for diverse materials and has also been verified by experimental results [10-13]. For the fatigue failure analysis, the loading history dependent development of material degradation has to be taken into account under cyclic loading. Establishing a physical solid cohesive model for finite fatigue life is under intensive investigation in many research groups worldwide [2, 3, 14-17].

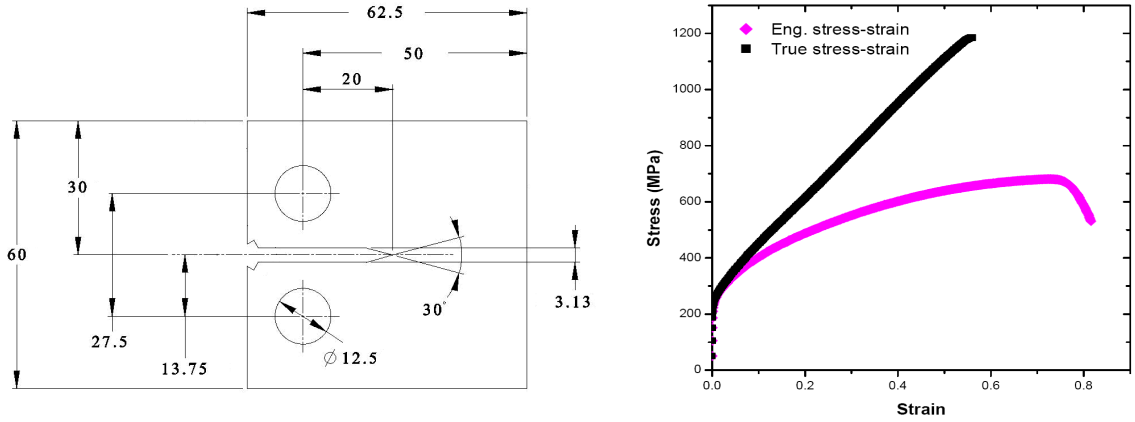
In the present study, the fatigue crack propagation experiments have been conducted using compact tension C(T) of type 304 stainless steel associated with large plastic deformations. A cohesive model coupled with damage for prediction of fracture and fatigue behavior is introduced for elastic-plastic crack propagation associated with both normal and shear displacements of the crack surface. Both rupture damage and cyclic damage accumulation are considered in the damage evolution equations. The numerical results agree with experimental data and reproduce the high

fatigue crack propagation rate. The present analysis is limited to a two-dimensional configuration by the plane strain assumption.

2. Experimental arrangement

2.1. Material and specimens

The material used in the present investigation comes with 304 austenitic stainless steel cylindrical bars with a 200mm diameter. The mechanical properties were obtained through tensile test performed on cylindrical specimen of 6mm diameter and about 70mm gauge length. The C(T) specimens were fabricated following the ASTM E399. The dimensions of C(T) specimen are illustrated in Figure 1(a). The material curves are shown in Figure 1(b).

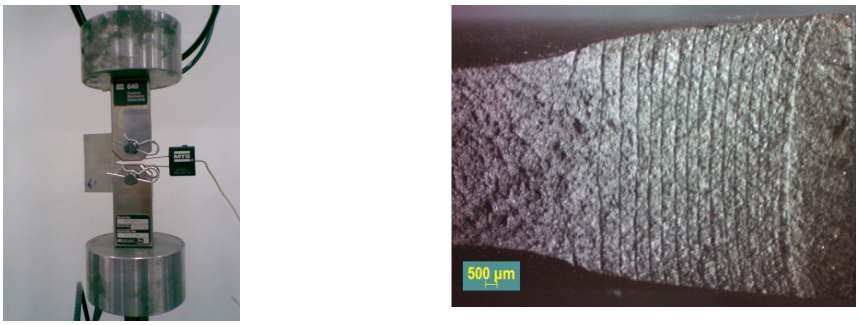


(a) (b)

Figure 1. (a) Dimensions of C(T) specimen, the thickness is 12.5mm. (b) Engineering and true stress-strain curves for the stainless 304 steel.

2.2. Experimental apparatus and conditions

The configuration of clevis used for C(T) specimen is based on ASTM E647. All fatigue pre-cracks of the specimens were generated under mode I loading using high frequency testing machine at a loading frequency of approx. 90 Hz. The fracture test was conducted to determine the plane strain fracture toughness of the stainless steel 304. Fatigue loading during the crack growth process was carried out in a MTS servo-hydraulic testing machine.



(a) (b)

Figure 2. (a) The compliance method and (b) beachmarks on the fracture surface for CT specimen.

The tests were performed in air at room temperature with sine waveform at a frequency of 8 Hz. The fatigue crack growth rate was measured by using the compliance method and also creating beachmark to record the crack front as displayed in Figure 2.

3. Cohesive zone model

3.1. Kinematics and constitutive relation under quasi-static and cyclic loading

Taking the principle of virtual work of the boundary value problem into account, the weak form of the equilibrium equation without body forces can be written as

$$\int_V \boldsymbol{\sigma} : \delta\boldsymbol{\varepsilon} \mathrm{d}V + \int_S \mathbf{T} \cdot \delta\boldsymbol{\Delta} \mathrm{d}S = \int_{\partial V} \mathbf{T}' \cdot \delta\mathbf{u} \mathrm{d}s \tag{1}$$

with $\boldsymbol{\sigma}$ as the Cauchy stress tensor, $\mathbf{T}'$ denotes the external traction vector and $<\delta\boldsymbol{\varepsilon}, \delta\boldsymbol{\Delta}, \delta\mathbf{u}>$ are the admissible displacement fields. The cohesive traction $\mathbf{T}$ is taken to have the following form,

$$\mathbf{T} = T_s\mathbf{s} + T_n\mathbf{n} = \frac{T}{\Delta}(\xi^2\Delta_s\mathbf{s} + \Delta_n\mathbf{n}), \tag{2}$$

where T_s and T_n are the cohesive traction components in shear and normal direction, respectively. Following the Ortiz et al. [1] and Ural et al. [17], the effective displacement jump Δ is a scalar parameter defined as

$$\Delta = \sqrt{\xi^2\Delta_s^2 + \Delta_n^2}, \tag{3}$$

where $\Delta_s = |\boldsymbol{\Delta}_s|$ and Δ_n are the displacement jumps in shear and normal directions and ξ weights the shear displacement jump over normal one. T is a scalar effective traction relates to the effective displacement jump Δ in the process zone where a crack may arise. The formulation of T used in the present study refers to a coupled damage model defined as

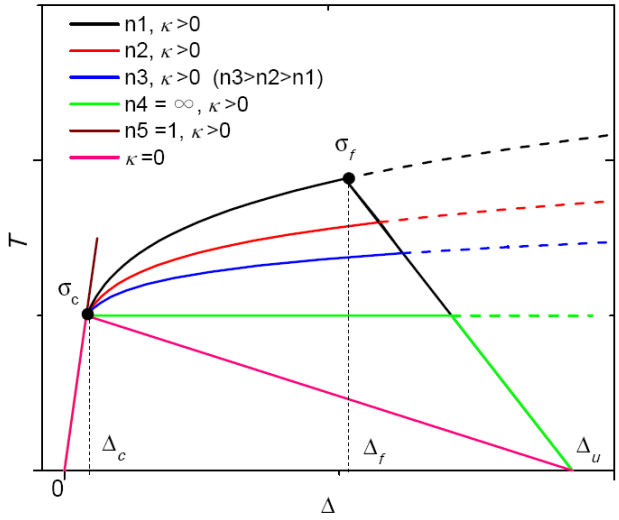


Figure 3. Illustration of the cohesive zone model under monotonic loading.

$$\Delta = \begin{cases} \dfrac{T}{\sigma_c}\Delta_c + \kappa\left(\dfrac{T}{\sigma_c}\right)^n & 0 \le \Delta \le \Delta_f \\ -\dfrac{T}{\sigma_f}\left(\Delta_u - \Delta_f\right) + \Delta_u & \Delta_f < \Delta \le \Delta_u \end{cases}, \tag{4}$$

where Δ_c is the onset of the displacement jump associated with initiation of the cohesive zone hardening, σ_c refers to the initial cohesive strength of the process zone corresponding to Δ_c and Δ_u is the final displacement jump which mirrors the complete loss of stress carrying capacity when the traction equals to zero. κ is a parameter which has the same unit as the displacement jump and n is the hardening exponent. Δ_f is the value of displacement jump after which the initiation of damage begins and the corresponding cohesive strength is σ_f, the effects of these parameters are shown in Figure 3. For the application of Eq. (4), the inequality must be satisfied that

$$T \le C(D) = \sigma_f(1-D), \tag{5}$$

where D is a scalar variable representing the overall damage in materials and C is identified with the cohesion as the function of the damage. The monotonic cohesive law is insufficient and the cyclic damage should be taken into account in the constitutive description. Should the cohesive model be applied for both fracture and fatigue crack growth, the material damage depends on both monotonic loading and loading cycles, i.e.

$$\frac{\mathrm{d}D}{\mathrm{d}t} = \dot{D} = \dot{D}_s + \dot{D}_c \tag{6}$$

with D_s for damage under monotonic loading and D_c for damage under cyclic loading. Obviously, both damage variables have to be expressed in evolution equations.

Under the monotonic loading condition, Eq. (4) denotes inelastic behavior of the material in the cohesive zone and Eq. (5) implies that the degradation of the material strength for $\Delta < \Delta_f$. For $\Delta > \Delta_f$, the damage grows and assumes to be expressed in a linear function of the displacement increment [17],

$$D_S = \frac{\Delta - \Delta_f}{\Delta_u - \Delta_f} \tag{7}$$

under monotonic loading condition.

For fatigue, the material should be damaged even under the cohesive strength, σ_f. The damage evolution equation proposed by Ural et al. [17] is used to characterize fatigue process reads

$$\dot{D}_c = \begin{cases} \alpha D_c(T-\beta C)\dot{\Delta} & T-\beta C > 0, \dot{\Delta} > 0 \\ \gamma D_c(T-\beta C)\dot{\Delta} & T-\beta C < 0, \dot{\Delta} < 0 \\ 0 & (T-\beta C)\dot{\Delta} < 0 \\ \dot{\lambda} & T = C, \dot{\Delta} > 0 \end{cases}, \tag{8}$$

where α and γ are two difference material constants used to conduct the damage accumulation during the reloading and unloading under the given conditions, respectively. The parameter β is adopted to denote the fatigue threshold in conjunction with the current cohesion C. The rate form of λ is a free variable is defined to represent the damage growth rate at a random stress state associated with the second equation of Eq. (4).

Following the suggestion in [17], the unloading and reloading paths of the present study can be

described in the incremental form as

$$\dot{T} = F(D)\dot{\Delta} \quad \text{with} \quad F(D) = \frac{\sigma_f(1-D)}{D(\Delta_u - \Delta_f) + q\Delta_c} \quad \text{and} \quad q = \frac{\sigma_f}{\sigma_c}. \tag{9}$$

The equation above indicates that the unloading/reloading stiffness the cohesive zone, $F(D)$, varies with D from σ_c/Δ_c for no damage (D=0) to zero for D=1.
The total damage in terms of a loading history should be the sum of the monotonic damage and cyclic damage

$$\dot{D} = \dot{D}_s + \dot{D}_c = \frac{\dot{\Delta}}{\Delta_u - \Delta_f} + \dot{D}_c \tag{10}$$

3.2. Implementation of cohesive element into ABAQUS

The commercial software ABAQUS[18] allows the user to define a new element conveniently, via the interface UEL. The formulation of the cohesive element is referred to the ABAQUS theoretical manual. We have to provide the cohesive element stiffness, the residual nodal force vector and derive the cohesive traction and displacement jump according to the cohesive law. These variables are needed to calculate the virtual work generated by the cohesive zone such that the internal work equals to the external virtual work for every kinematically admissible displacement field in accordance with Eq. (1). As illustrated in Figure 4, a four node cohesive element is defined in two dimensional x-y coordinates. The nodal displacement vector corresponding to 4 nodes is defined by

$$\mathbf{u} = [u_i, v_i]^{\mathrm{T}} \qquad i = 1, 2, 3, 4 \tag{11}$$

with u and v as nodal displacements in x and y direction, respectively. Then the local displacement jump vectors $\boldsymbol{\Delta}$ are written using the shape functions and the nodal displacement as

$$\boldsymbol{\Delta} = \begin{bmatrix} \Delta_s \\ \Delta_n \end{bmatrix} = \boldsymbol{\alpha}\mathbf{B}\mathbf{u} \tag{12}$$

with $\mathbf{B}$ as the matrix about the shape functions,

$$\mathbf{B} = \begin{bmatrix} -N_1 & 0 & -N_2 & 0 & N_2 & 0 & N_1 & 0 \\ 0 & -N_1 & 0 & -N_2 & 0 & -N_2 & 0 & N_1 \end{bmatrix}, \tag{13}$$

where N_1=(1-s)/2 and N_2=(1+s)/2 are linear interpolation functions in the intrinsic coordinate system and $\boldsymbol{\alpha}$ is the rotation matrix denoted by

$$\boldsymbol{\alpha} = \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix}. \tag{14}$$

The cohesive element stiffness matrix and the traction force term are given by

$$\begin{aligned} \mathbf{K}^e &= \int_e \mathbf{B}^{\mathrm{T}}\mathbf{D}\mathbf{B}\mathrm{d}A = \frac{l_e}{2}\int_{-1}^{1} \mathbf{B}^{\mathrm{T}}\mathbf{D}\mathbf{B}\mathrm{d}s, \\ \mathbf{T}^e &= \int_e \mathbf{B}^{\mathrm{T}}\mathbf{T}\mathrm{d}A = \frac{l_e}{2}\int_{-1}^{1} \mathbf{B}^{\mathrm{T}}\mathbf{T}\mathrm{d}s, \end{aligned} \tag{15}$$

where l_e is the length of the element , $\mathbf{T}$ is the traction vector based on the Eq. (2) and $\mathbf{D}$ is the

material Jacobian matrix denoted as

$$\mathbf{D} = \begin{bmatrix} \dfrac{dT_s}{d\Delta_s} & \dfrac{dT_s}{d\Delta_n} \\ \dfrac{dT_n}{d\Delta_s} & \dfrac{dT_n}{d\Delta_n} \end{bmatrix}. \tag{16}$$

During the implementation, the matrices of Eq. (15) should be transformed to *x*-*y* coordinates according to Eq. (14).

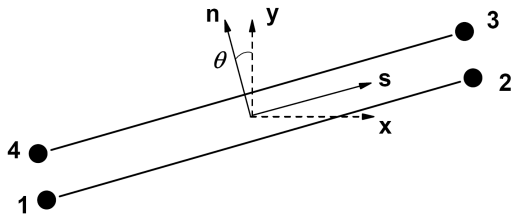

Figure 4. Illustration of a cohesive element

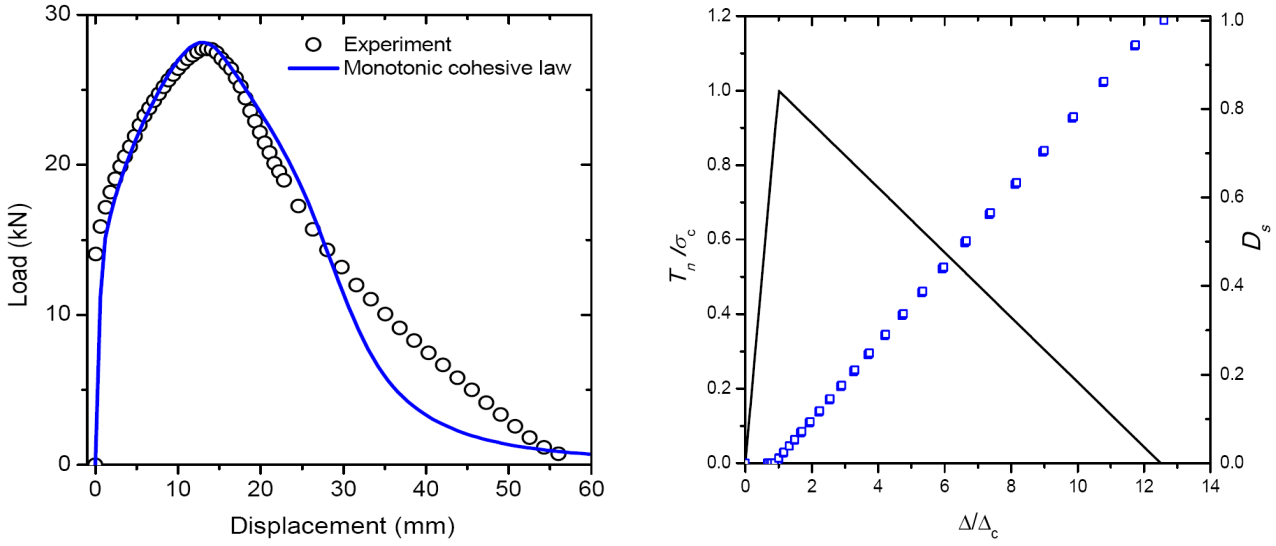
4. Results and discussion

4.1. Crack growth under monotonic loading

C(T) specimens were tested to determine cohesive parameters under monotonic loading. The load-displacement curve was recorded in the experiment. In computations the finite element mesh of the potential damage zone ahead of the crack tip is refined and the minimal element size is about 0.4mm. In the process of numerical simulation, cohesive elements are placed at the symmetric line of the mesh with zero thickness. The rest of region is occupied by the conventional four nodal elements under the plane strain assumption. The initial crack length is around 29mm. The stainless steel is described by the J_2 plasticity for simplicity.



(a) (b)

Figure 5. Computational prediction of monotonic crack growth in a C(T) specimen. (a) Comparison between the simulation and the test result. (b) Cohesive response of a ruptured element during the crack propagation.

As mentioned in the previous sections, Eq. (4) shows the bilinear behavior if κ=0 under the monotonic loading and the initial cohesive strength of $\sigma_c=\sigma_f$ =1100MPa associated with $\Delta_c=\Delta_f$ =0.2mm. Computational simulation based on the cohesive zone model according to Eq. (4) is shown in Figure 5(a) for monotonic fracture. It confirms that the final displacement jump Δ_u=2.5mm gives a reasonable prediction in comparing with the experiment. This kind of the cohesive law is popular in simulation of quasi-brittle material failure. Figure 5(b) illustrates the cohesive response of a ruptured element along crack path, the static damage evolution of the element can be seen additionally and this result should be imagined according to Eq. (7) or Eq. (10).

4.2. Crack growth under cyclic loading

The crack growth under cyclic loading case is conducted within elasto-plastic region in this section. Considering the cyclic damage equation as mentioned in Eq. (8), the damage accumulation depends on the current cohesive traction and the increment of the displacement jump corresponding to the loading history. We use the concept of the loading cycles to capture the evolution of damage and predict the fatigue life. By recording the crack growth length, Δa, the fatigue crack growth rate can be determined by $\Delta a/\Delta N$. Since the global loading behavior of the C(T) specimen is represented by the amplitude of the stress intensity factor, ΔK, the numerical simulation by using the cohesive element can be verified through the experimental da/dN vs. ΔK curve.

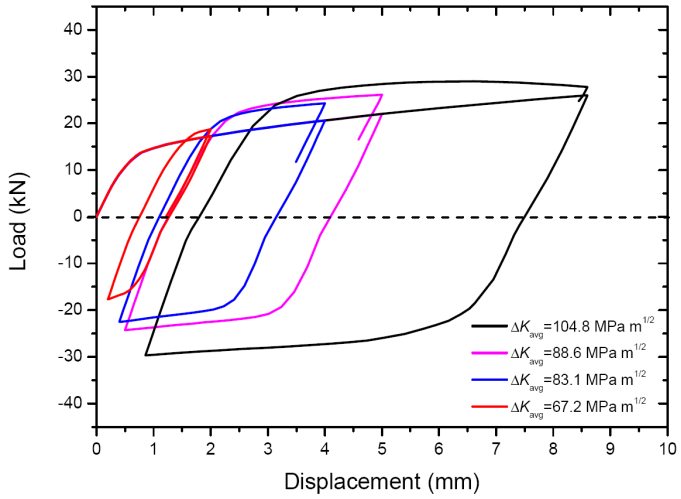


Figure 6. Four loading amplitudes for the CT specimen as a function of load line displacement.

As shown in Figure 6, four different loading amplitudes were performed under the displacement control at the loading ratio R=0.1. Because the stainless steel 304 is a cyclic instable material which associates the stress variation as a function of loading cycles, the average stress amplitude ΔK_{avg} is used to express the loading level during the crack growth process. The specimen dimensions and mesh configurations for the fatigue simulation are the same as those for the fracture test. The material parameters for the damage evolution are α=0.00053, β=0.15 and γ=0.0 combined with the monotonic cohesive law which has been determined from the fracture simulation. The damage growth process in an element ahead of the crack-tip is displayed in Figures 7, 8 and 9 under the conditions with ΔK_{avg}=83.1MPa m$^{1/2}$ and ΔK_{avg} =104.8 MPa m$^{1/2}$, respectively. In the figures, the traction and displacement jump are non-dimensionalized by σ_c and Δ_c, respectively. The negative displacement jump associated the compression of the crack surface is constrained by introducing a

penalty equation for contact. Comparing the amplitudes, the higher loading level results in a faster material degradation (Figure 7) and so shorter fatigue life (Figure 8). Actually, ΔK_{avg}=104.8 MPa $m^{1/2}$ asymptotically approaches the plain strain toughness K_c of 133MPa $m^{1/2}$ at the loading ratio R=0.1, larger amount of damage accumulation is coincident with that caused by the fracture loading. In Figure 8, the traction against the loading segment (half cycle) is illustrated in both loading and unloading path, no damage growth is assumed in the unloading path including the compression in terms of Eq. (8), as shown in Figure 9. In order to verify the simulation results, the popular crack growth law proposed by Erdogan et al. [19] is used to consider all ranges of cyclic crack growth which is given by

$$\frac{\mathrm{d}a}{\mathrm{d}N}=\frac{C(\Delta K-\Delta K_{\mathrm{th}})^{n}}{(1-R)K_{c}-\Delta K}, \tag{17}$$

where the fracture toughness of K_c=133MPa $m^{1/2}$, the threshold value of ΔK_{th} is 7.5MPa $m^{1/2}$ and material constants C=$10^{-5.578}$ and n=2.697 for correlating the experimental data. The computational result together with the experiment are compared in Figure 10, the prediction gives a better agreement with the test, especially in the region III of fatigue crack growth.

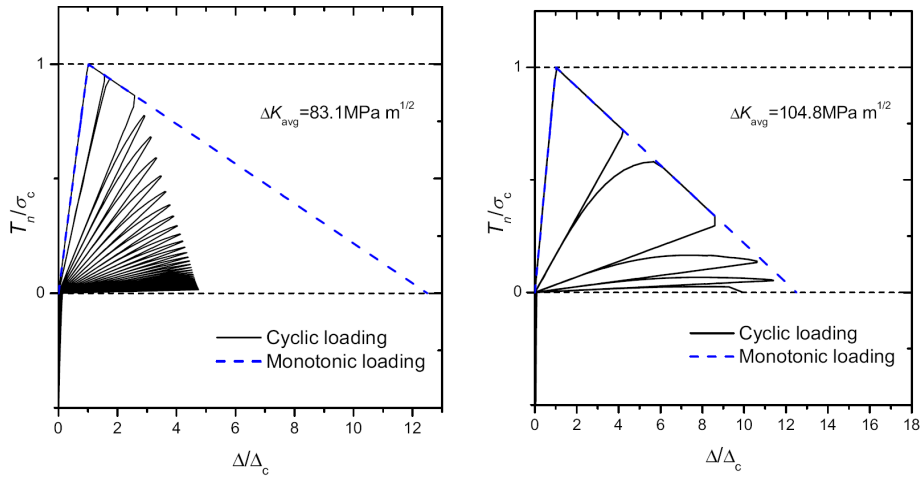

Figure 7. The traction vs. displacement jump curves in a cohesive element for ΔK_{avg}=83.1MPa $m^{1/2}$ and ΔK_{avg}=104.8MPa $m^{1/2}$.

5. Concluding remarks

In the present paper a cohesive zone model in conjunction with monotonic damage and cyclic fatigue damage was investigated based on experimental tests, to create a unified fatigue crack growth model for both elastic and elastic-plastic fatigue crack growth.

In simulations the initial cohesive strength and the corresponding displacement jump are defined based on the true stress-strain relationship so that the cohesive zone does not affect the compliance of the specimen before damage initiation. The penetration of the crack surface under compression is prevented using the contact formulation. The first results confirm that the present cohesive zone model coupled with monotonic and cyclic damage evolution is suitable to describe fracture and fatigue crack growth of stainless steel 304 with severe plastic deformations.

In addition, the present computations reveal that the damage evolution in the low stress level and the material compression process could not be properly described need further improvement. More extensive studies on the cohesive model and the damage evolution equation may provide further understanding of ductile fatigue damage under more complex loading conditions.

Abstract. Distributions of the singular (K_I, K_{II}) and the non-singular (T_{xx}, T_{zz}) terms along the 3D crack front are analyzed for the case of mixed (mode I and II) loading. Relations between the singular, non-singular terms and specimen thickness are calculated in the specimen middle plane for different values of the mixity parameter. The values of the mixity parameter are varied through 1 (pure mode I), 0.75, 0.5, 0.25–0 for pure mode II. It is shown that the increase of thickness in 8 times influences on values of K_I , K_{II} and T_{zz} . The strong effect of thickness and mixed mode loading conditions on the T_{zz}-stress is observed. At the same time, there is not the effect of thickness on the non-singular T_{xx} at the same loading conditions.

Keywords T-stress, Mixed mode, In-plane and out-of-plane constraint, Specimen thickness

Introduction

The development of modern fracture mechanics is closely related to the formation of two-parameter approaches and criteria, which introduce and nonsingular components of the stress field at the crack tip, such as the T-stress. Primarily it is due to the fact that the fracture toughness of structural materials shows a significant effect of the specimen geometry and thickness, load conditions, etc. (e.g. [1, 2]). The results of analytical and numerical calculations show that stress fields in the vicinity of the crack tip, in many cases, are strongly dependent on the non-singular terms of the stress field [3, 4]. Introduction of an additional parameter, namely, the nonsingular T_{xx}-stress in the criteria allows to eliminate the above-mentioned effects [5, 6]. It should be noted that the T_{xx}-stress describes in-plane constraint. In contrast to the T_{xx}-stress, out-of-constraint is connected with the T_{zz}-stress. However, investigation of joint influence of the nonsingular T-stress (T_{zz} and T_{xx}) terms on the fracture mechanics parameters is not carried out yet.

Present paper deals with numerical analysis of three-dimensional stress fields in the vicinity of through-thickness crack tip under mixed mode (I + II) loading. The combined effect of thickness on the effective stress intensity factor and T-stress terms are discussed.

Statement of the problem

An analysis of 3D stress field in the vicinity of the crack front is performed on the CCCD-specimen with the thorough-thickness crack of arbitrary space orientation. The specimen is loaded by 2 compressive forces acting in the vertical direction (Fig. 1). This configuration of the specimen is very suitable to create different conditions of mixed loading [7].

Finite element method is employed to estimate the 3D stress field in the vicinity of crack front. The orientation of the crack plane with respect to the disk can be arbitrary, since it is determined by both the angle α (Fig. 1) and the other two spatial angles. Changing the combination of angles can provide almost any relationship between the magnitudes of the K_I, K_{II}, K_{III}. The geometrical parameters of the model are given in dimensionless form, namely, $b=B/R$, $l=a/R$ (Fig. 1). Note that the developed procedure for the construction of the model allows taking into account the spatial symmetry of the problem and getting the best mesh in terms of accuracy and speed of calculation.

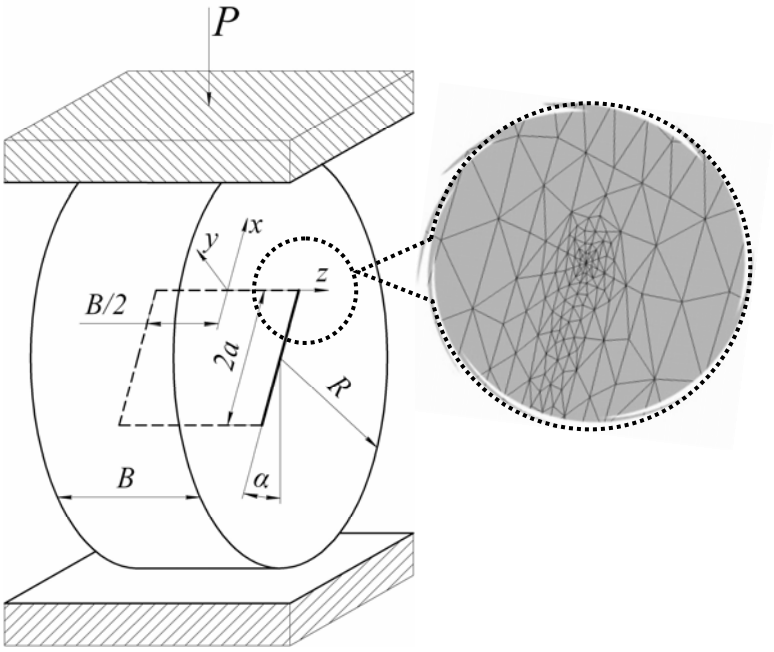

Figure 1. Model of the CCCD-specimen

The stress field in the vicinity of the crack tip of mixed type (I+II) can be represented in the form [8]:

$$\sigma_{xx} = \frac{1}{\sqrt{2\pi r}}\left[K_I \cos\frac{\theta}{2}\left(1-\sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right) - K_{II}\sin\frac{\theta}{2}\left(2+\cos\frac{\theta}{2}\cos\frac{3\theta}{2}\right)\right] + T_{xx},$$

$$\sigma_{yy} = \frac{1}{\sqrt{2\pi r}}\left[K_I \cos\frac{\theta}{2}\left(1+\sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right) + K_{II}\sin\frac{\theta}{2}\left(\cos\frac{\theta}{2}\cos\frac{3\theta}{2}\right)\right],$$

$$\sigma_{xy} = \frac{1}{\sqrt{2\pi r}}\left[K_I \sin\frac{\theta}{2}\left(\cos\frac{\theta}{2}\cos\frac{3\theta}{2}\right) + K_{II}\cos\frac{\theta}{2}\left(1-\sin\frac{\theta}{2}\sin\frac{3\theta}{2}\right)\right], \quad (1)$$

$$\sigma_{zz} = \frac{2\nu}{\sqrt{2\pi r}}\left[K_I \cos\frac{\theta}{2} - K_{II}\sin\frac{\theta}{2}\right] + T_{zz},$$

$$T_{zz} = E\varepsilon_{zz} + \upsilon T_{xx}.$$

where x is the direction formed by the intersection of the plane normal to the crack front and the crack plane, y is the direction orthogonal to the crack plane, z is the direction orthogonal to x and y directions (tangent to crack front); r and θ are the in-plane polar coordinates in plane $x0y$. Here, E and ν are the elastic modulus and Poisson's ratio, respectively.

The value of the angle α and the corresponding parameters M_e, which characterize loading mode mixity, for the specimen under consideration are shown in Table 1. Note that in the case of mode I crack (K_{II}=0) M_e=1, in the case of mode II crack (K_I=0) M_e=0.

$$M_e = \frac{2}{\pi} arctg\left(\frac{K_I}{K_{II}}\right) \quad (2)$$

Table 1. The mixity parameter and crack orientation

α, º	0	5	10,5	18	27
M_e	1	0,75	0,5	0,25	0

Determination of K_I, K_{II}, T_{xx}, T_{zz}

The evaluation of the stress intensity factor (SIF) is based on the well-known approach that includes the calculating of the SIF in a number of points (at varied *r*) using relations obtained from Eq. (1):

$$K_I = \sqrt{\frac{\pi r}{2}}\left(2\sigma_{xx}|_{\theta=0} - \sigma_{xx}|_{\theta=-\pi} - \sigma_{xx}|_{\theta=+\pi}\right), \quad K_{II} = \sqrt{\frac{\pi r}{8}}\left(\sigma_{xx}|_{\theta=-\pi} - \sigma_{xx}|_{\theta=+\pi}\right) \tag{3}$$

and extrapolation of the obtained values of the SIFs to the point r=0.

The computational procedure considers the nodes of the finite element mesh as the calculation points, but the nodes are located at some small distance from the crack front. To obtain the distribution of the SIF along the crack front, this procedure is used for a number of planes (x0y) orthogonal to the crack front. Their location is characterized by local coordinate *s* along the front and starts from the center of the crack front.

To assess the accuracy of the values of SIF, the comparison of magnitudes of the *J*-integral, calculated as contour integral (Eq. 4a) and based on the known relationship (Eq. 4b), has been done.

$$J = \int_{\Gamma}\left(W(x,y)dx - \sigma_{ij}n_j\frac{du_i}{dy}ds\right) \tag{4a}$$

$$J = \frac{1-\upsilon}{E}\left[K_I + K_{II} + (1+\upsilon)K_{III}\right] \tag{4b}$$

The calculation of the T_{xx}- and T_{zz}-stress is performed using the stresses in the points on the crack surface:

$$T_{xx} = \frac{1}{2}\left[\sigma_{xx}|_{\theta=-\pi} + \sigma_{xx}|_{\theta=+\pi}\right], \quad T_{zz} = \frac{1}{2}\left[\sigma_{zz}|_{\theta=-\pi} + \sigma_{zz}|_{\theta=+\pi}\right] \tag{5}$$

The determination of T_{xx} T_{zz} is similar to the procedure for SIF including extrapolation to the point r=0.

The special macros that carry out the automatic computation of the SIF, *J*-integral and T-stresses (on referred above relations) along the crack front are created in ANSYS environment.

Estimation of the accuracy of the numerical model and computational procedures is based on comparison of the calculated values of the SIF and the T-stresses with one presented in [7] for the CCCB-specimen in case of R=50 mm, b=0,8, l=1/3. Comparison of the results shows that there is good coincidence and only in some cases the relative difference is close to 10%.

Discussion of the results

The results of distribution of the SIF and the T-stress along the crack front for different mixed mode loading conditions are summarized in Fig. 2 and 3. To study the effect of specimen thickness on T_{zz}-stress, the compressive load was adjusted so that the T_{xx}-stress was remained approximately constant at variation of the specimen thickness (b= 0,2; 0,4; 0,8 and 1,6) at constant l=1/3 (for the corresponding values of mixity parameter M_e).

The increase of the specimen thickness is 8 times greatly reduces (in absolute value) the T_{zz}-stress (up to 75% at M_e=0,25), whereas the value of T_{xx} is virtually unchanged (Table 2). The predicted results are consistent with the data of numerical calculations [6]. Thus, magnitudes of the T_{zz}- stress have significant correlation with thickness of the specimen and allows taking into account the level of the out-of-constraint which should be included into assessment of the fracture toughness of full-scale structures.

Table 2. The effect of thickness on the SIF and T-stresses for M_e=0,25

b	K_I, MPa·m^{0,5}	K_{II}, MPa·m^{0,5}	T_{xx}, MPa	T_{zz}, MPa
0,2	0,105	0,252	-2,691	-0,309
0,4	0,104	0,255	-2,681	-0,206
0,8	0,099	0,254	-2,647	-0,121
1,6	0,087	0,246	-2,581	-0,079

To reflect mixed mode loading conditions, an effective SIF (K_{eff}) is introduced into consideration as follows

$$K_{eff} = \sqrt{K_I^2 + K_{II}^2} \qquad (6)$$

There are dependence of K_{eff} on T_{xx} and T_{zz} in the middle plane of the crack front (s=0) for varied parameters M_e at different thickness (b=0,2; 0,4; 0,8; 1,6) of the specimen and constant value of l=1/3 (Fig. 2 and 3).

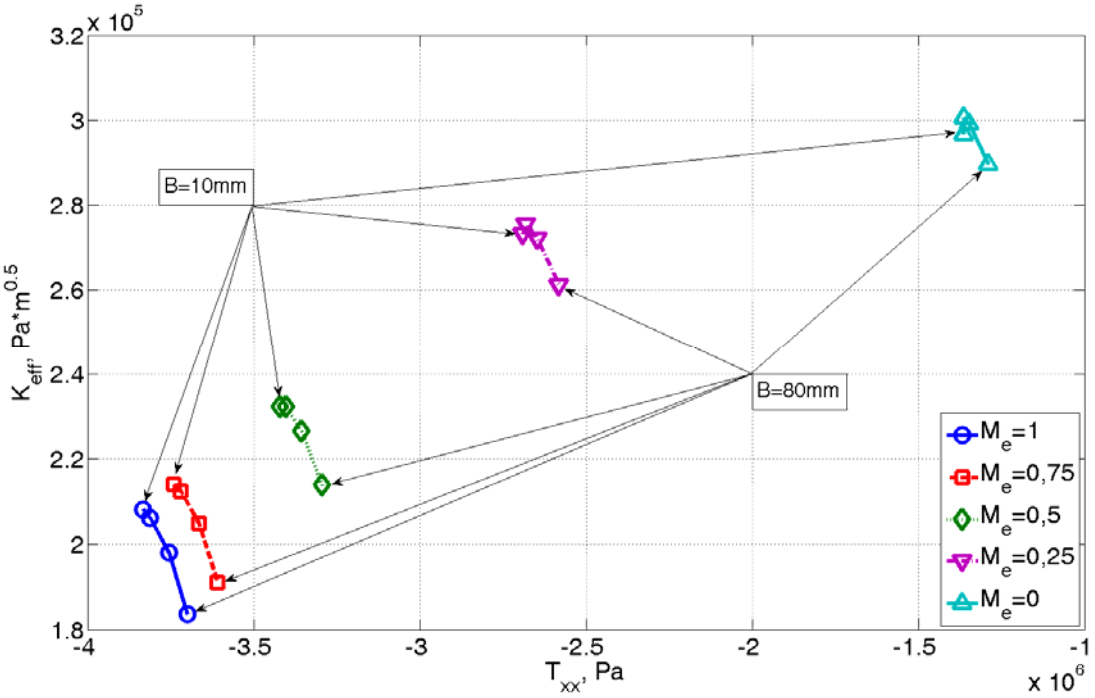

Figure 2. The effect of T_{xx}, M_e and thickness on K_{eff} at s=0

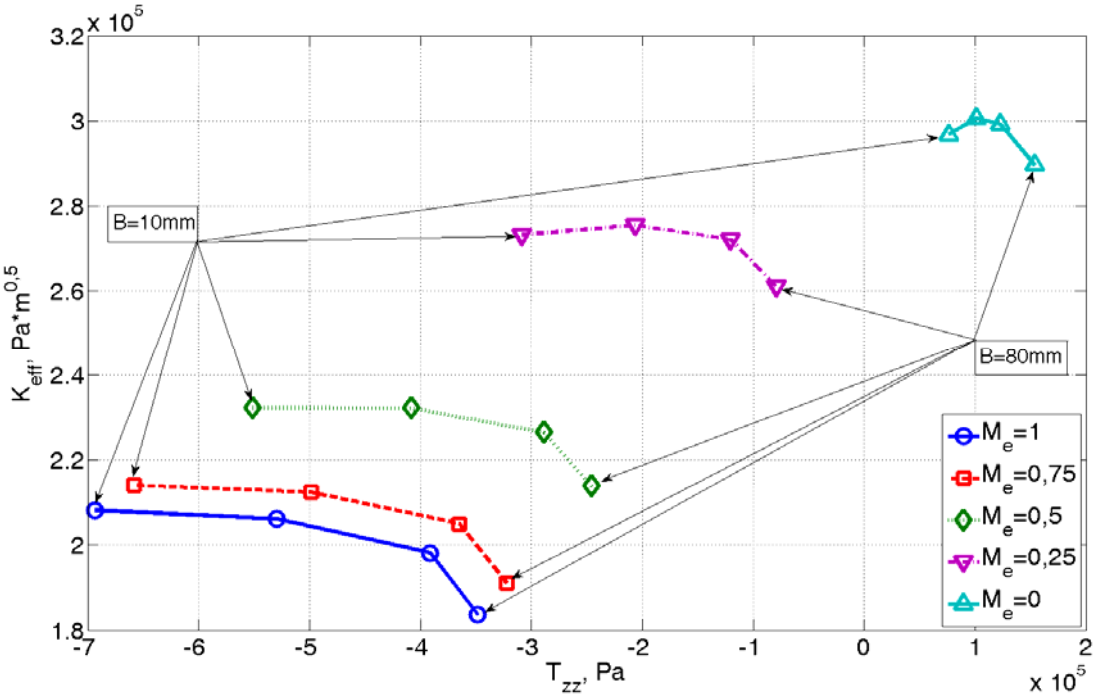

Figure 3. The effect of T_{zz}, M_e and thickness on K_{eff} at s=0 at s=0

Conclusions

The three-dimensional stress field ahead of the through-thickness crack under mixed mode (I+II) loading conditions is analyzed. The in-plane and out-of-plane constraint effect are discussed by means of the non-singular terms, namely, T_{xx}-stress and T_{zz}-stress, respectively. The distribution of the singular and non-singular terms along the crack front has been predicted. The significant effect of specimen thickness on the T_{zz}-stress in the middle plane of the crack front has been observed.

Abstract

The basic loading cases (Mode I, Mode II and Mode III) of cracks are generally defined by the near-field solutions for the stress distribution at the crack front. Cracks, whose stress near fields are symmetric due to geometry and/or loading of the structure, are called Mode I-cracks. In case of spatial loaded cracks the stress fields near the crack tip are unsymmetrical. The fracture mechanical treatment of such Mixed-Mode-loaded cracks is consequently more complicated as of pure Mode I-loaded cracks.

For experimental investigations of 3D-Mixed-Mode-loaded cracks the CTSR-specimen (Compact-Tension-Shear-Rotation-specimen) will be proposed. The CTSR-specimen with the corresponding loading device enables the generation of pure Mode I, pure Mode II, pure Mode III and several combinations of the three basic fracture modes.

In this paper the CTSR-specimen, the loading device and various experimental results for fracture and fatigue loading situations are illustrated. Furthermore these results will be compared with existing fracture criteria for 3D-Mixed-Mode-problems.

Keywords

3D-Mixed-Mode, fracture, fatigue, CTSR-specimen

1. Introduction

In real structures fracture processes are in many cases of a three dimensional character. Different defects, e.g. pre-cracks, which often exist in materials and structures, may experience complex loading conditions. Cracks under complex loading are subjected to a superposition of the three basic fracture modes I, II and III. In this case cracks tend to kink and/or twist, Fig. 1.

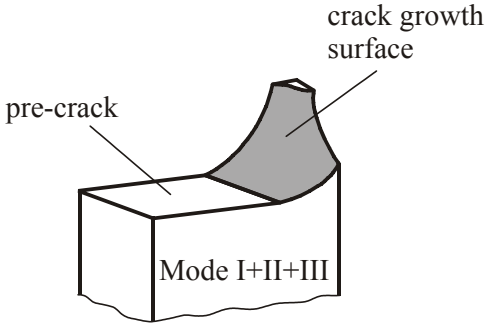

Figure 1. Crack screwing under combined loading

For static loading the stress field near the crack front (Eq. 1) here is not only defined by the stress intensity factor K_I, but also by K_{II} and K_{III}. In this case the calculation of a comparative stress intensity factor K_V is important (Eq. 2) [1].

$$\sigma_{ij} = \frac{1}{\sqrt{2\pi \cdot r}} \cdot \left[K_I \cdot f_{ij}^{I}(\varphi) + K_{II} \cdot f_{ij}^{II}(\varphi) + K_{III} \cdot f_{ij}^{III}(\varphi) \right] \tag{1}$$

$$K_V = \frac{K_I}{2} + \frac{1}{2} \cdot \sqrt{K_I^2 + 5{,}336 \cdot K_{II}^{\ 2} + 4 \cdot K_{III}^{\ 2}} \tag{2}$$

In this regard the fatigue crack growth then is governed by the cyclic stress intensity factors ΔK_I, ΔK_{II} and ΔK_{III} respectively the cyclic comparative stress intensity factor ΔK_V, which can be derived from Eq. 2:

$$\Delta K_V = \frac{\Delta K_I}{2} + \frac{1}{2} \cdot \sqrt{\Delta K_I^2 + 5{,}336 \cdot \Delta K_{II}^{\ 2} + 4 \cdot \Delta K_{III}^{\ 2}} \tag{3}$$

The *K*-concept for spatial Mixed-Mode-loading is based on the fact that unstable crack growth occurs, if the comparative stress intensity factor K_V reaches the fracture toughness value K_{IC} for Mode I. In case of fatigue crack growth the crack is propagable, if the cyclic comparative stress intensity factor ΔK_V for spatial Mixed-Mode-loading reaches or exceeds the threshold value ΔK_{th}. Both contexts can be illustrated clearly in a K_I-K_{II}-K_{III}-diagram, Fig. 2.
Unstable crack growth will occur, if a local loading condition along the crack front reaches a point on the fracture limit surface. Fatigue crack growth or stable crack growth develops, if points characterizing the local crack front loading conditions are lying between the threshold and the fracture limit surfaces.

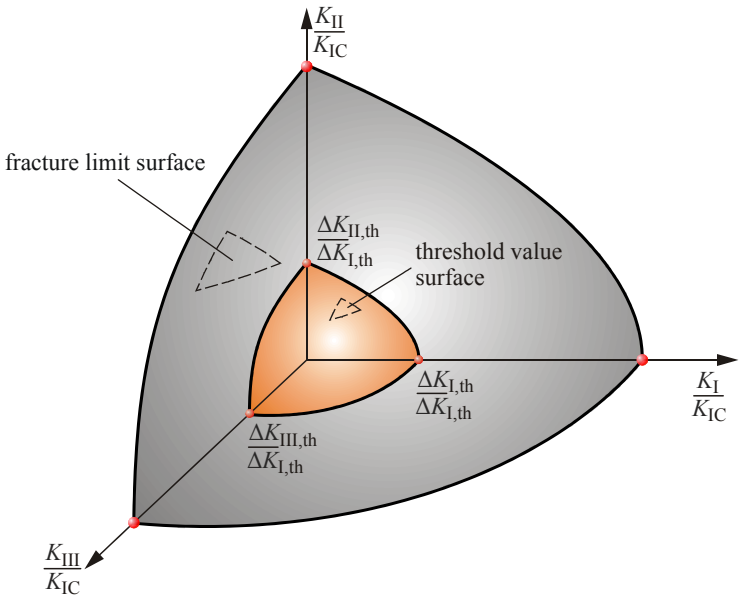

Figure 2. Fatigue crack growth limits at spatial Mixed-Mode-loading

Precisely because the fracture mechanical treatment of such three dimensional Mixed-Mode-loaded cracks is very complicated compared to pure Mode I-loaded cracks, the prediction of the above mentioned 3D-fracture-process is not yet well understood.
In addition there is a shortage of experimental investigations and findings regarding general spatial Mixed-Mode-fracture in order to compare the correlation between the experimental results and

existing fracture criteria for 3D-Mixed-Mode-loading conditions. Experimental investigations on spatial Mixed-Mode-loading are also necessary, in order to get a solid basis, on which, on the one hand, the existing fracture criteria for 3D-Mixed-Mode could be enhanced, on the other hand, new fracture criteria or hypotheses including the desired understanding could be established.

2. Mixed-Mode-criteria for 3D-loading conditions

For a complete prediction of crack growth behavior under combined loading not only the crack growth direction is required, but also the determination of comparative stress intensity factors, like K_V or ΔK_V, see Eq. 2 and Eq. 3.
Compared to characteristic fracture mechanical values, e.g. threshold value or fracture toughness value, conclusions could be drawn on crack growth behavior.
In this purpose some criteria for characterizing the crack growth under spatial Mixed-Mode-loading were established:

- Crack growth criterion by POOK [2-4]
- σ_1'-criterion by SCHÖLLMANN et al. [5, 6]
- Criterion by DHONDT [7]
- 3D-criterion by RICHARD [1]

A comparison of these criteria is given in e.g. [1].

3. Experiments on cracks under general loading

In order to understand the 3D-fracture-process completely not only further theoretical, but also experimental investigations have to be performed. Currently several types of specimens are available for experimental investigations of fatigue crack growth and fracture under various Mixed-Mode-loading conditions [8-17]. None of these specimens enables investigating the full range of all basic fracture modes or any combinations thereof.
But the AFM-specimen with the corresponding loading device and the so-called CTSR-specimen (Compact-Tension-Shear-Rotation-specimen) in combination with the special loading device fulfill these high requirements. Some of the experimental results of both specimen types are shown below.

3.1. Experiments on AFM-specimen

As already mentioned the AFM-specimen, developed by RICHARD, allows the investigation of crack problems under general loading conditions by using a simple uniaxial testing machine [18]. In the past experiments under static load were performed in order to determine the fracture limit surface and the crack deflection angles φ_0 and ψ_0 [19], see Fig. 3.
For fatigue tests this loading device is less suitable, due to its high weight and deformation. Only low test frequency, which leads to high test duration, can be realised for fatigue experiments. Making use of this background the CTSR-specimen (Fig. 4a) with the corresponding loading device (Fig. 4b) was developed.

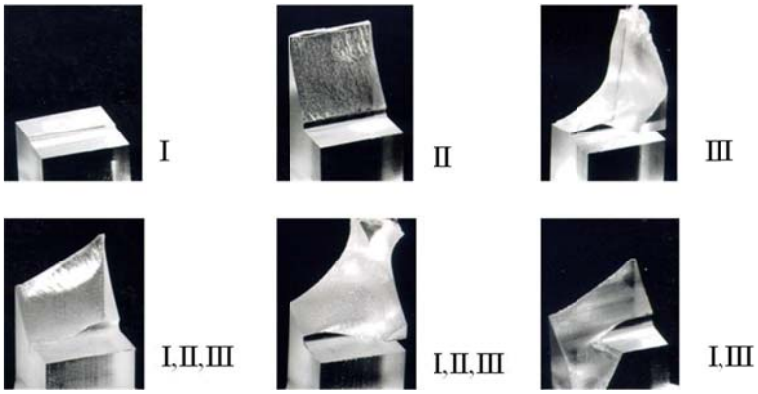

Figure 3. Crack growth direction under different loading conditions

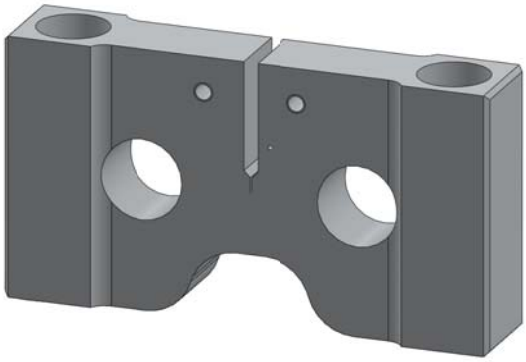
3.2. Experiments on CTSR-specimen

This concept was developed especially for investigating Mixed-Mode-loaded cracks under cyclic loading. The loading device is designed in a way, with which any ratio of Mode I to Mode II/Mode III can be generated by the adjustment of the loading angle α (see Fig. 5). Furthermore, the ratio of Mode II- or Mode III-load can be set by rotating the so-called turret inside the loading device (see Fig. 6).

a)



b)

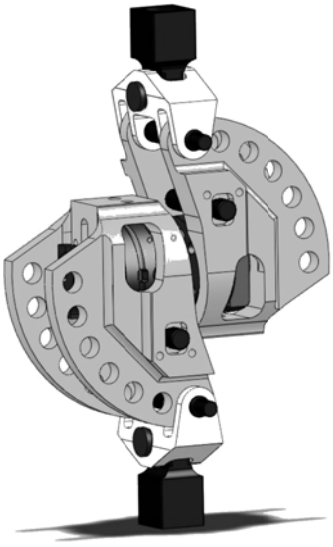


Figure 4. a) CTSR-specimen
b) Loading device for CTSR-specimen

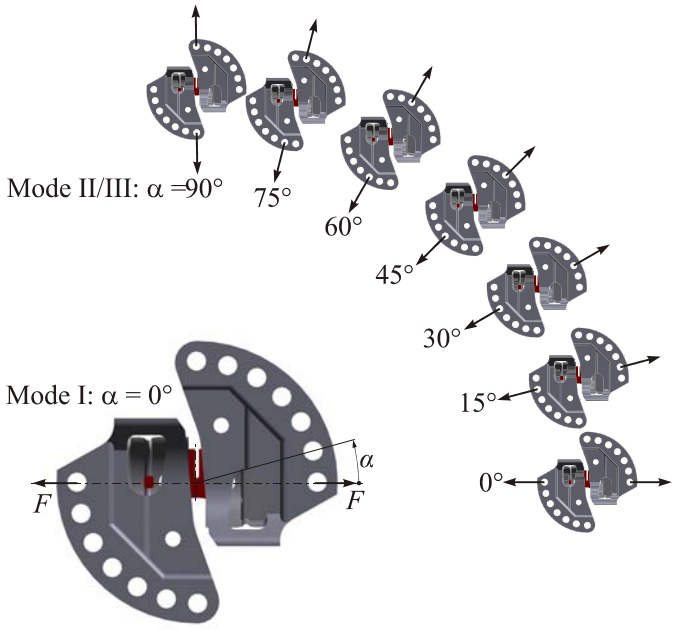

Figure 5. Setting of the ratio of Mode I to Mode II/Mode III

The superposition of Mode I, Mode II and Mode III takes place by the adjustment of both angles α and γ. Thereby the load line of action always passes through the center of the specimen.

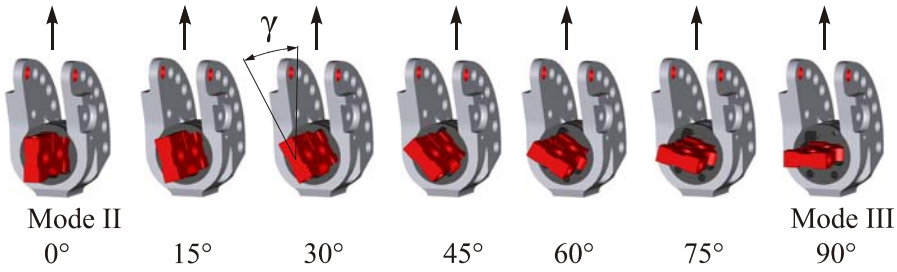

Figure 6. Setting of the ratio of Mode II- or Mode III-load

In this paper some experimental results on CTSR-specimen will be presented. On the one hand experiments on PMMA have been performed, in order to determine the fracture limit surface (cf. Fig. 2) for this material. On the other hand fatigue tests were performed on an EN AW-7075-T651 aluminium alloy, in order to identify the threshold value surface. The results of both experiment types are illustrated and discussed in the next chapter.

4. Results of experimental investigations

Figure 7 illustrates the measured fracture toughness values for PMMA material under several Mixed-Mode-loading combinations.

The fracture toughness values K_{IIIC} for pure Mode III-loading, measured on CTSR-specimen, exhibits a significant variation in comparison with the 3D-criterion by RICHARD. The resulting values for Mode III are around factor 2.7 above the hypothesis. Similar significant variations have already been observed on other specimen, e.g. [15]. Furthermore it is noticeable, that the difference between measured K_C values and the hypothesis decreases with decreasing Mode III-ratio. The

values are very close to the criterion as soon as there is no Mode III-loading. The same trend can be observed by the comparison with other criteria, mentioned in this paper. All these criteria are conservative.

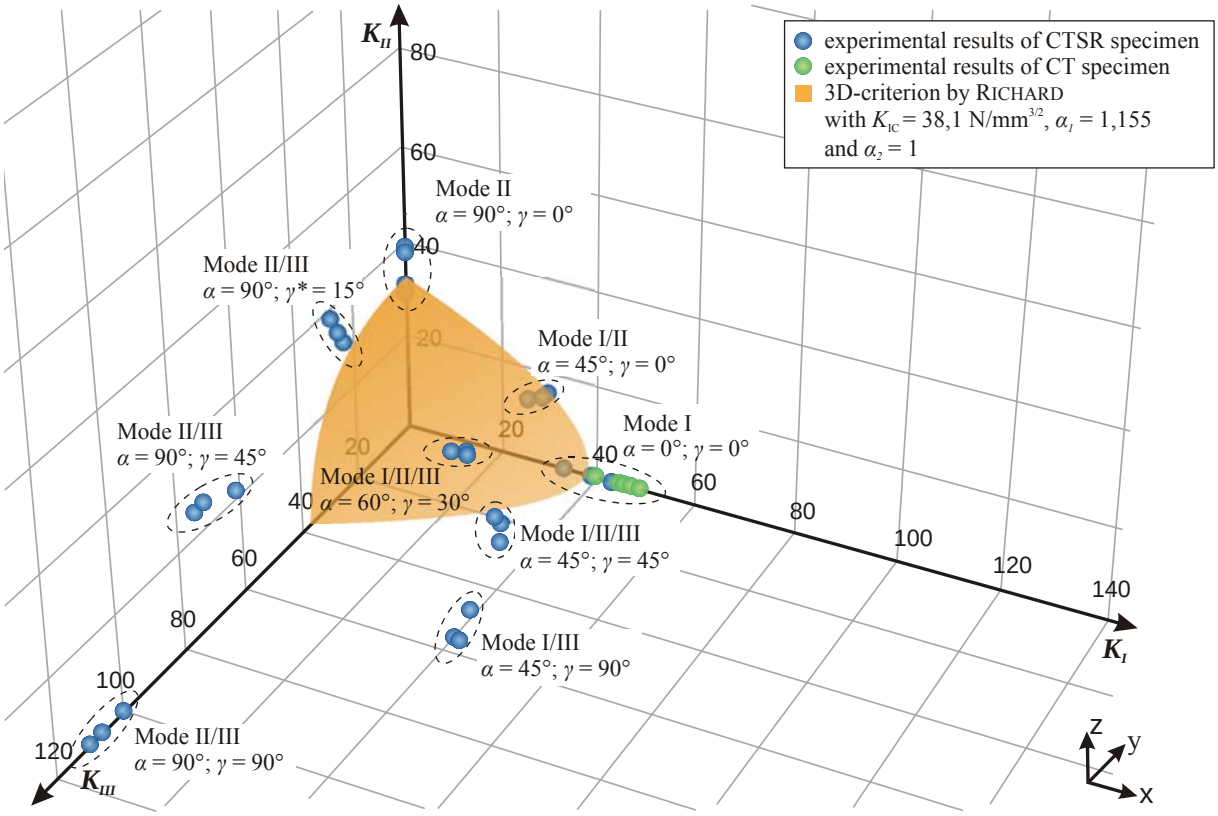

Figure 7. Comparison of experimental results with 3D-criterion by Richard

Due to these results and the significant difference to the hypothesis, an approximation of the 3D-criterion by Richard on the fracture toughness values for PMMA material is proposed. In Figure 8 the approximation of the criterion by RICHARD is shown. Here the α_2 parameter was changed to 0.36. This approximation is still conservative, but agrees very well with the experimental results.

In addition, fatigue tests on an EN AW-7075-T651 aluminium alloy were performed. The experimentally measured threshold values for different Mixed-Mode-loading conditions are pictured in Figure 9. Compared to the threshold value surface by RICHARD the experimentally determined threshold values depict also a significant variation under pure Mode III-loading. Here the $\Delta K_{III,th}$ values are around factor 2.2 above the hypothesis.

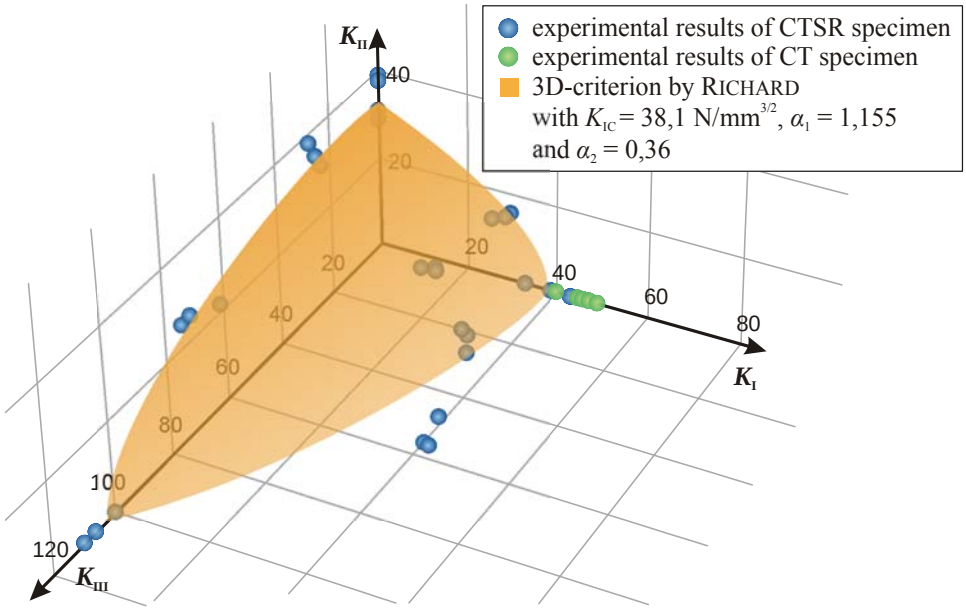

Figure 8. Approximation of the 3D-criterion by Richard on experimental results

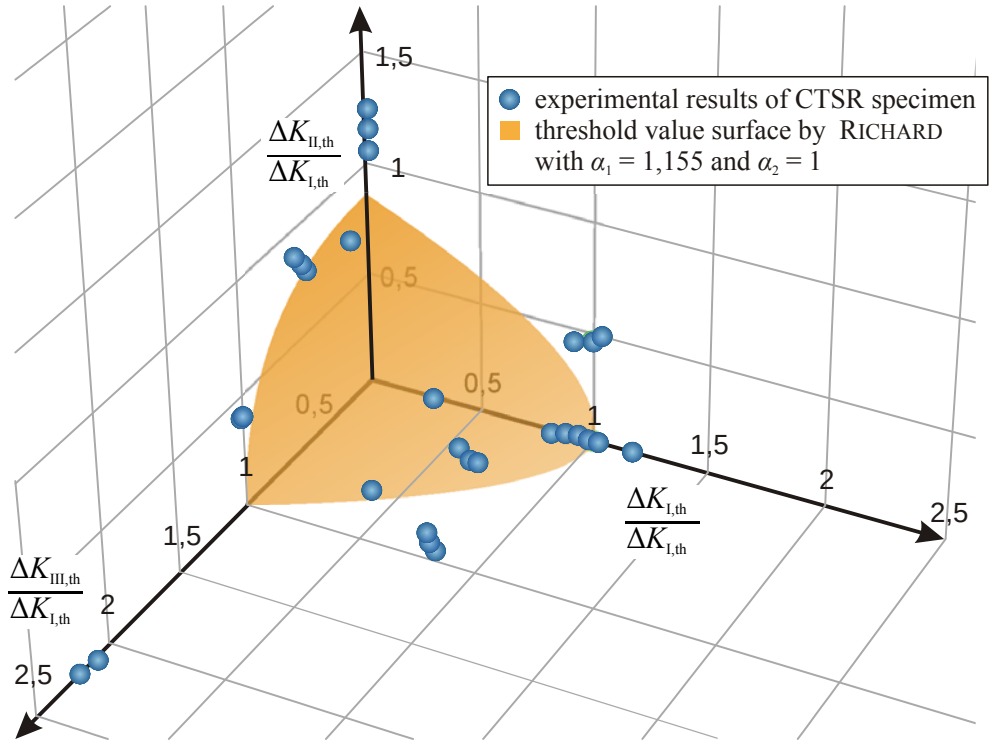

Figure 9. Threshold values for several Mixed-Mode-loading conditions

Moreover, for a complete description of crack growth behavior under general Mixed-Mode-loading the crack kinking and twisting angles were established by using an optical 3D-scanner. In order to prove the reliability of the criteria the determined crack deflection angles φ_0 and ψ_0 were compared with the predictions of the criteria. The comparison of the crack kinking angle φ_0 is shown in barycentric coordinates in Figure 10.

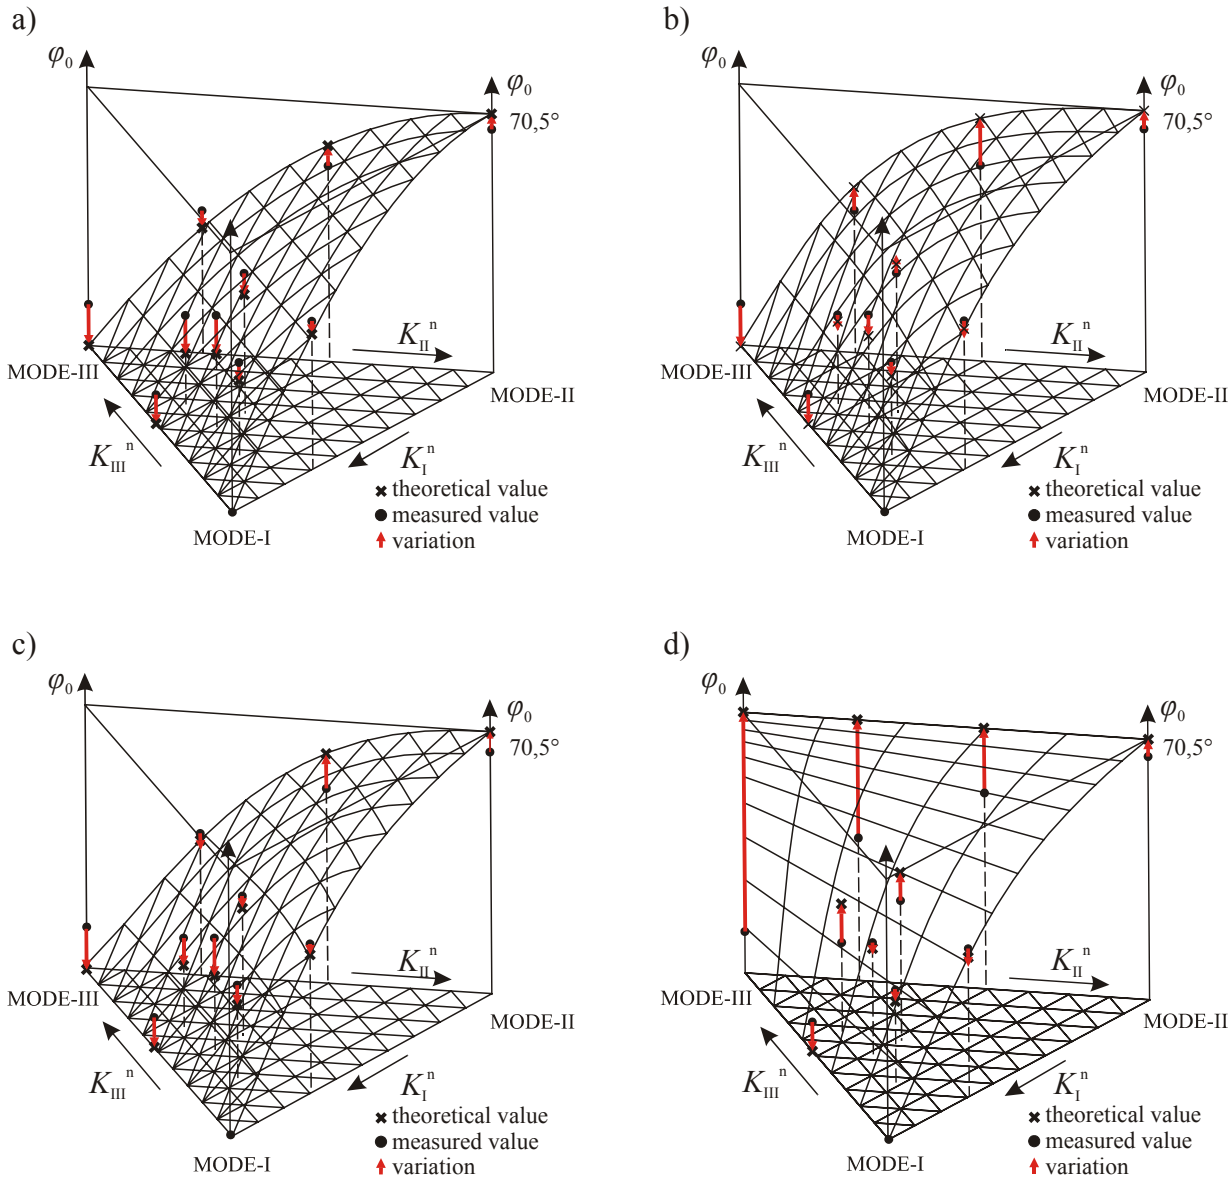

Figure 10. a) Comparison of kinking angle with criterion by RICHARD
b) Comparison of kinking angle with criterion by SCHÖLLMANN et al.
c) Comparison of kinking angle with criterion by DHONDT
d) Comparison of kinking angle with criterion by POOK

The measured crack kinking angle φ_0 coincides very well with the predictions of the hypotheses by RICHARD as well as by SCHÖLLMANN et al. and by DHONDT (see Fig. 10a-c). The maximal deviation here one finds at pure Mode III-loading. In Comparison with the predictions of the criterion by POOK the real crack kinking angle differs considerably from its predictions as soon as Mode III-loading part occurs (Fig. 10d).
The measurement results of the crack twisting angle ψ_0 exhibit also a very well agreement with the criterion by RICHARD as well as by SCHÖLLMANN et al. (Fig. 11a, 11b). The predictions of the criteria by DHONDT and by POOK show the greatest deviations from the real crack twisting angle (Fig. 11c, 11d).

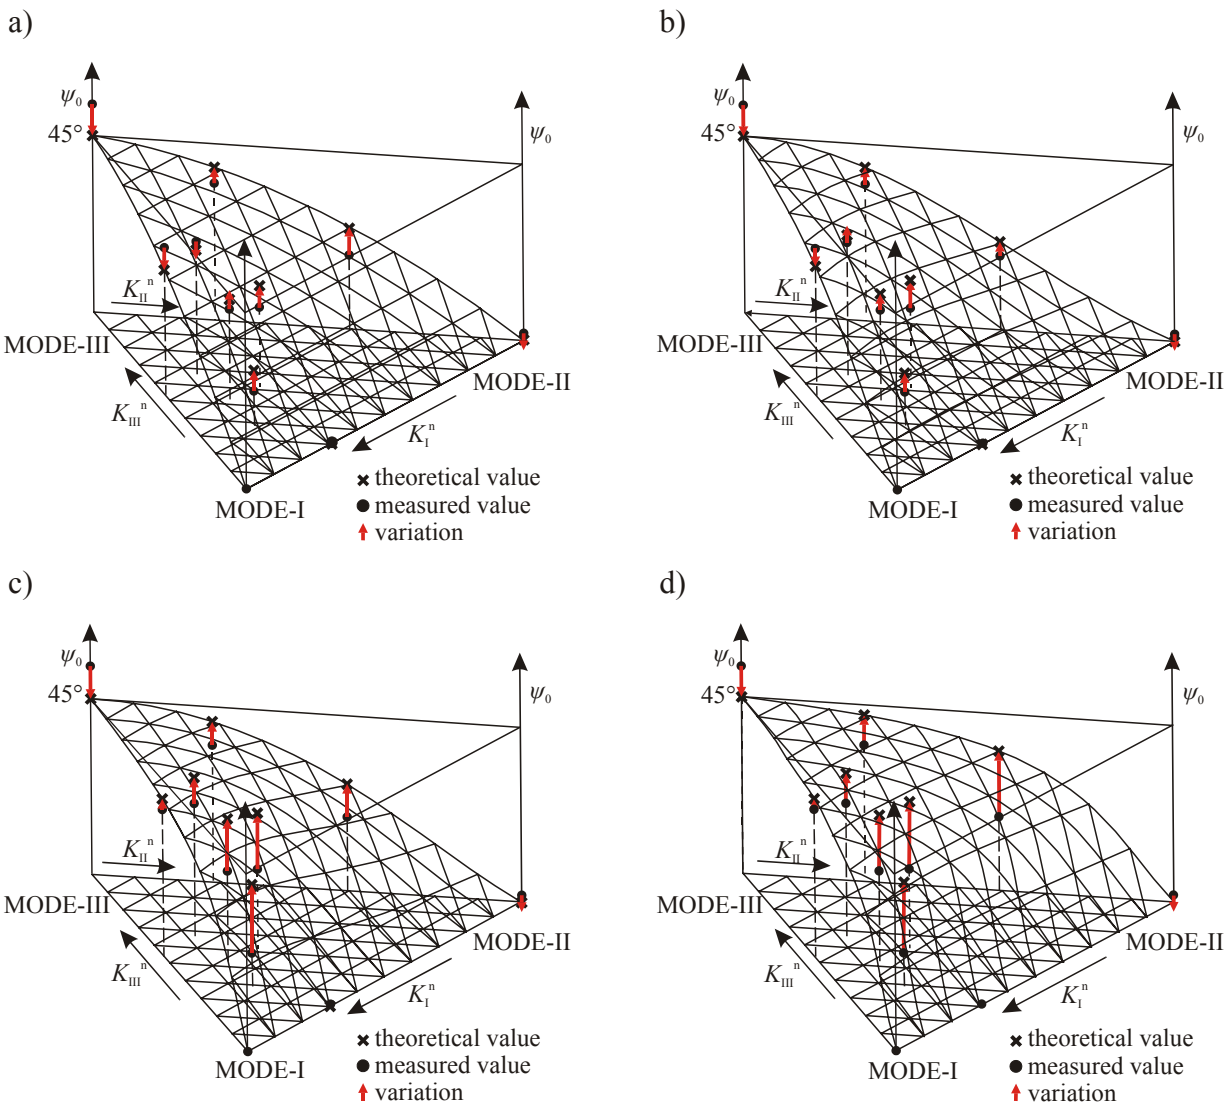

Figure 11. a) Comparison of twisting angle with criterion by RICHARD
b) Comparison of twisting angle with criterion by SCHÖLLMANN et al.
c) Comparison of twisting angle with criterion by DHONDT
d) Comparison of twisting angle with criterion by POOK

5. Conclusion

In this paper the suitability for experimental investigations under 3D-Mixed-Mode-loading conditions of the CTSR-specimen in combination with its loading device was presented.
The experimental results show obviously higher threshold and fracture toughness values for high Mode III-loading ratios than by criteria predicted. The most exactly predictions indicate the criteria by RICHARD and by SCHÖLLMANN et al.
These criteria give the best predictions regarding the crack kinking and twisting angle. Due to their exactness of predictions, they should be implemented in numerical calculation programs.

Abstract
The structural integrity of cracked mechanical components can be assessed using the fracture toughness material property. The fracture toughness of a particular component is often dependent upon the component geometry as well as the nature of loading (e.g. uniaxial or biaxial loading). This dependence is interpreted as the constraint effect in fracture. Various methods have been developed to investigate the constraint effect, including the two parameter J-A_2 method. The J-A_2 method is a more accurate representation of the stress fields near the crack tip, as additional terms from the well-known HRR series solution are included. The current study applies the J-A_2 method to fracture toughness data of cracked cruciform specimens subjected to uniaxial and biaxial stresses. The J-A_2 results of the cruciform specimens are compared to those of other plane strain specimens described by ASTM standards, including three point bend and compact tension, to determine if loss of constraint exists. Finite element models of each specimen were analyzed to determine the A_2 parameter used to quantify the level of constraint based on geometry and loading. The results reveal loss of constraint for shallow cracked specimens when compared to deep cracked specimens, and also that uniaxial loading results in loss of constraint when compared to biaxial loaded specimens. In summary, the J-A_2 method appears to be a viable tool to predict failure including the consideration of the constraint effect.

Keywords fracture, constraint, biaxial, cruciform

1. Introduction

A material's fracture toughness is used to determine the structural integrity of mechanical components containing cracks. Materials used in nuclear reactor pressure vessels (RPV), including A533B and A508, are of particular interest. RPVs can be subjected to conditions close to equibiaxial loading during extreme temperature gradients experienced during pressurized thermal shock (PTS).

Based on such biaxial loading, it is possible that traditional methods used to determine material properties may not provide accurate results. Widely used industry standards [1, 2] used to calculate material properties related to fracture toughness utilize specimens subjected to uniaxial loading, e.g., three point bend (3PB) and compact tension (CT) specimens. Therefore, the question arises regarding whether or not a "biaxial effect" exists for loading conditions similar to that of RPVs.

Much research has been conducted in recent years to determine how component geometry and applied loading affect fracture toughness. The industry standards mentioned previously typically use deep cracked (high constraint) specimens to determine the fracture toughness. But it is known that shallow cracked (low constraint) specimens exhibit higher fracture toughness, resulting in a "constraint effect" in fracture.

The current study uses a two-parameter method to quantify the constraint of a variety of specimens and also to predict failure of specimens of biaxial loads. The J-A_2 method has been applied to experimental data published by the Fraunhofer Institute for Mechanics. Fraunhofer conducted fracture toughness testing on 3PB and cruciform specimens, with the cruciform specimens subjected to biaxial loads. Such experimental data can be used to determine if the J-A_2 method can be used as a tool to i) predict failure of mechanical components of different constraints and ii) quantify the constraint due to loading and geometry.

2. J-A_2 Two Parameter Method

The stress distribution ahead of the crack tip described by the well-known HRR solution [3, 4] is

$$\sigma_{ij} = \sigma_0 \left(\frac{J}{\alpha \varepsilon_0 \sigma_0 I_n r} \right)^{1/n+1} \tilde{\sigma}_{ij}(\theta, n), \qquad (1)$$

where σ_0 is a reference (or yield) stress, $\varepsilon_0 = \sigma_0 / E$ is a reference (or yield) strain, E is Young's modulus, α is a material constant, and n is the strain-hardening exponent. The integration constant I_n and the dimensionless angular functions of stresses $\tilde{\sigma}_{ij}$ depend on the strain-hardening exponent. Equation 1 is the first term of a series solution. Further, the HRR solution described by Equation 1 is defined by only one parameter, the J-integral, which is related to the energy release rate around the crack tip during loading. As shown in Figure 1, the stress field as described by the HRR solution is valid as $r \to 0$. In theory, the stress approaching the crack tip increases asymptotically to infinity, meaning a component subjected to such stress would fail under very small loads.

In practice, this is typically not the case, especially with materials exhibiting elastic-plastic behavior. The HRR solution does not consider large deformations or blunting of the crack and is only valid for small strains as $r \to 0$. An example of the actual stress field near the crack tip is also shown in Figure 1. Ritchie, et al. [5] determined that cleavage fracture actually occurs at some critical distance (r_c) when the stress at that location exceeds the critical stress (σ_c) and this failure criterion is often referred to as the RKR model.

Clearly, the single term HRR solution can overestimate the actual stress ahead of the crack tip. As a result, various procedures have been developed to include additional terms from the series expansion. Yang et al. [6, 7] and Chao et al. [8] developed an asymptotic crack-tip solution using three terms of the series solution from which the HRR solution is derived. The *J-A_2* procedure uses two parameters to better define the stress ahead of the crack tip. The *J*-integral is representative of the magnitude of the applied loading, while the A_2 term is used to describe the constraint at the crack tip based on the loading and specimen geometry.

The procedure begins by using the Ramberg-Osgood power-law relationship for a strain-hardening material for a Mode I crack under plane strain conditions. The Ramberg-Osgood equation relating uniaxial strain ε to the uniaxial stress σ in tension is

$$\frac{\varepsilon}{\varepsilon_0} = \frac{\sigma}{\sigma_0} + \alpha \left(\frac{\sigma}{\sigma_0} \right)^n . \qquad (2)$$

Eq. 2 can be rewritten in general terms by applying the J_2 deformation theory of plasticity

$$\frac{\varepsilon_{ij}}{\varepsilon_0} = (1+\nu)\frac{\sigma_{ij}}{\sigma_0} - \nu\frac{\sigma_{kk}}{\sigma_0}\delta_{ij} + \frac{3}{2}\alpha\left(\frac{\sigma_e}{\sigma_0}\right)^{n-1}\frac{s_{ij}}{\sigma_0}, \qquad (3)$$

where ν is the Poisson's ratio, δ_{ij} is the Kronecker delta, s_{ij} is the deviatoric stress, and σ_e is the von Mises effective stress defined as $\sigma_e = \sqrt{3\,s_{ij}s_{ij}/2}$. The asymptotic stress field can then be expressed as

$$\frac{\sigma_{ij}}{\sigma_0} = A_1\left[\left(\frac{r}{L}\right)^{s_1}\tilde{\sigma}_{ij}^{(1)}(\theta,n) + A_2\left(\frac{r}{L}\right)^{s_2}\tilde{\sigma}_{ij}^{(2)}(\theta,n) + A_2^{\,2}\left(\frac{r}{L}\right)^{s_3}\tilde{\sigma}_{ij}^{(3)}(\theta,n)\right], \qquad (4)$$

The angular stress functions and the stress power exponents are functions solely of the hardening exponent and are independent of the applied load and any material properties. The characteristic length, L, in Equation 4 is typically assigned one of the primary dimensions of the specimen under investigation; possibilities include the crack length, the specimen width, the specimen thickness, or even unity. For the current study, L = 1 mm for all cases. The parameters A_1 and s_1 from Equation 4 are related to the HRR solution (Eq. 1) by

$$A_1 = \left(\frac{J}{\alpha\varepsilon_0\sigma_0 I_n L}\right)^{-s_1}, \quad s_1 = -\frac{1}{n+1}, \qquad (5)$$

Comparing Eq. 4 and 1, it can be seen that the first term of the two-parameter equation (Eq. 4) is the same as the HRR solution (Eq. 1). Further, the additional stress power exponents can be calculated using $s_3 = 2s_2 - s_1$ for $n \geq 3$. Thus, the final stress power exponent, s_2, can be calculated numerically.

An apparent application of the J-A_2 method is to use the two parameters to predict failure of flawed components. Chao et al. [9] described the development of Material Failure Curves by plotting J-integral values versus the absolute value of A_2 (J vs. $|A_2|$), as A_2 is always a negative value. Using a modified version of Equation 4,

$$\frac{\sigma_c}{\sigma_0} = A_1\left[\left(\frac{r_c}{L}\right)^{s_1}\tilde{\sigma}_{ij}^{(1)}(\theta,n) + A_2\left(\frac{r_c}{L}\right)^{s_2}\tilde{\sigma}_{ij}^{(2)}(\theta,n) + A_2^{\,2}\left(\frac{r_c}{L}\right)^{s_3}\tilde{\sigma}_{ij}^{(3)}(\theta,n)\right], \qquad (6)$$

the aforementioned critical stress (σ_c) and corresponding critical radial distance (r_c) from the RKR model are substituted and J and A_2 can be determined and plotted. According to the RKR model, the location where failure initiates, r_c, occurs in the range of 2-4 grain diameters ahead of the crack. This equates to 0.12mm to 0.24mm for A533B, or $1 < r/(J/\sigma_0) < 5$ where $r/(J/\sigma_0)$ is the normalized radial distance ahead of the crack. Once σ_c and r_c have been determined, the critical values can be used in Equation 6 to plot a Material Failure Curve as shown in the left portion of Fig. 1.

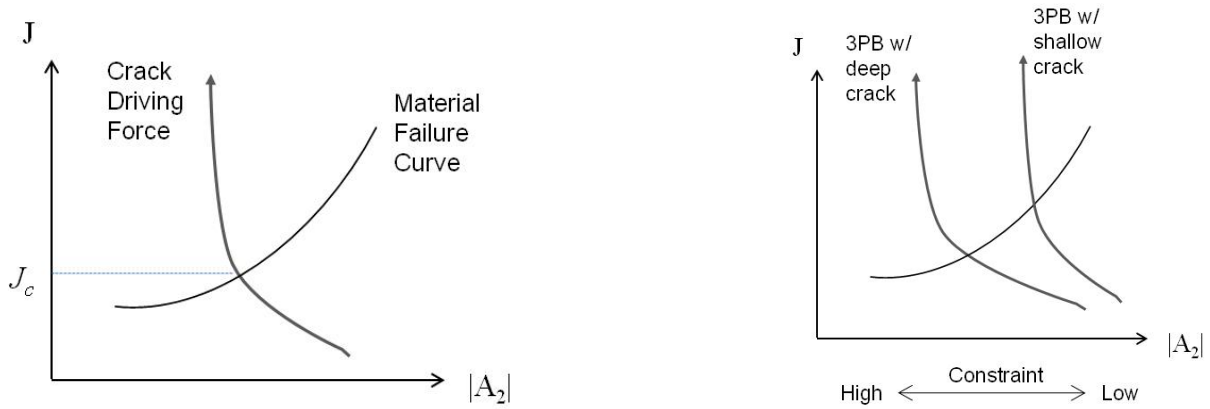

Figure 1. J vs. $|A_2|$ with Material Failure Curve and Crack Driving Force curve (left) and comparison of constraint levels (right)

The J vs. $|A_2|$ plot can be used to predict failure of components when the Crack Driving Force curve is added. The Crack Driving Force curve is a plot of multiple (J, $|A_2|$) pairs at any applied load, not just at the critical values. The intersection of the Material Failure Curve and the Crack Driving Force defines the critical J value (J_c) at which cleavage fracture will occur and can be used to predict the load at failure.

The J vs. $|A_2|$ plot can also be used to determine the constraint effect of specimens with different geometries and loading configurations. An example is shown in right diagram of Fig. 1. Crack Driving Force curves for 3PB specimens are shown on the J vs. $|A_2|$ plot. Specimens with deep cracks are high constraint specimens and typically exhibit lower fracture toughness than shallow cracked specimens. It should be noted that constraint is a relative term. A_2 provides a quantitative measure of constraint, although the magnitude of A_2 is of little value. The A_2 value of one specimen is simply compared to the A_2 value of other specimens to determine if there exists "loss of constraint" or, rather, an increase in fracture toughness.

3. Fraunhofer Experimental Data

3.1. Background

A set of published results to which the J-A_2 method could be applied were found in journal articles [10, 11] published by a team of researchers from the Fraunhofer Institute for Mechanics of Materials. These specimens and results presented in the article will be hereinafter referred to as the "Fraunhofer" specimens and results.

The goal of the Fraunhofer research was to determine the fracture toughness of a variety of cracked specimens. Specimens were tested over a wide range of lower shelf temperatures. Many trials with 3PB, C(T), and cruciform specimens were conducted at -85°C. The Fraunhofer cruciform specimen is shown below in Fig. 2. The cross sectional area of the small-scale cruciform arms

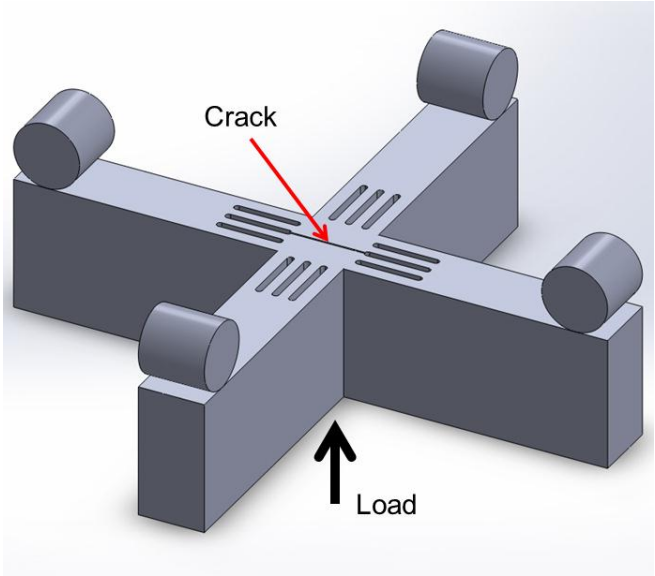

Figure 2. Fraunhofer cruciform specimen with five-point bending to simulate biaxial loading of crack

is only 10 mm x 20 mm (B = 10 mm and W = 20 mm). The distance between the roller supports in the five point bending test rig is 80 mm, while the overall dimensions of the specimen are 90 mm x 90 mm.

Also, smaller scale 3PB specimens are incorporated as well. The Fraunhofer study used pre-cracked Charpy test specimens rather than standard 3PB specimens specified in ASTM E1921 [2]. The 3PB specimens contained shallow cracks (a/W = 0.18). Standard 1T-C(T) specimens (a/W = 0.5) were also tested. Testing of such small specimens is completed in an effort to determine if the fracture toughness results are applicable to much larger scale components, including reactor pressure vessels.

3.2. Material Properties

The Fraunhofer specimens were machined from a section of A508 Class 2 steel, commonly used to fabricate reactor pressure vessels. Material properties for A508 were obtained from another recent study conducted by Scibetta et al. [12]. The researchers provided the following equation to correct the yield stress (in MPa) based on temperature (T, in degrees Celsius)

$$\sigma_{YS} = 398 + 45.2\exp(-0.01413\,T) \tag{7}$$

In addition, Scibetta et al. [12] also presented a temperature correction for E (in GPa) again where the temperature is in degrees Celsius,

$$E = 207 - 0.06\,T \tag{8}$$

Thus, at -85°C, the yield stress and Young's modulus were determined to be 550 MPa and 212.1 GPa, respectively. Poisson's ratio was assumed to be 0.3 as typical with many steels.

The Fraunhofer study [11] provided true stress vs. true strain curves for the material. A curve fitting procedure was used to determine the strain hardening exponent necessary for the elastic-plastic finite element analysis using the Ramberg-Osgood equation. The strain hardening exponent was determined to be n = 8. The angular stress functions and the stress power exponents

necessary to solve the two-parameter J-A_2 equation (Eq. 4) are provided in tables developed by Chao et al. [13].

3.3. Finite Element Analysis Models

The FEA models developed using Abaqus [14] for the 3PB and 1T C(T) specimens are shown below in Fig. 3.

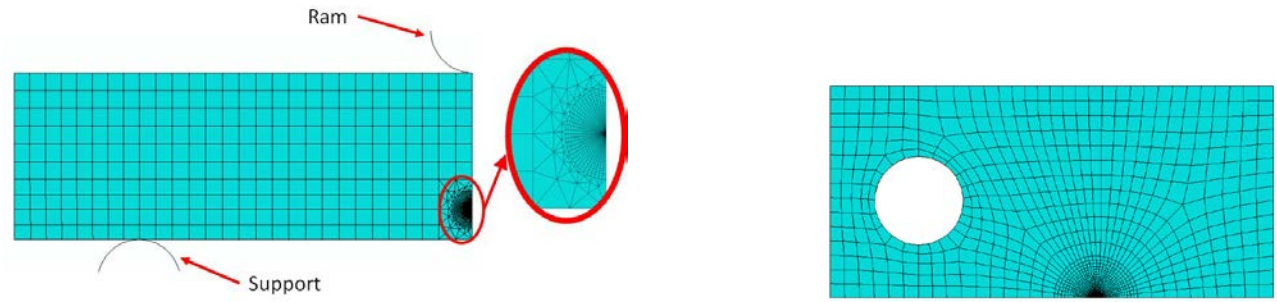

Figure 3. FEA mesh for Fraunhofer 3PB specimen (left) and 1T C(T) specimen (right).

Both meshes are composed mostly of eight node CPE8R quadratic plane strain elements, The extremely fine mesh around the crack tip includes elements with width of 0.001mm necessary to capture A_2 within the range of $1 < r/(J/\sigma_0) < 5$. The innermost ring of elements at the crack tip is comprised of eight node wedge elements with collapsed nodes at the tip to allow for blunting of the crack and large scale deformation.

The Fraunhofer cruciform is a small scale specimen. The overall dimensions are 90 mm x 90 mm. The specimen is machined with a shallow crack such that the crack depth ratio a/W = 0.08. The cruciform is tested in a five point bending configuration. In addition, two of the roller supports can be adjusted to allow for varying biaxiality ratios. However, only 1:1 biaxial loading was tested at the -85°C test temperature.

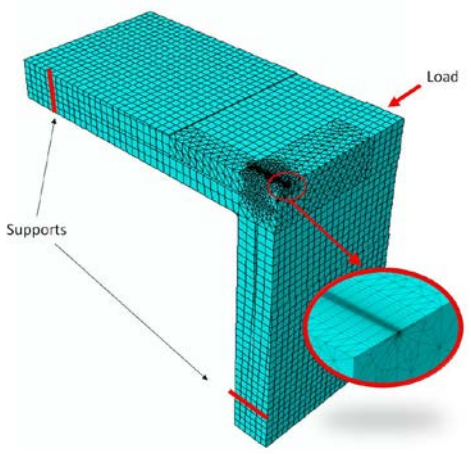

Figure 4. FEA mesh for Fraunhofer cruciform specimen

The cruciform specimen mesh shown in Fig. 4 contains 20,174 elements composed mostly of 20 node quadratic hexahedral C3D20R 3-D stress elements with a focused mesh around the crack tip. Elements in the focused mesh region are as small as 0.001 mm in order to capture the stress field in the region of cleavage fracture as defined by the RKR model. The average fracture toughness (J_c)

of the Fraunhofer biaxial cruciform specimens was determined to be 85.7 N/mm.

3.4. J-A_2 Method Applied to Fraunhofer Test Data

Loads were applied to the 3PB and C(T) FEA models until the J_c values presented in Table 1 were achieved. The stress (obtained from FEA output) perpendicular (i.e., $\theta = 0°$) to the crack front at a node ahead of the crack tip, along with radial position, r, of the node and J_c, can be substituted into Equation 4 to solve the quadratic equation for A_2 at each node. Again, according to the RKR model, fracture typically initiates within the range $1 < r/(J/\sigma_0) < 5$. Thus, A_2 was calculated at each node within this range and the average was tabulated. For this study, the average was actually taken approximately for the range $2 < r/(J/\sigma_0) < 5$ i.e., the first few nodes adjacent to the crack tip were neglected for the average A_2 calculation. The A_2 results are also summarized in Table 2 in the form of (J_c, A_2) pairs.

Table 1. (J_c, A_2) pairs for the 3PB and C(T) specimens

J_c is in N/mm, A_2 is unitless	
	-85°C
3PB shallow (a/W = 0.18)	(54.2, -0.392)
1T-C(T) (a/W = 0.5)	(13.1, -0.260)

Next, using the (J_c, A_2) pair for the 3PB specimen, and substituting the published value of σ_c = 1830 MPa [15, 16], Equation 6 can be used to solve for the fracture initiation location r_c, which is 0.104 mm for both specimens, a value which is in agreement with other published results. A study conducted by Wang et al. [17] focused on the determination of the fracture initiation location and they determined that, for temperatures in this range, r_c lies within the range of 0.1 mm to 0.25 mm. Additional evidence of an appropriate range of r_c values was found in [18], in which dozens of data points for the similar A508 material yielded 0.05 mm < r_c < 0.25 mm. Substituting r_c and σ_c into Equation 5, the Material Failure Curve can be plotted.

The FEA models are processed with incremental loads to determine a range of J values above and below J_c such that the Crack Driving Force curves for each specimen can be determined. The Material Failure Curve and Crack Driving Force curves are then plotted on the same J vs. $|A_2|$ plot. As the loading increases, the applied J increases from zero. And, therefore, referring to Figure 2, points on the plot above and left of the Material Failure Curve indicate fracture has occurred. Crack Driving Force curves, as shown in Figure 3, are indicative of each specimen's constraint and can be used to determine if the desirable "loss of constraint" occurs, i.e., fracture toughness increases due to geometry and/or loading conditions. The J vs. $|A_2|$ plot for the specimens is shown in Fig. 5. The triangles are actual data points obtained from the Fraunhofer study.

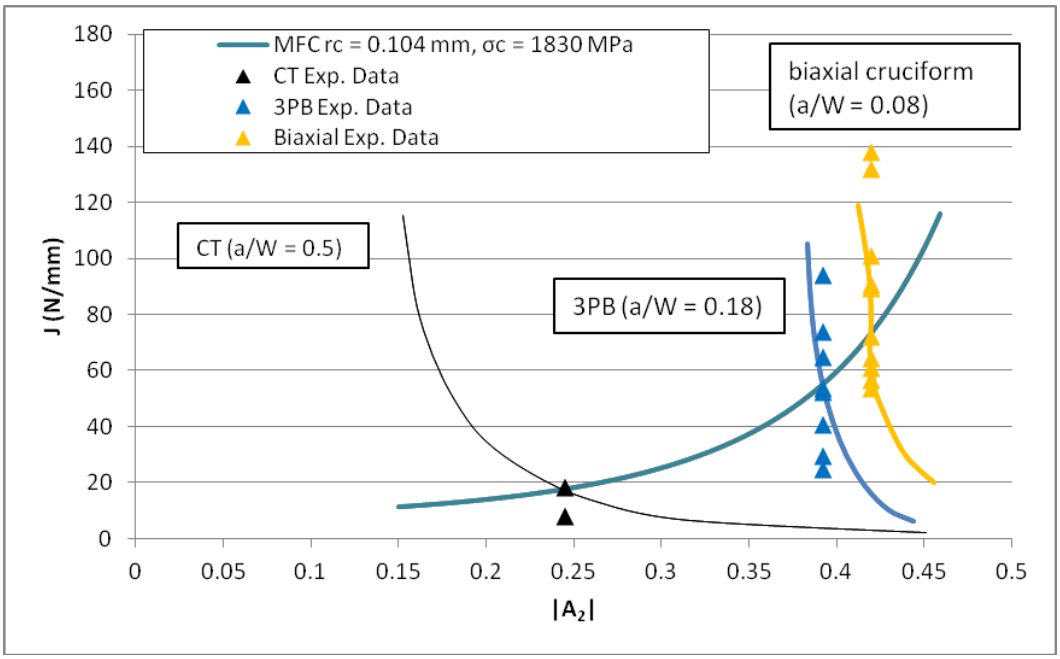

Figure 5. Material Failure Curve and Crack Driving Force curves for the Fraunhofer specimens (A508 material) at -85°C

4. Discussion of Results

The results presented in Fig. 5 reveal that the two parameter J-A_2 method does have the potential to i) predict failure, and ii) quantify constraint. The 3PB and biaxial cruciform specimens reveal significant loss of constraint when compared to the high constraint C(T) specimen. The biaxial cruciform exhibits higher fracture toughness (lower constraint) than the 3PB specimen. This may be attributed to the fact that the crack depth of the biaxial cruciform (a/W = 0.08) is more than twice as shallow as the 3PB specimen (a/W = 0.18), which may have overshadowed the biaxial effect. This supports the findings of Lidbury et al. [19] of a shallow crack effect.

Fig. 5 also shows the experimental fracture toughness data [10, 11] added to the Crack Driving Force curves in the form of the triangular symbols. The experimental fracture toughness data has been added at the $|A_2|$ values corresponding to the predicted critical $|A_2|$ to be compared with the Crack Driving Force curves. The average values of the experimental fracture toughness for all three specimens lies near the intersection of the MFC and the specimen CDFs. The constraint effect of each of the specimens can also be quantified and compared using the Crack Driving Force curves. The Crack Driving Force curves in Fig. 5 for the biaxial loading lies to the right of the 3PB specimen, meaning some loss of constraint and increased fracture toughness based on the loading and geometry.

For the purposes of comparing the fracture toughness values, a similar FEA and J-A_2 analysis of a uniaxial cruciform was conducted as part of the current investigation. The supports in the FEA model on the cruciform arms parallel to the crack, i.e., the horizontal arms shown in Fig. 2, were removed to simulate uniaxial loading. The same procedure was followed to develop the Crack Driving Force curve for the theoretical uniaxial cruciform specimen, which is shown as the red curve in Fig. 6. Clearly, the uniaxial cruciform specimen exhibits significant loss of constraint (increased fracture toughness) compared to the biaxial cruciform specimen.

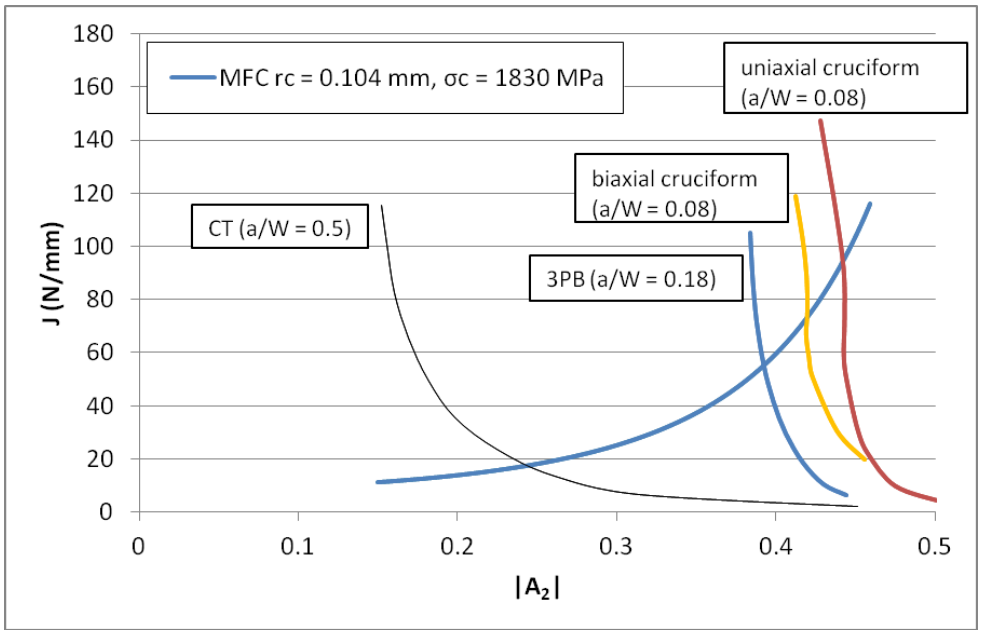

Figure 6. Crack Driving Force curve for theoretical uniaxial cruciform specimen indicated by the red curve (A508 material at -85°C)

The fracture toughness (J_c indicated by the intersection of the MFC and CDF) of the uniaxial cruciform specimen is estimated to be around 92 N/mm, while the fracture toughness of the biaxial cruciform is approximately 75 N/mm. In addition, the 3PB specimen has a slightly deeper crack than the cruciform specimens, therefore its fracture toughness is much less. The uniaxial specimen shows slightly greater loss of constraint (higher fracture toughness) when compared to biaxial specimens. This agrees with findings published by AREVA [20] related to RPV integrity assessment.

5. Conclusion

The two parameter J-A_2 method has been applied to experimental data obtained from testing A508B 3PB, C(T), and small scale cruciform specimens. The J-A_2 method shows great potential for use to predict failure in structural components and also to quantify the constraint effect due to varying loading and geometry. However, additional work is necessary to continue examination of the method. The current study utilized a small amount of data available from the literature. Future work will involve searching for larger available fracture toughness results necessary to conduct further evaluation of the J-A_2 method.

Abstract A two-dimensional electroelastic fracture analysis is performed on a plane piezoelectric material by the finite element model based on fundamental solution approximation. In the present element model, the fundamental solution of the piezoelectric problem is employed to construct the intra-element fields to make the final stiffness equation containing element boundary integrals only. Solving the stiffness equation can yield nodal displacement and electric potential, which are in turn used to evaluate the stress intensity factor and electric intensity factor by way of extrapolation techniques. Numerical results are provided to show the accuracy of the present method.

Keywords Piezoelectric materials, Crack, Stress intensity factor, Hybrid finite element method, Fundamental solution.

1. Introduction

Fracture analysis of piezoelectric materials is important for enhancing our understanding on the effect of the coupling properties on their fracture or damage behavior [1,2]. Because of complicated inherent coupling between electric and mechanical behaviors in piezoelectric solids, numerical simulation techniques have been widely employed for the fracture analysis of piezoelectric materials under complicated electric and mechanical load conditions. For example, finite element method [3, 4], boundary element method [5, 6], hybrid Trefftz finite element method [7,8], meshless methods [9], and virtual boundary integral method [10] have been developed for solving crack problems of piezoelectric materials.

In the paper, the hybrid finite element method developed recently by Wang and Qin [11-14] is extended to the case of cracked piezoelectricity. Different to other hybrid methods like the Trefftz finite element method [15-18], the basic idea of the proposed finite element model is the use of the novel interpolation kernels composed of fundamental solutions (or Green's functions) inside the multi-edge element to achieve the purpose of analytical satisfaction of governing equations of the problems of interest, and then the element stiffness equation which includes element boundary integrals only are formed for solving the electroelastic behavior.

In this work, the hybrid finite element method is extended for solving the piezoelectric problems. Using the fundamental solutions of piezoelectric problems, the intra-element displacement and electric potential fields are constructed. A modified variational functional is introduced to produce the linkage between intra-element and boundary fields. The minimization of the functional yields the stiffness matrix equation. As a result, the nodal displacements and electric potential can be determined by solving the linear stiffness equation. In the fracture analysis, the present hybrid finite element model is used to determine the displacement and electric potential distribution in the vicinity of the crack tip and then the stress and electric intensity factors can be obtained using the extrapolation technique [19].

2. Basic equations

For the transversely isotropic piezoelectric material, if the *x*-*y* plane is considered as the isotropic plane and the polarizing direction is assumed along the *z*-direction, one can employ either *x*-*z* or *y*-*z* plane to study the piezoelectric behavior. Here a plane piezoelectric media in the *x*-*z* plane is considered. In the absence of body forces and body electric charges, the equilibrium equations are given by [20]

$$\sigma_{ij,j} = 0, \qquad D_{i,i} = 0 \tag{1}$$

where $\sigma_{ij}(i, j = x, z)$ and D_i are stress tensor and electric displacement in the *i*-direction, respectively.

With plane strain assumption ($\varepsilon_{yy} = \varepsilon_{xy} = \varepsilon_{yz} = E_y = 0$), the constitutive equations in the *xz* system can be expressed as

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{zz} \\ \sigma_{xz} \end{Bmatrix} = \begin{bmatrix} c_{11} & c_{13} & 0 \\ c_{13} & c_{33} & 0 \\ 0 & 0 & c_{44} \end{bmatrix} \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{zz} \\ 2\varepsilon_{xz} \end{Bmatrix} - \begin{bmatrix} 0 & e_{31} \\ 0 & e_{33} \\ e_{15} & 0 \end{bmatrix} \begin{Bmatrix} E_x \\ E_z \end{Bmatrix}$$
$$\begin{Bmatrix} D_x \\ D_z \end{Bmatrix} = \begin{bmatrix} 0 & 0 & e_{15} \\ e_{31} & e_{33} & 0 \end{bmatrix} \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{zz} \\ 2\varepsilon_{xz} \end{Bmatrix} + \begin{bmatrix} \kappa_{11} & 0 \\ 0 & \kappa_{33} \end{bmatrix} \begin{Bmatrix} E_x \\ E_z \end{Bmatrix} \tag{2}$$

where ε_{ij} and E_i denote the strain tensor and electric field in the *i*-direction, respectively. c_{ij}, e_{ij} and κ_{ij} stand for two dimensional material elastic, piezoelectric and dielectric coefficients. For the case of plane stress, the constitutive equation can be obtained similarly [20].

The remaining elastic strain-displacement and electric field-potential relations are given by

$$\varepsilon_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i}), \qquad E_i = -\phi_{,i} \tag{3}$$

where u_i and ϕ are elastic displacement in the *i*-direction and electric potential, respectively.

The following boundary conditions are admissible on the boundary of the piezoelectric medium

$$\begin{aligned} u_i &= \overline{u}_i \quad \text{or} \quad t_i = \sigma_{ij} n_j = \overline{t}_i \\ \phi &= \overline{\phi} \quad \text{or} \quad D_n = D_i n_i = \overline{D}_n \end{aligned} \tag{4}$$

in which the components with an over bar denote specified values, and n_i is the *i*-component of outward unit normal vector.

3. Stress and electric intensity factors for plane piezoelectric crack

Now let us consider a crack embedded in an infinite plane piezoelectric solid, the origin of the local coordinate system is at the crack tip to be analyzed. Along the crack surface, the traction and normal electric displacement are free. According to Sosa's work [19] based on Lekhnitskii theory, the displacement components and electric potential along the upper crack surface near the crack tip can be written as

$$\begin{Bmatrix} u_x \\ u_z \\ \phi \end{Bmatrix} = \sqrt{\frac{2r}{\pi}} \,\mathrm{Re} \begin{bmatrix} \sum_{j=1}^{3} p_j \Lambda_{j1} & -\sum_{j=1}^{3} p_j \Lambda_{j2} & -\sum_{j=1}^{3} p_j \Lambda_{j3} \\ \sum_{j=1}^{3} q_j \Lambda_{j1} & -\sum_{j=1}^{3} q_j \Lambda_{j2} & -\sum_{j=1}^{3} q_j \Lambda_{j3} \\ \sum_{j=1}^{3} \lambda_j \Lambda_{j1} & -\sum_{j=1}^{3} \lambda_j \Lambda_{j2} & -\sum_{j=1}^{3} \lambda_j \Lambda_{j3} \end{bmatrix} \begin{Bmatrix} \mathrm{K_I} \\ \mathrm{K_{II}} \\ \mathrm{K_E} \end{Bmatrix} \tag{5}$$

where K_I,K_{II},K_E are respectively stress and electric intensity factors and r is the distance from the crack tip. In Eq. (5), the coefficients p_i, q_i, λ_i and Λ_{jk} can be found in Sosa's work [19].

From Eq. (5), it can be seen that the accuracy of displacement and electric potential can affect the results of stress and electric intensity factors. Therefore, developing new numerical approaches to achieve high accuracy of displacements and electric potential is important. The obtained numerical results below demonstrate that the proposed hybrid finite element formulation can serve for this purpose.

4. Hybrid finite element formulation

Consider a 2D electro-mechanical coupling problem, the energy functional used for constructing the proposed finite element model is given by

$$\Pi_e = \frac{1}{2}\int_{\Omega_e}(\sigma_{ij}\varepsilon_{ij} + D_i E_i)\mathrm{d}\Omega - \int_{\Gamma_t}\overline{t}_i\tilde{u}_i\mathrm{d}\Gamma - \int_{\Gamma_D}\overline{D}_n\tilde{\phi}\mathrm{d}\Gamma + \int_{\Gamma_e}t_i(\tilde{u}_i - u_i)\mathrm{d}\Gamma + \int_{\Gamma_e}D_n(\tilde{\phi}-\phi)\mathrm{d}\Gamma \quad (6)$$

in which $\tilde{u}_i$, $\tilde{\phi}$ and u_i, ϕ are the displacement components and electric potential respectively defined along the element boundary and inside the element domain.

In the present hybrid finite element model, the intra-element fields like displacement and electric potential inside the element can be approximated using the combination of the fundamental solution at different source points (the fundamental solution can be derived by either Lekhnitskii's formalism [21, 22] or Stroh's formalism [5]):

$$\begin{Bmatrix} u_x \\ u_z \\ \phi \end{Bmatrix} = \mathbf{N}_e\mathbf{c}_e \quad (\mathbf{x}\in\Omega_e, \mathbf{y}_{sk}\notin\Omega_e) \quad (7)$$

where

$$\mathbf{N}_e = \begin{bmatrix} u^*_{x1}(\mathbf{x},\mathbf{y}_{s1}) & u^*_{x2}(\mathbf{x},\mathbf{y}_{s1}) & u^*_{x3}(\mathbf{x},\mathbf{y}_{s1}) & \cdots & u^*_{x1}(\mathbf{x},\mathbf{y}_{sn_s}) & u^*_{x2}(\mathbf{x},\mathbf{y}_{sn_s}) & u^*_{x3}(\mathbf{x},\mathbf{y}_{sn_s}) \\ u^*_{z1}(\mathbf{x},\mathbf{y}_{s1}) & u^*_{z2}(\mathbf{x},\mathbf{y}_{s1}) & u^*_{z3}(\mathbf{x},\mathbf{y}_{s1}) & \cdots & u^*_{z1}(\mathbf{x},\mathbf{y}_{sn_s}) & u^*_{z2}(\mathbf{x},\mathbf{y}_{sn_s}) & u^*_{z3}(\mathbf{x},\mathbf{y}_{sn_s}) \\ \phi^*_1(\mathbf{x},\mathbf{y}_{s1}) & \phi^*_2(\mathbf{x},\mathbf{y}_{s1}) & \phi^*_3(\mathbf{x},\mathbf{y}_{s1}) & \cdots & \phi^*_1(\mathbf{x},\mathbf{y}_{sn_s}) & \phi^*_2(\mathbf{x},\mathbf{y}_{sn_s}) & \phi^*_3(\mathbf{x},\mathbf{y}_{sn_s}) \end{bmatrix} \quad (8)$$

is the interpolation matrix and

$$\mathbf{c}_e = [c_{11} \quad c_{21} \quad c_{31} \quad \cdots \quad c_{1n_s} \quad c_{2n_s} \quad c_{3n_s}]^{\mathrm{T}} \quad (9)$$

is the unknown coefficient vector. $u^*_{ij}(\mathbf{x},\mathbf{y}_{sk})$ and $\phi^*_j(\mathbf{x},\mathbf{y}_{sk})$ are induced displacement fundamental solutions at field point $\mathbf{x}$ due to a unit concentrated point load applied in the j-direction ($j=1,2$) and unit electric charge ($j=3$) at source point $\mathbf{y}_{sk}$ $(i=x,z;\ k=1,2,\cdots,n_s)$.

Whilst, the frame displacement and electric potential over the element boundary can be defined by

$$\begin{Bmatrix} \tilde{u}_x \\ \tilde{u}_z \\ \tilde{\phi} \end{Bmatrix} = \tilde{\mathbf{N}}_e\mathbf{d}_e \quad (10)$$

where $\tilde{\mathbf{N}}_e$ is the matrix of shape functions which is that same as those used in the conventional finite element method and boundary element method. $\mathbf{d}_e$ stands for the vector of the nodal displacements and electric potential.

Applying the Gauss theorem to the functional (6) and making use of the intra-element fields (7) and frame fields (10) yields

$$\Pi_e = -\frac{1}{2}\mathbf{c}_e{}^{\mathrm{T}}\mathbf{H}_e\mathbf{c}_e + \mathbf{c}_e{}^{\mathrm{T}}\mathbf{G}_e\mathbf{d}_e - \mathbf{d}_e{}^{\mathrm{T}}\mathbf{g}_e \tag{11}$$

where

$$\begin{aligned}\mathbf{H}_e &= \int_{\Gamma_e}\mathbf{Q}_e^{\mathrm{T}}\mathbf{N}_e \mathrm{d}\Gamma \\ \mathbf{G}_e &= \int_{\Gamma_e}\mathbf{Q}_e^{\mathrm{T}}\tilde{\mathbf{N}}_e \mathrm{d}\Gamma \\ \mathbf{g}_e &= \int_{\Gamma_t}\tilde{\mathbf{N}}_e^{\mathrm{T}}\bar{\mathbf{t}}\mathrm{d}\Gamma + \int_{\Gamma_D}\tilde{\mathbf{N}}_e^{\mathrm{T}}\bar{\mathbf{D}}\mathrm{d}\Gamma\end{aligned} \tag{12}$$

In Eq. (12), the matrix $\mathbf{Q}_e$ is a coefficient matrix in terms of intra-element traction and electric displacement induced by intra-element fields, that is

$$\begin{Bmatrix} t_x \\ t_z \\ D_n \end{Bmatrix} = \mathbf{Q_e c_e} \tag{13}$$

which can be derived from the assumed displacement and electric potential (7).

With the stationary condition of the functional (11), we finally have

$$\mathbf{G}_e{}^{\mathbf{T}}\mathbf{H}_e{}^{-1}\mathbf{G}_e\mathbf{d}_e = \mathbf{g}_e \tag{14}$$

and

$$\mathbf{c}_e = \mathbf{H}_e^{-1}\mathbf{G}_e\mathbf{d}_e \tag{15}$$

5. Numerical example

In this section, to investigate the performance of the present hybrid finite element formulation for the simulation of piezoelectric fracture behavior, a plane piezoelectric prism under uniform tension is considered with an embedded central crack and traction- and electric charge-free conditions are assumed along the crack surface (see Figure 1). Due to symmetry of the problem, only one quarter of the prism modeled, i.e. the shaded domain in Figure 1. The proper symmetrical mechanical boundary conditions should be applied along the symmetric lines x=0 and z=0 and the electric potential along the symmetric line z=0 is assumed to be zero. The plane strain case is assumed here and the PZT-4 material used in the computation has the following material constants [22]

$$c_{11} = 12.6\times10^{10}\,\mathrm{Nm}^{-2},\ c_{12} = 7.78\times10^{10}\,\mathrm{Nm}^{-2},\ c_{13} = 7.43\times10^{10}\,\mathrm{Nm}^{-2}$$

$$c_{33} = 11.5\times10^{10}\,\mathrm{Nm}^{-2},\ c_{44} = 2.56\times10^{10}\,\mathrm{Nm}^{-2}$$

$$e_{15} = 12.7\mathrm{Cm}^{-2},\ e_{31} = -5.2\mathrm{Cm}^{-2},\ e_{33} = 15.1\mathrm{Cm}^{-2}$$

$$\kappa_{11} = 6.464\times10^{-9}\,\mathrm{C/Nm},\ \kappa_{33} = 5.622\times10^{-9}\,\mathrm{C/Nm}$$

Firstly, to verify the present algorithm and show the accuracy of displacements and electric potential, the case without the crack is taken into consideration and the analytical results can be found in [22]. In the computation, thirty 8-node quadrilateral elements are used for the present hybrid finite element model (see Figure 2a). The results of displacements and electric potential at specific points are tabulated in Table 1, from which it's found that the numerical results from the proposed algorithm are in good agreement with the analytical results. Thus, the developed hybrid finite model can produce highly accurate displacement and electric potential results, which are important for the evaluation of stress intensity factors by displacement and electric potential extrapolation technique in the following analysis.

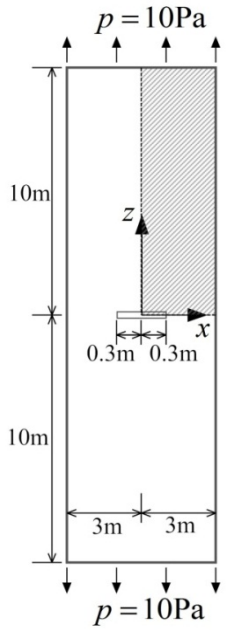

Figure 1 Geometry and boundary conditions of the piezoelectric prism with a central crack

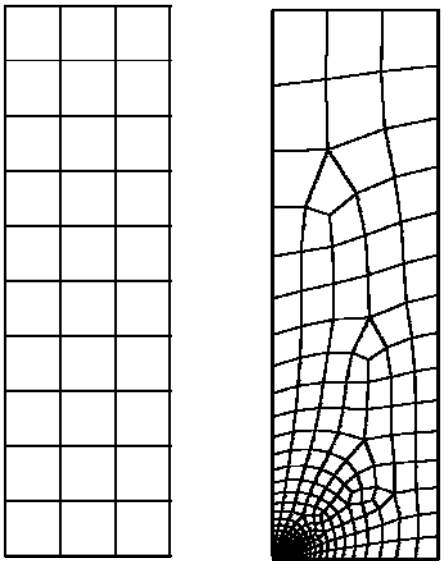

(a) (b)

Figure 2 Mesh configurations: (a) without central crack (b) with central crack

Table 1 Comparison of the numerical results by the present algorithm and the analytical solutions

Position	Analytical solutions			Numerical results		
	u_x	u_z	ϕ	u_x	u_z	ϕ
(2, 0)	-0.7222E-10	0	0	-0.7222E-10	0	0
(3, 0)	-1.0832E-10	0	0	-1.0832E-10	0	0
(0, 5)	0	3.915E-10	1.2184	0	3.915E-10	1.2184
(0,10)	0	7.829E-10	2.4367	0	7.829E-10	2.4367

Next, fracture analysis of the prism is considered and the corresponding mesh configuration is shown in Figure 2b, in which total 287 piezoelectric quadrilateral elements are used. The numerical results for crack is tabulated in Table 2, from we can find the displacement variation along the upper surface of the crack, also the corresponding electric displacement stress intensity factors $K_E \times 10^{-6} (Cm^{-3/2})$ can be evaluated by Eq. (5). The average value of it is 28.753.

Table 2 Variations of displacement and Stress intensity factor near the crack tip

r	0.01	0.02	0.03	0.04	0.05
u_x	-20.326E-12	-19.262E-12	-18.442E-12	-17.817E-12	-17.031E-12

ϕ	0	0	0	0	0
$K_E \times 10^{-6}$	28.793	28.834	28.834	28.784	28.521

6. Conclusions

In the paper, a new hybrid finite element formulation is present for performing fracture analysis of piezoelectric media using fundamental solution approach. The hybrid piezoelectric element established in the present method contains element boundary integrals only. Numerical verification is conducted by analysing electroelastic behavior of plane piezoelectric prism without any internal crack. It is found that the developed hybrid finite model can produce relatively high accurate displacement and electric potential results. Subsequently, the fracture analysis is performed by considering a central crack in the piezoelectric prism and the corresponding electric displacement stress intensity factors is evaluated by using the extrapolation technique in the vicinity of crack tip.

Abstract In this paper, the dynamic thermal stresses around a crack in a substrate bonded to a coating are obtained using the hyperbolic heat conduction theory. Fourier and Laplace transforms are applied and the hyperbolic heat conduction and thermo-elastic crack problems are reduced to solving singular integral equations. The crack kinking phenomenon under thermal loading is investigated by applying the criterion of maximum hoop stress. Numerical results show that the hyperbolic heat conduction parameters, the material properties and the geometric size of the composite have significant influence on the dynamic stress field. It seems that high temperature loading on the surface may lead to crack kinking away from the surface and low temperature loading may cause crack kinking toward the coating. Moreover, the hyperbolic heat conduction theory may give more conservative results than that the Fourier's heat conduction theory.

Keywords Cracked Substrate, Coating, Hyperbolic heat conduction, Singular integral equations, Crack kinking

1. Introduction

High-rate heat transfer has become a major concern in modern industries especially in material processing, such as the pulsed laser heat and ultrasonic waves, and accurate heat conduction analysis is of great importance for the material and structural integrity. Investigation of the temperature and stress fields is essential to the safety design of the composite structures under severe temperature loading. The Fourier heat conduction model, although give sufficient accuracy for many engineering applications, implies infinite thermal wave propagation speed, and renders ineffective at the very small length and time scales associated with small-scale systems [1]. Consideration of the hyperbolic heat conduction model becomes important if irreversible physical processes, such as crack or void initiation in a solid, are involved in the process of heat transport. In these cases, the hyperbolic heat conduction model should be used [2].

Inherent defects in materials such as dislocations and cracks may disturb the temperature distribution when thermal loading is applied, and singularities may be developed in the neighborhood of discontinuities. The singular behavior of temperature gradient around crack tip has been studied based on the classical Fourier heat conduction model [3]. Some investigations on crack problems in thermo-elastic materials have been made using the hyperbolic heat conduction model. The problem of a finite crack in a material layer under transient non-Fourier heat conduction was investigated by Wang and Han [4] and the problem of an interface crack in layered composite media under applied thermal flux was studied using the hyperbolic heat conduction theory [5]. A thermo-elastic analysis of a cracked substrate under a thermal shock was given in Chen and Hu [6] based on the hyperbolic heat conduction theory; and based on the same theory the transient temperature and thermal stresses around a partially insulated crack in a thermoelastic strip under a temperature impact were obtained [7]. The transient temperature field around a thermally insulated crack in a substrate bonded to a coating has been obtained by using the hyperbolic heat conduction model [8].

The thermo-elastic problem of a cracked substrate bonded by a coating under transient thermal loading is studied in this paper using the hyperbolic heat conduction model. Fourier and Laplace transforms are employed to reduce the problem to solving singular integral equations. The asymptotic fields around the crack tip are obtained in an explicit form and Laplace inversion is applied to get the dynamic temperature and stress fields. The crack kinking phenomenon is investigated by applying the criterion of maximum hoop stress.

2. Statement of the problem and basic equations

Consider a thermoelastic substrate containing a crack of length $2c$ parallel to the interface between the substrate and the coating, as shown in Figure 1. The composite is initially at certain temperature and the free surface of the coating $y=-h=-(a+b)$ is suddenly heated to by a temperature change T_0. The crack surfaces are assumed to be thermally insulated.

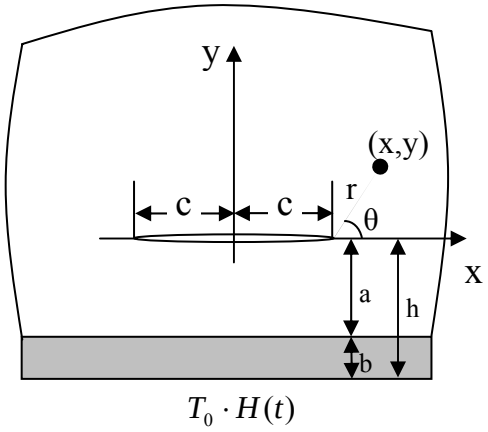

Figure 1. Crack geometry and coordinates.

2.1. Heat conduction equations

In the heat-transfer situations include extremely high temperature gradients, extremely large heat fluxes or extremely short transient durations, the Fourier's law may be modified to a relation of the type [9],

$$q+\tau\frac{\partial q}{\partial t}=-k\cdot\nabla T \tag{1}$$

where q is the heat flux, T is the temperature, k is the thermal conductivity of the material, ∇ is the spatial gradient operator, and τ is the so-called relaxation time. The local energy balance equation with vanishing heat source follows:

$$-\nabla q=\rho C\cdot\frac{\partial T}{\partial t} \tag{2}$$

where ρ and C are the mass density and the specific heat capacity, respectively. Incorporating Eq. (1) with Eq. (2) leads to the hyperbolic heat conduction equation for the substrate and the

coating,

$$d_i \cdot \nabla^2 T^{(i)} = \partial T^{(i)} / \partial t + \tau_i \, \partial^2 T^{(i)} / \partial t^2 , \qquad (i = 1,\ 2) \tag{3}$$

where ∇^2 is Laplace's differential operator, τ_i, $d_i = k_i / (\rho_i C_i)$ and k_i $(i = 1,\ 2)$ are the relaxation times, the thermal diffusivities and the thermal conductivities of the substrate and the coating, respectively. It is noted that here and afterwards the subscript "$i = 1,\ 2$" denote the quantities of the substrate and the coating, respectively.

By introducing the dimensionless variables

$$\bar{T} = T / T_0 , \quad \bar{t} = t d_0 / c^2 \tag{4}$$

where T_0 is the reference temperature and d_0 is the reference thermal diffusivity, the governing equations (3) have the following dimensionless forms:

$$\nabla^2 T^{(i)} = \frac{\partial T^{(i)}}{\partial t} \frac{d_0}{d_i} + \frac{\tau_i d_0^2}{c^2 d_i} \frac{\partial^2 T^{(i)}}{\partial t^2} , \qquad (i = 1,\ 2) \tag{5}$$

It is noted that here and afterwards, the hat "$\bar{}$" of the dimensionless variables is omitted for simplicity. The hyperbolic heat equation (5) is subjected to the following boundary and initial conditions in dimensionless forms

$$T(x,-h) = T_0 ,\ T(x,-a^+) = T(x,-a^-) ,\ k_1 \frac{\partial T(x,-a^+)}{\partial y} = k_2 \frac{\partial T(x,-a^-)}{\partial y} , \quad (|x| < \infty ,\ t > 0) \tag{6}$$

$$\begin{aligned} &\partial T(x,0) / \partial y = 0 ,\ (|x| < c) \\ &T(x,0^+) = T(x,0^-) ,\ \partial T(x,0^+) / \partial y = \partial T(x,0^-) / \partial y ,\ (|x| \geq c) \end{aligned} \tag{7}$$

It should be noted that the relaxation time (τ) for most engineering materials are of the order of $10^{-14} - 10^{-6}$ s and the thermal diffusivity $10^{-8} - 10^{-3}$ m^2/s, and therefore the Fourier parabolic heat conduction model can give good results. Experiments have shown that some special materials may have thermal relaxation time up to the order of 10s, which are important materials to work as thermal insulators [10]; in this case it is necessary to take into account the effect of the relaxation time and use the hyperbolic heat conduction model. Other applications of hyperbolic heat conduction model are in the area of transient thermal disturbance with small length and time scales.

2.2. Thermal-elastic field equations

The equilibrium equations, the strain-displacement relations, the compatibility equation and the constitutive law of plane stress thermoelasticity can be expressed as follows,

$$\partial \sigma_x / \partial x + \partial \sigma_{xy} / \partial y = 0 , \ \ \partial \sigma_{xy} / \partial x + \partial \sigma_y / \partial y = 0 \tag{8}$$

$$\varepsilon_x = \partial u/\partial x, \quad \varepsilon_y = \partial v/\partial y, \quad \varepsilon_{xy} = (\partial u/\partial y + \partial v/\partial x)/2 \tag{9}$$

$$\partial^2 \varepsilon_x/\partial y^2 + \partial^2 \varepsilon_y/\partial x^2 = 2\partial^2 \varepsilon_{xy}/\partial x \partial y \tag{10}$$

$$\varepsilon_x = (\sigma_x - \nu\sigma_y)/E + \alpha T, \ \varepsilon_y = (\sigma_y - \nu\sigma_x)/E + \alpha T, \ \varepsilon_{xy} = (1+\nu)\sigma_{xy}/E \tag{11}$$

where E, ν and α are Young's modulus, Poisson's ratio and the coefficient of linear thermal expansion, respectively.

Let $U(x, y)$ be the Airy stress function, then the stresses can be expresses in terms of U as

$$\sigma_x = \partial^2 U/\partial y^2, \quad \sigma_y = \partial^2 U/\partial x^2, \quad \sigma_{xy} = \partial^2 U/\partial x \partial y \tag{12}$$

Substitution of Eq. (12) into (10) and (11) leads to

$$\nabla^2 \nabla^2 U + E \cdot \nabla^2 (\alpha T) = 0 \tag{13}$$

By introducing the following dimensionless quantities

$$\bar{U} = U/(E\alpha c^2 T_0), \ \bar{\sigma}_{ij} = \sigma_{ij}/(E\alpha T_0), \ \bar{\varepsilon}_{ij} = \varepsilon_{ij}/(\alpha T_0), \ (\bar{u}, \ \bar{v}) = (u, \ v)/(\alpha c T_0) \tag{14}$$

the governing equations (13) can be rewritten in the following dimensionless forms:

$$\nabla^2 \nabla^2 U + \nabla^2 (T) = 0 \tag{15}$$

The mechanical boundary conditions can be expressed as

$$\sigma_{xy}(x,-a^+) = \sigma_{xy}(x,-a^-), \ \sigma_y(x,-a^+) = \sigma_y(x,-a^-), \ \sigma_{xy}(x,-h) = \sigma_y(x,-h) = 0, \quad (|x| < \infty) \tag{16}$$

$$\sigma_{xy}(x,0) = \sigma_y(x,0) = 0, \quad (|x| < c) \tag{17}$$

$$\sigma_{xy}(x,0^+) = \sigma_{xy}(x,0^-), \ \sigma_y(x,0^+) = \sigma_y(x,0^-), \ u(x,0^+) = u(x,0^-), \ v(x,0^+) = v(x,0^-), \ (|x| \geq c) \tag{18}$$

3. Temperature field

Apply Laplace transform to Eqs. (5):

$$\begin{aligned} T^{(i)*}(x, y, p) &= L\left(T^{(i)}(x, y, t)\right) = \int_0^\infty T^{(i)}(x, y, t) \exp(-pt) dt \\ T^{(i)}(x, y, t) &= L^{-1}\left(T^{(i)*}(x, y, p)\right) = \frac{1}{2\pi i} \int_{Br} T^{(i)*}(x, y, p) \exp(pt) dp \end{aligned} \tag{19}$$

where Br stands for the Bromwich path of integration, and assume the composite is at rest in the beginning, we have:

$$\nabla^2 T^{(i)*} = A_i p T^{(i)*} + B_i p^2 T^{(i)*}, \quad (i = 1, \ 2) \tag{20}$$

where $A_i = d_0/d_i$ and $B_i = \tau_i d_0^2/c^2 d_i$ $(i = 1, \ 2)$.

Following the procedure in Chen and Hu [8], the temperature field in the Laplace domain satisfying the boundary condition and regularity condition can be expressed as

$$T^{(1)*}(x,y,p)=\int_{-\infty}^{\infty}E_1(\xi)\exp(ry)\exp(-ix\xi)d\xi+W(y),\qquad (y\geq 0) \tag{21}$$

$$T^{(1)*}(x,y,p)=\int_{-\infty}^{\infty}\left[E_2(\xi)\exp(ry)+E_3(\xi)\exp(-ry)\right]\exp(-ix\xi)d\xi+W(y)\quad (-a\leq y\leq 0) \tag{22}$$

$$T^{(2)*}(x,y,p)=\int_{-\infty}^{\infty}\left[D_1(\xi)\exp(ny)+D_2(\xi)\exp(-ny)\right]\exp(-ix\xi)d\xi+V(y)\quad (-h\leq y\leq -a) \tag{23}$$

where $E_i(\xi)=E_i(\xi,p)$ ($i=1,2,3$) and $D_j(\xi)=D_j(\xi,p)$ ($j=1,2$) are unknowns to be determined, and

$$W(y)=W(y,p)=f\cdot\exp(-qy),\ V(y)=V(y,p)=C_1^0\cdot\exp(my)+C_2^0\cdot\exp(-my) \tag{24}$$

$$q=\sqrt{A_1p+B_1p^2},\ m=\sqrt{A_2p+B_2p^2},\ r=\sqrt{\xi^2+A_1p+B_1p^2},\ n=\sqrt{\xi^2+A_2p+B_2p^2} \tag{25}$$

Constants C_1^0, C_2^0 and f can be obtained from the boundary conditions. As the unknown functions are dependent, all other unknown functions can be expressed by only one independent unknown function, for example $D_1(\xi)$, as follows

$$D_2(\xi)=-D_1(\xi)/\exp[2n(a+b)] \tag{26-1}$$

$$E_1(\xi)=[\lambda_2(\xi)-\lambda_1(\xi)]D_1(\xi),\ E_2(\xi)=\lambda_1(\xi)D_1(\xi),\ E_3(\xi)=\lambda_2(\xi)D_1(\xi) \tag{26-2}$$

$$\lambda_1(\xi)=\exp(ra)(\alpha_1+\alpha_2)/2,\ \lambda_2(\xi)=\exp(-rh)(\alpha_1-\alpha_2)/2 \tag{26-3}$$

$$\alpha_1=[1-\exp(-2nb)]/\exp(na),\ \alpha_2=nk_2[1+\exp(-2nb)]/[rk_1\exp(na)] \tag{26-4}$$

Introduce the temperature density function as

$$\phi(x)=\phi(x,p)=\partial T^{(1)*}(x,0^+,p)/\partial x-\partial T^{(1)*}(x,0^-,p)/\partial x \tag{27}$$

It is clear from the boundary conditions (27) that

$$\int_{-c}^{c}\phi(t)dt=0,\quad \phi(x)=0\quad (|x|\geq c) \tag{28}$$

Substituting (21) and (22) into (27) and using Fourier inverse transform, we can get

$$D_1(\xi)=\frac{1}{i4\pi\lambda_1\xi}\int_{-c}^{c}\phi(s)\exp(is\xi)ds \tag{29}$$

Substituting (21) and (22) into (7) and applying the relation (29), we get the singular integral equation for $\varphi(t)=\phi(ct)$ as follows

$$\int_{-1}^{1}\varphi(t)[1/(t-x)+K(x,t)]dt=2\pi qf,\quad (|x|<1) \tag{30}$$

where the kernel function $K(x,t)$ is given as

$$K(x,t)=\int_0^{\infty}[1-R(\xi/c)]\sin[\xi(x-t)]d\xi \tag{31}$$

and $R(\xi) = r(\lambda_1 - \lambda_2)/\lambda_1\xi$. The singular integral equation (30) under the single-valuedness condition in (28) has the following form of solution [11]:

$$\varphi(x) = \Psi(x)\Big/\sqrt{1-x^2}\,, \qquad |x| < 1 \tag{32}$$

where $\Psi(x)$ is a bounded and continuous function. From the condition (28), it is clear that $\Psi(x)$ is an odd function of x, i.e., $\Psi(-x) = -\Psi(x)$.

Function $\Psi(x)$ can be solved numerically, as detailed in Chen and Hu [8], and function $D_1(\xi)$ can be calculated by using the Chebyshev quadrature for integration as

$$D_1(\xi) \cong \frac{c}{4\pi\xi\lambda_1}\sum_{i=1}^{n} w_i \Psi(x_i)\sin(c\xi x_i) \tag{33-1}$$

$$w_i = \pi/n\,,\ \ x_i = \cos[(2i-1)\pi/2n], \quad i = 1,2,...,n \tag{33-2}$$

By substituting Eq. (33) into (21)-(23) the temperature in the Laplace domain can be obtained. The temperature in the time domain can be determined by applying the Laplace inverse transform.

4. Thermal stress field

Considering the temperature expressions (21-23), the general solution of the Airy function satisfying the regular condition at infinity can be expressed as

$$U^* = \int_{-\infty}^{\infty}[(A_1 + A_2 y)\exp(|\xi|y) + G_{11}(\xi)\exp(-ry)]\exp(-ix\xi)d\xi - W(y,p)/q^2 \qquad (y \ge 0) \tag{34}$$

$$\begin{aligned} U^* = &\int_{-\infty}^{\infty}[(B_1 + B_2 y)\exp(|\xi|y) + (B_3 + B_4 y)\exp(-|\xi|y)]\exp(-ix\xi)d\xi \\ &+ \int_{-\infty}^{\infty}[G_{21}(\xi)\exp(ry) + G_{22}(\xi)\exp(-ry)]\exp(-ix\xi)d\xi - W(y,p)/q^2 \end{aligned} \qquad (-a \le y \le 0) \tag{35}$$

$$\begin{aligned} U^* = &\int_{-\infty}^{\infty}[(C_1 + C_2 y)\exp(|\xi|y) + (C_3 + C_4 y)\exp(-|\xi|y)]\exp(-ix\xi)d\xi \\ &+ \int_{-\infty}^{\infty}[G_{31}(\xi)\exp(my) + G_{32}(\xi)\exp(-my)]\exp(-ix\xi)d\xi - V(y,p)/m^2 \end{aligned} \qquad (-h \le y \le -a) \tag{36}$$

where B_i, C_i ($i = 1-4$), A_1 and A_2 are unknowns to be determined, and $G_{ij}(\xi)$ $(i = 1-3,\ j = 1,2)$ are known functions determined from the boundary conditions.

Denote the jumps of displacement across the plane $y = 0$ by $\langle u\rangle$ and $\langle v\rangle$,

$$\langle u\rangle = u(x,0^+,p) - u(x,0^-,p),\ \ \langle v\rangle = v(x,0^+,p) - v(x,0^-,p) \tag{37}$$

Following the procedure in Jin and Noda [12] and introducing two dislocation density functions $f_j(x)$ ($j = 1,\ 2$) as

$$f_1(x) = f_1(x, p) = \partial\langle u\rangle/\partial x, \quad f_2(x) = f_2(x, p) = \partial\langle v\rangle/\partial x \tag{38}$$

By applying the boundary conditions (16-18), it can be shown that $f_i(x)$ $(i = 1,\ 2)$ satisfy the following singular integral equations:

$$\int_{-c}^{c} f_1(t)[1/(x-t) + M_{11}(x,t)]dt + \int_{-1}^{1} f_2(t)M_{12}(x,t)dt = U_1(x) \tag{39-1}$$

$$\int_{-c}^{c} f_1(t)M_{21}(x,t)dt + \int_{-1}^{1} f_2(t)[1/(x-t) + M_{22}(x,t)]dt = U_2(x) \tag{39-2}$$

where functions $U_i(x),\ M_{ij}(x,t)$ $(i, j = 1,2)$ are known functions. Functions $f_j(x)$ $(j = 1,\ 2)$ also need to satisfy the single-valuedness conditions

$$\int_{-c}^{c} f_j(x)dx = 0, \qquad (j = 1,\ 2) \tag{40}$$

The solution of the integral Eqs. (39), $f_j(x)$ $(j = 1,\ 2)$, can be expressed as follows

$$f_j(ct) = F_j(t, p)\Big/\sqrt{1-t^2}, \qquad (j = 1,\ 2) \tag{41}$$

and the singular integral equations can be reduced to solving a system of algebraic equations in terms of $F_1(t, p)$ and $F_2(t, p)$, see [6, 7].

Following the procedure in Chen and Hu [9], the stress intensity factors (SIFs) $K_1^*(p)$ and $K_2^*(p)$ are obtained as

$$K_1^*(p) = -\sqrt{\pi c}F_2(1, p)/4, \quad K_2^*(p) = -\sqrt{\pi c}F_1(1, p)/4 \tag{42}$$

and the dynamic singular stresses near the crack tip are

$$\sigma_y(r,\theta,t) = \sqrt{\frac{c}{2\pi r}}\left\{K_1(t)\cos\left(\frac{\theta}{2}\right)\left[1+\sin\left(\frac{\theta}{2}\right)\sin\left(\frac{3\theta}{2}\right)\right] + K_2(t)\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)\cos\left(\frac{3\theta}{2}\right)\right\} \tag{43}$$

$$\sigma_{xy}(r,\theta,t) = \sqrt{\frac{c}{2\pi r}}\left\{K_1(t)\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)\cos\left(\frac{3\theta}{2}\right) + K_2(t)\cos\left(\frac{\theta}{2}\right)\left[1-\sin\left(\frac{\theta}{2}\right)\sin\left(\frac{3\theta}{2}\right)\right]\right\} \tag{44}$$

$$\sigma_x(r,\theta,t) = \sqrt{\frac{c}{2\pi r}}\left\{K_1(t)\cos\left(\frac{\theta}{2}\right)\left[1-\sin\left(\frac{\theta}{2}\right)\sin\left(\frac{3\theta}{2}\right)\right] - K_2(t)\sin\left(\frac{\theta}{2}\right)\left[2+\cos\left(\frac{\theta}{2}\right)\cos\left(\frac{3\theta}{2}\right)\right]\right\} \tag{45}$$

where the dynamic SIFs $K_1(t)$ and $K_2(t)$ are given by

$$K_1(t) = L^{-1}\left(K_1^*(p)\right), \quad K_2(t) = L^{-1}\left(K_2^*(p)\right) \tag{46}$$

and (r,θ) are the polar coordinates measured from the crack tip defined by

$$r^2 = (x-c)^2 + y^2, \quad \tan(\theta) = y/(x-c) \tag{47}$$

The hoop and shear stresses at an angle θ near the crack tip can be obtained in terms of the polar coordinates (r,θ) as

$$\begin{aligned} \sigma_{\theta\theta}(r,\theta) &= \sigma_y(r,\theta)\cos^2\theta + \sigma_x(r,\theta)\sin^2\theta - \sigma_{xy}(r,\theta)\sin 2\theta \\ \sigma_{r\theta}(r,\theta) &= \sin 2\theta\left[\sigma_y(r,\theta) - \sigma_x(r,\theta)\right]/2 + \sigma_{xy}(r,\theta)\cos 2\theta \end{aligned} \tag{48}$$

The hoop stress intensity factor and shear stress intensity factor associated with the hoop and shear stresses at an arbitrary angle θ can be defined as:

$$K_{\theta\theta} = \lim_{r\to 0}\left(\sqrt{2r}\sigma_{\theta\theta}\right), \quad K_{r\theta} = \lim_{r\to 0}\left(\sqrt{2r}\sigma_{r\theta}\right) \tag{49}$$

5. Numerical results and discussion

The effect of the thickness of coating b/c on the dynamic SIFs is shown in Figure 2 when the geometry of the cracked substrate is $a/c = 1$, the material properties are $k_1 = k_2 = 1$, $\nu = 0.4$ and $\tau_1 = 1$, $\tau_2 = 0.5$ and the boundary temperature condition $T_0 = +1$. The SIFs oscillate and increase in magnitude till they reach the peak values and oscillate for some time before approaching their static values. The magnitude of the peak value decreases as the size ratio b/c increases, which indicates that a thicker coating may decrease the magnitude of SIF.

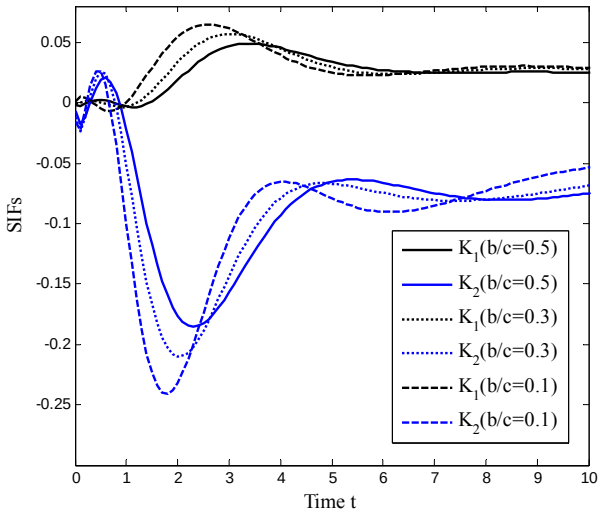

Figure 2. Effect of b/c on the dynamic SIFs when $a/c = 1$.

Figure 3 exhibits the variation of the dynamic SIFs with different thermal relaxation times τ_1 and τ_2 when $k_1 = k_2 = 1$, $\nu = 0.4$, $a/c = 1$, $b/c = 0.5$ and $T_0 = +1$. The results based on the Fourier heat conduction is the special case when $\tau_1 = \tau_2 = 0$, which shows that the dynamic SIF increases smoothly to reach the peak values and then decrease to the static values. The oscillating feature of the dynamic SIFs is observed when the hyperbolic heat conduction theory is applied, and as the relaxation time of the coating decreases the magnitude of the dynamic SIF decreases. This conclusion indicates that the structure safety design based on the hyperbolic heat conduction theory may lead to more conservative design than Fourier's heat conduction theory.

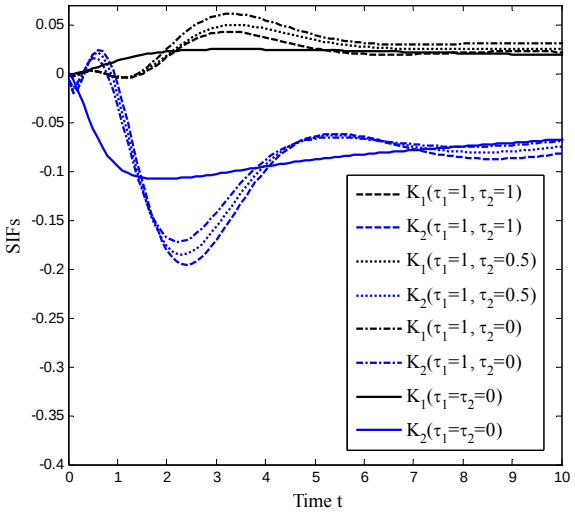

Figure 3. Effect of relaxation time on dynamic SIFs.

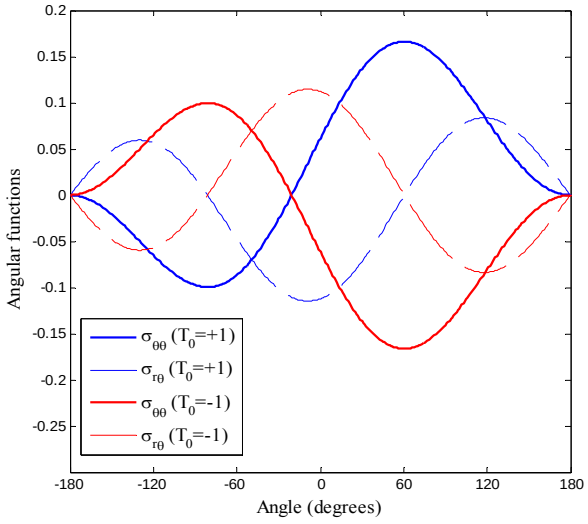

Figure 4. Angular functions of the normalized hoop stresses and shear stresses at a time instant.

The angular functions of the normalized dynamic hoop stresses $\sigma_{\theta\theta}\sqrt{2\pi r/c}$ and shear stresses $\sigma_{r\theta}\sqrt{2\pi r/c}$ at a specific time instant $t=3.0$ are displayed in Figure 4 when $a/c=1$, $b/c=0.1$, $k_1=k_2=1$ and $\nu=0.4$. The maximum hoop stress criterion is used to study crack kinking in this paper. It is shown that when the hoop stress reaches the maximum value, the shear stress is zero. When the temperature loading on the surface of the coating is positive, the maximum hoop stress appears at the angle $\theta=+60$ degrees, which indicates that the crack may kink in this direction; when a negative temperature is applied on the coating surface, the hoop stress reaches the maximum value at the angle $\theta=-70$ degrees, which means that the crack may kink toward the coating in this direction. It seems that high temperature loading on the surface may lead to crack kinking away

from the surface and low temperature loading may cause the crack to kink toward the coating.

6. Conclusions

The transient thermal stresses around a crack in a substrate bonded to a coating have been obtained using the hyperbolic heat conduction theory. Integral transform method is applied and the hyperbolic heat conduction and thermo-elastic crack problem are reduced to solving singular integral equations. The crack kinking phenomenon is investigated by applying the criterion of maximum hoop stress. Numerical results show that the hyperbolic heat conduction parameters, the material properties and the geometric size of the composite have significant influence on the dynamic stress field. Hot or cold temperature loadings may lead to different crack kinking directions. The results predicted by the hyperbolic heat conduction model are more conservative than that by the Fourier's heat conduction model.

Numerical simulations of thermo-electro-magnetic phenomena in YBCO films subjected to strains

Jing Xia and You-He Zhou*

Department of Mechanics and Engineering Sciences, Lanzhou University, 730000, People's Republic of China
* Corresponding author: zhouyh@lzu.edu.cn

Abstract Due to thermal contractions, tensions and electromagnetic forces, YBCO coated conductors in high-temperature superconductors apparatuses are subjected to mechanical strains. The strains cause the degradation of the critical current densities and influence thermo-electro-magnetic features in the conductors. Based on the dynamic process of thermo-electro-magnetic interaction, we report the results of numerical simulation of thermo-electro-magnetic phenomena in an infinite YBCO film subjected to a uniform in-plane strain in an alternating external magnetic field parallel to the sample surface. The numerical simulation shows the distributions of magnetic induction, electric intensity, current density and temperature in the film and their dependences on the uniform strain. The AC loss in the film is also calculated. We find that whether the magnetic field fully penetrates the superconductor is the key factor to influence the feature of AC loss. When the magnetic field cannot fully penetrate the superconductor the loss rises with increasing strain. When the magnetic field can fully penetrate the superconductor the feature is just opposite.

Keywords YBCO film; thermo-electro-magnetic phenomenon; strain

1. Introduction

The second-generation high-temperature superconductors consisting of a YBCO film deposited on a metallic substrate, referred to as YBCO coated conductors, are promising materials for power applications, such as cables, fault-current limiters and transformers. During the past several years impressive development is being made for the conductors. Very high critical current densities of $2.5-3.0\ \mathrm{MA\,cm^{-2}}$ at $77\ \mathrm{K}$ have been reached in long conductor lengths [1]. Due to thermal contractions, tensions and electromagnetic forces, the coated conductors in high-temperature superconductors apparatuses are subjected to mechanical strains. The strains cause the degradation of the critical current densities and influence thermo-electro-magnetic features in the conductors. But it is impossible to avoid the strains. The effects of strains on the critical current densities have been reported by many researches. However, researches investigating the effects of strains on the other thermo-electro-magnetic features are relatively less. Osami Tsukamoto and his partners have done a series of studies on the AC losses in coated conductors subjected to strains [2-6]. But they have not studied the details of thermo-electro-magnetic phenomena in the coated conductors, such as the distributions of magnetic induction, temperature, electric intensity and current density.

In this paper, we propose an approach to investigate the thermo-electro-magnetic features in an infinite YBCO film subjected to a uniform strain in an external AC magnetic field parallel to the surface of film. The approach is based on numerically solving the coupled magnetic and heat diffusion equations associated with the intrinsic nonlinear behaviors of $\rho(B,T,\varepsilon)$, $J_c(T,B,\varepsilon)$, $c(T)$, etc., from which the details of thermo-electro-magnetic phenomena in the film and their dependences on the strain are obtained.

2. Mathematical model and numerical analysis method

We consider an infinite YBCO film in yz plane with thickness $2d$ in x direction subjected to a uniform strain ε in y direction and an external magnetic field $\mathbf{B}_{ex}$ parallel to the sample

surface in z direction (see Fig. 1).

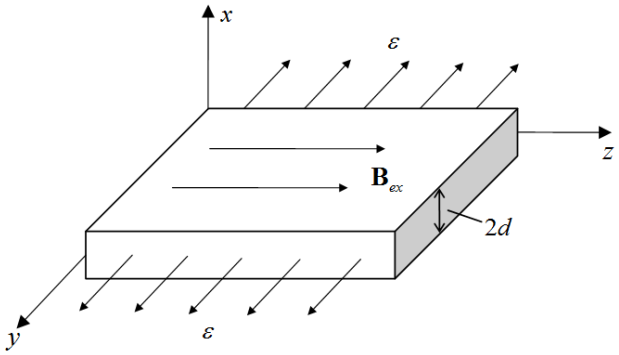

Figure 1. Sketch of the model.

The YBCO film is modeled as a slab, at which the distributions of the z component of magnetic induction $B(x,t)$, the y component of electric intensity $E(x,t)$, and the current density $J(x,t)$ are governed by the Maxwell equations

$$\frac{\partial B}{\partial x}+\mu_0 J=0, \tag{1}$$

$$\frac{\partial B}{\partial t}+\frac{\partial E}{\partial x}=0, \qquad -d\le x\le d. \tag{2}$$

Here, $\mu_0=4\pi\times10^{-7}$ N A^{-2} is the permeability of free space. Considering the $E-J$ relation of superconductor can be assimilated with that of normal conductor, i.e.,

$$E=\rho(B,T,\varepsilon)J, \tag{3}$$

where $\rho(B,T,\varepsilon)$ stands for the effective electric resistance, hence Eqs. (1) and (2) can be reduced into the form

$$\frac{\partial}{\partial x}\left(\rho(B,T,\varepsilon)\frac{\partial B}{\partial x}\right)-\mu_0\frac{\partial B}{\partial t}=0, \qquad -d\le x\le d. \tag{4}$$

The temperature $T(x,t)$ is satisfied with one-dimensional Fourier's heat conducting equation

$$\frac{\partial}{\partial x}\left(\kappa\frac{\partial T}{\partial x}\right)-c(T)\frac{\partial T}{\partial t}+W=0, \qquad -d\le x\le d, \tag{5}$$

in which κ represents the thermal conductivity, $c(T)$ is the heat capacity, and $W=EJ$ indicates the heat source intensity. After the YBCO film is cooled to the temperature of the coolant in the zero magnetic field (i.e., the external magnetic field is equal to zero), the boundary and initial conditions of the magnetic field and the temperature field can be written as

$$x=\pm d: \qquad B(x,t)=B_{ex}(t), \tag{6}$$

$$x=\pm d: \qquad \kappa\frac{\partial T}{\partial x}=\pm h(T)(T-T_0), \tag{7}$$

$$t=0: \qquad B(x,t)=0, \qquad T(x,t)=T_0, \tag{8}$$

where $h(T)$ is the heat transfer coefficient, T_0 denotes the temperature of the coolant, and $B_{ex}(t)$ stands for the external magnetic field. Here, we apply a sinusoidal field $B_{ex}(t)=B_0\sin 2\pi ft$.

At the temperature zone of liquid nitrogen, a power law $E=E_c(J/J_c)^{U_0/kT}$ is reasonable for describing electromagnetic constitutive relation of the high-temperature superconductor, where J_c is the critical current density defined by the reference electric field E_c, U_0 denotes the activation energy and k is the Boltzmann constant [7]. According to Eq. (3), the effective electric resistance

ρ is given by

$$\rho(B,T,\varepsilon)=\frac{E_c}{J_c}\left|\frac{J}{J_c}\right|^{U_0/kT-1}. \tag{9}$$

The present research on the activation energy indicates that the energy is dependent on the local temperature and magnetic field, and it is explicitly expressed by [8]

$$U_0(T,B)=U_{00}[1-(T/T_c)^4][1-B/B_{c2}(T)], \tag{10}$$

where U_{00} denotes the barrier height in the zero magnetic field at 0 K, T_c is the critical temperature, and $B_{c2}(T)=B_{c2}(0)[1-(T/T_c)^2]$ stands for the upper critical magnetic field.

For the samples of YBCO, the dependence of the critical current density on strain $J_c(\varepsilon)$ is given by fitting the experimental data with relation [9, 10]

$$J_c(\varepsilon)=J_c(\varepsilon=0)(1-a|\varepsilon|^{2.2}), \tag{11}$$

in which a is the fitting parameter. After the temperature and magnetic field dependence of critical current density is taken into account [11, 12], i.e.,

$$J_c(T,B)=J_{c0}[1+(T/T_c)^2]^{-1/2}[1-(T/T_c)^2]^{5/2}\frac{B^*}{|B|+B^*}, \tag{12}$$

we can get the temperature, magnetic field and strain dependence of critical current density, i.e.,

$$J_c(T,B,\varepsilon)=J_{c0}[1+(T/T_c)^2]^{-1/2}[1-(T/T_c)^2]^{5/2}(1-a|\varepsilon|^{2.2})\frac{B^*}{|B|+B^*}, \tag{13}$$

where the parameter J_{c0} is the critical current density when the temperature, magnetic field and strain are equal to zero, and B^* is a phenomenological parameter.

Consequently, the system with thermo-electro-magnetic interaction can be described by the initial-boundary problem of Eqs. (4)-(8). It is hard to solve the nonlinear coupling problem analytically, so we propose a numerical code by means of the finite difference method and iteration to solve it.

3. Results and discussions

In this section, thermo-electro-magnetic phenomena in the YBCO film subjected to a uniform strain in an external magnetic field parallel to the sample surface at the temperature zone of liquid nitrogen are displayed by the numerical results which are obtained from the essential equations in the previous section. We investigate the distributions of magnetic induction, temperature, electric intensity and current density in the film and their dependences on the uniform strain. Two situations are taken into account. One is that the magnetic field does not fully penetrate the YBCO film. The other one is that the magnetic field fully penetrates the YBCO film. In addition, the AC loss in the film is calculated. In the numerical analysis, we select the parameters in their possible regions given in literatures [9, 13-18]: $a=9900$, $J_{c0}=6.4\times10^{11}$ A m^{-2}, $2d=0.8\times10^{-6}$ m, $T_c=92$ K, $T_0=76$ K, $B_{c2}(0)=200$ T, $U_{00}/kT_0=54$, $B^*=0.3$ T, $E_c=10^{-4}$ V m^{-1}, $h=1$ J m^{-2} s^{-1} K^{-1}, $\kappa=4$ J m^{-1} s^{-1} K^{-1}, $c(T)=2.02\times10^2T^2-7.82\times10^{-3}T^4$ (J K^{-1} m^{-3}). The external magnetic field frequency f is selected as 50 Hz.

3.1. The magnetic field does not fully penetrate the YBCO film

Fig. 2 shows the distributions of the z component of magnetic induction $B(x,t)$, temperature

$T(x,t)$, the y component of electric intensity $E(x,t)$ and current density $J(x,t)$ in the YBCO film at $\varepsilon = 0.2\%$ and $B_0 = 0.001$ T. The curves at different times in a magnetization period T^{cycle} are displayed. When the external magnetic field amplitude B_0 is applied to 0.001 T, the magnetic field cannot fully penetrate the film. From Fig. 2(a), one sees that the magnetic field penetration depth increases with increasing external magnetic field. When $t = T^{cycle}/4$, the external magnetic field gets to the maximum. After the time, the external magnetic field decreases gradually. The magnetic induction in the film near the surface decreases with that. However, the magnetic field penetration depth does not decrease. This is because the pinning force hinders flux lines from moving out of the superconductor. After $T^{cycle}/2$, the external magnetic field increases in the opposite direction. When $t = 3T^{cycle}/4$ the external magnetic field gets to the maximum in the negative direction. The distribution of magnetic induction in the film at this time is just opposite compared with that when $t = T^{cycle}/4$, which means the distributions at the two times have the same values, however, their directions are opposite. The distributions of magnetic induction at $T^{cycle}/2$ and T^{cycle} have the same feature. Fig. 2(b) illustrates the temperature at every position in the film is the same during the magnetization period. Due to the AC loss in the film, the temperature of the film increases with time. But the increments of temperature are slight. From Fig. 2(c), one sees that the distributions of electric intensity are antisymmetrical about the middle layer of the film. At the surface of the film, the values of electric intensity at $T^{cycle}/2$ and T^{cycle} are larger than those at $T^{cycle}/4$ and $3T^{cycle}/4$. This is because the external magnetic field sweep rate $|dB_{ex}/dt|$ at $T^{cycle}/2$ and T^{cycle} is faster than that at $T^{cycle}/4$ and $3T^{cycle}/4$, the vortex electric intensities generated are larger. The current density has the same direction with the electric intensity, so the distributions of electric intensity are also antisymmetrical about the middle layer of the film (see Fig. 2(d)).

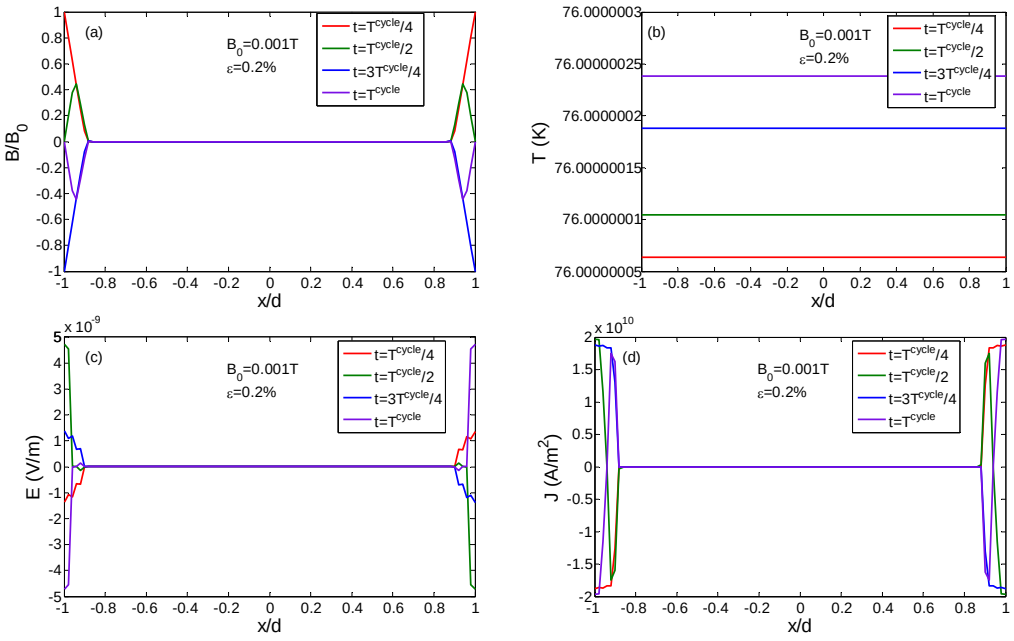

Figure 2. The distributions of the z component of magnetic induction $B(x,t)$, temperature $T(x,t)$, the y component of electric intensity $E(x,t)$ and current density $J(x,t)$ in the YBCO film at $\varepsilon = 0.2\%$ and $B_0 = 0.001$ T. In Fig. 2(a), the magnetic induction B is normalized by the external magnetic field amplitude B_0.

Fig. 3 demonstrates the dependences of the distributions of magnetic induction, temperature, electric intensity and current density on the uniform strain under the situation that the magnetic field does not fully penetrate the film. We find that their dependences on the strain are slight. Fig. 3(a) shows the distributions of magnetic induction at $\varepsilon = 0\%, 0.2\%, 0.4\%$ when the time is equal to $T^{cycle}/4$. One sees that the magnetic induction in the superconducting film increases slightly when the strain increases. According to Eq. (13) the critical current density J_c decreases with increasing strain ε, so the pinning force decreases with increasing strain. When the pinning force decreases, it is easier for the flux lines to move into the superconductor. So the magnetic induction in the film increases. However, the increment is slight, which indicates the effect of strain on the pinning force is very small when the magnetic field does not fully penetrate the film. From Fig. 3(b) and Fig. 3(c), one sees that the strain almost has no effect on the distributions of temperature and electric intensity. The three curves at $\varepsilon = 0\%, 0.2\%, 0.4\%$ superpose. Fig. 3(d) illustrates the current density in the film near the surface decreases with increasing strain. At the deeper position in the film, the feature is opposite. We need to point out that only the range of reversible strain is considered in our simulations. When the strain exceeds the irreversible strain limit ε_{irr} ($\varepsilon_{irr} = 0.5\%$ in this paper), cracks begin to appear in the superconductor, which result in the irreversible degradation in critical current density [9]. This is not permitted in applications [10, 19, 20].

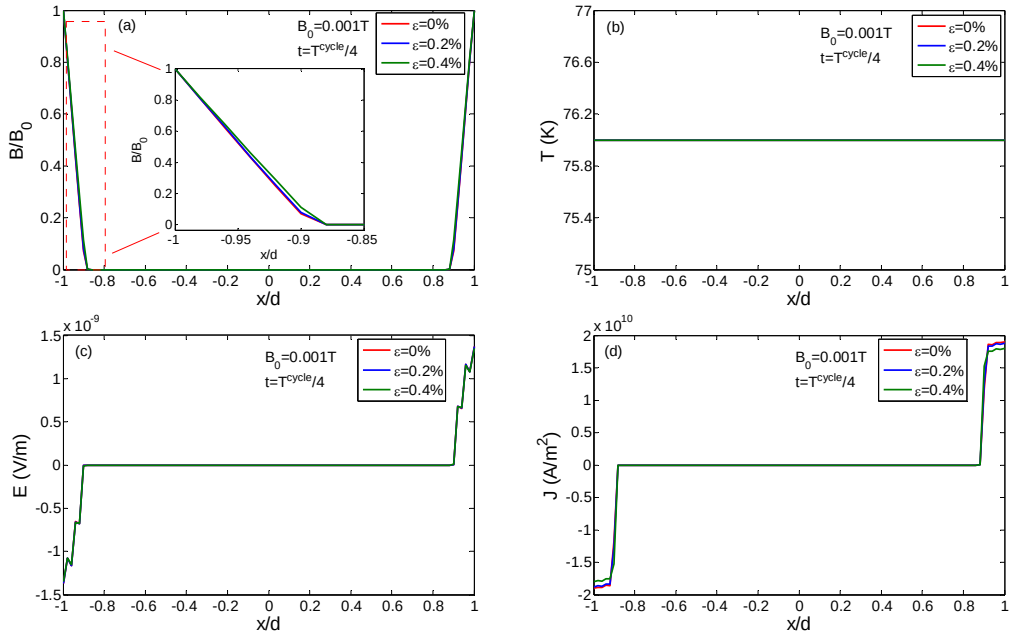

Figure 3. The dependences of the distributions of magnetic induction, temperature, electric intensity and current density on the uniform strain when $B_0 = 0.001$ T. In Fig. 3(b) and Fig. 3(c), the three curves at $\varepsilon = 0\%, 0.2\%, 0.4\%$ superpose.

3.2. The magnetic field fully penetrates the YBCO film

Fig. 4 shows the distributions of magnetic induction, temperature, electric intensity and current density in the YBCO film at different times when $\varepsilon = 0.2\%$ and $B_0 = 0.02$ T. When the external magnetic field amplitude B_0 is applied to 0.02 T, the magnetic field can fully penetrate the film. The features of the evolutions of these distributions with time are similar to those when the magnetic field cannot fully penetrate the film. From Fig. 4(a), one also sees that after $T^{cycle}/4$ although the external magnetic field decreases, the magnetic induction in the film closed to the

middle layer increases. According to this phenomenon, we can deduce the pinning force in the film closed to the middle layer reduces during the decrease of external magnetic field (Fig. 2(a) illustrates the same feature).

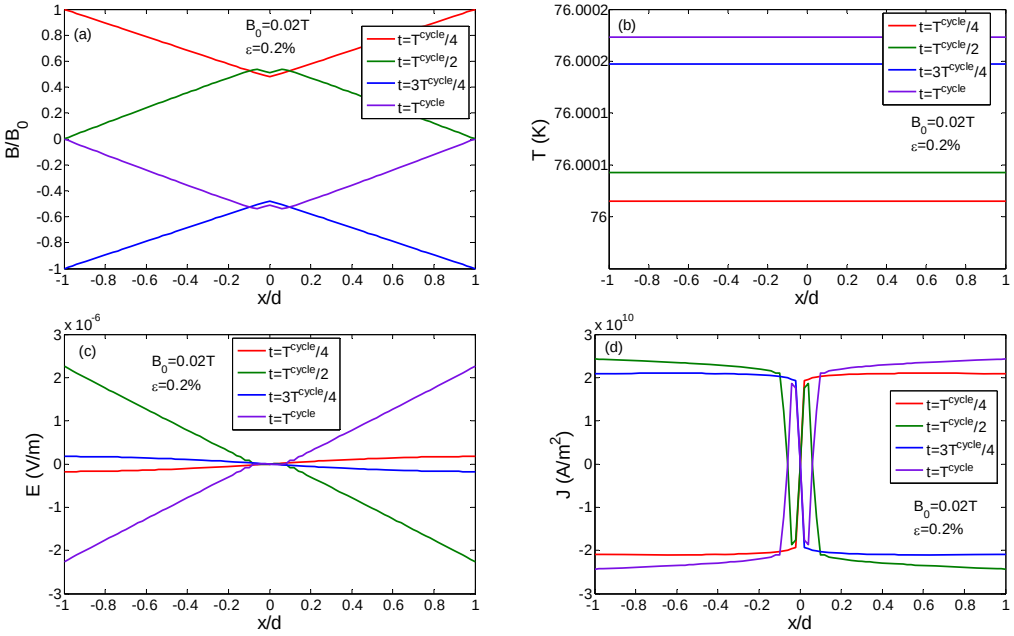

Figure 4. The distributions of magnetic induction, temperature, electric intensity and current density in the YBCO film at $\varepsilon = 0.2\%$ and $B_0 = 0.02$ T.

Fig. 5 demonstrates the dependences of the distributions of magnetic induction, temperature, electric intensity and current density on the uniform strain under the situation that the magnetic field fully penetrates the film. It is found that the effects of strain on these distributions are more obvious than those when the magnetic field does not fully penetrate the film in the range of reversible strain. When the strain increases the AC loss in the film decreases, which results in the decrease of temperature in the film (see Fig. 5(b)). Fig. 5(c) and Fig. 5(d) indicate that the larger the strain is, the smaller the electric intensity and current density are. This feature is different from that when the magnetic field does not fully penetrate the film.

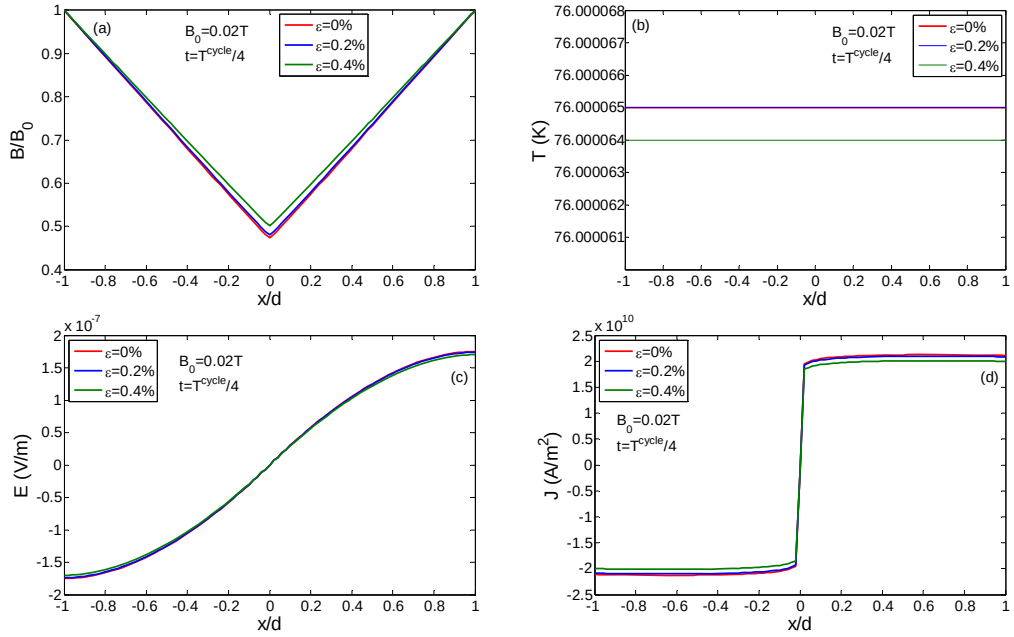

Figure 5. The dependences of the distributions of magnetic induction, temperature, electric intensity and

current density on the uniform strain when $B_0 = 0.02$ T. In Fig. 5(b), the red line and blue line superpose.

3.3. The AC loss in the YBCO film

After $E(x,t)$ and $J(x,t)$ in the YBCO film are numerically obtained, AC loss per unit volume per cycle Q is obtained by the following formula

$$Q = \frac{1}{2d}\int_{T^{\text{cycle}}} \mathrm{d}t \int_{-d}^{d} EJ\mathrm{d}x. \tag{14}$$

Fig. 6 shows curves of the AC loss Q versus the uniform strain ε at different external magnetic field amplitudes. It is interesting to find that when the magnetic field cannot fully penetrate the superconducting film ($B_0 = 0.001$ T), the loss rises with increasing strain. However, the feature is opposite when the magnetic field can fully penetrate the film ($B_0 = 0.02$ T).

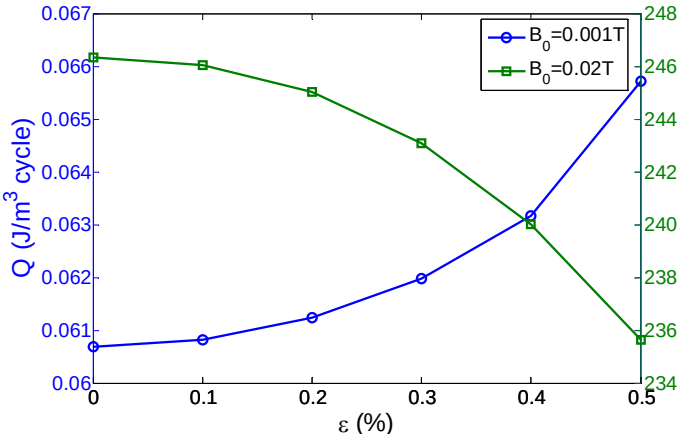

Figure 6. Curves of the AC loss Q versus the uniform strain ε when $B_0 = 0.001$ T and $B_0 = 0.02$ T.

4. Conclusions

By solving the nonlinear coupled equations of magnetic and heat diffusions numerically, we study thermo-electro-magnetic phenomena in an infinite YBCO film subjected to a uniform in-plane strain in an alternating external magnetic field parallel to the sample surface. The distributions of magnetic induction, temperature, electric intensity and current density in the film are investigated at different times under two situations. In one of the situations the magnetic field does not fully penetrate the film and in the other one the magnetic field does. In addition, we investigate the effects of the uniform strain on those distributions. It is found that the effects of the uniform strain are small in the range of reversible strain. At last, the AC loss in the film is reported. We find that whether the magnetic field fully penetrates the superconductor is the key factor to influence the feature of AC loss. When the magnetic field cannot fully penetrate the superconductor the loss rises with increasing strain. When the magnetic field can fully penetrate the superconductor the feature is just opposite.

Abstract J-integral of nonlinear fracture for the colloid soft material is calculated by the finite element method in this paper. The J-integral is based on the concept of conservation of energy, hardly depending on the crack-tip stress singularity. Therefore, the fracture of colloidal soft material could be characterized by the J-integral. In this paper, a limited area near the crack tip replacing the integral loop is used to calculate J-integral value. J-integral within one unit is approximated by summation of the formulas related with gauss points. Such repeatedly, J-integral corresponding to integral path is calculated. Effect of different loading conditions and crack lengths on J-integral of PVA-H nonlinear fracture mainly is emphasized. This study shows that the J-integral can effectively characterize the nonlinear fracture of colloidal soft material.

Keywords PVA-H, Fracture, J-integral, Finite element method

1. Introduction

The wide use of hydrogels in the biomedical field is getting more and more frequent in recent years, and enormous potential in the tissue engineering is showed for the swelling and indissolvable features in the water. Especially, polyvinyl alcohol hydrogel (PVA-H) is a very promising material. A few studies have confirmed that the biomechanical properties of the polyvinyl alcohol hydrogel are similar to that of the articular cartilage, which is based on the good biocompatibility and is able to be a partial substitute for the articular cartilage, delay or prevent the occurrence of traumatic osteoarthritis. So PVA-H has become an alternative material with great promise in a clinical context [1-2]. However, after implantation into the human body PVA-H will appear wearing and cracks which can impact its function as well as what articular cartilage damage seriously affects. Therefore, the study of the PVA-H fracture characteristics is obviously important, but few international scholars research on the aspect at present.

Although the mechanical constitutive relation of the PVA-H is complicated, a relatively simple elastic-plastic theory model is adopted to research PVA-H material by simplifying the relation in this paper. On linear elasticity or small range yield condition, PVA-H crack tip energy release rate is evaluated by J-integral fracture criterion which is commonly used to deal with nonlinear fracture problem. The J-integral is based on the concept of conservation of energy, hardly depending on the crack-tip stress singularity and treating specially for the unit at the crack tip. Hence, J-integral can effectively characterize the nonlinear fracture of PVA-H material.

In this paper, aiming at PVA-H as articular cartilage repair material, the energy release rate of PVA-H crack tip is calculated by finite element method. J values of the crack tip under different loading conditions and different integration paths are obtained, also in consideration of the impact of the crack length on the J-integral.

2. Theoretical model

Polyvinyl alcohol aqueous solution gel can be made into polyvinyl alcohol hydrogel elastomer by repeated freezing-melting method. In 2007, Pan et al. [3] obtained the PVA-H curves of the stress and instant tensile modulus with changing strain through five freezing-melting cycles (see Fig.1). PVA gel is a kind of viscoelastic material, whose stress-strain relationship has typical viscoelastic properties. Taking the modulus-strain relationship into consideration, it is known that the tensile modulus of PVA gel is significantly various in different strain range. When strain range is 0 ~ 100%, PVA gel whose tensile modulus is essentially unchanged has elasticity characteristic, so its stress-strain shows a good linear relationship. In 100 ~ 250% strain, PVA tensile modulus increases up to 4 times with the increment of strain. In this range, PVA gel demonstrates typical viscoelastic character, whose stress-strain relationship is distinctly nonlinear.

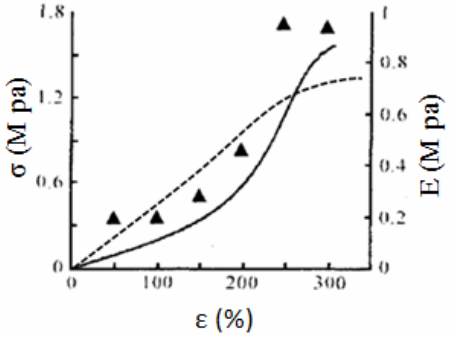

Fig.1 Stress-strain, modulus-strain and simplified stress-strain characteristic of PVA hydrogel
—: tension strength ▲: tension modulus ----: simplified stress-strain

Rice [4] introduced the J integral theory to analyze the crack behavior in an elastic body. This theory can quantitatively describe stress-strain field intensity of elastic materials with a crack, which has clear definition and strict theoretical basis. Consider a homogeneous plate containing a penetrating crack. There is no external force near the crack tip, but tension stress acting on the homogeneous plate produces 2D stress-strain field around the crack. J integral is defined as

$$J=\int_{\Gamma}\left(\text{wdy-T}\frac{\partial U}{\partial x}ds\right) \tag{1}$$

Where Γ loop shown in Fig.2 is around the crack tip, which starts from the crack lower surface and ends at the upper surface (counterclockwise direction), w is the strain energy density of the plate, T is the force vector acting on micro arc, and U is the displacement on Γ loop.

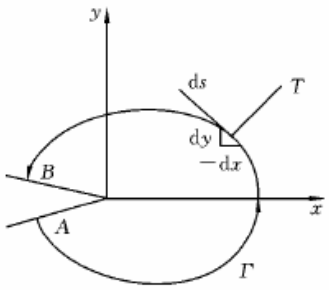

Fig.2 Schematic of the J-integral path

Rice [4] proved the path-independence of the J integral in the case of linear and nonlinear elastic material. Eq. (1) is not suitable for numerical calculation, because of not only the infeasibility of calculating stress and strain on Γ loop but the results are not always compatible when integral circuit is very close to the crack tip. Therefore, Shih [5] and Raju et al. [6] proposed the equivalent integral area method to compute J-integral by numerical calculation. A limited area near the crack tip replacing the integral loop is used to calculate J-integral value. According to divergence theorem,

Eq. (1) translates into

$$J=\int_A \left(\sigma_{ij} \frac{\partial u_j}{\partial x_1} - \omega \delta_{1i} \right) \frac{\partial q}{\partial x_i} dA \tag{2}$$

For 2D crack analysis, Eq. (2) can be divided into

$$J=\int_A \left[\left(\sigma_{xx} \frac{\partial u}{\partial x} + \tau_{xy} \frac{\partial v}{\partial x} - \omega \right) \frac{\partial q}{\partial x} + \left(\tau_{xy} \frac{\partial u}{\partial x} + \sigma_{yy} \frac{\partial v}{\partial x} \right) \frac{\partial q}{\partial y} \right] dA \tag{3}$$

In order to easily calculate the integral numerically, function q(x, y) must have a certain value on each node of the integral area. Shih etc. proofed that the J integral is not sensitive to the assumption form of q(x, y), i.e., q(x, y) can be arbitrarily selected [5]. But the boundary values of the integral area are strictly prescribed. For example, q = 1on the internal boundary, then q=0 on the external boundary for a plane problem. Equivalent integral area method is very convenient in finite element analysis, surely becoming the common tools calculating J integral.

In this paper, the plane stress four node unit calculating the J integral of the PVA-H crack tip is used, which is corresponding to standard CPS4 in ABAQUS. Using the gauss integral method, J-integral within one unit is approximated by summation of the formulas related with gauss points, i.e.

$$\bar{J} \approx I(r_1,s_1)+I(r_2,s_2)+I(r_3,s_3)+I(r_4,s_4) \tag{4}$$

In which

$$I(r,s)=\left[\left(\sigma_{xx} \frac{\partial u}{\partial x} + \tau_{xy} \frac{\partial v}{\partial x} - \omega \right) \frac{\partial q}{\partial x} + \left(\tau_{xy} \frac{\partial u}{\partial x} + \sigma_{yy} \frac{\partial v}{\partial x} \right) \frac{\partial q}{\partial y} \right] \det(J^e) \tag{5}$$

$$r=\left\{ -\frac{1}{\sqrt{3}}, \frac{1}{\sqrt{3}}, \frac{1}{\sqrt{3}}, -\frac{1}{\sqrt{3}} \right\}, \quad s=\left\{ -\frac{1}{\sqrt{3}}, -\frac{1}{\sqrt{3}}, \frac{1}{\sqrt{3}}, \frac{1}{\sqrt{3}} \right\}$$

Thus, J integral of PVA-H corresponding to one unit is obtained. Such repeatedly, J values of all units covering integral area are calculated. By determining J integral of different integral paths, whether the J integral of nonlinear fracture of PVA-H depends on the integral loop near the crack tip or not is given. Moreover, the influence of loadings and crack lengths on the J integral of nonlinear fracture of PVA-H is obtained by changing different loadings and crack lengths.

2. Determination of J integral

Figure 3 shows a center crack in a limited plate subjected to tension stress. It has a span 2H=400mm, a width 2W=200mm, a thickness B=1mm and the length of the crack a=20mm. Tensile modulus of PVA-H material is various as different manufacture method. According to the results given by Gao etc. [7], PVA-H with the following material properties is considered

$$E=10\text{Mpa}, \quad \nu=0.49, \quad \sigma_s=4.47\text{Mpa}$$

Where E is the elastic modulus, ν is the Poisson ratio, σ_s is the tensile strength.

According to the asymmetry, the finite element model of a quarter PHV-H plate is shown in Fig.4 by ABAQUS pretreatment with transverse 100 division and vertical 200 division. Then all the information including geometric and material properties of the model extracted from ABAQUS is input into the FORTRAN input data file. The units from 1 to 20 are free, and the twenty-first node is the crack tip. Hence, y direction displacement of the right nodes of the crack tip and x direction displacement of the left boundary nodes is restrained, then the upper boundary nodes are applied by tensile load σ =0.1Mpa.

Equivalent integral area (gray section) including 8*2 units near the crack tip is selected shown in

Fig.5. J value of nonlinear fracture of PVA-H by FORTRAN program is given as J= 0.065082349N/mm.

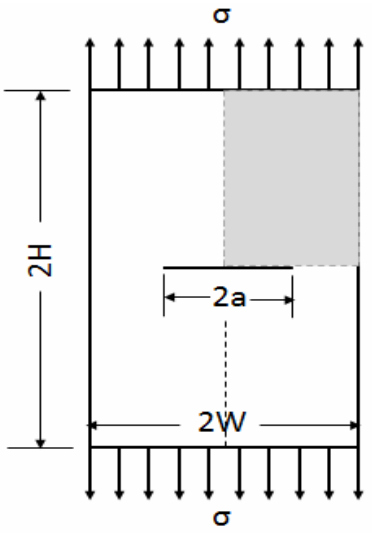

Fig.3 A center crack in a limited plate subjected to tension stress.

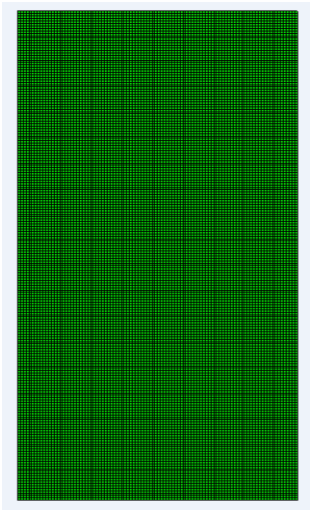

Fig.4 PHV-H plate finite element model

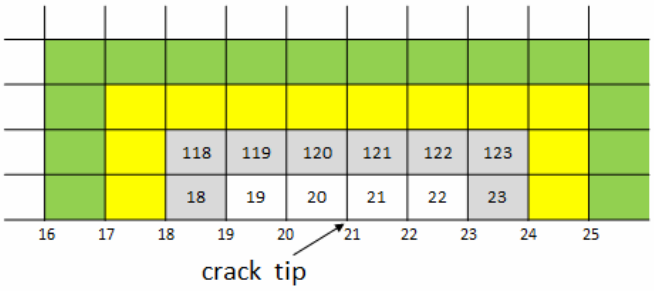

Fig.5 Equivalent integral area

Change tensile load σ , respectively, σ = 0.1、0.4、0.7、1.0、1.5 and 2.0Mpa. The calculated J integral values by FORTRAN in equivalent integral area are plotted in Fig.6. It shows that the J integral of nonlinear fracture of PVA-H increases as the increment of the applied loading, approximately, for square relation.

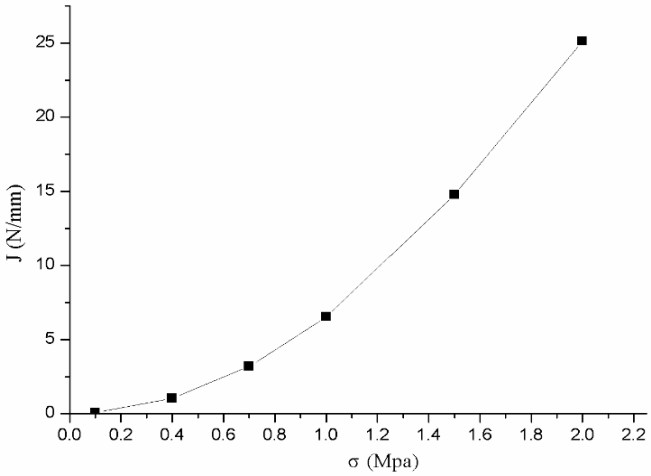

Fig.6 J-σ curve under different loadings

Each layer starting from the third layer outside of the crack tip is taken as integral path. The largest number of units of the layer is 24*2. Fig.7 plots the J-integral by FORTRAN in equivalent integral area against different integral paths under different loadings. It shows J integral in a certain loading remains unchanged as the increment of the chosen integral units, namely the J integral of nonlinear fracture of PVA-H is independent on the integral path. The result is found in very nice agreement with path-independent of the J integral in the case of linear and nonlinear elastic materials proved by Rice. Moreover, the bigger the applied loading, the greater the J integral value in the same integral path.

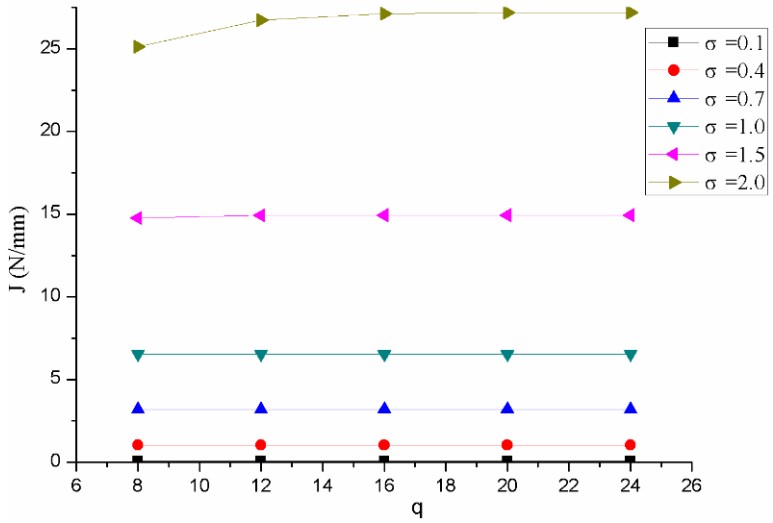

Fig.7 J curves for different integral paths under different loadings

In order to get the influence of the crack length on the J integral of nonlinear fracture of PVA-H, the location of the crack tip is changed from the eighteenth to the twenty-four node and the crack length ranges from 34 mm to 46 mm. The equivalent integral area is similar to that of Fig.5 (gray section). When the crack tip moves one unit length to the left or to the right, correspondingly, the equivalent integral area also moves a unit length to the left or to the right for guaranteeing the area covering 8*2 units. Change the tensile load, respectively, σ = 0.1、0.4、0.7、1.0、1.5 and 2.0Mpa. The calculated J values by FORTRAN in equivalent integral area are shown in Fig.8. It shows that J integral value at the crack tip increases linearly along with the PVA-H crack length increasing. It is clear that J integral or energy release rate of nonlinear fracture of PVA-H is severely affected by the crack length.

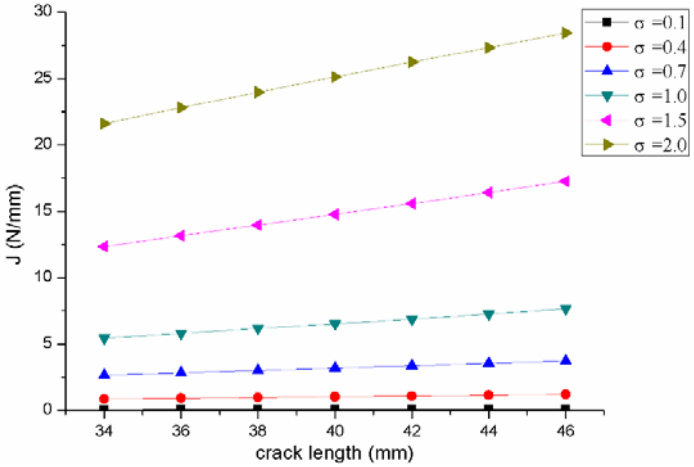

Fig.8 Effect of crack length on J-integral under different loadings

3. Conclusin

In this work, J-integral of nonlinear fracture for the colloid soft material with a center crack is calculated by the finite element method. When the integral circuit is very close to the crack tip, using the equivalent integral area method simulates J integral numerically. Through the divergence theorem, a limited area near the crack tip replacing the integral loop is used to calculate J-integral value. The PVA-H colloid soft material is simplified to elastic plastic model. J-integral within one unit is approximated by the gauss integral method. By summing for the J values of all units, J integral of the equivalent integral area corresponding to integral path is derived. Change integral path and calculate J integral of PVA-H colloid soft material in different integral path. The results can be summarized as follows:

(1) J integral of nonlinear fracture of PVA-H in a certain loading is independent on the integral path. Path-independent of the J integral obtained by Rice is proved once again by numerical method.

(2) The bigger the applied loading, the greater the J integral value of nonlinear fracture of PVA-H in the same integral path, approximately, for square relation.

(3) J integral value at the crack tip increases linearly along with the PVA-H crack length increasing. It is obvious that J integral or energy release rate of nonlinear fracture of PVA-H is severely affected by the crack length.

In the future, the above conclusions will provide certain theoretical guidance for PVA hydrogel as articular cartilage repair materials.

Abstract A mixed-mode crack in a magnetoelectroelastic layer under in-plane mechanical, electric and magnetic loadings is considered for electrically and magnetically impermeable crack surface conditions. Fourier transforms are applied to reduce the mixed-boundary-value problem of the crack to a system of singular integral equations. The asymptotic fields near the crack tip are obtained in an explicit form and the corresponding field intensity factors are obtained. The exact solution for a crack in an infinite magnetoelectroelastic material can be recovered if the width of the layer tends to infinity. The crack kinking phenomenon is investigated by applying the criterion of maximum hoop stress intensity factors. The results show that the size of the layer and the electric and magnetic loadings have significant effects on the singular field distributions around the crack tip, and the hoop stress intensity factors are influenced by the material parameters, the electric loadings and the geometric size ratios.

Keywords Mixed-mode crack, Magnetoelectroelastic layer, Singular integral equations, Crack kinking, Hoop stress intensity factor

1. Introduction

In the recent decade, effect, magentoelectroelastic materials can be used in intelligent structures as sensors, actuators and transducers Owing to the unique magneto-electro-mechanical coupling effect. In the recent decade, there is a growing interest among researchers in solving fracture mechanics problems in magnetoelectroelastic media.

Crack initiation behavior in magnetoelectroelastic composite under in-plane deformation was investigated by Song and Sih [1]. Gao et al. [2] developed an exact treatment on the crack problems in a magnetoelectroelastic solid subjected to far-field loadings. Qin [3] obtained 2D Green's functions of defective magnetoelectroelastic solids under thermal loading, which can be used to establish boundary formulation and to analyze relevant fracture problems. The moving crack problem in an infinite size magnetoelectroelastic body under anti-plane shear and in-plane electro-magnetic loadings has recently been solved by Hu and Li [4] whose results predicted that the moving crack may curve when the velocity of the crack is greater than a certain value. The dynamic response of a penny-shaped crack in a magnetoelectroelastic layer was studied by Feng et al. [5]. Boundary element method was developed by Rojas-Díaz et al. [6] to study crack problem in linear magnetoelectroelastic materials under static loading conditions. Wang and Mai [7] discussed the different electromagnetic boundary conditions on the crack-faces in magnetoelectroelastic materials, which possess coupled piezoelectric, piezomagnetic and magnetoelectric effects. Zhong and Li [8] gave a magnetoelectroelastic analysis for an opening crack in a piezoelectromagnetic solid. Zhou and Chen [9] analyzed a partially conducting mode I crack in piezoelectromagnetic materials. Zhao and Fan [10] proposed a strip electric-magnetic breakdown model in magnetoelectroelastic medium to study the nonlinear character of electric field and magnetic field on fracture of magnetoelectroelastic materials. The problem of a planar magnetoelectroelastic

layered half-plane subjected to generalized line forces and edge dislocations is analyzed by Ma and Lee [11]. Li and Lee [12] established real fundamental solutions for in-plane magnetoelectroelastic governing equations and studied collinear unequal cracks in magnetoelectroelastic materials. An embedded mixed-mode crack in a functionally graded magnetoelectroelastic infinite medium has been studied by Rekik et al. [13]. Recently, the pre-curving analysis of a crack in a magnetoelctroelastic strip under in-plane dynamic loading has been conducted by Hu and Chen [14] and the same authors [15] also studied the anti-plane problem of a magnetoelectroelastic strip sandwiched between elastic layers. The mode III crack crossing the magnetoelectroelastic bimaterial interface under concentrated magnetoelectromechanical loads was investigated by Wan et al. [16].

To the best knowledge of the authors, the mixed-mode crack in a magnetoelectroelastic layer with finite width under in-plane magneto-electro-elastic loadings has not been reported in the literature. This problem is solved in this paper. Fourier transforms are applied to reduce the mixed-boundary-value problem to a system of singular integral equations which can be solved numerically. The asymptotic fields near the crack tip are obtained in an explicit form and the corresponding field intensity factors are determined. The crack kinking phenomena is investigated by applying the criterion of maximum hoop stress intensity factors. The coupling magneto-electro-elastic effects on the crack-tip fields are investigated and the finite size effects on the dynamic fracture properties are discussed.

2. Problem statement and method of solution

Consider a transversely isotropic, linear magnetoelectroelastic material and denote the rectangular coordinates of a point by (x, y, z). The constitutive equations can be written as

$$\begin{Bmatrix}\sigma_{xx}\\ \sigma_{zz}\\ \sigma_{xz}\end{Bmatrix}=\begin{bmatrix}C_{11} & C_{13} & 0\\ C_{13} & C_{33} & 0\\ 0 & 0 & C_{44}\end{bmatrix}\begin{Bmatrix}\partial u_x/\partial x\\ \partial u_z/\partial z\\ \partial u_x/\partial z+\partial u_z/\partial x\end{Bmatrix}+\begin{bmatrix}0 & e_{31}\\ 0 & e_{33}\\ e_{15} & 0\end{bmatrix}\begin{Bmatrix}\partial\phi/\partial x\\ \partial\phi/\partial z\end{Bmatrix}+\begin{bmatrix}0 & h_{13}\\ 0 & h_{33}\\ h_{15} & 0\end{bmatrix}\begin{Bmatrix}\partial\varphi/\partial x\\ \partial\varphi/\partial z\end{Bmatrix}$$

$$\begin{Bmatrix}D_x\\ D_z\end{Bmatrix}=\begin{bmatrix}0 & 0 & e_{15}\\ e_{31} & e_{33} & 0\end{bmatrix}\begin{Bmatrix}\partial u_x/\partial x\\ \partial u_z/\partial z\\ \partial u_x/\partial z+\partial u_z/\partial x\end{Bmatrix}-\begin{bmatrix}\lambda_{11} & 0\\ 0 & \lambda_{33}\end{bmatrix}\begin{Bmatrix}\partial\phi/\partial x\\ \partial\phi/\partial z\end{Bmatrix}-\begin{bmatrix}d_{11} & 0\\ 0 & d_{33}\end{bmatrix}\begin{Bmatrix}\partial\varphi/\partial x\\ \partial\varphi/\partial z\end{Bmatrix} \tag{1}$$

$$\begin{Bmatrix}B_x\\ B_z\end{Bmatrix}=\begin{bmatrix}0 & 0 & h_{15}\\ h_{31} & h_{33} & 0\end{bmatrix}\begin{Bmatrix}\partial u_x/\partial x\\ \partial u_z/\partial z\\ \partial u_x/\partial z+\partial u_z/\partial x\end{Bmatrix}-\begin{bmatrix}d_{11} & 0\\ 0 & d_{33}\end{bmatrix}\begin{Bmatrix}\partial\phi/\partial x\\ \partial\phi/\partial z\end{Bmatrix}-\begin{bmatrix}\mu_{11} & 0\\ 0 & \mu_{33}\end{bmatrix}\begin{Bmatrix}\partial\varphi/\partial x\\ \partial\varphi/\partial z\end{Bmatrix}$$

where u_x, u_z are components of the displacement vector, ϕ and φ are the electric and magnetic potentials, respectively; $C_{11}, C_{13}, C_{33}, C_{44}$ are elastic constants, e_{15}, e_{31} are piezoelectric constants, h_{15}, h_{31} are piezomagnetic constants, $\lambda_{11}, \lambda_{33}$ are dielectric permittivities, and d_{11}, d_{33} are

electromagnetic constants; σ_{ij}, D_i and B_i ($i, j = x, z$) are components of stress, electric displacement and magnetic induction, respectively.

We study an electrically and magnetically impermeable crack of length $2c$ in a magnetoelectroelastic layer of width $h_1 + h_2$, with the poling direction perpendicular to the crack plane, as shown in Fig. 1. Uniform normal stress P_0 and in-plane electric field E_0 and magnetic field H_0 are applied on the cracked layer. Symmetry conditions can be applied and then it is necessary to consider only the region ($x \geq 0,\ -h_2 \leq z \leq h_1$).

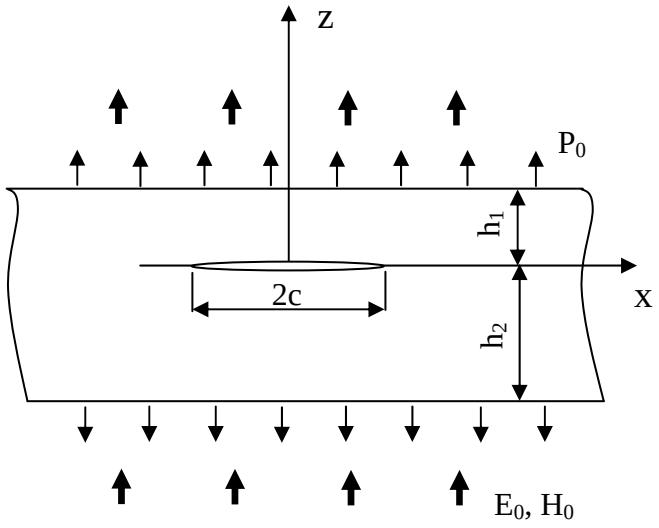

Figure 1. A cracked magnetoelectroelastic layer under in-plane magnetoelectromechanical loadings

Under the assumption of plane strain, the governing equations take the form

$$\begin{aligned}
&C_{11}u_{x,xx} + C_{44}u_{x,zz} + (C_{13} + C_{44})u_{z,xz} + (e_{31} + e_{15})\phi_{,xz} + (h_{31} + h_{15})\varphi_{,xz} = 0\\
&(C_{13} + C_{44})u_{x,xz} + C_{44}u_{z,xx} + C_{33}u_{z,zz} + e_{15}\phi_{,xx} + e_{33}\phi_{,zz} + h_{15}\varphi_{,xx} + h_{33}\varphi_{,zz} = 0\\
&(e_{31} + e_{15})u_{x,xz} + e_{15}u_{z,xx} + e_{33}u_{z,zz} - \lambda_{11}\phi_{,xx} - \lambda_{33}\phi_{,zz} - d_{11}\varphi_{,xx} - d_{33}\varphi_{,zz} = 0\\
&(h_{31} + h_{15})u_{x,xz} + h_{15}u_{z,xx} + h_{33}u_{z,zz} - d_{11}\phi_{,xx} - d_{33}\phi_{,zz} - \mu_{11}\varphi_{,xx} - \mu_{33}\varphi_{,zz} = 0
\end{aligned} \tag{2}$$

The boundary conditions on the layer surfaces and the impermeable crack faces are:

$$\sigma_{zz}(x, h_1) = \sigma_{zz}(x, -h_2) = P_0 \qquad (0 \leq x < \infty) \tag{3}$$

$$\sigma_{zx}(x, h_1) = \sigma_{zx}(x, -h_2) = 0 \qquad (0 \leq x < \infty) \tag{4}$$

$$E_z(x, h_1) = E_z(x, -h_2) = E_0 \qquad (0 \leq x < \infty) \tag{5}$$

$$H_z(x, h_1) = H_z(x, -h_2) = H_0 \qquad (0 \leq x < \infty) \tag{6}$$

$$\sigma_{zz}(x,0)=0,\ \ \sigma_{zx}(x,0)=0 \qquad (0\le x<c) \tag{7}$$

$$D_z(x,0)=0,\ \ B_z(x,0)=0 \qquad (0\le x<c) \tag{8}$$

The continuity conditions for the physical quantities across the crack plane are:

$$\sigma_{zx}(x,0^+)=\sigma_{zx}(x,0^-),\ \ \sigma_{zz}(x,0^+)=\sigma_{zz}(x,0^-), \qquad (x\ge c) \tag{9}$$

$$D_z(x,0^+)=D_z(x,0^-),\ \ B_z(x,0^+)=B_z(x,0^-), \qquad (x\ge c) \tag{10}$$

$$u_x(x,0^+)=u_x(x,0^-),\ \ u_z(x,0^+)=u_z(x,0^-), \qquad (x\ge c) \tag{11}$$

$$\phi(x,0^+)=\phi(x,0^-),\ \ \varphi(x,0^+)=\varphi(x,0^-), \qquad (x\ge c) \tag{12}$$

Fourier transforms are then applied on Eq. (2) and the solutions may be expressed as

$$u_{iz}^{(n)}(x,z)=\sum_{j=1}^{4}\Omega_{ij}\int_0^\infty\left[A_j^{(n)}(\xi)\cosh(\gamma_j\xi z)+B_j^{(n)}(\xi)\sinh(\gamma_j\xi z)\right]\cos(\xi x)d\xi+T_i z \qquad (i=1-3) \tag{13}$$

$$u_x^{(n)}(x,z)=-\sum_{j=1}^{4}a_j\gamma_j\int_0^\infty\left[A_j^{(n)}(\xi)\sinh(\gamma_j\xi z)+B_j^{(n)}(\xi)\cosh(\gamma_j\xi z)\right]\sin(\xi x)d\xi \tag{14}$$

where $u_{1z}=u_z,\ u_{2z}=\phi,\ u_{3z}=\varphi,\ \Omega_{1j}=1,\ \Omega_{2j}=b_j,\ \Omega_{3j}=d_j,\ \mathrm{T}_j\ (j=1,2,3)$ are constants and $a_j,\ b_j,\ d_j \quad (j=1-4)$ are known functions defined in Appendix A, $A_j^{(n)}(\xi),\ B_j^{(n)}(\xi),\ (n=1,2;\ j=1,2,3,4)$ are unknowns to be determined and the superscripts (1), (2) denote the fields quantities in the upper $0\le y\le h_1$ and lower parts $-h_2\le y\le 0$ of the cracked magnetoelectroelastic layer (as shown in Fig. 1), respectively.

The roots γ_j $(j=1-4)$ are determined from solving the following characteristic equation:

$$\begin{vmatrix} C_{11}-C_{44}\gamma^2 & (C_{13}+C_{44})\gamma & (e_{31}+e_{15})\gamma & (h_{31}+h_{15})\gamma \\ (C_{13}+C_{44})\gamma & C_{33}\gamma^2-C_{44} & e_{33}\gamma^2-e_{15} & h_{33}\gamma^2-h_{15} \\ (e_{31}+e_{15})\gamma & e_{33}\gamma^2-e_{15} & \lambda_{11}-\lambda_{33}\gamma^2 & d_{11}-d_{33}\gamma^2 \\ (h_{31}+h_{15})\gamma & h_{33}\gamma^2-h_{15} & d_{11}-d_{33}\gamma^2 & \mu_{11}-\mu_{33}\gamma^2 \end{vmatrix}=0 \tag{15}$$

It is noted that the eighth-order characteristic equation (15) has eight roots which occur in pairs with the same magnitude but opposite signs, and for complex roots, the roots always appear in conjugate pairs. In the expressions (13, 14), the roots γ_j $(j=1-4)$ are chosen as $\mathrm{Re}(\gamma_j)>0$ by requiring a positive internal energy for the system to be in a steady state.

The expressions for the stresses, electric displacement and magnetic induction can be obtained as follows:

$$\sigma_{ix}^{(n)}=-\sum_{j=1}^{4}V_{ij}\int_0^\infty\xi\left[A_j^{(n)}(\xi)\cosh(\gamma_j\xi z)+B_j^{(n)}(\xi)\sinh(\gamma_j\xi z)\right]\sin(\xi x)d\xi \qquad (i=1-3) \tag{16}$$

$$\sigma_{iz}^{(n)} = \sigma_{i0} - \sum_{j=1}^{4} U_{ij} \int_0^\infty \xi \left[A_j^{(n)}(\xi) \sinh(\gamma_j \xi z) + B_j^{(n)}(\xi) \cosh(\gamma_j \xi z) \right] \cos(\xi x) d\xi \quad (i = 1-4) \tag{17}$$

where

$$\begin{aligned} &\sigma_{1x} = \sigma_{zx},\ \sigma_{2x} = D_x,\ \sigma_{3x} = B_x;\ V_{1j} = f_j,\ V_{2j} = s_j,\ V_{3j} = t_j \\ &\sigma_{1z} = \sigma_{zz},\ \sigma_{2z} = D_z,\ \sigma_{3z} = B_z,\ \sigma_{4z} = \sigma_{xx};\ U_{1j} = g_j,\ U_{2j} = m_j,\ U_{3j} = n_j,\ U_{4j} = q_j \\ &\sigma_{10} = P_0,\ \sigma_{20} = e_{33}T_1 - \lambda_{33}T_2 - d_{33}T_{33},\ \sigma_{30} = h_{33}T_1 - d_{33}T_2 - \mu_{33}T_3,\ \sigma_{40} = C_{13}T_1 + e_{31}T_2 + h_{31}T_3 \end{aligned} \tag{18}$$

and the coefficients are defined as:

$$\begin{aligned} &f_j = C_{44}(a_j\gamma_j^2 + 1) - e_{15}b_j - h_{15}d_j,\ g_j = (C_{13}a_j + e_{33}b_j + h_{33}d_j - c_{33})\gamma_j \\ &q_j = (C_{11}a_j + e_{31}b_j + h_{31}d_j - c_{13})\gamma_j,\ m_j = (e_{31}a_j - \lambda_{33}b_j - d_{33}d_j - e_{33})\gamma_j \\ &n_j = (h_{31}a_j - d_{33}b_j - \mu_{33}d_j - h_{33})\gamma_j,\ s_j = e_{15}(a_j\gamma_j^2 + 1) + \lambda_{11}b_j + d_{11}d_j \\ &t_j = h_{15}(a_j\gamma_j^2 + 1) + d_{11}b_j + \mu_{11}d_j \end{aligned} \tag{19}$$

From the boundary conditions (3-10), the unknown functions $B_j^{(1)}(\xi)$, $A_j^{(2)}(\xi)$, $B_j^{(2)}(\xi)$ $(j = 1-4)$ can be expressed by the four independent unknowns $A_j^{(1)}(\xi)$ $(j = 1-4)$ as

$$B_j^{(1)}(\xi) = \sum_{i=1}^{4} R_{ji}^{(1)}(\xi, h_1) A_i^{(1)}(\xi) \tag{20}$$

$$A_j^{(2)}(\xi) = \sum_{i=1}^{4} T_{ji}(\xi, h_1, h_2) A_i^{(1)}(\xi) \tag{21}$$

$$B_j^{(2)}(\xi) = \sum_{i=1}^{4} R_{ji}^{(2)}(\xi, h_2) A_i^{(2)}(\xi) = \sum_{i=1}^{4} Q_{ji}(\xi, h_1, h_2) A_i^{(1)}(\xi) \tag{22}$$

where $R_{ji}^{(1)}(\xi, h_1)$, $T_{ji}(\xi, h_1, h_2)$ and $R_{ji}^{(2)}(\xi, h_2)$ are known functions.

Introduce the auxiliary functions $\Phi_i(x)$ $(i = 1-4)$ such that

$$\begin{Bmatrix} \Phi_1(x) \\ \Phi_2(x) \\ \Phi_3(x) \\ \Phi_4(x) \end{Bmatrix} = \frac{\partial}{\partial x} \begin{Bmatrix} u_x^{(1)}(x,0^+) - u_x^{(2)}(x,0^-) \\ u_z^{(1)}(x,0^+) - u_z^{(2)}(x,0^-) \\ \phi^{(2)}(x,0^+) - \phi^{(1)}(x,0^-) \\ \varphi^{(2)}(x,0^+) - \varphi^{(1)}(x,0^-) \end{Bmatrix} \tag{23}$$

By applying the solutions (13, 14) and using the Fourier inverse transform, the unknowns can be obtained as

$$\begin{Bmatrix} A_1^{(1)}(\xi) \\ A_2^{(1)}(\xi) \\ A_3^{(1)}(\xi) \\ A_4^{(1)}(\xi) \end{Bmatrix} = -\frac{2}{\pi\xi} \begin{bmatrix} Y_{11}(\xi) & Y_{12}(\xi) & Y_{13}(\xi) & Y_{14}(\xi) \\ Y_{21}(\xi) & Y_{22}(\xi) & Y_{23}(\xi) & Y_{24}(\xi) \\ Y_{31}(\xi) & Y_{32}(\xi) & Y_{33}(\xi) & Y_{34}(\xi) \\ Y_{41}(\xi) & Y_{42}(\xi) & Y_{43}(\xi) & Y_{44}(\xi) \end{bmatrix} \begin{Bmatrix} \int_0^c \Phi_1(s)\cos(s\xi)ds \\ \int_0^c \Phi_2(s)\sin(s\xi)ds \\ \int_0^c \Phi_3(s)\sin(s\xi)ds \\ \int_0^c \Phi_4(s)\sin(s\xi)ds \end{Bmatrix} \tag{24}$$

where $Y_{ij}(\xi)$ $(i, j = 1-4)$ are known functions. Satisfaction of the mixed boundary conditions (7, 8) on the crack face plane leads to the simultaneous singular integral equations

$$\begin{aligned}
&\int_{-1}^{1}\left\{\kappa_{i1}(s,x)\Psi_1(s)+\sum_{j=2}^{4}\left[\frac{U_{ij}^0}{s-x}+\kappa_{ij}(s,x)\right]\Psi_j(s)\right\}ds=-\pi\sigma_{i0}, \quad (i=1-3)\\
&\int_{-1}^{1}\left\{\left[\frac{U_{41}^0}{x-s}+\kappa_{41}(s,x)\right]\Psi_1(s,p)+\sum_{j=2}^{4}\kappa_{4j}(s,x)\Psi_j(s)\right\}ds=0
\end{aligned} \tag{25}$$

where $\Psi_i(s)=\Phi_i(cs)$, and $\kappa_{ij}(s,x)$ $(i=1-4)$ are known kernel functions, the constants U_{ij}^0 are defined as $U_{ij}^0=\lim_{\xi\to\infty}U_{ij}(\xi)$, and $U_{ij}(\xi)$ are known functions. The functions $\Psi_i(s)$ $(i=1-4)$ satisfy the single-valuedness condition:

$$\int_{-1}^{1}\Psi_i(s)ds=0, \quad (i=1-4) \tag{26}$$

The solution of $\Psi_i(s)$ may be expressed as

$$\Psi_i(s)=H_i(s)\Big/\sqrt{1-s^2} \tag{27}$$

where $H_i(s)$ $(i=1-4)$ are new unknowns to be solved.

The singular integral equations can be solved numerically as [17], [18]:

$$\begin{aligned}
&\sum_{i=1}^{n}A_i\left\{[\kappa_{m1}(x_k,s_i)]H_1(s_i)+\sum_{j=2}^{4}\left[\frac{U_{mj}^0}{s_i-x_k}+\kappa_{mj}(x_k,s_i)\right]H_j(s_i)\right\}=-\pi\sigma_{m0}, \quad (m=1-3)\\
&\sum_{i=1}^{n}A_i\left\{\left[\frac{U_{41}^0}{x_k-s_i}+\kappa_{41}(x_k,s_i)\right]H_1(s_i)+\sum_{j=2}^{4}[\kappa_{4j}(x_k,s_i)]H_j(s_i)\right\}=0
\end{aligned} \tag{28}$$

where,

$$\begin{aligned}
&s_i=\cos\left[\frac{(i-1)\pi}{n-1}\right], \quad (i=1,2,...,n); \quad x_k=\cos\left[\frac{(2k-1)\pi}{2(n-1)}\right], \quad (k=1,2,...,n-1)\\
&A_i=\frac{\pi}{2(n-1)}, \quad (i=1,n); \quad A_i=\frac{\pi}{(n-1)}, \quad (i=2,3,...,n-1)
\end{aligned} \tag{29}$$

For $h_1,\ h_2\to\infty$, $\kappa_{ij}(s,x)=0$ and from (25) the exact solution can be obtained as

$$\Psi_1(s)=0,\ \Psi_i(s)=c_i s\Big/\sqrt{1-s^2} \qquad (i=2-4) \tag{30}$$

where c_i $(i=2-4)$ are constants related to U_{ij}^0.

3. Asymptotic fields near the crack tip

Once the functions $H_j(s)$ ($j=1-4$) are obtained from solving the algebraic equations (28), following the procedure in Li and Lee [19], the asymptotic solutions of the magnetoelectroelastic fields near the crack tip can be obtained by introducing a polar coordinate system (r,θ) with the origin at the right crack tip as

$$r=\sqrt{(x-c)^2+z^2},\quad \theta=\tan^{-1}[z/(x-c)] \tag{31}$$

The hoop and shear stresses at an angle θ near the right tip of the crack are obtained from the following relations in terms of the polar coordinates (r,θ)

$$\begin{aligned}\sigma_{\theta\theta}(r,\theta)&=\sigma_{zz}(r,\theta)\cos^2\theta+\sigma_{xx}(r,\theta)\sin^2\theta-\sigma_{xz}(r,\theta)\sin 2\theta\\ \sigma_{r\theta}(r,\theta)&=\sin 2\theta[\sigma_{zz}(r,\theta)-\sigma_{xx}(r,\theta)]/2+\sigma_{xz}(r,\theta)\cos 2\theta\end{aligned} \tag{32}$$

Define the hoop stress intensity factor and shear stress intensity factor associated with the hoop and shear stresses at an arbitrary as angle θ as [20]:

$$K_{\theta\theta}=\lim_{r\to 0}\left(\sqrt{2r}\sigma_{\theta\theta}\right),\quad K_{r\theta}=\lim_{r\to 0}\left(\sqrt{2r}\sigma_{r\theta}\right) \tag{33}$$

The hoop and shear stress intensity factors can be obtained as:

$$K_{\theta\theta}^{(n)}=\sqrt{c}\sum_{j=1}^{4}\left\{\begin{array}{l}H_1(1)Y_{j1}^0\left[(-1)^n\Lambda_{1j}(\theta)\left(g_j\cos^2\theta+q_j\sin^2\theta\right)-\Lambda_{2j}(\theta)f_j\sin 2\theta\right]\\ +\sum_{k=2}^{4}H_k(1)Y_{jk}^0\left[(-1)^n\Lambda_{1j}(\theta)f_j\sin 2\theta+\Lambda_{2j}(\theta)\left(g_j\cos^2\theta+q_j\sin^2\theta\right)\right]\end{array}\right\} \tag{34}$$

$$K_{r\theta}^{(n)}=\sqrt{c}\sum_{j=1}^{4}\left\{\begin{array}{l}H_1(1)Y_{j1}^0\left[(-1)^n\Lambda_{1j}(\theta)\sin 2\theta\left(q_j-g_j\right)/2+\Lambda_{2j}(\theta)f_j\cos 2\theta\right]\\ +\sum_{k=2}^{4}H_k(1)Y_{jk}^0\left[\Lambda_{2j}(\theta)\sin 2\theta\left(g_j-q_j\right)/2-(-1)^n\Lambda_{1j}(\theta)f_j\cos 2\theta\right]\end{array}\right\} \tag{35}$$

where $0\le\theta\le\pi$ when $n=1$ for the upper part and $-\pi\le\theta\le 0$ when $n=2$ for the lower part of the cracked layer, respectively; $Y_{ij}^0=\lim_{\xi\to\infty}Y_{ij}(\xi)$, and the angular functions $\Lambda_{1j}(\theta)$ and $\Lambda_{2j}(\theta)$ ($j=1-4$) are defined as

$$\Lambda_{nj}(\theta)=\sqrt{\frac{\sqrt{\cos^2(\theta)+\left[\gamma_j\sin(\theta)\right]^2}+(-1)^n\cos(\theta)}{2\left[\cos^2(\theta)+\left[\gamma_j\sin(\theta)\right]^2\right]}}\qquad (n=1,2) \tag{36}$$

By setting the angle θ equal to zero, the common expressions for the Mode-I and Mode-II stress intensity factors can be recovered

$$K_I=K_{\theta\theta}|_{\theta=0}=\sqrt{c}\sum_{j=1}^{4}g_j\sum_{k=2}^{4}Y_{jk}^0H_k(1),\quad K_{II}=K_{r\theta}|_{\theta=0}=\sqrt{c}H_1(1)\sum_{j=1}^{4}f_jY_{j1}^0 \tag{37}$$

In this paper the criterion of maximum hoop stress intensity factors is applied to predict the crack kinking phenomena. It is noted that the applied electric and magnetic loadings and material properties have influence on the singular field near the crack tip, as shown in Eqs. (18), (25), (34), and (35).

4. Numerical results and discussions

For the magneto-electrically impermeable crack problem, the crack-tip fields are dependent on the remote mechanical, electrical and magnetic loading. To study the effect of magneto-electro-elastic interaction, the electric and magnetic loading parameters are introduced as:

$$L_E = e_{33}E_0/P_0, \quad L_H = h_{33}H_0/P_0 \tag{38}$$

The material constants used in the numerical calculation are selected as $BaTiO_3$-$CoFe_2O_4$ composite [21]:

$$\begin{aligned}
&C_{11} = 22.6\times10^{10}(\mathrm{N/m^2}),\ C_{13} = 12.4\times10^{10}(\mathrm{N/m^2}),\ C_{33} = 21.6\times10^{10}(\mathrm{N/m^2})\\
&C_{44} = 4.4\times10^{10}(\mathrm{N/m^2}),\ e_{15} = 5.8\ (\mathrm{C/m^2}),\ e_{31} = -2.2\ (\mathrm{C/m^2}),\\
&e_{33} = 9.3\ (\mathrm{C/m^2}),\ h_{15} = 275\ (\mathrm{N/Am}),\ h_{31} = 290.2\ (\mathrm{N/Am})\\
&h_{33} = 350\ (\mathrm{N/Am}),\ \lambda_{11} = 56.4\times10^{-10}(\mathrm{C^2/Nm^2}),\ \lambda_{33} = 63.5\times10^{-10}(\mathrm{C^2/Nm^2})\\
&\mu_{11} = 29.7\times10^{-5}(\mathrm{Ns^2/C^2}),\ \mu_{33} = 6.35\times10^{-5}(\mathrm{Ns^2/C^2})\\
&d_{11} = 5.367\times10^{-12}(\mathrm{Ns/VC}),\ d_{33} = 2737.5\times10^{-12}(\mathrm{Ns/VC})
\end{aligned} \tag{39}$$

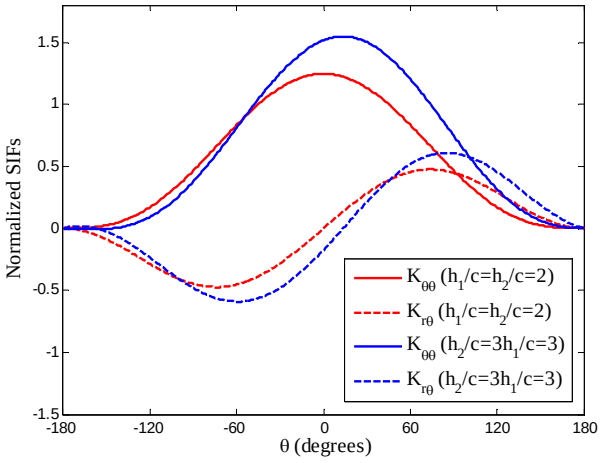

Figure 2. Normalized SIFs versus angle θ when $L_E = +0.5,\ L_H = -0.3$.

The variation of the normalized hoop and shear stress intensity factors (normalized by $P_0\sqrt{c}$) with angular position θ are displayed in Fig. 2. Without loss of generality, the applied stress is taken as $P_0 = 4.2$ MPa, and the magnitudes of the electric and magnetic loading parameters are chosen as $L_E = +0.5,\ L_H = -0.3$. The maximum hoop stress intensity factor (HSIF) occurs at $\theta = 0$ when the crack locates on the central plane of the layer, which indicates that the crack has a tendency to propagate along its original plane when the criterion of the maximum hoop stress

intensity factor is applied. When $h_1 \neq h_2$, the maximum HSIF occurs at $\theta \neq 0$, which indicates that the crack has a tendency to deviate from its original plane. When the HSIFs reach the maximum, the magnitude of the SSIF is zero.

5. Concluding remarks

A mixed-mode crack in a magnetoelectroelastic layer under in-plane mechanical, electric and magnetic loadings is studied for impermeable crack surface conditions. Fourier transforms are applied to reduce the mixed-boundary-value problem of the crack to a system of singular integral equations. Asymptotic fields near the crack tip are obtained explicitly and the corresponding field intensity factors are defined. The analytic solution of the degenerated case for a cracked infinite magnetoelectroelastic solid is recovered when the width of the layer tends to infinity. The crack kinking phenomena is investigated by applying the criterion of maximum hoop stress intensity factors.

Appendix A

$$\mathrm{T}_1 = \left(P_0 + e_{33}E_0 + h_{33}H_0\right)/C_{33}, \quad \mathrm{T}_2 = -E_0, \quad \mathrm{T}_3 = -H_0 \tag{A.1}$$

$$\begin{Bmatrix} a_j \\ b_j \\ d_j \end{Bmatrix} = \begin{bmatrix} C_{11} - C_{44}\gamma_j^2 & e_{31} + e_{15} & h_{31} + h_{15} \\ (C_{13} + C_{44})\gamma_j^2 & e_{33}\gamma_j^2 - e_{15} & h_{33}\gamma_j^2 - h_{15} \\ (e_{31} + e_{15})\gamma_j^2 & \lambda_{11} - \lambda_{33}\gamma_j^2 & d_{11} - d_{33}\gamma_j^2 \end{bmatrix}^{-1} \begin{Bmatrix} C_{13} + C_{44} \\ C_{33}\gamma_j^2 - C_{44} \\ e_{33}\gamma_j^2 - e_{15} \end{Bmatrix} \tag{A.2}$$

Abstract: This contribution presents a new theory with lattice Boltzmann & finite element & hypersingular integral equation (LB-FE-HIE) to explore the three-dimensional pore-network cracks transient hydrofacturing-liquefaction in tight sandstone (3D PC-TH-TS) under seismic waves & electro-magneto-thermo-elastic fields through intricate theoretical analysis and numerical simulations. First, the 3D PN-TH-TS problem is reduced to solving a set of coupled LB-FE-HIEs by using the Green functions and distribution functions, in which the unknown functions are the extended pore-network cracks displacement discontinuities. Then, the behavior of the extended displacement discontinuities at the pore-network cracks surface terminating at the solid-liquid film interface are analyzed through extended dynamic hypersingular integral main-part analysis method of LB-FE-HIEs. Closed formed solutions for the extended singular dynamic stress, the extended dynamic stress intensity factor and the extended dynamic energy release rate near the dislocations interface are provided. Last, the tight sandstone sample from the Ordos Basin Triassic formation is selected, the fluid-solid coupled digital rock physical modeling is established, and the simulations of 3D PC-TH-TS process is presented on the parallel CPU-GPU platform. The hydrofacturing-liquefaction varying with the amplitude, frequency and constituting time of earthquake wave is obtained. The relationship between the tight sandstone pore-network cracks transient propagation-evolution and the maximum tight sandstone fracturing-liquefaction stress criteria is explored.

Keywords Hydrofracturing-liquefaction, tight sandstone, lattice Boltzmann method, finite element method, hypersingular integral equation, seismic wave & electro-magneto-thermo-elastic fields, parallel CPU-GPU technology.

1. Introduction

Hydrofracturing-liquefaction mechanism is the basic theory for understanding the in-situ stress measurement, the petroleum-gas (nature gas and shale gas)-geothermic develop, and the earthquake evaluation and mechanism exploration. With the complex and challenge of this issue, the mechanism of dynamic Hydrofracturing-liquefaction is still not clear even a lot of fundamental and landmark achievements have been obtained in this field since the last century 60's. The oscillation singularity of dynamic stress wave as well as stress oscillation singularity index of pore-network cracks transient Hydrofracturing-liquefaction (PC-TH) fluid pore-solid sketch interface under seismic wave & electro-magneto-thermo-elastic fields (SW&EMTE) makes it much more difficult than the unsaturated cased of the ordinary cracks, for in this process, including fluid transient undrained process, fluid transient compression and expansion process, physical properties of tight

stone varying with PC-TH propagation process and tight stone transient failure with the liquefaction process (the liquefaction process time is around 10E-5s).

The mode I stress intensity factor for a constant velocity semi-infinite crack moving in a fluid-saturated porous medium with finite height is calculate[1]. The linear elastic solid with cavities containing nonviscous compressible fluid is explored[2], and the abnormally high fluid pressure in the cavities affects is analyzed. The mode I crack in an elastic fluid-saturated porous solids is studied[3], and relatively closed-form asymptotic solution near the crack tip is obtained. Extended horizontal cracks in a vertical column of saturated sand is explored [4], and the theory is good qualitative agreement with the experimental findings. The interaction of a normally incident time-harmonic longitudinal plane wave with a circular crack imbedded in a porous medium is considered [5], and the problem is formulated in dual integral equations for the Hankel transform of the wave field. The formation mechanism of "water film" (or crack) in saturated sand is analyzed theoretically and numerically[6]. The cracks in fluid-saturated two-phase medium is explored [7] by finite element method. A circular crack imbedded in a porous medium under a normally incident time-harmonic longitudinal plane wave is studied by second kind single Fredholm integral equation[8]. A finite element algorithm is presented for the numerical modeling of cohesive fracture in a partially saturated porous media[9]. The saturated cracks in 4% porosity Fontainebleau sandstone fro an effective mean pressure ranging from 2 to 95MPa under high ultrasonic frequencies, Vp/Vs, ratio is explored [10]. The narrow distribution of cavities permeability model is devised combining the hydraulic radium and percolation concepts [11]. But this problem is far from solved for complex relationship between fluid states, physical properties of tight sandstone and ultra high temperature-pressure (UHTP). There are four differences between classical porous medium and tight sandstone. First, the pore/void size is located at atom-molecular-pico-nano scale level, the fluid viscous (as function of UHTP), the effects of boundary layer, and the unsteady fluid flow (eddy flow and turbulent flow) can not be neglected; Second, when the P-T conditions are high enough, the water role in the rock/mineral includes free-supercritical-constitutional state, the fluid flow particles are composed of four components [H2O, H+, (OH)-, (H3O)+]. Third, the micro pore is composed of four types [multi-grain gap, polycrystalline space, crystal space and crystal internal space] and the deformation of the micro-structure had to be considered; Last, the fluid flow permeability and diffusion include intermolecular collisions and diffusion (Fick's laws of diffusion), molecular collisions with interface (Knudsen diffusion), molecular and interfacial adhesive and viscous flow (Darcy and Forchheimer flow). With the scale decrease, the surface stress component became domain, the effect of the body stress component reducing, and the classical N-S equation is no longer applies.

In this work, based on the previous work on saturated dislocation transient propagation-evolution in olivine structure under ultra-high temperature and pressure (UHTP)[12], and general solutions of extended displacement (elastic displacement, electrical potential, magnetic potential and thermal potential) given in the previous work[13, 14], the three-dimensional pore-network crack transient Hydrofracturing-liquefaction in tight sandstone (3D PC-TH-TS) under seismic waves & electro-magneto-thermo-elastic fields is studied by using lattice Boltzmann & finite element & hypersingular integral equation (LB-FE-HIE) on parallel GPU-CPU environment.

First, the 3D PN-TH-TS problem is reduced to solving a set of LB-FE-HIEs coupled with extended boundary integral equations by using the Green functions and distribution functions, in which the

unknown functions are the extended pore-network cracks displacement discontinuities. Then, the behavior of the extended displacement discontinuities around the pore-network cracks surface terminating at the solid-liquid film interface are analyzed by the extended hypersingular integral main-part analysis method of LB-FE-HIEs. Analytical solutions for the extended singular dynamic stresses, the extended dynamic stress intensity factors and the extended dynamic energy release rate near the dislocations front are provided. Thrid, the tight sandstone sample from the Ordos Basin Triassic formation is selected and different tomography resolution data is obtained by X-ray CT digital technology, the fluid-solid coupled porous medium physical modeling is established, and the relatively Hydrofracturing-liquefaction numerical modelling of tight sandstone is obtained for the first time. Last, The simulations of 3D PC-TH-TS process is presented, the hydrofacturing-liquefaction varying with the amplitude, frequency and time of earthquake wave is obtained. The relationship between the tight sandstone pore-network cracks transient propagation-evolution and the maximum tight sandstone fracturing-liquefaction stress criteria is explored.

2. Basic equations

Here summation from 1 to 3(1 to 6) over repeated lowercase (uppercase) subscripts is assumed, and a subscript comma denotes the partial differentiation with respect to the coordinates. The ultralow permeability tight sandstone (UPTS) consists of six constituents, i.e. the particles of solid skeleton (the 1st component), bound liquid film (the 2nd component), static pore-liquid (the 3rd component, free state water), dynamic pore-liquid I (the four component, free state water), dynamic pore-liquid II (the five component, supercritical state water) and dynamic pore-liquid III (the 6th component, constitutional state water [H+, (OH)-, (H3O)+]. The governing equations and constitutive relations of UPTS under EMTE field can be expressed as [15, 16],

$$A_L \tau^L_{ij,j} + B_L + \Sigma_{iJ,i} + f_J = 0 \tag{1}$$

where

$$A_L = \begin{cases} 1-(1-\alpha)\kappa & L=1 \\ \phi_2^P & L=2 \\ \phi_3^P & L=3 \\ \phi_4^P & L=4 \\ \phi_5^P & L=5 \\ \phi_6^P & L=6 \end{cases} \qquad B_L = \begin{cases} \left[(1-\kappa)\rho_1 + \alpha\kappa\rho_2\right]\ddot{U}(x_i,t)_{1i} - \sum_{N=1}^{5}\left\{v_N\delta_N^2\chi^{-1}\chi_N^{-1}\left[\dot{U}(x_i,t)_{(N+1)i} - \dot{U}(x_i,t)_{Ni}\right]\right\} & L=1 \\ \phi_2^P\rho_2\ddot{U}(x_i,t)_{2i} - \sum_{N=2}^{5}\left\{v_N\delta_N^2\chi^{-1}\chi_N^{-1}\left[\dot{U}(x_i,t)_{(N+1)i} - \dot{U}(x_i,t)_{Ni}\right]\right\} & L=2 \\ \phi_3^P\rho_3\ddot{U}(x_i,t)_{3i} - \sum_{N=3}^{5}\left\{v_N\delta_N^2\chi^{-1}\chi_N^{-1}\left[\dot{U}(x_i,t)_{(N+1)i} - \dot{U}(x_i,t)_{Ni}\right]\right\} & L=3 \\ \phi_4^P\rho_4\ddot{U}(x_i,t)_{4i} - \sum_{N=4}^{5}\left\{v_N\delta_N^2\chi^{-1}\chi_N^{-1}\left[\dot{U}(x_i,t)_{(N+1)i} - \dot{U}(x_i,t)_{Ni}\right]\right\} & L=4 \\ \phi_5^P\rho_5\ddot{U}(x_i,t)_{5i} - v_5\delta_5^2\chi^{-1}\chi_5^{-1}\left[\dot{U}(x_i,t)_{6i} - \dot{U}(x_i,t)_{5i}\right] & L=5 \\ \phi_6^P\rho_6\ddot{U}(x_i,t)_{6i} + v_6\delta_6^2\chi^{-1}\chi_6^{-1}\dot{U}(x_i,t)_{6i} & L=6 \end{cases}$$

$U(x_i,t)_{i1}, U(x_i,t)_{i2}, U(x_i,t)_{i3}, U(x_i,t)_{i4}, U(x_i,t)_{i5}$ and $U(x_i,t)_{i6}$ denote the components of displacements of drained porous solid frame, the components of displacements of drained bound liquid film, denote the components of displacements of the static pore-liquid, the components of displacements of the dynamic pore-liquid I, the components of displacements of the dynamic pore-liquid II, and the components of displacements of the dynamic pore-liquid III respectively; ρ_L, v_{NL}, χ, χ_{NL} and δ_L denote density, viscosity, intrinsic permeability, relative permeability and volume fractions of L th component of ultra-low permeability porous rock respectively; κ, α, ϕ_2^P, ϕ_3^P, ϕ_4^P, ϕ_5^P and ϕ_6^P represent macro porosity of ultra-low permeability rock, fraction occupied by bound liquid film, the connected porosity of bound liquid film, the connected porosity of static pore-liquid part, the connected porosity of dynamic pore-liquid I, II and III respectively. In addition, the extended stress displacement matrix tensor and the extended body load vector, $\sum_{iJ}$ and f_J, are defined respectively as

$$\sum_{iJ}=\begin{cases}\sigma_{ij} & J=j=1,2,3\\ D_i & J=4\\ B_i & J=5\\ \vartheta_i & J=6\end{cases}\qquad f_J=\begin{cases}f_j & J=j=1,2,3\\ -f_e & J=4\\ -f_m & J=5\\ -f_\vartheta & J=6\end{cases}\tag{2}$$

The combined constitutive equation is written as

$$\sum_{iJ}=E_{iJKl}Z_{Kl}\tag{3}$$

where the EMTE constant matrix tensor and the extended strain field matrix tensor, E_{iJKl} and Z_{Kl}, take the form

$$E_{iJKl}=\begin{bmatrix}C_{iJKl} & -\Pi_{iJ} & 0\\ 0 & 0 & -\lambda_{iJ}\end{bmatrix}\qquad Z_{Kl}=[\ U^s_{K,l}\quad \Upsilon_{,l}\ ]^T\tag{4}$$

The extended elastic stiffness tensor, the extended thermal stress constants tensor and the extend elastic displacement vector, C_{iJKl}, Π_{iJ} and U_K, are defined as

$$C_{iJKl}=\begin{cases}c_{ijkl} & J,K=1,2,3\\ e_{lij} & J=1,2,3;K=4\\ e_{ikl} & J=4;K=1,2,3\\ d_{lij} & J=1,2,3;K=5\\ d_{ikl} & J=5;K=1,2,3\\ -g_{il} & J=4;K=5 or J=5;K=4\\ -\in_{il} & J,K=4\\ -\mu_{il} & J,K=5\end{cases}\quad \Pi_{iJ}=\begin{cases}\iota_{ij} & J=1,2,3;K=6\\ \varsigma_{il} & J=4;K=6\\ \eta_{il} & J=5;K=6\end{cases}\quad U^s_K=\begin{cases}u^s_i & K=1,2,3\\ \phi^s_4 & K=4\\ \varphi^s_5 & K=5\\ \Upsilon^s_6 & K=6\end{cases}\tag{5}$$

σ_{ij}, D_i, B_i, ϑ_i, f_i, f_e, f_m , f_ϑ, c_{ijkl}, e_{lij}, d_{lij}, $\in_{il}$, g_{il}, μ_{il}, ι_{ij}, ς_{il}, η_{il}, λ_{ij}, u^s_i, ϕ^s_4, φ^s_5 and Υ^s_6 are defined in [14]. The drained porous solid frame and the drained bound liquid film have the same displacement and pressure; The static pore-liquid, the dynamic pore-liquid I have the same displacement; The pressure of saturated porous solid frame is the sum of static pore-liquid, dynamic pore-liquid I, dynamic pore-liquid II and dynamic pore-liquid III components pressure. The seismic wave displacement in ultra-low permeability porous rock can be written as

$$U(x_i,t)_{iL}=\Phi^1(x_i,t)_{iL,i}+\varepsilon_{ijk}\Phi^2(x_i,t)_{jL,k}$$

where

$$\Phi(x_i,t)^\alpha_{iL}=-A^\alpha_i E(\omega t)\left\{\delta_{3i}\begin{bmatrix}E(-2\omega^\alpha_L x_1x_2x_3\sin\theta^\alpha_{1L}\cos\theta^\alpha_{2L})+E(-2\omega^\alpha_L x_1x_2x_3\cos\theta^\alpha_{1L}\sin\theta^\alpha_{2L})\\ +E(-2\omega^\alpha_L x_1x_2x_3\cos\theta^\alpha_{1L}\cos\theta^\alpha_{2L})+E(-2\omega^\alpha_L x_1x_2x_3\sin\theta^\alpha_{1L}\sin\theta^\alpha_{2L})\end{bmatrix}\right\}$$
$$\begin{bmatrix}+E(-2\omega^\alpha_L x_3\cos\angle(x_3,x_2)^\alpha_{pL})+E(-2\omega^\alpha_L x_3\cos\angle(x_3,x_1)^\alpha_{pL})\end{bmatrix}$$
$$\times\begin{bmatrix}E(\omega^\alpha_L x_1\sin\angle(x_3,x_2)^\alpha_{pL})+E(\omega^\alpha_L x_2\sin\angle(x_3,x_1)^\alpha_{pL})+E(2\omega^\alpha_L x_1x_2\sin\theta^\alpha_{1L}\cos\theta^\alpha_{2L})+E(2\omega^\alpha_L x_1x_2\cos\theta^\alpha_{1L}\sin\theta^\alpha_{2L})\\ +E(2\omega^\alpha_L x_1x_2\cos\theta^\alpha_{1L}\cos\theta^\alpha_{2L})+E(2\omega^\alpha_L x_1x_2\sin\theta^\alpha_{1L}\sin\theta^\alpha_{2L})\end{bmatrix}$$

$$\theta^\alpha_{1L}=\begin{cases}\angle(x_3,x_2)_{pL}+\angle(x_3,x_1)_{pL} & \alpha=1\\ \angle(x_3,x_2)_{pL}-\angle(x_3,x_1)_{pL} & \alpha=2\end{cases},\ \theta^\alpha_{2L}=\begin{cases}\angle(x_3,x_2)_{sL}+\angle(x_3,x_1)_{sL} & \alpha=1\\ \angle(x_3,x_2)_{sL}-\angle(x_3,x_1)_{sL} & \alpha=2\end{cases},\ \omega^\alpha_L=\begin{cases}\omega/v^L_P & \alpha=1\\ \omega/v^L_S & \alpha=2\end{cases},\ E()=e^{i()}$$

v^1_P, v^2_P, v^3_P, v^4_P, v^5_P and v^6_P denote the P-wave velocity in drained porous solid frame, drained bound liquid film, static pore-liquid, dynamic pore-liquid I, dynamic pore-liquid II and dynamic pore-liquid III respectively; v^1_S, v^2_S, v^3_S, v^4_S, v^5_S and v^6_S denote the P-wave velocity in drained porous solid frame, drained bound liquid film, static pore-liquid, dynamic pore-liquid I, dynamic pore-liquid II and dynamic pore-liquid III respectively; $\angle(x_3,x_2)_{pL}$, $\angle(x_3,x_1)_{pL}$, $\angle(x_3,x_2)_{sL}$ and $\angle(x_3,x_1)_{sL}$ denote the P-wave incidence angle between x_3 and x_2 axes, the P-wave incidence angle between x_3 and x_1 axes, the S-wave incidence angle between x_3 and x_2 axes and the S-wave incidence angle between x_3 and x_1 axes in the L th component of ultra-low permeability porous rock

respectively. If we defined that solid skeleton component and liquid components are parallel and subjected to the same strain, the time-dependent rigidity modulus components G_L of ultra-low permeability porous rocks can be defined as

$$G_L = (1-f)G_0 + \alpha f (v_s^L \varepsilon_L^{-2})_{,t}$$

f, α, ε_L^{-2} and G_0 represent macro-porosity of ultra-low permeability porous rocks, fraction occupied by bound liquid film, non-dimensional parameter (linked fluid viscosity, bulk modulus, density and permeability) of L th component of ultra-low permeability porous rock, and rigidity modulus of solid grains.

3.LB-FE-HIE for 3D PC-TH-TS under seismic wave & electro-magneto-thermo-elastic fields

3.1 Lattice Boltzmann & finite element (LB-FE) coupled modeling

It is shown in the Fig 1, The LB-FE coupled modeling for tight sand porous media is established. The finite element method is using to analyze solid sketch part of the porous tight sand (the strain/strain rate-stress/stress rate-temporal spatial solid sketch structure-macro strength) (Fig1D, 1E); D3Q27 lattice Boltzmann method is using to analyze fluid pore part of the porous tight sand (fluid stress-viscous-density-time-bulk strain) (Fig 1F); LB-FE coupled modeling can deal with interface stress-strain between solid sketch and fluid pore (surface of pore-network cracks) (Fig 1C). In our work, the three-dimensional 20 node arbitrary hexahedral element (3D-20 Hexahedral element) is defined for the solid sketch part of the porous tight sand, and the three-dimensional 27 particle arbitrary hexahedral node (D3Q27) is defined for the fluid pore part of the porous tight sand; if the element is located at the surface of the pore-network cracks, then we defined that each D3Q27 node has the same physical meaning as one arbitrary node of 3D-20 Hexahedra element (Fig 1G,1H and 1I), the distribution function of lattice Boltzmann and the shape function in finite element can be linked through intricate theoretical formulation, and the LB-FE coupled fluid pore-solid sketch porous modeling can be established, the theoretical derivation can be written as follows,The equation of shape function for 3D-20 Hexahedra isoparametric element is defined as

$$N_k = \begin{cases} \prod_{i=1}^{3}(1+x_{ik}x_i)\left(\sum_{i=1}^{3}x_{ik}x_i - 2\right) & k = 1 \sim 8 \\ 2\prod_{i=1}^{3}(1+x_1^2) & k = 9 \sim 12 \\ 2(1-x_2^2)(1+x_{ik}x_1)(1+x_{3k}x_3) & k = 13 \sim 16 \\ 2(1-x_3^2)(1+x_{1k}x_1)(1+x_{3k}x_3) & k = 16 \sim 20 \end{cases} \tag{6}$$

The relatively stiffness matrix for 3D-20 Hexahedra isoparametric element is defined as

$$[K] = \int_{-1}^{1}\int_{-1}^{1}\int_{-1}^{1}[B]^T[D][B]\lfloor J \rfloor dx_1 dx_2 dx_3 \tag{7}$$

where

$$[B_K] = \begin{bmatrix} \frac{\partial N_K}{\partial \xi_1} & 0 & 0 \\ 0 & \frac{\partial N_K}{\partial \xi_2} & 0 \\ 0 & 0 & \frac{\partial N_K}{\partial \xi_3} \\ \frac{\partial N_K}{\partial \xi_2} & \frac{\partial N_K}{\partial \xi_1} & 0 \\ 0 & \frac{\partial N_K}{\partial \xi_1} & \frac{\partial N_K}{\partial \xi_2} \\ \frac{\partial N_K}{\partial \xi_3} & 0 & \frac{\partial N_K}{\partial \xi_1} \end{bmatrix} \quad [D] = \frac{E(1-v)}{(1+v)(1-2v)}\begin{bmatrix} 1 & A_1 & A_2 & 0 & 0 & 0 \\ A_1 & 1 & A_1 & 0 & 0 & 0 \\ A_2 & A_1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & A_2 & 0 & 0 \\ 0 & 0 & 0 & 0 & A_2 & 0 \\ 0 & 0 & 0 & 0 & 0 & A_2 \end{bmatrix} \quad [J] = \begin{bmatrix} \frac{\partial \xi_1}{\partial x_1} & \frac{\partial \xi_2}{\partial x_1} & \frac{\partial \xi_3}{\partial x_1} \\ \frac{\partial \xi_1}{\partial x_2} & \frac{\partial \xi_2}{\partial x_2} & \frac{\partial \xi_3}{\partial x_2} \\ \frac{\partial \xi_1}{\partial x_3} & \frac{\partial \xi_1}{\partial x_3} & \frac{\partial \xi_1}{\partial x_3} \end{bmatrix} \quad A_1 = \frac{v}{1-v} \quad A_2 = \frac{1-2v}{2(1-v)}$$

The extended equivalent stress and tension for 3D-20 Hexahedra isoparametric element is defined as

$$\{R\}_{volume} = \int_{-1}^{1}\int_{-1}^{1}\int_{-1}^{1}[N]^T\{p\}|J|dx_1dx_2dx_3 \tag{8}$$

$$\{R\}_{surface} = \iint_{A_{x_1x_2}}[N]^T\{\bar{p}\}\Big|_{x_1=1}dA \tag{9}$$

Take the distribution function of D3Q27 LB node[17] into the shape function of 3D-20 Hexahedra element, the LB-FE modeling can be established to analyze the fluid-solid coupled porous structure problem.

3. 2 LB-FE-HIE for 3D PC-TH-TS under seismic wave & electro-magneto-thermo-elastic fields

Using Micro XCT-400 CT system, the high resolution data are obtained, the 3D virtual digital rock are reestablished, and the LB-FE-HIE physical model are constructed; The threshold is arrange from 78~100, the interior geometry structure at low level scales translate from the pix RGB color into the cell-mesh-grid model, the initial/boundary conditions, the physical/chemical parameters of rock and water, and the low level scales geometry pore-solid structure can be defined.

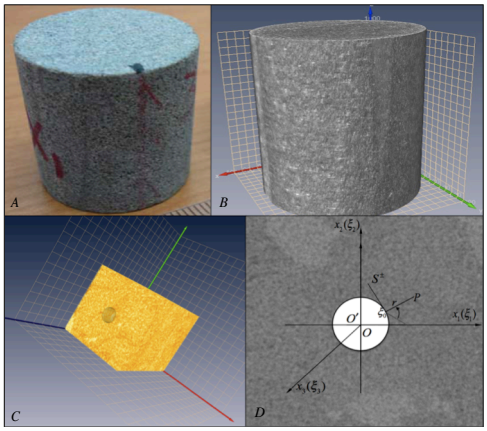

Fig 2. The tight sandstone transient hydrofracturing-liquefaction lattice Boltzmann & finite element fluid-solid coupled modelling
Fig 2A. Sample of tight sandstone, Fig 2B. Virtual digital rock sample of tight sandstone
Fig 2C, A circle drilling in the tight sandstone, Fig 1D. Sketch of transient hydrofracturing-liquefaction in the tight sandstone

Fig 2. shows the PC-TD-TS LB-FE-HHIE coupled modeling, the diameter and the length of the core samples are equal to 5cm and 10cm respectively; the resolution of cross-section and the interval between cross-sections are equal to 10μm. The general model was formulated by utilizing an automatic local amplification grid technique, and the initial LB-FE-HIE physical model is equal to 1024×1024×1024 pixels, which does not include the extended variables. Applying function in references [18, 19] to the initial virtual digital rock modeling, we can obtained the random LB-FE-HIE modeling (decreasing the computational scale in parallel CPU-GPU environment). The pore/void size is located at atom-molecular-pico-nano scale level, the fluid viscous (as function of

pressure-temperature), the effects of boundary layer, and the unsteady fluid flow (eddy flow and turbulent flow) had to be considered. The water role in the rock includes free state, supercritical state and constitutional state; the fluid flow particles are composed of four components [H2O, H+, (OH)-, (H3O)+]. The micro pore is composed of four kinds [multi-grain gap, polycrystalline clearance, crystal space and crystal internal clearance] and the deformation of the microstructure had to be considered. The fluid flow permeability and diffusion include intermolecular collisions and diffusion (Fick's laws of diffusion); molecular collisions with interface (Knudsen diffusion), molecular and interfacial adhesive and viscous flow (Darcy flow and Forchheimer flow). With the scale decrease, the surface stress component became domain, the effect of the body stress component reducing, and the classical N-S equation is no longer applies. The more detailed introduction can be found elsewhere in the literature[20-23].

Consider the tight sandstone containing a random three-dimensional transient hydrofacturing-liquefaction crack as shown in Fig.2D. A fixed global rectangular Cartesian system x_i (i=1,2,3) is chosen. Assume that the pore-network crack S ($S^+ \bigcup S^-$) is subjected to remote the seismic wave mechanical loads $p_j(P,Q,t)$, the seismic wave electrical loads $q(P,Q,t)$, the seismic magnetic loads $b(P,Q,t)$ and the thermal loads $\rho(P,Q,t)$, respectively. The local rectangular Cartesian system ξ_i are chosen, the stochastic flaws are assumed to be in the $\xi_1\xi_2^i$ plane and normal to the ξ_3 axis. Using the EMTE form of the Somigliana identity, the extended displacement vector, $U_I(p)$, at interior point $p(x_1,x_2,x_3)$ is expressed as

$$U_I(p)=\int_{S^+}(U_{IJ}(p,q)T_J(q)-T_{IJ}(p,q)U_J(q))ds(q)-\int_{\Gamma}(T_{IJ}(p,q)U_J(q)+U_{IJ}(p,q)T_J(q))ds(q)+\int_{\Omega}U_{IJ}(p,q)f_J(q)ds(q) \tag{10}$$

where Ω is the domain occupied by the EMTE-CMCs, Γ is the external boundary, $T_J(q)$ is the extended elastic tractions on boundaries, $U_{IJ}(p,q)$ and $T_{IJ}(p,q)$ are the fundamental solutions. Using constitutive Equation (10), the corresponding extended stresses tensor, Σ_{IJ}, is expressed as

$$\Sigma_{IJ}(p)=-\int_{S^+}S_{KiJ}(p,q)\tilde{U}_K(q)ds(q)+\int_{\Gamma}(D_{KiJ}(p,q)T_K(q)-S_{KiJ}(p,q)U_K(q))ds(q)+\int_{\Omega}D_{KiJ}(p,q)f_K(q)ds(q) \tag{11}$$

The kernels functions, S_{KiJ} and D_{KiJ}, are as follows:

$$S_{KiJ}(p,q)=-E_{iJMn}T_{MK,n}(p,q) \qquad D_{KiJ}(p,q)=-E_{iJMn}U_{MK,n}(p,q) \tag{12}$$

The hypersingular integral equations can be obtained as

$$\sum_{i=1}^{5}\rho_i^2t_i^2\sum_{m=3}^{6}\tilde{u}_{m,1}=\int_{S^+}\left(\frac{c_{44}^2D_0s_0^2(\delta_{\bar{\alpha}\bar{\beta}}-3r_{,\bar{\alpha}}r_{,\bar{\beta}})+(\delta_{\alpha\beta}-3r_{,\alpha}r_{,\beta})\sum_{i=1}^{5}\rho_i^2t_i^2}{r^3}\hat{K}\,\tilde{u}_{\beta}+\frac{3r_{,\alpha}\sum_{i=1}^{5}\lambda_{33}s_i^2t_i}{r^4}\tilde{u}_6\right)ds+\int_{S^+}K_{\alpha i}\tilde{u}_i\,ds=-p_{\alpha} \tag{13}$$

$$\sum_{n=3}^{5}\sum_{i=1}^{5}\rho_i^mt_i^t\sum_{m=3}^{6}\tilde{u}_{m,2}+\int_{S^+}\left(\frac{r_{,\alpha}\sum_{i=1}^{5}A_i^{\Upsilon}t_i^2\rho_i^1}{r^2}\tilde{u}_{\alpha}+\frac{\sum_{n=3}^{5}\sum_{i=1}^{5}\rho_i^mt_i^t}{r^3}\tilde{u}_n+\frac{3\lambda_{3\alpha}r_{,\alpha}\sum_{i=1}^{5}s_i^2\lambda_i^{\vartheta}\rho_i^m}{r^4}\tilde{u}_6\right)ds+\int_{S^+}K_{mi}\tilde{u}_i\,ds=-p_m \tag{14}$$

$$\sum_{i=1}^{5}A_i^{\Upsilon}\lambda_{3\beta}t_i^2\tilde{u}_{\alpha,\alpha}+\int_{S^+}\left(\frac{(\delta_{\alpha\beta}-3r_{,\alpha}r_{,\beta})\sum_{i=1}^{5}A_i^{\Upsilon}\lambda_{3\beta}t_i^2}{r^2}\tilde{u}_{\beta}+\frac{3\lambda_{3\alpha}r_{,\alpha}\sum_{i=1}^{5}A_i^{\Upsilon}s_i^2\lambda_i^{\vartheta}\lambda_{33}\rho_i^6}{r^4}\tilde{u}_6\right)ds+\int_{S^+}K_{6i}\tilde{u}_i\,ds=-p_6 \tag{15}$$

where $p_i^{\hat{i}}$, $p_4^{\hat{i}}(q^{\hat{i}})$, $p_5^{\hat{i}}(b^{\hat{i}})$ and $p_5^{\hat{i}}(\rho^{\hat{i}})$ can obtained from the solution for the loads of the solids.

4. Dynamic stress, dynamic stress intensity factors and energy release rate near the dislocations front

In order to investigate the singularity of the dislocations front, consider a local coordinate system defined as $x_1\ x_2\ x_3$. The x_1-axis is the tangent line of the dislocation front at point q_0, x_2-axis is the internal normal line in the dislocation plane, and x_3-axis is the normal of the dislocation. Then, the extended displacement discontinuities of the dislocation surface near a dislocation front point q_0 can be assumed as

$$[\ \tilde{u}_i^{\hat{I}}(q)\quad \tilde{\phi}^{\hat{I}}(q)\quad \tilde{\varphi}^{\hat{I}}(q)\quad \tilde{\Upsilon}^{\hat{I}}(q)\ ] = g_k^{\hat{I}}(q_0)\xi_2^{\lambda_k} \qquad 0 < Re(\lambda_k) < 1 \tag{16}$$

where $g_k(q_0)$ and λ_k represent non-zero constants and singular index, respectively. The dynamic stress intensity factors are defined as

$$K_1^{\hat{I}} = \lim_{r\to 0}\sqrt{2r}\sigma_{33}^{\hat{I}}(r,\theta)\Big|_{\theta=0}, K_2^{\hat{I}} = \lim_{r\to 0}\sqrt{2r}\sigma_{32}^{\hat{I}}(r,\theta)\Big|_{\theta=0}, K_3^{\hat{I}} = \lim_{r\to 0}\sqrt{2r}\sigma_{31}^{\hat{I}}(r,\theta)\Big|_{\theta=0} \tag{17}$$

$$K_4^{\hat{I}} = \lim_{r\to 0}\sqrt{2r}D_3^{\hat{I}}(r,\theta)\Big|_{\theta=0}, K_5^{\hat{I}} = \lim_{r\to 0}\sqrt{2r}B_3^{\hat{I}}(r,\theta)\Big|_{\theta=0}, K_6^{\hat{I}} = \lim_{r\to 0}\sqrt{2r}\vartheta_3^{\hat{I}}(r,\theta)\Big|_{\theta=0} \tag{18}$$

where r is the distance from point p to the dislocation front point q_0, the dynamic stress around the dislocation front can be expressed as follows

$$\sigma_{13}^{\hat{I}} = c_{44}^2 D_0 s_0^2 \frac{\pi g_1^{\hat{I}}}{\sqrt{rr_0}}\cos\frac{\theta_0}{2} \tag{19}$$

$$\begin{aligned}\sigma_{23}^{\hat{I}} = \sum_{i=1}^{5}\frac{\pi}{\sqrt{rr_i}}\{&g_6^{\hat{I}}\lambda_{33}[15\lambda_{33}s_i^2\cot\theta_i(3\cos\frac{\theta_i}{4}-3\sin^2\frac{\theta_i}{2}\cos\frac{\theta_i}{2}-\frac{1}{4}\sin^2\theta_i\cos\frac{3\theta_i}{2})-\frac{2\lambda_{33}}{r^2r_i^2}\sin^{-1}\frac{\theta_i}{2}\\ &+\frac{\lambda_{32}}{2rr_i\sin\theta}(2\cos^{-1}\frac{\theta_i}{2}-3\cos\frac{\theta_i}{2}-\cos\frac{5\theta_i}{2})]+\rho_i^2\pi\cos\frac{\theta_i}{2}(t_2g_2+4\sum_{m=3}^{5}t_i^m g_m^{\hat{I}})\}\end{aligned} \tag{20}$$

$$\begin{aligned}\dot{\sigma}_{3n}^{\hat{I}} = \sum_{i=1}^{5}\rho_i^n s_i\pi[&\frac{1}{\sqrt{rr_i}}(t_i^2 g_2^{\hat{I}}\cot\theta_i\cos^{-1}\frac{\theta_i}{2}+6\cot\frac{\theta_i}{2}\sum_{m=3}^{5}t_i^m g_m^{\hat{I}})+g_6^{\hat{I}}s_i\lambda_i^{\vartheta}\sqrt{rr_i}\cot\theta_i\cos\frac{\theta_i}{2})]\\ &+2\pi A_i^{\Upsilon}\mathfrak{t}_{33}[\sqrt{rr_i}\cos\frac{\theta_i}{2}(g_2^{\hat{I}}\cot\theta_i+\sum_{m=3}^{5}t_i^m g_m^{\hat{I}})+\frac{s_i^2\lambda_{33}\lambda_i^{\vartheta}g_6^{\hat{I}}}{\sqrt{rr_i}}\cos\frac{\theta_i}{2}],n=3-5\end{aligned} \tag{21}$$

$$\begin{aligned}\vartheta_3^{\hat{I}} = \sum_{i=1}^{5}\frac{A_i^{\Upsilon}\pi}{\sqrt{rr_i}}&[\cos\frac{\theta_i}{2}(\lambda_{32}+4\lambda_{33}s_i^2)\sum_{m=2}^{5}t_i^m g_m^{\hat{I}}+\frac{4\lambda_{32}t_i^2 g_2^{\hat{I}}s_i^2\lambda_i^{\vartheta}}{3}(2\lambda_{32}\cos\frac{\theta_i}{2}+\frac{3\lambda_{33}}{r^2r_i^2}\sin^{-1}\frac{\theta_i}{2})\\ &15rr_i g_6^{\hat{I}}\lambda_{32}s_i^2\lambda_i^{\vartheta}\cot\theta_i(3\cos\frac{\theta_i}{4}-6\cos\frac{\theta_i}{2}\sin^2\frac{\theta_i}{2}-\frac{1}{4}\sin^2\theta_i\cos\frac{3\theta_i}{2})(2s_i^2\lambda_{33}+\frac{\lambda_{32}}{rr_i\sin\theta_i})]\end{aligned} \tag{22}$$

The extended singular stresses, $\dot{\sigma}_{3n}^{\hat{I}} = [\ \sigma_{33}^{\hat{I}}\quad D_3^{\hat{I}}\quad B_3^{\hat{I}}\ ]$, can be rewritten as

$$\sigma_{13}^{\hat{I}} = K_3^{\hat{I}}\cos\frac{\theta_0}{2}/\sqrt{2rr_0} \tag{23}$$

$$\hat{\sigma}_{n3}^{\hat{I}} = [\quad \sigma_{23}^{\hat{I}}\quad \sigma_{33}^{\hat{I}}\quad D_3^{\hat{I}}\quad B_3^{\hat{I}}\quad \vartheta_3^{\hat{I}}\quad] = (K_1^{\hat{I}}f_{n1}+K_2^{\hat{I}}f_{n2}+K_4^{\hat{I}}f_{n4}+K_5^{\hat{I}}f_{n5}+K_6^{\hat{I}}f_{n6})/\sqrt{2r}, n=2-6 \tag{24}$$

where the coefficient functions f_{IJ} are listed in [14]. Other extended singular stresses near point q_0 can also be obtained by use of above method. $K_2^{\hat{I}}$ is coupled with $K_3^{\hat{I}}$ and $K_6^{\hat{I}}$, $K_1^{\hat{I}}$ is coupled with $K_4^{\hat{I}}$, $K_5^{\hat{I}}$ and $K_6^{\hat{I}}$. The energy release rate can be obtained and expressed as followings,

$$\frac{dW}{dV} = 2\sqrt{2r}S = \frac{K_n^2}{2\sqrt{2r}}\left(\frac{a_{3n}^2}{E}+\frac{a_{1n}^2+a_{2n}^2}{\tilde{\mu}}+\frac{a_{4n}^2+a_{5n}^2+a_{6n}^2}{E'}\right) \tag{13}$$

$$W = U_s + U_k + U_f \tag{14}$$

5. Numerical simulation and discussion

A tight sandstone core samples from the Ordos Basin Triassic formation of China which include multi pore-network cracks is selected, the rock depth, the diameter, the length, the density, the confining pressure, the pore stress and the temperature are defined as 862.76~864.36m, 25.4mm, 25~30mm, 2.359~2.426g/cm3, 0~200MPa, 0~10MPa, 35~45 °C respectively, the more detail parameters of the tight sandstone core sample are shown in Tab.1.

Tab.1. Mineral composition, porosity and matrix density of the tight sandstone samples

Sample Number	Direction	Mineral composition(volume percent)					Porosity (%)	Density (g/cm^3)
		Quarzt	Feldspar	Rock debris	Mica	Heavy placer mineral		

	X1	24.34	63.05	8.17	3.73	0.71	8.216	2.368

5.1 Hydrofacturing-liquefaction process varying with the frequency of earthquake wave

The pore-network cracks transient hydrofacturing-liquefaction as function of the frequency of the earthquake wave is shown in Fig. 3. At the fixed amplitude and constituting time, the dynamic fluid stress act on the tight sandstone as electromagnetic wave and stress wave, at the range of 10Hz～100Hz, the surface of pore-network cracks do not appear liquefaction phenomena, even the surface of pore-net-work cracks began propagation and hydrofacturing phenomena appears; with the frequency increasing, when it reach to 200Hz～300Hz, the hydrofacturing phenomena is domain and some pore-network cracks zone of the tight sandstone appear hydrofacturing-liquefaction phenomena, and the constituting time and amplitude decreasing with the frequency increased, the constituting time is around 10E-5s and no draining phenomena appears during hydrofacturing-liquefaction process..

When the frequency is lower than 10Hz, the dynamic fluid stress act on the tight sandstone as quasi-static pore hydrostatic stress, and accompanying draining phenomena in the hydrofacturing failure progress; the maximum tight sandstone fracturing-liquefaction stress is the criteria which leading the hydrofacturing failure.

In general, the low frequency part of the earthquake wave act on the tight sandstone as static/quasi-static style, when the maximum principle stress is reach to the tight sandstone strength criteria, the pore-network cracks begin propagation and accompanying with draining process, no liquefaction appearing for do not reach the maximum micro tight sandstone structure strength limit; the dynamic stress released sharply with the distance between the surface of cracks, we defined it as crack surface frequency earthquake wave or near-field (around the crack surface) frequency earthquake wave.

The high frequency part of the earthquake wave act on the tight sandstone as transient electromagnetic wave and stress wave, the constituting time is very short and no draining accompanied in the whole process; the high frequency energy reach the maximum micro tight sandstone structure strength limit and destroy the tight micro pore-network structure in 10E-5s (Non-connected pore throat destruction); when the frequency is exceed to 400Hz, the electromagnetic wave can leading pore stress oscillation sharply and make the transient liquefaction appear in the whole tight sandstone zone, without draining and hydrofacturing process.

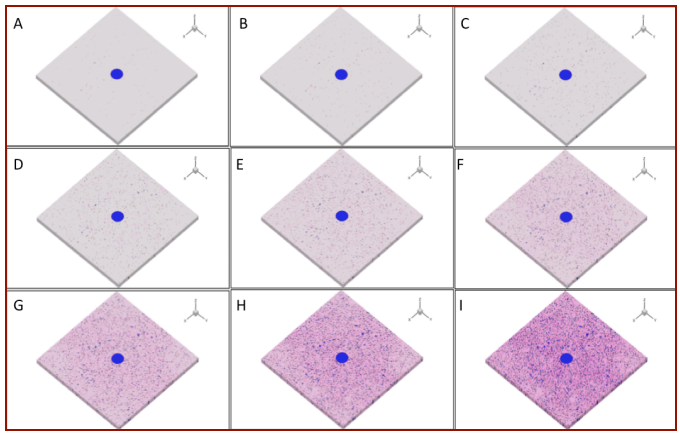

Fig 3. The transient hydrofracturing-liquefaction process as function of frequency of earthquake wave
Fig3A. Frequency is 10Hz, Fig3B. Frequency is 50Hz, Fig3C. Frequency is 100Hz
Fig3D. Frequency is 200Hz, Fig3E.Frequency is 250Hz, Fig3F. Frequency is 300Hz
Fig3G. Frequency is 400Hz, Fig3H. Frequency is 450Hz, Fig3I. Frequency is 500Hz

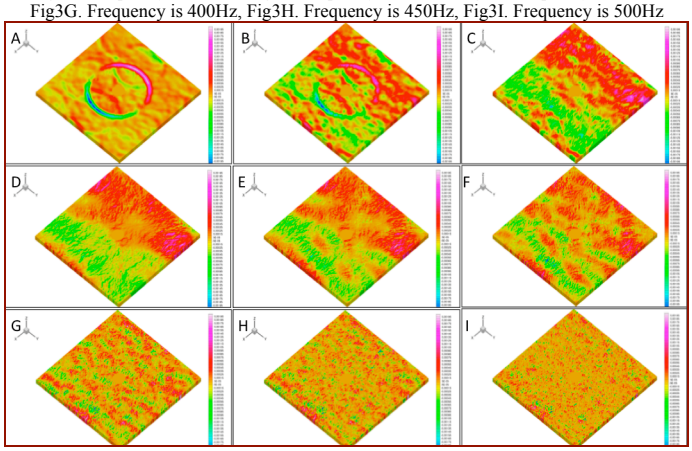

Figure 4. Dynamic stress in x direction as function of frequency at undrained state under earthquake wave
Fig4A. Frequency is 10Hz, Fig4B. Frequency is 50Hz, Fig4C. Frequency is 100Hz
Fig4D. Frequency is 200Hz, Fig4E. Frequency is 250Hz, Fig4F. Frequency is 300Hz
Fig4G. Frequency is 400Hz, Fig4H. Frequency is 450Hz, Fig4I. Frequency is 500Hz

The dynamic stress in x and y direction as function of frequency at undrained state are shown in the Fig.4 and Fig.5, the low frequency dynamic stress destroy the structure closed to the surface of the pore-network cracks, the high frequency dynamic stress destroy the structure far from the pore-network cracks surface. The low frequency earthquake wave have little energy than frequency part, with the distance (far from the front of the crack) increased, their effect to the structure of the tight sandstone decreased sharply; while the high frequency carry major energy of the earthquake wave, their effect distance to the tight sandstone can reach the whole zone. All these results are consisted with the observation data in tight sandstone liquefaction process in nature earthquake[25-28].

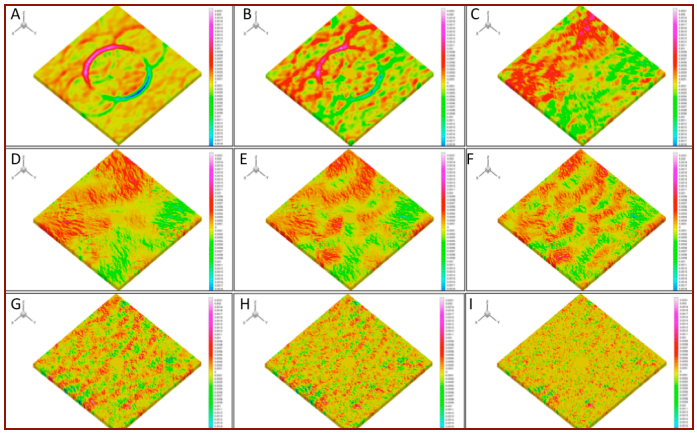

Figure 5. Dynamic stress in y direction as function of frequency at undrained state under earthquake wave

Fig5A. Frequency is 10Hz, Fig5B. Frequency is 50Hz, Fig5C. Frequency is 100Hz
Fig5D. Frequency is 200Hz, Fig5E. Frequency is 250Hz, Fig5F. Frequency is 300Hz
Fig5G. Frequency is 400Hz, Fig5H. Frequency is 450Hz, Fig5I. Frequency is 500Hz

The transient liquefaction process as function of frequency of the earthquake wave are plotted in Fig.6, when the frequency of the earthquake is higher than 1250Hz, the electromagnetic wave energy make the fluid volume in the three-dimensional pore-network cracks changed sharply, let the dynamic stress in the three-dimensional pore-network cracks surface (solid sketch interface) exceed the solid sketch part strength criteria in 10E-5s, the liquefaction in the micro tight sandstone zone appears in 10E-5s and propagates to the whole domain zone of the tight sandstone in 10E-5s, only seldom higher strength components in the tight sandstone can keep macro-structure (the white zone in the Fig 6D).

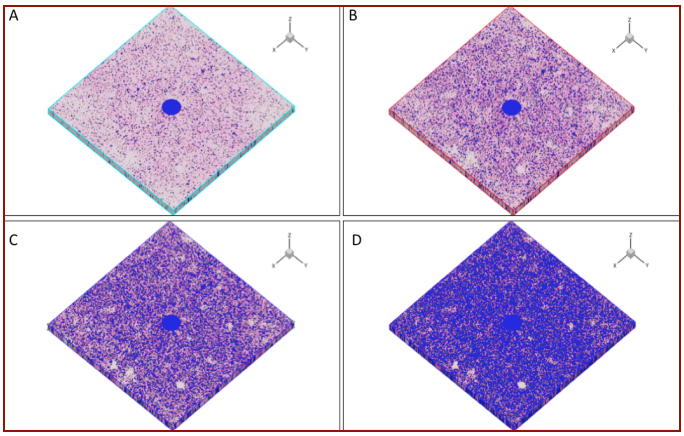

Fig 6. The transient liquefaction process as function of frequency of the earthquake wave
Fig6A. Frequency is 500Hz, Fig6B Frequency is 750Hz, Fig6C. Frequency is 1000Hz, Fig6D Frequency is 1250Hz

5.2 Hydrofacturing-liquefaction process varying with the amplitude of earthquake wave

The pore-network cracks hydrofacturing-liquefaction process as function of the amplitude of the earthquake wave is shown in the Fig. 7, at the fixed constituting time and frequency of the earthquake condition, when the amplitude is arrange at 0.01GPa~0.03GPa, the surface of the pore-network cracks begin propagate, the hydrofracturing around the big pore-network cracks fronts appear, and the liquefaction phenomena do not happen; with the amplitude of the earthquake increased, when it reach to 0.05GPa~0.07GPa, the coupled hydrofacturing-liquefaction begin at most of the pore-network cracks fronts; when the amplitude of the earthquake is exceeded to 0.07GPa~0.1GPa, the pore-network cracks propagate sharply and the hydrofacturing-liquefaction happen in the whole tight sandstone zone, only seldom components micro structure do not failure(white zone in Fig7E, 7F).

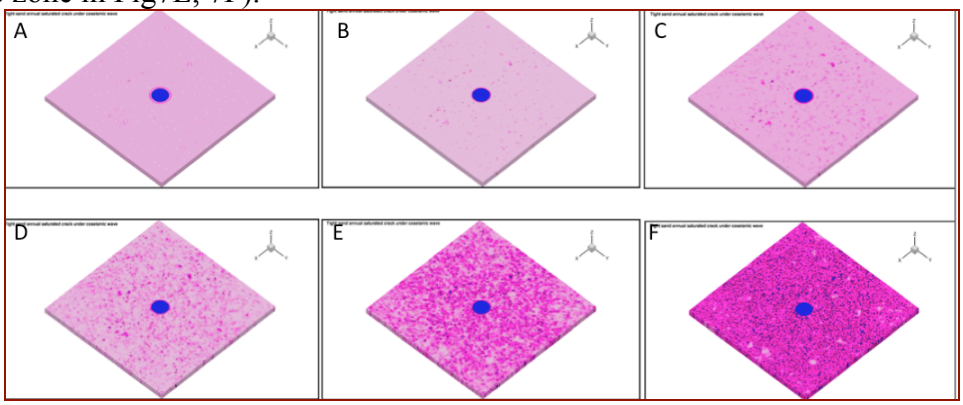

Fig 7. The cracking propagating process variation as the AM of the earthquake wave
Fig7A. AM of earthquake wave is 0.01GPa, Fig7B AM of earthquake wave is 0.03GPa, Fig7C AM of earthquake wave is 0.05GPa
Fig7D. AM of earthquake wave is 0.07GPa, Fig7E AM of earthquake wave is 0.09GPa, Fig7F AM of earthquake wave is 0.1GPa

The distribution of dynamic stress in x and y direction as function of amplitude of the earthquake are shown in the Fig.8 and Fig 9, respectively. When the amplitude arrange at 0.01GPa~0.03GPa, the electromagnetic wave and stress wave propagation far in the tight sandstone, for the whole tight

sandstone structure remains intact, low earthquake energy consumed in the spreading process; When the amplitude of the earthquake reach to 0.05GPa~0.07GPa, with the pore-network cracks propagation, the non-connected pore throats in the tight sandstone are destroyed quickly, most of the earthquake energy are used to providing the surface energy of the pore-network cracks interface, the electromagnetic wave and stress wave propagation distance decrease with the amplitude increasing; When the amplitude of the earthquake is exceeded to 0.07GPa~0.1GPa, the vase majority non-connected pore throats in the tight sandstones are destroyed and the whole tight sandstone structure instability and failure, the propagation media of the electromagnetic wave and stress wave translate from solid (tight porous structure) to fluid (liquefaction sandstone structure), their spreading distance decreased sharply.

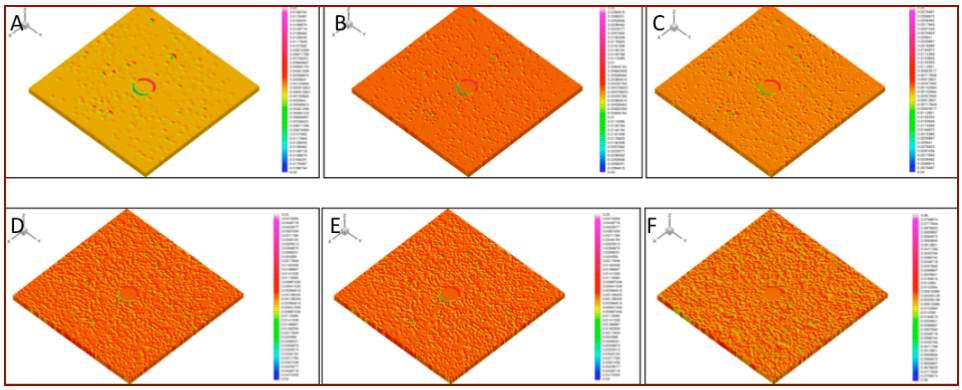

Figure 8. Dynamic stress in x direction variation as function of time at undrained state under earthquake
Fig8A. AM of earthquake wave is 0.01GPa, Fig8B AM of earthquake wave is 0.03GPa, Fig8C AM of earthquake wave is 0.05GPa
Fig8D. AM of earthquake wave is 0.07GPa, Fig8E AM of earthquake wave is 0.09GPa, Fig8F AM of earthquake wave is 0.1GPa

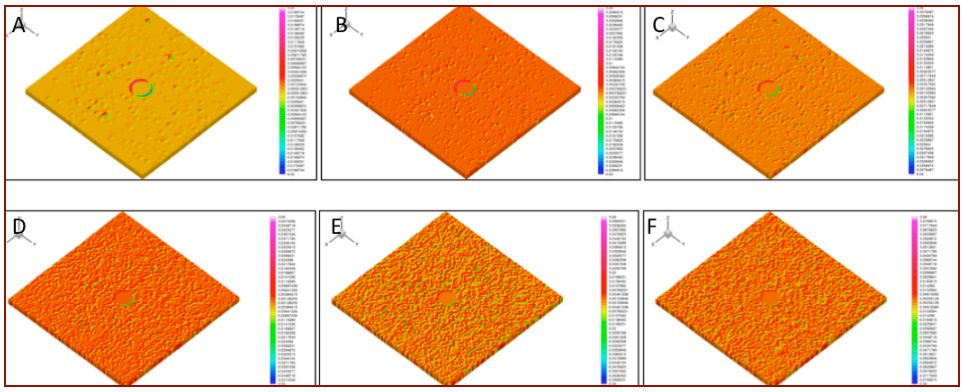

Figure 9. Dynamic stress in y direction variation as function of time at undrained state under earthquake wave
Fig9A. AM of earthquake wave is 0.01GPa, Fig9B AM of earthquake wave is 0.03GPa, Fig9C AM of earthquake wave is 0.05GPa
Fig9D. AM of earthquake wave is 0.07GPa, Fig9E AM of earthquake wave is 0.09GPa, Fig9F AM of earthquake wave is 0.1GPa

In general, both high frequency and amplitude of the earthquake wave are the main factors which lead to the pore-network cracks transient Hydrofracturing-liquefaction process; high frequency of electromagnetic wave and stress wave make the porous and permeability of the tight sandstone changed sharply in 10E-5s which lead the strength criteria of the tight sand stone decrease; high amplitude of the electromagnetic wave and stress wave make the dynamic pore stress in the tight sandstone changed sharply in 10E-5s which lead the maximum principle stress increased to the macro tight sandstone strength criteria; all these leading to pore-network cracks propagation, local area hydrofacturing-liquefaction, and the eventual entire region liquefaction occurred. All these results are consisted with the nature earthquake liquefaction observation data [28, 29].

At practice drilling project, with the hydro-pressure increasing, the pore stress in the tight sandstone is reach to the maximum principal stresses and the sandstone begin failure, this stage is a static/quasi-static process which including the drained propagation; once the tight sandstone begin rupture, this means that the micro pore-network cracks begin propagation, the pore stress will spreading as stress wave way, the stage is transient process and the drained propagation do not happen. The results well consisted with the practical observation data and can well explain why

secondary hydrofacturing stage maximum principal stress reduced.

6. Conclusions

In this work, an novel intricate theoretical analysis and numerical simulations methods (LB-FE-HIE) is proposed by the author to explore the three-dimensional pore-network cracks transient hydrofacturing-liquefaction in tight sandstone under seismic wave & electro-magneto-thermo-elastic field. The conclusion can be drawn as follows.

1. The problem is reduced to solving a set of coupled lattice Boltzmann & finite element & hypersingular integral equations by using the Green functions and distribution functions.

2. The behavior of the extended displacement discontinuities around the pore-network cracks surface terminating at the solid-liquid film interface is analyzed. Analytical solutions for the extended singular dynamic stresses, the extended dynamic stress intensity factors and the extended dynamic energy release rate near the dislocations front are provided.

3.The tight sandstone sample from the Ordos Basin Triassic formation is selected and the fluid-solid coupled digital rock physical modeling is established. The simulations of 3D PC-TH-TS process is presented, the hydrofacturing-liquefaction varying with the amplitude, frequency and time of earthquake wave is obtained, the results are consisted with the nauture earthquake observation data and practical drilling project observation data.

4. The relationship between the tight sandstone pore-network cracks transient propagation-evolution and the maximum tight sandstone fracturing-liquefaction stress criteria is explored, which are useful to guide the in-situ stress measurement in practical drilling project and are helpful to understand the liquefaction mechanismu of earthquake.

Abstract The interaction between an annular crack and the interface is of practical significance. The interface, which is imperfect with the assumption that it is mechanically compliant and magnetoelectrically weakly conducting. For a mechanically compliant interface tractions are continuous but displacements are discontinuous across the imperfect interface. For a magnetoelectrically weakly conducting interface the normal electric displacement and magnetic induction are continuous but the electric and magnetic potentials are discontinuous across the interface. Such a problem is investigated by the method of singular integral equation in the present work. The field intensity factors and energy release rate are derived. Numerical results reveal the effects of electric or magnetic loadings, material parameters and interfacial imperfection on crack propagation and growth. The results seem useful for design of the magnetoelectroelastic composite structures and devices of high performance.

Keywords Annular crack, Imperfect interface, Energy release rate, Magnetoelectroelastic materials, Fracture mechanics

1. Introduction

Magnetoelectroelastic materials, which are composed of a piezoelectric and piezomagnetic phase, not only have original piezoelectric and piezomagnetic properties but also exhibit a remarkable magneto-electric coupling effect that is not present in the constituents. Such composites have found increasing applications in several engineering fields such as magnetic field probes, electronic packaging, hydrophones, medical ultrasonic imaging and in general as transducers, sensors and actuators. Micromechanics modeling to predict and estimate the material properties of piezoelectric/piezomagnetic composites was presented [1-3].

These magnetoelectroelastic materials are generally brittle; therefore cracks inevitably form during the manufacturing process and subsequent handling. For that reason, it is of great importance to study the fracture behavior of such composites and its influence on the coupled response. Recently, research on fracture mechanics of magnetoelectroelastic materials has drawn increased interest. Most of the achievements are made on the anti-plane and in-plane crack problem [4-8]. For the axisymmetric crack in magnetoelectroelastic materials, some progress has also been made. Studies related to penny-shaped or annular cracks can be found in the literature [9-11].

When two dissimilar materials bonded together, it is difficult to guarantee them to be perfectly bonded. Some interfacial models, i.e. spring-like model, are presented. Meguid and Wang [12] dealt with the interaction of crack and imperfect interface when dynamic antiplane shear waves are applied. a crack situated at the imperfect interface has been considered by Lenci [13], who found only the logarithmic stress singularity near the crack tips. Instead of the usual traction-free crack surface condition, Udea et al. [14] applied the spring-like imperfect interface condition to reconsider the corresponding antiplane shear problem, and found that the stress singularity at the crack tips is no longer an inverse square-root singularity, but a singularity of power law governed by the interface parameters. Zhong et al. [15] investigated the elastostatic problem of a mode-I crack embedded in a bimaterial with an imperfect interface.

This paper aims at analyzing the interaction of an annular crack and an imperfect interface. The interface, which is imperfect with the assumption that it is mechanically compliant and magnetoelectrically weakly conducting. For a mechanically compliant interface tractions are continuous but displacements are discontinuous across the imperfect interface. For a magnetoelectrically weakly conducting interface the normal electric displacement and magnetic induction are continuous but the electric and magnetic potentials are discontinuous across the interface. Using the Hankel transform technique, the associated mixed-boundary value problem is reduced to a singular integral equation. Numerical results are presented. The influences of interfacial imperfection on energy release rates near the crack tips are analyzed in detail.

2. Formulation of the problem

As shown in Fig. 1, two dissimilar magnetoelectroelastic materials bonded with an imperfect interface. For convenience, they are marked with material I and material II, which occupy the region $-h_2 < z < h_1$ and region $h_1 < z < h_1 + h_3$ respectively. An annular crack with the outer radius *b* and inner radius *a* perpendicular to the poling axis is situated in the magnetoelectroelastic material I and occupies the region $a \le r \le b$, $z = 0$. And the crack width *c* is introduced with $c = b - a$.

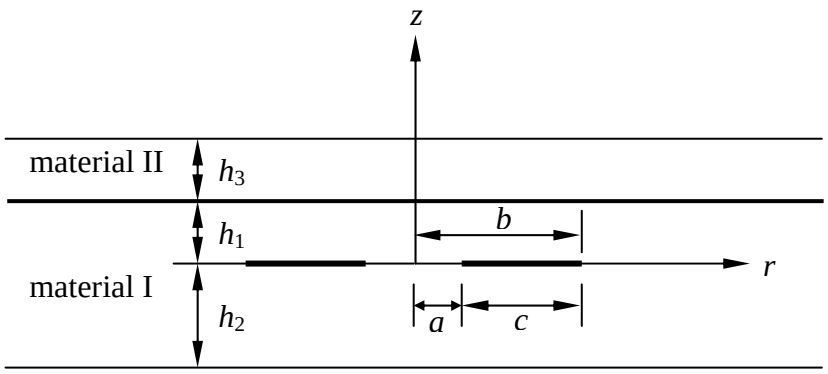

Figure 1. Configuration of the annular and imperfect interface in bonded magnetoelectroelastic layers

The boundary conditions for the magnetoelectrically impermeable annular crack and mechanically compliant and magnetoelectrically weakly conducting interface conditions are set as

$$\sigma_{rzI}^{(1)}(r,0) = \sigma_{rzI}^{(2)}(r,0) = p_1(r),\ \sigma_{zzI}^{(1)}(r,0) = \sigma_{zzI}^{(2)}(r,0) = p_2(r),\ (a < r < b) \tag{1}$$

$$D_{zI}^{(1)}(r,0) = D_{zI}^{(2)}(r,0) = p_3(r),\ B_{zI}^{(1)}(r,0) = B_{zI}^{(2)}(r,0) = p_4(r),\ (a < r < b) \tag{2}$$

$$u_{rI}^{(1)}(r,0) = u_{rI}^{(2)}(r,0),\ u_{zI}^{(1)}(r,0) = u_{zI}^{(2)}(r,0),\ (0 \le r \le a, b \le r < \infty) \tag{3}$$

$$\phi_I^{(1)}(r,0) = \phi_I^{(2)}(r,0),\ \psi_I^{(1)}(r,0) = \psi_I^{(2)}(r,0),\ (0 \le r \le a, b \le r < \infty) \tag{4}$$

$$\sigma_{rzI}^{(1)}(r,0) = \sigma_{rzI}^{(2)}(r,0),\ \sigma_{zzI}^{(1)}(r,0) = \sigma_{zzI}^{(2)}(r,0),\ (0 \le r \le a, b \le r < \infty) \tag{5}$$

$$D_{zI}^{(1)}(r,0) = D_{zI}^{(2)}(r,0), B_{zI}^{(1)}(r,0) = B_{zI}^{(2)}(r,0), (0 \le r \le a, b \le r < \infty) \tag{6}$$

$$\sigma_{rzI}^{(2)}(r,-h_2) = 0,\ \sigma_{zzI}^{(2)}(r,-h_2) = 0,\ D_{zI}^{(2)}(r,-h_2) = 0, B_{zI}^{(2)}(r,-h_2) = 0\ (0 \le r < \infty) \tag{7}$$

$$\sigma_{rzI}^{(1)}(r,h_1) = \sigma_{rzII}(r,h_1),\ \sigma_{zzI}^{(1)}(r,h_1) = \sigma_{zzII}(r,h_1), \tag{8}$$

$$D_{zI}^{(1)}(r,h_1) = D_{zII}(r,h_1),\ B_{zI}^{(1)}(r,h_1) = B_{zII}(r,h_1),\ (0 \le r < \infty) \tag{9}$$

$$u_{rI}^{(1)}(r,h_1) - u_{rII}(r,h_1) = \beta_1 \sigma_{rzII}(r,h_1),\ u_{zI}^{(1)}(r,h_1) - u_{zII}(r,h_1) = \beta_2 \sigma_{zzII}(r,h_1), \tag{10}$$

$$\phi_{rI}^{(1)}\left(r,h_1\right)-\phi_{rII}\left(r,h_1\right)=\beta_3 D_{zII}\left(r,h_1\right),\ \psi_{rI}^{(1)}\left(r,h_1\right)-\psi_{rII}\left(r,h_1\right)=\beta_4 B_{zII}\left(r,h_1\right),\ \left(0\le r<\infty\right) \tag{11}$$

$$\sigma_{rzII}\left(r,h_1+h_3\right)=0,\ \sigma_{zzII}\left(r,h_1+h_3\right)=0,\ D_{zII}\left(r,h_1+h_3\right)=0,B_{zII}\left(r,h_1+h_3\right)=0\ \left(0\le r<\infty\right) \tag{12}$$

where the superscripts (1) and (2) denote the upper and lower of the magnetoelectroelastic material I, respectively; $p_1(r)$, $p_2(r)$, $p_3(r)$ and $p_4(r)$ are the given amplitude of the applied loadings. β_1, β_2, β_3 and β_4 are interface parameters, respectively.

For the axisymmtric problem, the government equations of magnetoelectroelastic material are

$$c_{11}\left(\frac{\partial^2 u_r}{\partial r^2}+\frac{1}{r}\frac{\partial u_r}{\partial r}-\frac{1}{r^2}\right)+c_{44}\frac{\partial^2 u_r}{\partial z^2}+\left(c_{13}+c_{44}\right)\frac{\partial^2 u_z}{\partial r\partial z}+\left(e_{31}+e_{15}\right)\frac{\partial^2 \phi}{\partial r\partial z}+\left(f_{31}+f_{15}\right)\frac{\partial^2 \psi}{\partial r\partial z}=0, \tag{13}$$

$$\begin{aligned}&\left(c_{13}+c_{44}\right)\left(\frac{\partial^2 u_r}{\partial r\partial z}+\frac{1}{r}\frac{\partial u_r}{\partial z}\right)+c_{44}\left(\frac{\partial^2 u_z}{\partial r^2}+\frac{1}{r}\frac{\partial u_z}{\partial r}\right)+c_{33}\frac{\partial^2 u_z}{\partial z^2}\\&+e_{15}\left(\frac{\partial^2 \phi}{\partial r^2}+\frac{1}{r}\frac{\partial \phi}{\partial r}\right)+e_{33}\frac{\partial^2 \phi}{\partial z^2}+f_{15}\left(\frac{\partial^2 \psi}{\partial r^2}+\frac{1}{r}\frac{\partial \psi}{\partial r}\right)+f_{33}\frac{\partial^2 \psi}{\partial z^2}=0,\end{aligned} \tag{14}$$

$$\begin{aligned}&\left(e_{15}+e_{31}\right)\left(\frac{\partial^2 u_r}{\partial r\partial z}+\frac{1}{r}\frac{\partial u_r}{\partial z}\right)+e_{15}\left(\frac{\partial^2 u_z}{\partial r^2}+\frac{1}{r}\frac{\partial u_z}{\partial r}\right)+e_{33}\frac{\partial^2 u_z}{\partial z^2}\\&-\varepsilon_{11}\left(\frac{\partial^2 \phi}{\partial r^2}+\frac{1}{r}\frac{\partial \phi}{\partial r}\right)-\varepsilon_{33}\frac{\partial^2 \phi}{\partial z^2}-g_{11}\left(\frac{\partial^2 \psi}{\partial r^2}+\frac{1}{r}\frac{\partial \psi}{\partial r}\right)-g_{33}\frac{\partial^2 \psi}{\partial z^2}=0,\end{aligned} \tag{15}$$

$$\begin{aligned}&\left(f_{15}+f_{31}\right)\left(\frac{\partial^2 u_r}{\partial r\partial z}+\frac{1}{r}\frac{\partial u_r}{\partial z}\right)+f_{15}\left(\frac{\partial^2 u_z}{\partial r^2}+\frac{1}{r}\frac{\partial u_z}{\partial r}\right)+f_{33}\frac{\partial^2 u_z}{\partial z^2}\\&-g_{11}\left(\frac{\partial^2 \phi}{\partial r^2}+\frac{1}{r}\frac{\partial \phi}{\partial r}\right)-g_{33}\frac{\partial^2 \phi}{\partial z^2}-\mu_{11}\left(\frac{\partial^2 \psi}{\partial r^2}+\frac{1}{r}\frac{\partial \psi}{\partial r}\right)-\mu_{33}\frac{\partial^2 \psi}{\partial z^2}=0,\end{aligned} \tag{16}$$

The generally solutions of the equations above mentioned are

$$u_r\left(r,z\right)=\sum_{j=1}^{8}\int_0^\infty a_{1j}\exp\left(\rho\lambda_j z\right)A_j\left(\rho\right)J_1\left(\rho r\right)d\rho, \tag{17}$$

$$u_z\left(r,z\right)=\sum_{j=1}^{8}\int_0^\infty a_{2j}\exp\left(\rho\lambda_j z\right)A_j\left(\rho\right)J_0\left(\rho r\right)d\rho, \tag{18}$$

$$\phi\left(r,z\right)=\sum_{j=1}^{8}\int_0^\infty a_{3j}\exp\left(\rho\lambda_j z\right)A_j\left(\rho\right)J_0\left(\rho r\right)d\rho, \tag{19}$$

$$\psi\left(r,z\right)=\sum_{j=1}^{8}\int_0^\infty a_{4j}\exp\left(\rho\lambda_j z\right)A_j\left(\rho\right)J_0\left(\rho r\right)d\rho, \tag{20}$$

where $A_j\left(\rho\right)\left(j=1,2,\mathrm{L}\ ,8\right)$ are unknown functions to be determined and $J_i\left(i=0,1\right)$ are i th order Bessel functions of the first kind. The constants $\left\{a_{1j},a_{2j},a_{3j}\right\}$ and parameters λ_j are constant related to material parameters.

3. The derivation of the integral equations

A set of new unknown functions are now introduced

$$d_1\left(r\right)=\frac{1}{r}\frac{\partial}{\partial r}\left\{ru_{rI}^{(1)}\left(r,0\right)-ru_{rI}^{(2)}\left(r,0\right)\right\}, \tag{21}$$

$$d_2(r)=\frac{\partial}{\partial r}\left\{u_{zI}^{(1)}(r,0)-u_{zI}^{(2)}(r,0)\right\}, \tag{22}$$

$$d_3(r)=\frac{\partial}{\partial r}\left\{\phi_I^{(1)}(r,0)-\phi_I^{(2)}(r,0)\right\}, \tag{23}$$

$$d_4(r)=\frac{\partial}{\partial r}\left\{\psi_I^{(1)}(r,0)-\psi_I^{(2)}(r,0)\right\}. \tag{24}$$

In the annular crack shown in Fig. 1, physical considerations require that

$$\left[u_r^{(1)}(r,0)-u_r^{(2)}(r,0)\right]\to 0\text{, for } r\to a,b\text{,} \tag{25}$$

$$\left[u_z^{(1)}(r,0)-u_z^{(2)}(r,0)\right]\to 0\text{, for } r\to a,b\text{,} \tag{26}$$

$$\left[\phi_I^{(1)}(r,0)-\phi_I^{(2)}(r,0)\right]\to 0 \text{ for } r\to a,b\text{.} \tag{27}$$

$$\left[\phi_I^{(1)}(r,0)-\phi_I^{(2)}(r,0)\right]\to 0 \text{ for } r\to a,b\text{.} \tag{28}$$

Therefore, the unknown function defined by Eq. (10) must satisfy the following conditions

$$\int_a^b r d_1(r)\,dr=0, \tag{29}$$

$$\int_a^b d_2(r)\,dr=0, \tag{30}$$

$$\int_a^b d_3(r)\,dr=0, \tag{31}$$

$$\int_a^b d_4(r)\,dr=0. \tag{32}$$

Substitute Eqs. (17)-(20) into boundary conditions Eqs. (1)-(12) and using Eqs. (21)-(24), one obtains

$$\frac{1}{\pi}\mathbf{M}\int_a^b\frac{1}{s-r}\mathbf{F}(s)\,ds+\frac{1}{\pi}\int_a^b\mathbf{Q}\mathbf{F}(s)\,ds=\mathbf{\Gamma}(r), \tag{33}$$

where

$$\mathbf{M}=\begin{bmatrix} M_{11} & 0 & 0 & 0\\ 0 & M_{22} & M_{23} & M_{24}\\ 0 & M_{32} & M_{33} & M_{34}\\ 0 & M_{42} & M_{43} & M_{44}\end{bmatrix}, \tag{34}$$

$$\mathbf{Q}=\boldsymbol{\kappa}\mathbf{M}+\pi\int_0^\infty\rho s\mathbf{J}_{10}(\rho r)\left[\mathbf{K}(\rho)-\mathbf{M}\right]\mathbf{J}_{01}(\rho s)\,d\rho, \tag{35}$$

$$M_{ij}=\lim_{\rho\to\infty}K_{ij}(\rho), \tag{36}$$

with $K_{ij}(\rho)$ can be found in Appendix A. And

$$\boldsymbol{\kappa}=diag\left[\kappa_{11}(r,s),\kappa_{22}(r,s),\kappa_{22}(r,s),\kappa_{22}(r,s)\right], \tag{37}$$

$$\kappa_{11}(r,s)=\left[\frac{2rM_1(r,s)}{s^2-r^2}-\frac{1}{s-r}\right], \tag{38}$$

$$\kappa_{22}(r,s)=\left[\frac{2sM_2(r,s)}{s^2-r^2}-\frac{1}{s-r}\right], \tag{39}$$

and

$$M_1(r,s)=\begin{cases}\dfrac{s}{r}E(s/r), & s<r,\\ \dfrac{s^2}{r^2}E(r/s)-\dfrac{s^2-r^2}{r^2}K(r/s), & s>r,\end{cases} \tag{40}$$

$$M_2(r,s)=\begin{cases}\dfrac{r}{s}E(s/r)+\dfrac{s^2-r^2}{rs}K(s/r), & s<r,\\ E(r/s), & s>r.\end{cases} \tag{41}$$

Introducing two non-dimensional variables η and ξ

$$s=(b-a)\eta/2+(b+a)/2, \tag{42}$$

$$r=(b-a)\xi/2+(b+a)/2. \tag{43}$$

Eq. (33) becomes

$$\frac{\mathbf{M}}{\pi}\int_{-1}^{1}\frac{\mathbf{G}(\eta)}{\eta-\xi}d\eta+\frac{1}{\pi}\int_{-1}^{1}\bar{\mathbf{Q}}(\xi,\eta)\mathbf{G}(\eta)d\eta=\mathbf{L}(\xi), \tag{44}$$

where

$$\mathbf{G}(\eta)=\mathbf{F}\left(\frac{b-a}{2}\eta+\frac{b+a}{2}\right), \tag{45}$$

$$\bar{\mathbf{Q}}(\eta,\xi)=\frac{b-a}{2}\mathbf{Q}\left(\frac{b-a}{2}\eta+\frac{b+a}{2},\frac{b-a}{2}\xi+\frac{b+a}{2}\right), \tag{46}$$

$$\mathbf{L}(\xi)=\Gamma\left(\frac{b-a}{2}\xi+\frac{b+a}{2}\right). \tag{47}$$

4. The solution of integral equations

So far, the Cauchy singular integral Eq. (44) and the single-valued conditions Eqs. (29)-(32) have been derived. By using the numerical method of Erdogan and Gupta [16], a system of linear algebraic equations can be obtained

$$\frac{1}{n}\sum_{l=1}^{n}\left(\frac{\mathbf{M}}{\eta_l-\xi_m}+\bar{\mathbf{Q}}(\eta_l,\xi_m)\right)\mathbf{R}(\eta_l)=\mathbf{L}(\xi_m), \tag{48}$$

$$\frac{1}{n}\sum_{l=1}^{n}diag\left(\left(\frac{b-a}{2}\right)\eta_l+\frac{b+a}{2},1,1,1\right)\mathbf{R}(\eta_l)=0, \tag{49}$$

where $\mathbf{R}(\eta)=\sqrt{1-\eta^2}\mathbf{G}(\eta)$, and n is the number of the discrete points of $\mathbf{R}(\eta_l)$ between -1 and +1. The discrete values of ξ_m and η_l are the roots of the Chebyshev polynomials of the first and second kind, respectively:

$$\xi_m=\cos(m\pi/n),\quad m=1,2,\mathrm{L}\ n-1, \tag{50}$$

$$\eta_l=\cos\left[(2l-1)\pi/2n\right],\quad l=1,2,\mathrm{L}\ n. \tag{51}$$

One may solve Eqs. (48) and (49) numerically to get the solutions of $\mathbf{R}(\eta_l)$, which can be further used to determine the stress intensity factor (SIF).

5. Field intensity factors and energy release rates

The field intensity factors (FIFs) including mode-I and mode-II stress intensity factors (SIFs) and electric displacement intensity factor (EDIF), which characterize magnitudes of stress, electric displacement respectively, of the outer and inner crack tips can be deduced

$$\mathbf{K}_b = \left\{ K_{\mathrm{II}b} \quad K_{\mathrm{I}b} \quad K_{\mathrm{D}b} \quad K_{\mathrm{B}b} \right\}^T = -\sqrt{\pi\left(b-a\right)/2}\mathbf{M}\mathbf{R}\left(1\right) \tag{52}$$

and

$$\mathbf{K}_a = \left\{ K_{\mathrm{II}a} \quad K_{\mathrm{I}a} \quad K_{\mathrm{D}a} \quad K_{\mathrm{B}a} \right\}^T = \sqrt{\pi\left(b-a\right)/2}\mathbf{M}\mathbf{R}\left(-1\right) \tag{53}$$

The energy release rates (ERRs) of the outer and inner crack tips can be derived as

$$G_\upsilon = \frac{1}{4}\mathbf{K}_\upsilon^{\mathrm{T}}\mathbf{M}^{-1}\mathbf{K}_\upsilon, \quad \left(\upsilon = b, a\right) \tag{54}$$

6. Numerical results

For the numerical examples, magnetoelectroelastic composite $BaTiO_3$-$CoFe_2O_4$ are used as materials I and II. For simplicity, only the loading case of $\Gamma\left(r\right) = \left\{0 \quad -\sigma_0 \quad -D_0 \quad -B_0\right\}^{\mathrm{T}}$ is considered. Also, D_0 and B_0 are determined by the load combination parameters $\lambda_D = D_0 c_{33}/\left(\sigma_0 e_{33}\right)$ and $\lambda_B = D_0 c_{33}/\left(\sigma_0 f_{33}\right)$. The numerical results are plotted in Figs. 2-5, where ERRs, G_b and G_a, are normalized by G_0, which can be expressed as

$$G_0 = \frac{\pi}{8}\Lambda_{22}\sigma_0^2 c, \tag{55}$$

where Λ_{22} is the element of matrix $\mathbf{\Lambda}$, and

$$\mathbf{\Lambda} = \mathbf{M}^{-1}. \tag{56}$$

Figs. 2 and 3 show the effects of β_1 and β_2 on the normalized ERRs of the outer and inner crack-tips. From Fig. 2, it is clear that the normalized ERRs increase with increasing β_1. Similar phenomena can be observe in Fig. 3. This means that increasing β_1 and β_2 will promote the crack propagation or growth.

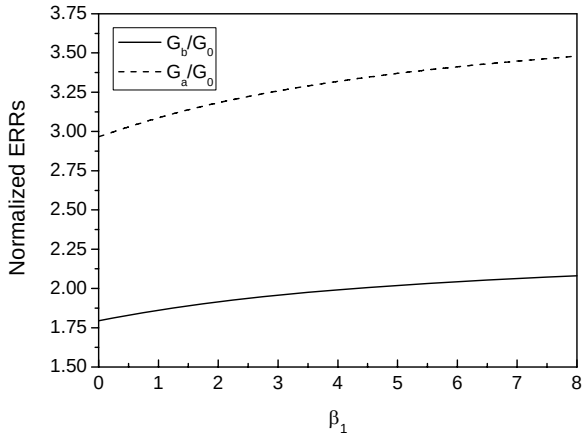

Figure 2. The effect of β_1 on the normalized ERRs of the outer and inner crack tips of an annular crack

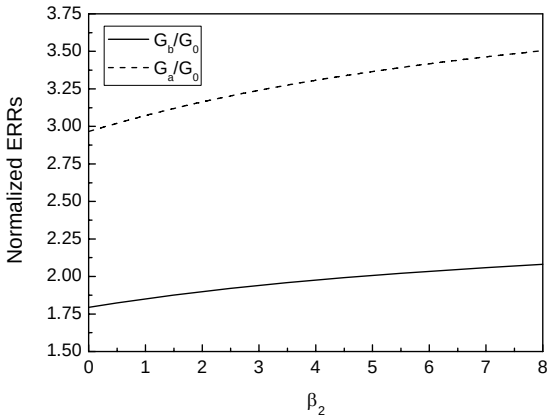

Figure 3. The effect of β_2 on the normalized ERRs of the outer and inner crack tips of an annular crack

The effects of β_3 and β_4 on the normalized ERRs are plotted in Figs. 4 and 5. From these figures, one knows that the normalized ERRs are almost independence of β_3 and β_4.

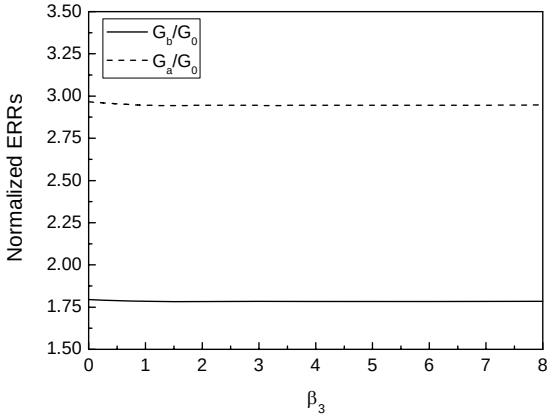

Figure 4. The effect of β_3 on the normalized ERRs of the outer and inner crack tips of an annular crack

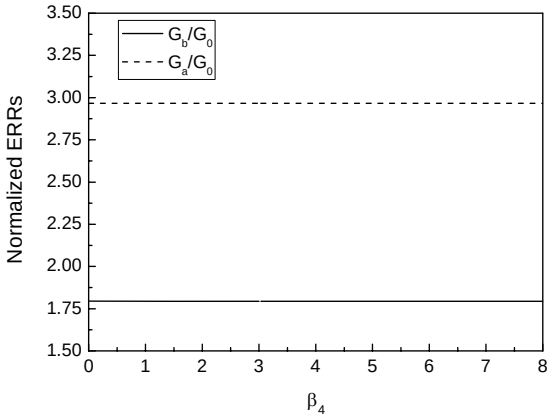

Figure 5. The effect of β_4 on the normalized ERRs of the outer and inner crack tips of an annular crack

From Figs. 2-5, one can also know that the fracture parameters ERR of the inner crack tip of the annular crack are always larger than those of the outer one.

7. Conclusions

In this paper, the interaction of an annular crack and an imperfect interface in bonded magnetoelectroelastic layers is investigated. The interface, which is imperfect with the assumption that it is mechanically compliant and magnetoelectrically weakly conducting. Using the Hankel transform technique, the associated mixed-boundary value problem is reduced to a singular integral equation, which are further reduced to a system of algebraic equations. Finally, the field intensity factor and energy release rate are determined and numerically solved. The following conclusions may be drawn:

(i) Different interfacial parameters have different influences on the propagation and growth of the annular crack. Increasing β_1 and β_2 can promote the crack propagation or growth. However, the effects of β_3 and β_4 on energy release rates are very small.

(ii) The energy release rates of the inner crack tip of the annular crack are always larger than those of the outer one.

Appendix A

The matrix $\mathbf{K}(\rho)$ can be expressed as

$$\mathbf{K}(\rho)=\frac{1}{\rho}\begin{bmatrix} \sum_{j=1}^{8}\frac{H_{17j}\Delta_{21j}(\rho)}{\Delta(\rho)} & -\sum_{j=1}^{8}\frac{H_{17j}\Delta_{22j}(\rho)}{\Delta(\rho)} & -\sum_{j=1}^{8}\frac{H_{17j}\Delta_{23j}(\rho)}{\Delta(\rho)} & -\sum_{j=1}^{8}\frac{H_{17j}\Delta_{24j}(\rho)}{\Delta(\rho)} \\ \sum_{j=1}^{8}\frac{H_{18j}\Delta_{21j}(\rho)}{\Delta(\rho)} & -\sum_{j=1}^{8}\frac{H_{18j}\Delta_{22j}(\rho)}{\Delta(\rho)} & -\sum_{j=1}^{8}\frac{H_{18j}\Delta_{23j}(\rho)}{\Delta(\rho)} & -\sum_{j=1}^{8}\frac{H_{18j}\Delta_{24j}(\rho)}{\Delta(\rho)} \\ \sum_{j=1}^{8}\frac{H_{19j}\Delta_{21j}(\rho)}{\Delta(\rho)} & \sum_{j=1}^{8}\frac{H_{19j}\Delta_{22j}(\rho)}{\Delta(\rho)} & \sum_{j=1}^{8}\frac{H_{19j}\Delta_{23j}(\rho)}{\Delta(\rho)} & \sum_{j=1}^{8}\frac{H_{19j}\Delta_{24j}(\rho)}{\Delta(\rho)} \\ \sum_{j=1}^{8}\frac{H_{20j}\Delta_{21j}(\rho)}{\Delta(\rho)} & \sum_{j=1}^{8}\frac{H_{20j}\Delta_{22j}(\rho)}{\Delta(\rho)} & \sum_{j=1}^{8}\frac{H_{20j}\Delta_{23j}(\rho)}{\Delta(\rho)} & \sum_{j=1}^{8}\frac{H_{20j}\Delta_{24j}(\rho)}{\Delta(\rho)} \end{bmatrix},$$

where $\Delta(\rho)$ is the determinant of the coefficient matrix $\mathbf{H}$, whose elements can be expressed as H_{ij} with i th row and j th column; $\Delta_{kj}(\rho)(k=21,22,23,24)$ are, respectively, the corresponding algebra cofactors. The components of $\mathbf{H}$ are given by

$$H_{1j}=\left(c_{44II}\lambda_{jII}a_{1jII}-c_{44II}a_{2jII}-e_{15II}a_{3jII}-f_{15II}a_{4jII}\right)\exp\left(\rho\lambda_{jII}\left(h_1+h_3\right)\right),H_{1(j+8)}=0,H_{1(j+16)}=0,$$

$$H_{2j}=\left(c_{13II}a_{1jII}+c_{33II}\lambda_{jII}a_{2jII}+e_{33II}\lambda_{jII}a_{3jII}+f_{33II}\lambda_{jII}a_{4jII}\right)\exp\left(\rho\lambda_{jII}\left(h_1+h_3\right)\right),H_{2(j+8)}=0,H_{2(j+16)}=0,$$

$$H_{3j}=\left(e_{31II}a_{1jII}+e_{33II}\lambda_{jII}a_{2jII}-\varepsilon_{33II}\lambda_{jII}a_{3jII}-g_{33II}\lambda_{jII}a_{4jII}\right)\exp\left(\rho\lambda_{jII}\left(h_1+h_3\right)\right),H_{3(j+8)}=0,H_{3(j+16)}=0,$$

$$H_{4j}=\left(f_{31II}a_{1jII}+f_{33II}\lambda_{jII}a_{2jII}-g_{33II}\lambda_{jII}a_{3jII}-\mu_{33II}\lambda_{jII}a_{4jII}\right)\exp\left(\rho\lambda_{jII}\left(h_1+h_3\right)\right),H_{4(j+8)}=0,H_{4(j+16)}=0,$$

$$H_{5j}=0,H_{5(j+8)}=0,H_{5(j+16)}=\left(c_{44I}\lambda_{jI}a_{1jI}-c_{44I}a_{2jI}-e_{15I}a_{3jI}-f_{15I}a_{4jI}\right)\exp\left(-\rho\lambda_{jI}h_2\right),$$

$$H_{6j}=0,H_{6(j+8)}=0,H_{6(j+16)}=\left(c_{13I}a_{1jI}+c_{33I}\lambda_{jI}a_{2jI}+e_{33I}\lambda_{jI}a_{3jI}+f_{33I}\lambda_{jI}a_{4jI}\right)\exp\left(-\rho\lambda_{jII}h_2\right),$$

$$H_{7j}=0, H_{7(j+8)}=0, H_{7(j+16)}=\left(e_{31I}a_{1jI}+e_{33I}\lambda_{jI}a_{2jI}-\varepsilon_{33I}\lambda_{jI}a_{3jI}-g_{33I}\lambda_{jI}a_{4jI}\right)\exp\left(-\rho\lambda_{jI}h_2\right),$$

$$H_{8j}=0, H_{8(j+8)}=0, H_{8(j+16)}=\left(f_{31I}a_{1jI}+f_{33I}\lambda_{jI}a_{2jI}-g_{33I}\lambda_{jI}a_{3jI}-\mu_{33I}\lambda_{jI}a_{4jI}\right)\exp\left(-\rho\lambda_{jI}h_2\right),$$

$$H_{9j}=\left(c_{44II}\lambda_{jII}a_{1jII}-c_{44II}a_{2jII}-e_{15II}a_{3jII}-f_{15II}a_{4jII}\right)\exp\left(\rho\lambda_{jII}h_1\right),$$

Abstract In this paper, transient dynamic crack analysis in two-dimensional, layered, anisotropic and linear magnetoelectroelastic solids is presented. For this purpose, a time-domain boundary element method (BEM) is developed. The layered magnetoelectroelastic solids are modeled by the multi-domain BEM formulation. The time-domain dynamic fundamental solutions for homogeneous and linear magnetoelectroelastic solids are applied in the present BEM. The spatial discretization of the boundary integral equations is performed by a Galerkin-method, while a collocation method is implemented for the temporal discretization of the arising convolution integrals. An explicit time-stepping scheme is obtained to compute the discrete boundary data including the generalized crack-opening-displacements (CODs). To show the effects of the interface, the material combinations and the dynamic loading on the intensity factors, numerical examples are presented and discussed.

Keywords transient dynamic crack analysis, linear magnetoelectroelastic solids, impact loading, interface-cracks, dynamic intensity factors.

1. Introduction

Magnetoelectroelastic materials offer many possibilities for advanced engineering structures due to their inherent coupling effects between mechanical, electrical and magnetic fields [3]. Important applications of magnetoelectroelastic materials are layered or laminated composites because they can be optimized to satisfy the high-performance requirements according to different in-service conditions. Beside cracks inside homogeneous domains, one of the most dominant failure mechanisms in layered or laminated composites is the interface failure. Interface cracks or interface debonding may be induced by the mismatch of the mechanical, electric, magnetic and thermal properties of the material constituents during the manufacturing process and the in-service loading conditions. Although the dynamic crack analysis in homogenous magnetoelectroelastic solids have been investigated by several authors (e.g., [5,6,7,9]) the corresponding investigation of interface cracks in layered magnetoelectroelastic solids is rather limited due to the problem complexity.
In this paper, an interface crack analysis in two-dimensional, layered and linear magnetoelectroelastic solids under impact loading is presented. For this purpose, a time-domain boundary element method (BEM) is developed. The layered magnetoelectroelastic solids are modeled by the multi-domain BEM formulation. The time-domain dynamic fundamental solutions for homogeneous and linear magnetoelectroelastic solids are applied in the present BEM. The spatial discretization of the boundary integral equations is performed by a Galerkin-method, while a collocation method is implemented for the temporal discretization of the arising convolution integrals. An explicit time-stepping scheme is obtained to compute the discrete boundary data including the generalized crack-opening-displacements (CODs). Since the asymptotic crack-tip field for an interface crack between two dissimilar anisotropic and linear magnetoelectroelastic materials shows different kinds of oscillating and non-oscillating singularities [1], which makes an implementation of a special crack-tip element somehow cumbersome, only standard elements are used at the crack-tips. For the accurate computation of the dynamic intensity factors the numerical error is minimized by a displacement-based extrapolation technique. To show the effects of the

interface, the material combinations and the dynamic loading on the intensity factors, numerical examples are presented and discussed.

2. Problem formulation

Let us consider a piecewise homogeneous, layered and linear magnetoelectroelastic solid with an interface crack as shown in Figure 1.

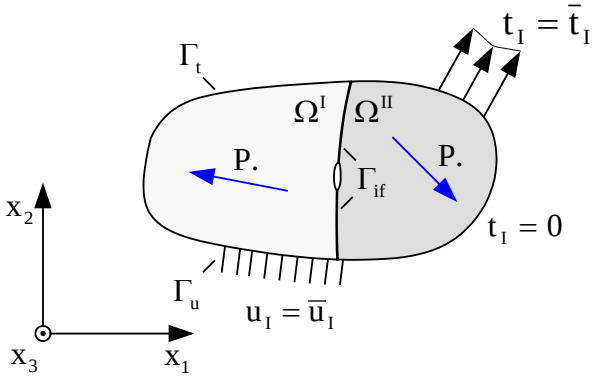

Figure 1. A cracked piecewise homogeneous and linear magnetoelectroelastic solid

In the absence of body forces, free electric charges, magnetic induction sources and applying the quasi-static assumption for the electric and magnetic fields, the cracked solid satisfies the generalized equations of motion

$$\sigma_{iJ,i}(\mathbf{x},t) = \rho^{\varsigma}\delta^{*}_{JK}\ddot{u}_K(\mathbf{x},t), \quad \delta^{*}_{JK} = \begin{cases} \delta_{JK}, J,K = 1,2 \\ 0, \text{otherwise} \end{cases}, \tag{1}$$

the constitutive equations

$$\sigma_{iJ}(\mathbf{x},t) = C^{\varsigma}_{iJKl}u_{K,l}(\mathbf{x},t), \tag{2}$$

where the generalized displacements, the generalized stresses and the generalized elasticity matrix C_{iJKl} for a homogenous domains Ω^{ζ} (ζ=1,2,…,N) are defined by

$$u_I = \begin{cases} u_i, I = 1,2 \\ \varphi, I = 4 \\ \phi, I = 5 \end{cases}, \quad \sigma_{iJ} = \begin{cases} \sigma_{iJ}, J = 1,2 \\ D_i, J = 4 \\ B_i, J = 5 \end{cases}, \quad C_{iJKl} = \begin{cases} c_{ijkl}, \ J,K = 1,2 \\ e_{lij}, \ J = 1,2, \quad K = 4 \\ h_{lij}, \ J = 1,2, \quad K = 5 \\ e_{ikl}, \ J = 4, \quad K = 1,2 \\ -\varepsilon_{il}, \ J,K = 4 \\ -\beta_{il}, \ J = 4, \quad K = 5 \\ h_{ikl}, \ J = 5, \quad K = 1,2 \\ -\beta_{il}, \ J = 5, \quad K = 4 \\ -\gamma_{il}, \ J,K = 5 \end{cases}, \tag{3}$$

the initial conditions

$$u_i(\mathbf{x}, t = 0) = \dot{u}_i(\mathbf{x}, t = 0) = 0, \tag{4}$$

the boundary conditions

$$t_I(\mathbf{x},t) = \bar{t}_I(\mathbf{x},t), \quad \mathbf{x} \in \Gamma_t, \tag{5}$$

$$u_I(\mathbf{x},t) = \bar{u}_I(\mathbf{x},t), \quad \mathbf{x} \in \Gamma_u, \tag{6}$$

and the continuity conditions on the interface without debonding

$$u_I^I(\mathbf{x},t) = u_I^{II}(\mathbf{x},t), \quad \mathbf{x} \in \Gamma_{if}, \tag{7}$$

$$t_I^I(\mathbf{x},t) = -t_I^{II}(\mathbf{x},t), \quad \mathbf{x} \in \Gamma_{if}. \tag{8}$$

In Eqs. (1)-(8), u_i, φ, Φ, σ_{ij}, D_i, B_i are the mechanical displacements, the electric potential, the magnetic potential, the mechanical stresses, the electric displacements and the magnetic inductions; ρ, c_{ijkl}, ε_{ij}, γ_{ij}, e_{ijk}, h_{ijk} and β_{ij} denote the mass density, the elasticity tensor, the dielectric permittivity tensor, the magnetic permittivity tensor, the piezoelectric tensor, the piezomagnetic tensor and the magnetoelectric tensor, respectively. Further, Γ_{if} is the interface between the homogenous domains Ω^{ζ} (ζ=1,2,…,N), Γ_t and Γ_u stand for the external boundaries where the generalized tractions t_I and the generalized displacements u_I are prescribed. The interface cracks are considered as free of mechanical stresses, electric displacements and magnetic inductions

$$\sigma_{iJ}(\mathbf{x} \in \Gamma_{c^+}, t) = \sigma_{iJ}(\mathbf{x} \in \Gamma_{c^-}, t) = 0, \tag{9}$$

where $\Gamma_{c\pm}$ are the two crack-faces. The generalized crack-opening-displacements (CODs) are defined by

$$\Delta u_I(\mathbf{x},t) = u_I(\mathbf{x} \in \Gamma_{c+}, t) - u_I(\mathbf{x} \in \Gamma_{c-}, t). \tag{10}$$

A comma after a quantity represents spatial derivatives while a dot over the quantity denotes time differentiation. Lower case Latin indices take the values 1 and 2 (elastic), while capital Latin indices take the values 1, 2 (elastic), 4 (electric) and 5 (magnetic).

3. Time-domain boundary integral equations

To solve the initial-boundary value problem, a spatial Galerkin-method is implemented, where the time-domain BIEs are treated in a weighted residual sense. The generalized time-domain displacement and traction BIEs can be written as

$$\int_\Gamma \psi(\mathbf{x})\, u_J(\mathbf{x},t)\, d\Gamma_x = \int_\Gamma \psi(\mathbf{x}) \int_\Gamma \left[u_{IJ}^G(\mathbf{x},\mathbf{y},t) * t_I(\mathbf{y},t) - t_{IJ}^G(\mathbf{x},\mathbf{y},t) * u_I(\mathbf{y},t) \right] d\Gamma_y d\Gamma_x, \tag{11}$$

$$\int_\Gamma \psi(\mathbf{x})\, t_J(\mathbf{x},t)\, d\Gamma_x = \int_\Gamma \psi(\mathbf{x}) \int_\Gamma \left[v_{IJ}^G(\mathbf{x},\mathbf{y},t) * t_I(\mathbf{y},t) - w_{IJ}^G(\mathbf{x},\mathbf{y},t) * u_I(\mathbf{y},t) \right] d\Gamma_y d\Gamma_x, \tag{12}$$

where ψ is the weighting function, an asterisk " * " denotes the Riemann convolution, $u_{IJ}^G(\mathbf{x},\mathbf{y},t)$, $t_{IJ}^G(\mathbf{x},\mathbf{y},t)$, $v_{IJ}^G(\mathbf{x},\mathbf{y},t)$ and $w_{IJ}^G(\mathbf{x},\mathbf{y},t)$ are the generalized displacement, traction and higher-order traction fundamental solutions. It should be mentioned that the dynamic time-domain fundamental solutions for homogeneous, anisotropic and linear magnetoelectroelastic solids are not available in an explicit form. In the two-dimensional case they can be expressed by a line integral over the unit-circle [4,9].

4. Numerical solution algorithm

A solution procedure is presented in this section to solve the time-domain BIEs (11) and (12) numerically. The procedure uses a Galerkin-method for the spatial discretization and a collocation method for the temporal discretization. A sub-domain technique is utilized, which divides the layered piecewise homogenous solid into two or several sub-domains with homogeneous material properties and to each sub-domain the time-domain BIEs (11) and (12) are applied. In the following, some details of the numerical solution algorithm are described. For the spatial discretization, the crack-faces, the external boundary of each homogeneous sub-domain and the interfaces are discretized by linear elements. Linear shape functions are also used for the temporal discretization in the present analysis. Since the asymptotic crack-tip field in the case of an interfacial crack between two dissimilar magnetoelectroelastic materials shows different oscillating and non-oscillating singularities in the generalized stress field, which makes an implementation of a special crack-tip element quite cumbersome, only standard elements are applied at the crack-tips. The strongly singular and hypersingular boundary integrals can be computed analytically by special

techniques. By using linear temporal shape-functions, time integrations can also be performed analytically. Only the line integrals over the unit-circle arising in the regular parts of the dynamic fundamental solutions have to be computed numerically by the standard Gaussian quadrature.
After temporal and spatial discretizations and considering the initial conditions the following systems of linear algebraic equations can be obtained for each sub-domain Ω^{ζ} (ζ=1,2,…,N)

$$\mathbf{C}_{\zeta}\,\mathbf{u}_{\zeta}^{\mathrm{K}} = \mathbf{U}_{\zeta}^{\mathrm{S}}\,\mathbf{t}_{\zeta}^{\mathrm{K}} - \mathbf{T}_{\zeta}^{\mathrm{S}}\,\mathbf{u}_{\zeta}^{\mathrm{K}} + \mathbf{T}_{\zeta}^{\mathrm{S}}\,\Delta\mathbf{u}_{\zeta}^{\mathrm{K}} + \sum_{\mathrm{k}=1}^{\mathrm{K}}\left[\mathbf{U}_{\zeta}^{\mathrm{D;K-k+1}}\,\mathbf{t}_{\zeta}^{\mathrm{k}} - \mathbf{T}_{\zeta}^{\mathrm{D;K-k+1}}\,\mathbf{u}_{\zeta}^{\mathrm{k}}\right], \tag{13}$$

$$\mathbf{D}_{\zeta}\,\mathbf{t}_{\zeta}^{\mathrm{K}} = \mathbf{V}_{\zeta}^{\mathrm{S}}\,\mathbf{t}_{\zeta}^{\mathrm{K}} - \mathbf{W}_{\zeta}^{\mathrm{S}}\,\mathbf{u}_{\zeta}^{\mathrm{K}} + \mathbf{W}_{\zeta}^{\mathrm{S}}\,\Delta\mathbf{u}_{\zeta}^{\mathrm{K}} + \sum_{\mathrm{k}=1}^{\mathrm{K}}\left[\mathbf{V}_{\zeta}^{\mathrm{D;K-k+1}}\,\mathbf{t}_{\zeta}^{\mathrm{k}} - \mathbf{W}_{\zeta}^{\mathrm{D;K-k+1}}\,\mathbf{u}_{\zeta}^{\mathrm{k}}\right]. \tag{14}$$

By invoking the continuity conditions (7) and (8) on the interface Γ_{if} and the crack-face boundary conditions (9) on Γ_{c^+} and Γ_{c^-}, and by considering the boundary conditions (5) and (6), Eqs. (13) and (14) can be summarized and recast into the following system of linear algebraic equations

$$\mathbf{x}^{\mathrm{K}} = (\mathbf{C}^{1})^{-1}\left[\mathbf{D}^{1}\,\mathbf{y}^{\mathrm{K}} + \sum_{\mathrm{k}=1}^{\mathrm{K-1}}(\mathbf{B}^{\mathrm{K-k+1}}\,\mathbf{t}^{\mathrm{k}} - \mathbf{A}^{\mathrm{K-k+1}}\,\mathbf{u}^{\mathrm{k}})\right], \tag{15}$$

where $\mathbf{y}^{\mathrm{K}}$ is the vector of the prescribed boundary data, $\mathbf{x}^{\mathrm{K}}$ represents the vector of the unknown boundary data, $\mathbf{A}^{\mathrm{k}}$, $\mathbf{B}^{\mathrm{k}}$, $\mathbf{C}^{1}$ and $\mathbf{D}^{1}$ are the system matrices. Eq. (15) can be computed time-step by time-step.

5. Intensity factors for an interfacial crack

The intensity factors for an interface crack between two dissimilar anisotropic and linear magnetoelectroelastic materials can be computed from the generalized crack-opening displacements (CODs)

$$\Delta\mathbf{u}(\mathrm{r}) = (\mathbf{H}+\overline{\mathbf{H}})\sqrt{\frac{\mathrm{r}}{2\pi}}\left[\frac{\mathrm{K}\mathrm{r}^{\mathrm{i}\varepsilon_1}\mathbf{w}}{(1+2\mathrm{i}\varepsilon_1)\cosh(\pi\varepsilon_1)} + \frac{\overline{\mathrm{K}}\mathrm{r}^{-\mathrm{i}\varepsilon_1}\overline{\mathbf{w}}}{(1-2\mathrm{i}\varepsilon_1)\cosh(\pi\varepsilon_1)} + \frac{\mathrm{K}_4\mathrm{r}^{-\varepsilon_2}\mathbf{w}_4}{(1-2\varepsilon_2)\cos(\pi\varepsilon_2)} + \mathrm{K}_5\mathbf{w}_5\right], \tag{16}$$

where $\mathrm{K}=\mathrm{K}_1+\mathrm{i}\mathrm{K}_2$, is the complex stress intensity factor, K_4 is the electric displacement intensity factor and K_5 is the magnetic induction intensity factor, ε_1 and ε_2 are the bimaterial constants, an overbar denotes the complex conjugate and i stands for the imaginary unit. The complex Hermitian matrix **H** is defined by

$$\mathbf{H} = \mathbf{Y}_{\mathrm{I}} + \overline{\mathbf{Y}}_{\mathrm{II}}, \quad \mathbf{Y}_{\mathrm{I}} = \mathrm{i}\mathbf{A}_{\mathrm{I}}\mathbf{B}_{\mathrm{I}}^{-1}, \quad \mathbf{Y}_{\mathrm{II}} = \mathrm{i}\mathbf{A}_{\mathrm{II}}\mathbf{B}_{\mathrm{II}}^{-1}, \tag{17}$$

where the subscripts I and II indicate the two layers. The matrices **A** and **B** are computed from the eigenvalue problem as shown in [1,2]. The two bimaterial constants ε_1 and ε_2 as well as the eigenvectors **w**, $\mathbf{w}_4$ and $\mathbf{w}_5$ are determined by the eigenvalue problem

$$\mathbf{D}^{-1}\mathbf{W}\mathbf{w} = -\mathrm{i}\beta\mathbf{w}, \tag{18}$$

with **D**=Re(**H**) and **W**=Im(**H**) being the real and the imaginary part of the matrix **H**. The eigenvalue β is either real or purely imaginary and related to the bimaterial constants by

$$\varepsilon_1 = \frac{1}{2}\ln\frac{1-\beta}{1+\beta}, \qquad \varepsilon_2 = \frac{1}{2}\ln\frac{1-\mathrm{i}\beta}{1+\mathrm{i}\beta}. \tag{19}$$

As shown by Eq. (16) the generalized crack-opening-displacements (CODs) in the crack-tip vicinity of interface cracks between two dissimilar linear magnetoelectroelastic materials show $\mathrm{a}\mathrm{r}^{1/2\pm\mathrm{i}\varepsilon}$-oscillating behavior and additionally a non-oscillating $\mathrm{r}^{1/2\pm\varepsilon}$-behavior. A similar behavior is known for interface cracks between two dissimilar piezoelectric materials [8]. This makes an implementation of special spatial crack-tip shape functions rather difficult. For this reason, only standard linear elements near the tips of interface cracks are used in this analysis. To minimize the numerical errors, a displacement-based extrapolation technique is applied to calculate the dynamic intensity factors from the numerically computed generalized crack-opening-displacements (CODs).

6. Numerical examples

In this section, numerical examples are presented and discussed to show the effects of the coupled fields, the interface, the material combinations and the dynamic loading on the dynamic intensity factors (IFs). The following loading parameters are introduced in order to measure the intensity of the electric and magnetic loading

$$\chi^{e}=\frac{e_{22}^{I}}{\varepsilon_{22}^{I}}\frac{D_0}{\sigma_0},\quad \chi^{m}=\frac{h_{22}^{I}}{\gamma_{22}^{I}}\frac{D_0}{\sigma_0}, \tag{20}$$

where σ_0, D_0 and B_0 are the mechanical, electric and magnetic loading amplitudes. For convenience of the presentation, the real part K_1 and the imaginary part K_2 of the complex dynamic stress intensity factors as well as the electric displacement intensity factor K_4 and the magnetic induction intensity factor K_5 of the interface crack are normalized by

$$K_1^{*}(t)=\frac{K_1(t)}{K_0},\quad K_2^{*}(t)=\frac{K_2(t)}{K_0},\quad K_4^{*}(t)=\frac{e_{22}^{I}}{\varepsilon_{22}^{I}}\frac{K_4(t)}{K_0},\quad K_5^{*}(t)=\frac{h_{22}^{I}}{\gamma_{22}^{I}}\frac{K_5(t)}{K_0}, \tag{21}$$

with $K_0=\sigma_0\sqrt{\pi a}$ and a is the half-length of an internal interface crack.

In the example we consider a central interface crack of length 2a in a rectangular, layered, anisotropic and linear magnetoelectroelastic plate with the poling direction normal to the interface crack as shown in Figure 2.

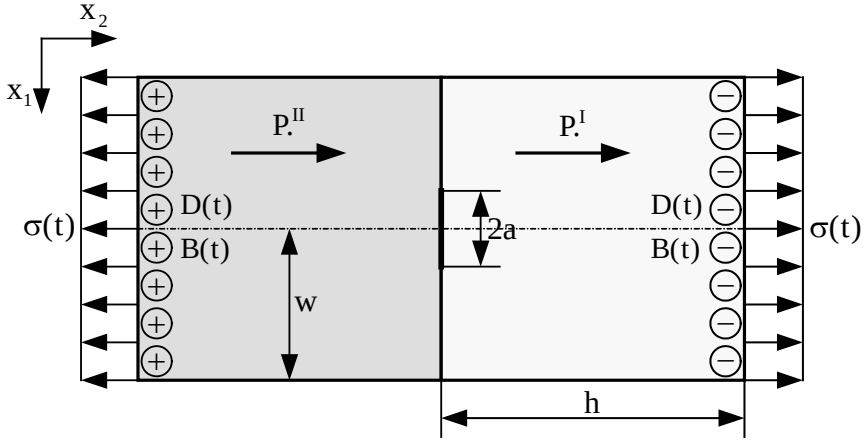

Figure 2. An interface crack in a rectangular layered magnetoelectroelastic plate

The cracked plate is subjected to an impact tensile loading $\sigma(t)=\sigma_0 H(t)$, an impact electric loading $D(t)=D_0 H(t)$ and an impact magnetic loading $B(t)=B_0 H(t)$, where H(t) denotes the Heaviside step function. The geometry is determined by h=20.0mm, w=10.0mm and 2a=4.8mm. The spatial discretization of the external boundary and the interface is performed by an element-length of 1.0mm. Each crack-face is approximated by 20 elements and a normalized time-step of $c_L\Delta t/h=0.05$ is chosen, where c_L is the quasi-longitudinal wave velocity. Numerical calculations are carried out for $BaTiO_3$-$CoFe_2O_4$ composite, with $BaTiO_3$ being its piezoelectric phase and $CoFe_2O_4$ its piezomagnetic phase. The magnetoelectroelastic material for the domain I has the constants

$$C_{11}=226.0\,\mathrm{GPa},\quad C_{12}=125.0\,\mathrm{GPa},\quad C_{22}=216.0\,\mathrm{GPa},\quad C_{66}=44.0\,\mathrm{GPa},$$
$$e_{16}=5.8\,\mathrm{C/m^2},\quad e_{21}=-2.2\,\mathrm{C/m^2},\quad e_{22}=9.3\,\mathrm{C/m^2},$$
$$h_{16}=275.0\,\mathrm{N/(Am)},\quad h_{21}=290.2\,\mathrm{N/(Am)},\quad h_{22}=350.0\,\mathrm{N/(Am)},$$
$$\varepsilon_{11}=56.4\,\mathrm{C^2/(GNm^2)},\quad \varepsilon_{22}=63.5\,\mathrm{C^2/(GNm^2)},$$
$$\beta_{11}=0.005367\,\mathrm{N/(GAV)},\quad \beta_{22}=2.7375\,\mathrm{N/(GAV)},$$
$$\gamma_{11}=297.0\,\mathrm{N/MA^2},\quad \gamma_{22}=83.5\,\mathrm{N/MA^2}, \tag{22}$$

while for domain II the material constants

$$C_{11} = 260.0\,GPa\,,\quad C_{12} = 150.0\,GPa\,,\quad C_{22} = 248.0\,GPa\,,\quad C_{66} = 45.0\,GPa\,,$$
$$e_{16} = 2.3\,C/m^2\,,\quad e_{21} = -0.9\,C/m^2\,,\quad e_{22} = 3.7\,C/m^2\,,$$
$$h_{16} = 440.0\,N/(Am)\,,\quad h_{21} = 464.2\,N/(Am)\,,\quad h_{22} = 560.0\,N/(Am)\,,$$
$$\varepsilon_{11} = 23.0\,C^2/(GNm^2)\,,\quad \varepsilon_{22} = 25.9\,C^2/(GNm^2)\,,$$
$$\beta_{11} = 0.0028\,N/(GAV)\,,\quad \beta_{22} = 2.0\,N/(GAV)\,,$$
$$\gamma_{11} = 473.0\,N/MA^2\,,\quad \gamma_{22} = 127.6\,N/MA^2\,, \tag{23}$$

are applied. The numerical results of the present time-domain BEM obtained for different loading combinations and the application of material (22) for both layers are presented in Figure 3. This special case is equal to an interior crack inside a homogenous magnetoelectroelastic plate and the intensity factors are given in [9]. The normalized dynamic intensity factors for the interface crack are shown in Figure 4.

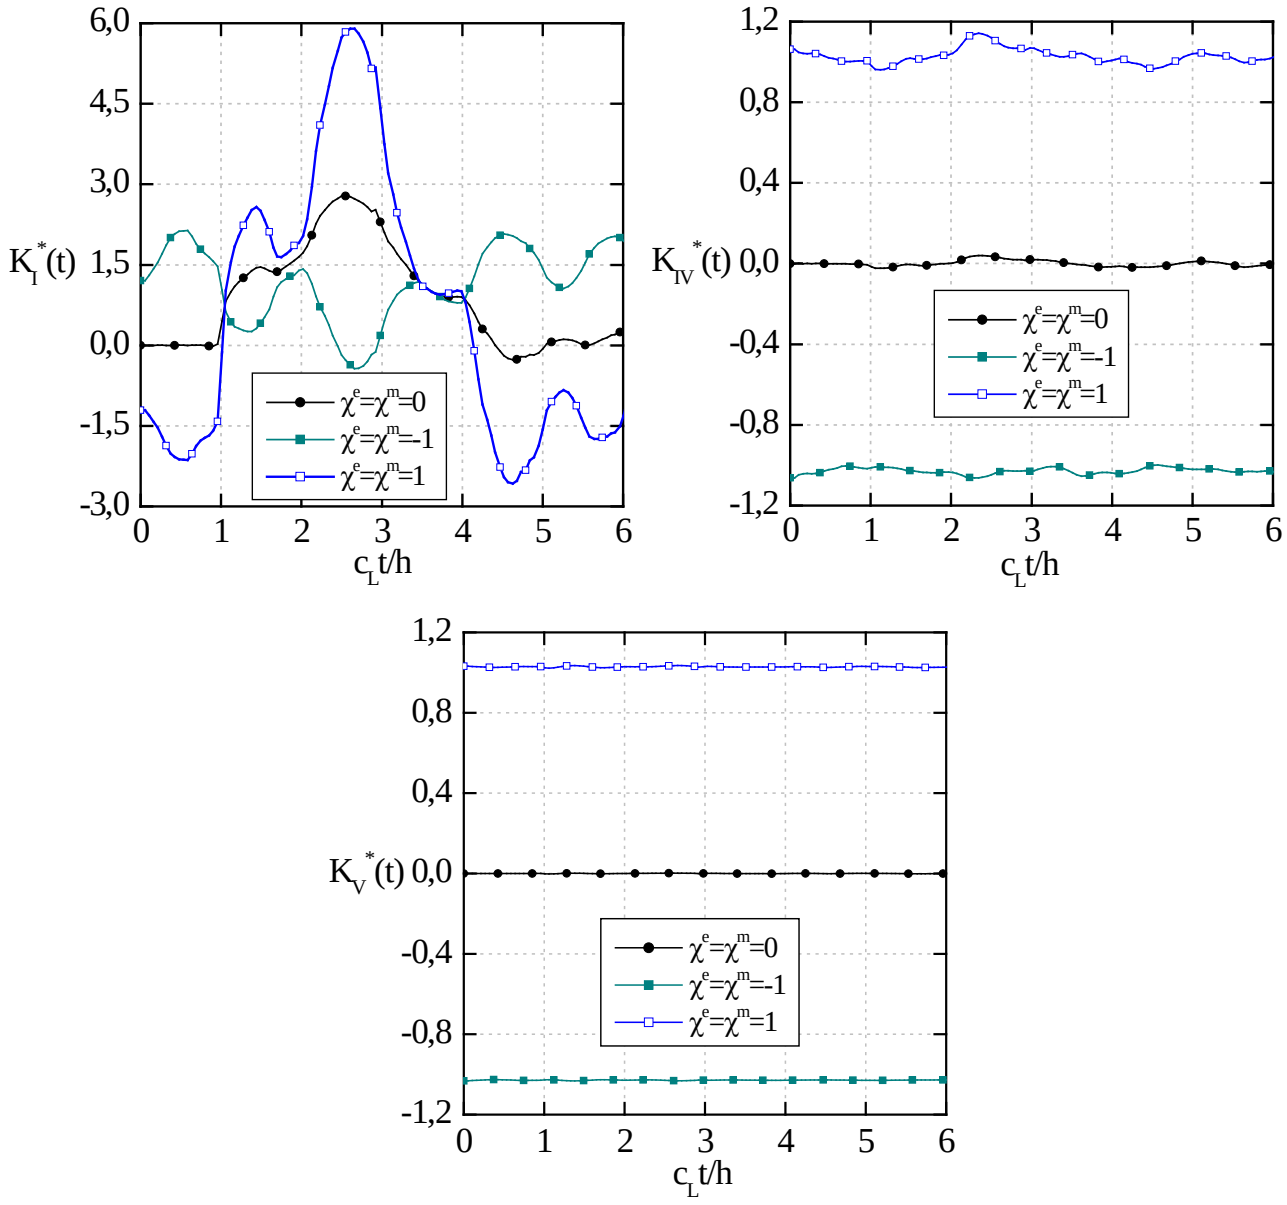

Figure 3. Normalized dynamic intensity factors for an interior crack subjected to different loadings

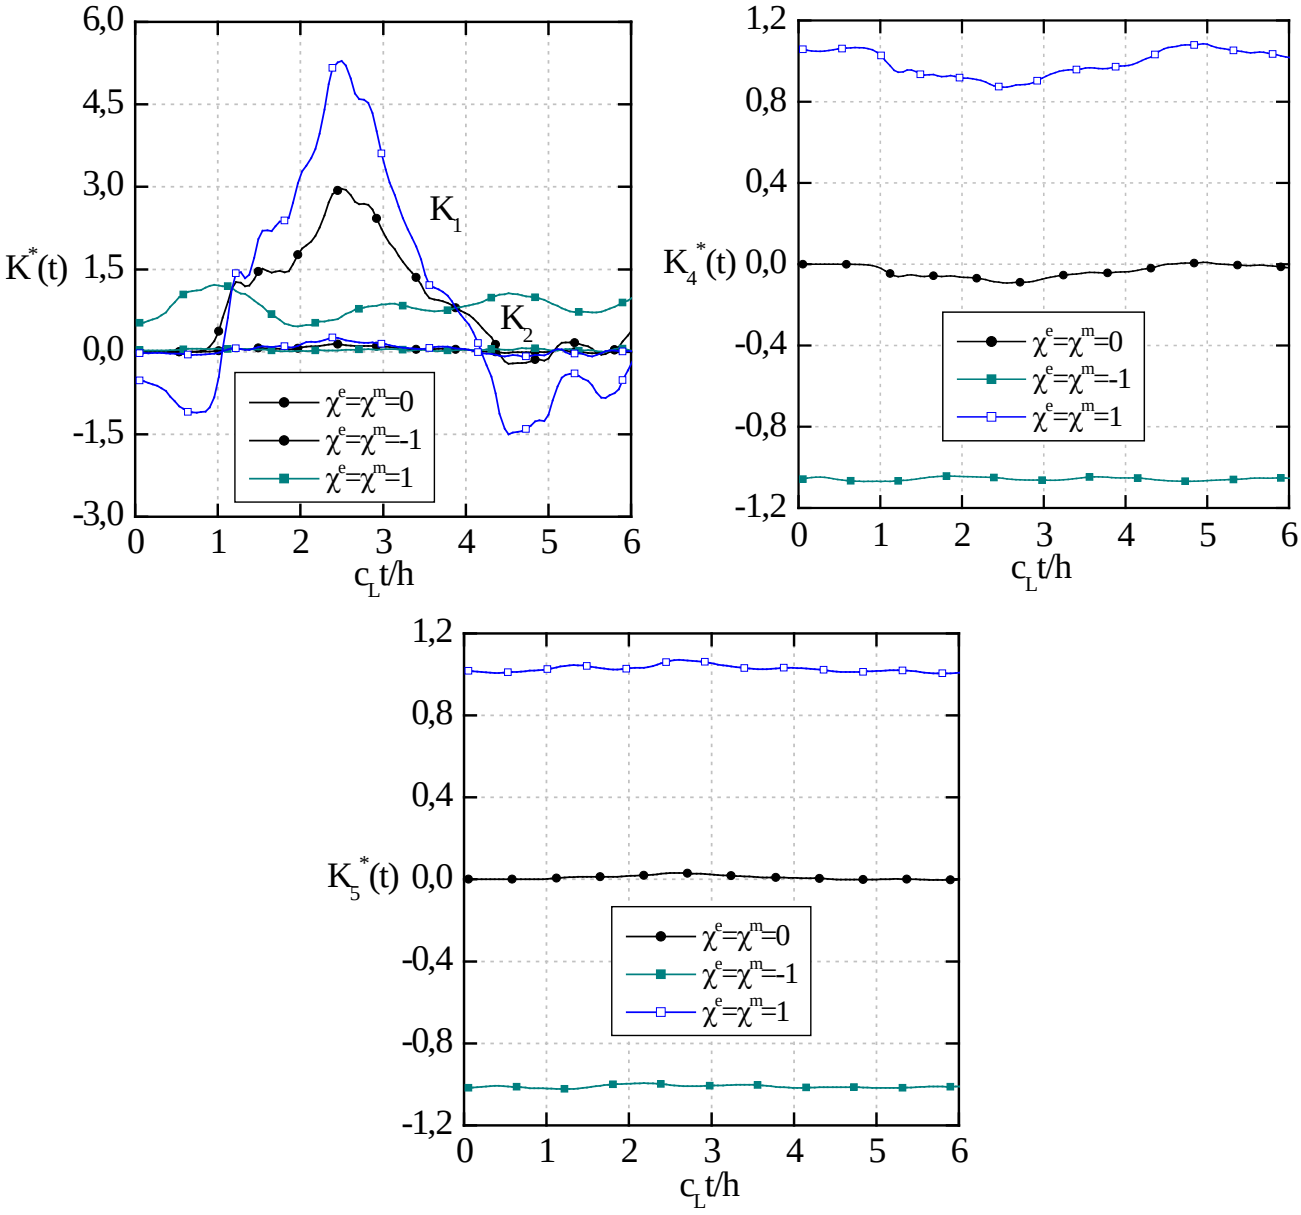

Figure 4. Normalized dynamic intensity factors for an interface crack subjected to different loadings

The normalized dynamic mode-I, mode-IV and mode-V intensity factors for an interior crack in a homogenous magnetoelectroelastic plate as well as the real part of the complex intensity factor, the electrical displacement intensity factor and the magnetic induction intensity factor for the interface crack obtained by the present TDBEM have a similar global behavior. The mode-II intensity factors vanish, since no shear stress components are induced for all applied loadings in the case of a transversely isotropic material behavior. In contrast, the crack opening and sliding modes I and II are coupled each other for the interface crack and therefore the imaginary part of the complex intensity factor is unequal zero. It can be observed that, when an electric and magnetic impact is applied, the normalized dynamic mode-I stress intensity factor and the complex stress intensity factor start from a non-zero value at t=0. This is due to the quasi-static assumption on the electromagnetic fields, which implies that the cracked magnetoelectroelatic plate is immediately subjected to an electromagnetic wave and therefore the crack opens at t=0. In contrast, the elastic waves induced by the mechanical impact need some time to reach and excite the crack, as clearly observed for the case $\chi^e=\chi^m=0$. It should further be mentioned here, that the applied electric and

magnetic loading may lead to a physically meaningless crack-face intersection in different time ranges for the case $\chi^e=\chi^m=1$. This requires an advanced iterative solution procedure for the crack-face contact analysis which is not considered in this work. The peak values of the normalized dynamic intensity factors decrease with increasing electric and magnetic loading amplitudes.

Abstract

Advanced ceramics comprise a class of new materials finding increased application used in extreme conditions, such as high speed turning of aerospace alloys and rock drilling. Their high hardness makes them suitable for these applications, however their lower toughness means that premature failure due to fracture and chipping is still a major issue. Typically, they are composed of micron-sized particles of a primary hard phase together with a ceramic or metallic matrix.

A combined experimental-numerical method was used to investigate the role of microstructure on the fracture of these advanced ceramics. In particular, the effect of grain size and matrix content was examined. Representative finite volume (FV) microstructures were created using Voronoi tessellation. The cohesive zone parameters for the FV model were found experimentally using an adapted Three-Point-Bend (TPB) fracture toughness test method [1]. Image analysis was carried out on actual representative microstructures and compared to the FV microstructures to ensure that they were statistically similar.

It was found that the underlying microstructure significantly affects the fracture toughness of the advanced ceramic. Furthermore, it was found that by altering the microstructural parameters in the numerical model, such as grain size and binder content, it is possible to specify material improvements.

Keywords Advanced ceramics, microstructure, Voronoi tessellation, cohesive zone model

1. Introduction

In this study, we examine a two-phase ceramic structure composed of stiff hard particles together with a softer ceramic matrix material. Carolan et al [1, 2] have shown that the strength and toughness of polycrystalline materials are affected by both the grain size and matrix content. Therefore it is desirable to be able to virtually optimise these parameters to be able to produce stronger or tougher materials for specific applications. Current methods adopt a so-called "trial-and-error" approach to the design of new materials, which is both costly and time consuming. Hence, it is beneficial to be able to specify improvements to materials numerically. By specifying materials virtually, the influence of individual material parameters on the microstructural scale can easily be investigated and altered to change bulk material properties. In order to better model and predict material behaviour, the first step is the ability to produce statistically representative microstructures.

A number of authors [7–10] have generated finite element meshes directly based on actual microstructural images. In this work, however, a representative synthetically generated geometry is

produced, which is then compared to a real microstructure. Numerous studies have been carried out to produce numerical microstructures using Voronoi tessellation [11–13], with an emphasis on investigating stress distributions in plasticity [14–17] and fracture [18–20]. However there is little in the literature to show that numerical microstructures are actually representative of the real microstructures they were created to replace. This is important, especially in the case of fracture problems, where the morphology of a grain boundary interface is of added importance in initiating fracture. The present work attempts to produce numerical microstructures and subsequently compare them to these real microstructures to prove that they are statistically representative.

2. Synthetic microstructure generation

Voronoi tessellation was used to generate the geometrical model of the microstructure. It is a commonly used method for the generation of numerical microstructures of ceramic [19, 20] and metallic [11, 16, 21, 22] materials in both two- and three-dimensions. The Voronoi tessellation algorithm produces a random structure, which is representative of a polycrystalline material. A periodic microstructure was generated with periodic boundary conditions. To generate a dual interpenetrating phase microstructure, typical of some advanced ceramics, the Voronoi tessellation is applied. Each Voronoi tile is then reduced in area around the circumcentre of the tile until the desired area fraction of the second interpenetrating phase is reached, as shown in Figure 1.

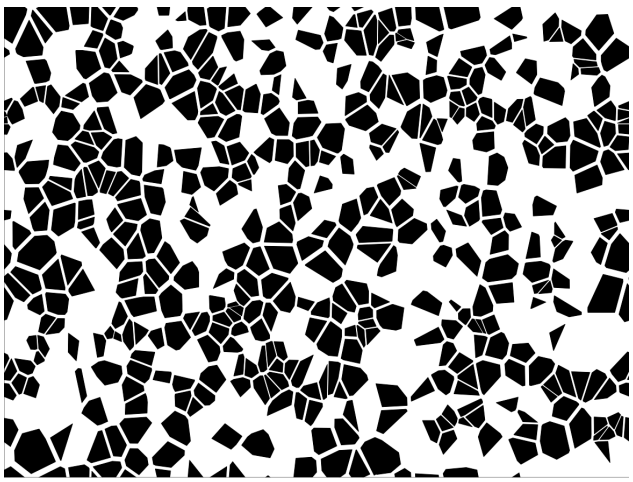

Figure 1: Numerically generated microstructure with 50% primary phase.

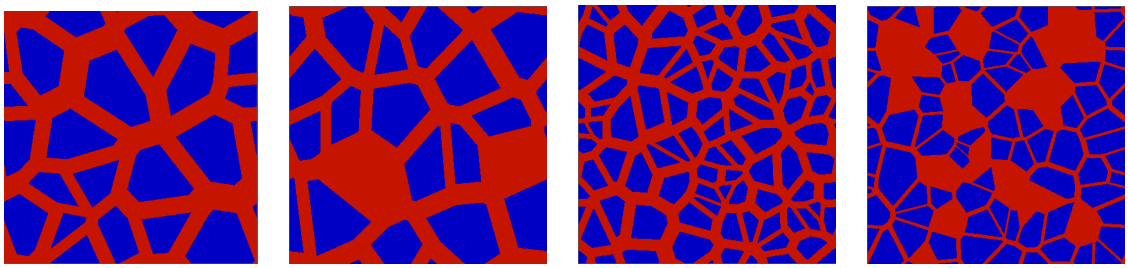
3. Results

3.1 Comparison of real and numerical microstructures

Grain size distribution, aspect ratio, percentage matrix agglomerations (MA) and percentage primary phase were obtained through image analysis. Matrix agglomerations are large regions containing no primary phase. From the image analysis it was found that the two real microstructures being investigated had an average areal primary phase content of 50.5% and 47.2% respectively. Four synthetic microstructures were generated for comparison, as shown in Figure 2. The generated microstructures all had a particle content in the range of 49-54%, which was close to the real

microstructures investigated. The percentage matrix agglomerations with respect to matrix phase content was calculated for the two real microstructures and was found to have an average value of 57.5% and 45.9% respectively. The two synthetic microstructures with matrix agglomerations, Figures 2b and 2d, had matrix agglomerations of 52.6% and 52.3% respectively.



(a) 5×5 grains (b) 5×5 grains with MA (c) 10×10 grains (d) 10×10 grains with MA

Figure 2: Numerical microstructures used for finite volume

Grain size distribution, percentage particle phase and aspect ratio were obtained for both the numerical and corresponding real microstructures. A comparison between the two confirms that the numerical model is a good representation of the real microstructure, see Figures 3a and 3d. The grain size distribution of both the real and the numerical microstructure follow a log-normal distribution with a greater number of small grains, see Figure 3b and 3e. The real microstructure has a higher percentage of these small grains than its numerical counterpart due to small fragmented grains. However, it is not thought that these small fragments affect the mechanical properties of the bulk material. The aspect ratio of the real and the numerical microstructures show excellent agreement, as shown in Figure 3c and 3f. Visually it was also observed that the numerical microstructure resembled the real microstructure.

(d) Numerical microstructure (e) Grain size distribution (f) Aspect ratio

Figure 3: Comparison of real (a,b,c) and numerical (d,e,f) microstructures in terms of grain size distribution and aspect ratio.

3.2 Finite volume stress analysis

Finite volume based stress analysis was carried out on the four generated microstructures using OpenFOAM 1.6-ext [23]. Each generated microstructure was 100×100μm in size with approximately 50% particulates, but with varying grain sizes and matrix agglomerations, as shown in Figure 2. The simulations were 2-dimensional and plane strain was specified in the third direction. The Young's modulus and Poisson's ratio for the grains are 800 GPa and 0.1 respectively, while for the matrix material E = 300 GPa and ν = 0.1 were chosen for illustration. Both the particulates and matrix were treated as linear elastic over the course of the simulation. It should be noted that the elastic constants picked for each phase are not representative of any particular material.

The microstructures were subjected to a normal traction rate of 10 MPa/s in the y-direction for a total loading time of 10 seconds, while cyclic boundary conditions were applied in the x-direction, see Figure 4. The cyclic boundary conditions ensure that both material and displacement distribution are continuous from right to left. Furthermore, the 10×10 grain microstructures were increased to 200×200μm to investigate size effects.

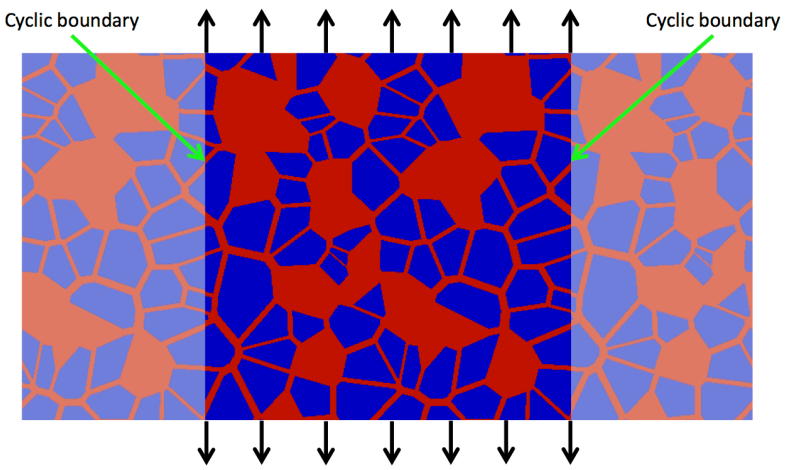

Figure 4: Generated microstructure with periodic boundary conditions subjected to a fixed traction

3.3 Effective elastic properties

The Young's Modulus value of a multiphase material depends on the properties of the individual phases. The upper and lower bounds for the elastic properties of the microstructures can be found using the Hashin-Shtrikman method from Eq. (1) and (2). The Hashin-Shtrikman bounds can be applied to transversely isotropic composites with arbitrary phase geometry [24–26].

$$k_l = k_2 + \frac{m_1}{\frac{1}{k_1-k_2}+\frac{m_2}{k_2+\mu_2}}, \quad k_u = k_1 + \frac{m_2}{\frac{1}{k_2-k_1}+\frac{m_2}{k_1+\mu_1}} \tag{1}$$

$$\mu_l = \mu_2 + \frac{m_1}{\frac{1}{\mu_1-\mu_2}+\frac{m_2(k_2+2\mu_2)}{2\mu_2(k_2+\mu_2)}}, \quad \mu_u = \mu_1 + \frac{m_2}{\frac{1}{\mu_2-\mu_1}+\frac{m_1(k_1+2\mu_1)}{2\mu_1(k_1+\mu_1)}} \tag{2}$$

Where *l* and *u* represent the upper and lower bounds respectively, k is the bulk modulus, μ is the shear modulus, m is the volume fraction and *1* and *2* represent the two phases in the material.

$$E = \frac{9k_i\mu_i}{3k_i+\mu_i} \tag{3}$$

$$\nu = \frac{3k_i-2\mu_i}{6k_i+2\mu_i} \tag{4}$$

The upper and lower bounds for the Young's modulus and Poisson's ratio can then be calculated from Eq. (3) and (4) respectively [21], by letting i equal u and l from Eq. (1) and (2). Using the Hashin-Shtrikman method the Young's modulus bounds for 50% particulates was found to be 459.9-480.6 GPa (Table 1).

The Eshelby-Mori-Tanaka approach [27–29] for determining the elastic properties of composites containing randomly oriented inclusions was also employed in the current work. Using this approach, and treating the inclusions as circular, i.e. an aspect ratio of one, the ratio of bulk modulus, k, and shear modulus, μ of a composite material to that of the matrix can be written as:

$$\frac{k}{k_m} = \frac{1}{1+V_f p} \tag{5}$$

$$\frac{\mu}{\mu_m} = \frac{1}{1+V_f q} \tag{6}$$

where k_m, μ_m and V_f are the bulk modulus of the matrix, shear modulus of the matrix and volume fraction of the inclusion respectively, and p and q are parameters derived from the Eshelby tensor and defined in Tandon and Weng [27]. Using the Eshelby-Mori-Tanaka method, the Poisson's ratio was found to be 0.114 for all the microstructures.

The effective stress, σ^e, and strain, ε^e, were found by averaging the local stress and strain in each cell using Eq. (7) and (8) [30]. This is known as homogenisation.

$$\sigma^e = \frac{1}{V_\Omega}\int_{V_\Omega} \sigma \, dV \tag{7}$$

$$\varepsilon^e = \frac{1}{V_\Omega}\int_{V_\Omega} \varepsilon \, dV \tag{8}$$

Where V_Ω is the total volume of integration. These values were then used to calculate the effective Young's Modulus E^e from

$$E^e = \frac{1}{\varepsilon^e_{yy}}[\sigma^e_{yy} - \nu^e(\sigma^e_{xx} + \sigma^e_{zz})] \tag{9}$$

where the effective Poisson's ratio, ν^e, is

$$\nu^e = \frac{\sigma^e_{xx}}{\sigma^e_{yy} + \sigma^e_{zz}} \tag{10}$$

The effective Young's modulus, $E_{Eq.9}$ of the microstructures is as shown in Table 1. The Poisson's ratio was found to be 0.112 for all the microstructures. The Young's modulus was also determined by calculating the average tractions and strains on the loading boundaries. Using these values the stress, σ, and strain, ε, and hence the Young's Modulus, E, could be calculated by:

$$\sigma^e = \frac{F_1}{L_1 t} \tag{11}$$

$$\varepsilon^e = \frac{u_1}{L_2} \tag{12}$$

$$E^e = \frac{\sigma^e}{\varepsilon^e} \tag{13}$$

Where F_1 is the loading force on the prescribed boundary, L_1 and L_2 are the width and height of the specimen, t is the thickness of the specimen and u_1 is the displacement of the sample along the loading direction. The Young's modulus value calculated using Eq. (13), was found to be higher than the value calculated using the average volumes (Table 1).

Table 1: Elastic properties of numerical microstructures where $E_{Eq.9}$ is calculated using the homogenisation method in Eq. (9), $E_{Eq.13}$ is calculated using the load-displacement method in Eq. (13), E_{EMT} is calculated using the Eshelby-Mori-Tanaka method, and E_{HS} is calculated using the Hashin-Shtrikman method

Microstructure	V_f	$E_{Eq.9}$ **(GPa)**	$E_{Eq.13}$ **(GPa)**	E_{EMT} **(GPa)**	E_{HS} **(GPa)**
5×5	0.5	463.2	475.9	462.1	459.6 - 480.6
10×10	0.5	463.3	476.3	462.1	459.6 - 480.6
5×5 with MA	0.49	459.7	472.4	457.7	455.3 - 476.1
10×10 with MA	0.54	485.1	498.6	484.7	477.4 - 499.8
10×10 (200×200μm)	0.5	463.3	476.3	462.1	459.6 - 480.6
10×10 with MA (200×200μm)	0.54	485.1	498.6	484.7	477.4 - 499.8

The Young's modulus value for the two microstructures with no matrix agglomerations was found to be very similar using all the methods for calculating the Young's modulus. This suggests that the Young's modulus is not affected by the grain size. It was also observed that increasing the specimen size to 200×200μm did not change the Young's modulus value showing that it is not size dependent. Furthermore, the matrix agglomerations were not found to affect the Young's modulus values. Only the volume fraction of particles was found to make a difference.

It was found that the load-displacement method consistently gave higher results than both the Eshelby-Mori-Tanaka and the homogenisation methods. The load-displacement values were found to lie close to the upper bounds of the Hashin-Shtrikman limits. The homogenising was found to give realistic values for Young's modulus and Poisson's ratio, and these values were found to be in good agreement with the Eshelby-Mori-Tanaka method. Both these values tend to lie close to the lower bound of the Hashin-Shtrikman limits.

Figures 5a and 5b plot the distribution of Von-Mises equivalent strain for a 5×5 and 10×10 microstructure with no matrix agglomerations. Figures 5c and 5d plot the distribution of Von-Mises

equivalent stress for the same two microstructures. Similarly Figures 6a and 6b plot the Von-Mises equivalent strain for a 5×5 and 10×10 microstructure with matrix agglomerations and Figures 6c and 6d plot the corresponding Von-Mises stresses. From Figure 5 it may be observed that the distribution of local stress and strain does not vary significantly between the two microstructures, showing that stress and strain are not size dependent. However, when comparing Figure 5 and 6, it can be observed that the matrix agglomerations do affect the local distribution of stress and strain in the microstructure, with higher stress and strain being detected near the agglomerations. The highest stresses are seen in the hard phase at the phase interface, while the highest strains are seen in the more compliant matrix phase. This shows that matrix agglomerations in the microstructure act as stress concentration factors. Carolan has previously observed this effect in the context of dynamic fracture of advanced ceramics [31].

4. Conclusion

The purpose of this paper was to develop statistically representative numerical models of advanced ceramic microstructures. The microstructures were generated using the Voronoi tessellation algorithm and subsequently altered to add a specified percentage primary inclusion phase and secondary phase matrix agglomerations to the microstructure. In the current paper it has been shown that the Voronoi Tessellation technique is a good method for the production of synthetic microstructures. The synthetic microstructures were compared to true microstructures and were found to be statistically representative in terms of grain size distribution, aspect ratio and agglomeration of a second phase material.

Using the numerically generated microstructures, Finite Volume analysis was carried out to investigate the stress and strain distributions in the microstructures and hence calculate the effective Young's modulus and Poisson's ratio. It was observed that the higher strains occur in the more compliant second phase material. This was more prevalent when there were agglomerations of the second phase material. Furthermore, it was observed that the presence of matrix agglomerations act as a stress concentration factor. Hence, the interface between particulates and a matrix agglomeration is likely to be the source of failure. This emphasises the need for accurate representation of microstructures in a numerical model.

The current paper presents a useful and implementable tool for investigating the effect of microstructural parameters on the microscopic stress distribution in a polycrystalline material. It is intended that the work will be extended to include other types of advanced ceramic material including single-phase ceramic as well as complex structures containing many different phases. Future work will concentrate on comparing the bulk elastic predictions with experimentally determined values for a range of advanced ceramics. It is also intended to extend the predictive capabilities of the models to capture strength and fracture behaviour.

Abstract Indentation induced cracking may have widely encountered in rock engineering, such as drilling and cutting process. It is significant to investigate the deformation and failure process for further understanding the failure mechanism of rock under cyclic indentation. In the present work, we have experimentally investigated the deformation fields on the sample surface via digital image correlation (DIC) technique. It has been found that the force-indentation displacement exhibits hysteresis during the loading-unloading cycles. The energy dissipation and the displacement field in the samples during the process has been analyzed. Furthermore, a median crack has been observed to nucleate running almost parallel to the loading axis when indentation force amounts to a critical value. Experimental analysis reveals that local tensile strain dominates the crack nucleation of rock and the shear strain has an effective influence on crack propagation. In unload-reloading process, crack behavior closure and re-opening is clearly observed by DIC technique. By the displacement distribution along the crack surface, crack opening displacement (COD) and stress intensity factor can be calculated for further fracture analysis.

Keywords Rock, Cyclic indentation, Digital image correlation, Deformation and failure

1. Introduction

Rock fragmentation induced by mechanical tools is an effective technique in mining and civil engineering. Rock cutting by various bits, such as drilling bit, rolling cutter, could be simplified as the cyclic indentation process [1]. Knowledge on deformation and failure process of rock is an important basis for the study of rock failure mechanisms. Therefore, it is necessary to experimentally investigate the damage and fragmentation of rock during cyclic indentation.

Many experimental tests have been conducted in the past decades to investigate the fragmentation of rock. Damage pattern which consists of inelastic zone and a region of multiple cracks is observed in rock under indentation [2]. Laboratory tests, simulating the disk cutter action at the tunnel face by means of an indenter, were carried out to explore the influence of the lateral confinement acting on the rock failure [3]. Acoustic emission (AE) and electronic speckle pattern interferometry (ESPI) techniques were used to detect the events of microcrack nucleation [4]. Numerical methods, such as the finite element method (FEM) [5], rock failure process analysis of two dimensions (RFPA2D) [6], have been developed to simulate the fragmentation process in rocks under indentation. Repeated loading–unloading conditions are widely encountered in practical excavation and drilling engineering. However, affects of cyclic loading on indentation-induced failure remains unclear.

In this work, cyclic indentation tests have been conducted to investigate the deformation and damage evolution of Yunnan sandstone. During the loading-unloading process, images of rock specimens have been sequently captured, from which deformation fields can be obtained by digital image correlation (DIC) processing. Displacement and apparent strain fields calculated by DIC, are

used to analyze the deformation, crack initiation, propagation during cyclic loading tests.

2. Experimental setup

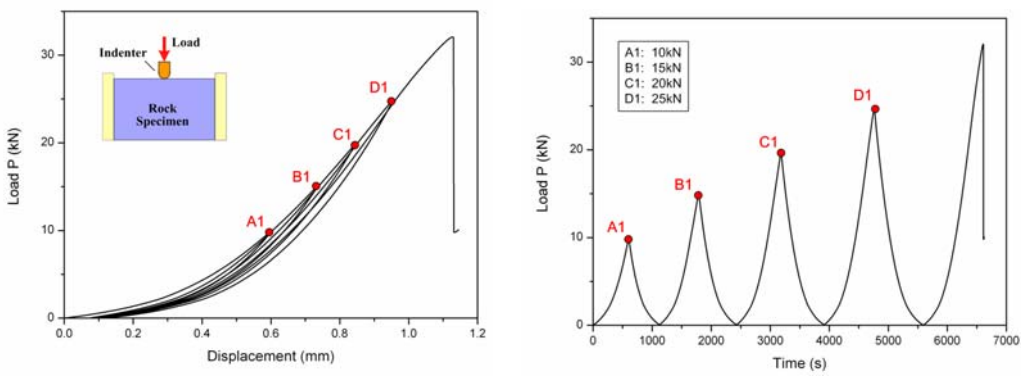
Indentation tests were conducted on Yunnan sandstone plates with a dimension of 150×100×25 mm. Its surface was painted with randomly artificial speckle.Loading system includes electric universal machine (CSS-44100), indenter(diameter Φ=20 mm) and the fixture on which the specimen is mounted. During experiments, the load cell moved down and up with a constant velocity of 0.06 mm/min, the displacements, loads and time from the load cell, were continuously recorded during the experiment.

CCD camera with 1004×1003 pixels, a Matrox meteor Ⅱ image capture, a frame grabber and two white lights are used to capture images of the specimen. The observed area of specimen surface is 57×57mm. Sequential images were captured by a digital image system at a rate of 1 frame/s. Digital image correlation (DIC) is a powerful tool to measure the full field displacement distribution on the surface of specimens [7-9]. Then the displacement field can be used to derive the strain field by smoothing difference with numerical methods [10].Deformation information of specimen surface obtained by DIC, is used to characterize the damage and fracture process of rock.

3. Experiment

Samples of Yunnan sandstone were subjected to increasing-amplitude cyclic indentation experiments to investigate the evolution of deformation and fracture as rock approaches failure. The typical Load-displacement and Load-time curves are shown in Fig.1. The peak load of the first cycle is 10 kN (~30% peak load) and is increased by 5 kN in the subsequent cycles until the sample failed. The loading curves are usually not coincidence with the unloading curves and hence they form hysteresis loops which indicate that residual displacement develops.

The residual deformation exists not only at end of each cycle, but virtually at any load level during loading-unloading stage. It can be verified upon examining the load-displacement curves during different loading cycles but at the same load level. For instance, Fig.2 shows that during cycle 1 and 2 at the same load of 5 kN, the loading and unloading points A01, A11, B01, B11 are not coincident with each other on the load-displacement curves. To look into the displacement field in the indented sample, Fig.3 demonstrates DIC contours corresponding to points A01, A11, B01 and B11 designated in Fig. 2. One may find that the sequence of the severity of the vertical deformation at those points are A01, A11, B01 and B11, which is in good agreement with overall force-indenter displacement curves, but the horizontal displacement field at those points seems not to follow that simple sequence.



(a) (b)

Fig.1 Load-displacement and load-time curves of cyclic indentation tests.

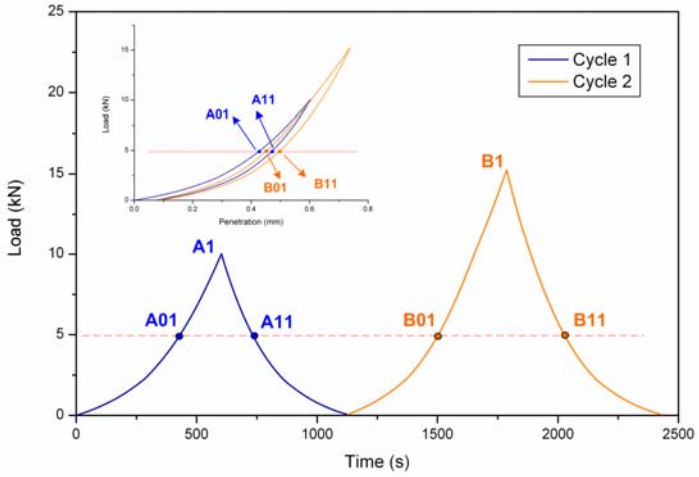


Fig.2 Mechanical response in the first two cycles

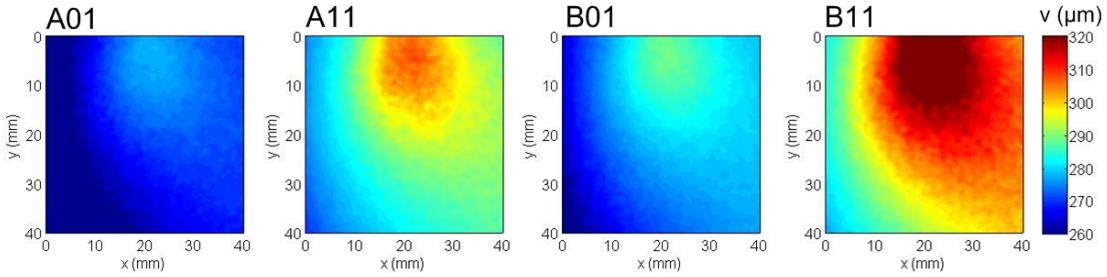

Fig.3 Vertical displacement fields at selected points with the same load P=5 kN.

It is well known that when the indentation force attains at a critical value, crack will nucleate and propagate in the sample that may lead to the final failure. By using the DIC technique, apparent strains at final stage of loading-unloading cycle are presented in Fig.4.Upon reloading to point D01 with load P=20 kN, tensile strain appears beneath the indenter and its maximum magnitude is about 0.6% located in the local region (Fig.5 D01 ε_x). Apparent shear strains were recognized by the contrast of red and blue regions, indicating concentration of shear strains in the central part of the specimen.

At D1 for load P=25 kN, the tensile strain concentrates in a very narrow belt, the value is far larger than those at other load level. Giving the sharp gradient of displacement, it can be concluded that a

crack has nucleated there. During the unloading period the peak of apparent strain is lower Fig.5 D2). It indicates that no additional new crack appears but only the existed crack begins to close. The value of ε_x is smallest at point D2 (load=0kN).

With increased subsequent loading, the crack develops both in length and opening. The significant increase was found in D21 (Load=25kN), apparent strains at the crack surfaces were obviously greater than D1. Afterwards, on continuous development of the cracking, the fracture eventually went through the specimen. After the test, it was observed that the crack identified by DIC developed along the path of the final failure.

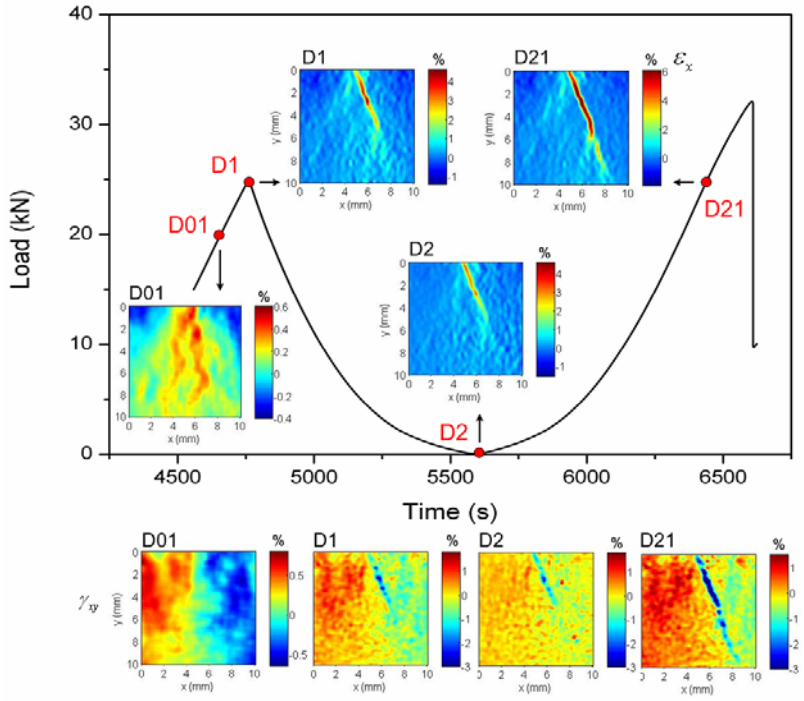

Fig.4 Distribution of the apparent strains ε_x and γ_{xy} during the final unloading and reloading stage

4. Conclusion

Cyclic indentation tests have been conducted in conjunction with the nondestructive technique of DIC to study the deformation and failure of rock samples. It has been found that DIC is an efficient method in tracing the deformation behavior and identifying the onset of the crack in rock.

By analysis of the experimental results, it has been detected that tensile strains concentrate beneath the indenter just before cracking, and a crack nucleates when the indentation load exceeds a critical value. The closure and propagation of the crack during unloading-reloading can be well described by the apparent strain fields.

Abstract Tungsten promises great potential in very high temperature applications due to its very high melting point. Yet its brittleness, far above room temperature, limits its application. Investigations have already shown that fracture toughness of polycrystalline tungsten strongly depends on microstructural characteristics like grain size and shape, and texture. To gain a better insight into the basic mechanisms, fracture toughness experiments are carried out at the micro-scale. First experiments focus on the influence of the crystal orientation with respect to cracking. Here, we report on micro bending tests on free standing, notched, single crystal micro cantilevers. With respect to the {110}<1$\bar{1}$0> crack system, the beam axis was normal to the {110} crystal plane.

Keywords Tungsten, fracture toughness, crystal orientation, micro bending experiments

1. Introduction

Tungsten is a very promising material for power generation due to its outstanding properties at high temperatures such as high strength, high Young's modulus, and of course its high melting point. A huge drawback, though, is its brittleness and high brittle-to-ductile temperature which limits the use of tungsten significantly. Therefore, several studies have already been carried out to investigate the fracture behavior and to provide suitable remedies.

An extensive study of the fracture toughness of tungsten single crystals had been carried out by Riedle and Gumbsch [1-3]. They considered the influence of crystal orientation, loading rate, and temperature on the fracture behavior. Furthermore, studies on the fracture behavior of polycrystalline tungsten were reported by Gludovatz et al. [4], who investigated pure polycrystalline tungsten as well as doped tungsten to gain different microstructures at various temperatures. Experiments on pure rolled polycrystalline tungsten were carried out by Rupp and Weygand [5]. They observed the influence of different grain boundary orientations on the fracture behavior. All those investigations showed that fracture toughness in single crystal and commercial polycrystalline tungsten strongly depend on microstructural characteristics and loading conditions. However, most studies were carried out at the macro-scale with few exceptions such as Wurster et al. [6] who studied the fracture behavior of single crystalline tungsten at the micro-scale.

The aim of this study is to observe the fracture behavior of tungsten at the micro-scale to deepen the insight into the fracture behavior of tungsten on a micromechanical basis. For this, free standing single crystal bending cantilevers with a typical dimension of 20 µm in width and 40 µm in height have been manufactured and tested using a nanoindenter. To investigate the influence of different crack systems, experiments will be carried out with differently oriented beams. Further experiments

on bi-crystals will be conducted in situ using the SEM to see the influence of grain boundary. Here, we report on the development of the testing procedure as well as first results for beams that are oriented to induce fracture in the {110}<1$\bar{1}$0> crack system. The investigations are accompanied by crystal plasticity simulations [7] addressing the interplay of cracking and plastic deformation at small scale.

2. Experimental

Tungsten single crystals with 3 mm in width and height and 5 mm in length were used for the manufacturing of the free-standing micro bending beams. The samples were aligned in a specific crystal orientation.

At the scale the experiments are conducted, the standard geometry and procedure of the ASTM E 399-90 for the determination of the fracture toughness does not apply, the plastic zone is too large relative to the cantilever dimensions. Also, no standardized testing device is available to conduct standard fracture toughness tests at this length-scale. Therefore, a new specimen geometry was developed which is shown in Figure 1. The geometry is a result of the available manufacturing and testing conditions. To design the experiment close to the standard test, the relations of width, length, and height are derived from the ASTM E 399-90 for standard fracture toughness tests. As the samples are going to be tested with a nanoindenter free-standing cantilevers were chosen. The length of the cantilevers is roughly 160 µm, the width is 33 µm and the height is 40 µm. At this scale the focused ion beam (FIB, FEI Company, Nova 200 NanoLab) is an accurate and nearly inevitable tool, yet at the targeted dimensions it is rather time consuming and inefficient. Therefore, the basic cantilevers were carved by a micro electrical discharge machining (µ-EDM) process. The actual width of the gage section width is thinned to 20 µm and the notch is cut to a depth of 20 µm at a distance of 50 µm from the shoulder using a focused ion beam (FIB). The radii between the bulk material and the cantilever are roughly 20 µm which can be realized reliably by µ-EDM. Due to the manufacturing process, however, the geometry varies from the design dimensions, and the size and shape of each individual beam is inspected by scanning electron microscopy (SEM).

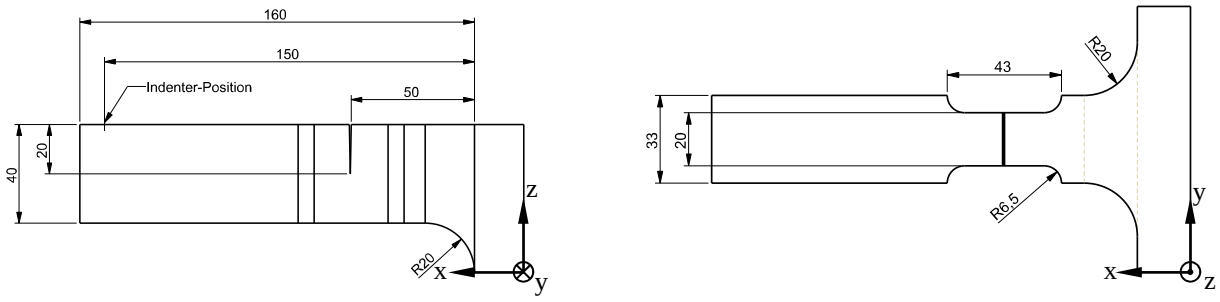

Figure 1. Developed free standing micro bending beam geometry as a result of manufacturing and testing restrictions.

In the first preparation step, the samples were mechanically polished using a Struers TriPod polishing fixture and Allied diamond lapping foils (9 µm, 6 µm, 3 µm, 1 µm, 0.5 µm). This results in an almost plane surface and sharp edges. This is necessary, as the bending cantilevers will be

carved from the edges of the single crystals. Rounded edges would lead to cantilevers with decreasing thickness.

A custom-built specimen holder based on a goniometer was used to align the samples accurately for the µ-EDM process. First, a thin plate with the thickness of the cantilevers was prepared by a horizontal cut parallel to the polished surface. Afterwards, every single cantilever was carved from the thin plate by vertical cuts.

Due to the heat input and the re-deposition of molten material, the µ-EDM process results in a rather rough surface of the micro cantilevers. Also micro-cracks and changes of the microstructure may be possible. The µ-EDM exposed surfaces did not yield a diffraction pattern when investigated by electron backscatter diffraction (EBSD). However, EBSD investigations on a beam cross-section after EDM showed that less than 1 µm beneath that modified layer the EBSD pattern indicates no orientation changes, with respect to the initial material. Thus, we conclude that the beams remain single crystalline after the EDM process.

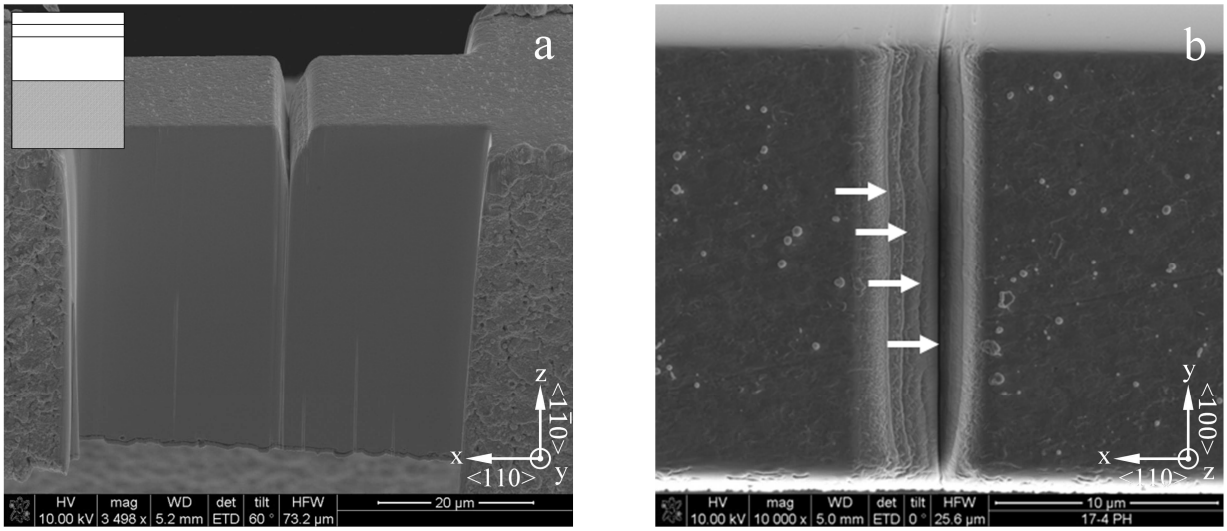

Figure 2. SEM micrographs showing the introduced notch which is cut with the ion beam perpendicular to the surface. The SEM micrograph 2a shows the cleaned gage section and the notch from the side. The insert shows a schematic cross-section of the notch. The SEM micrograph 2b shows a top-view. The arrows show the individual millings steps for 5, 3, 1 µm and the line milling mode.

To minimize the influence of µ-EDM processing, FIB was used to polish the gage sections of the cantilevers. Successive cutting from the surface towards the middle of the beam by FIB was conducted to remove the damage layer, to machine the necessary dimensions, and to smoothen the surface of the beam. For all milling steps an acceleration voltage of 30 kV was used. To remove the main part of the material relatively high gallium ion currents of 5 to 20 nA were applied. In order to reduce the influence of the gallium ions in the material the last cleaning steps were carried out by lower gallium ion currents of 1 to 3 nA. Finally, a notch was cut from the top surface with a depth of approximately 8 µm. For the notches a current of 1 nA was used. In order to gain a deep and sharp notch the machining process was carried out in several milling steps. The steps were

successively narrowed from 5 to 3 and 1 µm and as a last milling step, the final notch was introduced using the line milling mode. The ion beam was always perpendicular to the surface. Figure 2 shows the notch shape.

The successive milling process of the gage section showed that the µ-EDM induced micro-cracks. However, they never reached deeper than 3 µm. Therefore, the milling process was adjusted such that roughly 4 µm of the material was removed to exclude the influence of micro-cracking on the fracture behavior. Figure 3 shows a typical surface of a micro-cantilever which was treated by µ-EDM, micro-cracks can be observed.

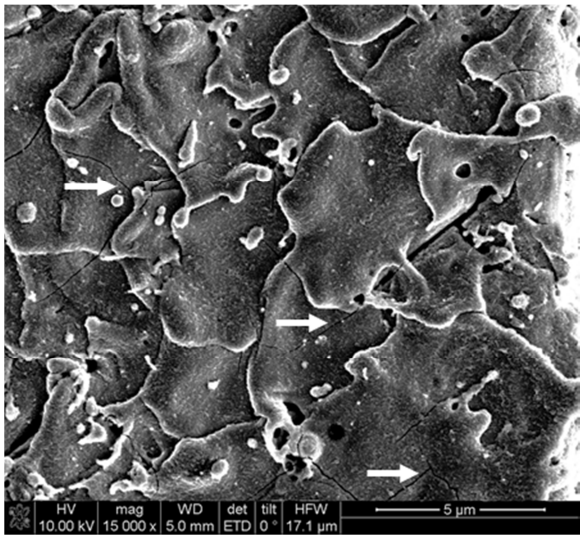

Figure 3. The rough surface of the micro cantilever as a result of the µ-EDM process. Micro cracks in the surface can be observed. The white arrows highlight some of the micro cracks.

For the bending experiments two commercially available nanoindentation systems were used (MTS, Nano Indenter XP and Agilent Technologies, G200). The indenter tip was used to bend the cantilever at a defined distance to the notch. Then, a holding segment of 10 seconds was applied before unloading. For all experiments a Berkovich tip was used. Afterwards the broken cantilevers were investigated by scanning electron microscopy (SEM).

3. Results and Discussion

The force-displacement curves shown in Figure 4 belong to two beams that are oriented to induce fracture in the $\{110\}\langle 1\bar{1}0\rangle$ crack system. The cantilevers were displaced to 12 µm (blue curve) and 15 µm (green curve) at a distance of about 120 µm from the notch. As the maximum displacement is reached, the holding segment follows and the maximum load is held constant. The curve shows clearly an elastic-plastic transition but no abrupt load drop which would be indicative of brittle fracture. Interestingly, a large deflection takes place during the hold segment. Presumably this is caused by an increasing crack length over time which in turn is correlated to an increasing ΔK under constant load. Since this is a rather peculiar behavior, it will be investigated further by

changing the loading sequence of the test.

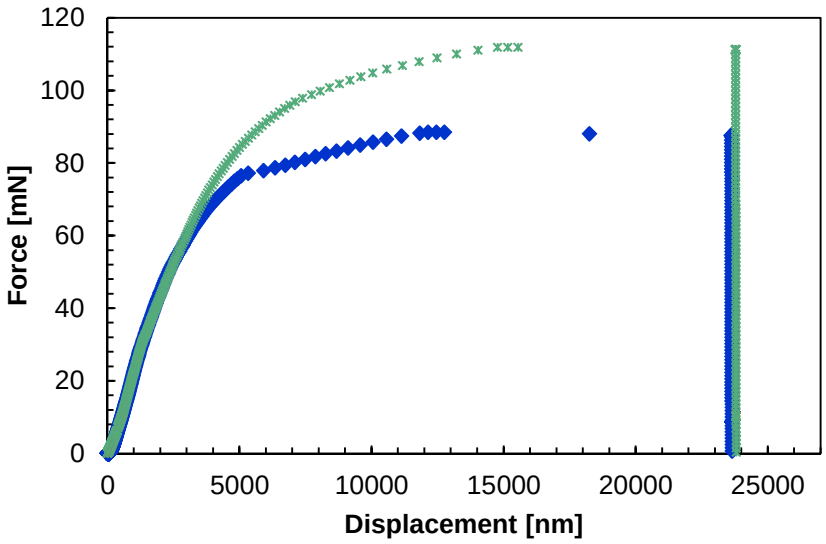

Figure 4. Two force-displacement curves of two notched beams. One beam was loaded to a displacement of 12 µm (blue curve) the other one to 15 µm (green curve) (Figure 5a). With respect to the {110}<1$\bar{1}$0> crack system, the beam axis was normal to the {110} crystal plane for both notched beams.

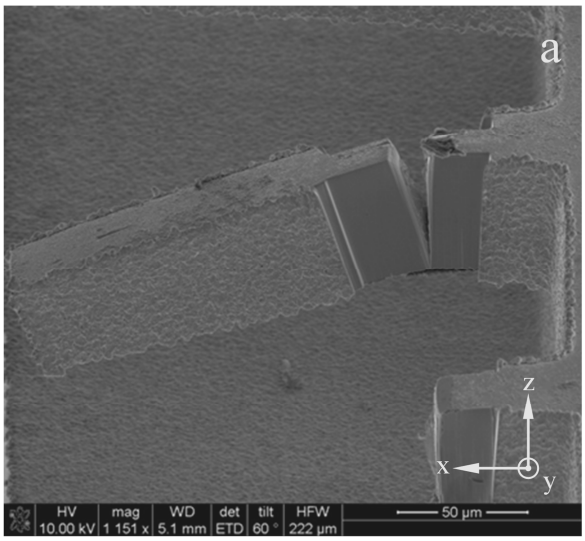
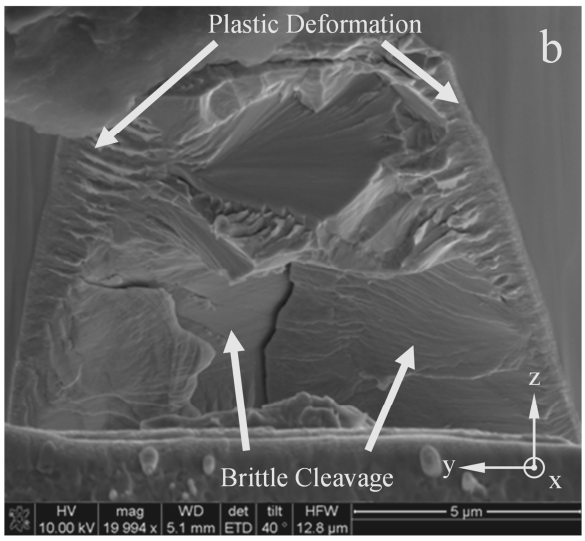
The curves show a rather ductile behavior, however, an investigation of the fractured surface indicates partially brittle failure. Figure 5a shows the fractured beams and Figure 5b and c the surface of the broken cantilevers. It clearly shows brittle cleavage in the middle of the beam, while at the upper edges signs of plastic deformation are seen.





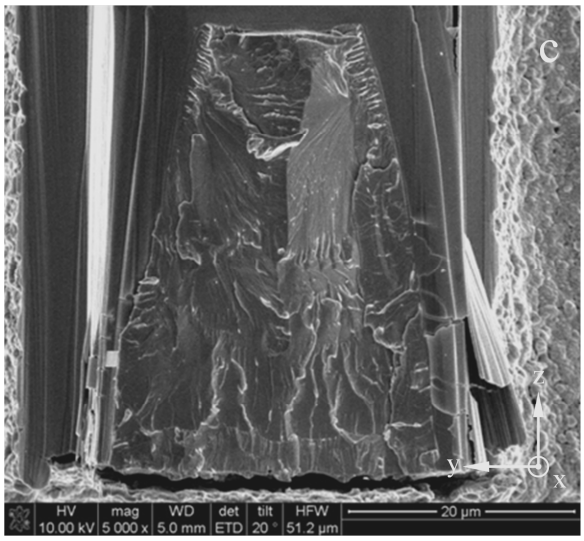


Figure 5. a) Post-test overview of beam 1 and 2. b) Cleavage surface of beam 1 which was deflected 12 µm under displacement control and fractured further under constant load. The beam did not fail completely. c) Cleavage surface of beam 2 which was displaced 15 µm. It fractured completely during the holding segment

The fracture toughness cannot be calculated following the ASTM E 399-90 as it does not apply at this small scale. Also, it is not trivial to determine the weight function for this geometry. Therefore, we take a simplistic approach to estimate the fracture toughness by looking at an energy relation. Equation (1) relates the fracture toughness K_Q and the energy release rate G_Q were E is Young's modulus [8].

$$K_Q^2 = G_Q \cdot \mathrm{E}, \tag{1}$$

Thereby G_Q can be calculated after [9]:

$$G_Q = \frac{d(W - U_{el})}{dA}, \tag{2}$$

Here, W is the work of the external forces, U_{el} the elastically stored energy and dA the change of the area of the crack which is taken here to be the entire fracture plane. As the elastically stored energy U_{el} is subtracted from the external forces W, the shape modification energy only remains. To gain the work of the external forces, the load-displacement curve was integrated. For the elastically stored energy, the area enclosed by Hook's' straight line and the curve at the maximum displacement was calculated. For the calculation of the size of the fracture plane the program ImageJ was used. Therefore, the fracture surface, depicted in an SEM Image, was enclosed by a polygon. The resulting surface area was calculated by the program in dependence of the SEM magnification. With this calculation, values of the fracture toughness K_Q = 31 MPa·m$^{1/2}$ and 35 MPa·m$^{1/2}$ were obtained when including the displacement during the hold segment. These values are quite high and can be only considered as an upper bound. For a lower bound, a second value was calculated neglecting the holding segment. Thereby, values for the fracture toughness K_Q of 6.7 MPa·m$^{1/2}$ and 5.9 MPa·m$^{1/2}$

were obtained. These values are pretty low compared to data of Gumbsch and Riedel [1,3] of 12.9 ± 2.1 MPa·m$^{1/2}$ for the fracture toughness of the {110}<1$\bar{1}$0> crack system. However, the experiments are not completely comparable as different sample dimensions and loading conditions were used. As shown in Figure 5, for our small samples, it is seen that the plastic zone size is large relative to the sample dimensions. Therefore, we would rather expect a larger value than the one reported by Riedel and Gumbsch. This also confirms the need to improve the test method. Errors in the fracture surface analysis cannot account for the large difference.

Improvements in the manufacturing process, testing conditions and also analysis are currently in progress. For instance, the surface of the basic material can be treated by µ-EDM. This would lead to sharper edges. Therefore, cantilevers with decreasing cross sections along the axis will be avoided, compared to the polishing with the Struers TriPod and diamond lapping foils. Also, a wedge tip will be used instead of the Berkovich tip in order to avoid slipping and other effects related to the point loading.

Most importantly, another notch geometry will be tested. As it is not possible to introduce a sharp crack via fatigue at this specimen dimension, a Chevron notch geometry will be tested in the future. This should lead to a more controlled crack propagation as the resistance against crack propagation will increase with increasing crack propagation. An example of the FIB machined Chevron notch geometry is shown in Figure 6. For fabrication, the specimen was tilted so that the ion beam cut the specimen at an angle of about 30°. The middle of the width of the specimen, where the notch should be placed, was marked by FIB. From this mark, the notch was cut under the given angle, then the specimen was rotated by 180° and the second part of the notch was milled.

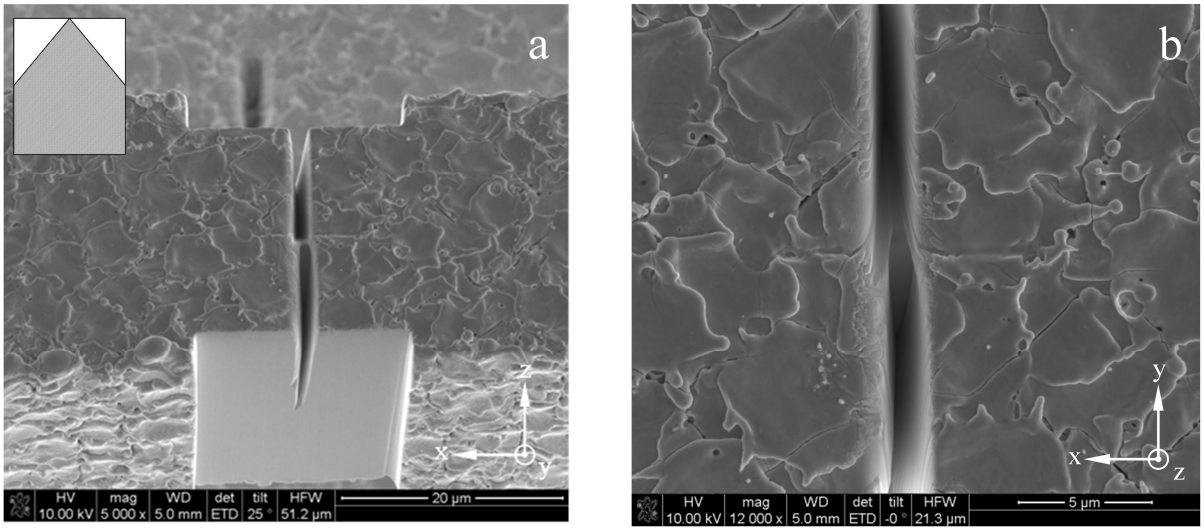

Figure 6. The introduced Chevron notch. The SEM micrograph 6a shows the cleaned gage section and the notch from the side. The insert shows a schematic cross-section of the Chevron notch. The SEM micrograph 6b shows the top-view.

4. Summary

The fracture toughness of single crystalline tungsten for the {110}<1$\bar{1}$0> crack system at the micro scale has been investigated. Free-standing single crystal micro cantilevers were manufactured by µ-EDM followed by surface cleaning and cutting a notch by FIB. The micro cantilevers were tested with a nanoindenter. The cantilever axes were aligned with the normal direction of the {110} crystal plane, while the loading direction was parallel to the <1$\bar{1}$0> direction. The force-displacement curves show a rather elastic-plastic behavior, whereas the observation of the fracture surface reveals ductile features at the edges of the crack surface and brittle ones in the middle. The K_Q values were estimated via an energy relation. The estimated values were in a range between 5.9 and 35 MPa·m$^{1/2}$ as the lower and upper limits. Further improvements of the test method will be made in the future including optimizing the beam shape, testing method as well as the notch shape. Furthermore, the investigations will be extended towards other crack systems as well as bi-crystals and in situ experiments in the SEM.

Abstract A numerical model to quantitatively predict a cleavage fracture toughness in ferrite-cementite steel is proposed based on a microscopic fracture initiation process of three stages; (I) formation of fracture origin by cementite cracking, (II) propagation of the cementite crack into ferrite matrix, and (III) propagation across ferrite grain boundary. The fracture condition of Stage (I) is formulated as a ratio of cementite cracking based on experimental results of a tensile testing with notched specimens and SEM observation. Stage (II) and Stage (III) conditions are formulated based on a concept of fracture stress criterion. In the numerical model, an active zone is divided into finite volume elements. Ferrite grains and cementite particles are assigned based on their distributions into each volume element. Strain and stress at each volume element are calculated by a macroscopic FEA. Fracture is assumed to initiate at the time when the fracture conditions of the all stages are satisfied in any one of the volume elements. The model is validated by three point bend testing with notched specimens. The predicted values of fracture toughness show good agreement with the experimental results. Therefore, the effectiveness of the proposed model is found out.

1. Introduction

In order to prevent brittle fracture in steel structures, it is critically important to predict fracture toughness by clarification of crack initiation mechanism.

It is widely known that fracture appearance transition temperature of Charpy impact testing changes linearly with reciprocal of the square root of grain size [1]. The reason is, however, not clarified completely. It is also known that the fracture toughness depends on the size of brittle phase such as cementite [2]. In addition, several formulations to evaluate the influence of microstructures including the size of ferrite grain and brittle phase are proposed by Almond *et al*. [3], Petch [4] and Bingley [5]. However, there remains a problem to improve their accuracy.

The cleavage fracture of steel is generally interpreted by the weakest-link mechanism differently from the yielding and the work hardening. Scatter in the fracture toughness is therefore essential. This is a principal reason of the difficulty to quantify the influence of microstructures on fracture toughness. A formulation to evaluate the variation of fracture toughness was proposed by Beremin [6] based on the weakest-link theory. It was, however, based on the concept of the macroscopic continuum mechanics and thus was not able to clarify the relationship between the variation of the fracture toughness and microstructures.

In the present paper, a numerical model is proposed to quantitatively predict the influence of microstructures on the fracture toughness of ferrite-cementite steels, based on the formulation of the cleavage fracture initiation process.

2. Formulation of Cleavage Fracture Initiation Process

2.1. Process of fracture initiation

We assume that the process of cleavage fracture initiation in ferrite-cementite steels is composed of three stages; (I) formation of fracture origin by cementite cracking, (II) propagation of the crack in cementite into the ferrite matrix and formation of a cleavage crack, and (III) propagation of the cleavage crack across ferrite grain boundary. Schematic view of this process is shown in Fig. 1. It is assumed that a macroscopic brittle fracture occurs if fracture conditions of all the above stages are satisfied. In the following section, the fracture conditions of respective stages are formulated.

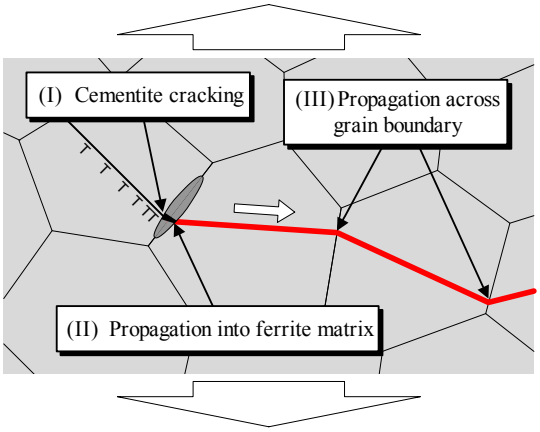

Fig. 1 Three stages of cleavage fracture initiation process

2.2. Formulations of fracture conditions

Stage (I). Formation of fracture origin by cementite cracking

We quantify the influencing factors on the cementite cracking based on experimental facts.

Test steels with various sizes of ferrite grains and cementite particles were produced and tensile testing with a circumferential notched round bar specimen was performed. The test steels were produced by laboratory scale vacuum melting and rolling. Two types of chemical compositions are employed, as shown in Table 1. It can be regarded that their compositions are practically the same except for carbon concentration. Seven types of steels were produced whose sizes of ferrite grains and cementite particles were systematically changed by combinations of controlled rolling, controlled cooling, normalizing and annealing processes. Definitions of symbols relating to the sizes of ferrite grains and cementite particles are shown in Table 2. Grain sizes of the steels were measured as area equivalent diameter by EBSD observation [7]. In addition, cementite particle thickness was measured as minor axis of approximated ellipse by FE-SEM observation of the microstructure etched by nital and an image analysis [8]. Representative values of ferrite grain size

and cementite particle thickness, together with yield stress at room temperature are shown in Table 3.

Quasi-static tensile test using circumferential notched round bar specimens was conducted. The specimen configuration is shown in Fig. 2. After tensile strain was applied, the specimen was unloaded and cementite cracking was observed. Extensometer gauge displacement at unloading was determined so that the maximum principal plastic strain at the minimum cross section is equal to 0.4. The displacement was estimated by a preliminary elasto–plastic FEA. An example of the numerical results is described as Fig. 3. The results show that the maximum principal plastic strain and stress change in the axial direction but are almost constant on each transverse cross section.

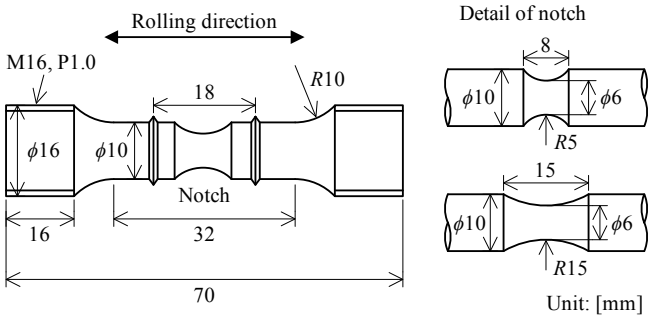

Fig. 2 Configuration of circumferential notched round bar specimen

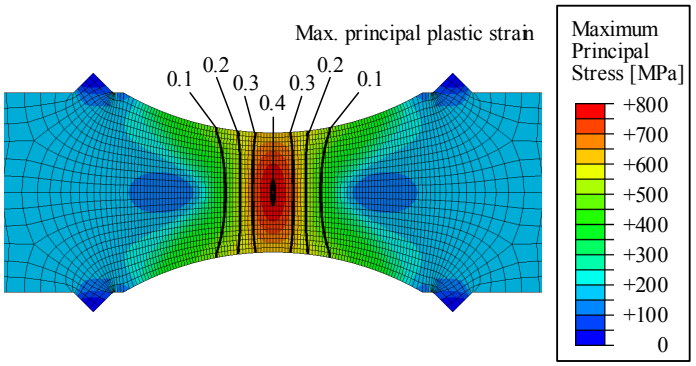

Fig. 3 Strain and stress distributions in circumferential notched round specimen (10MM, $R = 15$ mm, -80°C)

The unloaded specimen was cut in the axis direction. The maximum principal plastic strain and stress are assumed constant along the transverse direction on the cut surface. The cracked cementite was measured by scanning the surface in the transverse direction by SEM observation after polishing and etching. The applied strain can be varied by changing the scanning location in the axial direction.

The numbers of the cracked cementite particles were measured for the steels and conditions of temperature and strain. An example of the SEM images of the cracked cementite is shown in Fig. 4. Results of dependence of the number of the cracked cementite on the maximum principal plastic strain and the temperature for 10LM steel are shown in Fig. 5. The number of the cracked cementite is almost in proportion to the principal plastic strain. The results also show that the lower temperature makes the larger number of the cementite cracking.

The cementite cracking might be regarded as stress-controlled fracture. However, the stress applied to a cementite particle is controlled by the applied strain of the ferrite matrix. It can be understood that the larger deformation resistance of ferrite matrix makes the larger applied stress in the cementite particle. Furthermore, total number of the cementite particles must be proportional to carbon content if cementite size distribution remains unchanged.

Now, it may be rationalized that the number of cracked cementite particles is normalized by a parameter η, which is defined as a product of the applied maximum principal stress $\sigma_{\max}$ (normalized by Young's modulus E) and mass fraction of carbon r_C as

$$\eta = \frac{\sigma_{\max}}{E} r_C \tag{1}$$

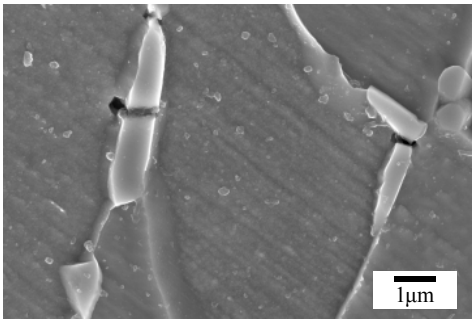

Fig. 4 SEM image of cracked cementite (10LM, $\varepsilon_p = 0.2$)

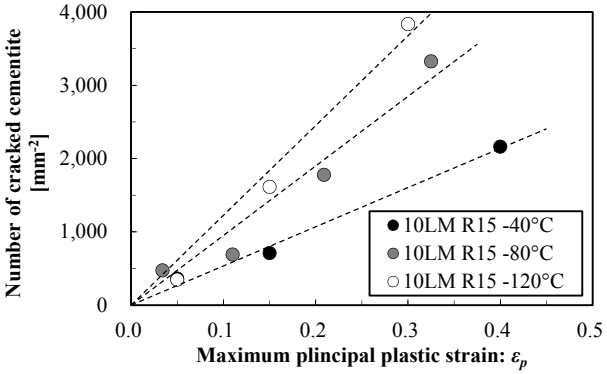

Fig. 5 Dependence of the number of cementite cracking on plastic strain and temperature

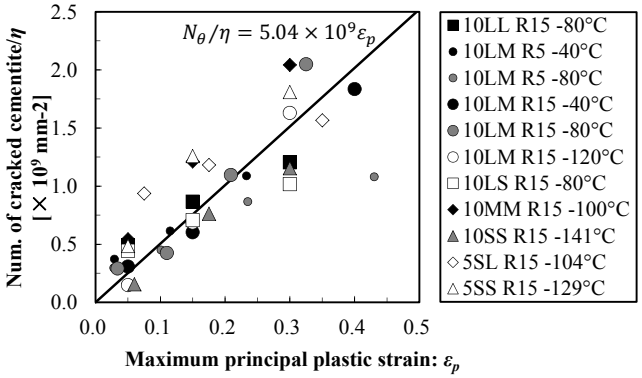

Fig. 6 Number of cracked cementite normalized by applied maximum principal stress and mass fraction of carbon

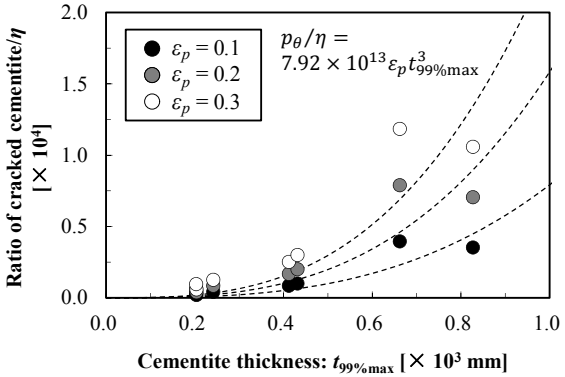

Fig. 7 Ratio of cementite cracking normalized by applied maximum principal stress and mass carbon content

Results of all the tests are shown in Fig. 6. Although a data scatter is found, the number of the cracked cementite particles mig ht be approximated as

$$\frac{N_\theta}{\eta} = 5.04 \times 10^9 \varepsilon_p \tag{2}$$

where N_θ is the number of the cracked cementite particles per unit area (1 mm^2) and ε_p is the maximum principal plastic strain. It is noted that N_θ/η is independent from the cementite particle thickness distribution.

A ratio of cementite cracking p_θ is defined as the number of the cracked cementite particles divided by the number of the all cementite particles per unit area. It is found that the ratio of the cementite cracking is higher in the steel with larger cementite size. Plots of p_θ/η related to $t_{99\%\max}$ (unit: mm) of each steel (see Table 3) are shown in Fig. 7. By fitting the relationship between p_θ/η and $t_{99\%\max}$, we obtain

$$\frac{p_\theta}{\eta} = 7.92 \times 10^{13} \varepsilon_p t_{99\%\max}^3 \tag{3}$$

as indicated by the lines in Fig. 7.

As a generalization of Eq. (3), the ratio of cementite cracking for arbitrary cementite particle thickness t (unit: mm) is expressed as

$$p_\theta = 7.92 \times 10^{13} \eta \varepsilon_p t^3 \quad (4)$$

Stage (II). Propagation of crack in cementite into ferrite matrix

Local fracture stress required for a propagation of a cementite crack into ferrite matrix was formulated by Petch [4]. We assume a fracture condition of Stage (II) as

$$\sigma_n \geq \sigma_{F\theta\alpha} \quad (5)$$

σ_n is a maximum normal stress on the {100}-plane of the ferrite grain because it is known that a cleavage fracture surface in a BCC polycrystal including ferrite-cementite steel are generally formed on a {100}-plane [9]. σ_n is calculated as

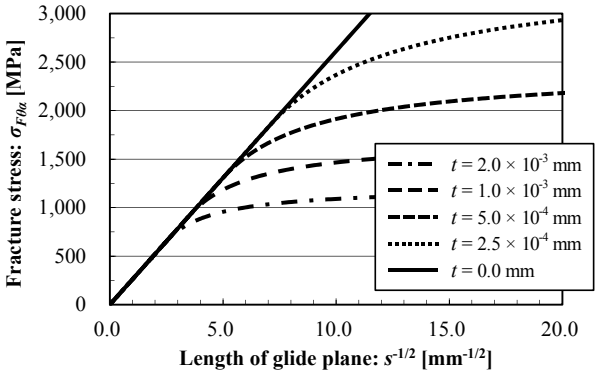

Fig. 8 Dependence of fracture stress $\sigma_{F\theta\alpha}$ on grain size d and cementite particle thickness t

$$\sigma_n = \max_{m=1,2,3} (\mathbf{n}_m)^T \cdot \boldsymbol{\sigma} \cdot \mathbf{n}_m \quad (6)$$

where $\mathbf{n}_m$ is a normal vector of the m-th {100}-plane and $\boldsymbol{\sigma}$ is a applied stress tensor.

$\sigma_{F\theta\alpha}$ in Eq (5) is the fracture stress of Stage (II) originally formulated by Petch [4] as

$$\sigma_{F\theta\alpha} = \begin{cases} \dfrac{4E\gamma_{\theta\alpha}}{\left(1+\dfrac{1}{\sqrt{2}}\right)(1-\nu^2)k_y\sqrt{s}} & (t_\theta < c_c) \\ \sqrt{\dfrac{4E\gamma_{\theta\alpha}}{\pi(1-\nu^2)t_\theta} - \dfrac{k_y^2 s}{8\pi^2 t_\theta^2}} - \dfrac{k_y\sqrt{s}}{2\sqrt{2}\pi t_\theta} & (t_\theta \geq c_c) \end{cases} \quad (7)$$

where ν is a Poisson's ratio. The definition of $\sigma_{F\theta\alpha}$ is slightly modified from the original one by replacing a ferrite grain diameter with a length of the dislocation line s. k_y is a locking parameter in the Hall-Petch law and is assumed to equal 20.7 MPa mm$^{1/2}$ based on our preliminary test. $\gamma_{\theta\alpha}$ is effective surface energy and is given as 10 J/m^2 [4]. c_c is critical cementite particle thickness defined as

$$c_c = \frac{\left(1+\dfrac{1}{\sqrt{2}}\right)(1-\nu^2)k_y^2 s}{8\pi E\gamma_{\theta\alpha}} \quad (8)$$

$\sigma_{F\theta\alpha}$ is derived from a comparison of the sum of energy release rate of the crack and piled-up dislocation energy with the effective surface energy. The dependence of $\sigma_{F\theta\alpha}$ on s and t is shown in Fig. 8.

Stage (III). Propagation of cleavage crack across ferrite grain boundary

We assume fracture condition of propagation of a cleavage crack across ferrite grain boundary as

$$\sigma_n \geq \sigma_{F\alpha\alpha} \quad (9)$$

where σ_n can be calculated by the equation same as that for Stage (II), i.e. Eq. (6). On the other

hand, $\sigma_{F\alpha\alpha}$ is local fracture stress for Stage (III) formulated based on the Griffith theory, as

$$\sigma_{F\alpha\alpha} = \sqrt{\frac{\pi E \gamma_{\alpha\alpha}}{(1-\nu^2)D}} \tag{9}$$

where D is a diameter of cleaved surface formed in Stage (II) and $\gamma_{\alpha\alpha}$ is an effective surface energy for a cleavage crack in a ferrite grain to propagate across grain boundary. It is assumed that $\gamma_{\alpha\alpha}$ depends on temperature because plastic deformation below cleavage fracture surface changes with temperature [10]. Temperature dependence of $\gamma_{\alpha\alpha}$ is thus assumed based on the experimental results by San Martin and Rodriguez-Ibabe [11], as shown in Fig. 9. Although the figure shows steep increase at temperature higher than -70°C, the present study employs the value of $\gamma_{\alpha\alpha}$ in the temperature range lower than -80°C.

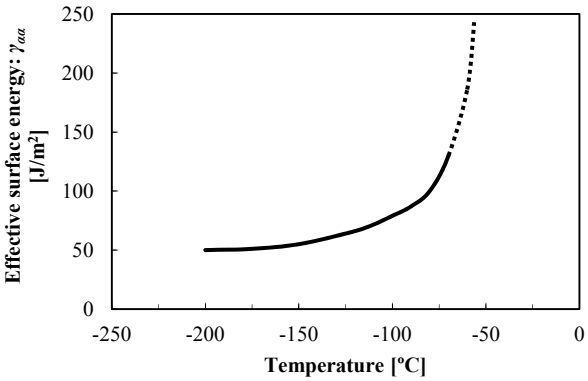

Fig. 9 Effective surface energy for across grain boundary [11]

3. Development of Numerical Model

Considering the fracture conditions of the three stages described in the previous section, a numerical model of the cleavage fracture initiation of ferrite-cementite steels is developed. Procedures of the modeling are described as follows.

(a) A domain where the cleavage fracture initiation is possible to occur is defined as an active zone.
(b) The active zone is divided by cubic volume elements of the same size. It is noted that the size of the volume elements must be larger than the maximum grain size. A schematic view of the volume element is shown in Fig. 10.
(c) Ferrite grains are assigned at random in each volume element based on ferrite grain size distribution until sum of the volume of the assigned grains reaches that of the elemental volume. At the same time, crystallographic orientation of each grain is determined at random.
(d) Cementite particles are assigned in each volume element based on cementite particle thickness (minor axis) distribution. The shape of the cementite is approximated as a prolate spheroid.
(e) Macroscopic elasto-plastic FEA is performed based on true stress-strain curve and stress tensor and a maximum principal plastic strain at each volume element are evaluated at each step time. In the calculation, step time increments are defined for the evaluation of the cleavage fracture initiation at the same time.
(f) The cleavage fracture initiation process based on the three stages is evaluated in each volume element for a time step as following (g) ~ (k).
(g) For Stage (I), cracked cementite particle distribution is evaluated based on Eq. (4) by using the distribution of cementite particle thickness in the volume element.
(h) For the stage (II), first, two ferrite grains (Grain A and Grain B) adjacent to the respective cracked cementite obtained in [g] are selected at random. Grain A and Grain B are used for the evaluation of σ_n in Eq. (6) and $\sigma_{F\theta\alpha}$ in Eq. (7), respectively. Assuming the location of the each cementite particle on the boundary of Grain B, the length of dislocation line s is determined. Then, the evaluation of fracture condition of Stage (II) is carried out based on Eq. (5) for all the combinations of the ferrite grains and the cracked cementite particles. If the fracture condition is satisfied, a cleavage crack is assumed to form in Grain A and the cleaved

grain is excluded in following time steps.

(i) In the case that Stage (II) is satisfied, Stage (III) is then evaluated. First, an additional grain (Grain C) is selected at random. Then, $\sigma_{F\alpha\alpha}$ and σ_n in Eq. (8) are respectively calculated by using Grain A and of Grain C, and the fracture condition of Stage (III) is evaluated.

(j) Cleavage fracture is assumed to be initiated at the time when the fracture condition of Stage (III) is satisfied in any one of the volume elements. That is a "weakest link" assumption in this model.

(k) If the fracture is not initiated, the calculations of (f) ~ (j) are carried out for the next time step.

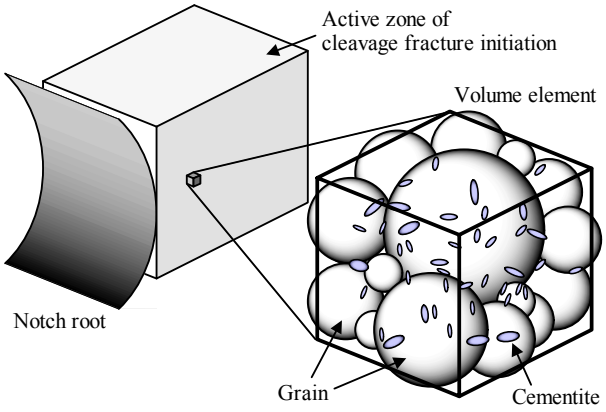

Fig. 10 Modeling of volume element

4. Simulation of Fracture Toughness Testing

4.1 Experiment

Three point bending test using notched specimens was conducted. The specimen was machined from the steels 10LL, 10LS, 5SL and 5SS, which were used in Section 2.2. Configuration of the specimen is shown in Fig. 11. Test temperature was changed between -150°C and -80°C. Loading rate was 1 mm/min. Notch opening displacement was measured by a clip gauge attached to the edge of the notch.

Quasi-CTOD is introduced as a parameter to evaluate the fracture toughness. The quasi-CTOD is calculated by simply applying the CTOD estimation formula [12], as

$$\delta = \frac{K^2(1-\nu^2)}{2\sigma_Y E} + \frac{r_p(W-a)V_p}{r_p(W-a)+a+z} \tag{9}$$

where K is a stress intensity factor, σ_Y is a yield stress at a test temperature, r_p is the rotation factor (= 0.4), W is the width of the specimen (= 20 mm), a is the notch depth (= 7 mm), z is the distance of the notch opening gauge location above the specimen surface (= 0 mm), V_p is plastic component of the notch opening displacement. It is noted that the quasi-CTOD does not represent physical crack tip opening displacement but just represents intensity of deformation at the notch root. Critical values of the quasi-CTOD are used for a validation of the developed model.

4.2 Model conditions

In the procedure (a), the active zone is defined as a rectangular parallelepiped whose side lengths are 1.6 mm, 1 mm and 20.0 mm in respective directions of the width, the axis and the thickness of the specimen, based on the preliminary observation of the fracture initiation points.

The size of each volume element in the procedure (b) is also defined as a rectangular parallelepiped. The side lengths are 0.2 mm, 0.167 mm and 0.2 mm in the respective directions. This is nearly equivalent to the size of a sphere whose diameter is 0.25 mm. The number of the volume elements is 6,000 in the active zone as a result.

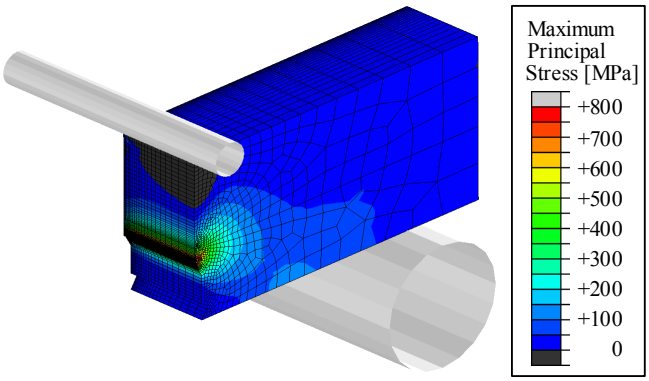

Fig. 14 Mesh division and stress distribution in FEA (10LL, -120°C)

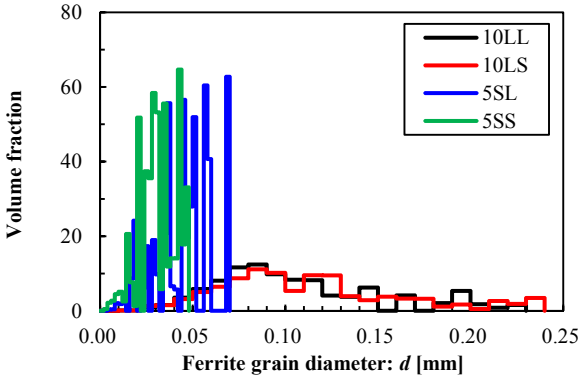
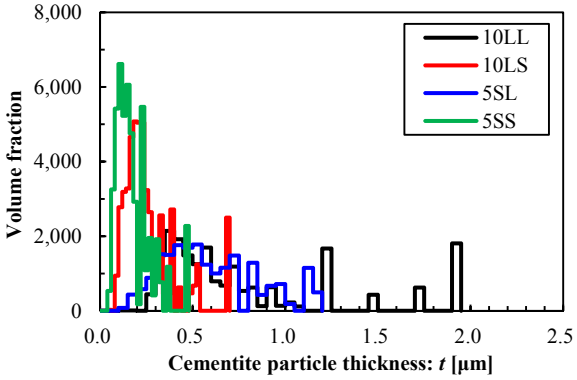


(a) Ferrite grain diameter



(b) Cementite particle thickness

Fig. 13 Distributions of ferrite grain diameter and cementite particle thickness

In the procedures (c) and (d), The ferrite grains and the cementite particles are assigned at random in each volume element based on their distributions shown in Fig. 13.

A quarter-symmetry finite element model is used to obtain stress and strain distributions in the active zone in the procedure (e). Displacement is applied by the jig. The mesh division and an example of the calculated stress distribution are shown in Fig. 14.

4.3 Results and discussions

Comparisons of the experimental results and the prediction values of the critical quasi-CTOD are shown in Fig. 15. The predicted values show good agreements with the experimental results in all the steels. The variation of the predicted critical values under the same conditions is derived from the stochastic nature of the developed model, i.e., the toughness scatter is derived from the statistical size distributions of ferrite grains and cementite particles. It is obviously found that the transition curve of the critical quasi-CTOD is shifted to lower temperature for finer ferrite grain steel. In addition, the same tendency is found for smaller cementite particle steel.

In the results of the respective steels, the predicted values reproduce the tendency that lower temperature makes lower values of the critical quasi-CTOD. The predicted values at high temperature are evaluated with high accuracy. On the other hand, the results at low temperature are underestimated in some cases. As causes of this result, an excessive cementite cracking in Stage (I) and accuracies of the effective surface energies $\gamma_{\theta\alpha}$ in Stage (II) and $\gamma_{\alpha\alpha}$ in Stage (III) might be

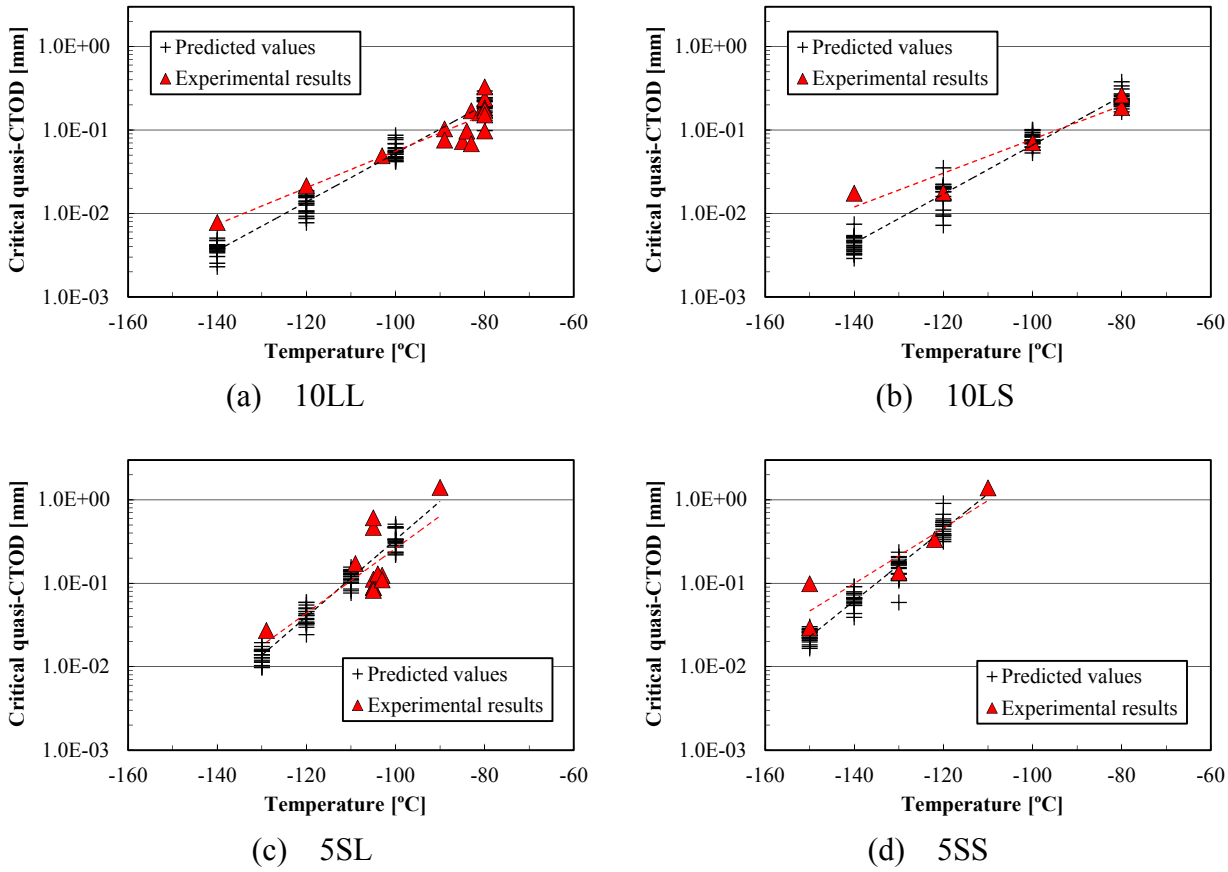


Fig. 15 Comparison between experimental and numerical results of critical quasi-CTOD

pointed out. In order to improve this problem, modification of the formulation of the ratio of the cementite cracking considering the shape of the cementite particles, and quantitative and accurate estimations of $\gamma_{\theta\alpha}$ and $\gamma_{\alpha\alpha}$ must be required. The maximum differences of the transition temperatures between the experimental results and the predicted values is however 15°C. Based on the aforementioned results, the validation and the effectiveness of the proposed model are found out.

5. Conclusions

A numerical model to quantitatively evaluate a cleavage fracture initiation in ferrite-cementite steel was developed. The model is based on the microscopic fracture process of the three stages; (I) formation of fracture origin by cementite cracking, (II) propagation of the cementite crack into ferrite matrix and formation of a cleavage crack, and (III) propagation of cleavage crack across ferrite grain boundary.

The fracture conditions of respective stages were formulated. The fracture condition of Stage (I) is formulated as a ratio of cementite cracking based on experimental results of a tensile testing with notched specimens and SEM observation using steels with various ferrite and cementite sizes. The fracture conditions of Stage (II) and Stage (III) were formulated based on the concept of the fracture stress.

In the development of numerical model, an active zone is defined and divided into volume elements. Ferrite grains and cementite particles are assigned based on their distributions into each volume

element. Strain and stress at each volume element are evaluated by macroscopic FEA. Cleavage fracture is assumed to initiate at the time when the fracture conditions of the all stages are satisfied in any one of the volume element.

The developed model was validated by three point bend testing of notched specimens using steels with various ferrite and cementite sizes. The numerical predicted values of fracture toughness show good agreement with the experimental results for all cases. It is therefore concluded that the proposed model is effective to predict the fracture toughness of ferrite-cementite steels.

Abstract This is a study of plastic strain localization, temperature evolution, surface roughening and of the origin of these phenomena in polycrystals. First, a review on different techniques of coupled kinematic-thermal measurements is given, and the two-face set-up, after several technical improvements, was employed in our work. Thanks to this integrated optical system, the full-field strain and temperature of the aluminium oligocrystal specimen were measured simultaneously during a tensile test. And the coupled data was further proceeded by following some particular methodologies, namely the Lagrangian thermography and the crystallography-based field projection. The surface profile of the deformed specimen was measured by interferometric profilometer, which showed clearly that the specimen had been suffered a strong out-of-plane deformation during the test. This out-of-plane effect was highlighted in the temperature field as well as in the strain field, which brought considerable affections on the measurement precisions of temperature and in-plane strain. Further data analysis shows that the heterogeneity of the out-of-plane deformation is closely associated with the crystallographic structure of the material, and reveals that the grain boundaries and grain interactions during the deformation play an important role in the process of deformation, temperature and surface profile evolutions.

1. Introduction

The polycrystalline metal is an aggregate of grains having a distribution of crystallographic orientations. During an applied mechanical loading, according to the different orientations and the influences from neighboring grains, some grains are submitted to a more important deformation than others, leading to local heterogeneous plasticity [1]. As known that when the metal is plastically deformed, a certain part of strain energy will be dissipated as heat, and the left will remain in the material. The latter, conventionally called stored energy, is associated with microstructure changes of material and was regarded as a sensitive indicator of damage evolution [2]. As a consequence, the study on "heat source" (or stored energy) needed to be linked with the material plasticity and microstructure evolution, and an experimental energy balance was expected to be built based on a full-field measurement of strain and temperature.

Nowadays the full-field optical measurement techniques, due to its advantages in non-contact, full-field and scalability, become more and more popular. Among these techniques, DIC (Digital Image Correlation) and IRT (InfraRed Thermography) have attracted increasingly attentions, which can provide the full-field measurements of strain and temperature, respectively. The heterogeneity feature of the plastic strain occurring on polycrystal was well characterized by DIC [3, 4], as well as the heterogeneous temperature field observed by IRT [5–7]. For promoting a better understanding of heat source, a coupled kinematic-thermal measurement becomes a necessary.

Recently, this anticipated coupled measurement has been realized, and it exists actually several different techniques, which can be classified according to their experimental set-ups: namely two-face measurement [8, 9], single-face measurement [10, 11] and one-shot measurement [12, 13]. In this paper we will also present our novel two-face measurement system, with its improvements in aspects of synchronization and spatial alignment.

Beyond these advances in aspects of technique, the research interest in this field appeared a noteworthy tendency: a transformation from macroscale to microscale [14, 15]. At the same time the role and importance of the microstructure were highlighted, which gave birth to a new methodology: microstructure-based full-field analysis [16, 17]. This method was applied on a polycrystalline material made of grown but still relatively small grains in the work [16]. Recently, some more simple and well-defined crystallographic structures, such as oligocrystal and bi-crystal, were tested [9, 11]. That certainly simplified the thermomechanical behavior of the material and thus facilitated a microstructure-based analysis.

In this work the studied material is a pure oligocrystal aluminium specimen with a single layer of coarse grains. It will undergo a plastic deformation in a tensile test, being measured in real time by the fully-coupled optical system, which thus provides the strain and temperature fields. The surface profile of the deformed specimen will be also measured after the test by interferometric profilometer. The various data will be treated in Lagrangian coordination system and be projected on a crystallographic base followed by the results analysis and discussions.

2. Coupled kinematic-thermal measurement

2.1. Review of techniques

To our knowledge, it exists actually four different experimental techniques that have been developed in the last few years for achieving the combined kinematic-thermal field measurements. Among them, each technique has its advantages and disadvantages, regarding on the studied material, measurement scale and expected precision. Nevertheless, it is important to note that IRT and DIC usually have contrast technique restraints, in particular on choosing the surface coatings for the specimen. IRT generally prefers a uniform coating with a very high emissivity, such as carbon black, thus an accurate infrared measurement can be conducted. On the contrast, DIC requires a very heterogeneous coating, such as speckled painting, for the purpose of tracking material points that should differ widely in gray levels. Several ways of achieving such a coupling are presented here.

1) Two-face measurement

Each imaging device (IR and visible camera) observes one face of the specimen [8, 9]. The main advantage of this set-up is that each technique has the flexibility to choose the surface coating for its own good without special constraints. This is very important concerning the measurement precision for each technique. The disadvantage of this set-up lies in the fact: for a thin, flat specimen being studied on a macroscale, it is assumed that the two faces of the specimen show virtually the same thermomechanical behaviors. But if thermal and kinematic fields are sought for comparison at the microstructural scale, this technique requires the microstructure to be the same on both faces.

2) Single-face measurement

Both IR and visible cameras observe the same face of the specimen. Two kinds of the experimental set-up can be found:

a) Introducing an angle between the IR and visible cameras [11]. Generally this kind of set-up needs a correction of the image distortions introduced by the inclination of the camera with respect to the normal direction to the specimen surface. This angle should be as small as possible, but still restricted by the physical volumes of the cameras.

b) Introducing a dichroic mirror [10]. The dichroic mirror, thanks to its filtering properties,

transmits the IR radiations towards the IR camera placed in the front of the specimen, and reflects the rest of the radiations towards the CCD camera located on the other side. This set-up can solve the image distortion problem, but the mirror may also introduce some experimental bias due to the transmission and reflection [16].

A common problem for the single-face measurement is the coating for the specimen surface, which is desired to be heterogeneous in the visible vision and be homogeneous in the IR vision. A special coating developed in the work [10] meets such a characteristic.

3) One-shot measurement

A single IR camera is used to measure both kinematic and thermal fields on the same surface of the specimen. In other words, the IR images will be treated not only for IRT but also for DIC. This technique, called "one-shot measurement", was recently developed in [12, 13]. The main advantage of this technique is that it needs neither synchronization nor spatial matching, thus any temporal/spatial bias between the kinematic and thermal fields can be avoided. However, the main problem with this method is that the DIC precision will be inevitably lowered as the IR camera cannot provide a comparable high-resolution sensor array as the visible camera. A decrease in performance should be also found in IRT because of a wide variation in emissivity on the surface coating, which serves for the point tracking of DIC.

After an overview on the available techniques, the two-face measurement was chosen in this study for two reasons: 1) a high requirement on the measurement precision; 2) the oligocrystal specimen used in this work exhibits a quasi-identical microstructure on the two faces.

2.2. Developments on "two-face" measurement

In order to perform a precise and reliable two-face measurement, the two cameras should be firstly synchronized, and then a spatial alignment should be achieved on the two kinds of images produced by the IR and visible cameras, respectively.

2.3.1. Synchronization

The digital camera for DIC technique adopted in this work is the Elphel network camera (Elphel 353), and the IR camera is the FLIR Titanium camera (SC7000). As there is no commercial trigger box available for synchronizing these two cameras, a micro-controller (Arduino Mega 2560) was thus employed for triggering them from external.

The working principle of the micro-controller is to trigger the two cameras, by sending two periodic pulse signals, so as to command them function at the same moment. It is important to note that each camera has a time delay (the time period from receive the signal to take the image), which should be considered in the controlling program in order to assure that they take images on exactly the same moment.

The time delay of FLIR camera was given by the manufacturer, which was as low as 2.8 μs. The time delay of Elphel camera, however, was unknown, and thus needed to be tested. To this end, a special free-fall test was designed in order to estimate this time delay. In this test, the two cameras observed the same zone on a background, a small object was dropped from the air to pass this common zone, and a position difference, due to the time delay, thus appeared in the two captured images. According to the distance and velocity, the time delay can be estimated.

The results showed that the measured time delay of Elphel camera was 2.65 ms with a slight

deviation. After considering each time delay of the two cameras in the trigger program, the coupled measurement system can be synchronized.

2.3.2. Reference target

In the experimental set-up of the two-face measurement, the two cameras are placed face-to-face, each measures one face of the specimen. To set the two cameras observing on the same zone of the specimen is difficult, not to mention adjusting them perfectly perpendicular to the specimen surfaces. As a result, a spatial matching on the obtained IR and visible images cannot be reached.

In order to solve this problem, a special target of reference was developed. This target was a perforated metal plate, with around 20 holes through the thickness and randomly distributed. Thus the target has two identical faces and the holes form a special pattern.

Before the test the two faces of the target will be observed by IR and visible cameras, respectively. Thus it offers two visions of the target: one in IR image and the other in visible image. Each of them will be correlated to the analytical model of the target, and further to be deformed by the estimated transformation functions so as to reach the spatial matching with the analytical model.

Figure 1. shows an example of the overlay of the targets from IR and visible images: (a) before spatial correction; (b) after spatial correction. It shows clearly that the unmatched holes in image (a) are superposed in image (b) after the spatial correction. The transformation functions applied in this example are an affine transformation plus a B-spline transformation.

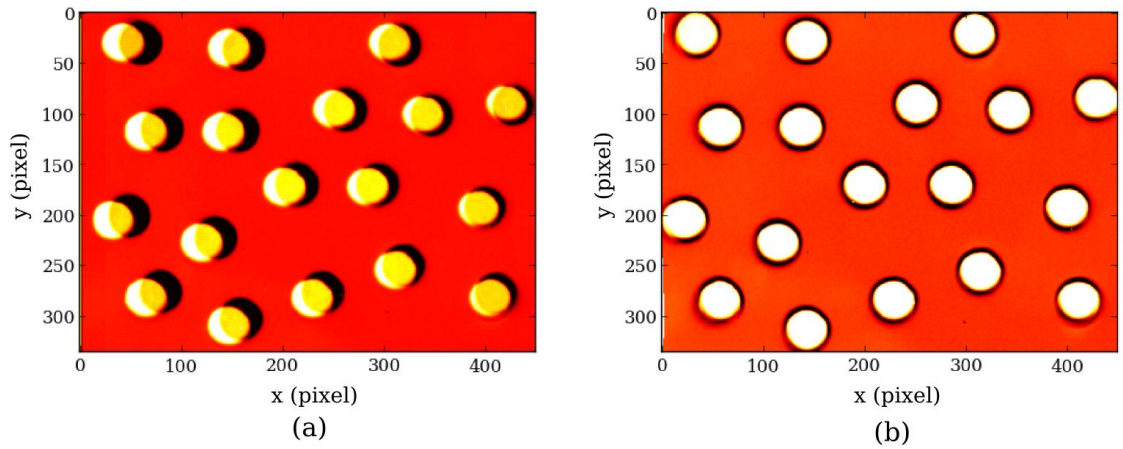

Figure 1. Overlay of the IR and visible images: (a) before spatial correction (b) after spatial correction

An affine transformation in Elastix is defined as:

$$T_\mu(x) = A(x-c)+t+c \tag{1}$$

where A is a matrix, c is the center of rotation and t the translation vector. The matrix A has no restrictions that means the image can be translated, rotated, scaled, and sheared.

B-splines are often used as a parameterization:

$$T_\mu(x) = x + \sum_{x_k \in N_x} p_k \beta^3\left(\frac{x-x_k}{\sigma}\right) \tag{2}$$

with x_k the control points, $\beta^3(x)$ the cubic multidimensional B-spline polynomial, p_k the B-spline

coefficient vectors, σ the B-spline control point spacing, and N_x the set of all control points within the compact support of the B-spline at x.

Since the two cameras are always fixed during the test and the target is placed at the same position as the specimen, so the correlation functions should be applicable for the specimen. Hence, the spatial alignment of the two faces of the specimen can be realized thanks to the reference target.

3. Experimental procedure

3.1. Specimen preparation

An oligocrystal specimen that contains only about ten grains in a single layer was prepared. The average size of the grains can attain 15 mm in diameter, and the thickness of the specimen is 1.5 mm. This type of oligocrystal specimen was prepared by the strain-annealing method [18, 19], from a very pure aluminium (purity 99.99%). The preparation of the oligocrystal specimens, following the strain-annealing method, required three steps.

1. Specimens cut from the original metal sheet were annealed at 545 ℃ for 1 h. This first annealing allows removing of the residual stresses resulting from the manufacturing process.

2. Annealed specimens were then stretched by around 3.5% longitudinal strain which corresponds to the ‘‘critical strain” value necessary to obtain, after a second annealing of re-crystallization, maximum grain size.

3. Stretched specimens were finally annealed at 545 ℃ for 1 h.

Concerning the two-face measurement, one important issue here is the identity of the crystallographic features of the two faces of the specimen. This point can be checked by overlapping the grain boundaries from the two faces. Figure 2. shows the grain textures of the two faces (face A for visible measurement and face B for IR measurement) and the overlay of the grain boundaries. The overlapping effect is, on the whole, satisfactory, in particular for the big grains in the middle.

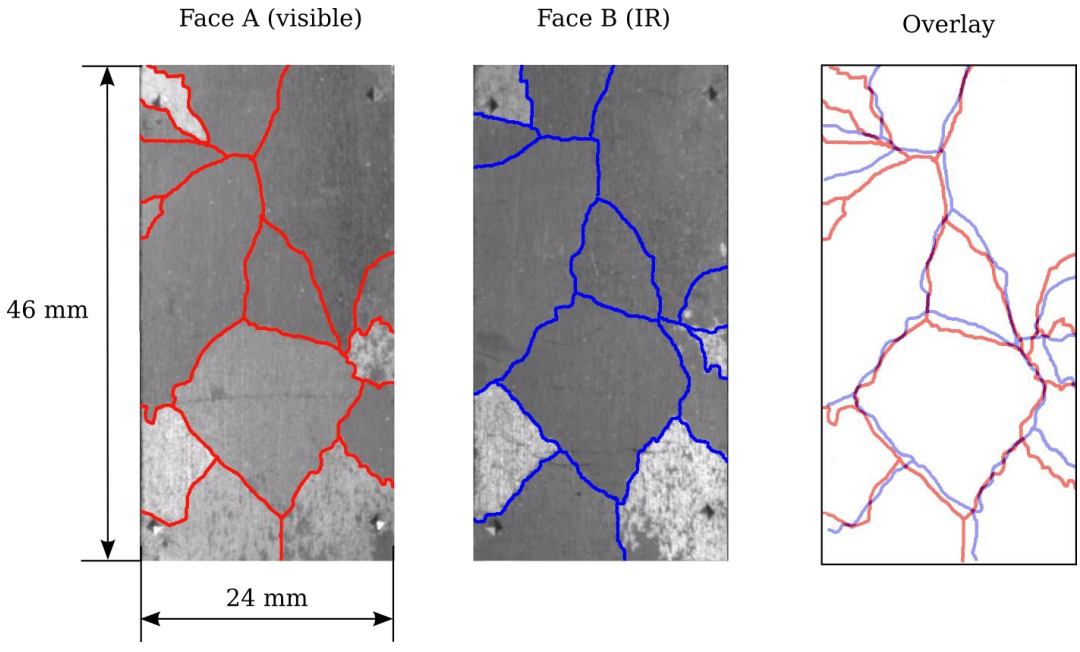

Figure 2. Grain textures of the two faces and the overlay of the grain boundaries

3.2. Test and measurements

Before the tensile test, an in-situ calibration was carried out in order to calibrate the IR camera, and the reference target was also measured in advance.

The tensile test was performed at room temperature and at a constant crosshead velocity of 1 mm/s. Strain and temperature were measured simultaneously by the two-face measurement system. The experimental set-up is shown in Figure 3. In the IR aspect, there was an enclosed box between the camera and the specimen for isolating the influences from environment; and for strain measurement a light made of LEDs was adopted to illuminate the specimen.

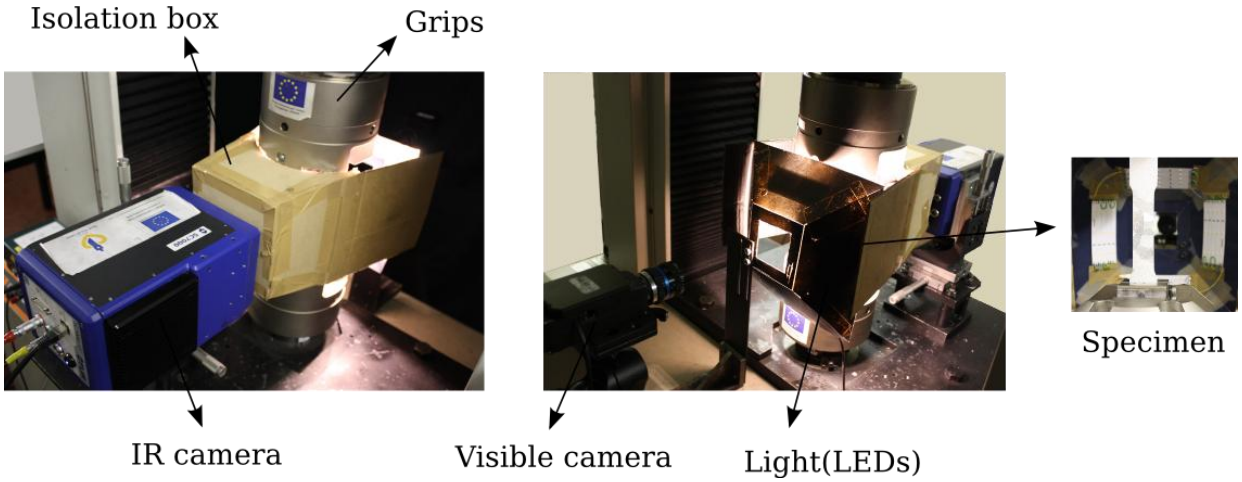

Figure 3. Experimental set-up of the two-face measurement system

The surfaces of the specimen were treated by depositing speckled painting for face A (strain measurement) and carbon black for face B (temperature measurement). Visible images were recorded by Elphel camera at 20 Hz with a resolution of 1712 × 1552 pixels. And IR images were recorded by FLIR Titanium camera at a frequency of 100 Hz with a resolution of 472 × 368 pixels.

It is important to note that there is an apparent difference in the sampling frequency for the two cameras, one is 5 times lower than the other. This is owing to our strategy on the parameter setting, as the sampling frequency was considered a priority for IR camera and the spatial resolution for visible camera. In this case, the two cameras were not synchronized in a strict sense, but the micro-controller guarantees that each visible image has a temporal corresponding IR image.

After the tensile test, the deformed specimen was measured by interferometric profilometer (Wyko NT1100) that provided the surface profiles of the two faces. Four marks on each face (see Figure 2) are the landmarks for the spatial alignment with the measured full-field strain and temperature.

3.3. Data treatment

First of all, the spatial alignment of IR and visible images was realized thanks to the reference target. Then, due to the fact that the visible camera has a lower sampling frequency, the visible images were interpolated linearly in order to produce the same number of images to the IR images. At this step, a data coupling, spatially and temporally, was done.

DIC technique was realized by Elastix [20], an open source software. B-spline transformation was applied as the correlation function with a final deformation grid 32 × 32 pixels following a

multi-resolution strategy. IR images were proceeded by converting original Digital Level (DL) to temperature through a so-called Quantitative Infrared Thermography (QIRT) procedure [16]. In this procedure, a N points Non-Uniformity Correction (NUC) was applied in order to eliminate the radiometric artifacts [21].

During the tensile test, as the two cameras were always fixed and the specimen had been displaced, thus the data recorded is in Euler coordination system. Since DIC provides the displacement information of the specimen and the kinematic-thermal data have been coupled, thus all IR images can be deformed so as to return to the initial coordination. This method is called Lagrangian thermography [10, 16]. The interest of performing Lagrangian Thermography is to follow the temperature evolution of each physical point of material, which is not evident when the material points are in the movement.

Another special data treatment was applied is so-called crystallography-based full-field projection proposed by Seghir [16]. In this method, the strain, temperature and profile data were projected on a crystallographic base: the data were fitted as polynomials in units of individual grains. Thus the hypothesis made here is the physical discontinuity of polycrystal because of grain boundaries.

5. Results and discussions

5.1. Out-of-plane deformation and its influences on measurement

The first noticeable phenomenon found in the results is that the specimen has suffered a strong out-of-plane deformation during the tensile test, as shown by Figure 4, the surface profiles of the deformed specimen. The two faces shows almost the same statistic results: the surface roughness average is about 70 µm, but the maximum height of the surface reaches around 700 µm regarding a thickness of 1.5 mm for the specimen. It is also interesting to notice that the two faces show a profile pattern similar and in opposite signs.

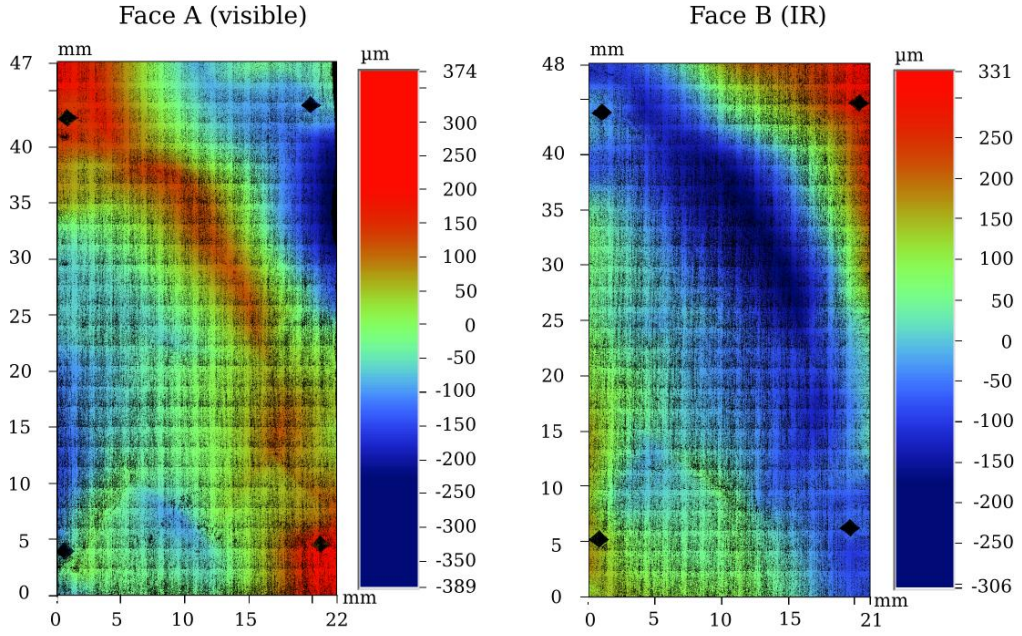

Figure 4. Surface profiles of the deformed specimen

This type of out-of-plane deformation has considerable influences on the in-situ full-filed measurements. For a 2D in-plane DIC system adopted in this work, the out-of-plane deformation brought inevitably errors on the image correlation. Figure 5(a). shows an error map (or residual

image) of DIC calculation for the last visible image (i.e., the final state of the deformed specimen). The special pattern observed in this residual image reflects the out-of-plane deformation, which changed the gray levels of the material points during the test in the light of the reflection effect.

Concerning IRT, the non-plane surface of the specimen will change the apparent emissivity of the surface coating due to the varied incidence angles with respect to the IR camera [22]. The apparent emissivity can be changed and re-distributed heterogeneously corresponding to the deformed shape of the specimen. Figure 5(b). shows the temperature field of the specimen in the final state, derived from the last IR image after proceeding Lagrangian thermography. Comparing to Figure 5(a), a similar pattern can be remarked, globally and in some zones particular. This is due to the fact that the two faces of the specimen showed a very similar profile feature and the optical reflection effect influenced the two optical measurements, DIC and IRT, almost in the same way.

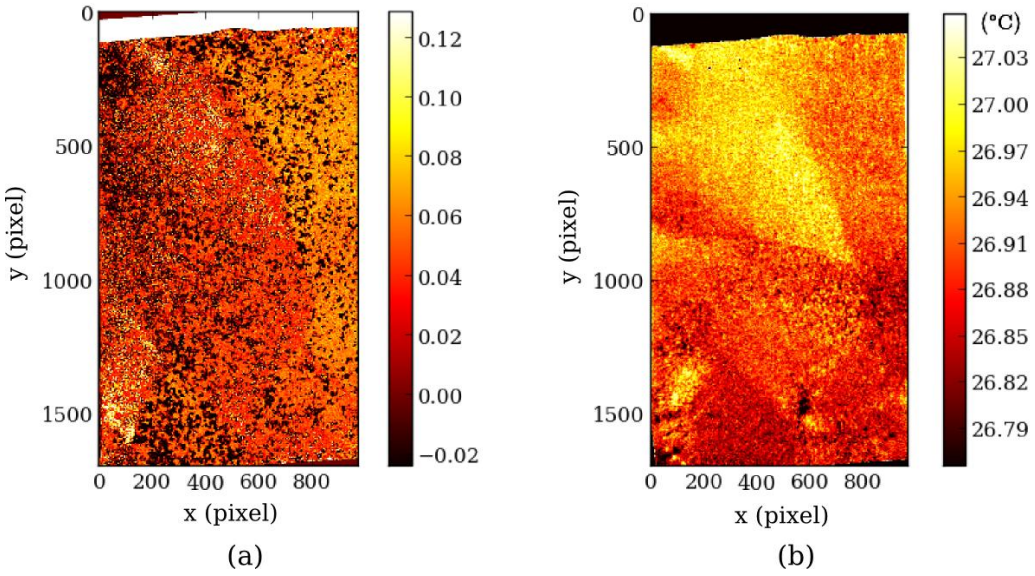

Figure 5. Reflection effects caused by out-of-plane deformation demonstrated by:
(a) Residual image of DIC (b) Temperature field

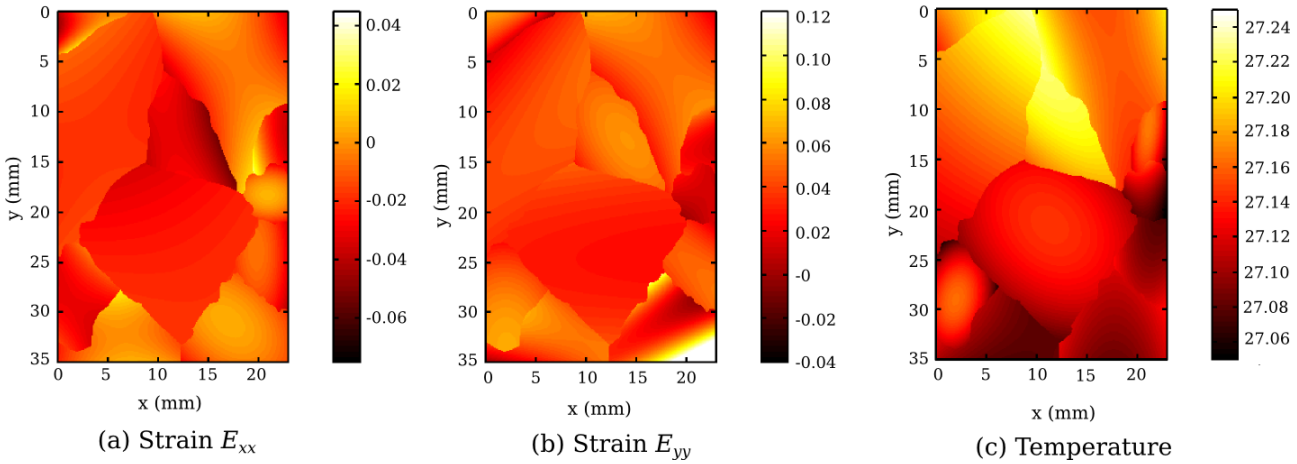
Nevertheless, it is worthy to mention that this type of artifact due to reflection is not so important regarding the absolute errors it may introduce, but its influences can be much magnified when a relatively homogeneous strain or temperature field is involved. This is what happened in this test, especially for the temperature field, as aluminium has a very high thermal conductivity.

5.2. Out-of-plane deformation and microstructure

For oligocrystal specimen, because of the difference in crystallographic orientations, the grains were subjected to the stresses of different levels during the uniaxial tensile test. This stress heterogeneity led to a heterogeneous deformation process. In this process, grain boundaries, as the interfaces of different grains, played an important role.

Comparing the surface profiles in Figure 4. with the initial grain texture in Figure 2, it is not difficult to find out that the most marked relieves, where the profile changes most abruptly, coincide with the grain boundaries. This point can be better investigated in the projection of full-filed measurements on a crystallographic base.

Figure 6. shows the projection results of the strains (E_{xx}, E_{yy}) and temperature at the final state of the specimen during the deformation. The interpolation, through second-degree polynomial fitting, was applied for each grain according to the grain texture provided by Figure 2.



(a) Strain E_{xx} (b) Strain E_{yy} (c) Temperature

Figure 6. The crystallography-based projection from the full-field measurements of: (a) Strain E_{xx} (b) Strain E_{yy} (c) Temperature

Both strain and temperature fields in Figure 6. demonstrate a heterogeneity, where the discontinuity of the grain boundaries is remarkable. This heterogeneity is mainly due to the out-of-plane deformation that is closely linked with the microstructure of the material. Nevertheless, a further analysis cannot be conducted unless the optical reflection effects can be quantified. This is one of the perspective studies in the near future.

Another work undergoing is the study on the thermomechanical behavior of nickel single crystal by using the two-face measurement system. One of the greatest interests on studying single crystal is to establish a quantitative relationship between the stored energy, stress-strain state and microstructural changes of the slip systems that are activated.

5. Conclusions

1. An overview of technique possibilities of coupled kinematic-thermal measurement was given, and several advances in technique have been achieved in this work for building an advanced two-face measurement system.

2. An aluminium oligocrystal specimen was measured during a monotonic deformation by the coupled optical system, which showed an important out-of-plane deformation. This kind of out-of-plane deformation has considerable affections on the optical measurements.

3. Further investigation shows that the heterogeneity of the out-of-plane deformation is closely associated with the microstructure of material, and reveals that the grain boundaries and grain interactions during the deformation play an important role in the process of deformation, temperature and surface profile evolutions.

Abstract: Strengthening steel structures containing semi-elliptical surface crack with fiber reinforced polymer (FRP) can delay crack propagation, and increase the service life of structures. In this paper, carbon fiber laminate (CFL), which has independent intellectual property, was adopted to strengthen X80 steel plate containing a 3D semi-elliptical surface crack, and based on this study object, the surface crack propagation rule in the specimens was studied by experimental method under cyclic bending loads. The results show that 3D semi-elliptical surface crack propagation rates in the crack length direction and crack depth direction can be described by corresponding Paris equation for the specimens strengthened with CFL, the constant coefficients in Paris equation can be obtained by fitting the data from fatigue crack propagation experiments, and stress intensity factor of the surface crack in steel plate strengthened with CFL can be obtained by numerical calculation with FEM.

Keywords：3D surface crack, fiber reinforced polymer (FRP), fatigue crack growth, beach-mark, stress intensity factor (SIF)

1. Introduction

Surface crack is a common defect in oil and gas pipelines, offshore oil platform, aviation mechanical and other steel structures [1,2]. Such kind of crack is easy to propagation and results in shortage of service life, especially can bring catastrophic results. So many researchers have done a lot of studies on surface crack [3,4]. In order to improve service life of structures which contain surface crack, some researchers propose to strengthen structures with fiber reinforced polymer (FRP), and have studied the strengthening method and strengthening effect [5,6]. Liu et al [7] discussed the fatigue lives and stress intensity factors of steel plate containing through crack strengthened with FRP, and their results indicate that fatigues lives of steel plates strengthened with FRP can increase 1.3 times than that of non-strengthened steel plates, and stress intensity factors can be reduced by 28%~60%. Tsai and Shen [8] studied the aluminum alloy plate containing through crack strengthened by FRP, and their results show that two face sides strengthening can delay crack propagation obviously, and fatigue lives can increase 2.6 times than non-strengthened plates. C.C.LAM's studies [9] show that stress intensity factors of through crack can be reduced by 54% in steel pipe after strengthening by FRP. However, the research for propagation rule of the semi-elliptic surface crack in steel structure strengthened with FRP has not yet been reported. For this reason, in this article, propagation behavior of the three dimensional semi-elliptic surface crack

in X80 steel plate strengthened with carbon fiber laminate (CFL) [10] was experimentally studied, and the stress intensity factor of the surface crack was computed by FEM method.

2. Fatigue crack propagation experiments

2.1 Specimens and pre-cracking

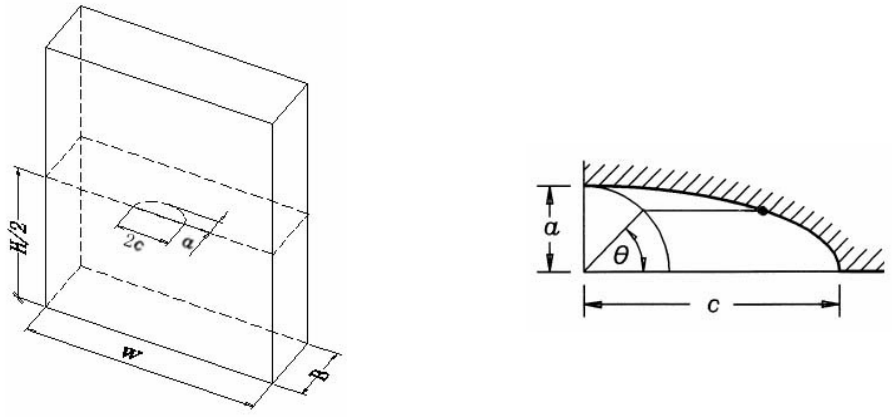
Specimens are made of X80 steel, which is a kind of high strength pipe steel. The size of steel plate was: length H=110mm, width W=70mm, thickness B=8mm. The mechanical properties were: yield strength $\sigma_{0.2}$=522MPa, Young' modulus E_s=200GPa and Poisson's ratio ν_s=0.3. In the surface centre of the specimen, an artificial semi-elliptical crack starter is machined by electrical discharge machining, show in figure 1(a), and fatigue pre-cracking is carried out on testing system by three-point bending method. The maximum load P_{max} of prefabricated fatigue crack can be calculated with the following equation [11] :

$$P_{max} = k\frac{2\sigma_{0.2}B^2W}{3S} \tag{1}$$

Where, S is the span of the specimen, and k is set to 1.0 for pre-cracking, and 0.5 for crack propagation. If the fatigue crack cannot be initiated by crack starter under current load after several ten thousand cycles, the current load should be increase by 10% of the maximum load. The stress ratio for pre-cracking is $R=P_{min}/P_{max}$=0.1. Crack size for pre-cracking is approximately following the empirical equation:

$$\frac{a_0}{B}+\frac{a_0}{c_0}=1\pm 0.1 \tag{2}$$

Where, a_0 and c_0 is initial depth and initial length of the surface crack. Based on Eq.(2), initial crack depth a_0 can be estimated by observation and controlling initial crack length approximately to $2c_0$.



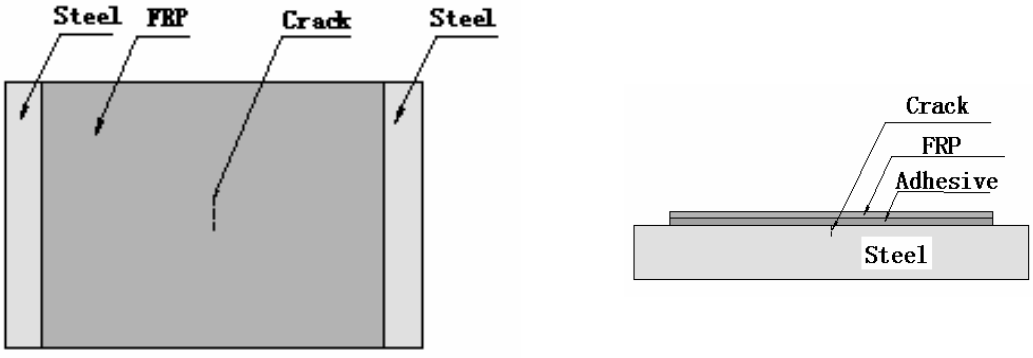
(a) Non-strengthened specimen (b) Parametric angle for the crack

Figure 1. Steel plate specimen with a semi-elliptical surface crack

After pre-cracking, CFL was bonded on the crack front side surface of the steel plate as shown in figure 2. The CFL has length H=90mm, width W=70mm, thickness t_f=0.2mm, Young' modulus E_f=230GPa and Poisson's ratio ν_f=0.25. After 5~7 days for adhesive to solidify, then the specimens

can be used in fatigue crack propagation experiments.

Six specimens were tested in the studies. Three non-strengthened specimens were symbolized by S1, S2 and S3, and three strengthened specimens were symbolized by SC1, SC2 and SC3.



(a) Plane view (b) Section view

Figure 2. Strengthened specimen

2.2 Experimental method

The test was carried out on electro-hydraulic servo dynamic and static testing machine which produced by Changchun Institute of Testing Machine. The testing data, such as load, time, strain, and corresponding fatigue loading cycles, are recorded automatically. Fatigue loads applied by force control mode with sinusoidal wave, and a frequency of 15 Hz and a stress ratio of 0.1. P_{max} and P_{min} denote the peak load and volley load respectively, corresponding to N cycles applied on the specimen. The non-strengthened specimens were applied to the maximum load, $P_{max,}$ as 8.0kN, and the strengthened specimens as 9.5kN.

For the measurement of crack depth and length, beach-mark method was used to obtain beach-mark boundary, as shown in figure 3. After a certain number of cycles of normal propagation, reduce the applied load to 2/3 of normal propagation load to slow down the propagation rate, then a clear striation will appear following the slow propagation. And repeating above procedures, more of striation, the beach-mark can be obtained. Based on this beach-mark, crack depth, a, and length, 2c, which is corresponding to a certain number of cycles, N, can be easily measured, and then a~N curves and c~N curves, and fatigue crack propagation rate, da/dN and dc/dN, can be easily obtained.

(a) Non-strengthened specimen S1

(b) Strengthened specimen SC1

Figure 3. Beach-mark on fracture surface of the specimens

3. Propagation rates of 3D surface crack

Three non-strengthened specimens（S1, S2, S3）and three strengthened specimens（SC1, SC2, SC3）were tested in fatigue crack propagation experiments by adopting experimental method in the above Chapter 2, and fatigue crack propagation curves (a～N curves) of each specimen were obtained.

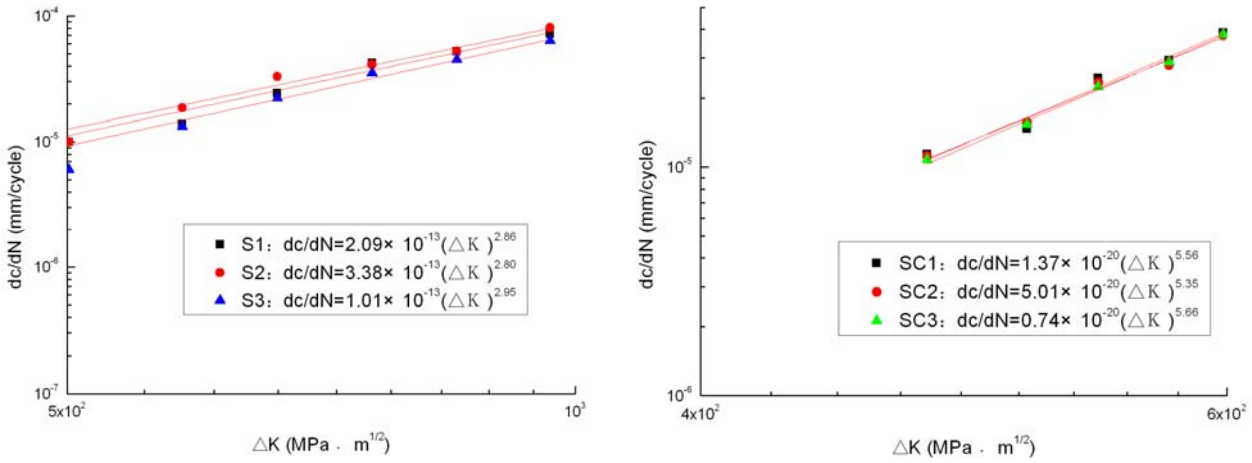
Based on the research results from the other metal materials, we assume that the propagation rates, da/dN and dc/dN (mm/cycles), of the surface crack in X80 steel plate strengthened with CFL and non-strengthened specimens all can be described by Paris formula [11] as,

$$\frac{dc}{dN} = C_L(\Delta K_c)^{m_L} \tag{3}$$

$$\frac{da}{dN} = C_D(\Delta K_a)^{m_D} \tag{4}$$

Where, C_L, C_D, and m_L, m_D were material constants, ΔK_c and ΔK_a (MPa·m$^{1/2}$) were the amplitude values of the stress intensity factors of the surface crack ($\Delta K=K_{max}-K_{min}$), whereas the stress intensity factor K can be calculated by Newman-Raju formula [2] for the non-strengthened specimens, but for the strengthened specimens, it has need to use the FEM [12].

Based on the test data obtained from the non-strengthened specimens S1, S2 and S3, and strengthened specimens SC1, SC2 and SC3, the relationship of ΔK_c and dc/dN, ΔK_a and da/dN were obtained and shown in figure 4 and figure 5.



(a) non-strengthened specimens (b) strengthened specimens

Fig.4 Relationship between ΔK_c and dc/dN

Fitting the data to Eq.(3), the average of C_L, and m_L were determined, and the fatigue crack propagation equations in crack length direction for non-strengthened and strengthened specimens were as follows:

$$\frac{dc}{dN} = 2.16\times10^{-13}(\Delta K_c)^{2.87}, \text{ for non-strengthened specimens} \tag{5}$$

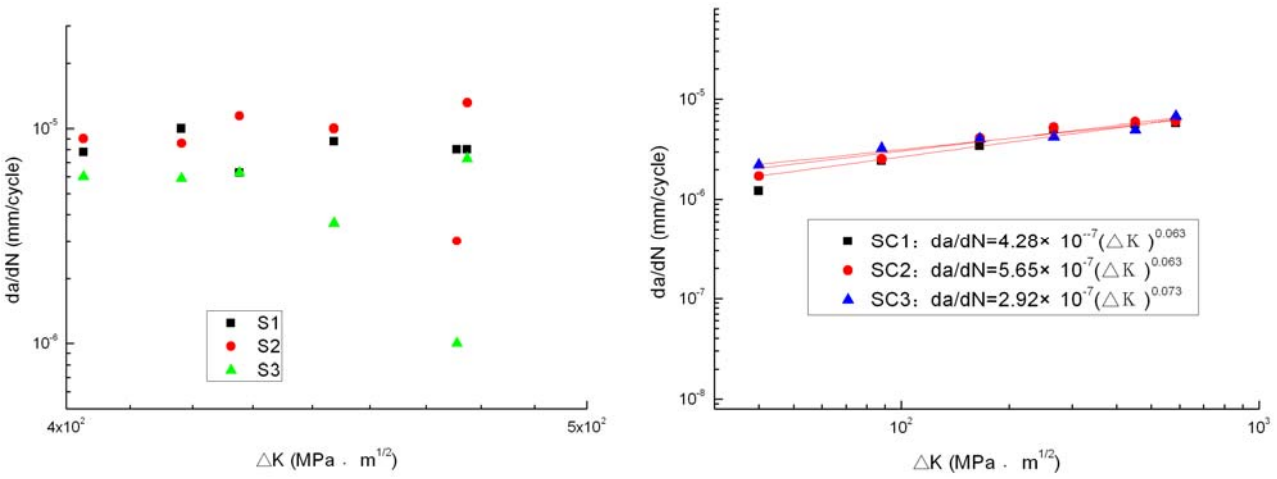
$$\frac{dc}{dN} = 2.37\times10^{-20}(\Delta K_c)^{5.52}, \quad \text{for strengthened specimens} \tag{6}$$

In surface crack length direction, the above two equations show that strengthened with CFL can change the crack propagation coefficient C and the index m in Paris law. The crack propagation coefficient C decreases, while the crack propagation index m increases.

In surface crack depth direction, there is no obvious regularity for the relationship of ΔK_a and da/dN for the non-strengthened specimens, shown in figure 5(a). This may be because the position of neutral axis in the non-strengthened specimens has been changing as crack propagation in depth direction, and this change has a great effect on propagation rate. But the relationship of ΔK_a and da/dN for the strengthened specimens agrees well with Paris law as shown in figure 5(b). This is because the position of neutral axis in the strengthened specimens became more stable than that of the non-strengthened specimens.

Fitting the data to Eq.(4), the average of C_D, and m_D were determined, and the fatigue crack propagation rate equation in crack depth direction for the strengthened specimens was as follows:

$$\frac{da}{dN} = 4.28\times10^{-7}(\Delta K_a)^{0.66} \tag{7}$$



(a) Non-strengthened specimens (b) Strengthened specimens

Figure 5. Relationship between ΔK_a and da/dN for strengthened specimens

4 Conclusions

A method of combination of experiment and numerical analysis was applied to study the 3D semi-elliptical surface crack propagation rule in non-strengthened and strengthened steel plate with carbon fiber laminate (CFL), and the main results are as follows:

1) Strengthening with CFL can reduce fatigue crack propagation rate, and increase fatigue life of the specimen.

2) 3D semi-elliptical surface crack propagation rate in crack length direction can be described by corresponding Paris equation. The constant coefficients in Paris equation can be obtained by fitting the data from fatigue crack propagation experiments, and stress intensity factor can be obtained by numerical calculation with FEM.

3) Beach-mark method was a better way to obtain data like the change of crack size in fatigue

surface crack propagation.

4) Crack propagation rule in crack depth direction in non-strengthened specimens do not accord with Paris law, while after strengthened with CFL, the crack propagation rule go back to accord with Paris law. The mechanism to be further discussed.

Abstract: Semi-elliptic surface crack is the common defect in metal structures. To ensure the structural integrity and security, the new material such as fiber reinforced polymer (FRP) was adopted for strengthening and repairing. In this paper, three dimensional semi-elliptic surface crack in X80 steel tension specimen strengthened with carbon fiber laminate (CFL) was studied, and numerical analysis was undertaken by Abaqus finite element software to study the stress intensity factor (SIF, K_I) of the surface crack for CFL reinforcement effect. The results shown that, strengthening by CFL reduced the stress intensity factors of semi-elliptical surface crack significantly; Crack shape ratio *a/c* and crack relative depth *a/B* had a great effect on stress intensity factors of strengthened specimen; An expression for calculating stress intensity factors of semi-elliptic surface crack under strengthening condition was obtained by adopting MATLAB software.

Keywords: surface crack, fiber reinforced polymer (FRP), stress intensity factor (SIF), numerical analysis

1. Introduction

With the development of society, the steel structure has been widely used in all kinds of engineering construction, such as oil and gas pipelines, bridges, marine oil platform and so on. In the process of long-term use, it will inevitably produce some defects in steel structure, such as surface crack, under the influence of environmental conditions and external load. Surface crack propagation will bring a lot of potential safety problems to engineering facilities. In recent years, scholars from home and abroad carried out a number of studies [1,2], and to the strengthening with crack repair technology have also made some progress [3-8]. Edberg et al [3] made some experimental studies to research the properties of I-font section steel beam strengthened with FRP using several different kinds of reinforcement scheme, the results show that the stiffness of the steel after strengthening increased by 23%, the ultimate bearing capacity increased by 42%. Nicholas G.Tsouvalis et al [4] conducted experiment and the finite element method to study the steel structures strengthened with composite. The results show that the bonded composite materials can effectively reduce crack propagation rate, the fatigue life of specimen increased by 74% or more. However, the research for stress intensity factor of the semi-elliptic surface crack in steel structure strengthened with FRP has not yet been reported. For this reason, in this paper, three dimensional semi-elliptic surface crack in X80 steel tension specimen strengthened with carbon fiber laminate (CFL) [9] was studied, and numerical analysis was undertaken by Abaqus finite element software to study the stress intensity factor (SIF, K_I) of the surface crack for CFL reinforcement effect.

2. Finite element model

Research object in this paper was the 3D semi-elliptical surface crack in the center of the rectangle X80 steel plate. The steel plate was strengthened with carbon fiber laminate (CFL) in front side invented by this research group [9], and was subjected to uniform tension load of 100MPa on both ends, shown in Figure.1 and Figure.2. Where, the size of X80 steel plate was: length

H=90mm, width W=70mm, thickness B=8mm, Young' modulus E_s=206GPa and Poisson's ratio ν_s=0.3. The CFL has length H=90mm, width W=70mm, thickness t_f =0.2, 0.4, 0.6, 0.8, 1.0mm, Young' modulus E_f =230GPa and Poisson's ratio ν_f =0.25. Surface crack shape ratio a/c=0.4, 0.6, 0.8, and relative depth a/B=0.1, 0.2, 0.3.

Figure 1. Steel plate with surface crack under tensile load

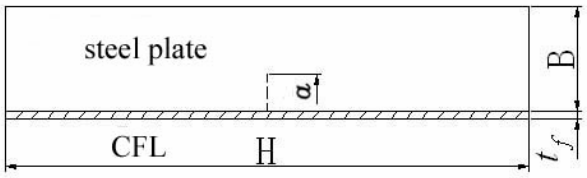

Figure 2. Steel plate strengthened with CFL

Finite element software Abaqus was used to establish the model for calculating the stress intensity factor of the semi-elliptical surface crack in different strengthening conditions. Due to symmetry of the analysis object, only one-quarter of the steel plate was analyzed. Two symmetrical surfaces of the model were restricted by symmetrical boundary conditions. In this analysis model, to avoid incompatible situations between CFL elements and crack front elements in front side strengthening, in the same time, to make the results comparable, steel plate and CFL were meshed using the three-dimensional elements. Around the crack tip area, a total of 11 layers elements were created. The first layer was wedge elements, and other 10 layers were hexahedral elements, there were totally 132 elements, shown in Figure. 3(a). Along the semi-elliptical curve, 20 equal parts were divided, which means there were 20 groups of elements and totally 2640 elements in the crack tip, shown in Figure. 3(b). The whole finite elements model was shown in Figure. 3(c), and there were totally 25932 elements.

3. SIF of 3D surface cracks

3.1 SIF of crack in non-strengthened steel plate

Finite element analysis for stress intensity factor (SIF, K_I) of 3D semi-elliptical surface crack in non-strengthened steel plate was compared with that obtained by the Newman-Raju equation to prove the effectiveness of the FEM method in this paper.

For finite element calculation, due to 11 layers of elements were meshed at the crack tip, the corresponding SIF obtained by contour J-integration at every point in front of the crack. Generally, the calculated values of the inside layer had a larger fluctuation, compared with that of the outer layer. In default situations, the results were outputted by the software Abaqus from the inner layer. Therefore, at least 6 SIFs were obtained at each point in front of the crack to insure the accuracy. The relatively stable value of the outer layer was selected as the final SIF.

SIF of three a/c ratios and three raletive deepth a/B of the surface crack were calculated using the above FEM method and Newman-Raju equation were shown in Figure.4. From this Figureure, the finite element analysis results agreed well with that of the Newman-Raju equation in generally, the average relative error is less than 3%.

The minimum relative error was 0.38% when $\theta = 90^{\circ}$. There was a larger error near $\theta = 0^{\circ}$ especially when the crack was shallower (*a*/*B* is smaller) and flatter (*a*/*c* is smaller). The maximum relative error was 7.8% when *a*/*B*=0.1, *a*/*c*=0.4 and $\theta = 0^{\circ}$. When the crack was shallower, flatter and the centrifugal angle was smaller (*a*/*B*, *a*/*c*, θ was smaller), the relative error was larger. This was caused by the default conditions that the whole model was in plane strain state during the finite element analysis. However, it was in fact in plane stress state near the surface of the steel plate which caused greater relative error around $\theta = 0^{\circ}$ and also caused larger relative error when *a*/*B* and *a*/*c* were smaller. The results show that the above method of calculating the SIF of 3D surface cracks in steel plates using Abaqus was effective and available.

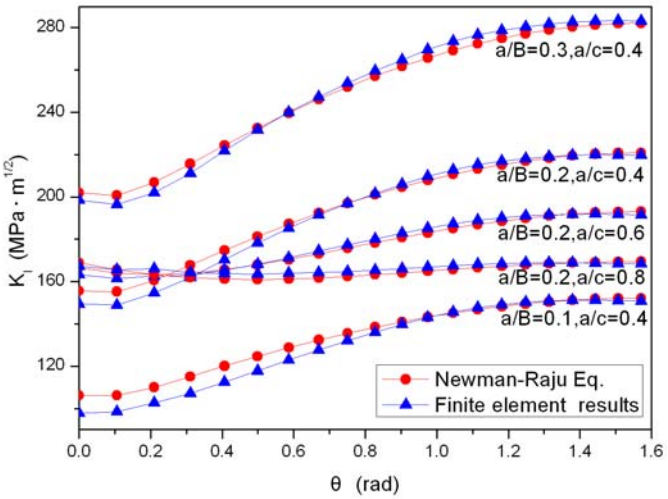

Figure 4. Computing values of K_I by FEM and Newman-Raju Eq.

3.2 SIF of crack in steel plate strengthened with FRP

In front surface strengthening (shown in Figure.2), the calculation values of SIF of 3D surface crack with t_f=0, 0.2, 0.4, 0.6, 0.8, 1.0 when a/B＝0.2，a/c＝0.6 were listed in Figure.5. This Figure shown that the SIF generally decreased by 21% in front surface strengthening compared with that of non-strengthening (t_f=0). As shown in Figure.5, the strengthening effect decreased as the angle changing from 0°to 90°, such as the reduction of stress intensity factor was the most (54.9%) when t_f = 0.2 and θ=0°, and the stress intensity factor to reduce small (20.6%) when θ=90°. This is because that the displacement between the upper and the underside of the crack was restricted by the CFL bonded to the surfaces. Therefore, the closer distance to the surface of the steel was, the better effect of the reinforcement was otained, where, the SIF on the surface of the steel was reduced most. Furthermore, the decreasing degree of SIF became smaller as the increasing of the thickness of CFL. That means overabundance of FRP caused material waste. The calculation values of SIF of the surface crack by FEM had the same properties when the shape and relative depth changed.

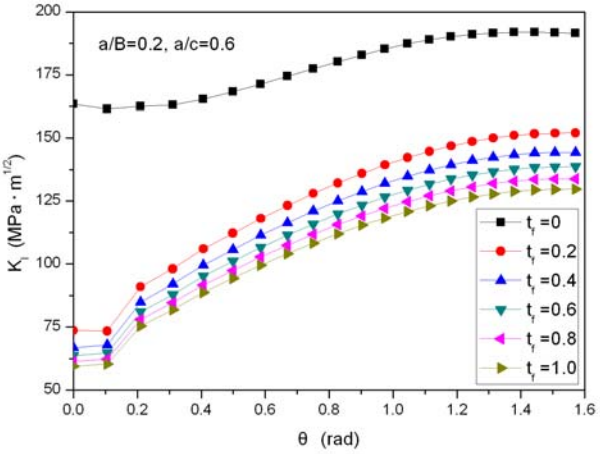

Figure 5. Computing values for K_I

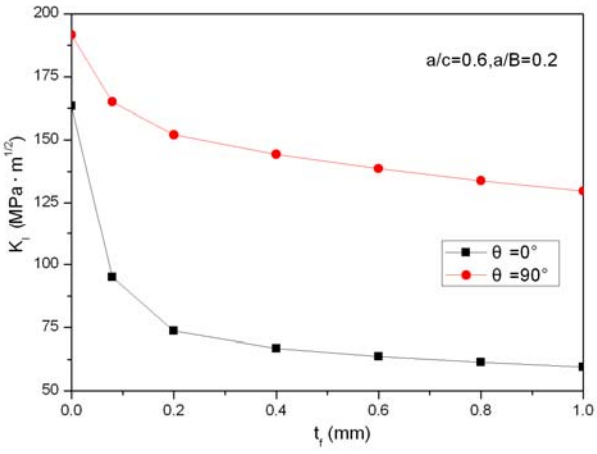

Figure 6. Relationship between K_I and t_f

The strengthening effect was lowest when θ=90°. For safety (conservative) considerations, the series was chosen as the calculation reference values in strengthening design. Therefore, functions of SIF and different thickness of CFL when θ=90° were simulated as:

$$K_{I,\theta=90^o} = K_0 - 2.49t_f^{0.29} \qquad \left(t_f \geq 0, \theta = 90°\right) \tag{1}$$

Where, K_I was the stress intensity factor (SIF), which unit was MPa·m$^{1/2}$; t_f was the thickness of FRP which unit was mm; K_0 was the stress intensity factor without strengthening (t_f=0).

The SIF was gradually decreasing as the increasing of the thickness of CFL in front surface strengthening from Figure.6, and becoming flat after $t_f \geq 0.6mm$.

3.3 Effect of crack parameters on K_I

3.3.1 Effect of *a/c*

To discuss the effect of crack shape ratio *a/c* on K_I, the relative depth *a/B* was supposed to be invariable in FEM analysis. The curves of K_I in front side strengthening were listed in Figure. 7 when t_f=0.2*mm*, *a/B*=0.2，*a/c*=0.4, 0.6 0.8. The strengthening effect was better from Figure.7, while *a/c* was larger, the effect was weaker. For example, strengthening effect was 26.1% when θ=90° and *a/c*=0.4, and that was 20.6% and 16.1% when *a/c*=0.6 and *a/c*=0.8 respectively as shown in Figure.8. It can be considered as *a/B* was invariant, *a/c* was larger, *c* was lower, and the interaction region between FRP and surface crack was shorter, the function of FRP was smaller.

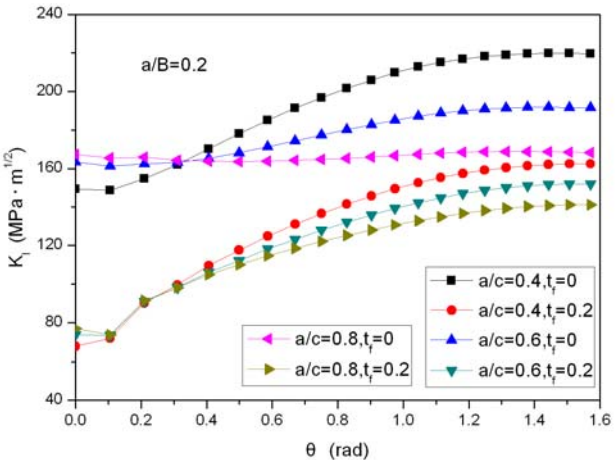

Figure 7. Effect of *a/c* on K_I

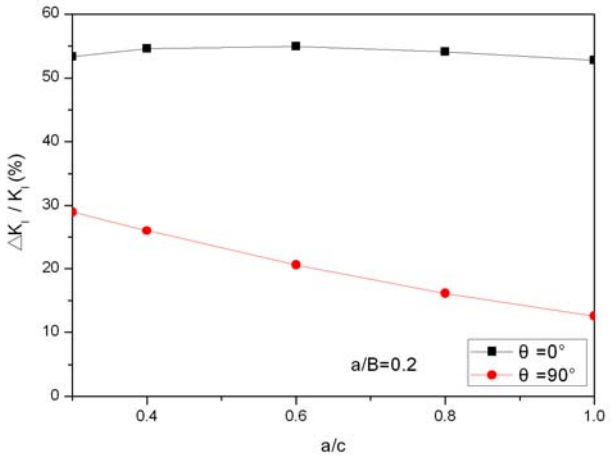

Figure 8. Effect of *a/c* on K_I for θ=90° and θ=0°

3.3.2 Effect of *a/B*

To discuss the effect of the relative depth *a/B* on K_I, the shape ratio *a/c* was supposed to be invariable for FEM analysis. The curves of K_I in front strengthening were listed in Figure. 9 when t_f =0.2, *a/c*=0.4，and *a/B* was equal to 0.1, 0.2 and 0.3. The strengthening effect in front side strengthening was better, while *a/B* was larger, the effect was weaker. As shown in Figure.10, the reinforcement effect can be reduced when *a/B*<0.3 and θ=90°, but the reinforcement effect will increase when *a/B* >0.3 and θ=90°. For example, the effect of reinforcement was 32.1%, 26.1%, 24.8%, 25.9% and 28.1% when *a/B* was equal to 0.1, 0.2, 0.3, 0.4 and 0.5 respectively near θ=90°. It was because that the increasing of the crack depth caused further distance from CFL to the crack

tip, and the resistance to crack development was weaker when the CFL was bonded to the front side surface.

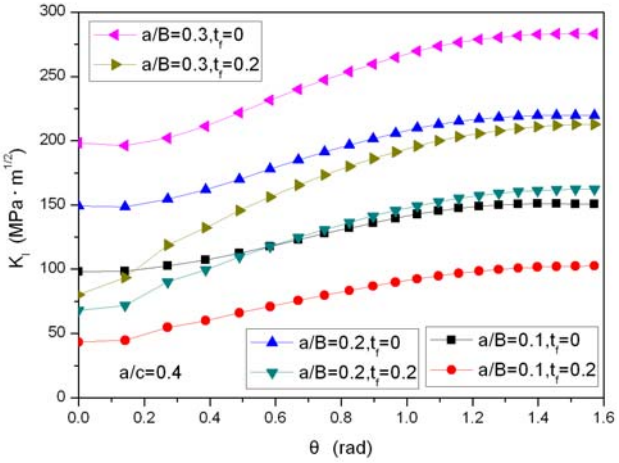

Figure 9. Effect of *a/B* on K_I

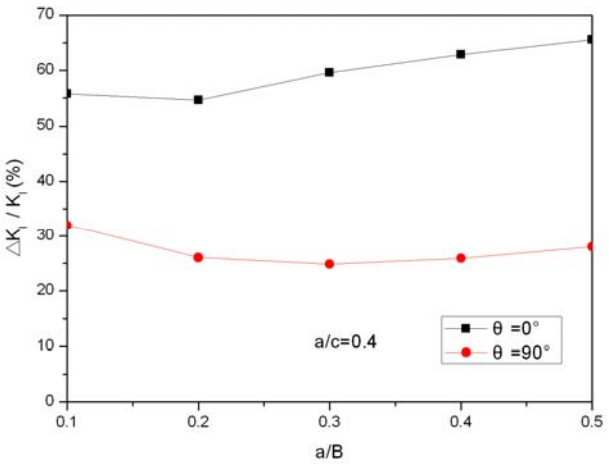

Figure 10. Effect of *a/B* on K_I for θ=90° and θ=0°

4. Expression for K_I

In order to facilitate the calculation of SIF for the 3D semi-elliptical surface crack in the center of the rectangle steel plate strengthened with FRP, and very convenient for engineering application, based on the analysis results of a large number of finite element calculation, the mathematical software Matlab was used to fit the calculation expression of SIF, and get the expression as follows:

$$K_I = \sigma \cdot F\left(\frac{a}{c}, \frac{a}{B}, t_f, \theta\right) \tag{2}$$

Where, σ is tensile stress acted on the ends of the steel plate, and

$$\begin{aligned} F\left(\frac{a}{c}, \frac{a}{B}, t_f, \theta\right) = {} & 0.4 + 0.23 \cdot p + q \cdot (4.96 - 10.09 \cdot t + 4.24 \cdot r) + t^2 \cdot (6.44 \cdot q - 0.39) + 0.44 \cdot r^2 \\ & + p \cdot q \cdot r \cdot (27.35 \cdot t - 6.82) + t \cdot r^2 \cdot (3.11 \cdot q - 0.82 \cdot p) - p \cdot q \cdot t \cdot r \cdot (26.09 \cdot t + 17.35 \cdot r) \\ & + t^2 \cdot r^2 \cdot (0.66 \cdot p - 6.4 \cdot q + 22.01 \cdot p \cdot q) \end{aligned} \tag{3}$$

Where, $p = a/c$, $q = a/B$, $t = \ln(1 + t_f^{0.25})$, $r = \sin\theta$, $0 < a/c < 1.0$, $0 < a/B < 1.0$, $2c/W \le 0.5$, $0^\circ \le \theta \le 90^\circ$.

Comparing the calculating values by equations (2) and (3) with the data from FEM, it is shown that the average error is within 3% and the fitting result is reasonable.

5. Conclusions

Finite element software Abaqus was applied to study the stress intensity factors (SIF) of 3D semi-elliptical surface crack in rectangle steel plate strengthened with CFL, and the strengthening effects were discussed. The conclusions were as follows:

(1) Front side strengthening reduced the stress intensity factors of 3D semi-elliptical surface crack significantly, but the increasing amplitude of strengthening effects decreased gradually with increasing of thickness of CFL.

(2) Crack shape ratio *a/c* had a great effect on front side strengthening, and its effect decreased with the increasing of *a/c*.

(3) Crack relative depth *a/B* also had some effect on front side strengthening. The strengthening effect decreased with the increasing of *a/B*. The strengthening effect can be reduced when $a/B<0.3$ and $\theta=90°$, but the strengthening effect will increase when $a/B>0.3$ and $\theta=90°$.

(4) An expression for calculating the stress intensity factors of semi-elliptic surface crack under strengthening condition was proposed by adopting MATLAB software.

Abstract The residual stresses in materials have a considerable effect on the mechanical properties, including creep and failure behaviour. Due to elastic and plastic anisotropy, differently oriented grains will exhibit different mechanical responses for a given macroscopic stress, leading to a variation of stresses within the grains. Experimental studies of meso-scale residual stress evolution can be used to validate crystal based plasticity and hardening models. In this paper, a self-consistent model and a simple multi-bar system are employed to determine how the evolution of the residual stress field depends on the constitutive assumptions for the individual grains. This framework has been used to evaluate data for the lattice strain evolution in 316H stainless steel measured from neutron diffraction experiments. A suitable model is identified, which captures the macroscopic response of the material and explains the way in which the meso-scale residual stresses evolve. The good agreement achieved between the self-consistent model and experiment demonstrates that this model reasonably reflects the mechanical physics of 316H stainless steel, and may help improve our understanding of the influence of the residual stress on the fracture and failure behaviour.

Keywords Residual stress, Self-consistent model, 316H stainless steel, Neutron diffraction

1. Introduction

Residual stresses developed within grains of a polycrystalline material have a considerable effect on material properties, including load carrying capacity, creep and crack initiation and propagation [1]. Thus, understanding the distribution and the evolution of residual stresses is vital to assessing the performance of engineering components. Elastic and plastic anisotropy of the differently oriented grains results in a variation in the mechanical response of different grains and the development of meso-scale intragranular residual stresses [2,3], i.e. the stresses within the grains. The development of these residual stresses depends on the detailed flow, hardening and recovery laws for the different slip systems in the body. A number of techniques have been developed for measuring residual stresses (or residual elastic strains) in a body. Neutron diffraction can provide information about the residual elastic strains in different families of grains within the bulk of a polycrystalline sample. Availability of the data offers the opportunity to identify the most appropriate forms of constitutive relationships for the individual grains, which can then be used to predict the evolution of residual stresses and the macroscopic material response under complex thermo-mechanical loading histories.

Various models have been proposed or developed to predict quantitative and qualitative features of the elastic-plastic behaviour of polycrystalline materials, such as Taylor model [4], which assumes that all grains experience identical strain, but elastic anisotropy plays no role. Self-consistent models which employ solutions of the classical Eshelby inclusion problem [5,6], have been employed extensively to describe the structure-property relationship of materials. Examples of this approach are given by Kroner [7], and Budiansky and Wu [8] to describe the effect of misfit strain on plastic deformation. However, the inclusion is simplified as being elastically isotropic and with the same properties as the matrix. Self-consistent models, suggested by Hill [9] and Hutchinson [10],

incorporate a more elaborate description of single crystal behaviour for calculating the stresses and strains in the individual grains, but with no physical description of work hardening. The physical characterization of work hardening is discussed by Kocks and Mecking [11], based on dislocation multiplication and the evolution of dislocation density. Lagneborg's dislocation link length model [12] provides a more detailed description of the dislocation structure and evolution of the structure based on Orowan bowing [13] and recovery of the dislocation structure.

In this paper, a self-consistent model is developed to consider both elastic and plastic anisotropy of the polycrystalline grains. A hardening model is described based on Lagneborg's dislocation link length model. A simplified multi-bar representation of the polycrytsal is also described. Both these models are used to predict the elastic-plastic responses and the development of meso-scale residual stresses of a Type 316H stainless steel under uniaxial tensile loading. These models are validated using elastic lattice strain and residual lattice strain data obtained by the neutron diffraction technique. A detailed description and explanation of the experiment is presented in the companion paper [14]. The ability of these models to capture the observed response is discussed.

2. Formulation of the self-consistent model

In the self-consistent approach, each individual grain of a polycrystalline material, is regarded as a spherical inclusion in an infinite homogeneous matrix with the average macroscopic properties [7,8]. The purpose of the Eshelby based deformation model is to establish the relationship between the local individual grain-scale responses and the polycrystal aggregate response.

2.1. Model of elasticity

Eshelby obtained the solution for the elastic field of a misfitting (with a stress-free transformation strain ε^t) ellipsoidal homogeneous inclusion embedded in an infinite isotropic matrix of the same elastic constants. The total strain in the inclusion is linked by the transformation strain and a 6th-order tensor S^i relating the final constrained inclusion shape to the original shape mismatch between the matrix and the inclusion, and is only dependent on the geometry of the inclusion and Poisson's ratio of the medium [5,15]. For an inhomogeneity (a single inhomogeneous grain in the model) with different elastic constants containing a transformation strain ε^{ta}, its elastic field can be simulated by an equivalent homogeneous inclusion with a properly chosen transformation strain ε^{t*}. Given a macroscopically applied stress σ, the relationship between the real transformation strain in the inhomogeneity and the virtual transformation strain in the equivalent inclusion can be derived as

$$\varepsilon^{ta}+\left[\left(C^a\right)^{-1}-\left(C^i\right)^{-1}\right]T\sigma=\left[\left(C^a\right)^{-1}C^i\left(I-S^i\right)+S^i\right]\varepsilon^{t*} \tag{1}$$

where C^a, C^i are respectively the stiffness matrices of the grain and the surrounding matrix. T is the orientation matrix of the grain described by the three Euler angles. I is the unity matrix. If the deformation is fully elastic, i.e. $\varepsilon^{ta}=0$, ε^{t*} can be solved and the relationship between the applied stress and the grain stress and strain can be established

$$\sigma^a=\left\{\left\{\left[I-\left(S^i\right)^{-1}\right]^{-1}\left(C^i\right)^{-1}-\left(C^a\right)^{-1}\right\}^{-1}\left[\left(C^a\right)^{-1}-\left(C^i\right)^{-1}\right]+I\right\}T\sigma=H^aT\sigma \tag{2}$$

$$\varepsilon^a=\left\{\left(C^i\right)^{-1}+\left\{\left[\left(C^a\right)^{-1}-\left(C^i\right)^{-1}\right]^{-1}\left(C^a\right)^{-1}C^i\left(S^i\right)^{-1}-C^i\right\}^{-1}\right\}T\sigma=K^aT\sigma \tag{3}$$

where $H^a=\left\{\left[I-\left(S^i\right)^{-1}\right]^{-1}\left(C^i\right)^{-1}-\left(C^a\right)^{-1}\right\}^{-1}\left[\left(C^a\right)^{-1}-\left(C^i\right)^{-1}\right]+I$ and

$$K^a = \left(C^i\right)^{-1} + \left\{\left[\left(C^a\right)^{-1} - \left(C^i\right)^{-1}\right]^{-1}\left(C^a\right)^{-1} C^i \left(S^i\right)^{-1} - C^i\right\}^{-1}$$

2.2. Model of plasticity

The expression of the transformation strain in the grain has been considered to be the plastic misfit strain between the grain and the matrix in the same coordinate [7,8]

$$\varepsilon^{ta} = \varepsilon^p - T^{-T} E^p \tag{4}$$

where ε^p is the local plastic strain in the grain and E^p is the polycrystal plastic strain obtained by the volume average over all the grains with possible orientations. In Eq. (1), if $\varepsilon^{ta} \neq 0$, i.e. the material is plastically deformed, a relationship between ε^{t*} and the real plastic misfit strain ε^{ta} can be obtained by macroscopically unloading the sample (i.e. setting $\sigma = 0$). Further, the residual stress in the grain (X^a) can be derived as a function of the plastic misfit strain ε^{ta}

$$X^a = C^i\left(I - S^i\right)\left(\left(C^a\right)^{-1} C^i S^i - \left(C^a\right)^{-1} C^i - S^i\right)^{-1} \varepsilon^{ta} \tag{5}$$

2.3. Crystal based plasticity model

Plastic deformation is the glide of dislocations on multiple slip systems [11,16]. Following the classical crystal plasticity model [16,17], the shear strain rate ($\dot{\gamma}^\beta$) of a slip system β ($\beta = 1 \sim m$, m: total number of slip systems) is related to the resolved shear stress (RSS, τ^β) and the critical resolved shear stress (CRSS, τ^β_{crss}) of the corresponding slip system by the power-law relationship

$$\dot{\gamma}^\beta = \dot{\gamma}_0 \left|\frac{\tau^\beta}{\tau^\beta_{crss}}\right|^t \mathrm{sgn}(\tau^\beta) \tag{6}$$

where $\dot{\gamma}_0$ is a reference shear strain rate and t is the rate sensitivity exponent. As $t \to \infty$ this constitutive response of each slip system is consistent with rate-independent deformation [17]. In the computations here a value of t=600 is used to provide a response that is essentially rate independent for the timescales employed in the simulations. If $\overline{n}^\beta(n_1^\beta, n_2^\beta, n_3^\beta)$ is the normal direction and $\overline{s}^\beta(s_1^\beta, s_2^\beta, s_3^\beta)$ is one of the slip directions associated with the slip system β, the shear strain rate $\dot{\gamma}^\beta$ on this slip system provides a contribution to the plastic strain rate given by:

$$\dot{\overline{\varepsilon}}^\beta = sym(\dot{\gamma}^\beta \overline{n}^\beta \otimes \overline{s}^\beta) = \theta^\beta \dot{\gamma}^\beta \tag{7}$$

where θ^β is the Schmid factor of the slip system, which also links the RSS with the stress of each individual grain [16,17]. The total plastic strain rate is the sum of $\dot{\overline{\varepsilon}}^\beta$ over all the slip systems

$$\dot{\varepsilon}^p = \sum_\beta \dot{\overline{\varepsilon}}^\beta = \sum_\beta \theta^\beta \dot{\gamma}^\beta \tag{8}$$

The controlling parameters for slip are the CRSS and the hardening law. The initial CRSS is assumed to be the same on all slip systems and it is taken to evolve as [9]

$$\dot{\tau}^i_{crss} = \sum_j h^{ij} \left|\dot{\gamma}^j\right| \quad \text{with} \quad h^{ij} = h\left(q + (1-q)\delta^{ij}\right) \tag{9}$$

where h^{ij} is the rate of strain hardening on slip system i due to a shearing on slip system j [16]. The summation is over all active slip systems. h is the hardening coefficient dependent on the previous deformation history and q is a factor determining the degree of latent hardening: q=0 provides only self-hardening, q=1 represents Taylor hardening, and q>1 gives stronger latent hardening. For latent hardening, the range of q has been reported to be $1<q<1.4$ [17,18]. As for the coefficient h, the specific form needs to be given by the physical hardening model.

2.4. Dislocation link length based hardening model

The strain hardening effect is physically characterized by the motion of mobile dislocations. The dislocation link length model originally proposed by Lagneborg [12] offers a reasonable illustration of such an effect. A dislocation link is defined as the segment between two pinning points (dislocation junctions or other obstacles). The hardening behaviour is characterized by the evolution of the distribution of dislocation link lengths associated with a particular slip system.

2.4.1. The structure of dislocation link distribution

In the model, the dislocation structure can be described as a population of dislocation links with spacing occurring as a spectrum of lengths, i.e. a 3D dislocation network [12]. The distribution of link lengths in the network is described by an instantaneous distribution function $\phi(\lambda)$, defined such that $\phi(\lambda)d\lambda$ equals the number of links per unit volume with lengths between λ and $\lambda + d\lambda$. The detailed form of the distribution function can be expressed as [19,20]

$$\phi(\lambda) = A\lambda^2 e^{-B\lambda^2} \tag{10}$$

where *A* and *B* are two constants which evolve during deformation. A typical distribution is shown in Fig. 1(a), as a truncated Weibull distribution. λ_{th} is the threshold or the current maximum link length on a slip system, directly related to the current CRSS on the corresponding system.

$$\lambda_{th} = \frac{\alpha G b}{\tau_{crss}} \tag{11}$$

where α is a dimensionless constant determining the strength of an obstacle, *G* is the shear modulus and *b* is the value of Burgers vector. The truncation in Fig. 1(a) indicates that no links longer than the threshold links can exist in the complex network without recovery. Thus the total number (*N*) per unit volume and the total density (ρ) of dislocation links can be expressed as

$$N = \int_0^{\lambda_{th}} \phi(\lambda) d\lambda \qquad \text{and} \qquad \rho = \int_0^{\lambda_{th}} \lambda\phi(\lambda) d\lambda = N\bar{\lambda} \tag{12}$$

where $\bar{\lambda}$ is the average link length, or mean free path of dislocation motion [12,21,22]. Meanwhile, a constant volume boundary condition is required and expressed as [12,21]

$$\int_0^{\lambda_{th}} c\lambda^3 \phi(\lambda) d\lambda = 1 \tag{13}$$

where *c* is a geometric constant close to 1.

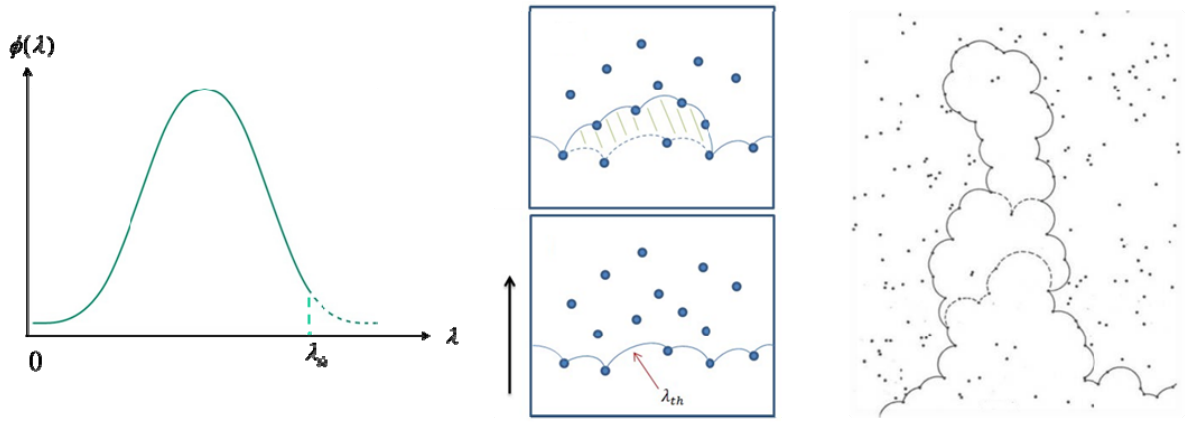
2.4.2. The dislocation unzipping movement

In Lagneborg's model, dislocation motion is described as long waiting times at the obstacles and occasional spurtlike movements of dislocation links between obstacles [12]. Thus at any instant, all the dislocations in the network can be considered as immobile and held up at obstacles. At a certain stress, dislocation links with the threshold length will be released and become mobile. They overcome the obstacles and then continue to glide and sweep out an area before being blocked and partitioned into shorter links by adjacent obstacles in the network, which become immobile again (Fig. 1b). If the area swept out by each released dislocation link is *s*, the shear strain rate is [12,22]

$$\dot{\gamma} = bs\dot{N}_m \tag{14}$$

where $\dot{N}_m$ is the release rate of mobile links, which is related to the current value of CRSS and its rate of increase. The expression of *s* is complicated and not reproduced here. The Orowan bowing [13] process was assumed in Lagneborg's original model, where the released links expand to circular loops and the area is assumed to be $4\pi\bar{\lambda}^2$. However, such encircling movement is often the characterization for strong obstacles (large α) and the spatial distribution of obstacles is always a

random array for a wide range of strengths [23]. A consecutive release process (Fig. 1c) is observed for weak obstacles (such as forest dislocations), which is commonly referred to as an unzipping mechanism [23]. Although it describes a release process by links with various lengths besides the threshold one, it is assumed that this does not influence the activation criterion of the release process in the model, but only offers a greater sweeping area than the original Orowan bowing process. The sweeping area in the model is assumed to be a circular arch and the averaged distance a link can reach is proportional to $\overline{\lambda}$ but needs to be determined by fitting with experimental data.



(a) (b) (c)

Figure 1. (a) Truncated Weibull dislocation distribution; (b) A schematic diagram of the kinetic motion of dislocation links before and after release, where the solid points are obstacles, e.g. dislocation junctions on other slip planes; (c) Unzipping movement of a dislocation which glides on a slip plane [23]

The evolution of the dislocation distribution function updates two state variables in the model: (1) the local threshold link length; (2) the global dislocation density. The dislocation multiplication is described by the generation and disappearance of links, which can be separated into different stages such as release, expansion and cut. The detailed model derivation for the structure evolution is not shown here. Finally, the relationship between the shear strain rate and the CRSS rate of increase on a single slip system can be derived from Eq. (14) as

$$\dot{\gamma} = f(\tau_{crss}, \rho, \dot{\rho})\dot{\tau}_{crss} \tag{15}$$

Compared with Eq. (9), $1/f(\tau_{crss}, \rho, \dot{\rho}) = h$ is the hardening coefficient. In the simulation, a simple linear hardening is considered, which is given by an assumption that the total unzipped link length in a slip system and the link length at which the distribution function has the maximum value are proportional to the threshold link length. The model gives a range of linear hardening coefficients obtained by the variation of different parameters such as the obstacle strength α. However, the coefficient as a whole is treated as a fitting parameter in the simulation, but its value must lie within a physical range for this model to hold.

3. A simplified multi-bar system

A simplified and straightforward 1D multi-bar system which captures the general structure of the self-consistent model was established. The general structure the system is shown in Fig. 2. Taking an face centred cubic (fcc) material as an example, all the thick bars (with the properties of single cubic grains with their specific orientation and with equal cross-sectional area) are representative components of the isotropic polycrystal and their average response gives the polycrystal behaviour. The small bar in the system represents a grain family, which does not influence the averaged behaviour of the system since its cross-sectional area is negligible. Therefore, this system demonstrates the framework of the basic structure of a self-consistent model, a single grain

embedded in an infinite matrix with the averaged isotropic property, despite the difference that the geometric feature requires equal strain for all the bars which is similar to a Taylor model.

The elastic anisotropy for the multi-bar system is determined such that each bar has a different Young's modulus along the loading direction related to the individual orientation. Whilst for the plastic anisotropy, the classic 1D incremental plasticity model of isotropic hardening [24] is used, where the strain hardening effect is characterised by a plastic modulus defined as the instantaneous slope of the stress-strain curve after micro-yielding. For the multi-bar system, the assumption of linear hardening of each grain is described by an orientation-dependent bilinear response [24] and the plastic modulus serves as the hardening coefficient of this system.

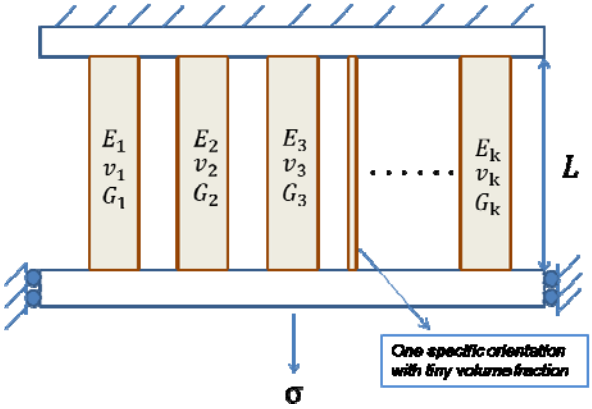


Figure 2. A schematic diagram of the multi-bar system

4. Model evaluation

4.1. Neutron diffraction experiment

To validate the self-consistent model, the lattice strain evolution, especially the residual lattice strain in different crystallographic planes of a fcc material of ex-serviced 316H stainless steel was measured using neutron diffraction (ND) combined with in-situ tensile deformation on the ENGIN-X instrument at the ISIS pulsed neutron facility, Rutherford Appleton Laboratory. A schematic diagram of the experimental setup is shown in Fig. 3.

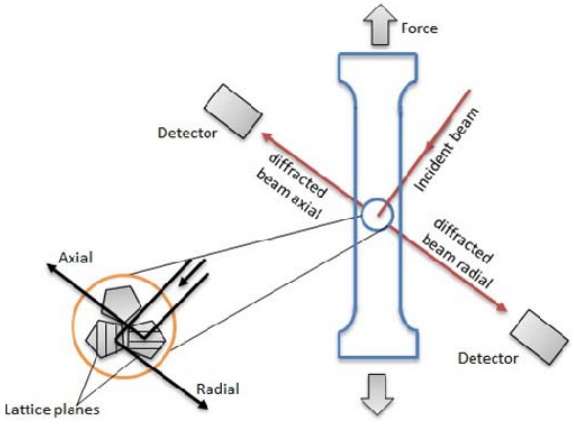

Figure 3. Schematic diagram of neutron diffraction experiment

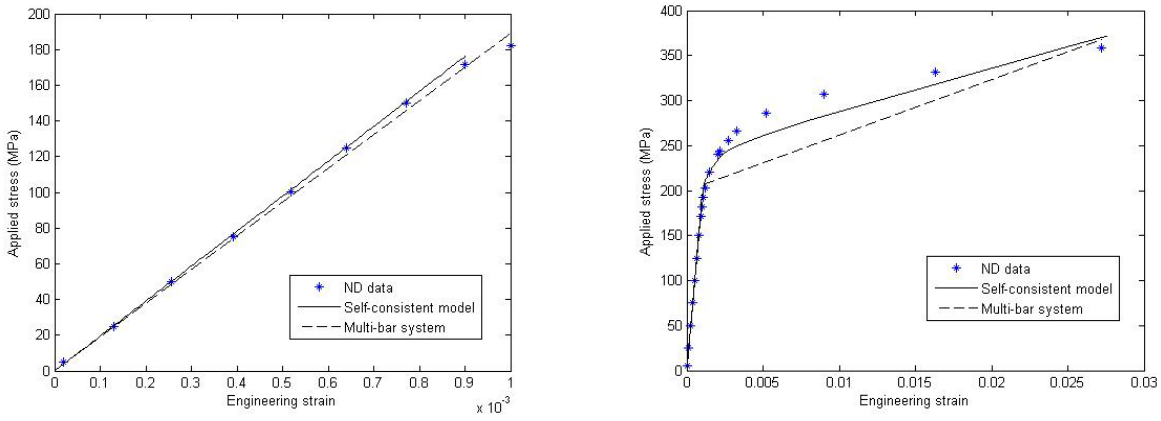
The incident beam directed at a specimen consists of a polychromatic spectra with a continuous range of wavelengths, which enables the recording of many lattice planes in each measurement. The loading direction is horizontal and at 45^{o} to the incident beam. Two detectors are positioned to

allow simultaneous measurement of lattice spacing both parallel (axial) and perpendicular (radial) to the loading direction. The lattice strain measured for each plane represents the average value of the elastic strain within a family of grains which are oriented such that a specific {*hk*l} plane diffracts to the detector. For example, in the axial direction, a specific {*hk*l} lattice strain indicates the average axial elastic strain over the grains located in the gauge volume with their {*hk*l} plane normal parallel to the loading axis. The complete description of the experiment and the full range of measurement are presented in Ref [14].

4.2. Simulation of the experimental results

4.2.1. Macroscopic behaviour and parameter identification

In the present calculations, no lattice rotation or texture development was incorporated due to the small plastic deformation [25]. The property of the matrix was initially undetermined and was solved by iteration from the average response of all the grains. This then served as the standard for the selection of the number of bars in the multi-bar system. The latent hardening factor q was pre-set as 1, i.e. the hardening on all slip systems were equal, which is reasonable in the current framework since the expansion and partition of dislocation links may generate equal obstacles for all slip planes. The effect of different values of q was considered elsewhere [26]. The fitting process was to initially make the macroscopic stress-strain response of the self-consistent model resemble the actual measured macroscopic behaviour of the sample and then to use the refined parameters to predict the macroscopic behaviour of the multi-bar model and the microscopic behaviours of the local grain family in both models. The fitting parameters are listed in Table 1 together with the single crystal elastic constants of the fcc material 316H stainless steel. The calculated macroscopic stress-strain responses are shown in Fig. 4, with the results obtained by both the self-consistent and multi-bar models.



(a) (b)

Table 1. Material parameters of 316H stainless steel used in the simulation

C_{11} (GPa)	C_{12} (GPa)	C_{44} (GPa)	$\dot{\gamma}_0$	t	τ_{crss0} (GPa)	b (m)	q	h *(MPa)*
198	125	122	5e-6	600	82	2.5e-10	1	370

4.2.2. The grain family and the Young's modulus

The family of grains contributing to the reflection of a certain crystallographic plane in neutron diffraction has one uniform orientation along the measurement direction. The averaged response of

this grain family can be determined either by averaging the responses of all the members or by considering the family as a whole with an averaged transversely isotropic property. In the present simulation, the results of two representative grain families {220} and {111} with the aggregate normal along the axial direction were considered. The diffraction elastic constants were measured in the experiment, in which the Young's modulus was defined as the slope of the applied stress over the elastic lattice strain [2,3]. The experimental measurement and the model prediction results for the two grain families are listed in Table 2, where the theoretical value and model prediction of the physical Young's modulus is also presented as a further validation of the model.

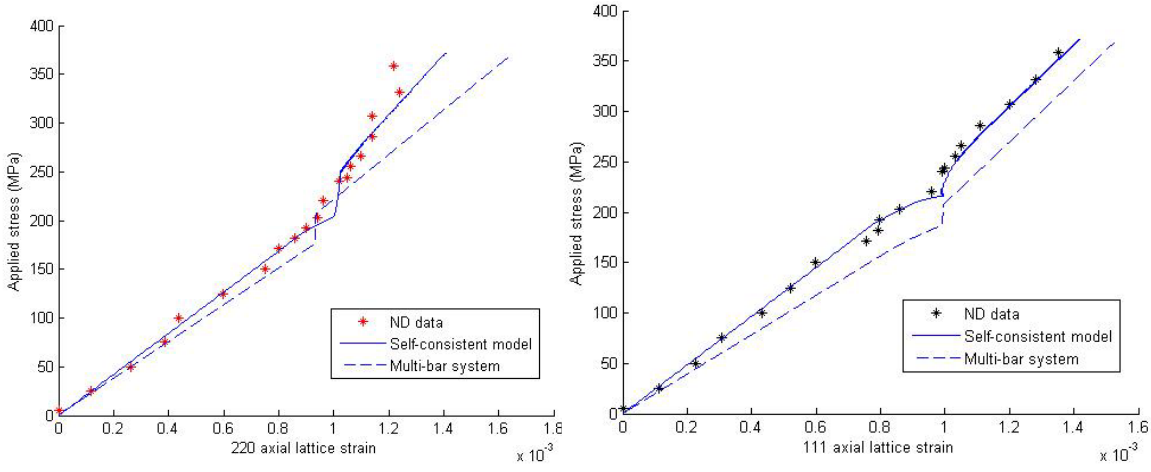
Table 2 Measurement and prediction of the Young's modulus of {220} and {111} grain family

Grain family	**{220}**	**{111}**
Diffraction Young's modulus (GPa)	209.1±15.8	225.3±11.9
Self-consistent model prediction	210.8	241.8
Physical Young's modulus (GPa) [27]	196	285
Self-consistent model prediction	225.1	285.1

4.2.3. The residual lattice strain

The results of axial elastic lattice strain evolution during loading, together with the predictions of the self-consistent (blue solid line) and multi-bar (blue dash line) models are demonstrated in Fig. 5. At each unloading step, the residual axial elastic lattice strain for the grain families was measured and was then plotted against the macroscopic residual plastic strain (shown in Fig. 6 with the model prediction). Good agreement is observed between the experimental data and the prediction of self-consistent model, while the quality of the prediction of multi-bar model is a mixture.

From the figures, although multi-bar model gives a poorer prediction than the self-consistent model, both of the models capture the major trend of the experimental data, particularly the transition that occurs in both the lattice strain and the residual lattice strain evolution upon micro-yielding. In addition, the two models predict that both grain families have an initially increasing residual lattice strain evolution, which is when the surrounding matrix yields (or some grains in the matrix yield) before each grain family. The subsequently decreasing residual lattice strain is when all the grains deform plastically, which is reflected in the difference in the plastic misfit strains in Eq. (4).



(a) (b)

Figure 6. Neutron diffraction (ND) measurement and model prediction results of the axial residual lattice strain vs the engineering plastic strain at unloading. (a) {220} grain family; (b) {111} grain family.

5. Discussion and conclusion

The mechanical features of {220} and {111} grain families have been discussed in [2,3]. From the results, the linear hardening assumption is acceptable and permits only one parameter, the hardening coefficient *h* to be used. The oscillation of the residual elastic lattice strain at relatively small plastic strain region in the measurement is expected to be a result of a combination of experimental error and the complex interaction between grains. Since the self-consistent model only considers the interaction between one single grain and the whole matrix, such oscillations cannot be predicted by the model. The poorer predictions from the multi-bar system in Fig. 5-6 may result from the identical strain for all the bars, regardless of their stiffness and hardening responses. Despite the same applied stress and yield stress with those in the self-consistent model, the multi-bar system may display a different mechanical response, especially the accumulation of residual elastic lattice strain. Such a discrepancy demonstrates that the identical strain assumption may not be acceptable for the local residual lattice strain evaluation.

A self-consistent model for polycrystal deformation is established with specific emphasis on the elastic and plastic anisotropy. The self-consistent scheme includes the elastic-plastic interaction between the grains which are regarded as spherical inclusions in an infinite homogeneous matrix with the averaged polycrystal response. A simplified multi-bar system is introduced which captures the basic structure of the self-consistent model. The models predictions were compared with the neutron diffraction measurements of elastic lattice strains in grain families within an ex-serviced 316H stainless steel polycrystal subjected to uniaxial tensile loading. The good agreement between the measured and calculated lattice strains validates the self-consistent model.

Abstract

Instabilities (pop-ins) in load-displacement records of fracture tests could be originated from small unstable crack growth in the main crack plane, as usual in welded joints, or from delamination of the ligament (splitting), as in some rolled steels. According to the standards, no matter the origin of the instability the fracture toughness need to be reported at the first significant pop-in. In most cases this treatment greatly penalizes the fracture toughness of the material. In that way a question arose: What would be the fracture toughness of a material featuring splitting if the specimen were not suffered split? To answer this question several test were made in rolled steels showing and not pop-ins from splitting. It is being now proposed that the change in the system energy associated to splitting instabilities could be neglected, the records corrected by adding the load drop caused by the split to the points on the right, and the toughness calculated at the maximum load. The results (for the magnitude of the instabilities we faced) showed that maximum load CTOD from corrected records and from records of the same material without pop-ins by splitting are statistically equivalent.

Keywords: Pop-in, Split-Out, Fracture Toughness, Rolled Steel.

1. Introduction

Pop-ins in load-displacement records of fracture tests are not always related to unstable crack growth and arrest in the main plane of the crack. Sometimes these instabilities are related to delamination (or splitting) of the ligament. This behavior could be present in some rolled steels and is related to some metallurgical characteristics of the material like crystallographic texture, elongated inclusions, banded microstructure, and/or central segregation, among others [1]-[3]. The origin of splitting is related to the stress triaxiality ahead of the crack-tip [2] [2] and the low toughness of the materials in the rolling plane, which can cause delaminations in the ligament in a plane perpendicular to the main crack one. An example of this behavior is shown in Figure 1.

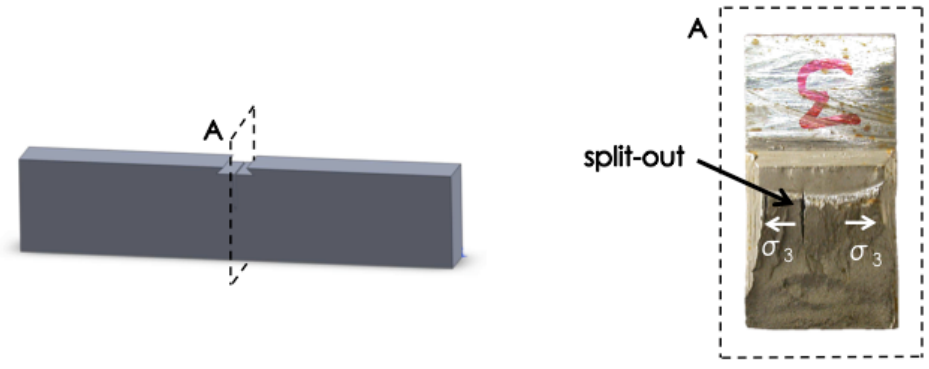

Figure 1. SE(B) specimen of rolled steel showing delamination (splitting) in the ligament.

When a split-out happens, one instability (pop-in) in the load-displacement records appears. Facing this kind of instabilities the standards have similar approaches, as shown in Table 1 [5]-[9].

Table 1. Excerpts of international standards on pop-ins caused by delaminations.

Standard	Excerpt
BS7448 part 1	Splits and delaminations can result in pop-ins with no arrested brittle crack extension in the plane of the fatigue precrack.
BS7448 part 2	Pop-in can be caused by an arrested crack running perpendicular to the plane of the fatigue precrack; this is sometimes referred to as a 'split'. The fracture toughness at pop-in caused by a split needs to be reported. However, the assessment of the structural significance of the split is outside the scope of this standard.
ASTM E1290 ASTM E1820	If the pop-in is attributed to an arrested unstable brittle crack extension in the plane of the fatigue precrack, the result must be considered as a characteristic of the material tested.
DS EN ISO 15653	Pop-in can be caused by an arrested crack running perpendicular to the plane of the fatigue precrack. This is sometimes referred to as a "split". The fracture toughness at pop-in caused by a split shall be reported, but might not characterize the fracture toughness of the material for the intended crack orientation. A different specimen and crack plane orientation might be necessary to characterize the fracture toughness of the material in the plane of the split. Assessment of the structural significance of a split is outside the scope of this International Standard.

As can be seen from Table 1, the standards do not offer alternative methodologies for fracture toughness evaluation when splitting occurs and the toughness basically needs to be calculated and reported at the first significant instability. The lack of alternatives for toughness evaluation in the presence of splitting could greatly penalize the toughness of the tested material, especially when the instabilities occur at the first stages of the test. Facing this scenario a question arose: What would be the fracture toughness of a material featuring splitting if the specimen were not suffered split? Or, in another words: It could be possible to estimate the fracture toughness of a material from a specimen that shows splitting? A possible answer to these questions was the main objective of the work and the results of our research follow.

2. Experimental

Fracture tests were performed on SE(B) specimens of rolled and accelerated cooled CLC DH36 ferritic steels (W=26 mm), as well as on conventional rolled API X65 and X70 steels (W=40 mm). The specimens were machined according to the ASTM 1820 standard in the LT orientation. The specimens were tested in an Instron 1332 servo-hydraulic testing machine with a 250 KN load cell, under displacement control and at different (low) temperatures. The specimens were submerged in an instrumented alcohol-cooled bath and the temperature was maintained at the nominal value with an accuracy of ±2°C. Load, crack mouth opening displacement and load line displacement were recorded. Additionally, on DH36 steels unloading compliance technique was applied for R-curves evaluation. J-Integral values and J-R curves were calculated according to the ASTM E1820 standard [8] and CTOD values were calculated according to the BS 7440 part 1 standard [5].

3. Results and Discussion

Figure 2a and 2b presents P-LLD and P-CMOD records of one test specimen of DH36 steel tested at –50°C. These records are representative of the behavior of specimens of the same steel at this temperature. As can be seen, the records show a pop-in caused by splitting. Figure 3 presents the J-R curve of this specimen. From Figure 2 it is possible to see that the pop-in occurred between the 5th and the 6th cycle in a total of 26 unloading-reloading cycles. The segment between the 5th and the 6th points in the J-R curve is pointed out by the arrow in Figure 3. It is interesting to observe that, without the help of the arrow, the position of the pop-in it is almost impossible to be identified in the J-R curve. In other words, there is no evidence of crack growth in the main plane of the crack associated to the split.

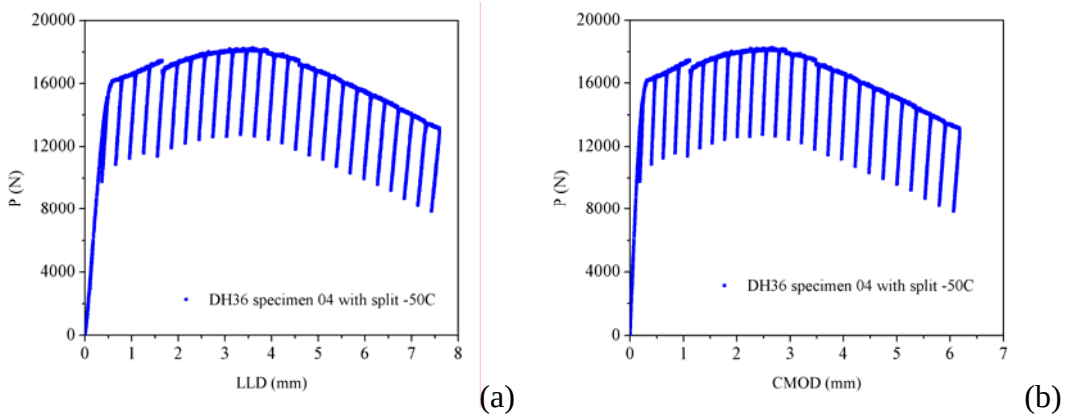

Figure 2. Experimental records of DH36 specimen 04 tested at -50°C. a) load vs. load line displacement; b) load vs. crack mouth opening displacement.

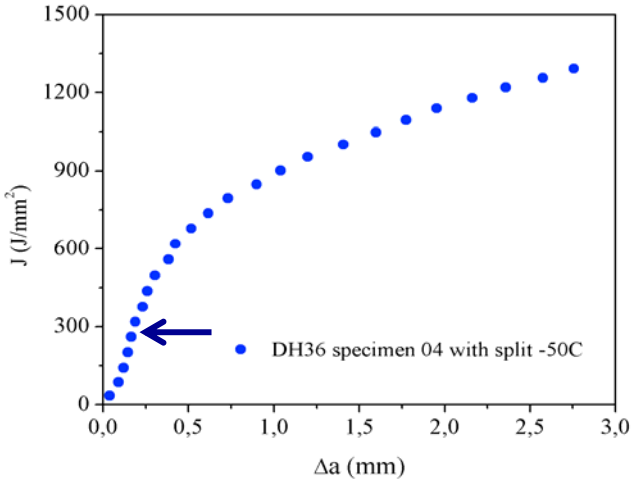

Figure 3. J-R curve of DH36 specimen 04 tested at -50°C.

This result shows that the change in the system energy associated to the pop-in caused by splitting could be almost completely related to the split formation itself and not to crack growth in the main plane of the crack. This idea is schematically shown in Figure 4, where the lower curve is represented in dots because its shape is still unknown. Being the energy change associated to

splitting independent of the main crack growth the effect of the pop-in by splitting on the fracture toughness of the material could be neglected. But, how to neglect the effect of splitting in the records? We think that this could be done through corrections of the experimental records. Several corrections were analyzed, being adding the load drop during the instability to the points on the right part of the records (that is, after split-out) the straightforward one. After corrected, the record are ready to be analyzed through standard methodologies and the fracture toughness calculated at the maximum load point or at the main crack instability one.

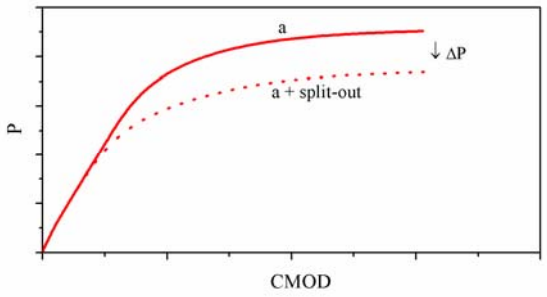

Figure 4. Scheme of the energy changes during a pop-in caused by splitting.

In a work on materials with delaminations Pisarski *et al.* [10] concluded that: "*when there is no significant loading perpendicular to the thickness direction, the pop-in can be ignored. Assuming that ductile behavior is indicated during the rest of the test, maximum load fracture toughness can be used to characterize toughness in the intended crack plane.*" We agree with this approach but we think that for improving the fracture toughness evaluation and for maintaining the equivalence among elastic-plastic methodologies, corrections of load-displacement records could still be necessary. The convenience of correcting load-displacement records was analyzed from a semi-hypothetical record, as follows.

Figure 5 presents modified P-LLD and P-CMOD records from the SE(B) specimens whose original records are shown in Figure 2. The unloading-reloading sequences are not shown here for clarity. The magnitude of the original load drop (approximately 4% of the load at the instability point) was now intentionally exaggerated by the addition of load drops of 10% and 20% as pop-ins. Additionally a corrected record was also added to the figure. When the fracture toughness at points A, B (as suggested by Pisarski), and C was calculated some controversial results were found. That is exemplified in Table 2, where J-Integral and CTOD values at points A, B and C are presented.

By comparing the results shown in Table 2 it is possible to see that $CTOD_A \approx CTOD_B \approx CTOD_C$ but $J_A < J_B < J_C$. Going further, when CTOD and J-Integral values are calculated at the beginning of each unloading-reloading sequence and the results plotted as J vs. CTOD (Figure 6), it is possible to see that J-Integral and CTOD values maintain linear proportionality before splitting in all records, as well as after splitting in the corrected record, but does not maintain the original proportionality after splitting in the uncorrected records. As can be shown, an increasing in the load drop in the pop-ins caused by splitting increases the deviation of J-CTOD pairs from its original equivalence. As far as we can understand, that effect is caused by taking into account in J-Integral calculations a change in the system energy that is not associated to crack growth in the pre-cracking plane and that did not substantially affected the main crack length nor the crack tip opening displacement. The load drop in such a kind of pop-ins is clearly associated to the creation of a crack in a plane perpendicular to the main crack one. The proposed correction to load-displacement records

featuring instabilities by splitting resolves this issue, being J-Integral and CTOD values continuously equivalent. Obviously, small splits produced small load drops in the load-displacement records and the effect on the J-CTOD equivalence is much less perceptible, but always existent.

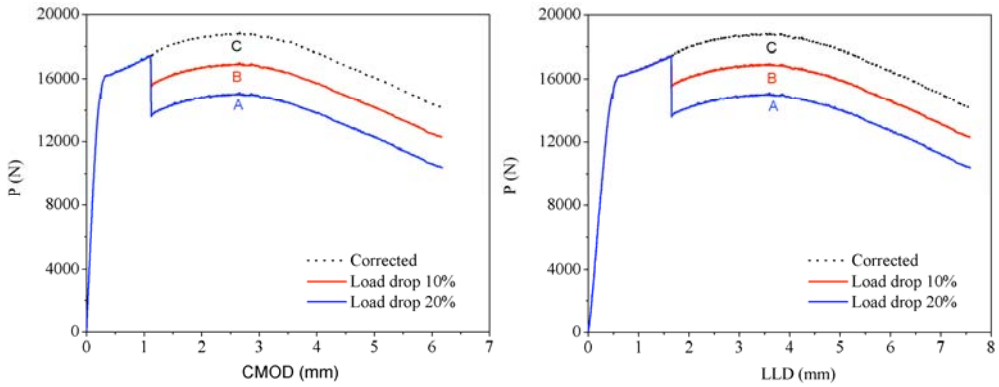

Figure 5. Semi-hypothetical P-CMOD and P-LLD records of a specimen of DH36 steel. The load drops at the instability were intentionally exaggerated.

Table 2. J-Integral and CTOD values calculated at points A, B, and C from the records shown in Figure 5.

Point	CTOD [mm]	J-Integral [J/mm^2]
A	0.623	513.33
B	0.624	546.27
C	0.628	590.63

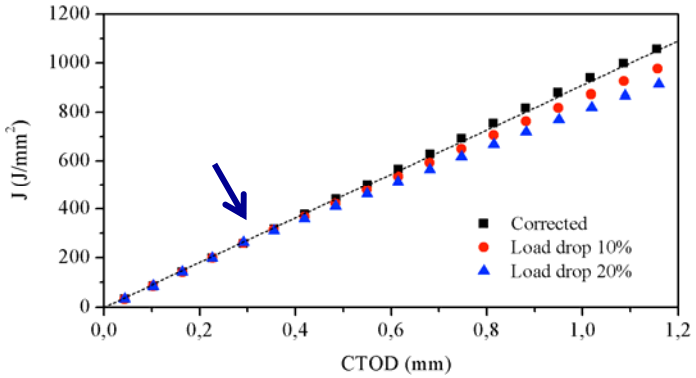

Figure 6. J-CTOD curves calculated from the records of Figure 5. The arrow indicates the position of splitting between the 5th and 6th unloading-reloading sequence.

The proposed correction of the load-displacement records has now been justified and the results of the whole experimental program will be now presented. When tested from room temperature to -30ºC the specimens of DH36 steel do not showed pop-ins. The specimens of this steel randomly showed pop-ins in the range from -40ºC to -58ºC. In all the cases the instabilities were associated to splitting. Almost 50% of the API X65 specimens showed splitting and mostly of API X70

specimens showed splitting at -20ºC. In most cases the splitting occurred before the attainment of maximum load plateau. Figures 7a, 7b and 7c show typical P-CMOD records with pop-ins of API X-65, API X-70 and DH36 steels, respectively (the unloading-reloading sequences of DH36 tests were removed from the records for clarity), as well as the corrected records. Figure 8 shows a comparison between the corrected records of Figure 7 and P-CMOD records of the same materials without split.

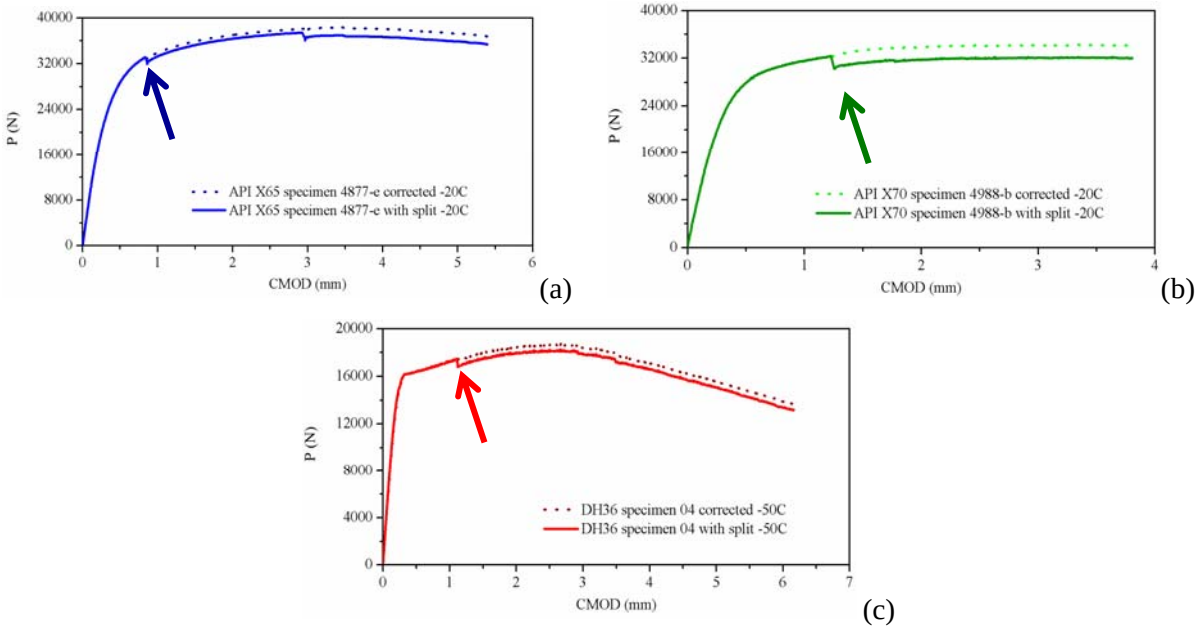

Figure 7. Original and corrected P-CMOD records of specimens featuring splitting. a) API X65, b) API X70, and c) DH36.

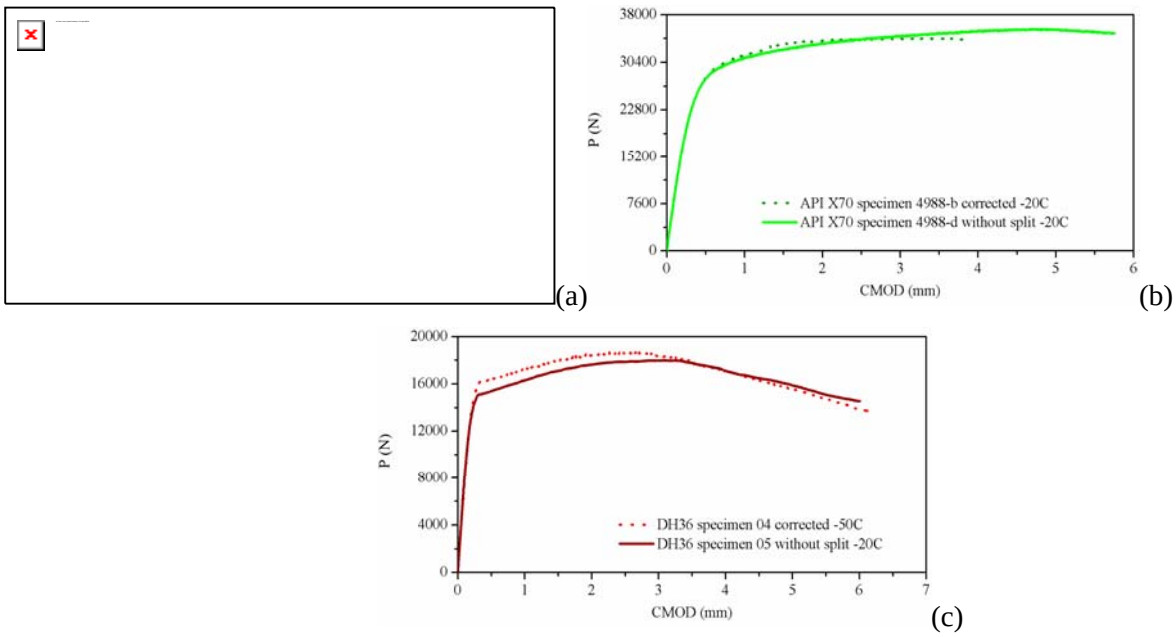

Figure 8. Corrected P-CMOD records and records from specimens of the same materials without splitting. a) API X65, b) API X70, and c) DH36.

Table 3 shows individual CTOD values of DH36 specimens calculated from the original and corrected P-CMOD records, as well as from specimens without splitting. Table 4 shows individual CTOD values of API X65 specimens, and Table 5 shows the same kind of data for API X70 specimens.

6006T 10	-20	Yes	0.791	--	0.910
6006T 11	-20	Yes	0.302	--	0.798

The mean and standard deviation of the different types of calculated CTOD are shown in Table 6, which also includes the minimum CTOD value of each set of specimens calculated according to the BS standard [5]. The mean values of DH36 steel were divided in two temperature ranges. One range going from room temperature to -30 ºC, in which no one of the specimens showed splitting, and another from -40 to -58 ºC.

Table 6. Minimum and mean CTOD values of the tested specimens.

Steel	Temp. (ºC)	Minimum CTOD (mm)	CTOD pop-in (mm)	CTOD max load (mm)	CTOD corrected (mm)
DH36	RT to -30	0.663	--	0.730 ±0.070	--
DH36	-40 to -58	0.248	0.531 ±0.194	0.746 ±0.030	0.688 ±0.088
API X65	-20	0.166	0.432 ±0.376	0.865 ±0.063	0.889 ±0.104
API X70	-20	0.254	0.523 ±0.299	0.951 ±0.216	0.867 ±0.159

A statistical analysis on the results of Table 6 using Student's t-tests [11] reveals, with 95% of confidence, that there is no statistical difference between CTOD values from corrected records and the CTOD values from specimens without splits. This result indicates that it could be possible to estimate the main crack fracture toughness of the analyzed steels from SE(B) specimen showing splitting, with reasonable accuracy. This was achieved through the proposed modification of the experimental records, based on the idea that the change in the system energy due to splitting is mainly associated to the creation of the split itself and can be neglected for the main crack toughness evaluation.

4. Conclusion

Based on the presented results and discussion it is possible to conclude:

Splitting in SE(B) specimens of DH36 steel did not influence the main crack length measured by the unloading compliance technique. As a result, the change in the system energy associated to the instability was totally related to the split creation itself.

The fracture toughness associated to the main crack of a specimen featuring splitting could be estimated, with reasonable accuracy, through the proposed correction of the original load-displacement records. The proposed correction consists in removing the load drop at instabilities associated to splitting.

J and CTOD values calculated from the modified records kept its equivalence along the entire test. When calculated from non-corrected load-displacement records of specimens featuring instabilities by splitting the J-CTOD equivalence deviates beyond the instability point.

The fracture toughness of SE(B) specimens of the same material showed no statistical differences when calculated from specimens featuring splitting and modified records or from specimens without splitting.

Abstract Damage mechanisms in a PolyAmide 6 semi-crystalline polymer were characterized by using Synchrotron Radiation Laminography technique on CT like specimen. Damage appeared as multiple penny shaped crazes. The maximum damage occurred at mid-thickness and located at a small distance from the notch root. An attempt was made to apply local approach of fracture concept thanks to finite element analysis using damage-based constitutive model. FE simulation successfully captured the aforementioned micro-mechanisms of crack initiation, by void coalescence. Further work is carried out to determine the crack dimension corresponding to the maximum net stress: the criterion being used for the global approach of fracture.

Keywords Polymers, X-ray laminography, Local approach of fracture, Finite element

1. Introduction

The use of fracture mechanics concepts for polymers is subjected to controversial discussions. It is often reported that many requirements are not fulfilled to obtain fracture mechanics characteristics such as the toughness. For instance, plane strain conditions together with tunneling effect (curved crack front), crack advance measurement, crack initiation/growth determination…are more difficult to obtain for polymers than in metallic materials. In the recent years, growing interest for X-ray tomography technique was observed. Indeed, this is a non destructive method allowing for construction of digital image in 3D. Therefore, virtual cuts and local observations of the microstructure can easily be carried out. The present contribution aims at highlighting the crack initiation concept from CT like specimen on a semi-crystalline polymer: PolyAmide 6 (PA6). The evolution of the microstructure during an increasing load could be observed thanks to laminography technique. The local coalescence of voids at mid-thickness was evidenced. The increase in macroscopic net stress was computed by Finite Element (FE) analysis, with a dedicated damage based model. The crack initiation criterion at macroscopic scale, based on the maximum net stress, was then assessed in terms of critical size of the principal damage within the microstructure.

2. Experimental procedure

2.1. Material - Specimen

The material of interest is a PolyAmide 6 (PA6) [1], selected among several semi-crystalline polymers. Indeed, for this polymer void morphology and distribution were already studied [2] for axi-symmetrically notched specimens, together with a dedicated constitutive model for FE analysis. In the present work, the approach consisted of application of the local approach of fracture which takes the damage evolution in the microstructure into account. Here a novel technique, known as laminography is utilized [3]. The method takes advantage of the Synchrotron Radiation Tomography (non destructive and 3D reconstructed images) but applied to plate like specimen. In situ test is carried out on CT like specimen. The geometry is described in fig.1a. The specific dimensions were: thickness B = 2mm, width W = 40mm, crack depth ratio a/W = 0.5, notch root

radius ρ = 250µm, half height H/2 = 20mm. For the following FEA (section 3), figs.1b-c respectively illustrate the CT specimen overall meshing and refined meshes (25µm) in the vicinity of the crack tip.

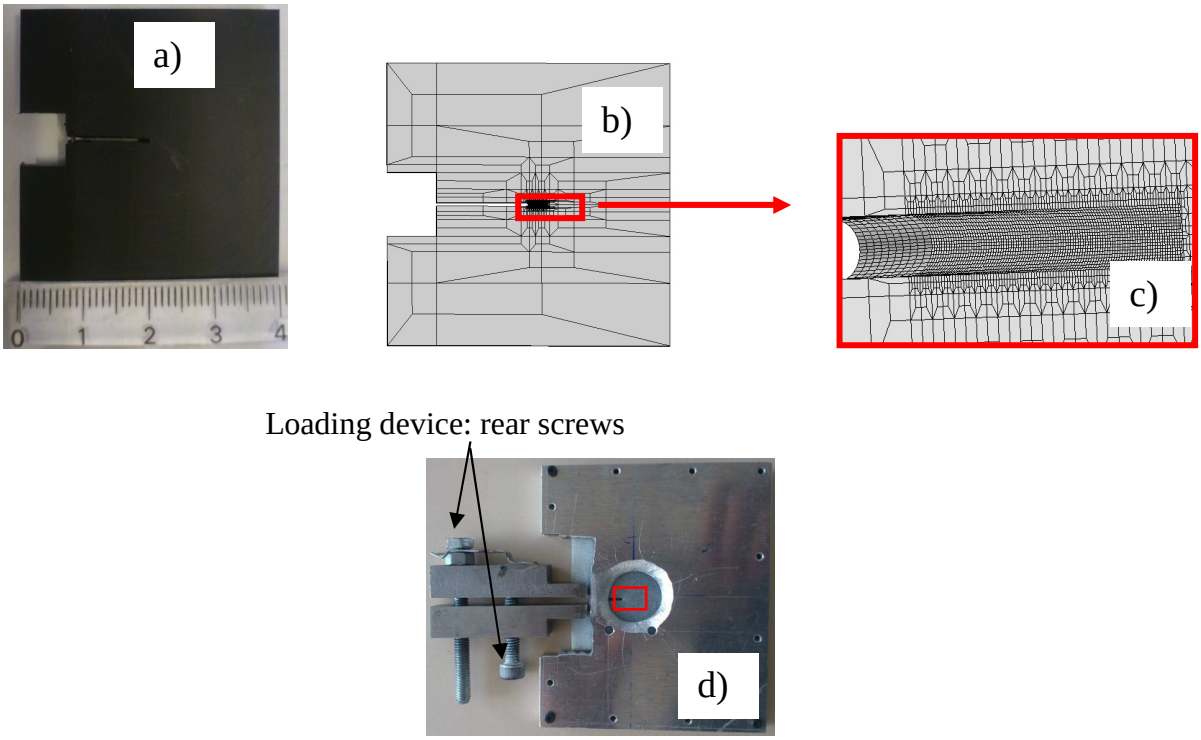

Figure 1. CT specimen geometry with the experimental setup: a) CT specimen sketch; b) Overall view of the sample meshing; c) Fine meshing near the notch root (mesh size 25µm); d) Experimental setup.

The experimental setup is presented in fig.1d. The CT specimen was inserted between two aluminum plates to avoid buckling in the compressive part of the remaining ligament. The opening displacement is applied thanks to the turns of both rear screws. A circular window was designed within the anti-buckling aluminum system allowing for inspection of the region near the notch root, at the macroscopic scale (pictures), as well as at the microscopic scale (laminography scans).

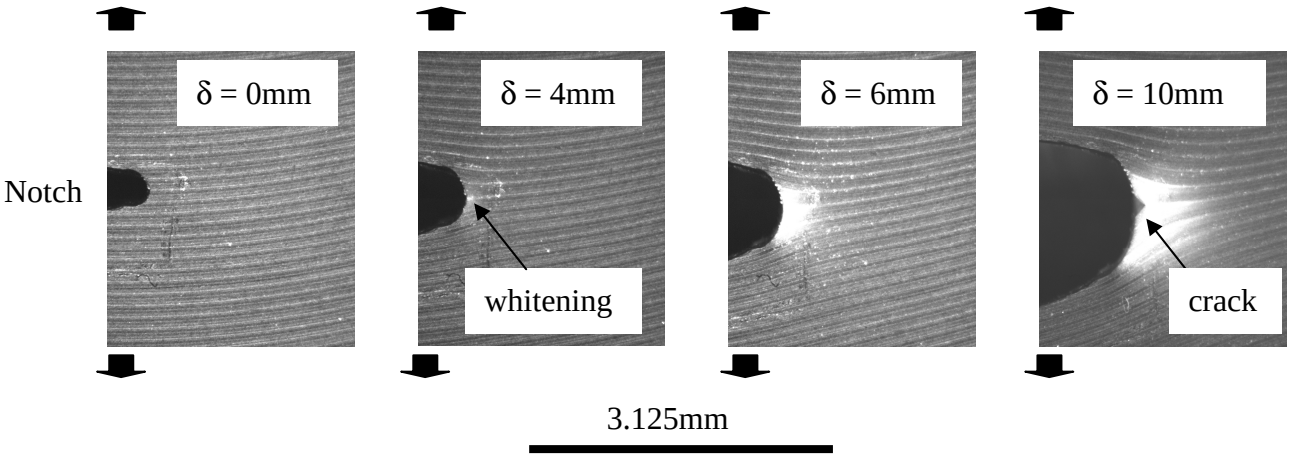

Figure 2. Evolution of the geometry observed at the external face of the CT specimen. Black arrows indicate the loading direction.

Stepwise loading was applied between laminography observations. Fig.2 shows a series of pictures made at the side view of the specimen before the laminography scans. The corresponding applied displacement δ is indicated in each viewgraph, starting from the initial material without any deformation, up to δ = 10 mm. For this latter, a crack is visible at the external surface of the sample. For δ = 4mm, a localized whitening at the notch root is observed. Being the first event appearing at the surface, it was considered that this corresponded to an internal crack initiation. For δ = 6mm, whitening is spreading out, surrounding the notch root. It should be mentioned that no scan was done between δ = 6mm and 10mm. Moreover, the present experimental setup was not equipped with a load cell. The load level was therefore estimated by using FEA with a dedicated constitutive model.

2.2. Laminography technique

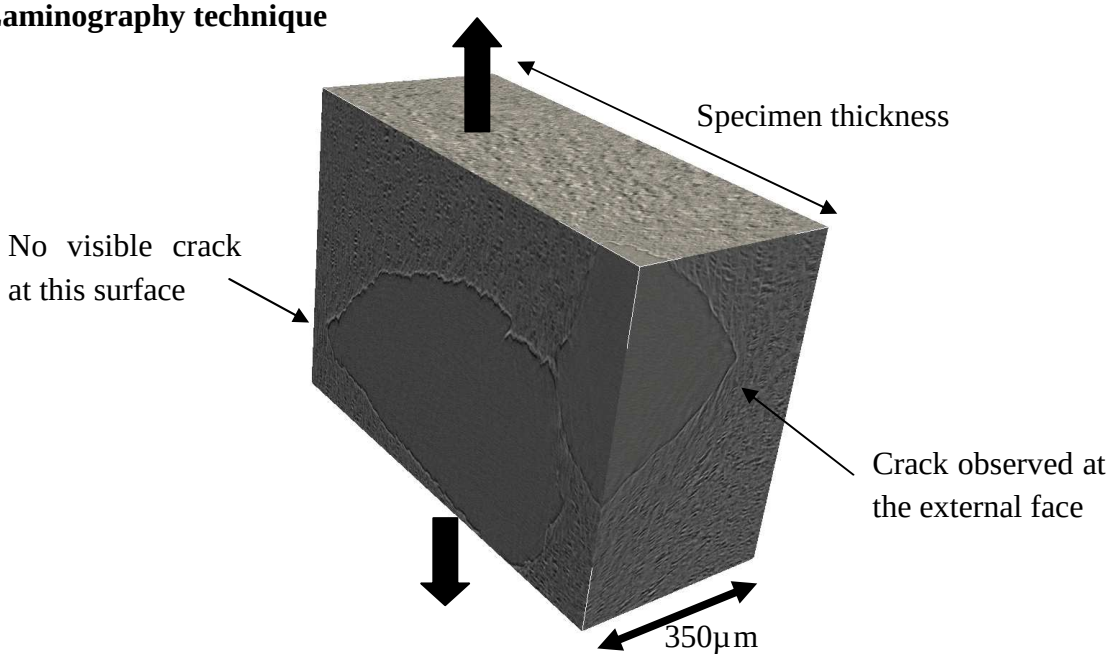

Figure 3. Volume corresponding to δ = 10mm: two cracks through the thickness

Synchrotron Radiation Laminography (SRL) technique is detailed elsewhere [3]. It has already been applied on both metallic and laminate composite materials. To the authors' best knowledge, it is the first time that this technique is utilized for semi-crystalline polymer investigations. To this end, for each value of the applied opening displacement δ the whole experimental setup (fig.1c) was mounted on adapted sample support of the laminography device at the ID19 beamline of the European Synchrotron Radiation Facility (ESRF) in Grenoble (France). The scanned volume was about 1 mm^3, with a voxel size of 0.7µm. Fig.3 shows a trough thickness microstructure around the crack tip in 3D. Apart from multiple crazes observed within the whole volume, two large cracks were evidenced. One of them appeared at the surface (fig.2, δ = 10 mm) whereas the opposite face did not show any crack. Attention is now paid on the scans corresponding to δ = 4mm and δ = 6mm to observe the microstructure, especially at mid-thickness.

Fig.4 illustrates such views in 3D where the plane at mid-thickness is shown in forefront. Multiple penny shaped crazes [2, 4] were observed around the notch root. These features could be linked to the whitening observed at the macroscopic scale.

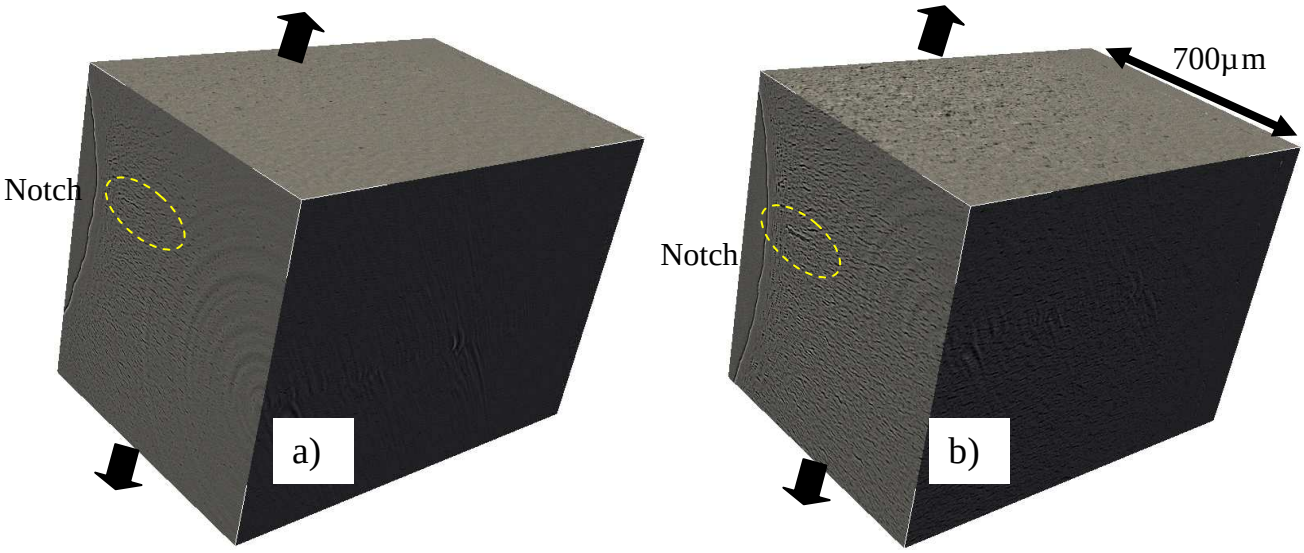

Figure 4. Observations at mid-thickness plane: a) δ = 4mm; b) δ = 6mm

A significant damage, surrounded by the dashed lines was evidenced at mid-thickness, located at a small distance (~100µm) from the initial notch root.

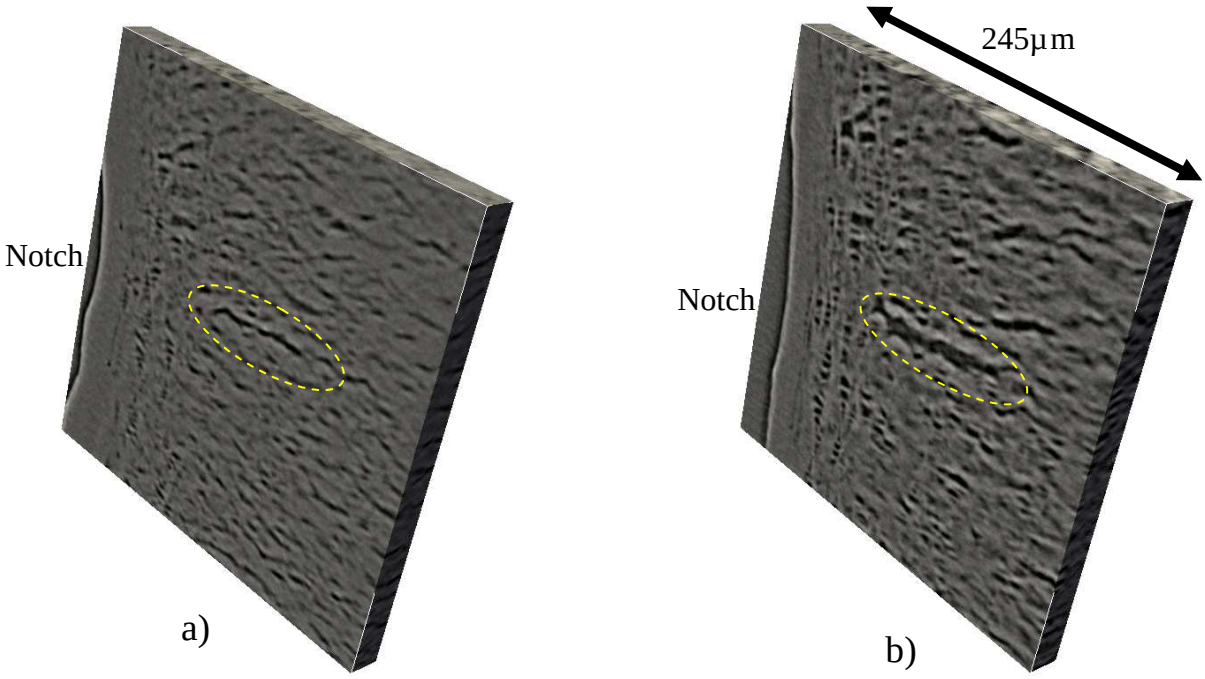

Figure 5. Maximum damage at mid-thickness surrounded by dashed lines: a) δ = 4mm; b) δ = 6mm

Fig.5 details the morphology and the size of this damage. To this end, a 19µm thick slice of PA6 scan was extracted and analyzed for both δ values. It was observed that the damage consisted of crazes (presence of fibrils within the voids) aligned (coalesced) following the crack remaining ligament plane. This damage increased in height from δ =4mm to 6mm. Its average values of the characteristic dimensions were summarized in Table 1.

Table 1. Characteristic dimensions of the damage located at mid-thickness

	δ = 4mm	δ = 6mm
Length	60µm	90µm
Height	5µm	10µm
Width	20µm	30µm

3. Finite element modeling

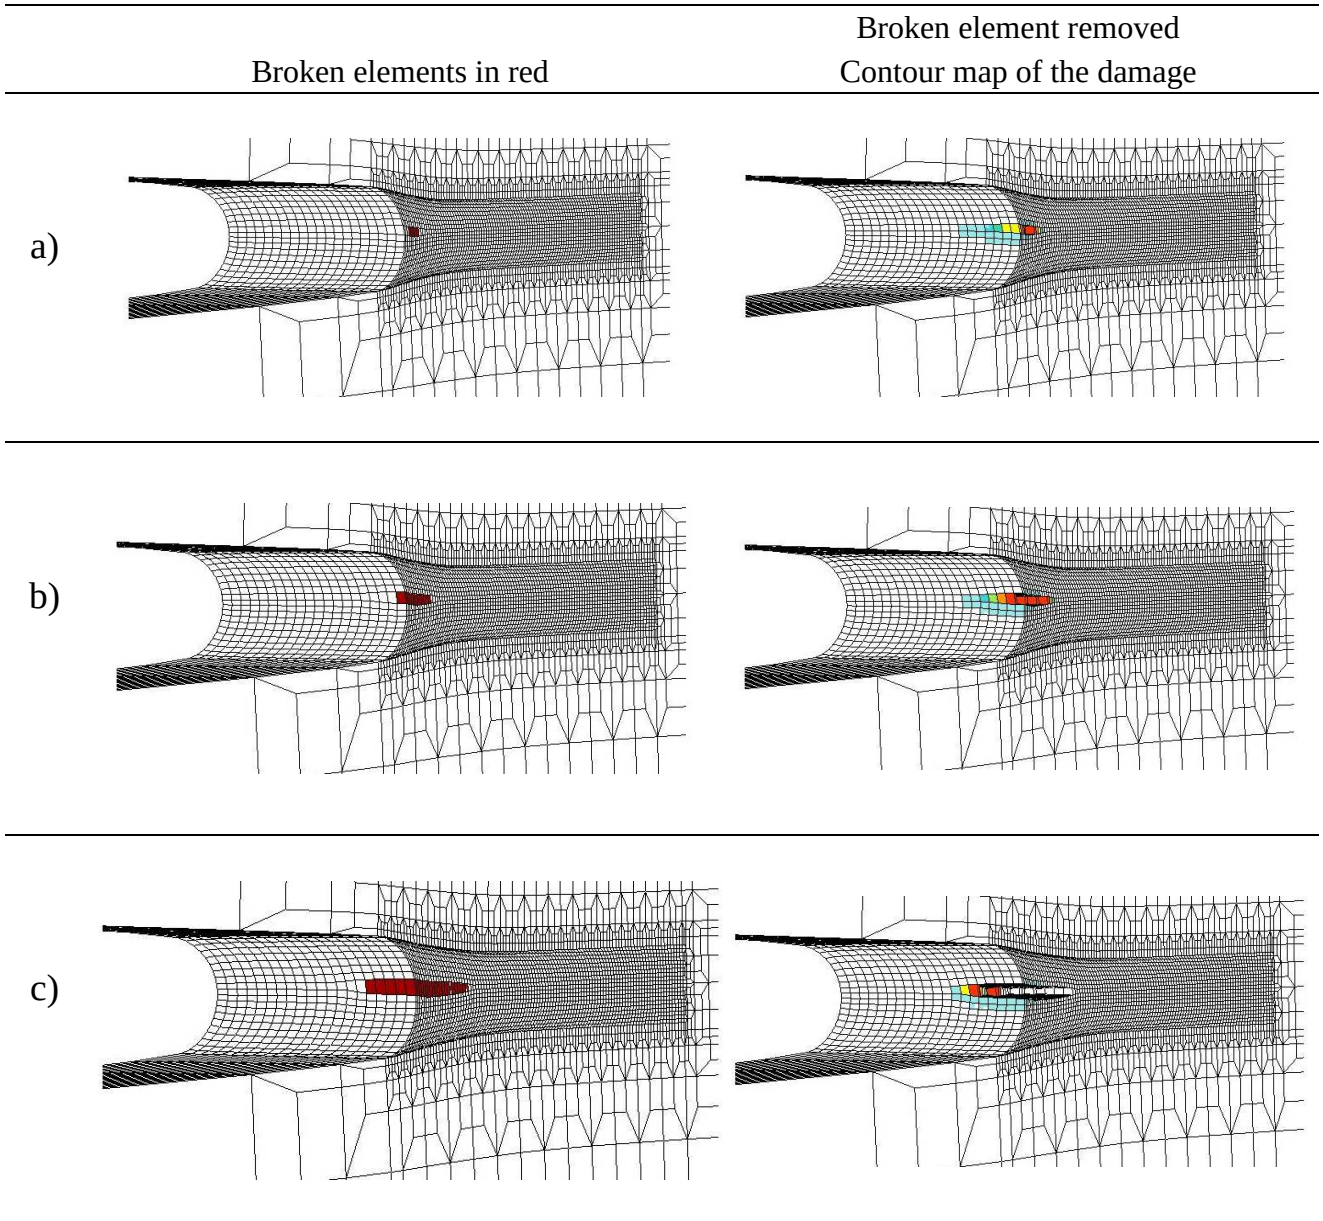

Figure 6. FE simulations of the crack initiation by using damage based constitutive model.

The local approach of fracture requires FE computation with a damage based constitutive model to better assess the stress/strain tensors distribution within the material. For the PA6 under study, a multi-mechanisms model was proposed [5-6] where the void volume fraction is considered as an internal variable. By using the same damage based model, simulation of laminography CT test was

carried out. A procedure of “kill/remove element” was applied when a critical porosity value was reached within this element. The following analyses focus on the refined meshes (fig. 1c) in the vicinity of the notch root. Constant mesh size of 25µm was set for 2.5mm along the ligament.

Fig.6 summarizes the evolution of damage (broken element) during the increasing load. The forefront face corresponds to the plane at mid-thickness. The first column of deformed meshes shows the broken elements in red. The second column illustrates the contour map of the void volume fraction over the deformed mesh where the broken elements were removed.
Fig.6a shows that four elements simultaneously broke for the first time (length ~100µm; width ~25µm). They appeared at mid-thickness and located at 3 elements away from the notch root (distance ~75µm). These characteristic values correspond to those of δ = 6mm. Fig.6b indicates that broken elements propagate into two opposite directions: ahead of and back to the notch root. The width seems to remain constant (one element size). Fig.6c evidences that the broken elements propagates through the thickness as well, but did not reach the external surface. These latter steps were not observed with SRL technique since no scan was done between δ = 6mm and δ = 10mm when the crack appeared at the external face. However, although fine tuning of damage parameters is still ongoing, these figures demonstrate that the FE analysis with the damage based model was able to reproduce the micro-mechanisms of crack initiation. At present time, computation is still running to obtain the configuration where the crack reaches the external surface.
Next investigation consists of using FE modelling to estimate the load evolution during the crack propagation. The aim is to determine the crack size allowing the crack initiation criterion at the macroscopic scale to be reached (maximum load). To this end, in fig.7 the load divided by the net section of the remaining ligament is plotted as a function of the applied opening displacement.

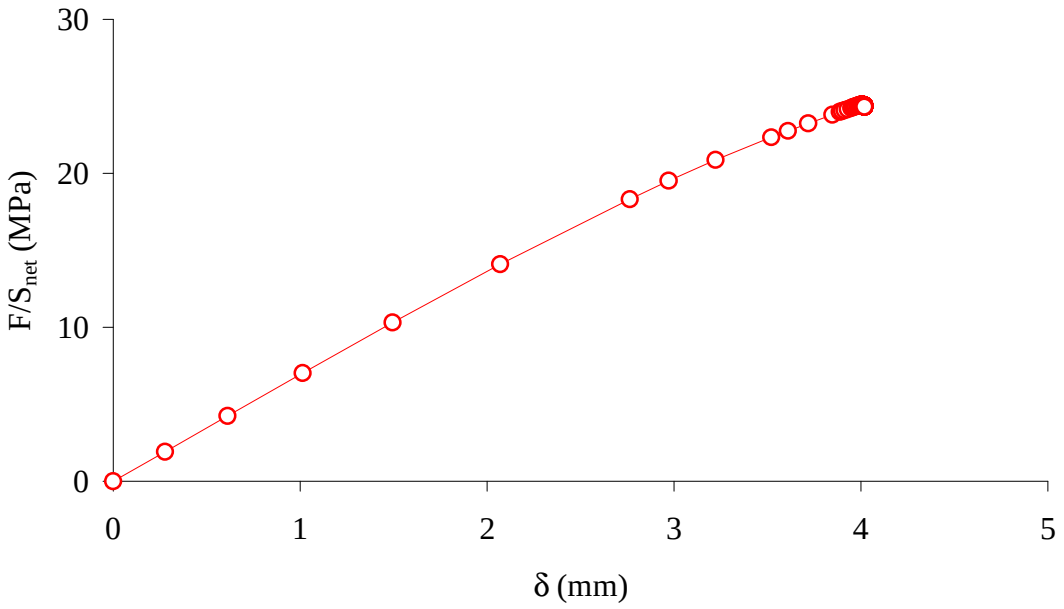

Figure 7. Net stress as a function of the opening displacement by FE analysis

Contour maps presented in fig.6 correspond to the last loading steps of the numerical simulations ($\delta \geq$ 4mm). The first results shown at this stage indicate that although a non linearity appears in the last part of the plot (fig.7), the net stress is still increasing. The maximum net stress is not yet reached. Final results will be shown later.

5. Conclusion

The micro-mechanisms of damage and crack initiation were investigated thanks to Synchrotron Radiation Laminography (SRL) technique. In situ tests were carried out on CT-like specimen. The local coalescence of voids leading to crack initiation occured at mid-thickness of the specimen located at a small distance from the initial notch root. Finite Element analysis, with a damage based constitutive model was able to capture the location of the crack initiation, as well as the damage mechanisms observed by SRL. The evolution of the macroscopic net stress was also computed by FEA. At present time, the crack initiation criterion based on the maximum net stress has not still been reached. Computation is still ongoing to compare this criterion with the critical size of the crack at the microscopic scale.

Abstract In this paper micro-scale testing techniques have been implemented on two types of quasi-brittle material: pile grade A (PGA) graphite and air-plasma sprayed yttria (7 wt.%) stabilized zirconia (APS-YSZ). One approach uses a force measurement system within a FEI Helios Dualbeam FIB/SEM workstation, which allows the fracture characteristics and mechanical properties of the two materials to be evaluated and correlated with local microstructural features. In addition for PGA graphite, disc-compression and trench-probe methods have been applied. Hence the initiation, propagation of the cracks and the corresponding deformation can be recorded and investigated. For the APS-YSZ, micro-scale cantilevers have been fabricated using FIB and a load-recording probe has been applied in-situ. The fracture toughness, flexural strength and the cracking path are analysed. Interpretation of these tests has contributed to the understanding of the macro-scale quasi-brittle mechanical behaviour of the two materials.

Keywords Pile grade A graphite, Air-plasma-sprayed yttria stabilized zirconia, Disc compression, Micro-scale cantilever testing

1. Introduction

Pile Grade A (PGA) graphite used for a wide range of applications, including nuclear reactor core, is often cited as a classic example of a brittle material because failure, in tension, is associated with small strains. It has been recognised that these graphites are multiphase, polygranular, aggregate structures and have features similar to other aggregate materials such as concrete [1, 2]. However, attempts to characterise the fracture behaviour of graphite by linear elastic fracture mechanics methods have been largely unsuccessful. Observations of graphite fracture show that elastic strain energy may be dissipated by the formation of distributed micro-cracks and their formation may be responsible for non-linearity in the rising load-displacement curve [3, 4]. A typical example is shown by the load-displacement response for bend geometry specimens, Fig. 1. There is no evidence that polygranular, aggregate graphites can be plastically deformed. Hence, the change in compliance together with any deviation from an initial linear shape of the load-displacement curve, Region II in Fig. 1, can be attributed to micro-cracking. Progressive softening is also observed in some specimens post the peak load, Region III. This type of load-displacement behaviour is a characteristic of quasi-brittle materials [2]. Air-plasma-sprayed (APS) yttria (7 wt.%) stabilized zirconia (YSZ) has been applied widely in thermal barrier coating systems (TBC) to isolate metallic components from the high temperature environmental gas in crucial parts of engines. APS produces TBC with a splat microstructure, moderate porosity and compliance, and low thermal conductivity. For example, APS-YSZ coatings on turbine blades are normally 150 to 300 μm thick sustaining a temperature difference up to 300 °C. Due to manufacturing, the APS-YSZ splat microstructure contains defects, pores and unmelted particles. These internal microstructures result in non-linear brittle behaviour of the coatings.

To understand the macro-scale mechanical behaviour of these types of quasi-brittle materials, micro-scale testing samples an appropriate small volume of material and localised microstructure to characterise initiation and propagation of micro-cracks. This paper considers micro-scale tests undertaken by the research group at the University of Bristol, UK [2, 4-6].

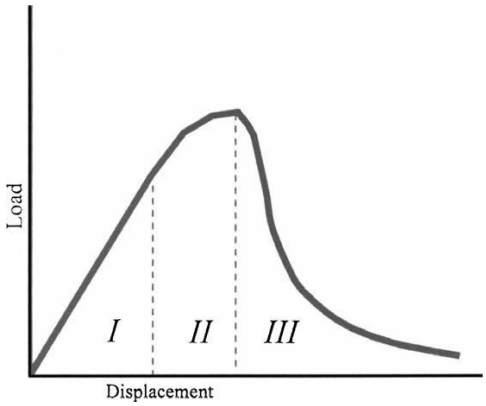

Fig.1 A characteristic bend geometry load-displacement curve for a quasi-brittle material, region I is linear, region II is non-linear, region III is post peak softening.

2. Experiments

2.1. Materials

Cylindrical PGA test specimens were made by trepanning 12 mm diameter rods extracted from bulk virgin PGA graphite reactor core bricks. These were sliced into 6 mm thick cylinders using a South Bay Technology Inc. Model 650 low speed diamond wheel saw with deionised water as coolant. The diamond saw produced smooth high-quality surfaces suitable for subsequent microscopic examination. The brick extrusion direction was diametrically across the flat surfaces of the cut cylinders. The extrusion direction was marked on the edges of the cylinders for reference during compression testing.

For testing of APS-YSZ specimens, samples manufactured by Praxair Surface Technologies Ltd with a curved geometry designed to simulate key features of coated blade were used. Each comprised a Superalloy substrate (CMSX4) with air plasma sprayed (APS) 7 wt.% Y_2O_3-stabilised ZrO_2 (YSZ) applied onto an Amdry 995 bond coat deposited using high velocity oxygen fuel (HVOF) [7]. The thickness of the TBC varied with position around the specimen from 130 µm to 230 µm. A typical cross-section of the TBC system is shown in Fig. 2a. The YSZ which is ~200 µm thick comprises lameller splats, micro-scale air pores and defects. The interfaces, YSZ-TBC/TGO and TGO/BC, are undulating with a variable thickness of TGO. In this present work, the focus was on the APS-YSZ material in as-coated condition, and the specimens are tapered to reveal the interfaces, Fig. 2b. Micro-cantilever specimens with the size of ~2×2×10 µm are created at preferred locations of this coating as shown in Fig. 2b.

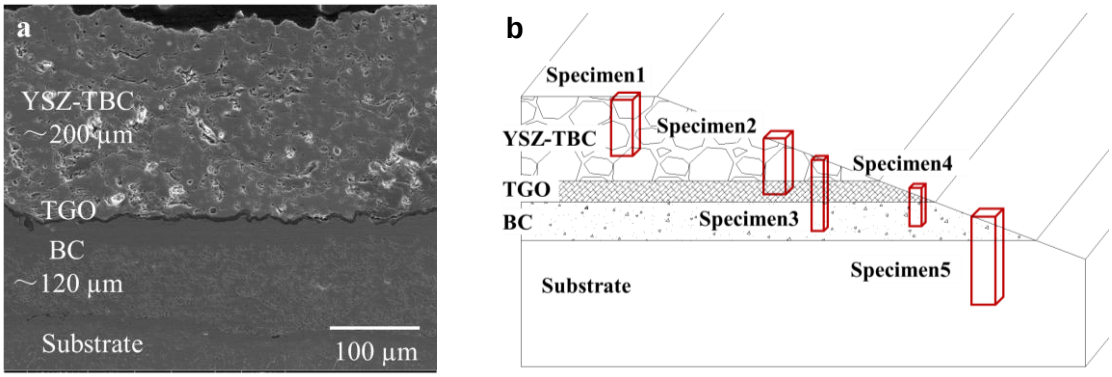

Fig. 2 The TBC system (a) typical cross-section for specimen that has been oxidised for 100 hours at 925°C and (b) creation of micro-cantilever specimen at preferred locations on tapered surface.

2.2 Testing methods

Controlled cracking was introduced in the quasi-brittle specimens using appropriate methods. Each method allowed specimens to be subsequently examined under load.

2.2.1 Disc compression method

Compression testing of the cylindrical graphite specimens was done using a Deben compression/tensile stage (MicroTest 2000 model, Gatan Ltd., Abingdon, Oxon, UK), Fig. 3. The unit is capable of operation externally or within a scanning electron microscope or focused ion beam (FIB) workstation. The stage can be operated at compression speeds of between 0.033 and 0.4 mm/min, with a load cell giving force measurements up to a maximum of 2 kN. The cylindrical graphite specimens were loaded into the compression tester such that the direction of the compressive load was along a diameter of the flat face of the cylinders, chosen here to be the extrusion direction of the graphite. This provided a tensile load normal to the direction of the applied load so that cracks would be induced in the plane parallel to the load direction. Load-displacement curves were recorded whilst observing the surface of the specimen by optical microscopy or focused ion beam imaging.

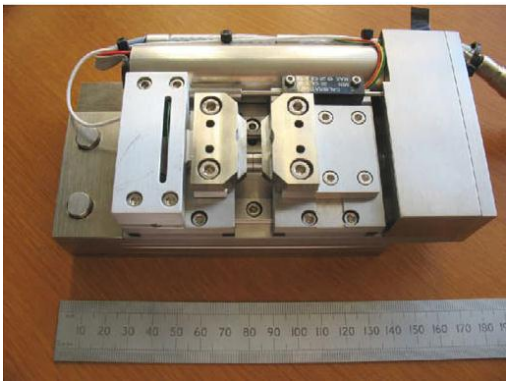

Fig. 3 Compression tester applied in micro-scale mechanical testing.

2.2.2 Trench-probe loading method

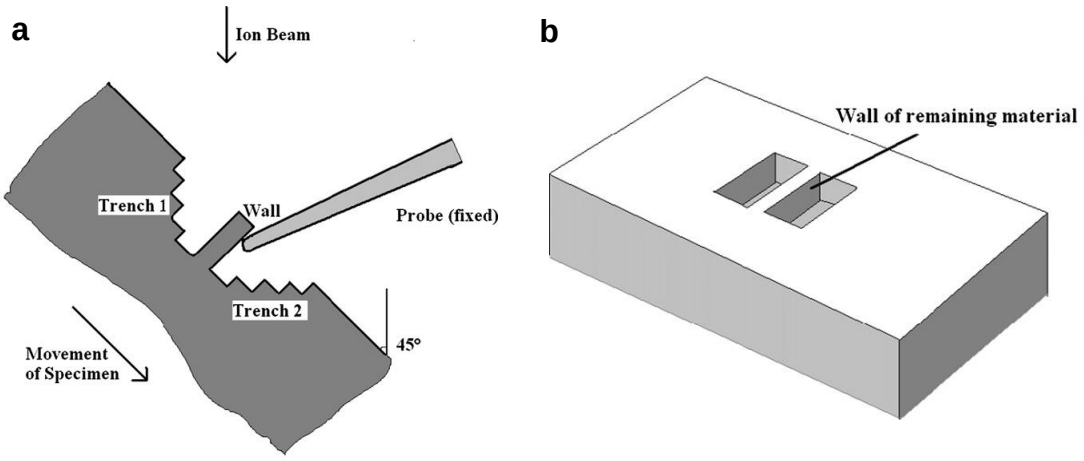

Fig. 4 (a) Schematic of the trench-probe method for applying a force to a prepared wall of material 35 μm long within the FIB; (b) the thin wall of residual materials created between the two trenches.

The trench-probe method provided a means of applying a small, progressive, localised force to a prepared region of a ‘wall’ specimen of graphite whilst it was under observation in the FIB workstation, Fig. 4. For this, a sharpened steel probe (tip radius 5 μm approximately) was attached to the end of a spare gas injector on the instrument. The retractable probe was aligned to be in the centre of the field of view, so that it could be used to push on a prepared part of the specimen, Fig. 4a. Local deformation and cracking could be studied at high resolution within chosen regions of a specimen, Fig. 4b.

2.2.3 Micro-cantilever beam bending method

The experimental arrangement for the mechanical property testing was a combination of a FEI Helios NanoLab 600i Dualbeam workstation and a compact force measurement system supplied by Kleindiek which allowed in-situ loading and force readout, Fig. 5a. The dualbeam workstation provided ion beam milling and in-situ SEM imaging. Before commencing the measurements, a calibration of the force sensor was carried out by loading a standard spring embedded in the system to provide the resistance conversion references and zero the load reading. Details of the force measurement system and the cantilever specimen preparation are described elsewhere [8, 9]. A typical set up of in-situ loading of a cantilever beam using the force measurement probe is shown in Fig. 5b.

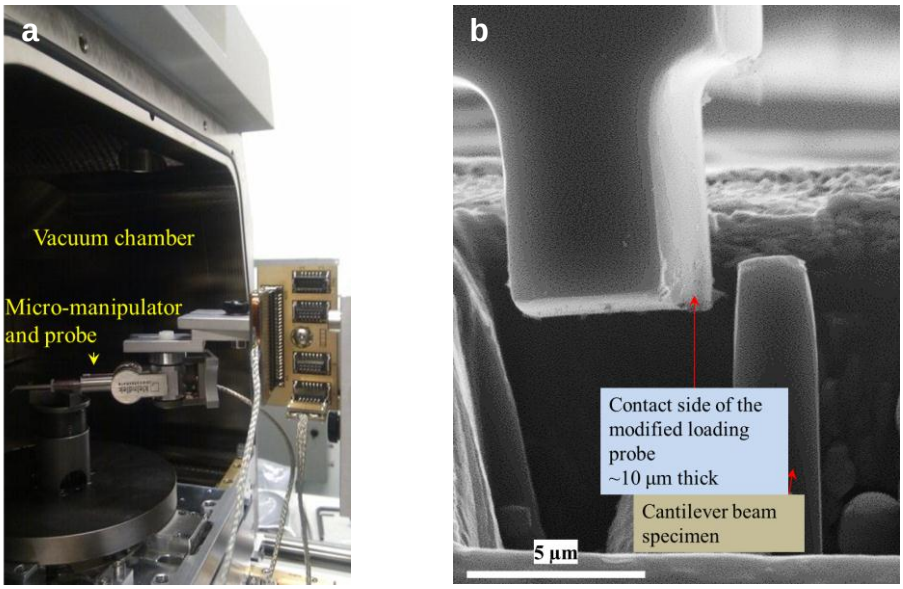

Fig. 5 (a) Installation of the FMS into the dualbeam FIB vacuum chamber. Side-view showing the FMS in the middle of the stage (b) SEM image showing loading the micro-cantilever specimen.

3. Results

3.1 Load and displacement

3.1.1 PGA graphite in compression

PGA graphite has a complex structure of filler particles interspersed within a matrix which consists of small flour particles and the graphitised pitch together with porosity. When examined at high resolution in the FIB, the two areas have very distinct microstructures. Filler particles (Fig. 6a left hand side) are solid with isolated shrinkage (Mrozowski) cracks. The matrix areas (Fig. 6a right hand side) are dominated by the presence of lamellar graphite. This is believed to be the graphite residue of the mesophase produced during the graphitisation of the pitch. Serial sections of the

region shown in Fig. 6a and in other similar areas reveal that the porosity in such regions is interconnected.

The load-displacement curve resulting from compression of a cylindrical PGA specimen is shown in Fig. 6b. Compression proceeded at a rate of 0.1 mm/min. Displacement and load measurements were recorded at 500 ms intervals. The initial region, up to 0.1 mm displacement, had a relatively low slope, characteristic of a ‘‘bedding-in” region in which the specimen accommodated to the compression clamps. A linear region was observed between 0.2 and 0.3 mm displacement, in which elastic deformation occurred. Beyond this point the curve became non-linear with a gradually reducing compliance, until peak force was reached. After the maximum force, failure was gradual with force reducing slowly with displacement.

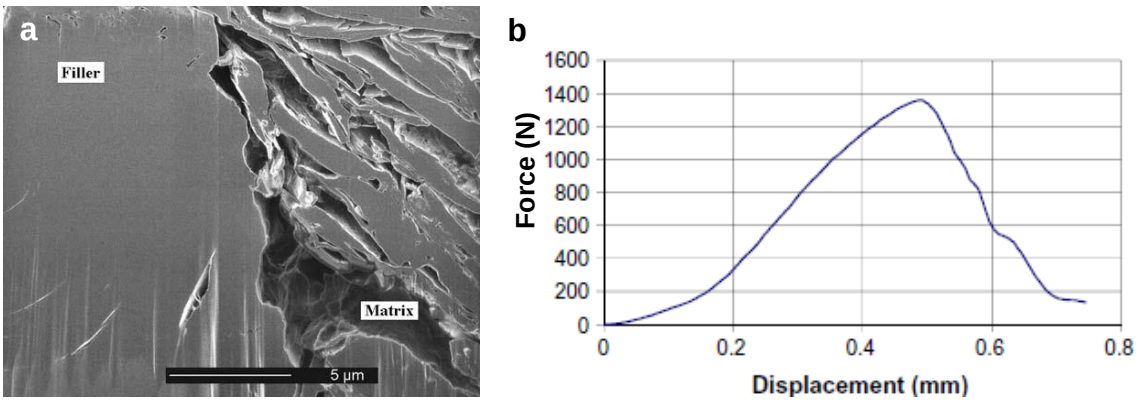

Fig. 6 (a) Microstructure of virgin PGA graphite revealed by FIB sectioning and imaging; (b) Load-displacement curve from compression of a cylindrical PGA specimen.

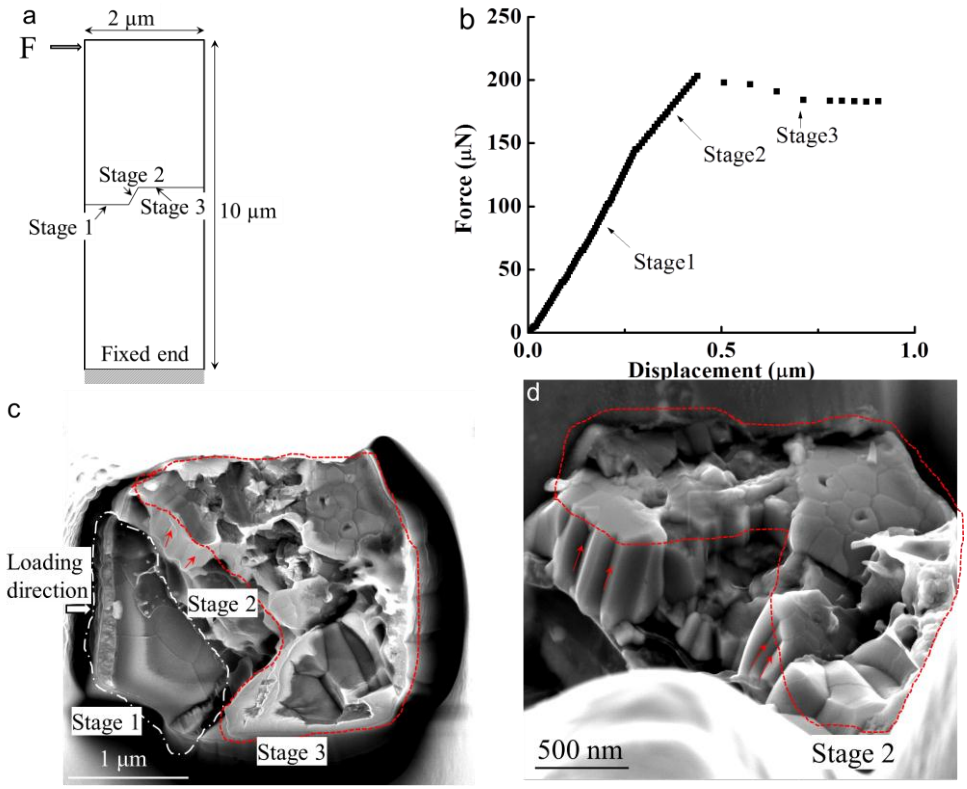

Fig. 7 A cantilever specimen containing a surface breaking flaw. (a) Schematic of the loaded specimen. (b) Force-deflection curve. (c) Surface of brittle fracture (the arrow indicates the load direction). (d) Side view of the fractured surface revealing vertical steps along the grains [6].

3.1.2 APS-YSZ in bending

In the case of a typical cantilever specimen, the force-deflection curve, Fig. 7b, containd three distinct stages 1 to 3. During stage 1 there was elastic deflection and at the end of this stage (~150 μN) the gradient changed. Stage 2 reached a maximum at ~200 μN. This was followed by a period of stable deflection as cracks propagated during stage 3. Examination of the final fracture surface, Fig. 7c, revealed the initial pre-existing flaw. There was evidence for some crack extension during stage 2 and then mainly inter-granular brittle fracture in stage 3, Fig. 7d. The elastic modulus calculated from the first linear part of the loading curve gave a value of ~35±5 GPa which is within the range of macroscopic values of 10 to 100 GPa [10-13]. Fracture toughness can be derived from the maximum load to be ~ 5.30 MPa·$m^{1/2}$ which is at the higher end of the macroscopic range of values, 0.7 to 5 MPa·$m^{1/2}$ [14-16].

3.2 Crack initiation and propagation

3.2.1 Disc compression

The compression method was used on a PGA graphite specimen within the FIB work station. Compression proceeded until fine cracking was observed at a pre-peak load at the top surface of the specimen. Sites were then chosen for FIB trenching, generally at positions across the observed cracks close to the crack tip, or ahead of the crack tip. The specimen was then tilted to 45° for high-resolution imaging of the cut face to observe sub-surface detail. Compression was resumed, increasing the load by small increments, realigning the specimen to centre the region of interest in the field of view and recording images. Force increments of 40 N were used and FIB images were captured at 8000× magnification, giving a horizontal field of view of 38 μm. Fig. 8 shows, optical images Fig. 8a and b and FIB images Fig. 8c and d, of the cut face of the specimen at compression loads of: (c) 497 N, and (d) 830 N respectively. The arrows in Figs. 8c and d mark the position of a crack forming and developing in the bulk of the graphite, within a filler particle. After crack formation, the two halves slide across each other.

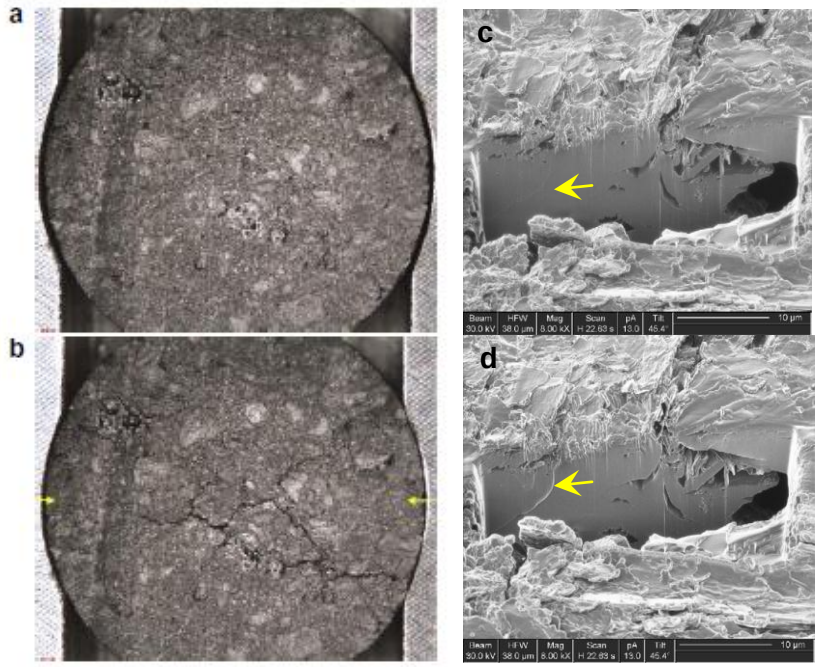

Fig. 8 Optical image of PGA specimen: (a) before compression and (b) after 0.55 mm compressive displacement showing macro-cracking (displacement is horizontal, as shown by arrows). FIB images of PGA specimen under (c) 560 N and (d) 830 N compression. Arrows show developing micro-crack.

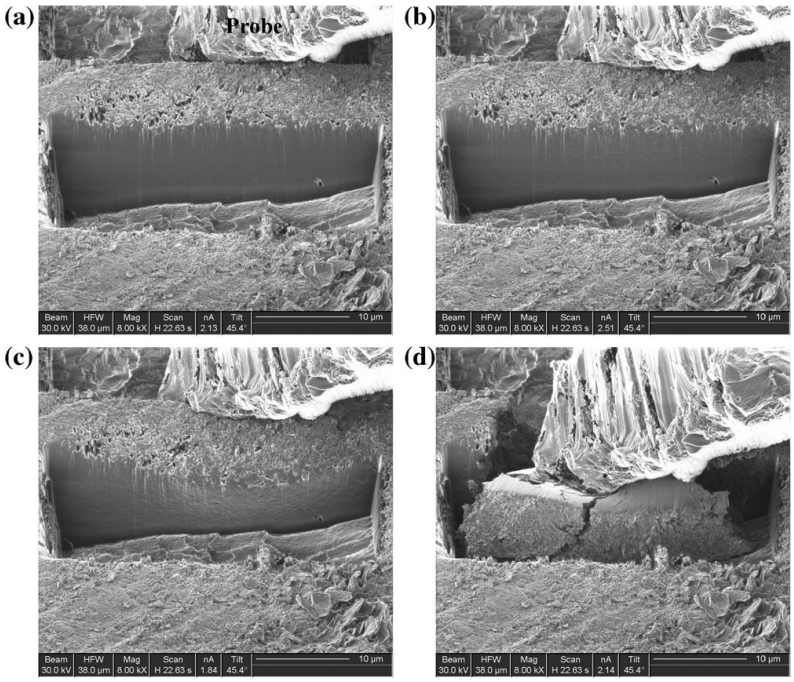

Fig. 9 Deformation of virgin PGA graphite filler using the trench-probe method. (a) Prior to loading (probe marked). (b) Showing onset of texturing. (c) Just prior to failure. (d) Just after failure.

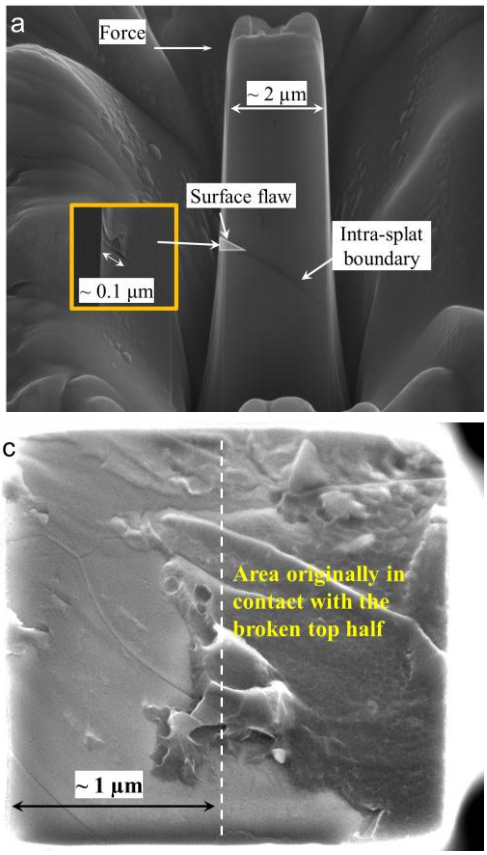
3.2.3 Trench probe method

The trench-probe method was used to study the cracking of the individual components of the graphite microstructure such as filler particles or matrix. The method was used first on a virgin PGA specimen. Fig. 9 shows a sequence of FIB images of a region containing a filler particle recorded during testing. Fine undulations appeared at the cut surface of the specimen as it deformed, Fig. 9b, similar to those previously observed in deformed graphite. Failure occurred suddenly after considerable deformation, Fig. 9c, and the rapid movement of the probe at failure indicated that significant energy had been stored in the probe during deformation, which was released upon failure. In this case cracks formed at the mid position and ends of the loaded wall micro-specimen, Fig. 9d. The crack path was irregular and branched. Further measurements were undertaken on radiolytically oxidised PGA where twinning was observed and the cracking pattern was modified by the increase porosity within the material [5].

3.2.4 Micro-scale cantilever bending

Fig. 10a showed a typical cantilever beam created in APS-YSZ with a pre-existed external flaw (~0.1 μm) which is visible at one end of the splat boundary. The top of the beam is ~2 μm × 2 μm and a slight taper is present so that the base of the beam is ~2.2 μm × 2.2 μm. The force-deflection curve is shown in Fig. 10b and fracture occurred when the force reached ~301 μN. The fractured surface revealed an amorphous phase at the splat boundary which was in contact with the upper half of the beam before fracture, Fig. 10c. A detailed check of the fractured surface gave an equivalent crack area of 2 μm ×1 μm. In this figure, the large grains of YSZ (~0.8 μm in length) could be observed which were different from the upper side of the beam, where there were grains of sub-micrometre size. The tensile stress at fracture was ~3.6 GPa, and the elastic modulus of this particular beam was calculated to be ~43 GPa [6].



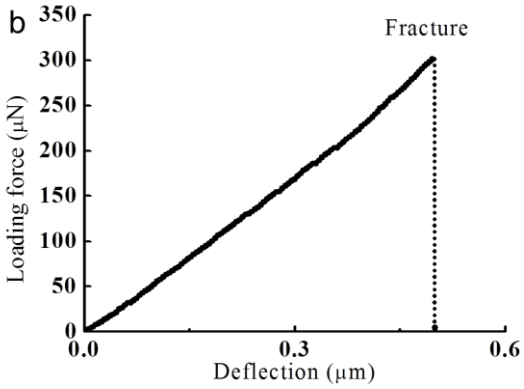


Fig. 10 A specimen created within APS-TBC. (a) Dimensions and a pre-existing flaw on the side of the cantilever with a size of ~0.1 µm as shown in insert. (b) Force-deflection curve. (c) Microstructure, dimensions of the fractured surface and the area which was in contact with the top half of the cantilever.

4. Discussion

Despite the widespread use of polygranular graphite for example for the construction of the gas cooled reactor cores in the UK reactor plant, there remain issues relating to the detailed understanding of the fracture processes at the micro-scale. Similar issues are associated with APS-YSZ as thermal barrier coatings. Here, the range of mechanical test methods assisted with understanding of the micro-scale mechanical fracture behaviour of these quasi-brittle materials.

The load-displacement curve, Fig. 6b, obtained for the compression disc test showed initial 'bedding' of the specimen to a load of about 300 N. There followed a short linear range where the material behaved elastically, prior to the onset of non-linearity. The ion milled section sequence, Figs. 8c and d, showed that as the load was increased to 560 N, Fig. 8c, a micro-crack formed and the feature became enhanced when the load reached 830 N, Fig. 8d. This sequence provides evidence that micro-cracks initiate and propagate prior to peak load to accommodate specimen displacement. At peak load and beyond, micro-cracks link to form the dominant macro-cracks shown in Fig. 6. Moreover Figs. 9a and 9b provided limited evidence for micro-cracking on the flank of a macro-crack. When interrupted post peak load, Figs. 9c and 9d showed that the macro-cracks follow an irregular path similar to that observed previously in the flexural test specimens of fractured un-irradiated PGA graphite [4]. The macro-cracks follow a path dominated by the direction of the applied tensile stress and the microstructure.

Two novel test procedures have been adopted to load graphite specimens combined with high-resolution imaging to investigate further the micro-cracking pre-peak load and macrocracking post peak load with respect to the microstructure of unirradiated PGA graphite. The disc compression test method provides the capability to view the surface of the small disc specimens when subject to a given load and under a progressively increasing applied load. The former is

important since, when using X-ray tomographic imaging of loaded and cracked, notched compact geometry unirradiated Gilsocarbon graphite specimens, Hodgkins et al. [3] observed closure of both the micro-and macro-cracks when the load was removed. This makes examination of cracking extremely difficult even when using high-resolution imaging techniques, for example focused ion beam imaging, unless a load is applied. The use of ion beam milling to produce surfaces normal to the specimen surface has provided the opportunity, for both test methods, to correlate surface and sub-surface microstructure and crack morphology. Fig. 6a provides a measure of the quality of such a milled surface in un-irradiated graphite.

One of the advantages of the in-situ micro-scale cantilever testing approach is the ability to record the specimen image at high resolution continually throughout the entire loading process. This enables the deflection of the cantilever at the loaded point to be captured and measured at the same time as the incremental loading force. This feature is especially important in the case of APS-TBC with its heterogeneous microstructure where the connecting ligaments fail. If the mechanical properties of these local ligaments can be mapped and incorporated into finite element analysis, the microstructural feature that promote failure can be identified with the potential for the manufacturing of the coatings to be improved. One of the challenges of this approach lies in that the manufacture of the beams is found to be more difficult in APS-YSZ than in homogeneous materials such as silicon due to changes in the milling or sputtering rate of the ion beam. It has been shown elsewhere that the complex local morphology leads to a varied milling rate resulting in a significant non-uniformity at the base [8, 9].

5. Conclusions

It may be concluded from this micro-scale investigation that: (i) The diametral compression of small disc specimens provides a useful tool for examining crack formation in quasi-brittle materials such as polygranular reactor core graphite, particularly when supported by focused ion beam milling and imaging. (ii) Micro-cracks in virgin PGA graphite have been confirmed to precede macro-crack formation. The micro-cracking accommodates the non-linearity in the load-displacement curves prior to the peak load. Such cracks have been observed at loads which are as low as 30% of the peak load. (iii) Micro-cantilever testing in APS-YSZ was found to produce comparable mechanical properties and fracture toughness with conventional macro-scale testing. This demonstrates that more insights into the fracture mechanics can be provided by the micro-scale testing.

Abstract

The fracture toughness, G_c, of pure epoxy and epoxy nanocomposites with 10 wt% nano-rubber and 10 wt% nano-silica particles, was determined using an orthogonal cutting method on a CNC machine. The cutting forces were measured by a multi-axis dynamometer, and depths of cut were precisely controlled from 30 μm to 120 μm. High speed cutting tools with three rake angles of 10º, 20º, and 30º were used for the cutting. The fracture results of pure epoxy and 10 wt% nano-silica epoxy composite determined by the cutting test has the same order of magnitude as which determined by the standard compact tension test. However, for 10 wt% nano-rubber epoxy, a much lower G_c value was measured due to the interaction between the plastic zone size of the crack tip and the magnitude of cutting depth. The results have indicated that orthogonal cutting could be an alternative approach to traditional LEFM testing for brittle polymeric nanocomposites. The specimen preparation and testing procedures would be greatly simplified compared with current fracture test technologies.

Keywords: Orthogonal cutting, fracture toughness, polymer nanocomposites

1. Introduction

The accurate estimation of fracture toughness for ductile, yet tough polymers remains to be a challenging task in material science. Traditional LEFM testing is affected by the blunting of the crack tip during crack propagation, which results in over-estimation of the toughness results. Recent research carried out by Patel et al. [9, 10] has proposed that orthogonal cutting may be a suitable method for measuring the strain energy release rate, G_c, for such polymers. The theory was initiated by Atkins [1-3, 5] who pointed out that the fracture energy in the orthogonal cutting process should be equally important as the plastic work and frictional loss, and that the critical fracture energy during cutting be equivalent to the cutting energy extrapolated to the zero depth of cut. Subsequently, Williams [9] developed a more sophisticated orthogonal cutting model by taking Tresca yield criterion and Coulomb friction of the workpiece material into account. A linear relationship between the cutting energy and the cutting depth with the inclusion of the constant global fracture energy, G_c, has been deduced. The new theory has been verified by the testing of some typical high toughness but low strength engineering polymers. The cutting experiment gives valid toughness results for these materials.

It is expected that this marvel fracture testing technique will also be applicable for a variety of engineering polymers, in particular, such as tough, yet brittle polymeric composites, thin polymeric film and micro-fabricated materials. The method will greatly simplify the preparation of testing specimens and avoid the limit of size requirements in the standard fracture toughness test. Our work has been focused on employing the orthogonal cutting method to measure fracture toughness of brittle amorphous epoxy and its nano-modified composites (10 wt% nano-rubber and 10 wt% nano-silica epoxies). The cutting experiment was performed on a rigid CNC machine where the depth of cut can be precisely controlled within few hundreds of microns. At this range of cutting depth, the cut material behaved sufficient plasticity. Continuous chipping process and steady-state cutting force signals were observed. The cutting condition satisfied Williams' notion of cutting

tough, yet ductile polymers. Hence, the same analytical method can be used in the cutting data analysis.

2. Analysis

2.1 Orthogonal Cutting with Consideration of Fracture Energy

A schematic representation of the orthogonal cutting model developed by Williams et al. [9] is illustrated in Fig. 1 (a), where a tool with a single cutting edge of rake angle α is driven at a constant velocity V to remove a chip of thickness h_c and width b from a testing material. The force relationship of the model may be considered by treating the chip as an isolated system. During a steady-state cutting process, the chip is hold by two equal and opposite resultant forces F and F' under equilibrium condition. F' is generated by the tool which acts on the back surface of the chip; F is due to the reaction of the testing material being cut which exerts on the base of the chip. F' may be resolved into a friction force S and its normal component N along the chip back surface. S is responsible for the work expended in fraction as the chip slides over the tool rake face. On the other hand, F may be resolved into a shear force F_s and a compressive force F_n on the base of the chip. The base of the chip can be considered as a shear plane, of a shear angle φ, where shear yielding of the testing material take places. The shear force F_s is then responsible for the work expended in plastic deformation of the testing material. [7-9]

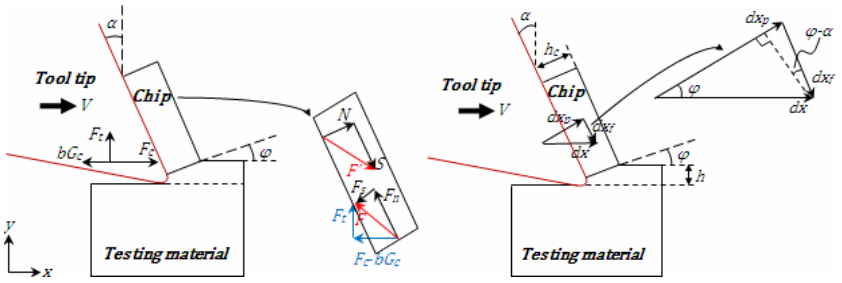

Figure 1. Schematic diagrams of orthogonal cutting (a) force relationship of the cutting system and (b) geometrical relationship of displacements of forces during cutting.

From another standpoint, the resultant force, F, may also be decomposed into F_c-bG_c along the tool moving direction and F_t which is perpendicular to the tool moving direction. F_c is the cutting force delivered from the tool which is responsible for the total work dissipated in the cutting process. F_t arises from the existence of F_c, which is described as a transverse force to maintain the steady-state during cutting process. G_c is considered as the global fracture energy reserved in the testing material. Furthermore, bG_c is modelled as a reaction force towards the cutting direction to prevent the material from separation, where b represents the width of cut. [9, 10]

2.2 An Energy-based Approach to Determine the Fracture Energy

In the orthogonal cutting system as illustrated in Fig.1 (a), the total cutting energy delivered by the tool is considered to be completely dissipated into the plastic work of the chip, the frictional loss due to tool-chip interaction and the fracture work of the testing material [9], where

$$dU_{diss} = dU_{plast} + dU_{frict} + dU_{fract} \tag{1}$$

In force-displacement relation, Eq. (1) becomes

$$F_c dx = F_s dx_p + S dx_f + bG_c dx \tag{2}$$

where dx represents the incremental displacement of tool movement. The corresponding displacements owing to F_s and S, dx_p and dx_f, respectively, can be derived based on the geometrical relationship as shown in Fig. 1 (b) [9]

$$dx_f = \frac{\sin\varphi}{\cos(\varphi-\alpha)}dx \tag{3}$$

$$dx_p = \frac{\sin\alpha}{\cos(\varphi-\alpha)}dx \tag{4}$$

Considering force equilibrium of the chip, the friction force on the tool-chip interface may be expressed as

$$S = (F_c - bG_c)\sin\alpha + F_t\cos\alpha \tag{5}$$

On the other hand, the shear force on the shear plane can be modelled in accordance with Tresca yielding criterion. It is assumed that the shear plane is formed at a critical shear stress which is half of the yield strength of the testing material [9], thus,

$$F_s = \frac{\sigma_Y}{2}\frac{bh}{\sin\varphi} \tag{6}$$

where $bh/\sin\varphi$ is the effective area of the shear plane.

Substituting Eq. (3) to (6) into (2), we have

$$\frac{F_c}{b} - \frac{F_t}{b}\tan\varphi = \frac{\sigma_Y}{2}(\tan\varphi + \frac{1}{\tan\varphi})h + G_c \tag{7}$$

Thus, the fracture energy, G_c, induced by the cutting process can be determined from the linear plot of F_c/b-$(Ft/b)\tan\varphi$ versus $(\tan\varphi+1/\tan\varphi)h$ data [9, 10], where

$$\tan\varphi = \frac{\cos\alpha}{\frac{h_c}{h} - \sin\alpha} \tag{8}$$

and h_c represents the chip thickness.

3. Experimental

3.1 Cutting Experiment Set-up

Cutting tests were carried out on a hydraulic driven rigid CNC machine (Minini Junior 90 M286). A customised tool post and a sample holder were made to cope with orthogonal cutting. The cutting forces were measured by a multi-component dynamometer (Kistler 9257B). The cutting force signals were recorded by an digital oscilloscope (Agilent 54621A) and the data were processed in Excel. A set of high speed cutting tools (Cobalt M42), of rake angles 10º, 20º and 30º and clearance angle 4º, were used in the experiment. The tools were sharpened with tip radii less than 5μm.

3.2 Testing Materials

A diglycidyl ether of bisphenol A (DGEBA) epoxy resin, Araldite-F (Ciba-Geigy, Australia), cured using piperidine (Sigma-Aldrich, Australia) with a ratio of 100:5 (epoxy/piperidine), was used as the base material. For two epoxy nanocomposites, one has 10 wt% SiO_2 nanoparticle produced from Nanopox XP 22/0616 resin (Hanse-Chemie AG, Germany), which consists of well dispersed silica nanoparticles (40 wt%) with an average particle size of 20 nm, while the other has 10 wt% spherical rubber particle produced from a bisphenol master batch resin with 25 wt% well dispersed rubber nanoparticles of 100 nm in size (Kaneka Corporation, Japan). [6, 11] For the cutting experiment, the testing materials were prepared into approximately 5mm thick rectangular blocks.

The values of fracture toughness G_c and yielding stress σ_Y of the testing materials have been determined from conventional compact tension and tensile tests [6, 11], where the CT test followed ASTM D5045 while the tensile test followed ASTM D638.

3.3 Cutting Test Method

The testing material and tool were firmly gripped on the sample holder and tool post, respectively. Cutting started with first a few thin sectioning of the testing material in order to flatten the cut surface. Subsequently, consecutive cutting operation was performed with a speed of *1 mm/s* and the depths of cut were varied from 30μm to 120μm. After each cut, the chip was collected for further measurement.

4. Results and Discussion

4.1 Cutting Results for Pure Epoxy and Epoxy Nanocomposites

Cutting results are presented for pure epoxy and two epoxy nanocomposites. Cutting forces F_c and F_t, and chip thickness h_c are measured for a range of cutting depths h. The data are evaluated by Eq. 7, as shown in Fig. 2.

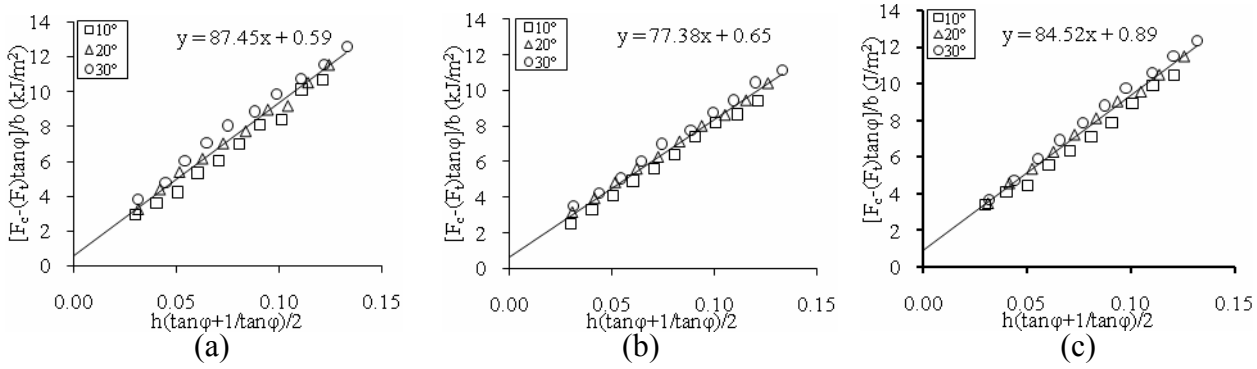

Figure 2. Cutting results for (a) pure epoxy with specimen width b=5.57*mm*, (b) 10% nano-rubber epoxy with specimen width b=5.04*mm*, and (c) 10% nano-silica epoxy with specimen width b=5.40*mm*. The cutting velocity was at *1 mm/s*. The legend shows the rake angle in degrees.

Table 1. Yield stress and fracture toughness for epoxy and its nanocomposites [6, 11].

		Pure epoxy		10% nano-rubber epoxy		10% nano-silica epoxy	
Method	Testing rate	$\sigma_Y(MPa)$	$G_c\,(kJ/m^2)$	$\sigma_Y(MPa)$	$G_c\,(kJ/m^2)$	$\sigma_Y(MPa)$	$G_c\,(kJ/m^2)$
Cutting test	1mm/s	87.46±2.47	0.59±0.21	77.38±1.25	0.65±0.09	84.52±1.73	0.89±0.15
CT test	1mm/min	--	0.28±0.25	--	1.93±0.1	--	0.69±0.05

Tensile test	5mm/min	42.1±2.6	--	37.6±0.8	--	46.5±1.1	--

The linear regression analysis has been shown in the plots of F_c/b-$(F_t/b)\tan\varphi$ versus $(\tan\varphi+1/\tan\varphi)h$ data. The gradient gives the yield stress, σ_Y, which was deduced in accordance with Tresca yield criterion, and the y-intercept is the fracture energy, G_c, of the testing material induced by cutting. The σ_Y and G_c determined from the cutting test are compared with those determined from standard compact tension and uni-axial tensile tests, as listed in Tab. 1.

4.2 Results Discussion

The compact tension test gives G_c values of 0.28±0.25 kJ/m^2, 1.93±0.1 kJ/m^2 and 0.69±0.05 kJ/m^2 for pure epoxy, 10% nano-rubber epoxy and 10% nano-silica epoxy, respectively. Cutting test gives higher G_c results for pure epoxy and 10% nano-silica epoxy, but within reasonable limits. The cause of discrepancy is attributed to the complication in the estimation of depth of cut, h. Since the tool cannot be perfectly sharp, the lower portion of the tool tip may result in a ploughing of the testing material during the cutting process. Thus, the measurements of the cutting depth were overestimated by the size of δ, as shown in Fig. 3 (b).

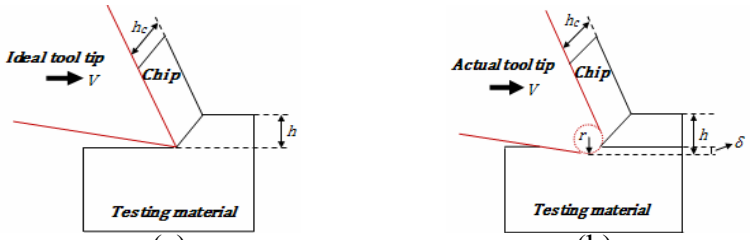

Figure 3. Schematics of orthogonal cutting with (a) an ideal sharp tool, and (b) an actual tool with a tip radius r.

Assuming that half size of the tip radius contributes to the ploughing process, the fracture energy that was over estimated by ploughing could be approximated by

$$G' = \delta\sigma_Y \tag{9}$$

where the tool tip radius used in the experiment was around 5μm; σ_Y is the yield stress determined from the cutting test. [4] Hence, the actual fracture energy induced by cutting for pure epoxy becomes

$$G_c = 0.59kJ/m^2 - \frac{2.5\times 87.46}{1000}kJ/m^2 \approx 0.37kJ/m^2 \tag{10}$$

and also, for 10% nano-silica epoxy

$$G_c = 0.89kJ/m^2 - \frac{2.5\times 84.52}{1000}kJ/m^2 \approx 0.68kJ/m^2 \tag{11}$$

which are in good agreement with the results derived from the compact tension test.

The cutting test gives 0.65±0.09 kJ/m^2 for the G_c value of 10% nano-rubber epoxy. The result is about 3 times lower than that given by the compact tension test. In this particular case, the cutting result is most likely affected by the crack tip plastic zone size of the testing material. The estimated plastic zone size in the compact tension test for 10% nano-rubber epoxy is about 190μm, which is

far above the nominal depth of cut for the cutting test: 30μm to 120μm. Thus, the plastic zone size induced by cutting is confined and the measured G_c value is much more conservative.

Finally, it is noticed that cutting method always determines high values of yield stress compared with those determined from the tensile test. This has been ascribed to large strain and high strain rate on the shear plane during the chip formation process [9].

5. Conclusion

The fracture toughness of epoxy and its epoxy nanocomposites with 10 wt% rubber and silica nanoparticle has been measured by use of an orthogonal cutting method. The cutting method has been proven as a valid way to characterise the G_c of ductile and moderately tough polymeric materials [10]. This work expands the applicability of the method to brittle and tough amorphous polymer and its nanocomposites. It is believed that with the careful examination of the cutting quantities and the material property, orthogonal cutting could become an alternative approach to easily determine the fracture toughness of a wide variety of engineering polymers.

Abstract The crack initiation behavior under the mixed-mode at the edge of a Cu/Si interface in nanoscale components has been investigated by a novel torsion method using a double nano-cantilever specimen consisting of a 20-nm-thick Cu layer and a Si substrate. By using this nano-cantilever torsion method, the shear stress is applied to the Cu/Si interface with the nanoscale stress concentration through the transverse arm. The mode mixity, which is the ratio of the shear stress to the normal stress, can be precisely controlled by changing the loading position. During the experiment, the crack is successfully initiated at the Cu/Si interface edge for various mode mixities by the developed method. The detailed stress fields along the Cu/Si interface at the critical loads for crack initiation are analyzed by the finite element method, and the stress concentration region near the interface edge in all specimens is within the scale of 100 nm. The critical normal stress and maximum shear stress at crack initiation have a circular relation.

Keywords Nanoscale, Mixed-mode, Crack initiation, Interface, Torsion test

1. Introduction

Micro- and nano-mechanical systems and electronic devices consist of dissimilar components, of which size is on the nanometer scale. Since intrinsic bi-material interfaces are inevitably introduced into these devices, deformation mismatch between the dissimilar materials induces a stress concentration at the interface. Thus, the interface is one of the potential sites of fracture [1–3].

Since the stress concentration region is proportionally scaled down for the shrinkage of component size, the stress concentration region at the interface edge is confined to the nanoscale in advanced devices [4–5]. On the other hand, as the state of internal stress is complex in micro-devices, the interface cracking usually takes place under a mixed-mode due to asymmetric loading across the interface and the difference in elastic properties [6]. Thus, to ensure the reliability of these devices, it is important to investigate the mixed-mode fracture criterion under a nanoscale stress concentration. Many investigations for various mode mixities have been conducted for macroscale materials [7], and they revealed that the critical normal and shear stresses for the interface fracture exhibit an elliptical relationship [7]. However, due to the difficulty in handling and applying effective loads to nanoscale specimens, conventional methods [8–11] cannot be applied in fracture experiments of nanoscale components. Recently, although the interfacial crack initiation by nanoscale stress concentration has been experimentally studied by a bending method using a straight nano-cantilever [12–14], the normal stress dominated the crack initiation at the interface edge, *i.e.*, mode-I fracture. It is thus necessary to develop a suitable method for performing mixed-mode fracture experiments on nanoscale components and to investigate the criterion in the mixed-mode due to the nanoscale stress concentration.

In this study, we develop a nano-cantilever torsion method and use it to perform crack initiation experiments for the interface between 20-nm-thick copper (Cu) film and silicon (Si) substrate under a 100-nm-scale stress concentration with different mode mixities.

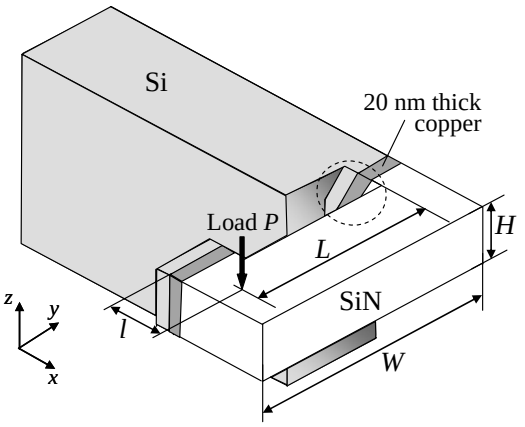
2. Experiments

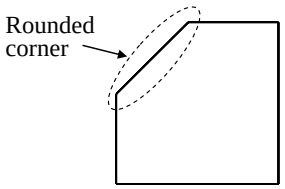
2.1. Tested material

The nano-cantilever torsion specimen is cut from a multi-layered material, *i.e*. silicon/copper/silicon nitride ($Si/Cu/Si_3N_4$). A Si(100) wafer surface is cleaned by inverse sputtering to remove the native oxide layer and then a 20-nm-thick Cu layer is deposited by radio-frequency magnetron sputtering in a 0.67 Pa argon atmosphere. An approximately 1000-nm-thick silicon nitride (SiN) layer is subsequently deposited by the same method without breaking the vacuum. This study focuses on the interface between the Cu layer and the Si substrate.

2.2. Nano-cantilever torsion specimen

Figure 1 schematically illustrates the nano-cantilever torsion specimen used to investigate the mixed-mode cracking at the Cu/Si interface edge in the present study. As shown in Fig. 1(a), the nano-cantilever torsion specimen is a three-dimensional bent structure in the shape of "⊐" that has three arms (see top view of specimen in Fig. 1(b)). The Cu/Si interface is located at arm ①. The load is applied to the SiN layer in arm ③ by a diamond loading tip to stress the Cu/Si interface by a torque and bending moment transferred through arm ②. In addition, to eliminate the strong stress singularity at the sharp corner of the rectangular cross-section of arm ① and obtain a controllable mild concentrated stress field, the inner corner is rounded by focused ion beam (FIB) processing, as shown in the cross-sectional view of Fig. 1(a). Three specimens with different size are prepared and their scales are summarized in the table of Fig. 1(a).





Cross section of arm ①

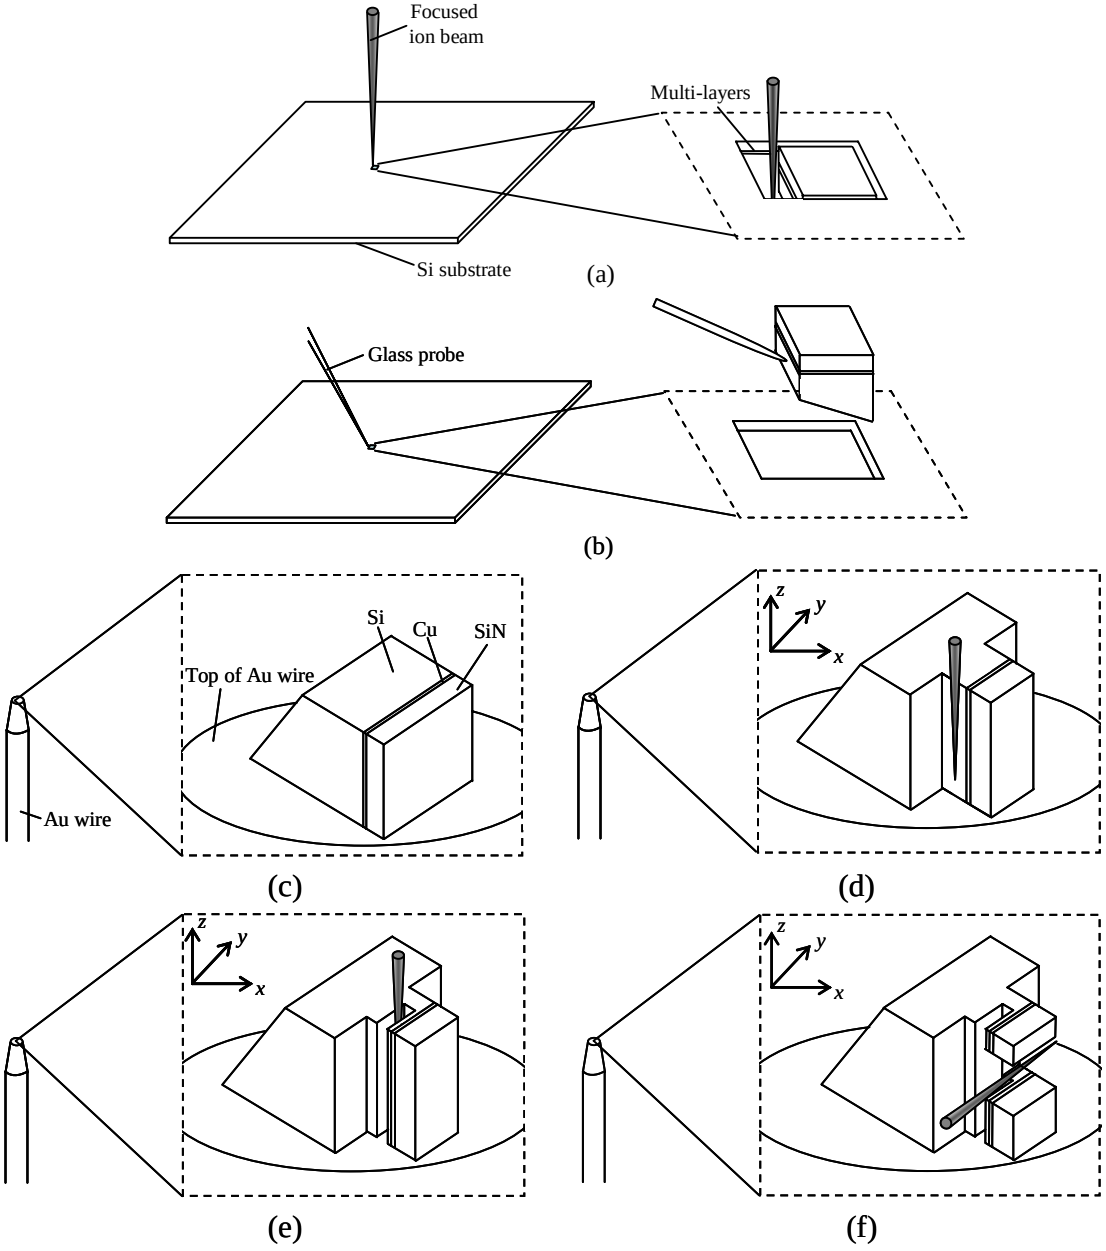
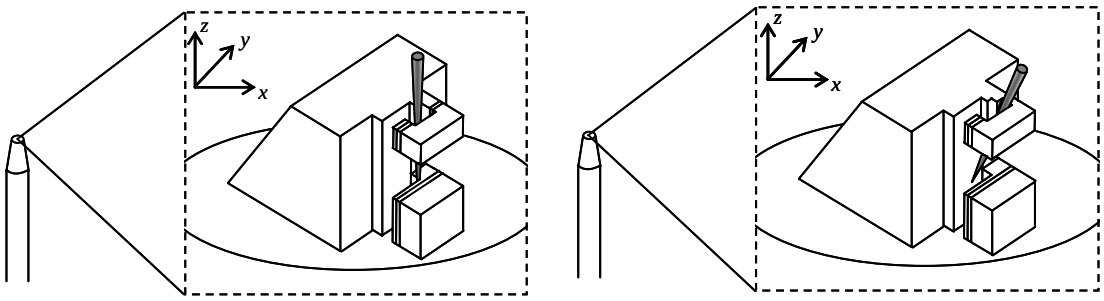
Figure 2 schematically illustrates the procedure used to fabricate the nano-cantilever torsion specimen. As it has three-dimensional shape, the process is much more complex than that for previous straight-cantilever specimen. Before the sample fabrication, passivation layers of gold (Au) and carbon (C) are formed on the SiN layer to protect the specimen from damage during processing. After a cubic block with the side length of about 10 μm is cut from the multi-layered material by a focused ion beam (FIB) (JEOL Ltd., SMI9200) (Fig. 2(a)), it is picked up by a glass probe manipulator (Fig. 2(b)) and is carefully glued to the flat top of a gold (Au) wire with a diameter of 0.25 mm (Fig. 2(c)). The block is thinned in the *y*-direction (Fig. 2(d)) and an L-shaped extension that includes multilayer Si/Cu/SiN is formed (Fig. 2(e)). After thinning the L-shaped extension in the *z*-direction to form a cantilever (Fig. 2(f)), the inner middle part of the long arm of the L-shaped cantilever is cut to expose the inner Cu/Si interface edge (Fig. 2(g)). The inner corner of the upper edge of the Cu/Si interface is rounded (Fig. 2(h)). Finally, the Au and C layers are removed. The gallium (Ga) ion beam energy is set to 30 kV and the beam current is controlled between 5 pA and 5 nA depending on the fabrication precision.





(g) (h)

Figure 2 Schematic illustrations of the procedure used to prepare nano-cantilever torsion specimen. (a) A block is cut from a multi-layered material by FIB. (b) The block is manipulated using a glass probe. (c) The block is mounted on the top of an Au wire. (d)–(h) The shape of the nano-cantilever torsion specimen is fabricated.

Figure 3 shows a scanning electron microscopy (SEM) micrograph of a nano-cantilever torsion specimen. It reveals that there is no damage on the Cu/Si interface edge before the experiment.

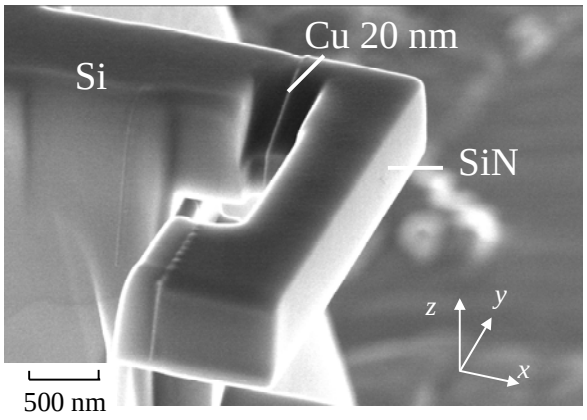


Figure 3 SEM image of a nano-cantilever torsion specimen (T1).

2.3. Loading apparatus

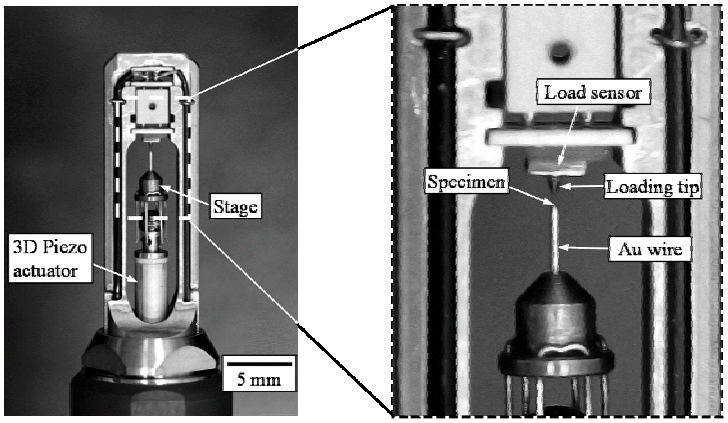

Figure 4 Mechanical loading apparatus used in the mixed-mode interface cracking experiments of nanoscale specimen.

Figure 4 shows the minute mechanical loading apparatus (Nanofactory Instruments AB, SA2000N) used in this study. The apparatus, which consists of a movable sample stage and a diamond loading tip with a load sensor, is built into a transmission electron microscopy (TEM) holder. The gold wire

with a nano-cantilever torsion specimen mounted on top is attached to the sample stage, which is actuated three-dimensionally by a piezoelectric actuator. The load resolution of the sensor is 0.1 μN and the alignment resolution of the piezoelectric actuator in each direction is approximately 1 nm.

3. Analytical procedure

To inquire the stress distribution along the Cu/Si interface at crack initiation, elasto-plastic analysis is performed by the finite element method (FEM) using the commercial software, ABAQUS. Figure 5 shows typical finite element meshes for specimen T1. The configuration of the simulation model is reconstructed using three-dimensional computer-aided design (CAD) software on the basis of 3D analysis of SEM and TEM micrographs. The area near the free edge of the Cu/Si interface, where the stress concentration is expected, is carefully divided into fine meshes. A perfect constraint condition is imposed on the back and bottom ends.

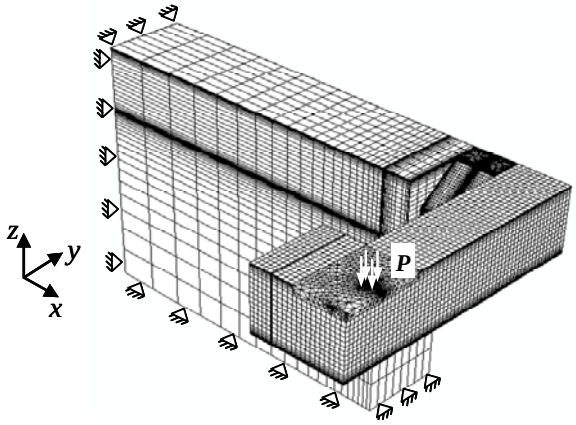

Figure 5 Typical finite element meshes for numerical analysis (specimen T1)

Because the Si substrate is a single crystal, it was treated as an orthotropic elastic material. The Young's modulus of the SiN layer which affects the stress distribution along the Cu/Si interface is measured by an indentation test. Table 1 lists the elastic constants of the component materials.

Table 1 Elastic constants of materials

Material	Young's modulus (GPa)		Poisson's ratio
Cu	129		0.34
SiN	197		0.27
Au	78		0.44
C	400		0.30
	C_{11} (GPa)	C_{12} (GPa)	C_{44} (GPa)
Si	167.4	65.23	79.57

Since the yield stress of the Cu layer is much lower than the Si substrate (σ_y > 3.4 GPa [15]) and the SiN layer (σ_y > 8.4 GPa [16]), only the Cu layer is subjected to elasto-plastic deformation during these experiments. The constitutive relation has been experimentally obtained in a previous study [13], and is given by:

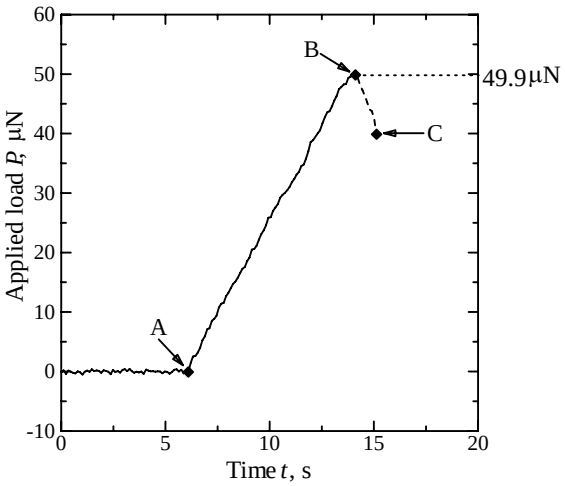
$$\sigma = \begin{cases} 129000\varepsilon & \text{for } \sigma \le 765\ \text{MPa} \\ 3316\varepsilon^{0.332} & \text{for } \sigma \ge 765\ \text{MPa} \end{cases} \quad (1)$$

where σ and ε are the von Mises stress and strain, respectively.

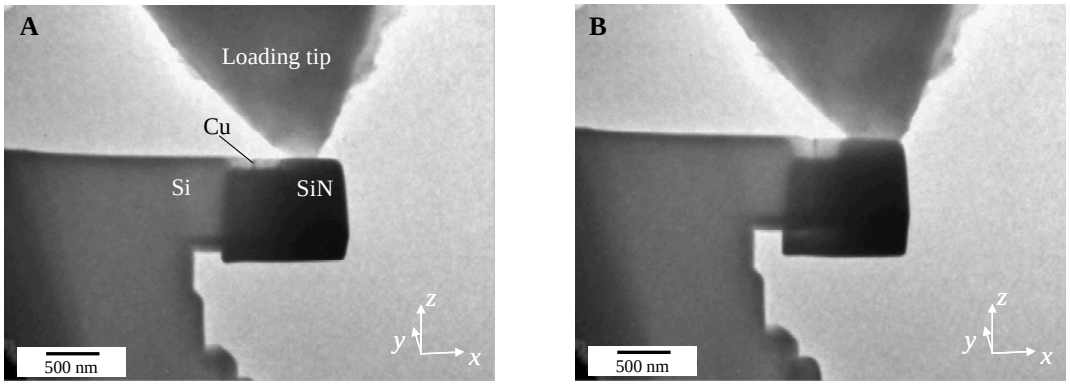
In addition, the residual stresses introduced during processing are measured experimentally (760 MPa for Cu layer; –290 MPa for SiN layer) [13] and are taken into account in the FEM analysis. After corresponding residual stresses are uniformly imposed on Cu and SiN layers respectively, they are relaxed by the FEM calculation.

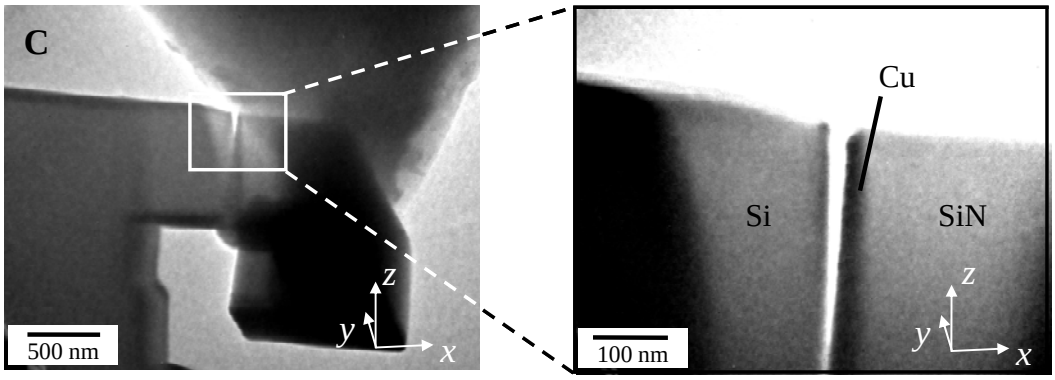
4. Results and discussion

Figure 6 shows the loading curve (*P*–*t*) obtained for specimen T1 and TEM micrographs of the specimen at three specific loading levels (A, B, and C). As shown in Fig. 6(a), after the loading tip hits the SiN layer at point A, the applied load, *P*, increases monotonically up to a peak magnitude of 49.9 μN (point B), after which it abruptly decreases (point C). Figure 6(b) clarifies that no crack initiation is recognized before the peak load while the specimen has an interface crack after. That is to say, the crack initiates at point B at the top edge of the Cu/Si interface and instantly propagates along the interface. A magnified image of the Cu/Si interface edge after crack initiation (at point C) indicates that no dissimilar material remains on either delaminated surface, which confirms the pure interface cracking. Similar behavior is also observed in the other specimens. Thus, the peak load for crack initiation, P_C, is defined as the critical load. Table 2 lists the magnitude of P_C, which shows that it depends greatly on the specimen geometry.



(a)





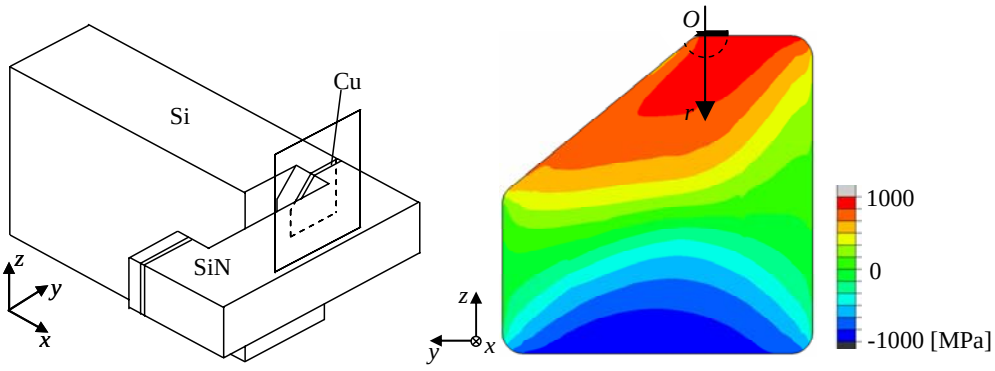
(b)

Figure 6 (a) Load–time relationship and (b) *in situ* observations of interfacial fracture of specimen T1.

Table 2 Critical load, P_C, for crack initiation at interface edge

Specimen No.	Critical load, P_C, μN
T1	49.9
T2	25.6
T3	12.0

Figure 7 shows the distribution of shear stress τ_{xy} on the Cu/Si interface of a nano-cantilever torsion specimen, T1. It shows that the stress concentrates at the adjacent area of the rounded inner corner and its size is in the scale of 100 nm. Similar stress distribution on the Cu/Si interface is also found in other specimens. Thus, we set the origin, *O*, on the rounded corner to be the site of crack initiation. Since the stress is almost constant within the area of 50 nm away from the origin (the area in the dashed circle in Fig. 7(b)), we take the *r*-axis along the loading direction.



(a) (b)

Figuer 7 Distribution of shear stress τ_{xy} on the Cu/Si interface of a nano-cantilever torsion specimen.

Since FEM analysis on stress distribution of the Cu/Si interface indicates that the shear stress τ_{xy} concentrates at the site of crack initiation and much larger than other shear stress components, following discussions focus on the shear stress τ_{xy} and the normal stress σ_{xx}. Figure 8 shows the distributions of the normal and shear stresses, σ_{xx} and τ_{xy}, on the Cu/Si interface along the *r*-axis at the critical loads for crack initiation in different specimens. For comparison, the critical interfacial stress distribution of a straight-cantilever specimen (A1) is referred in Fig. 8(a). In straight-cantilever specimen A1 (Fig. 8(a)), the normal stress is two orders of magnitude larger than the shear stress, which indicates that the normal stress dominates crack initiation at the Cu/Si interface edge. Figures 8(b)–(d) reveal that with changing the loading position, *i.e.*, the magnitude of *L*/*l*, different ratios of the shear stress to the normal stress are realized. In specimen T1, the shear

stress is comparably large with the normal stress (Fig. 8(b)), and a larger ratio of shear stress to normal stress is achieved in specimen T2 (Fig. 8(c)). In specimen T3, the shear stress is 10 times larger than the normal stress (Fig. 8(d)). It should be noted that the stress concentrated area is about 100 nm in all specimens. These indicate the success of the nano-cantilever torsion method for conducting fracture experiments under different mode mixities with the nanoscale stress concentration.

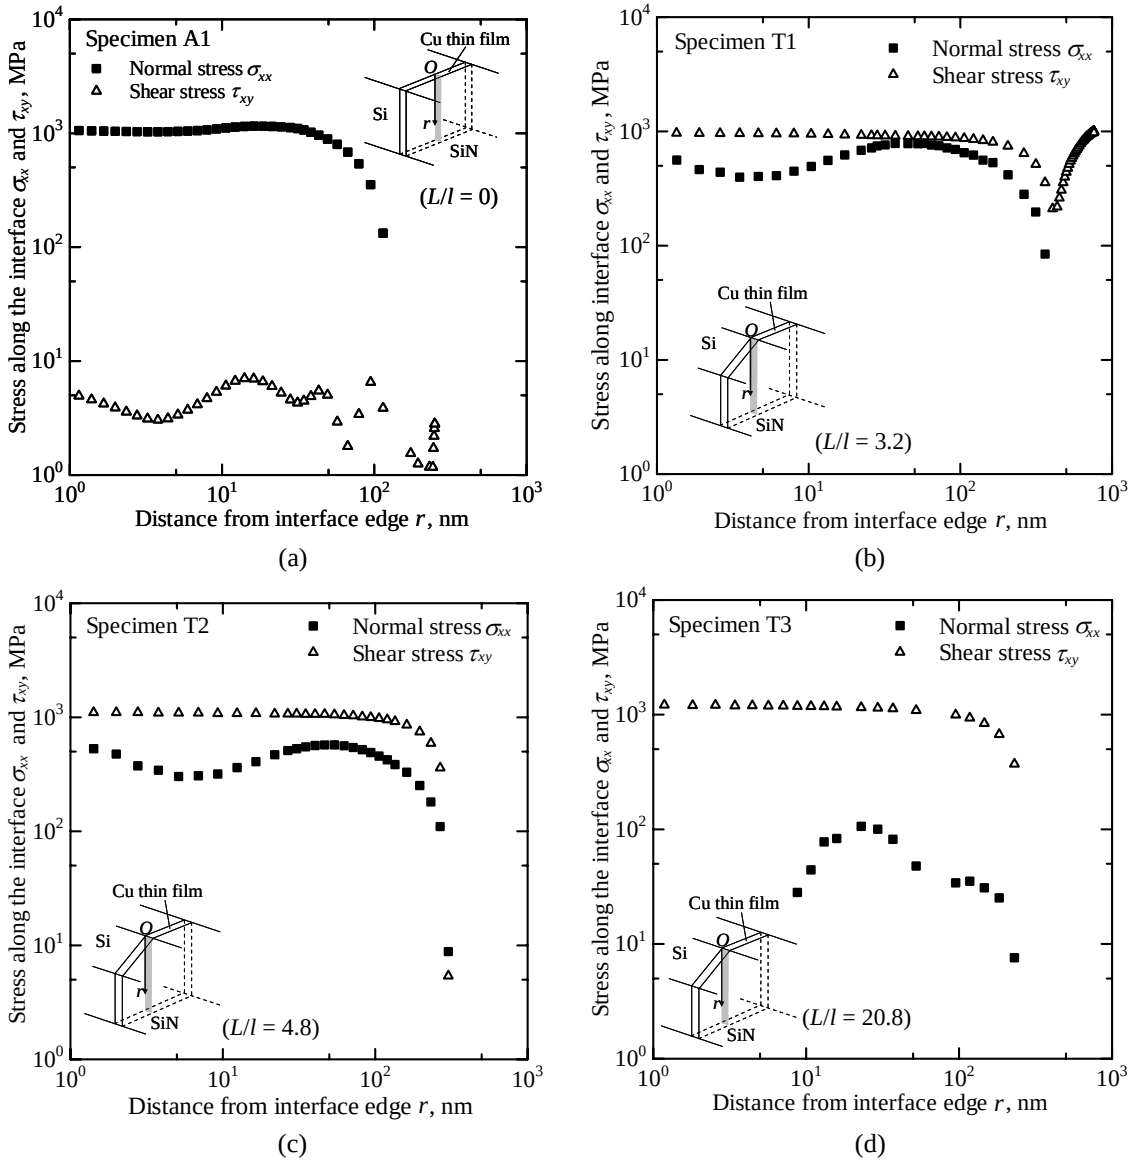


Figure 8 Critical stress distributions at crack initiation on the Cu/Si interface near the edge of (a) straight-cantilever bending specimen and (b)–(d) nano-cantilever torsion specimens.

Since both torsion and bending moments are applied to the Cu/Si interface with the nano-cantilever torsion method, the relation between the maximum shear stress and the normal stress is discussed to extract the mixed-mode fracture criterion of interfacial cracking. Here, it should be noted that the magnitude of maximum shear stress is almost same with that of τ_{xy} because of the domination of τ_{xy} for crack initiation compared with other shear stress components. On the other hand, a previous experimental study [14] revealed that the concentrated stress field of 30 nm from the edge of the Cu/Si interface dominates crack initiation at the edge of interface between the 20-nm-thick Cu layer and the Si substrate. Thus, the averages of the normal and the maximum shear stresses over the area of 30 nm away from the interface edge are used to represent the dominant stress components for

crack initiation; they are denoted by σ_{mc} and τ_{mc}, respectively. Figure 9 shows the plot of the normal stress σ_{mc} versus the maximum shear stress τ_{mc} for all four specimens (A1, T1, T2, and T3). In the straight-cantilever specimen A1, τ_{mc}/σ_{mc} is nearly zero, indicating the domination of normal stress for the crack initiation at the interface edge. In the nano-cantilever torsion specimens, *i.e.*, T1, T2, and T3, τ_{mc}/σ_{mc} is 1.6, 2.5, and 19, respectively, which shows that the crack is initiated at the interface edge with different mode mixities. By fitting the experimental results with the least-squares method, an elliptical relation that is commonly used for macroscopic materials and a circular relation between the σ_{mc} (MPa) and τ_{mc} (MPa) are obtained and respectively depicted in Eqs. (2) and (3):

$$\left(\sigma_{mC}/1106\right)^2+\left(\tau_{mC}/1129\right)^2=1 \tag{2}$$

As shown in Fig. 9, by calibrating with experimental results (circle points), the circular relation (red dash line) gives simple correspondence.

$$\sigma_{mC}{}^2+\tau_{mC}{}^2=1143^2 \tag{3}$$

This indicates that the mixed-mode fracture criterion for interfacial cracking in nanoscale components simply exhibits a circular relation between the critical normal stress and maximum shear stress.

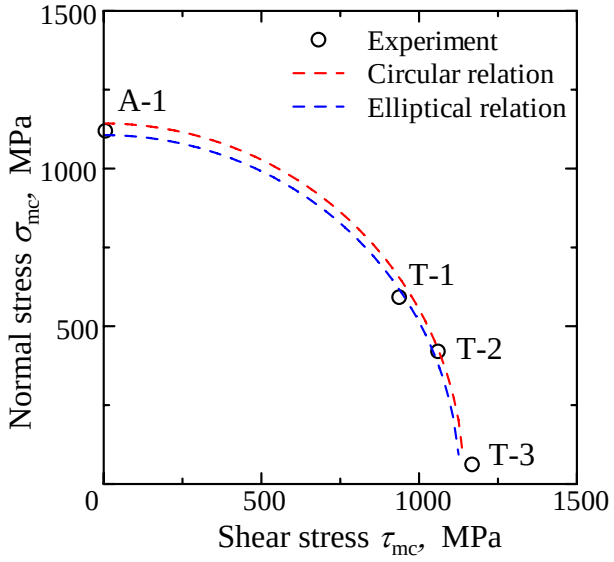

Figure 9 Critical relation of interfacial cracking under the mixed-mode.

5. Conclusions

In order to investigate the mixed-mode crack initiation due to the nanoscale stress concentration at the edge of the Cu/Si interface, we developed a methodology and conducted the fracture experiments using novel nano-cantilever torsion specimens with the interface between a 20-nm-thick Cu layer and a Si substrate. The results are summarized below:

(1). A novel nano-cantilever torsion method was developed that can apply the shear stress to the Cu/Si interface for crack initiation at the interface edge. The ratio of the critical shear stress to the normal one at crack initiation, *i.e.*, the mode mixity, could be controlled by varying the loading position. FEM analysis revealed that the concentrated stress region near the interface edge was within the scale of 100 nm in all specimens.

(2). In the nano-cantilever torsion specimens, the crack was successfully initiated from the edge of the Cu/Si interface under different ratios of the critical shear stress to the normal stress. The corresponding critical load was measured by in situ TEM observations on the cracking.

(3). The mixed-mode fracture criterion for interfacial cracking in nanoscale components is represented by a circular relation between the critical normal stress and maximum shear stress.

Abstract

In this study, the role of nanoclay particles (MMT) on the micro- and nano-scale deformation and fracture behaviour of a crosslink unsaturated polyester (UPE)-based nanocomposites is presented. Nanocomposites from well-dispersed MMT and UPE are prepared by a combination of mechanical stirrer and ultrasonication process. Fracture toughness represented by critical stress intensity factor (K_{Ic}) based on linear elastic fracture mechanics (LEFM) and compact tension (CT) configuration is evaluated. Morphological characteristics for all nanocomposites are examined by using TEM, and the fracture surface and the toughening mechanisms of materials are identified by SEM analysis. The morphological characterization showed an intercalation/ partially exfoliation structure of UPE/MMT nanocomposite with a moderate enhancement in fracture toughness in nanocomposite. The UPE/ 3 wt. % clay nanocomposite had the highest K_{Ic} by a 61 % improvement over the neat UPE. The incorporation of clay nanofiller into the crosslink UPE demonstrated a shift in toughening mechanism from a highly brittle fracture for the UPE into shear bands and particles' debonding and decohesion for nanocomposites.

Keywords fracture toughness; toughening mechanisms; unsaturated polyester; clay nanocomposites.

1. Introduction

In general, polymer-clay nanocomposites (PCNs) properties are directly dependent on the state of nanoparticles dispersion in the polymeric matrix, whether it is immiscible, intercalated or exfoliated nanocomposites [1-3]. The exfoliated/intercalated nanostructure and the strong interaction between clay nanolayers and polymer chains play a role in constraining the mobility of polymer matrix and delay the crack initiation and propagation and consequently induce reasonable mechanical strength and toughness [4, 5]. Fracture toughness is a critical mechanical property which characterizes the resistance of a material to crack propagation or to fracture. The toughness of materials is directly dependent on the energy dissipation, or on the energy absorbed in fracturing the part.

Unsaturated thermoset polyester resin (UPE) is one of the most used thermosetting polymers in different industrial applications due to its good mechanical properties and low cost and density [6]. However, the brittleness of this class of materials because of a radical polymerisation process between unsaturated prepolymer and styrene is one of their major drawbacks [7]. Hence numerous studies have been done on the introduction of second phase particles in them in order to control the toughness of thermoset polymers. For instance, Evora et al. [8] embedded small loadings of TiO_2 nanoparticles in the unsaturated polyester resin. The presence of the particles had the greatest effect on fracture toughness and tensile strength. Baskaran et al. [9] found that the fracture toughness of UPE resin has improved when 5 wt. % of Alumina (Al_2O_3) particles was added. Moreover, the investigation of the fracture behaviour and toughening mechanisms were done on the introduction

of multiwall carbon nanotubes in unsaturated polyester [10, 11], and halloysite nanotubes (HNTs) in epoxy [12]. It was found that the use of nanopatricles with polymers are effectively increased their fracture toughness without sacrificing other properties such as strength, modulus and glass transition temperature.

As a result of the abovementioned works, several toughening mechanisms have been observed in polymers filled by micro- and nano-particles such as multiple craze-like banding with dilatation (dilation) [13]. Crack-pinning mechanism while the crack front bows out between the filler particles and remains pinned at the particles [14]. Microcracking mechanism is another mechanism in which the toughness increases due to the incorporation of rubber or nano-scale particles into polymers [7]. Localized shear yielding (or shear banding) mechanism which is a narrow zone of intense shearing strain forming due to a material instability i.e. corresponding to an abrupt loss of homogeneity of deformation. However, increase in tendency to shear yield in nanocomposites may cause an increase in energy absorption prior to fracture [15]. Also, there is a massive shear-banding mechanism which occurs due to the reduction in yield stress by the stress concentration of the compliant nano-scale or rubber particles that facilitate shear yielding. Additionally, particle bridging (rigid particles) mechanism in which a rigid or ductile particle plays as a bridging particle that applies compressive traction in the crack wake and the ductile particle deforms plastically in the material surrounding the crack tip, which provides additional crack shielding. The particle bridging provides most of the improvements in toughness since it remain intact for some distance behind the crack-front [16]. In this study, the attempt is made to investigate the relationship between well-dispersed structure nanocomposites and the fracture behaviour of unsaturated polyester (UPE), and to understand to what extent clay particles can inhabit crack initiation, crack growth, and then enhance the fracture toughness of the networked UPE.

2. Experimental setup

2.1 Materials and nanocomposites preparation

Organoclay platelets (MMT, Cloisite® 30B, provided by Southern Clay Products, Inc. via Jim Chambers & Associates, Australia) were introduced into unsaturated polyester resin (UPE, AROPOL®-1472PLSE, Nupol, Australia having 45 % styrene) at different amounts (1, 3, 5, 7, and 9 wt. %). Nanocomposites from MMT/UPE were prepared by means of high shear mixing followed by sonication (agitation) to drive the air bubbles off. After mixing, the catalyst Methyl Ethyl Ketone Peroxide (MEKP/Butanox-M50) was added to the mixture at 2 % of UPE weight and stirred manually for 1 min as per the instructions of the supplied company. Later, the mixture was poured in a special plastic moulds having the fracture specimens geometry, and cured at room temperature for 24 h and post cured at 60°C for 2h followed by 90°C for 2h following an increment rate of 10°C/30 min.

2.2 Morphological characterization

Transmission electron microscope (TEM) was used to observe the dispersion of clay layers in the UPE polymer resin. Ultra-thin sections of approximately 70 nm in thickness were cut by diamond knife from the nanocomposites at room temperature and examined using a JEOL (JEM-1010) TEM instrument at an acceleration voltage of 100KV. Scanning Electron Microscope (SEM, Philip XL-30)

was utilized to identify the failure modes and toughening mechanism. SEM observations were carried out on the fracture surfaces of compact tension fracture specimens after sputter coating with a thin layer of platinum to increase electric conductivity.

2.3 Fracture mechanisms study

The stress intensity factor (K_{Ic}) and the strain energy release rate (G_{Ic}) of the cured neat UPE and the UPE/nanocomposites were evaluated using the compact tension (CT) configurations. The CT fracture specimens were prepared according to ASTM D5045 as shown in **Fig. 1**. A pre-crack was generated by tapping a fresh razor blade into the notch tip with a drop weight to maintain an accurate K_{Ic} values. 5 mm/min is adapted as loading rate and the following relationships are used to measure the K_{Ic}:

$$K_{Ic} = \frac{P_Q}{BW^{1/2}} \cdot f\left(\frac{a}{W}\right) \tag{1}$$

$$f\left(\frac{a}{W}\right) = \frac{\left(2+\frac{a}{W}\right)\left\{0.886+4.64\left(\frac{a}{W}\right)-13.32\left(\frac{a}{W}\right)^2+14.72\left(\frac{a}{W}\right)^3-5.6\left(\frac{a}{W}\right)^4\right\}}{\left(1-\frac{a}{W}\right)^{3/2}} \tag{2}$$

Where P_Q is the load determined from the load-displacement curve, B the specimen thickness. The calculated K_{Ic} values were checked against: B, a, (W-a) > 2.5 $(K_{Ic}/\sigma_y)^2$ (3)

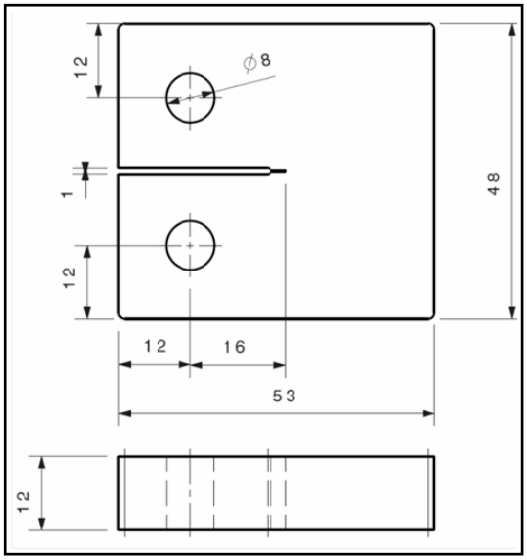

Fig.1 Dimension of the compact tension (CT) specimen.

3. Results and discussion

3.1 Morphology

Fig. 2 shows representative TEM micrographs of the cured unsaturated polyester (UPE) filled by different nanoclay loadings. From the figure, it can be noticed that a good dispersion of clay layers in the polymeric matrix with a plausible intercalation between nanoclay and the polymer chains has achieved by using direct high shear mixing and sonication. However, several agglomerates of micro-particles with thickness of 100 nm or greater are created at higher nanoclay loadings can also

be seen in **Fig. 2c**. The appearance of these clusters are attributed to the structure of clay that composed of platelets with an inner octahedral layer surrounded by two silicate tetrahedral layers and because of the natural state of clay which exists as stacks of many platelets at several hundred nanometres long and wide separated by an interlayer distance of ~1-3 nm [5, 17].

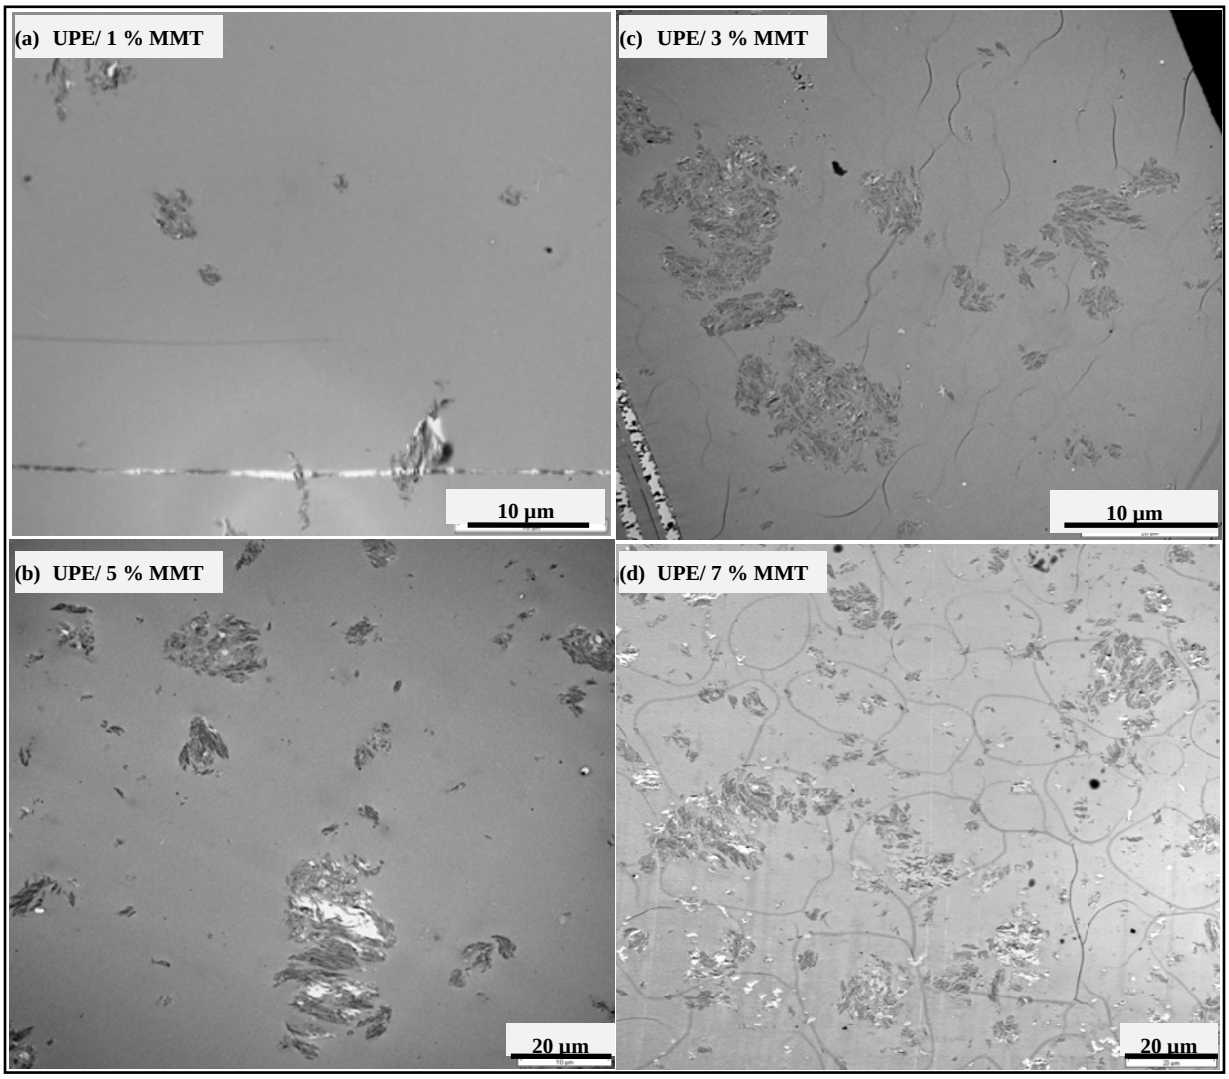

Fig. 2 TEM photomicrographs of UPE filled by different clay nanocomposites.

3.2 Fracture toughness and mechanism

Fig. 3 shows a set of typical load-crack opening displacement (COD) curves obtained from the CT fracture tests for the cured neat unsaturated polyester (UPE) and UPE filled by different contents of 3 wt. % and 5 wt clay nanocomposites. It can be found that all samples have undergone unstable crack propagation with s straight line when the maximum load is reached due to the high crosslink density of the UPE and its prone to fast fracture. Meanwhile, the UPE- based 3 wt. % MMT nanocomposites manifested their ability to carry higher loads with lesser displacements (COD) whereas the addition of 5 wt % MMT showed lower loads with higher displacements compared to the neat UPE resin.

The fracture toughness values (K_{Ic}) versus different clay loadings (1-9 wt. %) with respect to the

neat resin value were illustrated in **Fig. 4**. The magnitudes of K_{Ic} of the modified UPE have modestly improved after nanoclay platelets were incorporated where the introduction of 3 wt % MMT content showed the highest K_{Ic} value by 61% higher than the neat UPE. However, these values have decreased at higher nanofiller contents due to the appearance of clay aggregates and the weak interaction between clay layers and polymer resin thereof with the increase of clay contents. These results are in conformance with these reported in the literature [18]. A comparison of different studies where K_{Ic} values have been obtained is addressed in **Table 1.** From the table, it can be noted that the incorporation of even low levels of nanoparticle into unsaturated polyester resin resulted in noticeable changes in fracture toughness of the produced materials over the neat resin due to the presence of nanoparticles.

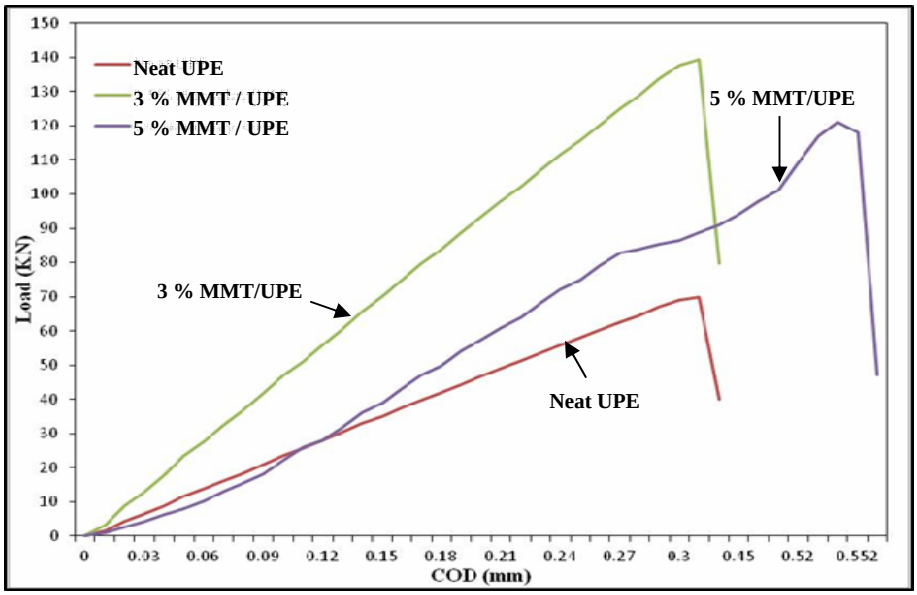

Fig. 3 Typical load vs. crack opening displacement (COD) curves.

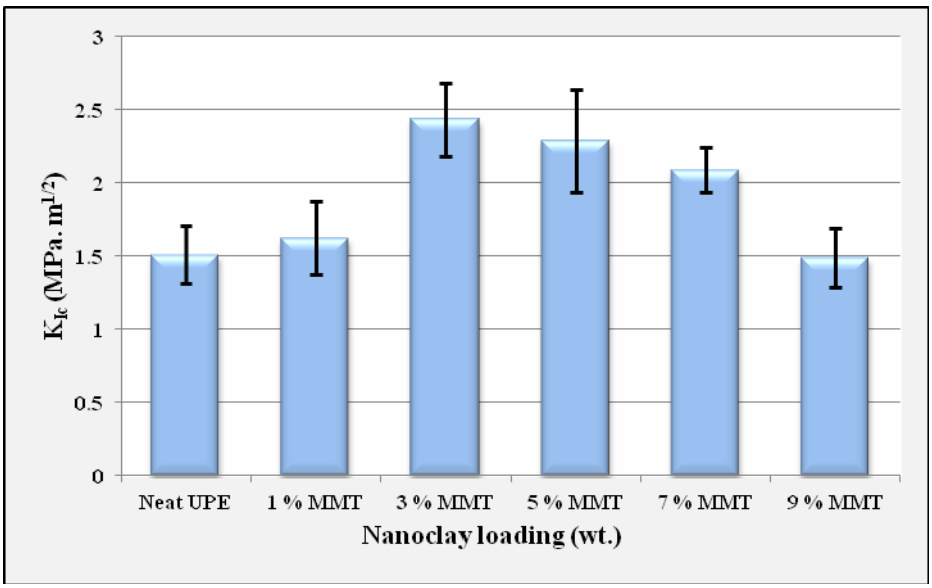

Fig. 4 Fracture toughness of the neat UPE and the UPE/MMT nanocomposites

Table 1 Fracture toughness for different nanoparticles-filled unsaturated polyester (UPE)

Materials	**K_{IC} (MPa $m^{1/2}$) {test specimen type }**	**Comments and Reference**
UPE/ 3 wt. % MMT	2.435 [1.51: Neat UPE] {CT}	The current study
UPE/ 1 wt.% TiO_2	0.85 [0.5: Neat UPE] {SENB}	Direct ultrasonification method, [8]
UPE / 40 % Bamboo fibre	1.2 [0.5: Neat UPE] {CT}	Laminating lay-up process, [19]
UPE / 1 wt. % Alumina	1.42 [1: Neat UPE] {SENB}	Prepared using direct mixing approach, [20]

CT: Compact tension, SENB: Single-edge notched bending,

The fracture modes and toughening mechanisms in the thermosetting unsaturated polyester (UPE) toughened by clay nanomaterials ruptured at ambient temperature are identified by using SEM analysis as shown in **Fig. 5.** The SEM micrograph (**Fig. 5a**) showed the failure mechanism of the fracture surface of the neat UPE is a highly brittle failure mode without crazing. However, the introduction of clay particles into the networked UPE resin associated with better absorbing of energy, leading to localized shear yielding. Similarly, the authors in [21] referred to the appearance of isolated shear bands as an energy absorption mechanism accompanied with better plastic deformation in the failure mode of polymer having a second phase. Furthermore, the addition of nanofiller into the UPE resin resulted in particle pinning of the crack (**Fig. 5c**) leaving behind tail-like structure. SEM image (**Fig. 5d**) of the fracture surface of UPE-5 wt. % clay nanocomposite depicts various crack propagation directions on the cleavage surface. The direction of crack advancement is from top to bottom with an irregular curved path. Further clay nanoparticles (> 5 wt. % MMT) incorporation into the crosslink UPE resin accompanied with mixed failure mechanism represented by cleavage and void-coalescence as shown in **Fig. 5 e and f**.

Additionally, in order to fully understand the nano-effect of clay particles on the fracture surface of UPE/clay nanocomposite, SEM images with different magnifications (**Fig. 6**) for the fracture surface of UPE- 3 wt % MMT nanocomposite were taken. This sample was chosen because of its relative higher fracture toughness. **Fig. 6a** illustrates the fracture topography at low magnification, showing the crack-initiation and crack-propagation zones. Another SEM view (**Fig. 6b**) at low magnification, showing the first zone of crack growth (zone 2A), in which the formation of microcracks can be noted. The tearing of the connected material (the particle-matrix interface) and decohesion occurred at the weakest locations in zone 2A (**Fig. 6c**) [22]. Comparatively, zone 2B (**Fig. 6d and e**), showing a similar flat cleavage along the fracture planes. The intergranular fracture mechanism or decohesion can also be observed in zone 2c (**Fig. 6f**).

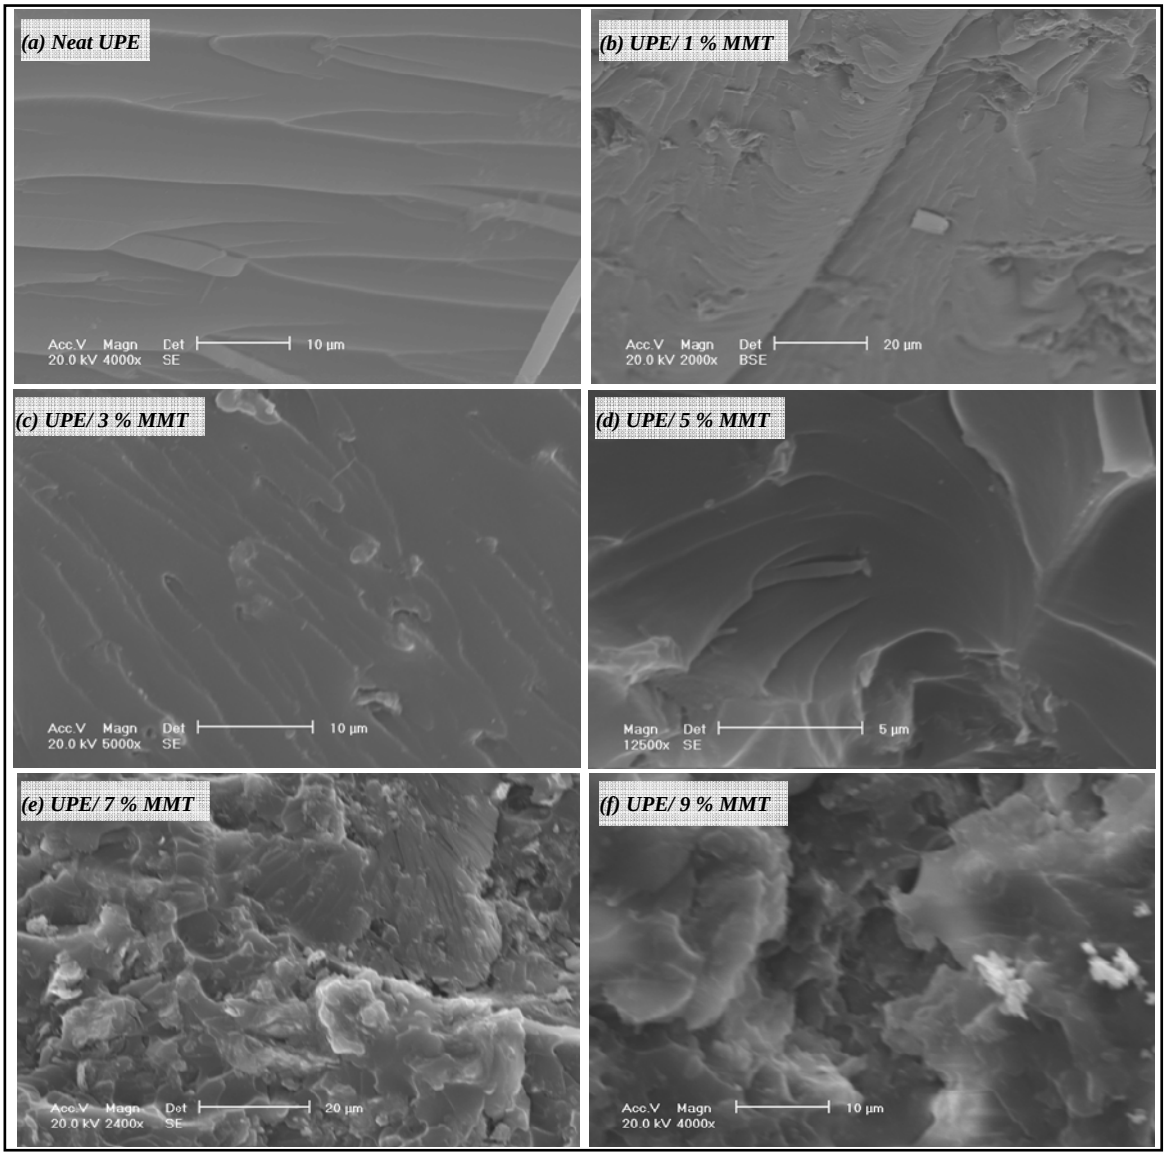

Fig. 5 SEM micrographs showing the failure mechanisms of the fracture surface obtained from the compact tension specimens of the neat UPE and the UPE-filled by different clay nanocomposites.

Conclusion

The nano-effect of clay nanoparticles on the fracture toughness and toughening mechanisms of fully crosslink thermoset unsaturated polyester (UPE) was experimentally investigated in this study. The morphological characterization was described by using TEM examination and the failure modes of the fracture surfaces of compact tension samples ruptured at room temperature was also identified by using SEM analysis. An intercalation structure with a uniform dispersion of UPE/clay nanocomposites prepared by direct high shear mixing and sonication process were observed. The incorporation of MMT into UPE resin induced higher fracture toughness where nanocomposites containing UPE and 3 wt. % MMT showed a higher stress intensity factor (K_{Ic}) by a 61 % increase over the neat UPE. The role of nanofiller on the deformation mechanism demonstrated a shift from

highly brittle fracture mode without crazing for the neat UPE into shear yielding deformation mechanism with plausible energy absorption for nanocomposites.

Abstract Experimental investigations were conducted to characterize mode I interlaminar fracture and fatigue delamination growth behaviors of carbon fiber-reinforced epoxy (CF/EP) laminates with modified epoxy matrices using nano-silica particles, a reactive CTBN liquid rubber and a hybrid of nano-silica particles and CTBN liquid rubber. The CF/EP composites were fabricated using unidirectional carbon fibre and a DGEBA epoxy by means of a vacuum resin infusion technique. The mode I interlaminar fracture toughness (G_{IC}) of the CF/EP laminates was increased significantly after the additives were incorporated in the matrices, especially for the laminates containing the hybrid particles of nano-silica and CTBN liquid rubber. Furthermore, nano-silica and CTBN liquid rubber were also found to effectively improve the fatigue performance of the CF/EP laminates by noticeably decreasing the fatigue crack propagation rates, particularly for the laminate with the matrices modified by the hybrid of nano-silica and CTBN liquid rubber. The results confirm that the enhancement in the fracture toughness due to the incorporation of the nanoparticles to the epoxy matrices has been partially transferred into the improvement of the interlaminar fracture resistance of the CF/EP composites, under both static and cyclic loadings.

Keywords Interlaminar fracture, fatigue delamination growth, nano-silica, CTBN liquid rubber

1. Introduction

Interlaminar fracture toughness and delamination growth resistance play a major role in determining long-term service life of carbon fibre-reinforced epoxy (CF/EP) composite structures. A large number of research efforts have been carried out to improve interlaminar properties of CF/EP composite laminates, including the use of toughened matrices, stitching, Z-pining, etc [1-7]. Toughened epoxy matrices can normally result in high interlaminar fracture toughness and delamination growth resistance [8-11]. Recently, nano-sized silica particles produced by a sol-gel process and CTBN liquid rubber have been reported to significantly increase the toughness of epoxies and also the mode I interlaminar fracture toughness for carbon fiber reinforced epoxy composites [12]. As a result of the unique combination of the additives, the hybrid epoxy matrices may also improve the interlaminar fatigue crack growth resistance of CF/EP composites.

The present paper presents the experimental results of a study in exploring the role of silica nano-particles and CTBN liquid rubber in the epoxy matrices of CF/EP composites. Mode I interlaminar fracture toughness and fatigue delamination growth rate are evaluated and possible mechanisms are discussed.

2. Experimental

2.1. Materials

A DGEBA epoxy (Araldite-F, Huntsman) was used for the study. Piperidine was used as hardener for curing the epoxy. The modifiers for the epoxy were a SiO_2 nano-particle dispersed epoxy (Nanopox XP, Nanoresins, Germany) and a CTBN liquid rubber (Hycar CTBN 1300X13). Nanopox

XP consists of surface-modified silica nano-particles (40 wt%) with an average particle size of 20nm. T300 unidirectional carbon fibre fabrics (FGI Fibre Glass International, Australia) were used.

2.2. Fabrication of CF/EP composites

The CF/EP composites were fabricated from the unidirectional carbon fibre fabric using a vacuum assisted resin infusion molding (VARIM) process. Neat epoxy and modified epoxies with 10 wt% silica nano-particles and/or 10 wt% rubber were premixed at 80^{o}C and later used in VARIM. Piperidine was added at a ratio of 5:100 (hardener/epoxy) in weight. The laminates consisted of 20 unidirectional carbon fiber layers. A polyimide thin film (50 μm in thickness and 120 mm in length) was inserted between the 10th and 11th layers at one end of the laminate, to serve as a "pre-crack" for the interlaminar fracture tests. Two loading blocks of 20 mm in width were bonded to up and bottom sides of one end of the specimen for load applying.

2.3. Mechanical tests

Double cantilever beam (DCB) specimens (dimensions of 20 mm in width, 240 mm in length, 4 mm in thickness and 50 mm in initial "pre-crack" length) were prepared for the interlaminar fracture tests of the laminates under static and fatigue loadings. For static testing on an Instron 5567 universal testing machine, a displacement rate of 1 mm/min was used. Mode I interlaminar fracture toughness (G_{IC}) of unidirectional CF/EP composites was determined by the Modified Beam Theory (MBT) Method, according to ASTM D5528,

$$G_{IC} = \frac{3P\delta}{2b(a+|\Delta|)} \tag{1}$$

Where b is the specimen width, P is the applied load, δ is the displacement of the load-point and $|\Delta|$ is the modification of actually measured crack length a. Two values of G_{IC} were defined, namely G_{IC} (init.), at the point when the delamination was observed visually to propagate from the pre-crack tip, and G_{IC} (prop.), the plateau value of the resistance curve (R-curve).
The fatigue tests were carried out on an MTS-810 servo-hydraulic machine in reference to ASTM D6115 to measure the interlaminar delamination growth rate. During fatigue testing, the displacement ratio (R) of the minimum to the maximum displacements was kept constant (R = 0.1), and a cyclic frequency of 1 Hz was adopted. At least 3 specimens were tested for each group starting from the maximum cyclic strain energy release rate at the peak of displacement cycle being 60% of mode I interlaminar fracture toughness measured from quasi-static tests of the corresponding CF/EP laminates. The maximum cyclic strain energy release rate can be calculated from:

$$G_{\mathrm{Im}ax} = \frac{3P_{\max}\delta_{\max}}{2b\left(a+|\Delta|_{av}\right)} \tag{2}$$

Where $P_{\max}$ is the maximum cyclic load, $\delta_{\max}$ is the maximum value of cyclic displacement, $|\Delta|_{av}$ is the average value of $|\Delta|$ from static tests. The crack length was determined by visual observation during the crack propagation. The corresponding number, N, of fatigue cycles required to generate delamination growth in the CF/EP laminates were recorded during the fatigue tests, thus allowing the crack growth rate, da/dN, to be calculated.

3. Results and discussion

3.1. Interlaminar fracture toughness

Typical curves of mode I interlaminar growth resistance as a function of crack length (R-curves) under static loading are shown in Figure 1 for CF/EP laiminates with unmodified and modified matrices. The corresponding mode I interlaminar fracture properties are shown in Table 1. It can be seen that both G_{IC} (init.) and G_{IC} (prop.) increased after the epoxy matrix was modified. The presence of 10 wt% nano-silica particles or 10 wt% CTBN rubber, showed a significant effect on the interlaminar fracture toughness, leading to increases in both G_{IC}(init.) and G_{IC}(prop.). The combined use of the nano-silica particles and the CTBN rubber with the epoxy, to form a "hybrid" epoxy matrix, gives a further enhancement to the fracture toughness, with the maximum values of 649 J/m^2 for G_{IC} (init.) and 1323 J/m^2 for G_{IC} (prop.) being recorded.

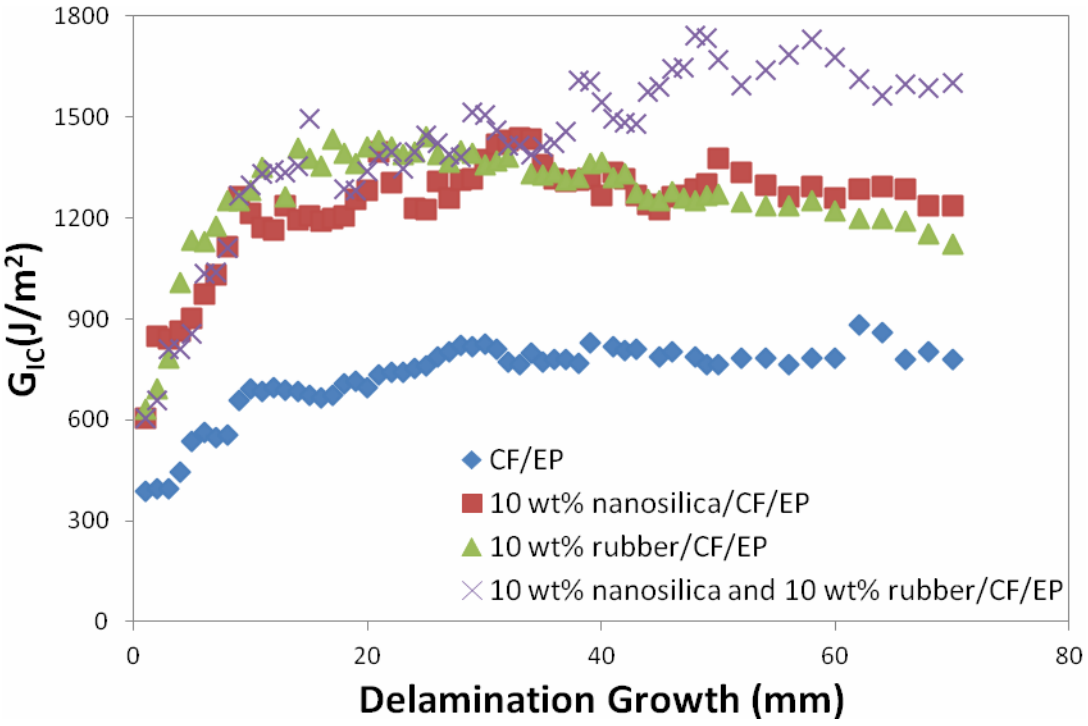

Figure 1 Typical R-curves for mode I interlaminar fracture of CF/EP laminates

Table 1. Mode I interlaminar fracture properties of CF/EP laminates

Laminates	G_{IC} (init.)[J/m^2]	G_{IC}(prop.)[J/m^2]
CF/EP	389±20	741±70
10 wt% nano-silica/CF/EP	602±4	1130±93
10 wt% rubber/CF/EP	629±31	1256±37
10 wt% nano-silica and 10 wt% rubber/CF/EP	649±112	1323±101

3.2. Fatigue delamination resistance

The crack growth rate (da/dN) versus delamination length curves are shown in Figure 2 for CF/EP laminates with unmodified and modified matrices. The results show that the fatigue delamination resistance in composite laminates with the matrix modified by nano-silica, CTBN rubber and the hybrid of these additives was greatly improved. Generally, the rate of delamination propagation was initially high and then decreased as the delamination growth because of reduced strain energy release rate under the constant peak displacement. In particular, the CF/EP composite laminate with the matrix modified by the hybrid of 10wt% nano-silica and 10 wt% rubber have the slowest delamination growth rate, being about almost two orders lower than that of the laminates with the neat epoxy at the early stage of delamination growth.

As shown in Figure 3, the da/dN-G_{Imax} curve characterized the relationship between delamination growth rates and the maximum delamination energy (G_{Imax}) used for different group of CF/EP laminate specimens. It can be seen that the plots for the four groups of CF/EP laminates show the same trend, i.e., a high growth rate corresponds to a high G_{Imax}. Furthermore, it requires higher G_{Imax} for the same delamination growth rate for the CF/EP laminates with modified matrices. Particularly, the CF/EP laminate with the matrix modified by the hybrid of 10 wt% nano-silica and 10 wt% rubber, requires the highest G_{Imax} for the same delamination growth rate, compared with other three groups of CF/EP laminates without modification, with 10 wt% nano-silica or 10 wt% rubber, respectively.

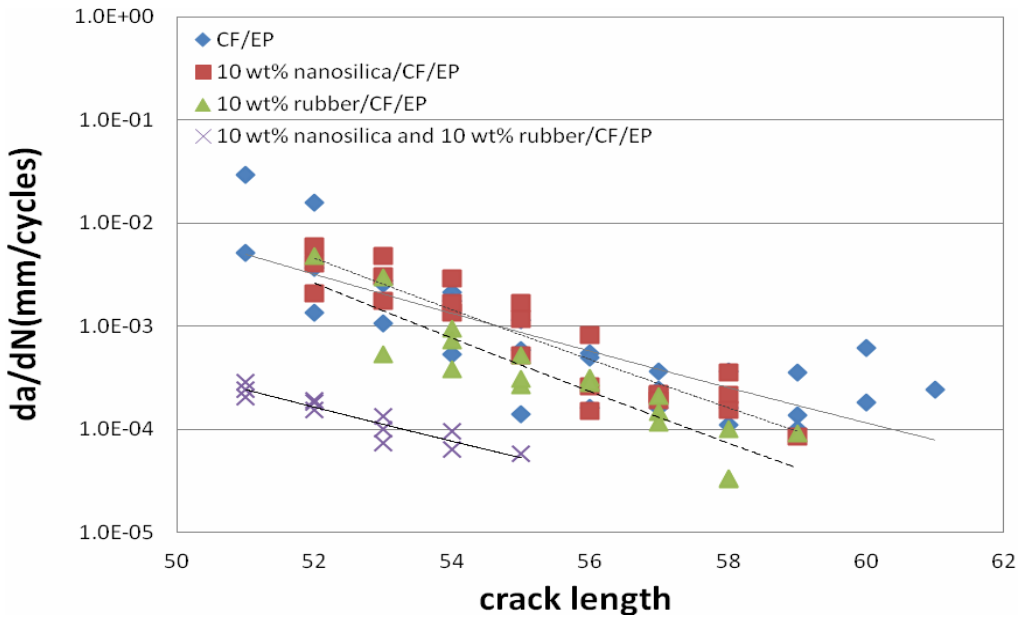

Figure 2 Propagation rate versus delamination length under cyclic fatigue for the CF/EP laminates

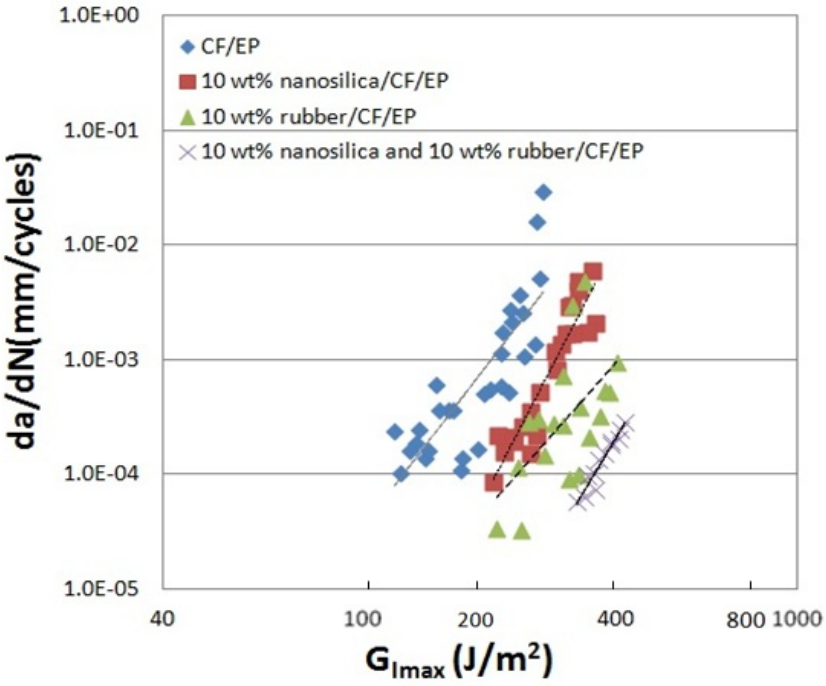

Figure 3 Propagation rate versus G_{Imax} under cyclic fatigue for the CF/EP laminates

SEM photographs in Figure 4 show the morphology of fracture surfaces in the initial region of crack growth for the fatigue delamination growth in CF/EP laminates. For the neat epoxy laminate, in Figure 4 (a), exposed fibres can be seen being completely stripped of matrix resin, indicating an interfacial failure in the unmodified CF/EP laminate. However, more matrix resin remains on the exposed fibre surfaces in the 10 wt% nano-silica modified CF/EP laminate, in Figure 4 (b), showing better adhesion at fibre-matrix interface. The same phenomenon were also reported by Tang et al [9], who investigated mode I and II interlaminar fracture toughness in CF/EP laminated modified with nano-silica particles under static loading. The increasing fatigue delamination resistance for 10 wt % nano-silica CF/EP laminates can be attributed to the toughening mechanisms in the matrix induced by nano-silica ahead of delamination tip. It was observed that the plastic void growth around the nano-silica particles makes a contribution to the fracture energy of the epoxy modified by nano-silica during the delamination propagation, reported by Hsieh et al [12]. Enhanced plastic deformation can also be observed for the matrix modified with 10 wt% rubber, as shown in Figure 4(c), indicating shear flow of the matrix resin due to the increased ductility. The hybrid matrix containing both 10 wt% nano-silica and 10 wt% rubber presented a rougher matrix surface that may be resulted from a synergistic effect of plastic void growth and shear yielding mechanisms, which correlates well with the highest delamination growth resistance under both static and cyclic loading.

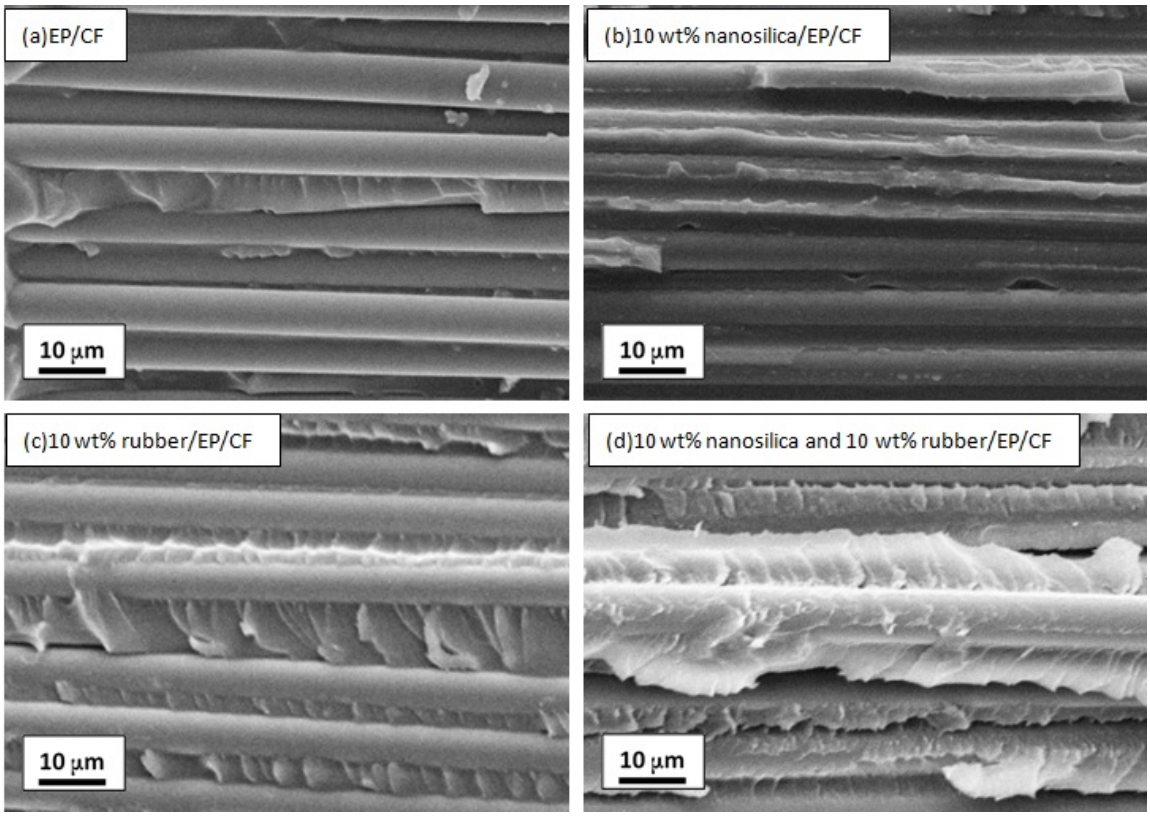

Figure 4 SEM photographs of fracture surfaces for fatigue tested CF/EP laminates

4. Conclusions

(1) The mode I interlaminar fracture toughness of CF/EP laminates under static loading was significantly improved after the epoxy matrix was modified with 10 wt% nano-silica particles or 10 wt% CTBN rubber. In particular, for the CF/EP laminate with the matrix modified by the hybrid of 10 wt% nano-silica and 10 wt% rubber, the interlaminar fracture toughness was further improved.

(2) The fatigue delamination growth resistance of the CF/EP laminates was also improved after the matrix was modified by nano-silica and/or CTBN rubber. It was observed that the CF/EP laminate with the matrix modified by the hybrid of 10 wt% nano-silica and 10 wt% rubber achieved the highest resistance to fatigue delamination growth, attributed to the synergistic contribution of toughening mechanisms induced by nano-silica particles and CTBN rubber, respectively.

Abstract By employing a multilayer thin film structure composed of thermally oxidized Si substrate and sputtered Sn film, a series of thermal annealing experiments are carried out to challenge the synthesis of Sn nanowires following thermal-stress-induced method. The effects of two vital influencing factors, i.e., surface morphology of Sn film and annealing conditions, are explored systematically. For Sn films with either isolated islands or voids in grain boundaries, there is no any change on surface morphology after annealing. Such behavior can be attributed to the existence of gaps among islands or voids in grain boundaries, which make it difficult to generate sufficient stress to grow Sn nanowire. On the other hand, for Sn films with dense grains or coalescent islands, the occurrence of hillocks or whiskers after annealing at high temperature indicates that the proper control of surface morphology of Sn film and thermal annealing conditions may grow Sn nanowires with large aspect ratio.

Keywords Atomic migration, Influencing factors, Metallic nanowire, Thermal stress

1. Introduction

The study of Sn nanowires has been motivated by the attractive properties of bulk Sn including excellent ductility, electrical conductivity, resistance to corrosion, and its extensive application in electronics industry. Recent experimental studies [1-6] have shown that Sn nanowires have unique superconductivity and magnetic properties, which indicates their potential application in superconductors. Moreover, vertical arrays of Sn nanowires have been expected to be ideal anode materials for lithium rechargeable batteries with improved cycling life and high power capabilities [7-9]. In addition, oxidation of Sn nanowires has provided an alternative method to prepare sensitive SnO_2 nanowires for gas sensors [10]. Such exciting applications and the reliability evaluation (e.g., thermal instability [11]) have promoted the development of various strategies to grow Sn nanowires.

Several template-assisted synthesis methods have been attempted, in which Sn nanowires have been grown inside the nanochannels of anodized aluminum oxide or track etched polycarbonate membrane by electrodeposition using an aqueous solution containing Sn^{2+} ions [1, 2], and by solidification of the molten Sn injected with gas pressure [12] or hydraulic pressure [13]. Although the above template-assisted methods have offered the advantages of predefined morphology and size controllability, there still exist extrinsic shortcomings such as the troublesome template removal and possible chemical contamination [14]. Besides, successful growth of Sn nanowires following vapor-solid mechanism has also been reported by employing a noncatalytic and template-free vapor transport process [3]. In this case, the source of Sn vapor is required, which is obtained by ultra-high temperature (i.e., 973K) heating of Sn. Additionally, Xiao *et al*. [15] have grown Sn nanowires using thermal-stress-induced method by annealing a Si-Sn nanocomposite film in vacuum.

In this study, the same mechanism (i.e., thermal-stress-induced method) is employed to challenge the growth of Sn nanowires by using a multilayer thin film structure following thermal annealing in ambient environment. The effects of two vital influencing factors including surface morphology of

Sn film and annealing conditions are explored systematically.

2. Fundamentals and Experiments

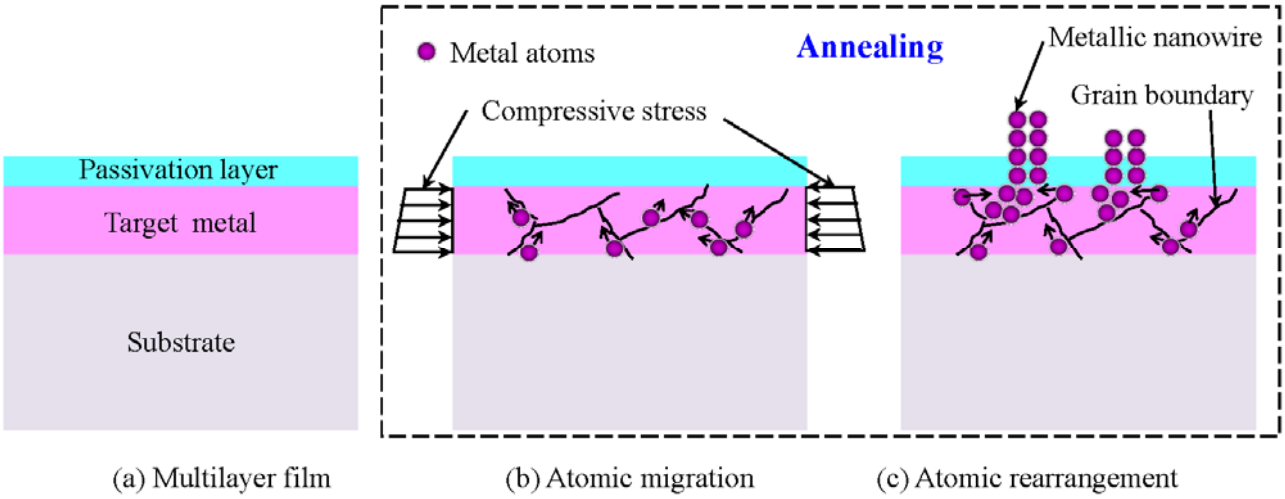

Fig. 1 Schematic thermal-stress-induced growth of metallic nanowires from a multilayer film

The mechanism of the present thermal-stress-induced growth of metallic nanowire using a multilayer is schematically illustrated in Fig. 1. A multilayer film shown in Fig. 1(a) is composed of three layers from top to down: passivation layer (e.g., natural oxide layer of Sn), target metal (e.g., Sn) and substrate (e.g., thermal oxidized Si). Because of the significant mismatch in the coefficient of thermal expansion (CTE) between target metal and substrate (α_{Sn} = 23.5×10^{-6}/K; α_{Si} = 7.6×10^{-6}/K [16]), the compressive thermal stress will be induced in target metal film during thermal annealing. Taking into account of material and geometrical singularities of the target metal film, the resulted local compressive stress gradient drives atoms migrating from more compressive areas to less compressive ones in the form of grain boundary diffusion and surface diffusion as shown in Fig. 1(b). With the accumulation of migrated atoms, the compressive stress gradient is generated between the interface of target metal/passivation layer and the free surface of passivation layer. Once the pressure resulted by the accumulated atoms attains a critical value, weak spots in the passivation layer will be broken and metallic nanowire will be formed through the rearrangement of metallic atoms. Based on the above growth mechanism, the similar multilayer thin film structure has been employed to fabricate various metallic nanowires, such as Cu [17], Bi [18], Ag [19], Al [20].

In the present work, a multilayer thin film structure for grow Sn nanowires are prepared. The Sn thin films are deposited on a 280μm-thick thermally oxidized Si wafer by radio frequency (RF) sputtering with an Ar flow of 20sccm and pressure of 5mTorr. The substrate temperature during sputtering is controlled to be room temperature (R.T.) by water cooling to assure thermal stress as high as possible in the following thermal annealing. By varying the RF power and sputtering time, a series of multilayer thin film structures are prepared in which the sputtered Sn films have different surface morphologies.

By using the obtained multilayer thin films, thermal annealing experiments are carried out at 473~503K for 2h in ambient environment. By observing the surface morphologies of the as-sputtered Sn films and the annealed ones using a scanning electron microscope (SEM), the effects of two vital influencing factors, including surface morphology of the as-sputtered Sn film and annealing conditions, are investigated.

3. Results and Discussion

3.1 Surface Morphologies of As-sputtered Sn Films

As a representative, the cross-sectional image of the prepared multilayer thin film is observed in Fig. 2 by using transmission electron microscope (TEM), in which the Sn film is sputtered at 20W and 240s. According to SEM observations, the surface morphologies of as-sputtered Sn films can be categorized into three representative sets, which are related to different RF power P and sputtering time t. For the films shown in Fig. 3 which are sputtered at RF power of 50W with sputtering rate of 1.5nm/s from 30s to 60s, the isolated island structure is clearly observed in each case. Moreover, the

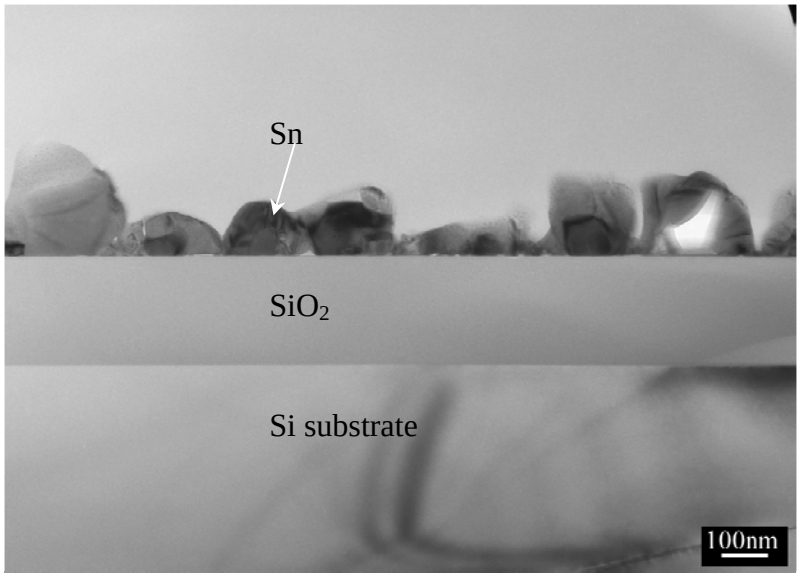

Fig. 2 Cross-sectional TEM image of the multilayer thin film (P=20W, t=240s)

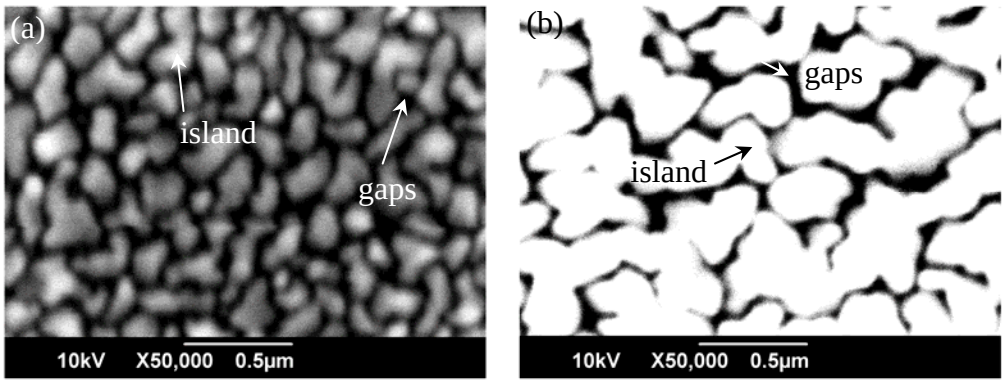

Fig. 3 Surface morphologies of Sn films with isolated island structure
(a) P=50W, t=30s; (b) P=50W, t=60s

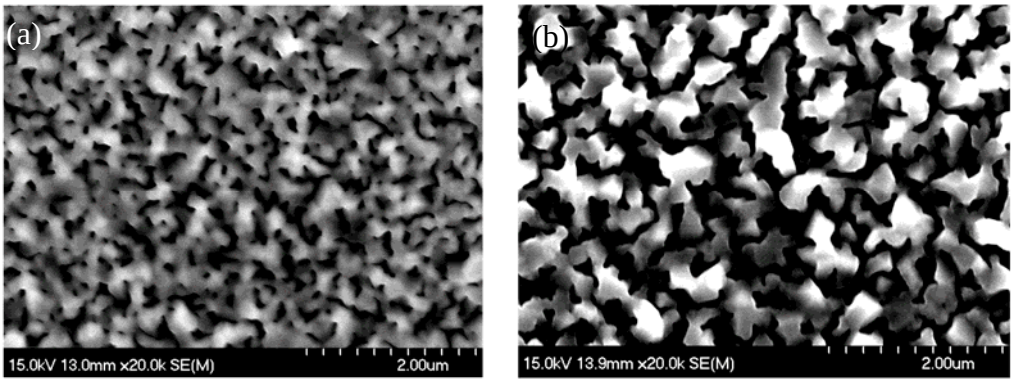

Fig. 4 Surface morphologies of Sn films with coalescent island structure
(a) P=50W, t=90s; (b) P=20W, t=240s

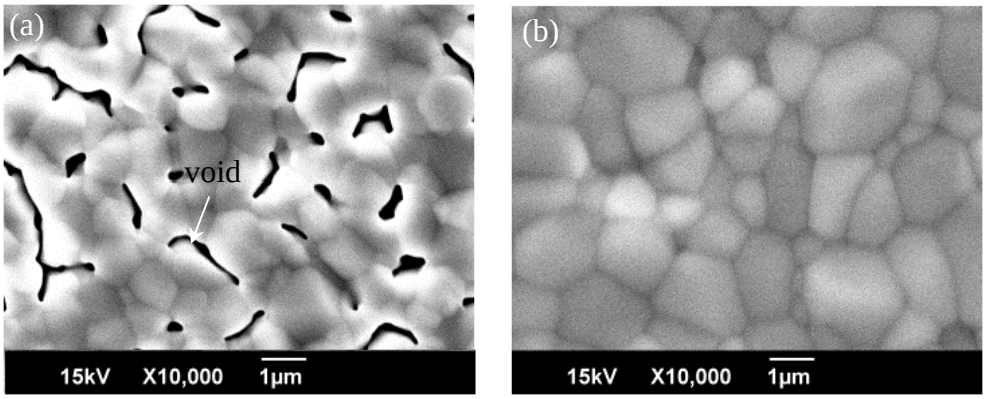

Fig. 5 Surface morphologies of Sn films with clear grains
(a) P=300W, t=125s; (b) P=300W, t=500s

size of island increases as the sputtering time increases. However, when the sputtering time increases to 90s, the isolated islands begin to coalesce with each other as shown in Fig.4 (a). This structure with coalescent islands is very similar with that in Fig. 4(b) sputtered at RF power of 20W for 240s with sputtering rate of 0.5nm/s. For films in Fig. 5 which are sputtered at RF power of 300W for 125~500s with sputtering ratio of 4nm/s, grain boundaries can be clearly observed. Interestingly, by comparing Fig. 5(a) and Fig. 5(b), it is found that with the sputtering time increases and the corresponding increasing film thickness, the voids at the grain boundaries decrease and finally vanish.

3.2 Surface Morphologies of Annealed Sn Films

The surface morphologies of the above as-sputtered Sn films after annealing at 473~503K for 2h are given in Fig. 6. Significant changes on the surface morphologies are only observed for Sn films which are sputtered under the following three conditions: (I) P=50W, t=90s (Fig. 6(a)); (II) P=20W, t=240s (Figs. 6(b, d)); (III) P=300W, t=500s (Fig. 6(c)). At the annealing temperature of T=473K, large numbers of hillocks shown are observed on the films sputtered at the above three cases (i.e., Figs. 6(a~c)) while no any change is found on the other films. When the annealing temperature is increased up to T=503K, large numbers of whiskers with various shapes are only observed on the film sputtered at P=20W (Fig. 6(d)). The representative images of hillock or whisker are shown in in Fig. 7. These distinctive differences can be discussed as below: for the sputtered Sn films with

isolated islands or voids in grain boundaries, it is difficult to result in stress concentration because of the existence of gap or voids. On the other hand, for Sn films with dense grains or coalescent islands, it is possible to induce thermal stress during the annealing with consideration of material and geometrical singularity. It should be noted that for the former (i.e., Sn film with dense grains) with thickness in micro-scale, the part of internal stress is released by recrystallization during the formation of grains. However, for the latter (i.e., Sn film with coalescent islands) with thickness in nanoscale, the induced thermal stress is much higher than that in the former.

4. Conclusions

By employing a multilayer thin film structure composed of thermally oxidized Si substrate and sputtered Sn film, a series of thermal annealing experiments are carried out to challenge the growth of Sn nanowires using thermal-stress-induced method. The effects of two vital influencing factors, i.e., surface morphology of Sn film and annealing conditions, are explored systematically. For Sn films with either isolated island structure or voids in grain boundaries, there is no any change on surface morphology after annealing. Such behavior can be attributed to the existence of gaps among islands or voids in grain boundaries, which make it difficult to generate sufficient stress to make Sn nanowires grow. On the other hand, for Sn films with dense grains or coalescent islands, the occurrence of hillocks or whiskers after annealing indicates that the proper control of surface morphology of Sn film and annealing conditions may grow Sn nanowires with large aspect ratio.

Abstract Neat epoxy and epoxy-based nanocomposites were subjected to monotonic uniaxial and fracture toughness testing. Samples of epoxy filled with 0.1wt% multi-wall carbon nanotubes (MWNT) and of epoxy filled with 0.1wt% graphene platelets (GPL) were considered. The nanoscale inclusions were used in the as-received state. The processing procedure involved sonication and high-speed mixing followed by degassing and curing. Traction tests were performed with ASTM-type specimens using both an Epsilon extensometer and the digital image correlation method (DIC). DIC was performed using an ARAMIS system and the entire length of each specimen was analyzed. The stress-strain behavior of these materials was essentially identical. However, the toughness of MWNT was even 50% higher than that of neat epoxy. The toughness of GPL-filled epoxy was only marginally larger than that of the neat matrix. These observations are attributed to the crack bridging effect of the MWNT.

Keywords Nanocomposites, Fracture toughness, Digital image correlation, Crack bridging

1. Introduction

Polymer nanocomposites have emerged as important structural materials, competing with neat polymers and classical composites. These materials exhibit a combination of exceptional properties which usually cannot be achieved in standard composites. Some of the most studied systems are nanocomposite thermosets, that is polymers filled with nanoparticles and various forms of nano-carbon (carbon nanotubes, graphene, graphene platelets, etc.).

In [1], [2], GPL and MWNT-epoxy composites with various weight fractions (0 to 0.5wt%) were prepared, and were tested under monotonic, cyclic (fatigue) and creep conditions. It was observed that the addition of GPL and MWNT has a marginal effect on the stress-strain curve at all strain rates investigated. However, GPL reduces the creep rate at elevated temperatures, especially in the transient creep regime [1]. Both MWNT and GPL lead to a dramatic reduction of crack growth rate under fatigue conditions [2].

Epoxy-based nanocomposites with 0.1wt% MWNT were subjected to monotonic uniaxial and fracture toughness testing on single-edge notched (SEN) specimens [3]. SEM analyses were performed to study the fracture surfaces and the effect of fillers on crack propagation. For dispersing the MWNT in the epoxy resin special equipment is needed. A high energy sonicator was used, Sonics VCX-750 (US), characterized by a generator with 750 W output, a 20 kHz convertor and a temperature controller. For mechanical mixing, a shear mixer Thinky ARE-250 (Japan) with maximum rotation speed of 2000 rpm was used.

In this work we study the mechanical properties of epoxy-based composites in which the additives are multiwall carbon nanotubes (MWNT) and graphene platelets (GPL), in separate materials, at 0.1wt% filling fraction. The nanocomposites were subjected to monotonic uniaxial and fracture toughness testing on single-edge notched (SEN) specimens. SEM analyses were performed to study the fracture surfaces and the effect of fillers on crack propagation.

2. Traction testing

Uniaxial tension tests were performed with ASTM-type specimens using both an Epsilon extensometer and the digital image correlation method (DIC). The testing speed was 1.5 mm/min which corresponds to an initial strain rate of approximately 10^{-3} s^{-1}; DIC was performed using an ARAMIS system and the entire length of each specimen was analyzed. The ultimate tensile stress was in the range 50 to 55 MPa and the elongation at failure about 3-4.5%. The Young's modulus is in the range 2300 to 2600 MPa. No significant difference was observed between MWNT and GPL-filled epoxy samples in this type of test.

For a pure epoxy specimen failure is typically brittle, and may initiate from a corner of the specimen, probably due to a local defect (Fig. 1). On the fracture surface the SEM analysis shows striations on a radial direction converging towards the fracture initiation area.

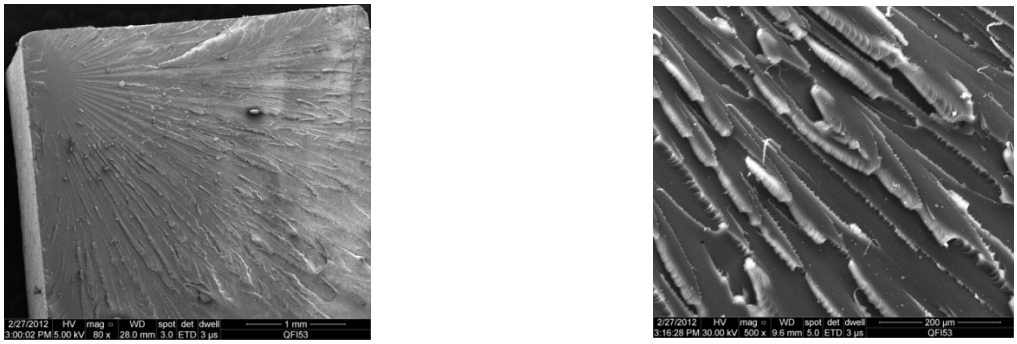

Figure 1. Fracture surface of a fractured pure epoxy specimen analyzed by SEM.

As an example, just before failure, for a MWNT filled epoxy, the maximum von Mises strain is 7.26 % due to a local stress raiser effect (Fig.2).

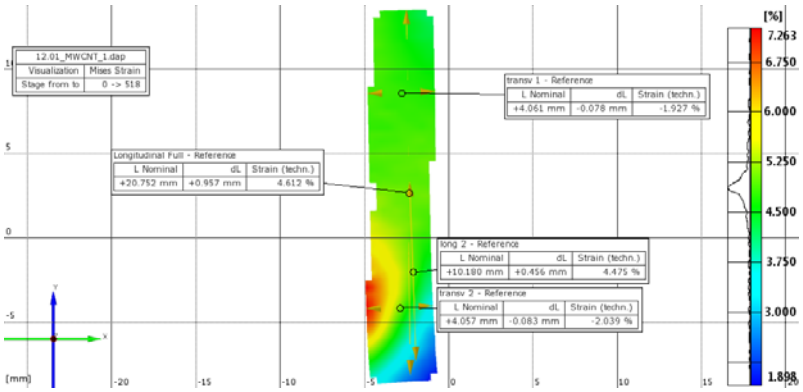

Figure 2. von Mises strains obtained experimentally for a MWNT specimen

We show in Fig. 3 the von Mises strains (from DIC) for a GPL epoxy specimen tested in uniaxial tension, just before unstable crack propagation was observed. The maximum von Mises strain is now 2.6% in the area where failure initiates.

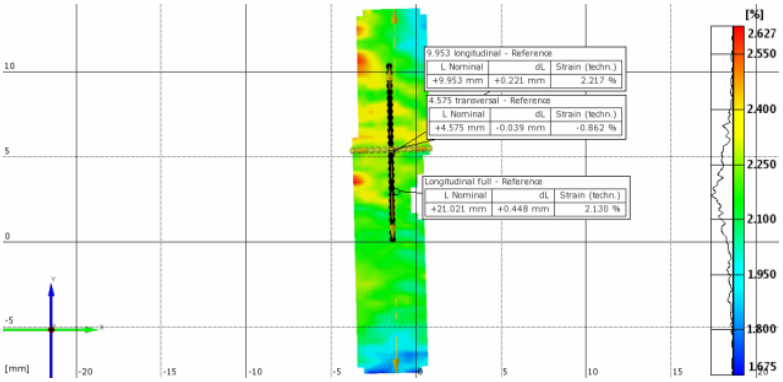

Figure 3. von Mises strains in a GPL specimen

3. Fracture toughness evaluation

The fracture toughness evaluation was performed using SEN specimens. Notches were cut with a fine saw and then sharpened with a razor blade. The total length of the crack was 1.3 mm. The DIC was used to monitor the local Mises strains at the tip of the crack up to failure. The crack area was masked to prevent obtaining spurious strains due to the relative movement of the crack flanks. Fig. 4 shows the von Mises strains in a MWNT nanocomposite specimen in the last frame before unstable crack propagation. The maximum strain is 2.4% and the failure was brittle.

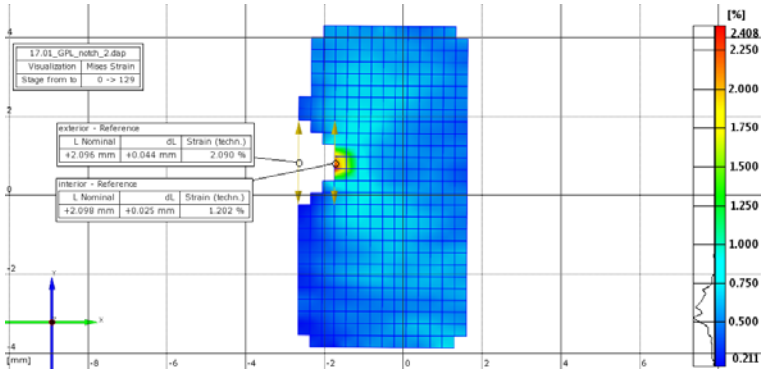

Figure 4. von Mises strains before failure in a MWNT SEN specimen; the crack area is masked

Analyzing by SEM the fracture surface of a MWNT SEN specimen (Fig. 5) it can be observed that fracture phenomena at the initial crack front are different than those observed in specimens from pure epoxy. Fibers of material are pulled-out, this being a common feature. These fibers are not necessarily associated with the MWNT and have diameters much larger than those of MWNT.

By observing in more detail the fracture surface (Fig. 6), one can notice that the MWNT were pulled out during the major crack propagation process, and can be seen on the crack surface. The measured diameters of the nanotubes are in between 30-45 nm.

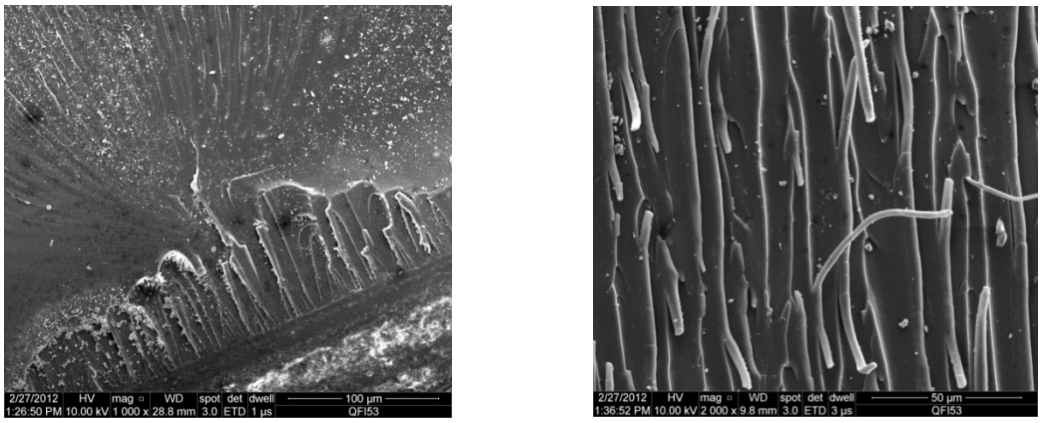

Figure 5. Fracture surface analyzed by SEM for a MWNT-epoxy SEN specimen

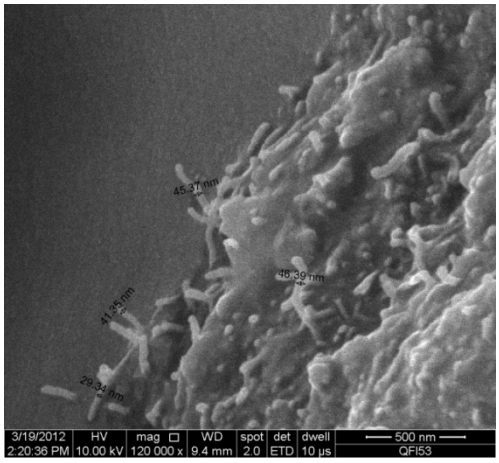

Figure 6. Fracture surface of a MWNT-epoxy sample showing MWNT pull-out.

In GPL-epoxy, both isolated and clustered platelets are observed. The distribution of cluster sizes is rather broad. These are observed on the crack surface, as seen in Fig. 7 (right). It is also observed that the initiation of crack propagation from the front of the artificially cut crack (Fig. 7 left) takes place at the site of a GPL cluster, which indicates that the clusters reduce the measured fracture toughness.

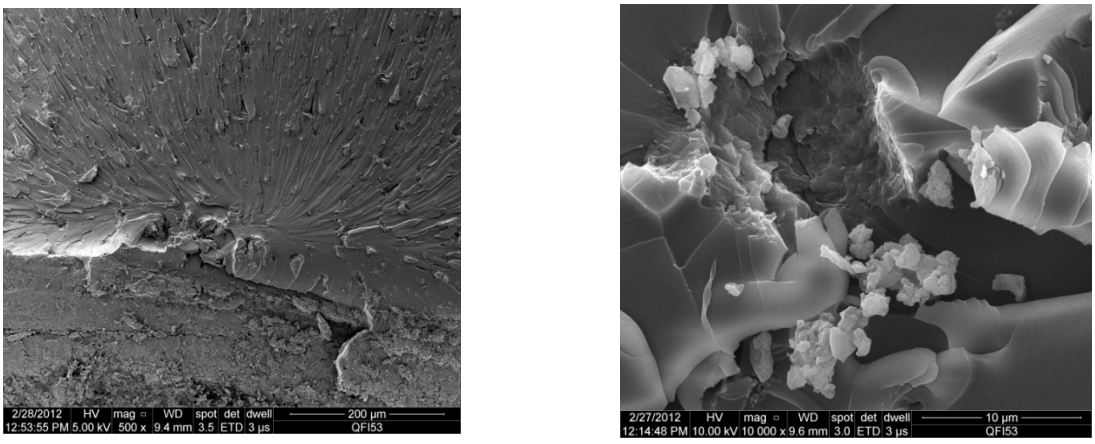

Figure 7. Fracture surface of GPL-epoxy SEN specimen

The fracture toughness is represented in Fig. 8 in the case of pure epoxy and both GPL-epoxy and MWNT-epoxy in the cases when good dispersion and insufficient dispersion are achieved. Clearly a good dispersion of the nanoparticles is essential to improve the critical fracture toughness of the material. However, an insufficient dispersion leads to no increase of the toughness, as one would expect.

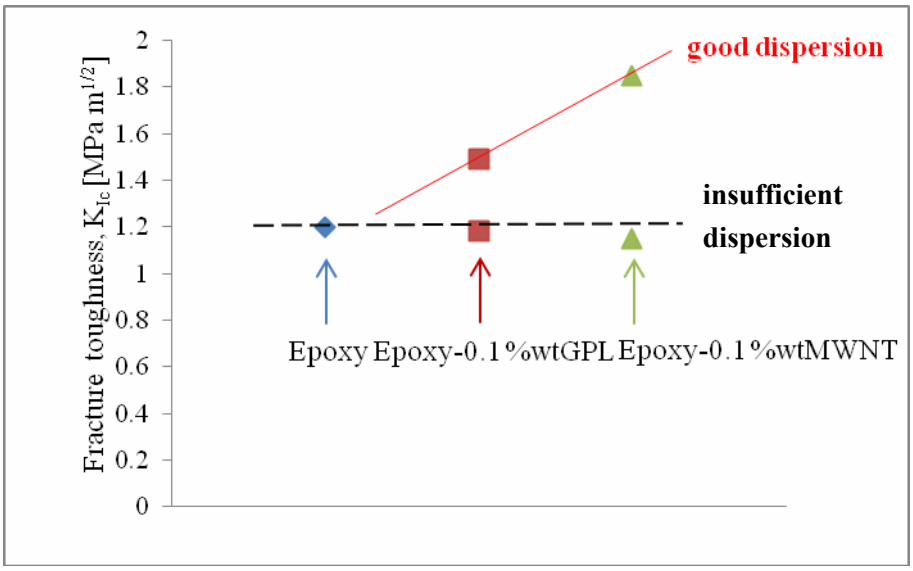

Figure 8. Critical fracture toughness values for pure epoxy and epoxy mixed with 0.1wt% graphene platelets (GPL) and with 0.1wt% carbon nanotubes (MWNT)

4. Conclusion

An adequate dispersion of the MWNT may lead to an increase of the fracture toughness of 80%. Smaller increases were obtained with GPL, even at similar dispersion quality. In the preliminary studies it was observed that the nanotubes increase the toughness through a *crack bridging* mechanism which is well-known in the case of standard composites with fibers of μm and mm dimensions. The results concerning the importance of good dispersion of nanofillers confirm observations of other research groups.

Abstract: Improvement of interlaminar mechanical properties in carbon fiber aluminum laminates (CARALL) fabricated by carbon fiber reinforced plastic (CFRP) layers combined with aluminum alloy layers was studied. Various toughing methods including acid etching treatment and patterned structure manufacturing on the surfaces of aluminum alloy layers, and addition of nanofiller, i.e., VGCF, to the interface of CFRP and aluminum alloy through powder method, were employed to improve the mechanical properties of CARALL. Experimental results of double cantilever beam (DCB) tests indicated the improvement on the interlaminar mechanical properties of Mode-I fracture from much higher critical load P_c and fracture toughness G_{IC} when using the acid etching treatment and VGCF addition. The acid etching treatment sample with VGCF 20 g/m^2 possesses the highest G_{IC}, which is 41 times higher than that of the sample without any treatment. The patterned structure manufacturing on the surfaces of aluminum alloy layers can further improve the fracture properties of CARALL without adding VGCF. While VGCF was included in CARALL specimens, the patterned structure manufacturing has a minor effect on the Mode-I interlaminar mechanical properties. Crack propagation and fracture surface have also been observed to interpret the improvement mechanism.

Keywords: Carbon fiber aluminum laminates (CARALL), vapor grown carbon fiber (VGCF), fracture toughness, interlaminar mechanical properties.

1. Introduction

Carbon fiber aluminum laminates (CARALL) are a kind of FML (fiber metal laminates) materials which are hybrid composite structures based on thin sheets of metal alloys and plies of fiber reinforced polymeric (FRPs) materials combining the advantages of metallic materials and fiber reinforced matrix systems. Metallic materials are for instance isotropic, have a high bearing strength and impact resistance and are easy to repair, while fiber reinforced matrix systems have excellent fatigue characteristics and high strength and stiffness. The fatigue and corrosion problems of metallic materials and the low bearing strength, impact resistance and reparability of fiber reinforced matrix systems can be overcome by the combination [1]. Nevertheless, laminates, and CARALL is no exception, have some disadvantages as well. Due to the combination of different materials, new failure mechanisms are introduced. One of such a mechanism is delamination, which can have serious consequences for the overall stiffness of the material, especially in those cases where compressive or shear loadings are dominate. The relatively weak bonding between metal/polymer interfaces still remains a problem to be solved.

In order to solve this problem, surface treatment methods (e.g. acid treatment, anodizing, and

patterned structure manufacturing etc.) were employed by many researches to improve the interface mechanical properties of FMLs [2-7]. Kim *et al.* [3] systematically investigated the influence of surface morphology on the adhesion strength of a CFRP/Steel bond by incorporating micro-periodic line patterned surface on the metal substrate. They pointed out that the major source of strength enhancement caused by metal surface topography modification in polymer/metal bonded joints is the transition from interfacial to cohesive failure. Nano- and micro-scale surface treatment effects on adhesion strength improvement for CFRP/aluminum interfaces were investigated by Jang *et al*. [6]. Micro-scale line pattern was made on the aluminum surface by using conventional photolithography and acid etching. Anodizing process was employed to create uniform nano-porous morphology across the whole line pattern region on the aluminum specimen. The results showed that the specimen with nano-scale morphology in micro-scale line pattern resulted in the highest maximum load bearing capacity compared with that of only with micro-scale line pattern.

With excellent mechanical properties, nanofillers (carbon nanotubes (CNTs), nanoclays, vapor grown carbon fiber (VGCF), etc.) are considered as ideal reinforcement candidates to the matrix or the interface of laminate composite to improve its mechanical properties. For instance, Jen *et al.* [8] observed that the incorporation of 1.0 wt.% SiO_2 nanoparticles into interfaces among CFRP plies resulted in the increase of the overall in-plane tensile strength and stiffness of CFRP, but little improvement in fatigue behavior. A prepared VGCF paste interlayer was inserted into the interface between two $[0^o]_7$ CFRP sublaminates by Arai *et al.* [9], and revealed that the Mode-I fracture toughness was enhanced by 50%. However, till now, there has been no report about using nanofillers as the reinforcement for FML. The combined effects of various toughing methods (e.g. acid etching treatment, patterned structure manufacturing, addition of nanofiller) have not been well explored.

In this study, various toughing methods including acid etching treatment and patterned structure manufacturing on the surfaces of aluminum alloy layers, and addition of nanofiller (i.e., VGCF) to the interface of CFRP and aluminum alloy through powder method, were employed to improve the interlaminar mechanical properties of CARALL. The area density of VGCF varies at 0, 10, 20, and 30g/m^2 at the interface. The results of DCB tests demonstrate that this new hybrid CARALL with acid etching treatment and 20g/m^2 VGCF addition possess the highest Mode-I interlaminar fracture toughness. While the patterned structure manufacturing on the surfaces of aluminum alloy layers only has an improvement effect on the Mode-I interlaminar mechanical properties when VGCF was not dispersed into the laminate interfaces. Crack propagation and fracture surface observations of specimens using optical microscopy have also been carried out to study the toughening mechanism of the hybrid CARALL.

2. Experiments

2.1 Fabrication of specimens

To systematically investigate the effects of different toughing technologies, as shown in Table 1, 9 kinds of CARALL specimens have been fabricated in an autoclave for 3h at curing temperature of 130℃. The producing process was schematically shown in Fig. 1. The CFRP prepregs (TOHO

TENAX Co., Ltd, Japan), one commercial aluminum alloy AL2017 (TOHO Hitetsu-Kinzoku Co., Ltd, Japan) and VGCF (Showa Denko K.K, Japan) were used, where the details of the physical and mechanical properties were given in Table 2, where "A" denotes the acid-treatment, and "G" denotes patterned structure manufacturing with grooves. All of the specimens except the first kind CARALL were treated by acid etching process. In the acid etching process, the aluminum alloy layers were socked in 1mol/l nitric acid for 24h to increase their surface roughness. In addition to acid etching treatment, the aluminum alloy layers of the last four kinds of specimens were also processed with small grooves which were vertical to the fiber direction of the CFRP laminates. The dimensions of the grooves were shown in Fig. 2. Moreover, in some specimens, three different contents of VGCF, as the reinforcement for interface, were dispersed at the interface of unidirectional CFRP laminates and the aluminum alloy layers during the hand lay-up process,

Table 1. Specimen list

Specimens	Acid treatment	Grooved	VGCF
CARALL	—	—	—
A-CARALL	○	—	—
A-CARALL(10)	○	—	10 [g/m^2]

Table 2. Physical and mechanical properties of CFRP prepregs, AL2017 and VGCF

CFRP prepreg		VGCF	
Young's modulus (Fiber direction)	116.8GPa	Diameter	150nm
Young's modulus (Transverse direction)	8.83GPa	Length	10-20mm
CF content	63%	Aspect ratio	10-500
AL2017		Density	2.0g/cm^3
Young's modulus	80GPa	Young's modulus	273-760GPa
Tensile strength	375MPa	Tensile stress	2700-3500MPa

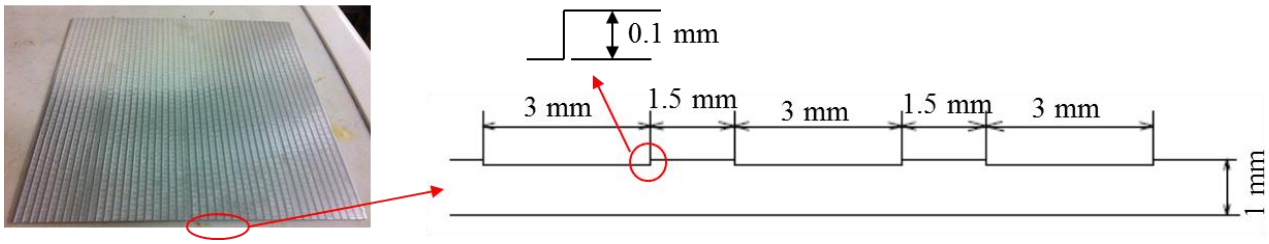

Figure 2. Dimensions of the grooves on the aluminum alloy layer

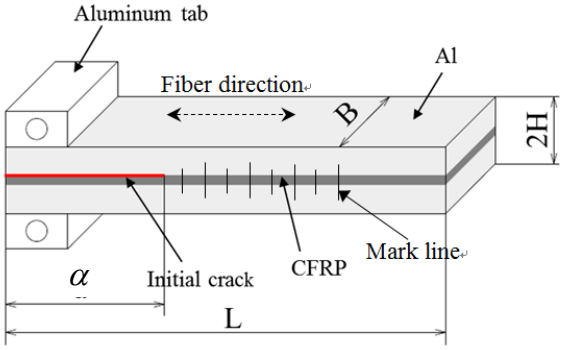
where a simple and newly-developed fabrication technology with low production cost, i.e., *powder method* [10], was employed.

2.2 DCB test procedure

In order to evaluate the Mode-I interlaminar fracture toughness, DCB tests have been carried out using a universal material testing machine at 25^{o}C by referring to Japanese Industrial Standards (JIS) K7086 [11]. Two specimens for each type of laminate with different toughing treatments were cut from the fabricated panels, where mark lines were painted on side surface for crack length measurement. The dimensions of specimens were schematically depicted in Fig. 3. Tensile loads



Length L=125mm; Width B=20mm; Height H=2.36mm~
Initial crack length *a*=45mm
Figure 3. Specimen for DCB tests

were applied at two aluminum tabs at one end of the specimen by using special apparatus through universal joints at a crosshead speed of 0.5mm/min. As given in Ref. [11], G_{IC} at the initial stage of crack growth and fracture resistance G_{IR} during crack propagation process can be calculated as a function of the crack growth, which is obtained by visually measuring the side surface of specimen. First, the relationship between the crack length a, and the compliance of load-COD (crack opening displacement) curve λ, are expressed in the following equation,

$$\frac{a}{2H} = \alpha_1 (B\lambda)^{\frac{1}{3}} + \alpha_0 \tag{1}$$

$$\lambda = \frac{\delta}{P} \tag{2}$$

Here δ and P stand for COD and the applied force respectively, α_0, α_1 are the fitted coefficients obtained from the experimental relation between a and λ. Then, by using the compliance method of homogeneous isotropic materials in classical fracture mechanics, G_{IC} and G_{IR} can be evaluated as follows,

$$G_{IC} = \frac{3}{2(2H)} \left(\frac{P_C}{B} \right)^2 \frac{(B\lambda_0)^{\frac{2}{3}}}{\alpha_1} \tag{3}$$

$$G_{IR} = \frac{3}{2(2H)} \left(\frac{P_R}{B} \right)^2 \frac{(B\lambda)^{\frac{2}{3}}}{\alpha_1} \tag{4}$$

where P_C is the critical load at the initialization of crack growth, and P_R the load during crack growth process, which can be obtained from load-COD curves.

3. Results and discussion

3.1 Mode-I interlaminar fracture toughness

Typical load-COD curves were plotted in Fig. 4, which shows the comparison of four representative types of specimens, i.e., CARALL, A-CARALL, A-CARALL(20), and A-G-CARALL. Critical loads at crack growth P_C for various types of specimens, which are obtained from peaks loads in Fig. 4, were shown in Fig. 5. From Figs. 4 and 5, it can be found that P_C of A-CARALL, A-CARALL(20), and A-G-CARALL were higher than that of base CARALL, which indicates the reinforcement effect of acid etching treatment, patterned surface manufacturing and VGCF interlayer. The highest P_C occurs in the case of A-CARALL(20), which is about 12 times higher than that of the base CARALL laminates and 4 times higher than that of the A-CARALL specimen.

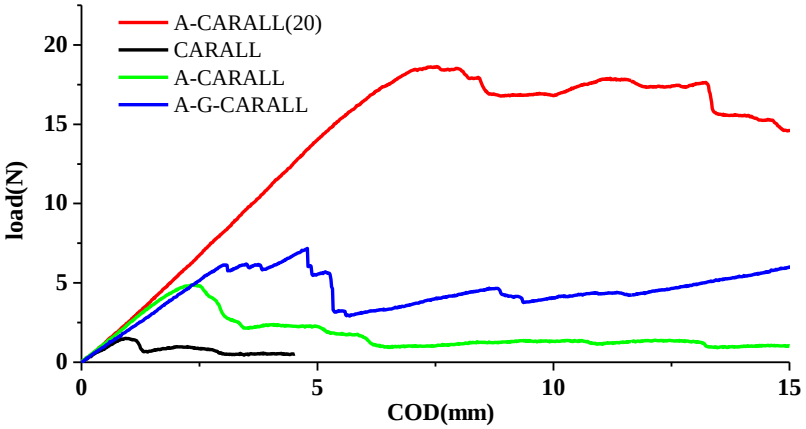


Figure 4. Comparison of load-COD curves for four kinds of specimens

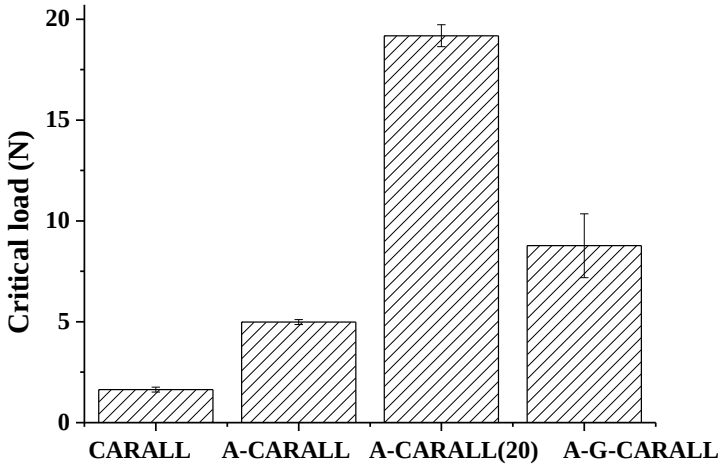

Figure 5. Critical load P_C for four kinds of specimens

Based on the load-COD curves of all fabricated samples and Eqs. (3-4), Mode-I fracture toughness G_{IC} and fracture resistance G_{IR} were demonstrated in Figs. 6 and 7 respectively. Note that G_{IR} was obtained by averaging the G_{IR} values of 5 points within the range of increment of crack length from 20 mm to 40 mm. For better understanding of the results from Figs. 6 and 7, two different situations were discussed. In the first situation, no VGCF was added into the specimens. In this case, it can be found from Figs. 6 and 7 that G_{IC} and G_{IR} were increased greatly for the A-CARALL and A-G-CARALL specimens. This indicates that the acid etching treatment can enhance the interlaminar mechanical properties of hybrid CARALL effectively. Without the addition of VGCF(0g/m^2), the higher G_{IC} and G_{IR} of A-G-CARALL compared to that of A-CARALL demonstrates that the patterned surface manufacturing in the acid treatment aluminum alloy layers can further improve the interlaminar mechanical properties of hybrid CARALL. Therefore, in the case of no nanofiller, the optimal toughing technique was the combination acid treatment and patterned surface manufacturing. In the other situation, VGCF interlayer was included in the specimens. In this case, we can see from Figs. 6 and 7 that the G_{IC} of A-CARALL and A-G-CARALL specimens were both improved significantly with the addition of VGCF. In particular, the specimens with VGCF 20g/m^2 loading have the highest fracture toughness which is of approximate 41 times higher G_{IC} than that of the pure CARALL specimen. However, as VGCF

content increases above 20g/m^2, the fracture toughness tends to decrease. By increasing the VGCF content to 30g/m^2, the G_{IC} of these specimens are approximate one half of the 20g/m^2 specimens. Moreover, it is easy to find that although the patterned surface can improve the interlaminar mechanical properties of A-CARALL composite without VGCF addition, however, when VGCF was added into the specimens, the G_{IC} of A-G-CARALL is all lower than that of A-CARALL except A-G-CARALL(30) specimen. This indicates that the improvement effects of VGCF addition for A-W-CARALL were lower than A-CARALL specimens. Therefore, in this case, the optimal toughing method was acid treatment combined with 20g/m^2 VGCF or 10g/m^2 VGCF. Note that the G_{IC} of A-CARALL(20) is only slightly higher than A-CARALL(10), however, the VGCF loading is two times of A-CARALL(10). As for G_{IR}, the trend of results was almost the same as that of G_{IC}, except for the result of A-G-CARALL(20). G_{IR} of the specimens increases with the addition of VGCF, passes through a peak value (for A-CARALL at 20g/m^2 loading, for A-G-CARALL at 10g/m^2 loading), and then decreases.

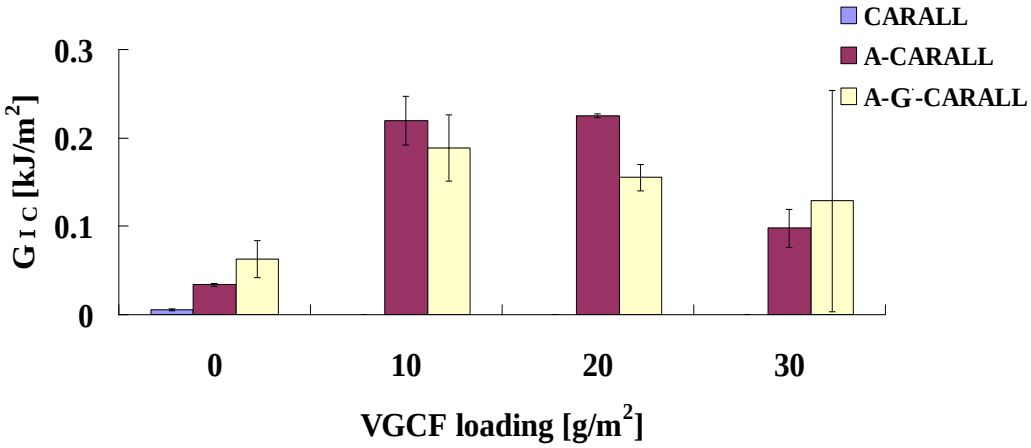

Figure 6. Comparison of G_{IC} for various specimens

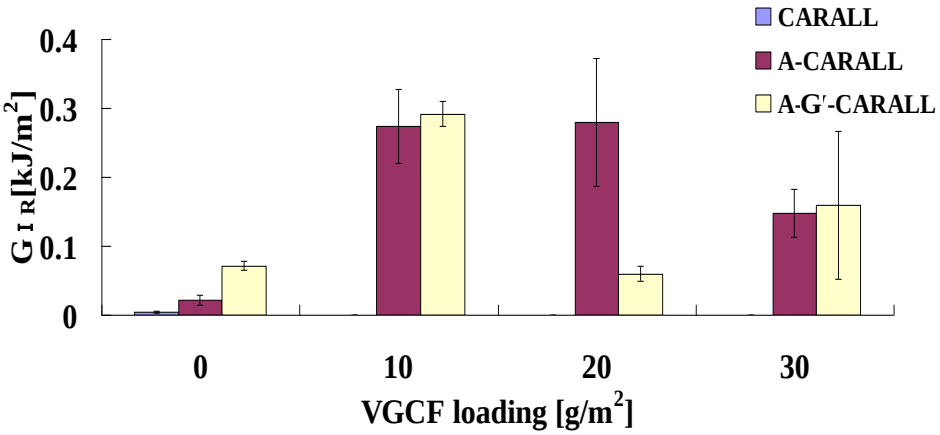

Figure 7. Comparison of G_{IR} for various specimens

3.2 Crack path and fracture surface observations

To uncover the relevant toughening mechanisms involved, the following experimental observations have been conducted.

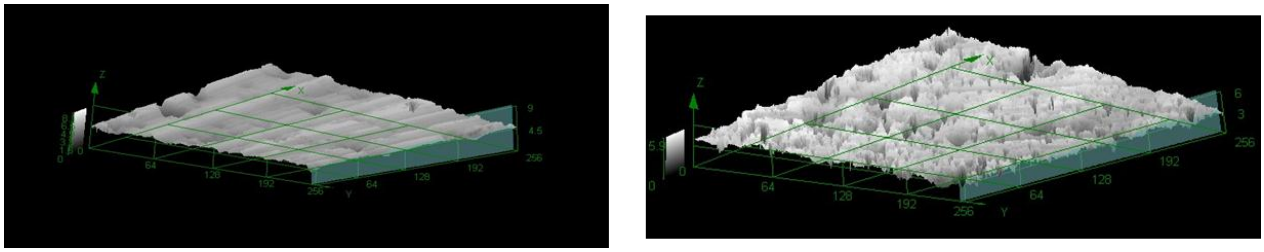

Figure 8. Surface morphology of the aluminum layers (a) before and (b) after acid etching treatment

For the first case, no VGCF was added into the specimens. Figure 8 describes the surface morphology of the aluminum layers before and after acid etching treatment respectively. It can be found that the acid etching treatment have produced a rough surface on the aluminum plate which consist of many small holes, grooves. The average diameter is about 18μm and the depth is approximately 2-5μm. When a liquid epoxy resin is applied to the rough surface, it conforms to the rough surface and tends to fill up the irregularities of the substrate surface such as microgrooves, holes. Consequently, mechanical interlock forms after the epoxy resin is cured. Due to the formed mechanical interlock, cohesive failure of the epoxy resin occurs near the interface as the epoxy is peeled away from the substrate, resulting in the crack path deviating from the interface. Such deviation of crack path away from the interface usually results in the increase of fracture surface area and requires additional energy associated with the crack propagation within the polymer. Moreover, cohesive failure, caused from the molecular decohesion of the polymer resin, expends larger energy for crack propagation than interfacial failure [4]. Furthermore, plastic energy dissipation in the bulk polymer material is effectively-induced during the crack growth in the polymer region rather than during the crack growth at the interface. Therefore, the acid etching treatment can effectively enhance the interface strength. As for the patterned structure manufacturing, the crack path deflected at the position of patterned grooves as shown in Fig. 9. Therefore, more cohesive failure occurred and more fracture surface formed during the crack propagation which explains the improvement of G_{IC} and G_{IR} compared to that of A-CARALL specimen.

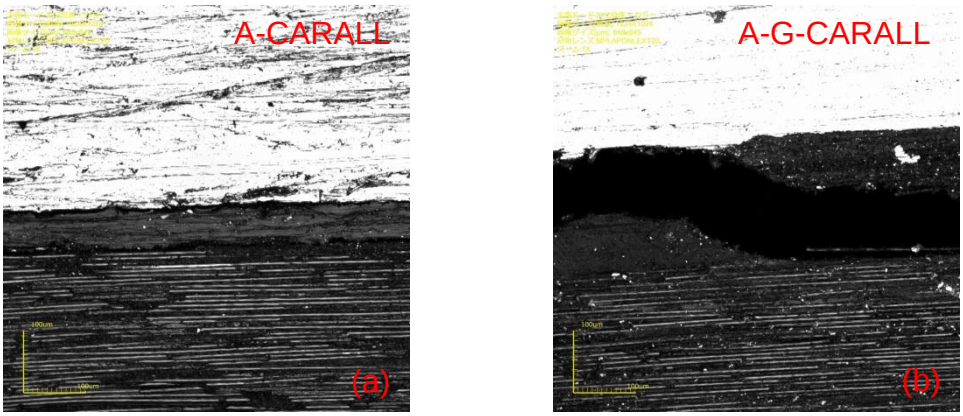

Figure 9. Crack propagation of A-CARALL and A-G-CARALL speimens

Figure 10 shows the fracture surface of three kinds of specimens which also confirm the aforementioned explanation. It can be found from Fig. 10(b) that there is more residual epoxy resin

on the fracture surface of A-CARALL specimen compared to CARALL specimen which indicates the more cohesive failure occurred in the A-CARALL specimen. Therefore, the fracture toughness of A-CARALL is higher than that of CARALL. From Fig. 10(c) we can see there are some fractured carbon fibers in the groove position which play a "bridging" role to resist the delamination propagation. Moreover, there is more cohesive failure than the A-CARALL specimen due to the existence of patterned grooves. This may explain the higher G_{IC} of A-G-CARALL than that of A-CARALL.

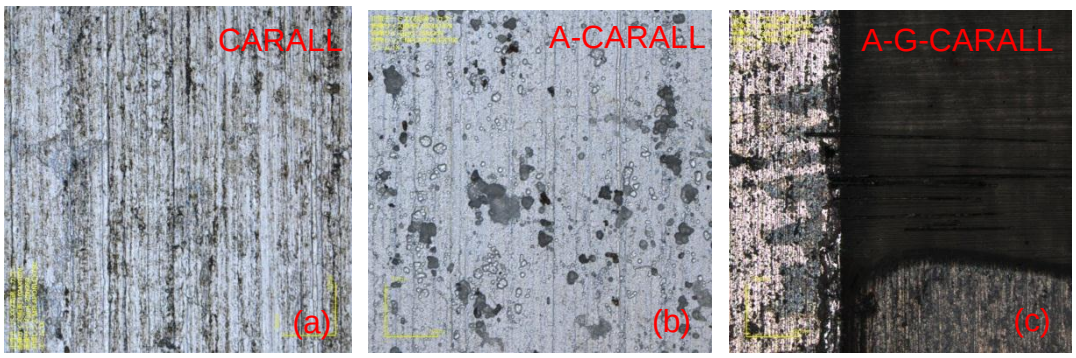

Figure 10. Fracture surface of (a) CARALL, (b) A-CARALL, (c) A-G-CARALL

For the second case, VGCF were included in the specimens. It can be found from Fig. 11(a) that almost all of the fracture surface were covered with residual epoxy resin and fractured fiber due to the proper addition of VGCF. This indicates that a lot of cohesive failure and "bridging" effect occurred on the fracture interface of A-CARALL(10) specimen. Therefore the fracture toughness was increased significantly compared with that of no VGCF. This is the same for Fig. 11(b), compared to A-G-CARALL, the residual epoxy resin and fractured fibers were left not only on the groove position but also on the flat part. This indicates that the flat part on the fracture surface of A-G-CARALL(10) was also contribute to the improvement of fracture toughness, which explains the enhancement of G_{IC} compared to A-G-CARALL specimens.

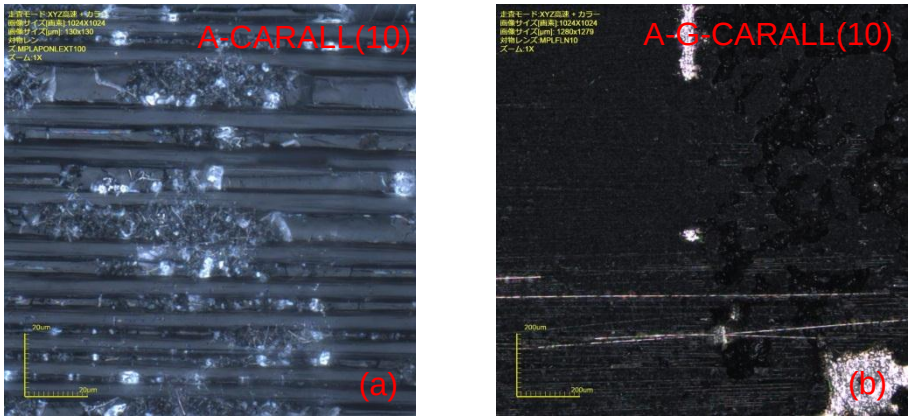

Figure 11. Fracture surface of (a) A-CARALL(10), (b) A-G-CARALL(10)

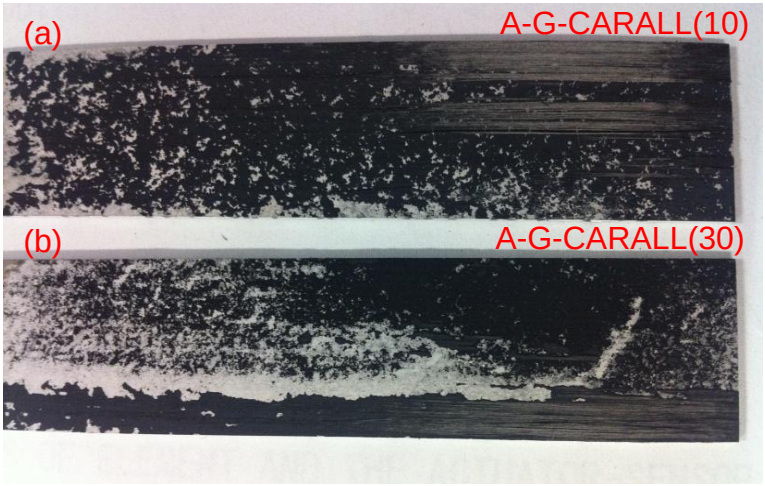

Figure 12. VGCF dispersion condition of (a) A-G-CARALL(10), (b) A-G-CARALL(30)

From the above analysis, it reveals that the incorporation of proper content of VGCF at interface of the hybrid CARALL results in the enhancement of interlaminar fracture toughness. However, the overdose of VGCF in the interface of CFRP and aluminum alloy layer may cause the decrease of its fracture toughness. This may be explained by Fig. 12, which shows that the dispersion of VGCF on the A-G-CARALL(10) specimen is better than that of the A-G-CARALL(30) specimen. The VGCF agglomerate condition of A-G-CARALL(10) specimens was not so severe. However, when the VGCF area density reaches to 30 g/m^2, as shown in Fig. 12(b), the fracture surface containing some large defects caused by insufficient dispersion of VGCF can be seen clearly, which implies its lower fracture toughness.

4. Conclusions

In this study, we systematically investigated the effects of various toughing methods on the mode-I fracture toughness of hybrid CARALL. The following conclusions can be made:

1. When there is no VGCF addition, by carrying out DCB tests, the critical load and Mode-I fracture toughness of hybrid CARALL have been verified to be improved with acid etching treatment. And the patterned surface manufacturing on the aluminum alloy layers can further enhance the fracture toughness and resistance based on the acid etching treatment.
2. The fracture toughness of A-CARALL and A-W-CARALL was improved significantly by adding controlled amount of VGCF into the interface of CFRP and aluminum layer. However, the improvement was less for A-W-CARALL compared to that of A-CARALL. This indicates that, when VGCF was dispersed into the hybrid CARALL, the patterned surface may have a negative effect.
3. The reinforcement and toughening effects of VGCF interlayer depend on the area density of VGCF, which do not certainly increase as the addition amount of VGCF increases. The fracture toughness of the specimen first increases with the addition of VGCF, passes through a peak value, and then decreases. From the previous results, at least for the fabrication method described in this work, the best value of VGCF area density at the interface is 20 g/m^2.

Abstract Orthorhombic structure perovskite $LaFeO_3$ (LFO) nanoparticles (NPs) were prepared by reverse micelles method. The control of particle size was achieved by varying the water to surfactant molar ratio. The dried precipitate was transformed to pure $LaFeO_3$ phase by calcinations at 750 ºC. The average particle size was found to increase with increase in water to surfactant ratio(R). The nanostructure properties were studied by using contact mode of atomic force microscopy (AFM), X-ray diffraction (XRD) and scanning electron microscopy (SEM) equipped with energy dispersive X-ray spectrometer (EDS) techniques. These techniques led themselves very well to investigate the structure of NPs and to find out properties and structure on surface of LFO. At room temperature the magnetic properties (M–H) were measured using a vibrating sample magnetometer (VSM) with a maximum magnetic field of 20 kOe.

Keywords Reverse micelle, Nanoparticles, XRD, Magnetization

1. Introduction

Reverse micelles, or water-in-oil microemulsions, incorporate a variety of solutes. The distribution of the solute between the surrounding solvent and the micelles can be described in terms of a partition constant based on a two pseudophases model that can be expanded to three pseudophases in micelles with high water to surfactant mole ratios. In these systems, two partition constants can be defined, one between the external solvent and the micellar interface, and other between the external solvent and the inner water pool [1]. The perovskite structures with general formula ABO_3 have been formed by mixed oxides of rare earth elements and d transition metals. Lanthanum ferrite ($LaFeO_3$) has orthorhombic symmetry perovskite structure (a= 8.135 Å, b= 6.040 Å, and c= 8.540 Å) and an antiferromagnetic insulator with Nell temperature T_N = 750K [2]. These materials are interesting for catalytic applications due to the extensive range of elemental compositions that can be prepared as crystalline structures [3]. The molecular structure of the surfactant affects the size of micelle water pools and is it common in some surfactant systems to use a co-surfactant to produce a larger range of micelle sizes, such as CTAB, NP4 and NP7. It has been shown that using this combination also improves solubilization and overall micelle stability when compared to the corresponding single surfactants [4]. By using reverse micelles, we have been able to control the size and partially the shape of metallic copper particles. Recently we observed that the reducing agent plays an important role in the control of particle size and in the final oxidation state at the surface.

2. Experimental

$LaFeO_3$ NPs were prepared using reverse micelle technique. A quaternary system of iso-octane/CTAB/n-buty alcohol/water was selected in this RM process. In this process we used two

kinds of RM solutions namely RM1 and RM2. For first solutionRM1contained (5 wt %) an aqueous solution of an equimolar mixture (0.1M) of ($La(No_3)_3.6H_2O$) and ($Fe(No_3)_3.9H_2O$), CTAB as a surfactant (7.5 wt%), n-buty alcohol as a co-surfactant (7.5 wt%) and iso-octane as oil (30 wt%). The stirring was continued for 30 min resulting in a stable reverse micelle (RM1). While RM2 contained the same constituent as RM1 except that the aqueous solution was NaOH (0.1 M) instead of ($La(No_3)_3.6H_2O$) and ($Fe(No_3)_3.9H_2O$) was prepared under similar conditions. These two reverse micelles were mixed under constant stirring and a brown color solution was obtained. In addition ammonium NH_3 was slowly added to adjust the PH and stirred 24 h on a magnetic stirrer. The resulting precipitate was separated from the surfactant and a polar solvent by centrifugation and washing it one time by ethanol and three times by distilled water. The precipitate was dried in an oven at 80 ºC for 6 h to obtain $LaFeO_3$ powder and heated at 750 ºC for 6 h in air.

The crystal structure was investigated by X-ray diffraction (Rigaku, Japan, Miniflex-II) using Cu-K_α radiation (λ= 1.5418 Å) in 2θ range from 20º to 80º. A scanning electron microscope (JEOL JSM-6510LV) equipped with an energy dispersive spectrometer (EDS) was used to check the morphology and particle size. The atomic force microscopy (Veeco-contact mode) was used to examine the morphology and the surface roughness. Room temperature magnetic measurements (M–H) were measured using a vibrating sample magnetometer (VSM) with a maximum magnetic field of 20 kOe.

3. Results and discussions

The X-ray diffraction (XRD) pattern of $LaFeO_3$ nanopowders calcined at 750 ºC is shown in Fig. 1.

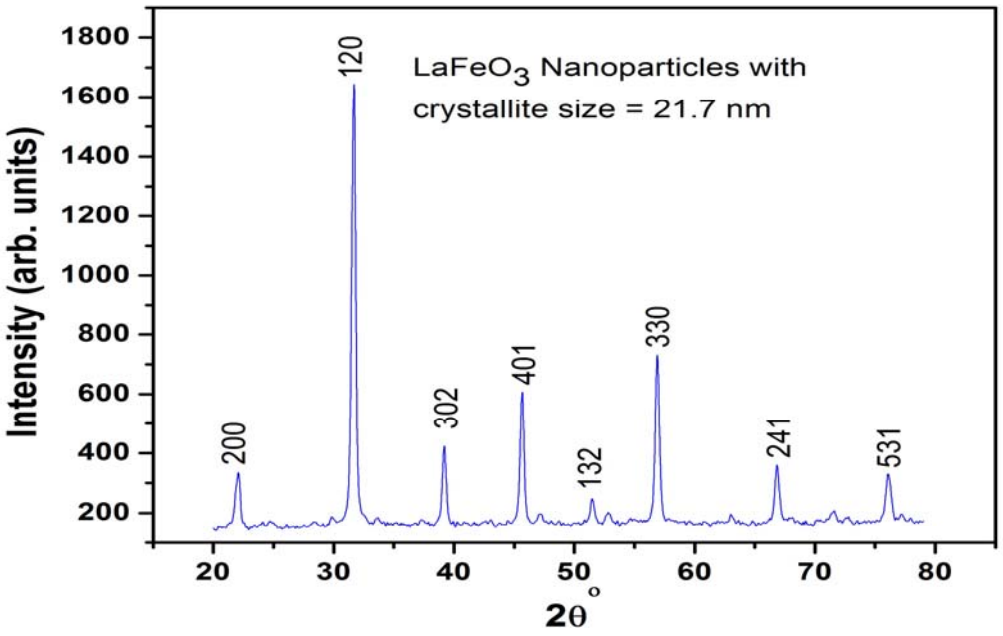

Figure 1. XRD pattern of the LFO NPs.

The position of the all peaks confirmed the high crystallinity and perovskite structure of the NPs and no other impurity peaks were detected in the XRD patterns. Furthermore, the products of the

three samples were observed in orthorhombic perovskite structure with space group Pbnm, which is well consistent with the standard JCPDS card of perovskite $LaFeO_3$ (JCPDS88-0641) [5] and lattice parameters were found a= 8.135 Å, b= 6.040 Å, and c= 8.540 Å. The average of crystallite size using the most intense peak (120) at angle 2θ~33° was estimated from the XRD pattern by using Debye–Scherer's formula.

The AFM images of $LaFeO_3$ standard roughness, two and three dimensions have shown in Fig. 2. The Fig. 2a, 2b and 2c are displayed the standard roughness of $LaFeO_3$ NPs, where R_a is the roughness average, R_p is the maximum height of the profile above the mean line, R_t is the maximum peak to valley height the profile and R_{pm}, R_{tm} are the mean values more representative of the entire profile. Fig. 2d and 2e are shown the uniform grains of $LaFeO_3$ NPs surface morphology. Actually, a homogeneous surface was formed and the grains were observed in different area. The AFM images for two and three dimensions reveal grains with size of few tens nanometers, that is meaning that the micron sized grains consisted of an agglomeration of small grains.

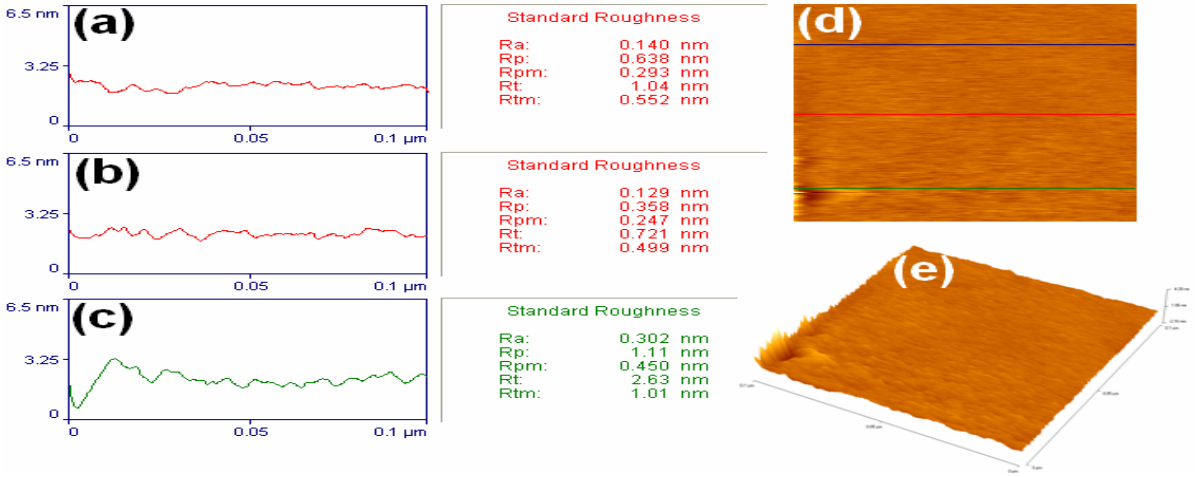

Figure 2. (a, b and c) the standard roughness area of $LaFeO_3$ NPs, (d) two dimensions AFM image for $LaFeO_3$ and (e) three dimensions AFM image for the same.

SEM image of $LaFeO_3$ NPs is displayed in Fig. 3a. The surface morphology of NPs reveals the uniform grains, which displays that the complete incorporation of $LaFeO_3$ as supported by XRD analysis. In addition the EDS analysis also confirms the presence of La, Fe and O elements in good stoichiometric as displayed in the Fig. 3b.

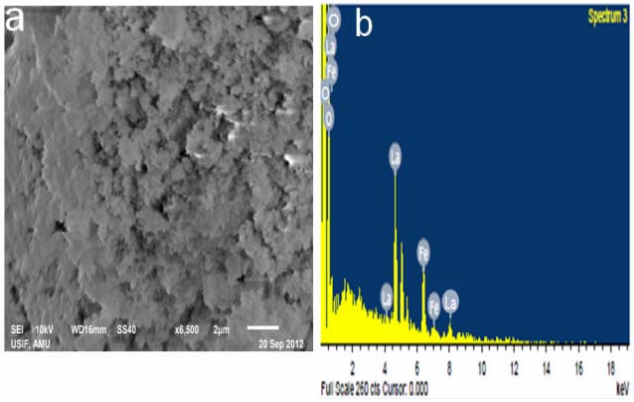

Figure 3. a) SEM image of the LFO NPs b) EDS microstructure of LFO NPs spectrum for the same.

The magnetization hysteresis (M-H) loops measured at room temperature of $LaFeO_3$ with maximum applied field of 20 kOe as displayed in Fig. 4. We can see that the magnetization of $LaFeO_3$ NPs is 0.136(emu/gm). The plot of the magnetization indicting that the ferromagnetic behavior was observed on the $LaFeO_3$ NPs.

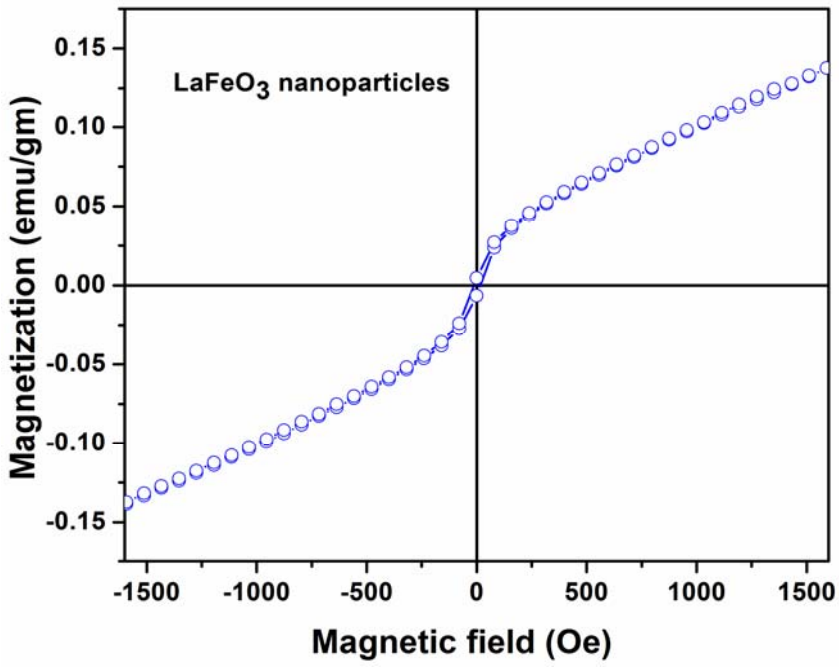

Figure 4. Magnetization versus field for $LaFeO_3$ NPs.

In summary, the $LaFeO_3$ NPs were successfully prepared by reverse micelle method, orthorhombic perovskite structure and phase conformation was confirmed by X-ray diffraction. Ferromagnetic behavior was observed in the $LaFeO_3$ NPs.

Abstract Systematic atomic simulations based on molecular mechanics are carried out to investigate the pull-out behavior of carbon nanotubes (CNTs) in CNT-reinforced nanocomposites. In contrast with open-ended CNT, capped CNT is incorporated into the current computational model to explore the effect of the CNT cap for the first time. Two common cases are discussed: the pull-out of a whole CNT from a polymer matrix in a CNT/Polymer nanocomposite, and the pull-out of the broken outer walls against the intact inner walls of a CNT (i.e., sword-in-sheath mode) in a CNT/Alumina nanocomposite. By analyzing the obtained relationship between energy increment and pull-out displacement, a set of simple empirical formulae is proposed to predict the corresponding pull-out force from the nanotube diameter. The obtained pull-out force agrees well with experimental measurement. Moreover, the much higher pull-out force in the case of capped CNT than that of open-ended CNT implies a great contribution of the CNT cap to the interfacial properties of CNT-reinforced nanocomposite. This finding provides valuable insight into designing nanocomposites with desirable mechanical properties.
Keywords Carbon nanotube, Nanocomposites, Mechanical properties, Pull-out behavior

1. Introduction

To date, many experiments have demonstrated that the pull-out of carbon nanotubes (CNT) from a matrix is a common critical phenomenon, as seen from observation of fractured surfaces of CNT-reinforced nanocomposites. CNT pull-out can be further divided into the following two categories: one is the pull-out of a whole CNT from a matrix [1-3] and the other is the pull-out of the broken outer walls against the intact inner walls embedded in matrix (the so-called sword-in-sheath mode) [4,5]. The reduced load carrying capability of CNT due to the above two representative pull-out modes may be detrimental to the overall mechanical properties of bulk nanocomposites, such as stiffness and strength [6]. Thus, the continuously increasing demand for nanocomposites with significant mechanical properties provokes a thorough investigation of this pull-out behavior with the hope of finding effective methods to improve the interfacial properties between CNTs and the matrix as desired.

Direct pull-out experiments [7-11] have been carried out in which the interfacial shear strength of CNT-reinforced nanocomposites was calculated by dividing the measured pull-out force by the embedded lateral area of CNT. On the other hand, various theoretical models [12, 13] based on continuum mechanics have also been developed to predict the interfacial shear strength. Moreover, atomic simulations [14, 15] have also provided an alternative method to predict the interfacial shear strength with the approach of potential energy variation.

However, to the best of our knowledge, there is no any systematical study about the effect of CNT's unique capped structure on CNT pull-out in CNT-reinforced nanocomposites, although this cap has a great influence on the pull-out of the outer walls against the inner walls of a multi-walled carbon nanotube (MWCNT) (i.e., interfacial sliding among nested walls in a MWCNT) [16-23]. It should be noted that the pull-out force of the outer wall against the inner walls in a MWCNT itself consists of the van der Waals (vdW) force and the frictional force between the walls. The frictional force may become significant when referring to the defects or chemical cross-linking [17-19]. On the other hand, for the perfect CNT, the vdW force will be dominant. In our previous experimental study [21] plus computational effort, due to very high quality of MWCNT, the frictional effect among the walls is very small as verified by the experimental evidences. Moreover, no direct quantitative comparison between the numerical pull-out forces and experimental data has been

reported to date since the existing numerical values are generally much (at least from 10 to several hundreds of times) lower than the existing experimental data. We have simulated the pull-out process of an open-ended CNT in detail based on molecular mechanics (MM) for CNT/Polymer [14] and CNT/Alumina nanocomposites [15]. As a continuous work, here, we investigate the pull-out behavior of a capped CNT in the above two nanocomposites *for the first time*. By carrying out a series of MM pull-out simulations, the detailed variation of systematic energy increment during the pull-out process is obtained. A set of empirical formulae is, therefore, proposed to predict the corresponding pull-out forces with good consistence of existing experimental data.

2. Pull-out simulation of a capped CNT in CNT/Polymer Nanocomposite

The pull-out of a whole CNT from various polymer matrices has been clearly observed from fractured surfaces in various CNT/Polymer nanocomposites [1-3], which may imply comparatively weak interfaces between CNT and polymer matrices. To understand the inherent characteristics of this pull-out behavior, we have analyzed, in detail, the pull-out process of an open-ended CNT from a polyethylene (PE) polymer matrix in our previous work [14]. It has been concluded that the corresponding pull-out force is independent of nanotube length and nanotube chirality, but proportional to nanotube diameter. Moreover, we have also demonstrated [20, 21] that the CNT capped structure significantly affects the pull-out behavior of the outer walls against inner walls in a MWCNT in the sword-in-sheath mode based on massive quantitative comparisons between the MM results and experimental data.

Based on the above outcomes, to investigate the effect of the cap on CNT pull-out behavior, three capped single walled carbon nanotubes (i.e., SWCNTs(5,5), (10,10), (12,12)), which are of the same length of 2.46nm, but different diameters, are incorporated into the PE matrix, respectively. The construction of the simulation cell is described elsewhere in detail [14], in which only vdW interactions between CNT and matrix are modeled without considering the chemical bonds or mechanical cross-links.

The pull-out of the above three capped SWCNTs based on MM are carried out in a similar way with previous works [14, 15]. The pull-out process of the capped SWCNT(5,5) is schematically described in Fig. 1 as a representative example, where a prescribed displacement on the CNT is applied on its axial direction. Note that a much smaller displacement increment, Δx_1 of 0.01nm, than that of the 0.2nm in previous simulations [14] is adopted in the present simulation in order to explore the cap effect in a more detailed way.

It should be noted that the quasi-static characteristics of MM simulations yield a considerable improvement in the computational efficiency compared to that of traditional molecular dynamics (MD) simulations since the velocity components of the individual atoms within the system are ignored. In other words, the MM method is insensitive to the effects of thermal instability and kinetic excitation, and can therefore be expected to provide an accurate representation of the low

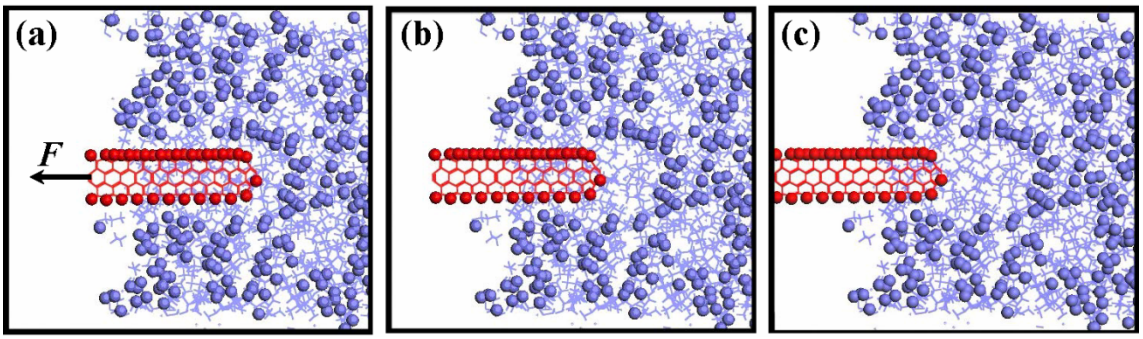

Figure 1. Pull-out process of SWCNT (5,5) from PE matrix

strain rate deformation of nano-scale materials.

The present results for the relationship between nanotube diameter and energy increment between two consecutive pull-out steps are shown in Fig. 2a for the three SWCNTs, where D_o is the nanotube diameter. It can be seen that for each SWCNT, the energy increment, ΔE, between two consecutive pull-out steps (referred to as *energy increment* hereafter for simplicity) increases rapidly to a peak value at a specified displacement (labeled as Stage-1 in Fig. 2a), then remains steady with continued pull-out (labeled as Stage-2 in Fig. 2a). Finally, ΔE decreases quickly and arrives at a comparatively flat stage (labeled as Stage-3 in Fig. 2a). After entering Stage-3, to save computational cost, the simulation stops without further pull-out once the energy increment becomes stable. It can be seen that this trend is surprisingly consistent with that of the pull-out of outer walls against the inner walls in a capped MWCNT [21]. Moreover, the maximum energy increment in Stage-2 (i.e., $\Delta E_{\max}$) increases with nanotube diameter.

The relationship between the maximum energy increment, $\Delta E_{\max}$ in Stage-2, and nanotube diameter D_o can be fit into a quadratic function (see Fig. 2b), as follows:

$$\Delta E_{\max} = 2.72 D_o^{\,2} - 3.65 D_o + 4.67 \tag{1}$$

in which $\Delta E_{\max}$ and D_o are in the units of kcal/mol and nm, respectively. In view of that the energy increment is equal to the work done by the pull-out force, the maximum pull-out force with the unit of nN, for the case of a capped SWCNT, can be evaluated as

$$F_{\mathrm{SWCNT}} = 1.89 D_o^{\,2} - 2.54 D_o + 3.25 \tag{2}$$

For the pull-out of a whole open-ended MWCNT from PE matrix [14], it is believed that only the outer three walls have an effect on the variation of energy increment during the pull-out process. The reason can be explained as follows: from the outermost wall to the innermost wall, the distance between the inner walls of the CNT and the pull-out interface increases gradually. The longer the distance is, the weaker the vdW interaction. Therefore, since the cut-off distance of the vdW interaction is around 0.95nm and the wall spacing of MWCNT is 0.34nm, the pull-out of a whole MWCNT with more than 3 walls can be simplified as that of a triple walled carbon nanotube (i.e., TWCNT) composed of the outermost three walls of the MWCNT. From MM simulations, the corresponding pull-out force is found to be approximately about 1.2 times of that of a SWCNT composed solely of the outermost wall of the MWCNT.

On this basis, for the pull-out of a whole capped MWCNT from PE matrix, we can approximately revise the above formula of the pull-out force as

$$F_{\mathrm{MWCNT}} = \lambda (1.89 D_o^{\,2} - 2.54 D_o + 3.25) \tag{3}$$

in which F_{MWCNT} and D_o are in the units of nN and nm, respectively. Note that the coefficient λ indicates the effect of the wall number, which is 1.0 for SWCNT and 1.2 for MWCNT.

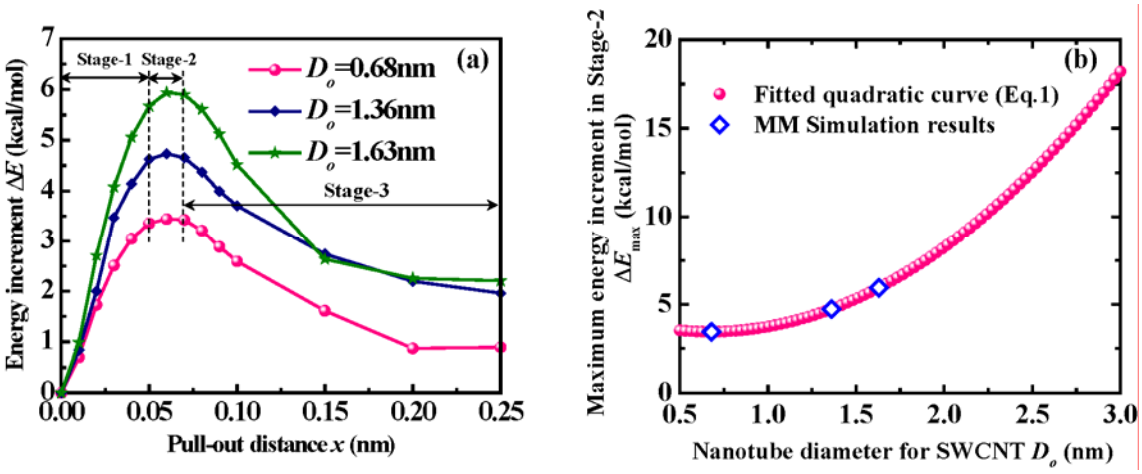

Figure 2. Energy increment during pull-out of SWCNT from PE matrix, (a) Energy increment ΔE versus pull-out displacement x; (b) Maximum energy increment in Stage-2 $\Delta E_{\max}$ versus nanotube diameter D_o

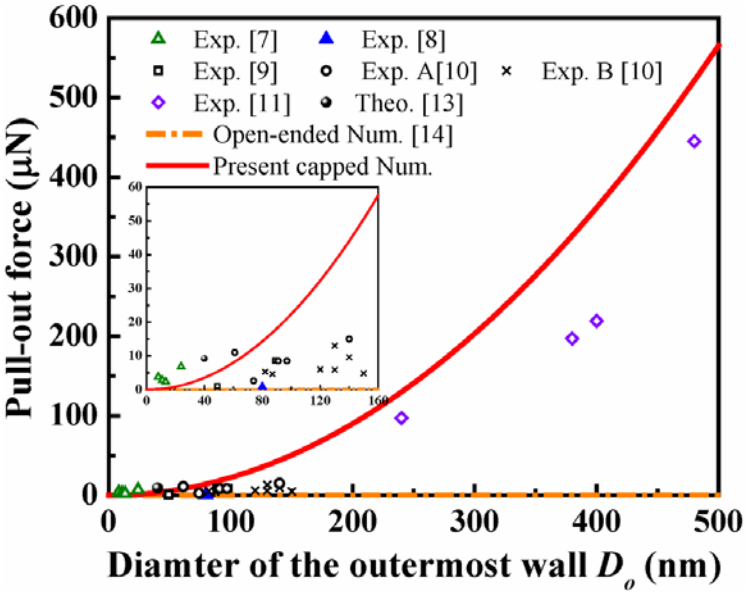

Figure 3. Comparison of experimental [7-11], theoretical [13] and present numerical pull-out forces in CNT/Polymer nanocomposites

Obviously, as given in Fig. 3, this predicted pull-out force for the capped MWCNT is much larger than that for open-ended CNT [14], which indicates the significant contribution of the CNT cap to the maximum pull-out force. Moreover, the predicted pull-out forces using the present method in Eq. (3) are also compared with the experimental results [7-11] in Fig. 3, in which the effect of polymer matrix type is ignored. It is found that the predicted values can comparatively effectively reflect the most of the experimental data (e.g., over 80%) very well, since it is very difficult to accurately match all experimental data at the nano-scale because of the difference of materials, fabrication conditions, test methods and etc. For example, Cooper *et al.* [7] attempted a drag-out configuration of a MWCNT bridging a hole in a CNT/Epoxy nanocomposite by loading the nanotube at its center. This set-up is analogous to a cable with two fixed ends and a center loading, in which the necessary force is obviously much higher than that during axial pull-out. On the other hand, the pull-out force measured by Barber *et al.* [8] is found to be much weaker than our predicted value. It can be explained by sample preparation, where their CNT is pushed into the molten polyethylene-butene thin film. Another set of pull-out tests are carried out using fractured specimens under tensile loading [9-11]. The small discrepancy can be attributed to the interface damage between CNT and matrix caused by tensile fracture, which can be positively recovered by the hot pressing method (Exp. A [10] in Fig.3) when compared to an untreated specimen (Exp. B [10] in Fig.3). It should be noted that there is large data scattering, even within the same research group. This scattering is probably due to the difficulty of nano-manipulation and precise measurement during these experiments.

The theoretical value calculated by multiplying the predicted interfacial shear strength [13] and the embedded lateral area of CNT is also incorporated into Fig. 3. Note that the adopted interfacial shear strength is predicted from experimental measured data using expansion of the classical Kelly-Tyson force balance method [22].

The above comparison validates the effectiveness of the proposed empirical formulae and further highlights the great contribution of the CNT cap to the pull-out force and interfacial properties of CNT/Polymer nanocomposites.

3. Pull-out Simulation of a Capped CNT in CNT/Alumina Nanocomposite

It has been experimentally reported that the sword-in-sheath mode is a common fracture mode for CNT/Alumina nanocomposites [4, 5]. The detailed process, as illustrated in Fig. 4, can be

summarized as follows [5]: initially, tensile stress leads to matrix crack formation and partial debonding. Then, as the displacement increases, some outer walls of the MWCNT break. The intact inner walls are then pulled away, leaving a fragment of the broken outer walls in the matrix (or the broken outer walls are pulled out against the intact inner walls). It should be noted that there are two pull-out interfaces, in contrast with the case of CNT/Polymer nanocomposites: one is between the outermost wall and the matrix, and the other is between the nested walls in the MWCNT. This observation indicates that this pull-out behavior, corresponding to the sword-in-sheath mode in CNT/Alumina nanocomposite, can be assumed to be the superimposition of the pull-out of the broken outer walls (Fig. 4b, I, left) against the matrix (Fig. 4b, I, right), and the pull-out of the broken outer walls (Fig. 4b, II, left) against the intact inner walls. By further decomposing the CNT into open-ended and capped components, the pull-out of the broken outer walls against the intact inner walls (Fig. 4b) can be divided into the pull-out of the open-ended component (Fig. 4b, II-O) and the pull-out of the capped component (Fig. 4b, II-C). It should be noted that the effect of the matrix (left) on the pull-out of the broken outer walls against the intact inner walls can be ignored, as the reported number of broken walls is about 10 or more [4], indicating a much longer distance from the matrix to the pull-out interface than the cut-off distance of the vdW interaction. The corresponding pull-out force for each part is discussed in the following:

(I)*Pull-out of broken outer walls against matrix*

As the number of the broken outer walls is usually more than 3, the model can be simplified as the pull-out of a TWCNT from alumina matrix. The corresponding energy increment for each pull-out step with constant displacement Δx_I of 0.2nm and the pull-out force can be predicted by [15]

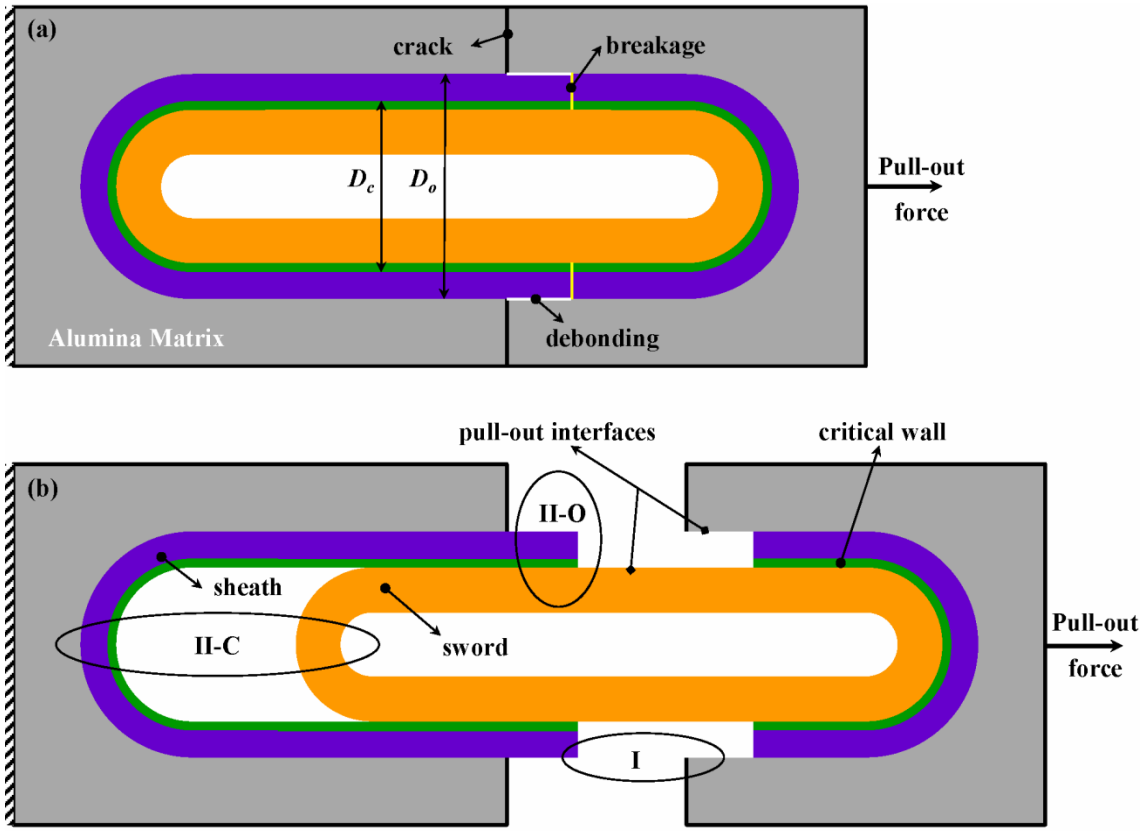

Figure 4. Schematic of CNT pull-out with sword-in-sheath mode in tensile tests of CNT/Alumina nanocomposites

$$\Delta E_{\mathrm{I}} = 58.26 D_o + 6.50$$
$$F_{\mathrm{I}} = \frac{\Delta E_{\mathrm{I}}}{\Delta x_{\mathrm{I}}} = 2.03 D_o + 0.23 \tag{4}$$

where D_o is the diameter of the outmost wall.

(II-O) ***Pull-out of open-ended component of broken outer walls against open-ended component of intact inner walls***

As the number of inner walls and outer walls are usually more than 3, the model can be simplified as the pull-out of a MWCNT with 5 walls, which consists of the immediate outer wall at the pull-out interface (the critical wall) in Fig. 4 and the two neighboring walls on each side [21]. The corresponding energy increment for each pull-out step with a constant displacement $\Delta x_{\mathrm{II\text{-}O}}$ of 0.2nm and the pull-out force can be therefore predicted by [21]

$$\Delta E_{\mathrm{II\text{-}O}} = 37.56 D_c - 10.5$$
$$F_{\mathrm{II\text{-}O}} = \frac{\Delta E_{\mathrm{II-O}}}{\Delta x_{\mathrm{II-O}}} = 1.31 D_c - 0.37 \tag{5}$$

where D_c is the diameter of the critical wall as shown in Fig. 4.

(II-C) ***Pull-out of capped component of broken outer walls against capped component of intact inner walls***

The corresponding energy increment for each pull-out step with a considerably smaller constant displacement of $\Delta x_{\mathrm{II\text{-}C}}$=0.01nm and the pull-out force can be predicted by [21]

$$\Delta E_{\mathrm{II-C}} = 1.29 \times (2.09 D_c^2 - 2.15 D_c + 0.94)$$
$$F_{\mathrm{II-C}} = \frac{\Delta E_{\mathrm{II-C}}}{\Delta x_{\mathrm{II-C}}} = 1.29 \times (1.45 D_c^2 - 1.49 D_c + 0.65) \tag{6}$$

In view of the above discussions, for the pull-out of a capped MWCNT from alumina matrix in a sword-in-sheath mode, the corresponding pull-out force can be assumed to be the sum of the above three parts (i.e., Eq. (4) for part I, Eq. (5) for part II-O, and Eq. (6) for part II-C):

$$F = F_{\mathrm{I}} + F_{\mathrm{II-O}} + F_{\mathrm{II-C}} = 1.87 D_c^2 - 0.61 D_c + 2.03 D_o + 0.7 \tag{7}$$

Note that the units of diameter and force are nm and nN, respectively.

The obtained relationship between nanotube diameter and the predicted pull-out force is shown in Fig. 5, which indicates that the pull-out force increases with wall diameters (D_o and D_c in Fig. 4) of both the outermost wall and the critical wall. The reason can be attributed to the atom number at both pull-out interfaces increases with the wall diameters. The larger the wall diameters, the stronger the vdW interaction needed to be overcome during the pull-out.

The results, without considering the effect of CNT cap, are also given in Fig. 5 based on the formula of

$$F^* = F_{\mathrm{I}} + F_{\mathrm{II-O}} = 2.03 D_o + 1.31 D_c - 0.14 \tag{8}$$

Obviously, the predicted pull-out force for capped MWCNTs is much larger than that for open-ended MWCNT, which indicates the significant effect of the CNT cap.

As of yet, it is impossible to carry out the corresponding experiment (Fig. 4) to validate the above proposed formula. Nevertheless, the present authors, e.g., Yamamoto *et al.* [5], have performed a series of MWCNT pull-out tests using an *in situ* SEM on fractured composite specimens by conducting bending tests, which strongly suggest that the broken outer walls of the MWCNT and the intact inner walls are completely pulled away, leaving the companion fragment of the outer walls in the alumina matrix. This process can be schematically illustrated in Fig. 6. It can be found that there is only one pull-out interface, in contrast with that in Fig. 5. By using the above

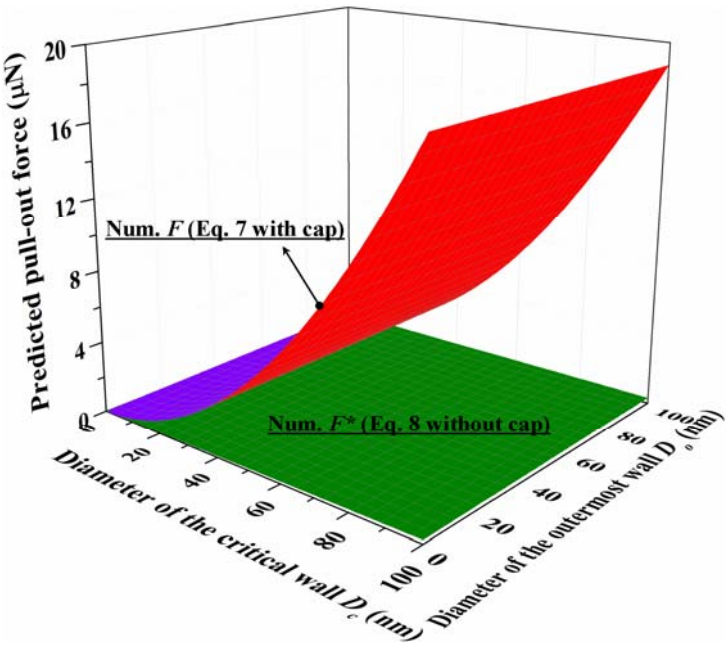

Figure 5. Comparison of numerical pull-out forces for capped and open-ended CNTs in CNT/Alumina nanocomposites

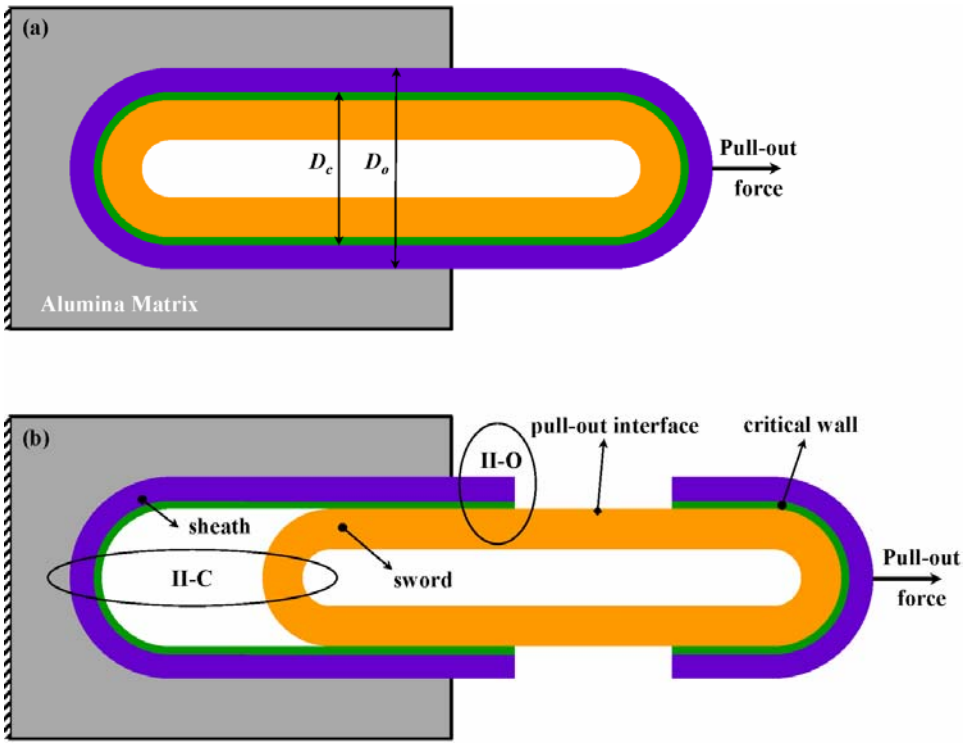

Figure 6. Schematic process of direct CNT pull-out experiment using fractured CNT/Alumina nanocomposite specimens [5]

method, the corresponding pull-out force should be composed only of part-II:

$$F^{**} = F_{\mathrm{II}} = F_{\mathrm{II-O}} + F_{\mathrm{II-C}} = 1.87D_c^{\,2} - 0.61D_c + 0.47 \qquad (9)$$

Note that both Eqs. (7) and (9) are dominated by $D_c^{\,2}$ and there is no big difference between F for the problem in Fig. 4 and F^{**} for the problem in Fig. 6. The present predicted pull-out forces by Eq. (9) are compared with the only one experimental value [5] obtained by directly performing CNT pull-out tests from CNT/Alumina nanocomposites in Table 1 and Fig. 7. Note that the diameter of the critical wall is calculated from the outermost wall and the number of broken walls observed in

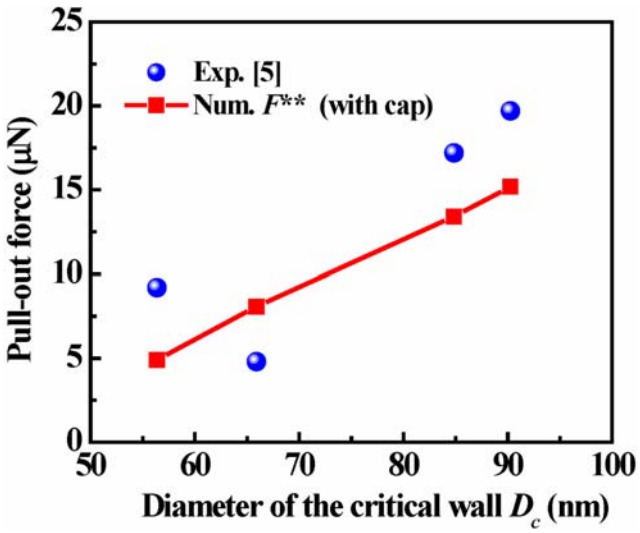

Figure 7. Comparison of experimental [5] and numerical pull-out forces in CNT/Alumina nanocomposites

Table 1 Comparison of experimental [5] and numerical pull-out forces in CNT/Alumina nanocomposites

D_o (nm)	Number of broken outer walls	D_c (nm)	Pull-out force (μN)	
			Experimental [5]	Numerical F** (Eq. (9))
71	15	65.9	4.8	8.08(+68%)
72	46	56.36	9.2	5.91(-36%)
93	24	84.84	17.2	13.41(-22%)
94	11	90.26	19.7	15.18(-23%)

experiments, with the assumption that the wall distance between MWCNT walls is 0.34nm. Obviously, there is good consistency between the experimentally measured pull-out forces and the numerical predictions by neglecting large data scattering resulted by great difficulties in nano-manipulation and precise measurement. The results suggest that the above analysis method is feasible and that the proposed empirical formula can approximately predict the pull-out force.

4. Conclusions

The present work incorporates, for the first time, a capped CNT into a computational model to investigate its pull-out behavior in CNT-reinforced nanocomposite. By using pull-out simulations based on MM, a set of simple and empirical formulae is proposed to predict the corresponding pull-out force, which has been validated by experimental results. The significant contribution of the CNT cap to the pull-out force is confirmed, which deepens the understanding of the interfacial properties of CNT-reinforced nanocomposites and provides a valuable guideline to design ideal materials with desirable interfacial properties.

Abstract With a monolayer honeycomb-lattice of sp^2-hybridized carbon atoms, graphene has demonstrated exceptional electrical, mechanical and thermal properties. One of its promising applications is to create graphene-polymer nanocomposites with tailored mechanical and physical properties. In general, the mechanical properties of graphene nanofiller as well as graphene-polymer interface govern the overall mechanical performance of graphene-polymer nanocomposites. However, the strengthening and toughening mechanisms in these novel nanocomposites have not been well understood. In this work, the deformation and failure of graphene sheet and graphene-polymer interface were investigated using molecular dynamics (MD) simulations. The effect of structural defects on the mechanical properties of graphene and graphene-polymer interface was investigated as well. The results showed that structural defects in graphene (e.g. Stone-Wales defect and multi-vacancy defect) can significantly deteriorate the fracture strength of graphene but may still make full utilization of corresponding strength of graphene and keep the interfacial strength and the overall mechanical performance of graphene-polymer nanocomposites.

Keywords Graphene, structural defect, fracture strength, graphene-polymer interface, load transfer

1. Introduction

Graphene has attracted increasing research effort since its discovery [1], largely due to its excellent electrical, mechanical and thermal properties. For example, graphene has high electron mobility (25000 cm^2/Vs) at room temperature [1], anomalous quantum Hall effect [2], extremely high Young's modulus (~1TPa) and fracture strength (~130 GPa) [3] and superior thermal conductivity (5000 $Wm^{-1}K^{-1}$) [4]. These exceptional properties make graphene an ideal candidate as reinforcement in functional and structural polymer composites. For instance, graphene-polymer composite has a electrical conductivity of ~0.1 Sm^{-1} when adding only 1 v% graphene [5]. Poly(acrylonitrile) with 1 wt% functionalized graphene obtains a remarkable shift in glass transition temperature of over 40 °C [6]. More significantly, the composites show notable improvement in fracture strength and toughness, buckling and fatigue resistance [7-12].

Graphene can be produced via chemical vapour deposition (CVD) [13], mechanical exfoliation [14], chemical reduction of graphene oxide sheets [15], etc. It has been confirmed the properties of graphene can be modified by chemical functionalization [16-18]. However, both material production processes and chemical treatment may introduce structural defects in graphene, such as Stone-Wales (S-W) type defects (nonhexagonal rings generated by reconstruction of graphene lattice) [19], single and multiply vacancies, dislocation like defects, carbon adatoms, or accessory chemical groups. Recently, Gorjizadeh et al. [20] demonstrated that the conductance decreases in defective graphene sheets. Pei et al. [21, 22] studied the influence of functionalized groups on mechanical properties of graphene. Furthermore, it is still not well understood the underlying strengthening and toughening mechanisms of graphene-polymer nanocomposites and the influence of defective graphene on them. Further study is much required. Due to the nano-scale dimensions, it is difficult to accurately evaluate the properties of graphene sheets via experiment. Alternatively, molecular dynamics (MD) method has been widely utilized to investigate carbon-based nanomaterials [23-27]. In this work, we present a MD investigation on the fracture strength of graphene with structural defects (S-W defect and multi-vacancy defect) and interfacial behaviour of

graphene-polymer nanocompsites. Our results are helpful for a better understanding of the design and performance of graphene-polymer nanocomposites.

2. Models and Methods

To simulate a monolayer graphene sheet, a MD model (42.6 Å × 49.2 Å) was built that consists of 800 carbon atoms. As confirmed by Zhao et al. [28], the possible model size effect on mechanical properties can be largely neglected when the diagonal length is over 5 nm. Therefore, the diagonal length of our model was chosen as 6.51 nm. The model was firstly relaxed to a minimum energy state with the conjugate gradient energy minimization. Then, Nose-Hoover thermostat [29, 30] was employed to equilibrate the graphene sheet at a certain temperature with periodic boundary conditions (PBCs). The adaptive intermolecular reactive bond order (AIREBO) potential [31] implemented in the software package LAMMPS [32], was used to simulate covalent bond formation and bond breaking. Such AIREBO potential has successfully simulated and predicted mechanical properties of carbon-based materials, i.e. fullerene, carbon nanotube and graphene.

In order to prepare the atomistic structures of graphene-polymer nanocomposite for simulation, a two-dimensional (2D) periodic model of polyethylene (PE) layer independent of graphene nanofiller was established. The polymer system consists of 25 PE molecules, with each molecule (CH_3-(CH2-CH2)$_{59}$-CH_3) composed of about 60 monomers. All the PE chains were prepared by commercial software Material Studio developed by Accelrys Inc. Then, two types of graphene-PE unit cells were constructed by stacking two PE layers with single graphene sheet (Case 1) and single defective graphene sheet (Case 2). To investigate the interfacial characteristics of graphene-PE nanocomposite, an ab initio force filed polymer consistent force field (PCFF) [33, 34] was employed with the effective open-source code LAMMPS [32]. The interfacial interaction has been widely investigated in carbon-based materials and polymer-matrix nanocomposites [35-41]. To obtain the equilibrated structure of such unit cell, the model was first put into a constant-temperature, constant-pressure (NPT) ensemble for 250 ps by fixing the graphene with temperature of T=100 K, pressure of P=1 atm and time step of Δt=1 fs after initial energy minimization (stage 1). Then, the unit cell model was further equilibrated for 250 ps with the same NPT ensemble and time step (stage 2). For the pull-out simulation of graphene from PE matrix, the displacement increment along the x axis of Δx=0.001 Å was applied. During such process, graphene nanofiller were fixed while PE matrix was relaxed to equilibrate the whole dynamic system.

3. Results and Discussion

3.1 Effect of Stone-Wales (S-W) on Fracture Strength

Due to the short-ranged covalent bonding between carbon atoms, bond rotation and bond breaking are two basic deformation mechanisms in graphene. In this study, we considered two types of S-W defects, namely S-W_1 and S-W_2, which are caused by 90° rotation of C-C bonds in different directions, as shown in Figure 1(a). Figure 1(b) showed corresponding stress-strain curves at different temperatures (300 K~900 K). In terms of true (Cauchy) stress, fracture strengths along armchair and zigzag directions at 300 K are 104 and 127 GPa, respectively. These values are in good agreement with experiment results $\sigma_f \approx$130 GPa [3], as well as previous atomistic simulation results [26, 28].

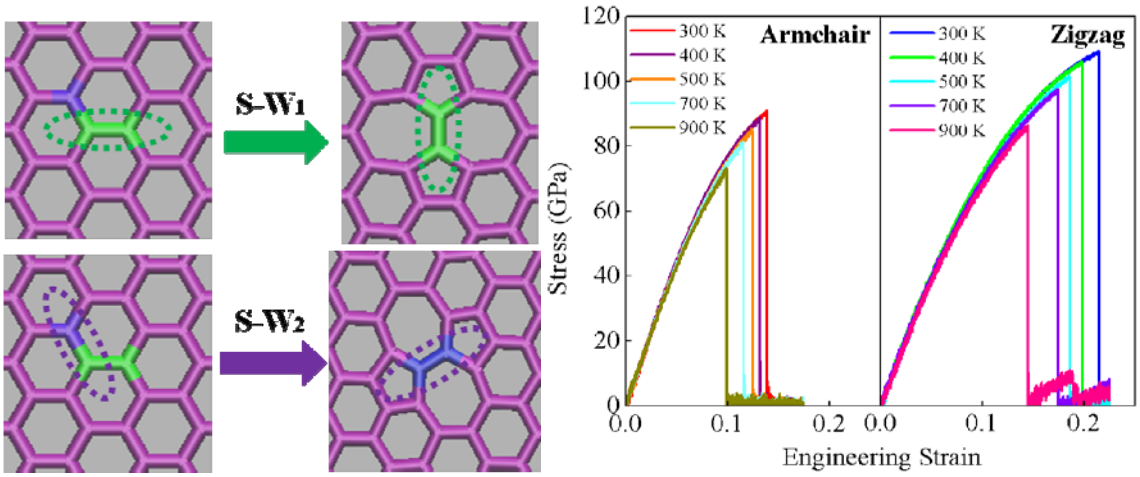

Figure 1. (a) Atomistic models of S-W_1 and S-W_2 defects. (b) Stress-strain curves of pristine graphene sheet under uniaxial tension along armchair and zigzag directions at different temperatures (300~900 K).

Our MD simulation results demonstrated that both S-W defects and temperature could significantly deteriorate the fracture strength of graphene. Figure 2 showed the fracture strength of graphene with S-W defects at different temperatures (300 K ~ 900 K). Under zigzag loading, the average strength loss caused by S-W_1 and S-W_2 was 16.26% and 41.30%, respectively. Under armchair loading, the average loss of facture strength by S-W_2 defect was about 15.75%. For S-W_1, however, fracture strength increased when temperature was above 600 K (C point in Figure 2(a)). This was attributed to the healing of S-W_1 defect with increasing temperature. As shown in Figure 2(b), at 600 K, the S-W_1 defect was stable. At 700 K, however, the S-W_1 defect was healed by 90° rotation of C-C bond. As mentioned above, mechanical strain could lower the healing energy barrier E_{eb}^{-}. Therefore, according to the kinetic rate of the healing of S-W defects (ν),

$$\nu = af_0 \exp^{-E_{eb}^{-}/kT} \quad (1)$$

Where f_0 is attempt frequency (about 10^{13}/s); k is the Boltzmann's constant and a is the lattice spacing $a = \sqrt{3}r_0$, where $r_0 = 1.42$ Å is the C-C bond length. From Eq. 1, the healing of S-W_1 defect became easier with increase of mechanical strain and temperature, consistent with the MD simulation.

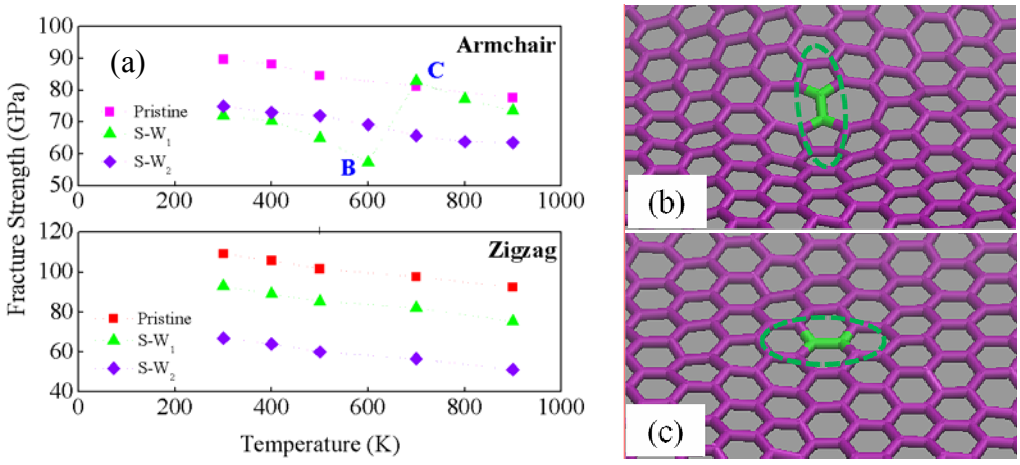

Figure 2. (a) Fracture strength of pristine, S-W_1 and S-W_2 defected graphene versus temperature under armchair and zigzag loading conditions. (b-c) Configuration change in the pre-existing S-W_1

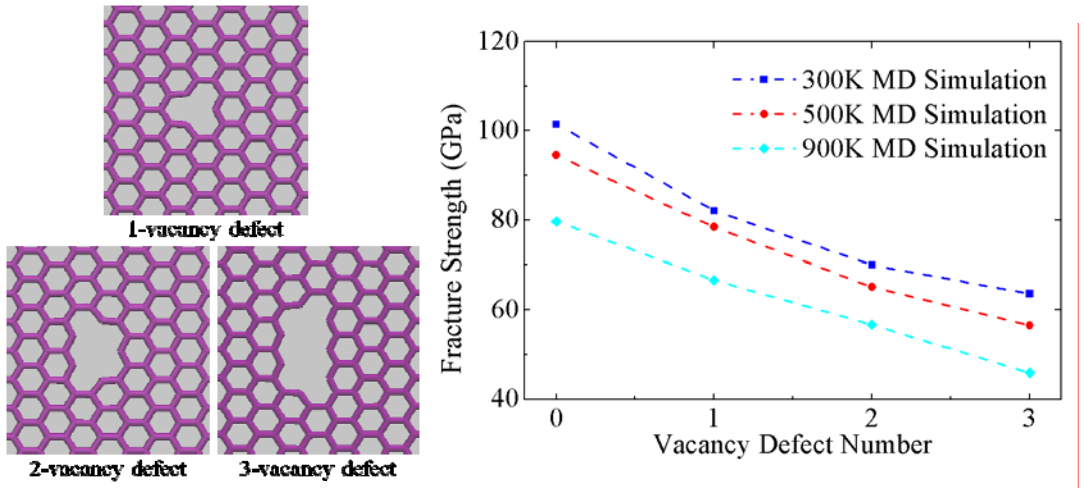
defect from point B (b) (at 600 K) to point C (c) (at 700 K) highlighted in (a).

3.2 Effect of Vacancy Defect on Fracture Strength

In the temperature range of 300~900 K, the fracture strength of graphene sheet with vacancy was evaluated under tension along the armchair direction. The simulation model with 1, 2, and 3 vacancies is shown in Figure 3(a). Figure 3(b) showed the fracture strength σ_f for the graphene sheets with different vacancy number at temperatures 300 K, 500 K, and 900 K. It can be seen that fracture strength decreases with increasing temperature as well as the number of vacancy. For the sheet with 3 vacancies, the fracture strength loss was 37.3%, 40.2% and 42.4%, corresponding to 300, 500 and 900 K, respectively. Therefore, atomic scale defect such as vacancy does play a critical role in dictating the mechanical performance of graphene.



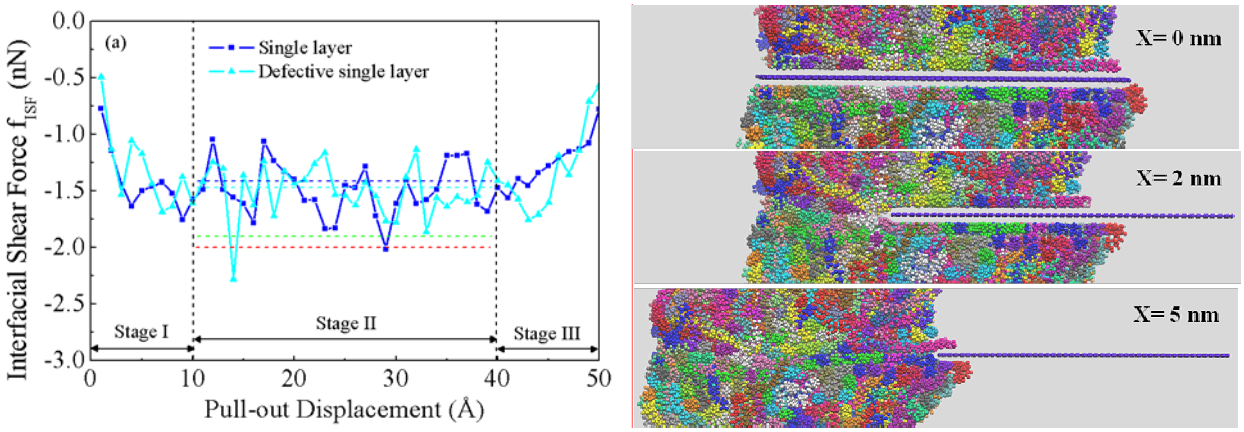
(a) **(b)**

Figure 3. (a) Three types of vacancy defect. (b) Fracture strength of defective graphene sheet versus the number of vacancy defect.

3.3 Interfacial Behaviour of Graphene-PE Nanocomposites

To study the interfacial behavior of graphene-PE nanocomposites, MD simulation of pull-out test was carried out by pulling out the graphene nanofiller from PE matrix. In particular, interfacial shear force (ISF) can govern the effectiveness of load transfer during pull-out process. On the basis of the expressions $f_{ISF} = -\partial E_{\text{int}} / \partial X$, f_{ISF} can be calculated in terms of the given E_{int}-X curve. As shown in Figure 4(a), f_{ISF}-X curve can also be divided into three stages. It can be found that the Stage I and Stage III had approximately the same range of X_I=X_{III}=1.0 nm, which was close to the cut-off distance of vdW interaction. At Stage I, the magnitude of f_{ISF} rose quickly in all cases. The increase of f_{ISF} can be attributed to the newly formed surface of graphene (outside part). Then, f_{ISF} went through a long and approximate platform at Stage II. This was because that the length of the effective newly formed surface kept at 1 nm from the pull-out end, thus leading to constant f_{ISF}. Finally, it decreased to the value similar to that at first beginning until complete pull-out. At all three stages, the values of f_{ISF} varied periodically with the variation of X, largely due to the inhomogeneous distribution of PE structures in the interfacial area. The effect of structural defect on f_{ISF} was considered as well. However, the effect of structural defects on f_{ISF} is unobvious, which might be beneficial for application of graphene-polymer nanocomposites. Then, pull-out stress could be calculated in the expression as σ_p=f_{ISF}/A_{eff}, where A_{eff} is the effective cross section of graphene sheet, A_{eff}=Wt with W=50 Å the width of graphene sheet and t=3.44 Å the sheet thickness.

According to Figure 4, the maximum pull-out stress $\sigma_p^{\max}$ in both cases was about 0.87 GPa, much lower than fracture strength of pure graphene and defective graphene, namely $\sigma_p^{\max} / \sigma_f = 1$. Therefore, in the pratical applications of graphene-polymer nanocomposites, graphene nanofiller could be full utilized even with structural defects on its surface. However, increasing the utilization of fracture strength of graphene deserves further investigation in future.



(a) (b)

Figure 4. (a) Interfacial shear force f_{ISF} versus pull-out displacement X in Case 1 (pure graphene sheet) and Case 2 (defective graphene sheet). (b) Snap shots of graphene pull-out from PE matrix in Case 1.

4. Conclusions

Deformation and failure of graphene sheet and graphene-polymer interface was investigated using MD simulations. Calculation results showed that the fracture strength of graphene is dependent on both structural defects and temperature. Structural defects in graphene (e.g. Stone-Wales defect and multi-vacancy defect) can remarkably damage the fracture strength of graphene. As for the interfacial behaviour of graphene-polymer nanocomposites, it was shown that the value of ISF vary at each end of the graphene nanofiller within the range of 1 nm, while keep approximately constant (ISF) and zero (ISS) at middle stage. Particularly, ISF is independent of the pre-existing vacancy defect in graphene. Furthermore, graphene nanofiller could be full utilized even with structural defects owing to much lower pull-out stress. The study of the mechanical performance of defective graphene and graphene-polymer interface sheds light on the better understanding of design and application of graphene-polymer nanocomposites.

Abstract For a plate with large deformation, where the possible fracture will be initiated is an important problem. It is true that the defects or voids of material usually are the initial positions. However, the more important problem is the local defect (fatigue-fracture) caused by the global deformation of medium, as this problem is very common in practical engineering. For this purpose, two sets of non-linear motion equations of deformation established in rational mechanics frame are used to study this problem. The stress concentration problem is defined as: for a given deformation, how the stresses are distributed to meet the motion equations under the cost of fatigue-fracture within the plate. The motion equations show that the local curvature is the main cause of fatigue-fracture. Taking the local deformation curvature as a parameter function, the stress transportation solution is obtained. The result shows that: for plate bending, the stress is varied in exponential law with the path-integral of local curvature of plate. In non-destructive detect, when the pressure wave data are recorded in an array, they can be used to inverse the intrinsic local curvature of target medium region. Then, the "inversed" local curvature can be used to predict the potential fatigue-cracking initiation region.

Keywords Nondestructive detect, Stress concentration, Stress transportation, Non-linear motion equation, Large deformation

1. Introduction

Stress concentration usually is addressed by the irregular boundary problems [1-3]. As a simple example, for a plate with small hole, the stress around hole will be increased rapidly when the in-plane stretching is increased. To express the effects of stress concentration, a factor (defined as maximum stress over name stress) is introduced. Its shortage is that the voids geometry features are required. Then, taking the voids as boundary, the motion equations are used to calculate the factor based on theoretic solutions. The crack tip field theory is fully developed along this theoretic line. Hence, it is understandable that many researchers focus on their attention upon micro-scale phenomena. However, based on experiences, we usually have no ad-hoc information about where the defects exist. What we want to know is where the fatigue-fracture will be initiated? The micro-scale structure description has little help on this topic. Generally, for uniform continuum, the stress concentration phenomena can be attributed to the cause of the defects of micro-scale structures. For a plate with arbitral deformation, the real fatigue-fracture frequently appears in the highest curvature position or the position inherited with large scale deformation or singularity. On phenomenon sense, the defects or voids of material were produced by the macro deformation in space-time domain.

Recently, how the macro deformation alters the microstructures of material is raised as an important problem for fracture mechanics. The dual scale or multiscale viewpoint is proposed to answer how the macro deformation causes the microstructure instability [4-6]. To answer this question, the first problem is returned to the question about where the stress will be concentrated. This problem may be answered by formulating related motion equations.

For this purpose, two sets of non-linear motion equations of deformation [7] established in rational

mechanics frame [8] are used to study this problem. One set of equations corresponds to linear momentum conservation, and another set of equations corresponds to angular momentum conservation. Then, the fatigue-fracture is initiated by local asymmetrical stress (which is related with local curvature [9]), although it may be very small comparing with the symmetrical stress. Hence, the research is looking for the "omitted" items in classical mechanics.

In this research, the stress concentration problem is defined as: for a given deformation, how the stresses are redistributed to meet the motion equations under the cost of fatigue-fracture within the plate. The motion equations show that the local curvature is the main cause of fatigue-fracture (in classical plate stability problem, the local curvature plays the similar role in von Karman equations [10]). Taking the local deformation curvature as a parameter function, the stress transportation solution is obtained. The result shows that: for plate bending, the stress is varied in exponential law with the path-integral of local curvature of plate.

For bending with harmonic local curvature, the integral along any path tends to be small, then, there is no stress concentration potential. However, for bending with monotone local curvature, the integral along any path tends to be large. Then, referring to a given stress position (as the path-integral starting point), the stress concentration will appear at the positions with maximum of path integral. In non-destructive detect, when the pressure wave data at different frequencies are recorded in an array, they can be used to inverse the intrinsic local curvature of target medium region. Then, the "inversed" local curvature can be used to predict the potential fatigue-cracking initiation region.

2. General Equations for Large Deformation

For large deformation, the deformation tensor (defined by displacement gradient) was introduced by Truesdell [11] and is named as a two-point tensor. Viewing that the base vector transformation for commoving dragging coordinator (natural coordinator) uniquely defines the deformation between initial configuration and current configuration, Chen Zhida [8, 12] established a new formulation for rational mechanics. This theoretic formulation is based on point-set transformation and is briefed as following. For a set of co-moving dragging coordinators defined in continuum, a material point is coordinated as (x^1, x^2, x^3). For initial configuration, the base vector is expressed as $(\overset{0}{\rho}\overset{}{g}_1(x), \overset{0}{\rho}\overset{}{g}_2(x), \overset{0}{\rho}\overset{}{g}_3(x))$. For current configuration, the base vector is expressed as $(\overset{}{\rho}\overset{}{g}_1(x), \overset{}{\rho}\overset{}{g}_2(x), \overset{}{\rho}\overset{}{g}_3(x))$. Then, the differential distance vector between two material points is expressed as: $d\overset{0}{\rho}\overset{}{s}_0(x) = dx^i \overset{0}{\rho}\overset{}{g}_i(x)$ (here and after repeating index summation convention is applied for $i = 1,2,3$) for initial configuration; $d\overset{}{\rho}\overset{}{s}(x) = dx^i \overset{}{\rho}\overset{}{g}_i(x)$ for current configuration (here and after, repeat index summation convention is used).

For large deformation, the deformation tensor $F_j^i(x)$ (the coordinator dependence x will be omitted below and after) is defined by base vector transformation equation (point-sets group transformation):

$$\overset{}{\rho}\overset{}{g}_i = F_i^{\ j} \overset{0}{\rho}\overset{}{g}_j = (\delta_i^j + u^j\big|_i)\overset{0}{\rho}\overset{}{g}_j . \tag{1}$$

Where, u^j is displacement field defined in initial configuration, the covariant derivative $\big|_i$ is performed in initial gauge field.

The Cauchy strain tensor is defined as:

$$\varepsilon_i^j = F_i^j - \delta_i^j = u^j\big|_i . \tag{2}$$

For simple idea isotropic elastic continuum, the stress tensor is defined as a mixture tensor $\sigma_i^j(\overset{0}{g}_i \otimes \overset{0}{g}_j)$ [7-9] through constitutive equations:

$$\sigma_i^j = \lambda\varepsilon_k^k\delta_i^j + 2\mu\varepsilon_i^j . \tag{3}$$

In engineering sense, the stress tensor component σ_i^j is explained as the surface force acting on current face $\overset{0}{g}_i$ in the direction $\overset{0}{g}_j$. In fact, this engineering interpretation is widely used in mechanics textbooks about stress tensor σ_{ij} (a kind of logic weakness on the sense that which one index represents surface or which one represents direction). For this mixture stress definition, the physical components of stress tensor are defined as $\tilde{\sigma}_i^j = \frac{\sqrt{g^0_{(jj)}}}{\sqrt{g_{(ii)}}}\sigma_i^j$. Surely, the stress symmetry in engineering stress sense does not mean the stress is symmetrical in intrinsic sense.

Then, as logic consequence, the stress differential for large deformation is:

$$\sigma_i^j\big|_k = \frac{\partial\sigma_i^j}{\partial x^k} + \sigma_i^l\Gamma_{lk}^j - \sigma_l^j\tilde{\Gamma}_{ik}^l . \tag{4}$$

Where, the connection Γ_{jk}^i is defined in initial configuration; $\tilde{\Gamma}_{jk}^i$ is defined in current configuration. Without losing generality [7], taking the initial configuration in standard rectangular coordinator system to make a simplification that $\Gamma_{jk}^i = 0$, it can be simplified as:

$$\sigma_i^j\big|_k = \frac{\partial\sigma_i^j}{\partial x^k} - \sigma_l^j\frac{\partial\varepsilon_i^l}{\partial x^k} \quad . \tag{5}$$

It shows that the non-linear items for large deformation are mainly originated from strain gradient and large stress. In resent years, the role of strain gradient has been studied extensively.

In rational mechanics of Chen formulation [7-9], the motion equations are classified into two categories as: covariant form and anti-variant form. In deformation mechanics, they must be satisfied at the same time. Generally speaking, the anti-variant force corresponds to linear momentum conservation and the covariant force corresponds to angular momentum conservation.

For large deformation with body force $\overset{\nu}{f} = f^i\overset{0}{g}_i$ in local standard rectangular coordinator system, the anti-variant form of motion equation (linear momentum conservation) is:

$$\frac{\partial\sigma_j^i}{\partial x^j} - \sigma_l^i\frac{\partial\varepsilon_j^l}{\partial x^j} = f^i . \tag{6}$$

The covariant form of motion equation (angular momentum conservation) is:

$$\frac{\partial\sigma_i^j}{\partial x^j} - \sigma_l^j\frac{\partial\varepsilon_i^l}{\partial x^j} = f^j F_i^j . \tag{7}$$

In von Karman elastic shell theory the item $-\frac{\partial\varepsilon_j^l}{\partial x^j} = -\frac{\partial^2 u^l}{\partial x^j\partial x^j}(l=3, i, j=1,2)$ is related with the curvature of shell or plate. So, the Eq.6 should be viewed as von Karman equation. Following this curvature interpretation, it is concluded that: for high stress deformation, the curvature produced by deformation must be taken into consideration.

3. Geometrical Equations for Plate Bending

For simplicity, the initial configuration of central plan is taking as standard rectangular coordinator system (x^1, x^2). Hence, the plate is described as a two dimension manifold. The thickness direction

is taken as coordinator (x^3). In this research, the plate bending problem is described by unit-orthogonal transformation of base vector as:

$$\overset{\rho}{g}_i = R_i^j \overset{\rho}{g}_j^0 . \tag{8}$$

Where, for plate bending, based on Chen's S+R additive decomposition of deformation tensor [7-9], the tensor R_i^j is defined as:

$$R_i^j = \delta_i^j + \sin\Theta \cdot L_i^j + (1-\cos\Theta) L_k^j L_i^k . \tag{9}$$

Where, the Θ is local whole rotation in average sense (local curvature) [12], and the tensor L_i^j is the rotation direction.

The related items are expressed by the displacement fields as:

$$L_1^3 = -L_3^1 = \frac{1}{2\sin\Theta}\left(\frac{\partial u^3}{\partial x^1} - \frac{\partial u^1}{\partial x^3}\right) = L_2 , \tag{10-1}$$

$$L_3^2 = -L_2^3 = \frac{1}{2\sin\Theta}\left(\frac{\partial u^2}{\partial x^3} - \frac{\partial u^3}{\partial x^2}\right) = L_1 , \tag{10-2}$$

$$L_2^1 = -L_1^2 = \frac{1}{2\sin\Theta}\left(\frac{\partial u^1}{\partial x^2} - \frac{\partial u^2}{\partial x^1}\right) = 0 , \tag{10-3}$$

$$\sin\Theta = \frac{1}{2}\sqrt{\left(\frac{\partial u^3}{\partial x^1} - \frac{\partial u^1}{\partial x^3}\right)^2 + \left(\frac{\partial u^2}{\partial x^3} - \frac{\partial u^3}{\partial x^2}\right)^2} . \tag{10-4}$$

For plate bending, as the gauge tensor is invariant, the geometrical conditions [7-9] are obtained as:

$$\frac{\partial u^1}{\partial x^1} = -(1-\cos\Theta)(L_2)^2 , \tag{11-1}$$

$$\frac{\partial u^2}{\partial x^2} = -(1-\cos\Theta)(L_1)^2 , \tag{11-2}$$

$$\frac{1}{2}\left(\frac{\partial u^1}{\partial x^2} + \frac{\partial u^2}{\partial x^1}\right) = -(1-\cos\Theta)(1-L_1 L_2) , \tag{11-3}$$

$$\frac{\partial u^3}{\partial x^3} = -(1-\cos\Theta) , \tag{11-4}$$

$$\frac{1}{2}\left(\frac{\partial u^1}{\partial x^3} + \frac{\partial u^3}{\partial x^1}\right) = 0 , \tag{11-5}$$

$$\frac{1}{2}\left(\frac{\partial u^2}{\partial x^3} + \frac{\partial u^3}{\partial x^2}\right) = 0 . \tag{11-6}$$

Combining Eqs.10 and Eqs.11, it is easy to find out that: all $\varepsilon_j^i = \frac{\partial u^i}{\partial x^j}$ are non-zeros, and the plate bending is completely determined by three independent quantities: $\Theta(x), L_1(x)$, and $L_2(x)$. Note that for small Θ, the $(1-\cos\Theta) \approx \frac{1}{2}\Theta^2$ is higher order smaller. The corresponding Cauchy stress components are defined by Eq.3. In engineering, the effective stresses (which contain non-linear effects) are used as a convention. In this research, the effective stress fields in the plate are studied by motion equations to study stress concentration problem.

4. Effective Stress Concentration for Plate Bending

Letting $\frac{\partial \varepsilon_j^l}{\partial x^j} = \kappa^l$ ($l = 1,2,3$) as local curvature functions, based on Eq.6, the anti-variant motion

equations are rewritten as:

$$\frac{\partial \sigma_j^i}{\partial x^j} - \sigma_j^i \kappa^j = f^i \tag{12}$$

As the plate bending is dominated by out-plan displacement u^3 measured by central plane coordinator (commoving dragging coordinator system), by Eqs.10 and Eqs.11, the curvature functions can be approximated as:

$$\kappa^3 = \frac{\partial^2 u^3}{\partial x^1 \partial x^1} + \frac{\partial^2 u^3}{\partial x^2 \partial x^2} = \frac{\partial (L_2 \sin\Theta)}{\partial x^1} + \frac{\partial (L_1 \sin\Theta)}{\partial x^2} \tag{13-1}$$

$$\kappa^1 = -\frac{\partial^2 u^3}{\partial x^1 \partial x^3} = \frac{\partial (L_2 \sin\Theta)}{\partial x^3} \tag{13-2}$$

$$\kappa^2 = -\frac{\partial^2 u^3}{\partial x^2 \partial x^3} = \frac{\partial (L_1 \sin\Theta)}{\partial x^3} \tag{13-3}$$

By these equations, the local curvature functions are the gradient of global bending curvature. In classical plate theory, the κ^1 and κ^2 are taken as linear function about thickness and are explained as curvature variation along thickness direction.

For fatigue-fracture problems, as the deformation is given, so the effective stress is varied to meet the motion equations.

Observing Eq.3, the effective stress field $\tilde{\sigma}_j^i$ can be defined by the following equation:

$$\frac{\partial \tilde{\sigma}_j^i}{\partial x^j} = \frac{\partial \sigma_j^i}{\partial x^j} - \sigma_j^i \kappa^j = f^i \tag{14}$$

Then the effective stresses meet classical motion equations. Omitting the derivatives of curvature functions (as first order approximation), one simple form solution for effective stress is:

$$\tilde{\sigma}_j^i(x) = \sigma_j^i(x) \cdot \exp(-\int_{x_0}^{x} \kappa^l dx^l) \tag{15}$$

Where, the x_0 is a reference point waiting to be determined by boundary conditions and loads. This solution means that: local effective stress is redistributed by the path-integral of global curvature functions. Therefore, stress concentration may appear somewhere. Based on Eq.3, for the effective stress, the constitutive equation is:

$$\tilde{\sigma}_i^j = (\lambda \varepsilon_k^k \delta_i^j + 2\mu \varepsilon_i^j) \cdot \exp(-\int_{x_0}^{x} \kappa^l dx^l) \tag{16}$$

It says that: for effective stress, the elasticity parameters are exponentially varied with the path-integral of curvature functions. In engineering mechanics, the increased elasticity is named as hardening and the decreased elasticity is named as softening. Then, by the above equations, the effective elasticity of bending plate has both effects. In engineering sense, the effective elasticity is varied by bending deformation significantly.

To make its meaning clear, the thickness effects can be expressed as:

$$\tilde{\sigma}_j^i(x)\Big|_{x^3} = \tilde{\sigma}_j^i(x)\Big|_{x^3=0} \cdot \exp(-\int_0^{x^3} \kappa^3 dx^3) \tag{17}$$

It shows that the effective stresses are exponentially distributed on thickness direction. In classical plate theory, the linear approximation is assumed.

It shows that: the effective stress on central plan parallel surface is exponentially varied with path-integral of curvature along thickness direction. So, the effective stress will concentrated on one surface parallel to central plan. If the local curvature is big enough, the fatigue-fracture may be initiated as surface cracking parallel to central plan (surface sliding or buckling). In some researches [13-15], the thickness direction stress concentration effects are studied under the terms distension or post-buckling). The above equation shows that, for given curvature, the plate thickness is limited by stress concentration effects along thickness direction.

Similarly, taking the effective stress at some potions as reference, the scale effects can be expressed

as effective stress transportation along plan directions as:

$$\tilde{\sigma}_j^i(x)\Big|_{x^1} = \tilde{\sigma}_j^i(x)\Big|_{x_0^1} \cdot \exp(-\int_{x_0^1}^{x^1} \kappa^1 dx^1) \tag{18-1}$$

$$\tilde{\sigma}_j^i(x)\Big|_{x^2} = \tilde{\sigma}_j^i(x)\Big|_{x_0^2} \cdot \exp(-\int_{x_0^2}^{x^2} \kappa^2 dx^2) \tag{18-2}$$

They show that: the effective stresses on central plan parallel surface are exponentially varied with path-integral of curvature along scale directions. So, the effective stress will concentrated on one side. If the local curvature is big enough, the fatigue-fracture may be initiated as surface cracking line (surface fracture). Therefore, for given curvatures, the plate scale is limited by stress concentration effects along plan directions.

For spatial harmonic bending with spatial frequencies (k_1, k_2, k_3), $\kappa^i = \kappa_0^i \sin(k_1 x^1 + k_2 x^2 + k_3 x^3)$, the path-integral values depends its corresponding spatial scales $(1/k_1, 1/k_2, 1/k_3)$. Therefore, multi-scale effects are very significant [4-6] for stress concentration phenomenon or fracture problems. This explains why microstructure analysis is always dominating the theoretic development about fatigue-fracture mechanism.

For forward problems of non-destructive detect, the central plan bending functions $\Theta(x)$, $L_1(x)$, and $L_2(x)$ are measured directly. Then, the curvature functions can be calculated by Eqs.13. In this case, the stress concentration effects can be evaluated by the Eqs.18.

For inverse problems of non-destructive detect, when the effective stress data can be acquitted, the Eqs.18 can be used to estimate the curvature functions. By the estimated curvatures, the potential fatigue-fracture positions can be predicted.

For supersonic wave methods, a lot of technology to get effective elasticity is available. By Eq.16, the effective elasticity for wave (incremental deformation [16]) is determined as:

$$\Delta\tilde{\sigma}_i^j = \lambda(\Delta\varepsilon_k^k)\delta_i^j + 2\mu(\Delta\varepsilon_i^j)] \cdot \exp(-\int_{x_0}^{x} \kappa^l dx^l) \tag{19}$$

So, as the original elasticity is known parameter, the curvature functions can be inversed. Therefore, stress concentration effects can be predicted.

5. Stress Concentration Caused by Load

Usually, the typical plate bending is produced normal loading (defined by $f^1 = f^2 = 0$). By subtracting Eq.6 and Eq.7, the asymmetrical stress motion equations are obtained as:

$$\frac{\partial(\sigma_1^3 - \sigma_3^1)}{\partial x^3} = f^3 \sin\Theta \cdot L_2 + (\sigma_l^j \frac{\partial \varepsilon_1^l}{\partial x^j} - \sigma_l^1 \frac{\partial \varepsilon_j^l}{\partial x^j}), \tag{20-1}$$

$$\frac{\partial(\sigma_2^3 - \sigma_3^2)}{\partial x^3} = -f^3 \sin\Theta \cdot L_1 + (\sigma_l^j \frac{\partial \varepsilon_2^l}{\partial x^j} - \sigma_l^2 \frac{\partial \varepsilon_j^l}{\partial x^j}), \tag{20-2}$$

$$\frac{\partial(\sigma_3^1 - \sigma_1^3)}{\partial x^1} + \frac{\partial(\sigma_3^2 - \sigma_2^3)}{\partial x^2} = (\sigma_l^j \frac{\partial \varepsilon_3^l}{\partial x^j} - \sigma_l^3 \frac{\partial \varepsilon_j^l}{\partial x^j}). \tag{20-3}$$

Where, the approximation $R_i^j \approx \delta_i^j + \sin\Theta \cdot L_i^j$ is applied. By Eq.3 and Eqs.11, the non-symmetrical stress components are σ_1^3, σ_3^1, σ_2^3, and σ_3^2. They are expressed as:

$$\sigma_1^3 = -\sigma_3^1 = 2\mu L_2 \sin\Theta, \tag{21-1}$$

$$\sigma_3^2 = -\sigma_2^3 = 2\mu L_1 \sin\Theta. \tag{21-2}$$

So, letting: $w_i = (\sigma_l^j \frac{\partial \varepsilon_i^l}{\partial x^j} - \sigma_l^i \frac{\partial \varepsilon_j^l}{\partial x^j})$, the asymmetrical stress motion equations are rewritten as:

$$4\mu\frac{\partial(L_2\sin\Theta)}{\partial x^3}=f^3\sin\Theta\cdot L_2+w_1 \tag{22-1}$$

$$-4\mu\frac{\partial(L_1\sin\Theta)}{\partial x^3}=-f^3\sin\Theta\cdot L_1+w_2 \tag{22-2}$$

$$-4\mu\frac{\partial(L_2\sin\Theta)}{\partial x^1}+4\mu\frac{\partial(L_1\sin\Theta)}{\partial x^2}=w_3 \tag{22-3}$$

Where, the third motion equation is used to determine the whole bending along plan direction.
Referring to the solutions $(L_2\sin\Theta)\big|_{f^3=0}$ at central plan for $f^3=0$, the body force caused asymmetrical stresses concentration in thickness direction are obtained as:

$$\sigma_1^3\big|_{f^3}=[\sigma_1^3\big|_{f^3=0}+\frac{1}{2}\int_0^{x^3}w_1\exp(-\int_0^{x^3}\frac{f^3}{4\mu}dx^3)dx^3]\cdot\exp(\int_0^{x^3}\frac{f^3}{4\mu}dx^3) \tag{23-1}$$

$$\sigma_2^3\big|_{f^3}=[\sigma_2^3\big|_{f^3=0}-\frac{1}{2}\int_0^{x^3}w_2\exp(-\int_0^{x^3}\frac{f^3}{4\mu}dx^3)dx^3]\cdot\exp(\int_0^{x^3}\frac{f^3}{4\mu}dx^3) \tag{23-2}$$

It shows that: the local body force (load) will cause local asymmetrical stress concentration along thickness direction with exponential law about thickness. If the local curvature at free load is big enough, the load-caused stress concentration will be significant for thick plate. Then, fatigue-fracture may be initiated.
It also shows that, at local load position, the asymmetry stress and non-linear effects will be very significant for thick plate bending, where wrinkling [17] may be produced.

6. Stress Concentration for Kirchhoff Approximation

The bending momentum motion equations, as the results of Kirchhoff approximation theory of plate, are widely used in engineering. How to estimate the stress redistribution caused by thickness and global curvature is a practical problems. As many linear results are well-known, how the non-linear behaves will be exposed in this section.
Using the approximation $R_i^j\approx\delta_i^j+\sin\Theta\cdot L_i^j$, for the typical plate bending produced by normal loading (defined by $f^1=f^2=0$), the Eq.12 will be used to obtain the bending momentum motion equations in Kirchhoff approximation. Letting $\sigma_{ij}=\frac{1}{2}(\sigma_j^i+\sigma_i^j)$, the plate bending momentums M_{ij} $(i,j=1,2)$ in Kirchhoff plate theory are defined as:

$$M_{ij}=\int_{-D/2}^{D/2}\sigma_{ij}x^3dx^3 \tag{24-1}$$

Where, D is plate thickness. Noting that, by Eqs.11 and Eq.3, $\sigma_{13}=\sigma_{31}=0$ and $\sigma_{23}=\sigma_{32}=0$, so, the Kirchhoff assumption is automatically satisfied. The load vector components are defined as:

$$Q_1=\frac{1}{2}\int_{-D/2}^{D/2}f^3\sin\Theta\cdot L_2\cdot x^3dx^3 \tag{24-2}$$

$$Q_2=\frac{1}{2}\int_{-D/2}^{D/2}f^3\sin\Theta\cdot L_1\cdot x^3dx^3 \tag{24-3}$$

$$q_3=\frac{1}{2}\int_{-D/2}^{D/2}f^3\cdot x^3dx^3 \tag{24-4}$$

By Eqs.20, omitting the non-linear items, the following approximations are obtained:

$$\frac{1}{2}\frac{\partial(\sigma_1^3-\sigma_3^1)}{\partial x^3}=\frac{1}{2}f^3\sin\Theta\cdot L_2, \tag{25-1}$$

$$\frac{1}{2}\frac{\partial(\sigma_2^3-\sigma_3^2)}{\partial x^3}=-\frac{1}{2}f^3\sin\Theta\cdot L_1, \tag{25-2}$$

$$\frac{1}{2}\frac{\partial(\sigma_3^1-\sigma_1^3)}{\partial x^1}+\frac{1}{2}\frac{\partial(\sigma_3^2-\sigma_2^3)}{\partial x^2}=0. \tag{25-3}$$

By Eqs.21, it is easy to identify that the above equations can be rewritten as:

$$Q_1=\int_{-D/2}^{D/2}\frac{\partial\sigma_1^3}{\partial x^3}x^3dx^3=-\int_{-D/2}^{D/2}\frac{\partial\sigma_3^1}{\partial x^3}x^3dx^3 \tag{26-1}$$

$$Q_2=\int_{-D/2}^{D/2}\frac{\partial\sigma_3^2}{\partial x^3}x^3dx^3=-\int_{-D/2}^{D/2}\frac{\partial\sigma_2^3}{\partial x^3}x^3dx^3 \tag{26-2}$$

Then, the Eqs.12 is rewritten as:

$$\frac{\partial M_{11}}{\partial x^1}+\frac{\partial M_{12}}{\partial x^2}-Q_1-\frac{1}{2}\int_{-D/2}^{D/2}\sigma_j^1\kappa^j x^3dx^3=0 \tag{27-1}$$

$$\frac{\partial M_{21}}{\partial x^1}+\frac{\partial M_{22}}{\partial x^2}+Q_2-\frac{1}{2}\int_{-D/2}^{D/2}\sigma_j^2\kappa^j x^3dx^3=0 \tag{27-2}$$

$$\frac{\partial Q_1}{\partial x^1}-\frac{\partial Q_2}{\partial x^2}+\frac{1}{2}\int_{-D/2}^{D/2}\frac{\partial\sigma_3^3}{\partial x^3}x^3dx^3-\frac{1}{2}\int_{-D/2}^{D/2}\sigma_j^3\kappa^j x^3dx^3=q_3 \tag{27-3}$$

Omitting the non-linear items and letting $\sigma_{33}=0$, they can be combined as the classical linear bending momentum equation [10]:

$$\frac{\partial^2 M_{11}}{\partial x^1\partial x^1}+2\frac{\partial^2 M_{12}}{\partial x^1\partial x^2}+\frac{\partial^2 M_{22}}{\partial x^2\partial x^2}=q_3 \tag{28}$$

This research shows that the classical linear bending momentum equation is the logic results of two sets of motion equations for unit orthogonal deformation (defined by Eq.8). It makes this research soundness.

For plate bending, the non-linear bending momentum equation is:

$$\begin{aligned}&\frac{\partial^2 M_{11}}{\partial x^1\partial x^1}+2\frac{\partial^2 M_{12}}{\partial x^1\partial x^2}+\frac{\partial^2 M_{22}}{\partial x^2\partial x^2}\\&-\frac{1}{2}\frac{\partial}{\partial x^1}\left(\int_{-D/2}^{D/2}\sigma_j^1\kappa^j x^3dx^3\right)-\frac{1}{2}\frac{\partial}{\partial x^2}\left(\int_{-D/2}^{D/2}\sigma_j^2\kappa^j x^3dx^3\right)\\&+\frac{1}{2}\int_{-D/2}^{D/2}\frac{\partial\sigma_3^3}{\partial x^3}x^3dx^3-\frac{1}{2}\int_{-D/2}^{D/2}\sigma_j^3\kappa^j x^3dx^3=q_3\end{aligned} \tag{29}$$

Only taking the effects of the asymmetrical stress components σ_1^3, σ_3^1, σ_2^3, and σ_3^2 into consideration, the Eq.29 is approximated as:

$$\begin{aligned}&\frac{\partial^2 M_{11}}{\partial x^1\partial x^1}+2\frac{\partial^2 M_{12}}{\partial x^1\partial x^2}+\frac{\partial^2 M_{22}}{\partial x^2\partial x^2}\\&-\frac{1}{2}\frac{\partial}{\partial x^1}\left(\int_{-D/2}^{D/2}\sigma_3^1\kappa^3 x^3dx^3\right)-\frac{1}{2}\frac{\partial}{\partial x^2}\left(\int_{-D/2}^{D/2}\sigma_3^2\kappa^3 x^3dx^3\right)\\&-\frac{1}{2}\int_{-D/2}^{D/2}\sigma_1^3\kappa^1 x^3dx^3-\frac{1}{2}\int_{-D/2}^{D/2}\sigma_2^3\kappa^2 x^3dx^3=q_3\end{aligned} \tag{30}$$

In non-destructive detect, the Eq.28 is assumed as precondition determined by manufacture or working condition. Therefore, the stress redistribution caused by non-linear items can be studied by introducing the effective load, which is defined as:

$$\tilde{q}_3 = q_3 + \frac{1}{2}\frac{\partial}{\partial x^1}(\int_{-D/2}^{D/2}\sigma_3^1\kappa^3 x^3 dx^3) + \frac{1}{2}\frac{\partial}{\partial x^2}(\int_{-D/2}^{D/2}\sigma_3^2\kappa^3 x^3 dx^3) + \frac{1}{2}\int_{-D/2}^{D/2}\sigma_1^3\kappa^1 x^3 dx^3 + \frac{1}{2}\int_{-D/2}^{D/2}\sigma_2^3\kappa^2 x^3 dx^3 \quad (31)$$

By this way, the fatigue-fracture initiation position can be predicted by calculating the effective load. Based on previous results (Eqs.13, Eqs.21, and Eqs.31), each items of effective load can be obtained. As a first approximation, on the thickness direction, the local whole rotation angle variation can be expressed as:

$$\Theta(x^3) = \Theta + (\Theta)^2 x^3 \quad (32)$$

Then, for small Θ (defined on central plan) and small thickness ($-D/2 \le x^3 \le D/2$), the following equation can be used to simplify the asymmetrical stress in Eq.31.

$$\sin\Theta(x^3) \approx \sin\Theta + (\Theta)^2 x^3 \quad (33)$$

Furthermore, omitting the higher order infinitesimals, the following approximations are obtained:

$$\frac{1}{2}\frac{\partial}{\partial x^1}(\int_{-D/2}^{D/2}\sigma_3^1\kappa^3 x^3 dx^3) \approx -\frac{(D)^3}{12}\cdot\mu\cdot\frac{\partial[(\Theta)^2 L_2\kappa^3]}{\partial x^1} \quad (34\text{-}1)$$

$$\frac{1}{2}\frac{\partial}{\partial x^2}(\int_{-D/2}^{D/2}\sigma_3^2\kappa^3 x^3 dx^3) \approx \frac{(D)^3}{12}\cdot\mu\cdot\frac{\partial[(\Theta)^2 L_1\kappa^3]}{\partial x^2} \quad (34\text{-}2)$$

$$\frac{1}{2}\int_{-D/2}^{D/2}\sigma_1^3\kappa^1 x^3 dx^3 \approx \frac{(D)^3}{12}\cdot\mu\cdot(\Theta)^2\cdot L_2\kappa^1 \quad (34\text{-}3)$$

$$\frac{1}{2}\int_{-D/2}^{D/2}\sigma_2^3\kappa^2 x^3 dx^3 \approx -\frac{(D)^3}{12}\cdot\mu\cdot(\Theta)^2\cdot L_1\kappa^2 \quad (34\text{-}4)$$

As a simple example, for simple bending $\frac{\partial u^3}{\partial x^1} \approx \Theta$, $L_2 = 1$, $L_1 = 0$, $\kappa^3 \approx \frac{\partial\Theta}{\partial x^1}$, $\kappa^1 \approx (\Theta)^2$, the effective load is simplified as:

$$\tilde{q}_3 = q_3 + \frac{(D)^3}{12}\cdot\mu\cdot\{(\Theta)^4 - \frac{\partial}{\partial x^1}[(\Theta)^2\frac{\partial\Theta}{\partial x^1}]\} \quad (35)$$

It shows that the local whole rotation in average sense (local curvature) has significant effects. Here, the stress concentration is expressed by effective load variation. Hence, it can be used in forward problems to predict possible fatigue-fracture initiating positions.

6. Conclusions

For large deformation, such as plate bending, the linear momentum conservation equations and angular momentum conservation equations are used to study the stress concentration problems. The research shows that, for plate bending, the dominate Cauchy stresses are asymmetrical. The symmetrical stress components are higher order smaller. By requiring both sets of motion equations are satisfied, the classical bending momentum linear motion equation is obtained as a linear approximation.

Based on the linear momentum conservation equations, the stress concentration caused by bending curvature functions is studied by introducing effective stress transportation solutions. The results show that: the effective stresses on central plan parallel surface are exponentially varied with path-integral of curvature along scale directions. The effective stresses on thickness direction are exponentially varied with the path-integral of curvature functions. The scale effects are very significant. As the effective stresses can be detected by many non-destructive methods, the curvature functions can be estimated. For supersonic wave method, the effective elasticity can be detected and used to estimate the curvature functions. Hence, the fatigue-fracture initiating position

can be predicted.

Based on the angular momentum conservation equations, the stress concentration caused by local load on thickness direction is studied. The results show that: the local body force (load) will cause local asymmetrical stress concentration along thickness direction with exponential law about thickness.

Finally, the effective load caused by local bending curvature is introduced to estimate the stress concentration as effective load variation. For simple bending, an explicit formula is given. It shows that the local rotation in average sense (local curvature) has significant effects. This equation can be easily used for non-destructive inverse problems.

Abstract To further reveal the mesomechanical damage behavior of the plastic material, quantitative evaluation the micromechanical damage state of material use acoustic emission characteristic parameters. Based on the Gurson-Tvergaard-Needleman micromechanical damage model, establish the quantitative evaluation model of acoustic emission cumulative hits, taking void growth ratio as the damage variable. Taking steel Q345 notched bar specimens tensile process as example, using acoustic emission testing technology, get the AE information from yield to fracture process. Using ABAQUS finite element analysis software, analyze the meso-damage process during tensile process of steel Q345 notched bar specimens, and get the numerical solution of meso-damage parameters. Based on AE testing and Finite Element Simulation, get the quantitative evaluation formula of void growth ratio based on AE cumulative hits N during Q345 steel notched bar specimens tensile process. Result shows that, in the tensile process of Q345 steel from yield to fracture damage, the function relationship of N and V_G is divided into two stage, linear damage stage and nonlinear damage stage, and when the N reaches 128, the material is at the transition state from linear damage stage to nonlinear damage stage. This critical transition area value could be used as steel Q345 damage fracture of acoustic emission recognition feature and safety evaluation threshold value.

Keywords Acoustic emission, Void growth ratio, Cumulative hits, Gurson-Tvergaard-Needleman model, steel Q345

1. Introduction

Acoustic emission refers to the material or components rapid release of strain energy and the transient stress wave phenomenon when stress exceeds yield stress into the irreversible stage of plastic deformation or crack initiation, growth and fracture. There is consistent correspondence relationship between acoustic emission and material interior damage. Acoustic emission cumulative hits directly correspond to different material damage state and the new damage must be accompany with the release of stress wave, which is the basis fundamental to the direct measurements and modeling of acoustic emission[1-3].Generally micro-void nucleation, growth and coalescence is a typical mechanism of microstructure damage and failure for metal plastic material. Gurson-Tvergaard-Needleman (GTN) model[4-6]is regard as a significant progress in meso-damage mechanics. Because it was well descript the metal plastic damage in the process of plastic deformation caused by the evolution of micro-voids and had been developed and applied in many fields[7,8]. Based on voids nucleation controlled by the stress triaxiality and equivalent plastic strain, Zheng Changqing[9]proposed the concept of critical void ratio V_{GC}.V_{GC} is an micromechanics parameters which built on the micro-void damage mechanism when metals got into the plastic deformation, and it contacts the meso-damage parameters and macro-mechanical behavior. The variation of void growth ratio V_G directly reflects the damage state of the materials. Therefore, established the relationship between the characteristics parameters of acoustic emission and the void growth ratio can be deeply understanding the macroscopic and micromechanics behavior in the process of metal plastic damage, and achieving quantitative evaluation materials micromechanical damage state used acoustic emission testing technology.

This paper from micro-void damage mechanisms of metal plastic materials, used acoustic emission testing the steel Q345 round notch specimen in tensile process, obtained of material's release of the stress wave from yielding to the fracture process. Using ABAQUS analyzed the changes of steel Q345 round bar notched specimen micromechanics parameters in tensile fracture process, obtained

numerical solution of void growth ratio in different damage states. Based on acoustic emission testing result, establish acoustic emission characteristics parameters of tensile process and quantitative evaluation formula of void growth ratio, in order to achieve Q345 quantitative evaluation of micro-damage state.

2.The relationships between AE and material micro-damage parameters

2.1. GTN model

Based on the previous work, Gurson researched the response under the axisymmetric triaxial stress state in limited large matrix of cylindrical or spherical with void. He constructed material damage yield function to describe the effect of micro-void damage to the metal plastic deformation behavior. After further amended to the Gurson model by Tvergaard and Needleman[5,6], the model's prediction accuracy has greatly improved[8,10].The GTN model yield function φ is expressed as follows:

$$\phi = (\frac{\sigma_{eq}}{\sigma_s})^2 + 2fq_1 \cosh(q_2 \frac{3\sigma_m}{2\sigma_s}) - (1+q_3 f)^2 = 0 \tag{1}$$

Where q_1, q_2, q_3,is revision coefficient; σ_{eq} is Misses stress; σ_m is macro hydrostatic stress; σ_s is flow stress of the base material in the unit; f is the percentage of void volume. In GTN model damage variable is considering as isotropic, which comprises two parts:

$$f = (f)_{growth} + (f)_{nucleation} = (1-f)\varepsilon_{ij}^{p} + A\langle R_\sigma \rangle \eta^p \tag{2}$$

Assumed the nucleation void mechanism by strain controlled and the void follows normal distribution. The voids nucleation intensity function A is expressed as:

$$A = \frac{f_N}{hs_N\sqrt{2}} \exp\left[-\frac{1}{2}(\frac{\eta^p - \varepsilon_N}{s_N})^2\right] \tag{3}$$

where $(f)_{\text{growth}}$ indicates the void-volume fraction caused by the void growth;$(f)_{\text{nucleation}}$ is the void-volume fraction caused by the nucleation of a void; ε_{ij}^{p} is macroscopic plastic strain rate tensor; R_σ is stress triaxiality ($R_\sigma=\sigma_m/\sigma_{eq}$); η^p is equivalent plastic strain of the matrix material; $\langle x \rangle$ Macauley operator; f_N for the nucleation of micro-voids volume percentage of the two-phase particles; h is material constants; S_N is void nucleation average strain standard; ε_N is void nucleation average strain.

2.2. The relationships between AE and material damage

The emergence and development of inside damage (micro-cracks and micro-voids) in the metal plastic material generates the acoustic emission, so there is inevitable relation between acoustic emission parameters and material damage variable. C.A.Tang etal.[11] obtain damage model which based on damage mechanics theory characterized by AE parameters, the relationship was written as:

$$D = \frac{A_d}{A} = \frac{N}{N_m} \tag{4}$$

Where the damage variable D represents the damage state of the material, Kachanov defined it as ratio of the instant all the area of the bearing surface defects A_d and sectional area when initial nondestructive; N_m is the total number of acoustic emission cumulative hits when material entire cross section A destructed, N is the instant acoustic emission cumulative hits.

Base on the microcosmic architectural feature, Gurson proposed that make the void-volume percentage f as a micro-mechanical damage variable for metal-plastic material. Zheng Changqing[9]

used an electron microscope to observe micro-void nucleation, growth, and coalescence of plastic deformation when metal stretching, necking as well as instability in the fracture process. Combined experiment and numerical simulation and analyzed the relations between the strain and stress, make the fracture strain ε_f and stress triaxiality $R_{\sigma 0}$ as critical void growth ratio V_{GC} when material fractured. Micromechanics fracture criterion was $V_G \geq V_{GC}$,V_G is the void growth ratio under the conditions of forcing. For notched specimen was the following relationship:

$$V_G = \varepsilon_p \exp(1.5R_\sigma) \tag{5}$$

Where ε_p is the equivalent plastic strain. The nucleation of micro-void controlled by the triaxiality stress and equivalent plastic strain. Also they were the function of void growth ratio V_G. The void growth ratio is the micromechanics parameters which establish on the micro-voids growth and coalescence in metal plastic materials. It is the bridge of contacting microscopic damage characteristic and micromechanics parameter. The change of V_G directly reflected the material damage of macro-micro state changes in real time, so make the void growth ratio V_G as the new damage variable of material deterioration state.

Considering formula (4) and (5), the void growth ratio V_G and acoustic emission cumulative hits N can be used as parameters which describe the damage state of the metal plastic materials. Therefore established the quantitative evaluation of the formula between the void growth ratio and acoustic emission cumulative hits:

$$V_G = f(N) \tag{6}$$

According to the formula (6), used the acoustic emission testing technology obtained the Q345 notched bar specimen's information in tensile process. Using ABAQUS finite element analysis software to obtained the numerical solution of void growth ratio in different damage state. Then establish quantitative evaluation formula between the acoustic emission characteristics parameters and void growth ratio when steel Q345 in stretch process. Finally realized use acoustic emission quantitative evaluation the material's microscopic damage state.

3. Steel Q345 notched specimen tensile process acoustic emission testing experiment

3.1. The Steel Q345 notched specimen size and mechanical properties

The size of Steel Q345 tensile specimen is shown in Figure 1. There are eight specimens, numbering from#1 to #8.

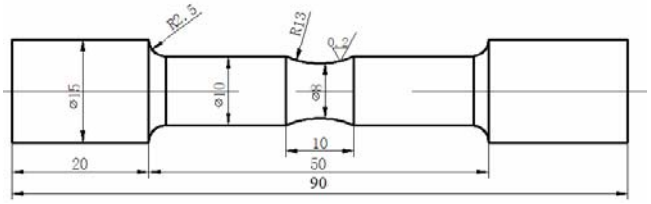

Fig.1 The shape and size of notched tensile specimens

Experiment mechanical properties and chemical composition of the steel Q345 are shown in Table 1.

Table 1 Steel Q345 mechanical properties and chemical composition

mechanical properties						chemical composition %				
σ_s	σ_b	E	γ	Ψ	Φ	C	Mn	Si	P	S
MPa	MPa	GPa		%	%					
408	533	200	0.3	4.58	60.58	0.17	1.42	0.019	0.020	0.031

3.2. Experimental equipment and methods

The tensile test was on the SANS electronic universal testing machine, adopted displacement loading, axial tensile in constant speed, loading rate was 0.3mm/min. Acoustic emission data acquisition system was the U.S. PAC PCI-2 acoustic emission system, and the sensor was WD broadband sensor, the frequency range of 100~1000kHz. The preamplifier was PAC2/4/6 produced in PAC. The sensors were installed at the end of the specimen, and coupled by vacuum grease. To calibrated the sensitivity of each channel used HB pencil(Φ=0.5mm) breaking signals as sound simulate source. In order to collect the acoustic emission signal that generated from material's microscopic damage during tensile stretched, need to lower the threshold value. In order to testing the experiment environment, environmental noise and electromagnetic noise of AE signal distribution levels under no-load operation, finally set threshold value is 30dB. Acoustic emission testing system parameter settings were shown in Table 2.

Table 2 Acoustic emission detection system parameter settings

Parameter category	Setting value	Parameter category	Setting value
Threshold value /dB	30	Peak definition time PDT/μs	200
Sampling rate /MB	2	Hits definition time HDT/μs	600
Sampling length /K	4	Hits lockout time HLT/μs	1000

3.3. Experimental results and analysis of acoustic emission testing

Table 3 shows the results of eight specimens' acoustic emission testing experimental. It listed axial displacements and acoustic emission cumulative hits and corresponding mean value of separately yield point B and yield end point C, tensile strength point D and breaking point E. Studies[11,12] indicated that acoustic emission cumulative hit can reflect the changes in the material damage state, so selected the acoustic emission cumulative hits combined with the amplitude to analyze different damage stage of Steel Q345 in tensile process. The amplitude of the #1 specimen's AE vs. the cumulative hit vs. stress increases with the experiment time is shown in Figure 2.

Table3 Steel Q345 axial tensile displacement and acoustic emission cumulative hitting statistics

		1#	2#	3#	4#	5#	6#	7#	8#	average
B	displacement /mm	1.79	0.98	1.86	2.28	1.91	1.92	1.82	1.76	1.79
	Accumulate strike count	20	23	18	24	20	22	19	22	21
C	displacement /mm	2.24	2.10	2.06	2.61	2.45	2.31	1.96	2.43	2.28
	Accumulate strike count	104	99	110	103	100	107	104	109	104.50
D	displacement /mm	4.33	4.45	4.01	4.45	4.66	4.51	4.41	4.57	4.42
	Accumulate strike count	148	150	165	150	160	162	150	160	155.62

	Accumulate strike count	157	160	176	156	164	171	162	171	164.63

Figure 2 shows Steel Q345 tensile damage process is divided into four phases, i.e., AB, BC, CD, and DE, respectively corresponding to the elastic deformation stage, the yield phase, strengthening phase and necking stages of the specimen. (1) The elastic deformation stage (0~320s, 0~408MPa). There are few acoustic emission signals in the stage and acoustic emission cumulative hit change is also very small. Amplitude are less than 35dB, most of the which are from mechanical noise caused by the loaded the initial specimen two ends of the fixture bite and friction; (2) Yield stage (321~496s, 408~432MPa),which are also known as the stage of plastic flow. After the specimen entering this phase, the acoustic emission signal was significantly increased, and then the acoustic emission yield effect appears. Signal amplitude between 30~54dB, the cumulative hit - time curve

appears apparent inflection in the vicinity of the point B, and rapid raised. The micro-voids generally nucleation at lower strain in the vicinity of the inclusions or second phase particles itself broken, or produced in the detachment of the inclusions and matrix interface[9,13].This stage acoustic signal reflects the sensitive to metal plastic material micro-voids nucleation process; (3) strengthening stage (497~931s, 432~533MPa). The specimen was in the uniform state of strain and begun to produce plastic deformation, the damage of micro-void continued to develop. The amount of AE signals reduced significantly and accompanied by a little amount of high-amplitude signal, the amplitude range between 30~55dB. The curve of accumulation hits vs. time rising trend was becoming slowly;(4) Necking stage(932~1230s,533~441MPa).When the stress reaches to the point D, since strength increase insufficient to compensate for size contraction caused by the work hardening, resulting in the phenomenon of necking. Since then, the deformation of the material became non-uniform. In this stage the amount of acoustic emission signals continued to reduce, the amplitude below 50dB, the curve of cumulative hits substantially in the horizontal direction.
Based on the above analysis, the acoustic emission amplitude and the slope of cumulative hits have obvious stage characteristics from yielding to plastic deformation then to the stages of the fracture process of steel Q345. The relationship between simulation and experiment with the load and time curve were fit well, which illustrates the changes of acoustic emission cumulative hits can reflect the different processes of the development of material damage state.

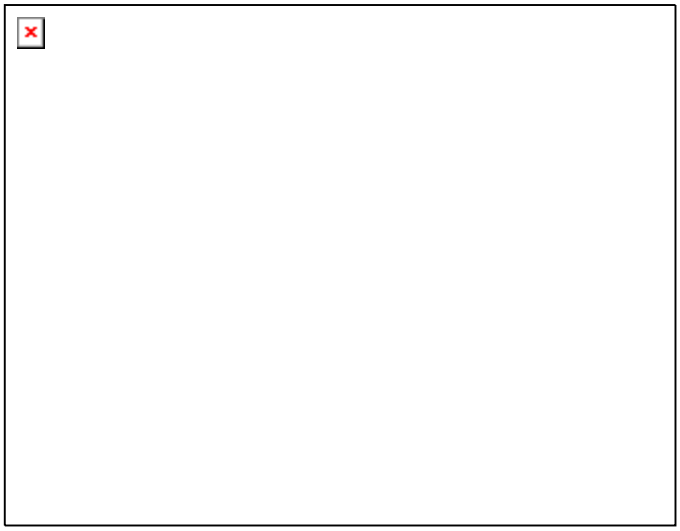

Fig.2 Accumulated hit-amplitude-stress vs. time for specimen 1.

4 The tensile process micro-damage of Steel Q345 notched specimen: simulation and analysis

4.1 The establishment of the Steel Q345 notched micro model and parameter selection

The voids growth ratio VG of Steel Q345 notched specimen are obtained with numerical simulation method in tensile process. Take GTN as the micro-damage model, using the ABAQUS finite element analysis software, we analyzed Steel Q345 notched specimen and observed micro-damage evolution, then obtain the numerical solution of the micro-damage parameters. Voids growth ratio V_G is a function of the stress triaxiality and equivalent plastic strain, so using the finite element software ABAQUS/Explicit can calculate stress triaxiality, equivalent plastic strain, void volume percent distribution and changes with the load in notched specimen. First, modeling of the notched specimen, due to the geometric axis of the specimen, took the modeling of the test piece of 1/4

which shown in Fig.3. The element type is CAX4R. Meshing principle is that the more close to the notched root the meshing was more dense, the minimum mesh size of the front notched is about 80μm. The number of nodes of the model was 496, the number of units was 328. The boundary conditions are consistent to the former experimental conditions, loading mode is displacement loading. Loading amount of displacement of eight specimens at the point B~E which listed in Table 2 is displacement average. Choice of the steel Q345 GTN model parameters are as follows: q_1=1.5，q_2=1.0，q_3=2.25，f_N=0.02，S_N=0.1，ε_N=0.25.

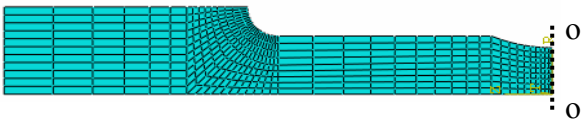

Fig.3 1/4 finite element model of notched tensile specimens

4.2 The numerical simulation results and analysis

Figure 4 is a numerical simulation proceeds that steel Q345 axial tensile stress-displacement curve compared with the specimen 1 of the experimental curves. The highest stress point D and the yield point B obtained by the numerical simulation agree with the experiment results, which are proved the GTN model parameter selected reasonable. These can truly reflect the macro-mechanics and micro-mechanics behavior of Steel Q345 axial tensile experiment. Figures 5~7 are respectively different loading stage of model notched o-o, they are the curves of stress triaxiality R_σ, equivalent plastic strain ε_p and the void volume percentage f versus x. x represents the specimen o-o surface center (x=0mm) to the distance of the notched root(x=4mm). To express the micro-damage parameters changes with the loading clearly, the middle of the loading process should select appropriately. Concluded from Fig.5, the R_σ of the specimen notched center is bigger than the value of the root of the specimen and the maximum R_σ always at the center of the specimen during the loading stage, and increasing with the loading. Fig.6 and Fig.7, ε_p and f change similar with x, but in the loading process they change different with R_σ , and can be divided into two stages. Stage I: Hardening stage (B~D point), the stage is the material yield and enhanced stage, ε_p and maximum f appear at the root of the notched, and they rise with the loading increase. Stage II: Necking stage (D~E point). When the material loaded to the strength limit point D, for the influence of R_σ intensified, ε_p at the middle of the specimen change greater than the growth of the roots. Micro voids move from the notched root to the core part. After plastic zone extends to the core part, stress triaxiality at the core part is much larger than the value of the root, ε_p and f at the core part of the specimen is far greater than the value, which lead to the occurrence of fracture of the specimen from the core part.

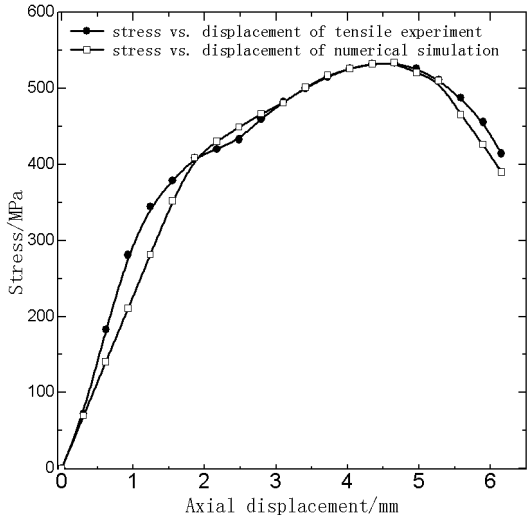

Fig.4 Numerical simulation and experimental results

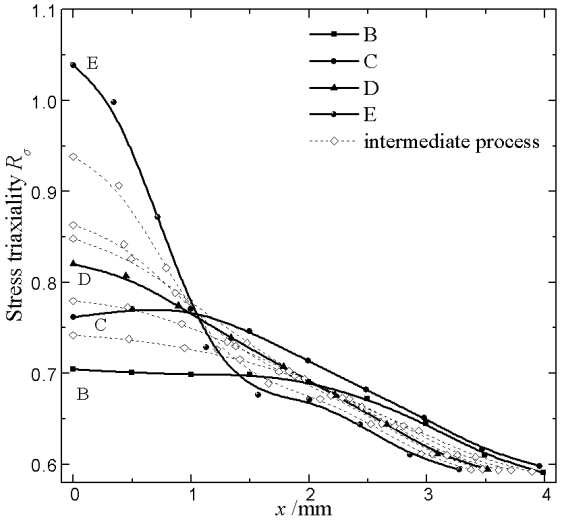

Fig.5 Distribution of Rσ on notch tip

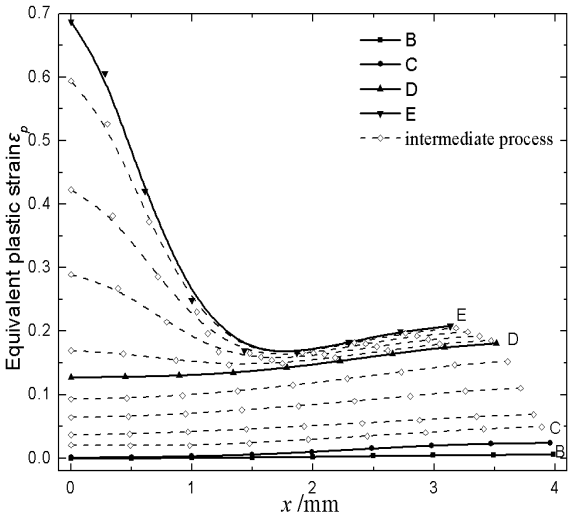

Fig.6 Distribution of εp on notch tip

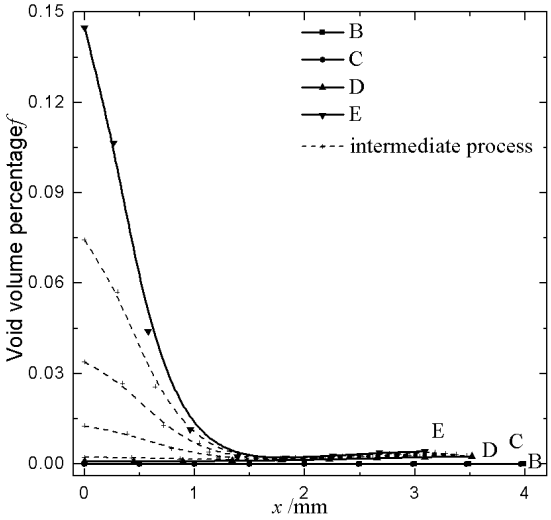

Fig.7 Distribution of f on notch tip

4.3 The numerical simulation of Steel Q345 notched specimen voids growth ratio

Concluded from the simulation results, the final fracture first occurs at o-o surface, so R_σ and ε_p at point B~E which located at model integrator x=0 from o-o surface, and select the appropriate middle point in the loading process. According to equation (6), the numerical simulation results of steel Q345 notched specimens in tensile process are showed in Table 4.

Table 4 Table of voids growth ratio calculation

	stress triaxiality	equivalent plastic strain	voids growth ratio
B	0.704	0	0
C	0.762	0.00104	0.00326
D	0.820	0.128	0.437
E	1.22	0.687	4.29

5. The quantitative evaluation formula between AE cumulative hits and the void growth ratio VG

Selecting the critical point B~E in the tensile process, so do the intermediate process in the loading process, the acoustic emission of each point in the cumulative hit average and numerical simulation of the void growth ratio V_G are showed in Figure 8. From Figure 8, the relationship between $\overline{N}$ and

V_G can be divided into two stages:
Stage I: point B~D, steel Q345 is in the yielding and hardening process. This stage is an important period of the material within the nucleation and growth of micro-voids, the void growth and acoustic cumulative hit are linear growth, and the growth trend is relatively slow. Therefore, this stage is defined as the stage of the linear damage of the material. By numerical fitting:

$$V_{G\,\mathrm{I}} = 0.0021\overline{N} - 0.109 \qquad (7)$$

Where $21 \leqslant \overline{N} \leqslant 155$.
Stage II: point D~E, steel Q345 is in the necking stage. This is the development of late damage, micro-void confluence occur in the material internal. With the cumulative hit increases, void growth ratio is increasing rapidly. Contrast to stage I, this stage increase evidently in exponential form. Therefore, the stage is defined as a nonlinear damage stage. By numerical fitting:

$$V_{G\,\mathrm{II}} = 0.058(\overline{N} - 153.05)^{1.75} \qquad (8)$$

Where $155 \leqslant \overline{N} \leqslant 164$.

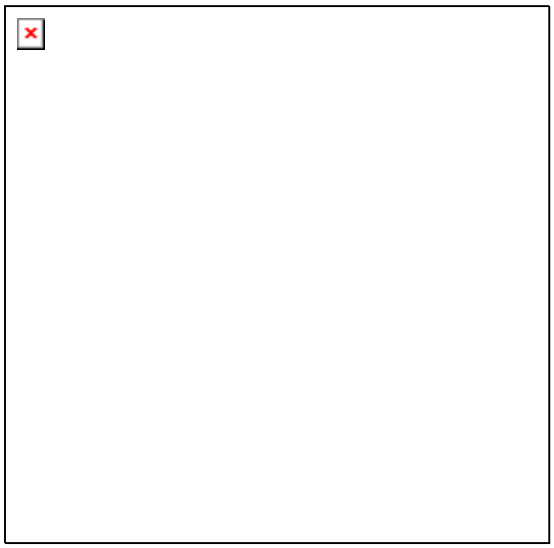

Fig.8 The diagram of AE average cumulative hit vs. void growth ratio

The intersection point F (147.28, 0.26) was obtained by simultaneous the equation (7) and (8), it revealed that steel Q345 notched specimen begins to transform from linear damage stage to nonlinear damage stage. Taking the uniformity of experimental material , the micro-voids distribution and mechanical noise impact in acoustic emission testing experimental process into consideration, the safety factor n range was 0.9~0.95. Material transform from linear damage to the next stage, the critical acoustic emission cumulative hits take $[N^*]=N_F \times n$. When n=0.9, acoustic emission cumulative hit is 128, which can be taken as the critical value of steel Q345 notched specimen in plastic damage. This is the evident to certify the transformation of steel Q345 notched specimen from linear damage stage to nonlinear damage stage.

6. Conclusions

(1) The meso-damage mechanism of metal-plastic material is micro-void nucleation, growth and coalescence. Steel Q345 notched specimen in tensile process shows that AE and micro-voids of metal plastic material have the consistent corresponding relationships, which the changing of AE cumulative hits directly corresponds with the different damage stage of material.
(2) Based on the micro-void damage theory of metal plastic materials, the micromechanics parameters of void growth ratio V_G is the bridge with which combined micromechanical

characteristics and macro mechanical parameters. The changes of V_G directly reflects the state of deterioration of the material. Applying GTN model to calculate the changes of V_G on tips of Steel Q345 notched specimen combined with AE testing experiment, and finally established the quantitative evaluation formulas between acoustic emission cumulative hits and void growth ratio.

(3) The quantitative evaluation formulas between acoustic emission cumulative hits and void growth ratio can be divided into two parts: linear damage stage and nonlinear damage stage. From the function of cumulative hits and void growth ratio, when the acoustic emission cumulative hits is larger than 128, the steel Q345 damage transform from linear damage stage to nonlinear damage stage.

Some Statistical Parameters of Acoustic Emission Signals in Porous Iron under Static Loading

Abstract Acoustic Emission (AE) method is based on detection of ultrasonic signal due to the process of plastic deformation and fracturing of a loaded material. In this paper two characteristics of the AE signal, distributions of time intervals between successive pulses and amplitude distributions of these pulses were obtained. Samples were made of the porous iron with a porosity in the range P=0.05-0.25. This class of materials can be considered as a model to study the influence of geometry of the inhomogeneous medium and percolation effects (due to changing of porosity) on the processes of deformation and fracture, and therefore the behavior of the various parameters of acoustic emission. Registered signals were broadband in a range of frequencies from 100 to 800 kHz. Consideration of amplitude distributions of AE signals showed that it is possible to identify two groups of AE pulses - low-amplitude and high-amplitude in the recorded signals. The first group corresponds to the plastic deformation of the compact sites of the material, and the latter one is usually generated by large plastic shears and crack propagation. It was showed that they have scaling with exponents vary with changes in porosity. Obtained distributions can be perceived as indirect evidence of self-organized processes occurring in porous metallic materials.

Keywords acoustic emission, plastic deformation, amplitude distribution, fracture

1. Introduction

Acoustic emission (AE) method is successfully used for nondestructive testing purposes. It is well developed for homogeneous metallic materials. New types of materials such as sintered powder metals or composites with high degree of heterogeneity have many potential mechanisms of ultrasonic emission. Therefore it is very important to understand how and when these mechanisms activate, and to be able to estimate their parameters.

Usually only some basic characteristics of acoustic emission process are used for AE diagnostics [1]. These characteristics are kinetic, such as rate or AE event count, and energy (energy of AE signal and energy of discrete events). But AE process in heterogeneous material is a complex phenomenon, with many mechanisms interacting with each other. Not without reason there are many synergetic and/or fractal theories of plastic deformation and fracturing of materials. For this kind of processes some new integral parameters of AE signal can be introduced.

In this paper two of such complex or integral parameters of AE were considered. First is well known. It is an amplitude distribution of AE signal. In heterogeneous materials this parameter has complex behavior. It is closely associated with second parameter - distribution of time intervals between successive AE events.

2. Materials and samples

As an example of material with highly heterogeneous structure porous metals were used. They can be considered as heterophase media with ultimately different properties of the two phases (solid framework and pores) [2].

Samples for acoustic emission tests were made of an iron powder obtained by spraying in air

(PZhRV2 grade). They were prepared by pressing to a preset porosity followed by sintering at 1500 K for 2.5 h in vacuum. The samples had the standard shape for tensile tests with a rectangular working part of 3X3 mm cross section. Their porosity varied within P=0.05-0.25. During static loading of these samples AE signals were recorded, and thereafter were digitally processed [3]. First, digital band-pass filtering with cutoff frequencies 100 and 800 kHz was done. Events with amplitudes under preassigned threshold (~0.2 V) were not taken into succeeding calculations.

3. Amplitude distributions

Amplitude distributions for extracted events were calculated. An example of such distribution is presented on Fig.1. Logarithmic scale was used. We can see two amplitude ranges. Dependence of amplitude rate in these ranges can be written as $n(u) \sim u^{-h}$, where h is an exponent coefficient. Amplitude of AE events is closely related to the size of the AE sources. Of course, inhomogeneity of material, reflection of acoustic waves on sample surfaces can change amplitudes of AE events, but qualitative dependence of amplitude distributions cannot be changed dramatically. So we see that there were two groups of AE events. First group of events with low amplitudes can be attributed to plastic deformation of material. From [4] we know that such type of deformation cause AE emission with frequent and low bursts. Second group of events with high amplitudes is related to nucleation and propagation of microcracks, originated from the pores [2, 4]. There's an amplitude threshold between two groups. This threshold didn't change for every sample in our setting. So we can use it for discrimination of AE events with different mechanisms.

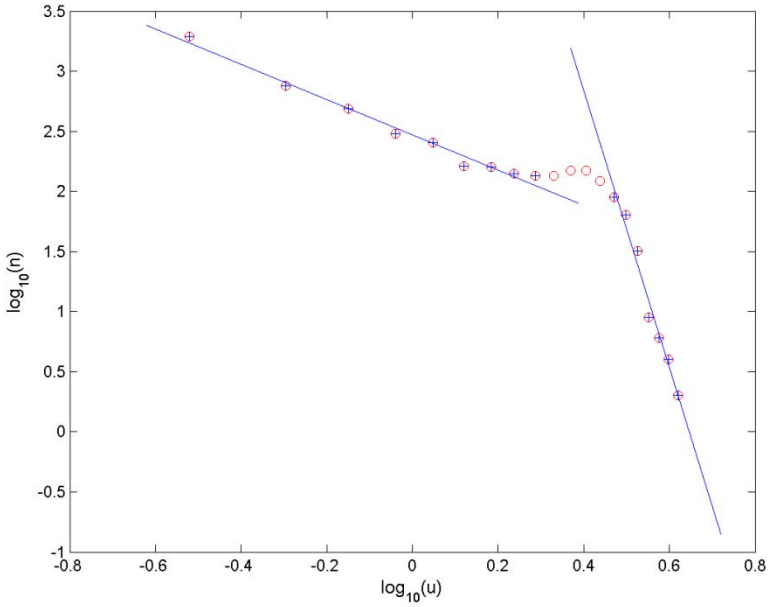

Figure 1. An example of amplitude distribution (P=0.09).

On Fig.2 the values of exponent coefficients for different samples were showed. The exponent coefficient of high amplitude events were changed for different values of porosity, while the other group of events had the same coefficients regardless of porosity. As we can see, for samples with porosity near percolation threshold (P~0.1 for porous iron [2, 5]) there was a large spread of coefficients for high amplitude AE events. It can be explained by the fact, that the structure of porous space varies from sample to sample and scale range of AE sources varies greatly respectively. For some samples isolated pores were prevailed, and for others pores form "infinite" clusters [5]. Plastic flow in compact regions of porous metal doesn't change and therefore there's no

dependence of low amplitude coefficients on porosity.

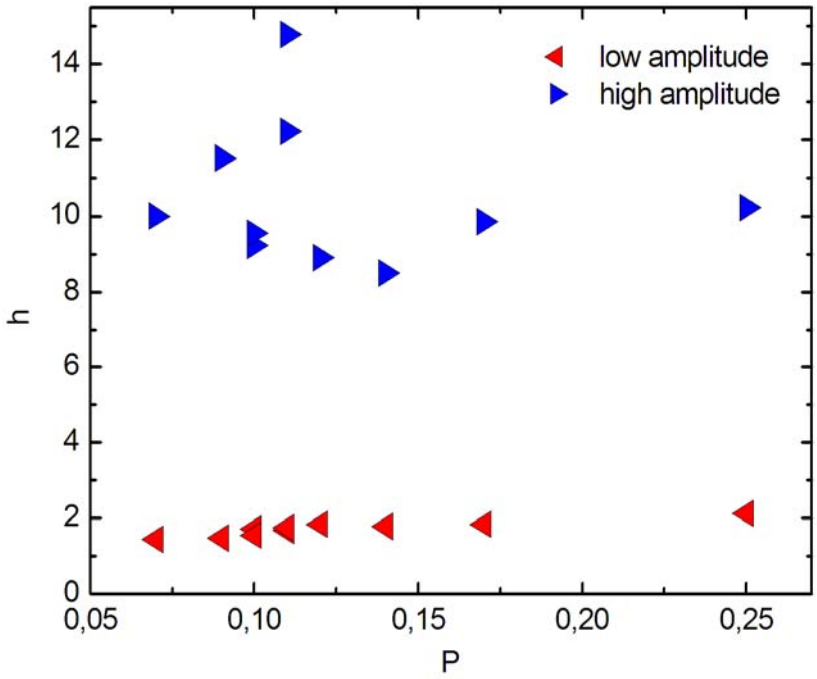

Figure 2. Exponent values of amplitude distributions for different porosities.

4. Distributions of time intervals between AE events

The next step of our work was calculation of distributions of time intervals. This parameter has a great advantage over other AE parameters, because it does not depend on peculiarities of acoustic wave propagation. Time intervals between registered AE bursts and corresponding AE events in media are the same. Also time intervals between AE events give more information about kinetic characteristics of AE process than usual parameters such as AE event count. There is only one difficulty in applying this parameter. Time distribution for all AE events takes into account all the processes that are responsible for the emission of acoustic waves. The structure of such distribution can be too intricate. To overcome this difficulty the following approach had been proposed.

All AE events had been divided into two groups according to the amplitude. Time intervals were calculated not for successive events but for successive events in one group. Fig.3 illustrates this idea. For low amplitude events with $U_{discr} < U < U_{threshold}$, where $U_{threshold}$ corresponds to amplitude threshold between "low" and "high" groups and U_{discr} was a preassigned threshold above, a distribution $w_{low}(\Delta t^{low})$ was calculated. And for high amplitude AE events with $U_{threshold} < U$ a distribution $w_{high}(\Delta t^{high})$ was obtained. These distributions had the same scaling form:

$$w_{low}(\Delta t^{low}) \sim (\Delta t^{low})^{-a_{low}}, \quad (1)$$

$$w_{high}(\Delta t^{high}) \sim (\Delta t^{high})^{-a_{high}} \quad (2)$$

Values of exponents a_{low} and a_{high} are showed in Fig.4. As we see from this figure, all exponents for low and high amplitude events were in two "bands" or value intervals.

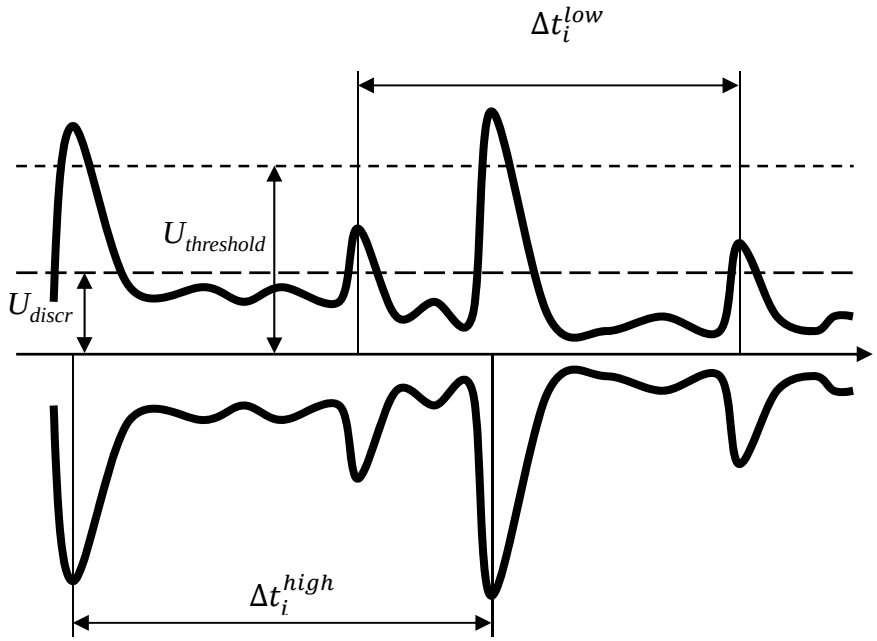

Figure 3. Explanation of the method of finding time interval distributions.

A theoretical approach for the self-organization of defects in material [6, 7] can be used to understand these experimental results. Low amplitude events strongly correlated with each other. Their exponents had higher values than for high amplitude events. Therefore “low” events and sources of acoustic emission in compact sites of porous material respectively were strongly correlated with each other. On the contrary, in the case of high amplitudes, correlation of events was weaker. The ensembles of microcracks emit acoustic waves synchronous and relatively independent of each other.

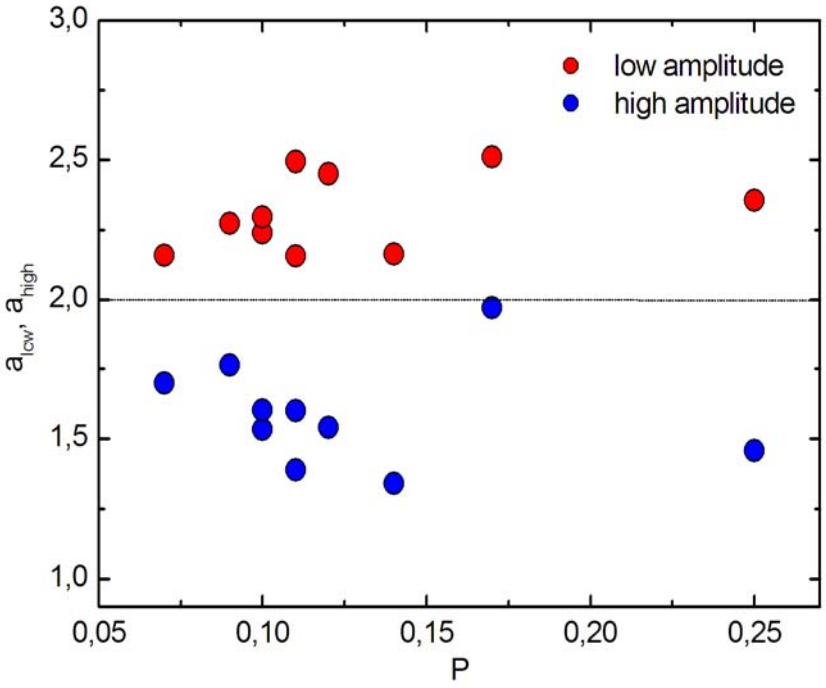

Figure 4. Exponent values of time intervals distributions for different porosities

5. Conclusion

The modified method of AE signal processing based on separate estimation of AE parameters for different groups of events was proposed. It was shown, that for the acoustic emission in porous metallic materials two groups of events and respectively two groups of AE sources can be identified. The first group was characterized by low amplitudes and the second had high amplitudes. They had different behavior of exponents for amplitude and time interval distributions. Proposed approach can be used for the development of nondestructive testing methods applied to inhomogeneous materials.

Abstract In the paper, aiming to build models of microcracks extension and damage evolution in the phase of microcracks evolution based on number series of microdefects nucleation, we firstly built a relation formula between accumulated number series of microdefects nucleation and microcracks size, which we called the crack growth model(CGM), by means of the fractal statistical method. Then, we set up a damage evolution model based on growing microcrack size which is determined by microdefects nucleation number series, which we called the damage evolution model(DEM).The statistical analysis on the microcracks evolution in a gradually fractured rock plate shows that the predictive crack size growth by CGM and damage evolution by DEM are in good accord with the measured values. Based on the fact that a microdefect nucleation is accompanied with a acoustic emission(AE), the two models maybe become good methods to predict microcrack growth and damage evolution by use of AE series.
Keywords fractal; microcrack; rough surface; microdefect; damage evolution; acoustic emission

1. Introduction

The research[1,2] shows that in the early stage of damage evolution, the evolution mechanism of microcrack system is microdefects random nucleation and growth in limited size. Microdefect nucleation means the embryo defects in inhomogeneous material extends by tension strain and grows into a microdefect which is the smallest size in microcrack system. In the macro stress field, microdefects nucleate at the inhomogeneous positions which are uniformly distributed in the materials. The microdefect size can be as small as a grain size. Then with the distribution of microdefects nucleation approaching saturation, microdefects nucleation take place closely next to the existing cracks under controlling of the macro shear stress field, which is called as microcrack growth. The microcracks in the larger deformation bands take the superiority of prior growth and in return they can stir up more microdefects nucleation at their two ends and grow into larger-scale microcracks. So the size distribution in the microcrack system is non-uniform. The connection of larger-sized microcracks brings about macro crack nucleation, which marks the end of microcracks system evolution .

In the following, based on the fact that microdefects nucleate in clustering arrange without overlapping and grow into microcrack, we establish the microcrack growth model based on ANMDN series.

2. The number of microdefects in single microcrack

As is well-known, the crack surface is rough, according to the fractal theory, the fractal area $A_T(\delta)$ could be calculated as[3]

$$A_T(\delta) = A_T \delta^{2-D_s} \tag{1}$$

In which A_T is the apparent area; D_s is the fractal dimension of the rough surface; δ is the measure size, its minimum is the grain size δ_c（Xie,1994）[4].So, on the surface of a penny-shaped crack with apparent diameter c, the number of grains n_d is calculated as

$$n_d \frac{\pi}{4}\left(\frac{\delta}{c}\right)^2 = \frac{\pi}{4}\left(\frac{c}{c}\right)^2 (\frac{\delta}{c})^{2-D_s} \quad (2)$$

Reduction to

$$n_d(c) = \left(\frac{\delta}{c}\right)^{-D_s} \quad (3)$$

For a penetrating crack in a two-dimensional plate, $D_s = d_f$. Here d_f is the fractal dimension of the crack line. The fracture mechanism of the fractal crack line was known as intergranular fracture, transgranular fracture, and coupling fracture of them. And the fractal dimensions d_f can be obtained by theoretical calculation（Xie,1988）[5]. For example, the crystallite size of marble is $\delta_c = 10^{-2} cm$, in tensile condition, the three kinds of fractal dimensions in theory are $d_f = 1.26$,1.365 and 1.30, and the measured values are $d_f = 1.18,1.31,1.29$. For a embedding crack in three dimensional condition, D_s is valued approximately as[6,7]

$$1 + \max(d_f^x,\ d_f^y) = D_s < d_f^x + d_f^y \quad (4)$$

In which, d_f^x and d_f^y represents respectively the mean value of fractal dimensions on fracture lines in x-direction and y-direction. So, if $d_f = 1.3$, then $D_s = 1 + d_f = 2.3$.

3The microcracks growth model based on ANMDN

At a certain time t, the parameters of the microcracks system are marked as

$$\Omega(t) = \left[c_{\min} \le c \le c_{\max},\ D_c,\ N(\delta),\ N_0(c_{\max}),\ N(c),\ N_d\right] \quad (5)$$

Here $c_{\min}$ represents the minimum microcrack size, in theory, can be valued as crystal grain size; $c_{\max}$ represents at time t the maximum crack size; D_c represents the fractal dimension of crack size scale-frequency distribution; $N(\delta)$ represents the total number of cracks with size no less than δ; $N(c)$ represents the total number of cracks with size no less than c; $N_0(c_{\max})$ represents the total number of cracks with maximum size $c_{\max}$; N_d represents the accumulated number of microdefects nucleation(ANMDN).

According to that the crack size-frequency distribution is fractal(Peng & Xie,1989[8]; Xie & Gao,1991[9]), at time t, we have the equation

$$N(c) = N_0(c_{\max})\left(\frac{c}{c_{\max}}\right)^{-D_c} \quad (6)$$

So in $\Omega(t)$， the number of microcracks with size in $c \sim dc + c$ is

$$N(c-dc)-N(c)=N_0(c_{\max})\left[\left(\frac{c-dc}{c_{\max}}\right)^{-D_c}-\left(\frac{c}{c_{\max}}\right)^{-D_c}\right]$$
$$=\frac{N_0(c_{\max})}{c_{\max}^{-D_c}}[(c-dc)^{-D_c}-(c)^{-D_c}] \quad (7)$$

Use Tailor series expansion

$$(c-dc)^{-D_c}=c^{-D_c}+(-D_c)c^{-D_c-1}(-dc)+\frac{1}{2}(-D_c)(-D_c-1)c^{-D_c-2}(-dc)^2+\Lambda$$
$$\approx c^{-D_c}+(-D_c)c^{-D_c-1}(-dc) \quad (8)$$

Substituting Eq.(8) into Eq.(7) we have

$$N(c-dc)-N(c)=\frac{N_0(c_{\max})}{c_{\max}^{-D_c}}D_c c^{-D_c-1}dc \quad (9)$$

Substituting in Eq.（3）we have the total number of microdefects nucleation that compose all the micro cracks with size in $c\sim dc+c$ in $\Omega(t)$

$$[N(c-dc)-N(c)]n_d(c)=\frac{N_0(c_{\max})}{c_{\max}^{-D_c}}D_c c^{-D_c-1}\left(\frac{\delta}{c}\right)^{-D_s}dc \quad (10)$$

Further, we have

$$[N(c-dc)-N(c)]n_d(c)=\frac{N_0(c_{\max})D_c\delta^{-D_S}}{c_{\max}^{-D_c}}c^{D_s-D_c-1}dc \quad (11)$$

So, the total number of all the micro defects nucleation in $\Omega(t)$ is

$$N_d(t)=\int_{\delta_c}^{c_{\max}}[N(c-dc)-N(c)]n_d(c)=\int_{\delta_c}^{c_{\max}}\frac{N_0(c_{\max})D_c\delta^{-D_S}}{c_{\max}^{-D_c}}c^{D_s-D_c-1}dc \quad (12)$$

Integration of Eq.(12) is

$$N_d(t)=\frac{N_0(c_{\max})D_c\delta^{-D_S}}{(D_s-D_c)}\left(\frac{c_{\max}^{D_s-D_c}-\delta^{D_s-D_c}}{c_{\max}^{-D_c}}\right) \quad (13)$$

From Eq.(6), if at time t, the total number of all the micro cracks $N(\delta)$ is known in $\Omega(t)$, then, $N_0(c_{\max})$ can be determined

$$N_0(c_{\max})=N(\delta)\left(\frac{\delta}{c_{\max}}\right)^{D_c} \quad (14)$$

Substituting Eq.(14) into Eq.(13), we have relation $N_d\sim c_{\max}$

$$N_d(t)=\frac{N(\delta)D_c}{(D_s-D_c)}\left[1-\left(\frac{c_{max}}{\delta}\right)^{D_s-D_c}\right] \quad (15)$$

From which, the maximum crack size should be expressed as

$$c_{max}=\delta\left(1-\frac{N_d(t)(D_s-D_c)}{N(\delta_c)D_c}\right)^{-(D_s-D_c)} \quad (16)$$

In which the parameters D_c , $N(\delta_c)$, N_d need to be obtained from the AE series.

4 Damage evolution model based on ANMDN series

The purpose of studying the microcracks system is to answer how the microcracks growth in material will affect the macroscopic mechanical properties. In statistical meso-scopic damage mechanics[1], a series of damage functions are used to describe the macro-effects caused by microcracks. The m-th order damage function is defined as（Bai & Xia,1991[10],Xia,1995[1]）

$$D_m(t,\sigma)=\int_0^\infty n(c,t;\sigma)c^m dc \tag{17}$$

Here c is the linear size of microcrack; $n(c,t;\sigma)$ represents in macro stress field σ , at time t , the number density of microcracks with size c . The zero-th order damage function, D_0 represents the total number effect of microcracks; The1st order damage function, D_1 represents the total size effect of microcracks; The second order damage function, D_2 represents the reduced load bearing area and D_3 is proportional to the volume occupied by the microcracks.

In the stage of microcracks evolution, the size of the microcracks is small and their spatial distribution is uniform and sparse[2], which is approximately thought to be suitable for mean field model[1], therefore the damage effects by microcracks on macro mechanical properties are isotropous. So in three dimensional conditions, we define the damage variable as

$$D=K\frac{D_3}{V} \tag{18}$$

In which V represents macro element volume with linear size L ; K is correction factor. Adopting the form of Eq.(17), we have

$$D=K\frac{\int_0^\infty n(c,t;\sigma)c^3 dc}{V} \tag{19}$$

In which $0<D<1$. Adopting the form of Eq.(9), $n(c,t;\sigma)dc$ takes the form of

$$n(c,t;\sigma)dc=\frac{N_0(c_{\max})}{c_{\max}^{-D_c}}D_c c^{-D_c-1}dc \tag{20}$$

Substituting Eq.(20) in Eq.(19), we have

$$D=K\frac{1}{V}\int_{c_{\max}}^{\delta}\frac{N_0(c_{\max})}{c_{\max}^{-D_c}}D_c c^{2-D_c}dc \tag{21}$$

Use $V=L^3$, and integrating, then

$$D=K\frac{N_0(c_{\max})D_c}{(3-D_c)}\left[\left(\frac{\delta}{L}\right)^3\cdot\left(\frac{\delta}{c_{\max}}\right)^{-D_c}-\left(\frac{c_{\max}}{L}\right)^3\right] \tag{22}$$

Substituting in Eq.（14）and put it in order, we have

$$D = K\frac{N(\delta)D_c}{(3-D_c)}\left[1-\left(\frac{c_{\max}}{\delta}\right)^{3-D_c}\right]\left(\frac{\delta}{L}\right)^3 \tag{23}$$

In which $c_{\max}$ is determined by the total number of microdefects, so, substituting in Eq.（16）,we have

$$D = K\frac{N(\delta)D_c}{(3-D_c)}\left[1-\left(1+\frac{N_d(t)(D_s-D_c)}{N(\delta)D_c}\right)^{-(D_s-D_c)(3-D_c)}\right]\left(\frac{\delta}{L}\right)^3 \tag{24}$$

Which is the damage evolution equation. The parameters $N(\delta)$, $N_d(t)$ and $D_c(t)$ are needed to be obtained from AE series.

In two dimensional condition, the material volume is written as $V = hL^2$, in which h represents the thickness of the plate. Substitute $V = hL^2$ in Eq.(21),we have another form of damage model

$$D = K\frac{N(\delta)D_c}{(3-D_c)}\left[1-\left(1+\frac{N_d(t)(D_s-D_c)}{N(\delta)D_c}\right)^{-(D_s-D_c)(3-D_c)}\right]\left(\frac{\delta}{L}\right)^2\cdot\frac{\delta}{h} \tag{25}$$

5 Test

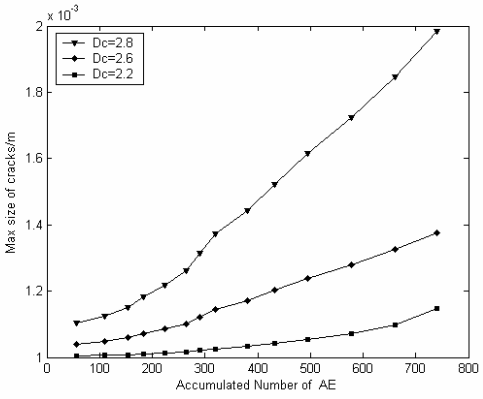
Now, use the AE data in literature[28] to test the validity of the model proposed in the paper. $L = 50mm$, $\delta_c = 10^{-2}cm$, $D_s = 2.3$ The series of AE number per 400 seconds is

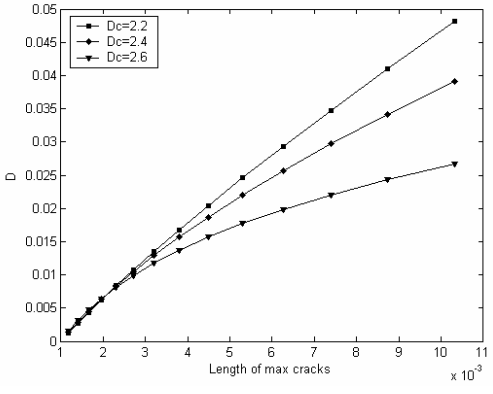
$$N_{AE}(t) = \{57\ \ 52\ \ 45\ \ 29\ \ 41\ \ 41\ \ 25\ \ 30\ \ 60\ \ 52\ \ 63\ \ 83\ \ 83\ \ 80\}、$$

Here we assume the total micro cracks number increases as a rule of

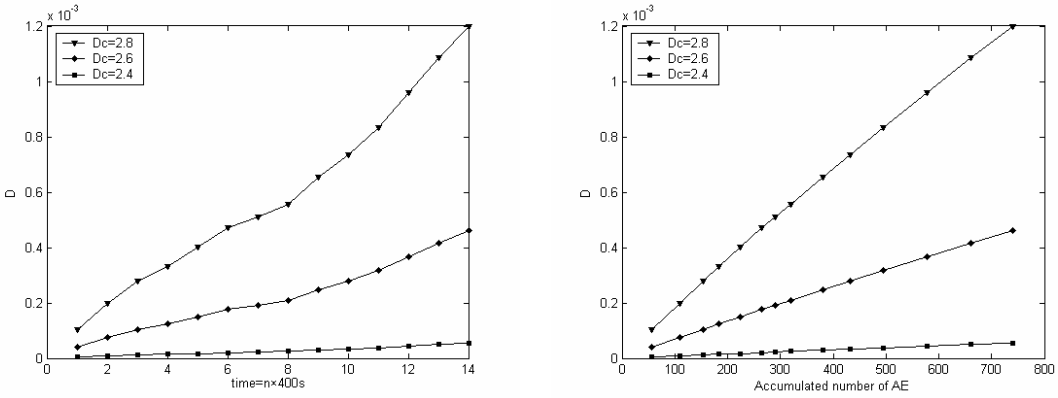
$$N(\delta_c,t) = N_\delta^i(t) = N_{AE}^i(t) = N_{AE}(t)/exp(n/5) \tag{26}$$

The evolution of the size of the maximum cracks and damage of sample according to the paper shows as figure 1.





（a） （b）



（c） （d）

Fig.4 The preliminary test of the model

6 Conclusions

In the paper, based on the idea of the microcrack formed by microdefects nucleation gathered in line without overlapping, and the fractal statistics relations between the number of microdefects nucleation and microcrack size, we established the microcrack growth model and elasticity damage model based on accumulated microdefects nucleation number. They are needed to be proved effective in predicting microcrack size growth and damage evolution using AE accounts series. In practical use, some problems needed to be resolved: (1) How to get $N(\delta,t)$, the total number of cracks with size no less than δ. A likely workable way is to detach the isolated nucleation AE accounts from the accumulated AE accounts, the isolated nucleation number represents $N(\delta,t)$;(2) How to get the microcrack size scale-freqiency fractal dimension $D_c(t)$ from the AE series. The fractal dimension of seismic magnitude-frequency distribution in AE series has been researched [11-13], the next work is to establish the relationship of the two kinds of fractal dimensions; (3) How to identify the microcrack evolution stage from the AE series. It needs to identify the macro Nucleation from the AE series, so the AE characters of macro Nucleation should be specially researched; (4) in engineering catastrophe monitoring, AE location is necessary to determine L, the size of the rock element. In the end, we need to note that the damage model in the paper is multiscaled with the rock element size L, microdefect size δ and macro crack nucleation size.

Abstract In this paper a new augmented finite element method (A-FEM) that can account for multiple, intra-elemental discontinuities in heterogeneous solids has been derived. It does not need the extra DoFs as in the extended finite element method (X-FEM), or the additional nodes as in the phantom node method (PNM). The new A-FEM employs four internal nodes to facilitate the calculation of subdomain stiffness and the crack displacements due to an intra-elemental discontinuity. It is shown that through a novel efficient solving algorithm the displacement DoFs associated with the internal nodes can be solved analytically as functions of the regular nodal DoFs for any piece-wise linear cohesive laws, which leads to a fully-condensed elemental equilibrium equation that is mathematically exact. The new formulation permits repeated elemental augmentation to include multiple interactive cracks within a single element, enabling a unified treatment of the evolution from a weak discontinuity, to a strong discontinuity, and to multiple intra-element discontinuities, all within a single element that employs standard DoFs only. The new A-FEM's capability in high-fidelity simulation of interactive cohesive cracks in homogeneous and heterogeneous solids has been demonstrated through several numerical examples. It has been demonstrated that the new A-FEM achieved more than two orders of magnitude improvement in numerical accuracy, efficiency, and robustness, compared to the X-FEM.

Keywords Augmented FEM, Extended FEM, Fracture, Cohesive model, Numerical simulation

1. Introduction

High-fidelity numerical simulation to the progressive damage evolution in complex heterogeneous materials such as composites remains a significant challenge despite decades of intensive research [1]. Heterogeneity poses special problems with the accurate prediction of local stress and strain fields, which can vary strongly with local material features; and with predicting cracks and localized damage bands, which can appear during damage evolution not only on the material boundaries, but also on other surfaces that cannot be specified *a priori*. The material heterogeneity issue cannot be resolved adequately by mainstream formulations of conventional materials/structures modeling, owing to the complex interaction between fiber tow architecture and constituent materials heterogeneity. One challenge is that many complex composites such as textiles are heterogeneous on the same scale as that of the features of the structures, which negates the common strategy of homogenizing the material properties in simulations. Furthermore, the structure will generally be subject to non-periodic mechanical and thermal loads, including spatial and temporal peaks.

The above challenges require the establishment of numerical modeling platforms that can deal with structural level performance with microscopic level resolution so that arbitrary local damage evolution, from their nucleation stage and coupled evolution to structurally critical dimensions, can be faithfully predicted. Traditional material degradation types of continuum mechanics based approaches are not likely to meet the challenges because the critical damage coupling information is lost during the homogenization process [2, 3]. Currently there are several promising methods that can deal with the material heterogeneity and the associated progressive damage issues. For example, the Peridynamics method [4, 5]. However, this method remains extremely computational intensive and its fidelity in dealing with complex material heterogeneity in 3D textiles has yet to be demonstrated. Another important class of numerical methods is the partition-of-unity based finite element methods (PUFEM[6], including the extended finite element method (X-FEM) [7-9] and the phantom node method (PNM) [10-14]. These methods are relatively mesh-independent and

computationally efficient when dealing with individual cracks. However, with these methods, tracing the evolution of complex fracture surfaces of multiple cracks quickly becomes extremely tedious and numerically burdensome [8, 15, 16].

Therefore, it is beneficial to seek numerical methods that can account for arbitrary discontinuities with less numerical burden for tracing complex crack surfaces. In this regard the embedded discontinuity FEM with internal DoFs is very promising [17-20]. This approach seeks to enrich the elemental strain field so that the discontinuity in strains or in displacements across a discontinuity can be represented. The additional DoFs associated with the crack displacements are then fully condensed at elemental level [19, 21]. However, this method suffers from possible stress locking because in many cases the assumed deformation modes are not permissible with the sub-domain element deformation modes. Furthermore, construction of an enhanced or augmented element with embedded multiple cracks to permit arbitrary crack merging and bifurcation becomes extremely tedious and difficult.

It is therefore highly desired to develop new finite element methods that can deal with discrete cracks without the need of introducing additional DoFs or nodes, so that the numerical burden for tracing crack surfaces can be minimized. In this paper, we present a new augmented finite element method (A-FEM) that can account for 1) intra-element material heterogeneity and 2) repeated elemental augmentation to enable multiple, interactive intra-element discontinuities. These capabilities are crucial to high-fidelity simulations of heterogeneous materials such as composites. In addition, we report a novel and efficient solving algorithm for elemental condensation that provides analytical solutions to the local equilibrium equations with embedded piece-wise linear cohesive crack like discontinuities. It will be demonstrated that the A-FEM empowered by the new condensation algorithm can provide orders of magnitude improvement in numerical efficiency, accuracy and robustness.

2. New A-FEM for Arbitrary, Multiple Cracking in Heterogeneous Solids

2.1 A-FE Formulation with Single Crack

Without the loss of generality, we choose the 4-node quadratic plane element to illustrate the augmented finite element scheme. The physical element with regular nodes 1, 2, 3, and 4 is severed by a cohesive crack (a strong discontinuity) or a bi-material interface (weak discontinuity) where the tractions are continuous but displacements are not. Figure 1 shows the two possible cut configurations. Instead of introducing two nodes with DoFs representing the assumed deformation modes (constant or linear) as in literature [19, 20], here we introduce 4 internal nodes (node No. 5, 6, 6' and 5' in Fig 1 (b & c)) with regular displacement DoFs so that the displacement jump is simply the difference between the respective node-pairs. As will be seen shortly this novel formulation allows us to derive accurate elemental equilibrium equations without the need to assume deformation modes, and more importantly, it offers the great advantage of permitting multiple intra-element discontinuities.

The internal nodes also facilitate the stiffness calculation of the sub-domains so that the equilibrium of the entire element can be expressed in general as the following.

$$\begin{bmatrix} [\mathbf{L}_{11}^{+}] & [\mathbf{L}_{12}^{+}] \\ [\mathbf{L}_{21}^{+}] & [\mathbf{L}_{22}^{+}] \end{bmatrix} \begin{Bmatrix} \mathbf{d}_{\text{ext}}^{+} \\ \mathbf{d}_{\text{int}}^{+} \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_{\text{ext}}^{+} \\ \mathbf{F}_{\text{int}}^{+} \end{Bmatrix} \quad (\text{for } \Omega^{+}); \quad \begin{bmatrix} [\mathbf{L}_{11}^{-}] & [\mathbf{L}_{12}^{-}] \\ [\mathbf{L}_{21}^{-}] & [\mathbf{L}_{22}^{-}] \end{bmatrix} \begin{Bmatrix} \mathbf{d}_{\text{ext}}^{-} \\ \mathbf{d}_{\text{int}}^{-} \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_{\text{ext}}^{-} \\ \mathbf{F}_{\text{int}}^{-} \end{Bmatrix} \quad (\text{for } \Omega^{-}) \quad (1)$$

where $\{\mathbf{d}_{\text{ext}}^{+}, \mathbf{d}_{\text{int}}^{+}\}^{\text{T}}$ and $\{\mathbf{d}_{\text{reg}}^{-}, \mathbf{d}_{\text{int}}^{-}\}^{\text{T}}$ are DoFs of the external or regular nodes and the internal nodes in the two subdomains, respectively. $\{\mathbf{F}_{\text{ext}}^{+}, \mathbf{F}_{\text{int}}^{+}\}^{\text{T}}$ and $\{\mathbf{F}_{\text{ext}}^{-}, \mathbf{F}_{\text{int}}^{-}\}^{\text{T}}$ are the nodal forces associated with regular and internal nodes; $[\mathbf{L}_{ij}^{+}]$ and $[\mathbf{L}_{ij}^{-}]$ $(i, j = 1, 2)$ are the stiffness sub-matrices of respective domains, which can be easily obtained with standard or subdomain integration schemes. The internal force arrays come from the integration of cohesive stresses along the crack surfaces, and,

due to stress continuity across the cohesive crack, $\mathbf{F}_{\text{int}}^{+} = \mathbf{F}_{6'5'}^{+} = -\mathbf{F}_{\text{int}}^{-} = -\mathbf{F}_{65}^{-}$. Note that, irrespective the cut configurations in Figure 1 (b) or (c), the internal displacements are always $\mathbf{d}_{\text{int}}^{+} = \mathbf{d}_{6'5'}; \mathbf{d}_{\text{int}}^{-} = \mathbf{d}_{65}$.

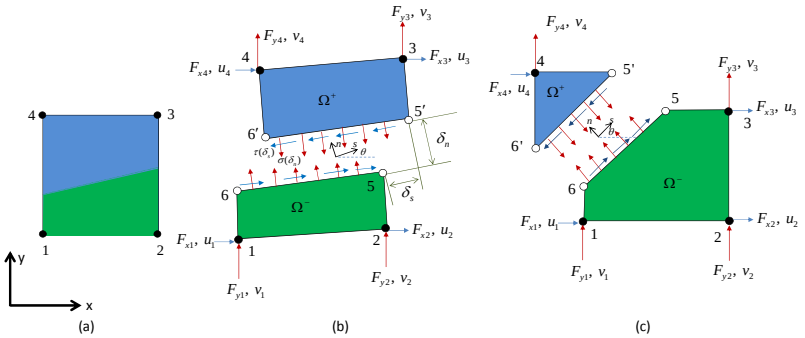

Figure 1 Illustration of the element augmentation from a regular element with possible different material domains (a), to an A-FE with two rectangular sub-domains (b), or to an A-FE with one triangular sub-domain and one pentagon sub-domain (c).

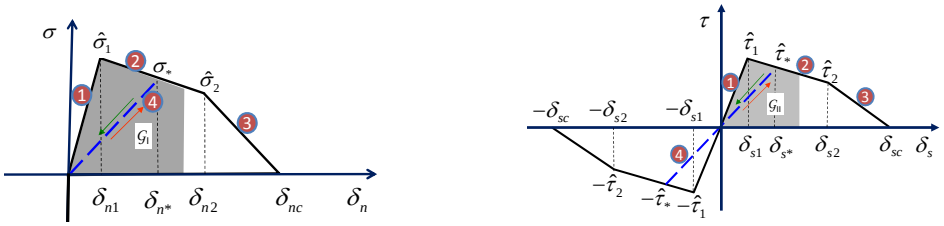
For the piece-wise linear cohesive laws shown in Figure 2, the cohesive stresses as functions of crack displacements can be written as

$$\begin{aligned} &\sigma(\delta_n) = \hat{\sigma}^{(i-1)} + \alpha_n^{(i)}(\delta_n - \delta_n^{(i-1)}) \qquad (\delta_n \subset [\delta_n^{(i-1)}, \delta_n^{(i)}] \qquad (i = 1,2,\cdots 4) \\ &\tau(\delta_s) = \text{sgn}(\delta_s)\left[\hat{\tau}^{(j-1)} + \alpha_s^{(j)}\left(|\delta_s| - \delta_s^{(j-1)}\right)\right] \quad (|\delta_s| \subset [\delta_s^{(i-1)}, \delta_s^{(i)}] \quad (j = 1,2,\cdots 4) \end{aligned} \tag{2}$$

where sgn(·) is a sign function, and |·| denotes absolute value; $\sigma(\delta_n)$ and $\tau(\delta_s)$ are normal and tangential tractions along the cohesive crack; δ_n and δ_s are normal and tangential crack displacement; the superscripts *i* and *j* denote the linear segment number as labeled in Figure 2. $\hat{\sigma}^{(i)}$ and $\hat{\tau}^{(j)}$, $\delta_n^{(i)}$ and $\delta_s^{(j)}$, $\alpha_n^{(i)}$ and $\alpha_s^{(j)}$ are the characteristic stresses, crack displacements, and slopes (Fig 2), and $\hat{\sigma}^{(0)} = \hat{\tau}^{(0)} = 0$ and $\delta_n^{(0)} = \delta_s^{(0)} = 0$.



(a) mode I cohesive law (b) mode II cohesive law

Figure 2 Mixed-mode cohesive model with piece-wise linear traction-separation laws used in this study

The propagation criterion used for the cohesive crack is one that has been widely used and validated in literature [22, 23]

$$\mathcal{G}_{\text{I}}^{*} / \Gamma_{\text{I}} + \mathcal{G}_{\text{II}}^{*} / \Gamma_{\text{II}} = 1 \tag{3}$$

where $\mathcal{G}_{\text{I}}^{*}$ and $\mathcal{G}_{\text{II}}^{*}$ are the energy dissipations at which the cohesive failure occurs (shaded areas in Fig 2), and Γ_{I} and Γ_{II} are the <u>total</u> areas under the pure opening and pure shear traction-separation laws.

With the above piece-wise linear cohesive law, the cohesive stresses between the two pairs of internal nodes 5-5' and 6-6' are known. The internal force arrays $\mathbf{F}_{65}$ and $\mathbf{F}_{6'5'}$ are the cohesive stresses integrated over the crack surfaces and transfer them into global coordinates,

$$\mathbf{F}_{65} = -\mathbf{F}_{6'5'} = l_e^{\theta}(\mathbf{S}_0 + \boldsymbol{\alpha}\{\Delta\mathbf{d}_{66'}, \Delta\mathbf{d}_{55'}\}^{\text{T}}) \tag{4}$$

where $\Delta\mathbf{d}_{6'6} = \mathbf{d}_{6'} - \mathbf{d}_6$ and $\Delta\mathbf{d}_{5'5} = \mathbf{d}_{5'} - \mathbf{d}_5$. $\mathbf{S}_0$ and $\boldsymbol{\alpha}$ are the matrices determined by the characteristic cohesive stresses and slopes. Substituting Eqn (4) to Eqn (1) the following is derived

$$\begin{Bmatrix}\mathbf{d}_{6'5'}\\ \mathbf{d}_{65}\end{Bmatrix}=\begin{bmatrix}-l_{e1}\mathbf{A}^{-1}\left(\mathbf{I}-l_{e1}\boldsymbol{\alpha}(\boldsymbol{\Psi}_{22}^{-})^{-1}\right) & \mathbf{0}\\ \mathbf{0} & l_{e1}\mathbf{B}^{-1}\left(\mathbf{I}-l_{e1}\boldsymbol{\alpha}(\boldsymbol{\Psi}_{22}^{+})^{-1}\right)\end{bmatrix}\begin{Bmatrix}\mathbf{S}_0\\ \mathbf{S}_0\end{Bmatrix}+\begin{bmatrix}-l_{e1}\mathbf{A}^{-1}\boldsymbol{\alpha}(\boldsymbol{\Psi}_{22}^{-})^{-1}\mathbf{L}_{21}^{-} & -\mathbf{A}^{-1}\mathbf{L}_{21}^{+}\\ -\mathbf{B}^{-1}\mathbf{L}_{21}^{-} & -l_{e1}\mathbf{B}^{-1}\boldsymbol{\alpha}(\boldsymbol{\Psi}_{22}^{+})^{-1}\mathbf{L}_{21}^{+}\end{bmatrix}\begin{Bmatrix}\mathbf{d}_{ext}^{-}\\ \mathbf{d}_{ext}^{+}\end{Bmatrix} \tag{5}$$

where $\boldsymbol{\Psi}_{22}^{+}=\mathbf{L}_{22}^{+}+l_{e1}\boldsymbol{\alpha};\boldsymbol{\Psi}_{22}^{-}=\mathbf{L}_{22}^{-}+l_{e1}\boldsymbol{\alpha};\mathbf{A}=\boldsymbol{\Psi}_{22}^{+}-l_{e1}{}^{2}\boldsymbol{\alpha}(\boldsymbol{\Psi}_{22}^{-})^{-1}\boldsymbol{\alpha};\ \mathbf{B}=\boldsymbol{\Psi}_{22}^{-}-l_{e1}{}^{2}\boldsymbol{\alpha}(\boldsymbol{\Psi}_{22}^{+})^{-1}\boldsymbol{\alpha}$, and $\mathbf{I}$ is the identity matrix. Substituting Eqn (5) it into Eqn (1) the full condensed equilibrium is obtained,

$$\begin{bmatrix}\mathbf{L}_{11}^{-}-\mathbf{L}_{12}^{-}\mathbf{B}^{-1}\mathbf{L}_{21}^{-} & -l_{e1}\mathbf{L}_{12}^{-}\mathbf{B}^{-1}\boldsymbol{\alpha}(\boldsymbol{\Psi}_{22}^{+})^{-1}\mathbf{L}_{21}^{+}\\ -l_{e1}\mathbf{L}_{12}^{+}\mathbf{A}^{-1}\boldsymbol{\alpha}(\boldsymbol{\Psi}_{22}^{-})^{-1}\mathbf{L}_{21}^{-} & \mathbf{L}_{11}^{+}-\mathbf{L}_{12}^{+}\mathbf{A}^{-1}\mathbf{L}_{21}^{+}\end{bmatrix}\begin{Bmatrix}\mathbf{d}_{ext}^{-}\\ \mathbf{d}_{ext}^{+}\end{Bmatrix}=\begin{Bmatrix}\mathbf{F}_{ext}^{-}\\ \mathbf{F}_{ext}^{+}\end{Bmatrix}-\begin{bmatrix}l_{e1}\mathbf{L}_{12}^{-}\mathbf{B}^{-1}\left(\mathbf{I}-l_{e1}\boldsymbol{\alpha}(\boldsymbol{\Psi}_{22}^{+})^{-1}\right) & 0\\ 0 & -l_{e1}\mathbf{L}_{12}^{+}\mathbf{A}^{-1}\left(\mathbf{I}-l_{e1}\boldsymbol{\alpha}(\boldsymbol{\Psi}_{22}^{-})^{-1}\right)\end{bmatrix}\begin{Bmatrix}\mathbf{S}_0\\ \mathbf{S}_0\end{Bmatrix} \tag{6}$$

Elemental Condensation Algorithm

Eqn (6) is nonlinear due to the nonlinearity from the cohesive laws. In the literature, Newton-Raphson method [19, 20] (or its modified variants) has been used to solve this equation iteratively. However, our novel derivation above has yielded an explicit expression between the displacements of the internal nodes and those of the external nodes, i.e., Eqn (5). We have proved that, for any piece-wise linear cohesive laws, $\mathbf{d}_{6'5'}$ and $\mathbf{d}_{65}$ can be uniquely determined with mathematical exactness through a very simple yet efficient algorithm. The algorithm solves Eqn (5) by consistent check between trial cohesive slopes and the resulted crack displacements. Once Eqn (5) is solved, the matrices $[\boldsymbol{\beta}]$, $[\mathbf{K}_{22}^{+}]$, and $[\mathbf{K}_{22}^{-}]$ are all determined and elemental equilibrium of Eqn (6) is determined with mathematical rigor. This novel way of solving the crack displacements has never been reported in literature and we later show that it leads to orders of magnitude improvement on numerical efficiency.

2.2 A-FE Formulation with Two Interactive Cracks

In such a case, there are altogether three basic cracking configurations as shown in Fig 3(a), Fig 3(b) and Fig3(c), where l_{e1} is the first crack length and l_{e2} is the second crack length. The second crack intersects and cuts the first crack into two segments with length γl_{e1} (left) and $(1-\gamma)l_{e1}$ (right). Despite the different crack configurations in Figure 3, the internal DoF and force arrays can be arranged in a unified way as below.

$$\mathbf{d}_{\text{int}}^{+}=\mathbf{d}_{6'5'};\ \mathbf{d}_{\text{int}}^{r-}=\mathbf{d}_{58'7'};\ \mathbf{d}_{\text{int}}^{l-}=\mathbf{d}_{786}\qquad \mathbf{F}_{\text{int}}^{+}=\mathbf{F}_{6'5'};\ \mathbf{F}_{\text{int}}^{r-}=\mathbf{F}_{58'7'};\ \mathbf{F}_{\text{int}}^{l-}=\mathbf{F}_{786} \tag{7}$$

This enables a unified expression for the equilibrium of all three subdomains as follows

$$\begin{cases}\begin{bmatrix}\mathbf{L}_{11}^{+} & \mathbf{L}_{12}^{+}\\ \mathbf{L}_{21}^{+} & \mathbf{L}_{22}^{+}\end{bmatrix}\begin{Bmatrix}\mathbf{d}_{ext}^{+}\\ \mathbf{d}_{6'5'}\end{Bmatrix}=\begin{Bmatrix}\mathbf{F}_{ext}^{+}\\ \mathbf{F}_{6'5'}\end{Bmatrix} & \text{(a)}\\ & \text{(b)}\end{cases}\quad(\text{for }\Omega^{+})$$

$$\begin{cases}\begin{bmatrix}\mathbf{L}_{11}^{r-} & \mathbf{L}_{12}^{r-}\\ \mathbf{L}_{21}^{r-} & \mathbf{L}_{22}^{r-}\end{bmatrix}\begin{Bmatrix}\mathbf{d}_{ext}^{r-}\\ \mathbf{d}_{58'7'}\end{Bmatrix}=\begin{Bmatrix}\mathbf{F}_{ext}^{r-}\\ \mathbf{F}_{58'7'}\end{Bmatrix} & \text{(c)}\\ & \text{(d)}\end{cases}\quad(\text{for }\Omega^{r-}) \tag{8}$$

$$\begin{cases}\begin{bmatrix}\mathbf{L}_{11}^{l-} & \mathbf{L}_{12}^{l-}\\ \mathbf{L}_{21}^{l-} & \mathbf{L}_{22}^{l-}\end{bmatrix}\begin{Bmatrix}\mathbf{d}_{ext}^{l-}\\ \mathbf{d}_{786}\end{Bmatrix}=\begin{Bmatrix}\mathbf{F}_{ext}^{l-}\\ \mathbf{F}_{786}\end{Bmatrix} & \text{(e)}\\ & \text{(f)}\end{cases}\quad(\text{for }\Omega^{l-})$$

Here, the sub-matrices ($\mathbf{L}_{ij}^{l-}, \mathbf{L}_{ij}^{r-}$, and $\mathbf{L}_{ij}^{+}$ $(i, j = 1, 2)$) are the stiffness matrices of the subdomains Ω^{+}, $\Omega^{r-}$and Ω^{l-}, respectively. To integrate the cohesive stress along the three cohesive crack segments into respective internal nodal forces, the first order Gaussian Integration scheme was used on each of the three cracked segments. The integration points are at the center of each crack

segment as indicated in Figure 3(b) by the solid dots labeled by I, II, and III.

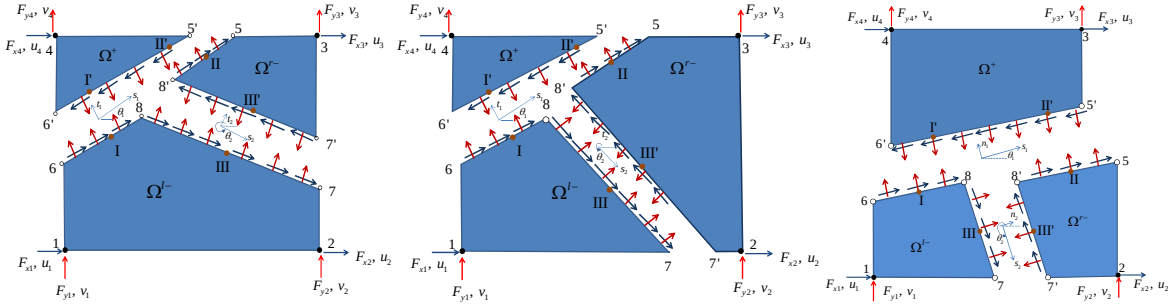
The relation between these cohesive stresses and the internal nodal displacements is

$$\begin{cases} \left\{\tau_{\mathrm{I}}^{(i)}, \sigma_{\mathrm{I}}^{(j)}\right\}^{\mathbf{T}} = \boldsymbol{\sigma}_{0\mathrm{I}} + \boldsymbol{\alpha}_{0\mathrm{I}}\mathbf{R}_1\left((1-\gamma/2)\mathbf{d}_{6'} + (\gamma/2)\mathbf{d}_{5'}\right) - \boldsymbol{\alpha}_{0\mathrm{I}}\mathbf{R}_1\left(\mathbf{d}_6 + \mathbf{d}_8\right)/2 \\ \left\{\tau_{\mathrm{II}}^{(k)}, \sigma_{\mathrm{II}}^{(l)}\right\}^{\mathbf{T}} = \boldsymbol{\sigma}_{0\mathrm{II}} + \boldsymbol{\alpha}_{0\mathrm{II}}\mathbf{R}_1\left((1-\gamma/2)\mathbf{d}_{6'} + (1+\gamma/2)\mathbf{d}_{5'}\right) - \boldsymbol{\alpha}_{0\mathrm{II}}\mathbf{R}_1\left(\mathbf{d}_5 + \mathbf{d}_{8'}\right)/2 \\ \left\{\tau_{\mathrm{III}}^{(m)}, \sigma_{\mathrm{III}}^{(n)}\right\}^{\mathbf{T}} = \boldsymbol{\sigma}_{0\mathrm{III}} + \boldsymbol{\alpha}_{0\mathrm{III}}\mathbf{R}_2\left(\mathbf{d}_{7'} + \mathbf{d}_{8'}\right)/2 - \boldsymbol{\alpha}_{0\mathrm{III}}\mathbf{R}_2\left(\mathbf{d}_7 + \mathbf{d}_8\right)/2 \end{cases} \tag{9}$$

where

$$\boldsymbol{\sigma}_{0\mathrm{I}} = \begin{Bmatrix} \hat{\tau}^{(i)} - \alpha_s^{(i)}\delta_s^{(i)} \\ \hat{\sigma}^{(j)} - \alpha_n^{(j)}\delta_n^{(j)} \end{Bmatrix}; \quad \boldsymbol{\sigma}_{0\mathrm{II}} = \begin{Bmatrix} \hat{\tau}^{(k)} - \alpha_s^{(k)}\delta_s^{(k)} \\ \hat{\sigma}^{(l)} - \alpha_n^{(l)}\delta_n^{(l)} \end{Bmatrix}; \quad \boldsymbol{\sigma}_{0\mathrm{III}} = \begin{Bmatrix} \hat{\tau}^{(m)} - \alpha_s^{(m)}\delta_s^{(m)} \\ \hat{\sigma}^{(n)} - \alpha_n^{(n)}\delta_n^{(n)} \end{Bmatrix}$$

$$\boldsymbol{\alpha}_{0\mathrm{I}} = \mathrm{Diag}[\alpha_s^{(i)}; \alpha_n^{(j)}]; \quad \boldsymbol{\alpha}_{0\mathrm{II}} = \mathrm{Diag}[\alpha_s^{(k)}; \alpha_n^{(l)}]; \quad \boldsymbol{\alpha}_{0\mathrm{III}} = \mathrm{Diag}[\alpha_s^{(m)}; \alpha_n^{(n)}];$$



(a) (b) (c)

Figure 3 Illustration of a 2D A-FE with two intra-elemental cracks (3 subdomains)

The internal forces, $\{\mathbf{F}_{6'5'}\}$, $\{\mathbf{F}_{58'7'}\}$, and $\{\mathbf{F}_{786}\}$, integrated from the cohesive stresses along the respective crack lengths are

$$\begin{cases} \mathbf{F}_{6'5'} = \mathbf{T}_{\mathbf{R}}^{+}\left\{\tau_{\mathrm{I}}^{(i)}, \quad \sigma_{\mathrm{I}}^{(j)}, \quad \tau_{\mathrm{II}}^{(k)}, \quad \sigma_{\mathrm{II}}^{(l)}\right\}^{\mathbf{T}} \\ \mathbf{F}_{786} = \mathbf{T}_{\mathbf{R}}^{l-}\left\{\tau_{\mathrm{I}}^{(i)}, \quad \sigma_{\mathrm{I}}^{(j)}, \quad \tau_{\mathrm{III}}^{(m)}, \quad \sigma_{\mathrm{III}}^{(n)}\right\}^{\mathbf{T}} \\ \mathbf{F}_{58'7'} = \mathbf{T}_{\mathbf{R}}^{r-}\left\{\tau_{\mathrm{I}}^{(k)}, \quad \sigma_{\mathrm{I}}^{(l)}, \quad \tau_{\mathrm{III}}^{(m)}, \quad \sigma_{\mathrm{III}}^{(n)}\right\}^{\mathbf{T}} \end{cases} \tag{10}$$

where $\mathbf{T}_{\mathbf{R}}^{+}$, $\mathbf{T}_{\mathbf{R}}^{l-}$, and $\mathbf{T}_{\mathbf{R}}^{r-}$ are the respective integration matrices:

$$\mathbf{T}_{\mathbf{R}}^{+} = -\frac{1}{2}\begin{bmatrix} \gamma(2-\gamma)l_{e1}\mathbf{R}_1^{\mathbf{T}} & (1-\gamma)^2 l_{e1}\mathbf{R}_1^{\mathbf{T}} \\ \gamma^2 l_{e1}\mathbf{R}_1^{\mathbf{T}} & (1-\gamma^2)l_{e1}\mathbf{R}_1^{\mathbf{T}} \end{bmatrix};$$

$$\mathbf{T}_{\mathbf{R}}^{l-} = \frac{1}{2}\begin{bmatrix} \mathbf{0} & l_{e2}\mathbf{R}_2^{\mathbf{T}} \\ \gamma l_{e1}\mathbf{R}_1^{\mathbf{T}} & l_{e2}\mathbf{R}_2^{\mathbf{T}} \\ \gamma l_{e1}\mathbf{R}_1^{\mathbf{T}} & \mathbf{0} \end{bmatrix}; \quad \mathbf{T}_{\mathbf{R}}^{r-} = \frac{1}{2}\begin{bmatrix} (1-\gamma)l_{e1}\mathbf{R}_1^{\mathbf{T}} & \mathbf{0} \\ (1-\gamma)l_{e1}\mathbf{R}_1^{\mathbf{T}} & -l_{e2}\mathbf{R}_2^{\mathbf{T}} \\ \mathbf{0} & -l_{e2}\mathbf{R}_2^{\mathbf{T}} \end{bmatrix} \tag{11}$$

Substituting Eqn (9) into (10) and then Eqn (8), the internal crack displacements can be derived as

$$\begin{Bmatrix} \mathbf{d}_{6'5'} \\ \mathbf{d}_{786} \\ \mathbf{d}_{58'7'} \end{Bmatrix} = \begin{bmatrix} \mathbf{Y}_7 & \mathbf{Y}_8 & \mathbf{Y}_9 \\ \mathbf{Y}_4 & \mathbf{Y}_5 & \mathbf{Y}_6 \\ \mathbf{Y}_1 & \mathbf{Y}_2 & \mathbf{Y}_3 \end{bmatrix}\begin{Bmatrix} \mathbf{S}_1 \\ \mathbf{S}_2 \\ \mathbf{S}_3 \end{Bmatrix} + \begin{bmatrix} \mathbf{X}_{13} & \mathbf{X}_{14} & \mathbf{X}_{15} \\ \mathbf{X}_{10} & \mathbf{X}_{11} & \mathbf{X}_{12} \\ \mathbf{X}_7 & \mathbf{X}_8 & \mathbf{X}_9 \end{bmatrix}\begin{Bmatrix} \mathbf{d}_{ext}^{l-} \\ \mathbf{d}_{ext}^{r-} \\ \mathbf{d}_{ext}^{+} \end{Bmatrix} \tag{12}$$

where $\mathbf{S}_1 = \mathbf{T}_{\mathbf{R}}^{+}\left\{\boldsymbol{\sigma}_{0\mathrm{I}}, \boldsymbol{\sigma}_{0\mathrm{II}}\right\}^{\mathbf{T}}$, $\mathbf{S}_2 = \mathbf{T}_{\mathbf{R}}^{l-}\left\{\boldsymbol{\sigma}_{0\mathrm{I}}, \boldsymbol{\sigma}_{0\mathrm{III}}\right\}^{\mathbf{T}}$, $\mathbf{S}_3 = \mathbf{T}_{\mathbf{R}}^{r-}\left\{\boldsymbol{\sigma}_{0\mathrm{II}}, \boldsymbol{\sigma}_{0\mathrm{III}}\right\}^{\mathbf{T}}$;

$$\mathbf{X}_1 = \mathbf{L}_{22}^{+} - \boldsymbol{\alpha}_{11}; \qquad \mathbf{X}_2 = \mathbf{L}_{22}^{l-} - \boldsymbol{\alpha}_{22} - \boldsymbol{\alpha}_{21}(\mathbf{X}_1)^{-1}\boldsymbol{\alpha}_{12};$$

$$\mathbf{X}_3 = -\boldsymbol{\alpha}_{21}(\mathbf{X}_1)^{-1}\boldsymbol{\alpha}_{13} - \boldsymbol{\alpha}_{23}; \qquad \mathbf{X}_4 = -\boldsymbol{\alpha}_{31}(\mathbf{X}_1)^{-1}\boldsymbol{\alpha}_{12} - \boldsymbol{\alpha}_{32};$$

$$\mathbf{X}_5 = \mathbf{L}_{22}^{r-} - \boldsymbol{\alpha}_{33} - \boldsymbol{\alpha}_{31}(\mathbf{X}_1)^{-1}\boldsymbol{\alpha}_{13}; \qquad \mathbf{X}_6 = \mathbf{X}_5 - \mathbf{X}_4(\mathbf{X}_2)^{-1}\mathbf{X}_3$$

$$\mathbf{X}_7 = (\mathbf{X}_6)^{-1}\mathbf{X}_4(\mathbf{X}_2)^{-1}\mathbf{L}_{21}^{l-}; \qquad \mathbf{X}_8 = -(\mathbf{X}_6)^{-1}\mathbf{L}_{21}^{r-};$$

$$\mathbf{X}_9 = (\mathbf{X}_6)^{-1}\left(\mathbf{X}_4(\mathbf{X}_2)^{-1}\boldsymbol{\alpha}_{21} - \boldsymbol{\alpha}_{31}\right)(\mathbf{X}_1)^{-1}\mathbf{L}_{21}^{+}$$

$$\mathbf{X}_{10} = -(\mathbf{X}_2)^{-1}\left(\mathbf{X}_3\mathbf{X}_7 + \mathbf{L}_{21}^{l-}\right); \qquad \mathbf{X}_{11} = -(\mathbf{X}_2)^{-1}\mathbf{X}_3\mathbf{X}_8;$$

$$\mathbf{X}_{12} = -(\mathbf{X}_2)^{-1}\left(\mathbf{X}_3\mathbf{X}_9 + \boldsymbol{\alpha}_{21}(\mathbf{X}_1)^{-1}\mathbf{L}_{21}^{+}\right) \qquad \mathbf{X}_{13} = (\mathbf{X}_1)^{-1}\left(\boldsymbol{\alpha}_{13}\mathbf{X}_7 + \boldsymbol{\alpha}_{12}\mathbf{X}_{10}\right);$$

$$\mathbf{X}_{14} = (\mathbf{X}_1)^{-1}\left(\boldsymbol{\alpha}_{13}\mathbf{X}_8 + \boldsymbol{\alpha}_{12}\mathbf{X}_{11}\right); \qquad \mathbf{X}_{15} = (\mathbf{X}_1)^{-1}\left(-\mathbf{L}_{21}^{+} + \boldsymbol{\alpha}_{13}\mathbf{X}_9 + \boldsymbol{\alpha}_{12}\mathbf{X}_{12}\right)$$

$$\mathbf{Y}_1 = (\mathbf{X}_6)^{-1}\left(\boldsymbol{\alpha}_{31} - \mathbf{X}_4(\mathbf{X}_2)^{-1}\boldsymbol{\alpha}_{21}\right)(\mathbf{X}_1)^{-1}; \qquad \mathbf{Y}_2 = -(\mathbf{X}_6)^{-1}\mathbf{X}_4(\mathbf{X}_2)^{-1};$$

$$\mathbf{Y}_3 = (\mathbf{X}_6)^{-1} \qquad \mathbf{Y}_4 = (\mathbf{X}_2)^{-1}\left(\boldsymbol{\alpha}_{21}(\mathbf{X}_1)^{-1} - \mathbf{X}_3\mathbf{Y}_1\right);$$

$$\mathbf{Y}_5 = (\mathbf{X}_2)^{-1}\left(\mathbf{I} - \mathbf{X}_3\mathbf{Y}_2\right); \qquad \mathbf{Y}_6 = -(\mathbf{X}_2)^{-1}\mathbf{X}_3\mathbf{Y}_3;$$

$$\mathbf{Y}_7 = (\mathbf{X}_1)^{-1}\left(\mathbf{I} + \boldsymbol{\alpha}_{13}\mathbf{Y}_1 + \boldsymbol{\alpha}_{12}\mathbf{Y}_4\right); \qquad \mathbf{Y}_8 = (\mathbf{X}_1)^{-1}\left(\boldsymbol{\alpha}_{13}\mathbf{Y}_2 + \boldsymbol{\alpha}_{12}\mathbf{Y}_5\right);$$

$$\mathbf{Y}_9 = (\mathbf{X}_1)^{-1}\left(\boldsymbol{\alpha}_{13}\mathbf{Y}_3 + \boldsymbol{\alpha}_{12}\mathbf{Y}_6\right)$$

$$\boldsymbol{\alpha}_{11} = \frac{1}{2}\mathbf{T}_{\mathbf{R}}^{+}\begin{bmatrix}(2-\gamma)\boldsymbol{\alpha}_{0\mathrm{I}}\mathbf{R}_1 & \gamma\boldsymbol{\alpha}_{0\mathrm{I}}\mathbf{R}_1 \\ (1-\gamma)\boldsymbol{\alpha}_{0\mathrm{II}}\mathbf{R}_1 & (1+\gamma)\boldsymbol{\alpha}_{0\mathrm{II}}\mathbf{R}_1\end{bmatrix}; \qquad \boldsymbol{\alpha}_{12} = \frac{1}{2}\mathbf{T}_{\mathbf{R}}^{+}\begin{bmatrix}\mathbf{0} & -\boldsymbol{\alpha}_{0\mathrm{I}}\mathbf{R}_1 & -\boldsymbol{\alpha}_{0\mathrm{I}}\mathbf{R}_1 \\ \mathbf{0} & \mathbf{0} & \mathbf{0}\end{bmatrix};$$

$$\boldsymbol{\alpha}_{13} = \frac{1}{2}\mathbf{T}_{\mathbf{R}}^{+}\begin{bmatrix}\mathbf{0} & \mathbf{0} & \mathbf{0} \\ -\boldsymbol{\alpha}_{0\mathrm{II}}\mathbf{R}_1 & -\boldsymbol{\alpha}_{0\mathrm{II}}\mathbf{R}_1 & \mathbf{0}\end{bmatrix}; \qquad \boldsymbol{\alpha}_{21} = \frac{1}{2}\mathbf{T}_{\mathbf{R}}^{l-}\begin{bmatrix}(2-\gamma)\boldsymbol{\alpha}_{0\mathrm{I}}\mathbf{R}_1 & \gamma\boldsymbol{\alpha}_{0\mathrm{I}}\mathbf{R}_1 \\ \mathbf{0} & \mathbf{0}\end{bmatrix};$$

$$\boldsymbol{\alpha}_{22} = \frac{1}{2}\mathbf{T}_{\mathbf{R}}^{l-}\begin{bmatrix}\mathbf{0} & -\boldsymbol{\alpha}_{0\mathrm{I}}\mathbf{R}_1 & -\boldsymbol{\alpha}_{0\mathrm{I}}\mathbf{R}_1 \\ -\boldsymbol{\alpha}_{0\mathrm{III}}\mathbf{R}_2 & -\boldsymbol{\alpha}_{0\mathrm{III}}\mathbf{R}_2 & \mathbf{0}\end{bmatrix}; \qquad \boldsymbol{\alpha}_{23} = \frac{1}{2}\mathbf{T}_{\mathbf{R}}^{l-}\begin{bmatrix}\mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\alpha}_{0\mathrm{III}}\mathbf{R}_2 & \boldsymbol{\alpha}_{0\mathrm{III}}\mathbf{R}_2\end{bmatrix};$$

$$\boldsymbol{\alpha}_{31} = \frac{1}{2}\mathbf{T}_{\mathbf{R}}^{r-}\begin{bmatrix}(1-\gamma)\boldsymbol{\alpha}_{0\mathrm{II}}\mathbf{R}_1 & (1+\gamma)\boldsymbol{\alpha}_{0\mathrm{II}}\mathbf{R}_1 \\ \mathbf{0} & \mathbf{0}\end{bmatrix}; \qquad \boldsymbol{\alpha}_{32} = \frac{1}{2}\mathbf{T}_{\mathbf{R}}^{r-}\begin{bmatrix}\mathbf{0} & \mathbf{0} & \mathbf{0} \\ -\boldsymbol{\alpha}_{0\mathrm{III}}\mathbf{R}_2 & -\boldsymbol{\alpha}_{0\mathrm{III}}\mathbf{R}_2 & \mathbf{0}\end{bmatrix};$$

$$\boldsymbol{\alpha}_{33} = \frac{1}{2}\mathbf{T}_{\mathbf{R}}^{r-}\begin{bmatrix}-\boldsymbol{\alpha}_{0\mathrm{II}}\mathbf{R}_1 & -\boldsymbol{\alpha}_{0\mathrm{II}}\mathbf{R}_1 & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\alpha}_{0\mathrm{III}}\mathbf{R}_2 & \boldsymbol{\alpha}_{0\mathrm{III}}\mathbf{R}_2\end{bmatrix}$$

Finally, by substituting Eqn (12) into expressions (a, c, e) in Eqn (8) to eliminate the internal nodal displacements, the fully condensed elemental equilibrium equation is obtained as

$$\begin{bmatrix}\mathbf{L}_{11}^{l-} + \mathbf{L}_{12}^{l-}\mathbf{X}_{10} & \mathbf{L}_{12}^{l-}\mathbf{X}_{11} & \mathbf{L}_{12}^{l-}\mathbf{X}_{12} \\ \mathbf{L}_{12}^{r-}\mathbf{X}_7 & \mathbf{L}_{11}^{r-} + \mathbf{L}_{12}^{r-}\mathbf{X}_8 & \mathbf{L}_{12}^{r-}\mathbf{X}_9 \\ \mathbf{L}_{12}^{+}\mathbf{X}_{13} & \mathbf{L}_{12}^{+}\mathbf{X}_{14} & \mathbf{L}_{11}^{+} + \mathbf{L}_{12}^{+}\mathbf{X}_{15}\end{bmatrix}\begin{Bmatrix}\mathbf{d}_{ext}^{l-} \\ \mathbf{d}_{ext}^{r-} \\ \mathbf{d}_{ext}^{+}\end{Bmatrix} = \begin{Bmatrix}\mathbf{F}_{ext}^{l-} \\ \mathbf{F}_{ext}^{r-} \\ \mathbf{F}_{ext}^{+}\end{Bmatrix} - \begin{bmatrix}\mathbf{L}_{12}^{l-}\mathbf{Y}_4 & \mathbf{L}_{12}^{l-}\mathbf{Y}_5 & \mathbf{L}_{12}^{l-}\mathbf{Y}_6 \\ \mathbf{L}_{12}^{r-}\mathbf{Y}_1 & \mathbf{L}_{12}^{r-}\mathbf{Y}_2 & \mathbf{L}_{12}^{r-}\mathbf{Y}_3 \\ \mathbf{L}_{12}^{+}\mathbf{Y}_7 & \mathbf{L}_{12}^{+}\mathbf{Y}_8 & \mathbf{L}_{12}^{+}\mathbf{Y}_9\end{bmatrix}\begin{Bmatrix}\mathbf{S}_1 \\ \mathbf{S}_2 \\ \mathbf{S}_3\end{Bmatrix} \quad (13)$$

Note that Eqn (12) and Eqn (13) share the same matrices $\mathbf{X}_p$ (p = 1, 2, …15), $\mathbf{Y}_q$ (q = 1, 2,…9),), and $\boldsymbol{S}_r$ (r = 1, ..3), which are all functions of the characteristic cohesive stresses ($\boldsymbol{\sigma}_{0\mathrm{I}}, \boldsymbol{\sigma}_{0\mathrm{II}}$, and $\boldsymbol{\sigma}_{0\mathrm{III}}$) and the cohesive stiffnesses ($\boldsymbol{\alpha}_{0\mathrm{I}}, \boldsymbol{\alpha}_{0\mathrm{II}}$, and $\boldsymbol{\alpha}_{0\mathrm{III}}$) (Eqn 9). The same elemental condensation procedure in section 2.1 applies to Eqn (12) and, once the solution is found, $\mathbf{X}_p$, $\mathbf{Y}_q$, $\boldsymbol{S}_r$ are all established. Substituting them into Eqn (13) the fully condensed elemental equilibrium is then satisfied with mathematical exactness.

3. A-FEM Simulated 4PSB Test and Compared with X-FEM

In this section, the capabilities of the proposed A-FEM is first evaluated by simulating the crack propagation in a 4-point shear beam (4PSB) test reported in [24]. The problem has been simulated

by Moes and Belytschko in [7] using the X-FEM with a non-structured triangular mesh. The numerical model setup used in [7] is reproduced in Figure 4(a). The geometry dimensions are: b = 200 mm; l/b = 4; a/b = 0.2; c/b = 0.4; $l_1 = l_2$ = 20 mm; t = 100 mm.

As in [7], the maximum principal stress criterion was used for crack initiation and the cohesive parmaeters for the concrete material are identical to those used in [7].

To investigate the mesh sensitivity of the present A-FEM, the problem was analyzed by five different structured meshes with characteristic mesh size of h = 2, 4, 8, 13.3, and 20 mm (the total elements are 10760, 2849, 1094, 640, and 410, respectively), and two unstructured meshes with h ~ 4, 8, and 15 mm (total elements 4062, 1333, and 463, respectively). The two finer meshes (h = 2 and 4 mm) are the typical of those used in literature [21, 25], while the larger meshes (8, 13.3, and 20 mm) are used in this study to explore the mesh limit of the present A-FEM. The unstructured meshes of ~ 4, 8, and 15 mm were intended to check the mesh sensitivity and the robustness of the new A-FEM. Five of the discretized models (structured h = 2, 8, and 20 mm meshes and unstructured h ~ 8 and 13 mm meshes) under deformed states are shown in Figure 4 (b, c, d, e, f) with the crack trajectories roughly following the center lines of the white bands.

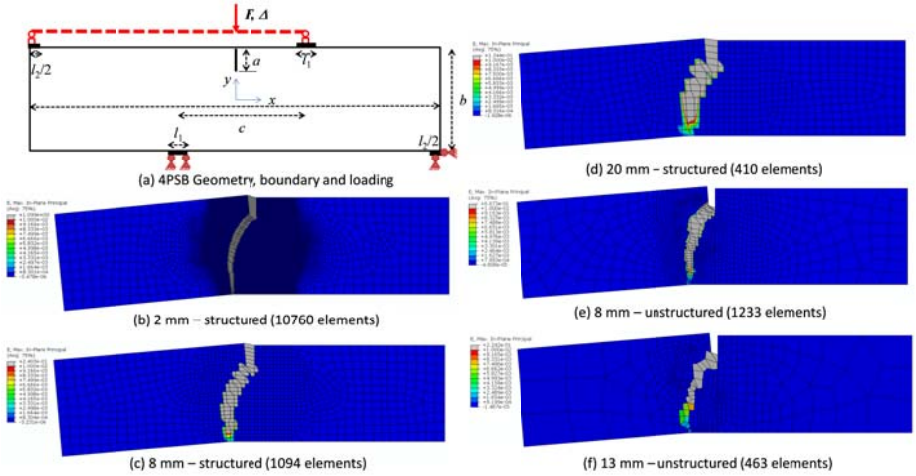


Figure 4 (a) Numerical models and simulated crack paths for structured 2mm (b), 8 mm mesh (c), and 20 mm mesh (d), and unstructured 8 mm (e) and 15 mm (f) meshes.

3.1 Mesh Sensitivity

The simulated load-displacement curves are plotted in Figure 5(a). The X-FEM prediction obtained by Moes and Belytschko [7], which used a triangular mesh of h ~ 3 mm, was superimposed on this plot for comparison (the dashed line). All curves exhibit a strong snap-back behavior. In this study, the strong snap-back behavior was captured using the arc-length method available in ABAQUS (Option RIKS).

The A-FEM computed load-displacement results are very consistent with the X-FEM result obtained in [7]. In particular, the load-displacement curves obtained with smaller mesh sizes (i.e., h = 2 mm, 4 mm, and 8 mm) are almost identical with the X-FEM results. For the larger meshes, i.e., h = 13.3 mm and 20 mm, the curves deviates mildly the finer mesh curves due to increases in initial stiffness. The systematic increase of initial stiffness with the increase of mesh sizes is largely due to the inherent numerical inaccuracy associated with the 4-node plane elements. This clearly demonstrates the mesh insensitivity of the present A-FEM.

Figure 5(b) summarizes the crack trajectories predicted by the five simulations with structured meshes. The crack paths are all very consistent and close to the experimental curve, despite they were obtained with vastly different mesh sizes. The predicted crack trajectories with the three unstructured meshes are also very consistent with those in Fig 5(b), which further demonstrates the mesh objectivity of the new A-FEM.

The insensitivity of the A-FEM to mesh structures is further demonstrated in Fig. 5(c) and Fig.

5(d). These plots compare the load-displacement curves (Fig 6c) and crack trajectories (Fig 6d) obtained with three structured meshes (4, 8 , and 13 mm) (solid lines) and those computed with unstructured meshes of similar mesh sizes (broken lines). The two sets of results are basically indistinguishable.

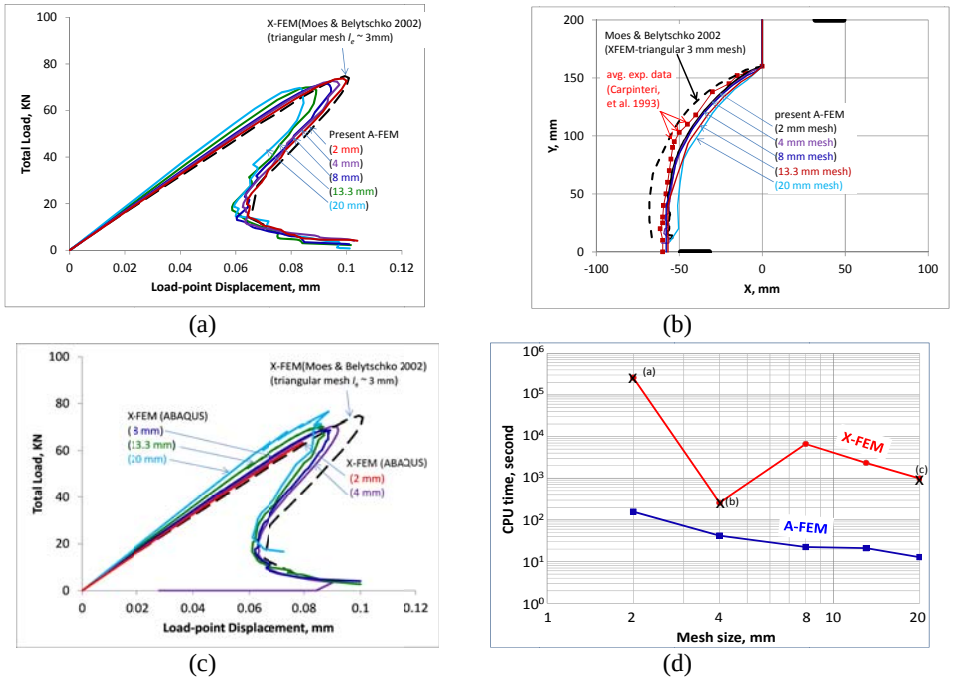

Figure 5 A-FEM simulated load-displacement curves (a) and crack trajectories (b) with the five meshes as compared to the X-FEM results and experimental results. (c) X-FEM predicted load-displacement curves compared with the A-FEM predictions. (d) Comparison of the CPU time (right vertical axis), and the numerical error (left axis) as function of mesh sizes

3.2 Numerical Efficiency and Stability as Compared to X-FEM in ABAQUS(v6.10)

In this section, the numerical accuracy, efficiency, and stability of the new A-FEM is compared against the X-FEM results obtained with ABAQUS (v6.10). Comparisons were carried out for the structure meshes only because the X-FEM failed to obtain converged solutions for any of the unstructured meshes. The meshes, boundary conditions, and loading are exactly the same as those used in previous section. All simulations were run on a Dell precision M4600 (x64 bit) mobile workstation with Intel Core i7–2860 QM CPU @ 2.5 GHz and with 8 GB of RAM.

The XFEM (ABAQUS) simulated load-displacement curves are plotted in Figure 5(c). The XFEM had enormous difficulty in completing these simulations. For the 2 mm mesh, the simulation proceeded with such a small incremental size (10^{-6} ~ 10^{-8} mm) that it had to be terminated at the displacement of 0.08 mm after 72 CPU hours of running. For the 4 mm mesh, a sudden strong snap back resulted from an incorrectly predicted crack path occurred at the displacement of 0.09 mm after the peak (Fig 5c). For the 20 mm mesh, the simulation diverged at the displacement of 0.072 mm (after snap back). For the rest cases (i.e., 8 mm and 13.3 mm mesh), the simulations were able to finish and the XFEM curves captures the peak loads and snap-back behavior reasonably well and they are close to the A-FEM results in Figure (5c).

Figure 5(d) compares the computational cost in terms of CPU time (in seconds) as functions of the mesh size. The CPU time corresponds to the point that when the displacement reached 0.1 mm (after snap-back). For the 2 mm, 4 mm, and 20 mm mesh, the X-FEM simulations were aborted due to the reasons discussed above. In these cases, the CPU times at the aborting points were taken and such data points were indicated by the X in Fig 5(d). From Figure 5(d), it is concluded that the

present A-FEM empowered by the novel condensation procedure, is at least 2 orders of magnitude more efficient than the X-FEM.

4. CONCLUSIONS

In this paper, an elemental augmentation procedure has been established to derive the augmented finite elements (A-FEs) that can accurately account for arbitrary intra-element cracks and their interaction without the need for additional external DoFs as in X-FEM or extra nodes as in PNM. It has been demonstrated that the new formulation makes it much easier in handling the multiple crack interaction problems including crack coalescence or bifurcation, since it does not require complex numerical algorithms to track the complex crack fronts.

The new A-FEM formulation does not need to assume deformation modes for elemental displacement enrichment as in the embedded discontinuity method either. Instead, it introduces internal node-pairs with normal displacements as internal nodal DoFs, which are eventually condensed at elemental level. With the proposed formulation, the crack displacements become natural outcomes of the elemental equilibrium consideration. The advantage is multi-fold. First, it enables a unified treatment of both weak and strong discontinuities. Second, for strong discontinuities with piece-wise linear constitutive relations, the new A-FEM formulation ensures an exact solution (in the piece-wise linear limit) to the condensed elemental equilibrium, which greatly improves the numerical accuracy, stability, and efficiency. Third, the unique A-FEM formulation makes it straightforward to repeat the augmentation procedure within an element to include multiple intra-element cracks, which is very powerful in dealing with multiple crack interaction problems because such augmented elements do not need extra external DoFs or nodes.

A novel elemental condensation algorithm that can provide analytical solution to local equilibrium has also been developed. The novelty in this algorithm is that, instead of assuming trial crack displacements and iterating for elemental equilibrium such as in the Newton-Raphson method, it starts with trial cohesive segments in the cohesive laws and finds the analytical solution (in piece-wise linear sense) to the elemental equilibrium through a simple consistency check. For piece-wise linear cohesive laws with only a small number of possible stiffness segments, this algorithm is very efficient.

Through the numerical examples, it has been demonstrated that the new A-FEM method, empowered by the new elemental condensation algorithm, achieved very significant improvements in numerical accuracy, efficiency, and stability. In particular, through a rigorous comparison study on a 4-point shear beam test, it has been found that the present A-FEM achieved an improvement in numerical efficiency by more than two orders of magnitude as compared to the X-FEM in ABAQUS. The A-FEM's capabilities in high-fidelity simulations of interactive cohesive cracks in heterogeneous solids have also demonstrated through the coupled debonding/kinking processes frequently observed in fiber-reinforced polymer matrix composites

Abstract: Engineering materials such as cast iron and concrete are quasi-brittle materials, and there is a fracture process zone in front of opening crack and it exist micro and macro defect and energy dissipation. The damage development area is simplified into fictitious crack, and its action stress distribution and opening displacement or deformation are along the cohesive crack. In order to investigate the constitutive relation of cohesive crack opening displacement and its stress distribution in quasi brittle materials, cast iron and concrete were used to test their fracture process by electronic equipment and micro view experiment facility. Through the analytical method of applied mathematics and mechanics, the material deformation stress constitutive relations were gotten for the cohesive crack. The theoretical calculation and test results are basically in agreement with each other. From the fracture criterion of Double K and the mechanics model of cohesive crack, the bearing capacity of structure with crack was estimated in this present paper.

Key Words: Quasi brittle materials; constitutive relation of cohesive crack; mesoscopic damage; fracture process testing; inverse problem

Engineering materials such as cast iron or concrete, not same as carbon steel and other reinforcement materials, its stress and deformation or constitutive behavior shows softening characteristics when stress or strain reaches a certain value. So them are classified to the quasi brittle materials. Those materials fracture phenomenon has attracted many scholars research. Hillerborg etc presented virtual crack model for concrete fracture based on the Dugdal-Barenblatt elastic-plastic fracture model, also other researchers have double parameters, equivalent crack, double K fracture model and size effect model ad so on[1-4]. In fact, this kind of material, its fracture process zone or a fuzzy damage crack area has action force each other when external load exerting among the area. If the strip area was named fictitious crack of being not completely separate, and it has bridging role on resistance crack opening. The cohesive force must be put along the fictitious crack segment. The mechanics behavior of those quasi-brittle materials will be analyzed in the present paper by combining cohesive crack model with macro and mesoscopic experiment investigation.

1. The cohesive crack model

As shown in Fig.1，a model of cohesive crack has been formed with both segments. One is completely opening crack segment without any force, and the other is the cohesive crack segment with stress distribution showing the fracture process damage area. The damage region was regarded as part of crack, the cohesive stress distribution express the interaction of material media. The medium outside of damage or cohesive crack is regarded as a linear elastic medium. The cohesive crack tip point is named as

the origin of rectangular coordinate, and the direction of level axis is for right. As the length of cohesive crack segment is indicated to '**b**', and the coordinate '**x**' to be the position of some point, then the follow polynomial express the opening displacement distribution of cohesive crack.

$$U(x)=\frac{4b}{E\pi}\sum_{n=1}^{N}c_n\left(\frac{x}{b}\right)^{n-1/2} \qquad (0\le x\le b) \qquad (1)$$

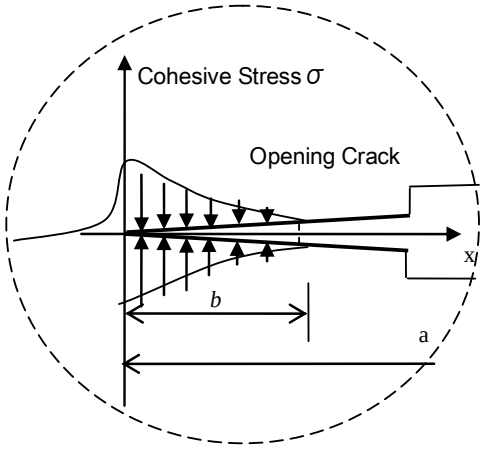

Figure 1. The cohesive crack model with cohesive stress and opening displacement in front of smooth crack

The Crack Opening Displacement or $\tilde{U}$ can be regarded as the superposition of both an opening displacement or V_K coursed by load P far from crack tip and a closing displacement done by the cohesive stress σ along crack together. Then, an integral equation was been formed with the unknown function σ being of cohesive stress distribution, based on the superposition principle of stress and deformation of the solid structure.

$$\int_0^b \tilde{G}(\xi,x)\sigma(\xi)d\xi=V_K(P,x)+\tilde{U}(x,u) \qquad (0\le x\le b) \qquad (2)$$

Here, $\tilde{G}(\xi,x)$ is a Green function about the displacement of point x by unit force at ξ point. The solution of equation was been worked out, and the formula of cohesion stress distribution is as follows [5].

$$\sigma(x)=\frac{K_I}{\sqrt{2\pi(b-x)}}+\frac{-1}{2\pi\sqrt{b}}\sum_{n=1}^{N}c_n\sqrt{\frac{1}{b-x}}\sum_{r=0}^{n-1}\left(\frac{x}{b}\right)^{n-r-1}\frac{2^{-2r}(2r)!}{(r!)^2}+\frac{1}{\pi\sqrt{b}}\sum_{n=2}^{N}c_n\sqrt{b-x}\sum_{r=0}^{n-2}\frac{2^{-2r}(n-r-1)(2r)!}{(r!)^2}\left(\frac{x}{b}\right)^{n-r-2} \qquad (0\le x\le b) \qquad (3)$$

Here, E is Young's elastic modulus of matrix materials for plane stress state. For the plane strain state the $E/(1-\nu^2)$ will be instead of the E, and ν is Poisson's ratio. The $c_i(i=1,2,...,N)$ is undetermined parameter with stress dimension. The K_I is the crack stress intensity factor by far field load P.

2 Experiment of micro detection and electronic measurement

2.1 The micro detection of iron and concrete

For the fracture process zone of quasi brittle material, its resistance part of crack opening is an area reflecting the characteristics of material nonlinear mechanical behavior. For the strip area with damage or plastic deformation, its microscopic characteristics are also complicated with load changing [6,7]. As shown in Figure 2, it is the microstructure morphology for cast iron or concrete. The status pictures of graphite piece in cast iron were shown in Fig2 (a, b) before and after loaded on the specimen. The former are not stress action in the pictures, and the latter shows the graphite flake being open or taking shape of crack in ferrite. As the area still has connection force among, this just be the mesoscopic experimental evidence of existing cohesive stress along virtual crack. Of course, the crack deformation of material with graphite flake will increase along with the increasing of load. The micro appearance of concrete were shown in Fig 2 (c, d), the interface crack between cement and stone being in picture 'c' and cracks in cement base doing in picture 'd'. The cracks existing in media is the increasing cause of deformation or strain.

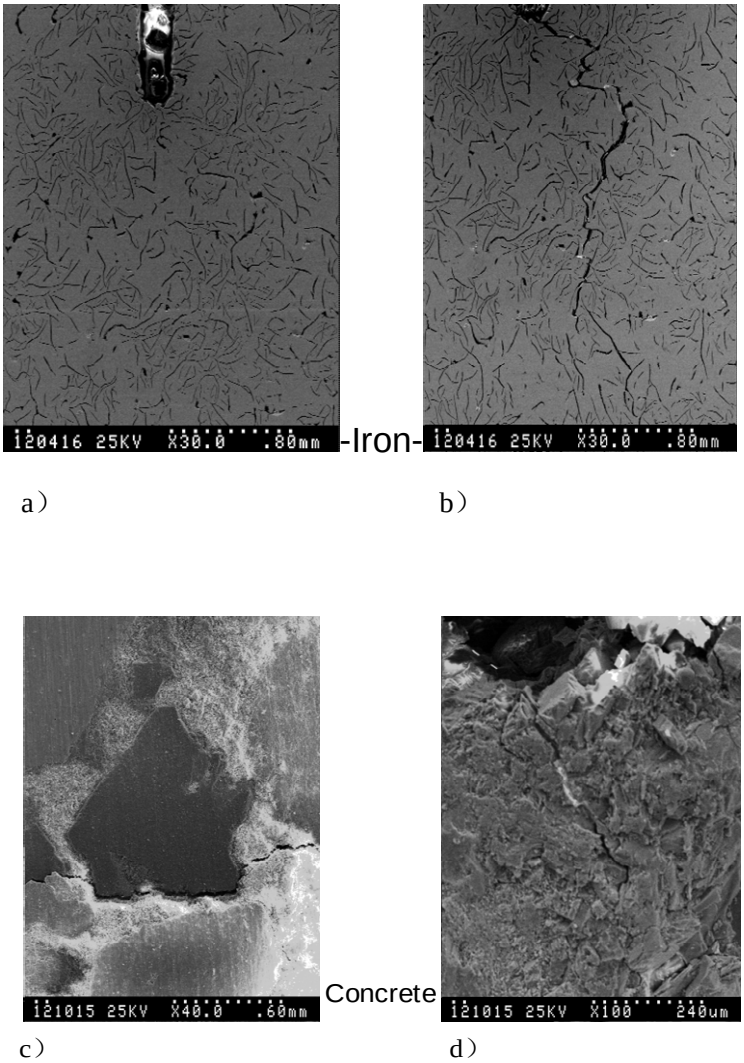

Figure 2. Electron microscopy (sem) surface images of Iron (a,b) and Concrete (c,d).

2.2 The fracture process test of materials

The specimen of iron and concrete with prefabricated crack were tested by three point bending or wedge splitting loading way, as shown in Fig 3. In order to record the process of crack ligament deformation, a few pieces of strain gauges were been pasted on front of prefabricated crack. Only, were the both sides of a strain gauge just posted at the materials surface in case of preventing the gauge film early to be pulled apart [8].

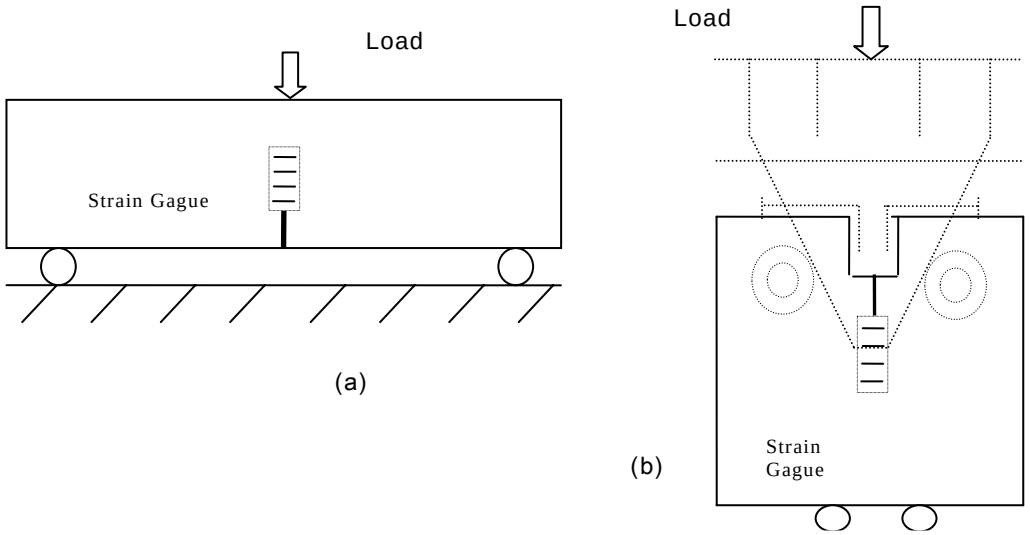

Figure 3. The experiment device of fracture process: a) Iron loaded by three point bending; b) Concrete loaded by wedge splitting pull

As shown in Fig 4, it is the deformation distribution of specimen ligament of iron or concrete under different load. The deformation is the relative displacement between its two sides of a gauge posted on materials ligament. In Fig 4 (i), the experimental curves are for cast iron specimen by the loading of three-point bending. The appearance size are respectively 'Length * Thick * High = 300 * 50 * 65 (mm*mm* mm), and loaded span is 260 mm, prefabricated crack length 5 mm. In Fig 4 (ii), the experiment curves are for concrete by loading of wedge splitting pull. The appearance size is that 'Wide*High*Thick=500*520*150(mm*mm*mm)' and the prefabricated crack length is about 120 mm.

Of course, the cohesive crack deformation distribution can be seen from the graphs of test on fracture process zone. Obviously, no matter what kind of material, it is the deformation changing with the load increasing.

3 The constitutive relation of cohesive stress and opening displacement of fictitious crack

From above formula (1) and (3) for the cohesive crack model, the simple calculation equations can be worked out. As the 'N'is selected to be 2 in Eq(1,3), the distribution of cohesive stress or opening displacement of virtual crack can be expressed as following.

$$u(x) = \frac{8K_I}{3E}\left(\frac{x}{b}\right)^{3/2}\sqrt{\frac{2b}{\pi}} \qquad (4a)$$

$$\sigma(x) = \frac{K_I \sqrt{2}}{b} \sqrt{\frac{b-x}{\pi}} \tag{4b}$$

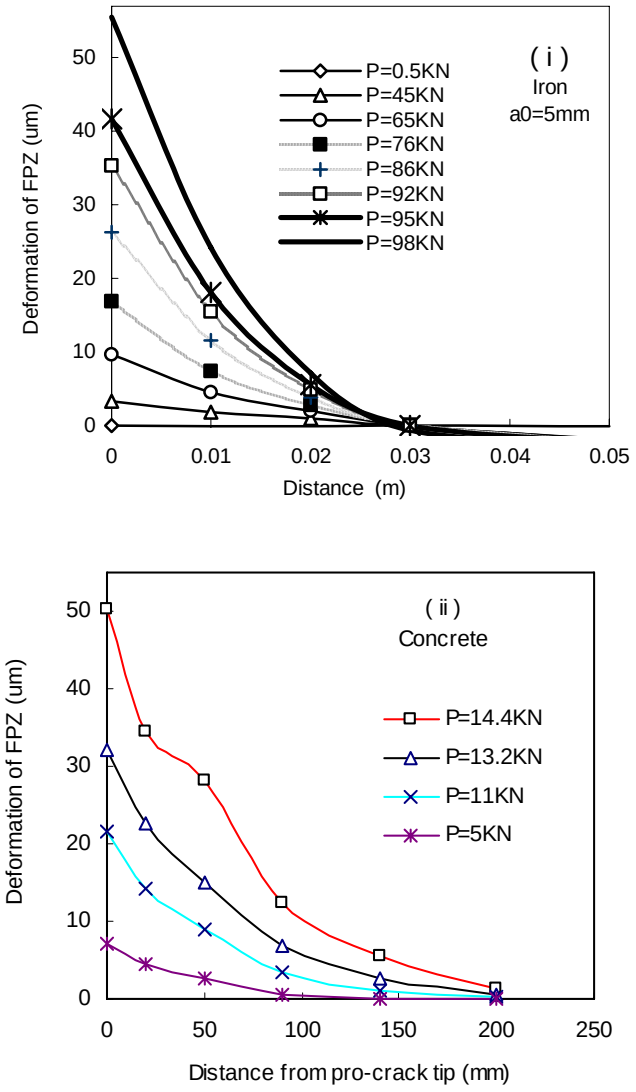

Figure 4. The deformation distribution along the crack ligament of （i）iron（ii）concrete under different load

If the coordinate x is taken away from Eq 4 (a,b), the constitutive equation of fictitious crack can be worked out between cohesive stress and opening displacement of cohesive crack. Refering to Fig 3 and 4, the displacement distribution can be calculated from the cast iron test data in Ref [8] through above Eq 4 (a). In Fig 5, the theoretical curve is compared with the experimental results of iron specimen, and the calculation curve is basely consistent with experiment data. In Fig 6, it is the constitutive relation curves between the cohesion stress and crack opening displacement for concrete specimens under different load. There is a little difference about concrete constitutive relation between different loading condition, but it also be consistent with reference early results [9,10].

4 The bearing capacity estimate of structure with crack

As the fracture process zone length changing with variable load in experiment specimen, the quantitative relationship of its loading and damage zone length can be worked out according to the fracture criterion of Double-K and the theoretical analysis results of cohesive crack [9]. For fracture specimen configuration such as three-point bending beam with crack, the equation can be written as followings.

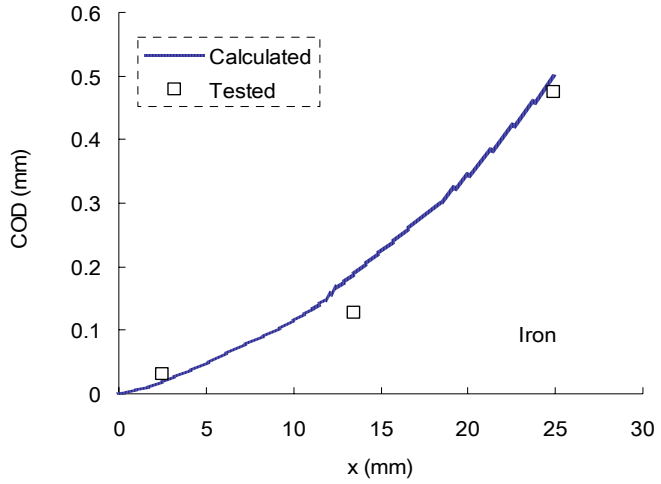

Figure 5. The compare of theory curve of cast iron cohesive crack opening displacement with experimental data

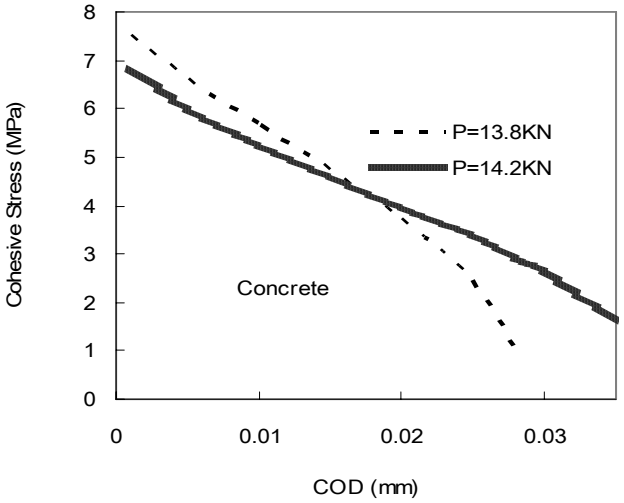

Figure 6. The constitutive relation between cohesive stress and opening displacement of cohesive crack for concrete being under different load

$$P=\frac{2Bh^{2}\left(k_{0}+\eta\sqrt{\frac{b}{2\pi}}\right)\left(1+2\frac{a_{0}+b}{h}\right)\left(1-\frac{a_{0}+b}{h}\right)^{3/2}}{3s\sqrt{a_{0}+b}\left[1.99-\frac{a_{0}+b}{h}\left(1-\frac{a_{0}+b}{h}\right)\left(2.15-3.93\frac{a_{0}+b}{h}+2.7\left(\frac{a_{0}+b}{h}\right)^{2}\right)\right]} \quad (4)$$

Where, k_0 is the stress intensity factor of initiation crack; and a_0 is for the

prefabricated crack length. Refer to Fig 3, the symbol *s* and *h* are span and high respectively. Regarding to the specimens with pre-crack length 5mm and 20 mm, the changing length of damage zone respectively with loading was shown in Fig 7 for iron materials [8]. Continuous curve is the theoretical calculation value, and scatter icons indicate experimental test results. From the figure it can be seen that theories values are in good agreement with experiment, and the maximum bearing capacity value of structure with cracked can be estimated from the curve peak.

5 Conclusion

(1) Through nonlinear crack model analysis, both the cohesive stress distribution and opening displacement of fictitious crack can be calculated by analytical equation.

(2) Regarding the cohesive crack model, specimen of cast iron or concrete was observed or tested in order to investigate the mechanics behavior of quasi-brittle materials. And its theoretical calculation is consistent with experimental observation.

Abstract

The work deals with the asymptotic stress-strain field around a crack tip, steadily propagating in a viscous material for antiplane conditions. A solution of this problem has been offered by Hui and Riedel, but with some unexpected features. In particular, the solution generally leads to an autonomous crack growth (independent on the loading state). This problem is revisiting here, using a multiscale asympotic analysis. Small scale yielding and low crack velocity are assumed. A small parameter ε, proportional to the crack growth rate, is introduced to switch from the inner solution (close to the crack tip) to the outer one (far field), using an asymptotic expansion of the solution. The outer solution is equivalent to the non linear elastic HRR field at the first order for ε=0, while the viscosity appears at the second order. Close to the crack tip, the viscous effects arise at the first order and the corresponding asymptotic field is governed the elastic field associated to the crack velocity, while the non linear term, corresponding to the nonlinear elasticity emerges at the second order . This is a basic difference with the Hui-Riedel solution where the two scale orders are merged. The matching conditions allow to link the far and close fields, and to correct the paradox whereby the crack velocity should not depend to the far field governed by the loading (except for perfect plasticity ($n \to \infty$) where the solution remains autonomous).

Keywords Hui-Riedel solution, creep, steadily growing crack, singularity, matched asymptotic expansions.

1. Introduction

An antiplane asymptotic solution for a steadily slowly growing crack in an elastic-non linear viscous medium has been suggested by Hui and Riedel [1]. A power law creep is considered. For uniaxial tension, the Norton law has the following form :

$$\dot{\varepsilon} = \frac{\dot{\sigma}}{\mu} + B\sigma^n \quad (1)$$

For $n > 3$ some paradox events arise, in particular the solution is autonomous, independent on the remote loading (this phenomenon is described by Bui as an analogy to the “soliton” in non linear waves problems [2]). Some authors have corrected this paradox, but with substantive changes to the law or introducing a threshold [3,4]. Keeping the original Norton law, a new antiplane shear analysis is offered here, using a matched asymptotic expansion method. Higher expansion terms of the stress function will allow to connect the « inner solution » (near the viscous crack tip) to the « outer solution » (corresponding to the far HRR field).

2. Initial problem formulation.

Figure 1 shows the crack, embedded inside the body Ω, located in the (x,z) plane at y=0. The stress and strain tensors in antiplane conditions are :

$$\tau_i = \sigma_{3i}, \gamma_i = 2\varepsilon_{3i}, \quad i = 1,2 \quad (2)$$

The equivalent stress is introduced as $\tau_e = (\tau_1^2 + \tau_2^2)^{1/2}$, so that the material law is (with $\bar{B} = \sqrt{3}^{(n+1)} B$) :

$$\dot{\gamma}_i = \frac{\dot{\tau}_i}{\mu} + \bar{B}\tau_e^{n-1}\tau_i, \quad i = 1,2 \quad (3),$$

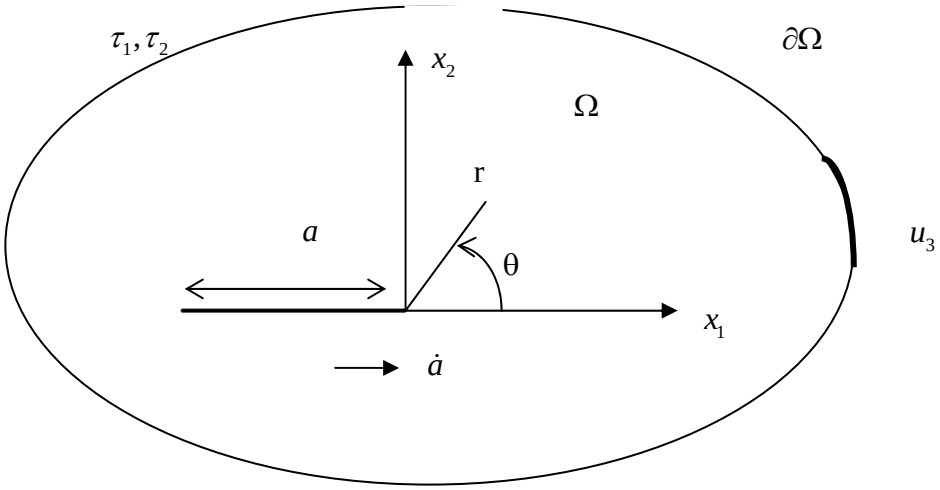

Figure 1 Crack steadily moving with velocity $\dot{a}$ under shear load in mode III.

The equilibrium equations are $\nabla_i \tau_i = 0$, where the summation convention holds. The stress function is then introduced, so that the previous equation is automatically fulfilled :

$$\tau_1 = -\frac{\partial \Psi}{\partial x_2}, \quad \tau_2 = \frac{\partial \Psi}{\partial x_1} \quad (4)$$

The crack is assumed to grow steadily so that in the moving coordinate system the fields remain constant, which involves :

$$\frac{\partial \Psi}{\partial t} = -\dot{a}\frac{\partial \Psi}{\partial x_1} \quad (5)$$

Using the compatibility of the strain rates, the following equation holds everywhere inside the body Ω :

$$-\frac{\dot{a}}{\mu}\frac{\partial \Psi}{\partial x_1}\Delta\Psi + \bar{B}\nabla_i(\tau_e^{n-1}\nabla_i\Psi) = 0 \quad (6)$$

3. Rescaling the problem.

Dimensionless variables will be used now ($\bar{x}_1 \equiv x_1 / a, \bar{x}_2 \equiv x_2 / a, \bar{\Psi}(\bar{x}_1, \bar{x}_2) \equiv \Psi / \mu$). Furthermore, a small parameter $\varepsilon = \frac{\dot{a}}{\bar{B} a \mu^n}$ is introduced, so that the Hui-Riedel relation may be written as :

$$-\varepsilon\,\Delta\frac{\partial \bar{\Psi}}{\partial \bar{x}_1} + \nabla_i\left[\bar{\tau}_e^{n-1}\nabla_i\bar{\Psi}\right] = 0 \quad (7)$$

with the boundary conditions : $\frac{\partial \bar{\Psi}}{\partial \bar{x}_1} = 0, \quad -1 < \bar{x}_1 < 0, \bar{x}_2 = 0$ on the crack lips and $\tau_i(\partial\Omega) = \tau_0$ for the remote loading. Henceforth, the bar will be removed from all the following notations, to lighten the notations. The key ideas are firstly to distinguish two observation scales (the fields in the crack tip vicinity and the far fields), secondly to expand the stress function at higher orders for each scale, and finally to match these asymptotic expansions. This method has been already applied for instance in elastic-plastic materials [5] or for a series of cracks in the frame of elasticity [6,7].

4. Asymptotic expansions of the stress function.

It is supposed that the stress function is asymptotically expanded, and that each i^{th} expansion term is weighed by the parameter ε^{α_i}.

Far from the crack tip, $r >> \varepsilon$ in Ω_o, the expansion will be designed by “outer”, in the vicinity of the crack tip in Ω_i, it will be called “inner”.

4.1. Outer expansion

It is assumed that the stress function may be expanded as :

$$\Psi(x_1, x_2) = \varepsilon^{\alpha_1}\Psi^{(1)}(x_1, x_2) + \varepsilon^{\alpha_2}\Psi^{(2)}(x_1, x_2) + \varepsilon^{\alpha_3}\Psi^{(3)}(x_1, x_2) + \ldots \quad (8)$$

Developing with the previous relation the equivalent stress, we find that :

$$\tau_e^{n-1} = \varepsilon^{\alpha_1(n-1)}(\nabla_i\Psi^{(1)}.\nabla_i\Psi^{(1)} + 2\varepsilon^{\alpha_{2-}\alpha_1}\nabla_i\Psi^{(1)}.\nabla_i\Psi^{(2)} + \varepsilon^{2(\alpha_{2-}\alpha_1)}\nabla_i\Psi^{(2)}.\nabla_i\Psi^{(2)} + ...)^{(n-1)/2} \quad (9)$$

The Taylor expansion of the previous expression is then :

$$\tau_e^{n-1} = \varepsilon^{\alpha_1(n-1)}\sigma^{(1)} + \varepsilon^{\alpha_{2+}\alpha_1(n-2)}\sigma^{(2)} + \varepsilon^{2\alpha_{2+}\alpha_1(n-3)}\sigma^{(3)} + O(\varepsilon^{\alpha_3+\alpha_1(n-2)}) \quad (10)$$

where $\sigma^{(1)}, \sigma^{(2)}, \sigma^{(3)}$ are functions depending on $\nabla_i\Psi^{(1)}, \nabla_i\Psi^{(2)}, n$. Using the relation (10), the equilibrium equation is therefore in Ω_o :

$$\begin{aligned} &-\Delta\frac{\partial}{\partial x_1}(\Psi^{(1)} + \varepsilon^{\alpha_{2-}\alpha_1}\Psi^{(2)} + \varepsilon^{\alpha_{3-}\alpha_1}\Psi^{(3)} + ...) + \\ &\varepsilon^{\nu}\nabla_i\left((\sigma^{(1)} + \varepsilon^{\alpha_{2-}\alpha_1}\sigma^{(2)} + \varepsilon^{2(\alpha_{2-}\alpha_1)}\sigma^{(3)} + ...)\nabla_i(\Psi^{(1)} + \varepsilon^{\alpha_{2-}\alpha_1}\Psi^{(2)} + ...)\right) = 0 \end{aligned} \quad (11)$$

where $\nu = \alpha_1(n-1) - 1$.

The first term in the relation (11) is relative to the viscous behaviour near the crack tip. The second term relative to the non linear behaviour far from the crack tip must be dominant here. Thus :

$$\nu = \alpha_1(n-1) - 1 < 0, \quad \forall n \geq 1 \quad (12)$$

The outer equilibrium equation at the first order is then :

$$\nabla_i\left(\sigma^{(1)}\nabla_i\Psi^{(1)}\right) = 0 \quad (13)$$

The following terms order is $\varepsilon^{\alpha_{2+}\alpha_1(n-2)-1}$ It is assumed now that :

$$\alpha_2 + \alpha_1(n-2) - 1 = 0 \quad (14)$$

This assumption will be explained in a next section, and justified by matching considerations. Therefore, the final equilibrium for the outer expansion, at the first order is :

$$-\Delta\frac{\partial}{\partial x_1}\Psi^{(1)} + \nabla_i\left(\sigma^{(1)}\nabla_i\Psi^{(2)} + \sigma^{(2)}\nabla_i\Psi^{(1)}\right) = 0 \quad (15)$$

with $\sigma^{(1)} = \left\|\nabla\ \Psi^{(1)}\right\|^{n-1}, \sigma^{(2)} = (n-1)\left\|\nabla\ \Psi^{(1)}\right\|^{n-3}\nabla_i\Psi^{(1)}\nabla_i\Psi^{(2)}$

4.2. Inner expansion

In the neighbouring of the crack tip, a new variable designed as : $y_i = \frac{x_i}{\varepsilon^{\beta}}$ is used as a microscope focal. This variable change is one of the clue to explain the paradox of the autonomous solution (in the original analysis $\beta = 1$). The inner expansion is then assumed as :

$$\Psi(x_1, x_2) = \varepsilon^{\beta_1}\varphi^{(1)}(y_1, y_2) + \varepsilon^{\beta_2}\varphi^{(2)}(y_1, y_2) + \varepsilon^{\beta_3}\varphi^{(3)}(y_1, y_2) + ... \quad (16)$$

The equilibrium equation in Ω_i is :

$$-\varepsilon^{\delta}\Delta\frac{\partial}{\partial y_1}(\varphi^{(1)}+\varepsilon^{\beta_2-\beta_1}\varphi^{(2)}+\varepsilon^{\beta_3-\beta_1}\varphi^{(3)}+...)+ \\ \nabla_i\left((\tau^{(1)}+\varepsilon^{\beta_2-\beta_1}\tau^{(2)}+\varepsilon^{2(\beta_2-\beta)}\tau^{(3)}+...)\nabla_i(\varphi^{(1)}+\varepsilon^{\beta_2-\beta_1}\varphi^{(2)}+...)\right)=0 \quad (17)$$

where $\delta=\beta\,(n-2)+\beta_1(1-n)+1$. We claim that :

$$\delta=\beta\,(n-2)+\beta_1(1-n)+1<0 \quad (18)$$

In fact, this parameter cannot be positive, otherwise the relation (17) would be the same as equ. (13) at the first order (note that in the Hui-Riedel analysis $\delta=0$). At the order ε^{δ}, the equilibrium condition holds :

$$-\Delta\frac{\partial}{\partial y_1}\varphi^{(1)}=0, \quad in\ \Omega_i \quad (19)$$

Transferring the expression (19) into (17), the remaining terms are of order 1 and $\varepsilon^{\delta+\beta_2-\beta_1}$. Both of them must be considered, otherwise the solution regress to the HRR field or to the solution of (19). Therefore :

$$\delta+\beta_2-\beta_1=0 \quad (20)$$

Finally, at the first order the inner equilibrium equation is (with $\tau^{(1)}=\left\|\nabla\ \varphi^{(1)}\right\|^{n-1}$) :

$$-\Delta\frac{\partial}{\partial y_1}\varphi^{(2)}+\nabla_i\left(\tau^{(1)}\nabla_i\varphi^{(1)}\right)=0, \quad in\ \Omega_i \quad (21)$$

It may be noticed that at the micro-scale, contrary to the macroscopic scale, the Laplace operator is relative to the second term of the stress function expansion and the non linear term is relative to the first one. Starting from now, it is necessary to solve the equations (15) and (21).

5. Stress functions solutions

5.1. Singularity analysis

From the equation (13), the singular HRR field emerges with :

$$\Psi^{(1)}(x_1,x_2)=K_1 r^s f_1(\theta)+more\ regular\ terms, \quad (22)$$

with $s=\dfrac{n}{n+1}$, and where K_1 will be clarified in a further section. Injecting the expression (22)

inside the complete equilibrium equation (15) allows to compute the second term $\Psi^{(2)}$:

$$\Psi^{(2)}(x_1, x_2) = K'_1 r^s f_1(\theta) + K_2 r^t f_2(\theta) + \textit{more regular terms} \quad (23)$$

the exponent t is deduced from s, so that :

$$t = \frac{n-2}{n+1} \quad (24)$$

A HRR field with higher order terms has been established for far fields. To clarify the fields close to the crack tip, it is necessary to use matching conditions.

5.2. Matching outer and inner expansions.

For the inner expansion, equilibrium equations (19) and (21) have only free stress boundary conditions on the crack lips, and no outer boundary conditions since Ω_i is unbounded. The matching conditions will substitute to these latter, and involve that in the overlapping area, the inner expansion matches the outer one for small ε values. The asymptotic matching principle will then applied [8]. The first outer term (respectively the first inner term) is rewriting in inner variable (resp. outer variable), with $r = \varepsilon^\beta \rho$ (resp. $(y_1 = \frac{x_1}{\varepsilon^\beta}, y_1 = \frac{x_1}{\varepsilon^\beta})$, and the relation (22) becomes :

$$\Psi^{(1)}(x_1, x_2) = K_1 \varepsilon^{\alpha_1} \varepsilon^{\beta s} \rho^s f_1(\theta) + ... = \varepsilon^{\alpha_1} \varphi^{(1)}(x_1 / \varepsilon^\beta, x_2 / \varepsilon^\beta) + ... \quad (25)$$

$\forall \varepsilon$, which leads to the supplementary relation :

$$\beta_1 = \alpha_1 + \beta s \quad (26)$$

When $\varepsilon \to 0, \rho \to \infty$, the first order matching holds :

$$\varphi^{(1)}(y_1, y_2) \square K_1 \rho^s f_1(\theta) \quad (27)$$

Let's tackle now the resolution of (19).

$$\varphi^{(1)}(y_1, y_2) = K_1 \rho^s f_1(\theta) + \tilde{\varphi}(y_1, y_2) \quad (28)$$

where $\tilde{\varphi}(y_1, y_2)$ is of order $\rho^p, \; p < s, \; for \; \rho \to \infty$

Moreover, the classical solution of linear elasticity is valid for the relation (19) :

$$\hat{\varphi}(y_1, y_2) = K_{III} \rho^{1/2} \sin\frac{\theta}{2} \quad (29)$$

Inserting the first term of (28) into (19) :

$$\zeta(y_1, y_2) = \Delta \frac{\partial \rho^s f_1(\theta)}{\partial y_1} \quad (30)$$

and reporting (28),(29),(30) in (19), the function $\tilde{\varphi}(y_1, y_2)$ may be found, solving the problem :

$$\begin{cases} -\Delta \dfrac{\partial \tilde{\varphi}}{\partial y_1} = K_1 \zeta \ in \ \Omega_i, \\ \dfrac{\partial \tilde{\varphi}}{\partial y_2} = 0, \forall y_1 \in]-\infty, 0[, \\ \tilde{\varphi} \to \hat{\varphi} \ for \ |y| \to \infty \end{cases} \quad (31)$$

Using the same way as in (25), the expansions second terms are matched :

$$\Psi(x_1, x_2) = K_1 \varepsilon^{\alpha_1} \varepsilon^{\beta_1} \rho^s f_1(\theta) + \varepsilon^{\alpha_2} \varepsilon^{\beta s} \rho^s f_1(\theta) + . = \varepsilon^{\beta_1} \varphi^{(1)}(x_1 / \varepsilon^{\beta}, x_2 / \varepsilon^{\beta}) + \varepsilon^{\beta_2} \varphi^{(2)}(x_1 / \varepsilon^{\beta}, x_2 / \varepsilon^{\beta}) \quad (32)$$

and the supplementary condition holds :

$$\alpha_2 = \alpha_1 - \frac{1}{2}\beta + \beta s \quad (33)$$

5.3. Complementary matching using path-independent integrals.

The problem unknowns are $(\alpha_1, \alpha_2, \beta_1, \beta_2, \beta)$ and considerations about dominant terms at each scale allow us to determine four relations (14,19,27,33). The missing relation will be built up starting from energy considerations. It is well known that for HRR fields [9,10] the crack-tip fracture behaviour may be characterized by a Γ path-independent line integral, where Γ is a line circumscribing the crack tip :

$$J = \int_{\Gamma} (\omega n_1 - \sigma . n \frac{\partial u}{\partial x_1}) \, ds \quad (34)$$

where ω is the material strain energy density and n the outer normal to the line Γ. For a steadily moving crack under creep conditions, a similar path-independent has been offered [11,12] :

$$C^* = \int_{\Gamma} (\omega n_1 - \sigma . n \frac{\partial u}{\partial y_1}) \, ds \quad (35)$$

Developing the two integrals, respectively for the far and the near crack tip fields, the following relations hold :

$$\begin{cases} J = \varepsilon^{(n+1)\alpha_1} K_1^{n+1} I \\ C^* = \varepsilon^{2\beta_1 - \beta} K_{III}^2 \end{cases} \quad (36)$$

In the transition area, the integral values have to coincide, so that :

$$2\beta_1 - \beta = (n+1)\alpha_1 \quad (37)$$

5.4. Summary of the results.

The equations (14,19,27,33,35) may be summarized :

$$\begin{cases} \delta - \beta_1 + \beta_2 = 0 \\ \alpha_2 + \alpha_1(n-2) - 1 = 0 \\ \beta_1 = \alpha_1 + \beta s, \qquad with \quad s = \dfrac{n}{n+1} \\ \alpha_2 = \beta_2 - \beta p, \qquad with \quad p = \dfrac{n+2}{n+1} \\ 2\beta_1 - \beta = (n+1)\alpha_1 \end{cases} \quad (38)$$

with $\delta = \beta\,(n-2) + \beta_1(1-n) + 1 < 0$

which leads to the solutions :

$$\begin{cases} \beta = \beta_1 = \dfrac{(n+1)}{(n-1)} \\ \alpha_1 = \dfrac{1}{(n-1)} \\ \alpha_2 = \dfrac{1}{(n-1)} \\ \beta_2 = \dfrac{n+3}{(n-1)} \end{cases} \quad (39)$$

The parameter β depends on the hardening coefficient. For $\beta = 1$, no zoom is available (this is the case of the Hui-Riedel analysis) so that the connection between the remote fields and the viscous fields is impossible (unless $n < 3$). When $n \to \infty$ (perfect plasticity), $\beta \to 1$, there is no matching again, and therefore an autonomous solution, but in an asymptotic way, which is natural because the material yields without supplementary loading.

6. Conclusions and outlines.

The matched asymptotic expansion method affords to connect the H.R.R. far fields and the fields near a crack tip steadily moving under creep conditions, as described in the Hui-Riedel analysis. The space variable magnifying designed by ε^{β} allows to adjust the viscous dominant area size with respect to the crack velocity and the material properties. The Hui-Riedel analysis is a particular case where no zoom is used ($\beta = 1$). A significant work remains to achieve a complete solution setting up. A further step in the analysis is to used this scaling method with the time variable, so as to break the assumption $\frac{\dot{a}}{B\mu^{n}} << 1$. The study must be also completed by the angular functions resolve.

Abstract During their application, refractory materials are submitted to several thermal shock attacks. That is why; improving their thermal shock resistance has a great importance and can enhance their lifetime. This characteristic is directly related to strains to rupture.

The non-linear mechanical behavior which characterizes specific developed ceramics, and is a consequence of their micro-cracked microstructure, leads to the increase of their strain to rupture level. This limit allows a better resistance to thermal shock solicitations.

Magnesia spinel materials are good candidates to characterize such non-linear mechanical behavior dependent on their microstructure. This non linearity is due to the presence of micro-cracks network. Indeed, mechanical behavior can vary from a fragile one to a large non-linear one according to the degree of micro-cracking present within the material.

In this paper, to investigate the crack propagation and the non-linear mechanical behavior of this material, wedge splitting test was used and coupled to digital image correlation technique. Results underline the influence of the addition of spinel on the non-linear mechanical behavior by comparing the non-linear mechanical behavior of magnesia spinel with pure magnesia. Besides, results clarified also the crack propagation mechanisms which are specific to these heterogeneous materials.

Keywords Magnesia spinel, Flexibility, Digital image correlation, Crack branching

1. Introduction

Due to their properties, pure magnesia and magnesia spinel materials showed a great interest for commercials and researchers [1-4]. Pure magnesia bricks are known by their resistance to corrosion and their relatively low thermal shock resistance. Besides, the incorporation of spinel improves the thermal shock resistance and can extend to three times longer service life of cement rotary kiln. Indeed, the addition of spinel, leads to a better adaptability of the material to severe solicitations generated during high and quick temperature variations. Even if their process of elaboration can affect the economy, but they still preferable to magnesia chromite refractories which have nearly the same properties such as their high resistance against thermal shock damage, erosion and corrosion but are not recommended due to the toxicity of waste refractories containing chrome.

The behavior of magnesia spinel is related to their microstructure and especially to the difference

between the thermal expansion of magnesia and spinel which is behind the development of micro-cracks around the spinel grains and can prevent crack propagation generated by thermal shock [5-6]. Moreover, their microstructure induces a significant non-linear stress-strain mechanical behavior allowing a high strain to rupture, high fracture energy and as a consequence improves their thermal shock resistance. It has been reported that micro-cracking caused by the addition of spinel reduces both strength and stiffness, and affect the fracture behavior [7]. Both the knowledge of the mechanisms initiating such behavior and the possibility to characterize those in the best accurate way are essential.

From these considerations, this study is a part of a work aiming to understand the relationship between microstructure and the non-linear mechanical behavior of magnesia-spinel materials and compared to pure magnesia materials.

The fracture characterization is done using wedge splitting test (WST) which affords stable crack propagation [8-11].

To assess to strain fields on the surface of the material, digital image correlation (DIC) technique has been chosen. This full-fields practical and effective tool for quantitative deformation measurement of a planar sample surface is now widely accepted and commonly used in the field of experimental mechanics. This non-contact optical method directly provides full-fields strains by comparing the digital images of the sample's surface obtained before and during deformation [12-14]. Using DIC, the propagation of the crack was studied thanks to kinematic fields approach in terms of strains. It allows highlighting the "crack branching" phenomenon due to the particularity of the microstructure of magnesia spinel materials.

2. Experimental

2.1. Materials

Pure magnesia and magnesia 15%-spinel (MSp) used in this study were elaborated from different grain distribution of industrial magnesia with low iron content (fines<0.1 mm ; 0-1 mm ; 1-3 mm ; 3-5 mm) and additional sub-stoichiometric spinel (1-3 mm) in the case of MSp. Spinel grains replaced the same content of magnesia aggregates having the same size.

Their elaboration was done using a maximum pressure of 140MPa and a maximum firing temperature of 1600°C.

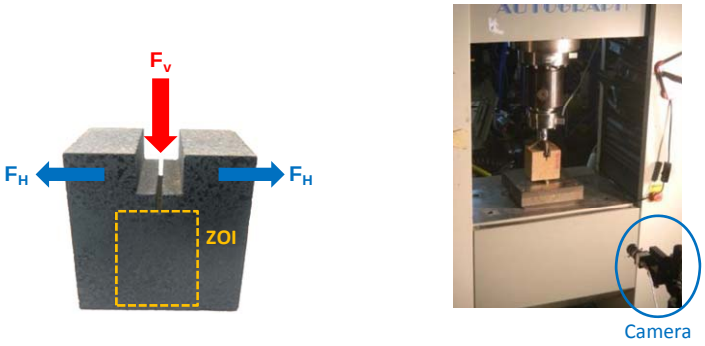
Due to the thermal expansion mismatch existing between the magnesia matrix ("the whole material excepting spinel inclusions") and the spinel inclusions (α_{MgO}=13.3 x 10^{-6} K^{-1} and $\alpha_{MgAl2O4}$=8.9 x 10^{-6} K^{-1}), it appears that there are some micro-cracks around the spinel inclusions. These micro-cracks appear during the cooling stage of the process conferring the material a "thermally damaged" character [.

2.2. Wedge Splitting Test

A more recent and widely accepted test, which has been used frequently for materials with coarse microstructures, is the method patented by Tschegg under the name "wedge splitting test". This technique is being used by a numerous research centers and universities, as well as by

manufacturers of refractories.

As shown in figure 1a the WST consists of opening a crack using a wedge. The principle of this test is to apply a vertical force (F_v) received from the device which is transformed in a much higher horizontal force (F_H) causing a symmetrical opening mode of the crack (Fig.1b). Samples were equipped with a groove in order to apply the splitting load and a starter notch. The specimen geometry and dimensions are illustrated in fig.1a.



- a - **- b -**

Figure 1: The principle of wedge splitting test with sample's geometry (a) and image acquisition setup (b).

Since the thermal shock resistance of these materials has to be improved, the brittleness of these materials has to be reduced and the deformation before cracking has to be higher by modifying the microstructure of the refractory. In fracture mechanics, the fracture energy is one parameter that characterizes the fracture strength of the material.

Then, from the experimental data in terms of load-displacement, the specific fracture energy $\mathbf{G}_f$ ($N.m^{-1}$) is defined as the mean work per unit of projected fracture area required to propagate a crack, and represented by the sum of distinct energies consumed during the crack propagation process. $\mathbf{G}_f$ is calculated using equation (1).

$$G_F = \frac{1}{A} \cdot \int_0^{\delta_{max}} F_H \cdot d\delta_H \qquad (1)$$

Where A is the crack area, F_H is the horizontal force and δ_H is the horizontal deformation. This specific fracture energy is calculated for δ values from zero up to the displacement δ_{max} corresponding to 10% of the maximum load.

The horizontal force (F_H) is calculated from the vertical force (F_v) neglecting any friction effects using the equation (2).

$$F_H = \frac{F_v}{2 \cdot \tan(\alpha / 2)} \qquad (2)$$

Where α is the wedge angle, which was 19.5° in this investigation. The fact that (F_H) is much higher than (F_v) reduces the load applied on the machine's frame and storing less elastic energy in it and helping the propagation of the crack.

Another mechanical property of material estimate from the WST is the nominal notched tensile

strength (σ_{NT}), which represents the stress at the point of beginning of rupture, is calculated by the equation (3).

$$\sigma_{NT} = \frac{6 \cdot y \cdot F_{H,max}}{b \cdot h^2} + \frac{F_{H,max}}{b \cdot h} \quad (3)$$

Where b (mm), h (mm) are sample's dimensions and y (mm) is the distance between $F_{H,max}$ and the middle of h.

In addition to the experimental setup, a 8-bits CMOS camera (1600 x 1900 pixels^2) used to record images is placed in front of the speckled surface in order to perform optical measurements thanks to digital image correlation (Fig 1b). This will stress crack growth during mechanical tests and the strain state around the crack tip. The acquisition frequency was 1 image per second.

2.3. Digital image correlation

The damage level neighborhood to the crack tip and the crack advancement are estimated from the strain cartographies obtained by digital image correlation (DIC). This full fields optical method is based on the analysis of successive digital images of a same sample during a mechanical test. The displacement fields are obtained by measuring the degree of similarity of series of subsets between the image corresponding to an unloaded state and the deformed image recorded during the test. The zone of interest, on which the calculation is done, is represented in figure 1a. Each pixel of these images stores a grey level value due to a pattern at the surface. To avoid ambiguities in the similarity process a random distribution of grey levels can be used called speckle pattern. This pattern can be the natural texture of the specimen surface or artificially made by spraying black and/or white paints. As an example for sample's surface preparation, a black opaque paint layer is deposited on the surface of sample then dried. After that, white speckles will be carefully projected on using spray paint.

The used DIC process consists in calculating displacements and strains on specific points several subsets which constitute a grid. The principle of this technique is explained in figure 2

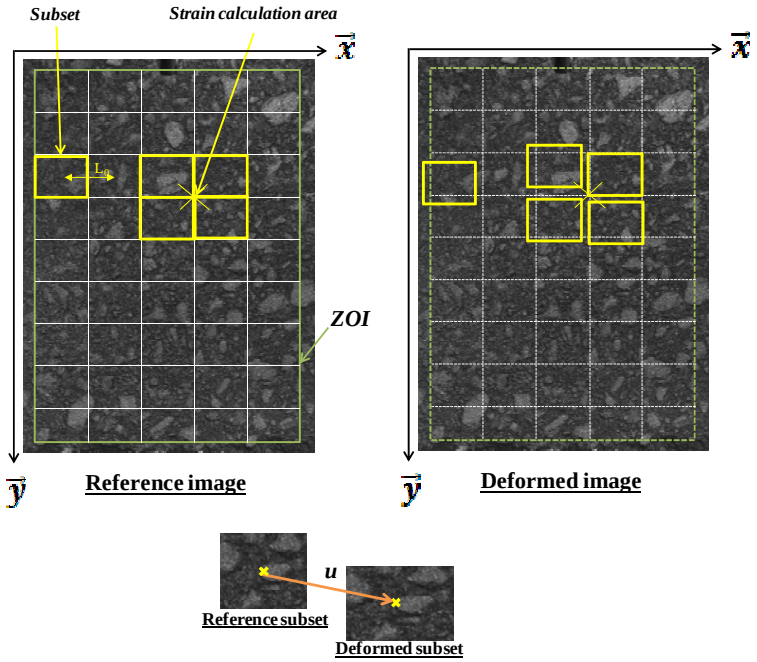


Figure 2: The principle of digital image correlation

3. Results

3.1. Mechanical properties

Figures 3, 4 represent the non-linear load-deflection curves of pure magnesia and magnesia spinel materials obtained by wedge splitting test.

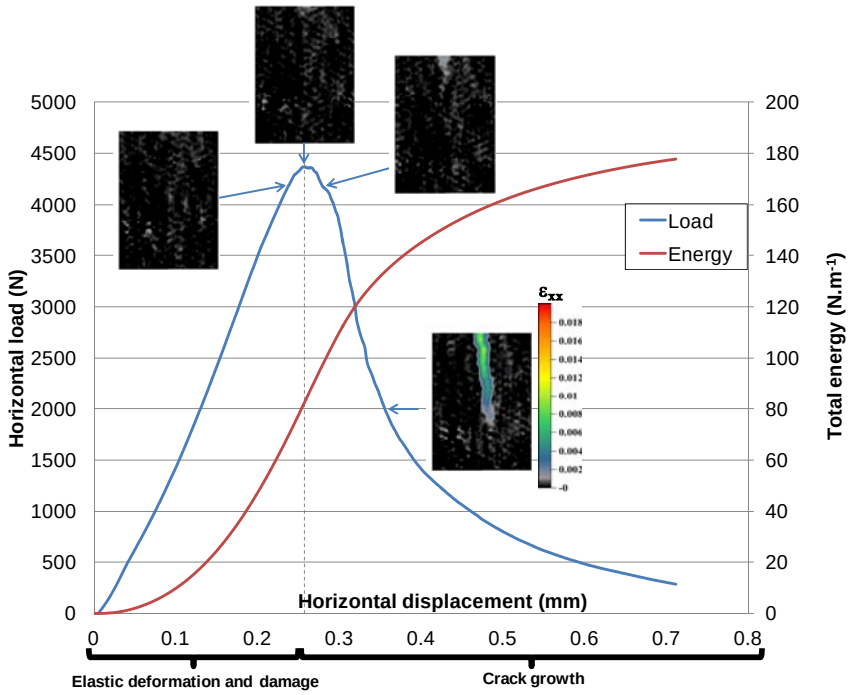

Figure 3: Horizontal load-displacement curve and total energy of pure magnesia material obtained thanks to

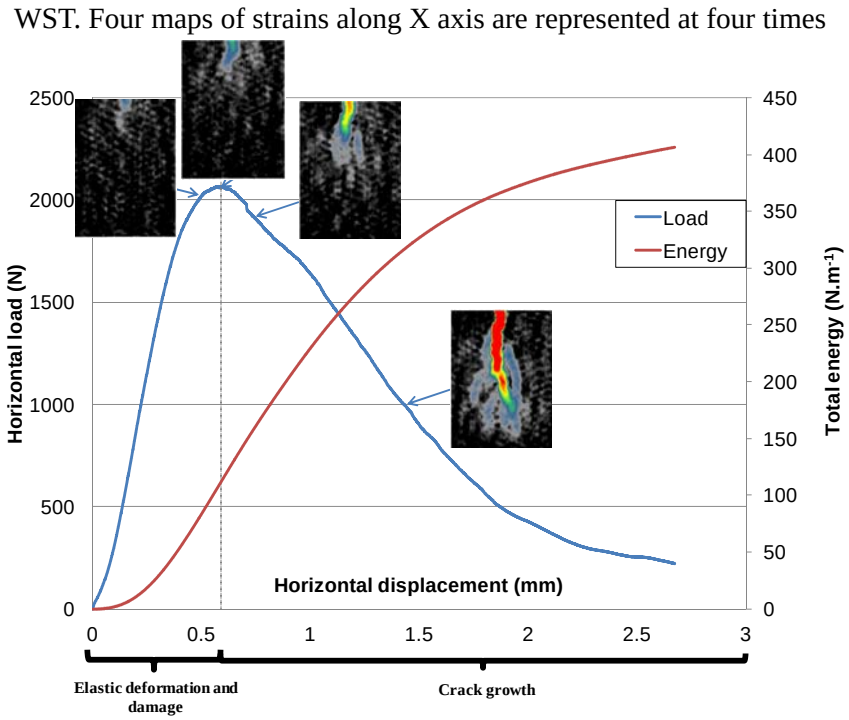

Figure 4: Horizontal load-displacement curve and total energy of magnesia spinel material obtained thanks to WST. Four maps of strains along X axis are represented at four times

The pure magnesia material presents a non-linear behavior (rather small) before the peak with a significant post-peak region and a high strain to rupture. It exhibits a much higher maximum load corresponding to the crack initiation, a lower strain at the peak, and a thinner peak due to a smaller post-peak region in comparison with MSp. This behavior is not common at room temperature for homogeneous ceramic materials. A possible explanation of this behavior is the coarse grain size (1-3 mm and 3-5 mm) distribution of this material which was reported to potentially improve fracture and thermal shock resistance of magnesia refractories.

Besides, load-deflection curve of magnesia spinel presents a non-linear mechanical behavior up to the peak with a significant post-peak region and residual strain when unloading. Moreover, the increase of spinel content seems mainly to lower the maximum load but does not influence so much the end of the post-peak region since it is close to pure magnesia. By considering the very beginning of this curve, the addition of spinel, and therefore, the thermal damage introduction, allows to enhance the non-linearity of the mechanical behavior. This material has a higher strain and a low mechanical resistance in comparison with pure magnesia; this can be explained by the higher volume of microcracks in the case of magnesia spinel developed during cooling and toughening mechanisms occurring around the crack, especially in the following wake region, which may increase the resistance to crack propagation. The higher volume of microcracks in the case of magnesia spinel is due to the difference between the thermal expansion coefficient of magnesia (α_{MgO}=13.3 x 10^{-6} K^{-1} and $\alpha_{MgAl2O4}$=8.9 x 10^{-6} K^{-1}) which leads to the apparition of microcracks around the grain of spinel.

In the two cases, the mechanical behavior of these materials is characterized by three phases, one corresponding to the elastic behavior, a second one characterized by the elastic behavior coupled

with damage (elastoplasticity), and the last one corresponding to the crack growth.
Only the main macrocrack can be detected by the naked eye, but the early apparition of the macrocrack, as well as all the stressed microcracks pre-existing around the middle plane, is not really visible. That is why; digital image correlation has been used in order to obtain the strain fields so as to analyze the crack propagation and the presence of damage process.
Thanks to digital image correlation, the evolution of the strains along X-axis has been represented for different instants corresponding to different loading states (fig 3, 4). These maps correspond to the zone of interest defined in figure 1a .According to DIC principle, this area is subdivided using subsets of 32 x 32 pixels^2 with a gap of 8 x 8 pixels^2 and a scale factor of 0.067295 mm/pixels. In the two materials, we notice before reaching $F_{H,max}$ the development of the damage zone in the neighbor of the crack tip. The initiation and the propagation of the crack take place after this critical load ($F_{H,max}$). Due to the higher ductile behavior of magnesia spinel, the damaged zone in the neighbor of the crack tip is larger than the case of pure magnesia. Besides, this zone is developing and moving with the crack tip advancement. This confirms the complexity of crack growth in heterogeneous materials which feature many physical mechanisms such as crack branching phenomenon.
Nominal notched tensile strength and specific fracture energy for each sample have been calculated thanks to the equations (2) and (3) and represented in Table 1.

Table 1: Nominal notched tensile strength and specific fracture energy values

	σ_{NT} (MPa)	G_F (N.m^{-1})	G_F/σ_{NT} (mm) x 10^{-3}
Pure MgO	14.36	206.50	14.39
	14.38	182,00	12,66
MgO-15% spinel	6.65	361.00	54.25
	6.75	396.00	58.63

These intrinsic fracture parameters introduced in table 1 stress the nominal notched tensile strength shows that mechanical resistance decreases whereas the energy stresses that the fracture resistance increases with the increase of the spinel rate. The ratio G_F/σ_{NT} indicates the brittleness of the material: the more brittle material is, the lower value of the ratio is.
Figures 10 and 11 represent also the evolution of the total energy during the test. The total energies are deduced from the total area under the horizontal load-displacement curves obtained by wedge splitting test divided by the section of fracture and represent the sum of the elastic energy and dissipated one. The curves confirm that during the test, the total energy is higher in the case of magnesia-15% spinel than pure magnesia. The dissipated energy is mainly due to the dense network of microcracks created during the test.

4. Conclusion

The impact of microstructure on the mechanical behavior has been clarified. Indeed, studying mechanical behavior is important to have an idea on the thermal shock resistance of materials. In

this paper, mechanical behavior of magnesia spinel products were analyzed and compared to pure magnesia. The difference between mechanical behaviors of these materials is due to the development of the network of micro-cracks in the case of magnesia-spinel materials. This is a consequence of the thermal expansion mismatch between magnesia and spinel grains. To study the mechanisms of micro-cracking and the influence of damage on the non-linearity, wedge splitting test has been used and coupled to digital image correlation. Indeed, by the calculation of mechanical properties such as nominal notched tensile strength and fracture energy in addition to the measurement of strain fields, the influence of the addition of spinel is clarified. In fact, it was confirmed that the addition of spinel influences clearly mechanical properties and the non-linearity of the mechanical behavior due to the presence of high level of damage induced by micro-cracks as shown thanks to digital image correlation. This microstructure optimization allows an increase of strain to rupture, which is considered as a key parameter for improving thermal shock resistance of refractories.

Abstract The objective of this research is to determine the best conditions to measure the fracture toughness of an ASTM A-743 grade CA-6NM stainless steel used in hydraulic turbine runners. The tests are performed on 12.7 mm and 25.4 mm thick compact tension (CT) specimens. Experimental results show that only the thicker specimen gives a valid test according to ASTM E1820 standard. However, very close crack initiation J_{IC} values are obtained with thinner specimens provided they are side-grooved. Thickness effect is exhibited both on the resistance curve *J-Δa* and the crack front during the stable crack propagation.
This paper is documented with both macroscopic and microscopic descriptions of fracture surfaces in the stable crack extension region.

Keywords J_{IC} fracture toughness, CA-6NM steel, CT specimen, thickness constraint effect

1. Introduction

The use of high-strength martensitic stainless steels in hydraulic turbine runners allows reduction in weight and cost of some components such as rotors, pumps and compressors. Designers take advantage of the high strength of these steels, which are also very little sensitive to corrosion and to cavitation damage [1-3]. Conventional turbine runners design is based on a so-called static stress design approach, which limits the Von Mises stress at operating condition to a prescribed fraction of the material yield stress (eg. $\sigma_e < 1/3\ \sigma_{YS}$). However, this approach does not guarantee reliability of runners as many other variables other than static stress can cause failure [4-5]. Welding blades, crown and band together unavoidably involves the presence of weld defects. It is not possible to detect accurately or size all defects with non-destructive inspection during the turbine runners manufacturing process, and due to economic reasons they cannot all repaired. Moreover, some defects can possibly be tolerated based on Fracture Mechanics assumptions for the whole runner lifetime (70 years). Hence, to determine a maximum allowable defect size, accurate knowledge of material properties and in particular fracture toughness need to be evaluated.

Measurement of fracture toughness K_{IC} is based on Linear-Elastic Fracture Mechanics (LEFM) [6-7]. It has been extensively used for high-strength and relatively brittle materials such as metals used in the aerospace industry and ceramics. However, the low carbon martensitic stainless steels used in hydraulic turbine runners manufacturing are in the range of immediate-strength and high toughness engineering materials. In order to get a valid K_{IC} test under small-scale yielding and plane-strain conditions, the required specimen can be as big as 300 mm in thickness for a compact tension specimen which is difficult to be tested in a common laboratory. Moreover, it is also impossible to fabricate steel in such dimension with homogeneous metallurgical properties (microstructure and texture) through the whole thickness. In this case, an alternative J_{IC} test method based on Elastic-Plastic Fracture Mechanics (EPFM) can be used [8-9]. J_{IC} test can be performed on a relatively small laboratory specimen. This testing method, firstly developed for the engineering materials used in nuclear power plants, is based on Rice's *J*-integral concept [10].

The objective of the present work is to determine the best conditions to measure the fracture

toughness of ASTM A-743 grade CA-6NM stainless steel used in hydraulic turbine runners. For this purpose, fracture toughness J_{IC} tests are performed on smooth and side-grooved compact tension (CT) specimens of different thicknesses. Tests are carried out based on ASTM E1820 guide lines [11]. The investigated material and the experimental technique are first presented. Results of mechanical tests are analyzed and compared; fractographic examinations are also made in the crack growth regions in order to interpret the fracture mechanisms of the tested steel.

2. Material studied

The experimental material studied in this work is a low carbon CA-6NM steel (13Cr-4Ni martensitic stainless cast steel). Table 1 gives the chemical composition limits of the tested material as required by ASTM A-743 standard [12]. Heat treatment consisted of austenitizing at 955 ^{o}C followed by air cooling. Then, a tempering was performed between 565^{o}C and 620^{o}C allowing the fresh martensite to temper, giving rise to a beneficial softening corresponding to reduce hardness but increase ductility. The resulting microstructure is mainly tempered martensite with about up to 15% reformed austenite. The basic mechanical properties have been characterized in an early study [1]. For brevity, only tensile properties are given here. The measured yield strength σ_{YS} is 763 MPa, the tensile strength σ_{TS} is 837 MPa and the elongation is 27%. All measured mechanical properties meet ASTM A-743 standard requirements.

Table 1. Chemical composition limits of tested steel (wt.%)

	C	Mn	Si	S	P	Cr	Ni	Mo
CA-6NM	0.03	0.57	0.37	0.02	0.02	12.68	4.03	0.67
ASTM A-743	0.06 max	1.0 max	1.0 max	0.03 max	0.04 max	11.5-14.0	3.5-4.5	0.4-1.0

3. Mechanical testing

Standard compact tension (CT) specimen according to the recommendations of ASTM designation E1820 is used. The geometry of J_{IC} test specimen (Figure 1) allows the measurement of load line displacement (LLD) by means of an extensometer. One 12.7 mm thick smooth specimen without side grooves was first tested. Then five side-grooved specimens were tested: two specimens with B = 12.7 mm (*B/W =1/4)* and three specimens with B = 25.4 mm (*B/W =1/2)*. Side grooves have each a depth of 10% of the gross thickness B. As the tested material is in a cast condition, there is no need to orientate it during machining. All tests were carried out at room temperature using partial unloading compliance method on a servo-hydraulic testing machine. The tests followed the guide-lines of the ASTM E1820 standard for the fracture toughness determination from a single specimen.

For the fatigue pre-cracking, two different procedures were assessed. First, four specimens were pre-cracked prior to the side-grooving operation as recommended by E1820 standard. The crack growth was followed by an optical microscope on specimen polished surfaces. Secondly, two other specimens were pre-cracked after the side-grooving operation, side grooves were machined at the same time as the specimens. In this case, the pre-cracking is monitored by a COD gage using elastic-compliance method. For all specimens, the pre-crack length is about 5 mm, providing an a_0/W value of 0.55. During pre-cracking, the loading ΔK is kept to 12 MPa$\sqrt{m}$ in order to limit the plastic zone size.

During the experiments, the specimens are subjected to about 20 loading/unloading cycles. The

unloading ratio is 10 % of actual maximum load. A representative experiment is shown in Figure 2 for a 12.7 mm thick side-grooved specimen. After the final unloading, the specimen was marked by heat tinting (450^{o}C for 1 hour). The initial and final crack lengths a_0, a_f are measured at 9 equally spaced locations on the broken specimens.

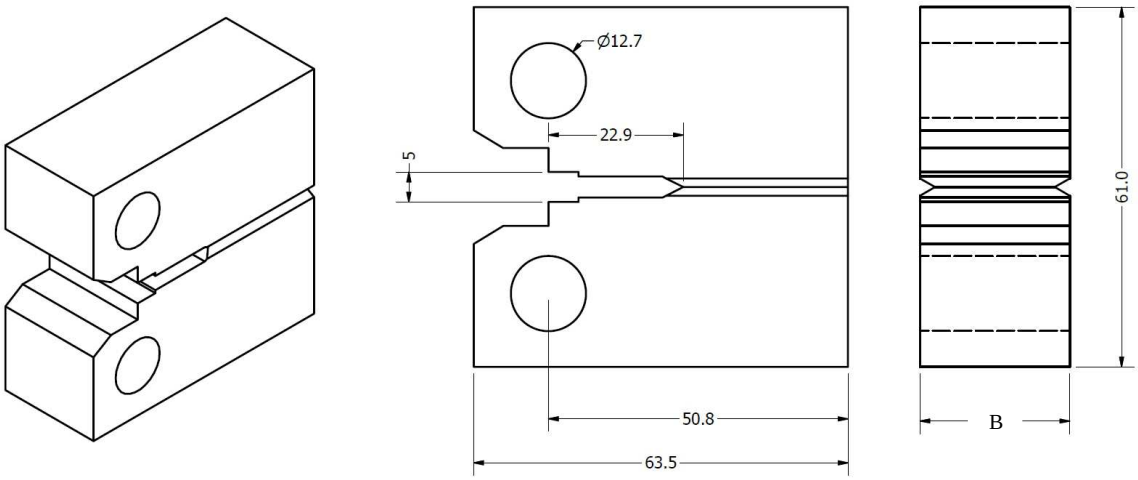

Figure 1. Compact tension J_{IC} specimen with side grooves (dimensions in mm); specimen gross thickness B is 12.7 mm or 25.4 mm; the side groove depth is $0.1B$ at each side.

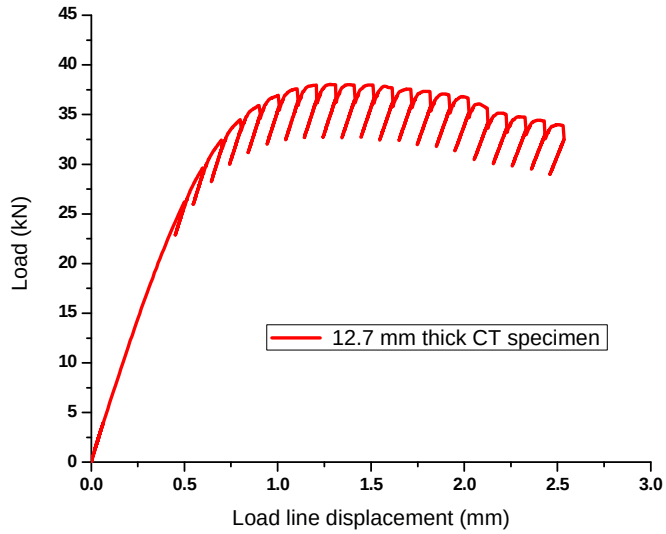

Figure 2. Load – load line displacement curve (10% unloading)

4. Results and discussion

4.1 Results

4.1.1 J_{IC} testing

Figure 3 shows a representative *J-Δa* curve obtained from the previous 12.7 mm thick side-grooved specimen. The blunting line is calculated from material tensile properties as following,

$$J = 2\sigma_Y \Delta a \tag{1}$$

$$\text{and} \quad \sigma_Y = \frac{\sigma_{YS} + \sigma_{TS}}{2}$$

The data points lie between the 0.15 mm offset line and 1.5 mm offset line parallel to the blunting line ($J = 2\sigma_Y \Delta a$) are used for regression line fitting. They can be represented by a power-law expression $J = A(\Delta a)^b$. The intersection point between the regression line and 0.2 mm offset line gives a candidate value J_Q which becomes J_{IC} provided that the validity requirements are satisfied.

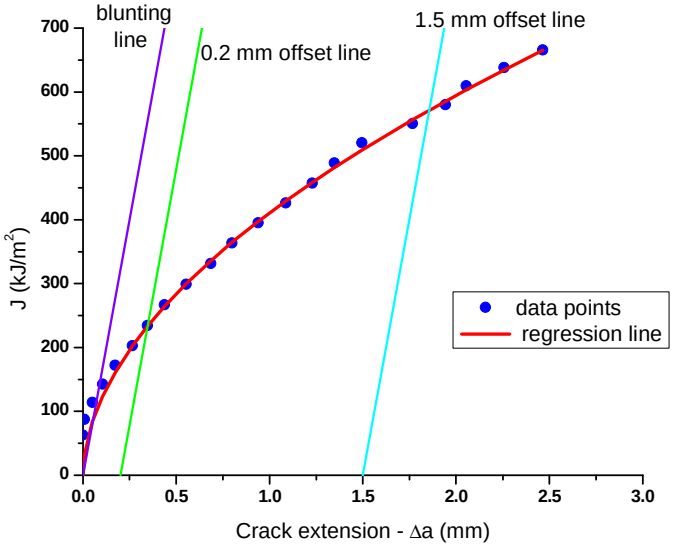

Figure 3. *J-Δa* curve for the 12.7 mm thick CT specimen

Then, K_{IC} can be estimated by

$$K_{IC} = \sqrt{\frac{EJ_Q}{(1-\nu^2)}} \tag{2}$$

where E is Young's modulus of the steel tested and ν is Poisson's ratio.

Table 2 gathers all test results on both 12.7 mm and 25.4 mm thick side-grooved specimens. For the smooth specimen (B = 12.7 mm) which was firstly assessed in the present study, no valid data point is found due to an extremely steep *J-Δa* curve. There is no intersection between the regression line and 0.2 mm offset line. So the testing result is not given here.

Table 2. Testing results of J_Q for CA-6NM steel

Specimen thickness (mm)	Test	J_Q (kJ/m^2)	dJ/da (MPa)	K_{IC} (MPa$\sqrt{m}$)
12.7	CT_05in_1	232	220	230
	CT_05in_2	280	210	252
25.4	CT_1in_1	256	128	241
	CT_1in_2	255	133	240
	CT_1in_3	286	124	255

As shown in Figure 4, there is little difference at the beginning of crack extension between 12.7 mm and 25.4 mm thick side-grooved specimens. Similar fracture initiation toughness J_Q values can be

obtained on both specimens. However, in the following crack growth region (Δa > 0.5 mm), thin specimen gives a steeper *J-Δa* curve and exhibits higher load carrying capacity than the thick sample. The tearing moduli *dJ/da*, which is more representative of crack propagation, is much higher for thin specimens than thick specimens (see Table 2).

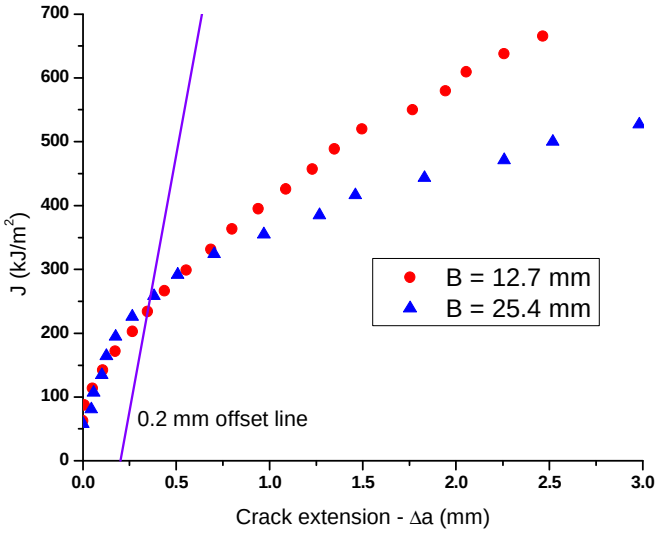

Figure 4. Effect of specimen thickness on *J-Δa* curve

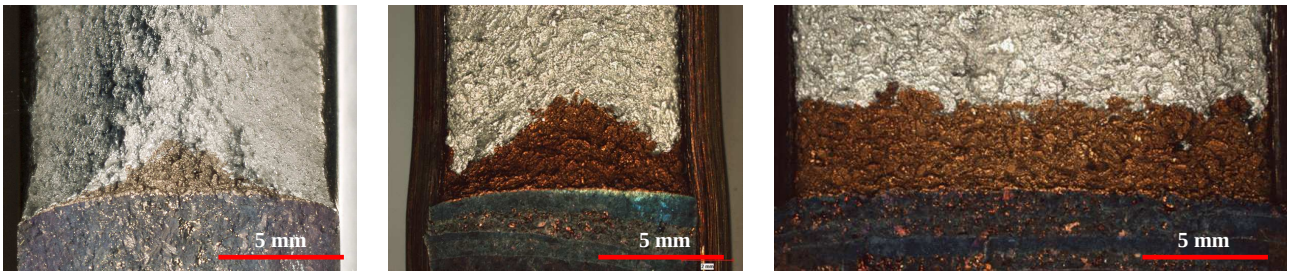
4.1.2 Fractography

Fracture surfaces are firstly examined at the macroscopic scale on both 12.7 mm and 25.4 mm thick samples (see Figure 5). In the 12.7 mm thick smooth specimen (Figure 5a), strong crack tunneling is observed. There are no crack growths at both side surfaces of specimen while the crack advances more than 2 mm in the center section of the specimen. In the 12.7 mm thick side-grooved specimen (Figure 5b), crack tunneling is less pronounced, but the crack grows again faster in the center section of the specimen than near the specimen surfaces. As it is stated in section 9.1 of E1820 standard, such a test cannot be valid due to the strong crack front curvature. In the 25.4 mm thick side-grooved specimen (Figure 5c), crack grows with the same rate at the center of the specimen as at the two side surfaces. The crack extension front is nearly straight, and the test is valid according to E1820 standard. In the final ductile tearing (white part of Figure 5), we can also see that there is stronger lateral contraction in the thin specimen than in the thick one.

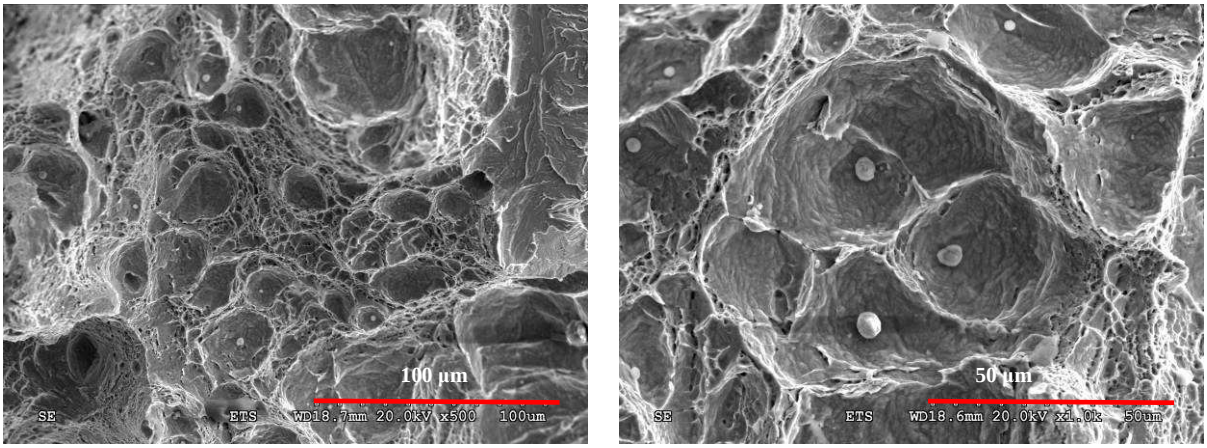


(a) (b) (c)

Figure 5. Fracture surface of broken specimens: (a) 12.7 mm thick smooth specimen, (b) 12.7 mm thick side-grooved specimen, (c) 25.4 mm thick side-grooved specimen. Crack front at the end of stable propagation was marked by heat tinting.

In order put into evidence the fracture mechanisms at microscopic scale, one 25.4 mm thick

side-grooved specimen was marked under fatigue instead of heat tinting after the final unloading. Broken sample was observed using scanning electron microscopy. In the stable crack extension region (Figure 6) void growth mechanism is dominant. Very large dimples can be seen, their size being about 20 μm. At a higher magnification (Figure 6b), the presence of inclusions in the bottom of dimples is clearly visible. It can be interpreted by the high stress triaxiality (plane-strain state) which triggers a fast void growth leading to formation of large dimples [13].



(a) (b)

Figure 6. SEM micrography of a broken specimen in the stable crack growth region

4.2 Discussion

4.2.1 Constraint effects

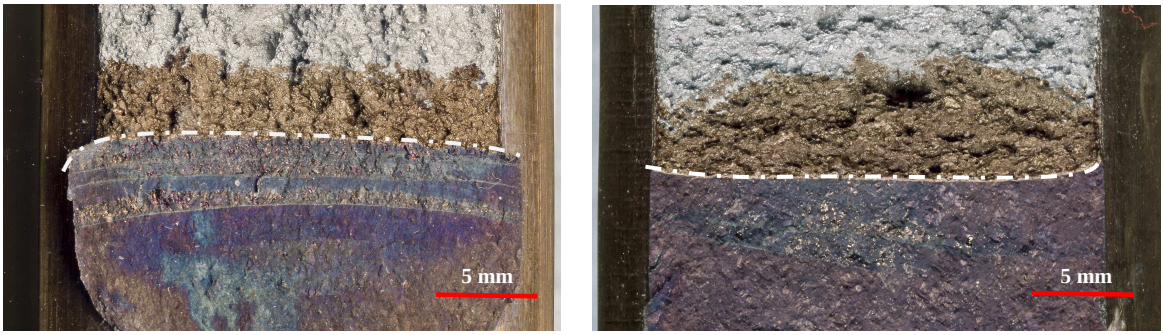
From the present study, experimental results show that the crack extension behavior is related to the variation of stress triaxiality across the specimen thickness. In 12.7 mm thick smooth specimen, strong crack tunneling is observed because of relatively low stress triaxiality and constraint level across the whole specimen thickness. And final fracture by ductile tearing or shearing can be seen on broken surfaces. In 12.7 mm thick side-grooved specimen, lateral constraint is increased by side grooving operations, and flat ductile fracture is observed. But the specimen is not thick enough to get a full constraint across the thickness and which caused a final curved crack front. In 25.4 mm thick side-grooved specimen, a perfectly straight crack front is obtained after stable crack extension. Because the side grooves promote practically uniform plane strain constraint along the crack front [14]. Similar results were reported in [15-18] for CT and SENB testing with various smooth and side-grooved specimen sizes.

Our investigations also show that the variation of stress triaxiality or thickness constraint leads to changes on the shape of *J-Δa* resistance curve after certain amount of crack extension. The slope of the *J-Δa* curve for the thin specimen is significantly steeper than the corresponding value for the thick specimen. In other words, thin specimen exhibits higher load carrying capacity (*dJ/da*) than thick specimen. It is known that the lateral constraint and average stress triaxiality increases with increasing specimen thickness. For thick specimen, the high stress triaxiality reduces the apparent ductility of the material by a faster void growth mechanism which is predominant as shown in Figure 6 in the previous section. While for thin specimen, the average stress triaxiality is lower and the lateral contraction is less constrained during the loading, so a relatively steeper resistance curve is generated.

4.2.2 Side-grooves and fatigue pre-cracking

Side-grooved specimen is recommended by E1820 when the compliance method of crack size prediction is used. One objective of using side-grooved specimen is to create a straight crack front to reduce the number of tests invalided by curved crack front. In this study, 0.2B side-grooved specimens were used after having an invalid test with a smooth specimen. In order to produce nearly straight fatigue pre-crack fronts, the pre-cracking is suggested to be performed prior to the side-grooving operations by E1820. However, this procedure is time consuming. The specimen needs to be polished on two surfaces in order to monitor the crack length with an optical microscope and the pre-cracked specimens have to be returned to the machine shop for side grooves machining. Moreover, the fatigue pre-cracking front is not straight. The crack grows faster in the center section of the specimen than near the specimen surfaces even with low pre-cracking load (ΔK = 12 MPa$\sqrt{m}$ in present work). As shown in Figure 7a, the crack measured on the specimen surfaces by microscopy is shorter than the real average crack length measured on the broken surface. This curvature probably results from slower crack growth under plane stress condition.

As mentioned earlier, two specimens with side grooves machined before the pre-cracking operations were also prepared. The crack growth is followed by a COD gage with the elastic compliance method. Experiments show a good agreement between calculated crack length by elastic compliance and the measured crack length on final broken specimens. With this procedure, polished surfaces are no longer needed and the side grooves are machined at the same time as the specimen itself. Time and machining cost can be saved. For the fatigue pre-cracking, due to a relative constant constraint level across the thickness, an approximately straight crack front is produced (Figure 7b).



(a) (b)

Figure 7. (a) Fatigue pre-cracking performed before side grooves operation and (b) fatigue pre-cracking performed after side grooves operation. White dashed line: fatigue pre-cracking front.

5. Conclusions

J_{IC} fracture toughness testing was performed on CA-6NM martensitic stainless steel, the following conclusions are drawn:

1. Due to high toughness of the material, side-grooved specimen must be used in order to get a valid test according to ASTM E1820. Side grooves can prevent the development of crack tunneling and to maintain a relatively straight crack growth.
2. Crack growth exhibits a thumb-nail front for both 12.7 mm thick side-grooved CT specimens. It cannot be valid per ASTM standard due to the significant curvature of final crack front.

3. Valid tests are obtained with 25.4 mm thick side-grooved CT specimens with a straight crack extension front.
4. Both thin and thick specimens give very close *J* values at crack initiation (0.2 mm offset line). So, thin specimen can also be used if only crack initiation toughness is required. It is recommended that thicker specimen should be used if the plane strain *J*-resistance curve is required.
5. Side grooves can be machined before the pre-cracking; it can reduce the preparation time and machining delay and it gives a straight pre-cracking crack front. No significant difference was found on the fracture toughness testing as recommended by ASTM E1820 (pre-cracking before side grooving).
6. Fractography analysis shows that the void growth from inclusions is dominant in the crack extension region; large dimples are observed which can be explained by the high stress triaxiality of specimen.

Nomenclature

a	Crack length (mm)	b_0	Uncracked ligament length (mm)
Δa	Crack extension (mm)	σ_{YS}	Yield stress (MPa)
B	Specimen gross thickness (mm)	σ_{TS}	Ultimate tensile stress (MPa)
B_N	Specimen net thickness (mm)	E	Young's Modulus (GPa)
W	Specimen width (mm)	ν	Poisson's ratio
K	Stress intensity factor (MPa$\sqrt{m}$)	J	J-integral (kJ/m^2)
K_{IC}	Fracture toughness (MPa$\sqrt{m}$)	J_Q	Fracture toughness (kJ/m^2)

Abstract Dynamic crack propagation in rubber is modeled and analyzed numerically using the finite element method. The problem of a suddenly initiated crack at the center of stretched sheet is studied under plane stress conditions. A nonlinear finite element analysis using implicit time integration scheme is used. The bulk material behavior is described by finite-viscoelasticity theory and the fracture separation process is characterized using a cohesive zone model with a bilinear traction-separation law. Hence, the numerical model is able to model and predict the different contributions to the fracture toughness, i.e. the surface energy, viscoelastic dissipation, and inertia effects. The separation work per unit area and the cohesive strength has been parameterized, and their influence on the separation process has been investigated. A steadily propagating crack is obtained and the corresponding crack tip position and velocity history as well as the steady crack propagation velocity are evaluated and compared with the experimental data. A minimum threshold stretch of 3.0 is required for crack propagation. The numerical model is able to predict the dynamic crack growth such that the strength and the surface energy vary with the crack speed.

1. Introduction

Elastomers are important materials in many engineering applications; consequently a wide variety of elastomeric materials is used in several products, e.g., tires, springs, dampers, gaskets, bearings, oil seals, etc. Fracture mechanics in elastomers is of great importance in the design process and it is fundamental in some applications such as adhesion technology, elastomers wear, etc.

Dynamic crack propagation in rubber-like materials has been investigated both theoretically and experimentally but the field is relatively undeveloped compared with brittle materials [8, 12, 21, 28]. Generally, the dynamic fracture in rubber shows remarkable deviation from the dynamic fracture theories for brittle materials, e.g. the cracks propagate at speeds greater than the speed of sound without branching and at high stretch levels oscillatory crack propagation results.

The fracture energy of rubber is the sum of different contributions [20, 22, 23]: the surface energy required to create new crack surfaces, the energy dissipated in the viscoelastic processes around the crack tip, and the inertia effects that contribute in the case of dynamic fracture. Furthermore, the separation process is accompanied with a viscoelastic dissipation process to which takes place in the crack tip vicinity [2].

The theoretical treatment of the problem of crack propagation in rubber-like solid reveals that the region around the crack tip can be divided into three different zones, determined by the relaxation spectrum, as shown in Fig. 1a [10]. These regions are: glassy region occurs at the closest to the crack tip, rubbery region occurs far from the crack tip, the viscous dissipation region that is located between these two regions. Depending on the relaxation spectrum and crack propagation velocity, the glassy and viscous dissipation regions may vanish, e.g. in the case of carbon-filled natural rubber glassy zones are not expected to exist, while viscous dissipation is expected.

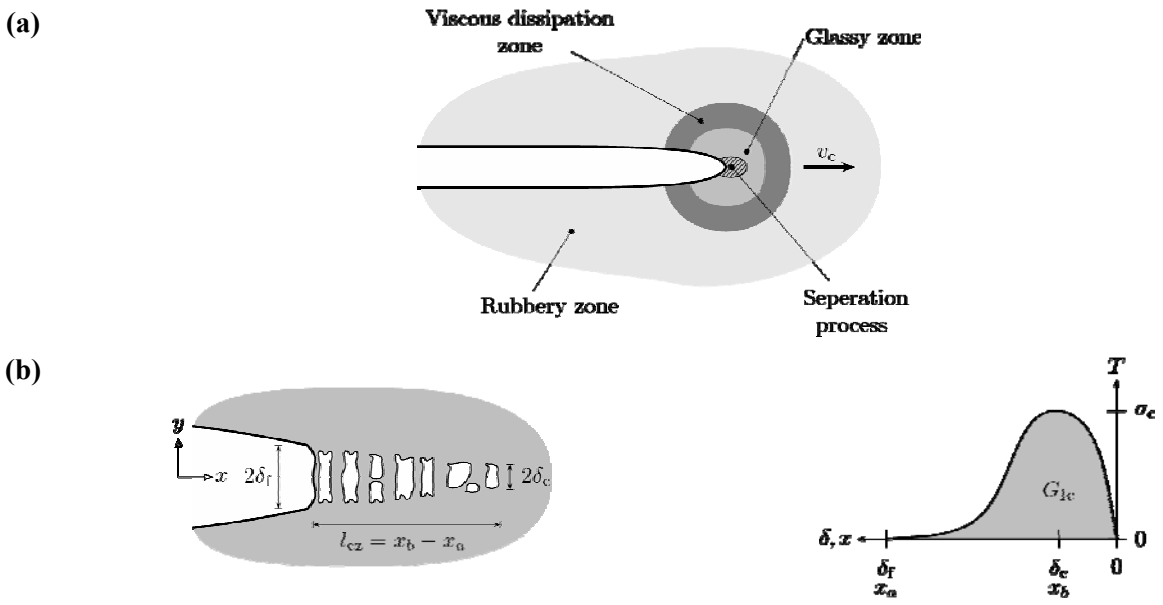

Figure 1. The fracture processes around a crack propagating in rubber with a speed v_c : **a** the different zones around the propagating crack tip determined by the viscoelastic behavior; and **b** the cohesive process zone and its traction-separation law ($T-\delta$). G_{Ic} is the fracture energy, l_{cz} is the length of the cohesive zone, δ_c is the critical displacement, δ_f is the failure displacement, and σ_c is the cohesive strength.

One way to give a quantitative description of the contribution from the different fracture-associated processes is to use the cohesive zone theories. The cohesive zone modeling approach was originally proposed by Dugdale and Barenblatt [9, 11] to simulate the fracture process and was later implemented in a finite element environment [3]. A cohesive zone model describes the fracture process in the crack tip vicinity as a gradual surface separation process, such that the normal and shear forces at the interface resist separation and relative sliding. Several cohesive zone models have been introduced in the literature including rate-dependent and independent models and have been successfully used in both quasi-static and dynamic crack growth problems [1, 4, 13, 27].

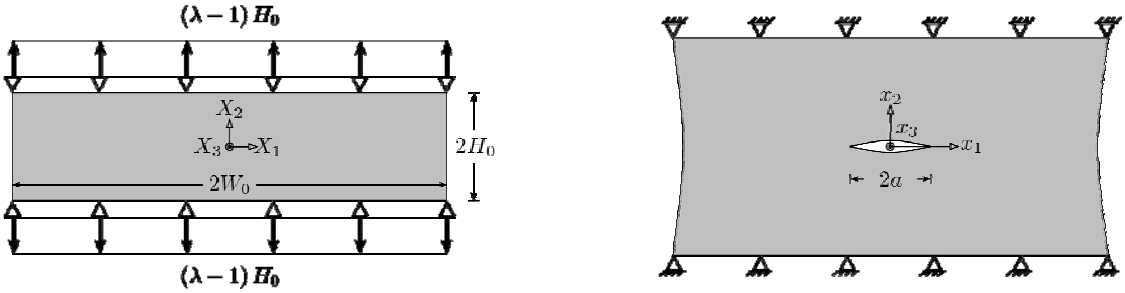
The purpose of the present study is to model as well as to analyze the dynamic crack propagation in rubber. The problem of a suddenly initiated crack at the center of stretched sheet is analyzed using finite element method, and plane stress conditions are assumed to prevail. A nonlinear finite element analysis using implicit time integration scheme is used. The bulk material behavior is described by finite-viscoelasticity theory. The fracture separation process is modeled using a cohesive zone model with a bilinear traction-separation law. A parametric study is performed over a range of cohesive zone properties, i.e. cohesive strength and energy, and the steady crack propagation velocity is calculated and compared with crack speeds obtained in experiments. The problem is formulated in Section 2, and the numerical analysis is provided in Section 3. A discussion is presented in Section 4.

2. Problem formulation

2.1. Geometry

Consider a thin rectangular sheet of rubber with the initial dimensions $2W_0$ (width), $2H_0$ (height), and B_0 (thickness), as shown in Fig. 2a. The sheet is initially unloaded, and the Cartesian material coordinates X_I, $I = 1,2,3$, are used to describe the reference configuration. Plane stress conditions are assumed to prevail, such that the $X_1 - X_2$-plane is the plane of stresses. The sheet is first subjected to a stretch λ in the X_2-direction at low rate of loading, such that inertia effects are

ignored. The deformation is assumed to be defined by the motion $\mathbf{x}=\boldsymbol{\chi}(\mathbf{X},t)$, where the Cartesian coordinates x_i, $i=1,2,3$, are defined in the deformed configuration, as shown in Fig. 2b. The position vectors in material and spatial coordinates are defined as $\mathbf{X}=X_i\mathbf{e}_i$ and $\mathbf{x}=x_i\mathbf{e}_i$, respectively, such that the two coordinates possess the same origin and the same set of orthogonal basis vectors $\mathbf{e}_i$, $i=1,2,3$. The displacement vector is defined as $\mathbf{u}=\mathbf{x}-\mathbf{X}$, and the first Piola-Kirchhoff traction vector $\mathbf{T}$ is defined as force per unit undeformed area. After the required extension has been achieved, a crack of length $2a$ is initiated at the center of the deformed sheet parallel to x_1-direction. Thereafter, the crack propagates dynamically and symmetrically along a path defined by $x_2=0$.



(a) **(b)**

Figure 2. The geometry of the thin rectangular rubber sheet: **a** the reference configuration; and **b** the current configuration.

Considering the symmetry of loading and geometry, only a half portion of the sheet, defined by $X_1\geq 0$, is modeled. The crack propagation is then studied over a length of Δa in the deformed configuration. The time scale is defined according to the following: the sheet is loaded quasi-statically for $t<0$, and at $t=0$, the crack is initiated. The boundary conditions applied for the whole period of time are defined according to

$$X_1=0: u_1=0, T_2=0, \tag{1}$$

$$X_1=W_0: T_1=T_2=0, \tag{2}$$

$$X_2=\pm H_0: u_1=0, u_2=\pm(\lambda-1)\cdot H_0. \tag{3}$$

The initial crack is located at $0\leq X_1\leq a_0$, $X_2=0$. Note that a pertains to the deformed configuration, while a_0 pertains to the reference configuration. The crack starts to propagate immediately after the initiation process, i.e. for $t>0$. The propagation process is determined by a cohesive law. Assuming that the crack tip position is defined as $\mathbf{x}_{\text{tip}}=x_{\text{tip}}\mathbf{e}_1$, the crack tip velocity is then determined as

$$v_{\text{tip}}=\frac{dx_{\text{tip}}}{dt}, \tag{4}$$

implying that the crack propagates in the X_1-direction, i.e. $\mathbf{v}_{\text{tip}}=v_{\text{tip}}\mathbf{e}_1$ and d/dt is the time derivative taken with respect to spatial coordinates.

2.2. Constitutive models

2.2.1. The finite-strain viscoelasticity model

The mechanical behavior of rubber-like materials is characterized by finite elasticity theory, i.e. hyperelasticity, for the quasi-static response. Further, the dynamic response is often characterized by viscoelasticity theory. The finite-strain viscoelasticity implementation in ABAQUS [14] is based on a local additive split of the stress tensor into initial and non-equilibrium parts [15]. The initial part

follows the finite-strain constitutive equations while the non-equilibrium part determines the viscous response.

Consider a deformation that is defined by the deformation gradient $\mathbf{F}$ and the associated Jacobian J. The deformation gradient is decomposed into volume changing (dilatational) part $J^{2/3}\mathbf{I}$ and volume preserving (distortional) part $\overline{\mathbf{F}} = J^{1/3}\mathbf{F}$. The initial free strain energy function, that determines the initial stress part, can be written in the decoupled form

$$\Psi = \Psi_{\text{vol}}(J) + \Psi_{\text{iso}}(\overline{\mathbf{F}}), \tag{5}$$

where $\Psi_{\text{vol}}(J)$ is the volumetric part and $\Psi_{\text{iso}}(\overline{\mathbf{F}})$ is the isochoric part. The total strain energy, including the viscous response, can be written using a generalized Maxwell model (Prony series) as

$$\Psi = k_R(t)\cdot\Psi_{\text{vol}}(J) + g_R(t)\cdot\Psi_{\text{iso}}(\overline{\mathbf{F}}), \tag{6}$$

where $k_R(t)$ and $g_R(t)$ are the Prony series dimensionless relaxation moduli.

In this context, an isotropic and incompressible hyperelastic material is considered, i.e. $J = 1$. Hence, the volumetric part of the strain energy function is then expressed in terms of a hydrostatic pressure p.

$$\Psi_{\text{vol}} = p(J-1), \tag{7}$$

The isochoric part of the strain energy function is defined by the Ogden model for incompressible materials [25], which reads

$$\Psi_{\text{iso}} = \sum_{p=1}^{M}\frac{\mu_p}{\alpha_p}\left(\lambda_1^{\alpha_p} + \lambda_2^{\alpha_p} + \lambda_3^{\alpha_p} - 3\right), \tag{8}$$

where the λ_i, $i = 1,2,3$, are the principal stretches, μ_p and α_p are material parameters that fulfill the condition $\mu_p\alpha_p > 0$ (no summation) and the shear modulus μ_p is defined by $\mu = \sum_{p=1}^{M}\mu_p\alpha_p$.

Further, the volumetric response is assumed to be purely elastic such that the viscoelastic response is determined by the isochoric response, i.e. $k_R(t) = 1$. The total strain energy function, including the viscoelastic response, can be written in the decoupled form

$$g_R(t) = 1 - \sum_{i=1}^{N}\overline{g}_i^P\left(1 - e^{-t/\tau_i}\right), \tag{9}$$

where N, $\overline{k}_i^P$, $\overline{g}_i^P$ and τ_i are material constants. The model includes N Maxwell elements, i.e. series combinations of spring and dash-pot.

2.2.2. The cohesive zone model

The constitutive response for the cohesive surface is modeled in terms of the relationship between the traction and the displacement jump across the surface. The traction-separation law (TSL) is a physically based or a phenomenological model that can be obtained from a free energy density function, ϕ, as

$$\mathbf{T} = \mathbf{T}(\boldsymbol{\Delta}) = \frac{\partial\phi}{\partial\boldsymbol{\Delta}}, \tag{10}$$

where $\mathbf{T}$ is a first Piola-Kirchhoff traction vector, and $\boldsymbol{\Delta}$ is the displacement jump vector between two initially coincident points which are defined in three different directions the normal (n) direction, and the two shear directions (s and t) with respect to the cohesive surface.

In this work, a bilinear traction-separation law is used, and only the opening mode fracture (mode I) is considered. For this reason, only the constitutive behavior in the normal direction is controlled, see Fig. 3. The material parameters of the bilinear traction-separation law are K_{n} (the initial elastic

or penalty stiffness), $\delta_{\mathrm{n}}^{\mathrm{c}}$ (the critical normal separation), $\delta_{\mathrm{n}}^{\mathrm{f}}$ (the failure separation), and σ_{c} (the cohesive strength in the normal direction).

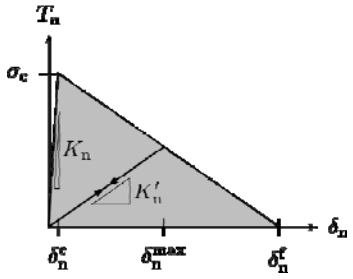


Figure 3. The bilinear traction-separation law

The cohesive element behavior in ABAQUS [14] is based on the characterization of the damage process as the degradation of the material stiffness. The initial behavior is assumed to be linear elastic and is active until damage is initiated. When damage is initiated, the material stiffness decreases and the rate of degradation is defined by the damage evolution law. A scalar damage variable, d, that determines the stiffness degradation, is used, which evolves monotonically from 0 to 1, i.e. from an undamaged to a fully damaged state. The irreversible bilinear traction-separation law is then written as

$$T_{\mathrm{n}} = \begin{cases} K_{\mathrm{n}}\delta_{\mathrm{n}} & \text{if } \delta_{\mathrm{n}} \le \delta_{\mathrm{n}}^{\mathrm{c}}, \\ (1-d)\cdot K_{\mathrm{n}}\delta_{\mathrm{n}} & \text{if } \delta_{\mathrm{n}} \ge \delta_{\mathrm{n}}^{\mathrm{c}}, \end{cases} \tag{11}$$

where the linear elastic unloading behavior after damage onset is determined by the degraded stiffness $K_{\mathrm{n}}' = (1-d)\cdot K_{\mathrm{n}}$. The damage variable, d, for linear softening is determined as

$$d = \frac{\delta_{\mathrm{n}}^{\mathrm{f}}\left(\delta_{\mathrm{n}}^{\max} - \delta_{\mathrm{n}}^{\mathrm{c}}\right)}{\delta_{\mathrm{n}}^{\max}\left(\delta_{\mathrm{n}}^{\mathrm{f}} - \delta_{\mathrm{n}}^{\mathrm{c}}\right)}, \tag{12}$$

where $\delta_{\mathrm{n}}^{\max}$ is the maximum value of the displacement attained during the loading history, see Fig. 3. A maximum nominal stress criterion is used to predict damage initiation, i.e. damage is assumed to be initiated when the maximum nominal stress reaches a critical level $T_{\mathrm{n}} \ge \sigma_{\mathrm{c}}$.

3. Numerical analysis

3.1 Estimation of material parameters

A carbon-black-filled natural rubber material is considered here and its physical and chemical properties are illustrated in [5, 10]. This material has been studied extensively [5-7].

Experimental data from a uniaxial tensile test for the carbon-black filled natural rubber [3] has been used to estimate the parameters in the Ogden strain energy function. The Cauchy (true) stress, σ, in the uniaxial test is defined by

$$\sigma = \sum_{p=1}^{M} \mu_p \left(\lambda^{\alpha_p} - \lambda^{-(1/2)\alpha_p}\right), \tag{13}$$

where λ is the stretch in the uniaxial tension direction. Using a nonlinear least squares method, the Cauchy stress in Eq. (13) is fitted to the uniaxial tension data and two sets of parameters are found to be sufficient, see Fig. 3. The parameter values are shown in Table 1.

Table 1. The Ogden strain energy function parameters ($M = 2$)

p	μ_p [MPa]	α_p [-]
1	1.639	2.724
2	0.088	0.004

Free retraction test experimental data [5] is used to estimate the model parameters in the

viscoelasticity model. Maxwell model with one element has been used, i.e. $N=1$. The relaxation time for rubber is experimentally found to be of the order of $1.0\,\mathrm{s}$ at ambient temperatures [19, 26], and therefore we assumed a relaxation time of $\tau_1 = 1.0\,\mathrm{s}$. (The viscoelastic response of the rubber material is much slower than the rapid processes that we are considering in the present dynamic crack propagation analysis, so the exact value of τ_1 is irrelevant.) The associated relative stiffness, g_1^P, then has to be determined from the experimental data from the retraction tests.

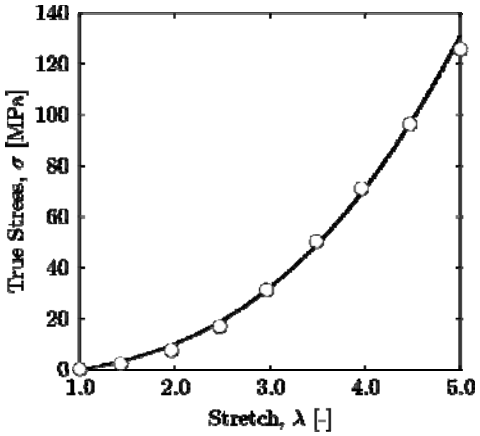

Figure 4. Comparison between the uniaxial true stress-stretch data ('∘') [5] and Ogden material model ($M=2$)

In the free retraction experiment, we consider a thin rectangular strip of rubber with initial dimensions $L_1 = 250\,\mathrm{mm}$, $L_2 = 10\,\mathrm{mm}$ and $L_3 = 0.5\,\mathrm{mm}$, see Fig. 5a (i). The strip is stretched quasi-statically to a certain stretch, λ_0, and then one end is released as shown in Fig. 5a (ii). Consequently, the released end undergoes retraction at a relatively high speed which depends on the initially imposed stretch as well as the material parameters.

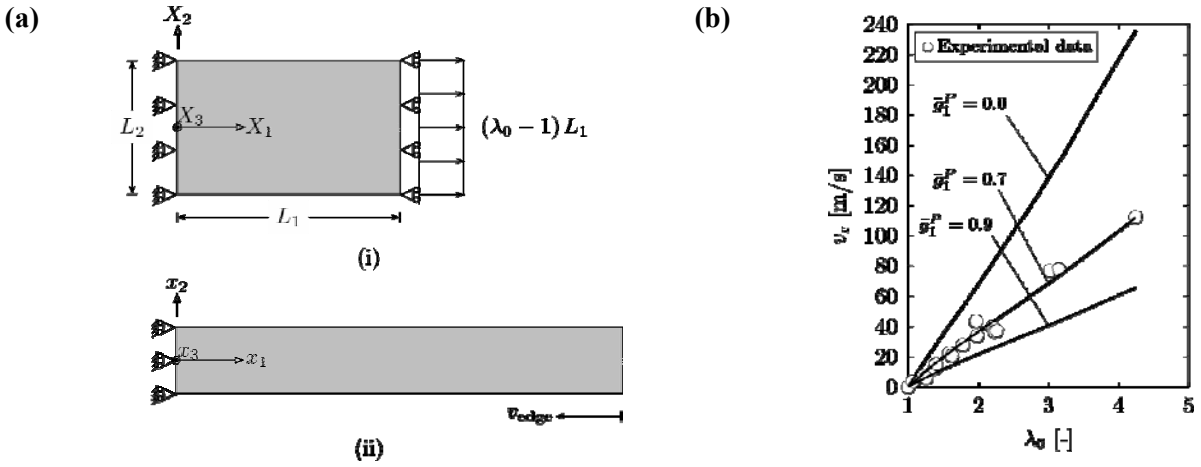

Figure 5. The free retraction experiment: **a** the geometry of the rubber specimen used in the free retraction experiments (i) the reference configuration; and (ii) the current configuration; **b** the predicted retraction speeds for different viscoelastic properties compared with the experimental data [7]. The dashed, full, and dotted lines represent different values of the relative stiffness ($g_1^P = 0.0, 0.7,$ and 0.9), respectively.

The initial-boundary value problem for the free retraction experiment is analyzed using a two-dimensional plane stress finite element model. A nonlinear dynamic analysis, using an implicit time integration scheme, is performed using the finite element code ABAQUS [14], and the free edge steady retraction velocity, v_r, is computed and fitted to the data from the retraction velocity tests, see Fig. 5(b) using different values of the relative stiffness, g_1^P. The parameter values obtained for the Maxwell model are shown in Table 2 below.

Table 2. Prony series coefficients

i	$\bar{g}_i^p$	τ_i
1	0.7	1.0

3.2 Numerical implementation

The initial-boundary value problem described in Sec. 2 is numerically solved using the finite element code ABAQUS [14]. A nonlinear quasi-static analysis is used for the initial loading, and a nonlinear dynamic analysis, using implicit time integration, is used for the crack propagation analysis.

The rubber material is modeled using finite-strain viscoelasticity as described in Sec. 2.2.1 and the material parameters in Tables 1 and 2 are used.

The fracture separation process is modeled using the cohesive zone model that is described in Sec. 2.2.2. The cohesive zone parameters, the cohesive strength and cohesive energy, are material parameters that determine the length of the process zone together with the other material properties [3, 17]. They are not easily measurable, and they are often estimated using experimental data of a known problem setup. The cohesive strength is directly related to the tensile strength of the material while the cohesive energy may be estimated on the basis of fracture mechanics experiments as the work needed for fracture. However, in such estimates, both the actual surface energy and additional dissipative work are included. In this work the cohesive energy is equal is assumed to be total fracture energy. The cohesive strength is chosen to be $\sigma_c = 30\,\text{MPa}$ and then the experimental data are fitted using variable fracture energy.

A high value of the initial stiffness K_n is often assumed in order to avoid ill-conditioning and to reduce the changes of the structure compliance due to the presence of the compliance of the cohesive elements. Therefore, the initial stiffness is assumed to be $K_n = 2.67\times10^6\,\text{MPa}$ such that a stiff behavior is obtained prior to damage initiation without risking the numerical instabilities.

The geometry of the thin rectangular sheet in Fig. 2 is discretized, and a typical finite element mesh is shown in Fig. 6. Due to symmetry, only one half of the specimen is analyzed. The initial dimensions are taken as $W_0 = 75\,\text{mm}$, $H_0 = 5\,\text{mm}$, and $B_0 = 0.5\,\text{mm}$ [6]. The initial crack is assumed to be $2a_0 = 10\,\text{mm}$, and the crack propagation is studied over a length of $\Delta a = 50\,\text{mm}$. Note that Δa pertains to the deformed configuration, while Δa_0 pertains to the reference configuration. The 4-node bilinear plane stress element CPS4 and 4-node two-dimensional linear cohesive element COH2D4 are used in the discretisation. The cohesive elements are inserted along the crack propagation path, i.e. along $X_2 = 0$, and the bulk elements are defined elsewhere. The top and bottom faces of the cohesive elements are tied to the adjacent bulk plane stress elements, implying that three cohesive elements are attached to two bulk elements, see Fig. 6b. The cohesive elements are modeled with zero initial thickness in the reference configuration, and consequently the top and bottom faces and nodes coincide. The mesh comprises 27207 elements, of which 25506 are bulk elements and 1701 are cohesive elements. A cohesive element length of $l_{ce} = 0.025\,\text{mm}$ is used.

The element death/birth technique is adopted to model crack initiation. The initial crack domain is discetized using cohesive elements, and therefore they have been removed at the instant of crack initiation, i.e. at $t = 0$.

The problem is solved for different values of the initial stretching, i.e. $\lambda = [2.0, 4.0]$. The relative normal separation displacement, Δu_2, between each pair of initially coincident nodes in the interface ($X_2 = 0$) is computed and recorded during the analysis. The crack tip position, x_{tip}, is

defined by $\Delta u_2 = \delta_{\mathrm{n}}^{\mathrm{c}}$, and the crack tip velocity is determined using forward differencing of Eq. (14) of the smoothed cohesive crack tip position data, $\bar{x}_{\mathrm{tip}}$, (using Savitzky-Golay smoothing filter).

$$v_{\mathrm{tip}}^{n} = \frac{\bar{x}_{\mathrm{tip}}^{n+1} - \bar{x}_{\mathrm{tip}}^{n}}{\Delta t_n}, \tag{14}$$

where indices n and $n+1$ denote variable values at time instants t_n and t_{n+1}, respectively, and $\Delta t_n = t_{n+1} - t_n$ is the time increment. Further, the steady crack velocity, v_{c}, is computed by taking the average velocity over the steady propagation period.

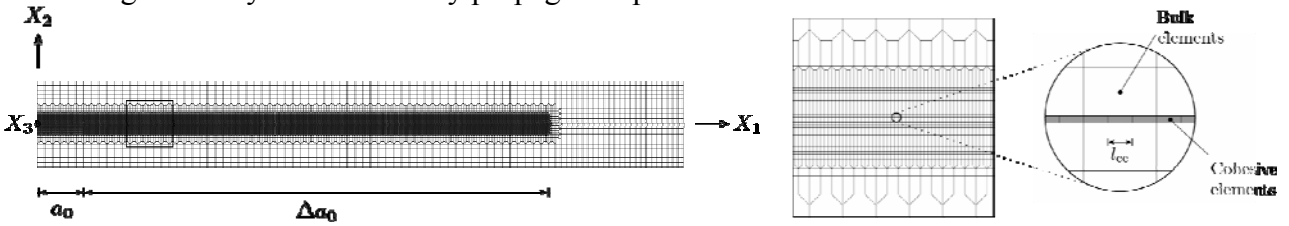

Figure 6. The finite element mesh of the thin rectangular sheet of rubber: **a** the mesh of the whole geometry; and **b** mesh details along the middle of the sheet where the cohesive elements are inserted along the crack propagation path

3.3 Numerical results

Several analyses have been performed for different combinations of stretch and cohesive zone properties. The cohesive crack tip position and velocity, as well as the steady crack propagation velocity, have been obtained for all the combinations.

Typical crack propagation results, including the cohesive crack tip position and velocity results, are shown in Figs. 8a and 8b. At $t = 0$, the crack is initiated such that it propagates immediately after the initiation, i.e. typically within less than $1\,\mathrm{ms}$, at low velocity and continues propagating with a slow acceleration, see in Fig. 8b. After approximately $1.5\,\mathrm{ms}$, the crack velocity approaches a transition region wherein the crack starts to accelerate rapidly and the velocity increases to high velocity levels. Then, after about $1.83\,\mathrm{ms}$, the crack tip velocity reaches a plateau region, where steady crack propagation occurs. Different cohesive properties virtually yield the same type of behavior. Stationary crack propagation was obtained for all sets of cohesive properties, provided that the crack was able to get started. There was a threshold stretch, λ_{th}, below which the initial crack was immediately arrested and no propagation occurred.

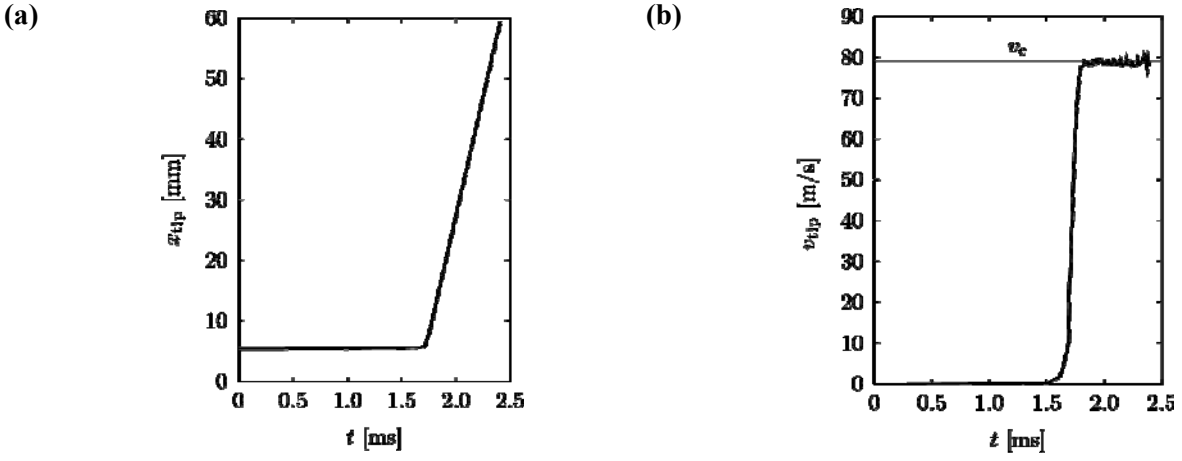

Figure 8. Crack propagation results for $\lambda = 4.0$, $\sigma_{\mathrm{c}} = 60\,\mathrm{MPa}$ and $G_{\mathrm{Ic}} = 20\,\mathrm{KJ/m^2}$: **a** crack tip position x_{tip} vs time t; and **b** crack tip velocity v_{tip} vs time t.

The numerical predictions of the steady crack propagation velocity are compared with the experimental data [6], as shown in Fig. 9. The numerical threshold stretch differs for the different cohesive properties, such that its minimum value, $\lambda_{th} = 3.0$, occurs for $\sigma_c = 60\,\text{MPa}$ and $G_{Ic} = 20\,\text{KJ/m}^2$. For low stretches, the model clearly overestimates the crack speeds from the experimental data. However, by using different cohesive properties, the numerical model is able to predict the crack speeds from the experiments, at least in the high stretch regime ($\lambda \geq 3.5$).

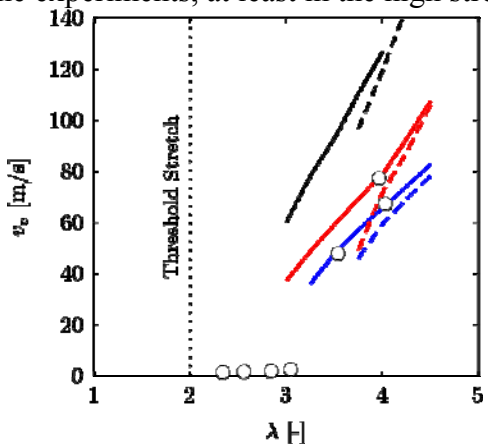

Figure 9. Comparison between numerical predictions of the steady crack propagation velocity and experimental data ('o') [4]. The black, red and blue lines indicate simulations with the cohesive strengths 30,60,90 MPa , respectively, and the full and dashed lines indicate simulations with cohesive energies 20,40 KJ/m^2, respectively.

4. Discussion and concluding remarks

In the present analysis, the contribution from viscoelastic dissipation in the bulk material to the total work of fracture is negligible. This is due to the fact that the crack propagation process is very rapid in comparison with the relaxation time of the rubber material.

In the analyses, the main properties of the cohesive law, i.e. the cohesive energy and the cohesive strength, were varied to enable a prediction of the experimentally obtained crack speeds. The analyses indicate that the effective fracture energy of the rubber material at hand is to be found roughly in the range $20-40\,\text{KJ/m}^2$, and the cohesive strength is expected to be approximately $30-90\,\text{MPa}$. We emphasize that this estimate of the fracture energy should not be taken as the actual surface energy required to create new crack surface at the very crack tip. Rather, this estimate should be taken as a value that contains the actual surface energy but also significant amounts of dissipation associated with damage processes in the vicinity of the crack tip. Strictly speaking, this would be dissipation that takes place in the bulk material surrounding the crack tip, which is not really accounted for by the continuum viscoelasticity model adopted for the bulk behavior.

Few experimental investigations have been concerned with characterization of high speed fracture of rubber, in which crack speed variation with fracture toughness has been experimentally measured under high strain or loading rate. Typical fracture toughness has been reported to be in the range $7-300\,\text{KJ/m}^2$ for the crack speed in the range $0.5-30\,\text{m/s}$ using pure shear and tensile strip specimens [12, 24]. It is also shown that a low fracture toughness of $30\,\text{KJ/m}^2$ can be measured at a crack speed of $30\,\text{m/s}$. Thus, the effective fracture energy reported in the literature shows good agreement with the values attained here.

Abstract A unit cell is adopted to numerically analyze the effect of plastic anisotropy on fracture evolution in a micro-reinforced fiber-composite. The matrix material exhibit size-effects and an anisotropic strain-gradient plasticity model accounting for such size-effects through a material length scale parameter is adopted. The fracture process along the fiber-matrix interface is modeled using a recently proposed cohesive law extension having an additional material length parameter. Due to the fiber-matrix fracture a sudden stress-drop is seen in the macroscopic stress-strain response which defines the failure strain of the composite. The effect of the two material length parameters on the failure strain of the composite is studied. For small values of the material length scale parameter conventional predictions are obtained. Larger values of the material length scale parameter result in corresponding larger failure strains, but only up to a material length scale parameter approximately equal to 15% of the reinforcement size. At this point, the failure strain becomes smaller again for further increasing values of the material length scale. It is shown that the cohesive length parameter monotonically affects the failure strain as a decreasing failure strain is predicted for smaller value of the material parameter.

Keywords Composite Materials, Strain-gradient plasticity, Debonding, Failure strain

1. Introduction

Failure mechanisms of fiber-reinforced composite materials are still a challenging topic due to the large number of failure modes compared to conventional homogeneous materials[1]. A unidirectional fiber-composite subjected to transverse tensile loading often fail by either matrix damage or microcracks evolving at the fiber-matrix interfaces. For longitudinal loading the most often seen failure modes are matrix and fiber cracking.

For a composite reinforced at the micron scale, two competing mechanisms affect the overall behavior: (I) interfacial failure reduces the strength and (II) strain-gradient effects enhance the strength. When analyzing such composites in general a full 3D analysis is required in order to fully represent the geometry, the loading and the boundary conditions. Such analyses are complicated and the computations become very time consuming when anisotropic plasticity and progressive debonding is to be accounted for. Thus, assuming a periodical distribution of the reinforcement allows for greatly simplified approaches.

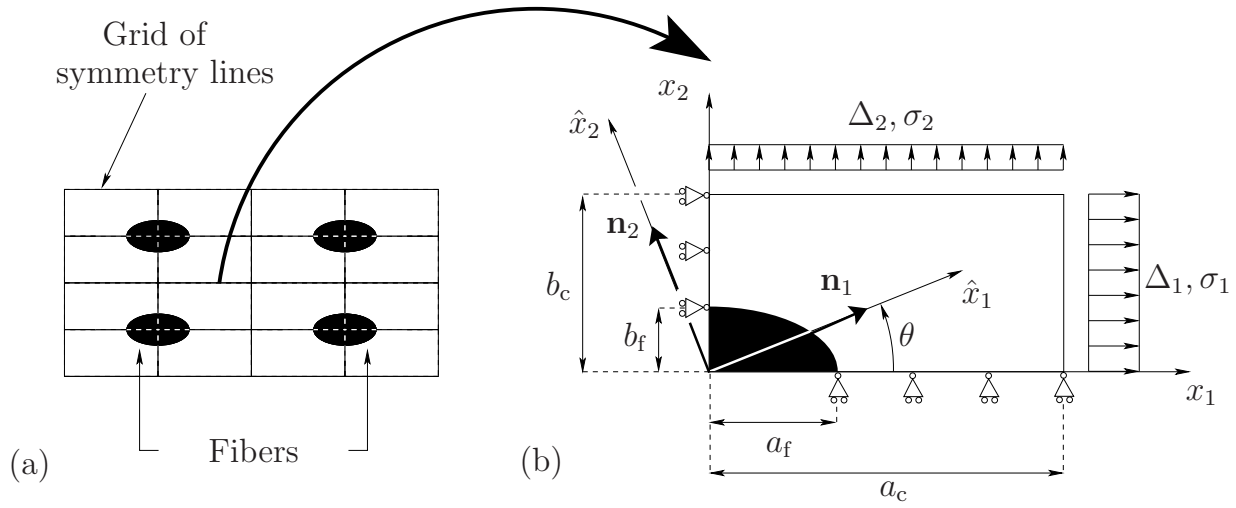

Figure 1. The plane strain cell model for the composite. (a) Periodically distributed fibers. (b) The cell used for modeling with initial dimensions, loads, supports and coordinate systems.

Here, a composite material having a periodical distribution of reinforcement is analyzed using a plane strain unit cell approach. Thus, the results presented in this study approximate a composite of rather long, almost aligned, stiff reinforcement which is subjected to a fixed stress state that is acting mainly in the transverse direction of the reinforcement. Fig. 1(a) shows the distribution of fibers and Fig. 1(b) shows the unit cell adopted here. The orthonormal basis, $\mathbf{n}_i$, of the principal axes of plastic anisotropy, $\hat{x}_i$, is defined by the angle θ, from from the global Cartesian coordinate system, x_i. The applied conventional boundary conditions are

$$\begin{array}{llllllll} \dot{u}_1 = 0, & \dot{T}_2 = 0 & \text{on} & x_1 = 0 & \text{and} & \dot{u}_1 = \Delta_1, & \dot{T}_2 = 0 & \text{on} \quad x_1 = a_c \\ \dot{u}_2 = 0, & \dot{T}_1 = 0 & \text{on} & x_2 = 0 & \text{and} & \dot{u}_2 = \Delta_2, & \dot{T}_1 = 0 & \text{on} \quad x_2 = b_c \end{array} \tag{1}$$

where u_i are the displacement components, Δ_1 and Δ_2 are displacement increment quantities on two sides of the cell, which are calculated such that the ratio of the average true stresses σ_2 and σ_1 remains fixed, $\sigma_2/\sigma_1 = \kappa$. These stresses are calculated as

$$\begin{aligned} \sigma_1 &= \tfrac{1}{b_c+\Delta b_c} \int_0^{b_c+\Delta b_c} [T_1]_{x_1=a_c+\Delta a_c}\, dx_2 \\ \sigma_2 &= \tfrac{1}{a_c+\Delta a_c} \int_0^{a_c+\Delta a_c} [T_2]_{x_2=b_c+\Delta b_c}\, dx_1 \end{aligned} \tag{2}$$

Here Δa_c and Δb_c denote the accumulated elongations of the cell sides whereas T_1 and T_2 are normal tractions. The corresponding average logarithmic strains are

$$\begin{aligned} \epsilon_1 &= \ln(1 + \Delta a_c/a_c) \\ \epsilon_2 &= \ln(1 + \Delta b_c/b_c) \end{aligned} \tag{3}$$

In this study, a micro-crack evolving at the fiber-matrix interfaces is analyzed for a two-phase composite material, where the matrix material exhibits size-effects. The higher-order strain-gradient plasticity model of Fleck and Hutchinson accounts for such size-effects and will be adopted here in the anisoropic version proposed by Legarth [2,3]. In this model a higher-order stress work-conjugate to the gradient of the effective plastic strain is introduced together with a material length scale parameter. The reinforcement is assumed to be much stiffer than the matrix material and will therefore be considered as perfectly stiff. As dislocations cannot penetrate into the perfectly elastic fiber they pile up

at the interface which corresponds to zero plastic deformations. Thus, zero plastic strain is imposed at the bonded part of the interface. This is known a higher-order boundary conditions. The fracture process along the fiber-matrix interface is modelled using a recently proposed cohesive law extension[4]. Hence, plasticity will affect the fracture process as both the average as well as the jump in plastic strain across the fiber-matrix interface are taking into account in this cohesive law. Using this extended cohesive law ensures stress-free crack faces after failure. The formulation used here only demands one additional interfacial cohesive zone parameter.

2. Material models

The material model used accounts for small elastic and finite plastic strain in an updated Lagrangian formulation in which the current configuration is taken as the reference configuration, i.e. $J = 1$ but $\dot{J} = \dot{\epsilon}_{kk}$ when J is the determinant of the metric tensor and the superposed dot denotes the time rate.

2.1 Higher order elasto-plastic constitutive model

The fibers are assumed to be purely elastic with a stiffness much larger than the elasto-plastic matrix material, which is assumed to obey the strain gradient model proposed by Fleck and Hutchinson [2]. Denoting the velocity field $\dot{u}_i$ the components of the second-order velocity gradient tensor, $\dot{e}_{ij}$, are determined by $\dot{e}_{ij} = \dot{u}_{i,j}$. The symmetric part of $\dot{e}_{ij}$ is the strain rate, $\dot{\epsilon}_{ij}$, and the antisymmetric part is the continuum spin tensor, $\dot{\omega}_{ij}$. Following the multiplicative decomposition of the deformation gradient into an elastic and a plastic part the kinematics of the material can be written as

$$\begin{aligned} \dot{\epsilon}_{ij} &= \tfrac{1}{2}(\dot{e}_{ij} + \dot{e}_{ji}) = \dot{\epsilon}^{\mathrm{e}}_{ij} + \dot{\epsilon}^{\mathrm{P}}_{ij} \\ \dot{\omega}_{ij} &= \tfrac{1}{2}(\dot{e}_{ij} - \dot{e}_{ji}) \end{aligned} \tag{4}$$

with $\dot{e}_{ij} = \dot{\epsilon}_{ij} + \dot{\omega}_{ij}$ and e and p denote the elastic and the plastic parts, respectively.

Plastic anisotropy is accounted for using the anisotropic version of the Fleck and Hutchinson model as suggested by Legarth [3]. Thus, the effective plastic strain, $\dot{E}^p$, is enriched by the gradients of the conventional effective plastic strain, $\dot{\epsilon}^{\,p}_{,i}$, and a material length scale parameter, l_*, as

$$\dot{E}^p = \sqrt{\frac{2}{3}\dot{\epsilon}^p_{ij}\dot{\epsilon}^p_{ij} + l_*^2\dot{\epsilon}^{\,p}_{,i}\,\dot{\epsilon}^{\,p}_{,i}} \qquad ; \qquad \dot{\epsilon}^p_{ij} = \dot{\epsilon}^p N^p_{ij} = \dot{\epsilon}^p \frac{\partial \Gamma}{\partial \sigma_{ij}} \qquad ; \qquad \dot{\epsilon}^p = \sqrt{\frac{2}{3}\dot{\epsilon}^p_{ij}\dot{\epsilon}^p_{ij}} \tag{5}$$

The work-conjugate effective stress is denoted σ_c and is given in Tab. 1 for the four posible cases of isotropy or anisotropy with and without strain gradient effects. Plastic anisotropy enters through the effective stress measure Γ whereas the higher-order stress, ρ_i, relates to the strain-gradient effects as the work-conjugate stress quantity to the gradient of the plastic strain rate, $\dot{\epsilon}^{\,p}_{,i}$. The work-conjugate stress quantity to the effective plastic strain rate, $\dot{\epsilon}^p$ is denoted q.

Two different anisotropic yield surfaces are adopted here, namely the classical anisotropic Hill yield surface [5] and the more recent non-quadratic proposal by Barlat et al. [6], here denoted Hill-48 and Barlat-91, respectively.

Table 1. Summary of the effective stress, σ_c, for different materials.

	Conventional materials $(l_* = 0, \rho_i = 0)$	Higher order materials $(l_* \neq 0, \rho_i \neq 0)$
Isotropic	$\rho_{i,i} = 0$	$\rho_{i,i} = q - \sigma_e$
$(\Gamma = \sigma_e)$	$\sigma_c = \sigma_e$	$\sigma_c = \sqrt{(\sigma_e + \rho_{i,i})^2 + l_*^{-2}\rho_i\rho_i}$
Anisotropic	$\rho_{i,i} = 0$	$\rho_{i,i} = q - \Gamma$
	$\sigma_c = \Gamma$	$\sigma_c = \sqrt{(\Gamma + \rho_{i,i})^2 + l_*^{-2}\rho_i\rho_i}$

Hill-48

For the case of plane strain conditions with $\sigma_{13} = \sigma_{23} = 0$ the yield surface of Hill is

$$\Gamma = \sqrt{\tfrac{3}{2(F+G+H)}\left[F(\hat{\sigma}_{22} - \hat{\sigma}_{33})^2 + G(\hat{\sigma}_{33} - \hat{\sigma}_{11})^2 + H(\hat{\sigma}_{11} - \hat{\sigma}_{22})^2 + 2N\hat{\sigma}_{12}^2\right]} \tag{6}$$

The Cauchy stresses, $\hat{\sigma}_{ij}$, refer to the principal axes of plastic anisotropy. For $F = G = H = 1$ and $N = L = M = 3$, Eq. (6) equals the isotropic Mises yield surface, σ_e.

Barlat-91

Barlat et al. [5] proposed the non-quadratic yield function

$$\Gamma \;\; = [S_1 - S_2]^d + [S_2 - S_3]^d + [S_1 - S_3]^d \tag{7}$$

where

$$\begin{aligned} S_1 &= 2\sqrt{I_2}\cos\left(\tfrac{\bar{\theta}}{3}\right) \\ S_2 &= 2\sqrt{I_2}\cos\left(\tfrac{\bar{\theta}-2\pi}{3}\right) \\ S_3 &= 2\sqrt{I_2}\cos\left(\tfrac{\bar{\theta}+2\pi}{3}\right) \end{aligned} \tag{8}$$

$$\begin{aligned} I_2 = \;& \tfrac{1}{3}\left[(\bar{f}\bar{F})^2 + (\bar{g}\bar{G})^2 + (\bar{h}\bar{H})^2\right] \\ & + \tfrac{1}{54}\left[(\bar{a}\bar{A} - \bar{c}\bar{C})^2 + (\bar{c}\bar{C} - \bar{b}\bar{B})^2 + (\bar{b}\bar{B} - \bar{a}\bar{A})^2\right] \\ I_3 = \;& \tfrac{1}{54}\left[(\bar{c}\bar{C} - \bar{b}\bar{B})(\bar{a}\bar{A} - \bar{c}\bar{C})(\bar{b}\bar{B} - \bar{a}\bar{A})\right] + \bar{f}\bar{g}\bar{h}\bar{F}\bar{G}\bar{H} \\ & - \tfrac{1}{6}\left[(\bar{c}\bar{C} - \bar{b}\bar{B})(\bar{f}\bar{F})^2 + (\bar{a}\bar{A} - \bar{c}\bar{C})(\bar{g}\bar{G})^2 + (\bar{b}\bar{B} - \bar{a}\bar{A})(\bar{h}\bar{H})^2\right] \end{aligned} \tag{9}$$

$$0 \leq \bar{\theta} = \arccos\left(\frac{I_3}{I_2^{3/2}}\right) \leq \pi \tag{10}$$

with

$$\begin{aligned} \bar{A} &= \hat{\sigma}_{22} - \hat{\sigma}_{33} \quad ; \quad \bar{F} = \hat{\sigma}_{23} \\ \bar{B} &= \hat{\sigma}_{33} - \hat{\sigma}_{11} \quad ; \quad \bar{G} = \hat{\sigma}_{31} \\ \bar{C} &= \hat{\sigma}_{11} - \hat{\sigma}_{22} \quad ; \quad \bar{H} = \hat{\sigma}_{12} \end{aligned} \tag{11}$$

For $\bar{\theta} = 0$ or $\bar{\theta} = \pi$ in Eq. (10) the derivatives in Eq. (5) are singular. For these particular cases Eq. (7) reduces to

$$\Gamma = 2 \cdot 3^d I_2^{\frac{d}{2}} \qquad \text{for } \bar{\theta} = 0 \quad \text{or} \quad \bar{\theta} = \pi \tag{12}$$

which are then directly used to evaluate the strain increments. If the coefficients of anisotropy, $\bar{a}, \bar{b}, \bar{c}, \bar{f}, \bar{g}$ and $\bar{h}$, are chosen to be unity and the exponent to $d = 2$, this criterion reduces to the von Mises yield surface.

2.2 Higher-order cohesive model

The bi-axial loading on the unit cell, Fig. 1(b), will tend to cause both normal and tangential interfacial separation, u_n and u_t, respectively, at the fiber-matrix interface. The cohesive zone model proposed by Tvergaard[7] takes both types of separation into account and therefore this model may seem suitable for the present study. However, due to the existence of the higher order stress, ρ_i with the corresponding higher order tractions, $\rho_i n_i$ additional terms need to be included in order to have a conventional as well as higher order stress-free surface after debonding failure. Hence, a non-dimensional damage parameter is introduces as[4]

$$\lambda = \sqrt{\left(\frac{u_n}{\delta_n}\right)^2 + \left(\frac{u_t}{\delta_t}\right)^2 + l_*^2\left[\left(\frac{<\epsilon^p>}{l_A}\right)^2 + \left(\frac{[\epsilon^p]}{l_J}\right)^2\right]} \tag{13}$$

where $<\epsilon^p>$ is the average (subscript A) and $[\epsilon^p]$ is the half jump (subscript J) in plastic strain across the interface, respectively, whereas l_A and l_J are corresponding critical interfacial length scale parameters. For $\lambda \geq 1$ total separation have occurred. It is noted, that since the fiber is taken to be purely elastic in this study the average plastic strain across the fiber-matrix interface equals the jump, i.e. $<\epsilon^p>=[\epsilon^p]$. The corresponding tractions are

$$T_n = \frac{u_n}{\delta_n}F(\lambda)\,; \quad T_t = \alpha\frac{u_t}{\delta_t}F(\lambda)\,; \quad T_A = l_*^2\frac{\delta_n}{l_A^2}F(\lambda)<\epsilon^p>\,; \quad T_J = l_*^2\frac{\delta_n}{l_J^2}F(\lambda)[\epsilon^p] \tag{14}$$

with $\alpha = \delta_n/\delta_t$ and $F(\lambda) = \frac{27}{4}\sigma_{max}(1-2\lambda+\lambda^2)$ for $0 \leq \lambda \leq 1$. The maximum interfacial stress is denoted σ_{max}. For the numerical implementation, an incremental version of these tractions can be stated generally as

$$\begin{Bmatrix} \dot{T}_n \\ \dot{T}_t \\ \dot{T}_A \\ \dot{T}_J \end{Bmatrix} = \begin{bmatrix} a_{nn} & a_{nt} & a_{nJ} & a_{nA} \\ a_{tn} & a_{tt} & a_{tJ} & a_{tA} \\ a_{Jn} & a_{Jt} & a_{JJ} & a_{JA} \\ a_{An} & a_{At} & a_{AJ} & a_{AA} \end{bmatrix} \begin{Bmatrix} \dot{u}_n \\ \dot{u}_t \\ [\dot{\epsilon}^p] \\ <\dot{\epsilon}^p> \end{Bmatrix} \tag{15}$$

where the a-coefficients can be found from the cohesive law. Using this higher order cohesive law ensures that the debonded part of the fiber-matrix interface is stress free both in terms of the conventional stress, σ_{ij}, as well as the higher order stress, ρ_i.

3. Computational Method

The problem is solved incrementally by a finite element code based on the principle of virtual work. In the updated Lagrangian formulation the incremental form of the principle of virtual work is, see [3,5]

$$\begin{aligned} &\Delta t\int_V \left(\overset{\triangledown}{\varsigma}_{ij}\,\delta\dot{\epsilon}_{ij} - \sigma_{ij}(2\dot{\epsilon}_{ik}\delta\dot{\epsilon}_{kj} - \dot{e}_{kj}\delta\dot{e}_{ki}) + \left(\dot{q} - \dot{\Gamma}^{\varsigma}\right)\delta\dot{\epsilon}^{\mathrm{P}} + \overset{\vee}{\rho}_i\,\delta\dot{\epsilon}^{\mathrm{P}}_{,i}\right) dV \\ &+\Delta t\int_{S_I}\left(\dot{T}_n\delta\dot{u}_n + \dot{T}_t\delta\dot{u}_t + \dot{p}\delta[\dot{\epsilon}^{\mathrm{P}}] + \dot{q}\delta<\dot{\epsilon}^{\mathrm{P}}>\right) dS = \Delta t\int_S\left(\dot{T}_i\delta\dot{u}_i + \dot{\rho}_i n_i\delta\dot{\epsilon}^{\mathrm{P}}\right) dS \end{aligned} \tag{16}$$

Here, Δt is the time step, V the volume, $\overset{\triangledown}{\varsigma}_{ij}$ denotes the Jaumann rate of the Kirchhoff stress with $\dot{\Gamma}^{\varsigma} = N_{ij}^{\mathrm{P}}\,\overset{\triangledown}{\varsigma}_{ij}$ and $T_i = \sigma_{ij}n_j$ are the surface tractions on the surface S with

the unit outward normal n_i. Due to the updated Lagrangian formulation all integrations are carried out in the current deformed configuration. The Jaumann rate of the Kirchhoff stress entering the virtual work principle is

$$\overset{\triangledown}{\varsigma}_{ij}\,\Delta t = R_{ijkl}\left(\Delta\epsilon_{kl} - N^{\mathrm{P}}_{kl}\Delta\epsilon^{\mathrm{P}}\right) = \Delta\varsigma_{ij} - \Delta\omega_{ik}\sigma_{kj} - \sigma_{ik}\Delta\omega_{jk} \tag{17}$$

where R_{ijkl} are the isotropic elastic moduli determined by Young's modulus, E, Poisson's ratio, ν, and Kronecker's delta, δ_{ij}, as

$$R_{ijkl} = \frac{E}{1+\nu}\left(\frac{1}{2}(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}) + \frac{\nu}{1-2\nu}\delta_{ij}\delta_{kl}\right) \tag{18}$$

The finite element procedure adopted here follows the method used by de Borst and Pamin[8] for time-independent plasticity and Borg et al.[9] for viscoplasticity, where both the conventional displacement increments, $\mathbf{\Delta D}$, as well as the increments of the effective plastic strain rates, $\mathbf{\Delta}\dot{\epsilon}^{\mathrm{P}}$, appear as unknowns. However, they solved for $\mathbf{\Delta D}$ and $\mathbf{\Delta}\dot{\epsilon}^{\mathrm{P}}$ simultaneously, even though the system of equations decouples. Here, the numerical solution is obtained by decoupling the equations. In doing so, the stiffness matrices become symmetric, less sparse and more well conditioned, leading to a significantly improved computational time. Thus, the equations to solve are

$$\mathrm{K_e}\mathbf{\Delta}\mathrm{D} = \mathbf{\Delta}\mathrm{F}_1 + \mathbf{\Delta}\mathrm{F}_{1\mathrm{c}} \tag{19}$$

for the displacement increments and

$$\mathrm{K_p}\mathbf{\Delta}\dot{\epsilon}^{\mathrm{P}} = \mathbf{\Delta}\mathrm{F}_2 + \mathbf{\Delta}\mathrm{F}_{2c} \tag{20}$$

for the increments of the conventional effective plastic strain rate. Here 8 node isoparametric elements are used for both the displacements as well as the plastic strain field using the shape functions N and M, respectively, within the bulk material. Thus, the field of total strains within an element is bi-linear whereas the plastic strains vary parabolically. The local stiffness matrices and load vectors are

$$\begin{aligned}
\mathrm{K_e}^{NM} = \;& \int_V \left(E^N_{ij} R_{ijkl} E^M_{kl} + \sigma_{ij}\left(N^M_{k,j}N^N_{k,i} - 2E^M_{ik}E^N_{jk}\right)\right)\mathrm{d}V + \\
& \int_{S_I}\left(\{a_{nn}(Q^N_i n_i) + a_{nt}(Q^N_i t_i)\}(Q^M_i n_i) + \right. \\
& \left.\{a_{tn}(Q^N_i n_i) + a_{tt}(Q^N_i t_i)\}(Q^M_i t_i)\right)\mathrm{d}S
\end{aligned} \tag{21}$$

$$\begin{aligned}
\mathrm{K_P}^{NM} = \;& \int_V \left(\left(\tfrac{\dot{\epsilon}^{\mathrm{P}}}{\dot{E}^{\mathrm{P}2}}(m-1)q + \tfrac{\sigma_{\mathrm{c}}}{\dot{E}^{\mathrm{P}}}\right) M^M M^N \right. \\
& + l^2_* \tfrac{\dot{\epsilon}^{\mathrm{P}}_{,i}}{\dot{E}^{\mathrm{P}2}} q M^M M^N_{,i} + \tfrac{\dot{\epsilon}^{\mathrm{P}}}{\dot{E}^{\mathrm{P}2}}(m-1)\rho_i M^M_{,i} M^N \\
& \left. + l^2_* \tfrac{\dot{\epsilon}^{\mathrm{P}}_{,i}}{\dot{E}^{\mathrm{P}2}}\rho_k M^M_{,k} M^N_{,i} + \tfrac{\sigma_{\mathrm{c}}}{\dot{E}^{\mathrm{P}}} M^M_{,i} M^N_{,i}\right)\mathrm{d}V
\end{aligned} \tag{22}$$

$$\mathbf{\Delta}\mathrm{F}_1{}^N = \int_S \Delta T_i N^N_i \mathrm{d}S + \Delta t \int_V E^N_{ij} R_{ijkl} N^{\mathrm{P}}_{kl} \dot{\epsilon}^{\mathrm{P}} \mathrm{d}V \tag{23}$$

$$\begin{aligned}
\mathbf{\Delta}\mathrm{F}_2{}^N = \;& \int_S \Delta\rho_i n_i M^N \mathrm{d}S - \Delta t \int_V \left(\left(N^{\mathrm{P}}_{ij} R_{ijkl}(N^{\mathrm{P}}_{kl}\dot{\epsilon}^{\mathrm{P}} - \dot{\epsilon}_{kl})\right.\right. \\
& \left.\left. + \tfrac{\dot{\epsilon}^{\mathrm{P}}}{\dot{\epsilon}^m_0}\dot{E}^{\mathrm{P}m}\tfrac{\mathrm{d}g}{\mathrm{d}E^{\mathrm{P}}}\right) M^N + \dot{\epsilon}^{\mathrm{P}}_{,i}\,\dot{E}^{\mathrm{P}m}\tfrac{\mathrm{d}g}{\mathrm{d}E^{\mathrm{P}}}\tfrac{l^2_*}{\dot{\epsilon}^m_0} M^N_{,i}\right)\mathrm{d}V
\end{aligned} \tag{24}$$

where $E_{ij} = \frac{1}{2}\left(N_{i,j} + N_{j,i}\right)$ and m is the rate sensitivity parameter. The additional load vectors $\Delta\mathrm{F}_{1c}$ and $\Delta\mathrm{F}_{2c}$ resulting from the higher order cohesive zone are

$$\begin{aligned}
\mathbf{\Delta}\mathrm{F}_{1c}{}^N = \;& -\Delta t \int_{S_I}\left(\{a_{nJ}[\dot{\epsilon}^p] + a_{nA} < \dot{\epsilon}^p >\}(Q^N_i n_i) \quad + \right. \\
& \left.\{a_{tJ}[\dot{\epsilon}^p] + a_{tA} < \dot{\epsilon}^p >\}(Q^N_i t_i)\right)\mathrm{d}S
\end{aligned} \tag{25}$$

$$\begin{aligned}
\mathbf{\Delta}\mathrm{F}_{2c}{}^N = \;& -\Delta t \int_{S_I}\left(a_{Jn}\dot{u}_n + a_{Jt}\dot{u}_t + a_{JJ}[\dot{\epsilon}^p] + a_{JA} < \dot{\epsilon}^p > \quad + \right. \\
& \left. a_{An}\dot{u}_n + a_{At}\dot{u}_t + a_{AJ}[\dot{\epsilon}^p] + a_{AA} < \dot{\epsilon}^p >\right) R^N \mathrm{d}S
\end{aligned} \tag{26}$$

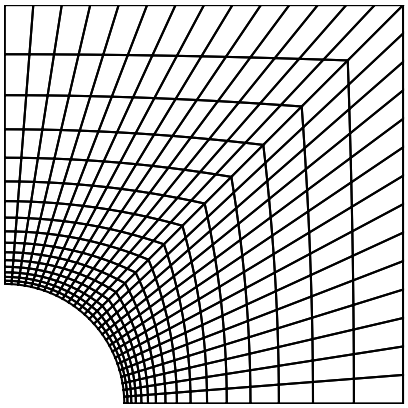

Figure 2. Example of mesh adopted.

Here, 6 node isoparametric elements with the shape functions Q and R for the displacement field and the plastic strain field, respectively, are used for the cohesive zone where the normal and tangential unit vectors are introduced as n_i and t_i, respectively. It noted that the incremental cohesive tractions, Eq. (15), depends on the rates of the displacement and the plastic strain, whereas the solution procedure outlined here solves for the rates of the displacement and the plastic strain increments, meaning that the higher order contributions from the cohesive law only enters through the load vectors, $\Delta \mathrm{F}_{1c}$ and $\Delta \mathrm{F}_{2c}$. The conventional part of the cohesive law also gives an stiffness contribution, Eq. (21). An example of a mesh used is shown in Fig. 2 for $\frac{a_f}{b_f} = \frac{a_c}{b_c} = 1$.

4. Results

Fig. 3 shows results for a load case with $\kappa = \frac{\sigma_2}{\sigma_1} = 0.5$ corresponding to bi-axial plane strain tension. The fiber volume fraction is $V_f = \frac{\pi a_f b_f}{4 a_c b_c}$, with $\frac{a_f}{b_f} = \frac{a_c}{b_c} = 1$. The initial yield stress is $\sigma_0/E = 0.003$, where E is Young's modulus. The coefficients of anisotropy using Hill-48 are $F = 0.7, G = 3.33, H = 1$ and $N = 9.6$ with $\theta = 0^o$ and $\sigma_{max} = 3\sigma_0$.

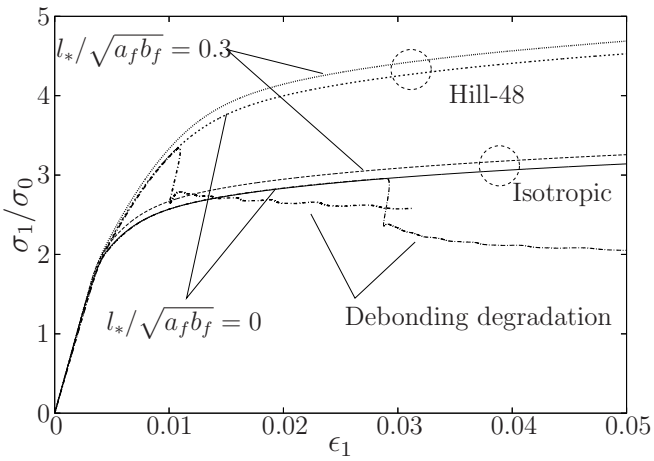

Figure 3. Bi-axial tension results, $\kappa = 0.5$, for isotropy and Hill-48 anisotropy. (a) Average stress-strain curves, Eqs. (2) and (3). (b) Contours of effective plastic strain for a conventional anisotropic material with debonding (c) Contours of effective plastic strain for a higher order anisotropic material without debonding.

For both isotropic and anisotropic behavior the effect of the material length scale parameter, l_*, is an increased load carrying capacity. A sudden stress drop occurs due to debonding which defines the failure strain of the composite, ϵ^f. In Fig. 4 this failure strain is plottet as function of the normalized material length scale parameter of the matrix material, $l_*/\sqrt{a_f b_f}$. It is seen, that the failure strain, ϵ^f, does not vary monotonically by the material length scale parameter, l_*, but reaches a maximum approximately for $l_*/\sqrt{a_f b_f} = 0.15$.

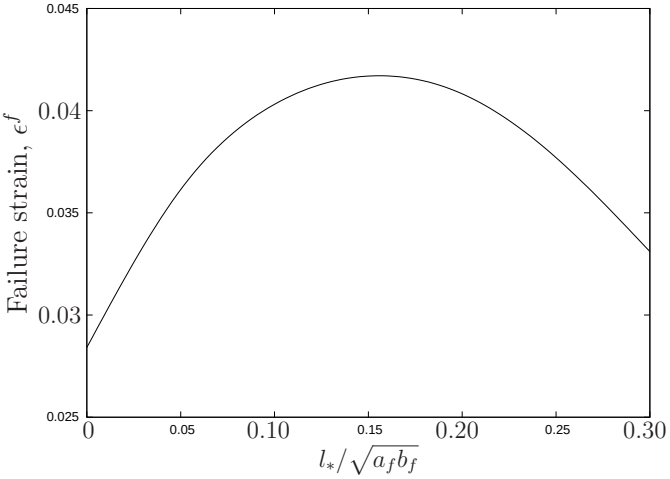

Figure 4. The failure strain as function of the material length scale parameter, l_*, normalized against the fiber radius, R. Isotropic results are shown for $\kappa = 0.5$.

On the other hand, a monotonic effect on the failure strain is found when studying the influence of the length scale parameter of the cohesive law, $l_A = l_J$ in Eq. (13). Fig. 5 shows the failure strain as function of the new cohesive length scale parameter, L_J, normalized against the matrix material length scale parameter, l_*. Both isotropic results as well as anisotropic results are shown using Hill-48 as well as Barlat-91. The coefficients of Barlat-91 are chosen such that the same plastic anisotropy as modeled by Hill-48 is reproduced. Thus, the two anisoropic results are directly comparable.

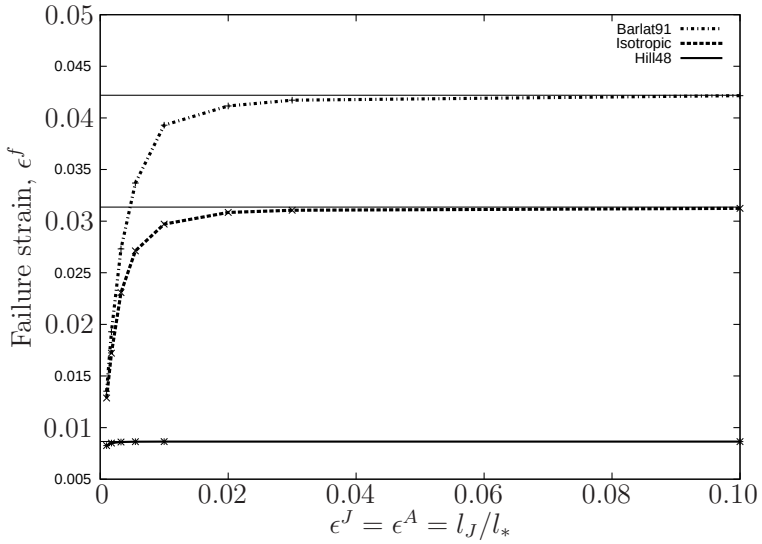

Figure 5. The failure strain as function of the cohesive length scale parameter, L_J, normalized by the matrix material length scale parameter, l_*. Isotropic as well as anisotropic results are shown for $\kappa = 0.5$.

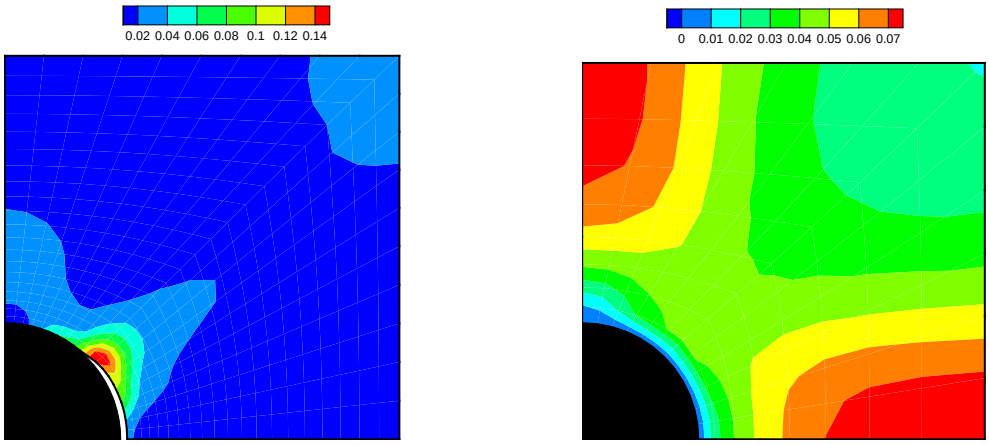
Compared to isotopy, the failure strain is larger using Barlat-91 and smaller using Hill-48. However, a significant effect of $l_J/l_* = l_A/l_*$ is seen for decreasing values as the failure strain decreases as well. On the other hand, for increasing larger l_J-values the plastic behaviour of the cohesive law is supressed and conventional results are obtained as shown by the asymptotic lines. For the Hill material the effect is very small, as debonding failure occurs at a rather small plastic strain, see Fig. 3. Thus, the influence of plasticity in the cohesive law is limited.



$\epsilon_1 = 0.02$

(a) (b)

Figure 6. Bi-axial tension results, $\kappa = 0.5$, for Hill-48 anisotropy at $\epsilon_1 = 0.02$. (a) Contours of effective plastic strain for a conventional anisotropic material with debonding (b) Contours of effective plastic strain for a higher order anisotropic material without debonding.

In Fig. 6(a) the micro-crack evolving at the fiber-matrix interface can be seen and the contours of the effective plastic strain shows severe strain with larger gradient at the crack-tip. Such large gradients are costly if strain-gradient effects are accounted for. Fig. 6(b) illustrates this for a case where a micro-crack has not evolved but the strain field is much more smooth. It can also be seen that the plastic strain near the fiber-matrix interface vanishes due to the imposed boundary conditions.

5. Conclusion

In conclusion, this study analyzes numerically the combined effects of plastic anisotropy, size-effects and debonding in a composite material. Debonding is seen as a sudden stress drop and plastic anisotropy highly affects the failure strain, while the size-effect is observed as an increased load carrying capacity. The material length scale of the cohesive law tends to reduce the failure strain of the composite, but as the parameter becomes sufficient large conventional results are predicted. This holds for both isotropic as well as anisotropic materials. The material length scale of the matrix material shows a non-monotonic effect on the failure strain such that a maximum failure strain is predicted for approximately a material length scale parameter of 15% of the fiber radius.

Abstract Nonlinear fracture mechanics of metal foams is discussed. The equivalent continuum constitutive model is introduced first. Then we studied analytic solutions on plastic analysis based on generalized cohesive force model, approximate analytic solution of elasto-plastic analysis for central crack, single edge crack specimens in tension and bending, respectively. The finite element analysis is also conducted. In addition, the crack slowly growth and fast propagation are studied as well.Atthe end we proposed a fracture criterion on metal foam.

Keywords Cellular/foam material, Crack tip opening displacement, Analytic solution in closed foam, Approximate solutions, Finite element analysis

1. Introduction

Cellular/foam material, which is one of advanced materials, has become an important engineering material to date due to its lower density and higher specific strength and other excellent mechanical, thermal and acoustical behaviour. For engineering usage, the structural integrity requires materials to have sufficient strength and toughness. Hence the study of crack problems in the material is significant. It is well-known that the basis of deformation and fracture investigation is constitutive law for any engineering materials. Triantafilou and Gibson [1], Gibson et al [2], Deshpande and Fleck [3], Miller [4] and others carried on considerable studies in this respect. Based on the equivalent continuum model they put forward some new macroscopic parameters out of the conventional materials to describe the influence of the substructure, which is called cells. The existence of cells leads to unusual plasticity of metal foams, that is the plasticity dependent from volume deformation.Thus the effect of hydrostatic pressure or the average stress should be considered, and these quantities should be contained into the new constitutive equations in the so-called equivalent continuum model. With these constitutive equations, the elasto-plastic analysis for cellular/foam material can be done. The nonlinearity of the governing equations of the material makes it difficult to construct analytic solutions of boundary value problems. Fan and co-workers [5,6] paid attention to developing a generalized cohesive force model and making the problem being linearized for static crack and moving crack problems, and they developed an asymptotic analysis method by using singular perturbation procedure for slowly steady crack growth problem. Within the linearization regime, the complex analysis presents its particular role and in this paper we report one of the works. The application of conformal mapping helps us to construct some solutions of finite size crack specimens, and it may be useful to experimental investigation and engineering

application.

2. Overview in brief of equivalent continuum constitutive laws

The artificial cellular materials include metal, polymer and ceramic foams respectively. The first two foams display plasticity of dependent of volume deformation, so that the hydrostatic pressure p or the average stress σ_{m} must be taken into account in the constitutive law of the material. The yield/loading surface can be expressed by

$$\Phi = \hat{\sigma} - Y = 0 \tag{1}$$

where $\hat{\sigma}$ represents the generalized effective stress which will be discussed in the following, and if

$$Y = \sigma_{\mathrm{Y}} = \text{const} \tag{2}$$

in which σ_{Y} denotes the uniaxial tensile yield limit of the material, then equation (1) stands for an initial surface. Alternatively if

$$Y = Y(h) \tag{3}$$

where h is a parameter describing plastic deformation history, then equation (1) represents the evolution equation of yield/loading surface.

Triantafilou and Gibson [1] ("TG" to "abbreviated as the TG model" in the following) suggested that

$$\hat{\sigma} = \sigma_{\mathrm{e}} + 0.03\frac{\rho^*}{\rho_{\mathrm{s}}}\sigma_{\mathrm{m}} \tag{4}$$

where ρ^* denotes the density of foam, and ρ_{s} the density of cell wall of the foam, and

$$\sigma_{\mathrm{e}} = \left(\frac{3}{2}s_{ij}s_{ij}\right)^{1/2} \tag{5}$$

is the von Mises effective stress, and

$$s_{ij} = \sigma_{ij} - \frac{1}{3}\sigma_{kk}\delta_{ij} = \sigma_{ij} - \sigma_{\mathrm{m}}\delta_{ij} = \sigma_{ij} + p\delta_{ij} \tag{6}$$

the deviate stress tensor, in which σ_{ij} represents stress tensor, and $\sigma_{kk} = \sigma_{11} + \sigma_{22} + \sigma_{33} = 3\sigma_{\mathrm{m}} = -3p$, δ_{ij} the unit tensor. Substituting equation (4) into equation (1) obtains the TG yield/loading surface of foams.

Gibson, Ashby, Zhang and Triantafilou[2] ("GAZT" to "abbreviated as the GAZT model" in the following) put forward

$$\hat{\sigma} = \sigma_{\mathrm{e}} + 0.81\frac{\rho^*}{\rho_{\mathrm{s}}}\frac{\sigma_{\mathrm{m}}{}^2}{\sigma_{\mathrm{Y}}} \tag{7}$$

Substituting equation (7) into equation (1) leads to the GAZT yield/loading surface of cellular materials.

After the work of TG and GAZT the constitutive models of foams were studied by many other groups. Distinguished from the above models, researchers take other parameters, according to experiments, to describe the effect of cells rather than the

relative density ρ^* / ρ_s.

Deshpande and Fleck [3] ("DF" to "abbreviated as the DF model" in the following) define a plastic Poisson's ratio as

$$v^{\mathrm{p}} = -\frac{\dot{\varepsilon}_{11}^{\mathrm{p}}}{\dot{\varepsilon}_{22}^{\mathrm{p}}} \tag{8}$$

where $\dot{\varepsilon}_{11}^{\mathrm{p}}$ and $\dot{\varepsilon}_{22}^{\mathrm{p}}$ are plastic strain rates. In terms of equation (8) DF derived a parameter α to describe plasticity of dependent volume deformation

$$\alpha = 3\left(\frac{1/2 - v^{\mathrm{p}}}{1 + v^{\mathrm{p}}}\right)^{1/2} \tag{9}$$

where the value of α is in range $1 < \alpha < 2$. Further they suggested the generalized effective stress as follows

$$\hat{\sigma} = \left[\frac{1}{1 + (\alpha/3)^2}(\sigma_{\mathrm{e}}{}^2 + \alpha^2 \sigma_{\mathrm{m}}{}^2)\right]^{1/2} \tag{10}$$

It is evident that if $v^{\mathrm{p}} = 1/2$, then $\alpha = 0$, this corresponds to the plasticity of independent volume deformation, i.e., the classical plasticity.

The substitution of equation (10) into equation (1) yields the DF yield/loading surface.

There are other models of constitutive law for metal foams and polymer foams, but we do not list again.

By considering isotropic hardening, based on flow rule and the above yield/loading surfaces, one can obtain the corresponding constitutive equations, which can be expressed uniformly as follows

$$\dot{\varepsilon}_{ij} = \dot{\varepsilon}_{ij}^{\mathrm{e}} + \dot{\varepsilon}_{ij}^{\mathrm{p}} = \frac{1+v}{E}\dot{\sigma}_{ij} - \frac{v}{E}\dot{\sigma}_{kk}\delta_{ij} + \frac{\dot{\hat{\sigma}}}{H(\hat{\sigma})}\frac{\partial \Phi}{\partial \sigma_{ij}} \tag{11}$$

where $\dot{\varepsilon}_{ij}$ represents strain rate tensor, $\dot{\varepsilon}_{ij}^{\mathrm{e}}$ the elastic strain rate one, $\dot{\varepsilon}_{ij}^{\mathrm{p}}$ the plastic strain rate one, $\dot{\sigma}_{ij}$ the stress rate one, E and v the Young's modulus and Poisson's ratio, and $H(\hat{\sigma})$ the hardening modulus, which can be approximately calibrated through a simple stress-strain relation, e.g. $H(\hat{\sigma}) = \mathrm{d}\sigma / \mathrm{d}\varepsilon^{\mathrm{p}}$ represents the hardening modulus at the stress amplitude value as $\hat{\sigma}$, respectively. From equations (1) and (4), (7), (10) and (11), we have

$$\frac{\partial \Phi}{\partial \sigma_{ij}} = \begin{cases} \dfrac{3}{2}\dfrac{1}{\sigma_{\mathrm{e}}}s_{ij} + 0.09\dfrac{\rho^*}{\rho_{\mathrm{s}}}\delta_{ij}, \text{ TG model} \\ \dfrac{3}{2}\dfrac{1}{\sigma_{\mathrm{e}}}s_{ij} + 0.18\dfrac{\rho^*}{\rho_{\mathrm{s}}}\dfrac{\sigma_{\mathrm{m}}}{\sigma_{\mathrm{Y}}}\delta_{ij}, \text{ GAZT model} \\ \dfrac{1}{[1+(\alpha/3)^2]\hat{\sigma}}\left(\dfrac{3}{2}s_{ij} + 3\left(\dfrac{\alpha}{3}\right)\sigma_{\mathrm{m}}\delta_{ij}\right), \text{ DF model} \end{cases} \tag{12}$$

The form of rate $\dot{\hat{\sigma}}$ can be easily found from the previous definitions of generalized effective stresses.

Coupling the constitutive equation (11) and the deformation geometry equationsand equilibrium equationsand appropriate boundary conditions, the elasto-plastic analysis for the foam materials can be carried out.

3. Generalized cohesive force model and solution

Due to the nonlinearity of equations we can find that the elasto-plastic analysis of crack problems of metal foams is very difficult, the exact analytical solution is almost not available. But the application of some simple physical models can simplify the solving dramatically. It is well-known that the Dugdale model [7], or the Dugdale-Barenblatt model [7, 8], or the cohesive force model is very effective in the study of plastic fracture of conventional structural materials. A similar work is the so-called BCS model [9, 10]. We extend the Dugdale model for conventional structural materials into the foam materials, the statement is as follows.

3.1 Generalized cohesive force model for cellular/foam materials --plane strain state

Assume that an infinite plane of foam material with a Griffith crack subjected a uniform tension $\sigma^{(\infty)}$ at infinity, refer to Fig.1, in which the pulling stress $p=\sigma^{(\infty)}$, and the plastic zone around crack tip is with a narrow band type, whose length is denoted by d, but its value is unknown at moment to be determined.

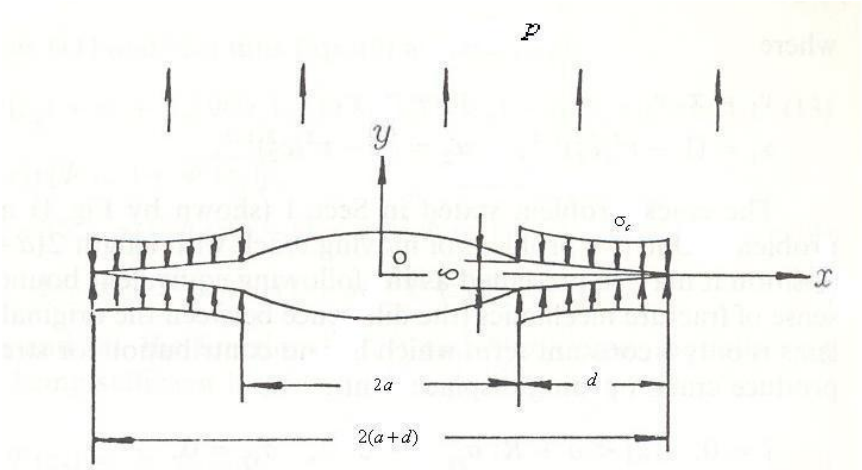

Fig. 1 The generalized cohesive force model for infinite specimen

According to the yield criteria of TG, GAZT, DF models respectively, the corresponding Dugdale plastic zone near the crack tip leads to

$$y=0,\ a<|x|<a+d:\ \sigma_{yy}=\beta\sigma_{\mathrm{Y}},\ \sigma_{xy}=0 \quad (13)$$

Based on the constitutive laws of listed by (11) with (4), (7), (10) respectively, where σ_{Y} represents the uniaxial tensile yield limit of foam materials, and the

parameter β describing cellular/foam materials behaviour and stress state, for plane stress case:

$$\beta=\begin{cases}\dfrac{1}{1+0.03\rho^{*}/\rho_{\mathrm{s}}}, & \text{TG model}\\ \dfrac{\left(1+1.44\rho^{*}/\rho_{\mathrm{s}}\right)^{1/2}-1}{1+0.03\rho^{*}/\rho_{\mathrm{s}}}, & \text{GAZT model}\\ \left[\dfrac{1+(\alpha/3)^{2}}{1+(2\alpha/3)^{2}}\right]^{1/2}, & \text{DF mod}\end{cases} \tag{14}$$

Though there is a new unknown quantity d , the nonlinear problems is linearized, so the equations are reduced to biharmonic equation:

$$\nabla^{2}\nabla^{2}U=0 \tag{15}$$

where $\partial^{2}U/\partial^{2}x=\sigma_{yy},\ \partial^{2}U/\partial^{2}y=\sigma_{xx},\ \partial^{2}U/\partial x\partial y=-\sigma_{xy}$ .The complex representations of U is the stress potential function, u_i the displacement vector and σ_{ij} is similar to that given in conventional structural materials.

The corresponding boundary conditions are

$$\begin{cases}\sqrt{x^{2}+y^{2}}\to\infty:\ \sigma_{yy}=\sigma^{(\infty)},\ \sigma_{xx}=\sigma_{xy}-0;\\ y=0,\ |x|<a:\ \sigma_{yy}=0,\ \sigma_{xy}=0;\\ y=0,\ a<|x|<a+d:\ \sigma_{yy}=\beta\sigma_{\mathrm{Y}},\ \sigma_{xy}=0\end{cases} \tag{16}$$

The linearization problem of cellular/foam materials is concluded to solve the boundary value problem.

Similar to the classical plastic fracture theory, the solutions are

$$d=a\left[\sec\left(\frac{\pi\sigma^{(\infty)}}{2\beta\sigma_{\mathrm{Y}}}\right)-1\right] \tag{17}$$

and

$$\delta_{\mathrm{t}}=\mathrm{CTOD}=\frac{8a\beta\sigma_{\mathrm{Y}}}{\pi E}\ln\sec\left(\frac{\pi\sigma^{(\infty)}}{2\beta\sigma_{\mathrm{Y}}}\right) \tag{18}$$

in which equation (17) determines the plastic zone size, and equation (18) gives the crack tip opening displacement (these two equations were first given by Fan et [5]), respectively. The both formulas contain the parameter β describing behaviour of foam materials. The variations of the crack tip opening displacement versus applied stress for different values of the new material constant α for DF model are shown in Figs. 2 in which the foam material constants $E=0.271\mathrm{GPa},\ \sigma_{Y}=0.811\mathrm{MPa}$.

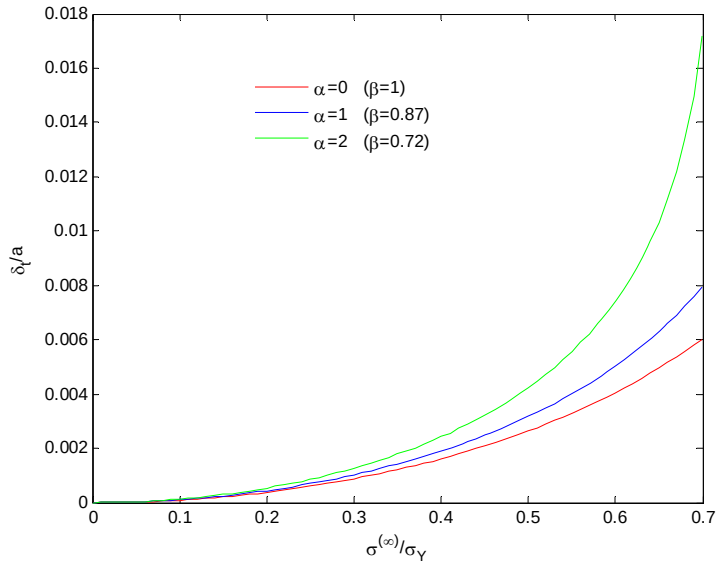

Fig. 2 Variation of values of δ_t versus applied stress for infinite specimen

3.2 Generalized cohesive force model for cellular/foam materials --plane strain state

The discussion is similar to Subsection 3.1, the only differences lie in that the boundary conditions (16) are replaced and the parameter β (given by (14)) is replaced by β' (given by the following (20))

$$y=0,\ a<|x|<a+d:\ \sigma_{yy}=\beta'\sigma_Y,\ \sigma_{xy}=0 \tag{19}$$

And

$$\beta'=\begin{cases}\dfrac{1}{1-2\nu+0.02(\rho^*/\rho_s)(1+\nu)}, & \text{TG model}\\ \dfrac{[(1-2\nu)^2+1.44(\rho^*/\rho_s)(1+\nu)^2]^{1/2}-(1-2\nu)}{0.72(\rho^*/\rho_s)(1+\nu)^2}, & \text{GAZT model}\\ \left[\dfrac{1+(\alpha/3)^2}{(1-2\nu)^2+(2\alpha/3)^2(1+\nu)^2}\right]^{1/2}, & \text{DF model}\end{cases} \tag{20}$$

The solutions are similar to those in Subsection 3.1, the only difference is that the parameter β should be replaced by β'

$$d=a\left[\sec\left(\frac{\pi\sigma^{(\infty)}}{2\beta'\sigma_Y}\right)-1\right] \tag{21}$$

$$\delta_t=\mathrm{CTOD}=\frac{8a\beta'\sigma_Y}{\pi E/(1-\nu^2)}\ln\sec\left(\frac{\pi\sigma^{(\infty)}}{2\beta'\sigma_Y}\right) \tag{22}$$

4. The development of the generalized cohesive force model

In the applications, the finite size specimens are particular important, which are discussed as following.

4.1 Central crack specimen of finite width

4.1.1 Plane stress state

The approximate analytic solution is obtained as follows

$$\delta_t = \mathrm{CTOD} = \left[\left(\frac{2W}{\pi a}\right)\tan\left(\frac{\pi a}{2W}\right)\right]\frac{8a\beta\sigma_Y}{\pi E}\ln\sec\left(\frac{\pi\sigma^{(\infty)}}{2\beta\sigma_Y}\right) \tag{23}$$

4.1.2 Plane strain state

The solution is

$$\delta_t = \mathrm{CTOD} = \left[\left(\frac{2W}{\pi a}\right)\tan\left(\frac{\pi a}{2W}\right)\right]\frac{8a\beta'\sigma_Y}{\pi E/(1-\nu^2)}\ln\sec\left(\frac{\pi\sigma^{(\infty)}}{2\beta'\sigma_Y}\right) \tag{24}$$

4.2 Single edge crack specimen with finite width

Another significant specimen is single edge crack specimen, shown as below:

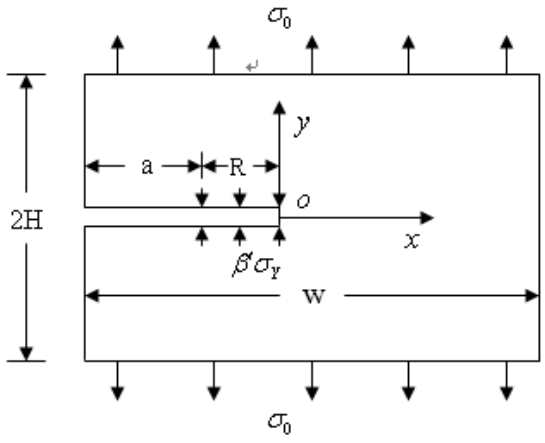

Fig. 3 Single edge crack specimen under tension

4.2.1 Plane stress state

The approximate analytic solution is obtained as follows

$$\delta_t = \mathrm{CTOD} = \frac{4}{\pi}\left[\left(\frac{2W}{\pi a}\right)\tan\left(\frac{\pi a}{2W}\right)\right]\frac{8a\beta\sigma_Y}{\pi E}\ln\sec\left(\frac{\pi\sigma^{(\infty)}}{2\beta\sigma_Y}\right) \tag{25}$$

In the derivation the conformal mapping

$$z = \omega(\zeta) = \frac{2W}{\pi}\arctan\left\{\sqrt{1-\zeta^2}\,\tan\left(\frac{\pi a}{2W}\right)\right\} - a \tag{26}$$

is used to transform region of the specimen at the physical plane (i.e., the $z-$plane) onto the upper half-plane at the mapping plane (i.e., the $\zeta-$plane).

4.2.2 Plane strain state

The solution for plane strain is

$$\delta_t = \mathrm{CTOD} = \frac{4}{\pi}\left[\left(\frac{2W}{\pi a}\right)\tan\left(\frac{\pi a}{2W}\right)\right]\frac{8a\beta'\sigma_Y}{\pi E}\ln\sec\left(\frac{\pi\sigma^{(\infty)}}{2\beta'\sigma_Y}\right) \tag{27}$$

The numerical results are shown in Fig.4.

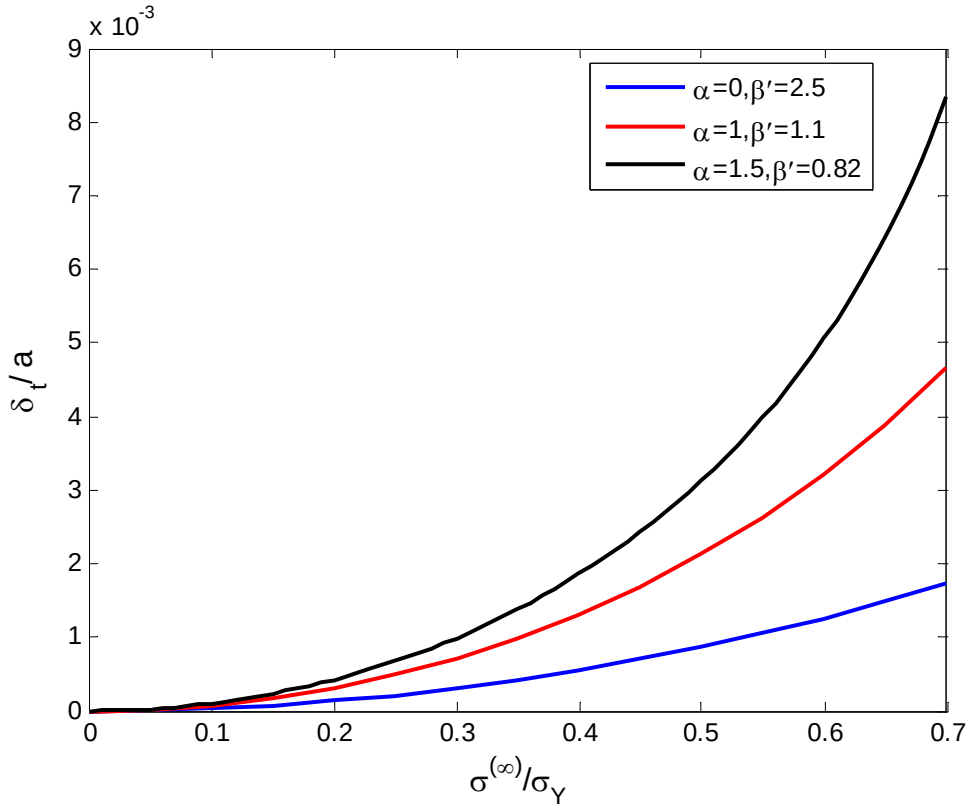

Fig.4Variation of values of δ_t versus applied stressfor finite specimen with a/W =0.3

4.3. Pure bending specimen of central crack

The pure bending specimen is significant in applications.

4.3.1 Plane stress state

The solution is

$$\delta_t = \text{CTOD} = \frac{8\boldsymbol{a}\beta\sigma_Y}{\pi \boldsymbol{E}} \ln \sec\left(\frac{\pi\sigma_N}{2\beta\sigma_Y}\right) \tag{28}$$

$$\sigma_N = 6\frac{M(a+d)}{BW^3} \tag{29}$$

in which M is bending moment, the a crack length, the W width of specimen, and

$$\boldsymbol{d} \approx \boldsymbol{a}\left[\sec\frac{\pi}{2\beta\sigma_Y}\left(6\frac{\boldsymbol{Ma}}{\boldsymbol{BW}^3}\right)-1\right] \tag{30}$$

the plastic zone size, and the others are the same defined before.

4.3.2 Plane strain state

The solution for plane strain is

$$\boldsymbol{d} \approx \boldsymbol{a}\left[\sec\frac{\pi}{2\beta'\sigma_Y}\left(6\frac{\boldsymbol{Ma}}{\boldsymbol{BW}^3}\right)-1\right] \tag{31}$$

and

$$\delta_t = \text{CTOD} = \frac{8\boldsymbol{a}\beta'\sigma_Y}{\pi \boldsymbol{E}/(1-\boldsymbol{\nu}^2)} \ln \sec\left(\frac{\pi\sigma_N}{2\beta'\sigma_Y}\right) \tag{32}$$

5. Finite element analysis

Analytic solutions also have their limitations, and numerical method is important as well. We list a part of numerical solutions conducted by finite element method.

5.1 Single edge crack under tension[14]

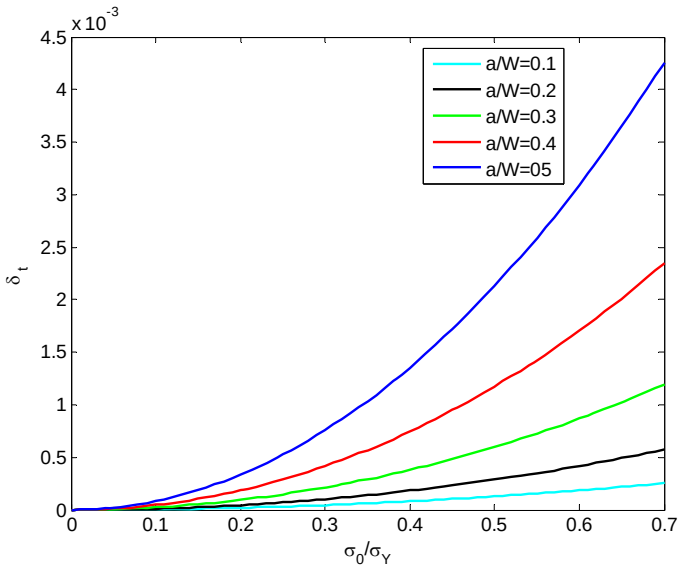

Fig. 5The CTOD of a finite size edge crack specimen of cellular/foam materials indifferent a/w

The comparison between Fig.4 and Fig.5 shows the analytic and numerical solutions are in good agreementwith each other.

5.2 Single edge crack under bending

The elasto-plastic analysis of metal foam in terms of finite element is carried out, the plastic zone around crack tip is shown in Fig.6.

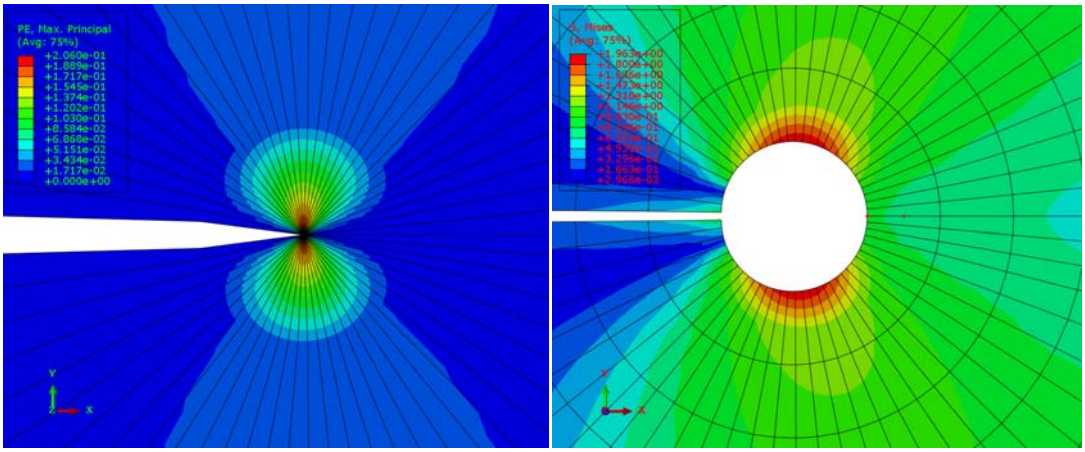

Fig.6The plastic zone around crack tip

6. Crack slowly growth

The crack growth in the metal foams is significant, we discussed two cases and introduce as below.

6.1 TG model [5,15]

In the analysis we developed the singular perturbation, see Fan et al [5]. The constitutive law for TG model is, refer to equations (15) and (16)

$$\dot{\varepsilon}_{ij} = \dot{\varepsilon}_{ij}^{\mathrm{e}} + \dot{\varepsilon}_{ij}^{\mathrm{p}} = \frac{1+\nu}{E}\dot{\sigma}_{ij} - \frac{\nu}{E}\dot{\sigma}_{kk}\delta_{ij} + \frac{\dot{\hat{\sigma}}}{H(\hat{\sigma})}\frac{\partial \Phi}{\partial \sigma_{ij}} = \frac{1+\nu}{E}\dot{\sigma}_{ij} - \frac{\nu}{E}\dot{\sigma}_{kk}\delta_{ij} + \dot{\Lambda} s_{ij}$$
$$\dot{\Lambda} = \frac{1}{H(\hat{\sigma})}\left\{\frac{9}{4}\frac{1}{\sigma_e^2}s_{kl}\dot{\sigma}_{kl} + 0.045\frac{\rho^*}{\rho_s}\sigma_m\right\} \tag{33}$$

The singular perturbation is taken as

$$\sigma_{ij} = \sigma_0 \xi^s \sum_{m=0}^{\infty} \sigma_{ij}^{(m)}(\theta)\xi^{-m}, \xi = \ln\frac{R}{r} \tag{34}$$

in which σ_0 denotes the yield stress in uniaxial tension, s a parameter to be determined, $\sigma_{ij}^{(m)}(\theta)$ the expansion coefficients, R the size of crack tip, and r the distance measured from crack tip.

The structure of the plastic zones around crack tip and the stress distribution are found by further analysis, but the results are omitted due to the limitation of space.

6.2 DF model[6]

The perturbation analysis and results are also constructed, but omitted due to the limitation of space.

7. Crack fast propagation[5]

Some approximate solutions for crack propagation in the material have been obtained as well but the discussions are omitted here.

8. Fracture criteria

Because the metal foams are plastic material, the fracture presents plastic behaviour, the fracture should be used the crack tip opening criterion rather than stress intensity factor criterion, i.e.,

$$\delta_t = \delta_t^c \tag{35}$$

in which δ_t^c is the critic value of δ_t, a material constant, measured by experimental tests. In the above the main attention of our analysis lies in the determination of the crack tip opening displacements for various specimens, because the quantity presents the fundamental importance in the plastic fracture analysis.

9. Conclusion and discussion

The above discussion gives a comprehensive introduction on the plasticity of metal foams, plastic fracture theory and some solutions for cracked specimens with infinite and finite sizes. These solutions are useful to the theoretical and experimental studies. In the work the complex analysis is developed.

CRACK DELOPMENT AND DYNAMIC NATURE OF CRACK PROPAGATION IN STRUCTURES

Dr.Subhash Chanda,

West Bengal , India
Email address: dsc3din@yahoo.co.in

Abstract: This paper aims at finding the sources of crack development in modern structures at an elevated temperature and under severe vibrations due to excessive load magnitudes and also of ceismic vibrations. In the present paper attempts have been made for solving the problems relating to large amplitude vibrations of uniform elasto plastic plates and shells under both static and dynamic loads using the method of constant deflection contour lines[8-15]. Also, the effect of crack development and its propagation through the structures have been studied rigorously. The works in this field by numerous researchers are discussed shortly in the introduction and considering all the assumptions made by them after proper correction compatible with the boundary conditions, the present author tries to develop the equations with consideration of multi aspect crack generating factors and their impact on the time periods of nonlinear vibration of the structures and the results obtained for a crack structure are presented along with that of the non cracked structure.

I N T R O D U C T I O N

Modern structures are often subjected to severe vibrations and high temperatures. Sometimes the magnitudes of the applied forces or loads become very large, exceeding the elastic limit and brittle strength of the material used. Ceismic vibrations during earth quake, crashes and blasting of bombs etc. sometimes initiate the growth of fractures within the structures Also, if there exist any source of fracture like crystal defects, brittle disorder, imperfections etc within the structures (may or may not be visible from outsides), fracture will be developed and during the load variations in static cases or during vibrations in all dynamic cases and also during temperature elevation , the fractures have got dynamic character; i.e., crack begins to propagate through the structures causing a notable variation of the magnitude of the flexural rigidity of the material. Gradually, the crack developed within the structures causes a damage of the system due it its growth and dynamic nature. Griffith [1], Irwin[2], E. Erdogan [3], Orowan [4], G.I. Barenblatt [5], D.S, Dugdale [6], J. R. Wills [7] had made extensive researches on fracture mechanics. Some had attempted to explain the fracture character in structures assuming some sort of flaws within it. But all the works are based on some highly simplified hypothesis. To verify the flaw hypothesis, Griffith introduced an artificial flaw in his experimental specimens. The artificial flaw was in the form of a surface crack which was much larger than other flaws in a specimen. Irwin strategically partitioned the energy in two parts; the stored elastic strain energy which is released as a crack grows. This is the thermodynamic driving force for fracture and the dissipated energy which includes plastic dissipation and the surface energy also any other dissipative forces that may be at work.

The dissipated energy provides the thermodynamic resistance to fracture. The Stress Intensity Factor is given by the following equations.

$$G = G_I = \begin{cases} \dfrac{K_I^2}{E} & \text{plane stress} \\ \dfrac{(1-\nu^2)K_I^2}{E} & \text{plane strain} \end{cases}$$

where E is the Young's modulus, v is Poisson's ratio, and K_I is the stress intensity factor in mode I. Irwin also showed that the strain energy release rate of a planar crack in a linear elastic body can be expressed in terms of the mode I, mode II (sliding mode), and mode III (tearing mode) stress intensity factors for the most general loading conditions. Irwin adopted the additional assumption that the size and shape of the energy dissipation zone remains approximately constant during brittle fracture. This assumption suggests that the energy needed to create a unit fracture surface is a constant that depends only on the material. This new material property was given the name *fracture toughness* and designated G_{Ic}. Today, it is the critical stress intensity factor K_{Ic}, found in the plain strain condition, which is accepted as the defining property in linear elastic fracture mechanics.

By applying the theory of fracture mechanics one can study the propagation of cracks in materials. Fracture Mechanics uses methods of analytical solid mechanics to calculate the driving force on a crack and those of experimental solid mechanics to characterize the material's resistance to fracture. It applies the Physics of Stress and Strain, in particular the theories of elasticity and Plasticity, to the microscopic Crystallographic defects found in real materials in order to predict the macroscopic mechanical failure of bodies.A comparative study of the static and dynamic characteristics of the structure will provide a notice for of such a failure before hand . The prediction of crack growth is at the heart of the damage tolerance discipline. Still, by studying the static and dynamic characteristics of the structures and comparing the results with the standard results of the same structures without any crack, an estimation of the safety factor may be obtained with ease.

Derivation Of The Governing Differential Equations for A Non Cracked Structure

A shallow shell of uniform thickness `h ` is considered. Let the equation of the middle surface of the shell, referred to an orthogonal coordinate system (x,y,z), be given by

$$Z = (x^2 / 2 R_x) + (xy / R_{xy}) + (y^2 / 2 R_y) \qquad (1)$$

For a shallow shell $r = \sqrt{(x^2 + y^2)}$ considered small in comparison to the least of the radii of curvature, R_x , R_{xy} and R_y which are taken to constants.When the shell experiences axisymmetric free vibration the intersections of the deflected surface and the parallels z = constant yield contour lines of constant deflection. Application of D` Alembert`s principle to an element of the shell bounded by such a contour at any time τ and subsequent summation of the forces in the direction normal to the surface yields the following dynamical equations [1] :

$$\int V_n \, ds + \int\int [\rho h (\partial^2 w) / \partial \tau^2 + (N_x) / R_x + (N_y) / R_y + 2 (N_{xy}) / R_{xy}] \, dx \, dy = 0 \qquad (2)$$

where the transverse reaction forces $V_n = Q_n - \partial/\partial s(M_{nt})$ in absence of fractures, (2,a)

$V_n = Q_n - \partial/\partial s(M_{nt}) – f(a, G, K)$, the last term is due to fractures, (2,b)

represents the effect of the shearing force Q_n and the edge-rate of change of twisting moment M_{nt} along the contour C_u. According to Ilyushin`s theory of the elastic plastic deformation (1948), the bending moments M_x, M_y, M_{xy} and their shear forces Q_x, Q_y are given by the following relations:

$$M_x = -D(1-\nu)\{(\partial^2 w/\partial x^2) + \nu(\partial^2 w/\partial y^2)\} \quad (3)$$
$$M_y = -D(1-\nu)\{(\partial^2 w/\partial y^2) + \nu(\partial^2 w/\partial x^2)\}$$
$$M_{xy} = D(1-\nu)(1-\Omega)(\partial^2 w/\partial x \partial y)$$
$$Q_x = (\partial/\partial x)\{M_y\} - (\partial/\partial y)\{M_{xy}\}$$
$$Q_y = (\partial/\partial y)\{M_x\} - (\partial/\partial x)\{M_{xy}\}$$
$$Q_n = Q_x \cos\alpha + Q_y \sin\alpha$$

$$M_{nt} = M_{xy}(\cos^2\alpha - \sin^2\alpha) + (M_x - M_y)\sin\alpha\cos\alpha \quad (4)$$

Where, $\cos\alpha = (dy/ds)$ and $\sin\alpha = -(dx/ds)$.

Here, ρ, h and w are, respectivly, the mass density, the shell thickness and the deflection. Using the well known expressions for the moments and shearing forces and assuming that the membrane forces N_x, N_y and N_{xy} are given by

$$N_x = (\partial^2\Phi/\partial y^2),\quad N_y = (\partial^2\Phi/\partial x^2),\quad N_{xy} = -(\partial^2\Phi/\partial x\partial y) \quad (5)$$

Equation (2) finally reduces to:

$$(\partial^3 w/\partial u^3)\int(1-\Omega)R\,ds + (\partial^2 w/\partial u^2)\int(1-\Omega)F\,ds + (\partial w/\partial u)\int(1-\Omega)G\,ds$$
$$+ (\partial^2 w/\partial u^2)\int D[(\partial\Omega/\partial x)(\partial u/\partial x) + (\partial\Omega/\partial y)(\partial u/\partial y)]\sqrt{t}\,ds + (\partial w/\partial u)\int (D/\sqrt{t})[K(\partial\Omega/\partial x) + L(\partial\Omega/\partial y)]\,ds + \iint[\rho h (\partial^2 w/\partial\tau^2 (1/R_x)(\partial^2\Phi/\partial y^2) + (1/R_y)(\partial^2\Phi/\partial x^2) - 2/(R_{xy}\partial^2\Phi/\partial x\partial y]\,dx\,dy = 0 \quad (6)$$

Where R,F,G are given in Ref.13, $D = (E h^3/12(1-\nu^2))$,is the flexural rigidity.
Here, $\Omega = 0$ when $e \le 1$, the region is elastic ; when $e > 1$ the region is plastic. Also, $\Omega = \lambda[1 - (3/2e) + (1/2e^3)$

and $e^2 = (h^2/3e_s^2)[(\partial^2 w/\partial x^2)+(\partial^2 w/\partial y^2)+(\partial^2 w/\partial x\partial y)+(\partial^2 w/\partial x^2)(\partial^2 w/\partial y^2)$

$$= (h^2/3e_s^2)[M(\partial w/\partial u)^2 + N(\partial w/\partial u)(\partial^2 w/\partial u^2)(\partial w/\partial u) + t^2(\partial^2 w/\partial u^2) \quad \textbf{(7)}$$

in which e_s is the yield strain, ν is the poisson`s ratio, D is the flexural rigidity of the plate material, λ is a material constant .

Here, $M = [u_{,xx}^2 + u_{,yy}^2 + u_{,xx}u_{,yy} + u_{,xy}^2]$
$N = [2u_{,x}^2 u_{,xx} + 2u_{,y}^2 u_{,yy} + u_{,xx}u_{,y}^2 + u_{,x}u_{,yy} + 2u_{,x}u_{,y}u_{,xy}]$
$t^2 = (u_{,x}^2 + u_{,y}^2)$

Considering only the transverse vibration, we assume that

$$w = W(x,y)f(t) \quad (8)$$
$$\Phi = \Phi(x,y)f(t) \quad (9)$$

Equation (6) will now reduce to

$$[(\partial^3 W/\partial u^3)\int(1-\Omega)R\,ds + (\partial^2 W/\partial u^2)\int(1-\Omega)F\,ds + (\partial W/\partial u)\int(1-\Omega)G\,ds$$
$$+ (\partial^2 W/\partial u^2)\int D[(\partial\Omega/\partial x)(\partial u/\partial x) + (\partial\Omega/\partial y)(\partial u/\partial y)]\sqrt{t}\,ds + (\partial W/\partial u)\int(D/\sqrt{t})[K(\partial$$

$\Omega / \partial x) + L (\partial \Omega / \partial y)] ds] f(t) + \iint [\rho h W f``(t) + \{ (1/ R_x)(\partial^2 \Phi / \partial y^2) + (1 / R_y) (\partial^2 \Phi / \partial x^2) - 2 / (R_{xy} \partial^2 \Phi / \partial x \partial y \} f(t)] dx dy = 0$ (10)

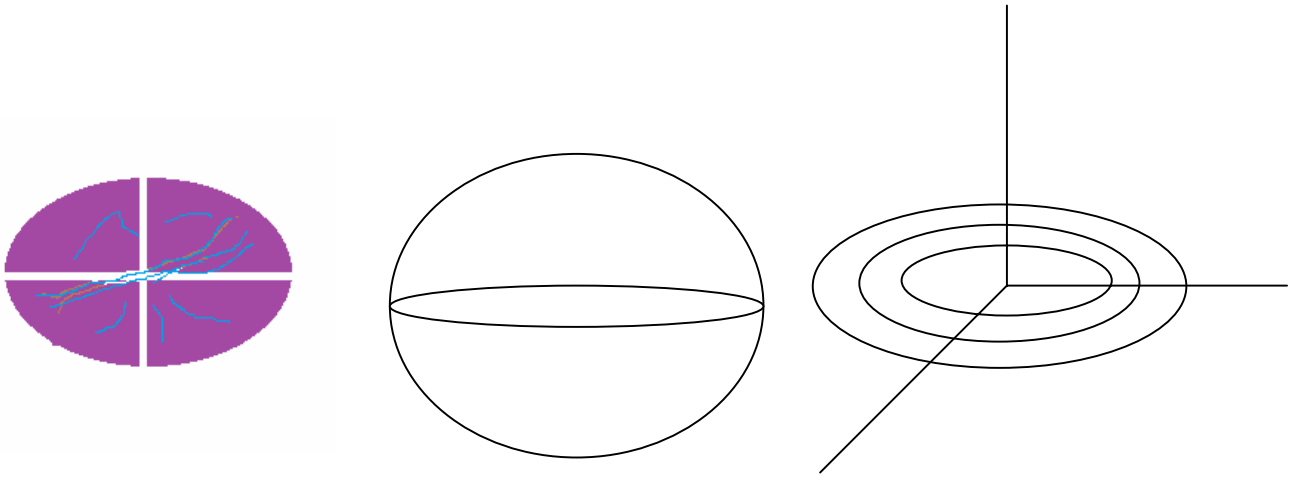
Consequently, the condition for continuity of deformation reduces to

$\nabla^4 \Phi = \{ 12D (1 - \nu^2) \} / h^2 (1 - \Omega) [(1/ R_x)(\partial^2 \Phi / \partial y^2) + (1 / R_y) (\partial^2 \Phi / \partial x^2) - 2 / (R_{xy})$ (11)

This equation must hold over all points in the interior of the shell. After integration over the area and application of Greens theorem one obtains :

$(d^3\Phi/du^3) \int Rds + (d^2 \Phi/du^2) \int Fds + (d\Phi/du) \int Gds * 12D^2 (1 - \nu^2) / h^2 (1 - \Omega)(dW/du)$
$\int K_x (\partial u / \partial y)^2 + Ky (\partial u / \partial x)^2 / t^{½} ds = 0$ (12)

where K_x and K y denote curvatures at a point and K xy has been assumed to be zero in accordance with the shallowshell theory. Equations (11) and (13) are now the two basic equations for large amplitude vibration of shallow shell.



Internally Cracked shallow domes and isodeflection contour lines

Figure-I

ILLUSTRATION:

Let us now consider a clamped dome of non-zero curvature upon an elliptic base. For the first approximation under symmetry consideration we may write

$$u = 1 - x^2 / a^2 - y^2 / b^2 \quad (13)$$

Performing the contour integrations taken around the closed contour

$$u = 1 - x^2 / a^2 - y^2 / b^2$$

And the double integration extending over the ellipse

$$x^2 / a^2 + y^2 / b^2 = 1 - u \qquad (14)$$

Equation (11) in non dimensional form becomes

$$(1 - \Omega)(1 - u)(d^3W/du^3) - 2(1 - \Omega)(d^2W/du^2) - (d\Omega/du)[(1 - u)(d^2W/du^2) - 2P\{(1/a^4) + (1/b^4) + 2\nu/a^2b^2)(dW/du)] + (\rho h^2 \omega^2 P)/(2 D e_s a^2) - \{(E h \gamma)/D\}(d\Phi/du) = 0 \qquad (15)$$

where $P = (a^4 b^4)/(3a^4 + 2a^2b^2 + 3b^4)$, while equation (12) in non dimensional form will reduce to

$$(1 - u)(d^3\Phi/du^3) - 2(d^2\Phi/d^2u) + (1 - \Omega)\gamma(dW/du) = 0 \qquad (16)$$

with $\gamma = p(k_x/b^2 + k_y/a^2)$; $W = wh/e_s a^2$; $\Phi = \varphi/E e_s a^2$ (17)

(18)

METHOD OF SOLUTION

On substitution of the value of Ω into equations (16) & (17), one obtains

$$[(1 - u)(d^3W/du^3) - 2(d^2W/du^2)] Q_1 f(t) - [2M(d^2W/du^2)(dW/du) + N(d^2W/du^2)^2 N(d^3W/du^3)(dW/du) + 2t^2(d^3W/du^3)(dW/du)][(1 - u)(d^2W/du^2) - 2P_1(dW/du)Q_2 f^3(t) - (Eh\gamma/D) f(t)(d\Phi/d + (\rho h/(2 D e_s a^2) f``(t) = 0 \qquad (18)$$

and $$(1 - u)(d^3\Phi/du^3) - 2(d^2\Phi/d^2u) + Q_1\gamma(dW/du) = 0 \qquad (19)$$

Where, $Q_1 = [2e^3(1 - \lambda) + \lambda(3e^2 - 1)]/2e^3$; $Q_2 = (\lambda/4e^5)(e^2 - 1)$

$P_1 = P(1/a^4 + 1/b^4 + 2\nu/a^2b^2)$

Also, e^2 is given by

$$e^2 = \tfrac{1}{3}[M(dW/du)^2 + N(dW/du)(d^2W/du^2) + t^2(d^2W/du)^2] \qquad (20)$$

Suppose the shell is completely clamped along the boundary.

The boundary conditions are given by

$$W|_{u=0} = 0 = (dW/du)|_{u=0}$$
$$\Phi|_{u=0} = 0 = (d\Phi/du)|_{u=0}$$

To find an approximate solution, we assume the following trial solutions:

$$W = \Sigma a_j u^j \; ; \quad \Phi = \Sigma b_j u^j \qquad (21)$$

On substitution of these trial solutions in equations (16) & (18), we get the residuals R_1 & R_2 which, after the application of Galerkin`s procedure, yield the following results.

$$(\rho h^2 P)/(6 D e_s a^2) f``(t) = [(4/3) Q_1 a_2 + (Eh\gamma/2D) b_2] f(t) + [(4/5) M + (2/3) N - (32/5) M P_1 - 4 N P_1] Q_2 a_2^3 f^3(t) \qquad (22)$$

and $$b_2 = (3/8) Q_1 \gamma a_2 \qquad (23)$$

while the average value of `e` happens to be

$$e = a_2 \sqrt{[(1/a^4) + (1/b^4) + (2/a^2 b^2)]} \, (40/9) \qquad (24)$$

From equations (22) & (23), one obtains the following time differential equations in f(t):

$$f``(t) + \mu f(t) + \zeta f^3(t) = 0 \qquad (25)$$

where, $\mu = -(6 D e_s a_2 / \rho h^2 P) [(4/5) M + (2/3) N - (32/5) M P_1 - 4 N P_1] Q 2 a_2^3$

Since the series is rapidly converging hence considering the first few terms one may obtain the approximate value of the central deflection w* as

$$w^* = \Sigma_j a_j$$

The solution of equation (25) is given by

$$f(t) = a_0 \operatorname{Sin} [\mu t \{ 1 + (3/8) a_0^2 (\zeta/\mu) \} + \theta_0] \qquad (26)$$

The time periods of the non-linear and linear oscillations are

$T^* = 2\pi / [\mu \{ 1 + (3/8) a_0^2 (\zeta/\mu) \}]$ and $T = 2\pi/\mu$.

Thus $[T/T^*] = 1/\{ 1 + (3/8) a_0^2 (\zeta/\mu) \} \qquad (27)$

NUMERICAL RESULTS

Numerical results are computed both for circular and elliptic plates & shallow domes upon the circular & elliptic bases in the elastic and elastic plastic regions and these are presented in tables (1 – 4). The computations are made with different values of the shallowness parameter (2 γ / h) and material constant ν = 0.3. Dynamic responses of the elasto-plastic shells for moderately large amplitude are obtained from the same differential equations. Moreover, effect of crack / fractures are computed with the same equation only changing the term for Vn in equation (2,b) and making subsequent changes in other equations and the results are presented in the tables from (1-4, red coloured) .This is no doubt advantageous as such both static and dynamic behaviors are obtained simultaneously with least effort.

O B S E R V A T I O N S A N D C O N C L U S I O N S

It is observed that the results obtained for elastic shallow shells are in excellent agreement with those obtained in [4, 5].Also, the results for plastic shells based on circular and elliptic domes are in good agreement with those obtained in [4]. It is found in both the cases that the ratio of nonlinear to linear time periods become larger in case of plastic shell in comparison to those obtained in case of elastic shells and which is expected. This actually supports the application of the isodeflection contour lines method to analyse such problems. Inspite of that the method has some limitations. It heavily relies on the accuraqcy of the choice of the iso-deflection contour function u(x,y). The main advantage of the method lies in the fact that once the form of the function u (x,y) is chosen suitably the remaining task can be tackled with ease and accuracy. Numerical results [red coloured] obtained for the plates and shells in presence of fractures reveal the fact that due to reduction of the values of elastic constants reaction falls and some irregularities are observed when the cracks propagating through the specimen increasing their dimensions which is expected.

Abstract

The concept of creating intense pulsed ion beam from source based on cryogenic target of inert gases (Xe) irradiated by intense electrons beam from the cathode with explosive emission in the nanosecond range was realized.
The studies were conducted on the modernized experimental equipment consisting of a short high- voltage pulse generator GKVI-300, high-vacuum pumping system based on turbo-molecular pump TMN-1000M with the ability to hold pressure in research chamber $\sim 1 \cdot 10^{-6}$ Torr, Gifford-McMahon cryocoolers MSMR-110-3, 2/20 with closed He – cycle that provides cooling temperature T=20K and a gas injection system.
Gas xenon (Xe 4,8, with the percentage of xenon 99,9988%) was used as working gas It ffreezes to copper anode plate cooled to a temperature of 45-50 K.
As a test materials were selected D16 aluminum alloy and stainless austenitic steel 12X18H10T (cryogenic constructional steel) having wide practical application.
Micro-topography surface and X-ray photoelectron spectra of samples were obtained at an atomic force microscope Solver PRO-M and the electron spectrometer ESCALAB-5 (line Kα Al ($h\nu$=1486.6 eV)) .
The impact of short-pulsed ion beam on a sample of D16 alloy and stainless steel 12X18H10T leads to erosion of the surface in the form of separate craters, the depth of which depends on the hardness of the material and the number of pulses. Uniform over the surface area distribution of craters can be achieved when placed in front of target fine-mesh nets of a refractory metal such as molybdenum.
A numerical simulation of fracture of aluminum target by a beam of high-energy ions, the finite element method, corresponding flow through one grid was realized. The results are in good agreement with experimental data.

Keywords: ion beam, electron beam, erosion, cryogenic target, computational modeling

1. Introduction

Influence of powerful short-time beam of particles – photons, electrons, ions – on physical and mechanical properties of constructional materials represents a great interest, both with theoretical, and from the practical point of view. It gains special relevance in connection with the technogenic accident which have occurred recently, especially on nuclear power plants where the processes caused by fast particles are extremely important. Influence is capable to modify significantly physical and chemical and mechanical properties of materials. The knowledge of mechanisms of changes of properties is extremely necessary as for an estimation of possible changes under the influence of particles, and in connection with prospects of creation of new functional materials and changes of characteristics in the necessary direction. Studying of influence of the ions having high energy, on constructional materials very important. Radiation bunch processing everything is wider and more widely applied to modifying of near-surface layers of parts that allows to improve considerably their operational characteristics [1]. The particular interest represents research of influence of the short-time beam having a number of features in relation to influence on physical and mechanical characteristics. The large number of the designs, allowing to receive ionic bunches with various parameters [2] is so far developed. However they represent rather difficult devices that does them extremely expensive. In this regard in this work researches on creation of the source, allowing to receive short-time, about 10-100 nanoseconds, a beam of ions of the high power which design has to be most adapted for the available equipment are conducted.

2. Experimental techniques

The main idea based on creation of a source of ions, consists in the following. The generator of short high-voltage impulses of GKVI-300 allows to receive a short-time pulse beam of the electrons having high energy. This beam can be directed on a material containing atoms of the necessary grade. This leads to a number of processes (thermal heating, an electronic and stimulated desorption, cascade ionization) and at a surface of the anode is formed the plasma consisting of electrons and ions of a various charges. These ions, being positively charged, move in the direction, return to electrons beam. It is a so-called passive source of ions. In our case the version of the cryogenic passive anode which allows to receive unicomponent structure of an ionic bunch is chosen.
When developing a design a number of the moments was considered. First, it is necessary that issue of electrons which in available strong electric fields has explosive character, didn't lead to changes on a surface of the sample which is a part of cathode assembly. Therefore the cathode was made compound. It represented a ring in which the sample (fig.1) took place.

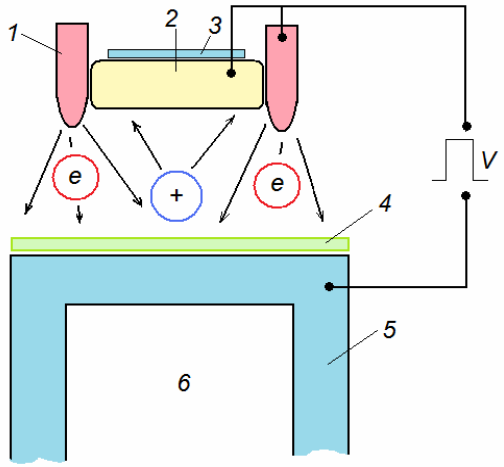

Fig. 1. Schematic image of a source of ions. 1 – cathod ring, 2 – a sample, 3 – a reflecting layer for registration of mechanical stress by an interferometric method, 4 - a layer of the condensed inert gas, 5 – the anode, 6 – the volume cooled by the cryorefrigerator.

Edges of a ring 1 have the pointed form and protrude from the sample 2. When giving a high-voltage impulse electron emission happens from a ring edge as such geometrical form provides the greatest intensity of electric field in this place. The sample thus doesn't participate in formation of an electronic beam. The back party of a sample is polished to mirror shine and serves as an informative mirror of the interferometer of Michelson by means of which shift of this surface is measured. Shift arises owing to impact on a sample of an ionic beam. In the ring cathode there are openings for leading of a laser beam of the interferometer.
The second important point belongs to an anode material. At impact of ions on a solid body it is important that there was no chemical interaction between ions and atoms of a material. Otherwise it can lead to change not only mechanical and structural properties, but also to change of a chemical composition. In this regard ions of inert atoms are the most suitable. As that xenon was chosen. The choice was dictated by possibility of condensation of this gas when cooling anode. For this purpose the anode was carried out in the form of a rod 5 cooled by system, consisting of compressor installation with the control and management block and a cooler. Such system allows to receive the xenon layer which thickness is defined by pressure of gas filled through a inlet valve and hold time on an anode surface. After achievement of a layer of the necessary thickness xenon is pumped out up to the pressure $\sim 10^{-6}$ Tor. Such

sequence of actions provides localization of a place of formation of ions. Ionization of atoms of xenon takes place only in close proximity to an anode surface. Besides, in high vacuum length of run of particles considerably exceeds an available interval between the anode and the cathode. It means that dispersion of ions in such conditions is negligible.

2.1. Experimental unit

Researches were conducted on the modernized experimental unit consisting of the generator of short high-voltage impulses of GKVI-300, the research camera which appearance is given on Fig. 2, high-vacuum pumping system, MCMP-110-3,2/20 Gifford-Makmagona cryorefrigerator with closed He – cycle providing temperature of cooling of $T_{coll}=20\ K$ and gases inlet system.

Fig. 2. Appearance of the research camera and gases inlet system .

Appearance of the block of a cooler and cooling head is given on Fig. 3.

(a)

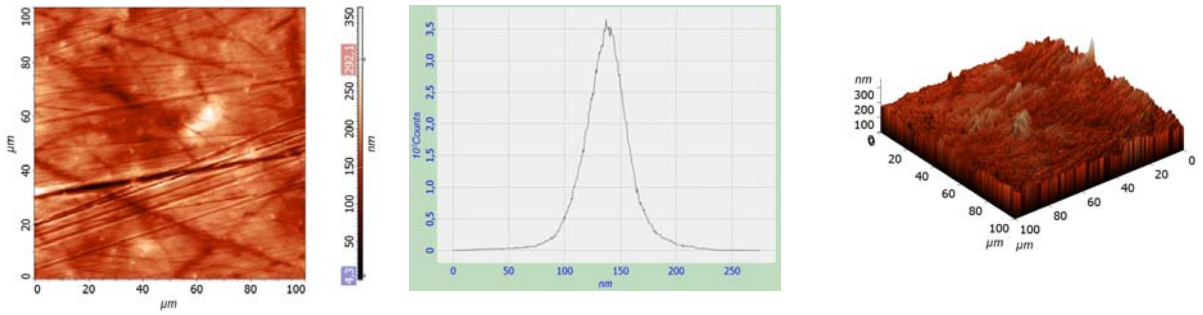
(b)

Fig. 3. Appearance of the block of a cooler (a) and cooling head (b).

Air pumping from the research camera was carried out by means of the turbomolecular pump TMN-1000M, for the purpose of an exception of vapors of oil in it. Thus working pressure in the research camera made ~ $1 \cdot 10^{-6}$ Tor.

As studied constructional materials the aluminum alloy of D16 and stainless steel of an austenitic class 12X18H10T (steel constructional cryogenic), having broad practical application were chosen.

Samples represented disks with a diameter of 7 mm and 3 mm high. Flat surfaces of disks were ground and polished from two parties to mirror shine. The typical micrograph of a surface measured by means of a atomic force microscope Solver PRO-M, is given on Fig. 4. The average size of a roughness of a surface on a site with sizes of 100x100 microns didn't exceed 170 nanometers



(a) (b) (c)

Fig. 4. Micrograph of a surface of a sample from D16 alloy: (a) - the two-dimensional image of a surface in brightness scale; (b) – average roughness of a surface; (c) – three-dimensional image of a surface.

When carrying out researches various options of placement of samples in the ring cylindrical cathode with explosive issue were used. This cathode took place in the removable cathode assembly shown on Fig. 5.

Fig. 5. Appearance of removable cathode assembly with explosive emission: 1 – ring cylindrical cathode; 2 – sample.

2.2. Parameters of an exciting pulse electronic beam

In the process of researches on studying of influence of intensive streams of ions of small duration on constructional materials the pulse heavy-current accelerator of electrons with average energy of electrons in a range 250 keV was used. Characteristic oscillograms of impulses of voltage and the current, measured at discharge on a cryotarget, are given in Fig.6. Amplitude of impulses of voltage made ~ 250 kV. Duration of impulses of voltage made ~ 40 nanoseconds. Assessment of amplitude of an impulse of current ~ 9.5 kA at distance the cathode anode ~ 5 mm.

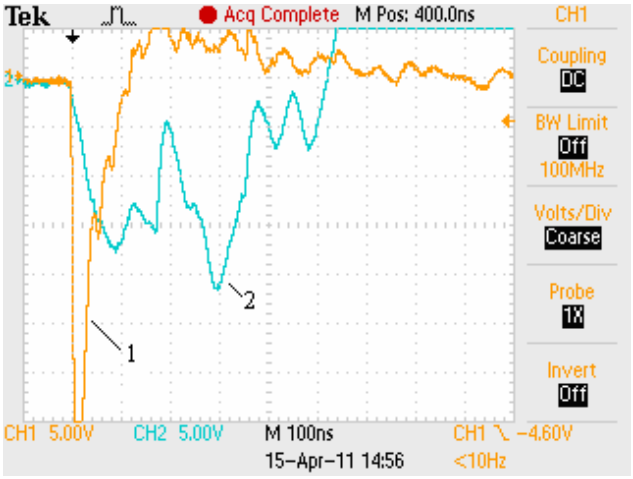


Fig. 6. Characteristic forms of oscillograms of impulses of current and voltage at direct release of an electronic beam on the cryotarget/anode from firm inert gas (Xe): 1 – voltage impulse (relative units), 2 – a current impulse (relative units).

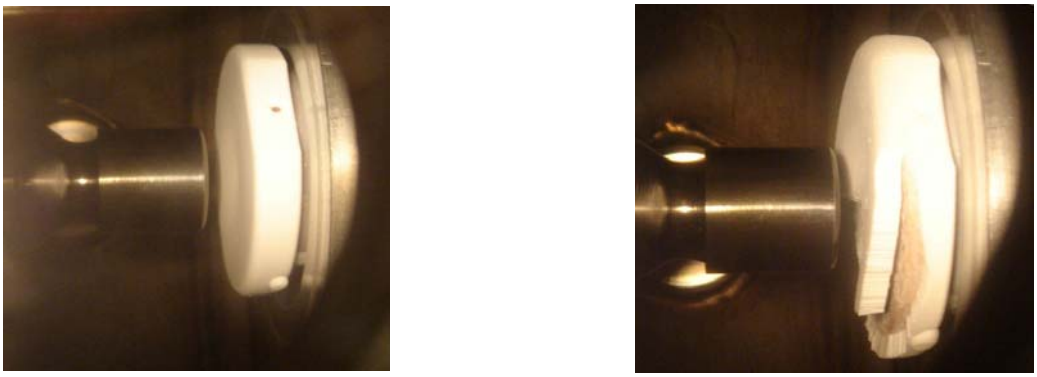
2.3. Cryotarget/anode formation from firm inert gases (Xe)

As the working gas which is freezing condensing at cooling of a copper anode plate (Fig.3) up to the temperature of 45 - 50 K, was used gas xenon (Xe 4.8, with percentage of xenon 99,9988 %). At such temperature all gases, except for helium, hydrogen and neon are condensed. Freezing / xenon condensation on the cooled copper plate of the anode was conducted for filling in the research



(a) (b)

Fig. 7. Cryotarget/anode photos with condensed layer of solid xenon: (a) – an initial layer; (b) – a type of a target after a splitting off.

camera xenon gas. The photo of a thin frozen layer of Xe is provided on Figs. 7(a).
At target radiation by a powerful high-voltage impulse of electrons in the center of a target the crater by diameter ~ 10 mm is formed. At repeated radiation such target needs to be restored, i.e. freez in the target center a new layer of Xe by a repeated blousing of xenon and to sustain necessary time (~ 10 min.). At rather thick layer of xenon in the process of discharge the splitting off of part of a layer, as shown in Figs is observed. 7. It is visible that the condensed layer of xenon possesses crystal structure. By a visual assessment thickness of a layer of xenon, frozen within 1 hour, made ~ 3 mm.

3. The experimental results

3.1. Radiation by an ionic bunch of samples from D16 alloy

At radiation by an ionic beam of samples from an alloy of D16 the following geometry of an arrangement of a sample in the cathode was used. Before a sample at distance of 1 mm the molybdenic grid with optical transparency of ~80% (3 lines/mm, thickness of Mo wire of 40 microns), welded on a ring from stainless steel 12X18H10T 1 mm thick was established. This sample was subjected to influence of five consecutive impulses of ions of Xe. Results of such impact are given in Fig.8.

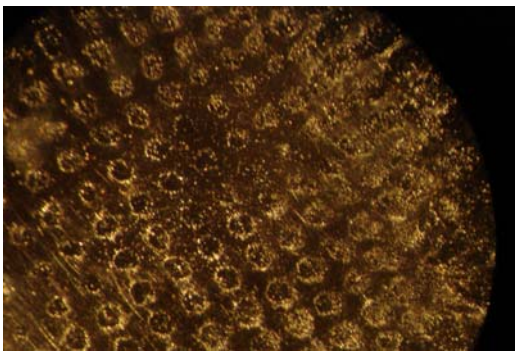


Fig. 8. The photo of a surface of a sample from an alloy of D16 subjected to influence of five impulses of ions of xenon through a molybdenic grid.

It is visible that on a surface of a sample accurately expressed regular relief from hollows (craters) and hills with approximately identical sizes is observed: width of hollows (craters) is equal ~ 180 microns, and width of hills ~ 160 microns. Thus distribution of intensity of a beam almost uniform on all area of a sample with primary concentration in the center of sample with a diameter about 3 mm, i.e. at the set configuration of cathodic knot is observed focusing of an ionic beam.
There is a probability of formation of craters at the expense of sample bombing by "spalls" microparticles from a firm xenon target which can arise because of a powerful irradiating impulse of electrons. To confirm or exclude such opportunity, experiment on sample radiation by an ionic bunch of xenon through an aluminum foil 10 microns thick was put. It was expected that in case of bombing by " spalls " microparticles of the xenon which is taking off from the cryotarget/anode with a huge speed, the aluminum foil will be punched and will contain a set of microopenings which can be registered by means of a nuclear and power microscope. As a result of such experiment the aluminum foil simply "exploded": the melted drop of a foil appeared on a sample surface, and on a copper plate of the anode drops of the melted aluminum were observed when defrosting target, as shown in Fig.9. The received result can be explained only with interaction of ions with an aluminum target, but not bombing by microparticles.

Fig. 9. The cryotarget/anode photo when defrosting after radiation of an aluminum foil (thickness of 10 microns) a powerful impulse of ions.

3.2. Radiation by an ionic beam of samples from stainless steel 12X18H10T

Experiments on radiation of samples were executed by a powerful pulse bunch of ions of xenon from stainless steel in the same geometry, as well as at impact on D16 alloy. Symmetric distribution of influence and the relief of a surface consisting of hollows and heights is here too observed, coincides with received earlier for samples from an aluminum alloy (Figs. 10).

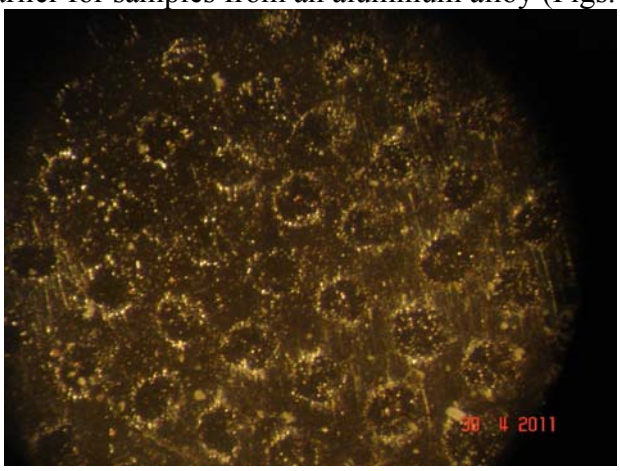

Fig.10. The photo of a surface of a sample from stainless steel 12X18H10T after radiation by a pulse beam of ions of xenon.

4. Numerical modeling of process of destruction of an aluminum sample

When carrying out experiment the bunch of ions was passed through a molybdenic grid with a cell size ~ 250x250μm^2. On an aluminum sample craters with sizes ~ 180 μm opposite to each cell of a grid are found. Let's consider the task corresponding to impact on a sample of a stream of ions, passing through one cell of a grid. In experiment it is possible to define the energy transferred to a sample by a stream, passing through one cell of a grid. Further, we replace impact of this stream on a sample with blow to a sample of the aluminum cylinder with a diameter of 60 microns and length corresponding to duration of influence (80-100 nanoseconds). Speed of the cylinder we choose from compliance of energy of the hammer of energy of a beam of the ions passing through one cell of a

molybdenic grid. When carrying out numerical modeling the developed approach [3-5], allowing to integrate criterion of incubation time into numerical schemes on the basis of a method of final elements was applied. For the solution of a task the finite element ANSYS [6] package was used.
The following parameters of a target, characteristic for aluminum were chosen: density – 2700 kg/m^3, the Young's modulus – 6.65•10^{10} Pa, Poisson's ratio – 0.34, critical stress on a gap – 3•10^8 Pa, the structural size – 15 microns, target thickness – 3 mm. The hammer material on properties corresponds to a target material. Diameter of the hammer – 60 microns, height – 90 microns. hammer speed at the time of the contact beginning – 650 m/s.
After completion of modeling the zone in which there was a material division was investigated. On a fig. 11 the type of a sample after completion of modeling is presented. On a fig. 12 on not deformed sample knots in which there was a destruction are noted.

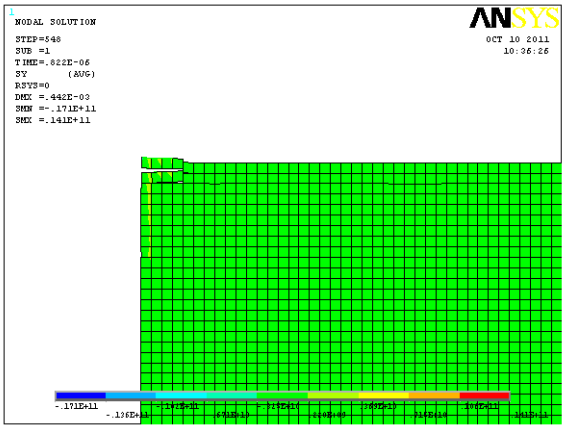

Fig. 11. Type of a sample after completion of modeling.

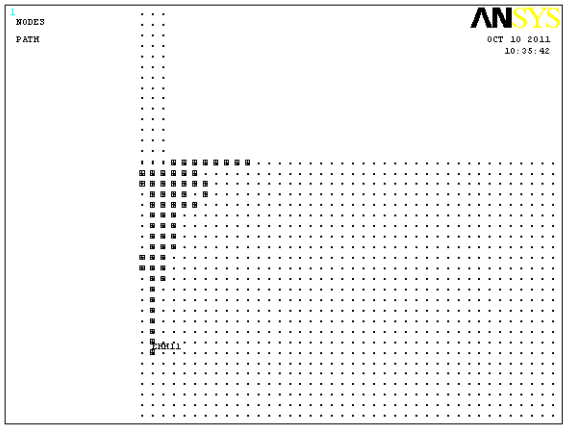

Figure 12. Node in which there was a destruction.

The size of the stamp formed on an irradiated surface, received as a result of numerical modeling coincides with observed in experiment. The received results speak about applicability of the developed approach for a prediction of destruction of the samples loaded by a stream of high-energy heavy ions.

5. Conclusion

On the basis of the conducted research on influence of intensive streams of ions (xenon) of small duration on physical and mechanical properties of constructional materials it is possible to draw the following conclusions:
1. The concept of creation of an intensive pulse source of ions on the basis of a cryotarget from solid inert gases (xenon) is realized at radiation by its powerful impulse of electrons from the cathode with explosive issue in the nanosecond range.
2. Impact of a short-time pulse ionic beam on samples from an alloy of D16 and stainless steel 12X18H10T leads to a surface erosion in the form of the separate craters which depth depends on the hardness of a material and quantity of impulses.
3. The measured parameters of craters on a surface of samples give the chance to formulate initial and boundary conditions in mathematical model for calculation of influence of intensive streams of ions of small duration on physical and mechanical properties of constructional materials.
4. Results of the carried-out numerical modeling of process of destruction of an aluminum target under the influence of a beam of high-energy ions by a method of final elements well coordinated with data of experiments.

Crack and fracture theory of liquid crystals and quasicrystals

Tian You Fan

School of Physics, Beijing Institute of Technology, Beijing, 100081,China

Corresponding author: tyfan2006@yahoo.com.cn

Abstract Liquid crystals and quasicrystals are fascinating phases of modern physics and chemistry, they are also important materials in current and potential applications. The liquid crystals belong to intermediate phase between fluids and solids in macroscopic sense, they present behaviour of anisotropic fluids, i.e., they behave both characters of conventional fluids and anisotropic elastic solids. The quasicrystals present unusual mechanical and physical properties due to the atomic arrangement being quite different from that of conventional crystals. To describe the mechanical behaviour of quasicrystals, one must introduce two different displacement fields, this leads to two different strain tensors and two stress tensors. This paper reports some results in the study on crack and fracture problems of liquid crystals and quasicrystals. The nonlinear fracture analysis is important for the both materials. However there is fundamental difficulty in the analysis due to lack of plastic constitutive equations for them. Some physical models and relevant mathematical methods are developed to overcome the difficulty, and some results have been obtained, which are of a development of fracture theory of conventional structural materials.

Keywords Liquid crystals, quasicrystal, crack, fracture

1. Introduction

Liquid crystals, in macroscopic sense, are anisotropic fluids. Therefore they belong to an intermediate phase between fluids and crystals. The mechanical behaviour of liquid crystals presents the character of both fluids and solids.

There are various types of liquid crystals, here we discuss the mechanics only for nematic, smectic and columnar liquid crystals.

Different from the behaviour of both fluids and solids, the deformation and motio of liquid crystals should be introduced a vector named director $\mathrm{n}=\left(n_x,n_y,n_z\right)$ apart from displacement vector $\mathrm{u}=\left(u_x,u_y,u_z\right)$ and velocity vector $V=\left(V_x,V_y,V_z\right)$.In addition, the constitutive equation of liquid crystals is different from either generalized Newton's equation or generalized Hooke's equation. For example, for the nematic liquid crystals, we have constitutive law [1]

$$\sigma_{ij} = \sigma_{ij}^{0} + \sigma_{ij}^{'}$$
$$\sigma_{ij}^{0} = -\Pi_{ik}\frac{\partial}{\partial x_j}n_k, \Pi_{ik} = \frac{\partial F}{\partial\left(\frac{\partial}{\partial x_i}n_k\right)} \tag{1}$$
$$\sigma_{ij}^{'} = -p\delta_{ij} + \mu\frac{1}{2}\left(\frac{\partial V_i}{\partial x_j} + \frac{\partial V_j}{\partial x_i}\right)$$

in which F is the free energy of the system, n_k the component of the director mentioned above, p the pressure, μ the fluid viscosity, V_i the component of velocity and δ_{ij} the unit tensor, respectively. The free energy consists of three parts: first one arising from bulk deformation (by the displacements), second one arising from deformation due to curvature, another arising from the coupling between distortion and curvature, i.e.,

$$F = F_e + F_c + F_{ec} \tag{2}$$

where

$$F_e = \frac{1}{2}C_{ijkl}\varepsilon_{ij}\varepsilon_{kl} \tag{3}$$

denotes the conventional elastic strain energy, or the Cauchy strain energy, C_{ijkl} the elastic constants, ε_{ij} the Cauchy strain tensor, and

$$F_c = \frac{1}{2}K_1(div(\mathbf{n}))^2 + \frac{1}{2}K_2(\mathbf{n}\cdot rot\mathbf{n}))^2 + \frac{1}{2}K_3(\mathbf{n}\times rot\mathbf{n}))^2 \tag{4}$$

the Frank energy due the curvature, and K_1, K_2, K_3 the modulia of Frank deformation, in addition

$F_{ec} =$ Deformation energy of coupling between Cauchy strain and Frank strain (5)

For the most cases F_{ec} can be omitted.

The equations of motion include the equations of momentum conservation,

$$\rho\left[\frac{\partial V_i}{\partial t} + (\mathrm{V}\cdot\nabla V_i)\right] = \frac{\partial\sigma_{ij}}{\partial x_j} \tag{6}$$

equation of mass conservation

$$\frac{\partial\rho}{\partial t} + div(\rho\mathrm{V}) = 0 \tag{7}$$

and equation of entropy conservation if there is no dissipation

$$\frac{\partial S}{\partial t} + div(S\mathrm{V}) = 0 \tag{8}$$

where ρ denotes the mass density of the matter, S the entropy. If there is dissipation the equation (8) should be changed, but the discussion is omitted here. From the above simple introduction, we can mind that the equations of the liquid crystals are quite complicated. Some detail for the solutions will be introduced later.

For smectic liquid crystals, the director stands for

$$\mathrm{n} = \left(\frac{\partial u_z}{\partial x}, \frac{\partial u_z}{\partial y}, 1\right) \tag{9}$$

where u_z is the displacement component in the direction normal to the layers of

smectics, and $u_x = u_y = 0$.

For columnar liquid crystals, the director stands for

$$\mathrm{n} = \left(\frac{\partial u_x}{\partial z}, \frac{\partial u_y}{\partial z}, 1 \right) \tag{10}$$

where u_x, u_y are the displacement components along the directions x, y respectively, and $u_z = 0$.

Quasicrystals belong to another fascinating phase of condensed matter, first observed in 1982[2]. Macroscopically their main feature is that there are two different displacement fields, one is the phonon field u, according to the terminology of physics, which is similar to the displacement field in the classical elasticity under the long-wave length approximation, the other is the phason field which is new concept out of the regime of the classical continuum mechanics. The introducing of the phason field results in a great challenge to the traditional continuum mechanics. This leads to two different strain tensors, one is the Cauchy strain tensor

$$\varepsilon_{ij} = \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \tag{11}$$

another is the phason strain

$$w_{ij} = \frac{\partial w_i}{\partial x_j} \tag{12}$$

The constitutive equations are

$$\sigma_{ij} = C_{ijkl}\varepsilon_{kl} + R_{ijkl}w_{kl} \qquad H_{ij} = R_{klij}\varepsilon_{kl} + K_{ijkl}w_{kl} \tag{13}$$

in which σ_{ij} is the stress tensor associated with strain tensor ε_{ij}, H_{ij} the stress tensor associated with the strain tensor w_{ij}, C_{ijkl} the phonon elastic constants, K_{ijkl} the phason elastic constants, and R_{ijkl} the phonon-phason coupling elastic constants, respectively.

The equations of motion are as follows [39,40]

$$\rho \frac{\partial^2 u_i}{\partial t^2} = \frac{\partial \sigma_{ij}}{\partial x_j} \tag{14}$$

$$\kappa \frac{\partial w_i}{\partial t} = \frac{\partial H_{ij}}{\partial x_j} \tag{15}$$

where $\kappa = 1/\Gamma_w$, in which Γ_w the dissipation kinematics coefficient of phason field of the material defined by Lubensky et al [3]. It is evident that the equation (14) represents the wave propagation, while equation (15) represents diffusion. Because σ_{ij} and H_{ij} are coupled, the motion of quasicrystals is in coupled of wave propagation and diffusion.

The above equations are only an outlook of dynamics of liquid crystals and quasicrystals, this reveals that the mechanics of either liquid crystals or quasicrystalsis quite different from that of conventional fluids as well as elastic solids (or periodic crystals), so the solutions of them are quite different from those of classical fluid dynamics and elasticity.

2. Crack and fracture of liquid crystals

The mechanics of liquid crystals are studied by de Gennes et al [4], Oswald et al [5] etc, the main attention of theirs was paid to discuss the dislocation and disclination problems, but there are some questions of the classical solutions which may be paradoxes, this suggests that the mechanics of liquid crystals needs to develop further. Brostow et al [5] started to study the crack problems in polymer liquid crystals. Because liquid crystals including nematic, smectic and columnar ones, they can be classified as monomer liquid crystals (MLCs) irrespectively of the fact whether they can or cannot polymerize into polymer liquid crystals (PLCs) [6]. That classification is due to Samuski [7] and has been used by a number of authors [8, 9]. The present model applies to MLCs and nematic, smectic and columnar phase LCs in particular. For studying crack problems of liquid crystals one must develop mechanics of liquid crystals, including three-dimensional elasticity, plasticity and dynamics.

The problem of screw dislocation in smectic liquid crystals A or smectics A for simplicity is a longstanding puzzle, de Gennes [4], Kleman [10], Pershan [11] and Landau and Lifscitz [12] presented the solution, but which may be of mistake. Pleineer [13] pointed out the problem of the solution, but the mistake could not be corrected. This problem shows in the theoretical system of mechanics of liquid crystals there may be some difficulties, in which the incompatibility between governing equations and boundary conditions is one of puzzles. For example, in the smectics A, the final governing equation is if only analyzing dislocation

$$\left(\rho B^{'}\frac{\partial^2}{\partial z^2}-K_1\nabla^2\nabla^2\right)u_z=0 \tag{16}$$

which is a partial differential equation of fourth order, which needs two boundary conditions to determine solutions, but the authors of Refs [4,10-13] gave only one boundary condition, this leads to the incompatibility between governing equation and boundary conditions and is the reason of their mistakes. Fan and Li [14] develop the elasticity of the smectic liquid crystals, pay attention to create the well-conditional boundary value problem of governing equation of mechanics of liquid crystals. So that Fan and Li give a correct solution for the dislocation problem as

$$u_z=\frac{b}{2\pi}\left[1+D_1 r\sin\theta\right]\theta \tag{17}$$

in which

$$D_1=\frac{-\frac{8}{3}\pi\alpha}{\left(R_0+r_0\right)\left(\frac{\pi}{4}\alpha\beta+\frac{b^2K_1}{8\pi}\right)\ln\frac{R_0}{r_0}+\frac{\pi}{320}\alpha\gamma\left(R_0-r_0\right)} \tag{18}$$

where

$$\alpha=\left(\frac{b}{2\pi}\right)^4\rho_0 B^{'},\beta=2+\frac{32\pi^2}{3},\gamma=75-160\pi^2+256\pi^4 \tag{19}$$

in equations (15) and (19), $\rho_0 B^{'}$ represents the Young's modulus in direction z of the smectics A, the meaning of K_1 is one of Frank modulus mentioned above, b the magnitude of the Burgers vector of dislocation, r_0 the size of dislocation core, R_0 the size of the body containing the dislocation. The solution (17) modifies the mistake of the classical solution of de Gennes-Kleman-Pershan.

The well-conditional boundary value problem just can develop the work on crack in liquid crystals. As an example, a solution of plastic crack in one of smenctics A is found by Fan [15] based on the dislocation pile-up concept, the size of plastic zone around crack tip and crack tip opening displacement are determined, shown in Figs. 1 and 2.

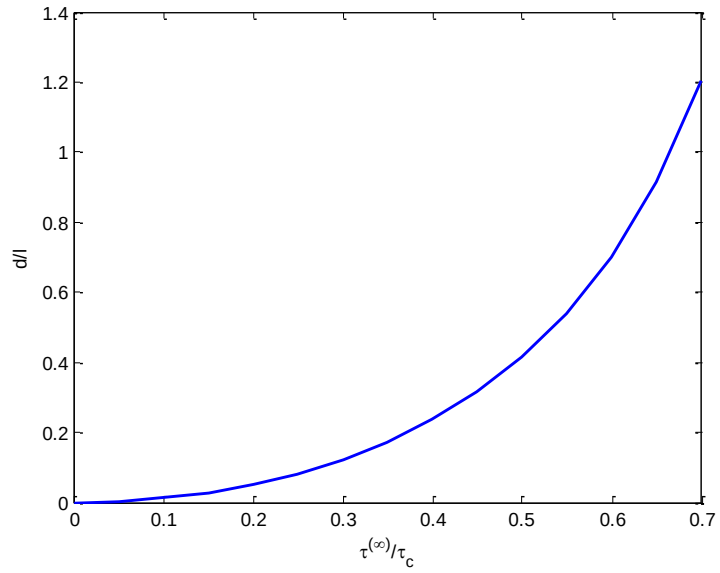

Fig.1 Variation of normalized plastic zone size with normalized applied stress

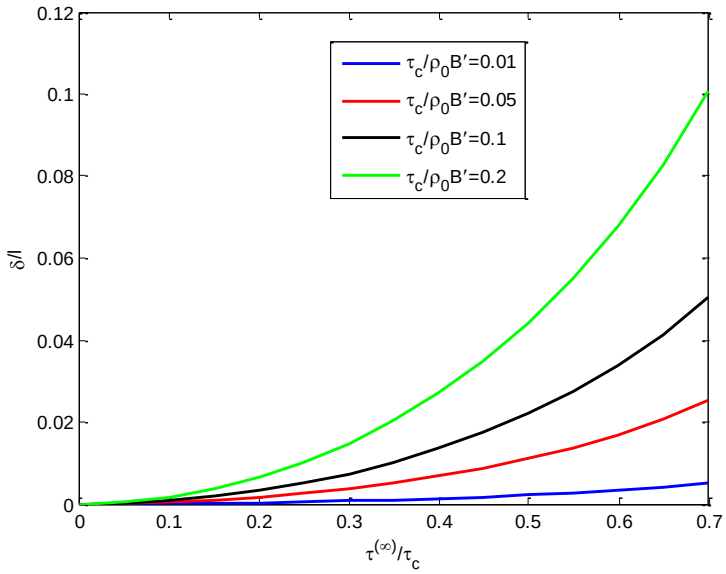

Fig.2 The variation of normalized crack tip opening displacement versus normalized applied stress

Other solutions for plastic crack in smectic A are obtained by Fan [16]. The three-dimensional elasticity of smectics B liquid crystals is studied by Fan [17], the governing equations are reduced to three generalized harmonic equations, and an elliptic disc-shaped crack problem is solved, an approximate analytic solution is constructed. Fan and Chen [18] studied the solution of plastic crack of columnar

liquid crystals, but the result is more complicated than those of smectic liquid crystals A.

Due to the unusual structure of stress field of liquid crystals leads to some difficulties of the crack problem, for example, in the smectics A

$$\sigma_{xx} = \sigma_{yy} = \boldsymbol{K}_1 \nabla^2 \frac{\partial \boldsymbol{u}}{\partial \boldsymbol{z}}, \sigma_{zz} = \rho_0 \boldsymbol{B}' \frac{\partial \boldsymbol{u}}{\partial \boldsymbol{z}}, \sigma_{zx} = \sigma_{xz} = -\boldsymbol{K}_1 \nabla^2 \frac{\partial \boldsymbol{u}}{\partial \boldsymbol{x}}$$

$$\sigma_{zy} = \sigma_{yz} = -\boldsymbol{K}_1 \nabla^2 \frac{\partial \boldsymbol{u}}{\partial \boldsymbol{y}}, \sigma_{xy} = \sigma_{yx} = 0$$

it is evident that between the stress components the stress singularities will be quite different .

Due to the space limitation, we do not list the other questions and other results on mechanics of liquid crystals.

3. Linear theory crack and fracture of quasicrystals

The mechanics of quasicrystals is developed by many scientists, in which the elasticity of the material is advanced for example, refer to Lubensky et al [3], Ding et al [19], Fan and Mai [20], Fan [21]. The systematical mathematical theory of elasticity of quasicrystals is developed by Chinese group [21]. The elasticity, plasticity and dynamics of icosahedral quasicrystals, the most important class of the material, are well studied in the work. By introducing displacement potential, the plane elasticity of icosahedral quaiscrystals is reduced to solve the sextuple harmonic equation [21,22,23]

$$\nabla^2\nabla^2\nabla^2\nabla^2\nabla^2\nabla^2 F(x,y) = 0 \tag{20}$$

From the equation we obtain the solution of a crack in icosahedral Al-Pd-Mn quasicrystals by the complex analysis of the Fourier analysis, which is given as follows

$$K_I^{\|} = \sqrt{\pi a}\, p \tag{21}$$

$$G_I = \frac{1}{2}\frac{\partial}{\partial a}[2\int_{-a}^{a}(\sigma_{yy}(x,0) \oplus H(x,0))(u_y(x,0) \oplus w_y(x,0))dx] = \frac{1}{2}(\frac{1}{\lambda+\mu} + \frac{c_7}{c_3})(K_I^{\|})^2$$

in which

$$c_3 = \mu(K_1 - K_2) - R^2 - \frac{(\mu K_2 - R^2)^2}{\mu K_1 - 2R^2}, c_7 = \frac{c_3 K_1 + 2c_1 R}{\mu K_1 - 2R^2}$$

$$c_1 = \frac{R(2K_2 - K_1)(\mu K_1 + \mu K_2 - 3R^2)}{2(\mu K_1 - 2R^2)}$$

The Fig. 3 shows the energy release rate variation and comparison between solutions of quasicrystals and crystals.

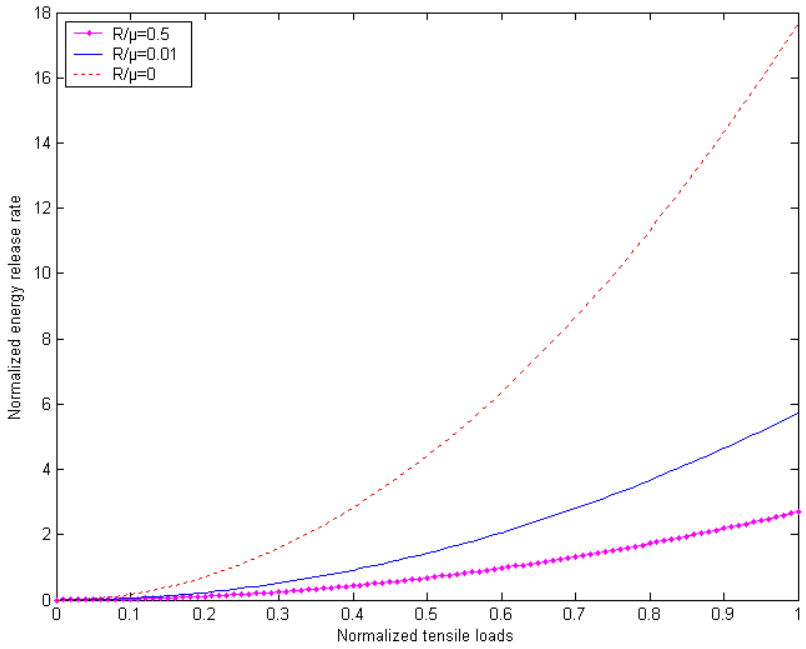

Fig.3 Influence of phason and phonon-phason coupling to the energy release rate

in which solution for crystals is also given. One can find that the solutions of quasicrystals and crystals are quite different each other (one corresponding to crystals is the case $R/\mu = 0$).

Other solutions can be found in Ref [21].

4. Nonlinear solutions of cracks of quasicrystals

Though there are people try to give some explanations on plastic deformation by using dislocation model and so on, the problem is substantively unsolved so far. Due to lack of enough experimental data in macroscopy, the constitutive equation of plasticity of quasicrystals has not been set up. This leads to difficulty doing stress analysis of the material. One can say that the study is in an infant stage. In spite of these difficulties, people pay effort to do some work as above pointed out, the experiments[24-33] reported in the above references provide some hints, which are beneficial for the stress analysis for plasticity and defects of the material. In the following some semi-phenomenological and semi-theoretical results are listed, they may provide a reference for the researchers in the community.

4.1 Generalized cohesive force model [34,35]

Due to lack of constitutive equation of plasticity of quasicrystals up to now, it may be a possible way that we draw the results of classical plasticity, classical dislocation theory and classical nonlinear fracture theory to study some relevant problems in quasicrystals. A useful model in classical elasto-plastic fracture theory is so-called Dugdale-Barenblatt model, the paper [34] extended it to plastic analysis of quasicrystals, and named it be generalized Dugdale-Barenblatt model, the classical work has been done by [34] and [35]. In terms of the model, we determined the size

of plastic zone around the crack tip of anti-plane problem of three-dimensional icosahedral quasicrystals

$$\delta_I = \lim_{x\to l} 2u_y(x,0) = \lim_{\varphi\to\varphi_2} 2u_y(x,0) = 2\left(\frac{1}{\lambda+\mu}+\frac{c_4}{c_2}\right)\cdot\frac{\sigma_s a}{\pi}\cdot\ln\sec\left(\frac{\pi}{2}\frac{p}{\sigma_s}\right) \qquad (22)$$

where

$$c_2 = \mu(K_1-K_2)-R^2-\frac{(\mu K_2-R^2)^2}{\mu K_1-2R^2},\quad c_4 = c_1 R+\frac{1}{2}c_2\left(K_1+\frac{\mu K_1-2R^2}{\lambda+\mu}\right) \qquad (23)$$

and

$$c_1 = \frac{R(2K_2-K_1)(\mu K_1+\mu K_2-3R^2)}{2(\mu K_1-2R^2)}$$

The curve drawn from（22）refer to Fig.4，which shows the effect of phason and phonon-phason coupling is significant.

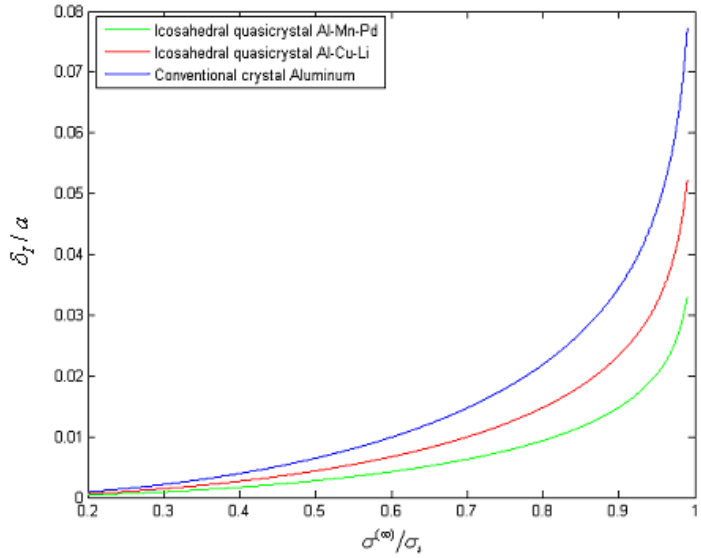

Fig. 4 Crack tip opening displacement versus applied stress for icosahedral quasicrystal [21]

4.2 Generalized continuum dislocations model [36]

We developed the continuous dislocation model [36], the results are identical to those given in Subsection 4.1.

4.3 Model based on generalized Eshelby energy-momentum tensor [37]

The generalized Dugdale-Barenblatt model and generalized continuum dislocation model, are quite different physically and mathematically, yield amazingly the complete identical solutions, we realized that there exist some inherent connection between the two models. Paper [37] gave a probe for the question. They proposed the generalized energy-momentum tensor of quasicrystals

$$G = Fn_1 - \sigma_{ij} n_j \frac{\partial u_i}{\partial x_1} - H_{ij} n_j \frac{\partial w_j}{\partial x_1} \tag{24}$$

and generalized integral of path independency

$$E = \int_\Gamma G d\Gamma \tag{25}$$

and found that they are the uniformly theoretical base of generalized Dugdale-Barenblatt model and generalized continuum dislocations model.The idea comes from the classical work of Eshelby [38] for crystals.

5. Dynamic solutions of cracks of quasicrystals

In the dynamic regime, the essential differences between phonons and phasons just can be profoundly revealed. However the problem presents fundamental difficulty because the mechanism of phason dynamics is not so clear so far.

Rocal and Lorman[39]and Fan et al [40]，suggested the dynamic equation set for quasicrystals (14) and (15).This is the simplest dynamic equation set of quasicrystals, which coupled deformation geometry equations and stress-strain relations and lead to.the final governing equations of elasto-dynamics (or call elasto-/hydro-dynamics)

$$\left.\begin{aligned}
&\frac{\partial^2 u_x}{\partial t^2} + \theta \frac{\partial u_x}{\partial t} = c_1^2 \frac{\partial^2 u_x}{\partial x^2} + (c_1^2 - c_2^2) \frac{\partial^2 u_y}{\partial x \partial y} + c_2^2 \frac{\partial^2 u_x}{\partial y^2} + c_3^2 \left(\frac{\partial^2 w_x}{\partial x^2} + 2 \frac{\partial^2 w_y}{\partial x \partial y} - \frac{\partial^2 w_x}{\partial y^2} \right) \\
&\frac{\partial^2 u_y}{\partial t^2} + \theta \frac{\partial u_y}{\partial t} = c_2^2 \frac{\partial^2 u_y}{\partial x^2} + (c_1^2 - c_2^2) \frac{\partial^2 u_x}{\partial x \partial y} + c_1^2 \frac{\partial^2 u_y}{\partial y^2} + c_3^2 \left(\frac{\partial^2 w_y}{\partial x^2} - 2 \frac{\partial^2 w_x}{\partial x \partial y} - \frac{\partial^2 w_y}{\partial y^2} \right) \\
&\frac{\partial^2 u_z}{\partial t^2} + \theta \frac{\partial u_z}{\partial t} = c_2^2 \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) u_z + c_3^2 \left(\frac{\partial^2 w_x}{\partial x^2} - \frac{\partial^2 w_x}{\partial y^2} - 2 \frac{\partial^2 w_y}{\partial x \partial y} + \frac{\partial^2 w_z}{\partial x^2} + \frac{\partial^2 w_z}{\partial y^2} \right) \\
&\frac{\partial w_x}{\partial t} + \theta w_x = d_1 \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) w_x + d_2 \left(\frac{\partial^2}{\partial x^2} - \frac{\partial^2}{\partial y^2} \right) w_z + d_3 \left(\frac{\partial^2 u_x}{\partial x^2} - 2 \frac{\partial^2 u_y}{\partial x \partial y} - \frac{\partial^2 u_x}{\partial y^2} + \frac{\partial^2 u_z}{\partial x^2} - \frac{\partial^2 u_z}{\partial y^2} \right) \\
&\frac{\partial w_y}{\partial t} + \theta w_y = d_1 \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) w_y - d_2 \frac{\partial^2 w_z}{\partial x \partial y} + d_3 \left(\frac{\partial^2 u_y}{\partial x^2} + 2 \frac{\partial^2 u_x}{\partial x \partial y} - \frac{\partial^2 u_y}{\partial y^2} - 2 \frac{\partial^2 u_z}{\partial x \partial y} \right) \\
&\frac{\partial w_z}{\partial t} + \theta w_z = (d_1 - d_2) \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) w_z + d_2 \left(\frac{\partial^2 w_x}{\partial x^2} - \frac{\partial^2 w_x}{\partial y^2} - 2 \frac{\partial^2 w_y}{\partial x \partial y} \right) + d_3 \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) u_z
\end{aligned}\right\} \tag{26}$$

where

$$c_1 = \sqrt{\frac{\lambda + 2\mu}{\rho}}, c_2 = \sqrt{\frac{\mu}{\rho}}, c_3 = \sqrt{\frac{R}{\rho}}, d_1 = \frac{K_1}{\kappa}, \ \mathrm{d}_2 = \frac{K_2}{\kappa}, d_3 = \frac{R}{\kappa} \tag{27}$$

Note that c_1, c_2 and c_3 represent speeds of elastic waves, while d_1, d_2 and d_3 are not wave speeds, which are diffusive coefficients of phasons.

The numerical analysis is given for the specimen shown in Fig.5 made of icosahedral quasicrystal. After finite difference treatment on equation set (26) and corresponding boundary and initial conditions, the dynamic stress intensity factor for initiation of crack growth is obtained and shown in Fig.6.In the computation this is a

simplest equation set of hydrodynamics of quasicrystals, which is simplified from the equations of Lubensky et al [3].

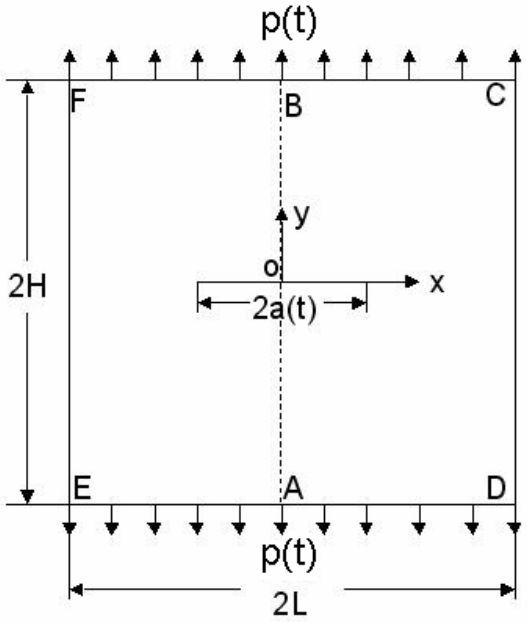

Figure 5 Sample containing a dynamic crack of two-dimensional quasicrystals

After finite difference treatment on equation set (26) and corresponding boundary and initial conditions, the dynamic stress intensity factor for initiation of crack growth is obtained and shown in Fig.6. In the computation

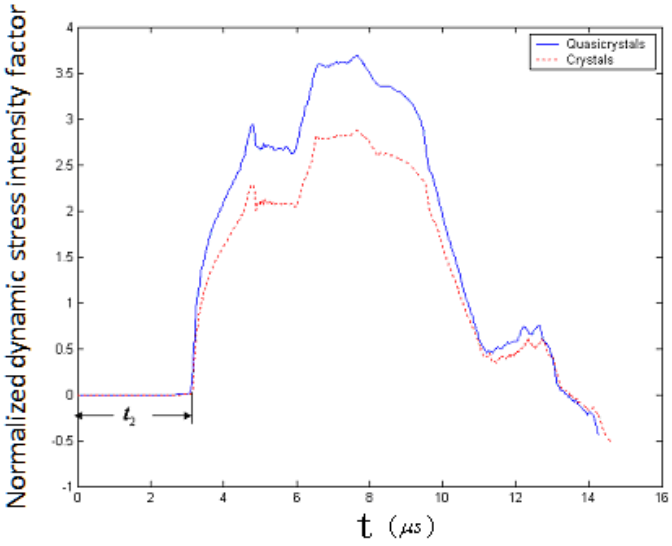

Figure 6 The dynamic stress intensity factor of rectangular specimen with a central crack of icosahedral Al-Pd-Mn quasicrystal under impact loading (for stationary crack)

the material is icosahedral Al-Pd-Mn quasicrystal with material constants：

$$\rho = 5.1\text{g/cm}^3, \lambda = 74.2, \mu = 70.4(GPa), K_1 = 72, K_2 = -37(MPa)$$

$$\Gamma_w = 1/\kappa = 4.8\times10^{-19}\text{m}^3\bullet\text{s/kg}=4.8\times10^{-10}cm^3\bullet\mu s/g$$

$R/\mu = 0.01$ for quasicrystal, and $R/\mu = 0$ for crystal. It is evident that the results between quasicrystal and crystal are quite large.

The dynamic stress intensity factor for fast crack propagation of the central specimen is illustrated in Fig.7, which comes from monograph [21].

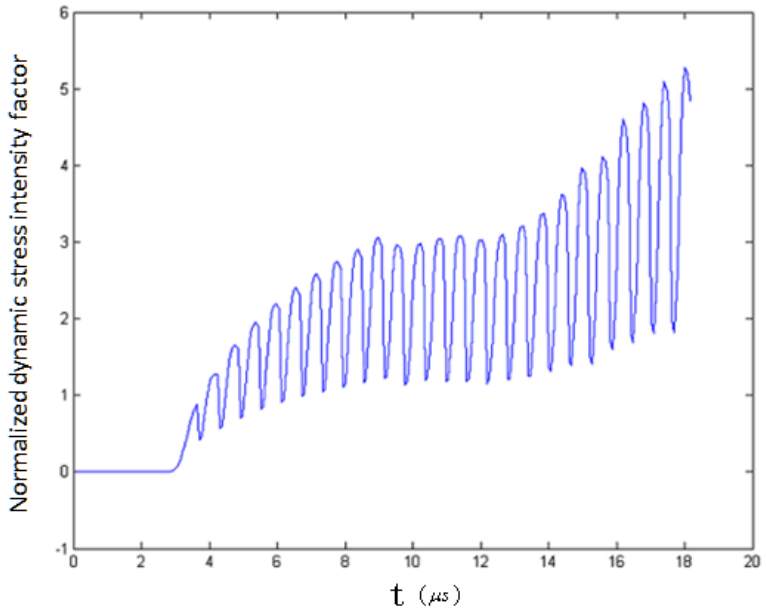

Figure 7 Dynamic stress intensity factor versus time of fast propagating crack in rectangular specimen with a central crack of icosahedral Al-Pd- Mn quasicrystal

The oscillation of the curve comes from the interference and reflection of waves, in which there are reasons come from numerical computation, it is needed doing further study.

6. Discussion and conclusion

The study of crack and fracture problems in liquid crystals is just begun, so it is in infant stage. The difficulty comes from some basic problems in the mechanics of liquid crystals, this also provides opportunity to gain the achievements in the field.

The linear elastic fracture theory of quasicrystals has been developed, the study of nonlinear and dynamic fracture theories of quasicrystals is also carried out, but faces some fundamental difficulties.

Because of many unsolved critical issues, the study is a fascinating research area of the materials science.

Analysis of Failure Waves with an Elasto-statistical-brittle Model

Zhijie Jiang[1], Mengfen Xia[1], Haiying Wang[1,*]

[1] Institute of Mechanics, Chinese Academy of Sciences, 100190, China

Abstract The origin and propagation mechanism of failure waves poses a challenge to our conventional understanding of dynamic failure. In this paper, the failure wave is attributed to the catastrophic rupture in brittle materials and an elasto-statistical-brittle (ESB) model is developed to describe the catastrophic behavior. In the ESB model, the disordered heterogeneity of brittle solids at mesoscopic scale is characterized with statistical description of the shear strength of mesoscopic units. The evolution of microdamage is controlled by the shear strength and the shear stress applied, and eventually induces catastrophic rupture in brittle materials. Considering the failure wave as a propagating boundary of catastrophic failure, the propagation of the failure wave is predicated with wave theory. Several predicted speeds of failure waves are in good agreement with experimental observations.

Keywords failure wave, wave speed, elasto-statistical-brittle model, catastrophic rupture, heterogeneity

1. Introduction

Shock induced delayed failure (the so called failure wave) in brittle materials has attracted extensive research in recent years [1-11]. This feature was first noted by Razorenov et al [2] as a small reload signal superimposed on rear surface velocity trace, suggesting the interaction of the release from the rear surface of the target with a moving front behind which the material undergoes a reduction of shock impedance. Further experiments [3] prove that the failure wave can be generated in glasses or ceramics at a stress near or below the HEL and the speed of failure wave does not correspond to any elastic wave. In addition, behind this wave, the longitudinal stress changes little but the transverse stress increases, indicating a decrease in shear strength, and spall tensile strength falls to essentially zero [4-6].

Several models have been proposed to address the origin of failure waves. However, a satisfactory explanation and description for the failure wave is still lacking. Clifton [7] assumes the failure wave as a propagating phase boundary. In his model, the square of the failure wave speed is proportional to the ratio of the jump in stress over the jump in strain. However, the available stress measurements clearly show that the failure wave causes either no change or small deduction in the longitudinal stress, but a large jump in the longitudinal strain. Feng [8] suggests that the propagation mechanism of failure front is a diffusive process. In his model, the failure front is not a mechanical wave, and the failure front speed is controlled by the stress deviator and dilated volume. To some extent, his simulation agrees with experiments, but the failure wave speed is disordered during the failure wave propagating. Moreover, his model assumes no changes in the longitudinal strain, which conflicts with experimental observations [9]. Kanel [2], Partom [10] and Espinosa [11] suppose the failure wave as a damage evolution process originating from the shocked surface. Hence, the predicted failure evolution behind the initial shock wave is independent of location instead of having an increasing time delay with propagation distance as observed experimentally. As a result, the simulations of the failure wave phenomenon based on this type of material model require the use of a nonphysical ‘‘failure wave’’, e.g. switching on a failure process cell by cell at an assumed successive sequence.

In this paper, we attribute the failure wave to a propagating catastrophe process in brittle materials. To describe catastrophic rupture in heterogeneous brittle materials, an elasto-statistical-brittle (ESB)

model is developed. Considering the failure wave as a propagating boundary of catastrophic failure, the critical condition to generate failure wave and the failure wave speed could be obtained from the law of conservation.

The paper is organized as follows: Section 2 describes the details of ESB model and Section 3 is the modelling of failure wave phenomenon. Numerical simulation and comparison with the experimental data are presented in Section 4. A summary is given in Section 5.

2. Elasto-statistical-brittle (ESB) MODEL

Generally speaking, the catastrophic failure of heterogeneous brittle materials under impact loading is resulted from the initiation, growth, and coalescence of microdamage, which is obviously controlled by the interactions of stress pulse with local material properties and microstructure. Hence, in the ESB model, we consider a macroscopic representative volume element (RVE) comprised of a great number of heterogeneous mesoscopic units. The heterogeneity of the mesoscopic units can be characterized by their shear strength. For instance, we assume their shear strength τ_c follows a statistiacal distribution $h(\tau_c)$. The Weibull distribution is often used in the field of failure analysis due to its flexibility. That is,

$$h(\tau_c) = \frac{m}{\eta}\left(\frac{\tau_c}{\eta}\right)^{m-1} \exp\left(-\left(\frac{\tau_c}{\eta}\right)^m\right) \tag{1}$$

where η and m are the scale parameter and shape parameter of Weibull distribution, respectively. The scale parameter η is proportional to the mean strength of mesoscopic units and the shape parameter m reflects the degree of material heterogeneity. Physically, a larger m implies a more homogeneous material. Fig. 1 shows the distribution of material shear strength with different heterogeneity index m.

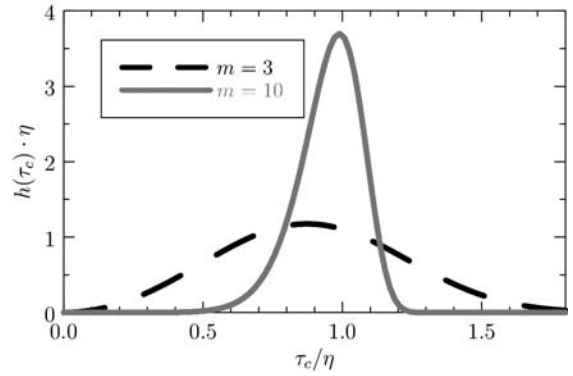

Figure 1. The distribution of material shear strength with different shape parameter m

If the applied shear stress on the mesoscopic unit τ_{meso} reaches its shear strength τ_c, the unit fails. Denote macroscopic damage of the RVE as D, which can be expressed as:

$$D = \int_0^{\tau_{meso}} h(\tau_c)\, d\tau_c = 1 - \exp\left(-(\tau_{meso}/\eta)^m\right) \tag{2}$$

We further assume that compared with intact unit, the breaking mesoscopic units can sustain less hydrostatic stress but no shear stress. This assumption physically means that the macroscopic damage causes reductions in both shear modulus and volumetric modulus of the material, and the latter degrades less than the former. That is,

$$\begin{aligned} G &= G_0(1-D) \\ K &= (1-\zeta D)K_0 \end{aligned} \tag{3}$$

where $\zeta < 1$, K_0 and G_0 are the volumetric modulus and shear modulus of intact material, respectively.

The material behavior at the macroscopic level can be written as

$$\sigma_{ij} = [1-\zeta+\zeta\exp(-(\tau_{meso}/\eta)^m)]K_0\theta\delta_{ij} + 2G_0\exp(-(\tau_{meso}/\eta)^m)(\varepsilon_{ij} - \frac{1}{3}\theta\delta_{ij}) \tag{4}$$

where ε_{ij} is the strain tensor, σ_{ij} the stress tensor, θ the volumetric strain. Provided small damage and mean field approximation, γ is the maximum shear strain of the macroscopic element. Hence,

$$\tau_{meso} = G_0\gamma\,. \tag{5}$$

Specifically, in uniaxial strain state($\varepsilon_x = \gamma \neq 0$, $\varepsilon_y = \varepsilon_z = 0$), the constitutive relation can be simplified as

$$\begin{aligned} \sigma_x &= [1-\zeta+\zeta\exp(-(G_0\varepsilon_x/\eta)^m)]K_0\varepsilon_x + \frac{4}{3}G_0\exp(-(G_0\varepsilon_x/\eta)^m)\varepsilon_x \\ \sigma_y &= [1-\zeta+\zeta\exp(-(G_0\varepsilon_x/\eta)^m)]K_0\varepsilon_x - \frac{2}{3}G_0\exp(-(G_0\varepsilon_x/\eta)^m)\varepsilon_x\,. \\ \tau_{xy} &= G_0\exp(-(G_0\varepsilon_x/\eta)^m)\varepsilon_x \end{aligned} \tag{6}$$

In order to show the response of material under impact, we normalize the constitutive relation and get the dimensionless constitutive relation as

$$\begin{aligned} \bar{\sigma}_x &= \frac{2(1+\nu)}{3(1-2\nu)}[1-\zeta+\zeta\exp(-\bar{\varepsilon}_x^{\,m})]\bar{\varepsilon}_x + \frac{4}{3}\bar{\varepsilon}_x\exp(-\bar{\varepsilon}_x^{\,m}) \\ \bar{\sigma}_y &= \frac{2(1+\nu)}{3(1-2\nu)}[1-\zeta+\zeta\exp(-\bar{\varepsilon}_x^{\,m})]\bar{\varepsilon}_x - \frac{2}{3}\bar{\varepsilon}_x\exp(-\bar{\varepsilon}_x^{\,m}) \\ \bar{\tau}_{xy} &= \bar{\varepsilon}_x\exp(-\bar{\varepsilon}_x^{\,m}) \end{aligned} \tag{7}$$

where ν is the Possion's ratio of the intact material, $\bar{\sigma}_{ii} = \sigma_{ii}/\eta$, $\bar{\varepsilon}_{ii} = G_0\varepsilon_{ii}/\eta$. Fig.2 plots the normalized stress-strain relationship with different parameters.

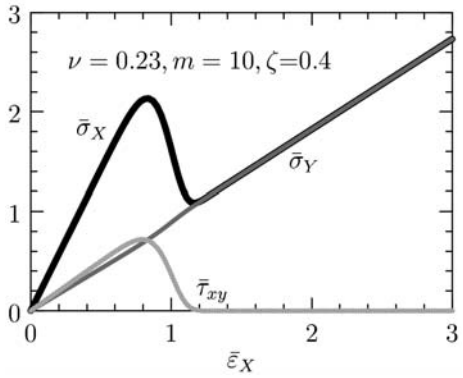

Figure 2. The simplified stress-strain relationship in uniaxial strain state

As Fig.2 shows, there exists a saddle point in the $\varepsilon_x - \sigma_x$ curve. Actually, the saddle point implies a catastrophic transition happening. As illustrated in Fig.3, when the longitudinal stress reaches σ_E, solids can not sustain any further compression, all of the meso-elements fail suddenly and the state directly jump from the unstable state A to the corresponding state B. In this process, the energy provided is used in fragmenting, thus, the longitudinal stress does not change.

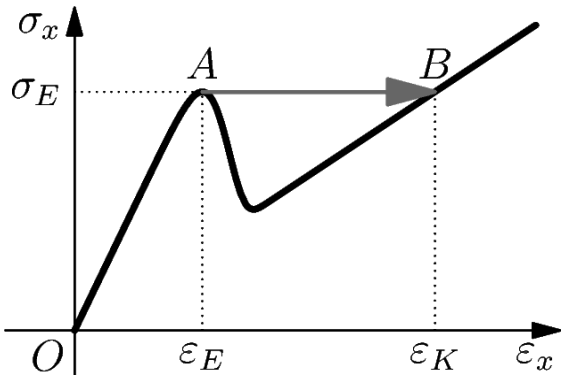

Figure 3. The catastrophic transition in ESB model

3. MODELLING OF THE FAILURE WAVE

In this section, we will analyze the origin of failure waves in a target plate described with a simplified ESB model.

Fig. 4 is the $x-t$ diagram of flyer plate and target plate. In the flyer plate, region 1 is in the initial state and region 4 in the final state. In the target plate, region 2 is the shocked region behind the elastic wave and region 3 is failed zone behind the failure wave. As the flyer plate and target plate do not split up, region 3 and region 4 have the same longitudinal stress and particle velocity.

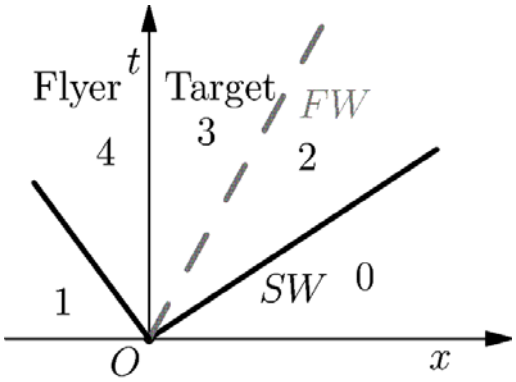

Figure 4. the $x-t$ diagram for waves

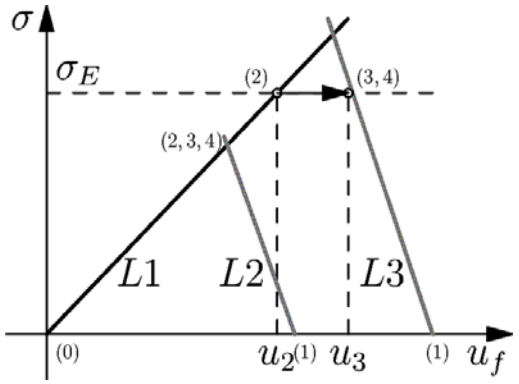

Figure 5. the $u-\sigma$ plane of plates system

Fig. 5 is the $u-\sigma$ plane of plates system. In the $u-\sigma$ plane, (u_2, σ_E) stands for region 2, and (u_3, σ_E) stands for region 3 and 4. L1 is the trajectory of states in flyer plate, and L2 is the trajectory of states of target subjected to low-velocity impact. When the impact loading is lower than the stress threshold σ_E, the catastrophic transition couldn't happen and there is no failure wave. However, if the stress state of target could exceed the stress threshold σ_E, as expressed by

L3 and L1, the catastrophic rupture happens and failure wave comes out.

Considering the law of conservation of mass, the failure wave speed can be obtained as,

$$C_{fw} = \frac{u_3 - u_2}{\varepsilon_3 - \varepsilon_2} = \frac{u_f - \rho_f \varepsilon_{fE} - \rho_t \varepsilon_2}{\varepsilon_3 - \varepsilon_2} \tag{8}$$

4. NUMBERICAL SIMULATION

In order to validate our theory, we simulate normal impact experiments on soda-lime glass specimens by copper plates. The properties of copper and soda-lime glass are summarized in Table 1.

Table 1 The properties of flyer plate materials [3]

Material	$C_L / km \cdot s^{-1}$	$\rho / kg \cdot m^{-3}$	ν
copper	4.560	8930	0.33
soda-lime glass	5.840	2490	0.23

Bourne et al. [3, 12] studied failure waves in soda-lime glass impacted with copper flyer. The results prove that the threshold stress to generate failure wave in soda-lime glass is 4.0 GPa. Therefore, in the simulation, we assume the threshold stress σ_E to be 4.0 GPa. In addition, since soda-lime glass is less heterogeneous, the shape parameter m is set as 10 and ζ as 0.4. The stress-strain relationship of soda-lime glass is presented in Fig. 6. As Fig. 6 shows, for soda-lime glass, the strain at the threshold stress is 0.0471 prior to the catastrophic rupture (ε_E) and 0.1330 after the catastrophic rupture (ε_K).With these parameters, we can calculate the speed of failure waves from Eq. (8).

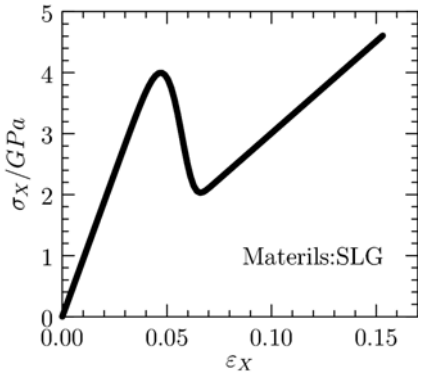

Figure 6. The response of soda-lime glass

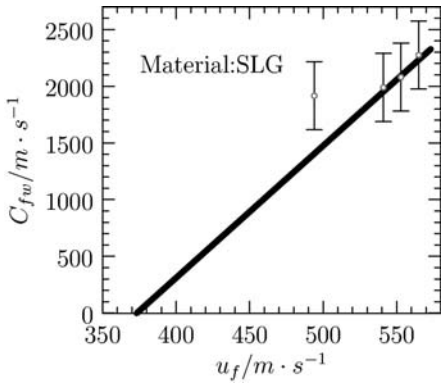

Figure 7. The relationship between u_f and C_{fw}

From Eq. (8), we obtain the relationship of failure wave speed vs. the impact velocity, as shown in Fig.7. It is obvious that, according to the ESB model, the speed of failure wave is linear with the impact velocity. In addition, Fig.7 demonstrates that the lowest impact velocity to generate the failure wave is 373.3 m/s, which approximately coincides with experimental observations [3, 12]. Table 2 quantitatively compares the speed of failure waves calculated with the ESB model with

experimental ones. Apparently, the model can basically replicate the experiments and the error is acceptable.

Table 2. Summary of Experimental data and the simulation results [3, 12]

Shot no.	Impactor	Target	Impact velocity u_f	C_{fw}(experimental)	C_{fw}(simulated)
98-01	copper	soda lime glass	494 m/s	1916 ± 300 m/s	1405 m/s
98-02	copper	soda lime glass	541 m/s	1989 ± 300 m/s	1952 m/s
98-03	copper	soda lime glass	553 m/s	2080 ± 300 m/s	2092 m/s
98-04	copper	soda lime glass	565 m/s	2275 ± 300 m/s	2232 m/s

5. SUMMARY

The origin and propagation of failure waves in brittle materials under impact loading have been investigated for many years. However, till now, failure waves cannot be well illustrated by any constitutive models. In this paper, the failure wave is attributed to the catastrophic rupture in brittle materials under impact loading. To describe the catastrophe behavior, an elasto-statistical-brittle (ESB) model is developed. In the ESB model, the shear strength of mesoscopic units follows a Weibull distribution, which reflects the heterogeneity of brittle solids. The evolution of microdamage is controlled by the shear strength and the shear stress applied, and induces reductions in shear modulus and volumetric modulus. Catastrophic rupture occurs when stress cannot be hold by the damaged material.

With the ESB model and wave theory, we predicted the failure waves in soda-lime glass impacted with copper plates. The critical impact velocity to generate the failure wave approximately coincides with experimental data. In addition, several predicted speeds of failure waves are in good agreement with experimental observations.

Abstract This paper presents the fracture behaviors in thin type-II superconducting strips with a transverse crack induced by the electromagnetic body force under a perpendicular applied field. Different from the longitudinal crack, the effect of the transverse crack on the current in the thin strip is considered. The Bean and Kim model of critical state are adopted to calculate the electromagnetic force. Based on the finite element method, the stress intensity factors of the transverse crack are obtained during one full cycle applied field (the field increasing process and decreasing process). Furthermore, the influences of the crack length on the stress intensity factors are also studied in this paper. Generally speaking, all the results are useful for understanding the critical state model and the fracture mechanism of high-temperature superconductors, which could provide a theoretical guide for the ITER CICC designer.

Keywords Thin superconducting strip, Bean model, Kim model, Transverse crack

1. Introduction

High-temperature superconductor (HTS) tapes have provided a wide range of engineering applications, such as ac power transmission cables [1, 2] and filters for wireless communication [3]. With the development of engineering applications, improvements on mechanical performances of HTS bulks in the presence of high magnetic fields have attracted considerable interest. The stress and the magnetostriction in bulk superconductors subjected to high magnetic fields were analyzed for various geometrical cases, critical state models, and magnetization conditions [4-7]. Cracks in samples can be explained by tensile stresses that occur during the magnetization process due to the stored flux density gradient and may exceed the tensile strength of the material [8]. In recent years, a multitude of theoretical analyses for the crack problem of long rectangular slabs and long cylinders under electromagnetic force have been achieved [9-11]. Owing to the strong demagnetization effects in the perpendicular geometry, the central crack in a thin superconducting strip was studied according to the Bean critical state model [12].

However, it is observed experimentally that the critical current density usually depends on the flux density in real materials. The body forces induced by flux-pinning and magneto-elastic behavior are significantly different in magnitude between the Kim model and Bean model in thin superconducting strip [13]. It is found that the magnetostrictive behavior for the Kim model is in much better agreement with experiment than that for the Bean model at low temperatures. The Kim model is chosen because it has been shown to fit well the $J_c\left(H_a\right)$ measured in thin YBCO films

[14]. Therefore, it is of great practical importance to investigate crack problem of HTS thin films for the Kim model. It is to be known that stress intensity factor is a good fracture criterion and can provide successful prediction for fracture behavior. Although the longitudinal crack problem was extensively studied, the influence of transverse crack on the transport current has not been considered for thin films in the literature. Our main aim of this paper is to study the fracture behaviors of transverse crack in a HTS thin film based on the framework of field-dependent critical current model [15]. Applying finite element method, the stress intensity factors of the transverse crack are obtained during one full cycle applied field (the field increasing process and decreasing process) for the Bean model and Kim model. The comparisons are made between the results from the transverse crack and the longitudinal crack. The influence of the crack length is also studied in this paper.

2. Basic equations

We consider a thin type-II superconducting strip with a transverse crack of length $2a$ in an applied perpendicular field. As shown in Figure 1 (a), the thin strip is located in the Cartesian coordinate system. The width and the thickness of the film is $2w$ and d, respectively. The film is assumed to be isotropic and infinite along the x axis. Different from the longitudinal crack, the effect of the transverse crack on the current distribution in the thin strip should be considered (see Figure 1 (b)).

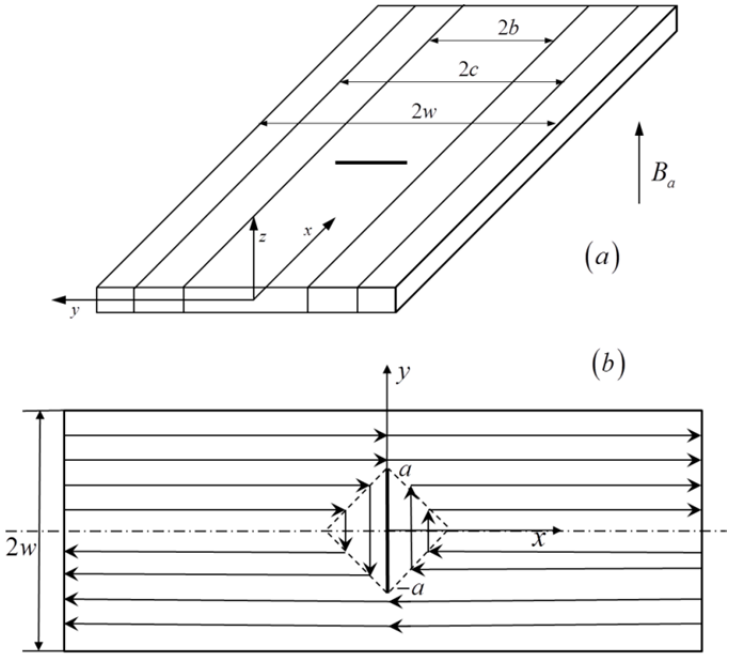

Figure 1. (a) A thin superconducting strip with a transverse crack in a perpendicular field. (b) The current distribution in the thin strip with a transverse crack.

When the superconducting strip is in a perpendicular field which exceeds the lower critical field B_{c1}, the flux and current starts to penetrate at the edge of the strip. Based on the critical state model, the shielding current density J is less than the critical current density J_c. Two classical critical

state models, Bean model and Kim model, are adopted to analyze this problem. For the Bean model, the critical current is constant, i.e. $J_c = J_{c0}$. The current density is dependent on the flux density in the Kim model, i.e.

$$\frac{J_c\left(B_z\left(y\right)\right)}{J_{c0}} = \frac{B_0}{B_0 + \left|B_z\left(y\right)\right|}, \tag{1}$$

where B_0 is a constant field that characterizes the degree of field dependence.

After ignoring the effect of the lower critical field, the current profile can be obtained by conformal mapping analytically for the Bean model [16]. When applied field increases from zero to a maximum B_{am}, the shielding current and penetrated flux are

$$J(y) = \begin{cases} \dfrac{2J_c}{\pi} \arctan \dfrac{y}{w}\sqrt{\dfrac{w^2 - b^2}{b^2 - y^2}}, & |y| < b \\ \dfrac{y}{|y|} J_c, & b < |y| < w \end{cases}, \tag{2}$$

$$B(y) = \begin{cases} 0, & |y| < b \\ B_f \arctan \mathrm{h} \dfrac{w}{|y|}\sqrt{\dfrac{y^2 - b^2}{w^2 - a^2}}, & b < |y| < w \end{cases}, \tag{3}$$

$$\tanh\left(\frac{B_a}{B_f}\right) = \frac{\left(a^2 - b^2\right)^{1/2}}{a}, \tag{4}$$

and the scaling field B_f is defined by

$$B_f = \frac{\mu_0 J_{c0} d}{\pi}, \tag{5}$$

where J_{c0} and μ_0 is the zero-field critical current and the permeability of free space, respectively.

When applied field decrease from the maximum B_{am} to $-B_{am}$, the current and penetrated flux can be obtained as

$$J\left(y, B_a, J_c\right) = J\left(y, B_{am}, J_c\right) - J\left(y, B_{am} - B_a, 2J_c\right), \tag{6}$$

$$B\left(y, B_a, J_c\right) = B\left(y, B_{am}, J_c\right) - B\left(y, B_{am} - B_a, 2J_c\right). \tag{7}$$

However, it can be found from the experimental results that the critical current density j_c is related to local flux density B. The results of magnetostriction in our preceding paper [13] also

that the Kim model is in better agreement with experiments than Bean model at low temperatures. Unfortunately, one cannot obtain the analytical solutions based on Kim model. However, for the applied magnetic field increased from zero to B_{am}, the profiles of current and flux density can be calculated numerically from the equations below [15]

$$J_x(y)=\begin{cases}-\dfrac{2}{\pi}y\sqrt{b^2-y^2}\displaystyle\int_b^w \frac{J_c\left(B_z(y')\right)dy'}{\left(y'^2-y^2\right)\sqrt{y'^2-b^2}}, & |y|<b\\ -\dfrac{y}{|y|}J_c\left(B_z(y)\right), & \mathrm{b}<|y|<w\end{cases}, \tag{8}$$

$$B_z(x)=B_f|x|\sqrt{x^2-b^2}\int_b^w \frac{J_c\left(B_z(x')\right)}{J_{c0}}\frac{dx'}{\left(x^2-x'^2\right)\sqrt{x'^2-b^2}},\ b<|x|\neq w, \tag{9}$$

$$B_a=B_f\int_b^w \frac{J_c\left(B_z(y')\right)}{J_{c0}}\frac{dy'}{\sqrt{y'^2-b^2}}. \tag{10}$$

When the applied magnetic field is increased from initial value B_{am} to B_a, the flux density changes in the outer regions ($c<|x|<w$) but is unchanged in the inner regions ($b<|x|<c$), and the central region ($|x|<b$) remains free of flux. Therefore, the distributions of current and flux density can be obtained by solving the following equations

$$J_x(y)=\begin{cases}\dfrac{2}{\pi}y\sqrt{c^2-y^2}\left[\begin{array}{l}\displaystyle\int_c^w \frac{J_c\left(B_z(y')\right)}{\left(y'^2-y^2\right)\sqrt{y'^2-c^2}}dy'\\ \displaystyle-\frac{2}{\pi}J_{c0}\int_b^c \frac{B_z(y')}{B_f}\frac{dy'}{\left(y'^2-y^2\right)\sqrt{c^2-y'^2}}\end{array}\right], & |y|<c\\ \dfrac{y}{|y|}J_c\left(B_z(y)\right), & \mathrm{c}<|y|<w\end{cases}, \tag{11}$$

$$B_z(y)=|y|\sqrt{y^2-c^2}\left[\begin{array}{l}\displaystyle-B_f\int_c^w \frac{J_c\left(B_z(y')\right)}{J_{c0}}\frac{dy'}{\left(y^2-y'^2\right)\sqrt{y'^2-c^2}}\\ \displaystyle+\frac{2}{\pi}\int_b^c \frac{B_z(y')}{\left(y^2-y'^2\right)\sqrt{c^2-y'^2}}dy'\end{array}\right],\ \mathrm{c}<|y|\neq w, \tag{12}$$

$$B_a=-B_f\int_c^w \frac{J_c\left(B_z(y')\right)}{J_{c0}}\frac{dy'}{\sqrt{y'^2-c^2}}+\frac{2}{\pi}\int_b^c \frac{B_z(y')}{\sqrt{c^2-y'^2}}dy'. \tag{13}$$

The body force (Lorentz force density) in the film is

$$\boldsymbol{f} = \boldsymbol{J} \times \boldsymbol{B}. \tag{14}$$

Because the thickness is very small compared with other two dimensions, this is a plane stress problem. For the symmetric model, it is convenient to analyze one quarter part of the film by means of finite element method. The famous virtual crack closure technique [17] is adopted to calculate the stress intensity factor, which can save our computational time and has high precision with fewer meshes. In our calculations, the Young's modulus and the Poisson's ratio equal to 125 GPa and 0.3, respectively.

3. Results and discussions

In this section, we will discuss the development of the stress intensity factor for applied field increasing to different maximum (B_f, $2B_f$, $3B_f$, $4B_f$) based on Bean model and Kim model. The crack length is the half of strip width. In addition, the crack length effect on the stress intensity factor is also discussed for applied field decreasing from $4B_f$ to B_f. The stress intensity factor is normalized by $K_0 = 1.2153\times10^6\,\mathrm{Pa}\cdot\mathrm{m}^{0.5}$ for applied field increasing to B_f with Kim model.

Figure 2 shows the development of the stress intensity factor in a full cycle applied field with maximum B_f. It can be found that the stress intensity factor is positive as applied field increases from zero to B_f. The depth of the penetrated flux has not reached the crack in this case. Therefore, all the body force is compressive and along y direction. The tensile stress along x direction induces positive stress intensity factor. The stress intensity factor for the Kim model is large than for the Bean model.

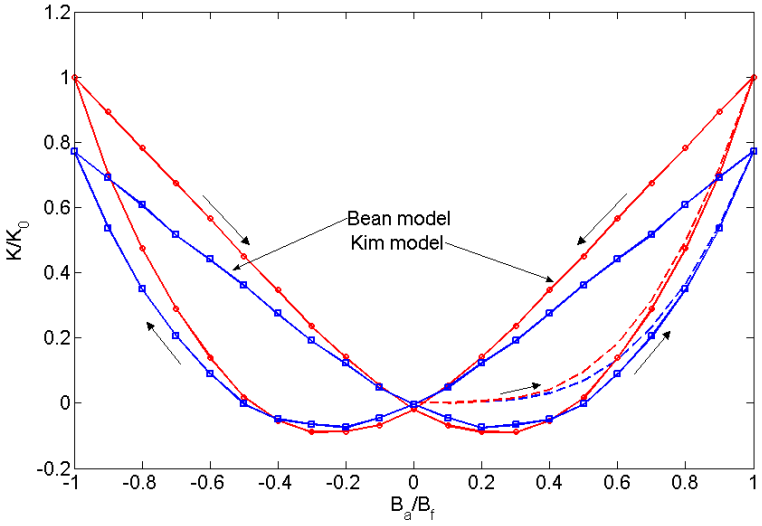

Figure 2. The development of the stress intensity factor in a full cycle applied field with maximum B_f.

If the applied field increases from zero to $2B_f$, the depth of the penetrated flux will reach the crack. The body force near the crack is along x direction in this case. Therefore, the stress intensity factor will decrease when applied field exceeds a certain value (see Figure 3). The value for the Kim model is less than for the Bean model since the filed dependence of J_c leads to a larger amount of penetration in a given applied field. The stress intensity factor increases firstly, and then decreases during the field decent. Moreover, it cannot recover zero when applied field decreases to zero because of remnant field.

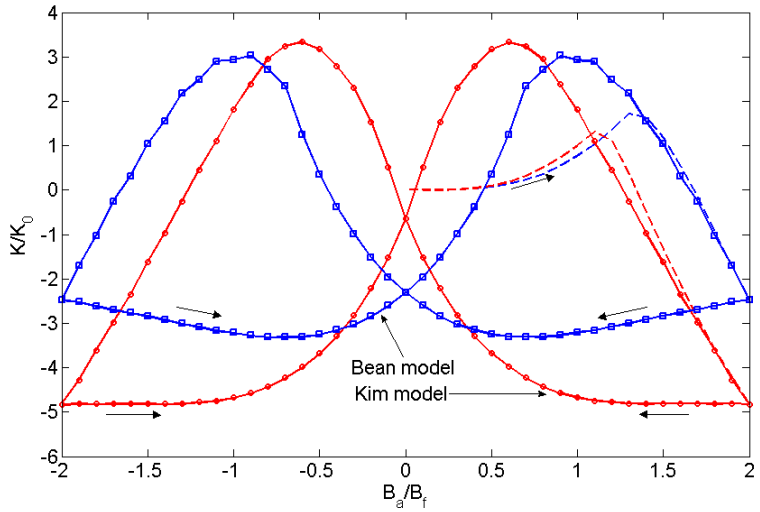

Figure 3. The development of the stress intensity factor in a full cycle applied field with maximum $2B_f$.

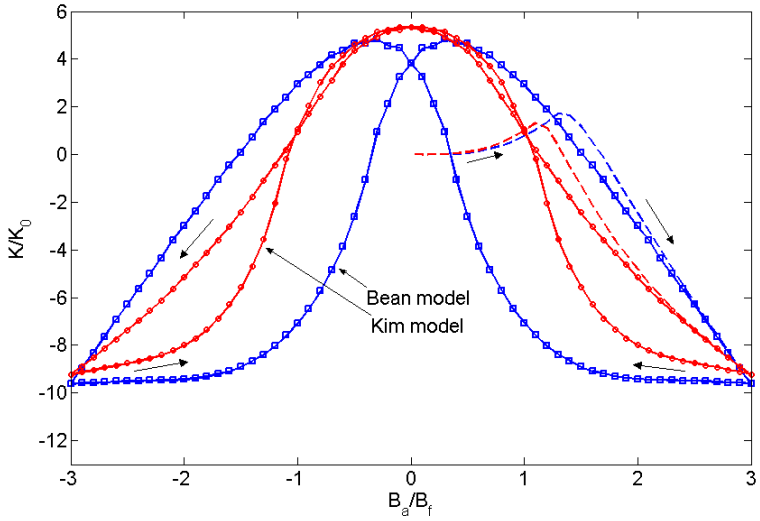

Figure 4. The development of the stress intensity factor in a full cycle applied field with maximum $3B_f$.

When applied field continue to increase, it can be found from Figure 4 that the stress intensity factor profiles is becoming complex. The development of the stress intensity factor during field decent is similar to Figure 3. However, different from Figure 3, the remnant stress intensity factor is positive when applied field decreases to zero. It is interesting that the stress intensity factor is maximal in the absence of applied field for the Kim model during field decent, and it is larger than for the Bean model.

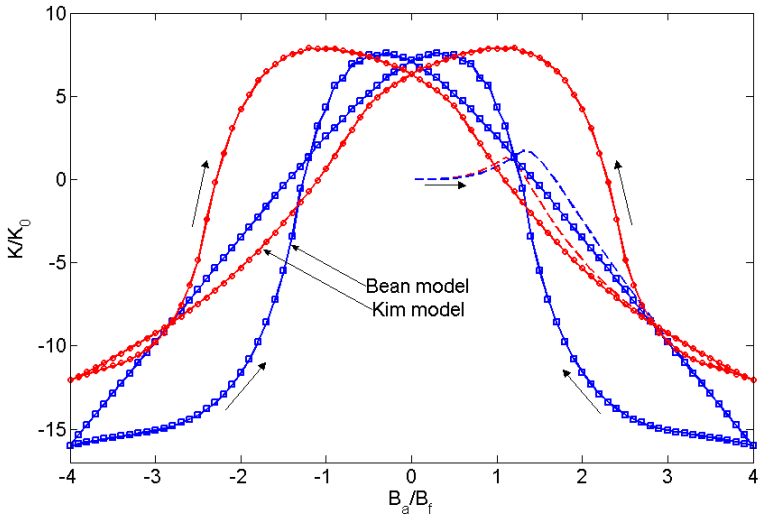

Figure 5. The development of the stress intensity factor in a full cycle applied field with maximum $4B_f$.

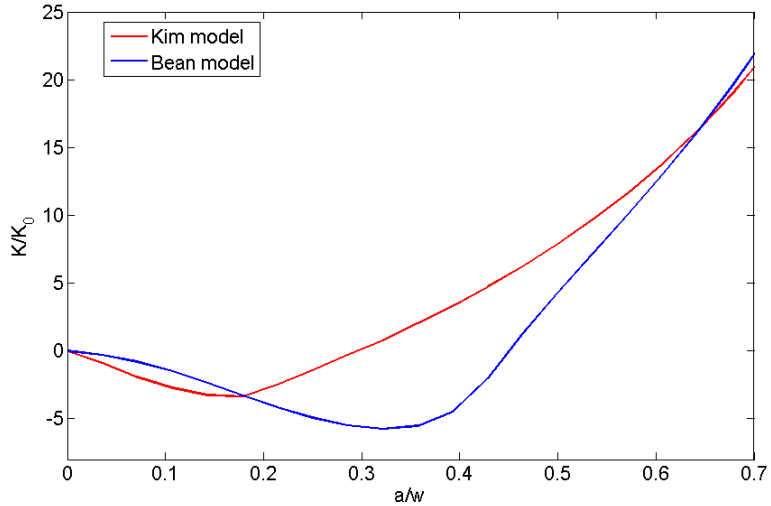

Figure 6. The stress intensity factor for different crack lengths in a perpendicular field which decreases from $4B_f$ to B_f.

Shown in Figure 5 is the development of the stress intensity as applied field increases to $4B_f$. In

this case, one can see that the stress intensity factor profiles become even more complex. The maximum of the stress intensity during field decent for both Bean model and Kim model is larger than that in Figure 4. Therefore, it is more dangerous in this case. Moreover, the decreasing field corresponding to the maximal stress intensity factor for the Kim model is greater than for the Bean model.

Finally we discuss the effect of crack length on the stress intensity factor for applied field decreasing from $4B_f$ to B_f. One can see from Figure 6 that the stress intensity factor firstly decreases as the crack length increases, and then increases when the crack length exceeds a certain value. The value for the Kim model is less than for the Bean model. The reason is that the depth of current change for the Kim model is larger than for Bean model. Moreover, Figure 6 demonstrates that it is more dangerous for large crack than for small crack.

4. Conclusions

The problem of thin superconducting strip with transverse crack in a perpendicular field is investigated in this paper. The Bean model and Kim model are adopted to analyze this problem. Different from the longitudinal crack, the transverse crack is more complex because of the effect of the transverse crack on the current. The results are useful for understanding the fracture mechanism of high-temperature superconductors, which could provide a theoretical guide for the ITER CICC designer.

Abstract The fracture behaviors under electromagnetic force with field-dependent critical current density in thin superconducting film are investigated. Applying finite element method, the stress intensity factors of one central crack versus applied field and crack length are obtained for the exponential model, which was compared with the Bean model and Kim model. This work can offer good estimations and provide a basis for interpretation of cracking and mechanical failure of HTS thin films in numerous real situations.

Keywords Fracture behaviors, Superconducting film, Stress intensity factor, Exponential model

1. Introduction

High-temperature superconductor (HTS) tapes have provided a variety of engineering applications, such as ac power transmission cables [1, 2], filters for wireless communication [3]. With the development of engineering applications, major efforts are directed towards improvements on mechanical performances of HTS bulks in the presence of high magnetic field. During the past years, a series of investigations were devoted to the magneto-elastic behaviors induced by flux-pinning in bulk superconductors for different sample shapes, critical state models and magnetization processes [4-6]. For example, Johansen studied magnetostrictive behavior during the field activation processes, and revealed that the giant irreversible magnetostriction and internal stress could often lead to fatal cracking of the HTS bulks [7]. It is well established experimentally that when an HTS bulk traps large magnetic fields, the mechanical stability can be threatened by the tensile stress induced by flux-pinning [8]. Due to their low tensile strength of melt-processed HTS materials, micro-cracks and macro-cracks parallel to the $a-b$ plane were both observed in large grain bulk RE–Ba–Cu–O (RE: rare earth elements) superconductors [9, 10]. In recent years, many theoretical analyses for the crack problem of long rectangular slabs and long cylinders under electromagnetic force have been achieved [11-13]. Very recently, the central crack and interface crack problem of a thin superconducting strip were investigated by a field-independent J_c (the Bean model) [14, 15].

However, it is observed experimentally that the critical current density strongly depends on the flux density in real materials. The body forces induced by flux-pinning and magneto-elastic behavior are significantly different in magnitude between the Kim model and Bean model in thin superconducting strip [16]. It is found that Kim model is in much better agreement with experiment than Bean model at low temperatures. Furthermore, the exponential model, on the other hand, is one of the models that has been recently discussed in relation to the high-temperature superconductors [17-19]. Therefore, it is very worthwhile to investigate crack problem of HTS thin films for the exponential model. Since the superconducting materials are brittle, the stress intensity factor is a good fracture criterion and can provide successful prediction for fracture behavior. Our main purpose of this paper is to study the fracture behaviors in a HTS thin film with one central

longitudinal crack under electromagnetic force. Compared with the Bean model and Kim model, we investigate center-situated crack problem in an infinitely long superconducting film for the exponential model. The stress intensity factors at the crack tips are obtained by means of finite element method, which are discussed for different applied fields and crack lengths. In our calculations, the Young's modulus and the Poisson's ratio are assumed to be 125 GPa and 0.3 as adopted in Ref. [17].

2. Basic equations

In the present article, we consider a thin film with one central crack in a perpendicular applied magnetic field, and the film is located in the Cartesian coordinate system [see Fig. 1]. The width and the thickness of the film is $2w$ and d, respectively. The film is assumed to be isotropic and infinite along the x axis. Due to the symmetry of the problem, the current density has only a x component $J_x(y)$. Since the crack is parallel to the current, the disturbance of crack on the current and flux are negligible. The current density $J_x(y)$ and flux density $B_z(y)$ can be regarded as average value over the film thickness in case of $d << w$. Based on the theory of field-dependent current [20], for the applied magnetic field increasing from zero to B_{am}, the profiles of current and flux density can be calculated numerically from the equations below

$$J_x(y)=\begin{cases} -\dfrac{2}{\pi}y\sqrt{b^2-y^2}\displaystyle\int_b^w \frac{J_c\left(B_z(y')\right)dy'}{\left(y'^2-y^2\right)\sqrt{y'^2-b^2}}, & |y|<b \\ -\dfrac{y}{|y|}J_c\left(B_z(y)\right), & \mathrm{b}<|y|<w \end{cases}, \tag{1}$$

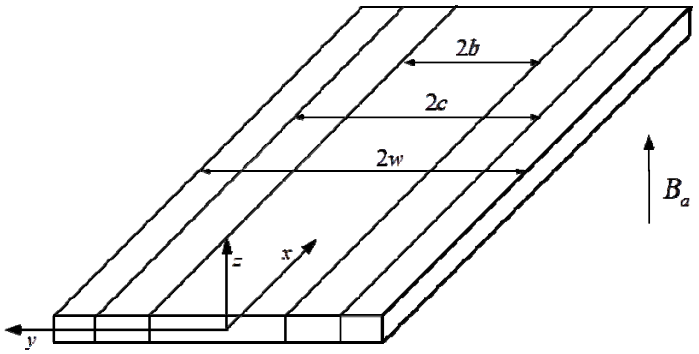
$$B_z(y)=B_f|y|\sqrt{y^2-b^2}\int_b^w \frac{J_c\left(B_z(y')\right)}{J_{c0}}\frac{dy'}{\left(y^2-y'^2\right)\sqrt{y'^2-b^2}},\ b<|y|\neq w, \tag{2}$$

$$B_a=B_f\int_b^w \frac{J_c\left(B_z(y')\right)}{J_{c0}}\frac{dy'}{\sqrt{y'^2-b^2}}, \tag{3}$$

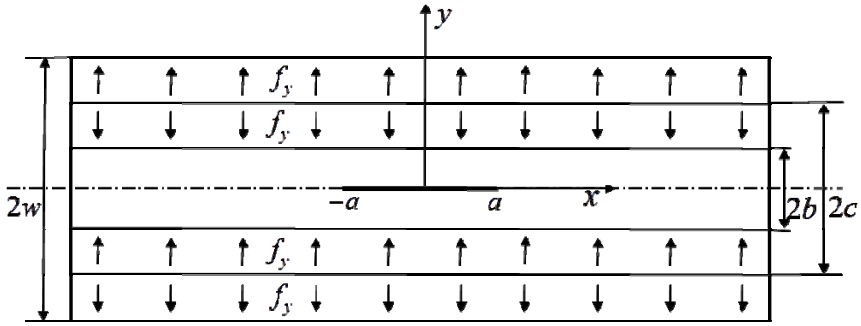
and the scaling field B_f is defined by

$$B_f=\frac{\mu_0 J_{c0} d}{\pi}, \tag{4}$$

where J_{c0} and μ_0 is the zero-field critical current and the permeability of free space, respectively.



(a)



(b)

Figure 1. (a) Schematic of the superconducting thin film and coordinate system in a perpendicular applied field. The superconducting film subjected to the Lorentz force with one central crack.

When the applied magnetic field decreases from initial value B_{am} to B_a, the flux density changes in the outer region ($c<|x|<w$) but is unchanged in the inner region ($b<|x|<c$), and the central region ($|x|<b$) remains free of flux. Therefore, the distributions of current and flux density can be obtained by solving the following equations

$$J_x(y)=\begin{cases}\dfrac{2}{\pi}y\sqrt{c^2-y^2}\left[\begin{array}{l}\displaystyle\int_c^w\frac{J_c\left(B_z(y')\right)}{\left(y'^2-y^2\right)\sqrt{y'^2-c^2}}dy'\\ \displaystyle-\frac{2}{\pi}J_{c0}\int_b^c\frac{B_z(y')}{B_f}\frac{dy'}{\left(y'^2-y^2\right)\sqrt{c^2-y'^2}}\end{array}\right], & |y|<c\\ \dfrac{y}{|y|}J_c\left(B_z(y)\right), & c<|y|<w\end{cases}, \tag{5}$$

$$B_z(y)=|y|\sqrt{y^2-c^2}\left[\begin{array}{l}\displaystyle-B_f\int_c^w\frac{J_c\left(B_z(y')\right)}{J_{c0}}\frac{dy'}{\left(y^2-y'^2\right)\sqrt{y'^2-c^2}}\\ \displaystyle+\frac{2}{\pi}\int_b^c\frac{B_z(y')}{\left(y^2-y'^2\right)\sqrt{c^2-y'^2}}dy'\end{array}\right],\ c<|y|\neq w, \tag{6}$$

$$B_a=-B_f\int_c^w\frac{J_c\left(B_z(y')\right)}{J_{c0}}\frac{dy'}{\sqrt{y'^2-c^2}}+\frac{2}{\pi}\int_b^c\frac{B_z(y')}{\sqrt{c^2-y'^2}}dy'. \tag{7}$$

In the Bean model, the critical current density is constant in the film. While in reality the critical current density is dependent on the flux density $B_z(y)$, so the Kim model and the exponential model are respectively expressed as follows:

$$\frac{J_c\left(B_z(y)\right)}{J_{c0}}=\frac{B_0}{B_0+\left|B_z(y)\right|}, \tag{8}$$

$$\frac{J_c\left(B_z(y)\right)}{J_{c0}}=\exp\left(-\left|B_z(y)\right|/B_0\right), \tag{9}$$

where B_0 is a constant field that characterizes the degree of field dependence. The body force (Lorentz force density) in the film is

$$\boldsymbol{f}=\boldsymbol{J}\times\boldsymbol{B}. \tag{10}$$

The magneto-elastic problem of thin superconducting strip for the two different critical-state models

has been studied in our preceding paper [16]. In the field ascent stage, the body force remains zero in the central region and increases in magnitude along y-direction, but it is always negative, which means the film with crack is subjected to compressive stress. During the field descent branch, the body force has both negative value and positive value. Its peak value moves towards the middle of the film, and the peak value decreases as the maximum applied field decreases. Therefore, at the intermediate state of field reduction, the crack may be subjected to the largest tensile body force. Attention is limited to the crack problem of thin film in the field reduction. Fig. 2 shows the variations of body force for the three models with the applied field reduction. There is an important distinction between the three models. Thus, it's essential to take field-dependent $J_c(B)$ into account for studying the fracture behaviors of superconducting film. Because the thickness is very small compared with other two dimensions, this is a plane stress problem. Since the crack is parallel to the x axis, the effect of body forces f_x along the x direction at infinity can be neglected, i.e. $f_x = f_z = 0$. The body force along y axis becomes $f_y(y) = J_x(y)B_z(y)$. Due to the symmetry of the problem, it is convenient to analyze one quarter part of the film by means of finite element method.

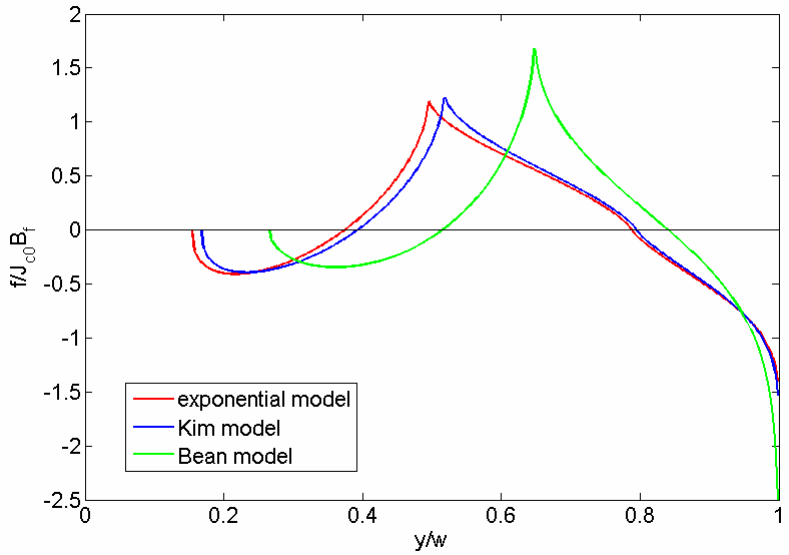


Figure 2. The variations of body force for the Bean model, Kim model and exponential model when the applied field decreases from the maximal value $2B_f$ to 0.

The stress intensity factor K is an important parameter in fracture mechanics, which determines whether the crack propagates or not. The crack would start to propagate the stress intensity factor K increases to the critical stress intensity factor K_{cr}. The critical stress intensity factor K_{cr} is material parameters, which is independent of the mechanical load and the applied field. Since the body force is perpendicular to the crack, only the mode I crack is considered in this paper and the energy release rate G_{II} is neglected. For the linear elastic fracture mechanics, the energy release rate is defined by

$$G = G_I = \lim_{\Delta a \to 0} \frac{1}{2d\Delta a} \int_0^{\Delta a} \sigma_{yy}(x)\Delta v(x)\,dx, \tag{11}$$

where Δa is the increment of the crack length at the crack front. In addition, $\sigma_{yy}(x)$ and $\Delta v(x)$ are the normal stress and the virtual crack opening displacement at the extension of the crack, respectively. Because this equation is complex in calculation, Rybicki and Kanninen [21] proposed

the famous virtual crack closure technique to calculate the energy release rate, which can save our computational time and has high precision with fewer meshes. Then the energy release rate can be obtained by

$$G \cong \frac{F_y \Delta v}{2d\Delta a}, \tag{12}$$

where F_y, Δa and Δv are the nodal force along y direction at the crack tip, the width of the mesh and the crack opening displacement at the node near the crack tip, respectively. The stress intensity factor K, one of the most important parameters in linear elastic fracture mechanics, reflects the singularity of the stress at the crack tip. The relationship between the stress intensity factor K and energy release rate G is given by

$$G = \frac{K^2}{E}. \tag{13}$$

3. Results and discussions

In this section, we discuss the crack problems of thin superconducting film with one central crack. The stress intensity factor is normalized by

$$K_0 = \sigma_0 \sqrt{a/\pi}, \tag{14}$$

where $\sigma_0 = \mu_0 J_{c0}^2 dw$. We mainly draw attention to the developments of stress intensity factor versus applied field and crack length for the three models.

Shown in Fig. 3 is the variation of K/K_0 for different critical state models when the applied field decreases from the initial value $2B_f$ to 0. It can be seen that the stress intensity factor firstly increases to the maximum value at a parameter field B_a^*, then decreases after it reaches peak value. Note that the superconducting film with crack is the most dangerous near the parameter field B_a^* during the field descent. What's more, although the profiles of stress intensity factor between the exponential model and the Kim model is nearly the same, it is not difficult to find that the maximum stress intensity factor and the corresponding parameter field B_a^* for the exponential model are larger than those for the Bean model and Kim model. These imply that the crack in the thin superconducting film will propagate more easily based on the results of the exponential model than that of the other two models. In addition, due to the trapped field, one can see obviously that the intensity factor cannot recover to zero even when the applied field decreases from B_{am} to zero.

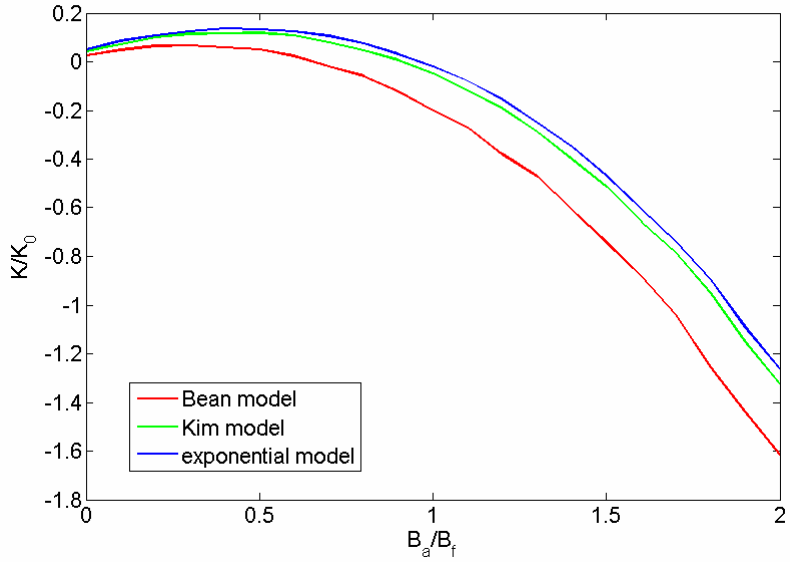

Figure 3. The stress intensity factors in the thin film with one central crack for the maximum field decreasing from $2B_f$ to 0.

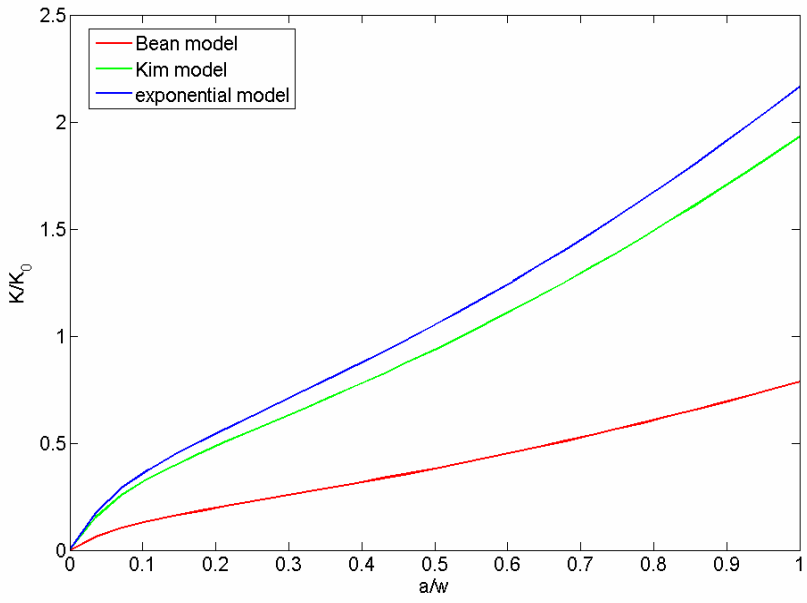

Figure 4. The stress intensity factors in the film with one central crack versus the crack length for the three models.

Fig. 4 shows the development of the stress intensity factor with respect to a/w for different critical state models. As anticipated, the stress intensity factor K increases as crack propagates, which indicates that the HTS film will have a tendency to break into pieces if the crack length increases to a critical value a_{cr}. One can tell the difference that the values derived from the exponential model increase more quickly than those from the other two models. That is to say, the effect of the crack length on stress intensity factor may be greater for the exponential model.

4. Conclusions

In this paper, we investigate the fracture behaviors induced by electromagnetic force with

field-dependent critical current in thin superconducting film. Applying finite element method, the stress intensity factors of one central crack versus applied field and crack length are obtained for different critical state models. From the comparison between the three models, it can be found that the magnitudes of the G and K are remarkably different. Thus the prediction of parameter field B_a^* corresponding to the overall maximum stress intensity factor, where the HTS thin film is the most dangerous, can be of practical importance. It is intended that these results presented in this paper may be useful for the interpretation of cracking and mechanical failure of HTS thin film in a number of real situations.

Abstract We found different failure mechanisms and mechanical properties for single-walled carbon nanotubes (SWCNTs) when subjected to electric fields and that subjected to tensile load by quantum mechanics calculations. The electric field induced breaking in SWCNT begins from the outmost carbon atomic layers while the tensile load breaks the nanotube near its middle. When a tube is tensioned in an electric field, the critical tensile strength of the tube decreases significantly with increasing intensity of the electric field. It is interesting to be shown that a piece of graphene sheet formed by unwrapping the SWCNT can also be stretched up to 2.5% by applied electric field and fractured at it edges. We also studied the mechanical response and structural evolution of graphene with topological line defect under tensile strain by using first-principles calculations. We studied the superelongation and fracture of carbon nanotubes at high temperatures by molecular dynamics simulations, and found that the nearly simultaneous activation and wide distribution of a large number of defects near the elastic limit play a key role in impeding the formation of localized predominant instability and facilitating large tensile elongation of carbon nanotubes at high temperature.

Keywords Carbon nanotubes, mechanical and electric coupling, failure, quantum mechanics

Carbon nanotubes (CNTs), a novel form of carbon materials, have been recognized as particularly important nanoscopic systems. The exceptional mechanical properties of carbon nanotubes have been the subject of numerical experimental and theoretical studies. Electric field will impose significant influence on the electronic and structural properties of carbon nanotubes. Electric field induced failure of carbon nanotubes as well as the corresponding mechanisms are key issues for nanotube applications in nanoelectromechanical devices. By using semi-empirical quantum mechanical calculations as well as quantum-molecular dynamics techniques based on the Roothaan–Hall equations and the Newton motion laws, we [1] found different failure mechanisms and mechanical properties for single-walled carbon nanotubes (SWCNTs) when subjected to electric fields and that subjected to tensile load. The electric field induced breaking in SWCNT begins from the outmost carbon atomic layers while the tensile load breaks the nanotube near its middle. Electronic polarization and mechanical deformation induced by an electric field can significantly change the electronic properties of a SWCNT. Under electric field, the SWCNT can be stretched but the toughness is much lower than that under mechanical loading. When a tube is tensioned in an electric field, the critical tensile strength of the tube decreases significantly with increasing intensity of the electric field, as shown in Fig. 1.

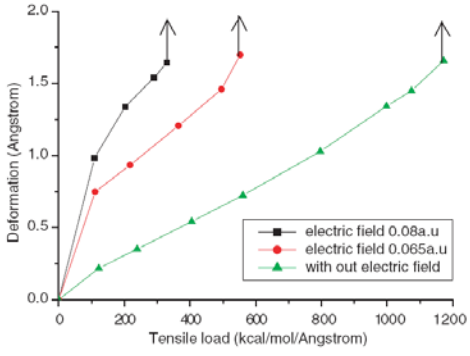

Figure 1. Deformation of SWCNTs versus the tensile load in the absence and presence of electric fields [1].

On the other hand, the mechanical behaviors and the electric and electronic properties of carbon nanotubes are always coupled with each other. By using Hartree-Fock and density functional quantum mechanics simulations, we [2] demonstrated a large axial electrostrictive deformation in short SWCNTs under electric field [Fig. 2 (a)]. The external field induced axial strains in armchair and zigzag tubes can be greater than 10% for a field strength within 1 V/Å. The corresponding volumetric and gravimetric work capacities of the SWCNTs are predicted to be three and six orders higher than those of the best known ferroelectric, electrostrictive, magnetostrictive materials and elastomers, respectively. Further study indicated the significant effect of axial electrostrictive deformation on the electronic properties of SWCNTs. It is also found that the band structures of SWCNTs change in electric fields and the change can be significantly enhanced by the electrostrictive deformation. The polarization of the orbital charge densities and the variation of the dipole moment are also enhanced by the electrostriction. The coupled mechanical and electrical behaviors of CNTs might lead to wider applications of nanotubes in nanoelectromechanical systems. It is interesting to be shown [2] that a piece of graphene sheet formed by unwrapping the single walled carbon nanotube can also be stretched up to 2.5% by applied electric field [Fig. 2 (b)].

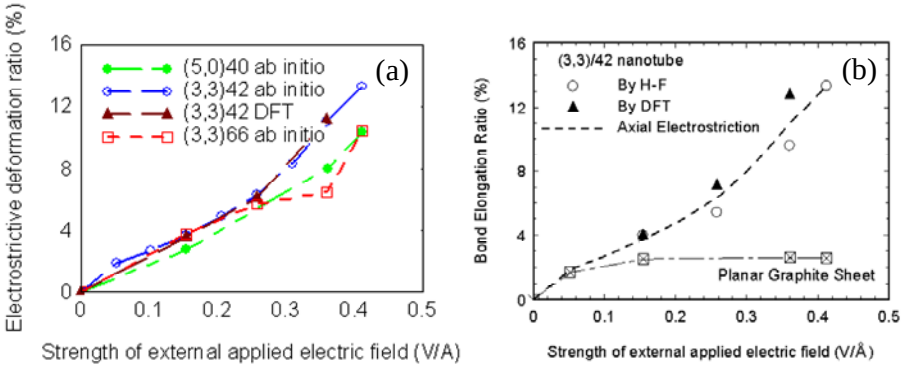

Figure 2. (a) Axial electrostrictive deformation ratio induced by external applied electric field in (3, 3) metallic single walled nanotubes of different lengths and a (5, 0) semi-metallic tube. (b) Average elongation ratios of the C-C bonds having a contribution to the deformation along the direction of the external electric field for the (3, 3)/42 tube and the corresponding single layer planar graphite sheet by unwrapping the nanotube. [2].

A recent experiment discovered that SWCNTs become superplastic and can accommodate extremely large plastic strains with a total elongation of 280% when being tensile loaded at high temperatures [3]. Similar ductile behaviors have been observed in individual double-walled and triple-walled carbon nanotubes at high temperatures above 2000 oC, with tensile elongation of 190% and diameter reduction of 90% [4]. However, several fundamental questions concerning the mechanism for superelongation of CNTs remain. By using molecular dynamics (MD) simulations, we [5] found that the nearly simultaneous activation and wide distribution of a large number of defects near the elastic limit play a key role in impeding the formation of localized predominant instability and facilitating large tensile elongation of carbon nanotubes at high temperature, as shown in Fig. 3. Intricate interplay between nanotube sizes and defect nucleation and motion determine the overall deformation pattern.

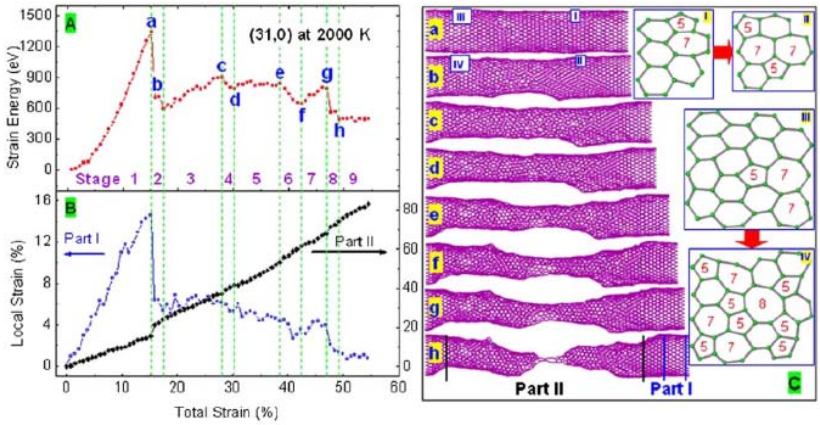

Figure 3. A (31,0) SWCNT subjected to tensile loading at 2000 K. The tube is 10.6 nm in length and 2.43 nm in diameter. (a) Strain energy. (b) Variation of local strain in two distinct parts of the tube: the elastic (part I) and plastic (part II) as shown in (c). Graphene, a two-dimensional honeycomb carbon layer of sp2 hybridized carbon atoms, exhibits exceptional electronic, magnetic, optical and chemical properties. As the carbon-carbon bond is one of the strongest covalent bonds in the world, the mechanical behaviors of graphene have attracted enormous scientific interests from experimental and theoretical studies. We studied the mechanical response and structural evolution of graphene with topological line defect under tensile strain by using first-principles calculations, as shown in Fig. 4 [6]. It is seen that, before the strain reaches the critical value of about 12%, both bond lengths l1 and l2 increase monotonically with strain. It is interesting to note that when strain reaches about 4% the two bond lengths intersect. When the strain exceeds 12%, the two bond lengths experience an abrupt change: l1 suddenly increases while l2 sharply decreases. Such sudden variations of bond lengths induce significant redistribution of spin-polarized electrons at the defected part, which indicates that the magnetism of defected graphene can be tuned by strain.

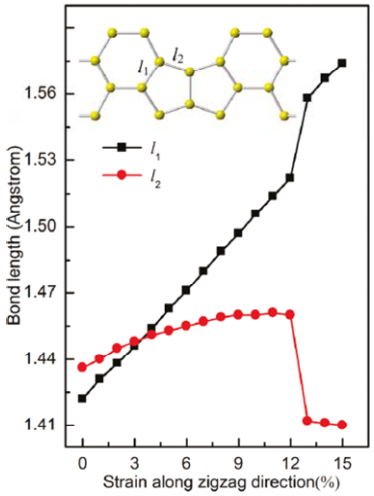

Fig. 4. Local bond length variation of defected graphene around the line defect region with strain [6].

Abstract: It is a cost-efficient approach to take the colloidal crystals (CCs) as template to fabricate three-dimensional photonic crystals. However, cracks occurring in the colloidal crystal synthesis process typically divided a colloidal crystal film into single crystalline domains of several tens of micrometers size, setting a major obstacle to the application of CCs template method. As a modified method, the co-deposition of microsphere and nanoparticles in CCs formation was put forward to reduce the formation of cracks. However, the physical mechanism of crack inhibition in co-deposition process was not well studied.

In this paper, we reported an in-situ observation study on the crack formation in the co-deposition process. It was found that the crack morphology has a large difference compared with that in the normal CCs template method. The cracks in normal CCs growth are usually formed and developed as parallel straight lines along the substrate surface in the growth direction. In contrary, the cracks present a pattern of regular triangular lattices in co-deposition. The crack morphology changes from CCs process to co-deposition process was considered to have a strong relationship to the gel formation in co-deposition procedure which can be ignored in the normal CCs growth. The corresponding physical model was developed and compared with the experimental results. The present study was helpful to give a deep insight into the crack formation mechanism in the colloidal spheres (CSs) assembling process.

Keywords：Crack, co-deposition, colloidal crystal

1. Introduction

Vertical self-depositing (VSD) method has proven to be highly-efficient for the synthesis of the colloidal crystals (CCs) which cannot be got by conventional top-down methods. The CCs are three-dimensional periodic structures formed from colloidal sub-microspheres. [1] The most remarkable property of the CCs is the photonic band gap (PGB)[2], which makes the CCs have great potential application in photonic crystals. At the same, the CCs can be as a template to get well-ordered, porous “inverse opal” structures for optical, electronic, and (bio) chemical application.[3] Such ordered, high surface area nanoporous solids are important for potential applications in fields from catalysis to tissue engineering, drug delivery, gas sensing, and filtration and PGB devices. Compared to conventional top-down process, this kind of bottom-up self-depositing method shows its low-cost and high-efficiency. However, during the deposition of the CCs, a number of defects such as cracks, domain boundaries and vacancies will be produced. Among them, the large length scale defects, cracks, will split the CCs into countless small domains, which make the practical applications of the CCs impossible.

In order to reduce or even eliminate cracks, researchers developed many growth methods of the CCs. van Blaaderen A. et al. [4] invented “colloidal epitaxy” to fabricate CCs. They made the slow sedimentation of CSs onto a patterned substrate (or template), which could direct the crystallization of bulk CCs, and permit tailoring of the lattice structure, orientation and size of the CCs.

Rudolf Zentel et al. [5] spread the colloidal suspension on the surface of the liquid substrate (gallium or

mercury) and the crystallization and drying of the CCs were finished at room temperature for about one day. In this way, they got crack-free CCs of a size of nearly a centimeter square. Norris et al. [6] found that the cracks could be avoided in fabricating adverse opals by sintering the silica spheres prior to assembly of the CCs. However, the methods mentioned above were too complicated, high cost and not reliable to produce crack-free CCs with large domains.

The co-depositing method was first used by Meng et al. [7] to fabricate ordered porous materials. Due to the co-assembly of the CSs and the ultrafine particles, such as TiO_2 or SiO_2, the researcher can get the CCs by a one-step process. With the water evaporation at the meniscus, the ultrafine particles were infiltrated into the voids of the CSs during the co-deposition. The following investigators went beyond the co-deposition of the binary particles and got crack-free colloidal films of centimeter square through co-assembly of the CSs and polymer precursors [8] or salt precursors [9]. The infiltrated materials could be as a sacrifice to be got rid of, and the large area CCs would be left.

In fact, cracking during drying of colloidal dispersion has been investigated for many years and made the model system for crack study [10-15]. In order to understand the mechanism of cracking, it is base to study the dying process and the crack morphology. Drying accompanies the whole process of the thin film formation and has very important effects on the quality and shape of the colloidal film. [16-19]Although through the co-depositing method researchers could improve the CCs' quality and get crack-free CCs of large domain, it is not clear whether there are differences between deposition of the CSs of single size and co-deposition of the binary particles. In this paper, we show the cracking process during the deposition of the CSs of 360nm and the binary deposition of the CSs (360nm) with the SiO_2 nanoparticles (7nm) by real time observation method. It is noteworthy that in spite of the same drying condition absolutely, the morphology of cracks is different from each other.

2. Experiment

The experimental set-up for the in-situ observation was shown in Fig. 1. A magnified schematic of the observed region is shown, as well as the image observed at the initial growth stage. To have a comprehensive understanding of the assembly process, large colloid spheres with the diameter of 3 micrometers were used for the observation of the initial assembly process. Cracks formation process by VSD was observed in a transparent glass cell and the inner temperature could be controlled. Polystyrene latex spheres (from Duke Scientific Corporation, California, USA) with 360nm diameter were used in this work. Polystyrene spheres were mono-dispersed in Milli-Q water with 0.1% volume fraction. The Silica nanoparticles with mean diameter of 7nm were used for co-deposition. A 4x1.5 mm rectangular, 1 mm thick glass substrate was inserted vertically into a semi-cylindrical glass growth cell. To guarantee good water wetting, the glass substrate and the growth cell walls were cleaned with detergent, followed by immersion in chromic acid for about 24 hours. Cleaned glass plates were kept in Milli-Q water for about 8 hours, and dried naturally in the clean room environment before experiments. The growth temperature was kept at 55 °C during the experiment. Mean water evaporation rate was about 0.19 grams/hour. A long working distance optical microscope (Questar QM100, USA) was used to carry out experimental observations. The crack growth process was recorded with a digital video recorder connected to the microscope camera.

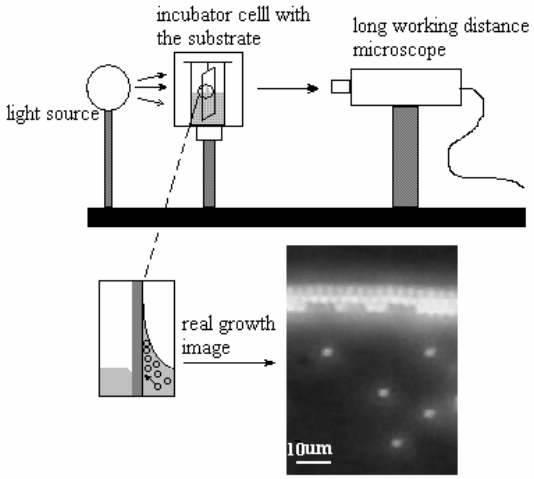

Figure 1. A schematic diagram of the experimental setup. A magnified schematic of the observed region is shown at the vicinity of the meniscus, as well as the image observed at the initial growing stage. Large colloid spheres with the diameter of 3 micrometers were used in the observation of the initial assembly process.

3. Results

The VSD experimental system of CSs is different from conventional colloidal suspension drying system [16-19]: a) it is capable of growing large-scale crystals from low particle concentration suspensions (0.1% volume fraction); b) without gel formation, the colloidal particles self-assemble to be a film by capillary forces and micro flow at the vicinity of the solvent menisci; c) a film with uniform thickness is formed of close-packed spheres. For the co-deposition, the CSs are close-packed orderly, and the nanoparticles infiltrate into the void among the CSs. [7]

Figure 2 shows the cracks of the colloidal films drying from the suspensions with different ratio of the CSs and silica nanoparticles. In all suspensions, the volume fraction of the CSs was 0.1%, and mixed the CSs with the silica nanoparticles in volume ratio of 5:0, 5:1, and 5:2. The line in fig.2 denotes the crack's tip and the arrows was the growth direction of the colloidal films. In fig.2a, the growth directions of the cracks and the colloidal film are same, the cracks are longitudinal. When the nanoparticles are added, the crack patterns change significantly (Fig. 2b, c). From fig. 2b, c, it is clear that the crack density has a relationship with the amount of the silica nanoparticles. There is higher crack density in fig. 2b. From the insets of the fig. 2, the directions of the crack also change with the addition of the nanoparticles.

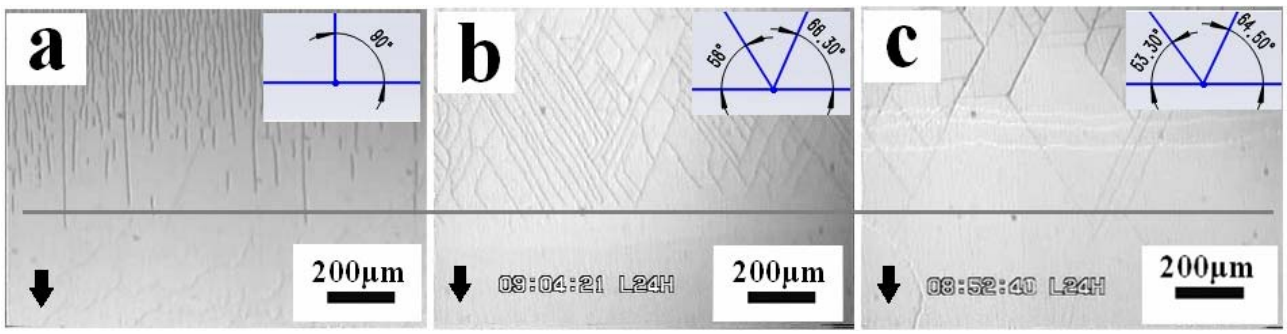

Figure 2 Different crack morphology drying from mixed suspension. The CSs with the silica nanoparticles in volume

ratio of a5:0 (a), 5:1(b), and 5:2 (c). The direction of the arrows is x axis. The insets show the angles between the cracks and x axis.

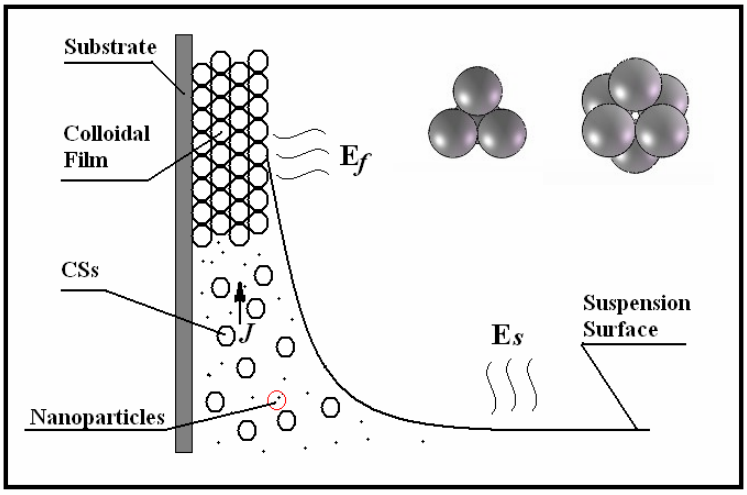

Figure 3 The VSD process of the CSs (or co deposition with nanoparticles) in meniscus region of the suspension. E_f and E_s are the evaporation of the colloidal film and the suspension respectively. J is the diffusive flux of the CSs (nanoparticles). Left inset is tetrahedral site. Right inset is octahedral site.

The VSD method (showed by Fig. 3) gets the colloidal film at the air-water-substrate interface from low-viscosity suspensions. The evaporation-driven flow makes the spheres or particles deposited in the meniscus. When the water reservoir is sufficiently large, the evaporation process does not significantly enrich the colloidal density. As the water evaporates, more substrate is exposed and coated colloidal film. The CSs or nanoparticles in suspension, within the solid-liquid-gas interface, are deposited on the substrate subject to interfacial forces. In this process, the thickness of the film can be adjusted by the concentration of the suspensions or by the descent speed of the suspension surface.

At the very beginning, the CSs and the silica nanoparticles are entrained toward the growth front at the same velocity, and the large spheres nucleate first in a close-packed network because of their higher volume fraction and larger size. With the evaporation and convective flow of the liquid medium through the pore space of the network, the nanoparticles can easily move and fill the voids of the fcc structure (formed by the CSs). From a simple geometric analysis indicated that, in the close-packed colloidal sphere arrays, two types of interstitial sites exist: the tetrahedral site and the octahedral site. One cubic unit cell contains four large spheres, eight tetrahedral voids, and four octahedral voids.

During the evaporation of the film, the strong particle wetting prevents the invasion of air into the colloidal film. With the sustained water loss, the nanomenisci will occur in the film interface, which create capillary the capillary tension to pull water through the network deposited by CSs (nanoparticles) to replace the lost by evaporation. For the wet film (no crack), the rate of fluid flow through (J) must balance the evaporation rate (E_f). The fig. 2a shows the directional cracks which indicate there is nearly uniaxial stress and the stress $\sigma_{xx} >> \sigma_{yy}$. When the nanoparticles were added into the suspension, the film stress state was changed into biaxial stress which leaded to a crack pattern of triangular lattices.

4. Conclusions

In summary, the comparison study of the crack formation during the VSD process with and without

nanoparticles. It was found that co-deposition lead to different crack morphology and decreased the crack density. In contrary, the cracks present a pattern of regular triangular lattices in co-deposition. The crack morphology changes from CCs process to co-deposition process was considered to have a strong relationship to the gel formation in co-deposition procedure which can be ignored in the normal CCs growth. This study indicates the co-VSD method is a cost-efficient approach to get single colloidal crystal of large domain.

Abstract

Metallic rings made of aluminum alloy are studied upon the application of a distributed radial load by a magnetic pulse technique. Two modifications of the magnetic pulse method were implemented on the basis of the GKVI-300 high voltage short pulse generator providing the formation of voltage pulses of 30-300 kV in amplitude. These two approaches making it possible to decrease the period of the harmonic load to 7,5 μs and 1 μs . Method to determine the instant of rupture of the ring from a flash arising at rupture with the help of a photo detector was developed and applied. Load signal and signal from the photo detector are displayed and saved with a digital oscilloscope.

Fracture stress value was estimated. It increased on load time shortens.

The surfaces of fracture of aluminum samples were investigated after the tests by optical microscope. It is shown, when the load time shortens, the ductile component of fracture declines and the samples fail in a more brittle manner.

Keywords: Magnetic Pulse Technique, Metallic Ring Samples, Dynamic Loading

1.Introduction

In the works of American authors [1-4], an original magnetic-pulse method is proposed for the tangential stretching thin metal rings up to destruction. The method allows them to achieve the radial velocities of ring expansion in the range of 80-200 m/s at strain rates of the order $10^4 s^{-1}$. The process of the formation of necks and fragmentation fixed using high-speed photography with high temporal and spatial resolution. It is shown that the destruction of the ring occurs in a time much less than the first period of the current oscillations in the ring. Fragmentation process takes less than 20 μs. The increase in the cross-section of the specimen significantly increases the deformation of localization start. Deformation of localization origin is independent of strain rate. An increase of deformation homogeneity takes place with increasing sample sizes.

The high-speed radial expansion of ring is analyzed in [5] in plane strain. The material behavior is ductile, deformation hardening takes into account also. Tensile tests of rings of aluminum alloy [6] with speeds $3 \cdot 10^3 - 2{,}3 \cdot 10^4 s^{-1}$ at pulse durations between 5 and 41 μs revealed the effect of the speed and size of the expanding rings on the deformation of an aluminum alloy. Loading rate below $2 \cdot 10^3 s^{-1}$ does not affect the deformation. Flow stress depends on the maximum strain rate and the size of the ring.

The work [7] shows the effect of pulse duration on the microstructure produced as a result of impact loading. The authors [8] have shown that the generation of dislocations and the formation of twins in copper alloy with low stacking fault energy depend on the pulse duration less than 0.3 μs. The main cause of hardening under the pulse duration of 0.5 μs is the twinning and slip contribution becomes more significant when pulse duration is large. Number of damage upon rings extension of aluminum alloy is independent of the ring radius and is proportional to its expansion rate as is shown in [9]. Paper [10] provides a method to represent the investigation of fragmentation in the rapidly expanding metal rings. A quick discharge system of the capacitor generates magnetic forces that accelerate the ring to the maximum radial velocity of about 200 m/s, which corresponds to the

peripheral strain rate at about $10^4 s^{-1}$ under fragmentation. The streak camera technique is used to record the movement of the rings. Experiments on the destruction and fragmentation were performed on the samples of OFHC copper and aluminum 1100-0. Thin rings have rapidly expanded in [11] using magnetic fields to study the effect of strain rate on the strain to failure of ductile metals. In the interval of studied expansion velocities (50 to 300 m/s), the experimental results showed that the plasticity of Al 6061 and OFHC Cu increases monotonically with increasing speed. In each case, the deformation of the specimen to the destruction is almost two times more at 300 m/s than in static conditions.
All peer-reviewed papers on the metal rings maximum tensile strain rate did not exceed $10^4 s^{-1}$. This paper presents the results of a study on the destruction of the metal ring samples of D16 aluminum alloy with a substantially reduced period of harmonic loading. Voltage of destruction was rated and it shows its increase with shortening of the loading duration. Short-term loading leads to dynamic recrystallization - the formation of new small grains. The method of determining when the sample breaks is developed and applied.

2. Technique of experiment and results

Figure 1 shows the loading scheme. The current flowing through the coil, in which the ring specimen is located coaxially, causes inductive current in it, and the interaction of these currents generates a force of repulsion between the solenoid and the ring.

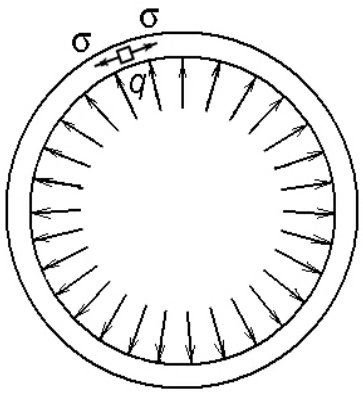

Fig. 1. Loading scheme of the sample (q- load, σ - tensile stress)

Two modifications of magnetic pulse method of loading were realized on the basis of short high-voltage pulse generator GKVI-300, which provides the formation of electrical voltages with amplitudes of 30 - 300 kV. Electrical block-schemes of the installation under the implementation of a sinusoidal load with a period of 7.5 μs (modification 1) and with a period of 1 μs (modification 2) are shown in Fig. 2 and 3, respectively.

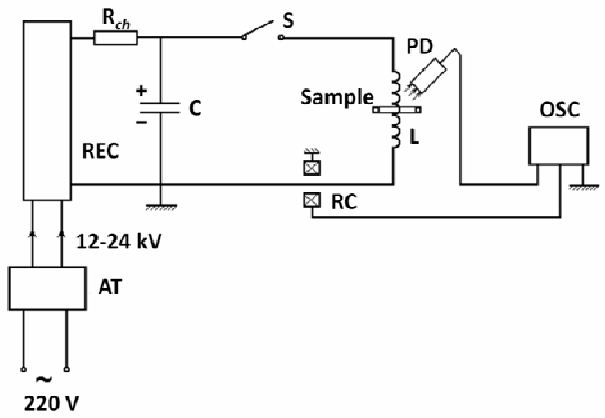

Figure 2. The block-scheme of the setup for sinusoidal electromagnetic load of period 7.5 μs: AT - autotransformer; REC - rectifier; R_{ch} - charge resistor; C - condenser; S - discharge; RC - Rogowski belt; L - coil (coil without core); Sample - sample (metal ring); PD - photodiode; OSC – oscilloscope

In testing of ring specimens with a period of sinusoidal current T = 7,5 μs (Fig. 2) the charge of capacitor (C) is carried out by rectifying device (REC) with variable voltage from 12 to 24 kV. Then the discharge of capacitor (C) was proceeded through the coil (L) with a high-voltage spark gap (S)

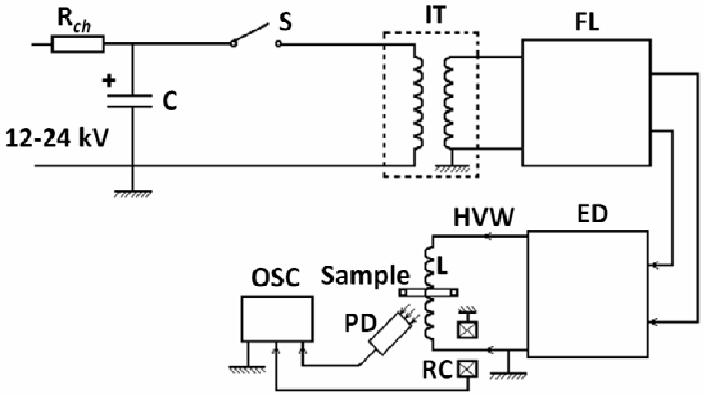

Fig. 3. The block-scheme of the setup for sinusoidal electromagnetic load of period 1 μs: IT - pulse transformer; FL - forming line; ED - output device; HVW - high-voltage electrode

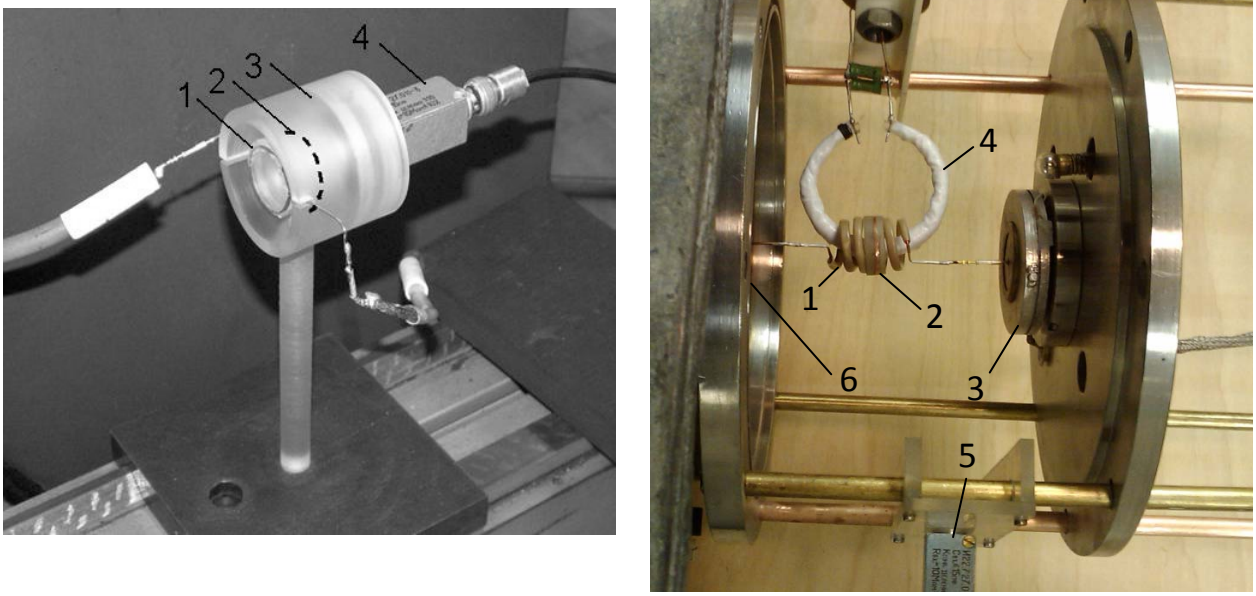
The coil is made of copper wire 1mm in diameter, has 5 turns of the coil 25 mm in diameter. The current flowing through the coil, was measured by Rogowski coil (RC) and displayed on a digital oscilloscope (OSC), from which the information was recorded on an electronic bearer. When the ring (Sample), coaxially mounted on the middle of the coil (L) is broken, a spark is appeared, which permits record the time of the destruction of the sample using a photodiode (PD). More complex unit is used in the test samples, when current was passed through the coil with a period of the damped oscillations T = 1μs. Its block-scheme is shown in Fig. 3. With the help of a pulse transformer (IT) the voltage of sine wave signal increased in 10 times, compared with the above case (Fig. 3) and by forming line (FL), and an output device (ED) (Fig. 3) was supplied to the same coil. However, the period of the current oscillations is already a T = 1μs. Appearance of plants is shown in Fig. 4

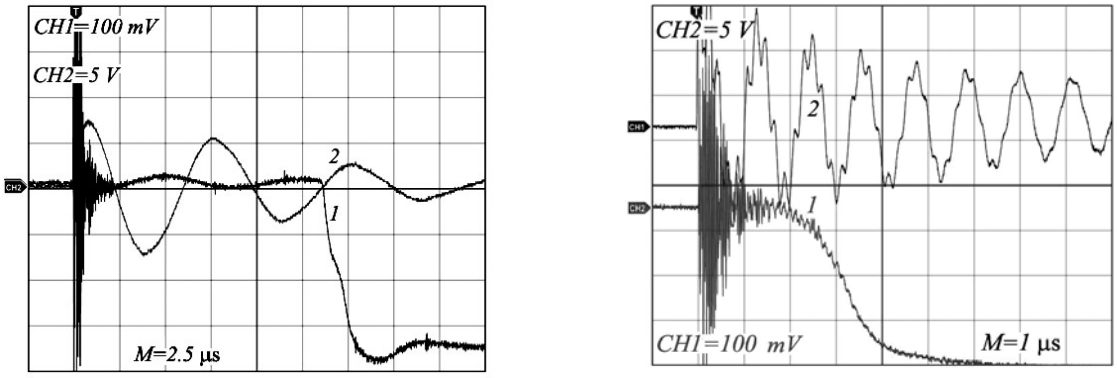


а б

Figure 4. Appearance of plants: a - at 7.5 μs (1 - solenoid, 2 - sample 3 - housing, 4 - photodiode), b - at 1 μs (1 - solenoid, 2 - sample 3 - Rogowski belt to measure the current in the coil 4 - Rogowski coil to measure the current in the ring, 5 - photodiode, 6 - output device).

The study of fracture surfaces of aluminum and copper samples after the test was carried out on an optical microscope Axio-Observer-Z1-M in a dark field, and study the structure of cross sections - in the bright field or polarized light. The structure has been studied in cross sections after appropriate etching. Grain size and the number of pores on the surface of cross sections were determined after etching. Microhardness was measured on a PMT-3 device with a load of 20g. Ring samples were tested from duralumin D16 brand with an inner diameter of 28 mm. The ring D16 had a thickness of 0.11 - 0.40 and a width of 0.5 - 1.0 mm, when they exposed to electric currents with a long period.

Fig. 5 shows the waveforms of current through the coil (2) and the signal from the photodiode (1) fixing the time of rupture of the sample for the two variants of tests: T = 7,5 μs and T = 1 μs.

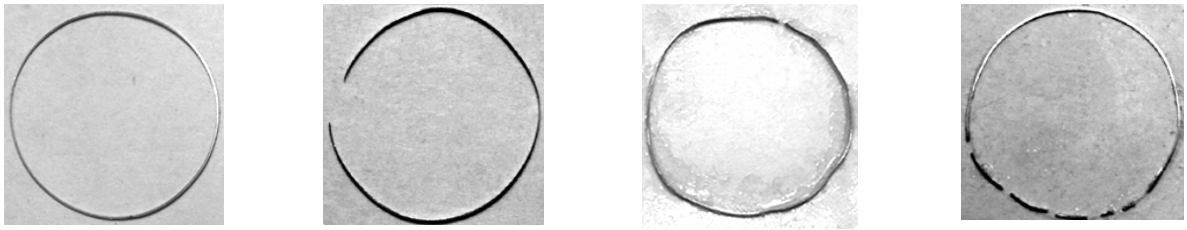


а б

Fig. 5. Waveform signal from the photodiode (1) and current from Rogowski belt (2), a - in the current period $T = 7.5$ μs; b - $T = 1$ μs. Sample size: b= 1.0, h=0,11 mm

3. Discussion of the results

Fig. 6 shows the samples in the initial (pre-test) state and after loading in different modes. The figure shows that failure occurs in one place for a period of change of the current 7,5 μs, and for the period of 1 μs, but in a shorter period can be seen multiple neck. When energy increases with the period of 7,5 μs the number of destruction fragments increases.



а б в г

Fig. 6. Photographs of aluminum samples: a - before loading; b - destruction at the threshold energy, T = 7,5 μs; c - the same at T = 1 μs; d - the destruction at an energy well above the threshold, T = 7,5 μs

Let us estimate the radial force acting on the ring from the side of the coil windings. Calculation scheme is shown in Fig. 7. Estimation of the force is held in the quasi-static approximation. It is believed that the main force is the Ampere force. The total force acting on the ring, adds together of the main force of the turns of the coil, which is located in the plane of the ring coaxially with it (Fig. 7) and on the side of turns. Calculations have shown that the main contribution is made to Ampere force by two side ring. From these considerations, the number of turns of the coil was chosen to be five.

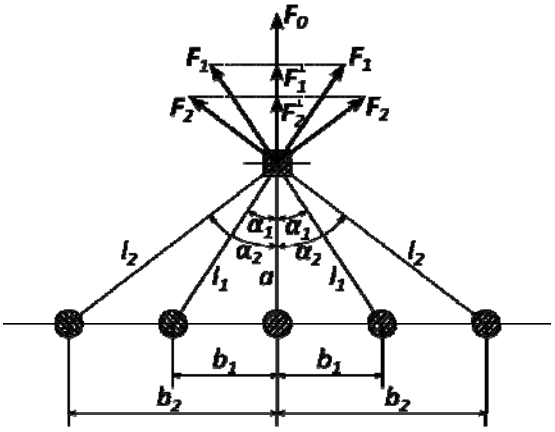


Figure 7. Scheme for calculation of the force acting on the ring

So the force acting on the ring will be

$$F(t) = F_0(t) + 2F_1^{\perp}(t) + 2F_2^{\perp}(t),$$

where

$$F_0(t) = \frac{\mu_0}{4\pi}\frac{2I_1(t)I_2(t)}{a}, \quad F_1^{\perp}(t) = F_1(t)Cos\alpha_1 = \frac{\mu_0}{4\pi}\frac{2I_1(t)I_2(t)}{l_1}Cos\alpha_1,$$

$$F_2^{\perp}(t) = F_2(t)Cos\alpha_2 = \frac{\mu_0}{4\pi}\frac{2I_1(t)I_2(t)}{l_2}Cos\alpha_2,$$

$\mu_0 = 4\pi 10^{-7} \frac{H}{m}$ - magnetic constant, $I_1(t)$ - the current in the loop coil, $I_2(t)$ - the current in the ring, a - the distance from the coil to the ring.

Distributed load acting on the inner surface of the ring,

$$q(t) = \frac{F(t)l}{S},$$

where l - length of the inner circumference of the ring, S = lc - area of the inner surface of the ring, c - the width of the ring.

Thus, $q(t) = \frac{F(t)}{c}$.

The tangential tensile stress (Fig. 1) can be calculated from the Laplace formula for thin shells:

$$\sigma(t) = \frac{q(t)R}{h},$$

where R - radius of the inner ring of the sample and h - its thickness.

In determining the tensile stress its pulsating value $\sigma(t)$ replaces averaged in the form of a rectangular pulse of amplitude σ_0 and duration equal to the time from the start of the current delivery in the coil until the breaking of the ring t_c (Fig. 8)

$$\int_0^{t_c} \sigma(t)dt = \sigma_0 t_c, \quad \sigma_0 = \frac{\int_0^{t_c} \sigma(t)dt}{t_c}.$$

Time recorded in the experiments

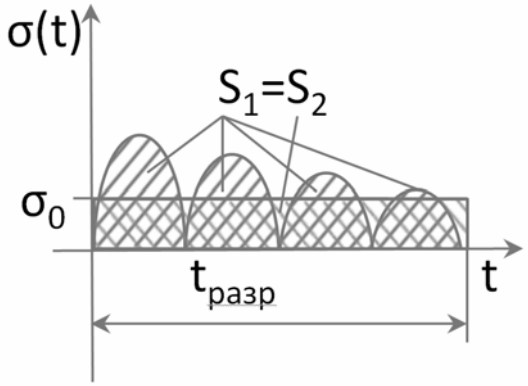

Fig. 8. Replacement scheme of ripple voltage: S_1 - the area under pulsed voltage, S_2 - the area under constant stress σ_0.

The following parameters of the device are used in made experiments and calculations: a = 3 mm, b_1 = 7.5 mm, b_2 = 15 mm.

Characteristics of the samples, the experimental conditions and results are summarized in Table 1, where T - the period of oscillation of the current in the coil; h - thickness of the ring; c - width of the ring; ∅ - ring diameter; U - capacitor charging voltage; σ_0 - tensile stress for rupture of the ring; τ - time to failure; W - energy of a charged capacitor; I - maximum amplitude of the current through the coil

Table 1. The experimental results

Material	T, μs	h, mm	c , mm	∅, mm	U, kv	σ_0 , MPa	τ, μs	W, J	I, A
Al	7,5	0,12	1,0	28	20	104	13,75	100	5700
Al	1	0,11	1,0	28	27	142	2,05	182	6000

Measurement results of ductile component in the fracture of aluminum samples are described in [12], which shows that the shortening of the current period the share of fiber in the fracture surface decreases monotonically, i.e. samples become more fragile.
In Table 2 and in the micrographs (Fig. 9) the results of microstructural studies is presented, where T - the period of oscillation of the current in the coil; S = hxb - section of the sample; D - grain size; n - number of pores in the area of 400 μm^2; HV - microhardness.

Table 2. Characteristics of the structure

Material	T, μs	$h \times b, \mu m^2$	D, μm	n, 1/400μm^2	HV, MPa
Al	7,5	$193{,}5 \times 10^3$	1,2	121	1318,6
Al	1	$68{,}4 \times 10^3$	3,0	70	639,1
Al initial		120 x10^3	4,6	53	720,4

Fig. 9 shows the structure of aluminum samples at initial state and after loading with different periods and different cross-section (scale factor).

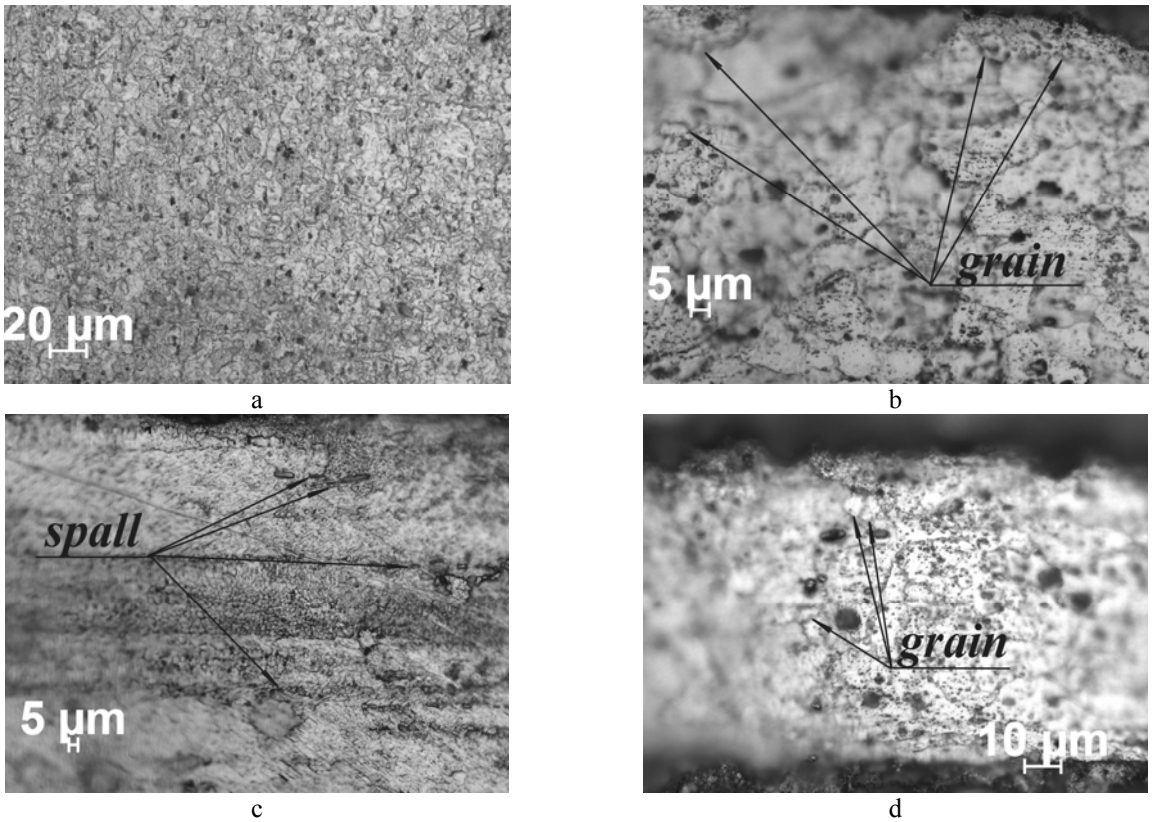

Figure 9. The structure of aluminum: (a) - in the initial state, (b) - after loading with the period T = 7,5 μs (S = 0,13 mm^2); (c) - after loading with the period T = 7,5 μs (S = 0, 19mm^2); (d) - after loading with the period T = 1μs (S = 0,07 mm^2), here the notation: spall - split, grain - recrystallized grains.

It is seen the dynamic recrystallization - the formation of new small grains for short-time loading. The highest degree of dynamic recrystallization is in the samples of aluminum with longer duration

of loading and a maximum cross-section (scale factor). Samples of aluminum after loading showed a greater tendency to pore formation with increasing loading period compared with initial state. In addition, with increasing loading duration the samples had the generation of multiple spallation (Fig. 9c).

4. Conclusion

1. It was developed and tested a magnetic pulse method of destruction and photographic registration moment of destruction for ring metalllic samples at much shorter pulses of loading.
2. It was proposed the evaluation method of the radial force acting on the ring, and the tensile stress at break of the ring.
3. The dynamic recrystallization, the formation of shear bands and multiple spallation were revealed using magnetic pulse loading of the ring samples.

On Kinetics of "Diffusion" Cracks and Delaminations

Ilya Nickolaevich Dashevskiy

A. Ishlinsky Institute for Problems in Mechanics, Russian Academy of Sciences, 119526, Russia
dash@ipmnet.ru

Abstract In the cracks contained in such materials as metals under the action of corrosive media, degrading polymers and ceramics (for example, HTSC-ceramics), gas-saturated rocks, etc., gas can be accumulated. For a penny-shaped crack in an unbounded elastic medium and for a thin penny-shaped delamination under the surface of a half-space, as well as for similar cracks-strips, in a new uniform way – on the basis of the energy approach and with the use of Clapeyron theorem – kinetic equations are derived describing the growth of specified defects under gas diffusion into them. The analysis of the reasons leading to identity of the equations named, allows (under some conditions) to extend the results obtained for these problems to a number of other important cases: cracks on the interface of an adhesive joint of two pliable half-spaces with different mechanical and diffusion properties (with the interface being permeable as well as impermeable), the account of anisotropy, etc. It is shown, that exactly the same reasons (and under the same restrictions) make it possible to extend to the same cases the results obtained earlier for growth laws of a penny-shaped crack in an unbounded elastic medium versus laws of gas inflow into it as well.

Keywords Kinetics, Diffusion, Cracks, Delaminations, Model

1. Introduction

One of the models of crack growth as a gas is accumulated in the crack according to the diffusion mechanism (in what follows, a "diffusion" crack), which, for example, is typical of the process of structural steel hydrogenizing, was formulated and justified in [1] (different approaches are represented, for example, in [2, 3, 4, 5]). Later, in [6, 7, 8, 9, 10], this model was developed and generalized in different directions. In what follows, we analyze the derivation of the kinetic equations for this model, which allows for better understanding of the role and the action mechanism of its principal factors and also for showing the directions of extrapolation of the earlier results to different cases.

2. Derivation of kinetic equations

Let obtain kinetic equations for a penny-shaped crack in an infinite elastic space and for a circular crack, which is a delamination from the boundary of the half-space under gas diffusion into them (Fig.1) in a uniform way.

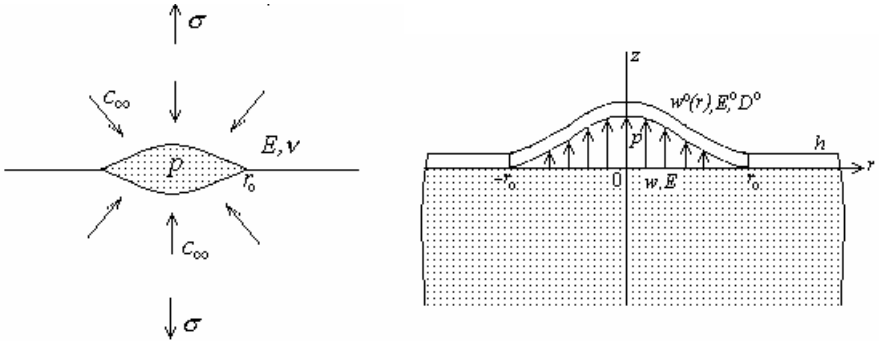

Fig.1.

First we derive expressions for the case of a gas influx into the crack. Since the problem on a

penny-shaped crack in infinite space is symmetric about the crack plane $z = 0$ ([6], p. 828), it suffices to consider the problem in the half-space $z \le 0$. We assume that the process is quasistationary ([1]; [9], p. 120) and take the axial symmetry of the problem into account. Then, for the unknown gas concentration $c(\rho, z, t)$, where ρ is the radial coordinate in the cylindrical system of coordinates, in the half-space $z \le 0$, we obtain the mixed problem from the theory of harmonic functions:

$$\Delta c = 0, \quad z \le 0; \qquad c|_{z=0} = 0, \quad \rho \le r(t);$$
$$\partial c/\partial z|_{z=0} = 0, \quad \rho > r(t); \qquad c|_{z=\infty} = c_\infty$$

where time t is a parameter. Subtracting the equilibrium state $c = c_\infty$, we obtain

$$\Delta c = 0, \quad z \le 0; \qquad c|_{z=0} = -c_\infty, \quad \rho \le r(t);$$
$$\partial c/\partial z|_{z=0} = 0, \quad \rho > r(t); \qquad c|_{z=\infty} = 0 \tag{1}$$

This mixed problem of potential theory is formally equivalent to the contact problem on the indenta-
tion of a rigid die, that is circular in cross-section and has a smooth bottom, in to an elastic isotropic half-space ([11], p. 385, formula (11.6.8) and later). Taking use of the solution of the latter contact problem we obtain for the density $q(\rho, t)$ of the gas diffusive flux into the crack

$$q(\rho,t) = -D\frac{\partial c}{\partial z}\bigg|_{z=0,\,\rho<r} = \frac{2c_\infty D}{\pi\sqrt{r^2-\rho^2}}$$

The total flux through the surface $z = -0$, $\rho < r$ is

$$Q_- = \int_0^r 2\pi\rho q(\rho,t)d\rho = 4c_\infty D\int_0^r \frac{\rho d\rho}{\sqrt{r^2-\rho^2}} = 4c_\infty Dr \tag{2}$$

For the delamination problem, the obtained quantity Q_- is simultaneously the total gas influx Q into the crack. But, for the case of a crack in infinite space gas influx goes through the lower and upper surfaces of the crack and is equal to

$$Q = Q_- + Q_+ = 2Q_- = 8c_\infty Dr \tag{3}$$

Combining Eq. 2 and Eq. 3, we write

$$Q = N\cdot 4c_\infty Dr \tag{4}$$

where N is the number of "gas transmitting" surfaces of the crack.
Taking into account the expression $Q/k = dn(t)/dt$, where k is the coefficient of gas recombination in the crack (in the case of hydrogen, $k = 2$, because, on the crack surface, the protons melted in the metal recover to the atomic hydrogen which, flowing inside the crack, recombines into molecular hydrogen) and $n(t)$ is the number of gas moles in the crack, we can rewrite Eq. 4 in the form

$$dn(t) = 4Nc_\infty Dr\, dt/k \tag{5}$$

From the equation of state for the ideal gas (the Mendeleev–Clapeyron equation), we have

$$pV = RTn(t) \tag{6}$$

where p is the gas pressure inside the crack and V is the crack volume.
Expressing $n(t)$ from Eq. 6 and substituting into Eq. 5, after the replacement $dt = dr/u$, we obtain

$$d(pV) = (4Nc_\infty DRT)rdr/(ku) \tag{7}$$

The Clapeyron theorem for linear media ([11], p. 160) implies that

$$U = pV/2, \quad pV = 2U \tag{8}$$

where U remains the elastic energy of the body.
We introduce G, which is the elastic energy release rate or the "crack-moving force" ([12], p. 71, formula (3.12) and further) or the "force of resistance to the crack propagation" ([11], p. 686) or the "energy flux towards the crack vertex", the "intensity of released elastic energy" ([3, pp. 28–30, p. 51), or the "strain energy release rate" ([13], p. 119). For a linearly elastic body, all these quantities, as well as the Γ-integral ([14], Chapter 1, Sec. 1), as well as the J-integral, coincide ([15], pp. 107–116). By definition ([12], pp. 73–74, formulas (3.21)–(3.23)), we write

$$G = \left.\frac{\partial U}{\partial S}\right|_p \tag{9}$$

where U is the elastic energy of the body and S is the crack area.
Under the axisymmetric extension of a penny-shaped crack, we have $dS = 2\pi rdr$, and

$$G = \left.\frac{\partial U}{\partial S}\right|_p = \frac{1}{2\pi r}\left.\frac{\partial U}{\partial r}\right|_p$$

If the dependence of U (or of V, which is the same in the linear case, as it follows from Eq. 8) on r is power-law, i.e.

$$U \sim r^m \tag{10}$$

then

$$\frac{1}{r}\frac{\partial U}{\partial r} = m\frac{U}{r^2}, \quad G = \frac{mU}{2\pi r^2}, \quad U = \frac{2\pi r^2 G}{m} \tag{11}$$

Substituting Eq. 11 into Eq. 8 and then into Eq. 7, we obtain

$$d(r^2G) = \frac{Nm}{2\pi k} c_\infty DRT \frac{d(r^2)}{u} \tag{12}$$

When a crack grows really, its propagation rate cannot be arbitrary, but, according to the kinetic diagram of static fracture strength at each time instant, is determined by the current value of the stress intensity factor on its contour or by the current energy release rate G. Thus, to derive the kinetic equation, we must assume in Eq. 12 that the the crack propagation rate u is the function of G determined by the kinetic diagram of static fracture strength, $u = u(G)$. This is that gives the desired kinetic equation, expressed in variables G и r, which, by the way, does not contain time t explicitly.

But what is the real, actual character of the dependences $U(r)$, $V(r)$? For a penny-shaped crack under internal pressure in an infinite body, we have $V = V(r, p, E, \nu)$, and it follows from dimension considerations that $V \sim r^3 p/E$ (the exact formulas see in ([16], p. 548, formula (10.131)). In this case $m = 3$, $N = 2$, and Eq. 12 becomes

$$d(r^2G) = \frac{3}{\pi} c_\infty DRT \frac{d(r^2)}{ku} \tag{13}$$

In the case of a thin parallel-to-the-boundary impenetrable delamination of thickness h from the half-space, the problem is reduced [9] to the problem of axisymmetric bending of a circular plate fixed on the boundary under the action of uniform pressure, $V = V(r, p, D_0)$, and it follows from dimension considerations that $V \sim r^6 p/D_0$ (the exact formula is ([9], Eq. 12)). Thus, here we have $m = 6$ and $N = 1$ and Eq. 12 becomes

$$d(r^2G) = \frac{6}{2\pi} c_\infty DRT \frac{d(r^2)}{ku} = \frac{3}{\pi} c_\infty DRT \frac{d(r^2)}{ku} \tag{14}$$

which coincides exactly with the similar Eq. 13.

3. Kinetic equation integral. Step-like kinetic diagram

Eq. 12 can be easily integrated

$$\ln\left(\frac{r}{r_0}\right) = \frac{1}{2} \int_{G_{SCC}}^{G} \frac{dG}{\dfrac{\alpha}{u(G)} - G}$$

$$\alpha = \frac{Nm}{2\pi k} c_\infty DRT$$

$$\begin{gathered} \text{When} \quad r \to \infty, \quad \ln(r/r_o)^2 \to \infty \quad \leftrightarrow \quad [\alpha/u(G) - G] \to 0 \\ G \to G_\infty: \quad u(G_\infty) = \alpha/G_\infty,\ u \to u_\infty = u(G_\infty) \end{gathered} \tag{15}$$

For metals and rocks kinetic diagram $u(G)$ is nearly step-like (Fig. 2). In this case it follows from Eq. 15 that

if $\alpha/G_{SCC} < u^*$, then $G_\infty = G_{SCC}$, $u_\infty = \alpha/G_{SCC}$,
if $\alpha/G_{SCC} > u^* \rightarrow u_\infty = u^*$, $G_\infty = \alpha/u^*$

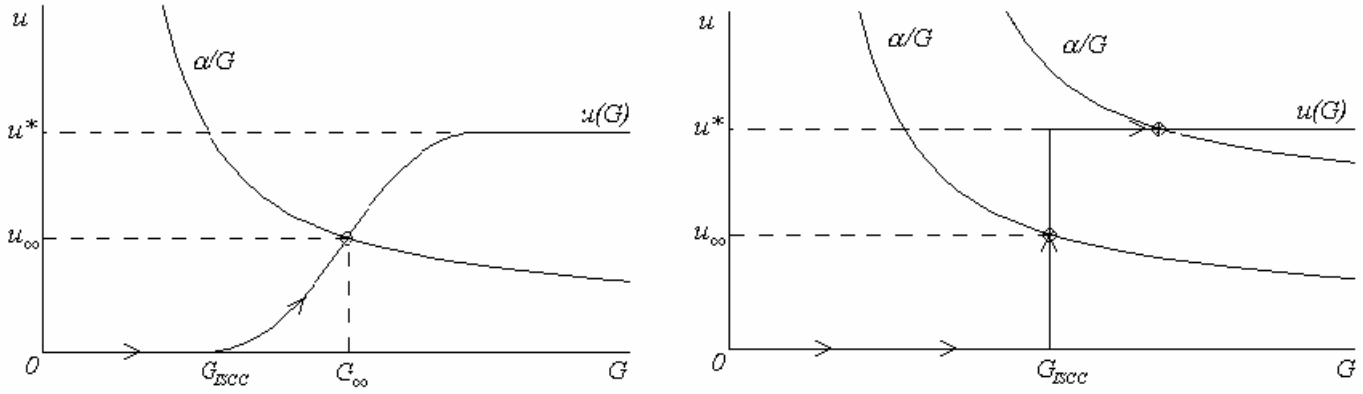

Fig. 2

4. Example: life-time evaluation of a massive piece of structural steel with a penny-shaped crack under hydrogenation

We use these results to analyze the kinetics of a penny-shaped crack in a bulk sample of low-carbon low-alloy steel in hydrogenation. We simulate a sample as infinite elastic medium and assume that the material has the $u(G)$ diagram of threshold type (which is close to reality).
The process of crack development consists of two stages: incubation period, t_i (gas accumulation in the stationary crack), followed by a period of growth (movement) t_m.
During the period of incubation, $r = r_0 = \text{const}$. Turning back in (2.16) from dr^2 to rdr, dividing both sides by r, substituting $k = 2$, substituting dr/u on dt, and r on r_0 and integrating, we obtain

$$G = 3c_\infty DRTt/(\pi r_0) \tag{16}$$

The incubation time is determined by the achievement of G its critical value G_{ISCC}, which gives

$$t_i = \pi r_0 G_{ISCC}/(3c_\infty DRT) \tag{17}$$

In the literature they give the values not for G_{ISCC}, but for the corresponding SIF K_{ISCC}, which is related to G_{ISCC} by the Irwin formula $G_{ISCC} = (1 - \nu^2)K^2_{ISCC}/E$. For the concentration c_∞ of the hydrogen dissolved in the metal the literature values given are for the so-called "weight parts" (the ratio of the weight of hydrogen per unit volume to the weight of the metal containing it), we denote this quantity by c^∞, while c_∞ has the dimension of mol/volume and is numerically equal to $c^\infty g$, where g is the steel density. Therefore, passing in Eq. 17 from G_{ISCC} to K_{ISCC} and from the c^∞ to c_∞ we finally obtain

$$t_i = \pi(1 - \nu^2)K^2_{ISCC} r_0/(3c^\infty g\, DRTE) \tag{18}$$

During the period of growth with the $u(G)$ diagram of threshold-type $G = const = G_{ISCC}$.

Substituting this into (2.16), substituting $k = 2$, dividing both sides by dr^2 and replacing c^∞ with c_∞ and G_{ISCC} with K_{ISCC}, we obtain

$$u = 3c_\infty DRT/(2\pi G_{ISCC}) = 3c^\infty gDRTE/[2\pi(1-\nu^2)K^2_{ISCC}] = const \quad (19)$$

$$t_i = r_0/(2u) \quad (20)$$

$$r = r_0 + (t - t_i)\cdot u = r_0 + t_m \cdot u \quad (21)$$

We assume room temperature $T = 273^0$K and use the default values for the universal gas constant $R = 8.31$ J/(mol·grad) = $8.32\cdot10^7$ erg /(mol·grad) ([17], p. 153 [18], p. 151) and typical values for density and elastic constants of low-alloy steel $g = 7.8$ g·cm^{-3} ([17], p. 40), $E = 2\cdot10^4$ kg·mm^{-2}, $\nu = 0.3$ ([17], p. 116). We also know that $D = 10^{-3}$ mm^{2}s^{-1} [19], $K_{ISCC} \cong 120$ kg·mm$^{-3/2}$ [20], and the values of c^∞ can reach 10^{-5} parts by weight [21]. In addition, we assume that the initial radius of the crack r_0 is equal to $r_0 = 10$ mm.

Table 1. The parameters values taken for calculations

T^0 [K]	R [J/(mole·K)]	g [g·cm^{-3}]	E [kG·mm^{-2}]	ν	D [mm^{2}c^{-1}]	K_{ISCC} [kG·mm$^{-3/2}$]	c^∞	r_0 [mm]
273	8.31	7.8	$2\cdot10^4$	0.3	10^{-3}	120	10^{-5}	10

Substituting these values in Eq. 19, we obtain

$u \cong 10^{-5}$ mm/s

Thus, the crack front velocity turned out to be of the order of 10^{-5} mm/s and according to Eq. 20, incubation time

$t_i = r_0/(2u) = 10$ mm/($2\cdot10^{-5}$ mm/s) = $5\cdot10^5$ s ≅ $1.5\cdot10^2$ h = 150 h ≈ 6 days and nights.

If the front crack after the start begins to move at a speed of about 10^{-5} mm/s, then the radius equal, for example, $r = 50$ mm, will be according to Eq. 21 achieved through

$t_m = (r - r_0)/u =$ (50–10) mm/(10^{-5} mm·s^{-1}) = $40\cdot10^5$ s ≅ $1.1\cdot10^3$ h ≈ 46 days and nights.

As can be seen from Eqs. 19-21, the values of durability can vary by orders of magnitude depending on the concentration of the gas in the metal.
In the case of the $u(G)$ diagram of general form, as well as in the presence of tensile stresses and taking into account a number of additional physical and physical-chemical factors [5] the range of possible values of life can range from several hours up to many hundreds of years.

5. Main assumptions and the scope of the equation obtained above

To specify the scope of the kinetic Eq. 12 and the results obtained from this equation earlier in [1, 6, 7, 8, 9], we list the assumptions used above in its derivation:
1. The medium is homogeneous and diffusively linear, see Eq. 5.

2. The gas is thermodynamically ideal (obeys the Mendeleev–Clapeyron equation of state), see Eq. 6.
3. The medium is mechanically linear, see Eq. 8.
4. The dependence of V , and hence of U, on r is power-law, see Eqs. 10, 11.

As to the last assumption, it follows from dimension considerations that, in any case, the expression for the volume V of the crack must have the form

$$V = r^3 \frac{p}{E} f(\frac{r}{h_i}, \nu_i)$$

where h_i are the problem parameters of dimension of length (except for r), ν_i are the dimensionless parameters (except for r/h_i), $f(r/h_i, \nu_i)$ is a function determined by the geometry and physics of the problem.

Thus, condition 4 means that either the problem does not contain any geometric parameters other than the crack dimensions (as in the case of an infinite homogeneous body) or all the parameters of dimension of length in the formula for the volume V are combined into a single factor (as in the case of delamination from the half-space).

On the one hand, this implies that all the main results must remain valid if the complication of the problem is not related to the appearance of new parameters of dimension of length. For example, these are (under some conditions) the following cases: cracks on the adhesion boundary between two compliant half-spaces with different mechanical but equal (close) diffusive properties (in the case of an impenetrable boundary, the diffusive properties can also be different); the case of taking the anisotropy into account; delamination from the membrane half-space; etc.

Since the argument in [8] is also based on the same assumptions 2–4, the results in [8] can be generalized (under the same conditions) to all problems where the above assumptions remain valid.

The elastic-plastic limit pressure of cylinder under internal pressure using a new yield criterion

Xiaoyu Liu [1], Zheng Yang [1,*], Shanshan Huang[1]

[1]Department of Civil Engineering, Xi'an Jiaotong University, Xi'an 710049, China
* zyang@mail.xjtu.edu.cn

Abstract Elastic-plastic limit pressure(EPLP) of closed-end cylinders under internal pressure is derived, using a new yield criterion that depends on stress triaxiality and Lode angle. The von Mises, Tresca, twin-shear and Drucker-Prager yield criterions are encompassed in the new yield criterion for the EPLP. The results reveal that, with the increasing of the parameters of stress triaxiality and Lode angle, the EPLP decreases for cylinder with fixed outer-to-inner radius ratio(k). As k increases, the EPLP increases when the parameters of stress triaxiality and Lode angle are certain value. The parameter of Lode angle is much more important than the parameter of stress triaxiality affecting the EPLP of cylinders. The new yield criterion with smaller parameters of stress triaxiality and Lode angle is used instead of the conventional von Mises, Tresca, twin-shear and Drucker-Prager yield criterions in design, it can lead to substantial saving the material required. While the new yield criterion with larger parameters of stress triaxiality and Lode angle is used in design, it can make the design more safe and reliable.

Keywords Closed-end cylinder, New yield criterion, Stress triaxiality, Lode angle

1. Introduction

Closed-end cylinders are used in engineering, as pressure vessels, nuclear reactors and capsules. It is important to know the EPLP of cylinders under internal pressure. A considerable amount of work has been done on the problem of elastic-plastic analysis in a closed-end cylinder under internal pressure[1-4]. However, when the conventional yield criterions are adopted to derive the EPLP, the Tresca[5] and von Mises[6] yield criterions ignore the effect of the intermediate principal stress and octahedral normal stress on yield, respectively. They lead to conservative predictions of limit pressures. Although the twin-shear[7] and Drucker-Prager[8] yield criterions overcome above deficiencies, they still ignore the effect of stress triaxiality and Lode angle on yield. By the view of equivalent stress, stress triaxiality and Lode angle, the von Mises yield criterion ignore the effect of stress triaxiality and Lode angle on yield, and the Tresca yield criterion also ignore the effect of stress triaxiality on yield. But the effect of stress triaxiality and Lode angle on yield have been confirmed[9-13]. Based on the von Mises, Tresca and Drucker-Prager yield criterions, a new yield criterion, which considers the effect of stress triaxiality and Lode angle on yield, is proposed and confirmed by experiments[9]. In this paper, the EPLP of closed-end cylinders under internal pressure, which are two important parameters in the design of closed-end cylinders, is determined using the new yield criterion. Important results concerning the influence of the EPLP determined with the new yield criterion on the design of closed-end cylinders under internal pressure are presented.

2. Determined the EPLP of closed-end cylinders under internal pressure using the new yield criterion

The new yield criterion, which considers the effect of stress triaxiality and Lode angle on yield, as follows,

$$\sigma_{\mathrm{yld}} = \sigma_{\mathrm{eq}}\left[1 - c_{\eta}\left(\eta - \eta_0\right)\right]\cdot\left[c_{\theta} + \left(c_{\mathrm{ax}} - c_{\theta}\right)\gamma\right]. \tag{1}$$

Where γ and c_{ax} are two parameters defined by

$$\gamma = \frac{\sqrt{3}}{2-\sqrt{3}}\left[\sec\left(\theta - \frac{\pi}{6}\right) - 1\right], \quad c_{ax} = \begin{cases} c_t & 0 \le \theta \le \dfrac{\pi}{6} \\ c_c & \dfrac{\pi}{6} < \theta \le \dfrac{\pi}{3} \end{cases}. \tag{2}$$

Where σ_{eq}, η and θ are equivalent stress, stress triaxiality and Lode angle, respectively. σ_{yld} is the yield stress. η_0, c_η, c_θ, c_t and c_c are material constants, this depends on which type of reference test is used to calibrate the relationship of stress-strain.

Let us consider a closed-end cylinder under an internal pressure p. The inner and outer radius of the cylinder are a and b, respectively. In elastic stage, the σ_{eq}, η and θ are determined with Lame solutions of the elastic stress distribution in cylindrical coordinates system[14] as follows,

$$\sigma_{eq} = \sqrt{3}\frac{\rho^2}{k^2-1}p, \eta = \frac{\sqrt{3}}{3}\frac{1}{\rho^2}, \theta = \frac{\pi}{6}. \tag{3}$$

Where $k=b/a$ and $\rho=b/r$ ($a \le r \le b$).

Yielding will appear at the inner surface of the closed-end cylinder at the elastic limit pressure(ELP) p_e. Substituting Eq. (3) into Eq. (1), the yield condition is satisfied at the inner surface $(\sigma_r)_{r=a}=-p_e$, the ELP obtained by the new yield criterion is

$$p_e = \sigma_{yld}\frac{\left(k^2-1\right)}{\sqrt{3}c_\theta k^2}\left[1 - c_\eta\left(\frac{\sqrt{3}}{3k^2} - \eta_0\right)\right]^{-1}. \tag{4}$$

Because θ is a constant ($\theta=\pi/6$), the effect of Lode angle on the ELP is equal to c_θ. The relationship of stress-strain is obtained from smooth round bar tensile test, therefore, η_0 is equal to 1/3. c_η represents the effect of stress triaxiality on material plasticity.

When the internal pressure exceeds p_e, a plastic zone will appear at the inner surface and spread toward the outer surface. The elastic-plastic boundary at any stage has radius r_y ($a \le r_y \le b$), in the elastic region ($r_y \le r \le b$), the radial stress is obtained from Lame's equations using the boundary condition $\sigma_r=0$ at $r=r_b$ as follows,

$$\sigma_r = \frac{1}{k_y^2-1}\left(1-\rho^2\right)p_y. \tag{5}$$

Where $p_y = \dfrac{\sigma_{yld}\cdot\left(k_y^2-1\right)}{\sqrt{3}c_\theta\cdot k_y^2}\left[1 - c_\eta\left(\dfrac{\sqrt{3}}{3}\dfrac{1}{k_y^2} - \dfrac{1}{3}\right)\right]^{-1}$ and $k_y = \dfrac{b}{r_y}$.

In plastic region, the material is assumed perfectly elastic-plastic, the equation of equilibrium is

$$\frac{d\sigma_r}{dr} + \frac{\sigma_r - \sigma_\theta}{r} = 0. \tag{6}$$

The cylinder is assumed at the plane strain condition, therefore, the longitudinal stress in the plastic region is

$$\sigma_z = \frac{1}{2}\left(\sigma_r + \sigma_\theta\right). \tag{7}$$

The σ_{eq}, η and θ are determined with Eq. (7), σ_r and σ_θ as follows,

$$\sigma_{eq}=\frac{\sqrt{3}}{2}(\sigma_\theta-\sigma_r),\ \ \eta=\frac{\sqrt{3}}{3}\frac{\sigma_\theta+\sigma_r}{\sigma_\theta-\sigma_r},\theta=\frac{\pi}{6}. \tag{8}$$

Substituting Eq. (8) into Eq. (1), we have

$$A=\sigma_\theta-B\sigma_r. \tag{9}$$

Where $A=\dfrac{2\sqrt{3}}{c_\theta}\dfrac{\sigma_{yld}}{3+\left(1-\sqrt{3}\right)c_\eta}$ and $B=\dfrac{3+\left(1+\sqrt{3}\right)c_\eta}{3+\left(1-\sqrt{3}\right)c_\eta}$.

When $c_\eta\neq0$, Substituting Eq. (9) into Eq. (6), then the boundary condition $(\sigma_r)_{r=a}=-p$ is satisfied, the stress distribution in the plastic region ($a\leq r\leq r_y$) is

$$\sigma_r=C\cdot r^{B-1}-\frac{A}{B-1},\sigma_\theta=B\cdot C\cdot r^{B-1}-\frac{A}{B-1}. \tag{10}$$

Where $C=\left(\dfrac{A}{B-1}-P\right)a^{-(B-1)}$.

According to the stress continuity of radial stress σ_r across $r=r_y$, it requires that

$$(\sigma_r)_{r=r_y}\text{ (elastic zone)}=(\sigma_r)_{r=r_y}\text{ (plastic zone)}. \tag{11}$$

Substituting the radial stress Eq. (5) for the elastic zone and the radial stress Eq. (10) for the plastic zone into Eq. (11), the relation of pressure p with plastic zone radius is obtained as follows

$$p=\frac{A}{B-1}+\left\{\frac{\sigma_{yld}\cdot\left(k_y^2-1\right)}{\sqrt{3}c_\theta\cdot k_y^2}\left[1-c_\eta\left(\frac{\sqrt{3}}{3}\frac{1}{k_y^2}-\frac{1}{3}\right)\right]^{-1}-\frac{A}{B-1}\right\}\left(\frac{r_y}{a}\right)^{-(B-1)}. \tag{12}$$

When r_y becomes equal to b, the closed-end cylinder is completely plastic, the plastic limit pressure(PLP) for closed-end cylinder is, therefore, obtained as

$$p_p=\frac{\sigma_{yld}}{c_\theta c_\eta}\left[1-k^{\frac{-2\sqrt{3}c_\eta}{3+\left(1-\sqrt{3}\right)c_\eta}}\right]. \tag{13}$$

When $c_\eta=0$, the PLP for closed-end cylinder also is obtained as follows,

$$p_p=\frac{2\sigma_{yld}}{\sqrt{3}c_\theta}\ln k. \tag{14}$$

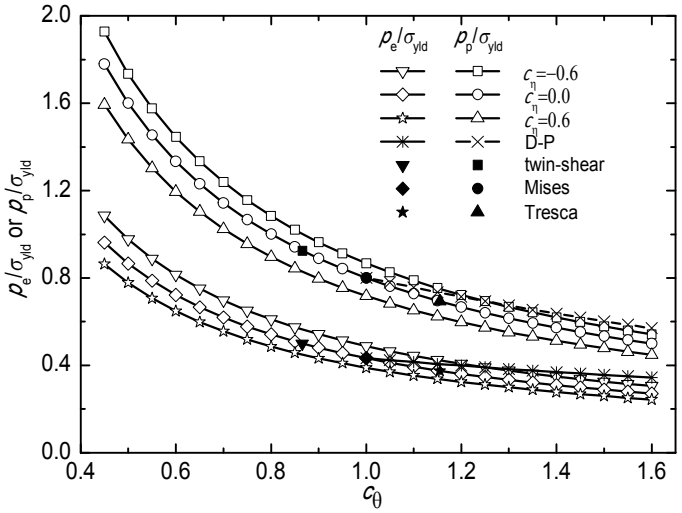

Fig.1 Relation of EPLP of closed-end cylinder under internal pressure with c_θ (k=2).

If the ratio of outer radius to the inner radius is 2(k=2), the relation of EPLP of closed-end cylinders under internal pressure with c_θ is illustrated in Fig.1. It can be seen that, the EPLP

calculated by von Mises, Tresca and twin-shear yield criterions equal these obtained by the new yield criterion when c_η=0 and c_θ=1, 2/√3 and √3/2, respectively. While $c_\eta \neq 0$, c_η=3(1-c_θ)/c_θ and c_θ>1, one will get the EPLP determined with Drucker-Prager. Therefore, it can be concluded that the von Mises, Tresca, twin-shear and Drucker-Prager yield criterions are encompassed in the new yield criterion for the EPLP. It is also found that, when c_η=0.0 and c_θ>√3/2, the EPLP is higher than those obtained by the von Mises, Tresca, twin-shear and Drucker-Prager yield criterions. When c_η=0.0 and c_θ<2/√3, the EPLP is lower than those obtained by conventional yield criterions. When c_θ is certain value, the EPLP in range of c_η<0.0 is larger than that at c_η=0.0, the EPLP in range of c_η>0.0 is smaller than that at c_η=0.0. c_θ is much more important than c_η affecting the EPLP of cylinder, similar conclusions are also found in earlier report[9, 15]. The EPLP decreases with the increasing of c_θ and c_η.

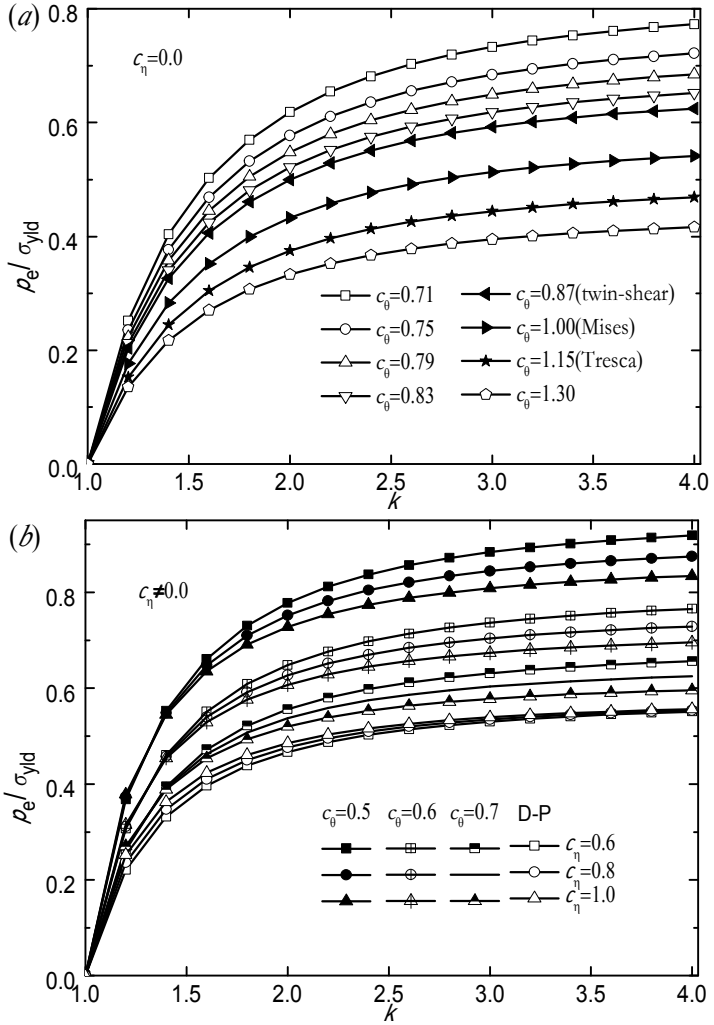

Fig.2 Relation of ELP of closed-end cylinders under internal pressure with k at c_η=0(*a*) and $c_\eta \neq 0$(*b*).

A number of the relations of EPLP with the ratio of outer radius to the inner radius, are shown in Fig. 2 and Fig. 3. In Fig.2 and Fig.3, the EPLP increases with the increasing of k, when c_θ and c_η are certain value. In Fig.2(*a*), when the effect of stress triaxiality on yield is ignored (c_η=0), it is worth noting that, if k approaches the value 3.0, the increase in the ELP is very small with the increasing of k. While the effect of stress triaxiality on yield is considered ($c_\eta \neq 0$), the increase in the ELP is also very small when $k \geq 2.5$, shown in Fig.2(*b*). From what I have mentioned above, we can see the new yield criterion with smaller c_θ and c_η is used instead of the conventional von Mises, Tresca, twin-shear and Drucker-Prager yield criterions in design, it can lead to substantial saving the material required. While the new yield criterion with larger c_θ and c_η is used in design, it can make

the design more safe and reliable.

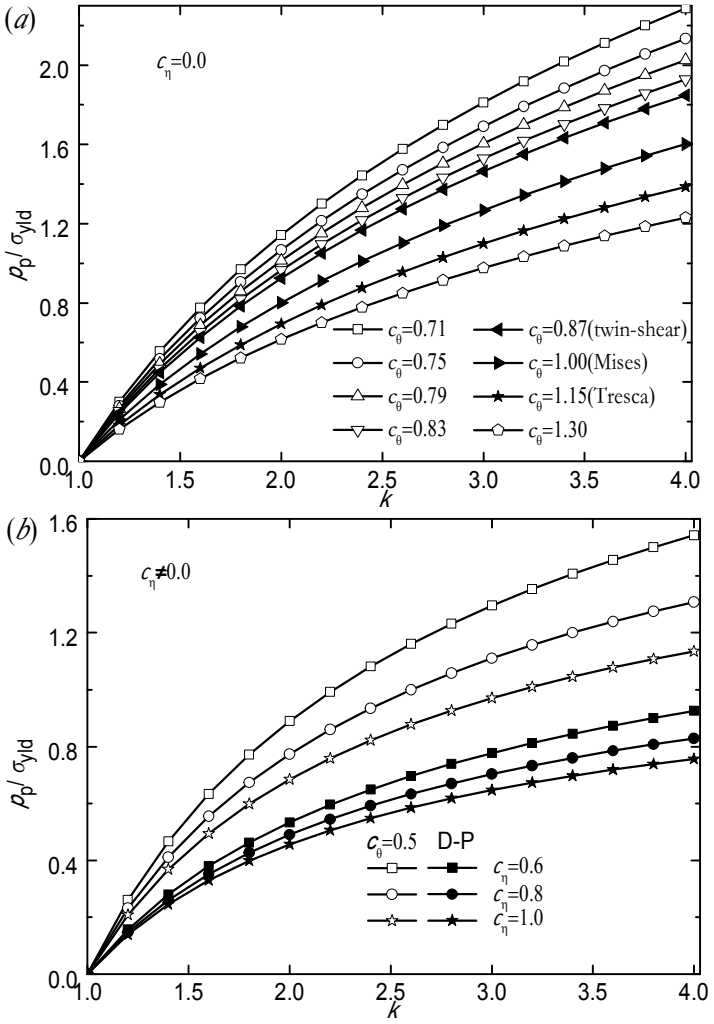

Fig.3 Relation of PLP of closed-end cylinders under internal pressure with k at c_η=0(a) and c_η≠0(b).

3. Summary

The EPLP of closed-end cylinders under internal pressure is derived using the new yield criterion that depends on stress triaxiality and Lode angle. The von Mises, Tresca, twin-shear and Drucker-Prager yield criterions are encompassed in the new yield criterion for the EPLP. The results reveal that, with the increasing of c_θ and c_η, the EPLP decreases for cylinder with fixed k. As k increases, the EPLP increases when c_θ and c_η are certain value. c_θ is much more important than c_η affecting the EPLP of cylinder, The new yield criterion with smaller c_θ and c_η is used instead of the conventional von Mises, Tresca, twin-shear and Drucker-Prager yield criterions in design, it can lead to substantial saving the material required. While the new yield criterion with larger c_θ and c_η is used in design, it can make the design more safe and reliable.

Abstract The effect of metal loses due to corrosion on burst pressure of API X42 steel pipes was studied using nonlinear finite element (FE) method. The nonlinear finite element method coupled with stress modified critical strain (SMCS) model was used to predict the failure of the pipes. In this paper, the corrosion defects were simplified to rectangular shape. The procedure in determining the SMCS model parameters from tensile bars was systematically discussed. The effect of defects length, depth and width was investigated. The burst pressure estimated was then compared to available design codes of corroded pipelines. For validation, the results of burst pressure from FE were compared to experimental data. The depth of corrosion defects appears as the most influential parameter that affects the burst pressure of the pipes.

Keywords Burst Pressure, Corrosion Defects, Stress Modified Critical Strain, Stress Triaxiality

1. Introduction

In petrochemical industry, pipelines play an important role in transporting crude oil and gas. As in service duration increases, the pipelines are affected by corrosion mechanism which leads to fatal accident. Corrosions can occur in both internal and external surfaces of the pipelines. In general, corrosion would cause metal loss which lead to reduction of pipe thickness and consequently decreases its strength. The probability of pipe to burst then will increase. Therefore, failure due to corrosion defects has been a major concern in maintaining pipeline integrity [1]. There are several design codes used in practice to evaluate the remaining strength of corroded pipelines such as American Society of Mechanical Engineer (ASME) B31G [2], modified ASME B31G [2] and DNV-RP-F101 [3] codes. These codes were developed many years ago and used throughout the industry. ASME B31G and modified ASME B31G simplify a short longitudinal corrosion defect as a parabolic curve whereas long corrosion defect can be simplified to a rectangular shape. According to ASME B31G and DNV-RP-F101 codes, the failure of corroded pipelines is controlled by the defect size as well as the flow stress of the material. The DNV-RP-F101 code can be applied for both defect subjected to internal pressure loading only or internal pressure loading combined with longitudinal compressive stresses. However, the ASME B31G is limited to defect subjected to internal pressure only. DNV-RP-F101 design code equations also include the assessment of single and interacting defects and complex shaped defects. The input parameter of these codes include outer diameter of the pipe, D, wall thickness, t, yield strength of the material, σ_y or ultimate tensile strength, σ_u, the length of the defect, L and defect depth, d. The width, w was considered to have less effect on strength of corroded pipe and therefore this factor was avoided in all assessment equations [4]. The equations used to calculate the burst pressure, P_b based on these codes are expressed as:

$$P_b = \frac{2ts_f}{D} \tag{1}$$

For ASME B31G:

$$S_f = 1.1\sigma_y \left[\frac{1-\frac{2}{3}\left(\frac{d}{t}\right)}{1-\frac{2}{3}\left(\frac{d}{t}\right)/M}\right]; \quad M = (1+0.8\frac{L^2}{Dt})^{0.5} \tag{2}$$

For Modified ASME B31G:

$$S_f = (\sigma_y + 69)\left[\frac{1-0.85\left(\frac{d}{t}\right)}{1-0.85\left(\frac{d}{t}\right)/M}\right]; \quad M = \left[1+0.6275\frac{L^2}{Dt}-0.003375\left(\frac{L^2}{Dt}\right)\right]^{0.5} \tag{3}$$

For DNV-RP-F101:

$$S_f = (\sigma_y + 69)\left[\frac{1-0.85\left(\frac{d}{t}\right)}{1-0.85\left(\frac{d}{t}\right)/M}\right]; \quad M = \left[1+0.31\frac{L^2}{Dt}\right]^{0.5} \tag{4}$$

where M represents as bulging stress magnification factor.

A numbers of researchers [5-7] have studied the remaining strength of pipelines with corrosion defect using FE method together with stress based failure criterion and used to predict failure in the damage pipe. However, this leads to conservative results because stress based failure criterion relies on flow stress of the materials only. Other methods use strain based failure criterion including Gurson–Tvergaard–Needleman (GTN) model [8], void growth model (VGM) [9], continuum damage model (CDM) [10] and SMCS model [11]. However, a few issues need to be resolved in practical applications of these methods. For example, GTN models consist of relatively high number of parameters compare to SMCS and VGM models [12]. These GTN parameters are difficult to identify and calibrate which require a large number of FE and experimental work.

Oh et al [13] recently developed the SMCS model based on local criteria for API X65. The model was used to predict the burst pressure of pipes with gouge and corrosion defects. The study is limited to API X65 steel material and pipe outer diameter of 762 mm. The accuracy and validity of the model is well discussed and acceptable in wide range of defect geometries. Mathematically, SMCS is evaluated by Eq. (5) through Eq. (8), where the stress triaxiality, T is defined by the ratio of hydrostatic stress, σ_m and equivalent stress σ_e given by:

$$T = \frac{\sigma_m}{\sigma_e} = \frac{\sigma_1+\sigma_2+\sigma_3}{3\sigma_e} \tag{5}$$

$$\sigma_e = \frac{1}{\sqrt{2}}[(\sigma_1-\sigma_2)^2+(\sigma_3-\sigma_1)^2+(\sigma_2-\sigma_3)^2]^{\frac{1}{2}} \tag{6}$$

On the other hand, the equivalent strain ε_e is given by:

$$\varepsilon_e = \frac{\sqrt{2}}{3}\left[(\varepsilon_1-\varepsilon_2)^2+(\varepsilon_3-\varepsilon_1)^2+(\varepsilon_2-\varepsilon_3)^2\right]^{\frac{1}{2}} \tag{7}$$

where the σ_1, σ_2, σ_3 and ε_1, ε_2, ε_3 are the principle stresses and principle strain, respectively. The fracture strain ε_f is determined using the equation proposed by Rice and Tracey [9]:

$$\varepsilon_f = A\exp\left(-\frac{3\sigma_m}{2\sigma_e}\right) \tag{8}$$

Where A is the material constant found through an experiment.

In the present work, the effect of corrosion defect on burst pressure was investigated through an experimental and numerical works. The burst pressure of defective pipes was predicted using a three-dimensional nonlinear, homogeneous isotropic elasto-plastic material model with large deformation finite element model. The SMCS model was used in predicting the failure of the defective pipe. The FE analysis results then were compared to available design codes for pipelines assessment with single longitudinal corrosion defects. The model was validated by comparing the FE results with physical testing and subsequently extensive parametric studies were carried out.

2. Material and Experimental Procedure

Tensile Test The material used in this study was API X42 steel. The chemical compositions and mechanical properties of the material are tabulated in Table 1 and Table 2, respectively.

Table 1. Chemical composition of API X42 steel (%wt)

C	P	Mn	S	Si	Fe	CE
0.03	0.01	0.98	0.003	0.19	98.6	0.21

Young Modulus, E (GPa)	Yield Strength, σ_y (MPa)	Tensile Strength, σ_u (MPa)
207	284.7	464.4

The detailed specimen dimensions used for uniaxial tensile test are shown in Fig. 1. The test was performed according to ASTM E08-08 [14]. The specimens were extracted in longitudinal direction from API X42 steel pipes with schedule of 120. An extensometer with gauge length of 25 mm was attached to the specimen in order to monitor the axial displacement of the material. A total of four specimens were tested for a given geometry.

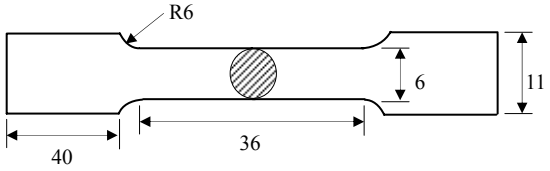

Figure 1. Smooth round tensile bar

Burst Pressure Test. Four API X42 steel pipes with different longitudinal artificial corrosion defect geometries were prepared. Detailed dimensions of the pipes with artificial corrosion defect are shown in Table 3. The defects on the pipe surface were machined using Computer Numerical Control (CNC) machine. The nominal outer diameter of the pipe is 60 mm. The overall length of the pipe was kept constant to be 600 mm. A schematic illustration of pipes with corrosion defect on its outer surface is shown in Fig. 2. The external thread with pitch of 2 mm was machined with 50 mm long on both ends of the defective pipes. The pipes were then attached to the cap with internal thread. The internal thread of the cap was machined with the same pitch of pipe thread. End of the pipes was sealed with aluminum O-rings to avoid leakage of the hydraulic oil when the pipes are pressurized. The cap has been covered by a solid cylinder to prevent the movement of the pipes in both transverse and longitudinal directions. Two solid cylinders were connected to each other using four threaded rods.

The defective pipe was internally pressurized by the oil using manual hydraulic pump. The pump was connected to the test rig through hydraulic line. Analog pressure gauge was attached between pump and defective pipe for pressure measurement. The oil was carefully pumped to the test rig to minimize the strain rate effect until the failure was detected on the pipe. During pressurization, the pipe was expanded and the localized bulge could be clearly seen in the weakest region. Detail experiment setup for the burst pressure testing is shown in Fig. 3a. The failure occurs on the principle plane direction. This is confirmed by observation on the failure pipe whereby the crack on defect is propagated in longitudinal direction. Figure 3b shows the API X42 steel pipe after performing the burst pressure test. The failure occurred at defective region where the minimum thickness of the pipe is placed. The maximum pressure which represents as the burst pressure was recorded and listed in Table 3.

EX4	50	4.5	14	5.62	44

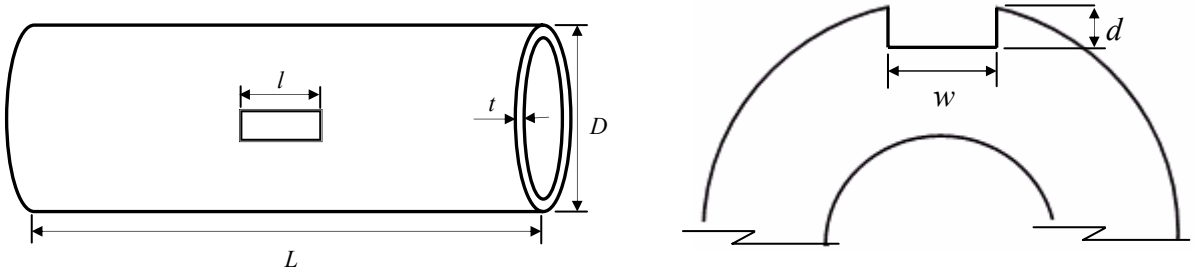

Figure 2. Schematic of pipes with corrosion defect

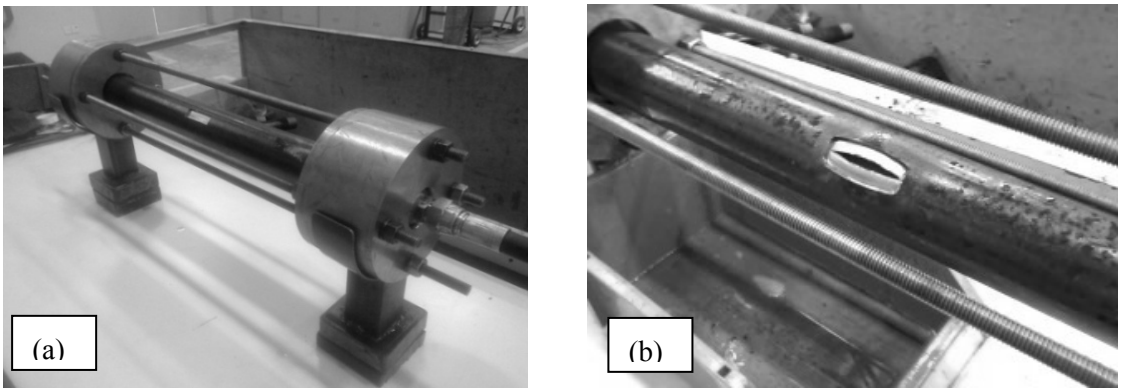

Figure 3. Experimental set up (a) Before Failure, (b) After Failure

3. Determination of SMCS Model Parameter

Remarking that the stress triaxiality for round bars is roughly $\sigma_m/\sigma_e \approx 1/3$. Substituting this value into Eq. (8), an approximate expression of the ratio of fracture strain ε_f is given by:

$$\frac{\varepsilon_f}{\varepsilon_f^*} = \frac{\exp\left(\frac{-3\sigma_m}{2\sigma_e}\right)}{\exp(0.5)} \tag{9}$$

where ε_f^* denotes the fracture strain obtained from tensile test of smooth round bar. The value of average fracture strain is $\varepsilon_f^* = 1.04$ and is shown in Fig 7. Thus, the ε_f for API X42 material used in this paper is proposed to be:

$$\varepsilon_f = 1.732\exp\left(-1.5\frac{\sigma_m}{\sigma_e}\right) \tag{10}$$

Figure 4 shows the failure curve proposed for API X42 steel pipes based on Eq. (10).

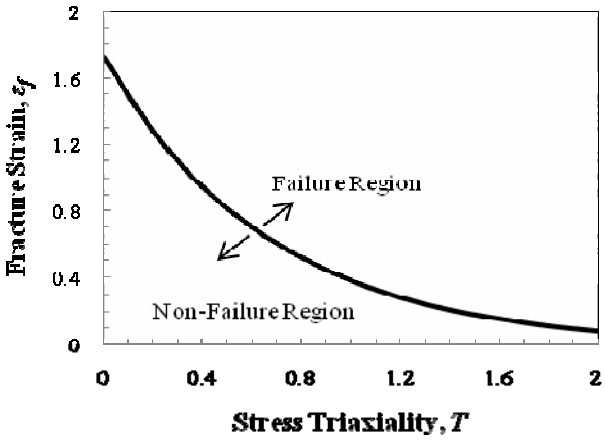

Figure 4. Failure curve for API X42 steel pipes

4. Validation of the Model

A 3-D nonlinear FE analysis was performed on experimental case studies listed in Table 3. The pipes with a rectangular artificial corrosion defects were modeled and eight node solid elements with reduced integration scheme are applied using commercial MSC PATRAN/MARC 2008r1 software. The material is modeled as an isotropic elasto-plastic material. Fig. 5 shows true stress strain data employed in FE analysis. The defective pipe with the same parameter used in experimental work was analyzed. A detailed finite element mesh applied on the models is shown in Fig. 6. Since the failure of the pipe was observed in defective region during the experiment, the FE mesh is designed sufficiently small around the defect area. The enlargement on the defective region is also shown in Fig. 6. Internal pressure was applied to the inner surface of the pipe. The boundary condition was applied at one end of the pipe to simulate the closed cap condition. The symmetrical condition was also applied for computational efficiency. The von Mises stress distribution on defect for pipe CS3 is shown in Fig. 7. At an applied pressure of 16 MPa, the pipe did not show any plastic deformation. However, at the onset of failure, the bulging on the defect can be clearly seen as shown in Fig. 7b. The reduction of pipe thickness at defective area was detected before the pipe started to burst.

To predict ductile failure of defective pipes made of API X42 steel pipes using the present approaches, the proposed Eq. (10) will be combined with detailed elasto-plastic FE analyses from which local stresses and strains are determined. For example, from the FE analysis, stress and strain data can be monitored as a function of pressure. Over the loading history, the stress triaxiality and equivalent strain were calculated using Eq. (5) to (7). Then, the equivalent strain to fracture or true fracture strain is estimated from Eq. (10). When the equivalent strain from the FE analysis equals to the fracture strain, failure is assumed to occur. The results of burst pressure from FE have been compared to experimental data and shown in Fig. 8. The percentage of the error for each case was also included. The maximum error between these two methods is 9%.

5. Parametric Study

The pipe with different defect depths, lengths and widths were simulated and the burst pressure for each case was predicted. In the present study, the totals of 10 cases represent by CS1 to CS10 were analyzed. The defect width, *t* depth, *d* and length, *l* for the case studies are summarized in Table 4. The wall thickness and outer diameter of the pipe are kept constant to be 6 mm and 60 mm, respectively.

Table 4. Different pipe sizes and defect dimensions

Case No.	Dimension (mm)			Failure Pressure (MPa)
	Length, *l*	Depth, *d*	Width, *w*	
CS1	50	3	14	83
CS2	50	3.5	14	72.4
CS3	50	4	14	64
CS4	50	4.5	14	52
CS5	50	3	10	83.2
CS6	50	3	6	84
CS7	50	3	4	84
CS8	30	3	14	88.4
CS9	40	3	14	86
CS10	60	3	14	81.6

Figure 9 shows the results of burst pressure predicted from FE analysis. The results of burst pressure calculated from ASME B31G, Modified ASME B31G and DNV-RP-F101 design codes for corroded pipelines were also included. Based on these three design codes, the failure of the pipelines is assume to occur when the stress developed in the pipes equal to or higher than the flow stress of the materials. Since the flow stress is always lower than the ultimate strength, the failure will be predicted before necking occurred. In contrast, SMCS model used in this paper predicted the failure based on the fracture strain of the materials. The parameter of the model is determined from fracture point during uniaxial tensile test, therefore necking of the material is allowed. Neglecting the increment of pressure from the onset of necking to fracture point causes the design codes to always give lower value in predicting the burst pressure. In general, the results of burst pressure calculated from these three design codes show lower values compared to FE. The results clearly show that ASME B31G design code gives lowest value of burst pressure in all cases studied. This is followed by modified ASME B31G and DNV-RP-F101 design codes except for cases CS3 and CS4 in which the modified ASME B31G appears as the most conservative compared to other codes. Referring to the FE results from Fig. 9a, the burst pressure slightly decreases as the length of defect increases from 30 mm to 60 mm. A similar pattern is shown by all design codes. In contrast, as the defect depths increase from 3 mm to 4.5 mm (50% to 75% of pipe thickness) as shown in Fig. 9b the burst pressure decreases significantly. The burst pressure drops higher than 13% as the depth of defect change even as small as 0.5 mm. In this respect, the defect depth appears as the main factor that governs the failure of the pipes. This observation is consistent with the fact that hoop stress is

dependent with the remaining effective thickness of the damage pipe as predicted in Eq. (1). The effect of defect width on burst pressure was also studied in this paper. Four different defect widths, *w* were simulated to investigate its effect on burst pressure. The results are summarized in Fig. 9c. Eq. (2) to Eq. (4) do not include the parameter, *w*. It is due to the assumption that the burst pressure is not affected by the width of the defect [4]. The assumption has been confirmed by the FE results in which as the width increases from 4 mm to 14 mm, almost no changes on burst pressure was detected.

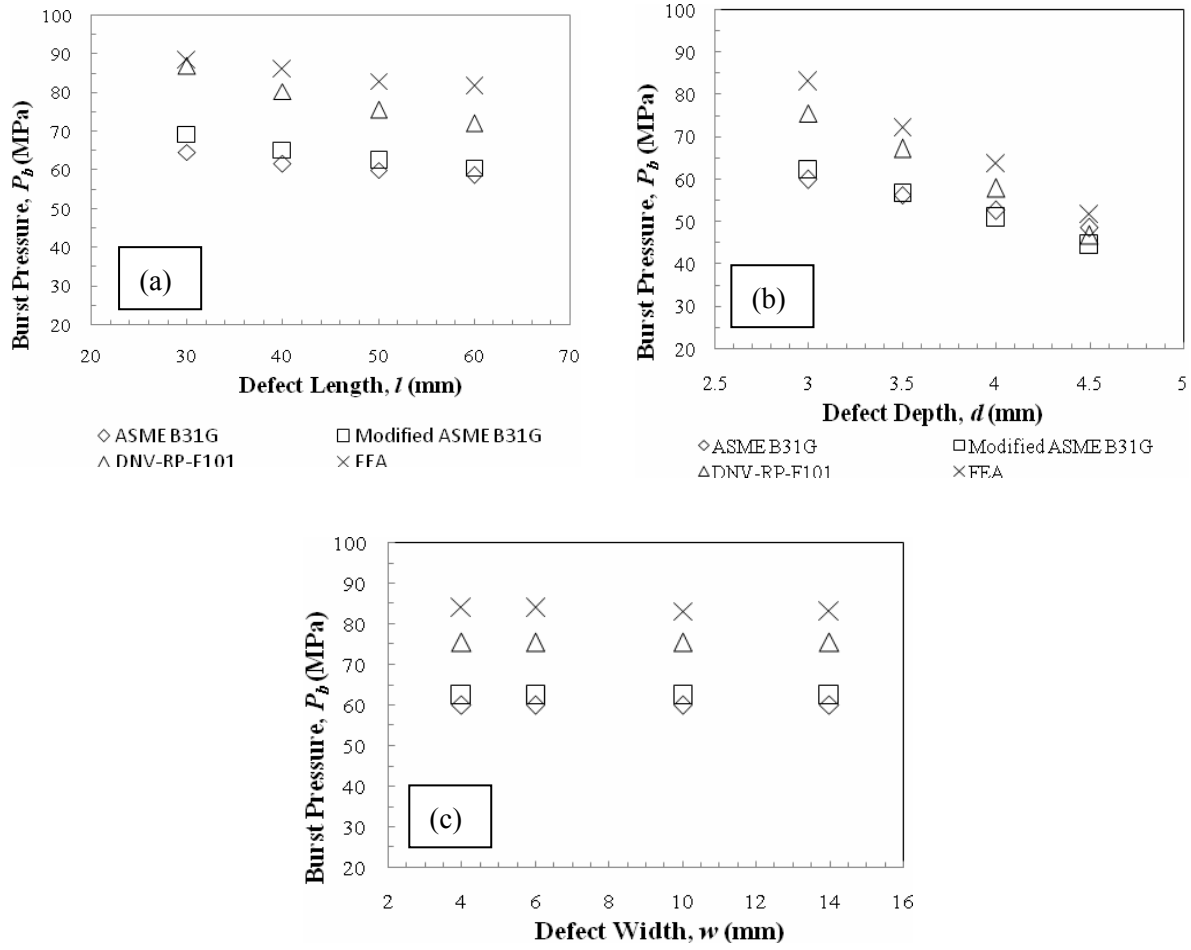

Figure 9. Effect on burst pressure (a) Defect length, (b) Defect depth, (c) Defect width

6. Conclusions

This paper has presented the effect of longitudinal corrosion defects on burst pressure of API X42 steel pipes. The results obtained are as follow:

1) The burst pressure of corroded pipelines is affected by the length and depth of the defects. The depth of corrosion defect is more influential parameter that would affect the burst pressure of pipes.

2) The width of the longitudinal corrosion defects affect insignificantly on burst pressure.

3) The FE results based on SMCS model always predict higher value of burst pressure compared to ASME B31G, Modified ASME B31G and DNV-RP-F101 design codes. ASME B31G is the most conservative design code.

Critical Strain Based Ductile Damage Criterion and its Application to Mechanical Damage in Pipelines

Ming Gao, Ravi Krishnamurthy, Samarth Tandon, Udayasankar Arumugam
Blade Energy Partners, Houston, TX, USA

Abstract

Strain based assessment of mechanical damage in pipelines requires a failure criterion for cracking based on plastic damage. Several criteria have been proposed by industry codes such as B31.8 and in the literature. However, these criteria essentially are based on engineering decisions. In this paper, a plastic damage based criterion that combines material critical strain and triaxiality of stress is used. The theoretical aspect of the criterion, including early work by Hancock and Mackenzie on strain limit (i.e., reference failure strain), ε_f, for ductile failure is discussed. The experimental aspect of material's critical strain and its measurement using uniaxial tensile testing is described. An elastic-plastic finite element analysis is employed to calculate ductile failure damage indicator (DFDI), which can be used to describe the amount of accumulated plastic strain in the damage and its susceptibility to cracking. Its application to assessing mechanical damage in pipelines, including dent with gouge/crack, is presented. Examples are given to illustrate the effectiveness of the criterion for prediction of cracks in dents in pipelines.

Keywords: Mechanical Damage, Dent, Critical strain, Damage Model (DFDI), ASME B31.8

1 Introduction

Strain calculations have been used in the past to estimate the severity of mechanical damage in pipelines. ASME B31.8 2004 established an allowable strain in dents to be 6% [1] based on the experience of the likelihood cracking of cold bend and puncture in dents when material strain exceeds 12% [2]. Numerous studies of failure criteria involving limit states due to crack initiation in the metal forming industry have been conducted in the past [3-14]. However, none of them have been applied to the pipeline industry for integrity management of mechanical damage.

One of the criteria [7, 10,11] that involves critical strain and utilization of damage parameter, i.e., ductile failure damage parameter (DFDI), is adopted by the present study to calculate the amount of plastic damage in pipelines due to mechanical damage, where the critical strain is a material's property defined as the true strain at the onset of incipient crack measured from uni-axial tensile testing, and the DFDI is a damage parameter that is a function of triaxiality of stresses, equivalent strain, and material's critical strain. The onset of incipient crack in a ductile material due to plastic damage is given when DFDI $\geq$1.

In this paper, the theoretical background of plastic damage due to large deformations in ductile materials is presented first. The critical strain and its measurements using uniaxial tensile testing are described. Its application to evaluate mechanical damage including dents in pipelines is then

discussed. The finite element simulation of the denting process is then performed to calculate the cumulative plastic damage and presented as "ductile failure damage indicator" (DFDI). The results demonstrate that the DFDI method predicted well for the crack initiation in dent and can be utilized as a severity indicator and failure criterion for dent repair/mitigation. Finally, an approach proposed by Wang et al [18] that combined DFDI and signal recognition from MFL (magnetic flux leakage) in-line-inspection for evaluation of dent with corrosion/cracking/gouge is presented.

2 Background

As early as the 1960's, a damage relevant stress, i.e., critical stress σ_{cr}, was used as the state limit for sheet forming [7], and was later further developed by others [8,9]. These simplified stress criteria have proven to be very restrictive, as well as related to a special forming process [7,8]. Later, researchers tried to correlate plastic damage to the plastic work done during deformation, and proposed critical work, W_c, as a damage relevant term. However, for the same reasons, the concept of W_c may be suspicious, especially when it is applied to significant crack propagation in a tension bar [9].

Large plastic deformation of ductile materials involves initiation, growth and coalescence of microvoids to form cracks, known as "ductile plastic damage", and is the mechanism for ductile cracking, tearing, and rupture of ductile materials. Considerable effort has been made since the mid-1960's [3-6] to establish a frame work (failure criteria, for example) for studying conditions and variables associated with the failures.

In the late 1960's, McClintock [10] and Rice and Tracey [11] established the basic relation between growth of a void and imposed stress and strain from a tri-axial stress field using a micro mechanics approach. Hancock and Mackenzie [6] in the mid-70's followed Rice et al's work, and proposed a reference failure strain, ε_f, i.e., a strain limit for ductile failure:

$$\varepsilon_f = 1.65\varepsilon_o \exp(-\frac{3}{2}\frac{\sigma_m}{\sigma_{eq}}) \qquad (1)$$

where σ_m = average stress of three principle stresses in a tri-axial stress field, and σ_{eq} = equivalent von Mises stress. The ratio of σ_m/σ_{eq} represents the tri-axiality of the stress field, and ε_o is the critical strain of ductile materials for incipient crack, a material property measured by uniaxial tension testing.

Equation (1) indicates that the strain limit of a structural component, ε_f, is not a constant. It is a function of stress tri-axiality and the material's critical strain. Equation (1) defines a generalized strain limit, i.e., reference failure strain, for large plastic deformations subject to both uni-axial and multi-axial stress states. In the uni-axial tension condition, Equation (1) becomes $\varepsilon_f = \varepsilon_o$ i.e., the reference failure strain in the uni-axial tension is equal to its critical strain of the material. Equation 1 is derived from the concept that ductile failure results from initiation, growth and coalescence of voids on a micro scale, and formation of cracks during large plastic deformation. Given the established strain limit for ductile failure, the degree of plastic damage is defined as:

$$dD_i = \frac{d\varepsilon_{eq}}{\varepsilon_f} \qquad (2)$$

$$D_i = \int_0^{\varepsilon_{eq}} \frac{d\varepsilon_{eq}}{\varepsilon_f} \qquad (3)$$

Equation (2) shows that the plastic damage induced by each increment of the plastic strain, $d\varepsilon_{eq}$, involved in the deformation process is the ratio of the increment to the failure strain. Equation (3) is the integral of Equation (2), i.e., the total plastic damage for entire plastic deformation. D_i is the indicator of cumulative plastic damage during plastic deformation which has a general form of $D_i = D_i(\sigma_m / \sigma_{eq}, \varepsilon_{eq}, \dot{\varepsilon}_{eq})$, where σ_{eq} is the equivalent von Mises stress, and σ_m is the average stress. Its value ranges from 0 (undamaged) to 1 (rupture). By the definition, ductile failure will occur when $D_i \geq 1$, where D_i is the measure, or indicator, of ductile failure damage. A safe DFDI less than one (<1) would be appropriate to prevent failures.

Substituting Hancock et al's failure strain ε_f (Eq. (1)) into Equation (3), gives

$$D_i = \int_0^{\varepsilon_{eq}} \frac{\exp\left(\frac{3}{2}\frac{\sigma_m}{\sigma_{eq}}\right)}{1.65\varepsilon_o} d\varepsilon_{eq} = \frac{1}{1.65\varepsilon_o} \int_0^{\varepsilon_{eq}} \exp\left(\frac{3}{2}\frac{\sigma_m}{\sigma_{eq}}\right) d\varepsilon_{eq} \qquad (4)$$

Equation (4) relates the ductile failure damage indicator D_i, the stress tri-axiality (σ_m/σ_{eq}) and the material's critical failure strain ε_o. Various modifications of the reference failure strain ε_f, which lead to a better agreement with experiments for high stress tri-axialities, are available in the literature [12-14].

3 Critical Strain and its measurement

Critical strain is a material property and measured by uni-axial tension testing. The critical strain of a material, ε_o, is defined as the critical point of the true strain at which incipient crack occurs. To measure the critical strain of a material from a uniaxial tension testing, both engineering and true stress vs. strain curves in the necking (non-uniform elongation) regime are required.

For true stress and strain measurement in the necking (non-uniform elongation) regime, a series of images of the necking area needs to be recorded either on a time or displacement basis. The recorded images are used to determine the radius or the cross-section area of the neck for true stress and strain calculation using the following Equation [5] and to establish the relationship between true stress and true strain:

$$\sigma_{true} = \frac{P}{A}, \ \varepsilon_{true} = \varepsilon_o = 2\ln\frac{A_o}{A} = 2\ln\frac{r_o}{r} \qquad (5)$$

where A_o and r_o are the initial cross-section area and radius of the tensile specimen, respectively, and A and r are the smallest cross section area and radius of the neck at the time of the measurement, respectively.

For the onset point at which incipient crack occurs, cracking, it cannot be determined from the true stress and true strain data itself. It is determined from the second sharp knee on the engineering stress-strain curve or load-displacement curve [7], shown in Figure 1(a).

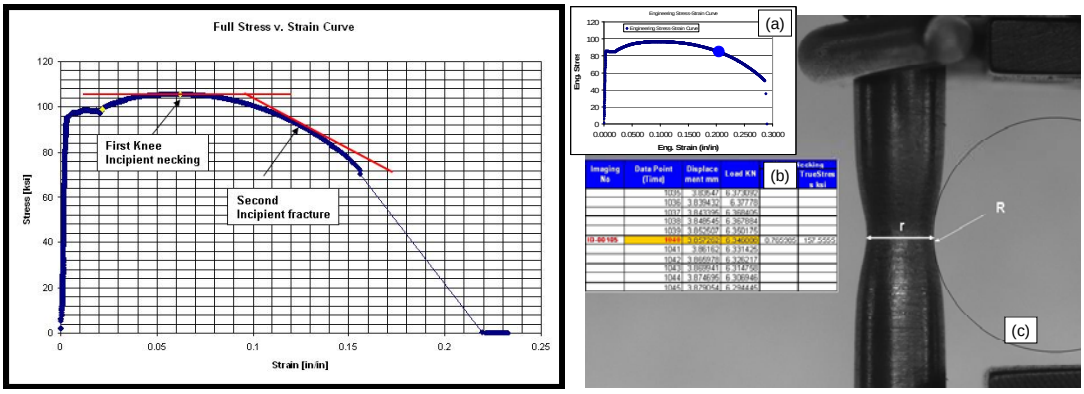

Figure 1: (a) A typical engineering Stress and Strain curve of LXS80, showing the second sharp knee related to the incipient crack (b) Typical image recorded by the video camera on a time-based sampling scheme. The insert shows the respective location of the image on the load-displacement curve

Using the identified onset point of incipient crack and the true strain and true stress curve, the critical strain can be determined by correlating the engineer strain at the onset point of incipient crack to the respective true strain. Efforts were made to develop a time-based switching and data acquisition system. The system consisted of three major components: a closed loop tensile test machine, a high resolution digital video camera, and a synchronized and data acquisition system for simultaneously sampling load-displacement data and image recording. The system provides a signal to trigger the video camera's "shutter" on and off for a given time interval and interfaces between the high resolution digital video camera and the tensile test machine. Each recorded image contains a time code that can be used to match a respective point on the load-displacement curve that was saved at the same time by the data acquisition system of the tensile testing machine. One of the recoded images that correspond to the point of the onset of incipient crack is the one corresponding to the critical strain that can be found from the true stress-strain curve. There is a possibility that no image could be matched with the onset point for critical strain calculation. However, this may be resolved either by interpolating the critical strain values obtained from two adjacent images that are across the onset point, or, more accurately, by establishing an engineering strain and true strain curve around the fracture incipient point and then using the curve-fit equation to calculate critical strain.

3.1 Determination of Crack-incipient from uniaxial tensile test

The information obtained from the synchronized system contains three sets of data: (1) load-displacement data directly obtained from the tensile test machine, (2) the time-based images recorded by the video camera, and (3) the time code for each image and corresponding load and displacement recorded by the synchronized data acquisition board. These three pieces of information were analyzed using the following methods to determine critical strain.

The crack-incipient point is a characteristic point on the load-displacement curve. This point can be diagnosed by a sharp knee in the engineering stress-strain curve or by a second knee in the $d\sigma/d\varepsilon$-ε curve as shown in (a) and (b) of Figure 2, respectively [7].

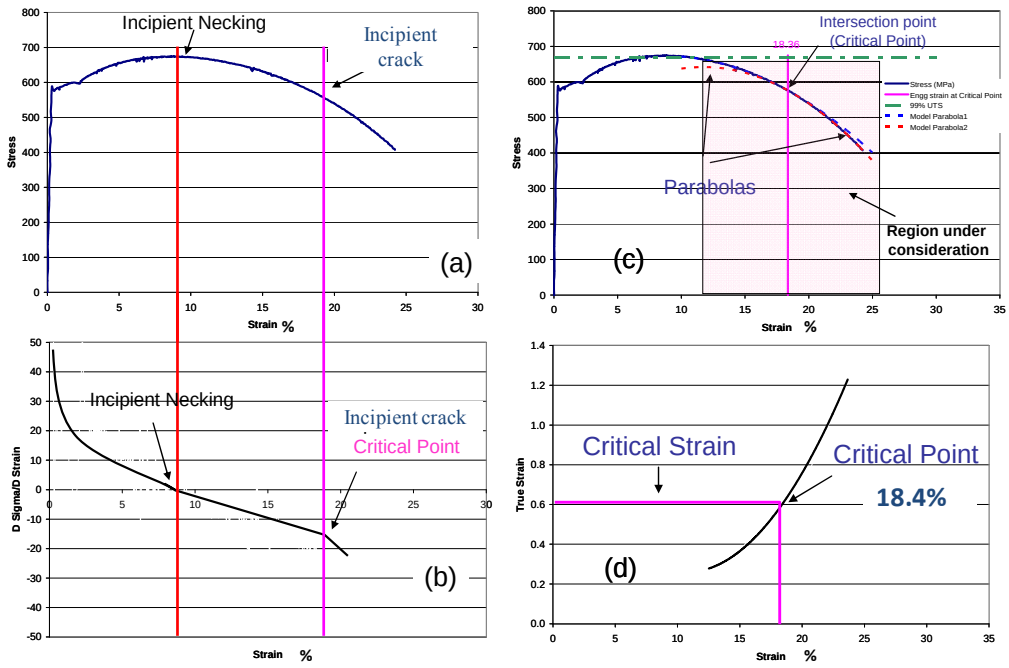

Figure 2: A composite figure showing (a) the engineering stress-strain (σ vs. ε) curve with the incipient necking and crack; (b) dσ/dε vs. ε plot – a knee shaped curve giving the incipient crack point which is the critical point; (c) the intersection of two parabolic curves derived from a mathematical best fit model for determination of critical point; and (d) the relationship between the true strain and engineering strain. The relationship is obtained from the synchronized camera system.

For the sharp knee diagnosis method from the engineering stress-strain curve, two parabolas are used to model the upper and lower portions of the curve [5]. The intersection of the two parabolas is the point that corresponds to the on-set point of incipient crack. For the "second knee" diagnosis method from the dσ/dε-ε curve, two straight lines are used to model the upper and lower portions of the dσ/dε-ε curve. Again the intersection of the two straight lines is the point corresponding to the crack incipient point.

These two diagnostic methods are equally applicable and should yield the same results. However, the data processing showed that because the "second knee" diagnosis method involves a derivative operation of σ with respect to ε from the experimental stress-strain data, which resulted in a large scattered band of the dσ/dε-ε curve, the uncertainty in linear regression for straight line modeling would be large. Therefore, the first method was adopted for the present study. The intersection of the parabolas was found by utilizing the "Method of Least Squares". Once the incipient point is determined, Figure 2(c) it may be used to calculate the critical strain by utilizing the curve fit equation between engineering and true strain, Figure 2(d).

4 Application of DFDI to Mechanical Damage

Dent or indentation in pipe is described as a permanent deformation of the pipe's circular cross section arising from external forces [1]. Depending on the severity of the dent or the amount of plastic deformation, crack(s) may be initiated in the dent. Ductile Failure Damage Indicator

(DFDI) can be utilized as a criterion to gage the severity of plastic damage in dents, and predict its susceptibility to cracking. To evaluate the effectiveness of this model, one case involving 2.7% OD bottom-side rock dent associated with 76% WT metal loss reported by a combo ILI tool (geometry + MFL) is studied. Elastic-plastic finite element modeling incorporating actual measured uni-axial tensile stress-strain curve from pipeline material and calculated critical strain is performed. More case studies involving dents associated with metal loss and plain dents can be found in Reference [21].

The pipe had an OD of 30in, nominal wall thickness of 9.5mm, Grade of X52, constructed in the year 1958 with depth of cover of 90cm, and was operating at 6,895 kPa (77% SMYS). The dent was 2.7% deep with length of 120mm, and width of 97mm, at a clock position of 6:15. Figure 3(a) shows the screenshot of the ILI reported dent deformation profiles in circumferential and axial direction, respectively.

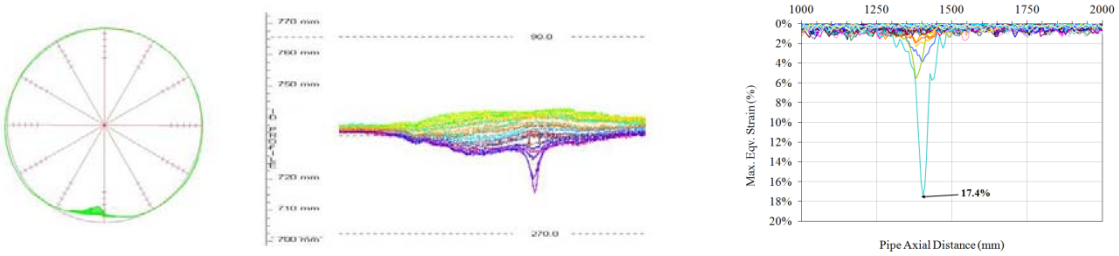

Figure 3: (a) Dent circumferential and axial profile (b) Strain profile using Blade's in-house dent strain software

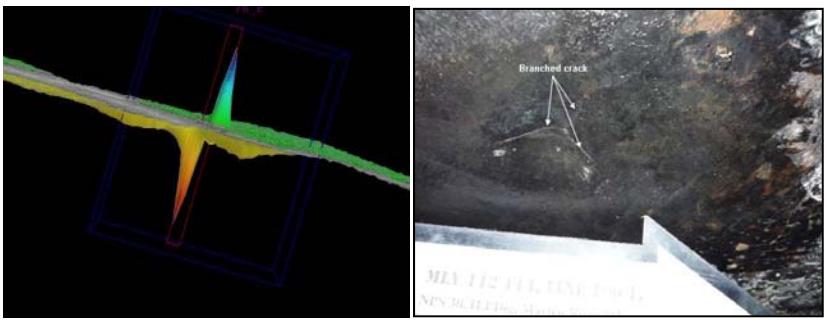
From Figure 3(a), dent apex seemed sharp, suggesting the possibility of high strain at this location. Strain analyses was performed on this dent utilizing an in-house point-to-point strain analysis tool [17] using the strain equation recommended in the Reference [15, 16]. The calculated maximum equivalent strain (true strain) is 17.4%, which is located at the dent apex.



(a) **(b)**

Figure 4: (a) Equivalent strain distribution plot around and in the dent area, (b) Dent with branched crack in-ditch (OD)

A review of the MFL raw signal showed sharp and strong signal characteristics of magnetic flux leakage, seen in Figure 4(a), suggesting that the reported 76% WT metal loss is more likely

cracking or gouging rather than corrosion. The dent was excavated for further investigation. On excavation, it was found to be in contact with a rock. On the removal of the rock, it was found to be associated with three cracks originating near its apex, Figure 4(b). No leak was detected in the field, indicating the cracks were partially through-wall. Since the dent was associated with cracks, the pipe joint was cut out for further investigation. The dent was inspected from inside, which showed branched cracks at the same location as the OD cracks, but in ID surface of the dent apex. A 3D mapping [17] of the cracked dent geometry was conducted using a portable 3D LaserScan system. The axial and circumferential profiles were extracted at the ID surface. The strain analysis was performed using the profiles. The maximum equivalent strain in the dent was found to be 16%, located at its apex.

The measured ILI maximum equivalent internal strain was 17.4%, compared to LaserScan profile internal strain of 16%. The maximum equivalent strain value obtained from LaserScan is comparable to that obtained from ILI; however, this apparent consistency may not be true because the dent profile was significantly changed due to spring back (rebound) when the constraint (rock) of the dent was removed. A comparison of the dent profile before and after excavation is given in Figure 5. The measured dent depth after the rock was removed was ~1.4% OD, which is one half of the ILI-reported depth of 2.7% OD. In order to estimate the change in plastic strain due to rebounding, the high resolution LaserScan ID profile was scaled by a factor of 1.7 to match closely with the ILI data. The calculated maximum equivalent strain after scaling was 32.3%, about twice after rebounding.

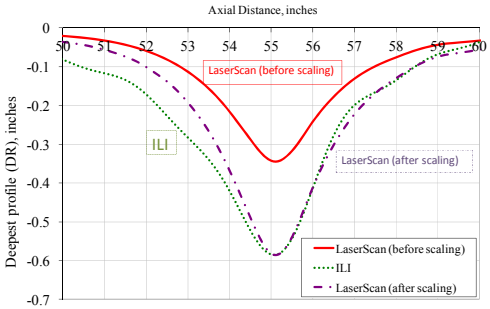


Figure 5: Change in dent ID profile before and after excavation, showing the dent had significantly rebounded.

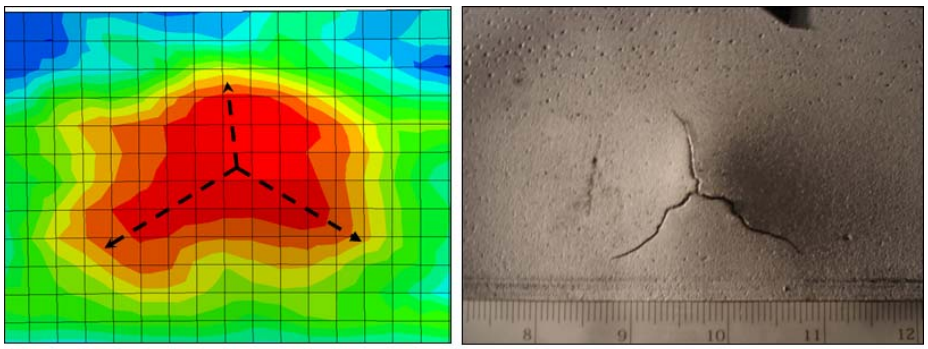
An elastic-plastic finite element analysis (FEA) was performed using the scaled ID LaserScan profile of the cracked dent. The Critical strain was measured utilizing the procedure in Section 3. The measured value of the material critical strain was 51.2%. The maximum equivalent plastic strain based on FEA in the dent was 35.0%, located at the dent apex. DFDI values were calculated at each of the deformation nodes using the FEA result. The calculated maximum DFDI is 1.1, which is greater than 1.0, indicating that the dent is susceptible to cracking at its internal surface.

Figure 6(a) shows the maximum principal stress contour plot with the probable crack propagation direction, compared with the ID actual crack path, as shown in Figure 6(b). The FEA-predicted crack path is in good agreement with the observed actual crack pattern. FEA also showed a high reaction force associated with the dent, indicating a very high external force might have caused this dent deformation, possibly during construction.



(a) Max principal stress plot with predicted crack path

(b) Actual crack path

Figure 6: Case-1: Color-coded contour plot of maximum principal stress plot (indicated probable crack path) vs. actual crack path (ID)

In summary, this case study showed a failure condition (cracking) of the dent by the plastic damage mode, and demonstrates its effectiveness of capturing critical dents i.e. dents with susceptibility to crack in pipeline which can pose an integrity threat. Inline inspection Magnetic Flux Leakage (MFL) signal data was also utilized as an added dimension in understanding whether the dent is associated with a crack. A combined approach, utilizing the DFDI model and MFL signal recognition to identify dent with corrosion/cracking/gouging is presented in the next section.

3 A combined approach for dent with Corrosion/cracking/gouging evaluation [18]

Current in-line inspection technologies (e.g., caliper/MFL or combo) for mechanical damage assessment can detect dent with metal loss but with limited ability. However, they are incapable of discriminating metal loss from corrosion, gouge and crack. Practical experience showed that, with the assistance of strain based dent analysis and strain limit damage criteria, detailed characterization of MFL signals could effectively facilitate to identify potential risk of dent with cracking and to discriminate between metal loss features of corrosion and cracking/gouging. Therefore, a dent assessment approach which combines the plastic damage model with MFL signal recognition was recently developed by Wang et al and some of the present authors [18]. The strain severity based criterion is used to assess dent susceptibility to cracking regardless if the dent was reported as plain dent or dent with metal loss. Only those dents that meet the strain criterion will be considered as a candidate for investigation of MFL signal characteristics to assure if the dent is associated with cracking/gouging. The flow chart shown in Figure 7 describes the combined approach used for the assessment.

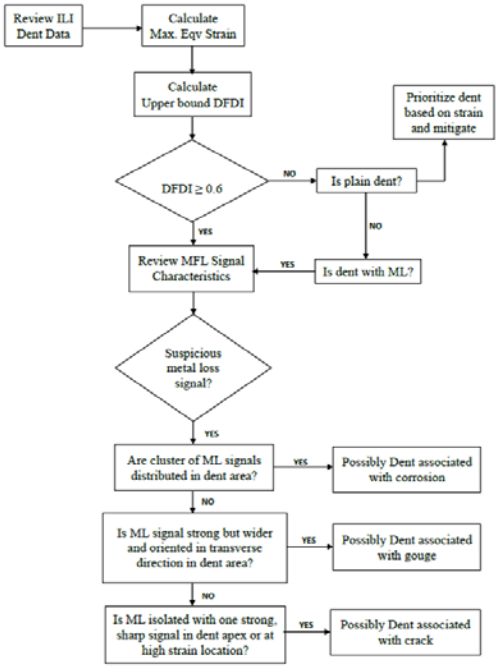


Figure 7: Flow chart – Procedure used in the combined assessment approach.

Using the above described procedure, case studies were performed to quantify the effectiveness of the approach for (1) identifying critical dents that are associated with cracking or gouging; and (2) the ability to discriminate the metal loss features of corrosion vs. cracking/gouging. Assessments were made using two recent in-line inspections which reported 4,823 dents in total. Among them, more than 150 dents were selected for assessment. Eight (8) dents were predicted to contain cracking or gouging. A total of fifteen (15) validation excavations, including the 8 predicted 'dent with crack' and 7 predicted 'dent without crack' were performed. All eight predictions were validated with excavations (true positive). Among them, two (2) were associated with through-wall cracks and were leaking during excavation, and the remaining 6 dents either contain surface cracks or gouges. The other seven (7) excavations showed no cracks or metal loss, i.e. true negative. The combined approach and its impact to integrity management of dents were successfully demonstrated with the case studies. The details of assessment approach, procedure, result and findings can be found in Reference [18] of this paper.

4 Summary

Critical strain based failure criterion, i.e., ductile failure damage indicator DFDI, can be applied to evaluate the severity of mechanical damage in pipelines for predicting susceptibility to cracking. Critical strain can be measured with uni-axial tensile testing and calculated using simplified mathematical model on uni-axial tensile full engineering and true stress-strain data recorded by synchronized data acquisition system. Finite element simulation demonstrated the effectiveness of the DFDI model for predicting cracks in dent. The study further demonstrates that the combined DFDI with MFL signal recognition approach can effectively identify potential risk of dent with cracking and to discriminate metal loss features between corrosion and cracking/ gouging.

API 579 G-factors for K Calculations and Improvements For Assessment of Crack-like Flaws in Pipelines

Shaikh Rahman, Ming Gao*, Ravi Krishnamurthy
Blade Energy Partners, Houston, TX, USA
Corresponding author: mgao@blade-energy.com

Abstract

API 579-1/ASME FFS-1 2007 gives a complete guideline of Fitness-For-Service (FFS) assessment of crack-like flaws in structural components based on the Failure Assessment Diagram (FAD) method. The assessment is carried out in FAD using a non-linear relationship between the load ratio (L_r) and the toughness ratio (K_r) where the toughness ratio (K_r) is defined as the ratio of the Mode I stress intensity factor (K_I) to the toughness of the material (K_{mat}). One of the methods for Mode I stress intensity factor (K_I) calculation in API 579-1/ASME FFS-1 2007 is FEA based, which correlates five influence coefficients, namely G_o to G_4, for K_I calculation. These influence coefficients are dimensionless and are tabulated for a range of two ratios; the wall thickness to the internal radius (t/R_i) and the flaw depth to the wall thickness (a/t) for infinite cracks and three ratios (crack depth to half crack length (a/c) besides a/t and t/R_i) for finite cracks. API 579-1/ASME FFS-1 2007 allows interpolation of the influence coefficients, Gs for intermediate values. Even though it is not explicitly mentioned about the method of interpolation, a linear interpolation is generally considered. Another possible method is explored here with the polynomial function fitted by the FEA data provided in the table given in API 579. A detail discussion on obtaining the influence coefficients for an intermediate value is outlined here. Case studies are provided to illustrate the advantages and disadvantages of the linear interpolation and the fitted polynomial function.

Keywords: Stress Intensity Factor, Influence Coefficients G_i, G Interpolation, FAD, Level 2 Limiting Pressure

1 Introduction

The Mode I Stress Intensity Factor (K_I) in API 579 is a fourth order polynomial function of (a/R_i) or (a/R_o) with applied internal pressure and pipe dimension. The solution is obtained from FEA work completed by T. L. Anderson Group [1]. According to API 579, the Mode I Stress Intensity Factors for the infinite length internal and external surface cracks in axial (longitudinal) direction are given by the following equations [2] respectively.

Internal axial infinite surface crack:

$$K_I = \frac{pR_o^2}{R_o^2 - R_i^2}\left[2G_o - 2G_1\left(\frac{a}{R_i}\right) + 3G_2\left(\frac{a}{R_i}\right)^2 - 4G_3\left(\frac{a}{R_i}\right)^3 + 5G_4\left(\frac{a}{R_i}\right)^4\right]\sqrt{\pi a}$$

External axial infinite surface crack:

$$K_I = \frac{pR_i^2}{R_o^2 - R_i^2}\left[2G_o + 2G_1\left(\frac{a}{R_o}\right) + 3G_2\left(\frac{a}{R_o}\right)^2 + 4G_3\left(\frac{a}{R_o}\right)^3 + 5G_4\left(\frac{a}{R_o}\right)^4\right]\sqrt{\pi a}$$

Where, p is the internal pressure, R_i and R_o are the internal and external radii respectively, a is the flaw depth and G_o to G_4 are the influence coefficients. This equation is valid for $0.0 \leq a/t \leq 0.8$ and $0.001 \leq t/R_i \leq 1.0$. The influence coefficients are given in Table C.10 and Table C.11 in API 579 document for infinite axial and circumferential cracks respectively. The table gives values of influence coefficients for various t/R_i and a/t. t/R_i is converted to R_i/t for the convenience in calculation performed in this work. R_i/t can also be readily converted to OD/t $[= 2(R_i/t + 1)]$ that is more common in tubular performance calculation in Oil and Gas Industry. For finite surface crack $\sqrt{\pi a}$ in the above two equations are replaced by $\sqrt{\pi a/Q}$. The influence coefficients for the finite crack are function of a/c in addition to a/t and t/R_i ratios. Therefore, for infinite crack, two interpolations and for finite crack, three interpolations are required to obtain the desired influence coefficients. It is mentioned in API 579 that "interpolation of the influence coefficients, G_i, may be used for intermediate values of t/R_i and a/t" but does not state explicitely how the interpolation should be performed, linearly or otherwise. The work described in this paper takes an attempt to explain if the linear interpolation is adequate or accurate enough for this purpose. The cubic polynomial interpolation is used for the comparative study.

2 Interpolation methods

2.1 Infinite Surface Crack

Table C.10 and Table C.11 in API 579 give the influence coefficients of infinite surface crack for axial and circumferential direction respectively. Figure 1 shows part of the Table C.10 and Table C.11 from API 579. The influence coefficients shown in these tables are function of t/R_i and a/t. Therefore, two interpolations are required to obtain the desired influence coefficients for a given pipe and crack dimensions.

Figure 1 – Partial Table C.10 and Table C.11 from API 579

Interpolation is performed in two steps using the following methodology:

- For a given pipe and crack geometry, a/t and t/R_i are calculated.
- The a/t and t/R_i are then used to identify the neighboring a/t and t/R_i in the table. There are two sets of influence coefficients for each t/R_i obtained from two neighboring a/t.
- First interpolation is performed for each t/R_i between the corresponding set of a/t for the desired a/t.

- The second and final interpolation is performed between those interpolated influence coefficients for the desired t/R_i.

The order of the interpolations (starting with a/t or t/R_i) is irrelevant. Linear interpolation requires two sets of data points surrounding the desired a/t or t/R_i. But for the cubic polynomial interpolation requires four sets of data points. In the subsequent sections a detail description is given with examples on how to perform the both interpolations and is shown the difference with respect to linear interpolation. Out of the five influence coefficients, the first one, G_o has the most influence in the stress intensity function. Therefore, the comparative analysis is performed on G_o alone.

2.1.1 Nature of nonlinearity

The influence coefficients are function of a/t and inverse of R_i/t. The nature of nonlinearity of the influence coefficients with a/t and R_i/t are discussed here starting with a/t.

Figure 2 shows the nature of non-linearity of all five influence coefficients for $R_i/t = 10$. The first influence coefficient shows the highest nonlinearity and the nonlinearity diminishes for the subsequent influence coefficients. It also shows a very good fit with cubic polynomial. For other R_i/t the cubic polynomial function will change. Figure 3a shows the first influence coefficient (G_o) for $R_i/t = 10$ and $R_i/t = 5$. It can be visually inferred from Figure 3a that linearity can be assumed between any two consecutive points without losing a considerable amount of accuracy. The effect of non-linearity on G_o can be observed from Figure 3b. Non-linearity reduces with lesser R_i/t as well as lesser a/t.

There are seven points identified in the Figure 3a. They are -

- Point A: a/t=0.6 and R_i/t=5
- Point B: a/t=0.6 and R_i/t=10
- Point C: a/t=0.8 and R_i/t=5
- Point D: a/t=0.8 and R_i/t=10
- Point E: a/t=0.7 and R_i/t=5. This is one of the two interpolated points obtained after the first interpolation.
- Point F: a/t=0.7 and R_i/t=10. This is one of the two interpolated points obtained after the first interpolation.
- Point X: a/t=0.7 and R_i/t=7. This is the final value after the second interpolation between points E and F.

Point A through Point D are obtained from Table C.10. The example discussed later uses these points and shows the differences in calculating G_o using cubic polynomial interpolation and linear interpolation. Next discussion is on the nonlinear nature of G_o with respect to R_i/t.

Figure 4a shows the nature of the nonlinearity of G_o with respect to R_i/t. It is observed from the earlier figures that the non-linearity reduces with decreasing a/t as well as with decreasing R_i/t. Even more interestingly, Figure 4a shows that the nonlinearity of G_o vanishes beyond a value of R_i/t. This value varies with variation of a/t. Assuming the maximum $R_i/t = 40$ after which the influence of R_i/t vanishes, Figure 4b shows a set of cubic polynomials of R_i/t for various a/t. These are not as good fit as we have seen earlier with cubic polynomial of a/t even though the maximum

of R_i/t is reduced down to 40. Improvement can be made in the curve fitting is to perform the curve fitting around the desired value. In explaining this, two piecewise curve fittings are performed and shown in Figure 5. Curve fittings with R_i/t from 1 to 10 (left in the figure) and from 10 to 40 (right in the figure) are considered in this figure.

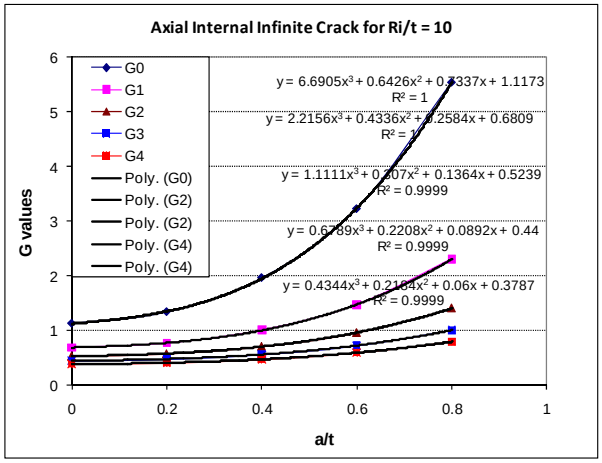

Figure 2 – Nonlinear behavior of the influence coefficients of the axial internal infinite surface crack for $t/R_i = 10$

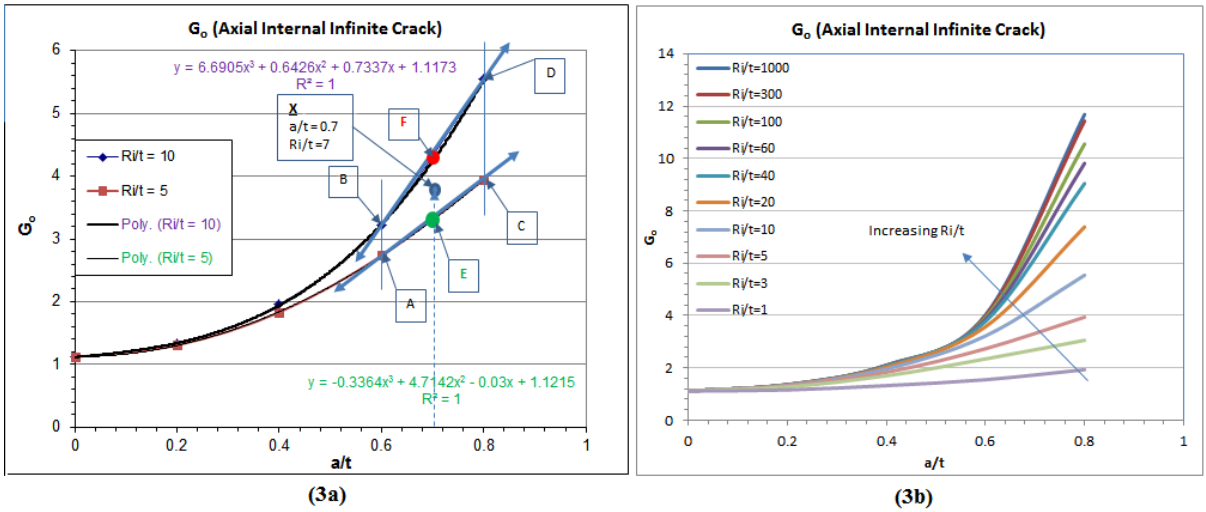

Figure 3 – (3a) First influence coefficient (G_o) for $t/R_i = 10$ and 5 and (3b) Effect of non-linearity in G_o with increasing R_i/t

Figure 6 shows the similar arrangement of points A through D described earlier along on the cubic curve fit between R_i/t of 1 to 10. It also shows the linear approximation lines. It can be clearly inferred from this figure that linearity can be assumed between two adjacent points as shown in the previous case.

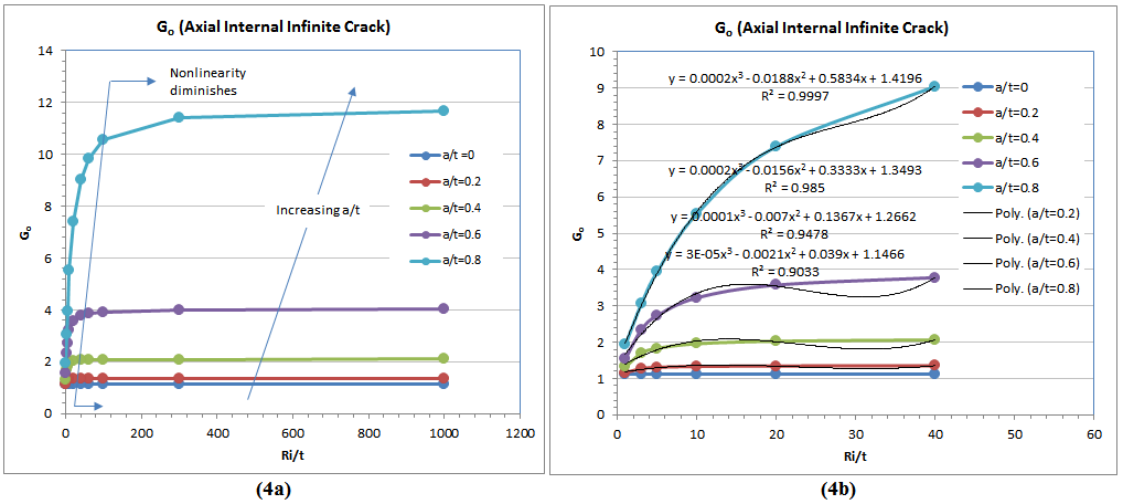

Figure 4 – (4a) The first influence coefficient (G_o) with respect to R_i/t and (4b) Nonlinear behavior of the first influence coefficient with respect to R_i/t

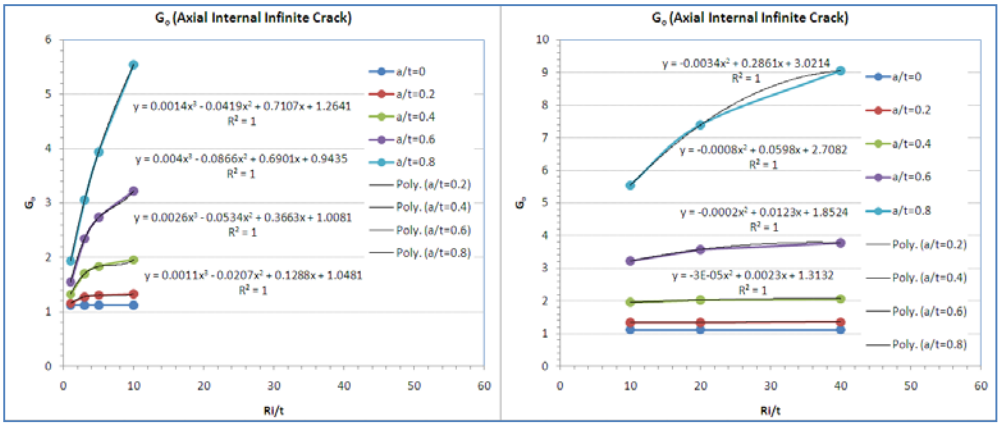

Figure 5 – Local cubic polynomial of the first influence coefficient with respect to R_i/t. (a) $R_i/t \leq 10$ (left figure) (b) $10 \leq R_i/t \leq 40$ (right figure)

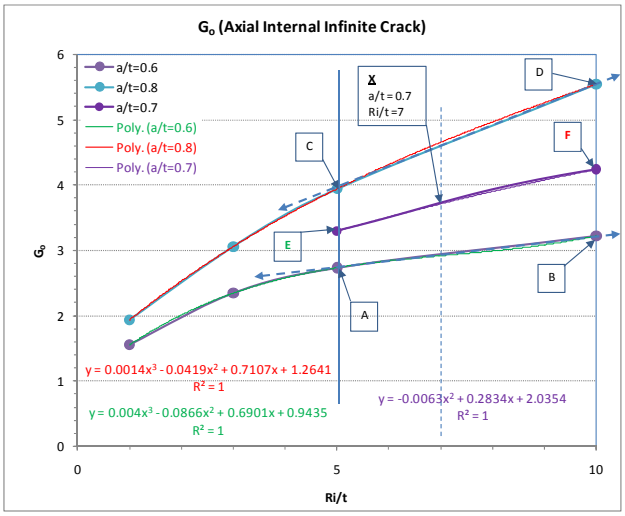

Figure 6 – First influence coefficient (G_o) for a/t = 0.6 and 0.8

Therefore, linearity between two adjacent a/t points and two R_i/t points can be assumed without losing much accuracy. Following example takes an attempt of quantifying the accuracy. The first influence coefficient (G_o) is selected because it has the most influence in stress intensity function (Equation is given at the beginning).

2.1.2 Example

Let us assume that the influence coefficients for a/t=0.7 and R_i/t=7 are needed for calculating stress intensity factor. Table 1 shows a portion of Table C.10 from API 579 for R_i/t of 10 and 5 and for a/t from 0 to 0.8. The values we are looking for are between R_i/t of 10 and 5 and a/t of 0.6 and 0.8. These values are marked in the table. As it is mentioned earlier that two interpolations are required. The first interpolation is performed for a/t = 0.7 that is in between a/t of 0.6 and 0.8. This yields two sets of influence coefficients; one for R_i/t = 10 and the other for R_i/t = 5. The next and final interpolation is performed for R_i/t = 7 that is in between R_i/t of 10 and 5. It is also important to note that the interpolations are performed between values of a/t and R_i/t that are adjacent to the desired values.

Table 1 – Influence coefficients for Axial Internal Infinite Crack

		Internal Crack				
Ri/t	a/t	G0	G1	G2	G3	G4
10	0	1.12	0.682	0.5245	0.4404	0.379075
10	0.2	1.332691	0.763153	0.569758	0.470495	0.401459
10	0.4	1.957764	1.002123	0.702473	0.556857	0.467621
10	0.6	3.223438	1.466106	0.953655	0.718048	0.585672
10	0.8	5.543784	2.300604	1.398958	1.000682	0.789201
5	0	1.12	0.682	0.5245	0.4404	0.379075
5	0.2	1.307452	0.753466	0.564298	0.466913	0.398757
5	0.4	1.8332	0.954938	0.676408	0.539874	0.454785
5	0.6	2.734052	1.28757	0.857474	0.656596	0.54072
5	0.8	3.940906	1.739955	1.10621	0.81823	0.661258

2.1.3 Interpolation between a/t

Following are couple of important notes that can be inferred from Figure 2:

- The first influence coefficient (G_o) is more nonlinear than other influence coefficients.
- For lesser a/t, the function is more linear than higher a/t.
- A linear behavior may be assumed between two adjacent a/t.

Figure 3 shows the first influence coefficients for R_i/t = 10 and R_i/t = 5. Two vertical straight lines are drawn between a/t = 0.6 and a/t = 0.8. Four points are identified on these two lines. The values of the points are given in Table 2 along with the values computed using cubic functions and the associated % difference. It is important to note that even at the known values of a/t and R_i/t the cubic functions yield difference even though the % difference are minor.

Table 2 – Values of four points used in the interpolations

Point	a/t	Ri/t	Go	Go using cubic function	% Difference
A	0.6	5	2.734052	2.727950	-0.22%
B	0.6	10	3.223438	3.234004	0.33%
C	0.8	5	3.940906	3.942351	0.04%
D	0.8	10	5.543784	5.541060	-0.05%

Next, we calculate G_o for a/t = 0.7 by using cubic polynomial function and by using linear interpolation method. Linear interpolation method uses the tabular values of G_o for a/t = 0.6 and a/t = 0.8. The points E and F in Figure 3 are the interpolated points for a/t = 0.7 for R_i/t = 5 and R_i/t = 10 respectively. Table 3 shows the values of points E and F by using cubic and linear interpolations. The % difference shown in the table indicate that the linear interpolation yields 1.27% and 2.36% higher G_o in reference to the cubic interpolated values. It is important to remember that the values using cubic functions associate with some difference.

Table 3 –Interpolation for a/t=0.7 between 0.6 and 0.8

Point	a/t	Ri/t	Go using cubic function	Go using linear function	% Difference
E	0.7	5	3.295073	3.337479	1.29%
F	0.7	10	4.240606	4.383611	3.37%

2.1.4 Interpolation between Ri/t

Figure 6 shows influence coefficient points A through F on R_i/t axis. A cubic curve fit is obtained for a/t=0.7. Since cubic polynomial interpolation requires four points to perform the calculation we calculated G_o for a/t=0.7 and R_i/t=20. Using the cubic polynomial function for a/t=0.7, G_o is calculated for R_i/t=7. Finally, linear interpolation is performed between Ri/t = 5 and 10 for Ri/t = 7 on a/t = 0.7. The final interpolated values for point X using cubic and linear interpolation are shown in Table 4. The overall % difference is 1.22% for linear interpolated value in reference to the cubic interpolated value.

Table 4 – Interpolation for Ri/t=7 between 5 and 10 at a/t=0.7

Point	a/t	Ri/t	Go using cubic function	Go using linear function	% Difference
E	0.7	5	3.295073	3.337479	1.29%
F	0.7	10	4.240606	4.383611	3.37%
	0.7	20	5.189129		
X	0.7	7	3.710500	3.755932	1.22%

2.1.5 Findings of the example

- Cubic interpolation introduces complexity in the calculation without improving much accuracy in the results.
- Besides computational complexity following are some comments and observations on cubic polynomial and curve fitting:
    - Cubic polynomial interpolation requires four consecutive points if local curve fitting is intended otherwise global curve fitting may be employed.
    - Global curve fitting introduces more difference in the interpolation.
    - Cubic polynomial function needs to be obtained for each set of Ri/t and a/t that will introduce complexity in the calculation and increase computation time.
- The % difference in reference to the cubic interpolation is reasonable if linear interpolation is performed.
- Similar arguments for linear interpolation on other influence coefficients can be made.

2.2 Finite Surface Crack

Figure 7 shows partial tables for influence coefficients of finite axial inside and outside surface cracks. Unlike the tables for infinite crack, these tables contain one more level of variable that is the ratio of crack depth to the half crack length (a/c). Hence, to obtain the desired influence coefficients, three interpolations are required.

Table C.12

Influence Coefficients For A Longitudinal Semi-Elliptical Surface Crack in A Cylinder - Inside Surface

Figure 7 – Partial Table C.12 and Table C.13 from API 579

Interpolation is performed using the following methodology:

- For a given pipe and crack geometry, t/R_i, a/c and a/t are calculated.
- The a/t a/c and t/R_i are then used to identify the neighboring a/t, a/c and t/R_i in the table. There are two sets of influence coefficients with the neighboring a/t for each t/R_i and a/c.
- First interpolation is performed for each t/R_i and a/c between the corresponding set of a/t for the desired a/t.
- The second interpolation is performed between those interpolated influence coefficients for the desired a/c for each t/R_i.
- Finally the third and final interpolation is performed for the desired t/R_i.

2.3 Effect of interpolation on limiting pressure prediction

In the earlier section, we discussed and showed in the example the differences in the influence coefficients when using the cubic polynomial interpolation instead of the linear interpolation. With the finite crack we will calculate Level 2 limiting pressure using both interpolation methods. Level 2 limiting pressure for a known crack is defined as the pressure at which the toughness ratio (K_r) equals to the toughness ratio calculated from the Level 2 FAD equation for the calculated load ratio (L_r). This is the maximum operation pressure beyond which the crack will be unacceptable for fitness for service according to Level 2 FAD. FAD is a relation between K_r and L_r, which is described as follows:

$$K_r = [1 - 0.14(L_r)^2]\{0.3 - 0.7e^{[-0.65(L_r)^6]}\} \quad for\ L_r \leq L_{r\,max}$$

Where, $L_{r\,max} = 1.25$ for Carbon Steels, $K_r = K_I/K_{mat}$ and $L_r = \sigma_{ref}/\sigma_{YS}$, K_I is the mode I stress intensity factor, K_{mat} is the materials fracture toughness, σ_{ref} is the reference stress, based on yield load and limit load solutions for the configuration of interest, and σ_{YS} is the yield strength of the material. Figure 8 shows the FAD using the above equation. If the assessment point lies inside the FAD, the structure is considered safe and the crack is acceptable for fit. The unacceptable crack is predicted when the assessment point falls outside the FAD.

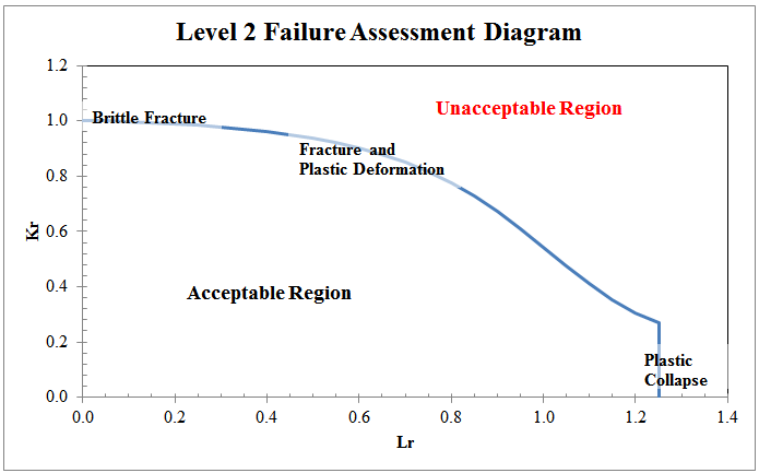

Figure 8 – FAD for Level 2 Assessment

Both K_I and σ_{ref} calculated for a given crack are function of operating pressure. The limiting pressure is that operating pressure at which the calculated K_r for the given crack equals to the K_r calculated from the above FAD equation. Therefore, a difference in K_I due to the use of linear instead of cubic interpolation method for estimating influence coefficients is carried in K_r calculation and there on to the limiting pressure prediction.

In this example, we choose a 914.4 mm (36 in.) X65 pipe with the wall thickness of 6.35 mm (0.25 in.) and 12.7 mm (0.50 in.). The internal pressure for this example is assumed as 4,356 kPa (70% SMYS). The cracks used in this example are defined as a/t varying from 0.1 to 0.8 and as a/c from 2 to 0.03125. Three material toughness values (20, 100 and 200 MPa√mm), K_{mat} are used in this example.

Figure 9 shows the percent difference in Level 2 limiting pressure versus the percent difference in K_r. The variation in K_r due to the use of interpolation method introduces a variation in limiting pressure for various crack dimensions. We can infer the following from the figure –

- The difference in limiting pressure is inversely varying with the difference in K_r.
- Difference in predicted limiting pressure diminishes with higher material toughness value. For a higher material toughness, the difference in limiting pressure is considerably lower than a lower material toughness value. It is also observed that with a higher toughness (i.e. K_{mat} = 200 MPa√mm) and shallower crack (i.e. a/t <0.4) the difference in limiting pressure is zero or negligible.

- The maximum difference in limiting pressure observed is less than 6%. However, it can be critical for a particular application. Therefore for a deep surface crack with low material toughness it is important to be cautious in predicting Level 2 limiting pressure.

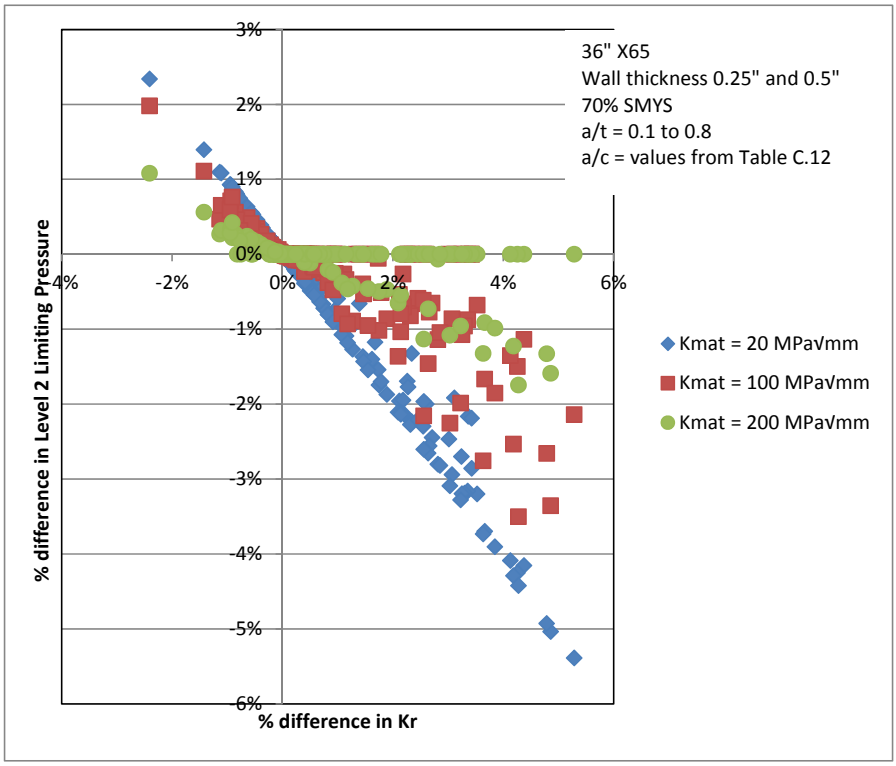

Figure 9 – Percent difference in the Level 2 limiting pressures

3 Conclusions

Even though the values of the influence coefficients given in the tables in API 579 fit with some cubic polynomial functions for a/t and also for R_i/t, the nonlinearity is found more in the first influence coefficient (G_o). For a/t equal or less than 0.4, the influence coefficients can be assumed linear. It is also concluded that shallower cracks (a/t <0.4) with a relatively high material toughness, the linear interpolation does not produce significant difference in predicting limiting pressure with respect to nonlinear interpolation. While for the deep surface cracks with low material toughness may be critical for a particular application and should require caution in predicting Level 2 limiting pressure. However the overall difference in K_I as well as in Level 2 limiting pressure by using the linear interpolation rather than the cubic polynomial interpolation is less than 6% which is reasonably within the acceptable error margin.

Improved Exploitation of High-strength Steels in Pressure Vessel Design by Simulations Based on Damage Mechanics

Abstract Pressure vessels are subjected to regulation by European standards, which define design procedures and nominal material properties that are guaranteed by the steel producers. Over-conservative safety factors for materials with high yield-to-tensile ratios hinder the application of modern high-strength steels despite their excellent toughness and possible economic and ecologic benefits. Damage mechanics enable a more adequate failure description for these steels since they can consider ductile crack initiation as limit state. Such concepts should refer to nominal material characteristics to enhance their applicability in design procedures. A method is presented to correlate the nominal Charpy impact toughness to simulations with the Gurson-Tvergaard-Needleman-model (GTN). The resulting GTN parameters are used in cell model simulations to derive strain-based empirical failure criteria as nominal ductility measure for simulations on component level. A sensitivity study on the GTN parameter choice shows that the initial pore volume is the most relevant parameter, but other non-unique parameters also influence the failure prediction. The impact of the individual parameters is discussed. By the definition of a reliable calibration scheme for the GTN parameters this approach enables an identification of adequate lower bound failure criteria for high-strength steels in pressure vessels as a preliminary pressure vessel simulation demonstrates.

Keywords Strain-based Design, Pressure vessel, Damage mechanics, Damage curve

1. Introduction

In Europe, pressure vessels are subjected to regulation by the European Standard EN 13445, which contains the corresponding design rules. Additionally, the material requirements for pressure vessel steels are part of EN 10028. Therein, nominal material properties are defined, which specify minimum values for the mechanical properties. These have to be guaranteed by the steel producers and are often exceeded, especially by high quality steels. The nominal characteristics form the basis of the design process for pressure vessels. The required wall thickness is determined in dependence of the materials' nominal yield or tensile strength. The relevant design stress is specified in EN 13445 as the minimum of the yield strength divided by a safety factor of 1.5 or the tensile strength divided by 2.4. Therefore, the yield-to-tensile (Y/T) ratio determines the magnitude of the applied safety factor. From a Y/T-ratio of 0.625 on, the tensile strength with an increased safety factor of 2.4 is relevant for the design. Modern high strength steels are often characterised by such an increased Y/T-ratio, e.g. steel grade P500Q with Y/T = 0.85 and P690Q with Y/T = 0.9. By the application of the increased safety factor, only a poor exploitation of their load bearing capacity can be achieved. In this safety factor domain, the design stress is only 41% of the yield strength. Consequently, these rather expensive steel grades are rarely applied in pressure vessel design. However, their application would foster substantial economic and ecological benefits by e.g. thinner walls, which result in lower welding, energy and transportation cost.

The current safety factors are mainly based on experience and do not consider the actual failure behaviour [1]. Since EN 13445 requires brittle fracture to be excluded by the toughness requirements, an improved prediction of ductile crack initiation is needed. Hence, to improve the exploitation of high strength steels in pressure vessel design it is necessary to include a description of their ductility. The methods of damage mechanics are able to provide such predictions [2]. Although research on this field has been conducted for several decades, the methods of damage mechanics are not used regularly in industrial applications, let alone considered standard design procedures. One reason is that the application of damage mechanics models requires considerable

expertise and experience since most of these models are strongly dependent on the non-unique parameter selection and the mesh size [2, 3]. A requirement for a safe and reliable use of damage mechanics models in pressure vessel design are therefore standardised application guidelines. Moreover, newly developed design criteria should be transferable to the standards and therefore need to refer to the nominal material properties. Currently, only yield and tensile strength are considered. The nominal property related to ductility is the minimum Charpy impact toughness. For example, EN10028-6 requires a nominal Charpy impact toughness of 60 J at room temperature for P500Q. Münstermann and Schruff have developed a method to determine ductile failure criteria for high strength pressure vessel steels out of these nominal characteristics [4, 5], which is further explained and discussed in the following.

2. A method for strain-based pressure vessel design with respect to nominal material properties

The ductile failure mechanism of metallic materials consists of the nucleation and coalescence of voids, which form under plastic deformation at inclusions [2]. This process is described by the damage model of Gurson, Tvergaard and Needleman (GTN). It was established by Gurson in 1977 [6] and is based on a continuum mechanics description of a hollow sphere in surrounding homogeneous material. Tvergaard and Needleman optimised the shape of the yield surface by the introduction of empirical fitting parameters [7]. The GTN model consists of a modified von Mises flow potential (Eq.1), and functions for the description of void nucleation (Eq.2) and coalescence (Eq.3).

(1)

(2)

(3)

The flow potential is a function of the equivalent stress σ_v, the hydrostatic stress σ_1, the empirical fit parameters q_i and the effective void volume fraction f^*. The latter is defined out of the nucleation function until the critical void volume fraction f_c is reached. Then the void growth is accelerated by the factor κ to account for the effects of void interaction. The nucleation function considers the plastic equivalent strain ε^{pl}, the volume fraction of possible nucleation sites for secondary voids f_N, the characteristic strain for nucleation of secondary voids ε_N as well as the standard deviation S_N.
The micromechanical motivation is one of the main advantages of this model. Some of its parameters, such as the initial void volume fraction, can be determined in metallographic analyses [2, 8]. This simplifies the parameter selection. Therefore, the GTN model is suitable to predict the crack initiation of high strength pressure vessel steels and is employed in the discussed approach.

However, the computational implementation of GTN requires too many resources for large scale component simulation as pressure vessel modelling. Therefore, a simpler model has to be applied in the component simulation. Such a model is the damage curve established by Johnson and Cook [9]. Depending on the evaluation procedure it describes the characteristic strain at failure or crack initiation as a function of stress triaxiality η, which is the ratio of hydrostatic to equivalent stress, and three constants c_i (Eq.4).

(4)

The damage curve can either be calibrated by experiments or by unit cell simulations based on the GTN model [10]. The unit cell (Fig. 1a) consists of one axisymmetric element, which is subjected to loads in two directions. By changing the ratio of the applied loads, it is possible to create different triaxiality states. Since the developed design approach shall be transferable to the standards it should refer to the nominal properties. An experimental calibration of the damage curve is only possible for a specific material of a single producer. Consequently, it allows no general application in standard design procedures. A derivation via unit cell simulations is a more general approach and is therefore applied.
The main idea of this approach is to re-calibrate an experimentally derived GTN parameter set for a specific steel grade in simulated Charpy tests [5]. The aim is to meet the nominal Charpy energy required in the standard for this steel grade. Such a set consequently characterizes the minimum ductile crack resistance. With this calibrated parameter set it is possible to determine a lower bound damage curve (Fig. 1b) for the simulation of ductile failure in pressure vessels with regard to nominal material properties [4, 5].

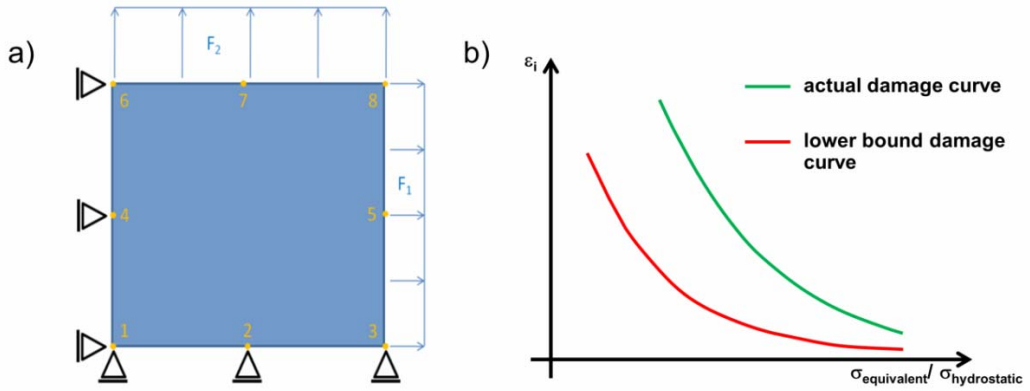

Figure 1. Schematic illustration of a) the axisymmetric unit cell and b) the damage curves.

The corresponding procedure based on [4, 5] consists of the following steps:

(1) Calibration of a suitable GTN parameter set and the corresponding mesh size for the selected material by metallography and an iterative optimisation process involving experimental and numerical results of notched round bar and fracture mechanics tests. Derivation of empirical functions for the materials strain rate and temperature dependence in an iterative process considering tensile tests at different temperatures and strain rates.
(2) Simulation of a Charpy impact toughness test with the determined values to validate the selection and the model and determine the corresponding friction value. Agreement between experimental and numerical results in overall energy and the course of the force-displacement curve shall be achieved.
(3) Derivation of the selected materials' damage curve via unit cell simulations with varying stress triaxiality according to [5, 10].
(4) Calibration of a lower bound GTN parameter set in the simulation of a Charpy impact test with the aim to meet the nominal Charpy impact toughness specified in the standard for the selected material.

(5) Derivation of the lower bound damage curve via unit cell simulations with varying stress triaxiality according to [5, 10].
(6) Application of the lower bound damage curve in burst simulations for pressure vessels.

The burst simulation based on the lower bound damage curve allows a prediction of the failure onset in pressure vessels under consideration of the nominal Charpy impact toughness. These simulations can be part of an approach to derive more adequate safety factors for high strength pressure vessel steels. However, this approach can also be easily transferred to other applications fields subjected to regulation, e.g. civil engineering.

3. Influence of the non-unique GTN parameter selection on the course of the damage curve.

The developed concept contains the required steps for the identification of suitable GTN parameter sets. However, this selection is well-known to be non-unique [3, 8, 11]. It is therefore necessary to investigate the influence of the GTN parameter selection on the derived damage curve, since it represents the failure prediction element in the developed concept. Therefore, a sensitivity analysis is conducted with a GTN parameter set determined for the steel P500Q.
The reference set is derived by metallography and the comparison of numerical and experimental results of notched round bars in a tensile test. The relevant mesh size is determined in comparison to results of Compact-Tension-tests. The parameter set is validated in the simulation of a Charpy test. Details of the calibration procedure can be found in [5]. Unit cell calculations are performed with this reference set at stress triaxialities of 0.5, 1.0, 1.5, 2.0 and 2.5. The strain corresponding to the maximum stress in the unit cell is selected as critical strain for the derivation of the damage curve. At low stress triaxialities the GTN model may fail to predict softening, consequently no point for the damage curve can be derived.
During the sensitivity analysis one parameter is varied in the unit cell simulations while the others are kept constant. The calculations are performed at the above mentioned five stress triaxialities. Table 1 shows the reference parameter set determined for steel grade P500Q and the selected values for variation, which were chosen in accordance with literature [3, 11]. For q_3 the common relation $q_3 = q_1^2$ was applied in accordance with [7]. The aim of the sensitivity analysis is a qualitative description of individual parameters' influence on the damage curve. This description can form the basis for a rule set for the parameter derivation in the investigated approach.

Table 1. Reference set and variations for GTN parameters of steel P500Q

Parameter	f_0	f_N	S_N	ε_N	f_c	κ	q_1	q_2
Reference value	0.00185	0.00215	0.4	0.12	0.015	1.1	1.5	1.0
Maximum value	0.01	0.015	0.6	0.3	0.05	6	2.5	1.5
Minimum value	0.0005	0.0005	0.1	0.05	0.005	1	1	0.5
Mean value	-	-	-	-	-	3	-	0.8

3.1. Results of the sensitivity analysis

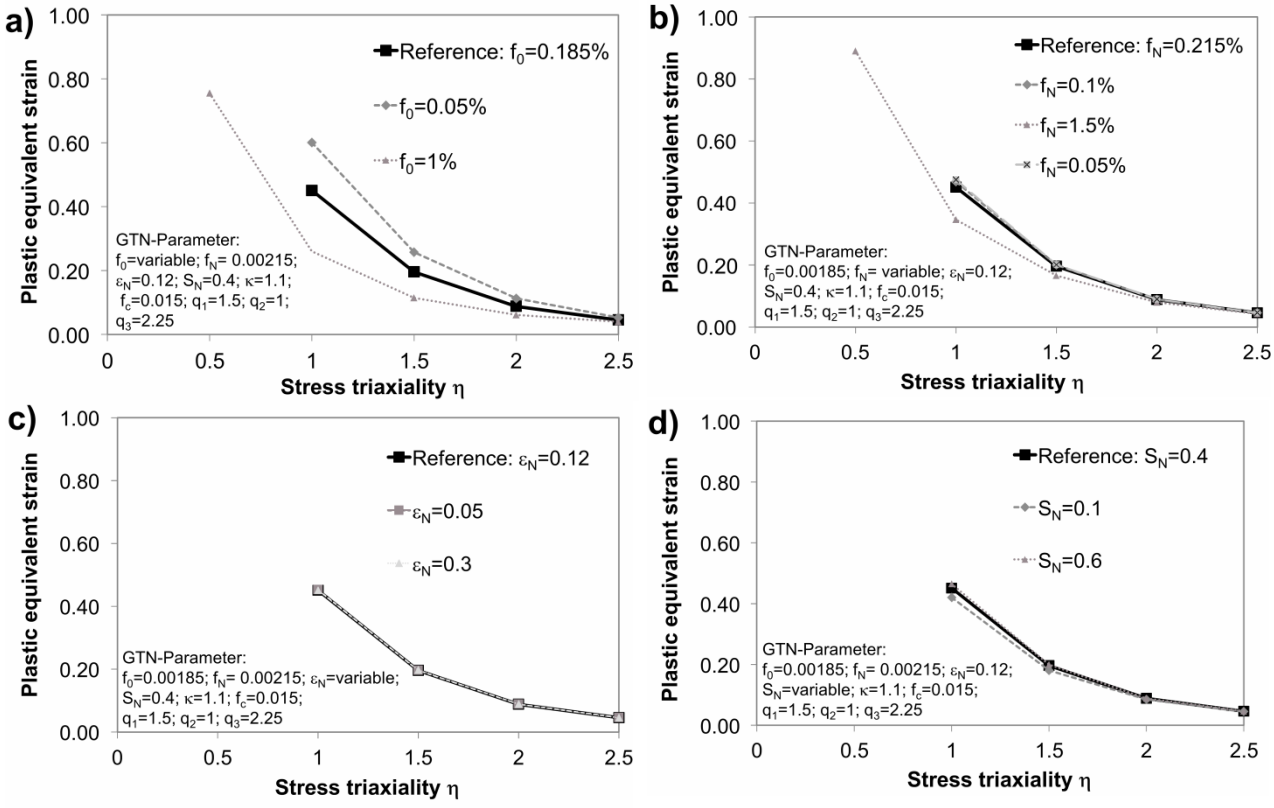
3.1.1. Influence of f_0

The variation of the initial pore volume f_0 has a strong influence on the course of the damage curve, as can be seen in Fig. 2a. This effect increases with decreasing stress triaxiality. At a triaxiality of η=1, there is a maximum difference in critical strain of 34%. One reason for the strong impact of f_0 is that the initial pore volume influences the computation right from the beginning. This is also

shown in Fig. 2e, which displays the equivalent stress in the unit cell and the effective void volume as a function of the equivalent strain for two triaxialities of η=1 and η=2.5. f_0 can very well be correlated to the volume content of non-metallic inclusions [5] and therefore be determined in metallographic analyses.

3.1.2. Influence of the void nucleation parameters f_N, ε_N and S_N

The void nucleation function (Eq.3) is based on a Gaussian distribution function. It is influenced by the volume fraction of possible nucleation sites for secondary voids f_N, the characteristic strain for nucleation of secondary voids ε_N and the corresponding standard deviation S_N. Consequently, these parameters interact. The secondary void volume f_N has a clear influence on the course of the damage curve at low triaxialities (Fig. 2b), the maximum difference at η=1 is 12%. However, this impact is lower than the one of f_0 although the input variation was comparable. Figure 2c and Figure 2d show that ε_N and S_N only have a minor influence on the predicted failure strains. This is due to the value of f_N, which limits the influence of ε_N and S_N. For many materials, the magnitude of f_N can also be determined in metallographic analyses. For the reference set it was determined as the volume fraction of carbides in P500Q. The minor influence of ε_N and S_N holds therefore true for realistic values of f_N, but it increases for higher values of f_N.



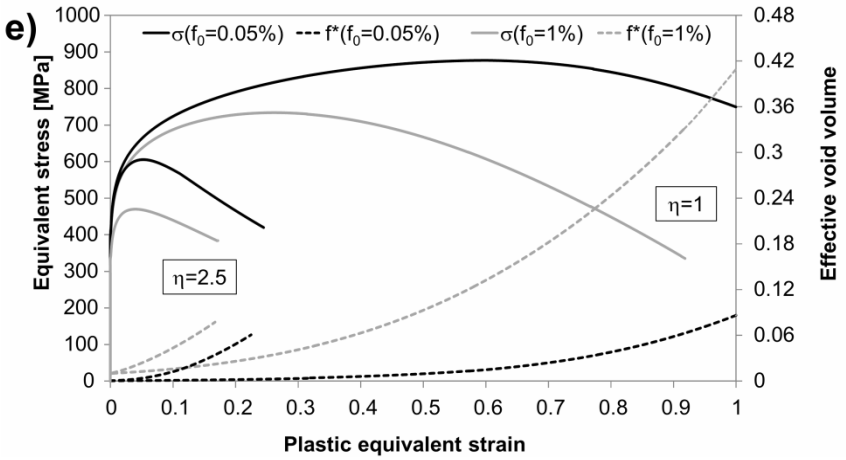


Figure 2. Damage curves under variation of a) f_0 b) f_N c) ε_N & d) S_N. Subfigure e) Equivalent stress and effective void volume as a function of the plastic equivalent strain under variation of f_0 for η=1 and η=2.5.

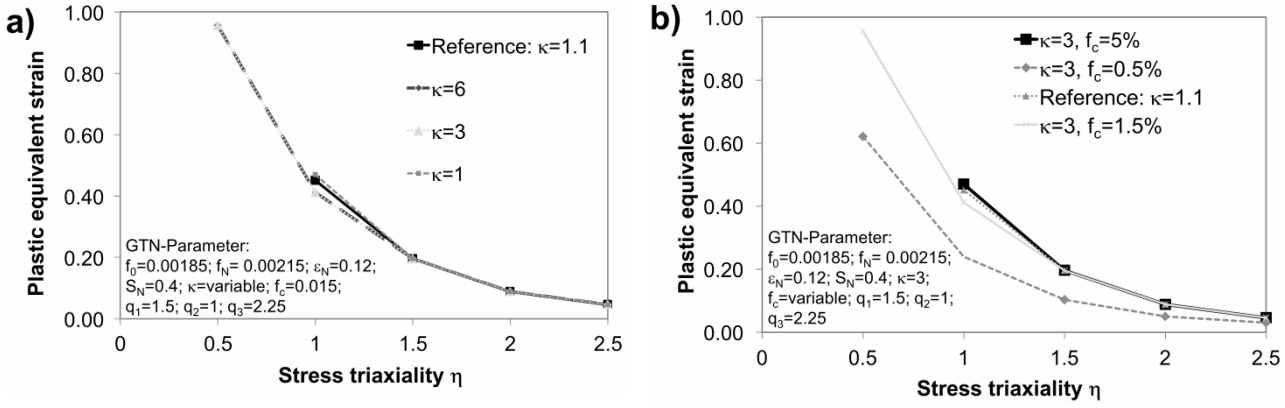
3.1.3. Influence of the void coalescence parameters f_c and κ

The void coalescence behaviour is implemented in the GTN model by an acceleration of void growth and nucleation. The critical void volume f_c determines the onset of acceleration, while the acceleration factor κ defines its magnitude. Therefore, f_c and κ have a crucial influence on the failure detection. Figure 3a displays the influence of κ on the damage curve. It is low with a maximum difference in critical strain of 6% at η=1. Figure 3c proves that there are significant differences in the corresponding stress-strain-curves. Since the strain at maximum stress is relevant for the derivation of the damage curve in this evaluation concept, κ only marginally impacts the damage curve. The value of f_c determines the onset of acceleration. With the currently calibrated low value of κ = 1.1 the influence of f_c on the damage curve is very small. It is therefore evaluated for an increased value of κ = 3. Figure 3b shows a significant influence of f_c on the damage curve for κ = 3, which is also reflected in the corresponding stress-strain-curves in Fig. 3c.



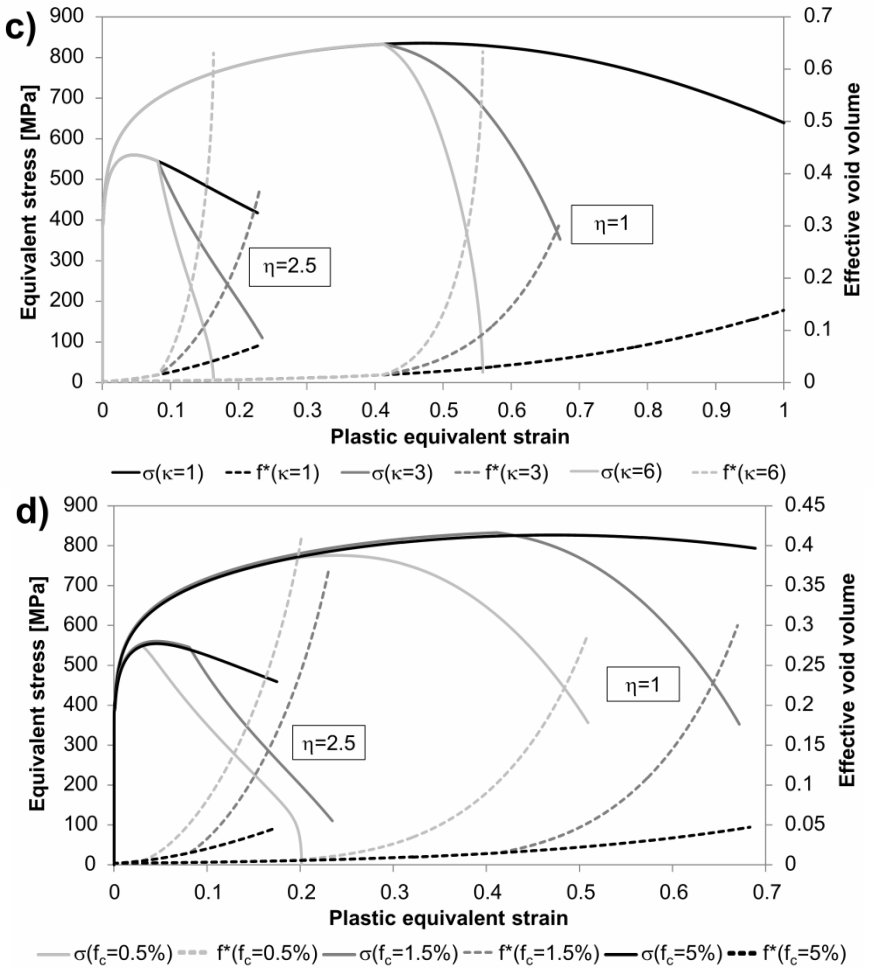


Figure 3. Damage curves under variation of a) κ b) f_c. Equivalent stress and effective void volume as a function of the plastic equivalent strain under variation of c) κ and d) f_c for η=1 and η=2.5.

3.1.4. Influence of the empirical fit parameters q_1 and q_2

The empirical fit parameters q_1 and q_2 have massive influence on the course of the damage curve, as can be seen in Fig. 4. The reason is that they directly change the shape of the yield surface. Contrary to most other parameters, the influence of q_2 is not decreasing with increasing triaxiality.

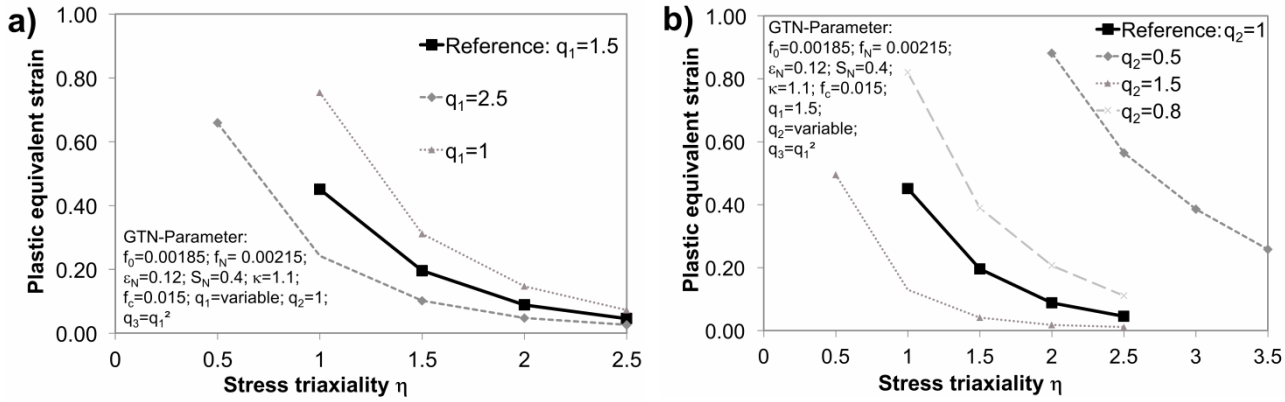

Figure 4. Damage curves under variation of a) q_1 and b) q_2.

3.1.5. Investigations on the uniqueness of the damage curve

The qualitative sensitivity analysis shows that the GTN parameter selection has a clear influence on

the course of the damage curve. The impact of the individual parameters varies and their interaction is non-linear. Therefore, it is possible to determine several different parameter sets that yield the same result, the solution is not unique. Since the lower bound damage curve is calibrated at Charpy simulations in this methodology, two parameter sets are determined that compute a similar impact toughness and force-displacement-curve. In version A, f_N and S_N were increased to f_N=0.01 and S_N=2. In version B f_0 is decreased to f_0=0.001, while f_N is increased to f_N=0.015. Figure 5 shows the damage curves for these parameter sets. A good agreement can be found at higher triaxialities but the maximum difference of critical strain is 8% at η=1. The damage curve of version A is identical to the reference damage curve. The increased f_N should affect the damage curve, but due to the high S_N the nucleation of secondary voids is distributed over a broad strain interval so that the actual influence of f_N is diminished. Consequently, an identical damage curve is produced. Considering the micromechanical motivation of the GTN model this parameter selection is not sensible. Although the version B parameter set has a similar force-displacement curve, the influence of the important void parameters f_0 and f_N affects the course of the damage curve at low triaxialities.

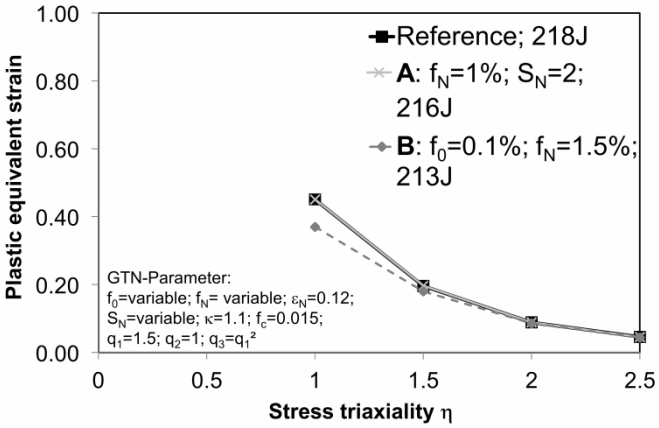

Figure 5. Damage curves for two parameter sets yielding a similar Charpy impact energy in simulation.

3.2. Discussion of the sensitivity analysis

The non-uniqueness of the GTN parameter selection may lead to identical damage curves resulting from different parameter sets if the interaction of individual parameters compensates their respective impacts. However, this is not always the case. Therefore, it is necessary to establish clear guidelines for the parameter derivation to ensure reproducible results. The guiding principle should be the micromechanical motivation of GTN. The basis for such a rule set is the performed sensitivity analysis. The impact and the consequences for the parameter derivation are discussed in the following for each variable.

Currently, the strain at maximum stress in the unit cell is considered as the crack initiation strain for the derivation of the damage curve. This enables a simple identification of the critical strain. This basic assumption needs to be considered during the GTN parameter calibration on tensile and fracture mechanics test. Consequently, the GTN parameter choice must ensure that in simulation of these samples the stress maximum of the failing element is correlated to the physical crack initiation measured in the experiment. An advantage of this criterion is that the mesh sensitivity of the results is reduced, since the mesh-dependence of the results begins with the onset of softening at the stress maximum [12].

The initial void volume fraction f_0 has a strong influence on the course of the damage curve. It can clearly be related to the microstructure of a material, since voids in many materials form at non-metallic inclusions at the onset of plastic deformation. f_0 has no direct interaction with other parameters but influences the whole computation from the beginning. Therefore, f_0 should be

considered as the main parameter for the derivation of the lower bound damage curve. The micromechanically based motivation behind this procedure is that steel grades of low ductility often exhibit an increased amount of inclusion resulting in a poor internal cleanness. If f_0 is used as the main or even single parameter for the derivation of the lower bound criteria, its strong influence on the damage curve also facilitates the derivation of unique damage curves, since its effects cannot be compensated easily.

The volume fraction of potential secondary voids, f_N, also has a significant influence on the course of the damage curve. However, it is lower than the impact of f_0. For some materials, the nucleation sites for secondary voids can also be correlated to metallographic results, such as the carbide volume fraction. Even if this is not possible, the order of magnitude of f_N should be chosen in a micromechanically sensible range. In the nucleation function, f_N interacts with ε_N and S_N, which only have a low impact on the damage curve for common values of f_N. Their impact is increased proportionally with f_N. Therefore, if the nucleation parameters are modified, matching magnitudes should be selected to avoid non-uniqueness due to interactions. Alternatively, the modification could be restricted to f_N.

The coalescence parameters f_c and κ have a strong influence on the stress-strain-curve of the unit cell, since they determine onset and magnitude of the accelerated void growth. Consequently, there is also a relevant interaction of these parameters. If the critical strain f_c is reached after the maximum stress, the choice of κ and f_c has only little influence on the damage curve. This is more likely for high triaxialities. Since the maximum is correlated to crack initiation, κ should have a minimum value clearly larger than unity to enable a rapid failure of the element. This also reduces the influence of κ on the maximum stress point and consequently the damage curve. A further aspect is that the area beneath the stress-strain-curve is a measure for the dissipated energy. This is important for the parameter calibration of f_c and κ in tensile and fracture mechanics test. Different studies show the dependence of f_c on the stress triaxiality [3]. If possible, it is therefore advantageous to calibrate f_c such that the critical value is reached after the stress maximum of the critical element. If f_0 is modified for the derivation of the lower bound damage curve, it may therefore also be necessary to adapt f_c and κ.

The empirical fitting parameters q_i have massive influence on the course of the damage curve. Different studies show that a calibration of these parameters can improve the agreement between simulation and experiment [3]. However, considering the acceptance of the method and the reliability of the result it is better to keep the standard literature values, especially since they are able to represent the failure behaviour.

The definition of a fixed calibration scheme with respect to the considered experimental results is currently under research. Such a scheme can help to foster the acceptance of damage mechanics and may also be transferred to other applications than pressure vessels.

4. Application example of the lower bound damage curve in a pressure vessel simulation

The concept of the lower bound damage curve was applied to a pressure vessel simulation. It is loaded with increasing internal pressure. The lower bound damage curve is applied as the failure criterion. The resulting critical pressure is compared to the one defined by the design formulae of the current standard EN 13445 in the procedure “Design by Formulae” (DBF). Figure 6a shows the model, which could be reduced to a quarter of the vessel due to symmetry. The vessel has a mean diameter of 2600 mm and a wall thickness of 50 mm. The lug has a diameter of 631 mm and a wall thickness of 72.5 mm. P500Q is assumed as the material for the pressure vessel. The lower bound damage curve is derived according to the above explained concept. The parameters according to Eq. 4 are c_1= 0.94, c_2 = 1.76 and c_3=0.01. However, due to missing data, temperature and strain rate

dependence are not yet considered. The results are therefore preliminary. Figure 6b shows the ductile damage criterion at the critical loading step, which highlights if the critical strain has been reached. The crack initiation takes place in the wall besides the lug. In this case, crack initiation happens in parallel with a plastic collapse.

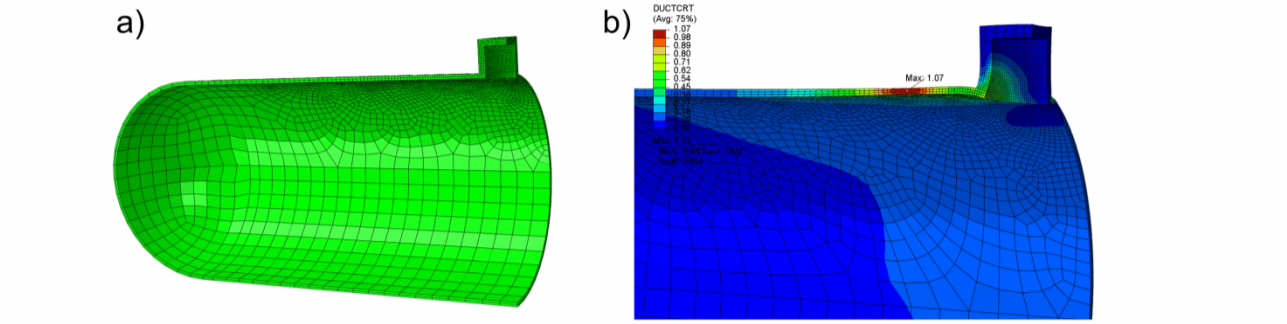

Figure 6. a) Quarter model of the pressure vessel b) Ductile crack initiation besides the lug

The internal pressure at failure is predicted to be 29.61 MPa. A design according to EN 13445 predicts a failure at a maximum pressure of 23.1 MPa. The damage curve concept can consequently be used to quantify unnecessary safety margins for high strength steels in pressure vessels.

5. Conclusions and Outlook

The nominal damage curve concept is a suitable approach to quantify unnecessary safety margins for high strength steels in pressure vessel design, which are included in the current European standard EN 13445. Its main advantage is that a failure prediction is possible under consideration of the nominal Charpy impact toughness by the application of the lower bound damage curve. Therefore, the materials ductility is considered in the design process. The application of this concept can help to derive more adequate safety factors for high strength steels. However, further research is necessary to ensure the safe application of this method. A sensitivity analysis shows that the course of the damage curve is influenced by the non-unique GTN parameter choice. Therefore, a calibration scheme with regard to the evaluated experimental results and considered nominal properties needs to be defined and is currently under research. Additionally, a modification of the applied GTN model towards a consideration of the third invariant of the stress tensor should be considered, since latest research shows that it has significant influence on the prediction of ductile fracture [2].

Abstract The objective of this work is to evaluate the capability of an advanced constitutive model, namely the Three Network Model (TNM) of simulating the mechanical response of HDPE liners undergoing buckling collapse. In order to determine the input parameters for the model, a series of tensile and compressive uniaxial tests were conducted. Simulations were performed using Finite element modeling (FEM) analysis with the ABAQUS 6.10 package. The complex strain rate, temperature and pressure dependent mechanical response of HDPE was analyzed by modeling the dynamic event as an increasing volume of fluid entering the gap cavity between liner and host pipe, and a mathematical relationship between fluid flow rate and collapse pressure was proposed.

Keywords buckling collapse, constitutive modeling, HDPE liners, Finite Element modeling

1. Introduction

The use of polymers in the gas and oil transportation industry is nowadays widely spread. One of their main uses is as lining materials for oil and gas pipelines. These liners serve the function of providing internal protection of metallic tubes mainly in two different situations, namely: by providing enhanced corrosion resistance from aggressive chemical agents, and, in a rehabilitation technique for damage pipes known as relining, during which these structures are slip lined with a polyethylene liner that replaces the inoperative section of the tube [1]. However, there is a number of ways in which polymeric liners can fail in service after a certain time. The present study specifically concerns with the buckling collapse of liners induced by external pressure. This failure mode takes place by the combined action of two separate factors, these are: *i)* the permeation of oil derived gases through the liner wall for extended periods of time, and *ii)* the rapid decompression of pipelines that can occur during service stoppages or maintenance and inspection shutdowns [2].

Recently, a number of studies have been devoted to understand the underlying mechanisms that eventually lead to liner failure [3,4]. Material failure is associated with the phenomenon known as physical swelling. This occurs in liners when some organic components, such as the CO_2 and CH_4 dissolved in oil, penetrate into the polymer macromolecular chain network aided by the high pressure operating conditions, increasing the space between molecules and decreasing the intermolecular bonding. As this operation takes place, the migratory gases can permeate throughout the liner wall and gradually balance the pressure difference between the inside of the liner and the annular region consisting of the gap between the liner and the pipe wall. This permeation mechanism worsens recursively since permeation rate increases with the severity of swelling of the liner. Finally, buckling collapse occurs when the liner is intentionally decompressed and the external pressure built up by the confined gases in the annular region, generates a stress state in the liner that induces the radial buckling failure.

Currently, a number of analytical models that deal with the buckling collapse of metallic tubes under external pressure have been developed in the literature [5-7]. In all cases, the analytical solutions found are restricted to purely elastic or ideal elastoplastic behavior and cannot analyze the influence of geometrical or surface defects, so commonly generated during the manufacturing, storage, transport and installation stages. Moreover, they are only useful for obtaining a critical

pressure value and are not able to describe the whole deformation process. On the other hand, in [8], Rueda et al. developed a specific FEM model for the simulation of the buckling collapse of HDPE liners. In their work, they were able to simulate an overall buckling collapse situation by introducing hydrostatic fluid elements in the model to allow for hydraulic effects. For the description of material constitutive response, they used linear elastic, linear elastoplastic, and linear elastoplastic with strain hardening behavior. Their investigation served as the first step for the prediction of actual failure situations since it showed that the transient dynamic response could be effectively simulated by FEM analysis. However, the traditional constitutive models used in their work cannot account for the intrinsic strain-rate, pressure and temperature dependence of polymer mechanical behavior and therefore are not sufficient to reproduce the complex multiaxial stress response and rate-dependent deformation evolution that will take place during an actual rapid pipe depressurization situation. As a consequence, it remains to include into the analysis an advanced constitutive model capable of accounting for the intricate response of polymers.

Constitutive modeling of polymers is nowadays a well-established field with a large number of advances over the last 40 years. In this regard, one of the most successful developments has been the family of tridimensional constitutive models started by Boyce and coworkers [9-13], which brought together current theories of macromolecular physics with recent work in the fields of statistical mechanics, continuum mechanics, and computational mechanics. These models employ a constitutive framework intended to be general enough to capture material behavior over a wide range of loading conditions, in order to be appropriate for their use in FEM analysis. The original work of Boyce et al. [9] was concerned with the large viscoplastic deformation of amorphous polymers, such as polycarbonate (PC) and acrylic glass (PMMA). So far, this constitutive approach has been consecutively enhanced in order to include additional features of polymer deformation such as, strain induced anisotropy, rubber elasticity, thermo-mechanical coupling, high strain-rate testing and so on. Among these, a notable contribution was the Hybrid Model (HM) of Bergstrom et al. [14] which was designed for capturing the mechanical response of a semi-crystalline polymer: Ultra-high molecular weight polyethylene (UHMWPE). Following this, in [15], Bergstrom et al. developed the Three Network Model (TNM) which is a further refinement of the HM model to be more accurate and computationally efficient. For its pertinence regarding semi-crystalline thermoplastic polymers, the TNM model results in a suitable choice for modeling the mechanical response of HDPE liners. Therefore, the objective of the present work is the evaluation and validation of the TNM model, for its use in FEM assisted design to accurately predict the buckling failure in pipes in a varying range of temperature and loading-rate conditions.

2. Experimental

2.1. Uniaxial tensile and compression tests

For the calibration of the TNM material model, tensile and compression tests were performed on an Instron 4467 universal testing machine. Tensile and compression specimens were machined out from a supplied liner as indicated in Figure 1. In order to univocally determine the viscous parameters, the tests were carried out at 3 different strain-rates, corresponding to crosshead speeds of 1, 10 and 50 mm/min. Tensile tests were performed using a extensometer of 12.5mm gauge length. Compression tests were carried out employing specimens of approximately 10 mm in height and 5 mm in diameter according to 2:1 (height : diameter) ratio recommended in [16]. For a complete characterization of deformation evolution, both loading and unloading response was registered.

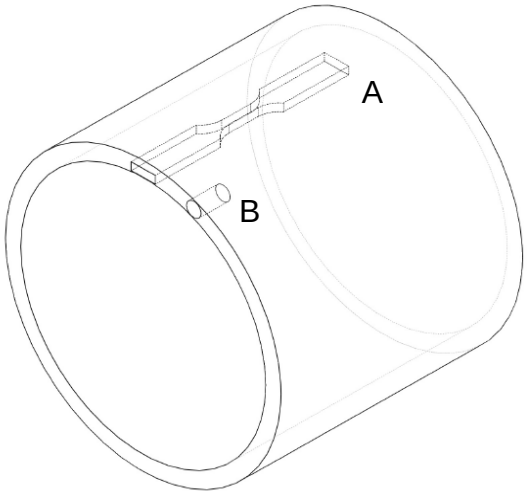

Figure 1. Tensile (A) and compression (B) specimens as obtained from the liner.

3. Computational efforts

3.1. Constitutive model

The main aspects of the TNM model constitutive framework will be described below, more details on the formulation can be found on the original works [14,15]. The TNM model consists of three networks acting in parallel as can be shown in the rheological representation (Fig.2)
The total deformation gradient of the assembly is decomposed into a thermal expansion component and a mechanical deformation component:

$$\mathbf{F}^{app} = \mathbf{F}\mathbf{F}^{th}$$

The mechanical deformation gradient of networks A and B are further decomposed into elastic and viscoplastic components:

$$\mathbf{F} = \mathbf{F}_n^e \mathbf{F}_n^v$$

Where *n* takes the value *A* and *B*, for networks *A* and *B* correspondingly. The Cauchy stress acting in networks A and B has the following form:

$$\boldsymbol{\sigma}_n = \frac{\mu_n}{J_n^e \overline{\lambda_n^{e*}}} \left[1 + \frac{\theta - \theta_0}{\hat{\theta}} \right] \frac{\mathcal{L}^{-1}\left(\overline{\lambda_n^{e*}} / \lambda_L \right)}{\mathcal{L}^{-1}\left(1/\lambda_L \right)} \mathrm{dev}\left[\mathbf{b}_n^{e*} \right] + \kappa \left(J_n^e - 1 \right) \mathbf{1}$$

Where, $J_n^e = \det[\mathbf{F}_n^e]$; $\mathbf{b}_n^{e*} = (J_n^e)^{-2/3} \mathbf{F}_n^e (\mathbf{F}_n^e)^{\mathrm{T}}$ is the Cauchy-Green deformation tensor; $\overline{\lambda}_n^{e*} = (\mathrm{tr}[\mathbf{b}_n^{e*}]/3)^{1/2}$ is the effective chain stretch and $\mathcal{L}^{-1}(x)$ is the inverse Langevin function.

The velocity gradient of networks A and B has the following form:

$$\dot{\mathbf{F}}_n = \dot{\chi}_n \mathbf{F}_n^{e-1} \frac{\mathrm{dev}[\boldsymbol{\sigma}_n]}{\tau_n} \mathbf{F}$$

Where:

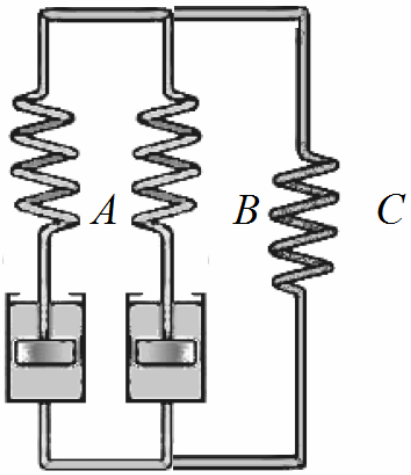

Figure 2. Rheological representation of the TNM constitutive model.

$$\dot{\gamma}_n = \dot{\gamma}_0 \left(\frac{\tau_n}{\hat{\tau}_n + aR(p_n)} \right)^{m_n} \left(\frac{\theta}{\theta_0} \right)^{n}$$

Here *R(x)* is the ramp function; p_n is the hydrostatic pressure; τ_n is the Fronebius norm of the deviatoric part of $\boldsymbol{\sigma}_n$.
The Cauchy stress acting in network C has the following form:

$$\boldsymbol{\sigma}_C = \frac{1}{1+q} \left\{ \frac{\mu_C}{J\lambda_{chain}} \left[1 + \frac{\theta - \theta_0}{\hat{\theta}} \right] \frac{\mathcal{L}^{-1}(\lambda_{chain}/\lambda_L)}{\mathcal{L}^{-1}(1/\lambda_L)} \mathrm{dev}\left[\mathbf{b}^* \right] + \kappa (J-1)\mathbf{1} + q \frac{\mu_C}{J} \left[I_1^* \mathbf{b}^* - \frac{2I_2^*}{3}\mathbf{I} - (\mathbf{b}^*)^2 \right] \right\}$$

Where $J = \det[\mathbf{F}]$; $\mathbf{b}^* = J^{-2/3}\mathbf{F}(\mathbf{F})^{\mathrm{T}}$ is the Cauchy-Green deformation tensor, and $\lambda_{chain} = (\mathrm{tr}[\mathbf{b}^*]/3)^{1/2}$
Finally, since they are in parallel, the three networks have equal mechanical deformation gradients and the total stress of the system is the sum of each network stress.

The TNM model was coded as a user material subroutine (UMAT/VUMAT) for ABAQUS and the constitutive parameters were determined using MCalibration software which uses a minimization algorithm based on the Nelder-Mead simplex method [17].

3.2. Liner-pipe system FEM model

The buckling collapse event was simplified assuming an ideal vacuum in the interior cavity of the liner and an increasing volume of fluid entering the liner-pipe cavity at a fluid flow rate *q*. This simplification has been made since this situation is easier to reproduce experimentally under controlled laboratory conditions. The event was simulated using ABAQUS/Implicit 6.10 for *q* values ranging from 10^{-5} to 10^{5} cm^3/s.

The thermoplastic liner was modeled as a planar bidimensional deformable solid (Fig.3a) using CPE8R elements and assuming plain strain, i.e. neglecting the effect of restraint at the liner ends. This assumption has proven to be valid for length to radius *L/R* values greater than 2 [18]. A small elliptical curvature was introduced in the upper part of the liner along the positive region of the

y-axis in order to induce single lob buckling (Fig.3b) in this region, which is the most critical failure mode and the most frequently observed in practice. Symmetry conditions were imposed with respect to the y-axis. The external metallic tube was assumed to be completely rigid in order to save CPU time. The fluid was modeled using F2D2 hydrostatic fluid elements and the depressurization event was modeled by imposing a fluid volume flux using the "fluid flux" option in ABAQUS/Implicit. These hydrostatic fluid elements are surface elements that cover the boundary of fluid containing cavity and provide the coupling between the deformation of the fluid-filled solid and the pressure exerted by the contained fluid on the solid surface defined as cavity boundary [19].

4. Results & Discussion

4.1. Uniaxial tensile and compression tests

Tensile and compression tests results are shown in Fig.5. In both cases, an initial time-independent elastic response can be observed. At a stress value of 5 MPa approximately the material enters the visco-elastoplastic regime, this region corresponds to the complex onset of different plastic flow mechanisms in the amorphous and semicrystalline domains of the thermoplastic material. In the constitutive model, the deformation gradients of the dashpots, which were at first negligible, start to flow at these stress values. Also in this regime, hardening is observed with increasing of strain rate, as expected. The material shows strain rate sensitivity both in tension and compression. Differences of approximately 30% in stresses are observed increasing 50 times the strain rate. Pressure dependency can be observed as the maximum stress achieved is higher in compression than in tension for equal deformation rates. A very good fit was obtained, with a R^2 (mean square difference) value of 1.5. The constitutive parameters obtained are presented in table 1.

4.1. FEM Simulations

Simulations predicted the buckling collapse pressure of the liner in all the range of q values. Fig 4 shows the final failure geometry in the simulations.

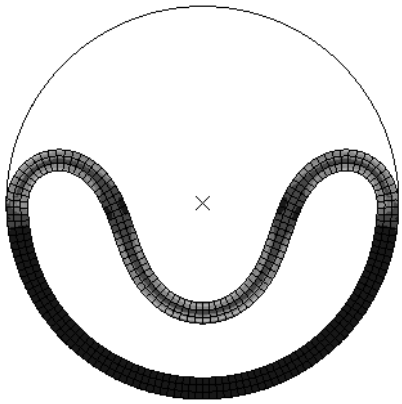

Figure 4. Final collapse geometry predicted by FEM simulations

Fig 6 shows the fluid pressure evolution as a function of fluid volume (V). Strain-rate dependency is manifested as it can be observed from the effect of increasing q values on fluid pressure, which are related to the speed at which the liner is accommodating deformation. Only at low values of V (up to V = 25 cm^3 approximately) a similar response can be observed for all q values, this is the initial elastic response which showed negligible strain-rate dependency as was noted in the tensile test results. In contrast, it can be seen that from V = 50 cm^3, higher q values lead to a more rapid increase in fluid pressure with fluid volume. This observation is consistent with the expected material stiffening as deformation rate increases (once in the visco-elastoplastic regime), meaning that, as the cavity is filled more rapidly, the liner can hold about the same volume of fluid at smaller deformations. This is done at the expense of the fluid high incompressibility, which therefore increases fluid pressure dramatically. Consequently, the maximum pressure attained, i.e. the collapse pressure, increases with q. Fig.7 shows the collapse pressure as a function of imposed flow rate. The logarithmic scale shows a potential relationship of the form $P_{max} = k.q^{RTF}$, where P_{max} is the collapse pressure, and *RTF* is a flow rate sensitivity exponent which ultimately characterizes the effect of material strain rate dependency on collapse pressure. The value of *RTF* is expected to be different for different materials, with *RTF* = 0 meaning a rate independent material. For the studied HDPE, the value of *RTF* obtained was approximately equal to 0.05. This factor can be of significant importance in the materials selection stage, when the values of expected depressurization velocities (v_{dep}) in service conditions are known. For this, a precise relationship between q and v_{dep} needs to be established. Furthermore, the possible influence of geometrical parameters such as the *t/D* ratio on the value of *RTF* still remains to be investigated.

Table 1. Constitutive parameters for the TNM model

Symbol	Name	Value
μ_A	Shear modulus of network A	40 MPa
λ_L	Chain locking stretch	1.02
$\hat{\theta}$	Temperature response of stiffness	-300 K
κ	Bulk modulus	2000 MPa
$\hat{\tau}_A$	Flow resistance of network A	2.07 MPa

a	Pressure dependence of flow	0.36
m_a	Stress exponential of network A	5.15
m_b	Stress exponential of network B	22.35
n	Viscosity parameter	40
$\hat{\tau}_B$	Flow resistance of network B	16.9 MPa
μ_{Bi}	Initial shear modulus of network B	259.3 MPa
μ_{Bf}	Final shear modulus of network B	60.51 MPa
μ_C	Shear modulus of network C	0.004 MPa
q	Relative contribution of I_2 of network C	zero

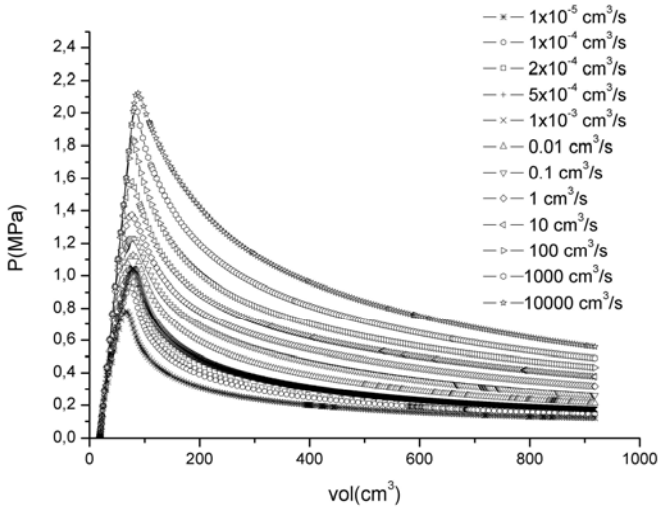

Figure 6. Evolution of fluid pressure, as a function of fluid volume in the liner-pipe cavity, for a wide range of fluid flow rates

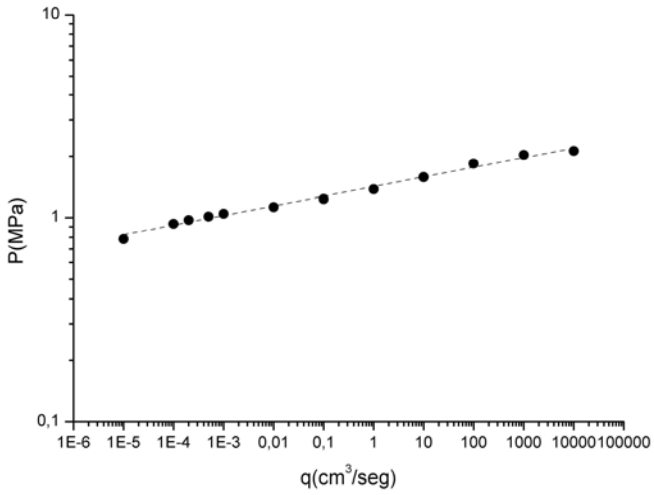

Figure 7. Collapse pressure as a function of imposed fluid flow rate.

5. Conclusion and forthcoming work

The external pressure-induced buckling collapse of thermoplastic liners was simulated using FEM analysis. The stress-strain response of the material and its intrinsic strain-rate and pressure dependency was modeled with the advanced TNM viscoelastic-viscoplastic model. Constitutive parameters were determined from tensile and compression stress-strain curves at different strain rates. The buckling failure event was simulated for a wide range of fluid flow rates. It was found that the material strain rate dependency has a significant effect on the collapse pressure P_{max} which leads to a potential relationship between P_{max} and q quantified by an exponent factor *RTF.* The value of *RTF* will vary with each material and quantifies the effect of strain rate dependency of the material on failure pressure. A forthcoming investigation will deepen the understanding of this factor and its dependence with the liner-pipe geometry. It also remains as future work to evaluate the prediction capability of the TNM model by comparing P_{max} FEM obtained values to empirical values determined under a controlled experimental setup.

Abstract This work presents an investigation of the ductile tearing properties for a girth weld made of an API 5L X80 pipeline steel using experimentally measured crack growth resistance curves. Use of these materials is motivated by the increasing demand in the number of applications for manufacturing high strength pipes for the oil and gas industry including marine applications and steel catenary risers. Testing of the pipeline girth welds employed side-grooved, clamped SE (T) specimens and 3P bend SE(B) specimens with a weld centerline notch and varying crack sizes to determine the crack growth resistance curves based upon the unloading compliance (UC) method using a single specimen technique. Recently developed compliance functions and η-factors applicable for SE (T) and SE(B) fracture specimens are introduced to determine crack growth resistance data from laboratory measurements of load-displacement records.

Keywords *J*-Resistance Curves, Ductile Fracture, SE(T) Specimen, SE(B) Specimen, Crack Growth

1. Introduction

Fracture mechanics based approaches to describe ductile fracture behavior in structural components rely upon crack growth resistance (J-Δa) curves to characterize crack extension followed by crack instability of the material. These approaches allow the specification of critical crack sizes based on the predicted growth of crack-like defects under service conditions. Current standardization efforts now underway advocate the use of single edge notch tension SE(T) specimens to measure experimental *R*-curves more applicable to high pressure piping systems, including girth welds of marine steel risers.

The primary motivation to use SE(T) fracture specimens in defect assessment procedures for this category of structural components is the strong similarity in crack-tip stress and strain fields which drive the fracture process for both crack configurations. However, while now utilized effectively in fracture testing of pipeline girth welds, some difficulties associated with SE(T) testing procedures, including fixture and gripping conditions, raise concerns about the significance and qualification of measured crack growth resistance curves. While slightly more conservative, testing of shallow-crack bend specimens (which is a nonstandard SE(B) configuration) may become more attractive due to its simpler testing protocol, laboratory procedures and much smaller loads required to propagate the crack.

This work presents an investigation of the ductile tearing properties for a girth weld made of an API 5L X80 pipeline steel using experimentally measured crack growth resistance curves. Use of these materials is motivated by the increasing demand in the number of applications for manufacturing high strength pipes for the oil and gas industry including marine applications and steel catenary risers. Testing of the pipeline girth welds employed side-grooved, clamped SE (T) specimens and 3P bend SE(B) specimens with a weld centerline notch and varying crack sizes to determine the crack growth resistance curves based upon the unloading compliance (UC) method using a single specimen technique. Recently developed compliance functions and η-factors applicable for SE (T) and SE(B) fracture specimens are introduced to determine crack growth resistance data from laboratory measurements of load-displacement records

2. *J*-Resistance Curve Measurements Based on the UC Procedure

2.1. Evaluation Procedure of the *J*-Integral

Conventional testing programs to measure crack growth resistance ($J-\Delta a$) curves in metallic materials routinely employ the unloading compliance (UC) method based on a single specimen test. A widely used approach (which forms the basis of current standards such as ASTM E1820 [1]) to evaluate *J* with crack extension follows from an incremental procedure which updates J_e and J_p at each partial unloading point, denoted *k*, during the measurement of the load vs. displacement curve as

$$J^k = J_e^k + J_p^k \tag{1}$$

where the current elastic term is simply given by

$$J_e^k = \left(\frac{K_I^2}{E'}\right)_k \tag{2}$$

and the current plastic term follows an incremental formulation which is applicable to CMOD data in the form [2,3]

$$J_p^k = \left[J_p^{k-1} + \frac{\eta_{J-CMOD}^{k-1}}{b_{k-1}B_N}\left(A_p^k - A_p^{k-1}\right)\right]\left[1 - \frac{\gamma_{LLD}^{k-1}}{b_{k-1}}\left(a_k - a_{k-1}\right)\right] \tag{3}$$

in which factor γ_{LLD} is evaluated from

$$\gamma_{LLD} = \left[-1 + \eta_{J-LLD}^{k-1} - \left(\frac{b_{k-1}}{W\eta_{J-LLD}^{k-1}}\frac{d\eta_{J-LLD}^{k-1}}{d(a/W)}\right)\right] \tag{4}$$

In the above expressions, K_I is the elastic stress intensity factor for the cracked configuration, A_p is the plastic area under the load-displacement curve, B_N is the net specimen thickness at the side groove roots ($B_N = B$ if the specimen has no side grooves where *B* is the specimen gross thickness), *b* is the uncracked ligament ($b = W - a$, where *W* is the width of the cracked configuration and *a* is the crack length). In writing Eq. (2), plane-strain conditions are adopted such that $E' = E/(1-\nu^2)$ where *E* and ν are the (longitudinal) elastic modulus and Poisson's ratio, respectively. Factor η_J appearing in Eqs. (3) and (4) represents a nondimensional parameter which relates the plastic contribution to the strain energy for the cracked body and *J*. Figure 1 illustrates the essential features of the estimation procedure for the plastic component J_p. Here, we note that A_p (and consequently, η_J) can be defined in terms of load-load line displacement (LLD or Δ) data or load-crack mouth opening displacement (CMOD or *V*) data. For definiteness, these quantities are denoted η_{J-LLD} and η_{J-CMOD}.

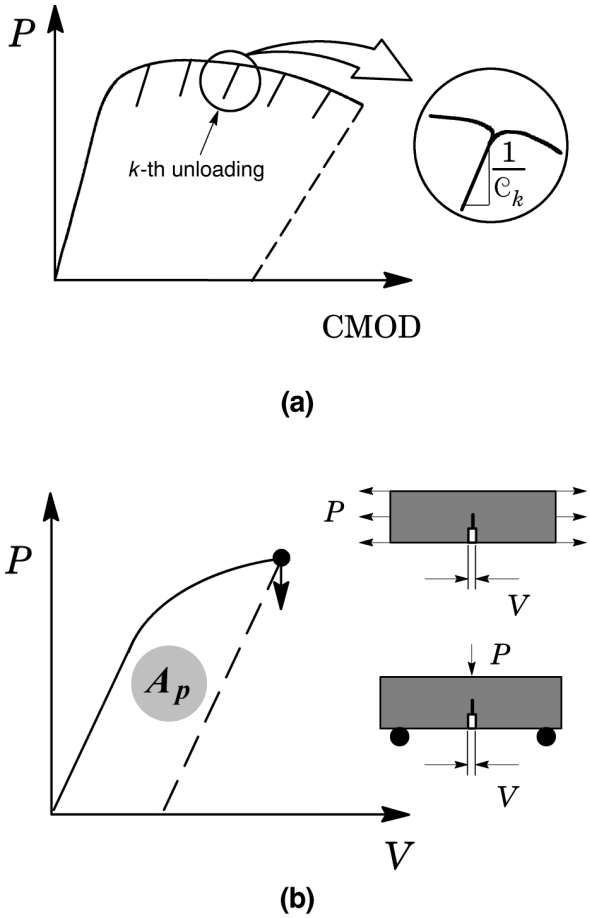

Figure 1. (a) Partial unloading during the evolution of load with crack mouth opening displacement (CMOD or *V*); (b) Definition of the plastic area under the load-displacement curve.

The incremental expression for J_p defined by Eq. (3) coupled with Eq. (4) contains two contributions: one is from the plastic work in terms of CMOD and, hence, η_{J-CMOD} and the other due to crack growth correction in terms of LLD by means of η_{J-LLD}. Evaluation of Eqs. (3) and (4) is relatively straightforward provided the two geometric factors, η_{J-CMOD} and η_{J-LLD}, are known. For the clamped SE(T) specimens with $H/W=10$ and the conventional SE(B) configuration utilized in this study, a convenient polynomial fitting of the results given by Cravero and Ruggieri [4], Ruggieri [5] and Donato and Ruggieri [6] provide the corresponding η-factor equations in the form

$$\eta_{J-CMOD}^{SET} = 1.067 - 1.767\frac{a}{W} + 7.808\left(\frac{a}{W}\right)^2 - 19.269\left(\frac{a}{W}\right)^3 + 15.295\left(\frac{a}{W}\right)^4 - 3.083\left(\frac{a}{W}\right)^5 \quad (5)$$

$$0.2 \le a/W \le 0.7$$

$$\eta_{J-LLD}^{SET} = -0.623 + 9.336\frac{a}{W} - 4.584\left(\frac{a}{W}\right)^2 - 47.963\left(\frac{a}{W}\right)^3 + 87.697\left(\frac{a}{W}\right)^4 - 44.875\left(\frac{a}{W}\right)^5 \quad (6)$$

$$0.2 \le a/W \le 0.7$$

$$\eta_{J-CMOD}^{SEB} = 3.650 - 2.111\frac{a}{W} + 0.341\left(\frac{a}{W}\right)^2 \qquad (7)$$

$$0.1 \le a/W \le 0.7$$

$$\eta_{J-LLD}^{SEB} = 0.020 + 18.086\frac{a}{W} - 72.256\left(\frac{a}{W}\right)^2 + 152.225\left(\frac{a}{W}\right)^3 - 159.769\left(\frac{a}{W}\right)^4 + 66.879\left(\frac{a}{W}\right)^5 \qquad (8)$$

$$0.1 \le a/W \le 0.7$$

2.2. Crack Extension Estimation

Current testing protocols to measure the crack growth resistance response using a single-specimen test are primarily based on the unloading compliance (UC) technique to obtain accurate estimates of the (current) crack length from the specimen compliance measured at periodic unloadings with increased deformation. Figure 1 illustrates the essential features of the method. The slope of the load-displacement curve during the *k*-th unloading defines the current specimen compliance, denoted C_k, which depends on specimen geometry and crack length. For the clamped SE(T) and SE(B) crack configurations analyzed here, the specimen compliance is most often defined in terms of normalized quantities expressed as [1,4]

$$\mu_{CMOD}^{SET} = \left[1 + \sqrt{EB_eC_{CMOD}}\right]^{-1} \qquad (9)$$

and

$$\mu_{CMOD}^{SEB} = \left[1 + \sqrt{\frac{EWB_eC_{CMOD}}{S/4}}\right]^{-1} \qquad (10)$$

where μ_{CMOD}^{SET} and μ_{CMOD}^{SEB} define the normalized compliances for the SE(T) and SE(B) specimens. In the above expressions, E is the longitudinal elastic modulus, C_{CMOD} denotes the specimen compliance defined in terms of crack mouth opening displacement ($C_{CMOD} = V/P$ where V is the CMOD and P represents the applied load) and the effective thickness, B_e, is defined by

$$B_e = B - \frac{(B - B_N)^2}{B} \qquad (11)$$

By measuring the instantaneous compliance during unloading of the specimen (see Fig. 1), the current crack length follows directly from solving the functional dependence of crack length and specimen compliance in terms of μ_{CMOD}. For the clamped SE(T) specimen and SE(B) configuration analyzed here, the corresponding compliance expressions follow from Cravero and Ruggieri [4] and ASTM E1820 [1] as

$$\left[\frac{a}{W}\right]_{SET} = 1.9215 - 13.2195\mu + 58.7080\mu^2 - 155.2823\mu^3 + 207.3987\mu^4 - 107.9176\mu^5 \quad (12)$$

$$0.1 \le a/W \le 0.7$$

$$\left[\frac{a}{W}\right]_{SEB} = 10.9997 - 3.9504\mu + 2.9821\mu^2 - 3.2141\mu^3 + 51.5164\mu^4 - 113.0310\mu^5 \quad (13)$$

$$0.1 \le a/W \le 0.8$$

3. Experimental Details

3.1. Material Description and Welding Procedures

The material utilized in this study was a high strength, low alloy (HSLA), API grade X80 pipeline steel produced as a base plate using a control-rolled processing route without accelerated cooling. The mechanical properties and strength/toughness combination for this material are mainly obtained by both grain size refinement and second-phase strengthening due to the small-size precipitates in the matrix. The 20-inch pipe with longitudinal seam weld from which the girth weld SE(T) and SE(B) specimens were extracted was fabricated using the UOE process.

The tested weld joint was made from the API X80 UOE pipe having thickness, $t_w = 19$ mm. Girth welding of the pipe was performed using the FCAW process in the 1G (flat) position with a single V-groove configuration in which the root pass was made by GMAW welding. The main weld parameters used for preparation of the test weld using the FCAW process are: i) number of passes 12 (including the root pass made by the GMAW process); ii) welding current 165 A; iii) welding voltage 23 V; iv) average heat input 1.5 kJ/mm. Mathias et al. [7] provide the tensile properties for the tested pipeline girth weld and base material which include: $\sigma_{ys}^{WM} = 715$ MPa, $\sigma_{uts}^{WM} = 750$ MPa, $\sigma_{ys}^{BM} = 609$ MPa, $\sigma_{uts}^{BM} = 679$ MPa. Here, σ_{ys} and σ_{uts} represent the material's yield stress and tensile strength, and WM and BM denote the weld metal and base plate. The degree of weld strength overmatch is ~18% so that mismatch effects on the measured crack growth resistance curves are very small.

3.2. Specimen Geometries

Unloading compliance (UC) tests at room temperature were performed on weld centerline notched SE(T) specimens with fixed-grip loading to measure tearing resistance curves in terms of $J - \Delta a$ data. The clamped SE(T) specimens have a fixed overall geometry and crack length to width ratio defined by $a/W = 0.4$, $H/W = 10$ with thickness $B = 14.8$ mm, width $W = 14.8$ mm and clamp distance $H = 148$ mm (refer to Fig. 2(a)). Here, a is the crack depth and W is the specimen width which is slightly smaller than the pipe thickness, t_w. UC tests at room temperature were also conducted on weld centerline notched SE(B) specimens with $a/W = 0.25$ with thickness $B = 14.8$ mm, width $W = 14.8$ mm and span $S = 4W$ (refer to Fig. 2(b)). Conducted as part of a collaborative research program conducted at University of São Paulo on structural integrity asssessment of marine steel catenary risers (SCRs), testing of these specimens focused on the

development of accurate procedures to evaluate crack growth resistance data for pipeline girth welds.

All specimens, including the SE(T) configuration, were precracked in bending using a three-point bend apparatus very similar to a conventional three-point bend test. After fatigue precracking, the specimens were side-grooved to a net thickness of ~85% the overall thickness (7.5% side-groove on each side) to promote uniform crack growth and tested following some general guidelines described in ASTM E1820 standard [1]. Records of load vs. crack mouth opening displacements (CMOD) were obtained for the specimens using a clip gauge mounted on knife edges attached to the specimen surface.

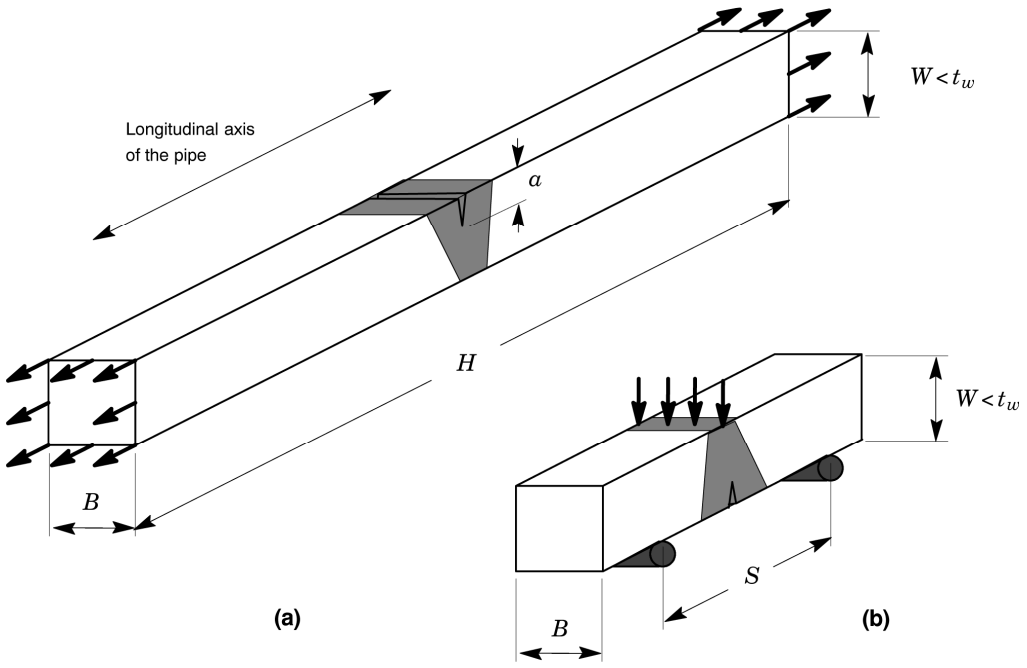

Figure 2.Geometry of tested fracture specimens with weld centerline notch. (a) Clamped SE(T) specimen with a/W = 0.4 and H/W = 10; (b) 3P SE(B) specimen with a/W = 0.25 and S/W = 4. All geometries follow (*BxB*) configuration

4. Crack Growth Resistance Curves

This section presents the crack growth resistance evaluated for the tested X80 pipeline girth weld based on laboratory measurements of load and CMOD for the clamped SE(T) specimens and the 3P bend SE(B) specimens with center notched welds. The geometrical features of each specimen type and the considered material properties were presented in the previous section. Figure 3 shows the measured load-displacement curve (*P vs.* CMOD) for both test specimens which clearly reveals the reduced test load for the SE(B) specimen compared with the SE(T) configuration.

Evaluation of the crack growth resistance curve follows from determining J and Δa at each unloading point of the measured load-displacement data. Based upon the previous results for the η-factors and compliance functions provided in previous Section 2, the present analysis employs η_{J-CMOD} and η_{J-LLD} to estimate the plastic component of the J-integral, J_p. Figures 4-5 present the measured crack growth resistance curves for the tested clamped SE(T) and 3P SE(B) specimens.

The significant features associated with these plots include: (1) The shallow-crack SE(B) specimen provides *R*-curves which exhibits levels of *J*-values which are comparable to the *J*-values corresponding to the deeply-cracked SE(T) specimen at a fixed amount of crack growth, Δa; (2) The value of the *J*-integral at onset of ductile tearing, J_{Ic}, is fairly independent of specimen geometry and loading mode.

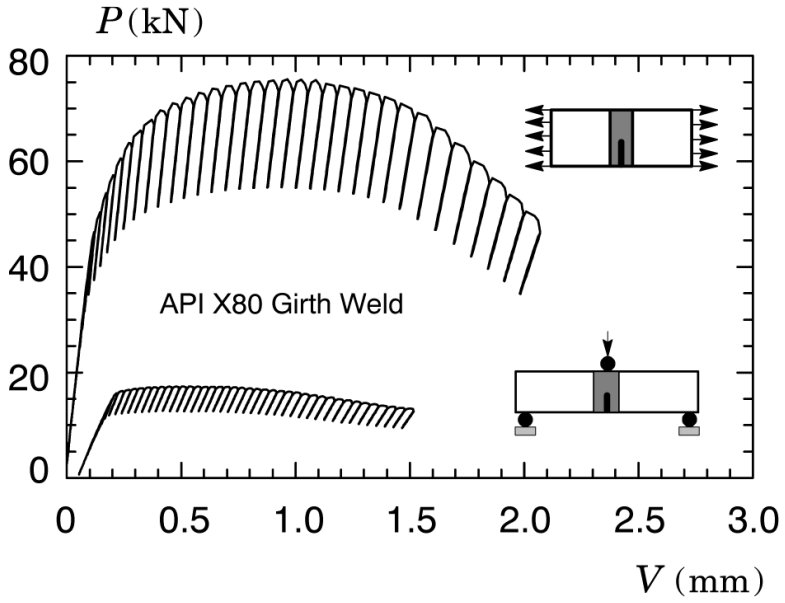

Figure 3. Measured load-CMOD curve for the tested X80 pipeline girth weld using clamped SE(T) specimens with $a/W = 0.4$ and 3P SE(B) specimens with $a/W = 0.25$.

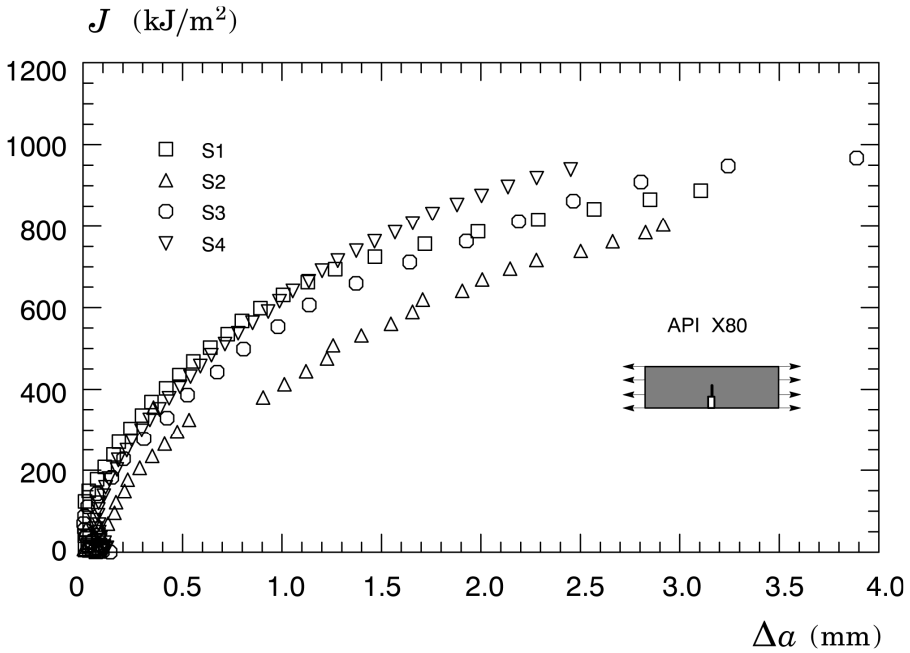

Figure 4. Experimental *R*-curves for tested clamped SE(T) specimens with $a/W = 0.4$

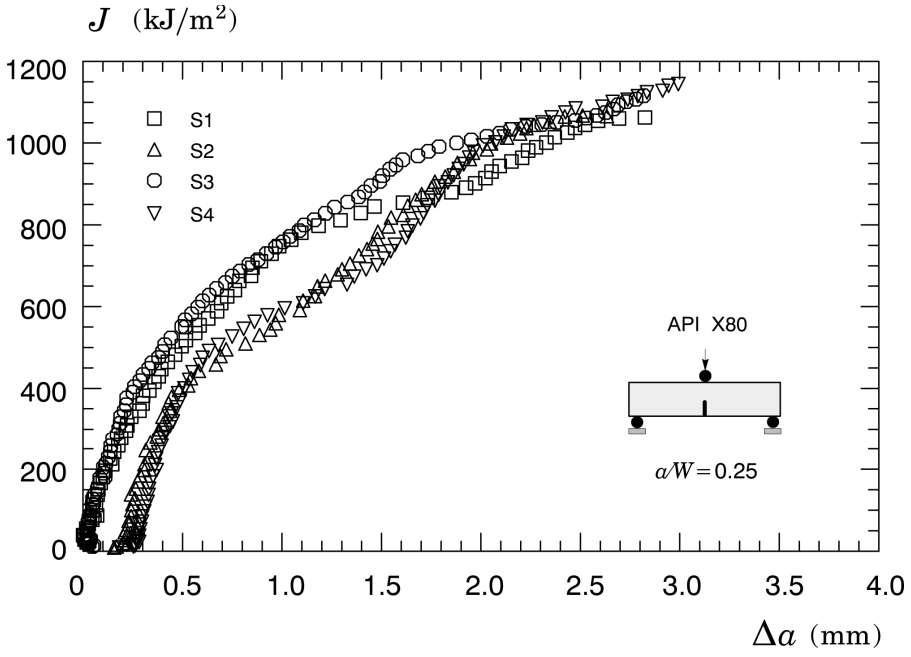

Figure 5. Experimental *R*-curves for tested SE(B) specimen with $a/W = 0.25$.

After testing, all specimens were subjected to heat tinting treatment (300°C for 30 min), and then air cooled before being broken apart. Table 1 shows a comparison of the predicted and estimated crack extension for the tested fracture specimens. For the SE(T) specimens, the deviation ($\Psi = \left|(a_{predicted} - a_{measured})/a_{measured}\right|$) is within 1.5~6.2% while for the SE(B) specimen, the accuracy is within 12~17%%. These results indicate that the UC procedure provides reasonable estimates of the final crack length for the SE(T) specimen. In contrast, crack length estimates for the SE(B) configuration display a somewhat larger deviation compared to the measured crack length; such behavior is mainly due to more severe crack front tunneling that occurred in these specimens.

Table 1. Crack length estimation based on UC procedure.

ID	a_0 (mm)	a_p (mm)		ψ (%)
		Measured	**Predicted**	
SE(B) Specimens				
S1	3.85	7.85	6.68	14.9

S2	6.11	8.06	8.56	6.2
S3	6.29	9.78	9.20	5.9
S4	6.70	10.75	10.59	1.5

5. Concluding Remarks

This work presents an investigation of the ductile tearing properties for a girth weld made of an API 5L X80 pipeline steel using experimentally measured crack growth resistance curves ($J-\Delta a$ curves). Testing of the pipeline girth welds utilized side-grooved, clamped SE (T) specimens and 3P bend SE(B) specimens with a weld centerline notch to determine the crack growth resistance curves based upon the unloading compliance (UC) method using a single specimen technique. This experimental characterization provides additional toughness data which serve to evaluate crack growth resistance properties of pipeline girth welds using SE (T) and SE(B) specimens with weld centerline cracks. Additional work is in progress to further validate the use of shallow-crack SE(B) specimens as an alternative fracture specimen to measure crack growth properties for pipeline girth welds. Ongoing investigation also focuses on establishing robust correlations between *J* and CTOD for stationary and growing cracks in SE(T) and SE(B) fracture specimens.

Comparison of different techniques for the monitoring of the Lüders bands development

J. Petit[1], D. Wagner[1], N. Ranc[2], G. Montay[3], M. François[3]

[1] LEME, EA4416, Université Paris Ouest, 92410 Ville d'Avray, France

In C-Mn and some low alloyed steels, the plastic deformation begins by a macroscopic heterogeneous strain which materializes into the propagation of a strain band along a tensile sample with a uniform cross-section. This band is named Lüders, or Piobert-Lüders, band and it is considered by some authors as a plastic wave. This particular strain localization, which goes through the length of the sample, is explained by an avalanche phenomenon which enables step by step to unfix the dislocations from their Cottrell's atmosphere. However, although its effects are well enough known, one knows much less its causes. In this paper, the travel of the Lüders band is monitored thanks to several techniques based on different physical principles: optical (speckle interferometry), thermal (infrared pyrometry) and acoustic (acoustic emission). The position of the band, its inclination, its propagation speed and the strain rate inside the band are the main points of comparison between each technique. They allow verifying some features about the propagation of the bands and giving some new assumptions about their formation and their development.

Keywords Lüders Band, Strain Localization, Infrared Thermography (IRT), Electronic Speckle Pattern Interferometry (ESPI), Acoustic Emission (AE), Tensile Test

1. Introduction

Plastic strain localization is a major problem in metalworking situations. In ductile metals, macroscopic plastic deformation heterogeneities such as Lüders bands [1-3], Portevin-Le Châtelier effect [4-6] or necking [7-10] can occur. Lüders bands and Portevin-Le Châtelier bands, in particular type A and type B, propagate in some metallic alloys for specific temperatures and strain rate conditions. This last localization phenomenon is described in many papers [11-14]. In ductile metals, the onset of necking is well referenced in literature and is particularly important for the characterization of the forming limit diagram [15-16].

Lüders bands propagation often occurs in hot-rolled low-carbon steels deformed or annealed at 300°C (static ageing). These bands are observed in ferritic phase of steels and form unaesthetic patterns on the material surface. They appear when the plastic deformation starts and disappear early. In uniaxial tensile test, Lüders bands propagate all along the gauge length of the specimen. Indeed, when interaction energy is strong between dislocations and solute atoms which can easily diffuse, like carbon and nitrogen atoms in iron, they gather around dislocations to form Cottrell's atmospheres. Dislocations are strongly anchored and a considerable stress is necessary to release them. Very often, this stress level is reached first in a point of the metal as the result of local effect of stress concentration, notably, in uniaxial tensile test, at the fillet radius with the specimen heads. Deformation remains localized in a narrow zone, corresponding to a Lüders band. The stress concentrations at the band front enable a gradual unlocking of the dislocations in the non-deformed part of the specimen. Thus, this process activates an avalanche that, from grain to grain, goes through all the polycrystal; there is band propagation [17-18]. Besides, the band propagates under a macroscopic stress, R_e^l, lower than the one, R_e^u, needed for initiation.

In order to go further concerning origins and activation modes understanding of this specific deformation mechanism, full-field measurements methods: Infrared Thermography (IRT) [19],

Electronic Speckle Pattern Interferometry (ESPI) and Acoustic Emission (AE) [3] are used, sometimes combined, and compared.

2. General experiments description

Lüders bands were studied during tensile test on two hot-rolled low-carbon steels: one S235 (0.16%wt Carbon) and one C35 (0.35%wt Carbon) according to the European standard. Both are centered cubic (cc) ferritic steels with pearlite. For the first one, propagation of the bands was followed by IRT. For the second one, propagation was followed by AE sole and by ESPI and AE simultaneously. Note that these two experiments were performed in two different laboratories, on two different tensile machines. One knows that the stiffness of the tensile machine can modify the Lüders bands generation and propagation. Here, machines are supposed stiff enough to have an insignificant influence on the Lüders bands behavior. In the future, coupling of the three investigation techniques is foreseen on the same machine.
Dog-bone like specimens with rectangular cross-section are used for the tests. The planar surfaces of the specimens are convenient for 2-D thermal and kinematics full-field measurements techniques and to fix acoustic sensors. The dimensions of the specimens are given on the Fig. 1. Although their influence was not studied here, curvature of the fillet radius are also reported.

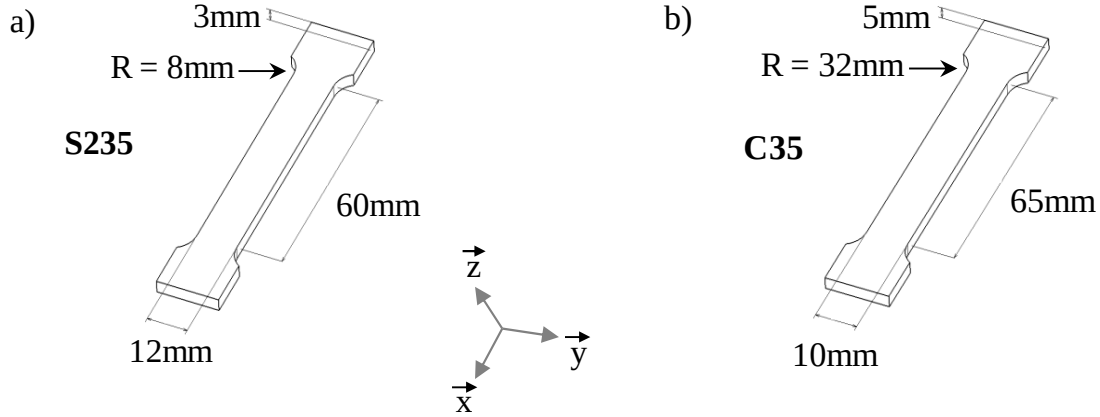

Figure 1. Scheme of the specimens: a) S235 and b) C35.

The initial microstructure of the as received materials is characterised by a grain size ranging between 10 and 15 µm for the S235 and 5 and 10 µm for the C35. The roughness of the S235 specimen is Ra / Rt ≈ 2.0 / 15 µm, the C35's one is Ra / Rt ≈ 5.3 / 35 µm.

3. IRT as Lüders bands following technique

3.1. Experimental procedure

Tests on the S235 steel were performed at 10 mm.min^{-1} on a hydraulic tensile machine with a 100 kN load cell. The stiffness of the machine is 156 kN.mm^{-1}. To characterize temperature increase due to the Lüders bands, specimens were placed in front of an infrared CCD camera. The camera model is a Cedip Silver Orion MW F/3 with InSb detectors. The size of the camera matrix and the spatial resolution are respectively about 320 x 256 pixels and 0.25 mm per pixel. The aperture time is fixed at 1000 µs. The refresh frequency of the camera is of 33 Hz, which corresponds to a duration between two pictures of 30.3 ms. Others acquisition parameters are given in Table 1. Under these conditions, the noise of the camera is about 25 mK. A calibration with a black body allows to deduce the links between the specimen surface temperature and the camera signal. In order to reduce the effect of the emmittance of the material surface, the samples were covered with black paint to get an emissivity close to 1.

Table 1. Acquisition parameters of the IRT device used during tensile test on the S235 steel.

Integration time	Frame rate	Bandwidth	Room temperature
1000 µs	33.33 Hz	3.7 - 4.8 µm	22.5°C

In most of metallic materials, during quasi-static tests at room temperature, plastic deformation goes with thermal energy dissipation, which is the result of dislocations movements inside grains. Another part, less important, of the mechanical energy brought to deform the sample is stored in the material. Thus, the temperature variation is related to the plastic deformation through the following relation [20]:

$$\rho c_p \dot{T} = \beta \underline{\underline{\sigma}} : \underline{\underline{\dot{\varepsilon}_p}} + \lambda \Delta T \quad (1)$$

where ρ is the density, c_p the specific heat, T the temperature, the symbol " $\dot{}$ " for the time derivative, β the Taylor-Quiney coefficient, $\underline{\underline{\sigma}}$ the stress tensor, $\underline{\underline{\dot{\varepsilon}_p}}$ the plastic deformation rate tensor, λ the thermal conductivity and the symbol Δ for the Laplacian.

More particularly, $\rho c_p \dot{T}$ represents the calorific power related to the atomic excitement. $\beta \underline{\underline{\sigma}} : \underline{\underline{\dot{\varepsilon}_p}}$ is the mechanical-thermal coupling term related to the dissipative thermal energy, which represents $100 \times \beta$ % of the energy creation inside the material; the other part corresponding to the stored energy. $\lambda \Delta T$ represents the thermal transfers by conduction.

During the Lüders band propagation and along an increment of plastic deformation, given the weak thermal conductivity of the S235 steel, the term $\lambda \Delta T$ in the Eq. 1 can be ignored such as the band propagation is adiabatic. Eq. 1 becomes:

$$\rho c_p dT = \beta \underline{\underline{\sigma}} : d\underline{\underline{\varepsilon_p}} \quad (2)$$

Consequently, if the constitutive law of the material is known, then the temperature variation is fully representative of the plastic deformation.

3.2. Thermal following of the Lüders band

The beginning of the tensile test (total strain under 10%) of the S235 steel followed by IRT is shown on Fig. 2. All the IRT images recorded during tensile test and shown in Fig. 2 were subtracted with the first image (0% of total strain) to get the temperature variation during the test. A constant scale with boundaries close to the max and the min values met through the 12 images sequence is chosen.

In the beginning of the tensile test, the temperature decreases. The associated homogeneous temperature variation is about -0.40°C until the upper yield stress R_e^u. Just before the upper yield stress (3rd image), a raising of the temperature corresponding to the beginning of the plastic deformation localization can be observed simultaneously near the two specimen edges. When stress is enough, a plastic deformation band, which makes growth the temperature on its way, leaves one side of the specimen to join the other one, deformation localization in the second edge fades; this phenomenon is typical of the Lüders band propagation.

On the 8th image, a second band is forming at the upper end of the specimen. But, this one will be rapidly absorbed by the main band. When the Lüders band stops, plastic deformation tends to become more and more homogeneous along the specimen.

The temperature recordings at the points 1, 2 and 3 (Fig. 2) show a sudden increase in the temperature when the band goes in front of the measurement point. After the band goes beyond each point, it can be remarked that the temperature remains constant, what means that neither elastic nor plastic strains take place; the specimen keeps the heat generated during the band passing.

Moreover, the amplitude of temperature reached after the band passing is observed to increase during the propagation, what means the properties of the Lüders band could change.

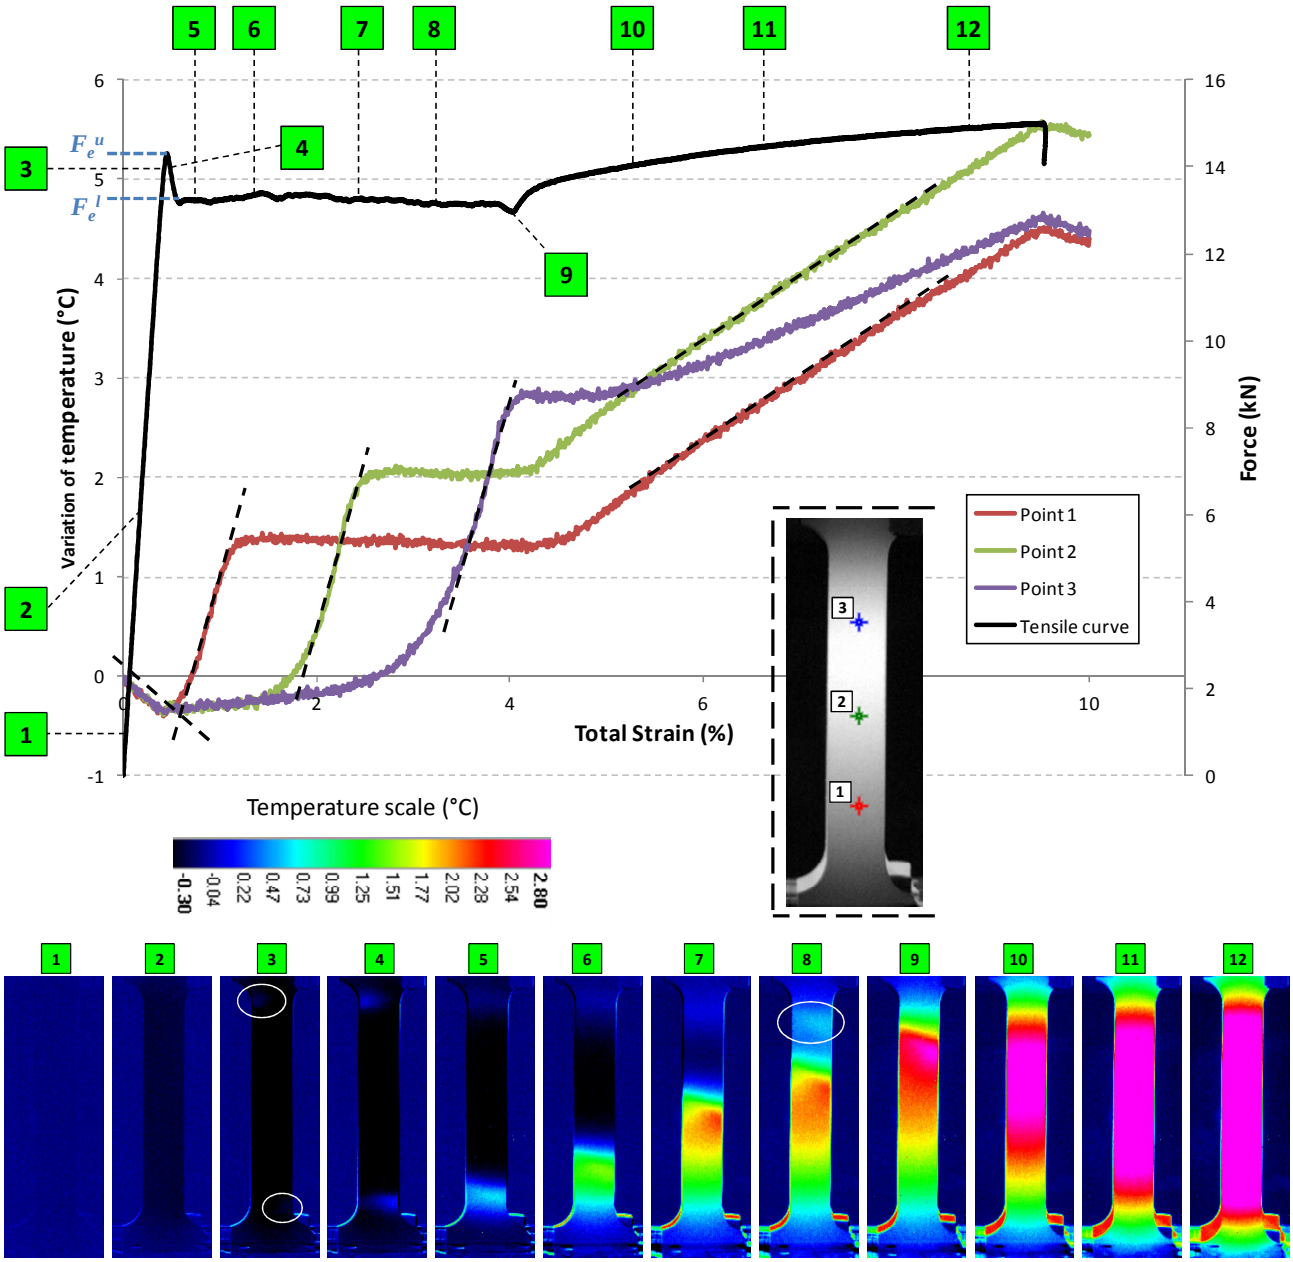

Figure 2. IRT maps obtained while the first 10% of total strain of a S235 steel. The tensile curve (black line) and the temperature evolution (red, green and blue lines) for three points placed on the specimen (see inset) are also depicted. The tensile forces F_e^u and F_e^l corresponding to the upper and lower yield stresses are showed on the tensile curve.

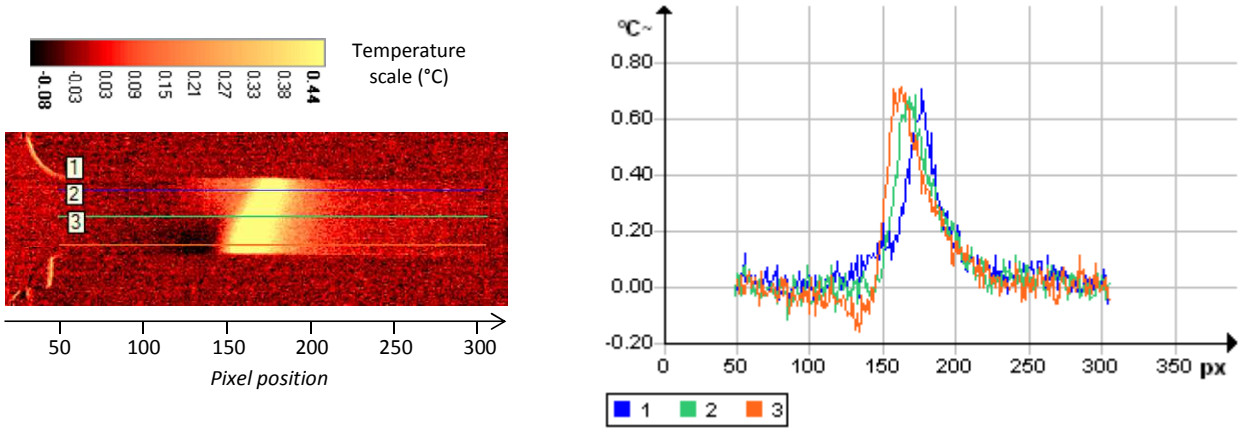
In order to be more sensitive to local variations of temperature on a short period, each image was subtracted with another one which arrives 0.6 s before. Fig. 3(a) shows the new type of obtained image. According to the IRT pictures, the velocity of the band propagation seems constant and approximately 24 times the crossbeam speed v_t. The inclination angle of the band varies hardly during propagation, it is mostly about 60° with respect to the tensile axis. For a given band position, temperature profiles of each line (Fig. 3) show maxima which don't superimpose, what proves the band is tilted.

The shape of the temperature profiles can be fitted by a Lorentz function, like proposed in [21], to deduce the maximum and the integral width of the band. It is found that the maximum is approximately 0.7°C and the integral width 11 mm. Both values strongly depend on the time

elapsed between the two subtracted images. In addition, this value is probably overestimated because of the conduction phenomenon which tends to spread the band.
It is also interesting to note the temperature profile associated to the line 3 on Fig. 3 presents a small negative hook to the rear of the band. This negative hook certainly corresponds to a tensile elastic stress which is higher in this zone than anywhere else. So, is it a consequence of the band propagation or does this tensile state contribute to the successive dislocations unpinning ? In addition, the temperature profile associated to the line 1 presents a small positive hook to the rear of the band. This one could correspond to an elastic compression state. By following this idea and by noticing that the temperature profile associated to the line 2 presents neither a negative nor a positive hook to the rear of the band, it can be assumed that the part of the specimen behind the band rotates.



(a) (b)

Figure 3. (a) Typical recomputed image (differences between two original images separated of 0.6 s) obtained during Lüders band propagation in a S235 steel. (b) Temperature profiles along three lines uniformly distributed through the specimen width (see (a)).

Finally, after the Lüders band passing, when the deformation is homogeneous in the specimen (last images on Fig. 2), the temperature is about constant on the whole surface of the gauge length of the specimen and raises much slower than during Lüders band propagation.

4. ESPI and AE as Lüders bands following techniques

4.1. Experimental procedure

Tests on the C35 steel were performed on a 150 kN capacity tensile machine at different crossbeam speeds. The experimental setup, mainly including the speckle interferometer, the acoustic sensors and the tensile machine, is presented on Fig. 4. The theoretical principles of ESPI and AE can be found respectively in reference books [22, 23] and [24]. At the sample scale, ESPI offers a better resolution, one or two orders of magnitude, on material displacements than DIC (Digital Image Correlation) or photoelasticity. Nevertheless, after surface coating preparation, DIC gives direct access to two sensibility vectors without additional equipment [2]. When sample surface is coated with birefringent resin, photoelasticity, as for it, allows to reveal naked-eye Lüders bands [25].
In the present case, the speckle interferometer setup is an in-plane sensitive configuration, known as a Leendertz set-up, with a sensitivity vector $\vec{s}$ parallel to the tensile direction. Speckle patterns are recorded on a CCD camera (1280 pixels × 980 pixels, monochromatic, 8 bits) with a 5µm spatial resolution. One of the mirrors is mounted on a piezo-electric transducer generating optical path differences by translation; it enables to get the phase of the interference pattern at all pixels of the image and obtain a better resolution on measured displacements (~25 nm in practice).

Note that no preparation of the surface of the specimens was performed for ESPI measurements. The surfaces were sufficiently rough to generate the speckle patterns and not too much to keep the plane surface hypothesis and avoid a premature localization.

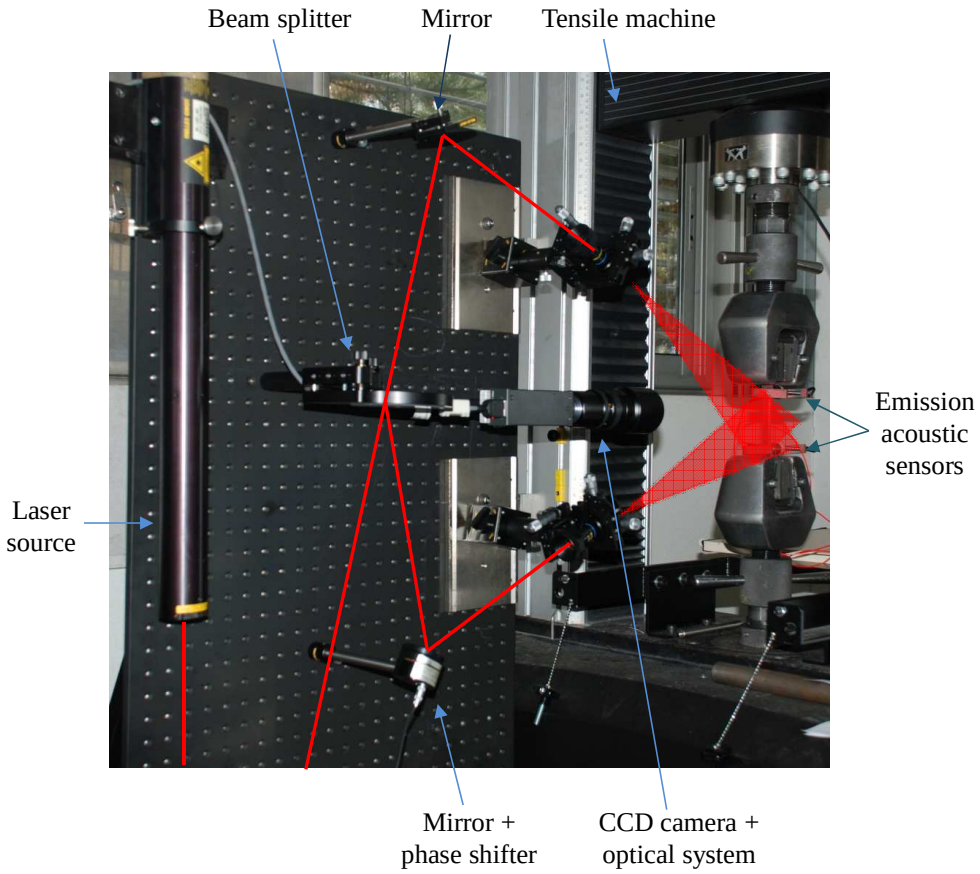


Figure 4. Experimental setup: in-plane speckle interferometer and micro-tensile machine. The laser beam path is schematized as a red line.

For AE measurements, two large-band (50 – 600 kHz) piezo-electric sensors were used. They convert acoustic signal into electric signal machine readable. These sensors are elastically maintained on the surface specimen with the same tension all along the test, Fig. 5. Because of the small size of the specimen heads, sensors are located near the fillet radius. To ensure the crossing of the acoustic wave between the specimen and the sensor, a coupling fluid (thixotropic gel) is inserted between both of them. The electric signal received by each sensor is amplified by a 40 dB pre-amplifier with a 1 MHz cut-off frequency, and then the electric signal is sent towards the acquisition card of the AEwin system (Euro Physical Acoustics). This latter gives intrinsic parameters related to the signals like amplitude, duration, energy, etc...

Many acoustic events do not come from the material been deforming, but they can come from the tensile machine working, slip of the sensors on the sample surface, micro-slips of the sample into the jaws, external noise… So, thanks to an acoustic events localization treatment, it is possible not to take into account those parasite events in the future analysis. The acoustic events localization requires at least two sensors set on the specimen and it enables to know, in our case, the position of the event sources along the gauge length of the specimen with an accuracy of about 5 mm. Given the small size of the specimens, the recorded signal for one acoustic event is a combination of the longitudinal wave, the transversal wave and possibly also some reverberated waves. For localization, longitudinal wave speed is considered, especially since the sensors are more sensible to this type of wave.

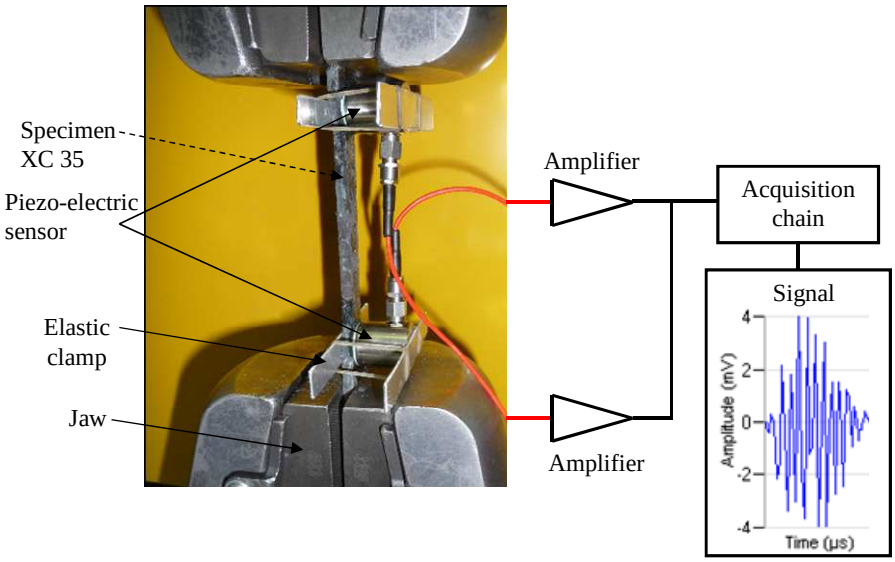

Figure 5. Scheme of the AE setup mounted on tensile specimen.

4.2. AE analysis

The Fig. 6, in a Event Amplitude versus Total Strain representation, shows all the detected events all along a tensile test performed at 0.5 mm.min^{-1}, with a signal amplitude higher than an arbitrary threshold (30 dB). It can be observed that until the disappearance of the Lüders band, a lot of events were detected. About 75% of the total acoustic activity corresponds to only 3% of the total strain, knowing that fracture occurs at 31.1% of the total strain. This observation is consistent with the fact of the band propagation produces a spectacular increase of the mobile dislocations density [26]. In the 5086-0 aluminium alloy [27], Baram also observed that deformation in the Lüders band region generated an high acoustic activity.

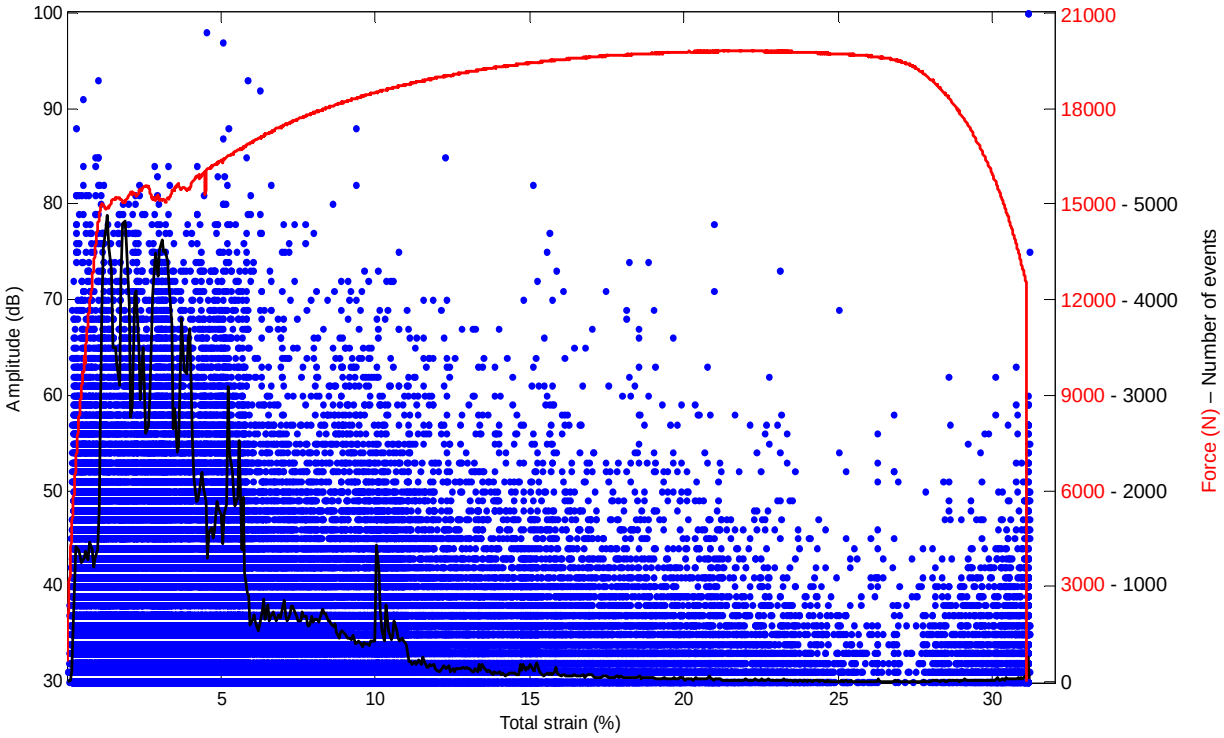

Figure 6. Amplitude versus Total Strain representation of the acoustic events recorded on the two sensors during tensile test of a C35 steel. The tensile curve (red line) and the number of events collected on a 5s time range (black line) are also depicted.

It can be highlighted that the number of events is very variable on a given short duration during the Lüders band propagation. AE activity shows important fluctuations and it can be remarked that this activity presents some intense local maxima when the tensile load presents local minima. Conversely, the AE activity presents some local minima when the tensile load presents maxima. Consequently, that means an important dislocation activity appears for each loading drop, as if each maximal local stress could unpin a lot of dislocations anchored in a certain neighborhood. This unpinning making fall down the stress, then it is necessarily to increase the tensile load again to set in motion dislocations fixed in a neighborhood adjacent to the previous one. That's why, during the reloading, the AE activity rapidly decreases because many less dislocations can move.

4.3. Localization treatment

Localization of the acoustic events along the gauge length of the specimen, Fig. 7, shows that the Lüders band propagation is followed with a good enough resolution, unlike the necking for example. As seen previously thanks to the IRT technique, strain localization occurs near both fillet radius at the end of the elasticity and then, a band with a high strain rate (= high density of events) propagates along the specimen.

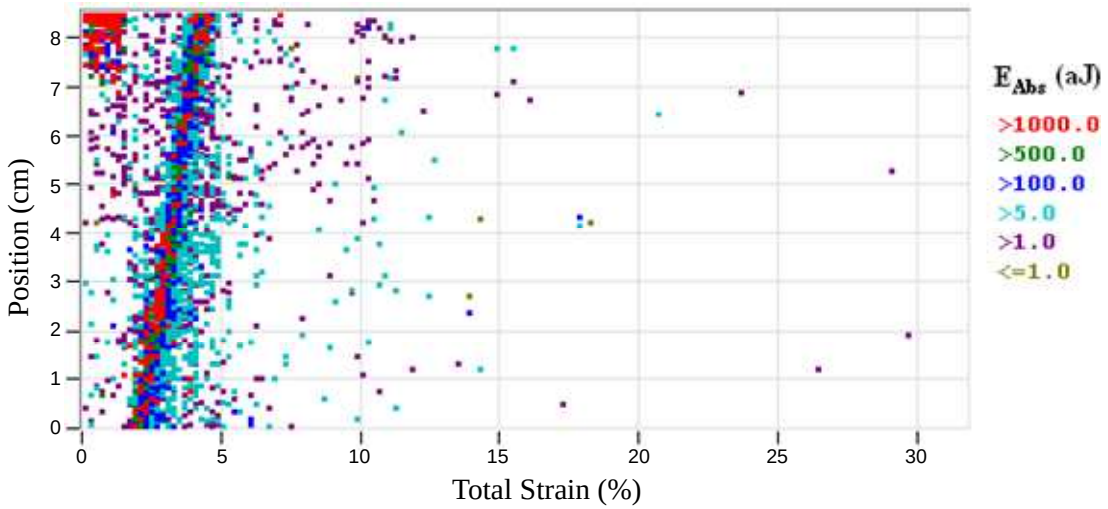

Figure 7. AE sources localization during tensile test on C35 steel.

Spatial distribution of the acoustic events is also correlated with their absolute energy. It can be observed that the most energetic events are localized at the band front. The reason is certainly due to a higher local dislocation activity, what is consistent with the dislocations avalanches which occur gradually at the band front. By keeping only events whose the absolute energy is higher than 500 aJ, a fortiori the most representative of the local strains, the standard deviation obtained on the Lüders band localization is less than 2 mm.

It can be noticed on Fig. 7, the band propagates at constant speed. This speed is about 40 times the crossbeam speed of the tensile machine. Others tests with a crossbeam speed varying between 0,02 and 1 $mm.min^{-1}$ on similar specimens led to the same result. Plekhov [28], in armco iron, finds also a linear dependence between the global deformation speed of the specimen and the propagation speed of the wave (Lüders band) where the plastic strains take place. In the SOLDUR 355 steel, Wattrisse [2] gets the same result.

4.4. AE – ESPI coupling results

To obtain good quality fringe patterns, crossbeam speed of the tensile machine was reduced to 0.02 $mm.min^{-1}$. All speckle patterns were saved manually, because of absence of automatic acquisition.

The Fig. 8 shows the very good correlation between both measurements techniques. As seen previously, at the beginning, plastic strains are localized in a fillet radius of the specimen (position between 0 and 1 cm). Then, when the stress is enough to activate gradually the slip systems in each grain of the gauge length of the specimen, deformation propagates at constant speed ($\approx 40 \times v_t$) by taking a localization band shape tilted of 58° with respect to the tensile axis.
It is interesting to note the inversion of the band inclination about half way (between fringe patterns 4 and 5 Fig. 8). This information can not be obtained with AE by using only two sensors. Thanks to the inclination angle measured on fringe patterns and the range of the AE zone along the specimen for a given total strain, it is possible to deduce the Lüders band width. This one is estimated to about 12 mm. Here, this value is not time dependent and about the same value was measured for different crossbeam speeds, in particular for the tests Fig. 7 (0.5 $mm.min^{-1}$) and Fig. 8 (0.02 $mm.min^{-1}$). Like for IRT, it is clear that Lorentz function applies on fringe patterns would give an integral band width depending on both the time elapsed to obtain these patterns and the crossbeam speed.
Fringes parallel to the tensile axis can be observed behind the band on several fringes patterns. These fringes, also parallel to the sensibility vector of the interferometer, show that the part of the specimen to the rear of the band rotates, as previously deduced by IRT. The same thing is more difficult to detect in front of the band, but these rotations can explain the AE activity outside of the band during its passing.

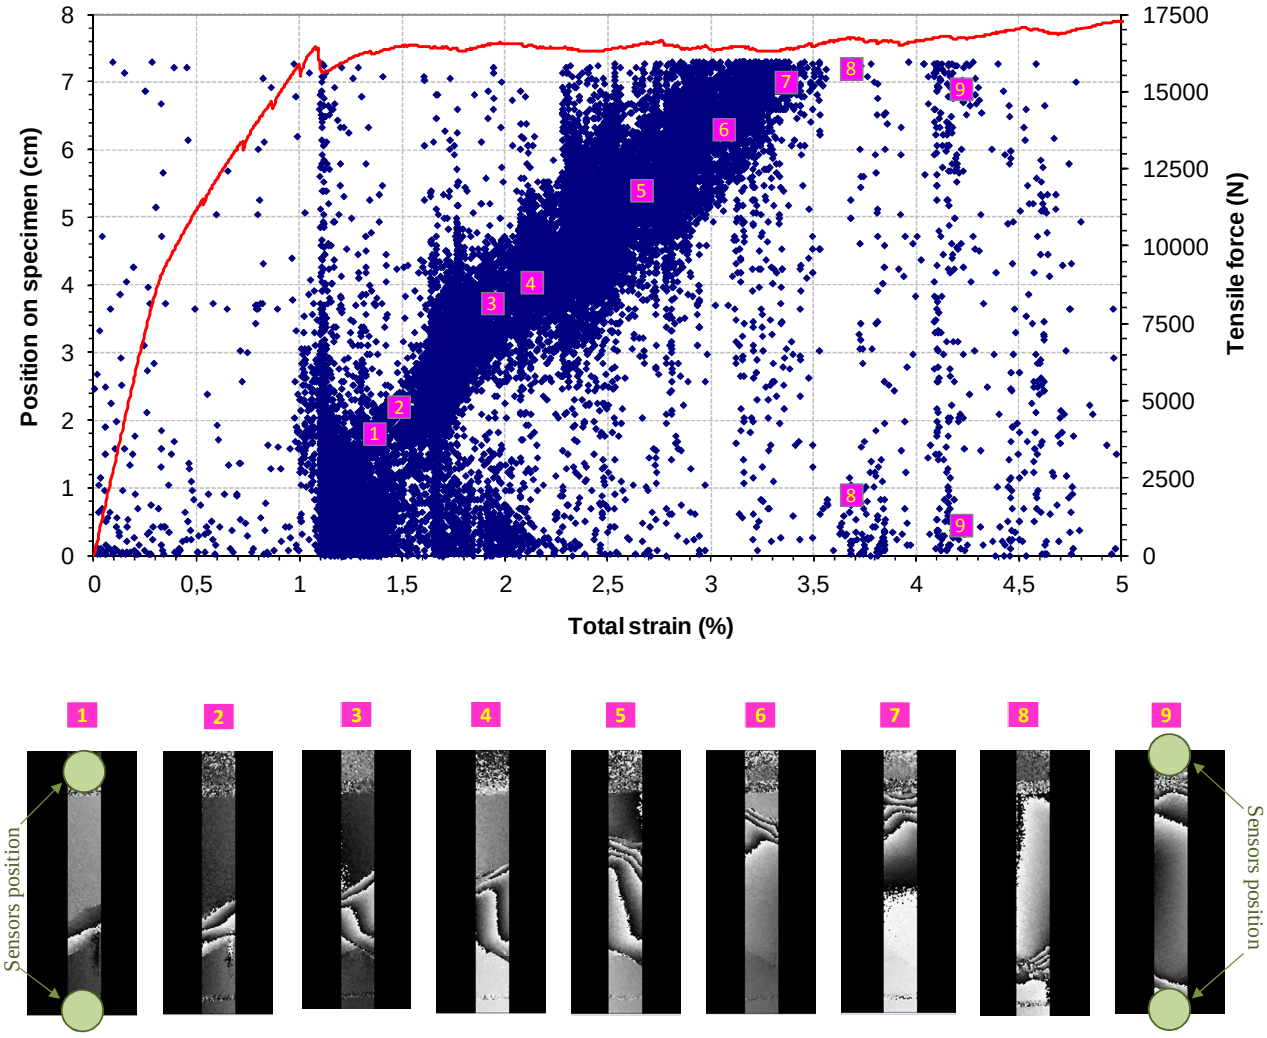

Figure 8. AE – ESPI coupling results collected while Lüders band propagation. The band position obtained by ESPI is reported on the AE data. A very good correlation is found between the two techniques.

Finally, by observing the evolution of the number of events on Fig. 6, one could think that the Lüders band propagates by jerks along the specimen, but according to ESPI results, the band propagation appears continuous. Indeed, it always exists a strain rate noticeably higher (presence of more close fringes) at the band front than in the rest of the specimen, on all fringe patterns, and it can be seen that the band front moves at constant speed from the ESPI pictures. However, jerky propagation of the band could not be measured if the break time or the slowing down of the band is less than the speckle patterns acquisition frequency.

5. Comparison and conclusion

The phenomenon of Lüders band propagation was investigated by three full-field measurements techniques: Infrared Thermography (IRT), Electronic Speckle Pattern Interferometry (ESPI) and Acoustic Emission (AE). Band features such as the ratio crossbeam speed / propagation velocity, inclination angle and band width were reported for a S235 steel by IRT and for a C35 steel by AE – ESPI coupling.

For the two materials, band propagation velocity is much higher than the crossbeam speed. Moreover, for the S235, the ratio crossbeam speed / propagation speed is more than the C35's one, what is consistent with a Lüders plateau greater in the case of the S235. In the two cases, it can be seen this ratio is approximately equal to the length of the plateau, *i.e.* data on S235 and C35 confirm the following equation given by Hähner [1]:

$$v_t = \varepsilon_p \times v_{BPL} \tag{4}$$

where v_t is the crossbeam speed, ε_p the plastic strain reached at the end of the Lüders plateau and v_{BPL} the Lüders band propagation velocity. This equation comes directly from an analysis of the propagation of the plastic front by assuming that the plastic strain is constant in the band and null outside, like shown in Fig. 9.

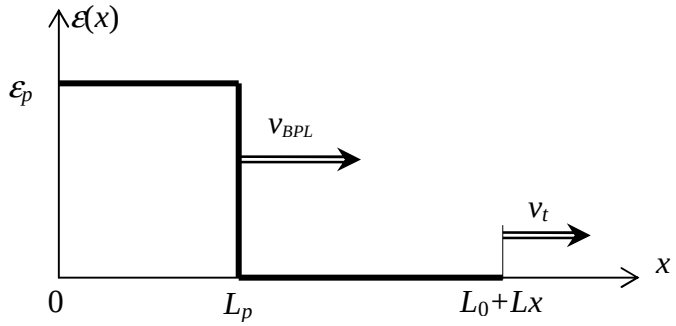

Figure 9. Scheme illustrating the propagation of the plastic front of a Lüders band.

So, the specimen elongation *Lx* would be only due to the propagation of the plastic front. AE measurements, Fig 7, confirm this hypothesis: there is only emission at the band front and, on each side of this front, there is a very weak acoustic activity, so no significant dislocation activity. When the length *Lp* travelled by the plastic front is equal to L_0+Lx (L_0: initial length of the specimen before the band apparition), the Lüders band crossed all the specimen and disappears.

The relation (4) was checked for the S235 at 10 mm.min^{-1} and for all experiments on C35 whatever the crossbeam speed between 0,02 mm.min^{-1} and 1 mm.min^{-1}, and it's found respectively : $\varepsilon_p = \frac{v_t}{v_{BPL}} \approx \frac{1}{24} = 4{,}1\%$ and $\varepsilon_p = \frac{v_t}{v_{BPL}} \approx \frac{1}{40} = 2{,}5\%$, what is close to the length of the experimental Lüders plateau on tensile curves (Fig. 2, Fig. 6 and Fig. 8). However, according to the temperature evolutions in front of the three points Fig. 2 and the relation Eq. 2, plastic strains inside the Lüders band could not be constant along the propagation and the modeling proposed in Fig. 9 would be unsuitable. More investigations have to be done.

For the two materials, the inclination angle with respect to the tensile axis is almost the same, 60° for the S235 and 58° for the C35. Nevertheless, this angle can vary and it was observed at the beginning of the test on the S235, the band was close to 90° and at half way of the band travel in the C35, the angle inverted, going from 58° to -58°.
Because of the movement of the band, it is difficult to measure a not time dependent band width. Yet, the AE – ESPI coupling allowed to introduce a way to determine a band width independently of the time and the crossbeam speed. But, accuracy of this method remains to define.
Concerning the band propagation, it was shown thanks to IRT, just behind the band, one part, the lower part for example, would be under purely elastic tensile stress while the other part, the upper part in this case, would be under purely elastic compressive stress. This particular mechanical state induces rotation of the part of the specimen located to the rear of the band. This assertion was confirmed by ESPI observations and, to a lesser extent, by AE.
Thanks to AE, important dislocations activity was observed during the Lüders band passing and correlation was found between the evolution of the dislocations activity and the tensile curve fluctuations. This serrated dislocations activity let think of a jerky propagation which seems in contradiction with ESPI and IRT (but on a different steel) measurements at the acquisition frequencies used. In fact, the bands determined by IRT and ESPI are obtained on time scales, relatively to the crossbeam speed, much smaller than the jerks measured by AE, what could explain the continuous aspect of the band get by IRT and ESPI, contrarily to the AE.
The following table, Table 2, summarizes the features of each technique and the measurements performed by.

Table 2. Technique features and possible Lüders band properties measurements.

Technique	**Type of propagation detected**	**Spatial resolution**	**Accuracy**	**Total strain rate (s^{-1})**	**Possibility of band inclination measurement**	**Possibility of band position estimation**	**Band velocity/ crossbeam speed ratio**
IRT	Continuous in S235 at 33Hz	0.25mm/pix	25mK on temperature	1.7×10^{-1}	Yes, 60° in S235	Yes	24
ESPI	Continuous in C35 at ~0.1Hz	5µm/pix	25nm on displacement 10^{-6} on strain	3×10^{-4} to 1.5×10^{-1}	Yes, 58°/-58° in C35	Yes	40
AE	Continuous but jerky at random time acquisition with a minimum interval of 2.10^{-5} s		±5mm on event localization		No with only 2 sensors	Yes	

At last, let's remind the two experiments were performed in two different laboratories, on two different tensile machines, with two different steels and at two different crossbeam speeds, what makes difficult the comparison between the techniques. Consequently, to refine this study, coupling of the three analysis techniques on the same material is being implemented.

Abstract The present work is devoted to the study of the anisotropic behavior of an extruded aluminum alloy under cyclic loading in axial and shear directions at room temperature. First, we have studied the elastoplastic behavior through the evolution of the isotropic and kinematic hardening evaluated considering the stress-strain loops in axial and shear directions. Second, we have investigated the fatigue damage of the material in both directions. The observed lifetimes seem rather short regarding the elastic shakedown obtained at the steady state.

Keywords: Anisotropic behavior, Extruded alloys, isotropic and kinematic hardening, cyclic plasticity.

1. Introduction

Aluminum alloys are frequently selected for many applications where low density and high strength-to-weight ratios are required. Thus, 2XXX series are currently being used as the main structure in components which are often subjected to cyclic loading. Therefore, we devote this work to the investigation of mechanical anisotropy in the cyclic behavior of aluminum alloy through stress controlled tests.

Many authors focused their work on the influence of microstructural and metallurgical states on the behavior of age hardened aluminum alloys during cyclic loading [1-6]. Furthermore, the anisotropy of mechanical behavior in metallic alloys during monotonic deformation was investigated by several authors [7-9]. Firstly, this anisotropy was discussed only for rolled or extruded alloys, such as metal sheets. Achani et al. [10] characterized the plastic anisotropy of extruded aluminum alloys 7003 and 6063 by uniaxial tensile testing and disc compression tests, showing that the increase of flow stress is directional and most significant for orthogonal sequences. On the other hand, some authors [11, 12] observed a strong anisotropic flow behavior between the rolling and transverse direction of rolled aluminum alloys during uniaxial tests. Recently, other authors have studied the effect of plastic anisotropy on the mechanical behavior of a rolled aluminum alloy 7075 [13]. They stated that the crystallographic texture and grain morphology gave rise to a strong plastic anisotropy in the rolled aluminum plate; they observed that the effect of plastic anisotropy is less for notched than for smooth tensile tests. Recently, Saï et al. [14] have focused their work on modeling the cyclic behavior of aluminum alloys. They up-dated the multi-mechanism models to be applied to anisotropic materials such as 2017 aluminum alloy.

The fatigue behavior of aluminum alloys under stress control tests has also been investigated for many years [3, 15, 16]. It has been shown that a microstructure strengthened by nonshearable and hard particles is usually preferable to resist more at fatigue crack initiation [17]. Similarly, Malekjani et al. [18] demonstrated the beneficial effect of precipitates at the core of the sample on the fatigue life during cyclic loading. Furthermore, according to [19, 20], fatigue evolution is not accompanied by any apparent modification of either the form or the aspect of the test specimen. Flaceliere et al. [21] studied the effect of shakedown phase on cyclic behavior of polycrystalline materials. They stated that the hardening saturation effect at the beginning of the fatigue lifetime and damage-induced softening at the end of fatigue lifetime describe all the cyclic behavior during loading. Despite all these studies, aluminum alloy anisotropy and its influence on the evolution of the cyclic behavior is not yet well investigated. Therefore, we devote the present paper to the following investigations performed on a 2017 aluminum alloy at room temperature:

- Study of the mechanical anisotropy in cyclic behavior through the stress-strain responses.
- Investigation of the cyclic hardening using the concept of isotropic and kinematic hardenings and their dependence on the loading direction.
- Correlation between the rate of isotropic hardening, elastic shakedown and fatigue lifetime.

This article is composed of three parts. The first section is devoted to the description of our experimental procedure, while the second section presents the results obtained about the cyclic behavior and their discussions. In the last section, the results obtained concerning fatigue damage evolution will be discussed.

1. Experimental procedure

1.1 Material

All the investigations carried out in this study were performed at room temperature using a 2017 aluminum alloy. The chemical composition is given in Table 1.

Table 1. Chemical composition of the material used (wt %)

Cu	Mg	Mn	Fe	Si	Zn	Ni	Cr	Al
3.9 – 4.0	1.1 – 1.2	0.7 – 0.8	0.5 – 0.6	0.6 – 0.7	< 0.21	< 0.16	< 0.10	Bal.

It is well-known that the hardening of this alloy arises from Al_2Cu and Al_2CuMg precipitation, provided that particles are finely and densely distributed. However, these precipitations lead to heterogeneity phenomena of the material that can generate anisotropy in mechanical behavior.

1.2. Specimens and experimental device

All the specimens were machined from solid bars extruded in the axial direction and a tubular shaped sample with two massive heads is used; its gage length is 46 mm in the central part where an extensometer of 25 mm gage length is installed. In this zone, the outer and inner diameters are 20 mm and 17 mm, respectively (Fig. 1), making it possible to have relatively thin tubes.

To ensure the same microstructural state of the material all specimens were heat treated according to a T3 thermal cycle (Fig. 2). The tests were performed with a MTS axial-torsional servo-hydraulic machine, an extensometer was used to measure the axial and torsional displacements in the central area of the specimen. The gage length of the extensometer is 25 mm for the shearing tests and 12 mm in tension/compression tests.

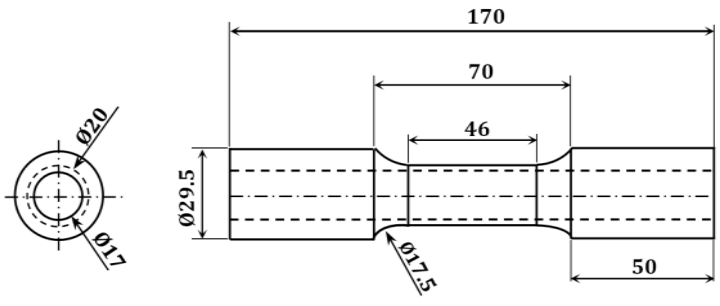

Figure 1. Geometry of the specimen used in the study

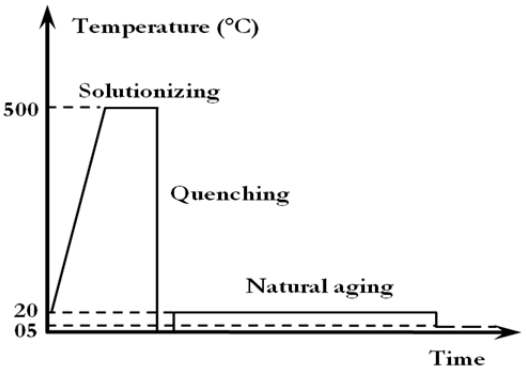

Figure 2. Sequences of the heat treatment applied to specimens

A permanent cooling of the specimen is applied during tests in order to remain close to room temperature and minimize the effect of heating due to the dissipation process observed under cyclic loading in the plastic domain.

1.3. Tests performed

Two types of stress-controlled tests were performed in this study. First, a cyclic tension-compression loading is applied with a zero mean stress (R = -1). In order to ensure a ‘‘perfect” uniaxial stress state, all the tests were performed under bi-axial controlled conditions, where the torque is set at zero (Fig. 3a). The second type is a cyclic shear tests applied with zero axial stress on six identical specimens (Fig. 3b). The applied frequency for both tests is 0.5 Hz during the first 400 cycles and 1 Hz after.

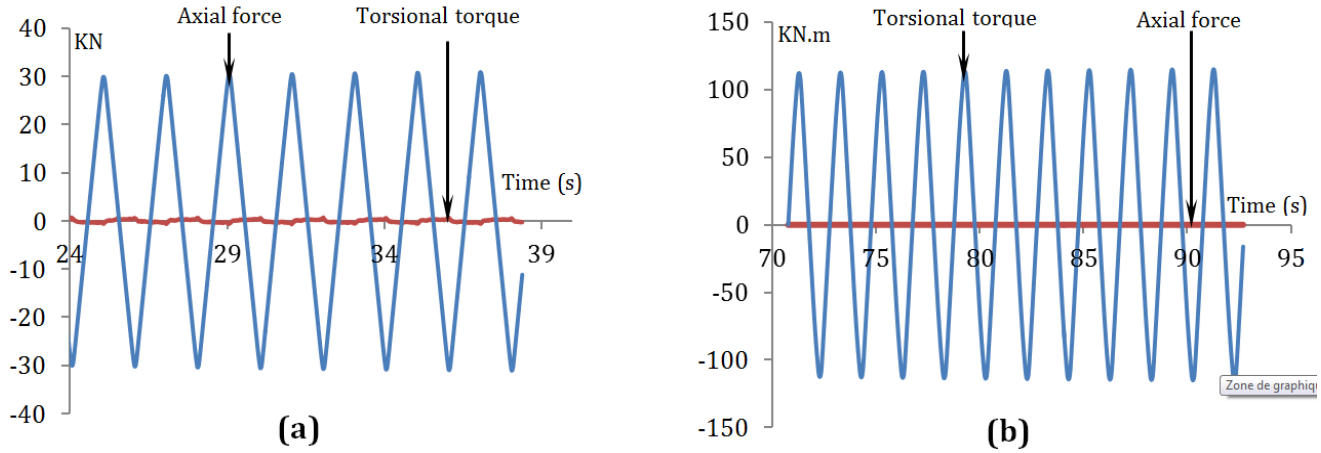

Figure 3. The two types of stress controlled tests performed in the study. (a) Cyclic tension-compression under zero shear stress; (b) Cyclic shearing stress under zero axial stress

The list of the tests performed in this study is shown in Table 2 where**:**

- σ_{zz} : is the maximum stress applied in tension – compression.
- $\sigma_{\theta z}$: is the maximum stress applied in shearing.
- σ^{eq} : is the equivalent maximum shearing stress using Von Mises criterion.

Note that the equivalent shearing amplitudes were calculated using Von Mises criterion.

Table 2. List of the tests performed in this study

Tension-compression tests		Shearing tests			
σ_{zz} (MPa)	Reference	Torque (N.m)	$\sigma_{\theta z}$ (MPa)	σ^{eq} (MPa)	Reference
240	ax240	80	98	170	sh80
260	ax260	90	110	190	sh90
280	ax280	100	122	211	sh100
300	ax300	110	136	235	sh110
320	ax320	120	148	256	sh120
340	ax340	130	160	277	sh130
360	ax360				

2. Results of the cyclic behavior

Before the analysis of the cyclic behavior, let us first see the evolution of lifetimes obtained under the axial and shear directions in Fig. 4.

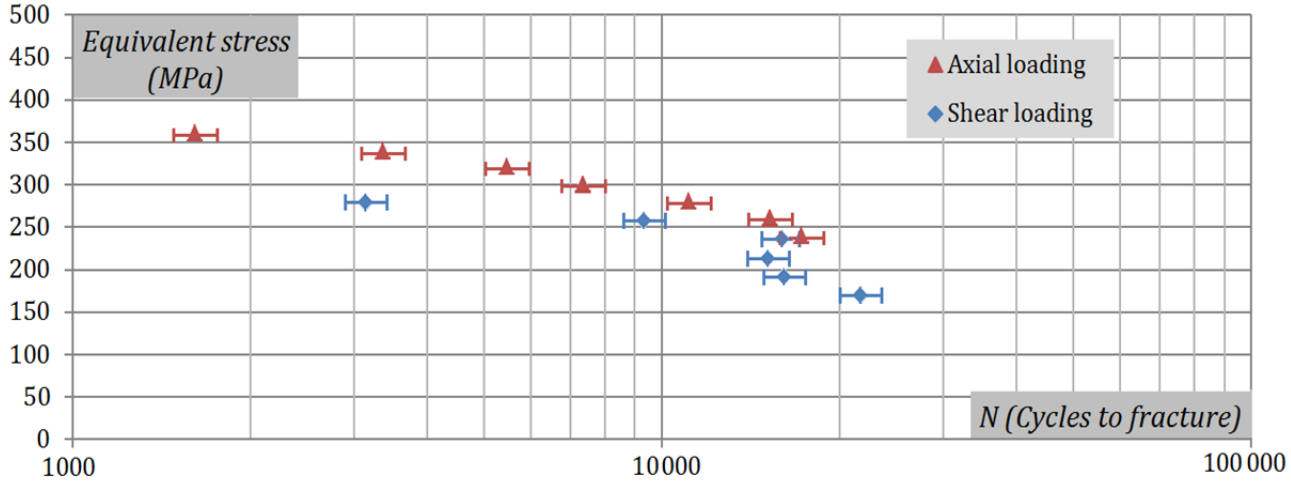

Figure 4. Wohler curve of a 2017 aluminum alloy for the axial and the shear loadings.

Note that each point of these curves represents the average result of at least two tests. Indeed, we have a more or less linear increase in the number of cycles to failure, when the applied maximum stress decreases. According to the two curves presented in Fig. 4, we can also remark anisotropy between the two directions in fatigue life. In fact, we notice a significant difference between lifetimes in axial and shear directions. Indeed, for the same equivalent stress amplitude, lifetime in the axial direction is higher compared to that in the shear direction. However, one can expect the opposite observation in case of strain control.

2.1. Test results under axial loading

To better represent the evolution of the stress-strain loops, we plot for each test and in the same graph the first and the stabilized loops. The first loop is taken when the maximum set-point stress is reached. The stabilized stress-strain loop is chosen at mid-life where the strain hardening does not evolve significantly. In Fig 5, we depict six graphs representing axial tests.

2.2. Test results under shear loading

In Fig. 6a, we depicted the equivalent stress versus the equivalent strain, where the maximum stress in Von Mises equivalence is 277 MPa. In this case, we have the plastic flow which remains high even in mid-life. However, in Fig. 5a, the maximum axial stress is 360 MPa, the plastic flow decreases gradually until it stops before mid-life and the behavior becomes almost elastic. This behavior suggests the anisotropy of the material between the axial and shear directions.
Such anisotropy appears also in the yield stress given in Table 3 where the axial elastic limit is 207 MPa while the equivalent shearing one is only 142 MPa. This behavior will be discussed in more details in the next section.

Table 3 Mechanical properties of the 2017 aluminum alloy determined from monotonic loading

Axial yield stress at 0.01%	Axial yield stress at 0.2%	Young's modulus E	Equivalent shear yield stress at 0.01%	Coulomb's modulus G
207 MPa	284 MPa	72 GPa	142 MPa	23.5 GPa

2.3. Discussion

To study the cyclic behavior of 2017 aluminum alloy in plasticity, we have to investigate the evolution of the elastic domain in the stress space which is usually represented by a translation of its center (kinematic hardening) and the expansion (isotropic hardening) of its size. In the case of isotropic material, the yield surface expands generally in a homogeneous manner all over the

directions. However, this behavior remains debatable for the majority of aluminum alloys under a high stress loading.
As it is not an easy task to identify the linear part of the stress–strain diagram and therefore the elastic domain, we have admitted a small equivalent plastic strain offset equal to 0.0001. The isotropic and kinematic hardening variables were evaluated in each cycle using the same formulation used in [22]**.** In Fig. 7, we show how the isotropic and kinematic cyclic hardening variables are estimated according to:

$$\begin{cases} |\sigma_{max} - X| - R - \sigma_y = 0 \\ |\sigma_{off} - X| - R - \sigma_y = 0 \end{cases} \text{ And since } \begin{cases} \sigma_{max} - X > 0 \\ \sigma_{off} - X < 0 \end{cases} \qquad \text{Then, } \begin{cases} R = \frac{\sigma_{max} - \sigma_{off}}{2} - \sigma_y \\ X = \frac{\sigma_{max} + \sigma_{off}}{2} \end{cases}$$

R and X represent a first approximation of the isotropic and kinematic hardening variables respectively; σ_{max} is the maximum equivalent stress reached in the considered cycle while σ_y is the initial elastic limit deduced from the first cycle. σ_{off} is the stress corresponding to 0.0001 of plastic strain offset obtained during the unloading (see Fig. 7a). In Fig. 7b, we depicted two experimental examples. The obtained results are given in Fig. 8 and Fig.9.
According to the results obtained under axial loadings, we note that the increase of R is slightly high during the first cycles, where the maximum stress set-point is reached (Fig. 8a); this progression seems to be less important after the 40 first cycles, which depends strongly on the maximum stress of each test. However, the X variable decreases in all the tests (Fig. 8b), especially when the maximal applied stress is slightly high.

The same work was done for shear loading; the obtained results are plotted in Fig. 9 which shows that shear loading leads to more kinematic hardening than the isotropic one when the maximum applied shear stress is relatively small. But when the shear stress is relatively high, we obtained a significant hardening for both isotropic and kinematic types.
Comparing the two types of the tests, we deduce once again a relatively significant anisotropy in cyclic behavior. In fact, the isotropic hardening increases cyclically in the two directions of the tests but more significantly in the axial one. Furthermore, kinematic hardening decreases in both directions but more significantly in the axial one.

The amount of anisotropy obtained in the two directions of loading can be attributed to the nature and the size of dispersed precipitates in the alloy. This anisotropy is even larger when the maximum stress is high, because of the increase in the resistance of the precipitates to the dislocation movements which become more and more dense.

Furthermore, we can notice that the evolution of isotropic hardening may be correlated with the evolution of the shakedown limit. In order to understand this relationship, we have to investigate the behavior of our material in shakedown phenomenon where the mechanical behavior becomes purely elastic. The plastic strain is used to estimate the shakedown occurrence. We assume that:
$\varepsilon = \varepsilon^e + \varepsilon^p$ where ε^e and ε^p are respectively the elastic and the plastic strains.
With this assumption, we estimate the plastic deformation at any point of the stress-strain loops. Then, we assume that shakedown state is reached when the plastic strain of a given cycle is less than 0.0001. This is a reasonable assumption, since beyond this limit, it becomes very difficult to assess both isotropic and kinematic hardening (R and X). The procedures presented in **Error! Reference source not found.** illustrate the method used to determine the occurrence of the shakedown phenomenon from the stress-strain loops and from the ε^p versus number of cycle curves. However, when the maximum stress is too high, the behavior may be different. Indeed, the plastic strain reaches a periodic stabilized limit state; this phenomenon is referred as plastic

shakedown.

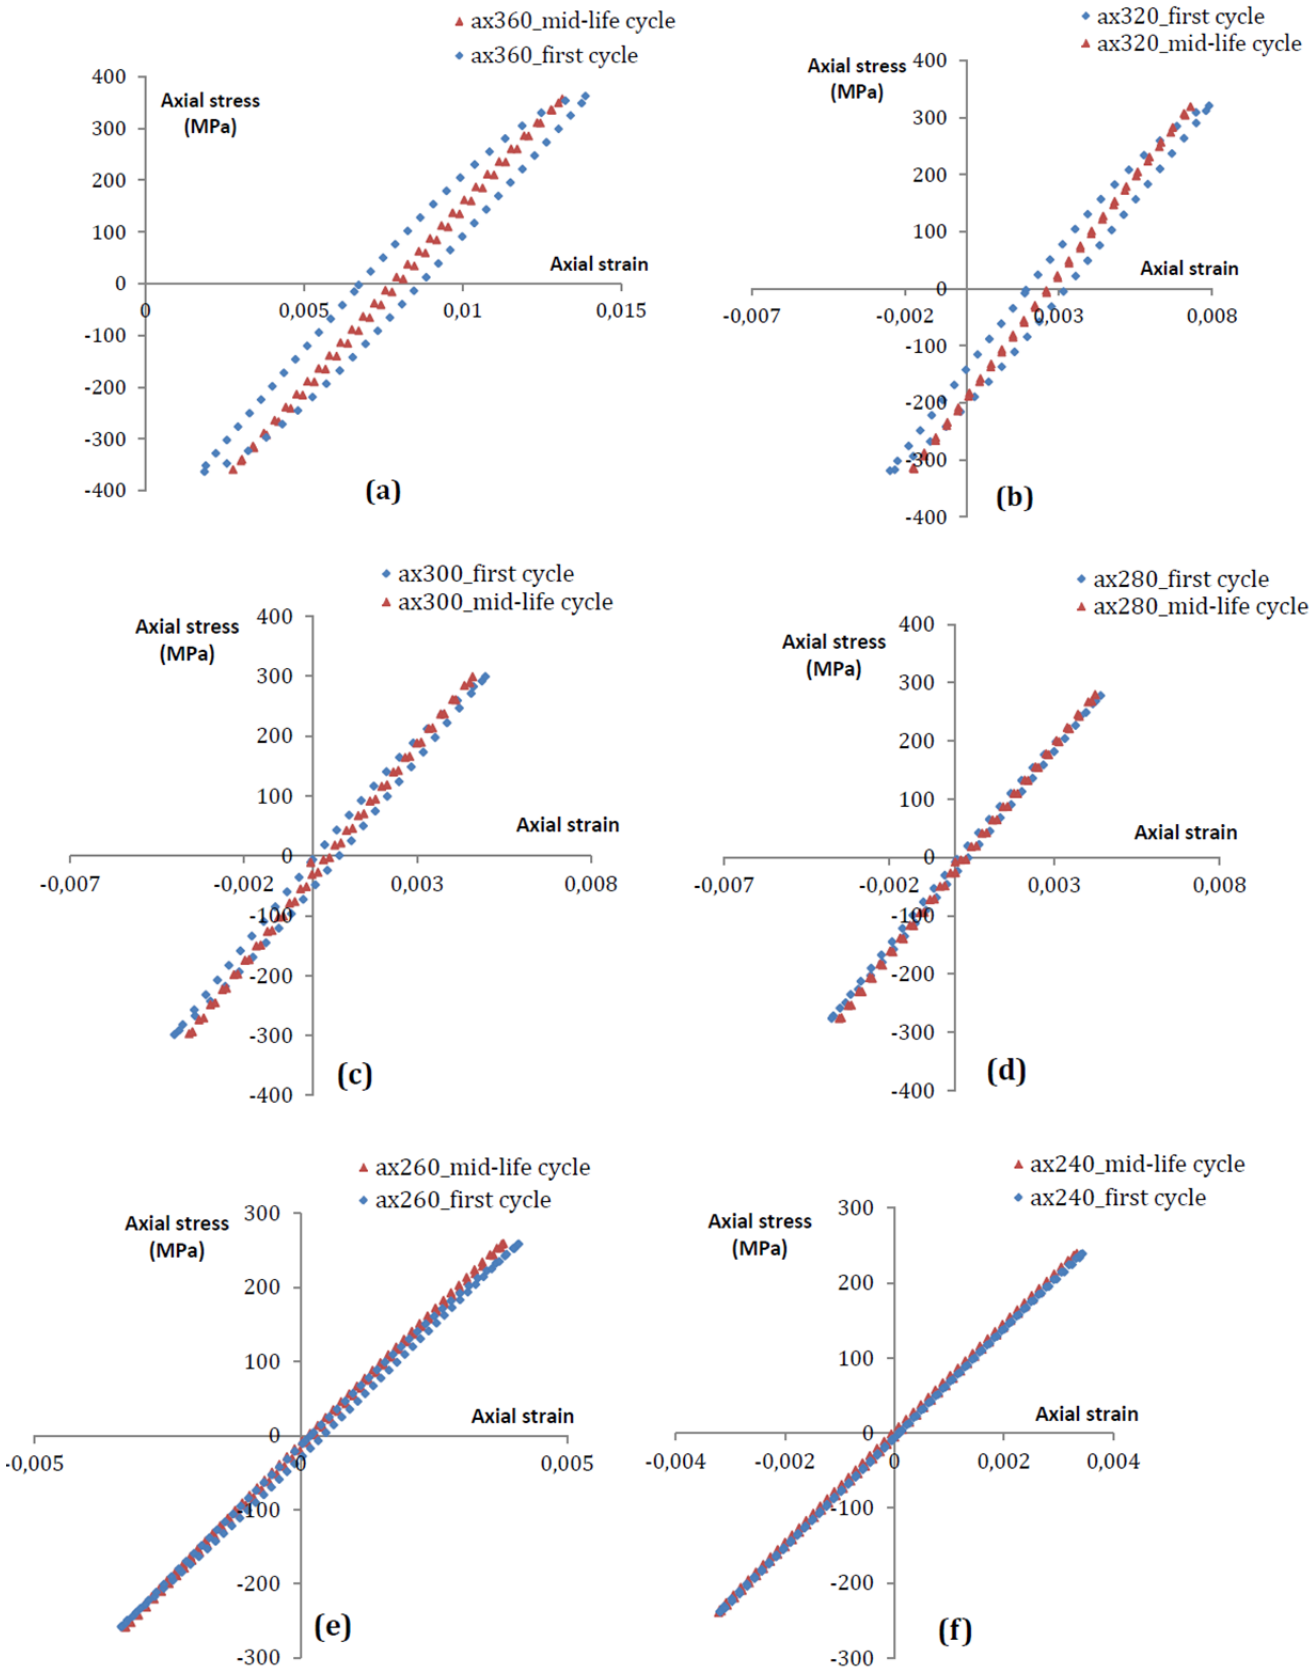

Figure 5. Axial stress–strain loops (first and mid-life cycles)

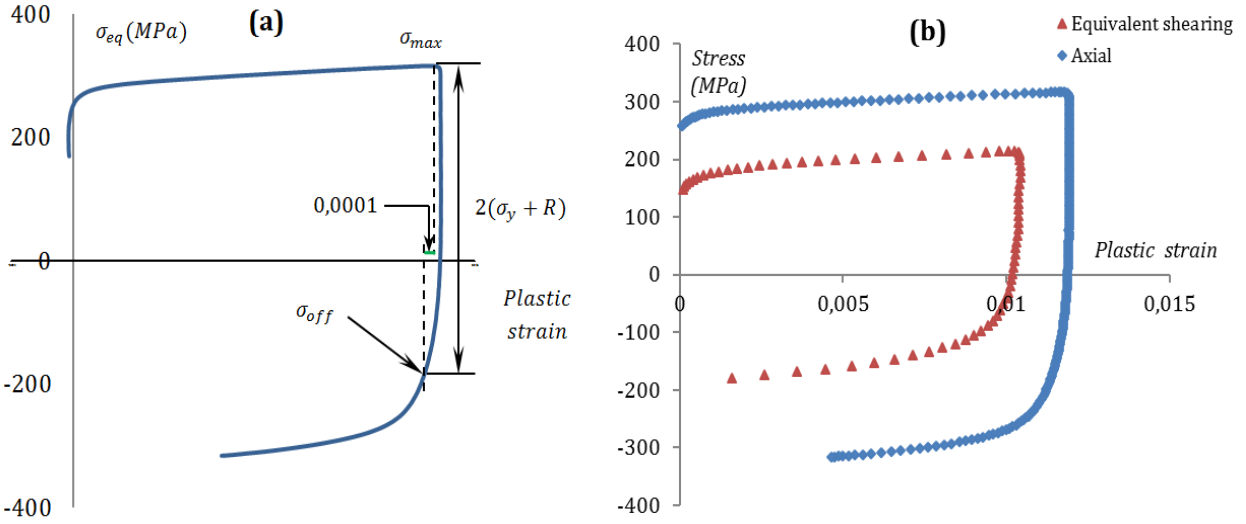

Figure 7. Evaluation of isotropic and kinematic hardenings: (a) Method of determining σ_{off} and σ_{max} (b) Experimental examples responses of the two test types performed in the present work

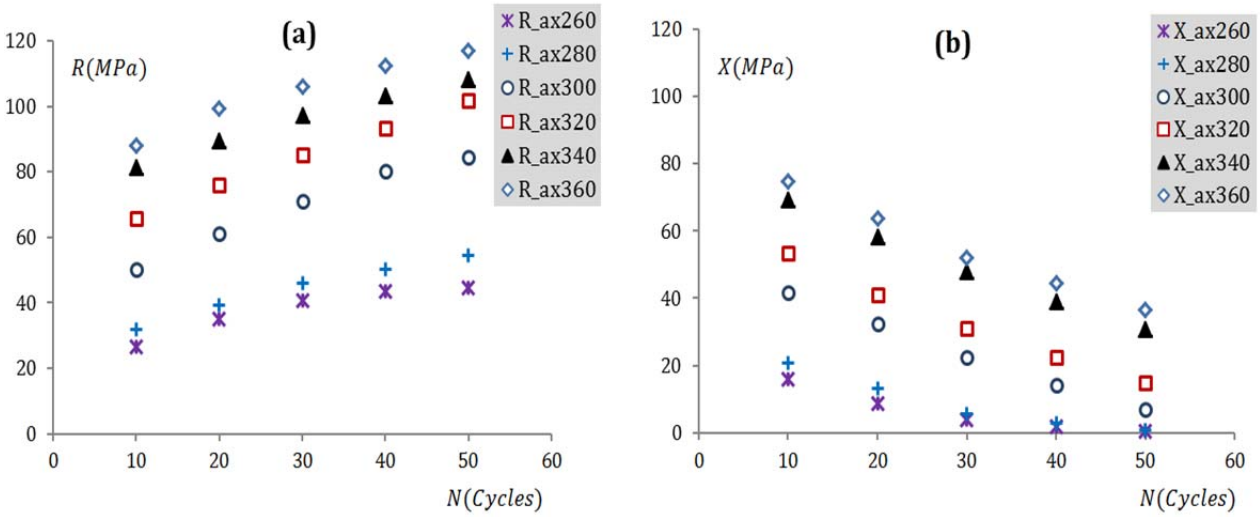

Figure 8. Evolution of cyclic hardening in axial loadings: (a) evolution of the variable R (pseudo isotropic hardening); (b) evolution of the variable X (pseudo kinematic hardening)

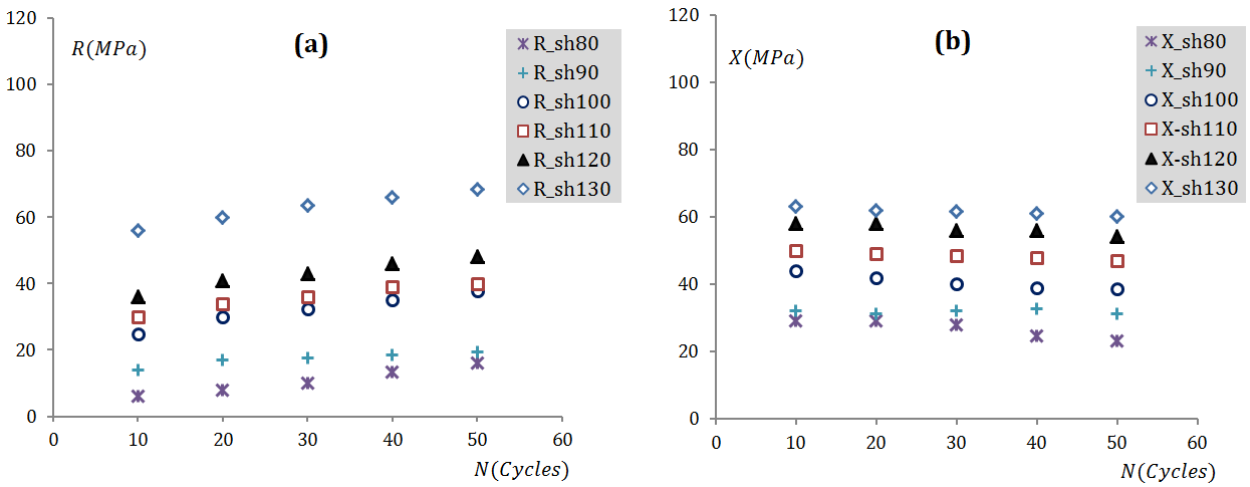

Figure 9. Evolution of cyclic hardening in shear loadings: (a) evolution of the variable R; (b) evolution of the variable X

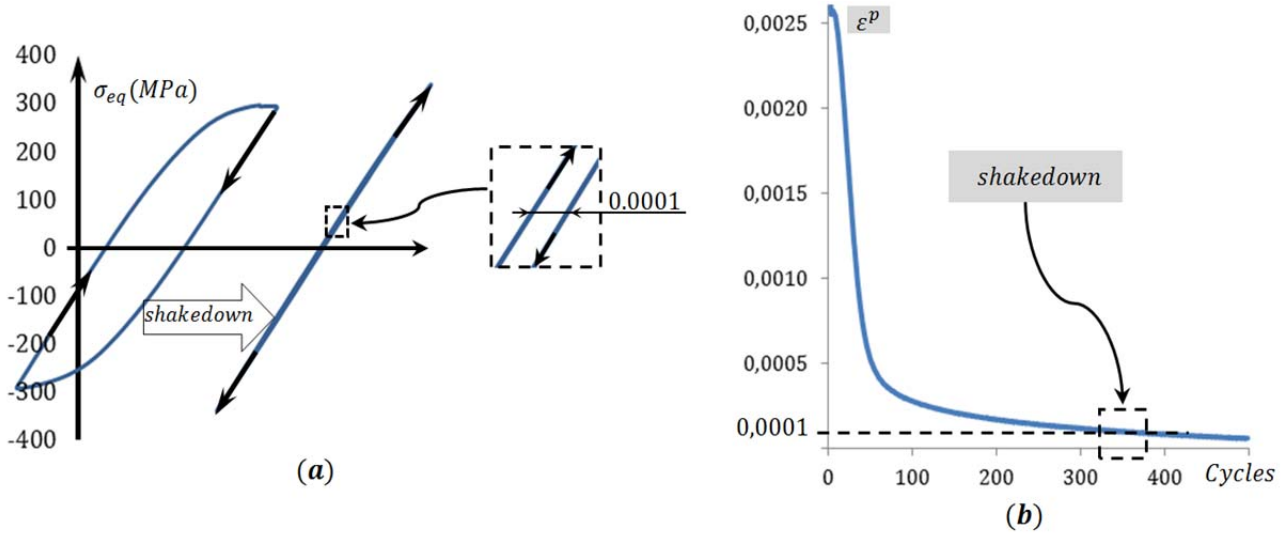

Figure 10. Evaluation of shakedown limit: (a) from the stress-strain loops; (b) from the plastic strain evolution

Following the previous method described in Fig. 10, we can easily evaluate the number of cycles corresponding to the elastic shakedown and the obtained results are given in Table 4. According to these findings and the results presented in Fig. 8 we deduce that a large increase of isotropic hardening leads to an early elastic shakedown despite the application of a high maximum stress. In other words, we can assert that a high isotropic hardening rate, found in the axial loadings, accelerates the shakedown limits.

Table 4. Evaluation of the number of cycles before the shakedown state

Test	ax240	ax260	ax280	ax300	ax320	ax340	ax360
Cycles to Shakedown	1st cycle	95th	77th	170th	320th	430th	>1400th

Under shear loading, elastic shakedown was also observed in the majority of the performed tests except in that of sh130, where the steady state is a closed elastic-plastic loop, but with very small accumulation of plastic deformation until final fracture. The obtained results for the shear loadings are summarized in Table 5.

Table 5. Evolution of the shakedown limit for the shearing tests

Test	sh80	sh90	sh100	sh110	sh120	sh130
Shakedown limit (Cycle)	180th cycle	390th	430th	800th	1600th	Plastic shakedown

According to these shakedown findings and the results presented in Fig. 9, we deduce the relationship between hardening and elastic shakedown in shear loading. Indeed, in these tests, the hardening rate (both isotropic and kinematic) is relatively low, leading to a very late shakedown.
The results presented in Table 5, confirm once again the anisotropic behavior of our alloy. Therefore, we deduce that elastic shakedown is quickly reached under axial loading but later in the shear one.
These results show that when the maximal stress is too high, the shakedown behavior is obtained after having a long time in plastic loading, which contributes largely to microstructural evolution of the specimen. Thus, the specimen breaks despite the elastic shakedown state is reached!

CONCLUDING REMARKS:

In the present work, the anisotropic behavior of a 2017 aluminum alloy is investigated through a stress controlled cyclic loading where two types of tests were performed. In the first one, seven tests using cyclic axial loading were done and in the second we have carried out six tests applying cyclic shear loading. The study is focused on the cyclic behavior as well as on the fatigue life: stress-strain loops, isotropic and kinematic hardenings and cyclic steady state were discussed.

The anisotropic behavior of our alloy is firstly deduced from the difference between the equivalent stress-strain loops obtained in the axial and shearing directions. The study of the cyclic behavior shows that isotropic hardening increases both in axial and shear directions, but more significantly in the axial one. On the other hand; isotropic hardening depends largely on the maximum amplitude of the loading for the two directions. Indeed, large stress amplitude generates a large amount of isotropic hardening which tends to grow during cyclic loading. The kinematic hardening decreases cyclically in both directions of loading, but more significantly in the axial tests where it tends to disappear very quickly. Furthermore, we can notice that the evolution of the isotropic hardening rate may be correlated with the evolution of the shakedown limit, where we can assert that a large isotropic hardening rate, found in the axial loadings, accelerates the shakedown limits. The same results obtained about shakedown limits allow us to conclude that the increase in maximum stress amplitude leads to a late elastic shakedown in the two directions of loading. Indeed, all the cycles done before elastic steady state, contribute largely to the nucleation of micro-voids causing microstructural evolution of the specimen and continue to grow despite the shakedown steady state. The anisotropy is also observed between the two directions in fatigue life as for the same equivalent stress amplitude, lifetime in the axial direction is higher compared to that in the shear direction. However, one can expect the opposite observation in case of strain control.

Abstract An experimental study was carried out to investigate the cyclic deformation characteristic and ratchetting behaviour of a hypereutectoid high strength rail steel subjected to uniaxial and non-proportionally compression-torsion cyclic loadings. The cyclic deformation characteristic of the material was investigated under uniaxial symmetrical strain cycling. The uniaxial ratchetting was studied under asymmetrical stress cycling with different mean stresses and stress amplitudes and the multiaxial ratchetting was investigated under stress cycling with different axial stresses, equivalent stress amplitudes and non-proportional loading paths. It is shown that the responding stress amplitude decreases with cyclic number, i.e., the steel exhibits cyclic softening under uniaxial symmetrical strain cycling. The uniaxial ratchetting strain increases with mean stress and stress amplitude, but behaves differently under tension and under compression. The multiaxial ratchetting behaviour strongly depends not only on the axial stress and equivalent shear stress amplitudes but also on the non-proportional loading path. Additionally, the material reaches cyclic stabilization after a certain number of loading cycles under both uniaxial and multiaxial stress cyclings. These results can be applied to develop a reliable multiaxial cyclic plasticity model for investigating the degradation behaviour of the high strength rail steel under cumulative wheel-rail contact.

Keywords Ratchetting, high strength rail steel, non-proportionally multiaxial loading, cyclic loading.

1. Introduction

In the wheel/rail rolling contact process, the rail is subjected to a cyclic loading and the mechanical responses are more complicated than that exhibited under monotonic loading. The rail degradation modes, wear and rolling contact fatigue, are the result of the accumulation of plastic deformation, so called ratchetting, under severe wheel and rail contact cyclic loading. Generally, the response of an elastic-plastic material subjected to cyclic loading can be categorized into four different levels [1]. If the external load is high and above the plastic shakedown limit or ratchetting threshold, e.g., the contact load in a heavy haul line, new plastic deformation will occur and accumulate, i.e., ratchetting, under each cycle of loading. When the ratchetting strain reaches the ductility of the material, the material will failure at the local point [2], which corresponds to the initiation of wear and rolling contact fatigue, e.g., in the form of head checks in the rail head. Therefore, an investigation on plastic ratchetting in the rail head under cyclic loading is of paramount importance in the development of new rail steel and development of rail maintenance strategy in order to mitigate rail degradation.

To quantify the plastic ratchetting in the rail head accurately, a combined isotropic-kinematic hardening model, which reasonably describes the ratchetting behaviour, has to be applied to simulate the rolling contact between the wheel and the rail. Such models included that developed by Armstrong and Frederick [3] and the one modified by Chaboche [4, 5]. The application of these hardening models requires the calibration of some material properties, including basic mechanical parameters and nonlinear coefficients for nonlinear isotropic and kinematic hardening rules, from monotonic and cyclic tests. Examples of calibrating such parameters for ratchetting studies can be found in recent studies by Fedele et al. [6] and Broggiato et al. [7]. To correlate and calibrate the

material data for the ratchetting models, both uniaxial and multiaxial cyclic loading tests should be carried out. These testing methods have been widely applied to investigate the uniaxial and multiaxial ratchetting behaviour of materials, such as stainless steels and ordinary carbon steels, see [8-15]. It was found that different materials exhibit different ratchetting behaviours. Some experimental results of ratchetting behaviour of rail steels under uniaxial and multiaxial strain/stress cycling have also been reported in [16-21]. Four rail steels used in their studies exhibit different features from each other. Therefore, to accurately model the cyclic stress-strain behaviour of a specific material, it is essential to carry out carefully designed uniaxial and multiaxial cyclic loading tests in order to reveal its cyclic deformation characteristics.

In the case of wheel/rail contact, the cyclic compression-torsion test is one of the most appropriate methods to simulate the loading experienced by rail steel in the rail head due to rolling contact between the wheel and the rail. The objective of present study is to experimentally investigate the ratchetting behaviour of a high strength rail steel, which is currently used in heavy haul railways in Australia, under uniaxial and biaxial compression-torsion cyclic loadings at room temperature.

2. Experimental Setup

The material studied herein is a hypereutectoid rail steel with carbon content of 0.85%, which is currently used in heavy haul railways in Australia. Uniaxial cyclic tests were performed on the round solid specimens with test section diameter of 5 mm and length of 30mm, see Fig. 1a. Biaxial compression-torsion tests were performed on thin-walled tubular specimens with outside diameter of 16 mm, inside diameter of 13 mm, and length of 30mm in the test section, see Fig. 1b. All specimens were machined from the rail head of a new flat bottom rail which has the mass of 68 kilogram per metre. The hole in the tubular specimen was made by deep hole drilling operation.

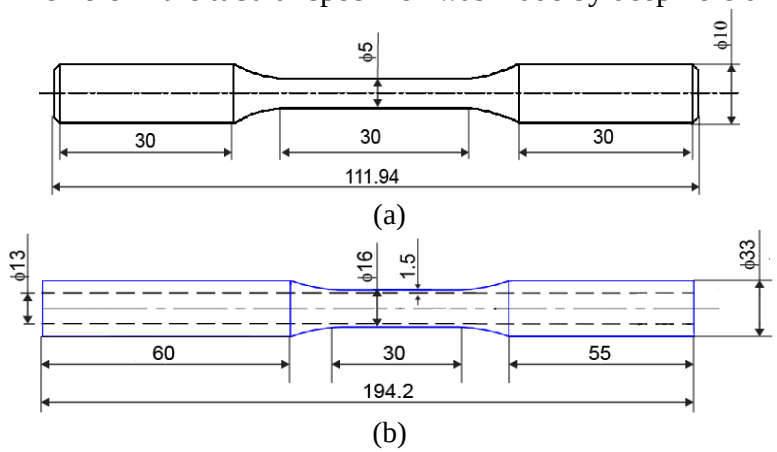

Figure 1. Drawing of (a) round solid specimen for uniaxial cycling tests; (b) thin-walled tubular specimen for biaxial compression-torsion stress cycling tests.

All tests were conducted at room temperature by employing a servo-valve controlled elector-hydraulic testing machine MTS809-250kN, which has the capacity to control axial force and torque independently. The testing process was controlled and the data were collected by a Teststar II control system. A tension-torsion extensometer with 25 mm gauge length and limit of axial strain of ±10% and shear angle of $\pm 5^{o}$ was employed to measure the axial elongation and torsional angle. Loading rates of strain cycling and stress cyclic were 0.2% s^{-1} and 200MPa s^{-1}, respectively. The total number of loading cycles in each case was 100.

The specimen was first tested under monotonic tensile test in order to obtain some basic mechanical parameters, such as, yield strength and ultimate tensile strength. Following the monotonic tensile test, the deformation behaviour of the specimen under symmetrical strain cycling was observed

from the relationship between the stress amplitude and the number of loading cycle. The maximum and minimum of axial stress σ_{max} and σ_{min} in each cycle was obtained from the collected experimental data and so the stress amplitude σ_a can be determined as,

$$\sigma_a = \frac{1}{2}(\sigma_{max} - \sigma_{min}) \tag{1}$$

After that, the ratchetting behaviour of the specimen under uniaxial and biaxial compression-torsion stress cycling with different mean stresses and stress amplitudes was studied. Under asymmetrical stress cycling, the maximum and minimum of axial strain ε_{max} and ε_{min} and the maximum and minimum of shear strain γ_{max} and γ_{min} in each cycle were obtained from the collected experimental data. Due to the unclosed hysteresis loop produced under asymmetric stress cycling, the axial ratchetting strain ε_r and torsional ratchetting strain γ_r are defined as:

$$\varepsilon_r = \frac{1}{2}(\varepsilon_{max} + \varepsilon_{min}) \tag{2}$$

$$\gamma_r = \frac{1}{2}(\gamma_{max} + \gamma_{min}) \tag{3}$$

Ratchetting strain rates are then defined as $d\varepsilon_r/dN$ and $d\gamma_r/dN$, i.e., the increment of ratchetting strains ε_r and γ_r per cycle. The ratchetting behaviour of the specimen under different loadings can be illustrated by the curve of ratchetting strain versus number of cycles. To investigate the influence of multiaxial loading path on the ratchetting behaviour of the material, five loading paths shown in Fig. 2 were adopted, where σ and $\sqrt{3}\tau$ represent the axial stress and the equivalent shear stress, respectively. In compression-torsion loading paths, the von Mises equivalent stress and strain can be determined as,

$$\sigma_{eq} = \sqrt{\sigma^2 + 3\tau^2} \tag{4}$$

$$\varepsilon_{eq} = \sqrt{\varepsilon^2 + \frac{\gamma^2}{3}} \tag{5}$$

where τ and γ represent the shear stress and shear strain and ε is the axial strain. Therefore, the equivalent shear stress and the equivalent shear strain under pure torsion can be defined as $\sqrt{3}\tau$ and $\gamma/3$, respectively.

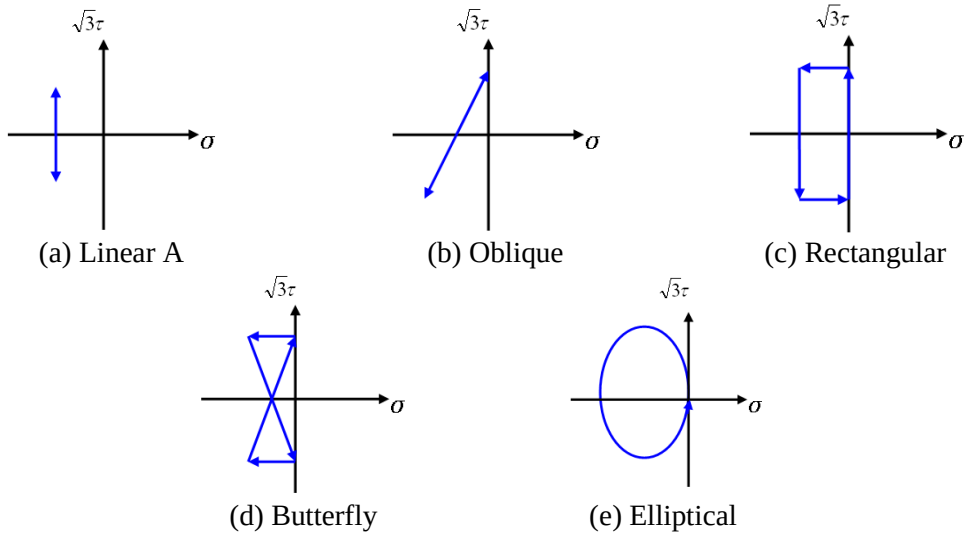

Figure 2. Loading paths for compression-torsion stress cycling.

3. Results

The tensile stress-strain curve for round solid specimen is shown in Fig. 3. The experimental results of elastic modulus E, nominal yield strength $\sigma_{0.2}$, ultimate tensile strength σ_b and elongation δ are 212 GPa, 910 MPa, 1384 MPa and about 12%, respectively.

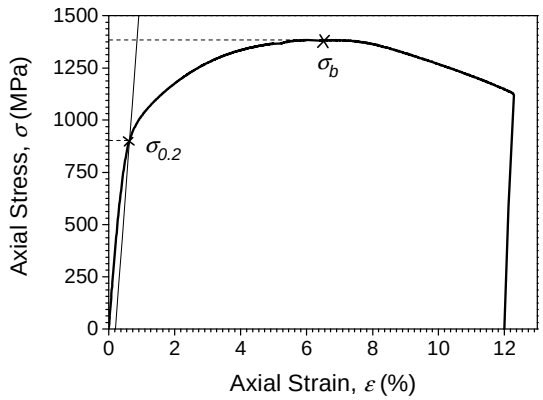

Figure 3. Monotonic tensile stress-strain curve of round solid specimen.

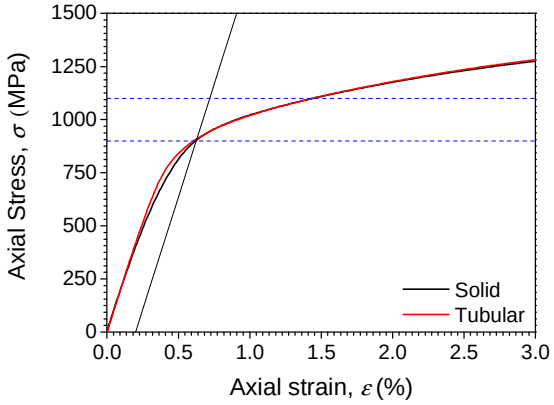

Figure 4. Comparison of mechanical responses from round solid and tubular specimens under monotonic tensile test.

To understand the effect of the specimen design on the measured mechanical properties, a monotonic tensile test was also performed on the tubular specimen. The stress-strain curves from the round solid and the tubular specimens are shown in Fig. 4. The comparison clearly shows that the measured curve of the tubular specimen agrees well with that of the solid specimen in the plastic region and both of them give the same nominal yield strength $\sigma_{0.2}$ of 910 MPa. The discrepancy in the elastic region is negligibly small. Based on the monotonic tensile stress-strain curves of the material, the peak stress applied in the uniaxial stress cycling and the multiaxial stress cycling was selected in the range of 910 MPa to 1100 MPa as illustrated by the dotted horizontal line in Fig. 4.

3.1 Uniaxial strain cycling

The specimen was tested under symmetrical strain cycling at room temperature with the strain amplitude of 0.8%. The cyclic hysteresis loop under uniaxial symmetrical strain cycling is shown in Fig. 5. The results clearly show that the size of the hysteresis loop decreases with the increase of number of cycles. To clearly identify the deformation behaviour of the material under uniaxial strain cycling, the curve of stress amplitude σ_a versus number of cycles N is shown in Fig. 6. It clearly illustrates that the material features cyclic softening remarkably over the first 10 cycles. The decreased rate of stress amplitude in the beginning stage is the largest and reaches a stable value after a certain number of cycles. Similar deformation behaviour was also found in ordinary carbon rail steel and heat-treated rail steel [19]. However, the cyclic softening of the hypereutectoid rail steel in current study is more remarkable.

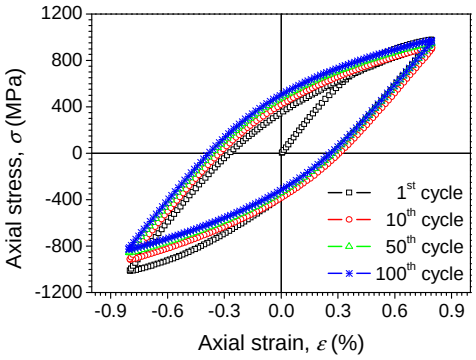

Figure 5. Cyclic hysteresis loops under uniaxial symmetrical strain cycling with strain amplitude of 0.8%.

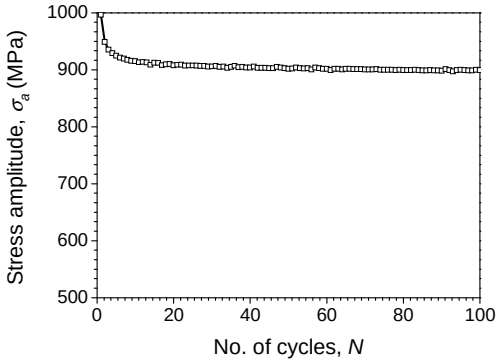

Figure 6. Diagram of stress amplitude σ_a versus number of loading cycle *N* under uniaxial symmetrical strain cycling with strain amplitude of 0.8%.

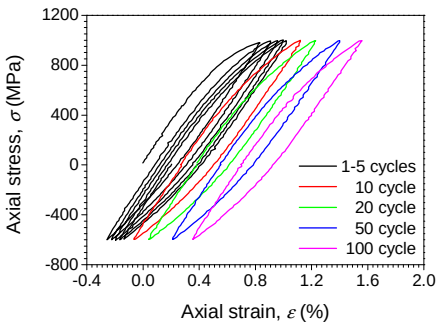
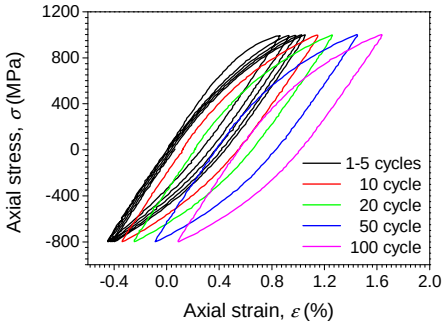
3.2 Uniaxial stress cycling

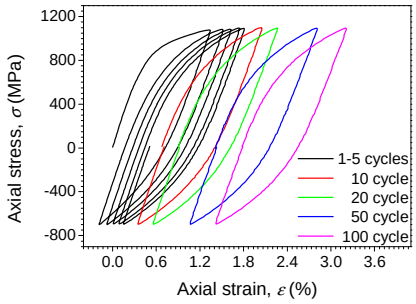
To observe the ratchetting behaviour of hypereutectoid rail steel under uniaxial asymmetrical stress cycling at room temperature, the material was tested with different mean stresses and stress amplitudes. Fig. 7a demonstrates the cyclic hysteresis loops of the specimen under an asymmetrical stress cycling with load condition of 200 ± 800 MPa. The results clearly show that ratchetting occurs under the asymmetrical stress cycling. The hysteresis loop becomes smaller and smaller at the beginning of cycling. After certain cycles, it almost keeps unchanged in the remaining cycles. Similar ratchetting behaviour can be found in the asymmetrical stress cycling with load condition of 200 ± 900 MPa and 100 ± 900 MPa as shown in Fig. 7b and 7c, respectively.



(a)



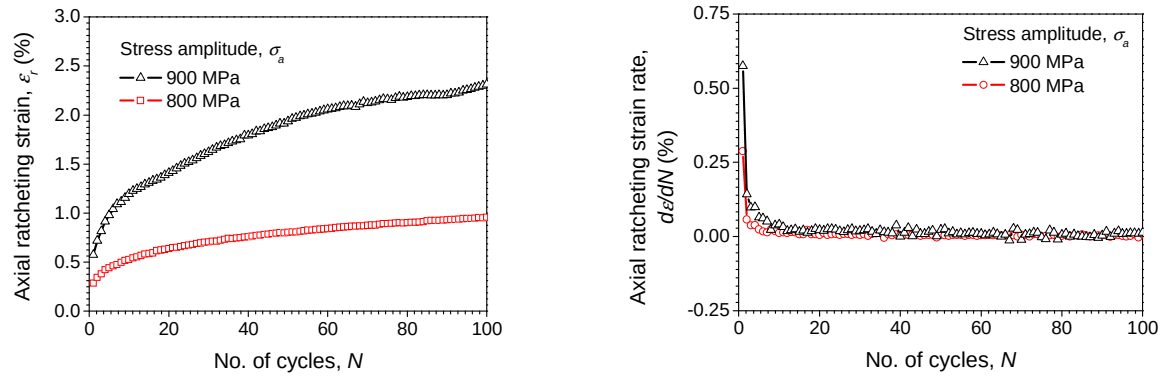
(b)



(c)

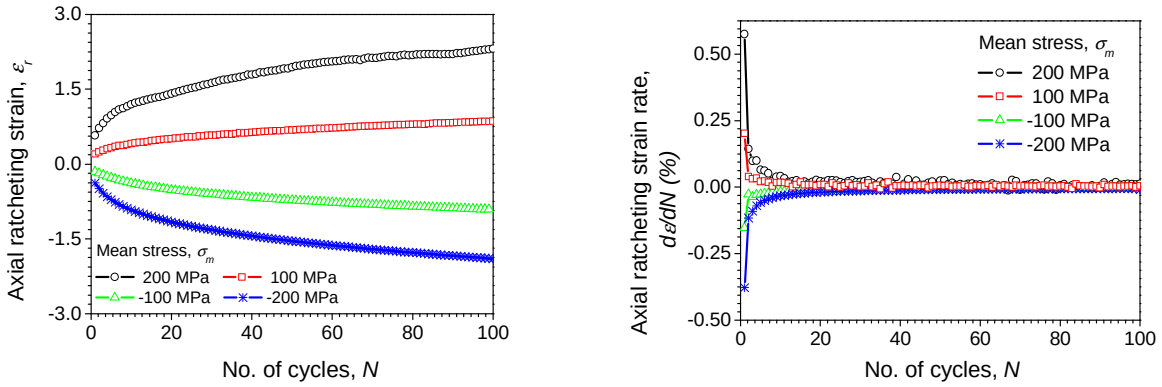
Figure 7. Cyclic hysteresis loops under asymmetrical stress cycling with load condition of (a) 200 ± 800 MPa; (b) 200 ± 900 MPa; (c) 100 ± 900 MPa.

To clearly illustrate the influence of stress amplitude on the ratchetting behaviour of the material, the axial ratchetting strain, which is determined by following Eq. (2), and the ratchetting strain rate versus number of cycles with different stress amplitudes are shown in Figs. 8a and 8b, respectively. The results clearly demonstrate that both ratchetting strain and ratchetting strain rate increase with stress amplitude. Furthermore, the axial ratchetting strain increases but the ratchetting strain rate decreases continuously with the increasing number of loading cycles. After about 10 cycles for σ_a = 800 MPa and about 15 cycles for σ_a = 900 MPa, the ratchetting strain rate becomes very small and almost remains constant over the remaining cycles.



(a) (b)

Figure 8. (a) Axial ratchetting strain ε_r; (b) Axial ratchetting strain rate $d\varepsilon_r/dN$, versus number of cycles N with different stress amplitude σ_a while the mean stress σ_m is kept constant in all cases.



(a) (b)

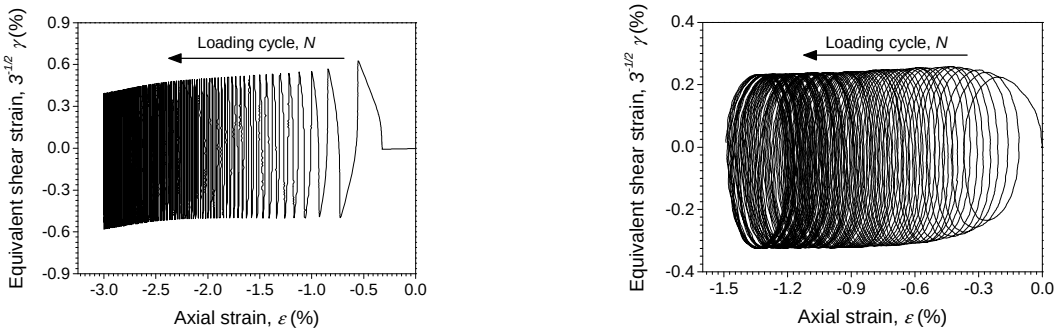
Figure 9. (a) Axial ratchetting strain ε_r; (b) Axial ratchetting strain rate $d\varepsilon_r/dN$, versus number of cycles N with different mean stress σ_m while the stress amplitude σ_a is kept constant in all cases.

Figs. 9a and 9b show the ratchetting strain ε_r and the ratchetting strain rate $d\varepsilon_r/dN$ versus number of cycles N with different mean stresses. The results show that both ratchetting strain and ratchetting strain rate increase with the mean stress. After certain cycles, the ratchetting strain rate $d\varepsilon_r/dN$ becomes very small and remains constant over the remaining cycles. It is also found that the material requires more cycle to stabilize when the mean stress is higher. Additionally, the results indicate that negative mean stress does not provide a perfectly symmetrical result as the positive mean stress does. This means that the material has a slight difference in ratchetting behaviour under tension and under compression. Furthermore, both Figs 8b and 9b show that the axial ratchetting strain rate decreases with increasing number of loading cycles and becomes almost constant in the remaining cycles, which indicates that the ratchetting of the material is dominated by kinematic

hardening and so a cyclic stabilization is reached after certain number of cycles under uniaxial stress cycling.

3.3 Compression-torsion stress cycling

Under the loading paths shown in Figs 3a to 3e, the material was tested under compressive-torsional stress cycling with different mean stresses and stress amplitudes. The relation between ratchetting behaviour and non-proportionally multiaxial loading path is also discussed. Experimental results of two of the loading cases are shown in Fig 10a and 10b. The case shown in Fig. 11a is under symmetrical torsional stress cycling and the results clearly show that the axial ratchetting is the dominant while the torsional ratchetting is relatively small and can be neglected. The same evolution tendency of ratchetting strain can be found in the stress cycling under elliptical path as illustrated in Fig 11b, and the other three paths. Comparing Fig. 10a and 10b, it is found that the absolute value of ratcheting strain at 100 cycles for elliptical path is smaller than that for linear path (1.5% to 3.0%).

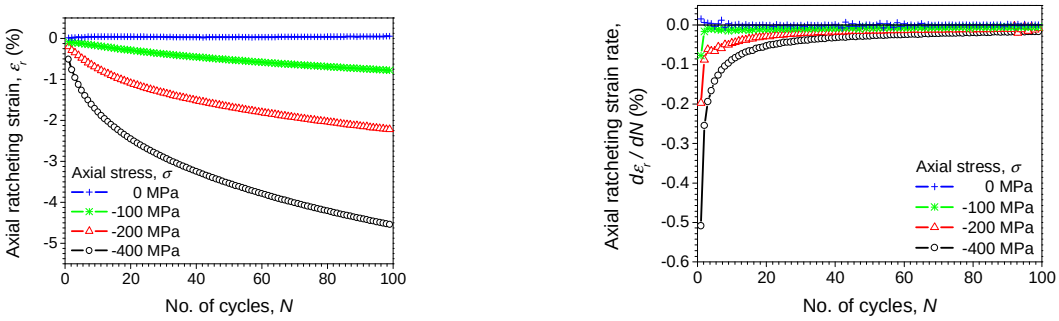


(a) (b)

Figure 10. Experimental results of equivalent shear strain $\gamma/\sqrt{3}$ versus axial strain, ε under (a) linear path; and (b) elliptical path with the same loading condition of σ_{eq} = 1019.8 MPa.

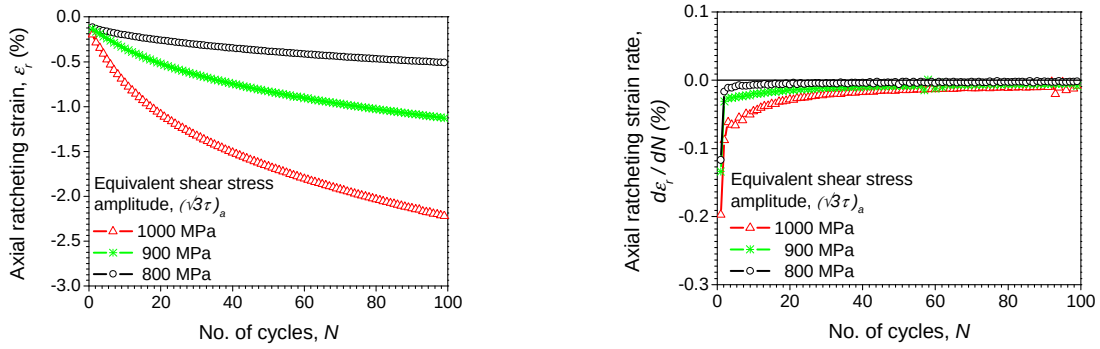
Figs. 11a and 11b demonstrate the influence of axial stresses on the ratchetting behaviour under linear path while the equivalent shear stress $\sqrt{3}\tau$ is kept constant as 0 ± 1000 MPa for all cases. The results show that ratchetting takes place when axial stress σ is high enough. Both axial ratchetting strain ε_r and axial ratchetting strain rate $d\varepsilon_r/dN$ increases with axial stress σ. Additionally, the ratchetting behaviour of the material depends on the equivalent shear stress amplitude under linear path, as shown in Figs. 12a and 12b. For all the cases, the axial stress σ and the mean equivalent shear stress $\left(\sqrt{3}\tau\right)_m$ are kept constant as -200 MPa and 0 MPa, respectively. The results indicate that both axial ratchetting strain ε_r and axial ratchetting strain rate $d\varepsilon_r/dN$ increases with the equivalent shear stress amplitude $\left(\sqrt{3}\tau\right)_a$.

The ratchetting behaviour of the specimen is significantly influenced not only by the axial stress and the equivalent shear stress amplitude but also by the non-proportional loading path as illustrated in Figs. 13a and 13b. For all cases, the applied equivalent stress σ_{eq} is kept constant as 1019.8 MPa. The results show that the non-proportional loading path influences not only the axial ratchetting strain ε_r but also the axial ratchetting strain rate $d\varepsilon_r/dN$. Among all the five loading paths, the elliptical path gives the lowest ratchetting strain and rate. When N is less than 65, the linear path gives the highest ratchetting strain. When N is larger than 65, the highest ratchetting strain is contributed by the rectangular path.



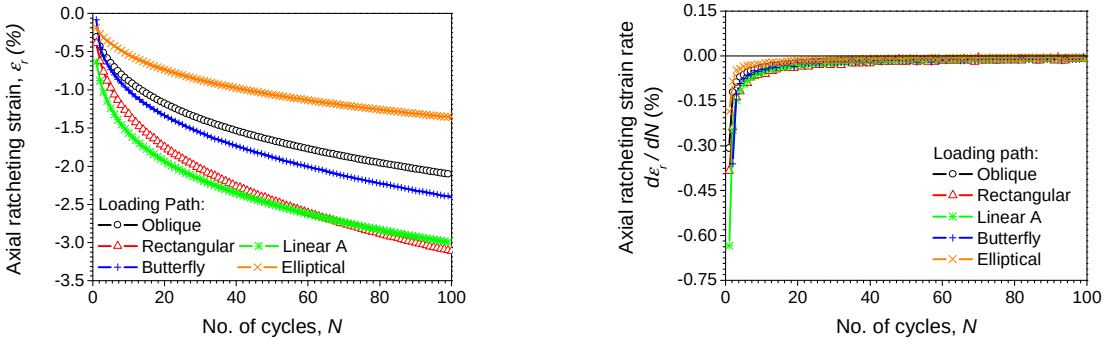
(a) (b)

Figure 11. (a) Axial ratchetting strain ε_r; (b) Axial ratchetting strain rate $d\varepsilon_r/dN$, versus number of cycles N under linear path with different axial stress σ while the equivalent shear stress $\sqrt{3}\tau$ is kept constant.



(a) (b)

Figure 12. (a) Axial ratchetting strain ε_r; (b) Axial ratchetting strain rate $d\varepsilon_r/dN$, versus number of cycles N under linear path with different equivalent shear stress amplitude $\left(\sqrt{3}\tau\right)_a$ while the axial stress is kept constant.



(a) (b)

Figure 13. (a) Axial ratchetting strain ε_r; (b) Axial ratchetting strain rate $d\varepsilon_r/dN$, versus number of cycles N with different non-proportional loading paths while the applied equivalent stress σ_{eq} is kept constant.

It is worth noting that Figs 11, 12 and 13 demonstrate that the axial ratchetting strain increases but its rate decreases continuously with increasing number of cycles. After a certain number of cycles, the axial ratchetting strain rate becomes very small and almost remains constant in the remaining cycles. Therefore, it can be concluded that the ratchetting of the material under multiaxial stress cycling is dominated by kinematic hardening and so a cyclic stabilization is reached after certain number of cycles, i.e. about 45 cycles when σ = -200 MPa in Fig 12b. It is also found that the increase of axial stress and equivalent shear stress lead to increase the required cyclic number to

reach cyclic stabilization of the material. Moreover, it is indicated from Fig 13a that the nonproportional additional hardening will restrain the ratchetting strain even under compression-torsion loading, which is consistent with [14] under tension-torsion loading. The elliptical path is more relevant to actual wheel/rail contact situations as the contact patch was often found to be elliptical in shape which implies that the relative weak ratchetting behaviour will occur in real wheel/rail rolling contact process. These features and their effects on ratchetting should be taken into account in cyclic constitutive model development in the future.

4. Conclusion

A hypereutectoid grade high strength rail steel, which is currently used in heavy haul operation in Australia, has been tested under uniaxial and compression-torsion cyclic loadings. The elastic modulus, nominal yield strength and ultimate tensile strength of the material are found as 212 GPa, 910 MPa and 1384 MPa, respectively. Under symmetrical strain cycling, the material exhibits cyclic softening at the start and then stabilizes quickly. Although this material's behaviour is similar to those found in the literature, the cyclic softening of the hypereutectoid rail steel is more remarkable.

Under uniaxial stress cycling, ratchetting behaviour strongly depends on mean stress and stress amplitude. Both ratchetting strain and ratchetting rate increase with mean stress and stress amplitude. The material stabilizes after certain number of loading cycles and the required number of cycles to reach cyclic stabilization also depends on mean stress and stress amplitude. It is found that the ratchetting of the material behaves slightly different under tension and compression.

Under multiaxial stress cycling, ratchetting is significantly influenced by axial stress, equivalent shear stress amplitude and non-proportional loading path. Both ratchetting and ratchetting strain rate increases with axial stress and equivalent shear stress amplitude. It is also found that kinematic hardening is dominant in the ratchetting of the material. It reaches cyclic stabilization after certain number of loading cycles and the required cyclic number is also influenced by the axial stress and equivalent shear stress amplitude. Among all the five studied loading paths, the elliptical loading path is more relevant to actual wheel/rail contact situations and it gives the lowest ratchetting strain and ratchetting strain rate.

Abstract A popular cyclic plasticity model at small deformations is extended to finite deformations for describing the Bauschinger effect and ratchetting behaviour by considering the combined isotropic and kinematic hardening rules. The model is based on the multiplicative decomposition of deformation gradient into elastic and inelastic parts. Following, a further multiplicative decomposition of inelastic part of deformation gradient into energetic and dissipative parts is adopted to extend the popular Ohno-Karim nonlinear kinematic hardening rule. Finally, numerical examples are carried out to validate the proposed model under strain controlled and stress controlled cyclic loadings.

Keywords Finite deformation, cyclic plasticity, ratchetting; kinematic hardening, Bauschinger effect

1. Introduction

In engineering applications, engineering components are usually subjected to complex cyclic loading. For instance, metal forming, mechanical cutting, wheel/rail contact in high speed railway and aero fasteners connection, etc. Cyclic plasticity models for describing Bauschinger effect and ratchetting behaviour of metals associated with cyclic loading have been one of the most popular research topic for solid mechanics in recent years. At small deformation regime, cyclic constitutive model research has reaped great achievements under the effort of numerous scholars [1-9]. The most popular model, which can describe Bauschinger effect and ratchetting behaviour, is Armstrong-Frederick kinematic model (shorted as A-F model) [1]. Even though the prediction of ratchetting behaviour by A-F model is too high relative to the actual situation, it is still widely applied in engineering analysis due to its solid physical background and concise theory system. And after then, there have been a lot of attempts to modify A-F model to improve predicting in ratcheting [2-9]. Ohno-Karim model, owing to the convenience of material parameters determination and the reasonable prediction in ratchetting, was widely adopted to simulate cyclic plastic behaviour of metal materials at present. The models were mostly constructed in the frame of small deformation.

It is must be noted that the deformation of structural components is finite and associated with finite rotation in practical modelling situations.. Cyclic constitutive models established at small deformation regime are no longer suitable for these circumstances due to without considering rotation effect. Recently, some constitutive models were extended from small deformation to finite deformation [10-24]. Among these models, two main strategies are followed. One class is hypo-elasticity theory which is developed by introducing a stress-like internal variable to model

kinematic hardening with the assumption that the stretching tensor is additively decomposed into the elastic part and plastic part. This theory requires adopting appropriate objective stress rate to establish the frame-indifference evolution equations. Alternatively, the other one is hyper-elasticity theory, in which the inelastic part is based on the standard Kröner multiplicative decomposition [25] and can be further multiplicatively decomposed into energetic and dissipative parts [15]. In hyper-elasticity theory, a strain-like internal variable is introduced to model kinematic hardening. The requirement of this strategy is to establish all evolution equations in the same configuration. For the first strategy, it has been shown that the rate form model for elastic response is integrable [18, 26] only in form of the logarithmic rate. Therefore, some unreasonable responses in elastic behaviour, such as shear oscillatory phenomenon and the nonzero work in a hysteretic loop, may appear. To avoid the nonzero work in elastic response, a continuum mechanical extension of A-F type kinematic hardening rule can be achieved naturally motivated by a typical rheological model description. However, as so far only A-F model is extended in both of the two strategies.

In the present work, the Ohno-Karim model is firstly extended from small deformations to finite deformations based on the hyper-elasticity theory. Some numerical examples were provided to display the prediction in Bauschinger effect and ratchetting behaviour under strain controlled and stress controlled cyclic loadings, respectively.

2. Continuum extension of Ohno-Karim model at finite deformations

2.1. Kinematic

In order to model the inelastic response of materials, the deformation gradient $\mathbf{F}$ may be classically multiplicatively decomposed as

$$\mathbf{F} = \mathbf{F}^e\mathbf{F}^p \tag{1}$$

where, $\mathbf{F}^p$ represents the local inelastic distortion of material due to “plastic mechanism”, and this local deformation carries the material from reference space ($\tilde{\mathrm{K}}$) to structure space ($\hat{\mathrm{K}}$); $\mathbf{F}^e$ represents the subsequent stretching and rotation, and it maps material element from structure space ($\hat{\mathrm{K}}$) to current space (K) (see Fig. 1) [25].

Following, $\mathbf{F}^p$ can be further multiplicatively decomposed into energetic part $\mathbf{F}^{pe}$ and dissipative part $\mathbf{F}^{pi}$ [15].

$$\mathbf{F}^p = \mathbf{F}^{pe}\mathbf{F}^{pi} \tag{2}$$

where, $\mathbf{F}^{pi}$ maps material element from reference space into intermediate configuration of kinematic hardening($\breve{\mathrm{K}}$); and $\mathbf{F}^{pe}$ maps material element from intermediate configuration($\breve{\mathrm{K}}$) into structure space(K) (see Fig. 4) [15, 24].
Three right Cauchy-Green tensors are given by

$$\mathbf{C} = \mathbf{F}^T\mathbf{F}, \quad \mathbf{C}^e = \mathbf{F}^{eT}\mathbf{F}^e = \mathbf{F}^{p-T}\mathbf{C}\mathbf{F}^{p-1}, \quad \mathbf{C}^{pe} = \mathbf{F}^{peT}\mathbf{F}^{pe} = \mathbf{F}^{pi-T}\mathbf{C}^p\mathbf{F}^{pi-1} \tag{3}$$

with

$$\mathbf{C}^p = \mathbf{F}^{pT}\mathbf{F}^p \tag{4}$$

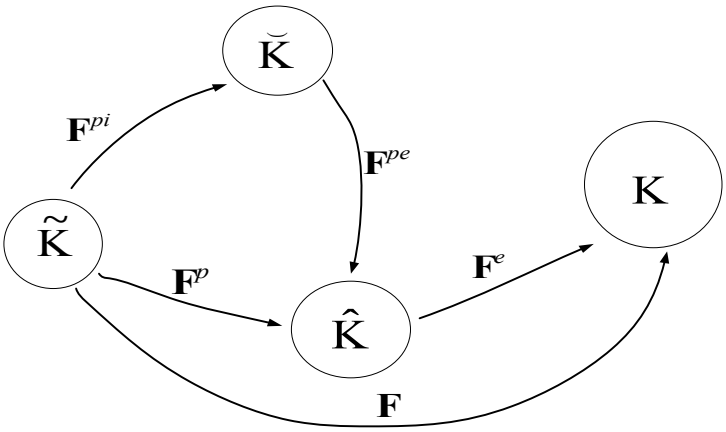

Figure 1. Elastic-inelastic decomposition of the kinematics deformation

2.2. Helmholtz free energy

Similar to the small deformation regime and based on the requirement of material objectivity, the Helmholtz free energy is additively decomposed into three parts

$$\psi = \psi^{e}\left(\mathbf{C}^{e}\right) + \psi^{kin}\left(\mathbf{C}^{pe}\right) + \psi^{iso}\left(p\right) \tag{5}$$

where ψ^{e} represents the standard energy associated with intermolecular interactions; ψ^{kin} is a defect-energy associated with plastic deformation; and $\psi^{iso}\left(p\right)$ represents the additional amount of stored energy related to isotropic hardening, where p is accumulated plastic strain.

2.3. Clausius-Duhem inequality

Inspired by the existing work [21, 23], we derive the constitutive equations of Ohno-Karim model in a continuum method in this paper. The derivation is based on the requirement of the Clausius-Duhem inequality.

For isothermal process, the reduced Clausius-Duhem inequality is

$$\mathbf{S} : \frac{1}{2}\dot{\mathbf{C}} - \dot{\psi} \geq 0 \tag{6}$$

where $\mathbf{S}$ is the second Piola-Kirchhoff stress tensor; $(:)$ represents the inner product of tensors.

For Ohno-Karim kinematic hardening rule, the kinematic free energy term is given by

$$\psi^{kin} = \sum_{i}^{N} \psi_{i}^{kin}\left(\mathbf{C}_{i}^{pe}\right)\left(N \geq 1\right) \tag{7}$$

with

$$\mathbf{C}_{i}^{pe} = \mathbf{F}_{i}^{pe^{T}}\mathbf{F}_{i}^{pe} \tag{8}$$

and

$$\mathbf{F}_{i}^{pe} = \mathbf{F}^{p}\mathbf{F}_{i}^{pi^{-1}} \tag{9}$$

Eq. (9) indicates that the form of multiplicative decomposition for $\mathbf{F}^{p}$ is not exclusive.

Combing Eq. (7) and Eq. (5), yields

$$\psi = \psi^{e}\left(\mathbf{C}^{e}\right) + \sum_{i}^{N} \psi_{i}^{kin}\left(\mathbf{C}_{i}^{pe}\right) + \psi^{iso}\left(p\right) \tag{10}$$

Substituting Eq. (10) into Eq. (6), the Clausius-Duhem inequality can be rewritten as

$$\mathbf{S}:\frac{1}{2}\dot{\mathbf{C}}-\frac{\partial\psi^{e}}{\partial\mathbf{C}^{e}}:\dot{\mathbf{C}}^{e}-\sum_{i}^{N}\frac{\partial\psi_{i}^{kin}}{\partial\mathbf{C}_{i}^{pe}}:\dot{\mathbf{C}}_{i}^{pe}-\frac{\partial\psi^{iso}}{\partial p}\dot{p}\geq 0 \tag{11}$$

According Eq. (3),

$$\dot{\mathbf{C}}^{e}=\dot{\mathbf{F}}^{p^{-T}}\mathbf{C}\mathbf{F}^{p^{-1}}+\mathbf{F}^{p^{-T}}\dot{\mathbf{C}}\mathbf{F}^{p^{-1}}+\mathbf{F}^{p^{-T}}\mathbf{C}\dot{\mathbf{F}}^{p^{-1}} \tag{12}$$

Furthermore, by adopting the two identities, gives

$$\dot{\mathbf{F}}^{p^{-1}}=-\mathbf{F}^{p^{-1}}\dot{\mathbf{F}}^{p}\mathbf{F}^{p^{-1}},\quad \dot{\mathbf{F}}^{p^{-T}}=-\mathbf{F}^{p^{-T}}\dot{\mathbf{F}}^{p}\mathbf{F}^{p^{-T}} \tag{13}$$

Combing Eq. (12) and Eq. (13), $\dot{\mathbf{C}}^{e}$ is derived as

$$\dot{\mathbf{C}}^{e}=-\mathbf{L}^{p^{T}}\mathbf{C}^{e}+\mathbf{F}^{p^{-T}}\dot{\mathbf{C}}\mathbf{F}^{p^{-1}}-\mathbf{C}^{e}\mathbf{L}^{p} \tag{14}$$

where $\mathbf{L}^{p}=\dot{\mathbf{F}}^{p}\mathbf{F}^{p^{-1}}$ is the plastic velocity gradient.

In the same process,

$$\dot{\mathbf{C}}_{i}^{pe}=-\mathbf{L}_{i}^{pi^{T}}\mathbf{C}_{i}^{pe}+\mathbf{F}_{i}^{pi^{-T}}\dot{\mathbf{C}}^{p}\mathbf{F}_{i}^{pi^{-1}}-\mathbf{C}_{i}^{pe}\mathbf{L}_{i}^{pi} \tag{15}$$

where $\mathbf{L}_{i}^{pi}=\dot{\mathbf{F}}_{i}^{pi}\mathbf{F}_{i}^{pi^{-1}}$ is the so called "inelastic" plastic velocity gradient.

Considering the symmetric property of tensor functions ψ^{e} and ψ_{i}^{kin} [23]

$$\frac{\partial\psi^{e}}{\partial\mathbf{C}^{e}}:\left(\mathbf{C}^{e}\mathbf{L}^{p}\right)=\left(\mathbf{C}^{e}\frac{\partial\psi^{e}}{\partial\mathbf{C}^{e}}\right):\mathbf{D}^{p} \tag{16a}$$

$$\frac{\partial\psi_{i}^{kin}}{\partial\mathbf{C}_{i}^{pe}}:\left(\mathbf{C}_{i}^{pe}\mathbf{L}_{i}^{pi}\right)=\left(\mathbf{C}_{i}^{pe}\frac{\partial\psi_{i}^{kin}}{\partial\mathbf{C}_{i}^{pe}}\right):\mathbf{D}_{i}^{pi} \tag{16b}$$

where $\mathbf{D}^{p}$ and $\mathbf{D}_{i}^{pi}$ are symmetric part of $\mathbf{L}^{p}$ and $\mathbf{L}_{i}^{pi}$, respectively.

Moreover

$$\mathbf{D}^{p}=\frac{1}{2}\mathbf{F}^{p^{-T}}\dot{\mathbf{C}}\mathbf{F}^{p^{-1}},\quad \mathbf{D}_{i}^{pi}=\mathbf{F}_{i}^{pi^{-T}}\dot{\mathbf{C}}^{p}\mathbf{F}_{i}^{pi^{-1}} \tag{17}$$

By Eqs. (14)- (17), the Clausius-Duhem inequality (11) yields the final form

$$\begin{aligned}&\left(\mathbf{S}-2\mathbf{F}^{p^{-1}}\frac{\partial\psi^{e}}{\partial\mathbf{C}^{e}}\mathbf{F}^{p^{-T}}\right):\frac{1}{2}\dot{\mathbf{C}}+\left(2\mathbf{C}^{e}\frac{\partial\psi^{e}}{\partial\mathbf{C}^{e}}-2\sum_{i}^{N}\mathbf{F}_{i}^{pe}\frac{\partial\psi_{i}^{kin}}{\partial\mathbf{C}_{i}^{pe}}\mathbf{F}_{i}^{pe^{T}}\right):\mathbf{D}^{p}\\&+2\sum_{i}^{N}\left(\mathbf{C}_{i}^{pe}\frac{\partial\psi_{i}^{kin}}{\partial\mathbf{C}_{i}^{pe}}:\mathbf{D}_{i}^{pi}\right)-\frac{\partial\psi^{iso}}{\partial p}\dot{p}\geq 0\left(N\geq 1\right)\end{aligned} \tag{18}$$

According to the Coleman-Noll procedure, the second Piola-Kirchhoff stress tensor can be defined as

$$\mathbf{S}=2\mathbf{F}^{p^{-1}}\frac{\partial\psi^{e}}{\partial\mathbf{C}^{e}}\mathbf{F}^{p^{-T}} \tag{19}$$

Furthermore, the so-called Mandel stress $\mathbf{M}$, kinematic Mandel stress $\mathbf{M}^{kin}$, back stress $\boldsymbol{\chi}$ and isotropic deformation resistance *R* are defined as follows:

$$\mathbf{M}=2\mathbf{C}^{e}\frac{\partial\psi^{e}}{\partial\mathbf{C}^{e}} \tag{20}$$

and

$$\mathbf{M}^{kin}=\sum_{i}^{N}\mathbf{M}_{i}^{kin} \tag{21}$$

with

$$\mathbf{M}_i^{kin} = 2\mathbf{C}_i^{pe}\frac{\partial \psi_i^{kin}}{\partial \mathbf{C}_i^{kin}} \tag{22}$$

and

$$\boldsymbol{\chi} = \sum_i^N \boldsymbol{\chi}_i \tag{23}$$

with

$$\boldsymbol{\chi}_i = 2\mathbf{F}_i^{pe}\frac{\partial \psi_i^{kin}}{\partial \mathbf{C}_i^{pe}}\mathbf{F}_i^{peT} \tag{24}$$

and

$$R = -\frac{\partial \psi^{iso}}{\partial p} \tag{25}$$

In general, R can be written in the Voce's exponential form

$$R = Q\left(1-\exp(-bp)\right) \tag{26}$$

where Q and b are nonnegative material parameters.

Finally, the Clausius-Duhem inequality reduces to the form

$$\left(\mathbf{M}-\boldsymbol{\chi}\right):\mathbf{D}^p + \sum_i^N \mathbf{M}_i^{kin}:\mathbf{D}_i^{pi} + R\dot{p} \geq 0 \tag{27}$$

The evolution equations of Ohno-Karim model can be given by

$$\mathbf{D}^p = \dot{\lambda}\frac{\partial F_y}{\partial \mathbf{M}} = \dot{\lambda}\frac{\mathbf{M}^D-\boldsymbol{\chi}}{\left\|\mathbf{M}^D-\boldsymbol{\chi}\right\|} \tag{28a}$$

$$\mathbf{D}_i^{pi} = u_i b_i \dot{\lambda}\mathbf{M}_i^{kin} + H\left(f_i\right)\frac{b_i}{c_i}\mathbf{M}_i^{kin}\left\langle \mathbf{D}^p:\mathbf{K}_i - u_i\dot{\lambda}\right\rangle \tag{28b}$$

$$\dot{p} = \sqrt{\frac{2}{3}}\dot{\lambda} \tag{28c}$$

with the yield function

$$F_y = \left\|\mathbf{M}^D-\boldsymbol{\chi}\right\| - \sqrt{\frac{2}{3}}\left(\sigma_y + R\right) \tag{29}$$

where the superscript D denotes the deviator of a tensor, i.e. $\mathbf{A}^D = \mathbf{A} - \frac{1}{3}tr\left(\mathbf{A}\right)\mathbf{1}$.

and the plastic multiplier $\dot{\lambda}$ is determined by the Kuhn-Tucker conditions

$$\dot{\lambda} \geq 0\,, \quad F_y \leq 0\,, \quad \dot{\lambda}F_y = 0\left(if\ F_y = 0\right) \tag{30}$$

In Eq. (28b), b_i and c_i are nonnegative kinematic parameters; H and $\left\langle\ \right\rangle$ are Heaviside function and Macauley operator, respectively; f_i represents the critical surface for i-th back stress which is defined by

$$f_i = \left\|\boldsymbol{\chi}_i\right\|^2 - \left(\frac{c_i}{b_i}\right)^2 \tag{31}$$

And forther more

$$\mathbf{K}_i = \frac{\boldsymbol{\chi}_i}{\left\|\boldsymbol{\chi}_i\right\|} \tag{32}$$

By the foregoing equations

$$
\begin{aligned}
&(\mathbf{M}-\boldsymbol{\chi}):\mathbf{D}^p+\sum_i^N \mathbf{M}_i^{kin}:\mathbf{D}_i^{pi}+R\dot{p}\\
&=\dot{\lambda}\left\|\mathbf{M}^D-\boldsymbol{\chi}\right\|+\dot{\lambda}\sum_i^N\left(u_i b_i+H(f_i)\frac{b_i}{c_i}\left\langle \mathbf{D}^p:\mathbf{K}_i-u_i\dot{\lambda}\right\rangle\right)\left\|\mathbf{M}_i^{kin}\right\|^2+R\sqrt{\frac{2}{3}}\dot{\lambda} \qquad (33)\\
&=\dot{\lambda}\left(F_y+\sqrt{\frac{2}{3}}\sigma_y\right)+\dot{\lambda}\sum_i^N\left(u_i b_i+H(f_i)\frac{b_i}{c_i}\left\langle \mathbf{D}^p:\mathbf{K}_i-u_i\dot{\lambda}\right\rangle\right)\left\|\mathbf{M}_i^{kin}\right\|^2
\end{aligned}
$$

Based on the foregoing statement, Eq. (33) is nonnegative can be obtained directly. Thus, the Clausius-Duhem inequality is satisfied.

However, it should be noted that the constitutive equations (19), (28) and (29) are not defined in the same configuration. The second Piola-Kirchhoff stress (Eq. (19)) is defined in the reference configuration; Eqs. (28a) and (28b) act in the structure configuration and the intermediate configuration of kinematic hardening, respectively; Eqs. (28c) and (29) are scalar equations [23]. In order to satisfy the basic requirement of constitutive model, the evolution equations (28a) and (28b) are transformed to the reference configuration, in the following. Obviously, the yield function is also rewritten in term of quantities defined in the reference configuration.

2.4. Representation in the reference configuration

It has been proved that the second Piola-Kirchhoff stress tensor is only the function of $\mathbf{C}$ and $\mathbf{C}^p$ [23], namely

$$\mathbf{S}=\tilde{\mathbf{S}}\left(\mathbf{C},\mathbf{C}^p\right) \qquad (34)$$

A new back stress tensor $\mathbf{X}_i$ defined as a pullback of $\boldsymbol{\chi}_i$ by $\mathbf{F}_i^p$, i.e.

$$\mathbf{X}_i=\mathbf{F}_i^{p^{-1}}\boldsymbol{\chi}_i\mathbf{F}_i^{p^{-T}}=2\mathbf{F}_i^{p^{-1}}\mathbf{F}_i^{pe}\frac{\partial\psi_i^{kin}}{\partial\mathbf{C}_i^{pe}}\mathbf{F}_i^{pe^T}\mathbf{F}_i^{p^{-T}}=2\mathbf{F}_i^{pi^{-1}}\frac{\partial\psi_i^{kin}}{\partial\mathbf{C}_i^{pe}}\mathbf{F}_i^{pi^{-T}} \qquad (35)$$

also is the function of $\mathbf{C}^p$ and $\mathbf{C}_i^{pi}$ only [23], namely

$$\mathbf{X}_i=\tilde{\mathbf{X}}_i\left(\mathbf{C}^p,\mathbf{C}_i^{pi}\right) \qquad (36)$$

It means that the back stress tensor $\mathbf{X}_i$ is defined in the reference configuration. Then, the total back stress is

$$\mathbf{X}=\sum_i^N\mathbf{X}_i \qquad (37)$$

Further, according to Eq. (17), it can be obtained that

$$\dot{\mathbf{C}}^p=2\mathbf{F}^{p^T}\mathbf{D}^p\mathbf{F}^p,\quad \dot{\mathbf{C}}_i^{pi}=\mathbf{F}_i^{pi^T}\mathbf{D}_i^{pi}\mathbf{F}_i^{pi} \qquad (38)$$

Thus, the evolution of $\dot{\mathbf{C}}^p$ and $\dot{\mathbf{C}}_i^{pi}$ have the form

$$\dot{\mathbf{C}}^p=2\dot{\lambda}\mathbf{F}^{p^T}\frac{\mathbf{M}^D-\boldsymbol{\chi}}{\left\|\mathbf{M}^D-\boldsymbol{\chi}\right\|}\mathbf{F}^p=2\dot{\lambda}\frac{\mathbf{Y}^D\mathbf{C}^p}{\sqrt{\mathbf{Y}^D:\mathbf{Y}^D}} \qquad (39a)$$

$$
\begin{aligned}
\dot{\mathbf{C}}_i^{pi}&=2\mathbf{F}_i^{pi^T}\left(u_i b_i\dot{\lambda}\mathbf{M}_i^{kin}+H(f_i)\frac{b_i}{c_i}\mathbf{M}_i^{kin}\left\langle \mathbf{D}^p:\mathbf{K}_i-u_i\dot{\lambda}\right\rangle\right)\mathbf{F}_i^{pi}\\
&=2\dot{\lambda}\left(u_i b_i+H(f_i)\frac{b_i}{c_i}\left\langle \mathbf{D}^p:\mathbf{K}_i-u_i\dot{\lambda}\right\rangle\right)\mathbf{Y}_i^{kin}\mathbf{C}_i^{pi}
\end{aligned} \qquad (39b)
$$

with

$$\mathbf{Y}=\mathbf{CS}-\mathbf{C}^{p}\mathbf{X}=\tilde{\mathbf{Y}}\left(\mathbf{C},\mathbf{C}^{p},\mathbf{C}_{i}^{pi}\right),\quad \mathbf{Y}_{i}^{kin}=\mathbf{C}^{p}\mathbf{X}_{i}=\tilde{\mathbf{Y}}_{i}^{kin}\left(\mathbf{C}^{p},\mathbf{C}_{i}^{pi}\right) \tag{40}$$

and

$$f_{i}=\left\|\boldsymbol{\chi}_{i}\right\|^{2}-\left(\frac{c_{i}}{b_{i}}\right)^{2},\quad \mathbf{K}_{i}=\frac{\boldsymbol{\chi}_{i}}{\left\|\boldsymbol{\chi}_{i}\right\|} \tag{41}$$

Clearly, all constitutive equations are represented in terms of the symmetric tensor $\mathbf{C}$, $\mathbf{C}^{p}$ and $\mathbf{C}_{i}^{pi}$ and the plastic multiplier $\dot{\lambda}$. And the yield function is

$$F_{y}=\sqrt{\mathbf{Y}^{D}:\mathbf{Y}^{D}}-\sqrt{\frac{2}{3}}\left(\sigma_{y}+R\right) \tag{42}$$

Kuhn-Tucker conditions are as following

$$\dot{\lambda}\geq 0,\quad F_{y}\leq 0,\quad \dot{\lambda}F_{y}=0\left(if\ F_{y}=0\right) \tag{43}$$

For numerical examples to be discussed in the follow section, the specific form of the second Piola-Kirchhoff stress and back stress can be given by the well-known neo-Hookean form [23], i.e.

$$\psi^{e}=\frac{\mu}{2}\left(tr\mathbf{C}^{e}-3\right)-\mu\ln\left(\sqrt{\det\mathbf{C}^{e}}\right)+\frac{\Lambda}{4}\left(\det\mathbf{C}^{e}-1-2\ln\left(\sqrt{\det\mathbf{C}^{e}}\right)\right) \tag{44a}$$

$$\psi_{i}^{kin}=\frac{c_{i}}{4}\left(tr\mathbf{C}_{i}^{pe}-3\right)-\frac{c_{i}}{2}\ln\left(\sqrt{\det\mathbf{C}_{i}^{pe}}\right) \tag{44b}$$

where μ and Λ are the Lamé constants, and c_i is the kinematic hardening parameter.

Thus, the corresponding constitutive relations for $\mathbf{S}$ and $\mathbf{X}_i$ are derived

$$\mathbf{S}=\mu\left(\mathbf{C}^{p^{-1}}-\mathbf{C}^{-1}\right)+\frac{\Lambda}{2}\left(\det\mathbf{C}\left(\det\mathbf{C}^{p}\right)^{-1}-1\right)\mathbf{C}^{-1} \tag{45a}$$

$$\mathbf{X}_{i}=\frac{c_{i}}{2}\left(\mathbf{C}_{i}^{pi^{-1}}-\mathbf{C}^{p^{-1}}\right) \tag{45b}$$

It should be noted that Ohno-Kairm model reduces to A-F model when $u_i=1$, and reduces to Ohno-Wang model when $u_i=0$ in Eq. (39b), respectively.

3. Numerical examples

The prediction ability and stability of A-F model at finite deformations had been investigated [21-23]. In this section, some numerical examples were carried out under strain controlled and stress controlled cyclic loadings, respectively.

The material parameters adopted is shown as table 1(parameters of Q and b are set to be zero as without considering isotropic hardening).

Table 1. Material parameters used in the proposed model

N=11, E=202GPa, v=0.33, σ_y=240MPa, Q=200, b=2.5, u_i=0.2;
$\zeta^{(1)}$=4000, $\zeta^{(2)}$=1052.6, $\zeta^{(3)}$=396.8, $\zeta^{(4)}$=200.4, $\zeta^{(5)}$=93.5, $\zeta^{(6)}$=50.1, $\zeta^{(7)}$=32.7, $\zeta^{(8)}$=22.9, $\zeta^{(9)}$=16.8, $\zeta^{(10)}$=12.6, $\zeta^{(11)}$=1.0;
$r^{(1)}$=1.29, $r^{(2)}$=4.83, $r^{(3)}$=6.39, $r^{(4)}$=5.42, $r^{(5)}$=25.3, $r^{(6)}$=30.8, $r^{(7)}$=67.7, $r^{(8)}$=66.7, $r^{(9)}$=65.6, $r^{(10)}$=111.4, $r^{(11)}$=5.0 (*MPa*).

It should be noted here

$$c_i = \frac{2}{3}\zeta_i r_i, \quad b_i = \zeta_i \tag{46}$$

The strain and stress at finite deformation modeling is logarithmic strain (true strain) and Cauchy stress, i.e.

$$\boldsymbol{\varepsilon} = \ln \mathbf{V}, \quad \boldsymbol{\sigma} = \frac{1}{\det \mathbf{F}} \mathbf{F}\mathbf{S}\mathbf{F}^T \tag{47}$$

with

$$\mathbf{V} = \mathbf{F}\mathbf{F}^T \tag{48}$$

3.1. Cyclic straining

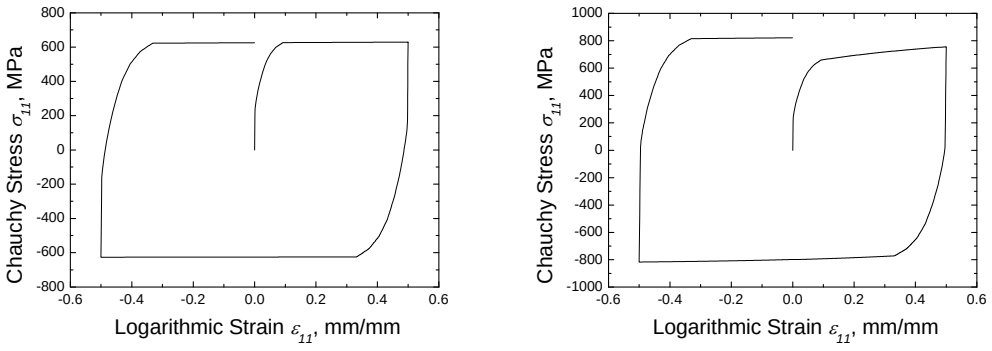
3.1.1. Uniaxial tension-compression

In the section, Capacity of the proposed model describing Bauschinger effect is investigated. For finite deformation modeling, it can be controlled by

$$\mathbf{F} = \begin{vmatrix} 1+\Delta & 0 & 0 \\ 0 & e & 0 \\ 0 & 0 & e \end{vmatrix}, \quad S_{22} = S_{33} = 0 \tag{49}$$

where Δ is the applied load, and the unknown e can be determined through Eq. (49).

The stress-strain curves (1 cycle, with $\Delta: 0 \to 0.6487 \to 0 \to 0.3935 \to 0$) are shown as follows:



(a) (b)

Figure 2. Uniaxial tension-compression under cyclic straining: (a) without isotropic hardening, (b) with isotropic hardening.

Figure 2 shows the stress-strain curves in one loading cycle under strain controlled. It is found that Bauschinger effect in loading-unloading cycle is reasonably reproduced even though in a relative large strain regime (maximum strain is up to 64.87%). Comparing figure 2(a) and 2(b), it is shown that if isotropic hardening is considered, the strain hardening process can be well simulated.

3.1.2. Simple shear

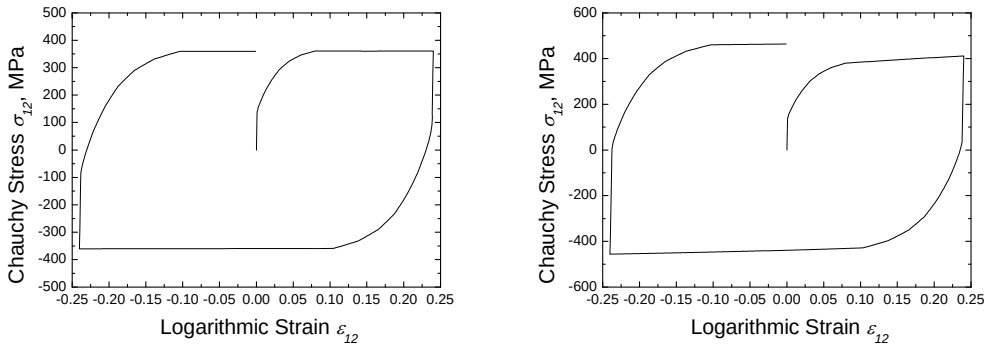
When shear deformation is very large, shear oscillatory phenomenon will appear if the unreasonable finite deformation frame is adopted. It is very important to validate the prediction in shear deformation case for a developed model at finite deformations.

For simple shear case, deformation gradient can be expressed as

$$F = \begin{vmatrix} 1 & \lambda & 0 \\ 0 & 1 & 0 \\ 0 & 0 & e \end{vmatrix}, \quad S_{33} = 0 \tag{50}$$

where λ is the load, and the unknown e can be determined through Eq. (50).

The stress-strain curves (1 cycle, with $\lambda : 0 \to 0.5 \to 0 \to -0.5 \to 0$) are shown as follows:



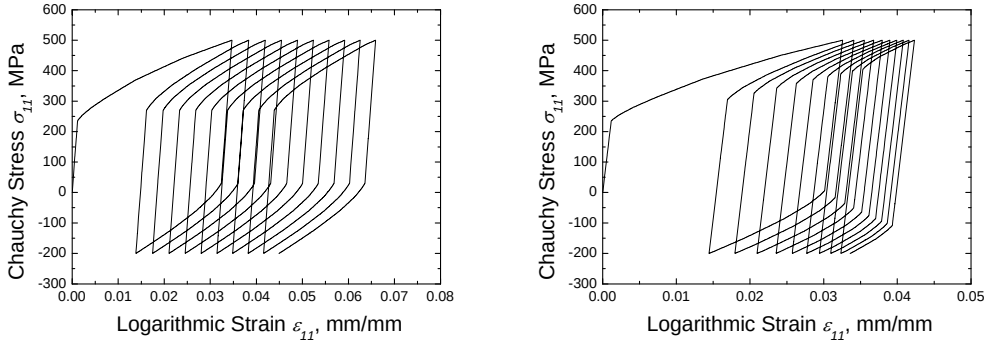
(a) (b)

Figure 3. Simple shear under cyclic straining: (a) without isotropic hardening, (b) with isotropic hardening.

It is shown from Figure 3 that no shear oscillatory phenomenon appears in simple shear case in a relative large strain regime, including with and without consider isotropic hardening cases.

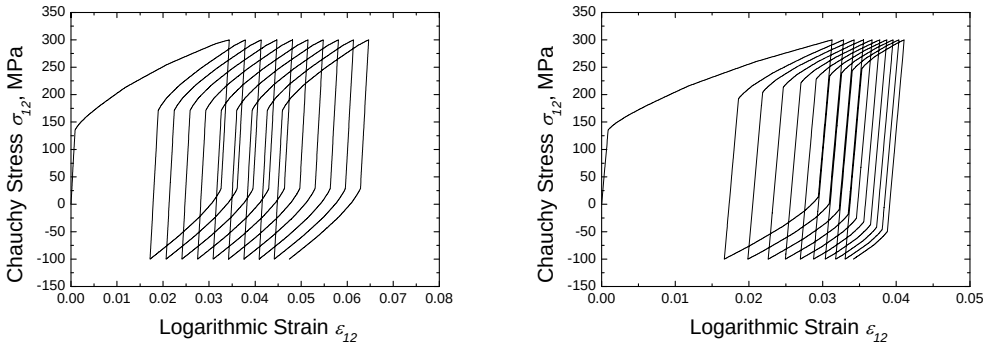
3.2. Cyclic stressing

The prediction ability of ratchetting behaviour is investigated in this section. The loading cases are (150 ± 350)MPa and (100 ± 200)MPa for uniaxial tension-compression and simple shear cases, respectively. The stress-strain curves (10 cycles) are shown as follows:



(a) (b)

Figure 4. Uniaxial tension-compression under cyclic stressing: (a) without isotropic hardening, (b) with isotropic hardening.



(a) (b)

Figure 5. Simple shear under cyclic stressing : (a) without isotropic hardening, (b) with isotropic hardening.

It is shown from Figure 4 that the presented model can reproduce ratchetting behaviour, regardless of uniaxial tension-compression or simple shear case. Moreover, the ratchetting strain exhibits a constant evolution rate without isotropic hardening; however, the evolution rate of ratchetting strain decreases as isotropic hardening is considered, which is a good agreement with constitutive models at small deformation [7].

4. Conclusions

Cyclic models at finite deformations were derived based on hyper-elastic theory. The deformation gradient is first additional multiplicatively decomposed into elastic and inelastic parts; inelastic part of deformation gradient is further decomposed into energetic and dissipative parts. Based on the frame of finite deformation, the cyclic constitutive model, combining isotropic hardening and Ohno-Karim nonlinear kinematic hardening rules, was proposed to describe Bauschinger effect and ratchetting behaviour. The proposed constitutive equations had been proven to satisfy Clausius-Duhem inequality. Tension-compression and simple shear simulations under cyclic stressing and straining were performed to validate the proposed model.

Time dependent ratcheting-fatigue interactions of tempered 42CrMo steel: Experiments and constitutive model

Juan Zhang*, Haibo Luo, Guozheng Kang, Qianhua Kan

Abstract The time dependent ratcheting behavior and fatigue failure, as well as their interaction were investigated by uniaxial cyclic stressing tests for tempered 42CrMo steel at room temperature. The effects of stress rates and peak stress hold on the ratcheting strain and final failure life were discussed. Then based on the experimental observations, a damage-coupled constitutive model was developed to simulate the whole-life ratcheting by employing a static recovery term in the nonlinear kinematic hardening rule. Comparing with the corresponding experimental results, it is shown that the developed model can describe the whole-life ratcheting behavior of the tempered 42CrMo steel reasonably.

Keywords Ratcheting, Low-cycle fatigue, Visco-plastic constitutive model, Damage, Tempered 42CrMo steel

1. Introduction

When the materials and structures are subjected to a stress-controlled cyclic loading with non-zero mean stress, ratcheting, a cyclic accumulation of inelastic deformation, will occur. Since ratcheting is a secondary deformation superposed on the primary cyclic stress–strain response and develops progressively during the cyclic loading, it is very important and should be addressed in the safety assessment and fatigue life estimation of the materials and structure components. Therefore, the ratcheting has been extensively studied in the last twenty years and many cyclic constitutive models were established to describe the ratcheting[1-8]. However, the referable literature focused mainly on the ratcheting deformation and its constitutive modeling, and the whole-life ratcheting and fatigue failure life were not addressed, since the number of applied cycles was relatively small there. The models do not consider any effect of fatigue damage on the ratcheting, and fail to simulate the whole-life ratcheting of the materials. It is necessary to discuss the ratcheting–fatigue interaction and simulate the whole-life ratcheting and fatigue failure life of the materials.

The low-cycle fatigue involving the ratcheting, i.e., ratcheting–fatigue interaction[9-11] has been investigated recently by some researchers due to its significance in the design and assessment of structure components. And a damage-coupled cyclic constitutive model was constructed by Kang et al.[12] to describe the whole-life ratcheting and predicting the failure life of the materials. It is proved that the simulated whole-life ratcheting behavior and predicted failure life of tempered 42CrMo steel are in a fairly good agreement with the experimental ones. However, the effects of some time-related factors, such as stress rate, hold-time, and so on, on the ratcheting behavior and fatigue failure are not involved in the referable literature. So in this work, the time dependent ratcheting behavior and fatigue failure, as well as their interaction were investigated. Firstly, the ratcheting behavior and low-cycle fatigue for tempered 42CrMo steel were investigated by uniaxial cyclic stressing tests at room temperature. The effects of stress rates and peak stress hold on the ratcheting strain and final failure life were discussed. Then based on the experimental observations, a damage-coupled constitutive model was developed to simulate the whole-life ratcheting by employing a static recovery term in the nonlinear kinematic hardening rule.

2. Experimental results and discussions

The material used in this work is 42CrMo steel. Its chemical composition is: C, 0.43%; Mn, 0.68%; Si, 0.27%; P, 0.014%; Cr, 1.11%; Ni, 0.05%; W, 0.01%; Mo, 0.17%; V, 0.01%; Ti, 0.004%; Cu, 0.03%; Fe, remained. The as-forged 42CrMo steel bars were tempered (tempering at 560℃ after heating at 850℃ for 1h and quenching in oil), and then were machined to be round, solid bar fatigue specimens with test section diameter of 10mm and gauge length of 30mm for uniaxial tests. The test machine was MTS809-250KN; the loading process was controlled and the experimental data were collected by Teststar control system attached to the machine. The axial strain was measured by a tensile extensometer, whose limited axial nominal strain was 50%. The specimens were tested under monotonic tension, uniaxial cyclic straining and uniaxial cyclic stressing at room temperature. To illustrate the ratcheting behavior more clearly, the variation of ratcheting strain ε_{r} (defined by Eq. (1)) with the number of cycles for each loading case of cyclic stressing, was obtained from the experimental data and is shown in the figures in this section. In this work, the ratcheting strain ε_{r} is defined as

$$\varepsilon_{\mathrm{r}} = \frac{1}{2}\left(\varepsilon_{\max} + \varepsilon_{\min}\right) \tag{1}$$

where $\varepsilon_{\max}$ is the maximum axial nominal strain in each cycle measured by the extensometer, and $\varepsilon_{\min}$ is the minimum. Meanwhile, in this work, the ratcheting true strain rate is defined as the increment of ratcheting strain after each cycle and denoted as $\mathrm{d}\varepsilon_{\mathrm{r}}/\mathrm{d}N$, where *N* means the number of cycles.

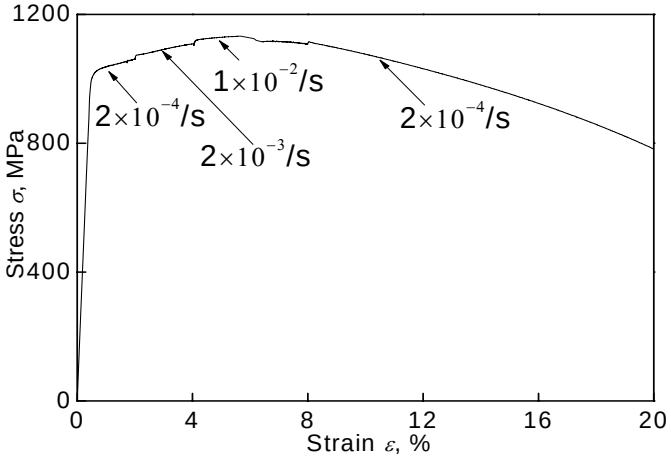

Figure 1. Monotonic tensile stress-strain curves with different straining rates

Monotonic tensile results of tempered 42CrMo steel at different straining rates are shown in Fig. 1. It is shown that the material exhibits rate-dependence at room temperature, and the responded stress at smaller strain rate is much lower than that at higher one.

2.1. Time-dependent strain cyclic features

The cyclic softening/hardening features of the material were investigated under the symmetrical axial cyclic straining (±0.6%) at different straining rates (0.2%/s and 0.04%/s). It can be seen from Fig. 2 that: (1) the material presents significant cyclic at two straining rates, (2) the cyclic softening behavior of the material is rate-dependent even at room temperature, i.e., responded stress amplitude at smaller straining rate is lower than that at higher one.

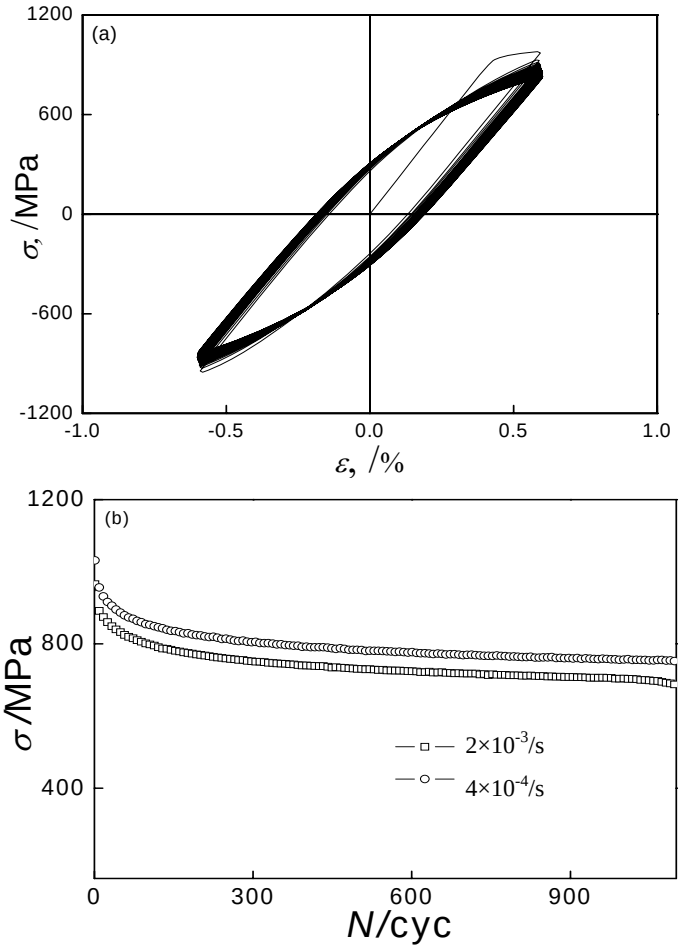

Figure 2. Results of symmetrical axial cyclic straining at different straining rates: (a) stress–strain curve at straining rate of 0.2%/s; (b) curves of stress amplitude vs. cyclic number at two straining rates

2.2. Time-dependent ratcheting-fatigue interactions

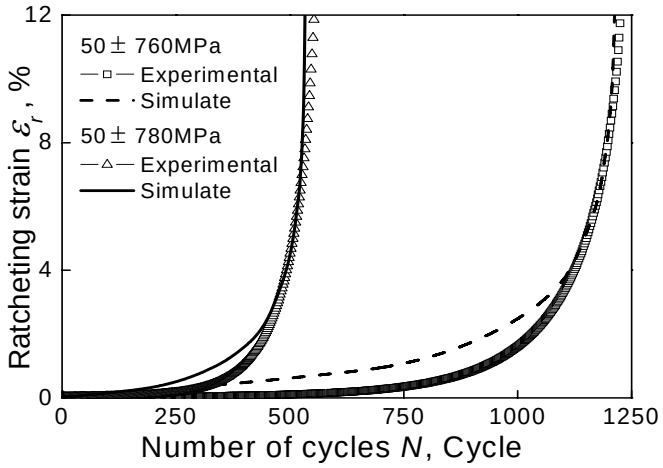

Figure 3. Experimental and simulated whole life ratcheting with different stress amplitude

Firstly, the specimens were tested by cyclic stressing with various nominal stress amplitudes, mean nominal stresses at the same stress rate till the failure occurred. The experimental results of ratcheting behavior of tempered 42CrMo steel at room temperature (shown in Fig.3 and Fig.4) is the same as that was observed in previous work[11]: (1) The evolution of ratcheting strain can be

divided as three stages regarding to the different ratcheting strain rates due to the cyclic softening feature of tempered 42CrMo steel, i.e., the first stage with decreasing ratcheting strain rate, the second stage with an almost constant rate and the third stage with quickly increasing rate. (2)When the stress amplitude or mean stress increases, the ratcheting strain ε_r increases correspondingly, and the first and second stages are ended and the third stage appears more quickly, causing the failure of the material within fewer cycles.

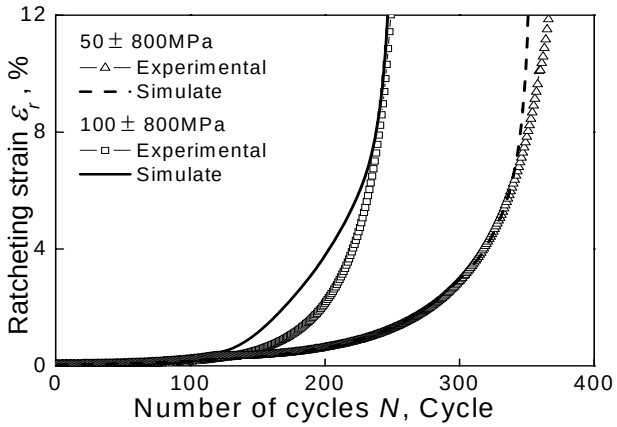

Figure 4. Experimental and simulated whole life ratcheting with different mean stress

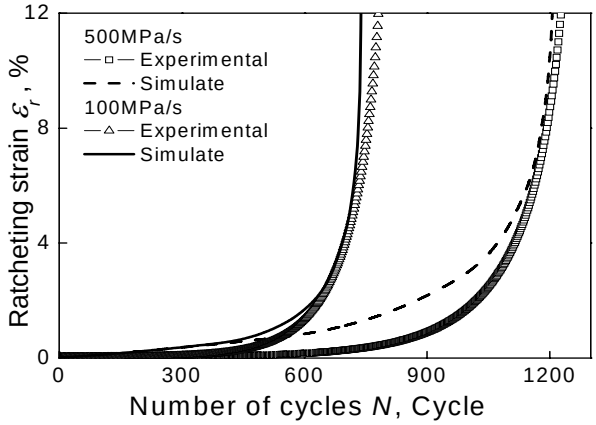

Figure 5. Experimental and simulated whole life ratcheting at different stress rate

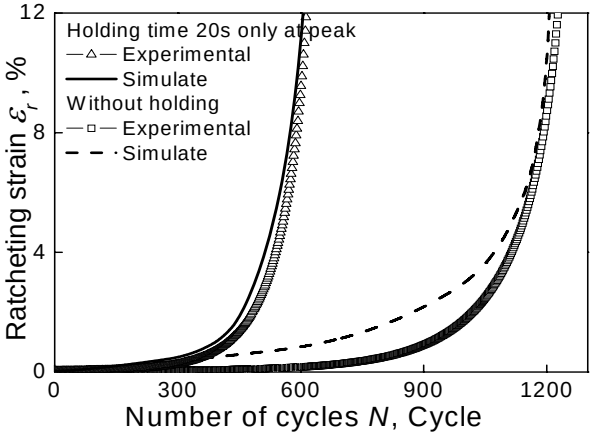

Figure 6. Experimental and simulated whole life ratcheting with and without peak stress holding time

Then the axial cyclic stressing tests were done with constant mean stress and stress amplitude (50 ± 760MPa) but at different stress rates (500 and 100MPa/s). The experimental result is shown in Fig.5. It can be seen that the effect of stressing rate on the ratcheting and fatigue life is remarkable. The evolution of ratcheting strain also can be divided as three stages at different stress rates, but the ratcheting strain ε_r increases with the increasing of stress rate, and the first and second stages are ended and the third stage appears more quickly at lower stress rate, causing the failure of the material within fewer cycles.

The effect of the peak stress hold in each cycle on ratcheting and fatigue life also was discussed under uni-stepped axial cyclic stressing test (50 ± 760MPa) at stressing rate of 500MPa/s. It is concluded from Fig. 6 that non-zero hold-time influences apparently the ratcheting and the fatigue life of the material. The ratcheting strain ε_r with peak stress holding is larger than that without peak stress holding. When the stress holds 20s at peak, the first and second stages of ratcheting are ended and the third stage appears more quickly, so the material fails within fewer cycles

3. Constitutive model and simulation

To describe the ratcheting–fatigue interaction of the tempered 42CrMo steel, Kang et al.[12] proposed a damage-coupled visco-plastic cyclic constitutive model. It has been verified their model could simulate the whole-life ratcheting and predict the fatigue failure life of the material reasonably. So in this work，the damage-coupled visco-plastic cyclic constitutive model proposed by Kang was used to describe the whole-life ratcheting of the material, except that a new nonlinear kinematic hardening rule was introduced to improve the description of time-dependent ratcheting behavior.

3.1. Damage-coupled constitutive model

The governing equations of the damage-coupled constitutive model are outlined as follows:

$$\varepsilon_{ij} = \varepsilon_{ij}^{e} + \varepsilon_{ij}^{vp} \tag{2}$$

$$\varepsilon_{ij}^{e} = \frac{1+\nu}{E}\left(\frac{\sigma_{ij}}{1-D}\right) - \frac{\nu}{E}\left(\frac{\sigma_{kk}\delta_{ij}}{1-D}\right) \tag{3}$$

$$\dot{\varepsilon}_{ij}^{vp} = \frac{3}{2}\frac{\dfrac{S_{ij}}{1-D} - \alpha_{ij}}{\left(\dfrac{S_{ij}}{1-D} - \alpha_{ij}\right)_{eq}}\left(\frac{\dot{\lambda}}{1-D}\right) \tag{4}$$

$$F_y = \left(\frac{S_{ij}}{1-D} - \alpha_{ij}\right)_{eq} - Q \tag{5}$$

$$\frac{\dot{\lambda}}{1-D} = \dot{p} = \left\langle \frac{F_y}{K} \right\rangle^{n} \tag{6}$$

$$(\frac{S_{ij}}{1-D}-\alpha_{ij})_{eq}=\sqrt{\frac{3}{2}\left(\frac{S_{ij}}{1-D}-\alpha_{ij}\right)\left(\frac{S_{ij}}{1-D}-\alpha_{ij}\right)} \quad (7)$$

In previous work[13], a new kinematic hardening rule with a static recovery term (based on the Ohno–Abdel-Karim equation[5]) provide a reasonable simulation to the time-dependent ratcheting of SS304 stainless steel. So in this work, the damage was introduced in the kinematic hardening rule with a static recovery term to describe the whole-life time-dependent ratcheting of tempered 42CrMo steel. The evolution law of nonlinear kinematic hardening rule is

$$\alpha_{ij}=\sum_{k=1}^{M}\alpha_{ij}^{(k)} \quad (8)$$

$$\dot{\alpha}_{ij}^{(k)}=\xi^{(k)}\left[\frac{2}{3}r^{(k)}(1-D)\dot{\varepsilon}_{ij}^{p}-\mu\alpha_{ij}^{(k)}\dot{\bar{\varepsilon}}^{p}-H(f^{(k)})(1-\mu)\alpha_{ij}^{(k)}\dot{\bar{\varepsilon}}^{p}\right]-\chi^{(k)}\left(\bar{\alpha}^{(k)}\right)^{m^{(k)}-1}\alpha_{ij}^{(k)} \quad (9)$$

The evolution law of isotropic hardening is

$$\dot{Q}=\gamma(Q_{\infty}-Q)\dot{\bar{\varepsilon}}^{p}=\gamma(Q_{\infty}-Q)\dot{p}(1-D) \quad (10)$$

In above equations, D is the damage variable. From the evolution feature of the damage during the stress cycling, it is concluded that the total damage presented in the stress cycling can be divided as two parts, i.e., elastic damage and plastic damage[12]:

$$D=D_{\mathrm{e}}+D_{\mathrm{p}} \quad (11)$$

The evolution rules of D_{e} and D_{p} are

$$\dot{D}_{e}=\left(\frac{\sigma_{eq}^{2}}{2E_{0}S_{e}(1-D)^{2}}\right)\dot{p} \quad (12)$$

$$\dot{D}_{p}=\left(\frac{\sigma_{eq}^{2}}{2E_{0}S_{p}(1-D_{p})^{2}}\right)\dot{p} \quad (13)$$

It can be seen that they have the same original form but different constants. When the plastic strain is very small, the macroscopic elastic damage is a main cause of the fatigue damage; however, when the plastic strain develops significantly due to the cyclic softening of the material, the plastic damage dominates the damage after certain cycles[12].

3.2. Simulations to whole life ratcheting

In the constitutive model, the material parameters relative to the evolution of elastic and plastic damages can be determined from the experimental results by the method mentioned in reference [12]. For simplicity, other material parameters are determined from the experiments without any fatigue damage considered. In this case, the procedure to determine the parameters is similar to that used by Kang[8]. The values of all material parameters used in the proposed damage-coupled constitutive model are listed in Table 1.

Table 1. Material parameters used in the constitutive model

M=10, E_0=213GPa, v=0.3, K=90MPa, n=10, Q_0=709.5MPa;
$\zeta^{(1)}=6060.6$, $\zeta^{(2)}=2020.2$, $\zeta^{(3)}=673.4$, $\zeta^{(4)}=303.3$, $\zeta^{(5)}=151.5$, $\zeta^{(6)}=75.7$, $\zeta^{(7)}=43.2$
$\zeta^{(8)}=28.8$, $\zeta^{(9)}=21.6$, $\zeta^{(10)}=17.3$; $r^{(1)}=203.5$, $r^{(2)}=26.4$, $r^{(3)}=13.6$, $r^{(4)}=1.8$, $r^{(5)}=2.1$,
$r^{(6)}=1.4$, $r^{(7)}=7.9$, $r^{(8)}=20.1$, $r^{(9)}=42.8$, $r^{(10)}=19.2$ (MPa);
$\gamma=0.2$, $\mu=0.15$, $Q_\infty=600$ MPa;
$\sigma_{-1}^{f}=419.6$ MPa, $A_1=7.4\times10^{-5}$, $A_2=2.2\times10^{-6}$, $A_3=8.16$, $A_4=-0.569$, $S_p=29$ MPa.

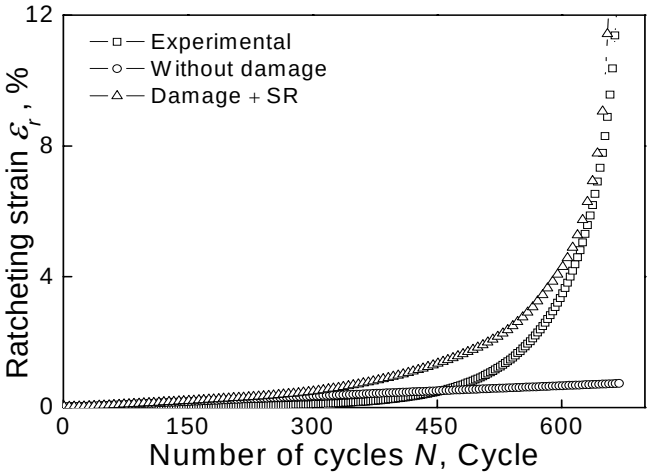

Figure 7. Experimental and simulated whole-life ratcheting by the model coupled with damage or not

The uniaxial whole-life time-dependent ratcheting behavior of tempered 42CrMo steel is simulated by the damage-coupled constitutive model. Fig. 7 shows the experimental and simulated results (50±780MPa, 500MPa/s) obtained by the damage-coupled model and the model with no damage, respectively. It is seen from Fig.7 that the constitutive model introducing damage gives a reasonable simulation for the whole-life ratcheting, especially for the accelerated increase of ratcheting strain at the end stage of cycling.

Figs. 3 and 4 provide some simulated results obtained by the model for some loading cases with various nominal stress amplitudes, mean nominal stresses at the same stress rate. It is shown that the simulated results are in fairly good agreement with the experimental ones and cyclic softening feature of the material on the ratcheting behavior are reasonably considered because of the introducing of damage.

Fig. 5 shows the simulated results of whole life ratcheting behavior at different stress rate, which loading condition is 50±760MPa. It is shown that the constitutive model proved good simulation to the effect of stress rate, and the ratcheting strain and ratcheting strain rate were increase with the decline of stress rate. Fig. 6 shows the simulated results of whole life ratcheting behavior with and without peak stress hold. It is shown that the simulated results are in fairly good agreement with the experimental ones. In one word, the developed constitutive model can describe the time dependent ratcheting reasonably since a static recovery term is introduced to the kinematic hardening rule.

4. Conclusions

(1) The tempered 42CrMo steel presents a rate-dependence under monotonic tension and uniaxial cyclic straining at room temperature. The variations of stress rate and peak stress hold-time have remarkable effect on the ratcheting behavior and low-cycle fatigue life.

(2) Based on the experimental results, a damage-coupled cyclic constitutive model is develops in the framework of continuum damage mechanics and unified visco-plasticity. In the model, the effects of cyclic softening feature and fatigue damage on the ratcheting are addressed by introducing the damage variable *D*. And the effects of stress rate and peak stress hold are simulated by employing a static recovery term in the nonlinear kinematic hardening rule. The model describes the whole-life ratcheting behavior of the material reasonably. The model describes the whole-life time dependent ratcheting behavior of the material reasonably.

Abstract
Micro mechanisms of plastic deformation and the defect structure evolution are sufficiently changing with the strain rate increase. It leads to non-monotonic relations between the macroscopic characteristics of metal strength or ductility and the structure parameters such as a grain size. Our simulations predict an inverse Hall-Petch relation for ultrafine-grained metals at extremely high strain rate (above $10^7 s^{-1}$). Mechanisms of the homogeneous nucleation of dislocations and the mechanical twining can effectively decrease the stresses at strain rates up to $10^9 s^{-1}$.

Keywords High strain rates plasticity, Ultrafine-grained materials, Inverse Hall-Petch relation, Grain boundary sliding

1. Introduction

Materials with ultrafine-grained structure (with the grain diameters of several tenth parts of micrometer), as well as nanocrystalline materials, are widely investigated both theoretically and experimentally for the last twenty years [1,2]. This goes in parallel with the development of experimental technic [3], and leads to discover and investigation of some new effects specific for these materials. One of them is an inverse Hall-Petch relation – the decrease of the yield stress at the grain size decrease. All observations of this effect can be divided on two parts: deformation at low strain rates - usually less than $10^{-1} s^{-1}$ [4-6], and the molecular dynamics simulation at extremely high strain rates - usually greater than $10^8 s^{-1}$ [7]. Preparation and experimental investigation of the nanocrystalline materials is very difficult. On the other hand, the molecular dynamics is very limited in application to macroscopic volumes of microcrystalline and coarse grained materials. It does not allow one to define directly the macroscopic characteristics of the material and to carry out simulations of deformation of the macroscopic volumes of substance with realistic strain rates.

For investigation of the internal defect structure influence on the macroscopic strength and ductility one can take some microscopic mechanisms proposed by theoretical investigations or molecular dynamics simulations and to include it in the modeling in the framework of continuum mechanics. Simulation results could be verified by comparison with experimental data. This way, supplemented by the procedure of averaging over the micro-volumes of substance, allows us to monitor the change of the defect structure and its influence on the strength parameters of different metals.

2. Yield strength at low strain rate

The yield strength σ_y is one of the key macroscopic parameters, which determines the strength of the material. It grows with the dislocation density ρ_D increase and the grain size d decrease, which are well-known effects in most polycrystalline metals and alloys. This dependences are expressed by the Taylor [8,9] and the Hall-Petch relations [10,11] for the barrier of dislocations gliding:

$$\sigma_y = \sigma_0 + \alpha G b \sqrt{\rho_D} + k_{HP} / \sqrt{d} \qquad (1)$$

Here σ_0 includes an influence of impurities and of the Pierls relief resistance for dislocation gliding; G is the shear modulus, b is the Burgers vector, k_{HP} is the Hall-Petch constant, which is a characteristic of the metal. This relation is exactly satisfied until the grain size in polycrystalline material is higher than 1 μm and at the low strain rates. Influence of the mechanical twinning on the resistance for dislocations gliding can be accounted in the form of the Hall-Petch relation with an average distance between the twins Δ instead of the grain size and with other constant k_{TW} [9].

If we introduce the volume fractions of the dislocations $R = b^2\rho_D$, the grain boundaries $\eta = 1-(1-\delta/d)^3 \approx 3\delta/d$ and the twins [12] $F = (1+\Delta/2e)^{-1}$ then the Eq. (1) takes the next form:

$$\sigma_y = \sigma_0 + k_1\frac{\sqrt{R}}{b} + k_2\frac{\sqrt{\eta}}{\sqrt{\delta}} + k_3\frac{\sqrt{F}}{\sqrt{e}}, \qquad (2)$$

were δ and e are the grain width and the twin width correspondently, which are almost constant for the material as well as the Burgers vector. Constants: $k_1 = \alpha Gb$, $k_2 \sim \sqrt{3}k_{HP}$, $k_3 \sim k_{TW}/\sqrt{2}$. As the volume fractions are less than unity, the yield stress is limited. Introduction of impurities apparently is the only way to the increase yield stress to the theoretical tensile strength value [13].

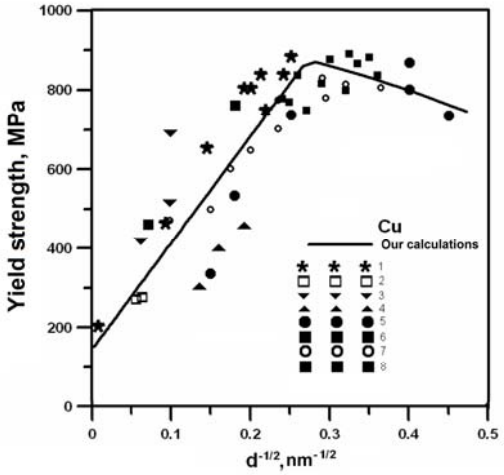

Figure 1 The grain size dependence of the yield strength for copper. Experimental data: 1 – [1], 2 – [17], 3 – [18], 4 – [19], 5 – [4], 6 – [20], 7 – [5], 8 – [6].

In microcrystalline metals ($d < 1$ μm), it is often observed the abnormal Hall-Petch relation with k_{HP} different from that in the coarse-grained crystal; as a result, slope of the Hall-Petch curve is changing [14]. Therefore, the yield stress does not achieve the value predicted from the Eq. (2). In many nanocrystalline materials with d lesser than 12 nm-15 nm an inverse Hall-Petch relation is observed: the yield strength decreases with the decrease of the grain size [4-6,15]. This effect is often related with the grain boundary sliding as an alternative mechanism of plasticity. As it was shown in [16], there is a barrier resistance stress y_b; it is equal to the doubled external stresses, which must be exceeded for initiating of the grain boundary sliding. It depends on the grain size.

$$y_b = 0.01\cdot\frac{G}{1-\nu}\left(1-\frac{\delta}{d}\right)^2, \qquad (3)$$

where ν is the Poisson ratio of the material, which is slightly varied for different metals. For activation of the grain boundary sliding one need to apply the stress exceeding $\sigma_y = 2y_b$; for copper and iron it is about 1GPa. Therefore, in ultrafine-grained and nanocrystalline materials the plastic

flow occurs only at high internal stresses. This model give a good fit with experimental results for different metals [16]. Fig. 1 presents the experimental observation points and the theoretical curve for copper in the Hall-Petch coordinates. One can see an existing of the maximum of the yield strength for grain size of about 12nm. Yield strength here is less than 1 GPa.

3. Yield strength at high strain rates

Micro mechanisms of plastic deformation and defect structure evolution are sufficiently changing with the strain rate increase. The high stain rate experiments demonstrate a deviation from the Hall-Petch relation even for ultrafine grained metals. At these deformation conditions we will define dynamical yield strength of the material through the maximal shear stresses, which is reached during the high-rate deformation. Dynamical yield stress not fully determined by the internal stresses from different obstacles as in the quasistatic deformation conditions. At extremely high strain rate (above 10^6 s^{-1}) it has a sufficiently dynamical nature and defined by dynamics properties of the dislocation and grains gliding, by the kinetics of the dislocation generation and annihilation. For the yield stress definition one must solve a full system of equation which describes the material plasticity as it was done in [21]. This system includes the equations for dislocation and grain boundary plasticity and the continuum mechanics equations.

3.1 Dislocation plasticity model

Theoretical description of the dislocation plasticity one can get using the model proposed in [22]. In monocrystalline metals, dislocations can glide along the limited numbers of slip planes; we shall numerate it by index β. Equation for plastic deformation caused by the dislocation glide [23] can be written as:

$$\frac{dw_{ik}^{D}}{dt} = -\frac{1}{2}\sum_{\beta}\left(b_i^{\beta}\, n_k^{\beta} + n_k^{\beta} b_i^{\beta}\right) V_D^{\beta}\, \rho_D^{\beta}\,. \tag{4}$$

Here b^{β} is the Burgers vector of dislocations, ρ_D^{β} is the scalar density of dislocation (their number per unit square) in glide plane with index β, V_D^{β} – velocity of dislocations. These parameters fully determine the plastic deformation of the coarse-grained crystals. Velocity of dislocation can be defined from the movement equation [22]:

$$\frac{m_0}{\left(1-\left(V_D^{\beta}/c_t\right)^2\right)^{3/2}}\frac{dV_D^{\beta}}{dt} = \left(F_D^{\beta} \pm \frac{b^{\beta}Y}{2}\right) - \frac{B(T)V_D^{\beta}}{\sqrt{1-\left(V_D^{\beta}/c_t\right)^2}}, \tag{5}$$

Here $F_D^{\beta} = S_{ik} b_i n_k$ is the Pitch-Keller force (it acts on the unit length of dislocation line from the external stresses), Y is the static yield stress of the material, which depends on the dislocation density, the grain size and the presence of different impurities [24]. m_0 is the field mass of dislocation, c_t is transverse sound velocity. The terms with sound velocity allows one to take into account an experimental fact that dislocation velocity is always limited above by the sound velocity. Coefficient of viscous friction $B(T)$ is temperature dependent [25,26]. Eq. (5) had demonstrated a good fit with experimental data for over barrier dislocation gliding at the high rate deformation [22].

For determination of the dislocation density one can write a kinetics equation in the next form [22]:

$$\frac{d\rho_D^{\beta}}{dt} = \frac{\eta}{\varepsilon_L}\frac{B\left(V_D^{\beta}\right)^2\rho_D^{\beta}}{\sqrt{1-\left(V_D^{\beta}/c_t\right)^2}} - k_a b\left|V_D^{\beta}\right|\left(\rho_D^{\beta}\right)^2 - \frac{\rho_D^{\beta}\left|V_D^{\beta}\right|}{d}. \tag{6}$$

Here the dislocation source (the first term in the Eq. (5)) has been recorded from the energy-wise consideration; $\eta = 0.1$ is a portion of dissipated power, which is spent on generation of new defects; the energy $\varepsilon_L = 8\text{э}B/b$ [25] is required for generation of new dislocations (per unit of length). Annihilation term (the second term in the Eq. (5)) was written similar to [27].

For nanocrystalline materials one has to take into account an additional term in the kinetic equation (5). Dislocation core are being delocalized in the disordered grain boundary material [28], when it reaches any grain boundary [29]. Therefore, dislocation in nanocristalline material has a lifetime, which is equal to the traveling time of dislocation through the grain $d/\left|V_D^\beta\right|$, where d is an average grain size. Corresponding additional term in the right-hand part of the kinetics equation (5) is the next: $-\rho_D^\beta \left|V_D^\beta\right| / d$. The proposed model was verified on the experiments at various high strain rate deformation conditions, including the shock wave propagation in metals [22,30]. Its application demonstrates a good fit with experimental data at minimum adjustable parameters.

3.2 Model for grain boundary sliding

The plastic deformation related with the grain boundary plasticity one can describe similar to the Maxwell model for a highly viscous liquid [31] with the exception of the barrier resistance stress y_b . It means that grain boundaries are elastically deformed during short intervals of time. But when the deformation ceases, shear stresses remain in them, although they are dumped in the course of time, so that after sufficiently long time almost no inertial stress remains in the boundaries, exception of y_b . Viscous force appears in the grain boundaries due to diffusion, which counteracts the sliding of the grains layers relative to each other; it can be characterized by a relaxation time τ . As a result, the plastic deformation caused by the grain boundary sliding can be written in the next form [16]:

$$\dot{w}_{ik}^{gb} = \frac{1}{2G}\sum_\alpha \tau_i^\alpha n_k^\alpha \frac{\Theta\left(\sigma_\tau^\alpha - y_b\right)}{\tau}, \tag{7}$$

where $\Theta(x)$ is a Heaviside function, index α numerates the possible shifting planes of the grains; normal vectors to these planes can be written as n_i^α . Stresses applied to corresponding plane are $\sigma_{ik} n_k^\alpha$ and the stress component, which acts in the tangent direction τ_i to the plane, is equal to the convolution product $\sigma_{ik} n_k^\alpha \tau_i$. We will denote τ_i^α as the direction of the tangent vector corresponding to the maximum shear stresses applied to this plane. Then the maximal shear stress acting on the layer of grains can be represented as $\sigma_\tau^\alpha = s_{ik} n_i^\alpha \tau_k^\alpha$, where s_{ik} is a deviator of stresses. Using a linear approximation, one can obtain the following expression for the relaxation time of grain boundary sliding [16] from data of the molecular dynamics simulation [32]:

$$\tau = \frac{dk_bT}{12Gb\nu_D V_s}\exp\left(\frac{U_s}{k_bT}\right) \tag{8}$$

Activation volume V_s can be estimated as $V_s \sim b^3$. Activation energy U_s has the same order as the activation energy of viscous flow in molten state of the metal [28].
Tensor of the full plastic deformation can be written as

$$w_{ik} = w_{ik}^D + w_{ik}^{gb} \tag{9}$$

4. Simulation results

4.1 Dislocation starvation

At increasing of the strain rate an over-barrier dislocation gliding occurs and the domination resistant force becomes a phonon drag to the gliding dislocations [23]. At the further increasing of the strain rate the main mechanism of strain hardening becomes the dislocation starvation - it is well known phenomena in the field of nanopillars and thin film modeling [33] at rapid deformation condition. A distinction between the bulk material and these nano-crystals is in the cause of the starvation. In nano-crystals there are no ordinary dislocation sources, and the plasticity is usually provided by several entered dislocations and by surface instabilities [33]. In the bulk materials there is relatively large dislocation density and active dislocation sources exist. But the maximal dislocation density can be estimated through critical stress for the Frank-Read sources activation:

$$\sigma_\tau = Gb/L_{FR} \,. \tag{10}$$

Here b $L_{FR} \sim 1/\sqrt{\rho_D}$ – a base of the Frank-Read source which has the same order as an inverse square root of the total dislocation density ρ_D. Then, for reasonable stresses $\sigma_\tau \sim 2$ GPa, the total dislocation density is limited by the value $\rho_D \sim 10^{16} m^{-2}$. On the other hand, the Orowan equation [24] gives:

$$\dot{\varepsilon} = \rho_D b V_D \,. \tag{11}$$

The dislocation velocity V_D can not exceeded the transverse sound velocity $c_t \approx 3000$ m/s. As a result, we obtain the maximal strain rate at which dislocations can theoretically provide the full relaxation of shear stresses: $\dot{\varepsilon} < 10^{10} s^{-1}$. In real metals sufficient part of dislocations consists of immobile dislocations, which is not contributing to plastic relaxation. Our calculations demonstrate that the dislocation starvation takes place already at $\dot{\varepsilon} > 10^7 s^{-1}$. Therefore, even in ultrafine crystals with the grain size of about hundreds of nanometers a sufficient deviation from the Hall-Petch relation takes place at high strain rates, and it is erroneously to extrapolate the molecular dynamics simulation results on microcrystalline material by experimental data obtained at low strain rate.

The dislocation mechanism of stress relaxation is very limited for the strain rates exceeding $10^9 s^{-1}$ because of a dislocation starvation. Figure 2 demonstrates the dislocation starvation in ultrafine-grained copper at the strain rate from $10^7 s^{-1}$ to $10^9 s^{-1}$.

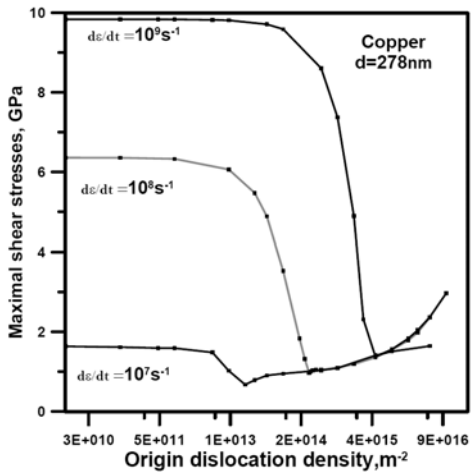

Figure 2 The dependence of the maximal shear stress on the origin dislocation density for copper at extremely high strain rates: 10^7-10^9 s^{-1}.
